A series of experiments were carried out to determine the formation constant, K, and molar absorptivity, ε, of the dye–amine product. In all the experiments, solutions of dye and amine whose molar ratio had been held constant were used to simplify the experimental methodology and the treatment of data. Measurements of absorbance of the solutions were always carried out with an excess of amine at temperatures from 15 to 40°C and at 410 nm, the wavelength of the absorption maximum of the association compound. Experimental data for the antipyrine – bromothymol blue associated species are presented in Table 1. The absorption spectra and the absorbance

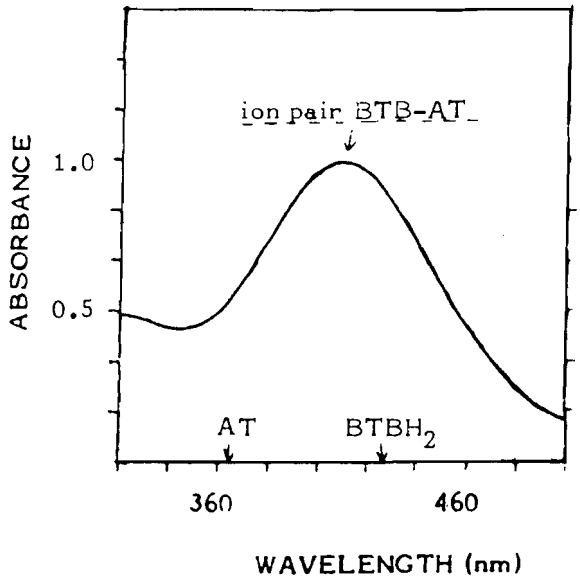

FIG. 1. Absorption spectra of dichloromethane solutions of antipyrine – bromothymol blue ion pair ($4 \times 10^{-4} M$ antipyrine, $4 \times 10^{-4} M$ bromothymol blue), antipyrine ($4 \times 10^{-4} M$), and bromothymol blue ($4 \times 10^{-4} M$), $T = 20°C$.

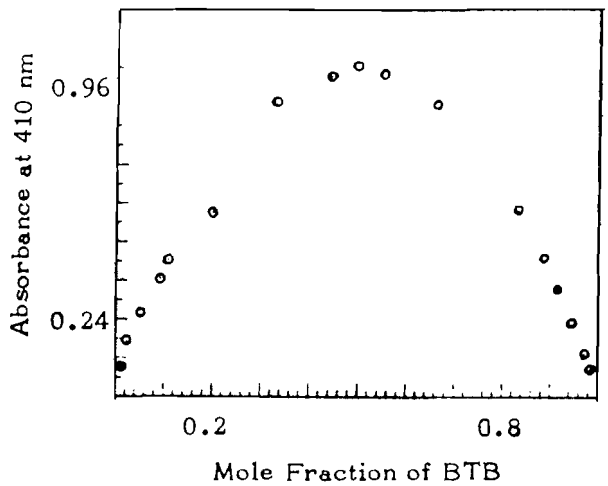

FIG. 2. Job's plot of absorbance values at 410 nm against mole fraction of BTB for antipyrine–dye complex; $C^0_{BTB} + C^0_{AT} = 8 \times 10^{-4} M$.

values at 410 nm of bromothymol blue – antipyrine mixtures remain constant for at least 48 h.

The conductivity in dichloromethane of solutions of bromothymol blue, antipyrine, and mixtures of the two were measured at 20°C. The results are presented in Table 2.

Discussion

The reaction of antipyrine (free base) with bromothymol blue (free acid) gives in dichloromethane solution an ion pair with an absorption maximum at 410 nm, a wavelength where absorption is not present for either the antipyrine of the dye (Fig. 1). Evidence for formation of this new compound only occurs at high concentrations of both reagents, which is in contrast to the associations that have been described for other amines (1, 8, 9). This suggests the weak character of the reaction. The stoichiometric balance of the product, using the method of continuous variations, is 1:1 given that the graphic representation in Fig. 2 shows a maximum at 0.5 molar fraction. On the other hand, the absence of inflections as well as the presence of a finite gradient, at zero and at unit mole fraction indicate that the complex formed is 1:1 and not 2:2 or 3:3 (15).

The absorption spectrum of the new compound is the same in shape and in wavelength at maximum absorption (410 nm) as those presented by other amines which are strongly associated with BTB (1, 8, 9). This suggests an interaction of the same chemical nature as that of amines which give strong reaction. Consequently, the reaction can be considered an acid–base process in which the antipyrine neutralizes the first proton of the dye and, in view of the low dielectric constant of the solvent, probably an antipyrine–dye ion pair is formed. The reaction can be shown by the equation:

[1] $BTBH_2 + AT \rightleftharpoons \{BTBH^-, ATH^+\}$

for which the equilibrium constant is

$$[2] \quad K = \frac{(\{BTBH^-, ATH^+\})}{(BTBH_2)(AT)}$$

where $BTBH_2$ is bromothymol blue (free acid), AT antipyrine (free base), and $\{BTBH^-, ATH^+\}$ the product formed and stabilized as a 1:1 ion pair.

Determination of the equilibrium constant, K, of process [1] requires the use of a calculation method suitable for weak associations, since the molar absorptivity of the 1:1 ion pair can not be determined directly.

It is easy to prove that the equation which relates the experimental absorbance at 410 nm, A, the initial concentrations of bromothymol blue and antipyrine, C^0_{BTB} and C^0_{AT}, the equilibrium constant, K, and the molar absorptivity, ε, of the product, $\{BTBH^-, ATH^+\}$, is (16, 17)

$$[3] \quad A = A_0 + \tfrac{1}{2}\varepsilon\{C^0_{BTB} + C^0_{AT} + K^{-1} - [(C^0_{BTB} + C^0_{AT} - K^{-1})^2 - 4C^0_{BTB}C^0_{AT}]^{1/2}\}$$

where A_0 is a correction factor for the experimental absorbance.

To resolve this equation in a general way Rosseinsky's iterative method can be applied, since the product formed is of 1:1 stoichiometry and the reagents do not absorb at 410 nm, the wavelength of maximum absorbance for the product. It is also assumed that the ion pair obeys Beer's law. The iterative procedure also supplies a criterion for eliminating data that present higher experimental error than the average. The chosen parameters are K^{-1}, $\sigma_{K^{-1}}$, ε, σ_ε and r.m.s.d., where $\sigma_{K^{-1}}$ and σ_ε are the standard deviations of K^{-1} and ε and r.m.s.d. is the mean square deviation of the experimental absorbance values.

The cycle of iterations is continued until $\Delta\varepsilon < 10^{-3}$ and $\Delta K^{-1} < 10^{-8}$. The estimation of K and ε with their confidence intervals is carried out by using Tchevicheff's equation (18*a*), which needs no assumptions about the type of distribution of errors, for the probability level 0.95. Application of this iteration method requires that an approximate first value of K and ε (K_1 and ε_1) be known. To obtain these values the Benesi–Hildebrand method was used since in all of the experiments the concentration of antipyrine was much higher than that of bromothymol blue. The Benesi–Hildebrand equation as applied to this reaction is

$$[4] \quad \frac{C^0_{BTB}}{A} = \frac{1}{K_1\varepsilon_1} \cdot \frac{1}{C^0_{AT}} + \frac{1}{\varepsilon_1}$$

Figure 3 shows that eq. [4] is satisfied over the range of concentrations used for all temperatures studied. The values of K_1 and ε_1, and the coefficient of determination r^2 were obtained by least squares.

The values of K and ε along with their statistical uncertainties obtained by Rosseinsky's method, and the coefficient of determination r^2 of the Benesi–Hildebrand approximation are listed in Table 3. Because the values of r^2 are close to 1 and the r.m.s.d. is less than 0.01 in most cases (the spectrophotometric error is 0.005) it is possible to conclude that the experimental data agree quantitatively with the proposed equations. Another important result is that the ε values for $\{BTBH^-, ATH^+\}$ are constant at different temperatures.

The absorption spectrum of the BTB–antipyrine associate in DCM (Fig. 1) is very similar to that of the strong associates in dichloromethane and chloroform (1, 8, 9). Moreover, the molar absorption value of the $\{BTBH^-, ATH^+\}$ ion pair is also equal to that of the strong associates (1, 8, 9), which suggests that for both strong and weak associates the reaction is of the same chemical nature. The only difference between the strong and weak associates is the extension of the acid–base reaction, which is governed by the pK_a value of the amine. Thus antipyrine gives a weak reaction with BTB since its pK_a value is 1.5, although atropine, atropamine, strychnine, tropine, quinine, etc. give strong associates since their pK_a values range from 8 to 11.

Gupta (8) has suggested that moderately high values for the formation constants can mean a complex character for the 1:1 addition products between bromothymol blue and those amines with pK_a's between 8–11 which give a quantitative reaction with BTB in chloroform (but not one of salts). By analogy the magnitude of the obtained constants reveals a complex character for the 1:1 compound given that the value of K is very small and oscillates widely with temperature. However, the reaction is apparently an acid–base process in which the magnitude of the equilibrium constants depends on the basic properties of the amine under consideration.

The conductivity data of dye and antipyrine solutions in dichloromethane reinforce the previous interpretation, since they suggest both the presence of ions in the organic phase and the ionic nature of the product formed. The specific conductivity of separate dye or antipyrine solutions in dichloromethane is next to zero, while solutions containing mixtures of both reagents show an increase in specific conductivity (Table 2). Although the specific conductivities increase with the concentrations of dye and amine taken, the specific conductivity values of BTB–AT solutions in dichloromethane are very low,

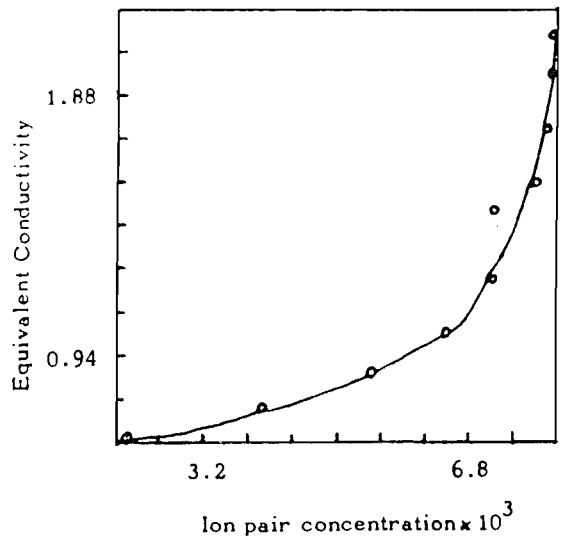

FIG. 4. Plot of equivalent conductivity values ($\mu S\,cm^2\,equiv.^{-1}$), against concentration (mol/L) of BTB–AT ion pair, T = 20°C.

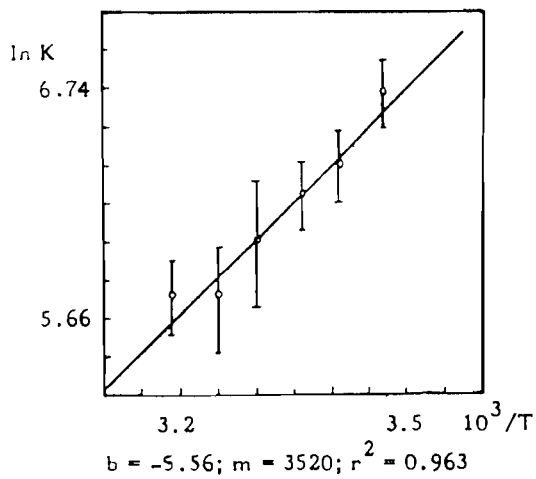

FIG. 5. Van't Hoff plot of antipyrine – bromothymol blue reaction. Formation constants plotted with confidence intervals. Intercept value b, slope m, and determination coefficient r^2 obtained by least squares method.

which shows that only a small fraction of the BTB–AT ion pair is dissociated in nonpolar solvents.

In Fig. 4 values of equivalent conductivity ($\mu S\,cm^2\,equiv^{-1}$) have been plotted against the ion pair concentration of BTB–AT. These have been calculated from K = 592 L/mol at 20°C. The specific and equivalent conductivity increases with ion pair concentration, probably owing to the presence of increasing concentrations of ions.

Calculations of changes in the thermodynamic quantities ΔG^0, ΔH^0, and ΔS^0 were carried out starting with the expressions (19)

$$[5] \quad \ln K = \frac{\Delta S^0}{R} - \frac{\Delta H^0}{RT}$$

and

$$[6] \quad \Delta G^0 = -RT \ln K$$

The calculated constants fall within the respective confidence intervals of the linear regression of eq. [5] (Fig. 5). The calculated thermodynamic parameters were $\Delta S^0 = -11.05 \pm 6.37$ cal/mol; $\Delta H^0 = -6994 \pm 1912$ cal/mol for the range 15 to 40°C; and $\Delta G^0 = -3534$ to -3850 cal/mol over these temperatures. These data are shown in Table 4. The 95% confidence intervals of ΔS^0 and ΔH^0 were calculated by Student's method (18*b*) and the confidence interval of ΔG^0 was calculated from the confidence interval of K.

TABLE 4. Thermodynamic parameters ΔH^0, ΔS^0, and ΔG^0 for AT–BTB system in dichloromethane, with 95% confidence intervals; values obtained from van't Hoff plot

T (°C)	ΔH^0 (cal/mol)	ΔS^0 (cal/K mol)	ΔG^0 (cal/mol)
15	−6994±1912	−11.05±6.37	−3850± 97
20	−6994±1912	−11.05±6.37	−3718±107
25	−6994±1912	−11.05±6.37	−3703±101
30	−6994±1912	−11.05±6.37	−3634±227
35	−6994±1912	−11.05±6.37	−3534±175
40	−6994±1912	−11.05±6.37	−3593±116

Values of ΔH^0 are negative, which suggests that formation of the ion pair is exothermic. The change in ΔS^0 is also negative, which points to a high degree of order in the complex; ΔG^0 is also less than zero since the process is spontaneous.

The study was repeated for diazepam, dipyrone, and ampyrone (analytical grade) for which the reaction with BTB has not been described. Apparently the reaction is very weak, and it was not possible to obtain values for ion pairs with satisfactory small statistical uncertainties.

Similar experiments to those carried out with antipyrine were performed with these amines. Solutions of BTB were mixed with each amine in dichloromethane and an absorbance at 410 nm (yellow) was shown. The experimental results were not, however, in agreement with the previous theoretical model proposed for antipyrine. The reason for the different behaviour of diazepam, dipyrone, and ampyrone in contrast to antipyrine could be due to their particular molecular structure, their insolubility in dichloromethane (which makes their study difficult), or dislocation factors of the charge over the nitrogens (the reactive element of the amine); as well, these amines have nitrogen more suitable to give both a weak and overlapped reaction. Thus in the absence of these factors, it is only the pK which is responsible for the greater or lesser extension of the amine–BTB reaction in DCM. For this reason atropine, atropamine, strychnine, tropine, quinine, belladonna, imipramine, etc., with pK_a's between 8 and 11, give a quantitative reaction with BTB in chloroform (8, 9), in contrast with antipyrine (pK_a = 1.5) which gives a weak reaction.

Conclusions

Antipyrine reacts with bromothymol blue in dichloromethane in an acid–base process forming a 1:1 ion pair (antipyrine–bromothymol blue). Conductivity and spectral data clearly indicate that the associated species with visible absorption are ion pairs. Formation constants for ion pair association are low, suggesting that the associated species are more complex in nature than the simple salts. The formation process is spontaneous, exothermic, and gives rise to a structured complex. Some of these conclusions could be extended to strongly associated species involving amines and bromothymol blue, for which the present study can not be repeated owing to the large formation constants for the reactions.

Model compounds for poly(oligomethylene glycol-4,4′-biphenyl dicarboxylates). An X-ray diffraction study

SUZANNE DEGUIRE, JOHANNE GAGNÉ, HERMANN DUGAS, AND FRANÇOIS BRISSE

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Qué.), Canada H3C 3J7

Received March 4, 1987

SUZANNE DEGUIRE, JOHANNE GAGNÉ, HERMANN DUGAS, and FRANÇOIS BRISSE. Can. J. Chem. **65**, 2291 (1987).

To provide the necessary parameters required for the conformational analysis of poly(oligomethylene glycol-4,4′-biphenyl dicarboxylates), two model compounds related to the above polyesters have been synthesized and their structures established by X-ray diffraction. The crystal structures of ethylene glycol di-*para*-phenylbenzoate (2DPPB) and 1,4-butylene glycol di-*para*-phenylbenzoate (4DPPB) have been solved by direct methods. 2DPPB is monoclinic with a = 7.174(2) Å, b = 8.101(2) Å, c = 19.183(4) Å, β = 102.48(2)°, Z = 2, space group $P2_1/c$. 4DPPB is triclinic with a = 9.978(2) Å, b = 11.172(3) Å, c = 11.437(2) Å, α = 85.46(2)°, β = 79.40(2)°, γ = 71.03(2)°, Z = 2, space group $P\bar{1}$. The weighted least-squares refinements converged to R_w = 0.054 (2DPPB) and R_w = 0.057 (4DPPB). The values of ε, the tilt angle of the carboxylate group with respect to the phenylene ring, are 3.5° for 2DPPB and 1.5° and 1.4° for 4DPPB. A systematic study of this dihedral angle showed that the values of ε remain in the vicinity of 0°–10° and the value observed most frequently is 5°. The values of Φ, the dihedral angle between the two six-membered rings, are 36.2° in 2DPPB and 14.7° and 31.0° for 4DPPB. A systematic study with 71 biphenyl molecular fragments showed that distribution of Φ presents two maxima: one around 30°–40° and the other in the range of 0°–10°. The conformation of the methylenic sequence is all-*trans* for 2BPPB and gtttt for 4DPPB.

SUZANNE DEGUIRE, JOHANNE GAGNÉ, HERMANN DUGAS et FRANÇOIS BRISSE. Can. J. Chem. **65**, 2291 (1987).

Dans le but d'obtenir les paramètres requis pour l'analyse conformationnelle des poly(carboxylates d'oligométhylèneglycol-biphényles-4,4′), on a synthétisé deux composés modèles apparentés à ces polyesters et on a déterminé leur structure par diffraction des rayons X. On a fait appel aux méthodes directes pour déterminer les structures cristallines des di-*para*-phénylbenzoates d'éthylèneglycol (2DPPB) et de butylèneglycol (4DPPB). Le 2DPPB est monoclinique avec a = 7,174(2), b = 8,101(2) et c = 19,183(4) Å, β = 102,48(2)°, Z = 2, et groupe d'espace $P2_1/c$. Le 4DPPB est triclinique avec a = 9,978(2), b = 11,172(3) et c = 11,437(2) Å, α = 85,46(2)°, β = 79,40(2)° et γ = 71,03(2)°, Z = 2 et groupe d'espace $P\bar{1}$. Un affinement par le méthode des moindres carrés converge à R_w = 0,054 (2DPPB) et R_w = 0,057 (4DPPB). Les valeurs de ε, l'angle de torsion du groupement carboxylate par rapport au noyau phénylène, est de 3,5° pour le 2DPPB et de 1,5° et 1,4° pour le 4DPPB. Une étude systématique de cet angle dièdre démontre que les valeurs de ε se maintiennent entre 0° et 10° et que la valeur observée le plus fréquemment est 5°. Les valeurs de Φ, l'angle dièdre entre les deux cycles à six chaînons, sont de 36,2° dans le 2DPPB et de 14,7° et 31,0° dans le 4DPPB. Une étude systématique de 71 fragments moléculaires biphénylés montre que la distribution de Φ présente deux maxima : l'un autour de 30°–40° et l'autre entre 0° et 10°. La conformation de la séquence des méthylènes est complètement *trans* pour le 2DPPB et gtttt pour le 4DPPB.

Introduction

The study of a new class of thermotropic polyesters, the poly(oligomethylene glycol biphenyl dicarboxylates) has recently been undertaken (1). These polyesters, which incorporate in their backbone a flexible aliphatic segment and a slightly more rigid biphenyl dicarboxylate group, melt to an ordered liquid. It is important to know the manner in which the macromolecules pack because it provides additional information regarding the identification and the structure of the liquid crystal phase. Since the crystal structures of the polyesters have not yet been established, we have chosen to tackle this problem by the model compound approach.

This approach, although it has its problems, has been quite successful in helping to solve the structure of the related polyester. The structure of poly(trimethylene terephthalate) or poly(3GT) was established using geometrical information obtained from the crystal structures of two related model compounds: trimethylene glycol dibenzoate and trimethylene glycol di-*para*-chlorobenzoate (2). It was not only the bond distances and angles but also the conformational angles of the model compounds that helped significantly in solving the parent polyester's structure. The torsion angles describing the conformation of the trimethylene sequence in the model compounds were found to be within 2° of those adopted for the most reasonable structure of poly(3GT). In the case of poly(1,4-*trans*-cyclohexanediyldimethylene succinate), the bond distances, bond angles, and torsion angles found in *trans*-1,4-cyclohexanedimethyl-3,3′-bis(methoxy carbonyl) dipropionate, the related model compound, allowed for the calculation of the fiber repeat of the above polyester to within 0.06 Å of its experimental fiber repeat (3, 4).

Two model compounds, ethylene glycol di-*para*-phenylben-

zoate (2DPPB) and 1,4-butylene glycol di-*para*-phenylbenzoate (4DPPB), have been synthesized and their structures have been determined by X-ray diffraction to compare the equivalent fiber repeat of the model compounds to the experimental values in the parent polyesters. The parameters of interest in this study are (*i*) the value of ε, the tilt angle of the carboxylate group with respect to the phenylene ring; (*ii*) the value of Φ, the dihedral angle between the two six-membered rings; and (*iii*) τ, the conformation of the methylenic sequence.

Experimental

The model compounds were synthesized by reacting *para*-phenylbenzoyl chloride with either ethylene glycol or 1,4-butanediol in the presence of pyridine for 30 min at room temperature (5). After decantation and washing with water the light yellow powders were purified by recrystallization in ethanol. In another slow crystallization in CCl_4 (2DPPB) or in $CHCl_3$ (4DPPB), clear prismatic crystals suitable for X-ray diffraction were obtained. The densities were measured by flotation in $ZnCl_2$ solutions. The unit cell dimensions and the crystal orientations were obtained by accurate centering of 25 reflections on the Nonius CAD-4 automatic diffractometer. The unit cell dimensions are listed with other crystal data of interest in Table 1. The integrated intensities were measured by the $\omega/2\theta$ technique using graphite monochromatized CuKᾱ radiation. The orientation of the crystal was verified after every 100 measurements. The intensities of 3 reference reflections were monitored every hour to assess the stability of the system.

Structure factors were obtained after scaling of the intensity data, and Lorentz and polarization corrections were applied.[1] No absorption correction was judged necessary due to the small value of the absorption coefficients. The details of the data collection are summarized in Table 2. The density of 2DPPB implies that there is only half a molecule per asymmetric unit. Thus 2DPPB possesses a crystallographic center of symmetry. The structure of 2DPPB was solved by direct methods (MULTAN 80) with some difficulty and only when the non-centrosymmetric space group $P2_1$ was assumed. Even then only the phenylbenzoate fragments could be recognized. The complete molecule was eventually revealed by the use of the DFOUR option. After a few cycles of full-matrix least-squares refinement, the correlation matrix indicated strong correlations between the coordinates of chemically equivalent atoms of 2DPPB. The refinement progressed smoothly in the centrosymmetric $P2_1/c$ space group. The various steps of the refinement, anisotropic for O and C, isotropic for H atoms, are given in Table 2. In the case of 4DPPB there is one molecule per asymmetric unit if the space group is $P\bar{1}$. Here again the symmetry had to be lowered to $P1$. Two nearly centrosymmetrically related molecules of 4DPPB were found. The coordinates of corresponding atoms turned out to be strongly correlated. Using the coordinates of one molecule in the $P\bar{1}$ space group, the refinement proceeded normally. In both cases the H atoms were found in difference Fourier syntheses. The weighted least-squares refinements of the atomic coordinates, minimizing $\Sigma w(|F_o| - |F_c|)^2$, were conducted with anisotropic temperature factors for O and C and isotropically for H atoms. The weights were derived from the counting statistics of the intensities. The details of the least-squares refinements are given in Table 2 for both compounds. The scattering curves for non-hydrogen atoms were taken from ref. 10 and those for H atoms from ref. 11. The tables of observed and calculated structure factors are part of the Supplementary Material.[2]

Results and discussion

The positional and equivalent thermal parameters and their standard deviations are presented in Tables 3*a* and *b*. The atomic numbering is shown in Fig. 1 and the molecular structures are presented as stereopairs in Fig. 2. The final bond distances and angles of the *para*-phenyl benzoate groups in 2DPPB and 4DPPB are compared in Table 4, while the geometries and conformations in the ethylene glycol and 1,4-butylene glycol segments are compared in Table 5 to those in other related compounds.

[1]The programs used here are modified versions of NRC-2, data reduction; NRC-10, bond distance and angles; NRC-22, mean planes; FORDAP, Fourier and Patterson maps (A. Zalkin); MULTAN, multisolution program; NUCLS, least-squares refinement; and ORTEP, stereodrawings (6–9).

[2]Structure factor tables, hydrogen atom coordinates, anisotropic temperature factor tables, and details of the least-squares planes calculations have been deposited. Copies may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The para*-phenylbenzoate group*

The least-squares plane calculations for the aromatic rings and the carboxylic groups reveal that the atoms in each of these groups are coplanar.

The carboxylic groups have bond lengths in excellent agreement with the average geometry computed from the distances and angles of several dibenzoates and terephthalates. The average values of the C—O and C=O bonds are 1.334(3) and 1.204(3) Å while the O—C=O, C—C=O, and C—C—O bond angles have averages of 123.0(3)°, 124.6(2)°, and 112.4(2)° respectively (12). The carboxylic planes of atoms are only slightly tilted from the aromatic plane. The tilt angle, ε, has values of 3.5° for the 2DPPB and 1.5° and 1.4° in the case of

4DPPB. The distribution of the values taken by the dihedral angle, ε, in 221 molecular fragments found in the Cambridge Data File, is represented in Fig. 3*a*. The dihedral angle values remain in the vicinity of 0°–10°, and the value observed most frequently is 5°.

In 2DPPB, the dihedral angle Φ between the two six-membered rings has a value of 36.2°, while in 4DPPB the two values are 14.7° and 31.0°.

It is very interesting to note that if the two symmetrically related torsion angles ϕ_1 and ϕ_5 ($= \phi_1'$) have the values of ±177.1(2)° in 2DPPB, they take the values of $\phi_1 = 100.3(2)°$ and $\phi_5 = -175.5(2)°$ in 4DPPB. In all the *para*-substituted benzoates studied, ϕ and the chemically equivalent ϕ_5 were always nearly 180°. However, this observation should be combined with the fact that the two rings in the diphenyl groups are at $\Phi = \pm 36°$ from one another in 2DPPB, while they take different tilt values, i.e., 15° and 31° in 4DPPB. These two effects (differences in ϕ_1 and differences in Φ) are attributed to packing interaction.

The Cambridge Data File revealed the existence of 71 biphenyl molecular fragments. The distribution of the dihedral angle, Φ, between the two phenylene rings is shown on Fig. 3*b*. The distribution of Φ, in the range of 0°–90°, presents two maxima: one around 30°–40° and the other in the range of 0°–10°. The larger values of Φ, in the interval of 30°–40°, are observed when the hydrogen atom on the *ortho* carbon is replaced by a larger atom such as chlorine (13).

The aromatic C—C distances observed average 1.385 Å for 2DPPB and 1.382 Å for 4DPPB. They are comparable to the mean bond length of 1.378 Å reported in ref. 14. The average

†t = *trans* ≃ 180°, $g^{\pm}$ = *gauche*$^{\pm}$ ≃ ±60°, s = skew ≃ ±120°.

angle in each of the six-membered ring is 120°. However, the angles, α, at the junction of the two phenyl groups deviate the most from the mean value. If we retain (from the systematic study) only the structures refined to an *R*-value lower than 5% and exclude structures not containing hydrogen atoms in the *ortho* position, we see that a trend seems to appear between the values of the α angles and Φ, the dihedral angle between the two rings (see Fig. 4*a*). The closer the two phenylene rings are to being coplanar, the smaller these α angles will be, to minimize the steric repulsions between the pairs of *ortho* hydrogen atoms. Conversely, when Φ is large, the angle α tends to get larger again, to minimize the interactions of the *ortho* H atoms.

At the same time, the inter-ring bond distance, *d*, is influenced by the repulsions between the hydrogen atoms in the *ortho* position (see Fig. 4*b*). Combining our observations with other published data yields another apparent relationship between the C—C distance, *d*, and the dihedral angle between the two rings (Fig. 4). The smaller the dihedral angle, the larger is the C—C distance. This is so to minimize the hydrogen–hydrogen interactions.

The methylenic sequence

In our two models and other related compounds, the methylenic sequence is quite flexible. The observed torsion angles take values near 180° or ±60°. A torsional angle of 180° corresponds to a *trans* (t) conformation while values of ±60° correspond to *gauche*$^+$ (g^+) or *gauche*$^-$ (g^-). The CH_2—CH_2 bond length in 2DPPB is 1.493(3) Å and those adjacent to oxygen atoms in 4DPPB are 1.494(3) and 1.489(3) Å. These values are significantly shorter than the expected C(sp^3)—C(sp^3) distance of 1.541(3) Å (15). Note also that the angles O—C—C involving these CH_2—CH_2 bonds have values of 104.9(2)° for 2DPPB and 110.0(2)° and 106.7(2)° for 4DPPB. The two lower angles are also strikingly smaller than is usually accepted for a molecule with no apparent strain.

Packing of the molecules

The shortest nonbonded intermolecular C...O distance is 3.561(3) Å for 2DPPB and 3.338(2) Å for 4DPPB. The C...C distances are all larger than 3.55 Å. Therefore, the molecules are held in the crystal by van der Waals forces only. The packing of the molecules is shown by the stereopairs in Figs. 5*a* and *b*. In 2DPPB, the molecules are packed in a herringbone manner, while in 4DPPB the molecules place themselves parallel to each other.

Extension to the parent polyesters

The 2DPPB molecule has a nearly fully extended conformation so that the distance between the midpoints of the central

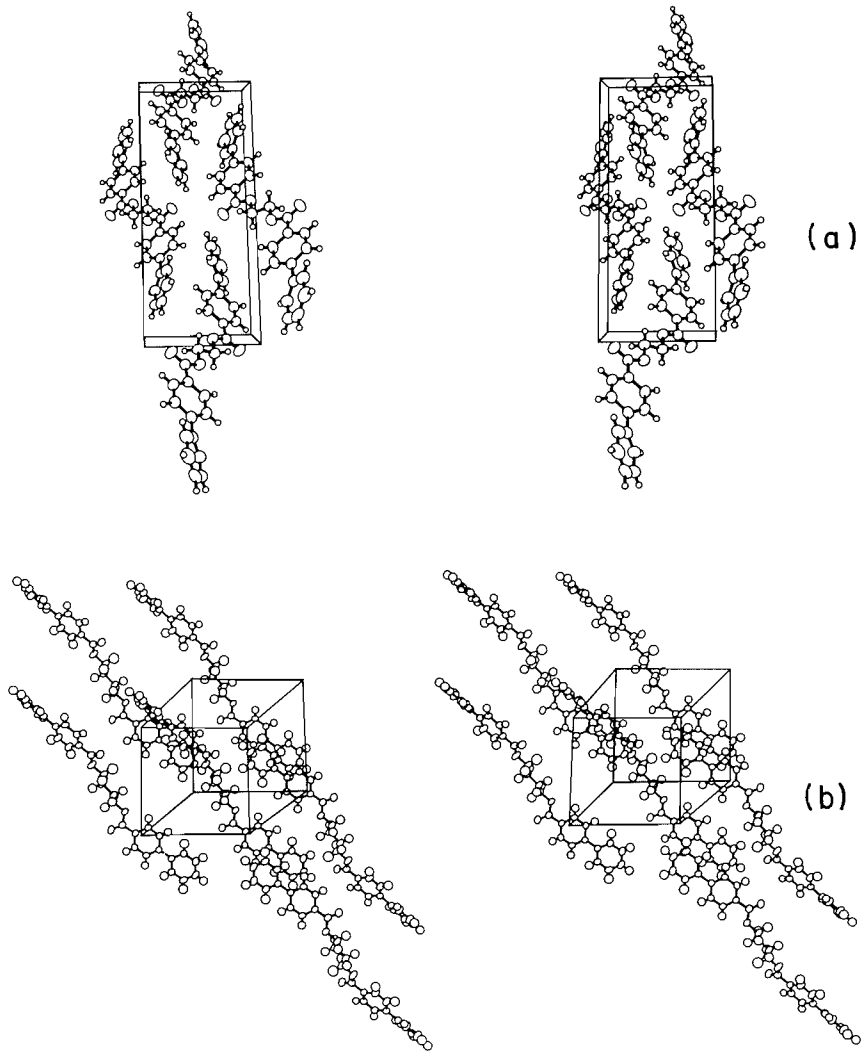

FIG. 5. Stereopairs showing the crystal packing of (*a*) 2DPPB and (*b*) 4DPPB.

C—C bond of the two biphenyl groups is 14.84 Å. This distance, which is defined as the equivalent fiber repeat of the polyester, would be 14.85 Å if all the torsion angles were exactly 180°.

In the case of 4DPPB the equivalent fiber repeat is only 15.78 Å. For a fully extended conformation this value would increase to 17.24 Å.

It is worth noting that, in both cases, the fiber repeat is not affected by the value taken by the dihedral angle Φ.

Poly(ethylene glycol-4,4′-biphenyldicarboxylate) and poly-(1,4-butylene-4,4′-diphenyldicarboxylate) have been synthesized by interfacial polycondensation according to the general method given by Eareckson (16). These syntheses proceeded normally but with yields of only 20%. That the polyesters have been thus produced was confirmed by infrared spectroscopy and X-ray powder diffraction. The two polymers are crystalline, but because the quantities produced were small, no film or fiber of the polyesters could be obtained to check on the value of their fiber repeats.

Conclusion

There are three types of information required to describe the structure of the poly(oligomethylene glycol-4,4′-biphenyl dicarboxylates).

In the biphenyl region, the Φ angle ranges from −60° to 60°, but is most likely to have a value of 30°. Furthermore, once this angle has been chosen, the inter-ring distance, *d*, as well as the α angles are defined.

The carboxylate tilt angle is restricted to around ±5°.

The methylenic sequence is flexible; torsion angles may take any value near 180°, 60°, or −60°. Care should be taken to select appropriate C—C bond length and O—C—C angle.

DOMINIQUE SOHOUNHLOUE, LOUIS TENEBRE, MIREILLE PRIVAT, JEAN-MARC DOUILLARD, RENÉ BENNES, and EMMANUEL TRONET-PEYROZ. Can. J. Chem. **65**, 2299 (1987).

The interface between the water (1) – ethanol (2) system and silicone oil was studied over the whole composition range of the aqueous mixtures by means of adsorption and ellipticity measurements. The adsorbed layer was treated as a phase and, after derelativization of the relative surface excess, the adsorption isotherm (in term of molar fractions) as well as the activity coefficients of water and ethanol were calculated. From the above results and by analysing the ellipticity coefficient, we calculated the contribution to this latter due to the anisotropy of the adsorbed layer; the resulting "polynomial of anisotropy" was analyzed as a consequence of water and ethanol reorientations as the surface composition is changed.

DOMINIQUE SOHOUNHLOUE, LOUIS TENEBRE, MIREILLE PRIVAT, JEAN-MARC DOUILLARD, RENÉ BENNES et EMMANUEL TRONET-PEYROZ. Can. J. Chem. **65**, 2299 (1987).

L'interface entre le système eau–éthanol et l'huile de silicone a été étudiée dans tout le domaine de composition du mélange aqueux au moyen de mesures d'adsorption et de coefficient d'ellipticité. La couche adsorbée a été traitée comme une phase et, après dérelativisation de l'excès superficiel relatif, l'isotherme d'adsorption (exprimée en fractions molaires) ainsi que les coefficients d'activité de l'eau et de l'éthanol ont été calculés. À partir des résultats précédents et de l'analyse du coefficient d'ellipticité, nous avons calculé la contribution à celui-ci due à l'anisotropie de la couche adsorbée; le « polynôme de polarisabilité » qui en résulte a été interprété comme la conséquence des réorientations de l'eau et de l'éthanol quand la composition de la phase de surface change.

I. Introduction

The study of interfaces considered as autonomous phases in equilibrium with contiguous bulk phases from a thermodynamical point of view has been extensively developed in the past (1–7). Its aim is to calculate the activity coefficients of the constituents of these layers (1, 5, 6), so as to explain the interactions between the molecules as well as to propose a plausible structure of the surface phase (9).

This procedure tends to give more vigour to adsorption studies, as has been noted in the study of other types of surface phase (8).

This kind of study is also of industrial interest, where many applications depend on the state of the surface, e.g., adhesion, wetting, corrosion, nucleation.

In our previous work (9) we considered the liquid–vapor interface of such simple binary systems as water–ethanol and water–*tert*-butanol. We tried to link the results of adsorption measurements, i.e., the relative excess Γ_{21}, to the ellipticity coefficient measured at the Brewster angle. This last parameter contains a contribution due to the heterogeneity along the perpendicular direction to the surface (Drude's theory (10)), as well as an anisotropic term due to the polarizability of molecules (11) and a contribution coming from the thermal fluctuations of the surface location (12).

As we have shown previously (9), the "Drude part" of the ellipticity coefficient can be related to the surface excesses; in turn, the anisotropic contributions may be calculated if the thermal fluctuations of the surface area are neglected. The anisotropic part of the ellipticity coefficient contains information concerning the orientations of surface molecules and their change with the composition.

Thus, this work is concerned with two kinds of results: the first involves the composition of the surface phase, the activities of the constituents, and other related thermodynamic properties (excess free energy), and the second concerns the structural meaning, such as an indication of molecular orientation.

In the present work, we extend our previous treatment on the liquid–vapor interphase to the oil – aqueous solution interface. The oil is a silicone oil of type 604 V 50 from Rhône–Poulenc Industry. We expect that this oil will have a strong influence on the water structure.

II. Theoretical part

For the system studied, we will demonstrate in the paragraph entitled "chemicals" that water and ethanol do not dissolve into the oil used in this work, and conversely. Thus in the following theoretical part we consider the oil to be a wall.

1. Determination of the adsorption isotherm: x_2^σ vs. x_2^α

We call σ the surface phase and α the aqueous bulk phase. Water is denoted by the subscript 1 and ethanol by 2. The first aim is to determine the mole fraction of constituent 2 in the surface phase, i.e., x_2^σ; the adsorption isotherm will be the relation between the mole fraction in the surface x_2^σ and in the bulk x_2^α. The aqueous mixture is the binary water (1) – ethanol (2) system.

The surface mole fraction is obtained after the resolution of the set of relations:

$$[1a] \quad \Gamma_{21} = \Gamma_2 - \Gamma_1 \frac{x_2^\alpha}{x_1^\alpha}$$

$$[1b] \quad 1 = A_1^\sigma \Gamma_1 + A_2^\sigma \Gamma_2$$

where

$$\Gamma_{21} = \text{Gibbs surface excess} = -\left(\frac{\partial \gamma}{\partial \mu_2^\alpha}\right)_T$$

In fact, the oil is composed of several polymer oils; however, water and alcohol being unsoluble in this mixed oil (Sect. IIIA), the chemical potentials of every component of the oil are

[1]Revision received April 10, 1987.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

constant as the composition of the water–ethanol mixture varies. So the terms in the Gibbs equation due to the components of the oil vanish:

$$\Sigma \Gamma_i^0 \, d\mu_i^0 = 0 \; (\mu_i^0 = C^t)$$

where

Γ_i ($i = 1, 2$) = total excess (4) in the absorbed layer

A_i^σ ($i = 1, 2$) = partial molar area of $i = \left(\frac{\partial A}{\partial ni}\right)_{TP\gamma n_{j\neq i}}$

A = area of the surface

γ = interfacial tension

So

$$[2] \quad x_2^\sigma = \Gamma_2/(\Gamma_2 + \Gamma_1)$$

Equation [1*b*] is a result of the molar area surface definition:

$$A^\sigma = \frac{1}{\Gamma_1 + \Gamma_2}$$

and also of its property of being a homogeneous function, of first degree, of the composition of the surface phase. This is expressed by the relation

$$[3a] \quad A^\sigma = x_1^\sigma A_1^\sigma + x_2^\sigma A_2^\sigma$$

where A_i^σ has the same meaning as in eq. [1*b*] and x_i^σ is defined by eq. [2].

There exists a similar property for the surface molar volume:

$$[3b] \quad v^\sigma = x_1^\sigma v_1^\sigma + x_2^\sigma v_2^\sigma$$

which is a copy of the ordinary property of the volumes to be a homogeneous function, of first degree, of the phase composition. The v_i^σ are the surface molar partial volumes for the i species.

Incidentally, the ratio between v^σ and A^σ gives the thickness of the surface phase (see below).

It is clear that, for solving the set of eqs. [1] or for calculating the interfacial thickness d, values of v_i^σ and A_i^σ are needed. These v_i^σ and A_i^σ values being a priori unknown, we assign them respectively the values of the molar volume, $v_i^{\sigma 0}$, and molar area, $A_i^{\sigma 0}$, for the pure components, in accord with a currently used hypothesis (1):

$$[4] \quad A_i^\sigma = A_i^{\sigma 0}; \; v_i^\sigma = v_i^{\sigma 0}$$

We suppose $A_i^{\sigma 0}$ and $v_i^{\sigma 0}$ to have the same value as these relative to the liquid vapor interface (9*b*).

The approximation $v_i^\sigma \simeq v_i^{\sigma 0}$ is based on the fact that within the bulk, even for mixtures showing strong volumic contractions (for example, water (1) – *tert*-butanol (2)), the volume versus the molar fraction x_2^α is practically linear from $v_1^{\alpha 0}$ to $v_2^{\alpha 0}$. We can imagine that the same behavior exists for the surface, and hence $v_i^\sigma \simeq v_i^\sigma$. In our opinion this simplification does not introduce an error of more than a few percent to the molar volume of the mixture. By analogy, the same assumption was made for the partial molar areas: $A_i^\sigma \simeq A_i^{\sigma 0}$. This kind of approximation is often made a priori (1, 3) in the literature since the volume and areas cannot be measured directly as in a bulk phase.

Now the mole fraction in the surface phase σ can be calculated for each corresponding bulk mole fraction.

2. Anisotropic part of the ellipticity coefficient

Once x_2^σ is known, the contribution of the heterogeneity along a normal direction with respect to the surface (due to a composition profile and thus to a dielectric constant profile) to the ellipticity coefficient can be calculated by means of Drude's theory, in the case, for instance, with the light incident from the oil phase (10):

$$[5] \quad \bar{\rho}_D = \frac{\pi}{\lambda} \frac{\sqrt{\varepsilon_H + \bar{\varepsilon}}}{\varepsilon_H - \bar{\varepsilon}} \left[\varepsilon_H + \bar{\varepsilon} - \frac{\varepsilon_H \bar{\varepsilon}}{\varepsilon^\sigma} - \varepsilon^\sigma \right] d$$

where ε_H = dielectric constant of the oil from which the light comes, $\bar{\varepsilon}$ = dielectric constant of water–ethanol mixture, ε^σ = mean dielectric constant of the surface layer, λ = wave length of the incident light, and d = thickness of the interfacial zone.

As is shown in ref. 9:

$$[6] \quad \varepsilon^\sigma = \frac{1}{d} \int_0^d \varepsilon(z) \, dz = 1 + \frac{4\pi N}{d} (\alpha_1 \Gamma_1 + \alpha_2 \Gamma_2)$$

$$= 1 + \frac{4\pi N}{v^\sigma} (\alpha_1 x_1^\sigma + \alpha_2 x_2^\sigma)$$

α_1, α_2 = polarizabilities of components 1 and 2.

Thus ε^σ can be calculated in terms of $v_i^{\sigma 0}$, $A_i^{\sigma 0}$, x_i^σ; the interfacial thickness d is defined as $d = v^\sigma/A^\sigma$.

Because the surface tension in our systems generally has a significant value (1–40 mN m^{-1}), we neglect the contribution due to thermically excited waves (14, 15). If the surface layer is anisotropic, i.e., if its dielectric constant in the direction parallel to the interfacial plane, ε_x, is different from the dielectric constant in a direction perpendicular to this same plane, ε_z, the ellipsometric coefficient is written as (11):

$$[7] \quad \bar{\rho} = \frac{\pi}{\lambda} \frac{\sqrt{\varepsilon_H + \bar{\varepsilon}}}{\varepsilon_H - \varepsilon} \left\{ \int_0^d \frac{[\bar{\varepsilon} - \varepsilon_z(z)][\varepsilon_z(z) - \varepsilon_H)]}{\varepsilon_z(z)} \, dz + \int_0^d [\varepsilon_z(z) - \varepsilon_x(z)] \, dz \right\}$$

The first term is the Drude term describing a heterogeneity perpendicular to the surface ($\bar{\rho}_D$); the second term corresponds to the anisotropic contribution of the layer ($\bar{\rho}_A$).

By writing:

$$\int_0^d [\varepsilon_z(z) - 1] \, dz = 4\pi N(\alpha_1^z \Gamma_1 + \alpha_2^z \Gamma_2)$$

and

$$\int_0^d [\varepsilon_x(z) - 1] \, dz = 4\pi N(\alpha_1^x \Gamma_1 + \alpha_2^x \Gamma_2)$$

where N is the Avogadro Number and $A^\sigma = 1/(\Gamma_1 + \Gamma_2)$, $\bar{\rho}_A$ is written as

$$[9] \quad \bar{\rho}_A = -\frac{4\pi^2}{\lambda} \frac{\sqrt{\varepsilon_H + \bar{\varepsilon}}}{\varepsilon_H - \bar{\varepsilon}} \frac{d}{v^\sigma} P(x_2^\sigma)$$

where $P(x_2^\sigma)$ is an anisotropic polynomial defined as

$$[10] \quad P(x_2^\sigma) = (\alpha_1^x - \alpha_1^z) x_1^\sigma + (\alpha_2^x - \alpha_2^z) x_2^\sigma$$

with α_i^x and α_i^z = polarizability along the parallel (x) and the perpendicular (z) directions with respect to the (horizontal) surface ($i = 1, 2$). $P(x_2^\sigma)$ will be treated as a homogeneous function of first degree in composition x_1^σ and x_2^σ. One can ob-

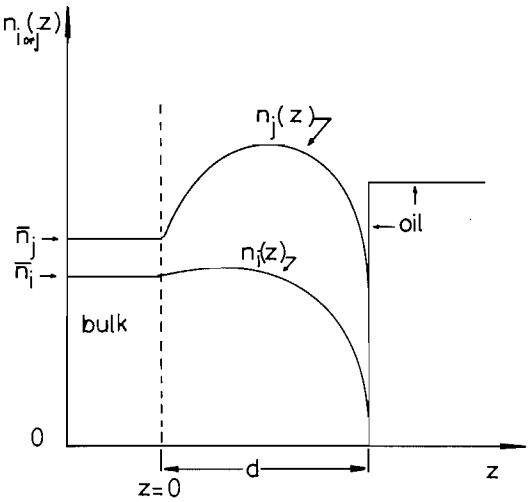

FIG. 1. An example of profiles in the interfacial region; the $z = 0$ and $z = d$ surfaces are chosen to take into account the totality of the molecules i and j in the interface. The oil is considered as a step, since water and ethanol are not soluble in this type of oil.

tain an idea of the structural changes occurring in the adsorbed layer, when the composition varies, by calculation of the $(\alpha_i^x - \alpha_i^{\bar{x}})$ terms.

Thus the total difference between the experimental ellipticity coefficient ($\bar{\rho}_E$) and the part calculated by Drude's law ($\bar{\rho}_D$) can be assigned to the anisotropic part of the ellipticity coefficient ($\bar{\rho}_A$):

$$[11] \quad \bar{\rho}_A = \bar{\rho}_E - \bar{\rho}_D$$

3. The choice of the dividing surfaces

As shown in the experimental part, the water and ethanol used in this study being insoluble in the oil, we consider this latter as a wall for water and ethanol (see Fig. 1). The interface considered goes from the dividing surface chosen as the origin ($z = 0$) (for which the bulk compositions are at negative values of z) to the oil surface. The oil profile is considered as a step at this point ($z = 0$). The excesses Γ_i and Γ_j are defined classically as being the surfaces under the curves $n_i(z)$ and $n_j(z)$, from $z = 0$ to $z = d$. This choice of surface permits us to take into account all the i and j molecules present in the interfacial zone (5).

At this stage, the thermodynamic and the ellipsometric reasoning (eqs. [5] and [9]) are in agreement in the sense that both apply to mean quantities (dielectric constant, molar volume, and areas of mixtures) or total quantities (Γ_i and Γ_j), the thickness of the layer being the distance characterizing the whole heterogeneous zone taken into account by the ellipsometry.

III. Experimental conditions and results

A. Chemicals

The water–ethanol/silicone oil (604 V 50) system at 25°C has been chosen because of its simplicity and the knowledge of thermodynamic values or properties: bulk activities for the water–ethanol binary system, insolubility of the ethanol in this oil, and known properties of the liquid–vapor interface (9) in terms of adsorption and the ellipticity coefficient.

Water–ethanol solutions from 0 to 100% were shaken with the oil and equilibrated for 3 days. Then the refractive indexes of the solutions and of the oil were measured with an Abbe refractometer; no change was detected for the concentration used, and so we considered the water and the ethanol as totally insoluble in the oil, and vice versa. In addition, the interfacial tension and the ellipticity coefficient do not change during the measurements (several hours), indicating no dissolution of water and ethanol in the oil.

Silicone oils are used extensively in industry (paper, textile, ...) often for emulsion conditioning. For such purposes, their stability is ensured by a tensioactive molecule coating the oil droplets to hinder their coalescence; the properties and structure of the adsorbed film that exists between the water solution and the oil are hence very important (16). Other interesting properties, for example, the viscoelasticity of the film, are not studied in this paper, but we shall see that a rudimentary property like the density of the phases may be important.

The oil used was a mixture of fully substituted polymethylsiloxanes ($R_3SiO(R_2SiO)_n$—$SiOR_3$ with R = methyl). Hence there are no reactive sites of the type SiOH on the molecules. The polydispersity ratio (equal to 2.15) was determinated by gpc (gel permeation chromatography), the mean distribution being 7605 and the number distribution 3530. The silicone oil was supplied by Rhône–Poulenc Silicone.

The water used was distilled on potassium permanganate in sulfuric acid medium. The ethanol was 100% from Carlo et Erba chemicals.

B. Techniques

All the measurements were made at a temperature of 25.0 ± 0.1°C.

1. The interfacial tension was measured by the determination of the maximum force acting on a horizontal straight platinum wire and a balance built in the laboratory, with a precision of $\pm 0.1\ \text{mN m}^{-1}$ (see results, Fig. 2).

Some care was necessary to make reproducible measurements. We started with the platinum wire immersed in the water–ethanol mixture. The oil was added to this phase (or conversely, depending on the relative densities) very gently to avoid the formation of an emulsion in the neighborhood of the interface. The platinum wire was located at the interface and the meniscus stretched toward the oil phase until it was broken. The measurement of the force was made at that very moment. Then, the measurements of the tension γ can be reproduced to a few tenths of mN m^{-1}. The contact angle on the platinum wire is nearly zero at the breaking of the film.

2. The activities of water and ethanol in the bulk aqueous solution, a_i^α at 25°C, were obtained from the literature (17).

From γ and a_2^α the relative surface excess is evaluated as:

$$[12] \quad \Gamma_{21} = -\left(\frac{\partial \gamma}{\partial \mu_2^\alpha}\right)_T$$

3. For the ellipsometric measurements a beam of light (laser He–Ne; 6328 Å), linearly polarized, was reflected on the surface studied. The reflected beam is elliptically polarized. The ratio between the minor and major axis of the ellipse at the Brewster incident angle is called $\bar{\rho}_E$, the ellipsometric coefficient (13). The apparatus was a homemade one (18).

The refractive indexes of the bulk phases, n, were measured with an Abbe refractometer; the necessary dielectric constants ε are known by the relation $\varepsilon = n^2$.

4. The contact angle θ was measured at the silica–solution–oil interfaces by the determination of the meniscus height h. The capillary ascension h of the interface along the silica plate is related to the contact angle through this equation (19):

$$[13] \quad \sin\theta = 1 - \frac{\Delta\rho g h^2}{2\gamma}$$

where $\Delta\rho$ = density difference between the two bulk phases, g = the acceleration of gravity, γ = interfacial tension measured independently (see above), and h = meniscus height.

The system studied shows an embarrassing peculiarity for each of the interfacial techniques: the binary aqueous phase has a decreasing density when increasing the ethanol composition; the density difference between the oil and water–ethanol bulk phases, $\Delta\rho$, becomes zero between 22 and 30% by weight of ethanol in water. The interfacial tension, ellipticity coefficient, and contact angle are of course

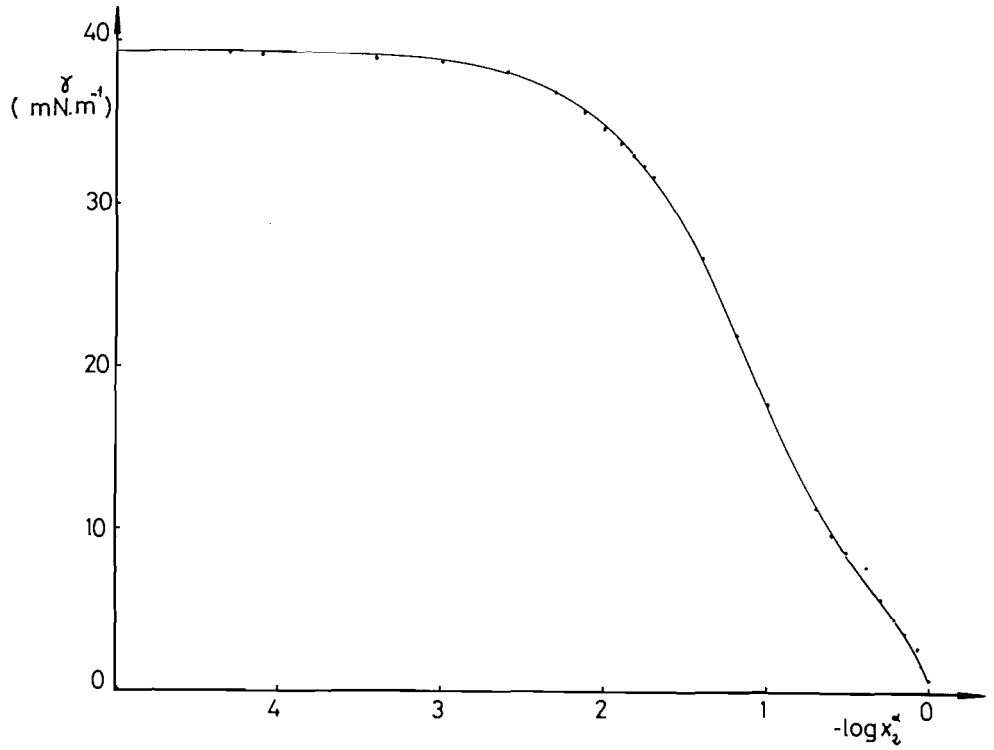

FIG. 2. Variation of the interfacial tension at the water + ethanol/silicone oil interface versus the logarithm of the ethanol molar fraction in the aqueous phase.

undeterminable in this domain with the methods used here, which are applicable only to flat and horizontal interfaces.

The experimental results are shown in Table 1.

IV. Discussion

A. Thermodynamics

The mole fraction of species 2 in the interfacial phase was calculated as indicated above (Fig. 3). The adsorption isotherm, x_2^σ vs. x_2^α, shows a classical shape similar to the corresponding one at the liquid–vapor interface.

The activities of water and ethanol (a_1^σ and a_2^σ respectively) are calculated from the equation giving the identity of the chemical potentials in the bulk and in the surface phase, namely $\mu_i^\alpha = \mu_i^\sigma$ or $RT \ln a_i^\alpha = A_i^{\sigma 0}(\gamma_i^0 - \gamma) + RT \ln a_i^\sigma$, with γ_i^0 the interfacial tension between water or ethanol and the silicone oil. The values of a_2^σ are in the neighborhood of the first bisector (Fig. 4). This indicates small deviations from ideal behavior. The shape of the curve is very close to that found at the liquid–vapor interface for the same aqueous system. The part of the curve corresponding to $x_2^\sigma < 0.275$ remains inferior to the first bisector, which corresponds to Raoult's Law. McGlashan (20) points out that such types of systems contain associated species like $(H_2O)_x(\text{ethanol})_y$.

From these activities, the activity coefficients can be calculated ($f_i^\sigma = a_i^\sigma / x_i^\sigma$), as well as the excess of Gibbs free energy in the surface (Fig. 5):

$$[14] \quad g^{E\sigma}/RT = x_1^\sigma \ln f_1^\sigma + x_2^\sigma \ln f_2^\sigma$$

$g^{E\sigma}/RT$ has a minimal value of -0.14; the deviations from ideality of the mixture are always negative.

B. Structural terms

The anisotropic polynomial, $P(x_2^\sigma)$ is shown in Fig. 6. Its peculiarity is to take into account all the anisotropic contributions in the adsorbed phase σ.

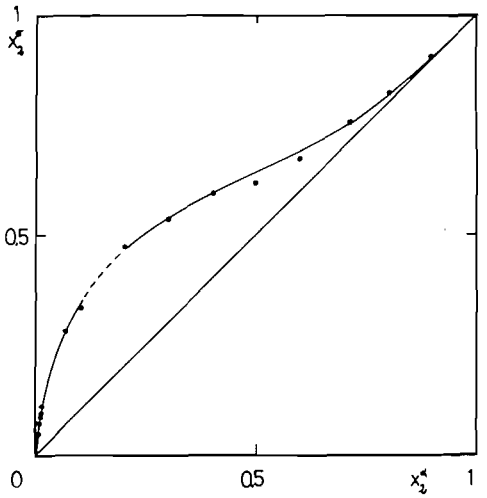

FIG. 3. Adsorption isotherm, 25°C. x_2^σ is the surface mole fraction and x_2^σ the bulk mole fraction.

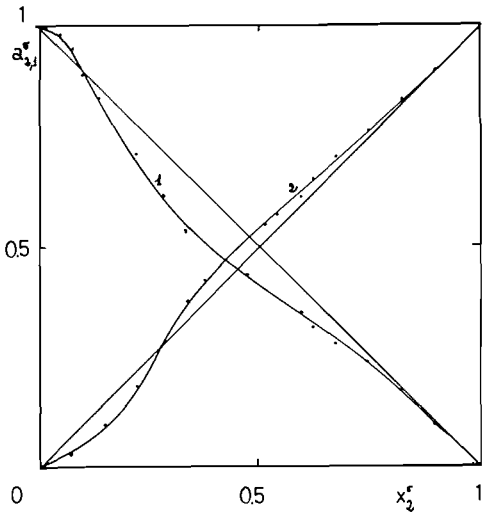

FIG. 4. Surface activities of the two constituents water (1) and ethanol (2) versus the mole fraction of the bulk.

The different changes in the slope of the curves $P(x_2^\sigma)$ vs. x_2^σ are linked to the different structures of the water and ethanol molecules in the surface mixture. $P(x_2^\sigma)$ can be interpreted as a homogeneous function of first degree of the mole fraction, as is done for a volume or an area. The behavior shown in Fig. 6 comes from the shape of the ellipticity coefficient curve, $\bar{\rho} = f(x_2^\sigma)$, and the isotherms; $\bar{\rho}$ vs. x_2^σ presents a maximum in the range of the dilute solutions of ethanol and a plateau in the range of the concentrated solutions with negative values of the ellipticity $\bar{\rho}_E$.

The curve of Fig. 6 shows the orientation of water and ethanol molecules to hardly vary with the composition.

First, for $x_2^\sigma = 0$, i.e., for pure water in contact with silicone oil, $P(x_2^\sigma = 0)$ has a negative value: $\alpha_1^x - \alpha_1^z = -0.12 \times 10^{-24}\,\text{cm}^3$; this value stays the same until $x_2^\sigma = 0.1$ where $\alpha_1^x - \alpha_1^z = -0.13 \times 10^{-24}\,\text{cm}^3$. This parameter reaches a value of $-0.05 \times 10^{-24}\,\text{cm}^3$ for $0.2 < x_2^\sigma < 0.3$ and slows down to $-0.17 \times 10^{-24}\,\text{cm}^3$ at $x_2^\sigma = 0.3$. For $x_2^\sigma > 0.55$ it reaches a constant value of $-0.116 \times 10^{-24}\,\text{cm}^3$.

The above description shows how much the water orientation is changing with the alcohol quantity present in the σ phase. The value $\alpha_1^x - \alpha_1^z = -0.06 \times 10^{-24}\,\text{cm}^3$ can be

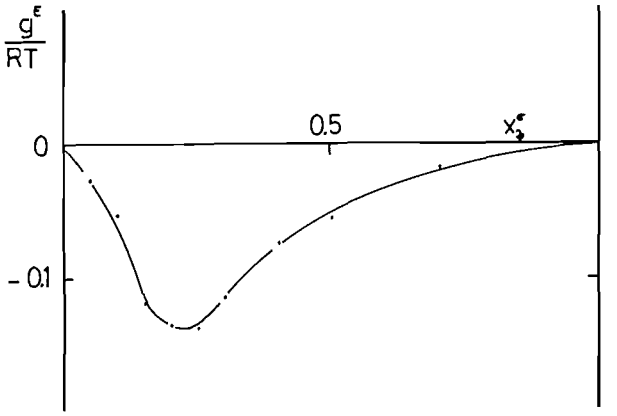

FIG. 5. Excess of the Gibbs free energy for the surface phase versus x_2^σ.

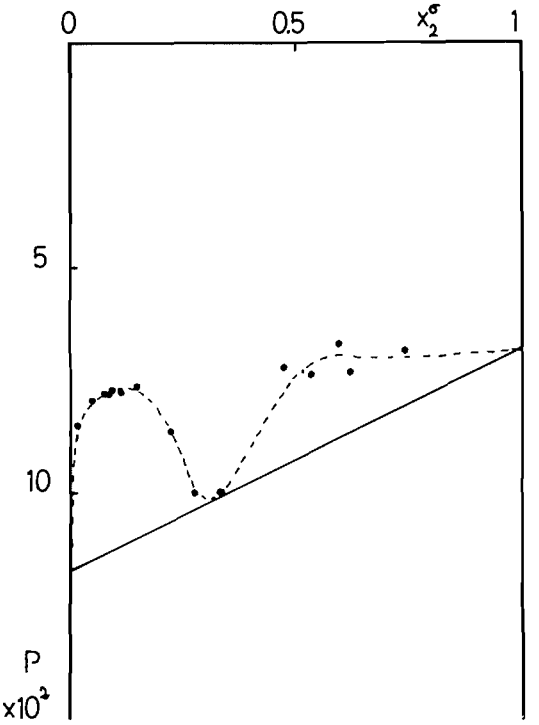

FIG. 6. Anisotropy polynomial P versus x_2^σ.

considered as characteristic of the "new water" invoked by one of us (21) in the case of aliphatic alcohols or acids adsorbed at the liquid–vapor interface.

This water, of a different structure than that of the pure water in contact with silicone oil, is certainly structured both by the alcohol polar group, —OH, and by the aliphatic chain, $-C_2H_5$.

A similar analysis concerning the ethanol can be made.

From the above discussion it seems the silicone oil influences the pure components in a marked way. The molecules of the interfacial mixture reorient themselves when the composition varies. The reorientations are different than those occurring at the liquid–vapor interface for the ethanol–water system. Thus the silicone oil induces a peculiar structure of the interface.

C. Correlation between these results and an interesting experimental fact

The structure change shown by the ellipticity results is closely correlated with the strong variation of surface tension and contact angle with the composition of the system.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

It is a remarkable fact that the water–ethanol mixture has a density very near to the density of the silicone oil in the same region of composition. There, the contact angle on a silica plate is nearly 90°.

The meeting of such properties of both surface phase and volume densities is certainly the cause of a very surprising ability of the system to emulsify. By shaking the two liquid phases in a turbine at 1500 rpm we produce an "oil in water" emulsion with a stability of a few hours; the diameters of the oil droplets are about 12 μm. It seems that, in this case, it is not very difficult to build a relatively stable film of ethanol and water between the oil droplets of the emulsion. The relative emulsion stability is due to the difficulty of the oil droplets to meet and coalesce, because the gravitational forces do not drive them upward or downward.

V. Conclusion

The water–ethanol/silicone oil interface at 25°C shows several reorientations of water and ethanol molecules when the composition is changed. The adsorption isotherm and the activities of the two constituents of the aqueous phase are not noticeably different from those calculated at the liquid–vapor interface.

Finally, the composition domain, where the densities of the two liquid phases are practically the same, corresponds to a zone of possible emulsion, partial or total, which is surprising when taking into account the short alkyl chain of the ethanol.

Synthesis and characterization of Hg(II) complexes of Me_3MCH_2SeMe, (M = Si, Ge). Crystal structures of $[HgX_2(Me_3SiCH_2SeMe)]_2$, X = Cl, Br, I

RAJ K. CHADHA, JOHN E. DRAKE, NEIL T. MCMANUS, AND ANIL MISLANKAR

Received December 10, 1986

RAJ K. CHADHA, JOHN E. DRAKE, NEIL T. MCMANUS, and ANIL MISLANKAR. Can. J. Chem. **65**, 2305 (1987).

Complexes of the general formula $[HgX_2(Me_3MCH_2SeMe)]_2$, where M = Si, Ge; X = Cl, Br, I, have been prepared and characterized by ^1H nuclear magnetic resonance and Raman spectroscopy. Crystal structures of $[HgX_2(Me_3SiCH_2SeMe)]_2$, where X = Cl, Br, and I (**1**, **2**, and **3** respectively), show that they have centrosymmetric dinuclear structures. The crystals of **1** and **2** are monoclinic, while those of **3** are triclinic. For **1**: $P2_1/c$, a = 14.235(11), b = 6.551(6), c = 14.211(9) Å, β = 117.33(5)°, Z = 2, and R = 0.0560. For **2**: $P2_1/c$, a = 14.329(6), b = 6.695(2), c = 14.819(4) Å, β = 118.47(2)°, Z = 2, and R = 0.0540. For **3**: $P\bar{1}$, a = 7.651(2), b = 8.387(2), c = 12.321(4) Å, α = 90.07(2), β = 91.80(2), γ = 116.02(2)°, Z = 1, and R = 0.0565. All three complexes show the expected pseudotetrahedral geometry about mercury. The stereochemical differences arise in the arrangement of the bulky trimethylsilylmethyl groups, which in the HgI_2 adduct are rotated away from the centre of the molecule but which in the $HgCl_2$ and $HgBr_2$ adducts are turned towards the centre. These are the first dinuclear structures reported of $HgBr_2$ and HgI_2 adducts since it was demonstrated 46 years ago by Evans *et al.* that $[HgBr_2(AsBu_3)]_2$ was present in $[HgBr_2(AsBu_3)_2 \cdot HgBr_2]$.

RAJ K. CHADHA, JOHN E. DRAKE, NEIL T. MCMANUS et ANIL MISLANKAR. Can. J. Chem. **65**, 2305 (1987).

On a préparé les complexes de la formule générale $[HgX_2(Me_3MCH_2SeMe)]_2$ dans lesquels M = Si et Ge; X = Cl, Br et I; de plus, on les a caractérisés par la résonance magnétique nucléaire du ^1H et par spectroscopie Raman. Les structures cristallines des complexes $[HgX_2(Me_3SiCH_2SeMe)]_3$ dans lesquels X = Cl, Br et I (respectivement **1**, **2** et **3**) démontrent qu'ils possèdent des structures dinucléaires centrosymétriques. Les cristaux des composés **1** et **2** sont monocliniques alors que ceux du composé **3** sont tricliniques. Pour **1**: $P2_1/c$, a = 14,235(11), b = 6,551(6) et c = 14,211(9) Å, β = 117,33(5)°, Z = 2 et R = 0,0560. Pour **2**: $P2_1/c$, a = 14,329(6), b = 6,695(2) et c = 14,819(4) Å, β = 118,47(2)°, Z = 2 et R = 0,0540. Pour **3**: $P\bar{1}$, a = 7,651(2), b = 8,387(2) et c = 12,321(4) Å, α = 90,07(2), β = 91,80(2) et γ = 116.02(2)°, Z = 1 et R = 0,0565. Ces trois complexes présentent tous, autour du mercure, la géométrie pseudotétraédrique qui est attendue. Les différences stéréochimiques proviennent d'un arrangement des groupements triméthylsilylméthyles qui sont volumineux et qui, dans l'adduit avec le HgI_2, sa retrouent en s'éloignant du centre de la molécule; toutefois, dans les adduits avec le $HgCl_2$ et le $HgBr_2$, ils se retournent vers le centre de la molécule. Ces produits correspondent aux premières structures dinucléaires à être rapportées pour des adduits de $HgBr_2$ et de HgI_3 depuis qu'il a été démontré par Evans *et al.* il y a 46 ans que du $[HgBr_2(AsBu_3)]_2$ est présent dans le $[HgBr_2(AsBu_3)_2 \cdot HgBr_2]$.

[Traduit par la revue]

Introduction

There have been extensive studies of metal–selenoether complexes with respect to the study of pyramidal inversion barriers at Se (2–7). However, there are few examples of crystallographic studies of such complexes. Apart from our recent description of the structures of *trans*-$(Me_3SiCH_2SeMe)_2PdCl_2$ and *trans*-$(Me_3SiCH_2SeMe)_2PtCl_2$ (8), there are three other reports of selenoether–metal complexes; *trans*-$(Et_2Se)_2PdCl_2$ (9), $(MeSeCHCH_3)_2PdCl_2$ (10), and *trans*-$(O(CH_2)_4Se)_2PtBr_2$ (11).

There are a number of reports of structures of mercuric halide adducts with phosphorus donors (12–16) and there have been a few reports of structures of adducts with chalcogen donor molecules, largely of sulfur-containing ligands (17–20). There has been a single report of a mercuric halide adduct with a selenium donor, that of $[HgCl_2(Ph_3P{=}Se]$ (21), and several structural reports of sulfur-containing mercuric chloride adducts (22).

In this paper we report on the preparation and crystal structures of the compounds $[HgX_2(Me_3SiCH_2SeMe)]_2$ (X = Cl, Br, I) as well as the preparation of the germanium analogues $[HgX_2(Me_3GeCH_2SeMe)]_2$ (X = Cl, Br).

Experimental

Materials

Mercuric halide salts were obtained from Mallinkrodt Chemical Co. Me_3MCH_2SeMe (M = Si, Ge) were prepared by the literature method (23).

Preparation of $[HgX_2(Me_3SiMCH_2SeMe)]_2$, where M = Si, Ge; X = Cl, Br)

Me_3MCH_2SeMe (1 mmol) in ethanol (1 mL) was added to an ethanol (5 mL) solution of HgX_2 (1 mmol). The solution was stirred for 1 h before the product was separated by filtration. Recrystallization from refluxing ethanol gave the pure product in ca. 80% yield.

Crystals of $[HgX_2(Me_3SiCH_2SeMe)]_2$, where X = Cl and Br, suitable for X-ray diffraction were obtained by slow evaporation of a saturated solution of the compounds in 50% methanol/acetone.

Preparation $[HgI_2(Me_3SiCH_2SeMe)]_2$

$MeSiCH_2SeMe$ (0.1 g; 0.55 mmol) in ethanol (1 mL) was added to a stirred slurry of HgI_2 (0.21 g; 0.44 mmol) in ethanol (5 mL). The mixture was stirred until the orange slurry had turned to an almost colorless solution (ca. 0.5 h). The volume of solvent was reduced to ca. 3 mL under vacuum and then the solution was stored at 4°C for 20 h, yielding yellow crystals (0.23 g; 82%). Crystals suitable for X-ray studies were obtained by slow evaporation of an acetone solution. The crystals were hygroscopic and decomposed on prolonged exposure to the atmosphere.

Attempted isolation of $[HgI_2(Me_3GeCH_2SeMe)]_2$

A procedure analogous to that just described for the preparation of $[HgI_2(Me_3SiCH_2SeMe)]_2$ was carried out starting with Me_3GeCH_2SeMe. However, whenever attempts were made to remove the solvent under vacuum, the pale yellow solid reverted to the orange red of HgI_2 and a suitable sample for analysis was not obtained.

Instrumentation

The ^1H nmr spectra were recorded on a Varian EM360 spectrometer in acetone-d_6 and $CDCl_3$ using TMS as internal standard. Raman

spectra were obtained of solid samples in glass capillaries on a Spex 1403 double monochromator using the 488-nm argon line for excitation.

Crystal structure determination

In each determination, a prismatic crystal sealed in a capillary tube was mounted along the largest dimension and the data were collected with a Syntex $P2_1$ diffractometer following the procedure described earlier (24). The intensities of three monitor reflections changed only by approximately ±2% during the entire period of data collection (69–72 h). The least-squares refinement of the setting angle of 15 high angle reflections ($15 < 2\theta < 30°$) yielded the cell constants given in Table 1. The systematic absences of $0k0$ and $h0l$ were noted for odd k and l in **1** and **2**, indicating the space group $P2_1/c$. For **3**, the space group $P\bar{1}$ was used and later assumed correct because of successful refinement. The data were corrected for Lorentz and polarization effects, and analytical absorption corrections were applied.

The structures of **1** was solved by using the conventional sharpened Patterson synthesis. Since **1** is isomorphous with **2**, the same set of atomic coordinates were used for **2**. The structure of **3** was solved by direct methods using the program SHELX.

The structure of **1** was solved by using the conventional sharpened minimizing the function $(|F_o| - |F_c|)^2$ with all non-hydrogen atoms being treated anisotropically. Hydrogen atoms were included at the idealized positions (C—H = 0.95 Å, HCH = 109.5°) with isotropic U's set at 0.01 Å^2 greater than that of the corresponding carbon atom. Convergence was achieved at R = 0.0560, 0.0540, and 0.0565 and $R_{\omega F}$ = 0.0580, 0.0580, 0.0601 for **1**, **2**, and **3** respectively. A weighting scheme of the form $\omega = [\Sigma\sigma^2(F) + \rho F^2]^{-1}$ was employed, with final ρ values of 0.00035, 0.00078, and 0.00040 in **1**, **2**, and **3** respectively. For **2** and **3**, a few low angle reflections were found to be affected by secondary extinctions. An empirical isotropic extinction parameter, x, was used employing the equation $F_c = F[1 - 0.0001x(F^2/\sin\theta)]$ and refined to the values of 0.00422 and 0.00400 respectively. The final difference map had a few peaks with intensities between 1 and 2 e Å^{-3}, which were without any chemically feasible connectivity.

Sources of scattering factors and computer programs are given elsewhere (24). The final atomic coordinates are given in Table 2 and important distances and angles in Table 3. The structure factor tables and unit cell diagrams have been deposited.[1]

Results and discussion

The adducts $[HgX_2(Me_3MCH_2SeMe)]_2$ (X = Cl, Br, I; M = Si, Ge) are prepared by mixing equimolar amounts of the appropriate mercuric halide and the selenoether in ethanol at room temperature; for X = Cl or Br the adducts precipitate from ethanol at room temperature whereas the adduct of mercuric iodide crystallizes out on cooling the solution to −4°C.

$$HgX_2 + Me_3MCH_2SeMe \rightarrow [HgX_2(Me_3MCH_2SeMe)]_2$$

(X = Cl, Br, I; M = Si)

(X = Cl, Br, M = Ge)

The analytical results, melting points, and ^{1}H nmr chemical shifts are given in Table 4. We had some difficulty in finding suitable solvents in which to record the ^{1}H nmr spectrum of the adducts because of their lack of solubility. In $CDCl_3$, the $CHCl_3$ peak was considerably stronger than any of the peaks attributable to the adduct. In acetone-d_6, the CD_3OCD_2H peak was also much in evidence but it was clear that the adducts were more soluble in this medium. There was no indication that acetone had displaced the selenium-containing ligand so this became the medium of choice. The lack of additional peaks in acetone-d_6 solution and the expected integration ratios indicate that there are no other proton-containing species present. Because of the lack of solubility we did not undertake any studies to establish if there was rapid exchange between complex and free ligand, and so the ^{1}H nmr spectra only serve to

[a]All compounds are white except **3**, which is yellow.
[b]Recorded in acetone-d_6.

indicate that the adducts do exist in solution because the chemical shifts are different from those of free ligands and differ from adduct to adduct.

All three Me_3SiCH_2SeMe adducts, **1**, **2**, and **3**, have the same basic structure, in the solid state, of centrosymmetric, dinuclear, halogen-bridged units. Similar structures have been observed for $[HgCl_2(Ph_3P{=}Se)]_2$ (21), $[HgCl_2(PPh_3)_2]_2$ (14), $[HgCl_2(1,1,5\text{-triphenylphosphate})]_2$ (14), $[HgCl_2(PBu_3)]_2$ (16), and $[HgCl_2(\text{methylpyrolidine 1-carbodithioate})]_2$ (17), but these are by no means the only possible structures for mercuric halide adducts, mononuclear complexes having been isolated such as $[HgCl_2(S(CH_2CH_2)O)_2]$ (19) as well as polymeric structures such as $[HgCl_2(PMe_3)]$ (13). Mononuclear and polymeric structures seem to be preferred when the donor ligand is strongly electron releasing, such as PMe_3 and PEt_3. However, **2** and **3** have dinuclear structures that are closely related to the structure of $[(HgBr_2)_3(AsBu_3)_2]$ in which there are units of $[HgBr_2(AsBu_3)]_2$ linked to $HgBr_2$ units by bromine bridges (1). Apart from this related compound, they are the first dinuclear structures reported for $HgBr_2$ and HgI_2 adducts.

All three adducts, **1**, **2**, and **3**, contain mercury atoms surrounded by a pseudotetrahedral arrangement. However, the distortion from all-tetrahedral angles is considerably larger in **1** and **2** than in **3**. Also, although the terminal Hg—X bonds, as expected, are significantly shorter than the bridging Hg—X bonds, the difference is once again much more marked for HgCl and HgBr (13 and 12% respectively), than for HgI (only 7%). Further, in **1** and **2**, the position of the selenoether group is such that the methylene group sits over the central bridging group so that the bulkier Me_3SiCH_2 moiety is essentially sitting on top of the bridge system (Figs. 1 and 2). By contrast, in **3**, the Me_3SiCH_2 moiety is positioned away from the central bridging system (Fig. 3). In all of the complexes the two selenoether groups are mutually *trans*.

The large distortion from tetrahedral angles in **1** and **2** is particularly evident for the terminal X(1)—Hg—Se angle (146.312°) for X = Cl and 143.2(1°) for X = Br), which thus displays a tendency towards a linear bonding system. This phenomenon has also been observed in $[HgCl_2(Ph_3P{=}Se)]_2$ (21) (Cl—Hg—Se = 136.3(2)°) and β$[HgCl_2(PBu_3)]_2$ (12) (Cl—Hg—P = 150.6(3)°) and has been ascribed to the strong donor–acceptor bond between mercury and the donor atom, which confers a high degree of *s*-character in the X—Hg—L bonding system. Such a postulate is supported by the fact that the X—Hg—X′ angles for the bridging halides, i.e., Cl(2)—Hg—Cl(2′) = 87.8(2)° and Br(2)—Hg—Br(2′) = 90.5(1)°, are close to 90°C, as they are in $[HgCl_2(Ph_3P{=}Se)]$ and β$[HgCl_2(PBu_3)]_2$, which would be expected if these bonds essentially use orbitals of *p*-character on mercury in forming the bridge. By contrast, in **3**, the

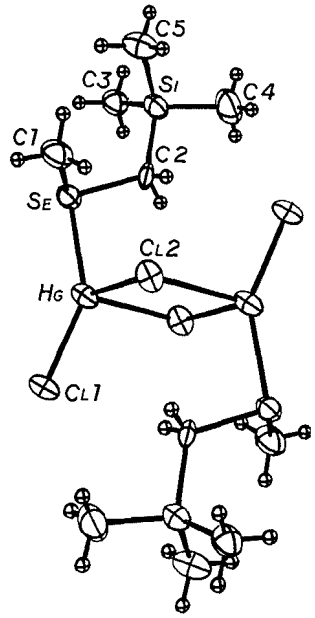

FIG. 1. ORTEP drawing of $[Me_3SiCH_2SeMe]HgCl_2$. The thermal parameters are drawn at 50% probability except for H atoms, which are at an arbitrary level. Unlabeled atoms are related to the labeled ones by a centre of inversion.

TABLE 5. Selected Raman spectroscopy data for $[HgX_2(Me_3MCH_2\text{-}SeMe)]_2$

X	M	ν(Hg—X_t) (terminal)	ν(Hg—X_b) (bridge)	ν(Hg—Se)	δ(Hg—X_t)
Cl	Si	301 (100)	169 (20)	205 (45)	119 (90)

Br	Ge	211 (40)	130 (30)	188 (50)	71 (80)

Numbers in parentheses indicate relative intensities of peaks below 400 cm^{-1}.

I(1)—Hg—Se angle is essentially tetrahedral, (109.3(1)°, with the I(2)—Hg—I2′) angle at 95.3(1)°. These trends are consistent with a weaker Hg—Se interaction, presumably because HgI_2 is the weakest Lewis acid of the three mercuric halides.

This assumption is supported by the fact that the Hg—Se bond of **3** is considerably longer, 2.687(2) Å, than in **1** and **2**, 2.528(2) and 2.558(2) Å respectively. The distance observed for **1** is virtually identical to that of $[HgCl(Ph_3P{=}Se)]$, 2.527 Å. In both **1** and **2** the distances are significantly shorter than that

[a]Anisotropic temperature factors are of the form

$$\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^* - 2U_{13}hla^*C^* + 2U_{23}klb^*C^*)].$$

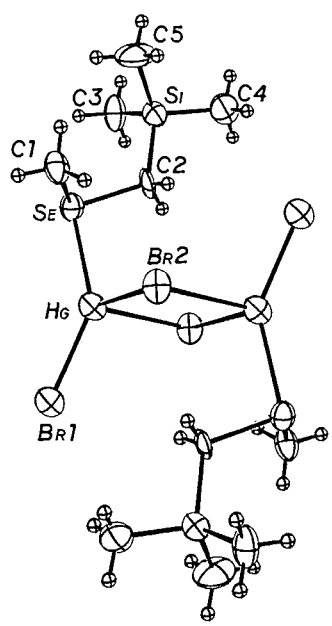

FIG. 2. Perspective view of $[Me_3SiCH_2SeMe]HgBr_2$.

predicted by summing the covalent radii of Se and tetrahedral Hg (2.63 Å) (25). The Hg—Se bond is markedly longer and the weakness of the Se—HgI_2 bond may be related to the ease with which the complex decomposes in moist air. The adduct between Me_3GeCH_2SeMe and HgI_2 was too weak to withstand attempts at isolation.

The bond angles around Se should also reflect the strength of the donor bond. With increased donation there should be an increase toward all tetrahedral angles, as has been illustrated well for trimethylarsine derivatives (26). The C(1)—Se—Hg angle is indeed slightly larger in **1** and **2** (100.8(9) and 100.5(6)° respectively) than in **3** (98.3(6)°). All are considerably smaller than the equivalent C—Pd—Se bond in $(Me_3SiCH_2SeMe)_2$-$PdCl_2$, which is 108.0(2)° (8). In the latter compound the Pd—Se bond is relatively short, suggesting that $PdCl_2$ is a better Lewis acid than $HgCl_2$. It has been observed for a number of $HgCl_2$ adducts that the terminal Hg—Cl distance reflects the donor action of the attached ligand in such a manner that longer Hg—Cl distances are obtained with stronger donors (27), e.g., for $\beta[HgCl_2(PBu_3)]_2$, Hg—Cl = 2.348(6) and for $[HgCl_2$-$(PPh_3)]_2$, Hg—Cl = 2.370(7). The Hg—Cl distance for **1** of 2.354(5) Å implies a donor strength intermediate between PBu_3 and PPh_3. The bridging Hg—Cl distances for **1** (2.698(5) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

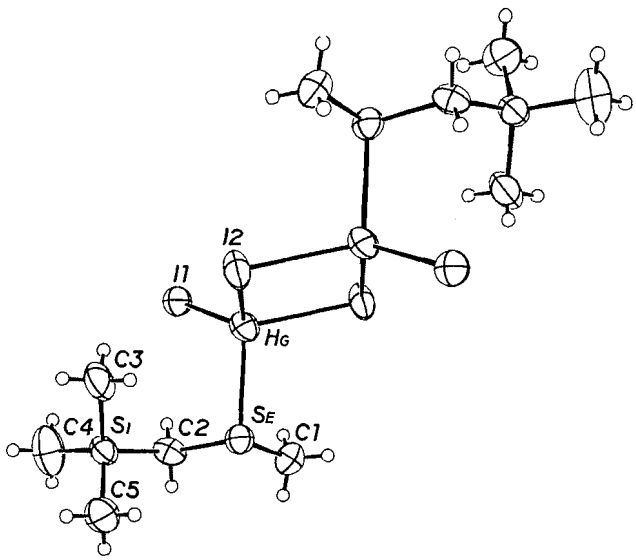

FIG. 3. Perspective view of $[Me_3SiCH_2SeMe]HgI_2$.

2.707(5) Å) also fall between those of the PPh_3 and PBu_3 adducts (2.623(8) and 2.658(8), and 2.718(6) and 2.737(6) Å, respectively). The Hg—Br distance for **2** of 2.473(2) Å is very close to that reported for the $[HgBr_2(AsBu_3)]_2$ unit in $[(HgBr_2)_3(AsBu_3)_2]$, while the Hg—Br bridging distances of 2.803(2) and 2.826(2) Å in **2** bracket the values of 2.6 and 2.9 Å reported for $[HgBr_2(AsBu_3)]_2$ (1). There has been a structural report of a Cd—Hg iodo-bridged species, $I_2Cd\mu(I)_2Hg(PPc_3)_2$ (28), and the monomeric species $HgI_2(PPh_3)_2$ (29). The bridging Hg—I distances in $I_2Cd\mu(I)_2Hg(PPr_3)_2$ of 3.077(1) and 3.056(1) Å are rather longer than those for **3** (2.863(1) and 2.861(1) Å). This is probably a reflection of electron-donating effects of the PPr_3 groups in the former complex.

Selected low frequency vibrational bands in the solid-state Raman spectra are shown with their assignments in Table 5. The far infrared region showed very broad bands from which it was impossible to identify individual features. The values of the bridging and terminal Hg—X bands are consistent with those reported for various HgX_2 phosphine adducts (30). It is clear that the bands in the Me_3GeCH_2SeMe adducts are in general similar in shape, position, and relative intensity to those of Me_3SiCH_2SeMe, suggesting that they probably also have a similar dimeric structure. Unfortunately, it was not possible to obtain crystals of sufficient quality to obtain their structures by X-ray diffraction.

The assignments of the Hg—X (terminal) stretching vibrations, $\nu(Hg—X_t)$, can also be readily made by comparison with the assignment of ν_1 in $HgCl_2$ (313), $HgBr_2$ (195) (31), and HgI_2 (137 cm^{-1} (32). Similarly the Hg—X_t bending mode, $\delta(Hg—X_t)$, can be assigned by comparison with ν_2 in $HgCl_2$ (126) (33), $HgBr_2$ (66) (34), and HgI_2 (26 cm^{-1} (32). The stretching vibrations are assigned in the spectrum of $[HgBr_2(Me_3SiCH_2SeMe)]_2$ as $\nu(Hg—Br_t)$, 213; $\nu(Hg—Se)$, 176; and $\nu(Hg—Br_b)$, 131 cm^{-1}. Given the different environments but at the same time recognizing that the masses of Br and Se are essentially the same, this successive lowering of the wave number fits well with the increasing bond lengths of Hg—Br_t, 2.473(2); Hg—Se, 2.558(2); and Hg—Br_b, 2.81(2) Å. Similar sequential shifts are noted in the assignments of the spectrum of $[HgBr_2(Me_3GeCH_2SeMe)]_2$. The assignment of $\nu(Hg—Se)$ in the chloride, bromide, and iodide adducts, $[HgX_2(Me_3SiCH_2SeMe)]_2$, of 205, 176, and 162 cm^{-1} respectively also match the increase in the bond lengths of Hg—Se along the series, i.e., 2.70(1), 2.81(2), and 2.862(2) Å. In species such as Al_2X_6, Ga_2X_6, and In_2I_6, where there are both bridging and terminal halogen bonds, the ratio of the assigned frequencies, $\nu(M—X_b)$, varies from approximately 1:2 (e.g., in Al_2I_6) (35) to 3:4 (e.g., Ga_2Cl_6) (36). The assignments in the $[HgX_2(Me_3MCH_2SeMe)]_2$ adducts fall in this range, with the biggest difference being noted for the chloride, where there is the largest difference between the Hg—Cl_t, 2.354(5), and Hg—Cl_b, 2.70(1) Å, bond lengths. In summation, the Raman spectra totally reflect the findings from the X-ray diffraction data.

Radical ions in photochemistry. 18. The photosensitized (electron transfer) tautomerization of alkenes; the 1,1-diphenyl alkene system

DONALD R. ARNOLD[1] AND SHELLEY A. MINES
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received March 12, 1987

This paper is dedicated to Professor Douglas E. Ryan

DONALD R. ARNOLD and SHELLEY A. MINES. Can. J. Chem. **65**, 2312 (1987).

The photosensitized (electron transfer) irradiation of several conjugated 1,1-diphenyl alkenes, in acetonitrile with 1,4-dicyanobenzene or 1-cyanonapthalene as electron accepting sensitizer and 2,6-lutidine as base, leads essentially quantitatively to tautomerization to the less stable unconjugated isomer(s). The proposed mechanism for this reaction involves formation of the alkene radical cation and sensitizer radical anion followed by deprotonation of the radical cation, reduction of the resulting radical to the ambident anion by back electron transfer from the radical anion, and reprotonation. There are several steps in this mechanism that could control the ratio of isomers. Evidence is provided that, at least in some cases, it is the relative rate of deprotonation from the isomeric radical cations that is the determining factor. This rate is influenced by the conformation of the radical cation; the carbon–hydrogen bond involved in the deprotonation step must overlap with the singly occupied molecular orbital.

DONALD R. ARNOLD et SHELLEY A. MINES. Can. J. Chem. **65**, 2312 (1987).

L'irradiation photosensibilisée (transfert d'électron) de plusieurs diphényl-1,1 alcènes conjugués, effectuée dans l'acétonitrile avec du dicyano-1,4 benzène ou du cyano-1 naphtalène comme sensibilisateur acceptant les électrons et de la lutidine-2,6 comme base, conduit essentiellement et avec un rendement quantitatif à une tautomérisation vers le (ou les) isomère(s) le(s) moins stable(s). Le mécanisme proposé pour cette réaction implique (*a*) la formation du cation radical de l'alcène et de l'anion radical du sensibilisateur, (*b*) une déprotonation du cation radical, (*c*) une réduction du radical qui en résulte, par un retransfert d'électron de la part du radical anion, conduisant à l'anion ambidentate et (*d*) une reprotonation. Plusieurs étapes de ce mécanisme pourraient contrôler le rapport des isomères. On présente des données qui suggèrent, au moins dans quelques cas, que c'est la vitesse relative de déprotonation des cations radicaux isomères qui est le facteur déterminant. Cette vitesse est influencée par la conformation du cation radical; il doit y avoir un recouvrement de la liaison carbone–hydrogène impliquée dans l'étape de déprotonation avec l'orbitale moléculaire qui est occupée d'une façon célibataire.

[Traduit par la revue]

The tautomerization of alkenes, by either acid or base catalysis, is an old and relatively well-understood process (1). The composition of the equilibrium mixture reflects the thermodynamic stability of the isomers. Conjugation of a double bond with an aryl group has a profound effect on stability; for example, at equilibrium β-methyl styrene dominates over allylbenzene by three to four orders of magnitude (2). Until now there has been no direct way to counteract the thermodynamic driving force of this equilibrium, that is, to convert a conjugated aryl alkene into a less stable unconjugated isomer. Such a process would have significant synthetic utility because the more stable isomer is usually much more readily prepared by classical methods. We can now describe the first examples of this process, the photosensitized (electron transfer) tautomerization of alkenes.

A solution of 1,1-diphenyl-2-methylpropene (**1**) in acetonitrile, with 1,4-dicyanobenzene or 1-cyanonapthalene as electron accepting sensitizer and 2,6-lutidine as base, was irradiated with a medium-pressure Hg vapor lamp through Pyrex. Progress of the reaction was followed by capillary column gas chromatography with a mass selective detector (gc/ms). The tautomer, 3,3-diphenyl-2-methylpropene (**2**), was the only volatile product detected. Irradiation was continued until the reaction was complete, when chromatography of the crude photolysate gave **2** in excellent yield. The photosensitizer was largely recovered.

Several related conjugated 1,1-diphenyl alkenes are likewise converted into less stable tautomers by irradiation under these conditions. Table 1 provides a summary of these results. In every case the isomerization went to completion and the isolated yield of the tautomer(s) was excellent.

All of the starting alkenes and most of the tautomers were known compounds; *E*-**4**, *Z*-**4**, **5**, **7**, and **12** have not, to our knowledge, been described previously. Structural assignments rest firmly on a thorough analysis of the ^{1}H and ^{13}C nmr spectra. The assignment of configuration of the isomers *E*-**4** and *Z*-**4** was made on the basis of the ^{1}H–^{13}C coupling constants observed in the ^{13}C nmr spectra.[2]

The proposed mechanism is shown (simplified) in Scheme 1. If we consider the process in general, there are several key steps ([2], [3], [4], and [7]) that could direct the product ratio toward the less thermodynamically stable tautomer.[3] The rates of steps [2*a*] and [2*b*] depend upon the oxidation potentials of the tautomers in relation to the reduction potential of the excited state of the photosensitizer. These rates can be estimated by use of the Weller equation (5). Since the oxidation potentials of the tautomers may be significantly different, it will be possible in some cases to choose a sensitizer that will accept an electron

[1]Author to whom correspondence may be addressed.

[2]Coupling of the vicinal vinyl proton to the carbon of the allylic methyl should be greater for the *Z*-**4** than for the *E*-**4**; the observed coupling constants are 7.1 and 2.9 Hz.

[3]A similar mechanism was recently proposed for the tautomerization of an acetylene to an allene (3). There are some other less closely related photochemical tautomerization reactions (4).

TABLE 1. The photosensitized (electron transfer) tautomerization of 1,1-diphenyl alkenes[a]

Starting alkene	Product
1,1-Diphenyl-2-methylpropene (**1**)	3,3-Diphenyl-2-methylpropene (**2**)
1,1-Diphenyl-2-methylbutene (**3**)	(*E*)-1,1-Diphenyl-2-methyl-2-butene (*E*-**4**)[b]
	(*Z*)-1,1-Diphenyl-2-methyl-2-butene (*Z*-**4**)
	3,3-Diphenyl-2-ethylpropene (**5**)
1,1-Diphenyl-2,3-dimethylbutene (**6**)	3-Methyl-2-(diphenylmethyl)-1-butene (**7**)[c]
	1,1-Diphenyl-2,3-dimethyl-2-butene (**8**)
1,1-Diphenylmethylenecyclohexane (**9**)	1-(Diphenylmethyl)cyclohexene (**10**)
1,1-Diphenylmethylenenorbornane (**11**)	2-(Diphenylmethyl)norbornene (**12**)
1-Phenyl-3,4-dihydronaphthalene (**13**)	1-Phenyl-1,4-dihydronaphthalene (**14**)[d]
	1-Phenylnaphthalene (**15**)

[a]A solution in acetonitrile of 2,6-lutidine (0.1 *M*), 1,4-dicyanobenzene or 1-cyanonaphthalene (0.1 *M*), and the starting alkene (0.15 *M*) was irradiated at 10°C with a 1-kW medium-pressure Hg vapor lamp until reaction was complete. The product(s) was (were) isolated, in high yield (>85%), by column chromatography on silica gel. Both sensitizers work well; both are largely recovered. The greater solubility and extended long-wavelength absorption of 1-cyanonaphthalene make it the sensitizer of choice.

[b]The initial ratio of *E*-**4**:*Z*-**4**:**5** was 80:10:1. This ratio was dependent upon extent of conversion; when the reaction was complete the ratio was 8:4:1.

[c]**7**:**8** > 200:1 (**8** was not detected (gc/ms, ^{1}Hmr).

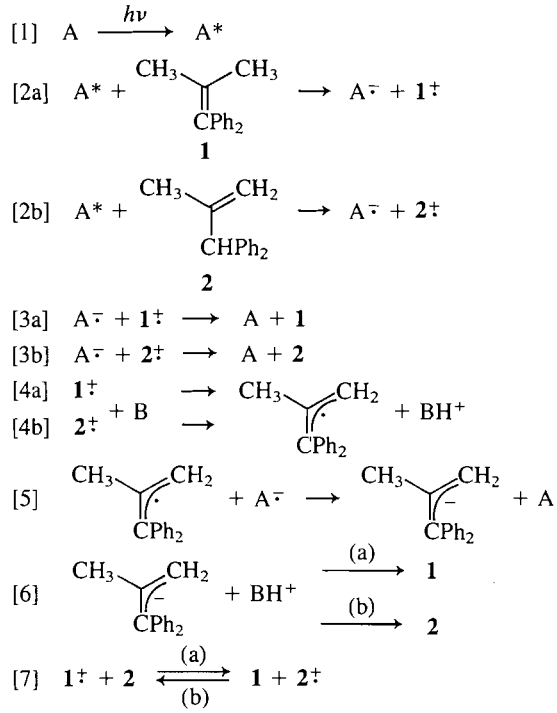
[d]**14**:**15**, 7:1. Disproportionation of the intermediate radical may account for the formation of **15**; driven by aromatization.

from the more easily oxidized tautomer at a significantly faster rate. The rates of the back electron transfer process, steps [3*a*] and [3*b*], will also depend upon the oxidation potentials of the two tautomers. Back electron transfer may be so energetically favourable that the rates are in the "inverted Marcus region"; that is, the more exothermic the process, the slower the rate (6). If the alkene radical cations can equilibrate (steps [7*a*] and [7*b*]), the tautomer with the lower oxidation potential will be favoured. Competition at all of these steps tends to favour the ultimate formation of the tautomer with the higher oxidation potential.

Steps [4*a*] and [4*b*] represent the deprotonation of the two radical cations. The tautomer with the higher oxidation potential will have the greater acidity and it may be possible to choose a base that will deprotonate it selectively (7). This would shift the product ratio in favour of the conjugated tautomer. However, it is the relative rates of steps [4*a*] and [4*b*] that are important and the relationship between the thermodynamic and kinetic acidity of radical cations is still poorly understood.

Relevant to the discussion of the specific mechanism involved in the case of these 1,1-diphenyl alkenes are the reactions of the series: 1,1-diphenyl-2-methylpropene (**1**), 1,1-diphenyl-2-methylbutene (**3**), and 1,1-diphenyl-2,3-dimethylbutene (**6**). While both [2*a*] and [2*b*] should be diffusion controlled when 1,4-dicyanobenzene is the acceptor, [2*a*] should be significantly faster than [2*b*] when 1-cyanonapthalene is used (8). Because the unconjugated tautomer(s) is (are) the exclusive product(s) with both sensitizers, the relative rates of these initial electron transfer processes cannot be the only factor influencing the product ratio.

The tautomerization of **1** indicates that deprotonation from a methyl group and subsequent isomerization to a terminal alkene (**2**) is possible. However, the predominant formation of *E*-**4** and *Z*-**4** from **3** indicates that deprotonation from the ethyl group is kinetically favoured over deprotonation from the methyl group. This is consistent with the relative thermodynamic acidity at these two positions since deprotonation from the ethyl group gives the more heavily substituted, and therefore more stable, allylic radical (7). In contrast, **7** is formed exclusively upon



SCHEME 1

tautomerization of **6**. In this case, deprotonation occurs preferentially from the methyl group rather than from the isopropyl group.

For deprotonation to occur, the radical cation must adapt a conformation that allows overlap of the allylic carbon–hydrogen bond with the singly occupied molecular orbital (SOMO). This is possible with the methyl groups of **1** and with the ethyl group of **3**, but the two methyls of the isopropyl group of **6** prefer the out-of-plane staggered orientation. In this conformation the allylic isopropyl hydrogen is orthogonal to the SOMO.[4] Therefore, we conclude that the ratio of product

[4]This line of reasoning has been used before (9).

tautomers is dependent upon the relative rates of deprotonation of the radical cation from the allylic positions (steps [4*a*] and [4*b*]).

A thorough study of the scope and mechanism of this reaction is now in progress.

The stereoselective alkylation and conformational analysis of 14-membered lactones

J. TERCIO B. FERREIRA,[1] EDWARD G. NEELAND, JAMES P. OUNSWORTH, AND LARRY WEILER[2]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received April 2, 1987

J. TERCIO B. FERREIRA, EDWARD G. NEELAND, JAMES P. OUNSWORTH, and LARRY WEILER. Can. J. Chem. **65**, 2314 (1987).

The 14-membered lactone, 13-tetradecanolide, can be alkylated to give mainly the 2*R**,13*S**-dimethyltridecanolide. A second alkylation gives the 2,2-dimethyl lactone. The conformation of the starting material and alkylation products exist in the regular [3434] conformation. This model is used to rationalize the stereochemical outcome of the reaction and suggest the conformation of the intermediate enolate.

J. TERCIO B. FERREIRA, EDWARD G. NEELAND, JAMES P. OUNSWORTH et LARRY WEILER. Can. J. Chem. **65**, 2314 (1987).

On peut alkyler la lactone à 14 chaînons, tétradécanolide-13, et l'on obtient principalement le diméthyl-2*R**,13*S** tridécanolide. Une seconde alkylation conduit à la lactone diméthylée en position 2,2. Les conformations du produit de départ ainsi que des produits d'alkylation sont les conformations régulières [3434]. On a utilisé ce modèle pour rationaliser l'évolution stéréochimique de la réaction et pour suggérer une conformation pour l'intermédiaire énolique.

[Traduit par la revue]

In 1981 Still and Galynker, in a seminal paper, reported the stereoselective alkylation of a number of monosubstituted 8- to 12-membered ring ketones and lactones (1). Invariably these reactions proceeded with high selectivity to yield one of the two possible diastereomeric products. This high diastereoselectivity was rationalized in terms of the conformational energies of the enolate intermediates, which were obtained from molecular mechanics calculations. The model that evolved from these studies was that of a relatively rigid enolate that was attacked by an electrophile from the more open face (1). Subsequent studies, particularly by Still's group, illustrated this conformational control of stereochemistry in other reactions of medium and large rings (2). Molecular mechanics calculations were required to rationalize the observed stereoselectivity because of the irregular conformations of many medium and large ring systems (3). However, the 14-membered ring is known to often exist in a well-defined diamond lattice, which can be considered to be composed of portions of a chair cyclohexane as illustrated in **1**. We were interested in studying the reactivity of the 14-membered lactone to see if the stereoelectronic properties of cyclohexane and other 6-membered rings might be extended to these systems. This communication reports our results on the alkylation and conformational properties of tridecanolides.

Treatment of lactone **2** with lithium 2,2,6,6-tetramethylpiperidide in THF at −78°C followed by alkylation of the resulting enolate with methyl iodide gave a mixture of two

The stereoselective alkylation and conformational analysis of 14-membered lactones

J. TERCIO B. FERREIRA,[1] EDWARD G. NEELAND, JAMES P. OUNSWORTH, AND LARRY WEILER[2]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received April 2, 1987

J. TERCIO B. FERREIRA, EDWARD G. NEELAND, JAMES P. OUNSWORTH, and LARRY WEILER. Can. J. Chem. **65**, 2314 (1987).

The 14-membered lactone, 13-tetradecanolide, can be alkylated to give mainly the 2*R**,13*S**-dimethyltridecanolide. A second alkylation gives the 2,2-dimethyl lactone. The conformation of the starting material and alkylation products exist in the regular [3434] conformation. This model is used to rationalize the stereochemical outcome of the reaction and suggest the conformation of the intermediate enolate.

J. TERCIO B. FERREIRA, EDWARD G. NEELAND, JAMES P. OUNSWORTH et LARRY WEILER. Can. J. Chem. **65**, 2314 (1987).

On peut alkyler la lactone à 14 chaînons, tétradécanolide-13, et l'on obtient principalement le diméthyl-2*R**,13*S** tridécanolide. Une seconde alkylation conduit à la lactone diméthylée en position 2,2. Les conformations du produit de départ ainsi que des produits d'alkylation sont les conformations régulières [3434]. On a utilisé ce modèle pour rationaliser l'évolution stéréochimique de la réaction et pour suggérer une conformation pour l'intermédiaire énolique.

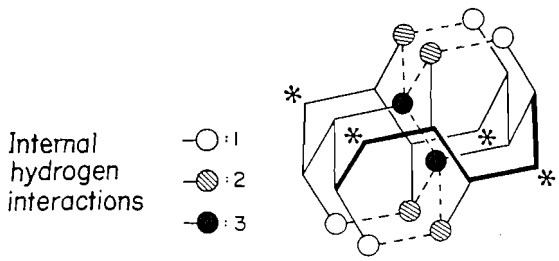
[Traduit par la revue]

In 1981 Still and Galynker, in a seminal paper, reported the stereoselective alkylation of a number of monosubstituted 8- to 12-membered ring ketones and lactones (1). Invariably these reactions proceeded with high selectivity to yield one of the two possible diastereomeric products. This high diastereoselectivity was rationalized in terms of the conformational energies of the enolate intermediates, which were obtained from molecular mechanics calculations. The model that evolved from these studies was that of a relatively rigid enolate that was attacked by an electrophile from the more open face (1). Subsequent studies, particularly by Still's group, illustrated this conformational control of stereochemistry in other reactions of medium and large rings (2). Molecular mechanics calculations were required to rationalize the observed stereoselectivity because of the irregular conformations of many medium and large ring systems (3). However, the 14-membered ring is known to often exist in a well-defined diamond lattice, which can be considered to be composed of portions of a chair cyclohexane as illustrated in **1**. We were interested in studying the reactivity of the 14-membered lactone to see if the stereoelectronic properties of cyclohexane and other 6-membered rings might be extended to these systems. This communication reports our results on the alkylation and conformational properties of tridecanolides.

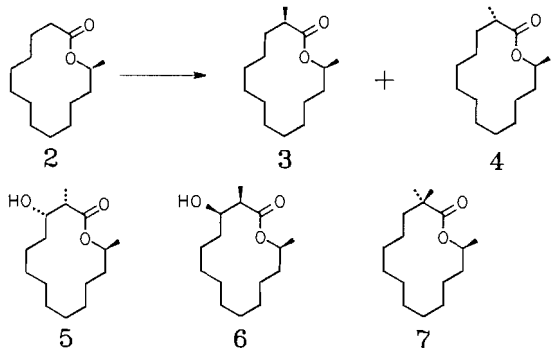
Treatment of lactone **2** with lithium 2,2,6,6-tetramethylpiperidide in THF at −78°C followed by alkylation of the resulting enolate with methyl iodide gave a mixture of two

[1]On leave from the Departamento de Quimica, Universidade Federal de Sao Carlos, Sao Carlos, Brazil.

[2]Author to whom correspondence may be addressed.



isomeric monoalkylated products, **3** and **4**, in 80–85% yield, and the ratio of isomers was 13:1. Surprisingly, the two isomers were easily separated by tlc or flash chromatography (4). The spectroscopic data of the two isomers, although clearly differ-

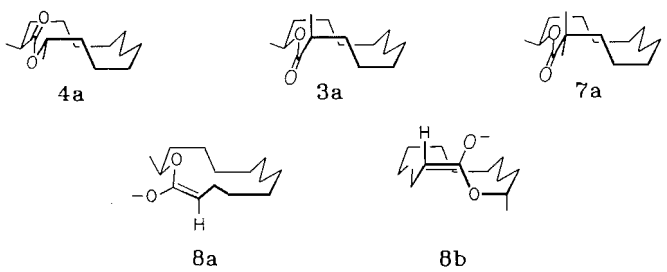


ent, did not allow us to readily assign the stereochemistry to each diastereomer.

We have prepared the substituted 14-membered lactones **5** and **6** (5), and determined their structures by X-ray crystallography[3] and spectroscopic methods. Treatment of the alcohol **5** with LDA, CS_2, and MeI gave the xanthate, which was deoxygenated with tri-*n*-butyltin hydride to give the 2*S**,13*S**-dimethyltridecanolide in 41% yield (6). This compound was identical in all respects to the minor isomer **4** in the alkylation. Similarly **6** was deoxygenated to the 2*R**,13*S** isomer, which was identical to the major alkylation product **3**.

Treatment of **3** or **4** with LDA and MeI gave the *gem*-dimethyl product **7**. The nmr spectrum of **7** contained a symmetric 11-line signal at δ 4.92 (J = 3, 6, 9 Hz) due to the C-13 methine. Dale has shown that a *gem*-dialkyl substituent will prefer a "corner" position in the conformations of large rings (7). The corner positions of the [3434] conformation of the 14-membered rings are shown with an asterisk (*) in **1**. From the coupling constants between the proton on C-13 and the protons on C-12 (J = 3 and 9 Hz), we conclude that **7a** is the preferred conformation.[4]

From an analysis of the ^{1}H nmr spectra of **3** and **4**, we concluded that the major dimethyl lactone **3** must exist mainly in



conformation **3a**.[5] The C-2 methine in **3** is an 11-line multiplet at δ 2.41 with J = 2.5, 6.8, and 10.9 Hz, and the C-13 methine is an 11-line multiplet at δ 4.93 with J = 2.7, 6.1, and 9.0 Hz. The C-2 methine in the minor isomer **4** is a symmetric 12-line multiplet at δ 2.53 with J = 3.5, 6.8, and 9.2 Hz, and the C-13 methine is a symmetric 6-line multiplet at δ 5.00 with J = 4.9, 6.3, and 6.7 Hz. This is consistent with conformation **4a** predominating for the minor isomer.[5] At present, we cannot offer an explanation for the fact that **3** and **4** adopt similar conformations, but with different positions for the lactone group.

The stereoselectivity in the alkylation of **2** can be rationalized as follows. The enolate of **2** was generated with LDA and trapped with trimethylsilyl chloride to give the *E*-enol ether. The geometry about the double bond in the silyl enol ether was determined by ^{1}H nmr nuclear Overhauser enhancements (9). Alkylation of this enol ether with chloromethyl phenyl sulfide and zinc bromide followed by Raney nickel desulphurization (10) gave a 3:1 mixture of **3**:**4**. Deprotonation of **2** should involve loss of the C-2 hydrogen, which is closest to being parallel to the *p* orbitals of the π bond of the carbonyl group (11). This would lead to **8a** or **8b** as possible conformations for the enolate or enol ether. Alkylation of **8a** or **8b** from the same direction as deprotonation would lead to the 2*R**,13*S** isomer as the major product. Thus the same stereoelectronic factors as found in small rings might be operative in this system (12). However, it should also be noted that **3** would be the expected product from attack of **8a** or **8b** from the more open face of the enolate.

MATTEO ADINOLFI, GASPARE BARONE, MARIA MICHELA CORSARO, ROSA LANZETTA, LORENZO MANGONI, and MICHELANGELO PARRILLI. Can. J. Chem. **65**, 2317 (1987).

Muscarosides D, E, and F, three new 27-norlanostane tetra-, penta-, and hexasaccharides, respectively, isolated from the bulbs of *Muscari comosum*, were respectively shown to be (23*S*,24*S*)-3-*O*-{α-L-arabinopyranosyl(1→3)[β-D-apio-D-furanosyl(1→2)]-β-D-glucopyranosyl(1→2)-α-L-arabinopyranosyl(1→6)-β-D-glucopyranosyl}-17,23-epoxy-3β,24,30,31-tetrahydroxy-27-nor-5α-lanost-8-ene **4**, (23*R*)-3-*O*-{α-L-arabinofuranosyl(1→2)-α-L-arabinopyranosyl(1→3)[α-L-rhamnopyranosyl(1→2)]-β-D-glucopyranosyl(1→2)-α-L-arabinopyranosyl(1→6)-β-D-glucopyranosyl}-17,23-epoxy-3β,31-dihydroxy-27-nor-5α-lanost-8-en-15,24-dione **5**, and (23*S*)-3-*O*-[β-D-apio-D-furanosyl(1→2)-β-D-glucopyranosyl(1→2)-α-L-arabinopyranosyl(1→6)-β-D-glucopyranosyl]-17,23-epoxy-3β,31-dihydroxy-27-nor-5α-lanost-8-en-15,24-dione **6**. The structural details were elucidated by a combination of fast-atom-bombardment mass spectroscopy, one- and two-dimensional nuclear magnatic resonance spectroscopy, and comparison to model compounds expressly synthesized.

MATTEO ADINOLFI, GASPARE BARONE, MARIA MICHELA CORSARO, ROSA LANZETTA, LORENZO MANGONI et MICHELANGELO PARRILLI. Can. J. Chem. **65**, 2317 (1987).

Les muscarosides D, E et F sont respectivement de nouveaux tétra-, penta- et hexasaccharides du nor-27 lanostane qui ont été isolés des bulbes du *Muscari comosum* et pour lesquels il a été établi que les structures sont respectivement les suivantes : {α-L-arabinopyrannosyl(1→3) [β-D-apio-D-furannosyl(1→2)]-β-D-glucopyrannosyl(1→2)-α-L-arabinopyrannosyl(1→6)-β-D-glucopyrannosyl}-3-*O* époxy-17,23 tétrahydroxy-3β,24,30,31 nor-27 5α-lanostène-8-(23*S*,24*S*) (**4**), {α-L-arabinofuranosyl(1→2)-α-L-arabinopyrannosyl(1→3)-[α-L-rhamnopyrannosyl(1→2)]-β-D-glucopyrannosyl(1→2)-α-L-arabinopyrannosyl(1→6)-β-D-glucopyrannosyl}-3-*O* époxy-17,23 dihydroxy-3β,31 nor-27 5α-lanostène-8 dione-15,24-(23*R*) (**5**) et [β-D-apio-D-furannosyl(1→2)-β-D-glucopyrannosyl(1→2)-α-L-arabinopyrannosyl(1→6)-β-D-glucopyrannosyl]-3*O* époxy-17,23 dihydroxy-3β,31 nor-27 5α-lanostène-8 dione-15,24-(23*S*) (**6**). On a établi les détails de ces structures en faisant appel à une combinaison de spectroscopie de masse par bombardement avec des atomes rapides, de spectroscopie en résonance magnétique nucléaire à une et à deux dimensions et par comparaison avec des composés modèles qui ont été synthétisés expressément dans ce but.

[Traduit par la revue]

Previous papers (1–3) have described the isolation and the structure determination of three main components (muscarosides A **1**, B **2**, and C **3** (see Chart 1)) of the glycoside mixture isolated from the bulbs of *Muscari comosum* Miller. The aglycone moieties of these glycosides possess a 27-norlanostane skeleton and their structures are characterized by a spiro-fused tetrahydrofuran ring at the C-17 position. They are structurally related to a series of free nortriterpenes that we have isolated from the same source (4–7). The accumulation of knowledge on the isolation and the structure of both these glycosides and these nortriterpenes has enabled us to thoroughly examine the glycoside mixture. Thus we have isolated three further glycosides, muscarosides D–F, and have assigned them structures **4**–**6**, respectively, mainly by nmr spectroscopy and FAB (free atom bombardment) ms. Whereas the aglycone moieties **8** and **14** of **5** and **6**, respectively, were known compounds, that of muscaroside D **4** is the novel nortriterpene **7**.

Muscarosides E and F were isolated by hplc (C-18 reverse phase column) of the mother liquors from the crystallization of muscaroside B (2). Muscaroside D was isolated by hplc (C-18 reverse phase column) and dry column chromatography (silica gel) of the fractions *c* of the crude glycoside mixture obtained from the bulbs. Muscarosides D–F were all homogeneous (tlc, ^{1}H and ^{13}C nmr spectroscopy) powder solids.

The negative-ion FAB mass spectrum of muscaroside D **4** (Fig. 1*a*) exhibited an ion peak at *m/z* 1195 $(M - H)^-$, which, together with ^{13}C and ^{1}H nmr data, suggested the molecular formula $C_{56}H_{92}O_{27}$. The corresponding molecular weight of 1196 daltons was confirmed by the presence of the peaks at *m/z* 1219 and 1197, formed by cationization of the molecule with Na^+ and H^+ respectively, in the positive-ion spectrum (Fig. 1*b*).

The appearance of the ^{1}H nmr signals of the aglycone moiety in the upfield part of the spectrum of muscaroside D in Py-d_5 at 500 MHz (Table 1, Fig. 2) was reminiscent of that of the 27-norlanostane triterpenes found in the bulbs of *Muscari comosum*. However, in the spectra of these latter the signals corresponding to the presence of the (24)C=O group ((25)CH_2 quartet at δ ca. 2.5) and (or) those corresponding to the presence of the (15)C=O group ((16)CH_2 ABq in the δ 2.3–3.1 zone) are clearly discerned (4–9). On the contrary, both these features are lacking in the spectrum of muscaroside D and, accordingly, no carbonyl-carbon signal was displayed in the ^{13}C spectrum. The novel structure **7** for the aglycone moiety of muscaroside D was mainly deduced from a 2D-COSY spectrum (Fig. 3), which allowed us to establish the scalar connectivity of the resonances of all the side-chain protons (positions 20–26), and from the comparison (Table 1) of the ^{13}C data of muscaroside D with those of known 27-norlanostanes **9** (8) and **10** (4) for the carbons 1–19 and 30–32 and for the carbons 20–26 respectively.

[f]$^3J_{H\text{-}1,H\text{-}2}$ (Hz).

Comparison with the nmr carbon lines of **10** suggested the *S* configuration for the chiral 24-position of muscaroside D. This was strengthened by comparison of the chemical shift of the 23- and 24-protons with those of model compounds. 27-Norlanostane **9** was transformed with acetic anhydride/pyridine into triacetate **11** and this latter was reduced with sodium borohydride to the 24-epimeric alcohols **12** and **13**, whose configuration at C-24, *S* and *R* respectively, was established by the glc modification of the Horeau method (12). Owing to the close similarity of the chemical shifts of the 23- and 24-protons of **4** (δ 4.10 and δ 3.52, respectively; Table 1) with those of **12** (δ 4.13 and δ 3.57, respectively) rather than with those of **13** (δ 4.20 and δ 3.78, respectively), *S* configuration may be confidently assigned to the chiral centre at C-24 of muscaroside D.

The 2D-COSY spectrum also allowed the identification of the proton signals of each monose unit of the sugar chain and then the assignment of the ^{13}C signals by tracing out the one-bond proton–carbon connectivities through the use of heteronuclear carbon–proton shift correlation. In addition to the nature of each monose unit, comparison of the ^{13}C chemical shifts with those of reference methyl glycosides also revealed the attachment positions in the sugar chain (through the glycosylation shifts) and the configuration at the anomeric centres. These data showed that muscaroside D possessed one terminal β-apiose unit, one terminal α-arabinopyranose unit, one nodal β-glucopyranose unit linked at its positions 2 and 3, one inner β-glucopyranose unit linked at its 6-position, and one inner arabinopyranose unit linked at its 2-position. The attachment of the sugar chain at the 3-position of the aglycone **7** was evident from the downfield shift (+4.4) observed for the 3-carbon of muscaroside D. The upfield shifts of the C-30 and C-5 signals were in agreement with this conclusion (13).

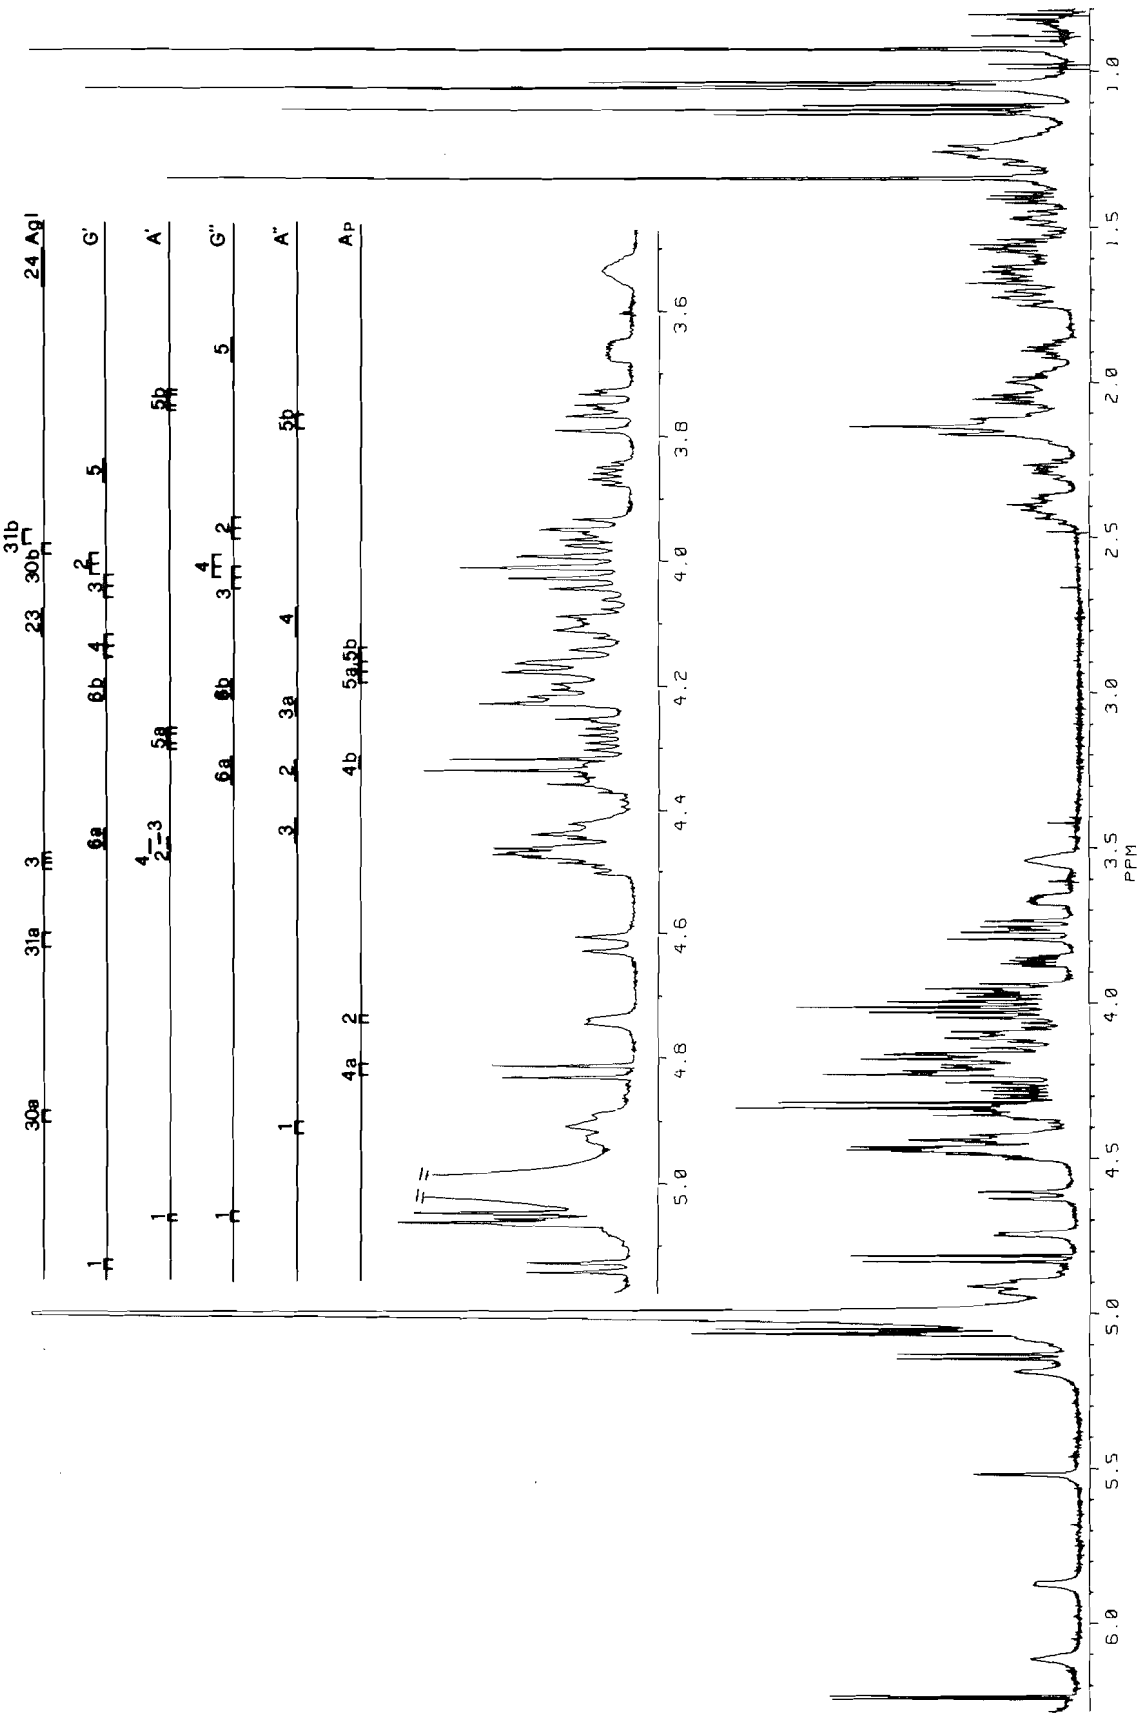

FIG. 2. The 500-MHz ^{1}H nmr spectrum of **4** in pyridine-d_5. The signals between δ 5.15 and δ 6.15 disappear upon addition of D_2O. In the insert, expansion of the sugar proton region is shown. Signal assignment derived from COSY (see Fig. 3) and C—H correlation experiments is indicated. Agl = aglycone; G′, G″, A′, A″, Ap = monose units as indicated in formula **4**.

The values of the coupling constants $^3J_{H\text{-}1,H\text{-}2}$ listed in Table 1 were consistent with the configuration of the anomeric centres determined from the ^{13}C data, the inner arabinopyranose unit excluded, owing to its high conformational mobility (1, 2, 14–16). However, the close similarity between the ^{13}C data of this monose unit of muscaroside D and those found for the α-arabinopyranosyl residues identically located in muscarosides A **1** and B **2** (Table 3) strongly supports the α-configuration for the relevant anomeric centre. The value of $^3J_{H\text{-}1,H\text{-}2}$ (4.8 Hz) observed for this monose unit, as compared to the value (7.9 Hz) displayed by the terminal arabinopyranose residue, would indicate that in the former a $^1C_4$ conformer is in considerable excess over the $^4C_1$ conformer.

A significant Overhauser effect measured for the nmr signal at δ 3.95 of the 2-proton of the nodal glucopyranose upon irradiation of the anomeric proton (δ 6.24) of the apiose terminal residue indicated that this latter is directly linked to the 2-proton of the nodal glucopyranose. The determination of the glycone sequence was completed on the basis of the positive-ion FAB-ms data. The peak at m/z 639 $[(M + H) - (132 + 132 + 132 + 162)]^+$ due to the loss of a fragment constituted by three pentose and one hexose indicated that the inner glucopyranose is directly linked to the aglycone. Thus the m/z 771 (= 639 + 132) peak indicated that the inner arabinopyranose is located between the nodal glucopyranose and the inner glucopyranose and, consequently, that also the terminal arabinopyranose is directly linked to the nodal residue. This latter point is also confirmed by the lack in the spectrum of a peak corresponding to the loss of a disaccharide. The sugar sequence, therefore, is that depicted in formula **4**.

Owing to the small amount of **4** available, chemical degradative methods could be applied to the structure determination of the compound only after the spectral data were collected. Acid hydrolysis (7% H_2SO_4) of **4** confirmed apiose, glucose, and arabinose to be the monose units of the sugar chain by tlc and hplc of the water-soluble fraction of the hydrolysate through comparison with authentic samples of the monosaccharides. A 1:2:2 molar ratio of the monoses was established on calibration of the hplc peak integrated areas against known concentrations. The monose-containing water-soluble fraction of the hydrolysate was perbenzoylated with benzoyl chloride and pyridine and the pure perbenzoates (α-anomers (17)) of glucose and arabinose were isolated by hplc. Identity in chirality and amplitude of their cd (circular dichroism) curves with those of the perbenzoates (α-anomers) obtained from authentic samples of D-glucose and L-arabinose established the absolute configuration D of both glucopyranose units and the absolute configuration L of both arabinopyranose units in the sugar chain of muscaroside D. The absolute configuration of the apiose unit was assumed to be the same as in muscaroside C **3** (3).

The positive-ion FAB mass spectrum of muscaroside E showed a pseudomolecular ion peak at m/z 1361 $[M + Na]^+$, which, together with ^{13}C data (Table 3), suggested the molecular formula $C_{62}H_{96}O_{31}$.

In the upfield part of the ^1H spectrum (Table 2) of muscaroside E the signals of four tertiary (δ 0.93 s, δ 0.96 s, δ 1.54 s, δ 1.55 s), one secondary (δ 0.87 d), and one primary (δ 1.13 t) methyl group are observed. In addition, the signals of one methylene group appear centered at δ 2.7 and δ 2.8 as 16 lines of the AB part of an ABX_3 system, correlated by scalar coupling with the primary methyl group, and the signals of a second methylene group appear centered at δ 2.37 and δ 2.78 as an AB quartet. The close similarity between these ^1H nmr

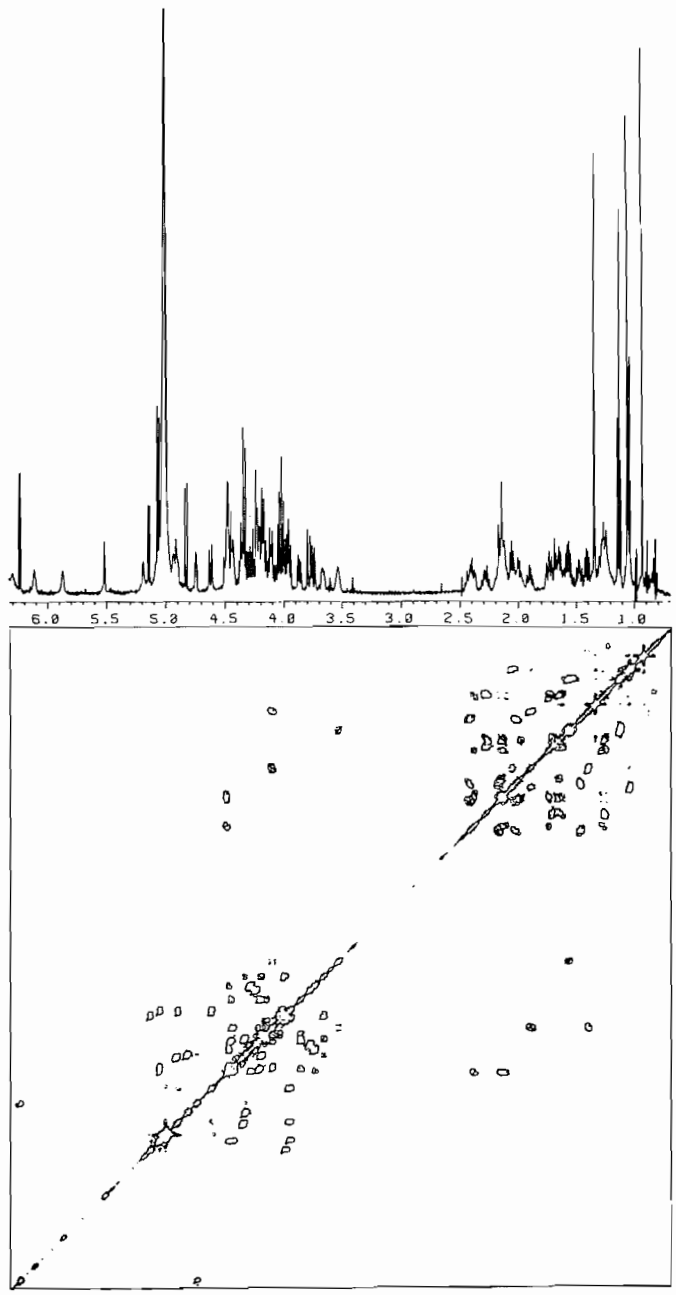

FIG. 3. Contour plot of COSY of **4** (500 MHz, pyridine-d_5).

data and the ^{13}C nmr data for the aglycone carbons of muscaroside E with the relevant nmr data obtained for (23*R*)-17,23-epoxy-3β,31-dihydroxy-27-nor-5α-lanost-8-ene-15,24-dione **8** (5) indicated that this latter constitutes the aglycone moiety of muscaroside E.

Upon the application of the chemical procedure used for **4**, the sugar chain of muscaroside E was confirmed to be constituted by one rhamnose, three arabinose, and two glucose units, whose absolute configuration was established to be L, L, and D, respectively, by the cd method already applied to **4**.

Comparison of the nmr data of muscaroside E with the ^{13}C (Table 3) and ^1H (Table 2) data of muscaroside B **2**, whose sugar chain has the same monose composition, showed the *quasi*-identity of the sugar-carbon chemical shifts in the two compounds and therefore indicated that the sequence of the

monose units, the configuration at the anomeric centres, the position of the interglycosidic linkages, and the monose-ring size were the same in both muscarosides. Therefore, muscaroside E possesses structure **5**.

On acid hydrolysis, muscaroside F afforded glucose, arabinose, and apiose (molar ratio 2:1:1) as sugar components. This result suggested that muscaroside F possessed a sugar chain identical with that of known muscaroside C **3**. This was confirmed by comparison of the ^{13}C signals. The aglycone portion was identified to be eucosterol **14** (9) as in muscaroside A **1** and muscaroside B **2** by analysis of the ^{13}C and ^{1}H spectra (Tables 2 and 3). Muscaroside F was consequently identified as eucosterol 3-*O*-β-D-apio-D-furanosyl(1→2)-β-D-glucopyranosyl-(1→2)-α-L-arabinopyranosyl(1→6)-β-D-glucopyranoside **6**. Structure **6** was confirmed by the negative-ion FAB mass spectrum, which displayed peaks at m/z 1059 (pseudomolecular ion, $(M - H)^-$) and at m/z 927, 765, and 633, corresponding to the losses of the apiosyl, apiosyl-glucosyl, and apiosyl-glucosyl-arabinosyl fragments, respectively.

Experimental

General

The ^{1}H (270 MHz) and ^{13}C (67.88 MHz) spectra were taken on a Fourier transform Bruker instrument WH 270 (TMS as internal reference) with an Aspect 2000 computer with 48 K memory (32 K data). Mass spectra were recorded with a VG ZAB HF or a Kratos MS 50 instrument equipped with an FAB source. The hplc was performed with a Varian 5060 instrument using a differential refractometer Waters R 401 as the detector. The tlc was carried out on precoated silica gel layers (0.25 mm, Merck F_{254}). Silica gel 0.05–0.20 (Merck) was used for column chromatography.

*Proton and carbon nuclear magnetic resonance spectra of **4***

Spectra were obtained at 500/125.77 MHz (^{1}H/^{13}C) on a Fourier transform Bruker WM 500 spectrometer equipped with a dual probe and with an Aspect 2000 computer.

One-dimensional spectra were obtained with 5000 Hz (0–10 ppm) and 27 500 Hz (0–220 ppm) spectral widths for proton and carbon respectively.

Nuclear Overhauser enhancements were obtained in the difference mode as reported in ref. 1.

Two-dimensional correlated spectroscopy (COSY-45) was executed with 90°–45° pulses separated by an incrementable evolution time t_1. Each spectrum required a total of 32 pulses in a 512 × 2048 data set, which took approximately 10 h to acquire. Quadrature detection was applied in both directions using a 16-step phase cycling for N-type peak selection. Data were multiplied with a sine-bell shaping function, zero filled, Fourier transformed, and symmetrized. Processing and plotting time for the spectrum was approximately 2 h.

Two-dimensional carbon–proton shift correlations were performed by choosing polarization transfer delays equal to average one-bond couplings of J(CH) = 140 Hz. Exponential multiplication in the ^{13}C domain and Gaussian resolution enhancement in the ^{1}H were applied to a 256 × 1024 data matrix prior to Fourier transformation.

Isolation of muscarosides D, E, and F

Fraction *c* (ref. 1) was subjected to hplc (Lichrosorb RP-18 (7 μm),

The ^{1}H and ^{13}C nmr data of **5** and **6** are given in Tables 2 and 3.

Acid hydrolysis of muscarosides D, E, and F

Acid hydrolysis of muscarosides D, E, and F was performed with 7% H_2SO_4 as for muscaroside A (1). The water-soluble fraction of each hydrolysate was analyzed by tlc (silica gel layers, 14:6:1 chloroform–methanol–water) and by hplc ((Lichrosorb RP-18 (10 μm), 4:1 acetonitrile–water, 0.5 mL min^{-1}). The presence of apiose, arabinose, and glucose in the 1:2:2 molar ratio in the hydrolysate from muscaroside D; of rhamnose, arabinose, and glucose in the 1:3:2 molar ratio in the hydrolysate from muscaroside E; and of apiose, arabinose, and glucose in the 1:1:2 molar ratio in the hydrolysate from muscaroside F was established by tlc and hplc comparison with authentic samples of the monoses and by integration of the hplc peaks (1).

Perbenzoylation of the hydrolysates from muscarosides D and E

The water-soluble fraction obtained from the hydrolysis of **4** was perbenzoylated with benzoyl chloride in dry pyridine at room temperature for 12 h. The reaction mixture was diluted with methanol and toluene and the excess solvent was evaporated. The residue was filtered through a short silica gel column with chloroform and then submitted to hplc (μ Porasil, 9:1 hexane – ethyl ether, 2 mL min^{-1}). The two fractions containing the perbenzoates of glucose and of arabinose, respectively, were evaporated and the residues were dissolved in methanol. The amplitudes +16 and +72, respectively, of the split cd curves (19) were measured for the two samples by deducing concentration from uv absorbance.

Upon application of the same procedure to the hydrolysate obtained from muscaroside E, perbenzoates of glucose, arabinose, and rhamnose were obtained. The amplitudes +14, +69, and −10, respectively, were calculated from the split cd curves in methanol.

Authentic samples of D-glucose, L-arabinose, and L-rhamnose were equilibrated in acidic water and then perbenzoylated under the same conditions as the above hydrolysates to give α-D-1,2,3,4,6-pentabenzoylglucopyranose, α-L-1,2,3,4-tetrabenzoylarabinofuranose, and α-L-1,2,3,4-tetrabenzoylrhamnopyranose. The amplitudes of their split cd curves in methanol were +15, +74, and −11, respectively.

*Alcohols **12** and **13***

A sample of **9** (8) (4 mg) was acetylated (acetic anhydride and pyridine, 24 h, room temperature) to give crude triacetate **11** (6 mg), which was dissolved in methanol (1 mL) and treated with sodium borohydride (5 mg) at 5°C for 30 min. Usual work-up and subsequent tlc (silica gel layer, 4:1 hexane – ethyl acetate, 4 runs) gave pure alcohols **12** (2 mg) and **13** (2 mg).

The ^{1}H nmr data of **12**, δ: 0.94 and 1.09 (3H, s each, 18-H_3 and 19-H_3), 1.08 (3H, d, $J_{20,21}$ = 6.6 Hz, 21-H_3), 1.14 (3H, t, $J_{25,26}$ = 7.3 Hz, 26-H_3), 1.39 (3H, s, 32-H_3), 3.57 (1H, m, 24-H), 4.13 (1H, m, 23-H), 4.42 and 4.51 (2H, ABq, J_{AB} = 11.6 Hz, 30-H_2 or 31-H_2), 4.46 and 4.72 (2H, ABq, J_{AB} = 12.2 Hz, 31-H_2 or 30-H_2), 5.16 (1H, X of ABX, J_{AX} + J_{BX} = 17.2 Hz, 3-H).

The ^{1}H nmr data of **13**, δ: 0.95 and 1.10 (3H, s each, 18-H_3 and 19-H_3), 1.11 (3H, d, $J_{20,21}$ = 6.6 Hz, 21-H_3), 1.18 (3H, t, $J_{25,26}$ = 7.3 Hz, 26-H_3), 1.40 (3H, s, 32-H_3), 3.78 (1H, m, 24-H), 4.20 (1H, m, 23-H), 4.42 and 4.51 (2H, ABq, J_{AB} = 11.8 Hz, 30-H_2 or 31-H_2), 4.47 and 4.72 (2H, ABq, J_{AB} = 12.1 Hz, 31-H_2 or 30-H_2), 5.17 (1H, X of ABX, J_{AX} + J_{BX} = 17.2 Hz, 3-H).

24-Alcohols **12** and **13** were separately treated with (±)-α-phenylbutyric anhydride, and the excess of anhydride was analyzed by glc at 200°C on a 25-m glass capillary column coated with OV-101 as (+)-*R*-α-phenylethylamides of (−)*R*- and (+)*S*-phenylbutyric acid, following the procedure described in ref. 12. A peak increment of +8% for the *R*-acid was calculated in the experiment for the alcohol **12**, indicating *S* configuration of C-24 in **12**. A peak increment of +5% for the *S*-acid was calculated in the experiment for the alcohol **13**, indicating *R* configuration of C-24 in **13**.

Acetyl transfer reactions on $AlPO_4$–Al_2O_3

ANTONIO COSTA AND JUAN MARTIN RIEGO
Department of Chemistry, Universitat de les Illes Balears, E-07071 Palma de Mallorca, Spain

Received March 10, 1987

ANTONIO COSTA and JUAN MARTIN RIEGO. Can. J. Chem. **65**, 2327 (1987).

An efficient acetylation of alcohols and aliphatic amines promoted by the $AlPO_4$–Al_2O_3/ethyl acetate system is described. The solid catalyst acts, at least in part, as the acetyl carrier.

ANTONIO COSTA et JUAN MARTIN RIEGO. Can. J. Chem. **65**, 2327 (1987).

On décrit une méthode efficace d'acétyler les alcools et les amines aliphatiques qui est catalysée par le système $AlPO_4$–Al_2O_3/acétate d'éthyle. Le catalyseur solide agit, au moins en partie, comme porteur de groupements acétyles.

Introduction

Derivatization of hydroxy and amino groups to the corresponding acetates and acetamides is a very common transformation in organic chemistry. Among the plethora of published methods, one of the most convenient is that of Posner *et al.* (1), which allows the chemoselective acetylation of primary alcohols under heterogeneous conditions, i.e., with ethyl acetate over commercial Al_2O_3 at room temperature.[1]

Continuing our work on solid acids (for a general discussion, see ref. 3), we would here like to report the use of synthetic $AlPO_4$–Al_2O_3 for the mild and efficient acetylation not only of aliphatic primary and (or) secondary alcohols but also of aliphatic amines.[2]

Experimental

The typical experimental procedure involves stirring a solution of the substrate (10 mmol) in dry ethyl acetate (150 mL) over 10 g of $AlPO_4$–Al_2O_3.[3] After 24 h at room temperature (or reflux in the case of secondary alcohols or aliphatic amines) work-up is simply carried out by filtration, solvent evaporation, and final distillation or recrystallization.

Results and discussion

As shown in Table 1, room temperature acetylation works well for primary monoalcohols and diols (entries 1–5). Refluxing is, however, required to drive the reaction of secondary alcohols to completion (entries 6–8). This difference in reactivity may be of utility for the chemoselective acetylation of primary alcohols. In accordance with this, in a competitive experiment carried out with an equimolar mixture of 1- and 2-pentanol under standard conditions (room temperature) only 1-pentyl acetate[4] was isolated in 75% yield (based on 1-pentanol). Not unexpectedly, however, 1,2- and 1,4-diols gave the corresponding diacetates (entries 9 and 10), probably because of the easy intramolecular migration of the acetate group.

Mild acetylation of labile molecules such as allylic and homoallylic alcohols (entries 12 and 13) was also successful, as it was with MOM (methyl-oxy-methyl) protected hydroxyalkyl phenol ethers (entry 14).

TABLE 1. $AlPO_4$–Al_2O_3 promoted acetylation of alcohols

[a]Isolated yields of spectroscopically pure acetates.
[b]The product was the corresponding diacetate.
[c]After column chromatography of crude product.
[d]The product was 3-hydroxy-4-methoxy-benzyl acetate.

On the other hand, whilst our catalyst does not promote the acetylation of phenols (entry 15) and aromatic amines (entries 19 and 20), it did facilitate, however, the conversion of aliphatic amines and aminoalcohols (6) to the corresponding acetyl derivatives (entries 16–18).

These results are in sharp contrast with those reported by Posner (1), who describes Al_2O_3 as being capable of acylating aromatic amines but inefficient for aliphatic amines.

Although the understanding of the mechanism of acetyl transfer is restricted by lack of information about the nature of the actual acetylating agent (7), we felt that acyl transfer might

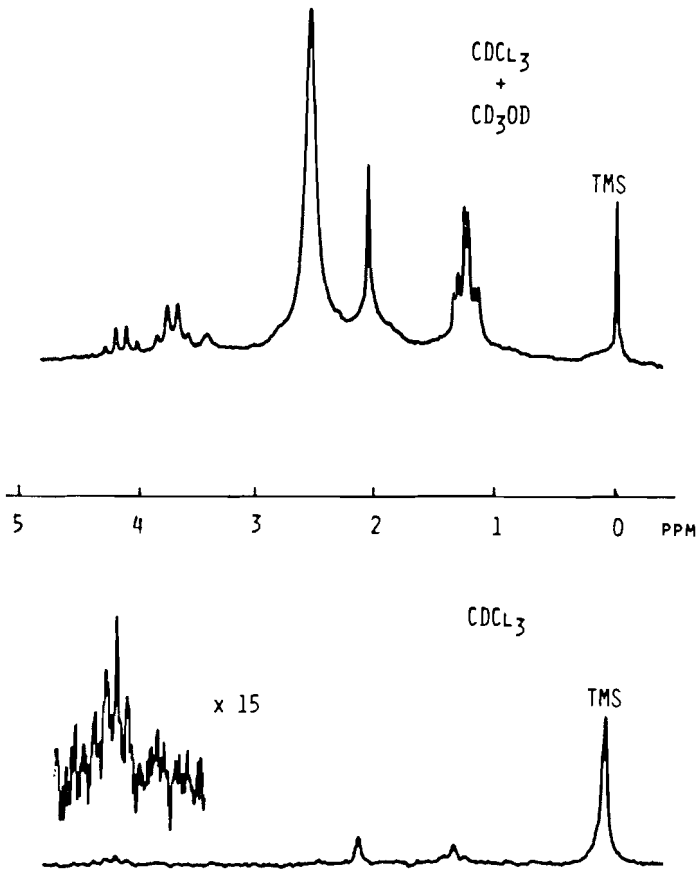

FIG. 2. The ^1H nmr spectrum of supernatant $CDCl_3$ over an acetylated catalyst before and after addition of CD_3OD.

take place first on the hydroxyl groups of the catalyst surface (8), thus generating a mixed anhydride-like structure that would eventually transfer the acetyl group to incoming nucleophiles (see Fig. 1).

Evidence in support of this mechanistic hypothesis was obtained by examining (gc, ^1H nmr) the behaviour of a sample of "acetylated catalyst" before and after the addition of alcohols. Thus treatment of a sample of $AlPO_4$–Al_2O_3 with *n*-butyl acetate (12 h, reflux) allowed us to unambiguously demonstrate (gc, ^1H nmr) the presence of *n*-butanol in the supernatant. Furthermore, filtration of the mixture followed by thorough drying of the solid under high vacuum (0.003 Torr, 10 h; 1 Torr = 133.3 Pa) yielded an acetylated catalyst that reacted with benzyl alcohol in toluene (room temperature, 24 h) providing the expected benzyl acetate (gc, ^1H nmr, ir). The presence of some *n*-butanol was also observed in the reaction mixture.

In a further experiment a sample of thoroughly dried acetylated catalyst (obtained as above by treatment of the solid catalyst with ethyl acetate) was suspended in $CDCl_3$. Its ^1H nmr spectrum (bottom, Fig. 2) indicated the presence of only trace amounts of ethyl acetate. After addition of CD_3OD to the mixture, the spectrum (top, Fig. 2) clearly showed signals corresponding to residual ethanol[5] and ethyl acetate. It therefore appears that acetylations promoted by $AlPO_4$–Al_2O_3 take place, at least to some extent, by a mechanism of acetyl transfer mediated by the solid catalyst acting as a carrier.

In summary, acetylation of alcohols and aliphatic amines can be carried out efficiently by the mild $AlPO_4$–Al_2O_3/ethyl acetate heterogeneous system, thus complementing the acylating capacity of alumina (1).

Permanganate oxidation of glycine: Kinetics, catalytic effects, and mechanisms

JOAQUIN F. PEREZ-BENITO,[1] FERNANDO MATA-PEREZ, AND ENRIQUE BRILLAS
Departamento de Quimica Fisica, Facultad de Quimica, Universidad de Barcelona, Avenida Diagonal, 647, 08028 Barcelona, Spain

Received January 27, 1987

JOAQUIN F. PEREZ-BENITO, FERNANDO MATA-PEREZ, and ENRIQUE BRILLAS. Can. J. Chem. **65**, 2329 (1987).

The oxidation of glycine by permanganate ion in aqueous phosphate buffers is autocatalyzed by the soluble form of colloidal manganese dioxide formed as a reaction product. Both the noncatalytic and the catalytic reaction pathways are first order in permanganate, the noncatalytic pathway is also first order in glycine, whereas the catalytic pathway has a kinetic order unity for the autocatalytic agent and a non-integral order (1.31) for glycine. Both reaction pathways are accelerated by an increase in the pH of the medium, whereas an increase in the buffer concentration at constant pH results in an increase in the rate of the noncatalytic pathway and a decrease in the rate of the catalytic one. Additions of potassium chloride to the solutions have no kinetic effect on the reaction. The apparent activation energies of the noncatalytic and catalytic reaction pathways are 64.5 and 62.0 kJ mol^{-1}, respectively. On the other hand, manganese(II), thiosulfate, and hexacyanoferrate(II) ions, as well as benzyltriethylammonium chloride and arabic gum, have all been found to increase the initial reaction rate. Mechanisms in concordance with the experimental findings are proposed.

JOAQUIN F. PEREZ-BENITO, FERNANDO MATA-PEREZ et ENRIQUE BRILLAS. Can. J. Chem. **65**, 2329 (1987).

L'oxydation de la glycine par l'ion permanganate dans des tampons de phosphates aqueux est autocatalysée par la forme soluble du bioxyde de manganèse colloïdal qui se forme comme produit de la réaction. Les voies réactionnelles tant de la réaction catalysée que de la réaction qui n'est pas catalysée sont toutes les deux du premier ordre en permanganate; par ailleurs, la réaction qui n'est pas catalysée est aussi du premier ordre en glycine alors que la réaction catalysée est du premier ordre pour l'agent autocatalytique et d'un ordre qui n'est pas entier (1,31) pour la glycine. Les deux voies réactionnelles sont accélérées par une augmentation du pH du milieu alors qu'une augmentation de la concentration du tampon à pH constant provoque une augmentation de la vitesse de la voie qui n'est pas catalysée et une diminution dans la vitesse de la réaction catalysé. Des additions de chlorure de potassium aux solutions n'ont aucun effet cinétique sur la réaction. Les énergies d'activation apparentes pour les réactions catalysée et non catalysée sont respectivement de 62,0 et 64,5 kJ mol^{-1}. Par ailleurs, on a trouvé que le manganèse(II), les ions thiosulfate et hexacyanoferrate(II) ainsi que le chlorure de benzyltriéthylammonium et la gomme arabique augmentent tous la vitesse initiale de la réaction. On propose des mécanismes qui sont en accord avec les données expérimentales.

Introduction

The permanganate oxidation of the components of large biological molecules such as nucleic acids and proteins has received considerable attention. For instance, kinetic studies of the permanganate oxidation of thymine (1), uracils (2), and several amino acids (3–5) have already been undertaken. In this paper, the results concerning the kinetic and mechanistic aspects of the reaction between glycine and potassium permanganate in neutral aqueous solutions will be presented and discussed in detail. It will be shown that it is in fact autocatalytic. Although a kinetic study concerning the same reaction has already been reported (6), it deals exclusively with very acid media and does not provide thorough information as far as the catalytic reaction pathway is concerned.

The occurrence of autocatalysis in permanganate reactions appears to be extensive (7–21). In particular, the permanganate oxidation of amines (22–25) deserves special mention among the autocatalytic reactions, due to the close relation that can be established between amines and amino acids. Because of the extensive occurrence of this phenomenon, one might think that kinetic and mechanistic information concerning the catalytic pathway is also abundant; however, the truth is that few rigorous kinetic data are available for the catalytic pathway, not only in permanganate reactions but also in all kinds of autocatalytic processes. A small contribution to fill this gap will be made in this paper.

[1]Author to whom correspondence may be addressed.

Experimental

The solvent used in the kinetic runs was twice-distilled water. The oxidizing agent was potassium permanganate and the reducing agent, glycine, was used in great excess with respect to the former. A KH_2PO_4–K_2HPO_4 buffer mixture was used with the double purpose of keeping the pH of the medium constant and of stabilizing manganese dioxide as a soluble colloid while the experiments were being performed. The possible effect of increasing ionic strength on the rate of reaction was analysed with the help of potassium chloride additions to the solutions. The effects of manganese(II) sulfate, sodium thiosulfate, potassium hexacyanoferrate(II), arabic gum, and benzyltriethylammonium chloride on the reaction were also studied.

The development of the reactions was monitored by following both the decrease in absorbance at 526 nm (reactant + product) and the increase in absorbance at 418 nm (product) by means of a Varian Cary 219 spectrophotometer. The permanganate concentrations were obtained according to the following equation:

$$[1] \qquad c = (A^{526} - \varepsilon_P^{526} A^{418}/\varepsilon_P^{418})/\varepsilon_R^{526} l$$

where the superscripts indicate wavelengths of the corresponding absorbances or extinction coefficients, and the subscripts R and P stand for reactant (permanganate ion) and product (colloidal manganese dioxide), respectively, whereas l is the cuvette pathlength (1 cm).

The pH of the solutions was measured by a conventional pH-meter provided with a combination electrode, and the temperature was kept constant by means of a thermostated bath with water continuously circulating through the cuvette holder of the spectrophotometer.

Results

The visible spectrum of the soluble form of colloidal manga-

Printed in Canada / Imprimé au Canada

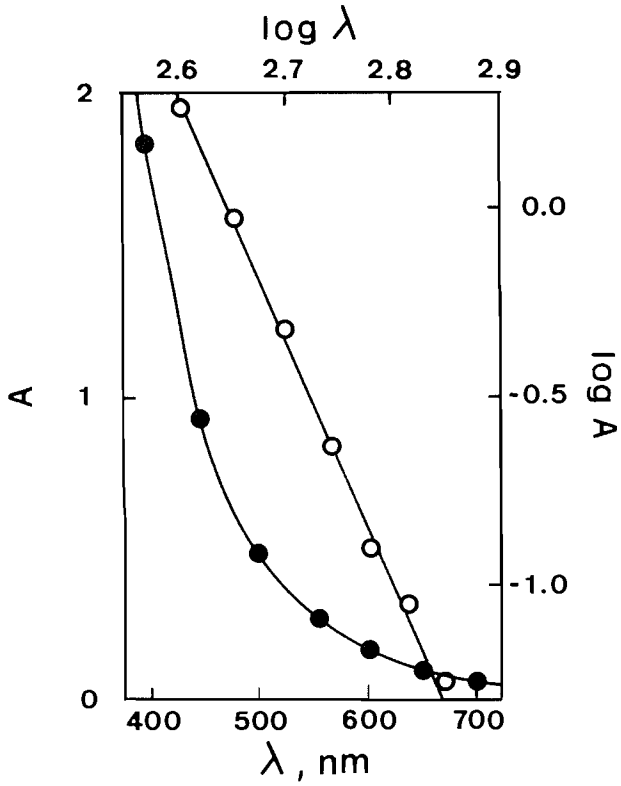

FIG. 1. Visible spectrum and log A vs. log λ linear plot for the product solution from the oxidation of glycine (0.01 M) by potassium permanganate (0.01 M) in aqueous KH_2PO_4 (0.04 M) – K_2HPO_4 (0.04 M) buffer at ionic strength 0.17 M, pH 6.78, and 25.0°C. The product solution was diluted 25 times before recording the spectrum (r = 0.998 for the linear plot).

nese dioxide generated as a reactant product is shown in Fig. 1. Since this spectrum overlaps the permanganate band at 526 nm, the absorbances at this wavelength must be corrected to obtain the permanganate concentrations. Taking into account that permanganate is transparent to radiation at 418 nm (26), eq. [1] can be used for that purpose.

We can see in Fig. 1 that a plot of log A vs. log λ is linear. This seems to be a reflection of the colloidal nature of the manganese reaction product (27), although the experimental slope (−6.48) is somehow different from the theoretical value (−4.00) expected from Rayleigh's Law (28). This deviation appears to be typical of colloidal manganese dioxide solutions, for which the absolute value of the slope of a log A vs. log λ linear plot is usually slightly higher than 4 (29, 30). Spectra similar to that in Fig. 1 were recorded for the products obtained from the reduction of permanganate by a great variety of reducing agents in both aqueous and methylene chloride solutions (31–40).

As shown in Fig. 2 for a typical kinetic run, all the experiments displayed a bell-shaped profile when the reaction rate was plotted against time. The rate values were determined from the experimental data as minus the derivative of the permanganate concentration with respect to time. It is clear that, if the rate presents both an acceleration and a decay period, a product concentration against time plot is necessarily S-shaped; i.e., the reaction is autocatalytic (41).

A differential rate law that can be tried for autocatalytic reactions is as follows:

$$[2] \quad -dc/dt = k_1 c + k_2 c(c_0 - c)$$

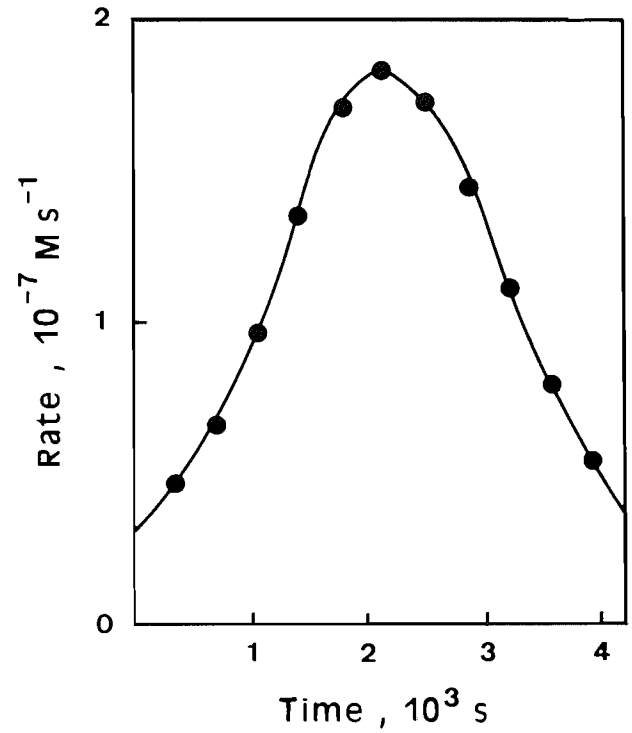

FIG. 2. Reaction rate vs. time plot for the oxidation of glycine (0.20 M) by potassium permanganate (5×10^{-4} M) in aqueous KH_2PO_4 (0.04 M) – K_2HPO_4 (0.04 M) buffer at ionic strength 0.16 M, pH 6.78, and 25.0°C.

its associated integral rate law being

$$[3] \quad \ln [(k_1 + k_2 c_0 - k_2 c)/c] = \ln (k_1/c_0) + (k_1 + k_2 c_0)t$$

In eqs. [2] and [3], c and c_0 are the concentrations of permanganate ion at time t and at the beginning of the reaction, while k_1 and k_2 are the pseudo rate constants of the noncatalytic and catalytic pathways, respectively. Owing to the fact that k_1 and k_2 appear not only in the intercept and the slope but also on the left-hand side of eq. [3], this equation must be used in an iterative way, starting with some trial values of the rate constants to fit the left-hand side of eq. [3] against time by the least-squares method, which allows new values of k_1 and k_2 to be derived from the intercept and the slope of that fit, and repeating the cycle till convergence is achieved.

Equation [3] was fulfilled in all the experiments performed, the linear correlation coefficients being between 0.9994 and 0.999997; a typical example is shown in Fig. 3. Reproducibility of the rate constants was assured within an acceptable error interval (4%). Since the experiments confirm the fulfilment of eq. [3], the differential form of the same law also holds (see eq. [2]). Therefore, it can be concluded that the rate of the noncatalytic pathway is first-order dependent on the permanganate concentration, whereas the rate of the catalytic pathway is first-order dependent on the concentrations of both permanganate ion and the autocatalytic agent, for in eq. [2] ($c_0 - c$) represents the autocatalytic agent concentration at time t.

The values of the rate constants corresponding to several initial permanganate concentrations have been compiled in Table 1; we can see that k_1 is independent of the initial permanganate concentration, but k_2 decreases as the initial permanganate concentration increases. The dependence of the rate constants on the glycine concentration is shown in Fig. 4; we can see that both log k_1 and log k_2 are linear when plotted

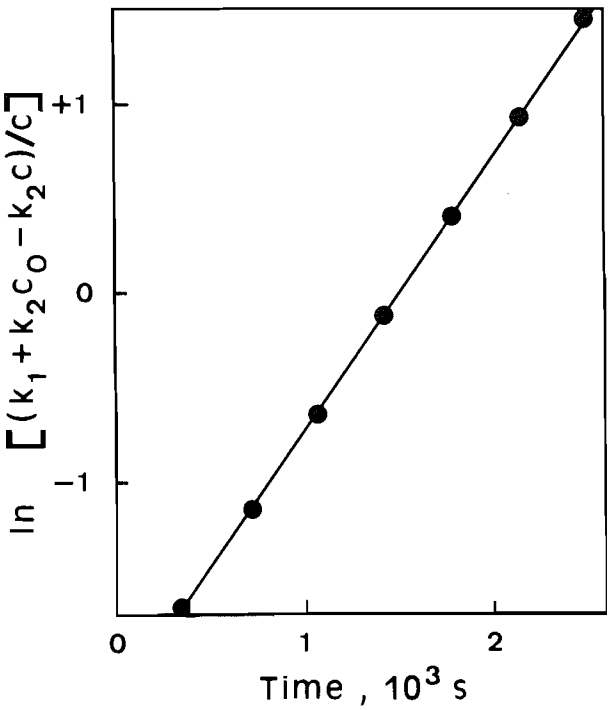

FIG. 3. Integral rate-law plot for the oxidation of glycine (0.20 M) by potassium permanganate (5×10^{-4} M) in aqueous KH_2PO_4 (0.04 M) – K_2HPO_4 (0.04 M) buffer at ionic strength 0.16 M, pH 6.78, and 25.0°C ($r = 0.99996$).

TABLE 1. Rate constants at several initial permanganate concentrations[a]

10^4 $[MnO_4^-]_0$ (M)	10^5 k_1 (s^{-1})	k_2 (M^{-1} s^{-1})[b]
5.01	4.79	1.92
6.51	5.26	1.75
7.83	5.21	1.62
9.07	5.00	1.57
10.26	5.15	1.48

[a][glycine] = 0.15 M; $[KH_2PO_4] = [K_2HPO_4] = 0.04$ M; ionic strength = 0.16 M; pH = 6.78; temperature = 25.0°C.
[b]$\log k_2 = -0.89 - 0.36 \log [MnO_4^-]_0$ ($r = 0.997$).

against log [glycine] but, although the slope corresponding to k_1 is fairly near unity (0.99), the slope corresponding to k_2 is higher than unity (1.31). As a result, only k_1 increases linearly with the glycine concentration, the corresponding intercept (5.12×10^{-7} s^{-1}) being negligible compared to the rate constant values involved in the plot (2.24×10^{-5} s^{-1} or higher); the slope and the linear correlation coefficient of the k_1 vs. [glycine] plot are 2.76×10^{-4} M^{-1} s^{-1} and 0.9998, respectively. Hence, the noncatalytic pathway is first order with respect to the reducing agent.

The concentrations of the components of the buffer mixture (KH_2PO_4 and K_2HPO_4) have been changed in two different ways, changing the concentrations of KH_2PO_4 and K_2HPO_4 so that the total phosphate concentration remains constant and the pH varies (as in Fig. 5), or changing the concentrations of KH_2PO_4 and K_2HPO_4 so that both are in equimolar amount and the pH of the solutions remains constant (as in Table 2). It can be seen in Fig. 5 that log k_1 increases in a nonlinear way as the pH increases, whereas log k_2 increases linearly with the pH (slope = 0.28). On the other hand, Table 2 indicates that when

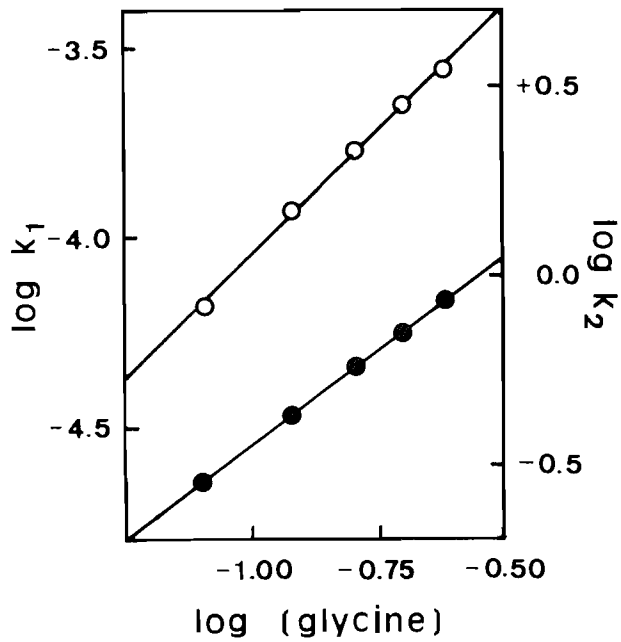

FIG. 4. Dependence of the rate constants on the reductant concentration for the oxidation of glycine by potassium permanganate (5×10^{-4} M) in aqueous KH_2PO_4 (0.04 M) – K_2HPO_4 (0.04 M) buffer at ionic strength 0.16 M, pH 6.78, and 25.0°C. Closed circles: k_1 in s^{-1} ($r = 0.9999$); open circles: k_2 in M^{-1} s^{-1} ($r = 0.9991$).

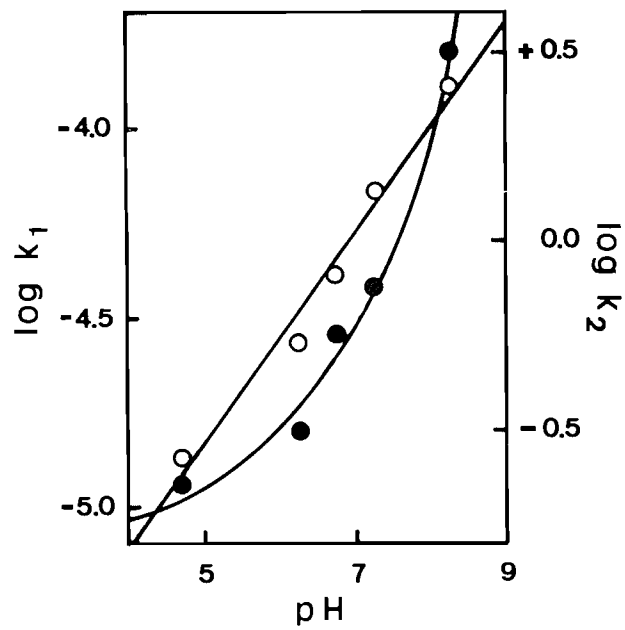

FIG. 5. Dependence of the rate constants on the pH for the oxidation of glycine (0.08 M) by potassium permanganate (5×10^{-4} M) in aqueous KH_2PO_4–K_2HPO_4 buffer ($[KH_2PO_4] + [K_2HPO_4] = 0.06$ M) at ionic strength 0.19 M (KCl) and 25.0°C. Closed circles: k_1 in s^{-1}; open circles: k_2 in M^{-1} s^{-1} ($r = 0.989$).

the buffer concentration increases at constant pH a slight increase in k_1 and a decrease in k_2 are observed.

Additions of potassium chloride to the solutions do not significantly affect the rate constants (see Table 3), so both k_1 and k_2 are independent of the ionic strength of the medium. The dependence of both k_1 and k_2 on temperature follows the Arrhenius equation (see Fig. 6), the corresponding activation energies being 64.5 and 62.0 kJ mol^{-1}.

TABLE 2. Rate constants at several buffer concentrations[a]

10^2 [K_2HPO_4] (M)[b]	10^5 k_1 (s^{-1})	k_2 (M^{-1} s^{-1})
1.6	4.75	2.34
3.2	4.93	1.98
4.8	5.01	1.86
6.4	5.28	1.80
8.0	5.55	1.75

[a] $[MnO_4^-]_0 = 5 \times 10^{-4} M$; [glycine] = $0.16 M$; ionic strength = $0.32 M$ (KCl); pH = 6.78; temperature = 25.0°C. [b] An equimolar amount of KH_2PO_4 was also used.

TABLE 3. Rate constants at several potassium chloride concentrations[a]

[KCl] (M)	10^5 k_1 (s^{-1})	k_2 (M^{-1} s^{-1})
0.00	6.94	2.72
0.08	6.89	2.76
0.16	7.30	2.73
0.24	7.04	2.69
0.32	6.97	2.69

[a] $[MnO_4^-]_0 = 5 \times 10^{-4} M$; [glycine] = $0.20 M$; [KH_2PO_4] = [K_2HPO_4] = $0.04 M$; ionic strength = 0.16 + [KCl] (M); pH = 6.78; temperature = 25.0°C.

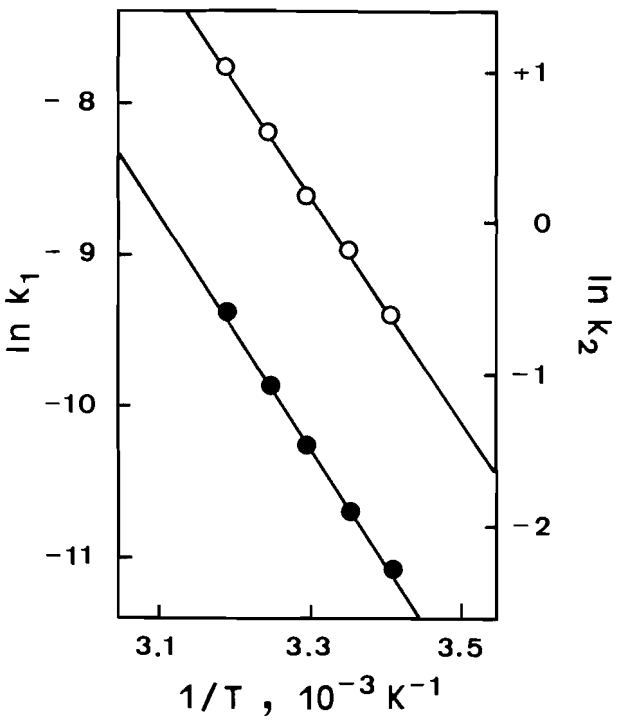

FIG. 6. Arrhenius plots for the oxidation of glycine ($0.08 M$) by potassium permanganate ($5 \times 10^{-4} M$) in aqueous KH_2PO_4 ($0.04 M$) – K_2HPO_4 ($0.04 M$) buffer at ionic strength $0.16 M$ and pH 6.78. Closed circles: k_1 in s^{-1} ($r = 0.9994$); open circles: k_2 in M^{-1} s^{-1} ($r = 0.9996$).

The effect of additives other than potassium chloride on the reaction was also studied. Upon stirring, the solutions immediately became red when manganese(II), thiosulfate, or hexacyanoferrate(II) ions were present; afterward, the colour slowly changed from red to yellow. When arabic gum or benzyltriethylammonium chloride was present, the transition of colour

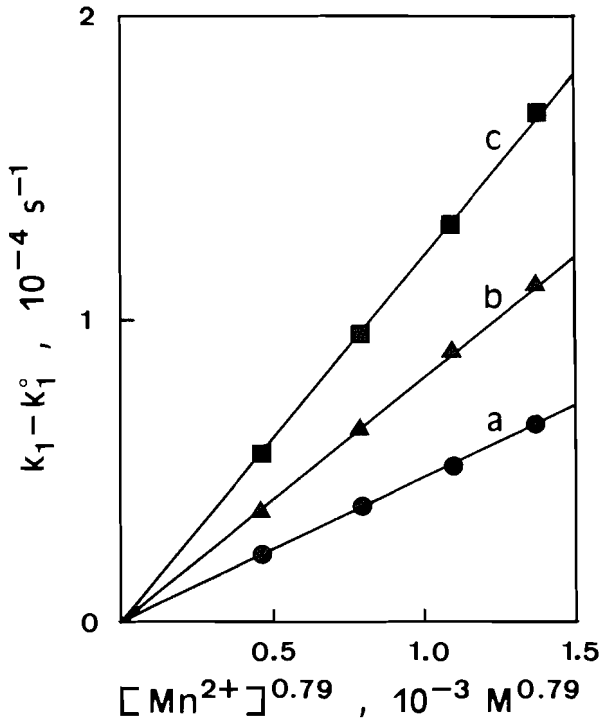

FIG. 7. $(k_1 - k_1^0)$ vs. $[Mn^{2+}]^{0.79}$ plots for the oxidation of glycine by permanganate ion ($5 \times 10^{-4} M$) at pH 6.78 and 25.0°C. [glycine] = $0.12 M$ (a); $0.16 M$ (b); and $0.20 M$ (c).

from purple to red, and also that from red to yellow, was slow. Moreover, the spectrophotometer showed that the initial absorbance at 526 nm decreased and the initial absorbance at 418 nm increased with increasing additive concentration when the additive was Mn^{2+}, $S_2O_3^{2-}$, or $Fe(CN)_6^{4-}$. On the contrary, neither arabic gum nor $BzEt_3NCl$ changed the initial absorbance values.

None of these additives seems to affect the value of k_2 to an important extent. However, the five of them have a definite increasing effect on k_1, as can be seen in Figs. 7–11 where k_1^0 stands for the rate constant of the noncatalytic pathway in the absence of any additive. Whilst $(k_1 - k_1^0)$ increases linearly with both the arabic gum and benzyltriethylammonium chloride concentrations, to get linear plots in the case of manganese(II), thiosulfate, and hexacyanoferrate(II) ions it is necessary to raise their concentrations to a certain power lower than unity (0.79, 0.89, and 0.70, respectively). The slopes and linear correlation coefficients corresponding to those plots are compiled in Tables 4–8. We observe that the slope associated with each additive also increases as the glycine concentration increases, and can thus conclude that the catalytic effect of each additive is a function of the concentration of amino acid present in the solutions.

Discussion

In the pH range used (4.70–8.25), the amino acid is present chiefly in the zwitterionic form, given the closeness of that range to the isoelectric point of glycine (6.06). The oxidation of the zwitterionic form of the amino acid through the noncatalytic pathway might happen according to the following mechanism:

[4] $^+H_3NCH_2CO_2^- + MnO_4^- \xrightarrow{\text{slow}} {}^+H_3NCH_2CO_2^{\bullet} + MnO_4^{2-}$

[5] $^+H_3NCH_2CO_2^{\bullet} \rightarrow {}^+H_3NCH_2^{\bullet} + CO_2$

[6] $^+H_3NCH_2^{\bullet} \rightarrow H_2NCH_2^{\bullet} + H^+$

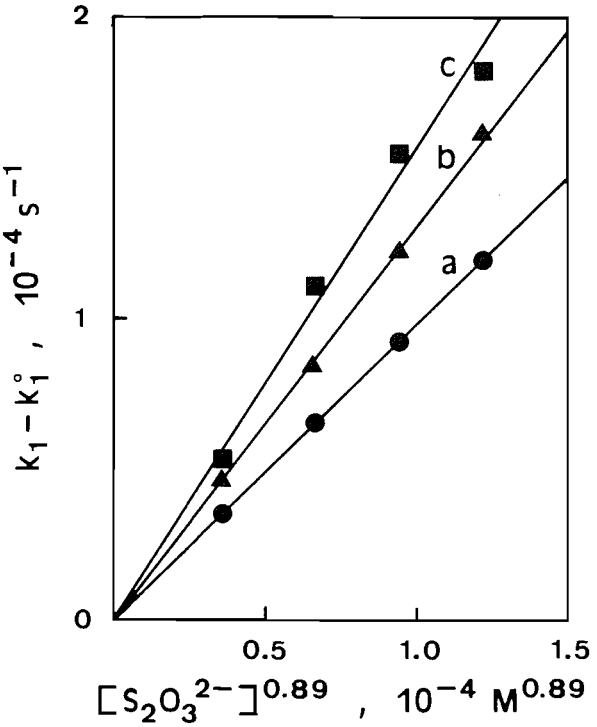

FIG. 8. $(k_1 - k_1^0)$ vs. $[S_2O_3^{2-}]^{0.89}$ plots for the oxidation of glycine by permanganate ion ($5 \times 10^{-4} M$) at pH 6.78 and 25.0°C. [glycine] = 0.12 M (a); 0.16 M (b); and 0.20 M (c).

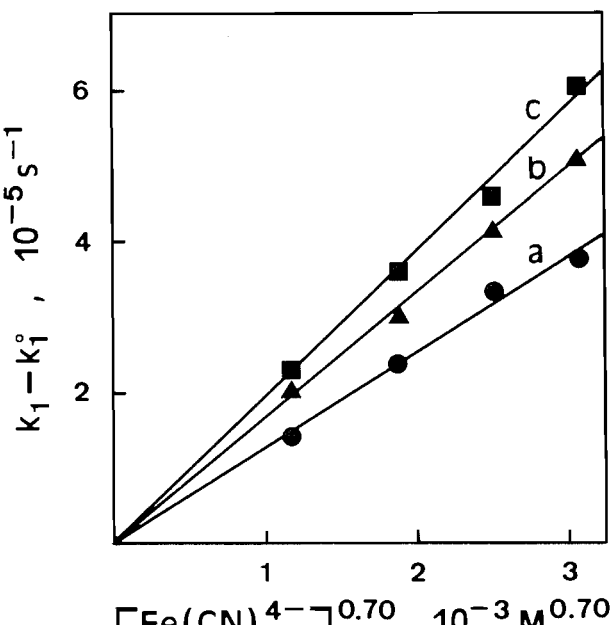

FIG. 9. $(k_1 - k_1^0)$ vs. $[Fe(CN)_6^{4-}]^{0.70}$ plots for the oxidation of glycine by permanganate ion ($5 \times 10^{-4} M$) at pH 6.78 and 25.0°C. [glycine] = 0.12 M (a); 0.16 M (b); and 0.20 M (c).

[7] $H_2NCH_2^\bullet + MnO_4^- \rightarrow CH_2{=}NH_2^+ + MnO_4^{2-}$

[8] $CH_2{=}NH_2^+ + H_2O \rightarrow CH_2O + NH_4^+$

[9] $3MnO_4^{2-} + 2H_2O \rightarrow 2MnO_4^- + MnO_2 + 4OH^-$

Although that mechanism probably accounts for a considerable proportion of the reaction, Fig. 5 suggests that the anionic form of the amino acid is also involved in the oxidation

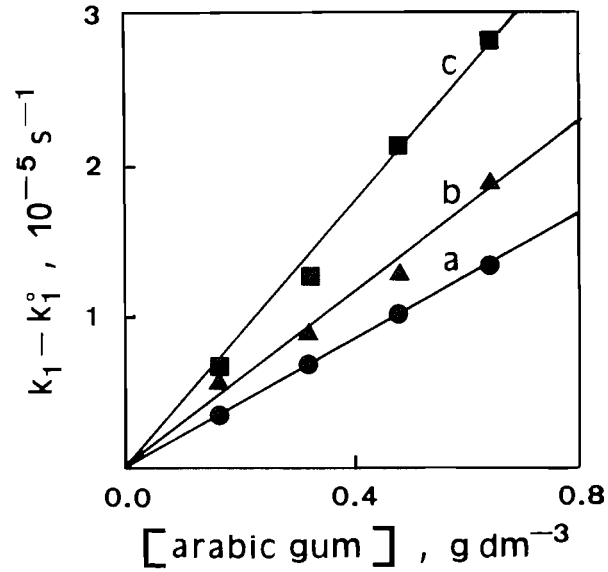

FIG. 10. $(k_1 - k_1^0)$ vs. [arabic gum] plots for the oxidation of glycine by permanganate ion ($5 \times 10^{-4} M$) at pH 6.78 and 25.0°C. [glycine] = 0.08 M (a); 0.12 M (b); and 0.20 M (c).

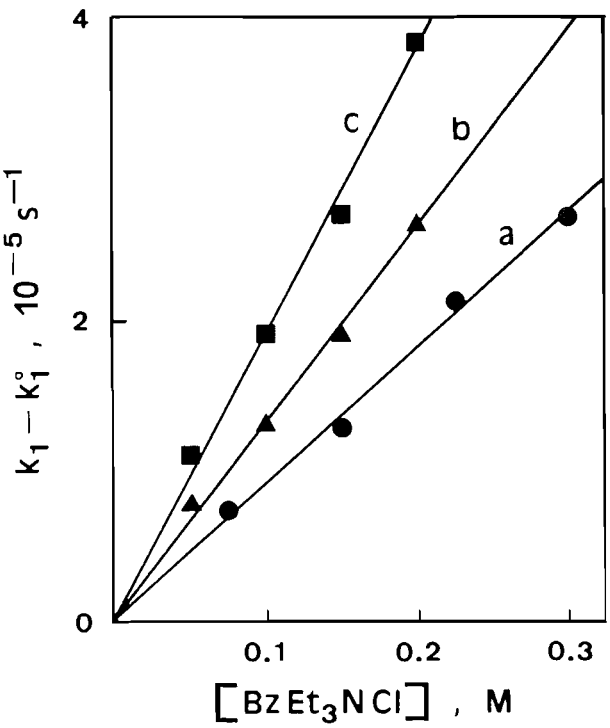

FIG. 11. $(k_1 - k_1^0)$ vs. $[BzEt_3NCl]$ plots for the oxidation of glycine by permanganate ion ($5 \times 10^{-4} M$) at pH 6.78 and 25.0°C. [glycine] = 0.08 M (a); 0.12 M (b); and 0.20 M (c).

process, for only then will rate constant k_1 increase with the pH of the medium. This oxidation will be similar to that of the zwitterionic form, as eqs. [10] and [11] show:

[10] $H_2NCH_2CO_2^- + MnO_4^- \xrightarrow{\text{slow}} H_2NCH_2CO_2^\bullet + MnO_4^{2-}$

[11] $H_2NCH_2CO_2^\bullet \rightarrow H_2NCH_2^\bullet + CO_2$

Once free radical $H_2NCH_2^\bullet$ is formed, its oxidation will take place as in eqs. [7] and [8].

The two mechanisms proposed for the noncatalytic pathway are indeed in agreement with the experimental results pre-

sented in this paper, for according to those mechanisms the rate of disappearance of permanganate ion through the noncatalytic pathway is

$$[12] \quad r_1 = k_1[MnO_4^-]$$

where k_1 is

$$[13] \quad k_1 = k_4[^+H_3NCH_2CO_2^-] + k_{10}[H_2NCH_2CO_2^-]$$

k_4 and k_{10} being the rate constants corresponding to eqs. [4] and [10], respectively. According to eqs. [12] and [13] the kinetic orders of the noncatalytic pathway with respect to permanganate and glycine are both unity. On the other hand, the different ionic forms of the amino acid are in equilibrium:

$$[14] \quad ^+H_3NCH_2CO_2H \rightleftharpoons ^+H_3NCH_2CO_2^- + H^+$$

$$[15] \quad ^+H_3NCH_2CO_2^- \rightleftharpoons H_2NCH_2CO_2^- + H^+$$

the respective pK_a's corresponding to eqs. [14] and [15] being 2.35 and 9.78 at 25.0°C (42). Thus, application of eq. [13] for the k_1 data measured at several pH values allows the obtention of the rate constants of the rate-controlling steps, these being $k_4 = 2.28 \times 10^{-4} M^{-1}$ s^{-1} and $k_{10} = 6.16 \times 10^{-2} M^{-1}$ s^{-1}. Hence, the anionic amino acid form is more reactive toward permanganate than the zwitterionic one, probably due to the higher electron density of $H_2NCH_2CO_2^-$ compared to that of $^+H_3NCH_2CO_2^-$, because an increase in the electron density results in a promotion of the reducing power.

Table 2 shows a slight increase in k_1 as the total phosphate concentration increases. Although this suggests that there might be a small contribution of general base catalysis due to HPO_4^{2-} ion, the minor importance of that dependence indicates that it might be due to a systematic error in the measurement of the rate constants instead.

The k_1 value at pH 6.78 is independent of the ionic strength of the medium (see Table 3); thus, we can infer that, at that pH, the oxidation of the zwitterionic form of the amino acid is predominant over the oxidation of the anionic form, since eq. [4] is a reaction between an ion and a neutral molecule, whereas eq. [10] is a reaction between two ions with like charges. This is consistent with the values found for rate constants k_4 and k_{10} (see above), for according to them at pH 6.78 eq. [4] accounts for most of the total reaction (80%). It should be noticed that the activation energy found for k_1 (64.5 kJ mol^{-1}) is an apparent value, in which the effects of temperature on rate constants k_4 and k_{10} and on the equilibrium constants associated with eqs. [14] and [15] are all included.

Although the kinetic data collected for the noncatalytic pathway give information only as far as the rate-controlling steps are concerned (eqs. [4] and [10]), there are some bibliographic references that support the noncontrolling steps proposed. In the first place, eq. [6] is analogous to the deprotonation of cation radicals formulated for the permanganate oxidation of amines (43), for which imines are also proposed as intermediary species (see eq. [7]). On the other hand, it is well known that hydrolysis of imines (or of methyliminium ion, as in eq. [8]) results in aldehydes and ammonia (or ammonium ion) formation, while dismutation of manganate ion into permanganate and manganese dioxide (see eq. [9]) is very fast in all but very alkaline solutions (44). The mechanisms proposed for the oxidations of the zwitterionic and anionic forms of glycine are similar to the one proposed for the permanganate oxidation of the cationic form of amino acids in very acid media (6).

As far as the reaction products are concerned, colloidal man-

ganese dioxide has been identified as the species responsible for the spectrum shown in Fig. 1. Moreover, it has been reported that carbon dioxide (45), aldehydes (46), and ammonia (47) are all obtained from the permanganate oxidation of amino acids. Under the experimental conditions of the present work, formaldehyde (generated as a reaction product in eq. [8]) is expected to behave as an intermediate since it will be readily oxidized by permanganate ion to formic acid and, further, to carbon dioxide (48).

In relation to the catalytic pathway, the following mechanism is proposed:

[16] MnO_2 + glycine $\rightleftharpoons$ adsorbate

[17] Adsorbate + MnO_4^- $\xrightarrow{\text{slow}}$ products

In eq. [16] glycine is adsorbed on the surface of colloidal manganese dioxide, since the capacity of that colloid to strongly adsorb organic substrates is known (49). Then the adsorbed species may suffer an oxidative attack by permanganate ion from the solution surrounding the colloidal particles (eq. [17]).

According to eqs. [16] and [17], the rate of disappearance of permanganate ion through the catalytic pathway is

[18] $r_2 = k_2[MnO_4^-][MnO_2]$

where k_2 is

[19] $k_2 = k_{17}a[\text{glycine}]^b$

k_{17} being the rate constant associated with eq. [17], whereas a and b are the parameters of the Freundlich isotherm for adsorption of glycine on the surface of the colloidal particles of manganese dioxide (see eq. [16]).

Equation [18] is indeed in agreement with the differential rate law (eq. [2]) whose integral form (eq. [3]) was experimentally confirmed, as shown in Fig. 3. It has been observed that k_2 decreases as the initial permanganate concentration increases (see Table 1); this may be due to the increase in the size of the colloidal particles as a consequence of an increasing manganese dioxide concentration. Moreover, eq. [19] is in agreement with the log k_2 vs. log [glycine] linear plot found in Fig. 4; the fact that the slope of this plot is higher than unity (1.31) indicates that the catalytic power of manganese dioxide increases with the glycine concentration, since the density of active sites on the colloid surface depends on its rate of formation as well as on the experimental conditions of the medium where it is formed.

It is convenient to mention that, although manganese dioxide is formed in eq. [9] of the noncatalytic pathway as a discrete species, prior to its participation in the catalytic pathway it must flocculate to generate colloidal particles on whose surface the autocatalytic reaction takes place. As a result, the size of these particles is a function of the flocculation rate and so it also depends on the experimental conditions that might affect the flocculation process. Hence, both the oxidant and reductant concentrations have some influence on the catalytic power of colloidal manganese dioxide. Since the number of molecules that are actually forming each colloidal particle is not known, in the differential rate law (eq. [2]) the autocatalytic agent concentration was taken as equal to $(c_0 - c)$; in fact, no problem arises with this assumption other than k_2 being expressed per manganese dioxide molecule instead of per colloidal particle.

We can see in Fig. 5 that log k_2 also increases linearly as the pH of the solution increases. Although a common explanation might be given for the variations of both k_1 and k_2 with the pH, the fact that the log k_2 vs. pH plot is linear whereas the other is not suggests that the dependence of k_2 on pH is due to a different reason. This dependence might be a reflection of the fact that hydroxyl ions linked to colloidal manganese dioxide (50–52) are the active sites for adsorption of glycine on its surface.

On the other hand, Table 2 shows a decrease in k_2 as the total phosphate concentration increases at constant pH. Retardation of permanganate reactions taking place on the surface of colloidal manganese dioxide as a consequence of an increasing phosphate concentration has previously been reported (53). Since phosphate ions are known to be strongly adsorbed on colloidal manganese dioxide generated as a product from the reduction of permanganate ion in aqueous phosphate buffers (54), that retardation might be due to the electrostatic repulsion between the phosphate ions linked to the colloid surface and the permanganate ion that must approach the surface so that the reaction depicted by eq. [17] can take place.

One is not entitled to infer conclusions from the independence of k_2 with respect to the ionic strength of the medium (see Table 3), at least as far as the Debye–Hückel theory is concerned, for that theory does not apply to reactions taking place on the surface of colloidal particles such as those of manganese dioxide. It should also be mentioned that the activation energy found for k_2 (62.0 kJ mol^{-1}) is not properly a true activation energy but only an apparent value in which the effects of temperature on both eqs. [16] and [17] (an adsorption enthalpy and an activation energy, respectively) are included.

As far as the effect of additives on the reaction is concerned, it is necessary to take into consideration that manganese(II), thiosulfate, and hexacyanoferrate(II) are all inorganic ions with a common property, that of reducing permanganate ion almost instantaneously in neutral aqueous solutions according to the following stoichiometries:

[20] $2MnO_4^- + 3Mn^{2+} + 2H_2O \rightarrow 5MnO_2 + 4H^+$

[21] $8MnO_4^- + 3S_2O_3^{2-} + 2H^+ \rightarrow 8MnO_2 + 6SO_4^{2-} + H_2O$

[22] $MnO_4^- + 3Fe(CN)_6^{4-} + 4H^+ \rightarrow MnO_2 + 3Fe(CN)_6^{3-} + 2H_2O$

Hence the red colour whose appearance was observed right after the solutions containing the reactants came in contact was due to a mixture of permanganate ion (purple), which was used in excess with respect to the additive, and colloidal manganese dioxide (yellow) formed according to eqs. [20]–[22]. This colloid was stabilized in aqueous solutions owing to the adsorption of phosphate ions on its surface (54). Since manganese dioxide is formed during the process of stirring the mixtures, the initial absorbances at 418 and 526 nm given by the spectrophotometer will depend on the Mn^{2+}, $S_2O_3^{2-}$, and $Fe(CN)_6^{4-}$ concentrations, for the higher the concentration of additive the lower the initial absorbance at 526 nm and the higher the initial absorbance at 418 nm will be, because more permanganate and more manganese dioxide will have been consumed and formed, respectively.

It is necessary to notice that the reaction monitored with the aid of the spectrophotometer was that of glycine with permanganate ion, but the MnO_4^-/Mn^{2+}, $MnO_4^-/S_2O_3^{2-}$, and $MnO_4^-/Fe(CN)_6^{4-}$ reactions cannot be followed with a conventional spectrophotometer due to their being extremely fast; other methods, such as the stopped-flow technique, would be needed for that purpose.

Therefore when the kinetic data were determined, manganese(II), thiosulfate, and hexacyanoferrate(II) ions were no longer in the solutions, their presence being replaced by that of colloidal manganese dioxide. Furthermore, we can see that the behavior of Mn^{2+} is similar to that of other inorganic species capable of instantaneously reducing permanganate ion in neutral solutions, such as $S_2O_3^{2-}$ and $Fe(CN)_6^{4-}$. Thus there is no reason to think that manganese(II) ion is the true autocatalytic agent for the permanganate oxidation of amino acids, as sometimes proposed (3, 5, 6, 55). In fact, such an explanation cannot account for the autocatalytic effect found for those reactions when they are performed in neutral solutions (in which the product is MnO_2) and would only apply (in principle) to very acid media (in which the product is Mn^{2+}). On the contrary, the catalytic effect of colloidal manganese dioxide is capable of explaining the autocatalysis found both in neutral solutions and in acid media, for at very low pH values manganese dioxide may form as a colloidal intermediate (56).

We can thus conclude that the increase in rate constant k_1 caused by addition of manganese(II) ion to the solution (see Fig. 7) is not due to the formation of a glycine–manganese(II) complex but to the obtention of colloidal manganese dioxide according to Guyard's reaction (57), as depicted in eq. [20]. Therefore, manganese(II) ion is not actually the catalytic agent but only a precursor of the true catalyst, colloidal manganese dioxide, and the same can be stated as far as thiosulfate and hexacyanoferrate(II) ions are concerned. Hence, this is a phenomenon of heterogeneous autocatalysis in which the colloid offers its surface for the encounter of the reactants.

Figures 7–9 show that the increases in k_1 due to additions of Mn^{2+}, $S_2O_3^{2-}$, and $Fe(CN)_6^{4-}$ are not directly proportional to the additive concentration, the function relating $(k_1 - k_1^0)$ with that concentration being different for each additive. On the other hand, Tables 4–6 show that the effect of the three additives on the rate of reaction depends on the glycine concentration, but the dependence in the case of manganese(II) ion is much stronger than in the other two cases. These differences are probably due to the colloidal nature of manganese dioxide, for its catalytic power is a function of the experimental conditions of the medium where it is formed. Consequently, it is not easy to establish a quantitative relationship between the kinetic effects of the additives and the stoichiometries given in eqs. [20]–[22], owing to the fact that the catalytic properties of colloidal manganese dioxide strongly depend on the nature of the species used to reduce permanganate.

On the other hand, arabic gum is a water-soluble colloid whose resistance to oxidation by permanganate ion has made it useful in kinetic studies of permanganate reactions (8). It seems clear that the catalytic effect of this colloid is totally similar to that of manganese dioxide, both colloids acting as heterogeneous catalysts on whose surface the reaction between the amino acid and permanganate ion can take place.

The effect of benzyltriethylammonium chloride on the reaction, however, requires a different explanation. Since potassium chloride additions had no effect on the reaction rate (see Table 3), the possibility of a salt effect due to an increase in the ionic strength of the medium has also to be excluded.

It has been reported (58) that quaternary ammonium salts are used as phase-transfer agents in permanganate reactions due to their tendency to form quaternary ammonium permanganate. Thus a small concentration of benzyltriethylammonium permanganate might be present in the solutions (in concentration too small to precipitate), and this new variety of permanganate might react with glycine to generate the reaction products according to the following scheme:

$$[23] \quad BzEt_3N^+ + MnO_4^- \rightleftharpoons BzEt_3NMnO_4$$

$$[24] \quad BzEt_3NMnO_4 + \text{glycine} \xrightarrow{\text{slow}} \text{products}$$

The rate law corresponding to that mechanism is

$$[25] \quad r = K_{23}k_{24}[MnO_4^-][\text{glycine}][BzEt_3N^+]$$

where K_{23} and k_{24} are the equilibrium and rate constants associated with eqs. [23] and [24], respectively. Hence, the increase in rate constant k_1 will be directly proportional to both the quaternary ammonium chloride and glycine concentrations, in reasonably good agreement with the results found in Fig. 11 and Table 8, respectively.

In conclusion, it can be stated that the reaction between glycine and permanganate ion in aqueous phosphate buffers is catalyzed by soluble colloids, such as arabic gum and colloidal manganese dioxide. Those species capable of instantaneously reducing permanganate to colloidal manganese dioxide have an increasing effect on the reaction rate. Quaternary ammonium salts also catalyze the reaction due to the formation of quaternary ammonium permanganate.

Formation of hydroxyl radicals, in relatively large quantities, by oxygen reduction due to the surface activity of asbestos in a cell-free system is demonstrated, using electron spin resonance and a spin trapping agent. The quantity of OH• produced (in general, above 10^{14} mg^{-1} for a Canadian chrysotile) is a function of activation or passivation of the electron donor surface sites of the minerals. The role of these radicals in oxidative stress in relation to the toxic properties of these minerals is discussed.

ROGER ZALMA, LIONEL BONNEAU, JOËLLE GUIGNARD, HENRI PEZERAT et MARIE-CLAUDE JAURAND. Can. J. Chem. **65**, 2338 (1987).

En utilisant la technique des piégeurs de radicaux et la spectroscopie en résonance paramagnétique électronique on peut montrer que la réactivité de surface des amiantes permet, en milieu tampon, la réduction de l'oxygène en radicaux hydroxyles (OH•). La quantité de radicaux formés (en général supérieure à 10^{14} mg^{-1} pour le chrysotile canadien) est fonction de l'activation ou de la passivation des sites de surface à caractère électro-donneur. Le rôle de ces radicaux dans les phénomènes de «stress oxydant» est discuté en relation avec les propriétés toxiques des amiantes.

It is known that asbestos fibres induce chromosome damage, which might be implicated in the sequential steps of carcinogenesis. This phenomenon might be related to the formation of oxy radicals in the presence of asbestos, this formation being postulated from biochemical data concerning asbestos-induced damage to cells and lipid peroxidation (1–4), and in relation to redox properties as shown up by electron spin resonance (esr) (5, 6).

Weitzman and Graceffa (7) and Eberhart and Romano-Franco (8) demonstrated that asbestos catalyzes the generation of hydroxyl (OH•) and superoxide (O_2^{-}•) radicals from hydrogen peroxide (H_2O_2) in a cell-free system. But all iron-containing minerals (with Fe^{2+} or Fe^{3+}) have approximately the same activity in such a system (9, 10), and the bioavailability of H_2O_2 is low. In our model system, with techniques similar to that of Weitzman and Graceffa (7) (esr and spin trapping agent), but taking into account the phenomenon of activation or passivation of the surface active sites of asbestos, we are able to demonstrate the formation of a high level of OH• from the reduction of oxygen, which is completely bioavailable. Our model system differs from the one employing H_2O_2 in that only part of the iron-containing minerals is active in the reduction of O_2, according to the following reactions:

$$[1]\quad O_2 \xrightarrow{+e^-} O_2^{-}\cdot$$

$$[2]\quad O_2^{-}\cdot \xrightarrow{+e^- + 2H^+} H_2O_2$$

$$[3]\quad H_2O_2 \xrightarrow{+e^-} OH\cdot + OH^-$$

$$[4]\quad OH\cdot \xrightarrow{+e^- + H^+} H_2O$$

Morever, if we have some organic molecules (RH) in the reactor, then we obtain:

$$[5]\quad OH\cdot + RH \rightarrow R\cdot + H_2O$$

Methods

We used 5,5′-dimethyl-1-pyrroline-*N*-oxide (DMPO) as a spin trapping agent to produce adducts with OH•, or more generally with a radical R•, sufficiently stable to be detected in esr (11, 12). The reaction medium in our study is a suspension of fibres or particles (45 mg) in aqueous buffer solution (potassium phosphate, pH = 7.4) at 37°C in a dark reactor. All reactions were duplicated in the presence of a probe anion $HCOO^-$ (cf. reaction [5]) to obtain, from OH•, the radical CO_2^{-}•, and consequently the (DMPO, CO_2)$^{-}$• adduct. This procedure was used to take into account the possible artefact in the formation of (DMPO, OH)• by an oxidative pathway without intervention of OH• (13), and also to reduce the importance of reaction [4], i.e., destruction of OH• in contact with active sites of the solid. Therefore we used 1 mL of 1 *M* sodium formate solution in the buffer, to which we added the solid and 1 mL of 100 m*M* DMPO solution, prepared according to Buettner and Oberley (14); time was counted from this moment. Aliquots of the suspension were withdrawn at the indicated times without modification of the relative concentrations and then filtered through 0.65 μm porosity filters. Controls contained no solid particles.

Detection of radical adducts was performed by epr (electron paramagnetic resonance) spectroscopy, 2 min after withdrawal of aliquots. Spectral data of radical adducts accorded well with those reported by Kirino *et al.* (15) and Makino *et al.* (13). Ethanol, acetone, or DMSO were also used instead of formate, and examples of esr spectra of DMPO-radical adducts, formed in our model system, are given in Fig. 1. In this publication, all the results are reported from the measuring of the intensity of the (DMPO, CO_2)$^{-}$• signal after the addition of formate. To ascertain mechanisms we added 250 μL of catalase (1 g L^{-1}) or 200 μL of superoxide dismutase (SOD, 2.5 g L^{-1}) to the reaction medium, which had a final volume of 2 mL for 45 mg of solid.

Materials

Asbestos samples

We used the following:

Rhodesian and Canadian chrysotile (A and B); crocidolite and amosite obtained from the Union Internationale contre le Cancer (UICC), the respective surface areas (BET) being 19, 27, 8, and 6 m^2 g^{-1}; and also two commercial asbestos samples.

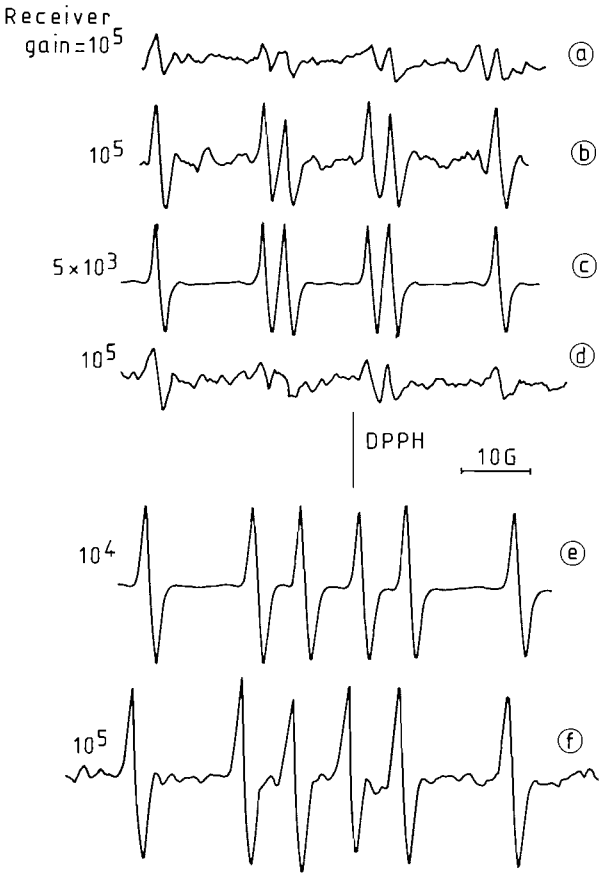

FIG. 1. Examples of spectra of DMPO-radical adducts, after 25 min of incubation of fibres in buffer, with DMPO and formate solution or ethanol or acetone. (a) Control in presence of formate anion. (b) Case of UICC crocidolite in presence of formate (Table 1). (c) Same sample but 5 min after grinding (Table 3). (d) Same sample, ground, then 2 h in buffer and 1 h with ultrasonic treatment (Table 4). (e) Case of commercial amosite, ground, in presence of ethanol. (f) Same sample, in presence of acetone. Varian CSE instrument, field set 3380 G, scan range 100 G, microwave power level 10 mW, time constant 1 s. Constants for (DMPO, OH)$^{\cdot}$: $g = 2.0054$, $a_N = a_H = 14.9$ G; for (DMPO, CO_2)$^{\cdot-}$: $g = 2.0055$, $a_N = 15.6$ G, $a_H = 19.0$ G; for (DMPO, CH_3CHOH)$^{\cdot}$: $g = 2.0052$, $a_N = 15.8$ G, $a_H = 23.2$ G.

Six samples of Canadian chrysotile, supplied by C. Jolicoeur (Asbestos research programme, Sherbrooke, Québec), from Bell asbestos mines (Ltd 7D-700 no. 6781), J. M. Asbestos Inc. (6D-12), Lac d'amiante Ltée (no. 85-530 7D-3), Carey Canada Inc. (7TS-3 O.S. 7021), Asbestos corporation Ltd. (BC-753-7m), J. M. Asbestos (gr 7).

Two samples of "short fiber" chrysotile, one of them after treatment with $POCl_3$ to obtain a "chrysophosphate" (supplied also by C. Jolicoeur). The short fibers were obtained by sedimentation from a sample of J. M. Asbestos mine.

Mineralogical samples

Magnetite (from Norway) and nemalite (from Asbestos, Quebec) are classical contaminants of chrysotile, but we have verified the absence of nemalite in Rhodesian chrysotile UICC. Nemalite is a fibrous brucite ($Mg(OH)_2$) where 8% of Mg^{2+} is substituted by Fe^{2+}. These substitutions led to slight modifications of the crystallographic parameters, which we have verified.

Reagents

Catalase, SOD, and DMPO were from Sigma, the last having been purified by filtering through activated charcoal.

Results

In Tables 1, 2, and 3 we present the results as the intensity of the (DMPO, CO_2)$^{\cdot-}$ signals (arbitrary scale) obtained with different materials. These radical adducts arise from:

$$OH^{\cdot} + HCO_2^- \rightarrow H_2O + CO_2^{\cdot-} \xrightarrow{\text{DMPO}} (\text{DMPO}, CO_2)^{\cdot-}$$

For purposes of comparison, we also added H_2O_2 (0.3%) to the reactor, following Weitzman and Graceffa (7). In this case the intensities of the same signals, after 30 min, are 2200 for magnetite, 720 for Canadian (UICC) chrysotile, 1000 for UICC crocidolite, and 800 for commercial chrysotile. Thus we

TABLE 1. Intensity of the esr signals of (DMPO, CO_2)$^{\cdot-}$. All values are given to ±20%

Nature of materials	(DMPO, CO_2)$^{\cdot-}$ signal intensity	
	After 25 min	After 60 min
Magnetite	40	30
Chrysotile UICC Rhod. (A)	25	30
Crocidolite UICC	25	40
Amosite UICC	30	50
Chrysotile (commercial)	1800	1500
Chrysotile UICC Can. (B)	1200	600
Nemalite	200	3000
Controls	10	15

TABLE 2. Results of "activation" treatments. Because of differences in grinding, the intensities of the (DMPO, CO_2)$^{\cdot-}$ signals may differ by ±30%. The controls are the same as in Table 1

Materials and treatment	(DMPO, CO_2)$^{\cdot-}$ signal intensity	
	After 25 min	After 60 min
Crocidolite (commercial) 5 min after grinding	690	1030
Crocidolite (UICC) 5 min after grinding	640	600
Amosite (UICC) 5 min after grinding	850	1000

TABLE 3. Results of "passivation" treatments. The controls are the same as in Table 1

Materials	(DMPO, CO_2)$^{\cdot-}$ signal intensity	
	After 25 min	After 60 min
Chrysotile (UICC) Can. after 16 h in buffer	20	15
Crocidolite (UICC) ground, then 2 h in buffer and 1h with ultrasonic treatment	15	15
Crocidolite (UICC) ground, then exposed to air, during 1 day	220	180
during 20 days	230	170
Chrysotile (short fibers)	490	225
Chrysotile (phosphated fibers)	135	75

observed that in some cases the intensities have the same order of magnitude, irrespective of the addition of H_2O_2.

The spin number was calculated using as a reference the signal of DPPH in benzene at different concentrations, in the same esr cell. The conversion of the signal intensity to radical concentrations is obtained by means of double integration of the area under the peaks for DPPH and (DMPO, CO_2)$^{\cdot}$ solutions. The tests were made rapidly to avoid problems with the stability of DPPH solutions. We may consider that a (DMPO, CO_2)$^{\cdot}$ signal of intensity 1000 implies presence of approximately 8×10^{15} R$^{\cdot}$ in our reactor, for 45 mg of solid. Consequently, for an active chrysotile giving a signal of 1000, we may consider that a fibre of 5 μm length and 0.1 μm diameter might lead to the formation of a minimum of 10^4 OH$^{\cdot}$ in such a model system.

Table 1 shows that some minerals are very active while others are poorly active in the reduction of oxygen. On the other hand, all the samples of Canadian chrysotile—UICC sample and the six samples supplied by C. Jolicoeur from different mines—are active. For the last six samples the intensity of the (DMPO, CO_2)$^{\cdot}$ signal varies from 940–1000, in the case of the less active one, to 2200–2700 for the most active one.

Table 2 reveals that poorly active amphibole fibres can become very active after moderate grinding without significant increase of their surface area (BET). The activation in this case implies merely the emergence of fresh surfaces (not oxidized).

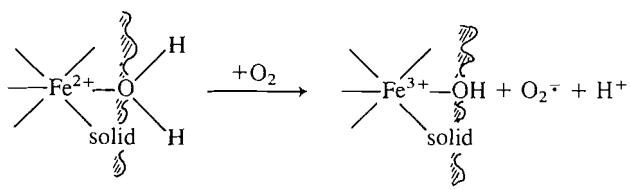
On the contrary, Table 3 presents evidence of a considerable alteration of surface properties of chrysotile after some hours in the buffer, and illustrates a lower passivation of crocidolite surface in air. In other respects the short fibres of chrysotile prepared in aqueous phase are less active than the fibers of Canadian chrysotile (Table 1) and the activity of phosphated fibers is clearly weaker.

Figure 1 (spectra b, c, d) illustrates the phenomena of activation and passivation with the UICC crocidolite.

Moreover, we confirm by addition of SOD and catalase that the reactions concerned are [1], [2], and [3]: SOD does not inhibit the reactivity but slightly enhances it, and catalase reduces the (DMPO, OH)$^{\cdot}$ signals to the control level. Finally, we have evidence that the activity is a surface activity, as shown by adding the DMPO to the filtrate at variable time, instead of adding DMPO to the suspension. In this case we do not observe the formation of the radical adducts.

Discussion

The reduction of O_2 in OH$^{\cdot}$ is realized by transfer of electrons from the electron donor surface sites of the solid. The initial step [1] can be schematized as below, where the active site is OH_2, in low coordination and linked to a Fe^{2+}:



Thus an active material may, for example, be a divalent iron-containing material, but this condition is not sufficient if there is easy reconstruction of the solid surface to an oxidized sheet, impermeable to air even in aqueous medium (case of the magnetite).

In amphiboles, Fe^{2+} is present in an octahedral sheet of the I-beams and Bonneau *et al.* have published studies on the surface sites (5, 16). The oxidation of these sites—which is relatively easy—indicates the need to use freshly ground fibres for in vitro experiments to test the redox activity of the surface of the fibers.

Examination of chrysotile samples leads to the consideration that the iron is found essentially in the contaminants (magnetite and nemalite), the reason being the steric constraints that hinder the insertion of iron in the brucitic sheets of the chrysotile.

The presence of magnetite in the samples studied is demonstrated either by electron microscopy and electron diffraction patterns or by X-ray diffraction from the fraction adhering to a magnetic stirring bar during the stirring of a suspension of chrysotile in benzene.

Nemalite is revealed from the X-ray diffraction of samples from Quebec. Mg^{2+} is partially substituted by Fe^{2+} in the brucite structure in a relatively homogeneous manner, as shown by the measurement of crystalline parameters and by electron diffraction spectroscopy. The weak solubility of this material probably allows a permanent creation of new active sites, explaining the high activity of this mineral, specially in potassium phosphate buffer, where the solubility increases because of the precipitation of $KMgPO_4 \cdot 6H_2O$ (verified by X-ray).

In addition, we can consider the presence of a coating containing Fe^{2+}, between the fibrils of chrysotile or in a closed porosity, becoming accessible to oxygen in aqueous medium. But for the time being it is not possible either to confirm or to exclude this hypothesis.

The redox activity of a mineral sample is a function of the density of surface active sites accessible to O_2 in the buffer medium, of the redox potential of these sites (related to their configuration), and of the surface area of the sample.

In biological media other phenomena may occur, as part of activation or passivation of surface activity of mineral dusts. For example, the leaching of mineral particles, the splitting of the amphiboles (17), or the "opening" of the bundles of chrysotile can lead to the emergence of new active sites. On the contrary, a coating by some biological molecules may "poison" these surface sites. The observed formation of OH$^{\cdot}$ and R$^{\cdot}$ in biological medium from the surface activity of fibres and other nonfibrous minerals, encountered for example in some metallic mine ores (10, 18), may give these dusts an important role in oxidative stress (19) and so explain their role in fibrogenesis (20) and in the steps of bronchopulmonary carcinogenesis.

Acknowledgment

Pulsed picosecond laser photolysis of the diphenyliodonium cation indicates that excitation of the allowed transition is followed by rapid (ps) deactivation to a homolytically dissociative state, presumably T_1. Steady-state photolysis yields iodobenzene and biphenyl from the primary radical products. Iodobiphenyl is also observed. We infer in-cage recombination of these radical products, with intervention of a carbocationic intermediate. Laser flash photolysis of diphenyliodonium iodide in its charge transfer band yields an initial transient with a lifetime of ca. 200 ps. A strongly absorbing secondary transient is observed on the nanosecond time scale. Iodobenzene is the exclusive reaction product. We infer that it is not formed directly from the primary photoproduct, but through in-cage recombination of phenyl cation with iodide anion, as in benzenediazonium iodide.

R. J. DEVOE, M. R. V. SAHYUN, N. SERPONE et D. K. SHARMA. Can. J. Chem. **65**, 2342 (1987).

La photolyse laser pulsée au picoseconde du cation diphényliodonium indique que l'excitation de la transition permise est suivie par une désactivation rapide (ps) conduisant à un état dissocié homolytique, probablement T_1. La photolyse à l'état dissocié homolytique, probablement T_1. La photolyse à l'état stationnaire conduit à la formation d'iodobenzène et de biphényle à partir des produits radicalaires primaires. On observe aussi la formation d'iodobiphényle. On en conclut qu'il se produit une recombinaison en cage de ces produits radicalaires, avec une intervention d'un intermédiare carbocationique. La photolyse laser flash de l'iodure de diphényliodonium dans sa bande de transfert de charge conduit initialement à la formation d'une espèce transitoire dont le temps de demi-vie est d'environ 200 ps. On observe aussi la formation d'une espèce transitoire secondaire qui absorbe fortement et dont le temps de demi-vie est de l'ordre de la nanoseconde. L'iodobenzène est le seul produit de la réaction. On en déduit qu'il ne se forme pas directement à partir du photoproduit primaire, mais plutôt par une recombinaison en cage du cation phényle avec un anion iodure, comme dans le cas de l'iodure de benzènediazonium.

[Traduit par la revue]

Introduction

Photolabile 'onium salts, particularly those of aryldiazonium, diaryliodonium, and triarylsulfonium cations, have found application in imaging media and in radiation curable coatings (1). The mechanism of photolysis of diphenyliodonium cations was probed by following the absorption spectroscopy of light absorbing transient intermediates on the nanosecond time scale by Klemm *et al.* (2) and by Pappas *et al.* (3). These workers observed iodobenzene radical cation and, in the former instance, phenyl radical, both of which had been formed on a time scale fast compared to the resolution capabilities of their experiments. Accordingly, we decided to probe this chemistry with picosecond time-resolved absorption spectroscopy.

Results

We flash photolyzed diphenyliodonium hexafluorophosphate (6×10^{-4} *M* in acetonitrile) with 30-ps (FWHM) pulses of 266-nm radiation from a mode-locked, frequency quadrupled Nd-YAG laser. Representative transient absorption spectra are shown as absorbance change, ΔA, vs. wavelength, in Fig. 1. The principal transient absorbance occurs at 650 nm; it is formed during the light pulse ($\leq$30 ps), hence in an essentially unactivated process. This transient barely begins to decay during the lifetime of the experiment (10 ns); it corresponds to the iodobenzene radical cation (4), observed by Klemm (2) to survive ca. 500 ns in the same medium.

The rising absorbance at the short wavelength limit of the probe continuum suggests the presence of phenyl cation, also found by Klemm. Although the changes in ΔA with time are small, they nevertheless suggest growth over the period of time from 1 to 5 ns of some broad transient centered at ca. 460 nm (see below), perhaps at the expense of the 650-nm species.

We complemented the spectroscopic observations with steady-state photolysis product studies, using the 254-nm line from a medium pressure mercury source, followed by glc. Within experimental error there was no difference in the product distribution from nitrogen-purged samples and that from air-equilibrated samples. The results of these analyses are reported in Table 1. The iodobiphenyl product comprised two isomers, distinguishable in the glc analysis. By comparison of the retention times with those of authentic samples we identify these isomers as *para*- and *ortho*-iodobiphenyl, obtained, typically, in 80:20 ratio.

It also appeared instructive to carry out a sensitized photolysis of the diphenyliodonium hexafluorophosphate. Although sensitizations with both acetophenone (1, 3) and benzophenone (5) have been reported, the mechanism of sensitization is ambiguous in these cases inasmuch as both electron transfer and triplet energy transfer (see below) are energetically feasible. We chose *m*-trifluoromethylacetophenone (0.05 *M* in acetonitrile) as sensitizer, insofar as its triplet energy (3.17 eV) is equal to that of acetophenone itself; however, it is 0.20 V less reducing (6), and hence energetically incapable of electron transfer from its triplet excited state to the diphenyliodonium cation (3). The quantum yield for iodobenzene formation (by glc) in this sensitized photolysis at 313 nm was 0.04. The same products were observed for the sensitized and the direct photolyses, though with altered distribution (Table 1). On the other hand,

with chloranil (triplet energy 2.7 eV) as sensitizer, no decomposition of the iodonium cation was obtained on irradiation into the chloranil absorption band.

Photolysis of both the iodonium hexafluorophosphate and chloride salts in water was complicated by insolubility of the products. Although the product distribution (Table 1) indicated no change in mechanism, in the case of the hexafluorophosphate salt, changing the solvent (acetonitrile to water), led to dramatic differences in the transient absorption spectra. The greatly enhanced absorption centered on 460 nm grew in on the time scale of the laser flash photolysis experiment, but not at the expense of the iodobenzene radical cation (see Fig. 2). The absorption bands are broader than in acetonitrile, probably an artifact resulting from light scattering by the insoluble photoproduct. In addition, broad absorption across the visible, arising from solvated electrons, a usual side-product observed in 266-nm aqueous photolyses, may contribute to the observed transient absorption. This species lives for at least tens of nanoseconds in neutral aqueous environment (7). Laser flash photolysis of the chloride salt in water yielded, in fact, only the broad transients associated with solvated electrons.

As a result of these complications, absolute values of ΔA for the photolysis of the hexafluorophosphate salt in water were reproducible only to $\pm 25\%$. From the time dependence of the 460-nm absorbance intensity, normalized to the 650-nm absorption, shown in Fig. 3, we infer a half-life of ca. 1 ns for its formation, consistent with an in-cage reaction.

Steady-state photolysis of the diphenyliodonium chloride in water generates new products (Table 1), principally at the expense of biphenyl and iodobiphenyl. The isomer distribution of the hydroxybiphenyl was unresolvable by glc. The overall product distribution was unaltered, within experimental error, when the photolysis was carried out in the presence of 0.017 *M* additional chloride ion (in 17-fold excess, as sodium chloride).

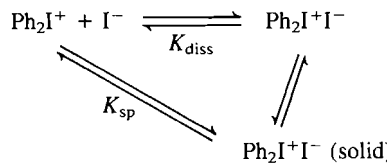
reflects the stoichiometry of the starting materials, suggesting complete recovery of products. An expected reaction product, benzene, could not be resolved from the extraction solvent, cyclohexane, by chromatographic methods. The low yield of biphenyl in the photolysis of the chloride salt, combined with the low phenyl-to-iodine ratio, suggests that the phenyl radicals have been diverted to benzene in this case; formation of benzene was confirmed by nmr. The low phenyl-to-iodine ratio for the sensitized photolysis lends itself to a similar interpretation. In addition, the high resolution mass spectrometric analyses of the reaction mixtures all indicated the presence of trace quantities of polyphenyls.

Formation of iodobenzene from the homolysis products has been rationalized by McEwen and co-workers (8); biphenyl results by in-cage recombination of the phenyl radicals. The higher polyphenyls are also typical products of radical reaction. The acetanilide may be formed by attack of either phenyl radical or phenyl cation on acetonitrile solvent. The origin of the *p*-iodobiphenyl will be discussed below.

Diphenyliodonium iodide, **5**, was prepared *in situ* from the hexafluorophosphate salt (6×10^{-4} M) and tetrabutylammonium iodide (0.045 M) in water, as direct dissolution of the pure iodonium iodide proved difficult to effect. The solubility product, K_{sp} of **1** was determined to be 3×10^{-5} M^{-1} in water. Solutions of this salt exhibited λ_{max} beyond 300 nm, which we assign to an iodide–iodonium (σ^*) charge transfer (CT) absorption, in keeping with the charge transfer absorption observed in *N*-alkylpyridinium iodides (9) and in triphenylsulfonium iodide (10). Other charge transfer complexes of the diaryliodonium cations have been reported (11). The identification of this electronic transition was confirmed by a study of its solvent dependence; as shown by the data of Table 2, in organic solvents the transition energy, hc/λ_{max}, varies systematically with the polarity index, E_T 30 (12), of the solvent. (The correlation coefficient for the regression of hc/λ_{max} on E_T 30 is 0.925 and the slope is 0.84; the data point obtained in pure water does not fit the correlation.)

Absorption in the CT band did not follow Beer's Law in water; in acetonitrile, in which the iodonium iodide is more soluble, Beer's Law is followed for concentrations below 10^{-4} M, and $\varepsilon = 1.2 \times 10^4$ L mol^{-1} cm^{-1} at 324 nm. These observations suggest the following scheme:

[1]



where the 324-nm absorption is associated with the ion-paired species. The Beer's Law behaviour suggests that only the ion-paired species obtains in acetonitrile. Based on the extinction coefficient from acetonitrile solution, the maximum *observed* concentration of **1** in water is 5×10^{-5} M, from which we infer a dissociation constant, K_{diss}, of ca. 0.6 M. We similarly estimate dissociation constants of 0.015 M in ethanol and 0.009 M in 90% acetonitrile – 10% water. There thus seems to be a trend for dissociation constant to increase with the polarity of the solvent (Table 2).

Excitation at 355 nm of the long wavelength tail of the charge transfer band was expected to lead to the diphenyliodo radical, **2**, plus iodine atom, by analogy to the photochemistry of the triphenylsulfonium iodide (10). The radical has been proposed as an intermediate in the sensitized photolysis of iodonium cations (1) and the mode and dynamics of its decomposition were accordingly of particular interest.

[2] $Ph_2I^+ I^- \xrightarrow{h\nu} [Ph_2I^{\cdot}\ I^{\cdot}] \longrightarrow 2\,PhI$

2

We carried out the laser flash photolysis of the iodonium–iodide ion pair with frequency tripled 355-nm Nd-YAG emission. The transients are shown in Figs. 4*a* and *b*. The initial broadly absorbing transient centered on 560 nm decays within 200 ps. Bands centered on 430 and at >670 nm grow in with first-order kinetics as shown in Fig. 5; $k = (7.1 \pm 0.4) \times$

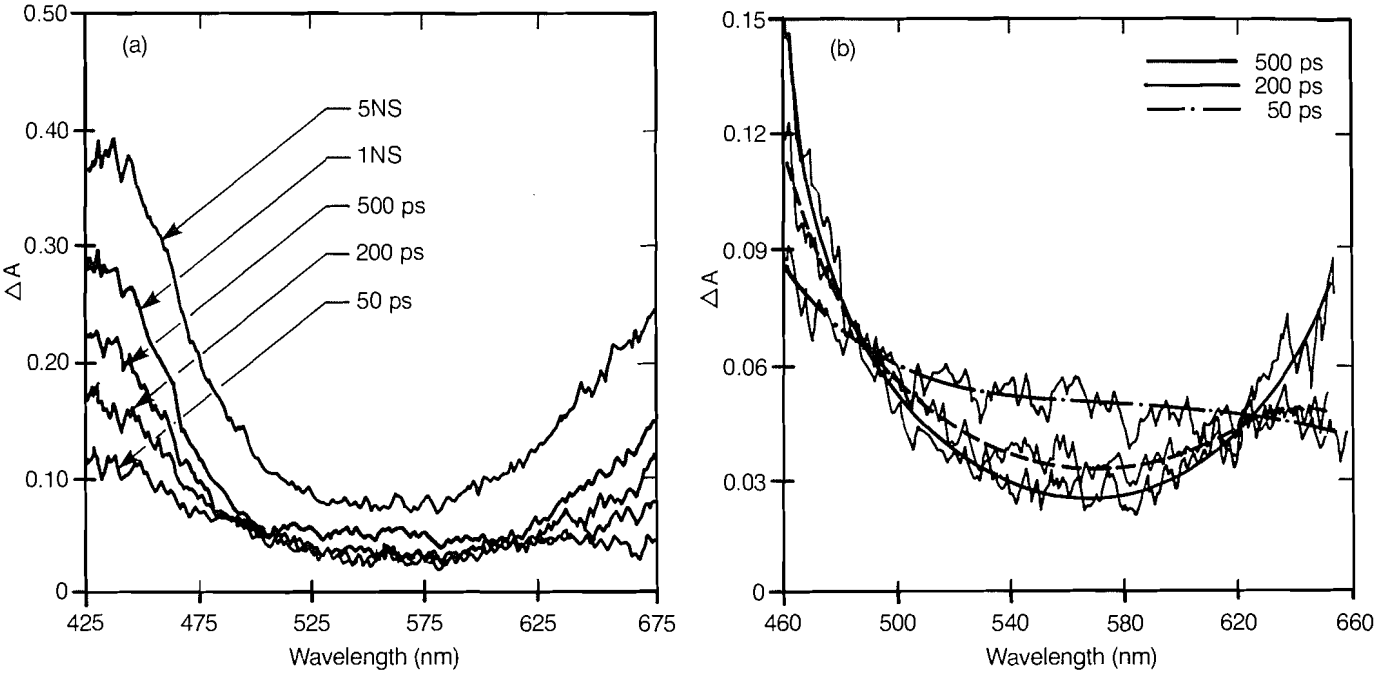

FIG. 4. (a) Spectra of light absorbing transients observed at various times following 355-nm laser flash photolysis of diphenyliodonium iodide in water; (b) detail of (a) for times 500 ps and shorter to show transient centered on 560 nm.

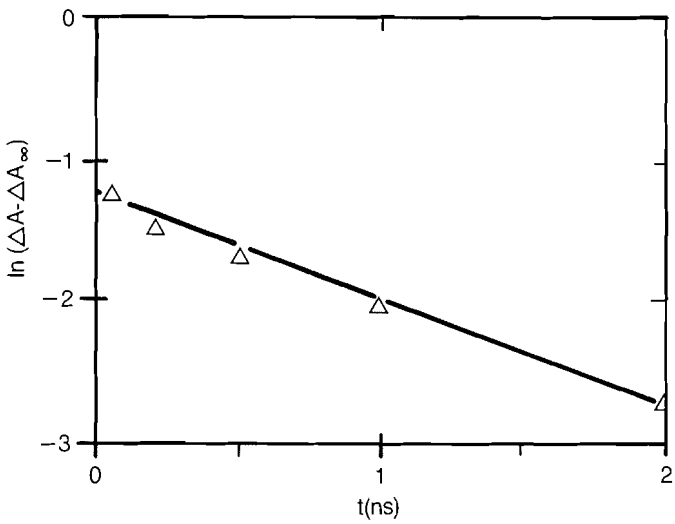

FIG. 5. First-order kinetics of rise of the 430-nm transient in laser flash photolysis of aqueous **1** at 355 nm, as ln $(\Delta A_\infty - \Delta A)$ vs. time where ΔA_∞ is taken as the value observed at 10-ns delay.

$10^8\ s^{-1}$. The latter two transitions thus appear to belong to the same species.

The only reproducibly isolable organic product of the steady-state photolysis of **1** is iodobenzene (Table 1). In this respect our results differ from the observation of a more complex mixture of products from solution irradiation into the CT band of triphenylsulfonium iodide (10) and from those of Irving and Reid (13) who, however, studied the photolysis of a suspension of **1** in chloroform, using a broad spectrum light source. These authors noted that the course of the photolysis was solvent dependent; in addition, the use of a broad spectrum source can lead to secondary photoreactions, e.g., of iodobenzene. Clean thermolyses of **1** and other iodonium iodides have been reported (14). In this context, it is important to note that photolysis of **1**, unlike that of other iodonium cations (e.g., from the hexafluorophosphate salt), does not initiate polymerization of vinyl monomers (15); this indicates either that the phenyl radical expected from the disproportionation of **2** (16) does not form, or that it is trapped rapidly in-cage.

Based on the formation of iodobenzene, the quantum yield for the photolysis of **1**, in aqueous solution of similar composition to that used for flash photolysis, is 0.05 ± 0.01. Steady-state photolysis of an acetonitrile solution of comparable optical density at 313 nm (6×10^{-5} *M* in iodonium cation) indicated a quantum yield for the disappearance of **1** (spectrophotometric) of 0.6 in this solvent; in 90% acetonitrile – 10% water the quantum yield is 0.25 ± 0.03. The only persistent absorption observed in the near-uv or visible, subsequent to photolysis in either pure solvent, occurred at 360 nm, outside the continuum used to probe the flash photolyses. This absorption was also observed on photolysis of the tetrabutylammonium iodide alone; the spectrum corresponds to that of triiodide ion (17). Absorption spectroscopy also indicated that I_3^- is formed in ca. 15% yield relative to that for iodobenzene; the quantum yield is thus <0.01 and also appears to be wavelength dependent.

Given the absence of typical radical products, the possible intervention of phenyl cation in the photolysis of **1**, as originally proposed for its thermolysis (14), had to be considered. The only reliable, independent means for generating phenyl cations appears to be the photolysis of benzenediazonium cation (18, 19). The fate of this hypothetical intermediate in the reaction environment was accordingly probed by photolyzing 1×10^{-3} *M* benzenediazonium tetrafluoroborate at 313 nm under similar conditions. The aqueous solution exhibits a pH of ca. 4 and the loss of the diazonium salt occurs with a (spectrophotometric) quantum yield of 0.20; the photolysis yields no products extractable with nonpolar organic solvents.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

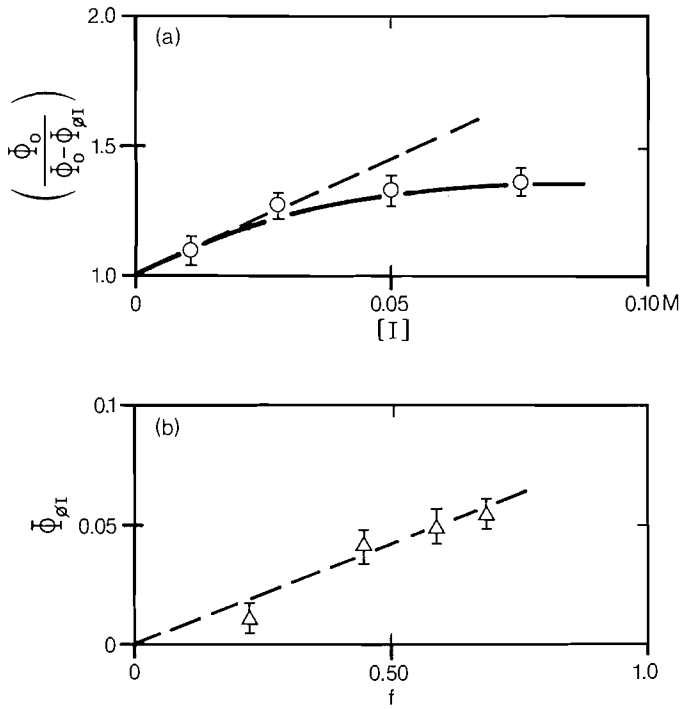

FIG. 6. Dependence of the quantum yield for iodobenzene formation from benzenediazonium cation photolysis on: (a) iodide ion concentration; (b) fraction, f, of the diazonium cation complexed by iodide ion.

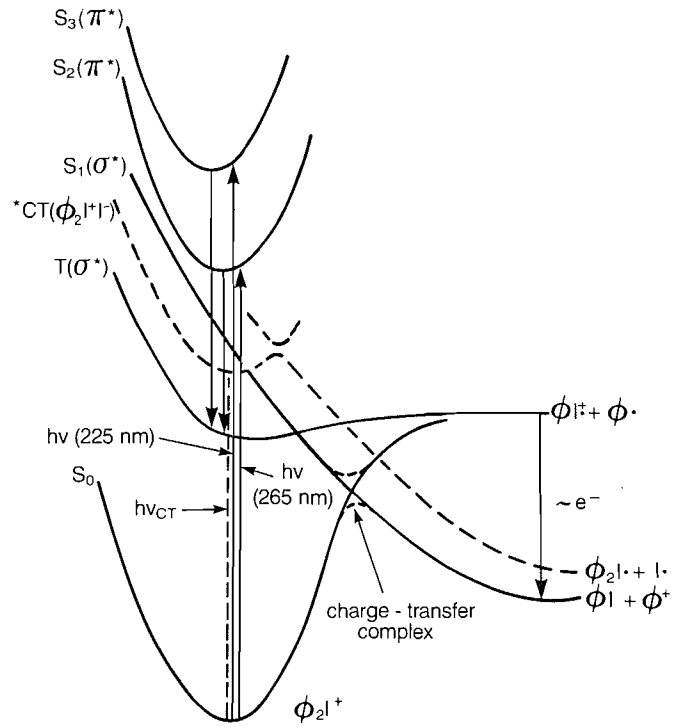

FIG. 7. Schematic diagram of potential energy levels for the diphenyliodonium cation (solid lines) and its charge transfer complex with iodide counterion (dashed lines). The reorganization coordinate (abscissa) for the latter is different from that for the former, insofar as the CT state dissociates primarily with increasing I—I bond length, while the cation, itself, dissociates by extension of a C—I bond.

When tetrabutylammonium iodide was added to the diazonium salt photolysis solution, a new optical absorption centered on 346 nm was observed, which we attribute to a charge transfer complex between iodide anion and the diazonium cation, i.e., "specific solvation" (20). A Benesi–Hildebrand treatment yielded $K_{diss} = 0.029 \pm 0.07\,M$ and $\varepsilon = (3.8 \pm 0.4) \times 10^2\,L\,mol^{-1}\,cm^{-1}$ at 346 nm.

Photolysis at 313 nm (free diazonium cation absorption band) in the presence of tetrabutylammonium iodide allowed isolation of iodobenzene. The quantum yield for its formation did not exhibit a Stern–Volmer type dependence on iodide concentration (Fig. 6*a*), indicative of diffusional capture of the primary photoproduct (19); instead it was reasonably linear with the fraction, f, of the iodonium salt in the iodide complexed form, as calculated from K_{diss}, and shown in Fig. 6*b*. We infer exclusive in-cage capture of the primary photoproduct, involving either direct reaction between phenyl cation and iodide anion, or an electron transfer from iodide anion to phenyl cation followed by radical recombination (18). Observation of the characteristic absorption of I_3^- after irradiation (formed with a quantum yield of ca. 0.01 with 0.05 M iodide ion) supports the latter interpretation. In either case, iodobenzene forms rapidly, in ca. 1 ns, compared to cage escape that occurs in ca. 2–5 ns (21) and presumably results in the triiodide product.

[3] $\mathrm{Ph{-}N{=}N^+\ I^-} \xrightarrow{h\nu} \mathrm{N_2 + [Ph^+\ I^-]}$

$\mathrm{[Ph^{\cdot}\ I^{\cdot}]} \xrightarrow[5\ ns]{1\ ns} \mathrm{PhI}$ or $\mathrm{Ph^{\cdot} + I^{\cdot}}$

Laser flash photolysis of benzenediazonium iodide at 352 nm (CT band) yielded no detectable light absorbing transients. We infer that intermediates in scheme [3] do not absorb in the continuum probed under our experimental conditions.

Discussion

A potential energy diagram correlating the various excited states of the diphenyliodonium cation with the photolysis products is shown in Fig. 7. The spectroscopically accessible levels are as assigned by Jaffe and Orchin (22); the ground state level is correlated with the electrochemical energy scale according to the procedure of Miller *et al.* (23). E_{red} was determined by cyclic voltammetry[2] to be −0.7 V vs. SCE, somewhat less oxidizing than reported earlier (16) from polarography. This level, which correlates with *CT of **1**, would be located on the diagram midway between the spectroscopically inaccessible singlet and triplet σ* states, for which a singlet–triplet splitting of 1 eV is assumed. The energy of the lowest triplet state of the diphenyliodonium cation is then 2.8 eV, consistent with its sensitizability by *m*-trifluoromethylacetophenone but not by chloranil.

The S_0 and S_1 surfaces cross at the top of the energy barrier for thermolysis of the cation; $\Delta H^* = 1.26$ eV for diphenyliodonium chloride in DMF (14). Using this experimental value in the Marcus equation, with $\Delta G^* \leq \Delta H^*$, as demonstrated by Beringer *et al.* (14), we estimate that the heterolysis (see below) of the diphenyliodonium cation is endergonic by ≤0.6 eV.

By analogy to other iodoaromatics (25), intersystem crossing in the free diphenyliodonium cation, from S_n ($n > 1$) to T_1, is rapid compared to the time scale of the experiment, so that

photolysis occurs in accord with the Bersohn mechanism (26):

[4] $S_0 \xrightarrow{h\nu} S_2 \longrightarrow [S_1\ ?] \longrightarrow T_1 \longrightarrow$ products

This interpretation has been disputed by Pappas *et al.* (3) as they did not observe triplet sensitized photolysis of diaryliodonium cations. Baumann and Timpe (5) have, however, observed a substantially higher quantum yield, ca. 0.06, for the benzophenone sensitized photolysis of diphenyliodonium hexafluorophosphate, than that reported by Pappas. The photolysis sensitized with *m*-trifluoromethylacetophenone is furthermore unequivocal, as electron transfer sensitization is not energetically feasible; it confirms that a triplet pathway can lead to the same photolysis products observed on direct irradiation. The photochemistry of the diphenyliodonium cation is, in this respect, different from that of the benzenediazonium cation, for which the triplet pathway has been excluded (27).

From spin conservation only C—I bond *homolysis* to phenyl radical (undetected) and iodobenzene radical cation can occur (scheme [5]) from the σ^* triplet state (7). This triplet state should be directly dissociative; in *p*-diiodobenzene the lowest triplet dissociates in a few hundred femtoseconds (28). As with

[5] $Ph_2I^+ \xrightarrow{h\nu} [PhI^+ + Ph^\cdot] \rightleftharpoons [PhI + Ph^+] \longrightarrow$ products

$PhI^+ + Ph^\cdot \longrightarrow$ products

diazonium salts (17) the heterolysis products correlate with the S_1 state and, accordingly, may also result along an "avoided crossing" pathway on thermolysis of the cation (Fig. 7), consistent with the observations that diaryliodonium salts thermally arylate nucleophiles (29) and that their hydrolysis proceeds by an S_N1-type mechanism (13, 30).

The transient absorption observed at 460 nm in the aqueous photolysis of diphenyliodonium hexafluorophosphate must correspond to an intermediate in iodobiphenyl formation, as the other observable products all form from the primary photoproducts by simple electron or hydrogen atom transfers (see above). The intermediate is more visible in water, compared to acetonitrile, owing to changes in solvation and (or) rate constants subsequent to the product-determining step.

The iodobiphenyl may, in principle, result from in-cage recombination of either the homolytic or heterolytic primary products, followed by deprotonation. The former possibility has been suggested by Pappas *et al.* (3). We accordingly assign

[6] $PhI^\ddagger + Ph^\cdot \xrightarrow{k_c}$  (**3**)

$PhI^\ddagger + Ph^\cdot$ (k_x)

$Ph—C_6H_4—I + H^+$ (k_h)

the 460-nm absorbance to intermediate **3**, as proposed by Pappas (3). Since it is formed in ca. 500 ps, its origin in homolytic primary photoproducts is reasonable; phenyl cation would be expected to react with water on this time scale (18). Deprotonation of **3** accounts, in part, for the differences observed in quantum yields of iodobenzene and proton formation in diaryliodonium cation photolyses (1, 3). The solid line in Fig. 3 corresponds to a computer model of the mechanism of scheme [6] with $k_c = 4 \times 10^8\ s^{-1}$, $k_x = 6 \times 10^8\ s^{-1}$, and $k_h = 3 \times 10^7\ s^{-1}$; the lifetime of **3** in aqueous medium is thus ca. 30 ns, and the cage escape efficiency is ca. 0.6.

The diversion of iodobiphenyl to hydroxybiphenyl in the photolysis of the chloride salt is additional evidence for the participation of **3**, insofar as the capture of **3** by water readily explains the formation of the hydroxy product:

[7] **3** $\longrightarrow$  (**4**) $\longrightarrow H_2O + Ph—C_6H_4—I$ / $\longrightarrow HI + Ph—C_6H_4—OH$

Observation of the hydroxy product from the readily soluble chloride salt, but not from the sparingly soluble hexafluorophosphate salt, suggests significant differences in solvation not only of the two salts, but of the intermediates in their photolyses, as well. The significant yield of biphenyl from the direct photolyses of the hexafluorophosphate salt suggests that it is present in either solvent in aggregated form.

The chloride ion concentration independence of the low yield of chlorobenzene in the photolysis of the chloride salt indicates that chloride ion does not diffusionally capture phenyl cation. Thus, if phenyl cation were formed by the process of eq. [4], it would not live as long as ca. 5 ns, the half-life expected for its diffusion controlled scavenging by 0.02 *M* chloride ion, let alone the 2 μs claimed by Klemm *et al.* (2). The inference is consistent with the observations of Scaiano and Kim-Thuan (19).

The transient absorption spectra obtained in the photolysis of diphenyliodonium iodide (Figs. 4*a* and *b*) provide evidence for two intermediates but do not provide clear evidence for their assignment. Since the decay time of the first does not correspond to the rise time of the second, it is not certain that they obtain sequentially. The involvement of a CT excited state under the conditions of irradiation is established both by analogy to the photolysis of the sulfonium iodide (9) and from the spectroscopic observations, above; i.e., the CT state is populated directly on irradiation. The initial 560-nm transient may thus be this CT state of the iodonium–iodide complex, with which the decay lifetime of ca. 200 ps is consistent. However, the transient may also arise from an adventitious impurity or along a minor photolysis pathway, not detected by the chemical analysis.

The following considerations bear on the identity of the species absorbing at 430 and >670 nm. The exclusive reaction product, iodobenzene, can result by two routes: (*a*) that of eq. [2], in which **2** decomposes to iodobenzene and phenyl radical (15), which then combines with iodine atom; and (*b*) that corresponding to heterolysis of the iodonium cation, to yield phenyl cation, which is captured in-cage by the iodide ion. The lifetime of this second transient (>10 ns) is, however, too long for either phenyl cation (18) or **2**.[3] *We therefore exclude the mechanism of eq. [2].* The diazonium salt experiment, on the other hand, demonstrates that *if formed in intimate association with iodide ion*, the phenyl cation can react to yield iodobenzene on the sub-ns time scale, without, however, producing any light absorbing transients in the process.

Intermediacy of the phenyl cation (13) thus remains consistent with all the experimental results, even though, on spectral (2) as well as kinetic grounds, it cannot be the observed

[3]We have recently generated **2** independently by electron-transfer sensitized photolysis of a diphenyliodonium salt, and shown that the upper limit to its lifetime in solution, under our conditions, is ca. 200 ps. A manuscript describing this work is in preparation for submission to this journal.

intermediate, itself. It correlates with the S_1 excited state of the iodonium cation, above. The iodonium–iodide charge transfer complexation mixes this directly inaccessible S_1 state with the ground S_0 state, so that the crossing of the potential surfaces of these states will be avoided (Fig. 7). (Since the activation energy for thermolysis of the iodonium cation is lowered by 0.15 eV on pairing with iodide ion (13), the splitting between the surfaces at the crossing must be 0.3 eV.) The dissociation products from the charge transfer excited state, **2** and iodine atom, would be formed endergonically, by $q[E_{ox}(I^-) - E_{red}(Ph_2I^+)]$, 0.98 eV, relative to the ground state, more endergonic than the products of heterolysis of **1**. The potential surfaces for dissociation of the CT and of the S_1 states must therefore cross, as shown in Fig. 7.

We hypothesize that the charge transfer excited state undergoes internal conversion to S_1 *at its conformational potential energy minimum*, i.e., at the crossing point with S_0. Thence it decays to S_0 on the potential energy surface for heterolytic dissociation of the cation. These considerations allow us to write the mechanism of scheme [8], which incorporates both the excitation of the CT state of **1** and the intermediacy of phenyl cation. There is precedent for decay of a CT excited state to a donor (or acceptor) localized excited state; for example, the CT excited state of the anthracene–TCNE complex decays to a triplet anthracene containing complex, which then dissociates to liberate triplet excited anthracene (32). Within this scheme we

$$Ph_2I^+\ I^- \xrightarrow{h\nu} CT^*\ [Ph_2I^+\ I^-] \longrightarrow [^1(Ph_2^+)^*\ I^-] \longrightarrow PhI + [Ph^+\ I^-] \longrightarrow PhI \quad [8]$$

are tempted to assign the 430 and >670 nm absorptions to the metastable S_1 state of the diphenyliodonium salt in its minimum potential energy conformation, although chemical intuition suggests that excited states trapped at such a "funnel" might also be shorter lived than the intermediate we have observed.

Experimental

Diphenyliodonium hexafluorophosphate (33), mp 136°C, was purified by recrystallization from isopropyl alcohol. Diphenyliodonium chloride, mp 233–235°C, was obtained from Aldrich Chemical Co., U.S.A. The *m*-trifluoromethylacetophone was also obtained from Aldrich and used without further purification when glc analysis showed it to be 99.4% pure. Glass distilled, deionized water and spectral quality acetonitrile were used to prepare solutions.

Laser flash photolyses were carried out in closed 2-mm quartz cuvettes. The frequency tripled or quadrupled Nd-YAG laser system delivered ca. 2 mJ per pulse to a 2-mm diameter spot of the sample cuvette; pulse width was typically of the order of 30 ps (FWHM). The optical arrangement for these photolyses and the data collection and processing procedures were as previously described (24). The design of the experiment allows detection of transients absorbing in the region 425–675 nm. Except as noted above, photolyses were conducted on samples in equilibrium with the ambient atmosphere; the reaction mixture for the photolysis sensitized by *m*-trifluoromethylacetophenone was, for example, purged of dissolved oxygen by passage of dry argon for 10 min.

Photolyses for product analysis were carried out on 3-mL samples, 0.001 *M* in the iodonium salt; the solutions in 13-mm quartz test tubes were irradiated by a 450-watt medium pressure mercury arc lamp, usually for 1 h with appropriate filters as necessary, in a "merry-go-round" apparatus. Shorter reaction times, as required for ca. 10% conversion, were used for quantum yield determinations. The products were separated by programmed temperature glc, identified by comparison with authentic samples, and confirmed by high resolution mass spectrometry. Product distributions were corrected for the relative sensitivity of the flame ionization detector to the various substances, as calculated from the signals obtained for known concentrations thereof, relative to dodecane as an internal standard.

In the preparative scale photolyses in water, the aqueous reaction mixtures were extracted with analytically pure (to glc) cyclohexane (1 mL) containing the dodecane internal standard (0.0010 *M*) and the extract chromatographed; control experiments indicated quantitative recovery of the major products, e.g., iodobenzene, by this technique. For quantum yield determination, the mercury source was calibrated by means of stilbene actinometry in toluene (31); whole sample irradiances of 5×10^{15} photons s^{-1} at 313 nm were typical.

Acknowledgments

We thank Ms. Judy Allbutt, 3M Corporate Research Laboratories, and Mr. Reza Danesh, Concordia University, for their expert technical assistance. This work was supported in part by 3M Canada, Ltd., and in part by a grant from the Natural Sciences and Engineering Research Council of Canada. Dr. Bradford B. Wright, 3M Corporate Research, provided the purified sample of benzenediazonium tetrafluoroborate. We also acknowledge helpful discussion with Dr. Ranjana C. Patel, Minnesota 3M Research, Ltd., Harlow, U.K., and with Dr. Alfred Marchetti, Research Laboratories, Eastman Kodak Co., Rochester, NY, U.S.A. The high resolution mass spectrometric analyses were carried out by Dr. Joseph Schroepfer of the 3M Corporate Research Laboratories.

Bis(dimethoxymethyl) peroxide and bis(1,1-dimethoxyethyl) peroxide[1]

KARL R. KOPECKY AND JOSÉ MOLINA[2]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received January 20, 1987

KARL R. KOPECKY and JOSÉ MOLINA. Can. J. Chem. **65**, 2350 (1987).

The title compounds **1** and **2**, the first examples of peroxides polysubstituted at the α and α′ positions by alkoxy groups, are formed by benzophenone sensitized photooxygenation of trimethoxymethane and 1,1,1-trimethoxyethane, respectively. No peroxide was formed from tetramethoxymethane. Allowing 98% hydrogen peroxide and trimethoxymethane to stand results in an 80% yield of **1**, so that **1** and **2** are probably formed by such a disproportionation reaction during photooxygenation. Compound **1** is converted quantitatively to methanol, methyl formate, and dimethyl carbonate in pyridine solution at 60°C. In acidic methanol both **1** and **2** undergo solvolysis rapidly with exclusive cleavage of the carbon – peroxy oxygen bond. Signals for the ether and peroxy oxygens of **1** appear at 34 and 263 ppm and those of **2** appear at 40 and 264 ppm in the ^{17}O nuclear magnetic resonance spectrum. Luminescence results when **1** and **2** are heated to 150°C.

KARL R. KOPECKY et JOSÉ MOLINA. Can. J. Chem. **65**, 2350 (1987).

Les composés **1** et **2** mentionnés dans le titre, qui sont les premiers exemples de peroxydes polysubstitués par des groupements alcoolates dans les positions α et α′, se forment respectivement par la photooxygénation, sensibilisée par la benzophénone, du triméthoxyméthane et du triméthoxy-1,1,1 éthane. Il ne se forme pas de peroxyde à partir du tétraméthoxyméthane. Lorsqu'on place du peroxyde d'hydrogène à 98% en présence de triméthoxyméthane, le composé **1** se forme avec un rendement de 80%; on en déduit que les composés **1** et **2** se forment probablement par une réaction de disproportionation qui accompagne la photooxygénation. En solution dans la pyridine, à 60°C, le composé **1** se transforme quantitativement en méthanol, en formate de méthyle et en carbonate de diméthyle. Dans le méthanol, en milieu acide, les composés **1** ainsi que **2** subissent une solvolyse rapide qui est uniquement accompagnée d'un clivage de la liaison carbone – oxygène du peroxyde. Dans le spectre en résonance magnétique nucléaire du ^{17}O, les signaux des oxygènes de l'éther et du peroxyde du composé **1** apparaissent respectivement à 34 et 263 ppm alors que ceux du composé **2** apparaissent respectivement à 40 et 264 ppm. Il se produit de la luminescence lorsqu'on chauffe les composés **1** ou **2** à 150°C.

[Traduit par la revue]

Introduction

The present study grew out of a desire to learn about the properties of trimethoxymethyl hydroperoxide and bis(trimethoxymethyl) peroxide in connection with another problem. A possible route to these compounds might be the benzophenone-sensitized photooxygenation of trimethoxymethane. Cyclic acetal derivatives of some aldehydes have been oxidized to hydroperoxides and peroxides with oxygen (1) but trimethoxymethane does not appear to have been converted to such products, although the central C—H bond ought to be relatively reactive with a bond dissociation energy (BDE) of about 89 kcal/mol. This value is estimated as follows. Replacement of an alkyl group by a methoxy group on a hydrocarbon lowers the C—H BDE by an amount that decreases with decreasing C—H BDE of the corresponding hydrocarbon (2). The BDE of the central C—H bond in isobutane is 93.3 kcal/mol (3) and substitution of a methyl group by a methoxy group should lower the BDE by about 3 kcal/mol (2). Replacement of the two remaining methyl groups by methoxy groups would lower the BDE more, but by decreasing amounts estimated to be 1 and 0.5 kcal/mol. Although attack on the central C—H hydrogen should be relatively easy, none of the desired peroxide or hydroperoxide was formed in the reaction.

Results and discussion

Isolation and characterization

The benzophenone-sensitized photooxidation of trimethoxymethane, neat or in benzene solution, results in formation of bis(dimethoxymethyl) peroxide **1**, which appears to be the first example of a peroxide polysubstituted in the α and α′ positions by alkoxy groups. This product was obtained nearly pure in 2% yield by simple vacuum distillation after removal of starting material and solvent from the reaction mixture. There is no evidence for the formation of either of the desired molecules trimethoxymethyl hydroperoxide or bis(trimethoxymethyl) peroxide. The structure of **1** is readily apparent. It gives an intense positive test with iodide ion and the ^1H nmr spectrum has only two signals at δ 3.50 (12H) and 5.50 (2H).

At 60°C in pyridine solution **1** is converted quantitatively to methanol, methyl formate, and dimethyl carbonate (Scheme 1), the result of an elimination reaction characteristic of peroxides that bear an α hydrogen atom (4, 5).

The ready formation of **1** suggested that replacement of a methoxy group by a peroxy group might be a general reaction with appropriate substrates under these conditions. No peroxidic material was formed from tetramethoxymethane but oxidation of the homologous molecule 1,1,1-trimethoxyethane did proceed in an analogous manner, Scheme 2. Bis(1,1-dimethoxyethyl) peroxide **2** was easily isolated in 1% yield but the crude product was contaminated with about 10% of another product, presumed to be the mixed peroxide 1,1-dimethoxyethyl 2,2,2-trimethoxyethyl peroxide **3**, from which it could not be separated by distillation. The ^1H nmr spectrum of the product mixture exhibited strong signals at δ 1.59 (6H) and 3.393 (12H) for **2** and weaker signals at δ 1.56 (3H), 3.27 (2H), and 3.385 (9H), which were assigned to **3**. The signal of the *gem* dimethoxy group of **3** is presumably under that of the methoxy groups of **2**. It was easy to destroy **3** preferentially by warming the product mixture with pyridine, thus allowing a pure sample of **2** to be isolated. No attempt was made to identify the products formed from **3**.

The ^{17}O nmr signals of the peroxy groups of both **1**, δ 263,

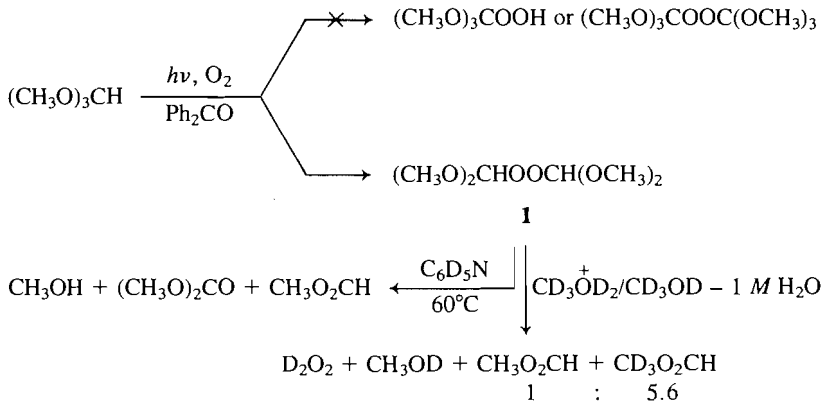
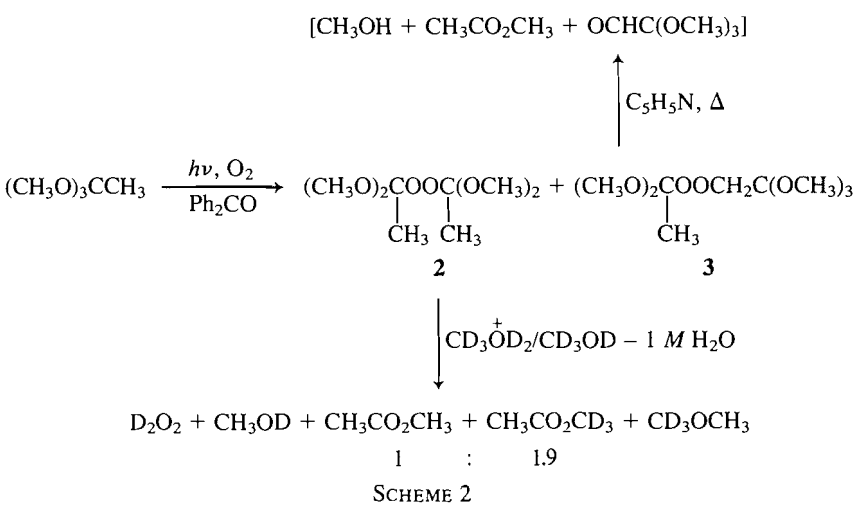


SCHEME 1



SCHEME 2

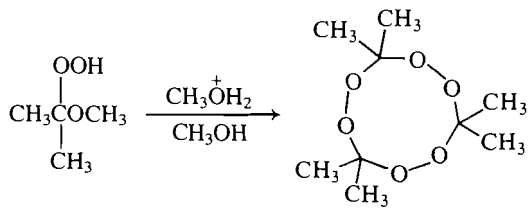
and **2**, δ 264, are near that of di-*tert*-butyl peroxide, δ 273. The ^{13}C nmr spectra of **1** and **2** are also consistent with their structures.

The O–O bond stretching frequency of **1** is 845 cm^{-1}, which is, as expected (6), appreciably higher than those of acyclic dialkyl peroxides without electronegative substituents.

Acid catalyzed solvolysis of 1 and 2

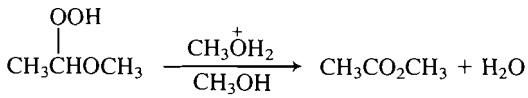
It was of interest to study the behaviour of **1** and **2** toward acid. In CD_3OD three reactions are possible, Scheme 3.

Protonation of the ether oxygen and subsequent reversible loss of methanol, path A, would lead to exchange of the methoxy groups in the starting material. Such a reaction appears to occur when (1-methoxy)methylethyl hydroperoxide is treated with acid in methanol, eq. [1] (7).



Reaction by path B, protonation of the peroxy group followed by ionization of the peroxy–carbon bond, would lead eventually to the trimethyl ortho esters (which would undergo methoxy group exchange).

Path C involves a rearrangement reaction, or loss of the α-proton when R = H, which would lead to different types of products from **1** and **2**. From **1** there would be formed dimethyl carbonate, methyl formate (both undeuterated), and methanol, while **2** would be converted to tetramethoxymethane, methyl acetate (undeuterated), and methanol. There are numerous examples of peroxide reactions following either path B or C (4). A recent relevant example of a reaction proceeding by path C is given by eq. [2] (7).



Solutions containing ~0.15 *M* of **1** or **2** in CD_3OD were treated with a trace of *p*-toluenesulfonic acid and the reactions monitored by ^1H nmr. The reactions proceeded at convenient rates at −30°C with **1** and at −70°C with **2**, having half-lives of ~30 min and ~10 min, respectively. Both **1** and **2** are consumed exclusively according to path B. Actually, the CD_3OD used was found to contain ~1 *M* of water and the proposed ortho ester products were immediately hydrolyzed. No signals attributable to these esters could be detected in the nmr spectra taken during the reaction. In a control experiment the methoxy groups of 1,1,1-trimethoxyethane were found to be completely exchanged within 5 min at −80°C in CD_3OD containing a trace of both *p*-toluenesulfonic acid and water. At this point ~15% of the ortho ester had been converted to methyl acetate. The $CH_3CO_2CH_3$:$CH_3CO_2CD_3$ ratio was 1:2.1. The ortho ester is thus much more reactive than is **2** and is also converted to a mixture of deuterated and undeuterated acetate. The observed final products were 2.0 moles of methyl formate from **1** and 2.0 moles of methyl acetate from **2**, together with the

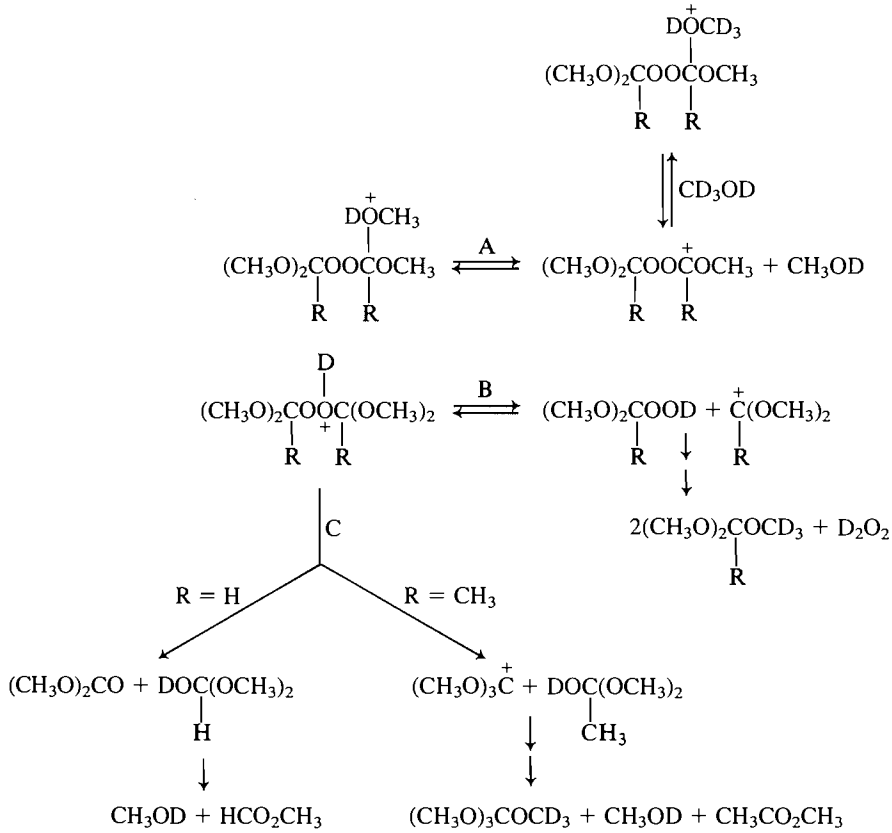
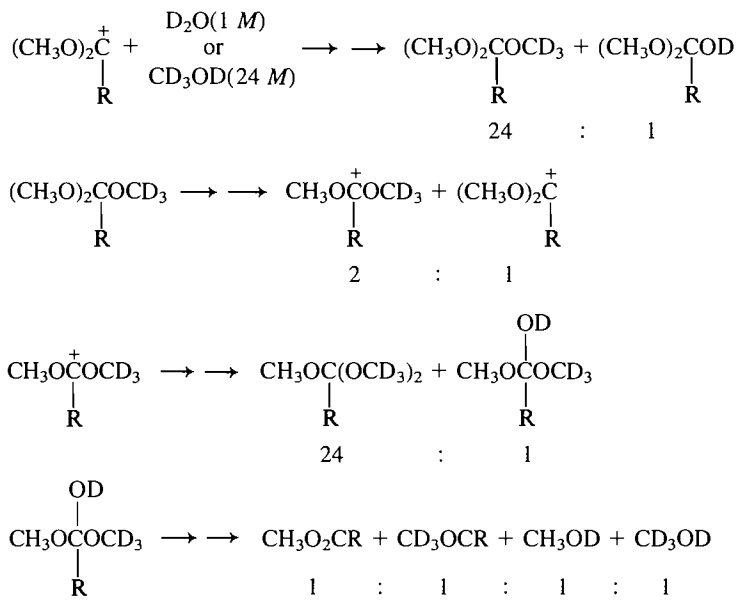


SCHEME 3



SCHEME 4

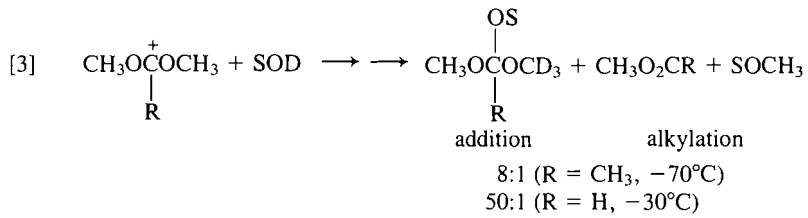
corresponding amounts of methanol. The deuterium content of the esters will be discussed later. The presence of hydrogen peroxide in the solutions was confirmed by an intense positive test with iodide ion.

There was no detectable methoxy interchange in either **1** or **2** during the reaction. The signal of CH_3OD grew in 15 and 7 Hz upfield from the signals of the methoxy groups of **1** and **2**, respectively, at the same rate as the signals of the C-H or C-CH_3 groups of the starting materials disappeared.

No signals for dimethyl carbonate, a primary product of **1** and the hydrolysis product of orthocarbonate from **2**, which would result from any reaction via path C, could be detected in the nmr spectra. A control experiment showed that there was no methoxy group interchange in dimethyl carbonate under the reaction conditions.

Signals attributed to the C-H and C-CH_3 groups of the hydroperoxides, which are the initial products of reaction via path B, appeared in the nmr spectra taken during the reaction at δ 5.23 and 1.50, respectively, slightly upfield from the corresponding signals of the starting materials. The hydro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.



peroxides would be expected to undergo solvolysis at rates similar to those of the starting materials. The concentration of the hydroperoxides built up to a maximum of about 10% of the initial concentration of the starting material.

The exclusive carbon – peroxy oxygen bond cleavage observed for **1** and **2** is a completely different type of reaction from those shown in eqs. [1] and [2] for hydroperoxides containing one α methoxy group. However, it may be that the products shown in eqs. [1] and [2] are not the initially formed products. Rapid solvolysis corresponding to that observed in the present study would be reversible in the absence of water, and the observed final products might be formed in slower side reactions.

The deuterated esters produced in the solvolysis of **1** and **2** should predominate by a ratio of about 8:1 under the reaction conditions (24 *M* CD_3OD and 1 *M* water) if there is no discrimination by the dimethoxy carbocations between CD_3OD and water to give tetrahedral intermediates. This ratio is obtained by an iterative calculation using the cascade of reactions, shown in part in Scheme 4, which the initial dimethoxy carbocation would undergo if only addition of solvent molecules occurred. Addition of D_2O would result in a product that would form undeuterated ester. Addition of CD_3OD would give partially exchanged ortho ester. This in turn would form both half-deuterated and undeuterated dimethoxy carbocation. The fraction of half-deuterated cation that would be captured by D_2O would result in the formation of equal amounts of deuterated and undeuterated esters, and so on. However, the observed ratios of deuterated:undeuterated esters, Schemes 1 and 2, are significantly different from 8:1 in such a way that would require water to be more nucleophilic than CD_3OD. There must be another reaction of the dimethoxy carbocations that occurs in competition with formation of a tetrahedral intermediate: alkylation of solvent. This would result in the formation of more undeuterated ester. The relative rates of addition and alkylation given in eq. [3] are required to reproduce the observed product distributions. These values were obtained from iterative calculations with the assumption that water and CD_3OD add to or are alkylated by the dimethoxy carbocation in a statistical manner, depending on their relative concentrations and without taking into account any possible isotope effects in the alkylation reactions or in the cascade of exchange reactions with CD_3OD. Alkylation of alcohol by dimethoxy carbocations has long been known and becomes more important as the stability of the carbocation increases (8).

Considering the reaction conditions under which **1** and **2** are formed, it is tempting to postulate that these compounds result by way of radical intermediates. However, this is unlikely as there are several difficulties with possible radical pathways. The pathways that would have to be considered if one tried to devise a radical route to **1** will be discussed. The conclusions reached should also apply to the formation of **2**.

Mechanism of formation of 1 and 2

The structures of some of the many radicals and compounds that might be formed from trimethoxymethane under the reaction conditions, along with the structures of some compounds needed to calculate the heats of formation of some radicals, are given below. The heats of formation, in kcal/mol at 298 K (1 atm; 1 atm = 101.3 kPa), are given under the structures. The number(s) below the heat of formation is the BDE of the relevant C—H or OH bond that is broken to derive a given radical. The values of the heats of formation and BDEs were calculated using known methods and approximations (9) where not already available (2, 3, 9, 10).

The ultimate product-forming step in a radical pathway would presumably be the coupling of two oxy radicals. These would have to couple in the solvent cage in which they were

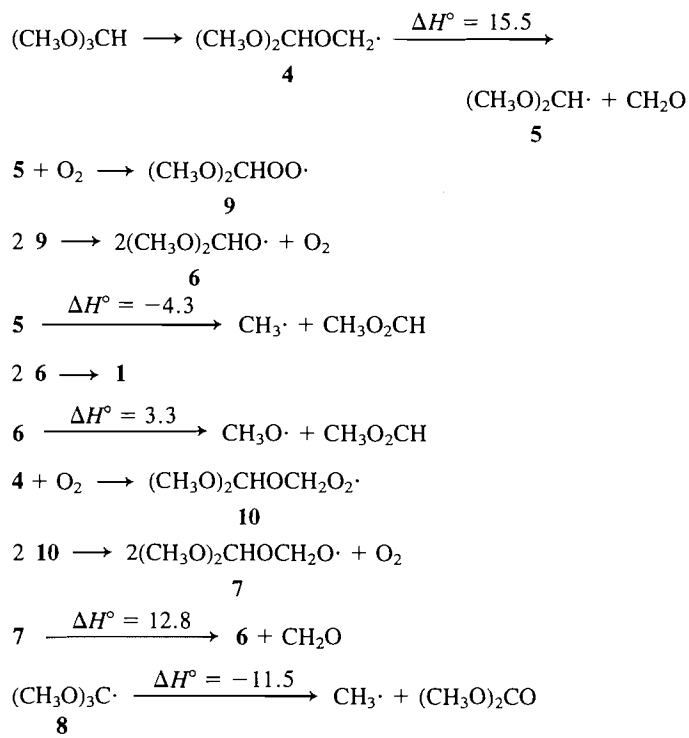


SCHEME 5[3]

formed. There would be two different possible routes to the caged oxy radicals **6**, Scheme 5. Each includes a rather endothermic step, which could result in diversion of reactants from a route to **6**. The most direct route involves fragmentation of the initially formed radical **4** to the radical **5** and formaldehyde, followed by reaction of **5** with oxygen to give the peroxy radical **9**. The oxy radical **6** would then be formed from **9**. The formation of oxy radicals from peroxy radicals with α hydrogen atoms was long thought to be impossible but there is growing evidence that this can occur (11). However, the fragmentation of **4** is endothermic by 15.5 kcal/mol and **4** should be trapped efficiently by oxygen in an oxygen-saturated solution before fragmentation can occur. Even if fragmentation occurred, the resulting radical **5** can fragment by an exothermic pathway, 4.3 kcal/mol, and may be too short-lived to react with oxygen. The trapping of **4** by oxygen could provide an alternate route to the oxy radical **6**. The product of **4** and oxygen is the peroxy radical **10**. In this route to **6**, conversion of **10** to the oxy radical **7** would be followed by fragmentation to formaldehyde and **6**. However, this fragmentation is also quite endothermic, 12.8 kcal/mol, and **7** should be long-lived enough so that no **6** would be formed in the original solvent cage. Any **6** formed without a caged radical partner would never undergo coupling with another radical **6** (12). Hydrogen abstraction and fragmentation reactions would intervene. In addition to the difficulty in finding a plausible route to a caged radical pair of **6**, there is an even more fundamental problem with a radical pathway to **1** (but not necessarily to **2**). Oxy radicals with α hydrogen atoms do not couple (11, 13). There is one apparent exception (14), which has been widely cited, but an alternative explanation for the observations will be proposed below. Clearly a different type of reaction must occur.

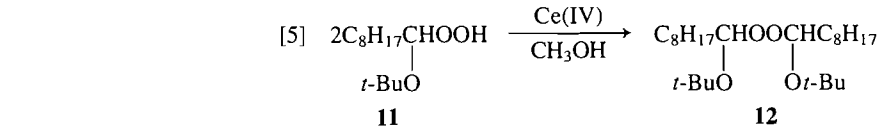
[3]Many more reactions than shown undoubtedly occur. Only those that might contribute to the formation or lack of formation of **1** are given here.

A simple route to **1** that avoids the above difficulties is the exchange reaction, eq. [4], between trimethoxymethane and

[4] $2(CH_3O)_3CH + H_2O_2 \rightarrow \mathbf{1} + 2CH_3OH$

hydrogen peroxide. It is easy to envisage the formation of hydrogen peroxide under the reaction conditions. The reaction of eq. [4] would be an ionic reaction catalyzed by adventitious acid. Indeed, an 80% yield of **1** could be isolated after a mixture of trimethoxymethane and 98% hydrogen peroxide was allowed to stand overnight. The analogous reaction to form **2** was not carried out, but it is likely that **2** was formed in the same way in the photosensitized oxidation reaction.

The apparent exception (14) to the conclusion that oxy (and peroxy) radicals bearing α hydrogen atoms do not form peroxides results from a study of the reaction between 1-*tert*-butoxy-1-hydroperoxynonane **11** and ceric ion, eq. [5]. A 50%



yield of the peroxide **12** was isolated. It was suggested that **12** was formed by coupling of oxy radicals generated from **11** by ceric ion, but an acid-catalyzed disproportionation reaction to give **12** seems to be a quite plausible alternative.

Abstraction of the methine hydrogen atom from trimethoxymethane should occur readily under the photosensitized oxidation conditions and would form the trimethoxymethyl radical **8**. This can undergo a fragmentation reaction to methyl radical and dimethyl carbonate that is exothermic by 11.5 kcal/mol. Thus **8** is probably too short-lived to react with oxygen, and the peroxide or hydroperoxide initially sought is not formed.

Thermolysis of 1 and 2

The concerted decompositions of **1** and **2** to dimethyl carbonate and hydrogen or ethane are calculated to be exothermic by over 70 kcal/mol. This is about as exothermic as is the decomposition of tetramethyl-1,2-dioxetane (15). These compounds might thus have enhanced rates of thermolysis (16) and be luminescent. Preliminary experiments have given ambiguous results. Solutions of **1** and **2** both emit clearly visible long-lived luminescence at 150°C, but not at 105°C, in the presence of a mixture of 9,10-dibromoanthracene and 9,10-bis(phenylethynyl)anthracene. Heating solutions of **1** and **2** in C_6D_6 at 77°C in neutralized glassware does result in the formation of dimethyl carbonate. However, there are ionic routes to this compound, and corresponding amounts of hydrogen or ethane were not formed (small amounts, <5%, would not have been detected). Methanol and the esters methyl formate or methyl acetate were the major products and the corresponding ortho esters were also formed. Obviously, acid-catalyzed reactions are predominating and conditions have not yet been found to suppress them with these very sensitive materials. In one run, 20% of **1** was left after 160 h at 77°C, which corresponds to a half-life of about 80 h. This compares with a calculated half-life of about 70 h at this temperature for bis(diphenylmethyl) peroxide, which undergoes concerted decomposition exclusively (16). In fact, the half-life of **1** is likely much greater than 80 h because the majority of **1** was probably consumed by acid-catalyzed reactions. The rate of thermolysis of **1** is not nearly as much enhanced as is that of bis(diphenylmethyl) peroxide.

Experimental

Boiling points are uncorrected. The nmr spectra were measured on Brucker WH 200 (^{1}H and ^{13}C) and WH 400 spectrometers (^{17}O), the latter operating at 54.244 MHz; sweepwidth 50,000 Hz; pulse width 350.0 μs (90°); acquisition time 0.041 s; data points 4,000; scans 70,000 (**1**) and 108,000 (**2**). The ^{17}O chemical shifts are reported relative to internal acetone. Raman spectra were recorded on a Beckman Model 700 laser Raman spectrometer using the 488.0-nm exciting line from a Coherent Radiation Model 52 argon laser using neat **1** in a capillary tube. Infrared spectra were recorded on a Perkin–Elmer Model 457 spectrometer.

Bis(dimethoxymethyl) peroxide 1

A. A solution of 150 g trimethoxymethane and 1.5 g benzophenone was irradiated for 20 h with a 200-watt medium pressure Hanovia lamp, which was in an immersion well, at 10°C through a Pyrex filter in a reaction vessel fitted with a Dry Ice condenser. A stream of oxygen was passed continuously through the solution. The resulting solution was concentrated under 20 Torr (1 Torr = 133.3 Pa) and the product was distilled from the residual oil through a short Vigreux column to give 2.5 g (2%) of a colorless oil; bp 66–69°C/4 Torr; ir (film): 3004, 2956, 2854, 1465, 1452, 1330, 1202, 1170, 1105, 1002, 950, 920 cm^{-1}; Raman (neat) (parallel polarization): 2970 (s), 2870 (s); 1465 (s), 1005 (m), 920 (m), 845 (m) cm^{-1}; (perpendicular polarization): 2970 (vw), 2870 (vw), 1465 (s), 1005 (w), 920 (w), 900 (m), 845 (w) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 3.50 (s, 12H) and 5.50 (s, 2H); ^{13}C nmr ($CDCl_3$) δ: 52.95 and 117.10; ^{17}O nmr (CH_2Cl_2) δ: 34 and 263. *Anal.* calcd. for $C_6H_{14}O_6$: C 39.56, H 7.75; found: C 39.72, H 7.70.

B. A solution of 25 mL trimethoxymethane and 1 mL of 98% hydrogen peroxide was allowed to stand at 22°C for 9 h and then concentrated. Distillation of the residual oil gave 4.1 g (80%) of **1** whose ^{1}H nmr spectrum was identical with that of the product obtained in A.

Bis(1,1-dimethoxyethyl) peroxide 2

Using the procedure for the preparation of **1** by method A, there was isolated from 200 mL of 1,1,1-trimethoxyethane 1.7 g (1%) of **2** as a colorless oil, bp 54–56°C/0.3 Torr. This material was contaminated with another compound, as described in the text. Redistillation gave a product with an identical nmr spectrum. It was taken up in 5 mL pyridine and warmed to 60°C for several min. Distillation gave a product with no extraneous signals in the ^{1}H nmr spectrum, ^{1}H nmr ($CDCl_3$) δ: 1.59 (s, 6H) and 3.39 (s, 12H); ^{13}C nmr ($CDCl_3$) δ: 19.16, 50.56, and 117.83; ^{17}O nmr (CH_2Cl_2) δ: 40 and 264. *Anal.* calcd. for $C_8H_{18}O_6$: C 45.70, H 8.63; found: C 45.02, H 8.41. Redistillation did not improve the analysis. An intense iodine color developed immediately upon addition of **2** to KI in acetic acid.

Methanolysis of 1 and 2

Solutions ~0.15 *M* of peroxide in CD_3OD in nmr tubes were cooled to −80°C and a tiny crystal of *p*-toluenesulfonic acid was added. The solutions were slowly warmed until reaction was observed to occur at a rate that could be conveniently monitored by ^{1}H nmr. It was found (^{1}H nmr) that the CD_3OD contained ~1 *M* water. The results have been described in the "Results and discussion" section.

ZBIGNIEW CZARNOCKI, DAVID B. MACLEAN, and WALTER A. SZAREK. Can. J. Chem. **65**, 2356 (1987).

A new and improved procedure for the preparation of (*R*)-2-alkoxycarbonyl-1-formyl-1,2,3,4-tetrahydro-6,7-dimethoxyisoquinolines has been developed beginning from D-(−)-tartaric acid. The utility of these aldehydes in the asymmetric synthesis of isoquinoline alkaloids of high enantiomeric purity has been extended to the synthesis of phenylethylisoquinolines, which have been further transformed in straightforward steps into the homoprotoberberine and homoaporphine ring systems. In this manner, (*S*)-homolaudanosine, (*S*)-5′-methoxyhomolaudanosine, (*S*)-2,3,9,10,11-pentamethoxyhomoprotoberberine, and (*S*)-*O*-methylkreysigine have been synthesized. The conversion of (*S*)-laudanosine to (*S*)-glaucine, an aporphine alkaloid, has also been realized.

ZBIGNIEW CZARNOCKI, DAVID B. MACLEAN et WALTER A. SZAREK. Can. J. Chem. **65**, 2356 (1987).

Utilisant l'acide D-(−)-tartrique comme produit de départ, on a développé une nouvelle méthode améliorée pour la préparation des alkoxycarbonyl-2(*R*) formyl-1 tétrahydro-1,2,3,4 diméthoxy-6,7 isoquinoléines. L'utilité de ces aldéhydes dans les synthèses asymétriques de haute pureté énantiomérique des alcaloïdes de l'isoquinoléine a déjà été démontrée et on l'a étendue aux synthèses des phényléthylisoquinoléines qui ont été transformées par la suite, par des étapes ne créant pas d'ambiguités, en systèmes cycliques homoprotoberbérine et homoaporphine. De cette façon, on a synthétisé l'homolaudanosine-(*S*), la méthoxy-5′ homolaudanosine-(*S*), la pentaméthoxy-2,3,9,10,11 homoprotoberbérine-(*S*) et la *O*-méthylkreysigine-(*S*). On a aussi réalisé la transformation de la laudanosine-(*S*) en glaucine-(*S*), un alcaloïde aporphine.

[Traduit par la revue]

The asymmetric synthesis of several classes of isoquinoline alkaloids from (*R*)- and (*S*)-2-ethoxycarbonyl-1-formyl-1,2,3,4-tetrahydro-6,7-dimethoxyisoquinolines, (*R*)-**1** and (*S*)-**1**, has been reported by us in several publications (1*a*–*c*). These publications include a review of previous approaches to the asymmetric synthesis of isoquinoline alkaloids; in the interim, Noyori *et al.* (2) have described a new method, and Meyers and Bailey (3) have extended the chiral amidine approach to the synthesis of morphinans. Two methods were used by us to generate the enantiomeric aldehydes. The first was based upon the induction of asymmetry at C-1 of the tetrahydroisoquinoline system through a Pictet–Spengler reaction of dopamine hydrochloride with (*R*)-glyceraldehyde (1*a*,*b*) followed by subsequent transformation of the condensation product. In the second method, optically pure (*R*)- and (*S*)-calycotomine (see **2**) were prepared by resolution and converted to *N*-ethoxycarbonyl derivatives, which were then oxidized to the aldehydes (1*c*). In this article we report a third and improved procedure for the formation of the (*R*)-aldehyde, which is based upon the use of D-(−)-tartaric acid as a means of inducing asymmetry at C-1 of the isoquinoline system. The enantiomeric aldehyde would be equally accessible from L-(+)-tartaric acid. We also show that aldehydes (*R*)-**1** and the 2-methoxycarbonyl analogue (*R*)-**5** may be used as starting materials for the asymmetric synthesis of phenylethylisoquinolines and report the transformation of the latter into the homoprotoberberine (4) and the homoaporphine (4) ring systems. The conversion of the previously prepared (1*b*) (*S*)-laudanosine (**3**) into (*S*)-glaucine (**4**) (4) has also been achieved.

The new and improved procedure for the preparation of (*R*)-**1** and its *N*-methoxycarbonyl analogue (*R*)-**5** is partially outlined in Scheme 1. The starting material, methyl [(2*S*,3*R*)-dihydroxy-3-(6′,7′-dimethoxy-1′,2′,3′,4′-tetrahydroisoquinolin-1′ (*R*)-yl)] propanoate hydrochloride (**6**), was prepared by the method employed by Dörnyei and Szántay (5) for the preparation of the enantiomer. Treatment of **6** with an excess of ethyl chloroformate or an excess of methyl chloroformate provided the *N*,*O*-acylated compounds, **7** and **8**, respectively. The *O*-acyl groups were selectively removed from **7** and **8** by methanolysis affording the *N*-alkoxycarbonyldihydroxy compounds **9** and **10**, which, on periodate oxidation, yielded the aldehydes **1** and **5**, respectively. Both aldehydes are prone to racemization and should be used immediately in subsequent steps.

This method of preparation of (*R*)-**1** has several advantages over the preparation from glyceraldehyde (1*b*). Fewer steps are involved in formation of the immediate precursor to the aldehyde and the reaction leading to generation of asymmetry at C-1 is for all practical purposes stereospecific; none of the diastereomer of **6** was detected, confirming the previous report (5). The periodate cleavage of the glycol unit of **9** and **10** proceeds in nearly quantitative yield, as does glycol cleavage in the first method. However, the tartaric acid route has the potential advantage that it may be used to prepare 1-formylisoquinolines, with substituents other than *O*-methyl on the aromatic ring; such preparations are not practicable beginning from glyceraldehyde. In comparison with the route from (±)-calycotomine (1*c*), the present method is superior in terms of yield (33% from tartaric acid vs. 22% from (±)-calycotomine for (*R*)-**1**) and roughly similar in terms of convenience.

The asymmetric synthesis of a variety of alkaloids belonging to the 1-benzylisoquinoline family beginning from (*R*)-**1** has been reported previously by us (1*b*,*c*). We demonstrate here

that (*R*)-**1** (or (*R*)-**5**) is an equally valuable starting material for the synthesis of several alkaloids and related compounds belonging to the 1-phenylethylisoquinoline group. Specifically, we have prepared (*S*)-homolaudanosine (**11**) (6, 7), (*S*)-5′-methoxyhomolaudanosine (**12**) (8, 9), (*S*)-2,3,9,10,11-pentamethoxyhomoprotoberberine (**13**) (10), and (*S*)-*O*-methylkreysigine (**14**) (8, 11).

The synthesis of (*S*)-homolaudanosine (**11**) is outlined in Scheme 2. The ylid **15** was prepared from 3,4-dimethoxybenzylphosphonium chloride by treatment with *n*-butyllithium in THF, first at −78°C and then at −20°C. The mixture was then cooled to −78°C and treated with a solution of **1** in THF. The product (**16**) was a *trans*-alkene as evidenced by ^{1}H nmr ($J_{7',8'} \approx 16$ Hz). Catalytic reduction of **16** afforded the carbamate **17**, which was reduced with lithium aluminium hydride (LAH) to (*S*)-homolaudanosine (**11**). The alkaloid was isolated as an oil in an overall chemical yield from (*R*)-**1** of 47% and in 78% ee (enantiomeric excess).

The synthesis of phenylethylisoquinoline **12**, homoprotoberberine **13**, and homoaporphine **14** is outlined in Scheme 3. Aldehyde **5** was used as starting material in these syntheses because the removal of the alkoxycarbonyl group is an essential step in the synthesis of **13** and it was thought that the methyl carbamate might be converted more readily into a secondary amine than the ethyl carbamate. Accordingly, aldehyde (*R*)-**5** was treated with 3,4,5-trimethoxybenzyltriphenylphosphonium ylid **18** under conditions similar to those used for the conversion of **1** to **16**. The product (**19**) of this reaction, also a *trans*-alkene ($J_{7',8'} \approx 15$ Hz), was reduced catalytically to the carbamate **20**. The conversion of **20** to the secondary amine proved to be difficult. Alkaline hydrolysis of the carbamate function of **20** proceeded slowly and was accompanied by racemization. Treatment with trimethylsilyl chloride and sodium iodide in refluxing acetonitrile yielded the secondary amine but there was extensive racemization and the reaction was therefore of little value in the context of this research. However, when **20** was treated with an excess of methyllithium in THF at room temperature, the reaction proceeded in acceptable chemical yield and without loss of optical purity. The conversion of **21** into homoprotoberberine **13** was accomplished by treatment of the hydrobromide of **21** with formaldehyde using a literature procedure (10). The spectroscopic properties of **13** were the same as those already reported (10) and the optical purity was 81.9% based on published data.

The synthesis of (*S*)-*O*-methylkreysigine (**14**) (11) was achieved by oxidative cyclization of **12** using the procedure of Taylor *et al.* (8). Compound **12**, prepared by reduction of **20** with LAH, was treated with thallium(III) trifluoroacetate. *O*-Methylkreysigine was isolated as an oil in 27% chemical yield based on **12** and in 84% ee. The spectroscopic properties of **12** and **14** were in accord with those reported (8, 11).

Finally, the procedure of Taylor *et al.* (8) was applied to the synthesis of (*S*)-glaucine (**4**). To this end, (*S*)-laudanosine (**3**) in 82% ee, prepared in the manner previously described (1*b*), was treated with thallium(III) trifluoroacetate. Oxidative coupling occurred in the expected fashion affording (+)-

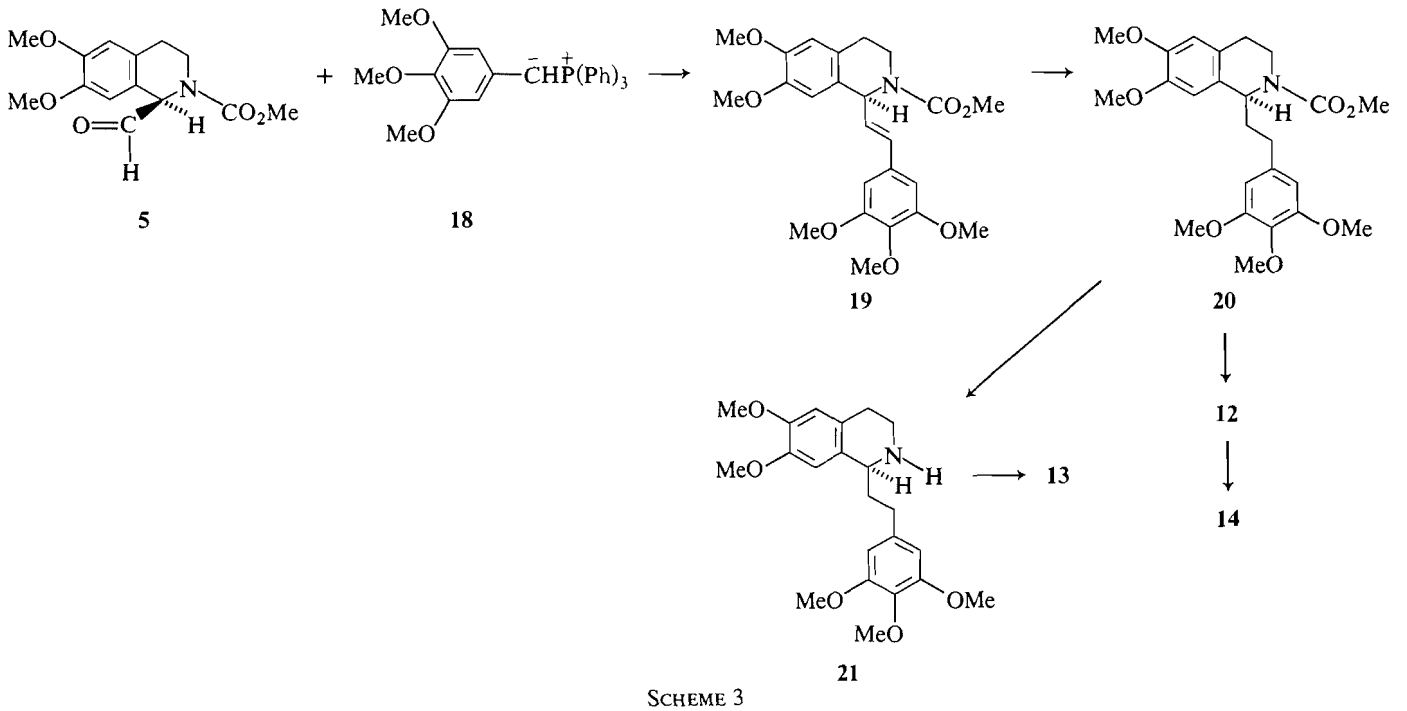

SCHEME 3

glaucine in 47% chemical yield and in 83% ee. Thus, the coupling reaction proceeded without racemization at the asymmetric centre.

The work described in this article is a further demonstration of the utility of 2-alkoxycarbonyl-1-formyl-1,2,3,4-tetrahydro-6,7-dimethoxyisoquinolines in the synthesis of a wide variety of isoquinoline alkaloids of high enantiomeric purity. Of the three routes developed by us for the preparation of the (*R*)-aldehydes, the one described in this article, namely that from D-(−)-tartaric acid, is the method of choice.

Experimental

The ^{1}H nmr spectra were recorded on a Bruker AM500 spectrometer at 500 MHz or a Varian EM390 spectrometer at 90 MHz; $CDCl_3$ was the solvent and, unless otherwise stated, tetramethylsilane (TMS) was used as the internal standard. Chemical shifts are reported in ppm (δ) downfield from the signal of TMS. The symbols, s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), and br (broadened), are used to report the multiplicity and shape of signals. EI mass spectra were recorded on a VG Micromass 7070F mass spectrometer at an ionizing voltage of 70 eV or on a VG Analytical ZAB-E mass spectrometer, and CI spectra were recorded using NH_3 at ~1 Torr (1 Torr = 133.3 Pa) as reagent gas; data are given as *m*/*z* (% relative intensity).

Melting points were determined using a Gallenkamp apparatus and are uncorrected. Optical rotations were measured using a Perkin–Elmer 247MC polarimeter in a 1-mL microcell that is 1 dm in length. The values for ee were calculated as described by Andersen *et al.* (12). Flash chromatography was performed on Kieselgel 60 (230–400 mesh).

The homogeneity of the products was established on the basis of chromatographic and spectroscopic (^{1}H nmr and mass spectral) examination.

*Methyl [(2S,3R)-dihydroxy-3-(6′,7′-dimethoxy-1′,2′,3′,4′-tetrahydroisoquinolin-1′(R)-yl)]propanoate hydrochloride (**6**)*

The compound was prepared by the procedure of Dörnyei and Szántay (5) except that D-tartaric acid (2*S*,3*S*) was used in place of the enantiomer employed in the earlier study.[3] The hydrochloride was obtained as colorless crystals from methanol in 57% overall yield from D-tartaric acid; mp 184–186°C (lit. (5) mp 186–187°C for the enantiomer); $[\alpha]_D^{25}$ −82.2° (*c* 1.31, H_2O); ^{1}H nmr (500 MHz, DMSO-d_6) δ: 2.84 (1H, m, C-3′ H_{ax}), 2.99 (2H, m, C-4′ H's), 3.05 (2H, m, disappeared in D_2O, 2 × OH), 3.33 (2H, br s, disappeared in D_2O, NH_2), 3.54 (1H, m, C-3′ H_{eq}), 3.67 (3H, s, CO_2CH_3), 3.75 and

[3]The previous authors have inadvertently designated the acid employed by them as D-tartaric acid; however, their stereostructures clearly show that the L-isomer, (2*R*,3*R*), was used.

3.76 (3H each, s's, 2 × OCH_3), 3.98 (1H, d, J = 1.1 Hz, C-1′ H), 4.45–4.65 (2H, br m, C-2 H and C-3′ H, collapses to br s at 4.64 on addition of D_2O), 6.85 and 6.89 (1H each, s's, C-5′ and C-8′ H's).

Preparation of carbamate 7 by treatment of 6 with ethyl chloroformate

Ethyl chloroformate (12 mL) was added dropwise over a period of 30 min to a vigorously stirred solution of **6** (10.77 g) in pyridine (100 mL). The temperature was maintained in the range 5–10°C during the addition and the mixture was stirred an additional 45 min at 5°C. The pyridine was then removed under reduced pressure and the residue taken up in $CHCl_3$. The $CHCl_3$ solution was washed first with water, then with 2% HCl(aq), and again with water before drying over $MgSO_4$. Evaporation of the solvent yielded a residue that crystallized from CH_3OH–Et_2O. The product **7** (13.99 g, 86% based on **1**) melted at 159–161°C; $[\alpha]_D^{25}$ +112.8° (*c* 1.66, $CHCl_3$); ^1H nmr (90 MHz, $CDCl_3$) δ: 1.11, 1.23, 1.38 (3H each, t's, J = 7.1, 7.3 and 6.7 Hz, resp., 3 × CH_2CH_3), 2.73–2.95 (2H, m, C-4′ H's), 3.30–3.57 (2H, m, C-3′ H's), 3.78 (3H, s, CO_2CH_3), 3.87 (6H, s, 2 × OCH_3), 3.93–4.37 (6H, m, 3 × CH_2CH_3), 5.27–5.40 (3H, m, C-1′ H, C-3 H, and C-2 H), 6.65 and 6.83 (1H each, s's, C-5′ H and C-8′ H); ms (CI, NH_3) *m/z* (%): 528 (M + 1, 100), 264 (85), 192 (10). *Anal.* calcd. for $C_{24}H_{33}NO_{12}$: C 54.64, H 6.31, N 2.65; found: C 54.83, H 6.63, N 2.40.

Preparation of carbamate 8 by treatment of 6 with methyl chloroformate

Methyl chloroformate (17.8 mL) was added to a solution of **6** (14.4 g) in pyridine (150 mL) under conditions identical with those described for the preparation of **7**. The reaction mixture was processed similarly affording **8** (17.7 g, 88% from **1**) as white crystals from $CHCl_3$–MeOH–Et_2O; mp 178–180°C; $[\alpha]_D^{25}$ +114.8° (*c* 1.97, $CHCl_3$); ^1H nmr (90 MHz, $CDCl_3$) δ: 2.73–2.97 (2H, m, C-4′ H's), 3.26–3.50 (2H, m, C-3′ H's), 3.57 (3H, s, CO_2CH_3), 3.70, 3.85, 3.88, 3.89, 3.90 (3H each, 5s, 5 × OCH_3), 5.27–5.38 (3H, m, C-1′ H, C-2 H, C-3 H), 6.65 and 6.95 (1H each, s's, C-5′ and C-8′ H's); ms (CI, NH_3) *m/z* (%): 486 (M + 1, 50), 250 (100).

Methyl [(2S,3R)-dihydroxy-3-(N-ethoxycarbonyl-6′,7′-dimethoxy-1′,2′,3′,4′-tetrahydroisoquinolin-1′-(R)-yl)]propanoate (9): methanolysis of 7

A solution of **7** (1.095 g) and NaOMe (200 mg) in dry MeOH (100 mL) was stirred at room temperature under nitrogen for 4 h or until the reaction was complete. The reaction was monitored by tlc (solvent system, 5% MeOH in $CHCl_3$). The solution was neutralized with acetic acid and evaporated to dryness. The residue was treated with H_2O (50 mL) and $CHCl_3$ (50 mL), the $CHCl_3$ layer separated and washed with saturated $NaHCO_3$(aq). The $CHCl_3$ solution was dried over $MgSO_4$ and evaporated, and the residue was taken up in $CHCl_3$ and chromatographed on a column of silica gel. The nonpolar impurities were eluted with $CHCl_3$ and compound **9** with 5% MeOH in $CHCl_3$. The product (640 mg, 80.4%) was obtained as an unstable oil; $[\alpha]_D^{25}$ +29.3° (*c* 1.28, $CHCl_3$); ^1H nmr (90 MHz, $CDCl_3$) δ: 1.27 (3H, t, J = 7.5 Hz, CH_2CH_3), 2.83 (2H, apparent t, J = 6.4 Hz, C-4′ H's), 3.30–3.67 (2H, m, C-3′ H's), 3.20 (2H, m, disappeared in D_2O, 2 × OH), 3.75 (3H, s, CO_2CH_3), 3.85 (6H, s, 2 × OCH_3), 4.02 (1H, m, sharpens on addition of D_2O to a broad doublet, J = 9.0 Hz, C-3 H), 4.20 (2H, q, J = 7.5 Hz, CH_2CH_3), 4.38 (1H, m, sharpens on addition of D_2O to doublet, J = 1.5 Hz, C-2 H), 4.98 (1H, d, J = 9.0 Hz, C-1′ H), 6.66 and 6.97 (1H each, s's, C-5′ H and C-8′ H); ms (CI, NH_3) *m/z* (%): 384 (M + 1, 25), 338 (28), 294 (85), 264 (80), 236 (60), 192 (100), 176 (40).

Methyl [(2S,3R)-dihydroxy-3-(N-methoxycarbonyl-6′,7′-dimethoxy-1′,2′,3′,4′-tetrahydroisoquinolin-1′-(R)-yl)]propanoate (10): methanolysis of 8

A solution of **8** (1.148 g) and NaOMe (238 mg) in dry MeOH (100 mL) was treated under the same conditions as those described above for the methanolysis of **7**. Compound **10** was isolated as an unstable oil (609 mg, 69.8%); $[\alpha]_D^{25}$ +27.3° (*c* 1.63, $CHCl_3$); ^1H nmr (90 MHz, $CDCl_3$) δ: 2.83 (2H apparent t, J = 7.5 Hz, C-4′ H's), 3.40–3.61 (2H, m, C-3′ H's), 3.50 (2H, m, disappeared in D_2O, 2 × OH), 3.78 and 3.88 (6H each, s's, 4 × OCH_3), 4.05 (1H, m, on addition of D_2O becomes dd, J = 1.5 and 9.0 Hz, C-3 H), 4.43 (1H, d, J = 1.5 Hz, C-2 H), 5.12 (1H, d, J = 9.0 Hz, C-1′ H); 6.68 and 7.00 (1H each, s's, C-5′ and C-8′ H); ms (CI, NH_3) *m/z* (%): 370 (M + 1, 100), 250 (100).

(R)-2-Ethoxycarbonyl-1-formyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (1)

A solution of $NaIO_4$ (852 mg) in H_2O (30 mL) was added over a period of 5 min to a stirred solution of **9** (762 mg) in MeOH (100 mL) at 5°C. The resulting mixture was stirred at the same temperature for 1 h and then filtered to remove inorganic precipitates. The methanol was then evaporated, benzene (100 mL) was added to the residue, and the organic layer was washed three times with water (50 mL each) before drying over $MgSO_4$. Evaporation of the solvent yielded **1** as a colorless oil (554 mg, 95%), which was used immediately. The analytical properties of **1** were identical with those already described (*1b,c*).

(R)-2-Methoxycarbonyl-1-formyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (5)

Compound **5** was prepared from **10** using a procedure identical with that described for the conversion of **9** to **1**. Thus, **10** (2.435 g) in MeOH (220 mL) was treated with $NaIO_4$ (2.72 g) in H_2O (50 mL). The product **5** isolated in similar fashion to **1** was an oil (1.84 g, 90%), which rapidly racemizes and must be used immediately in subsequent steps; ^1H nmr (90 MHz, $CDCl_3$) δ: 2.76–2.87 (2H, m, C-4 H's), 3.23–3.57 (2H, m, C-3 H's), 3.82 (3H, s, CO_2CH_3), 3.90 and 3.93 (3H each, s's, 2 × OCH_3), 5.36 (1H, br s, C-1 H), 6.72 and 6.88 (1H each, s's, C-5 H and C-8 H), 9.60 (1H, s, CH=O); ms (CI, NH_3) *m/z* (%): 280 (M + 1, 100), 250 (14). *Mol. Wt.* calcd. for $C_{14}H_{17}NO_5$: 279.1107; found (hrms): 279.1111.

Preparation of homolaudanosine (11)

(a) Preparation of the Wittig reagent 15

3,4-Dimethoxybenzyltriphenylphosphonium chloride was prepared by heating on the steam bath for 1 h a mixture of 3,4-dimethoxybenzyl chloride (2.98 g) and triphenylphosphine (4.21 g). The crystalline product (6.33 g, 88%) obtained from EtOH melted at 235–237°C. A suspension of the salt (908 mg) in dry THF (50 mL) was treated under nitrogen at −78°C over a 5-min period with *n*-butyllithium (0.93 mL of 2.4 *M* *n*-BuLi in hexane). The orange-colored mixture was stirred for another 0.5 h at the same temperature and then slowly warmed to −20°C at which temperature it was maintained for another 0.5 h. The solution containing the ylid **15** was cooled to −78°C before proceeding to the next step.

(b) Preparation of 16 by treatment of 1 with the Wittig reagent 15

To the solution prepared in (*a*) above was added all at once a solution of freshly prepared **1** (590 mg) in THF (10 mL). The reaction mixture was stirred vigorously during the addition and for another 2 h at −78 to −60°C. The mixture was stored in a freezer overnight at −30°C before removing the solvent. The residue was thoroughly extracted with dry Et_2O (6 × 30 mL each), and the extract dried and evaporated. The residue was taken up in 5% EtOAc in C_6H_6 and chromatographed on a column of silica gel with the same solvent system. Compound **16** was isolated as a colorless oil (596 mg, 69%); $[\alpha]_D^{25}$ +135.5° (*c* 0.90, $CHCl_3$); ^1H nmr (90 MHz, $CDCl_3$) δ: 1.32 (3H, t, J = 7.5 Hz, CH_2CH_3), 2.66–2.93 (2H, m, C-4 H's), 3.10–3.50 (2H, m, C-3 H's), 3.85 (3H, s, OCH_3), 3.88 (3H, s, OCH_3), 3.92 (6H, s, 2 × OCH_3), 4.23 (2H, q, J = 7.5 Hz, CH_2CH_3), 5.73 (1H, d, J = 4.5 Hz, C-1 H), 6.06–6.51 (2H, m, $J \approx$ 16.0 Hz, C-7′ H and C-8′ H),[4] 6.72 (2H, apparent s, C-5 and C-8 H's), 6.86 (1H, br s, C-2′ H), 6.93 (2H, m, C-5′ and C-6′ H's); ms (CI, NH_3) *m/z* (%): 428 (M + 1, 60), 354 (15), 264 (100).

(c) Preparation of 17 by catalytic reduction of 16

Compound **16** (224 mg) prepared above was dissolved in EtOH (50 mL) and treated with H_2 over Adams' catalyst for 4 h at 1 atm (1 atm = 101.3 kPa). The catalyst was separated by filtration and the solvent evaporated, affording **17** as a colorless oil (218 mg, 97%);

[4]The C-8′ proton is coupled to the C-1 proton but the signal is poorly resolved even at 50°C presumably because of restricted rotation of the carbamate function.

*(d) Preparation of **11** by reduction of **17** with lithium aluminium hydride*

Compound **17** (417 mg), dissolved in THF (75 mL), was treated with LAH (400 mg). The mixture was then heated under reflux for 1.5 h, cooled, and the excess of hydride decomposed by addition of saturated NaCl(aq). Chloroform (30 mL) and $MgSO_4$ (ca. 2 g) were added and the mixture was heated under reflux for 15 min. The cooled mixture was filtered free of inorganic salts, the solids were washed twice with boiling $CHCl_3$, and the combined filtrate evaporated to dryness. The residue was taken up in $CHCl_3$, adsorbed on a column of silica gel, and eluted with 2% MeOH in $CHCl_3$. Homolaudanosine (**11**) was obtained as a colorless oil (254 mg, 70.1%); $[\alpha]_D^{25}$ +8.61° (*c* 0.85, EtOH) (lit. (6) $[\alpha]_D^{25}$ +11.0° (*c* 0.21, EtOH)]; ^1H nmr (500 MHz, $CDCl_3$) δ: 2.02 (2H, m, C-8′ H's), 2.45 (3H, s, NCH_3), 2.51 (1H, m, C-3 H_{ax}), 2.70 (4H, m, C-4 H's and C-7′ H's), 3.13 (1H, m, C-3 H_{eq}), 3.40 (1H, t, *J* = 5.4 Hz, C-1 H), 3.78, 3.79, 3.80, 3.82 (3H each, s's, 4 × OCH_3), 6.51 and 6.54 (1H each, s's, C-5 and C-8 H's), 6.69 (1H, d, *J* = 1.8 Hz, C-2′ H), 6.70 (1H, dd, *J* = 1.8 and 8.4 Hz, C-6′ H), 6.75 (1H, d, *J* = 8.4 Hz, C-5′ H) (lit. spectrum (6)); ms (CI, NH_3) *m/z* (%): 372 (M + 1, 100), 342 (7). *Mol. *Preparation of homoprotoberberine **13***

*(a) Preparation of the Wittig reagent **18***

3,4,5-Trimethoxybenzyltriphenylphosphonium chloride was prepared by heating on the steam bath for 1 h a mixture of triphenylphosphine (1.65 g) and 3,4,5-trimethoxybenzyl chloride (1.37 g). The product was recrystallized from EtOH, affording colorless crystals (2.53 g, 84%), mp 234–236°C. A suspension of the product chloride (1.42 g) in THF (200 mL) was treated under nitrogen at −78°C over a period of 5 min with *n*-butyllithium (1.38 mL of 2.4 *M* *n*-BuLi in hexane). The orange solution containing the ylid **18** was kept at this temperature for 0.5 h and then warmed to −20°C for another 0.5 h.

*(b) Preparation of **19** by treatment of **5** with the Wittig reagent **18***

The Wittig reagent prepared above was cooled to −78°C and treated all at once with a solution of freshly prepared **5** (820 mg) in THF (10 mL). The reaction mixture was processed in the same manner as that described above for the preparation of **16**, affording **19** as a colorless oil (865 mg, 66%); $[\alpha]_D^{25}$ +129.4° (*c* 0.935, $CHCl_3$); ^1H nmr (90 MHz, $CDCl_3$) δ: 2.68–2.93 (2H, m, C-4 H's), 3.10–3.48 (2H, m, C-3 H's), 3.80 (3H, s, CO_2Me), 3.88 (15H, br s, 5 × OCH_3), 5.77 (1H, d, *J* ≈ 1.0 Hz, C-1 H), 5.97–6.40 (2H, AB m, *J* ≈ 15 Hz, C-7′ and C-8′ H's), 6.65 and 6.73 (2H each, apparent s's, C-2′ H, C-6′ H, C-5 H, and C-8 H); ms (CI, NH_3) *m/z* (%): 444 (M + 1, 45), 250 (100). *Mol. Wt.* calcd. for $C_{24}H_{29}NO_7$: 443.1944; found (hrms): 443.1955.

*(c) Preparation of **20** by catalytic reduction of **19***

Compound **19** (758 mg) was treated with H_2 over Adams' catalyst (140 mg) in methanol in the manner described for the conversion of **16** to **17**. The product **20** was obtained as a colorless oil (746 mg, 98%); $[\alpha]_D^{25}$ +66.2° (*c* 1.12, $CHCl_3$); ^1H nmr (90 MHz, $CDCl_3$) δ: 1.97–2.23 (2H, m, C-8′ H's), 2.58–2.88 (4H, m, C-4 H's and C-7′ H's), 3.05–3.47 (2H, m, C-3 H's), 3.78 (3H, s, CO_2CH_3), 3.88 (15H, apparent s, 5 × OCH_3), 5.18 (1H, br s, C-1 H), 6.48 (2H, apparent s, C-2′ and C-6′ H's), 6.62 and 6.65 (1H each, s's, C-5 and C-8 H's); ms (CI, NH_3) *m/z* (%): 446 (M + 1, 7), 392 (10), 362 (15), 280 (10), 250 (100). *Mol. Wt.* calcd. for $C_{24}H_{31}NO_7$: 445.2101; found (hrms): 445.2115.

*(d) Preparation of **21** by treatment of **20** with methyllithium*

A solution of **20** (255 mg) in THF (5 mL) was added dropwise to a vigorously stirred solution of methyllithium (2.67 mL of 1.5 *M* MeLi in Et_2O) in THF (25 mL) at room temperature. The mixture was stirred for a further 1 h and then the excess of methyllithium was decomposed by the addition of MeOH (1 mL). The solvents were evaporated and a saturated solution of NaCl and enough NH_3(aq) to make the solution strongly basic were added to the residue before extraction with benzene (4 × 20 mL). Evaporation of the dried extract yielded a residue from which compound **21** was obtained as a colorless oil (117 mg, 53%) after purification by column chromatography on silica gel; $[\alpha]_D^{25}$ −12.3° (*c* 1.71, $CHCl_3$); ^1H nmr (90 MHz, $CDCl_3$) δ: 1.83 (1H, br s, disappeared in D_2O, NH), 2.00–2.33 (2H, m, C-8′ H's), 2.60–2.86 (4H, m, C-4 H's and C-7′ H's), 2.98–3.40 (3H, C-1 H and C-3 H's), 3.87 (15H, br s, 5 × OCH_3), 6.48 (2H, apparent s, H-2′ and H-6′), 6.61 and 6.63 (1H each, s's, C-5 and C-8 H's); ms (CI, NH_3) *m/z* (%): 388 (M + 1, 100), 192 (10).

*(e) Preparation of **13** by treatment of **21** with formaldehyde*

A solution of the hydrobromide of **21** (109.0 mg) in H_2O (8 mL) and formaldehyde (5 mL, 37%) was heated under reflux in a nitrogen atmosphere for 3 h. The mixture was cooled, made strongly alkaline by addition of solid NaOH, and extracted 4 times with benzene (15 mL each). The extract was washed with saturated NaCl, dried, and evaporated. The residue was purified by chromatography on silica gel, eluting with 1% MeOH in $CHCl_3$. Compound **13** (54 mg, 58%) was obtained as a glass. The base was converted to the hydrochloride (for measurement of optical rotation), which was isolated also as a glassy solid; $[\alpha]_D^{25}$ −97.8° (*c* 1.07, MeOH) (lit. (10) $[\alpha]_D$ −112.5° (MeOH)); ^1H nmr (90 MHz, $CDCl_3$), free base, δ: 1.80–2.00 (2H, m, C-14 H's), 2.57–2.83 (4H, m, C-5 H's and C-13 H's), 2.97–3.40 (3H, m, C-14a H and C-6 H's), 3.79, 3.81, 3.82, 3.83, 3.84 (3H each, s's, 5 × OCH_3), 3.89 and 3.46 (1H each, ABq, *J* = 17 Hz, C-8 H's), 6.50, 6.57, 6.59 (1H each, s's, C-1 H, C-4 H, and C-12 H) (lit. spectrum (10)); ms (CI, NH_3) *m/z* (%): 400 (M + 1, 100), 208 (52). *Mol. Wt.* calcd. for $C_{23}H_{29}NO_5$: 399.2019; found (hrms): 399.2045.

*Preparation of **12** by treatment of **20** with lithium aluminium hydride*

To a solution of **20** (120 mg) in THF (50 mL) was added LAH (150 mg). The mixture was heated under reflux in a nitrogen atmosphere for 2 h, cooled, and the excess of hydride decomposed by careful addition of a saturated solution of sodium sulfate. Solid $MgSO_4$ and $CHCl_3$ were added to the system, which was then heated under reflux for 5 min. The suspension was filtered, the solid residue washed three times with boiling chloroform, and the combined filtrates evaporated to dryness. The residue was taken up in $CHCl_3$ and adsorbed on a column of silica gel. Elution of the column with 2% MeOH in $CHCl_3$ yielded **12** (78 mg, 72%) as a colorless oil, as the main fraction; $[\alpha]_D^{25}$ +4.51° (*c* 0.96, MeOH) (lit. (9) $[\alpha]_D^{25}$ 4.8° (MeOH)); ^1H nmr (90 MHz, $CDCl_3$) δ: 1.95–2.23 (2H, m, C-8′ H's), 2.50 (3H, s, NCH_3), 2.58–2.83 (4H, m, C-4 H's and C-7′ H's), 3.08–3.53 (3H, m, C-1 H and C-3 H's), 3.87 (15H, br s, 5 × OCH_3), 6.45 (2H, apparent s, H-2′ and H-6′), 6.60 and 6.62 (1H each, s, C-5 H and C-8 H) (lit. spectrum (8, 9)); ms (CI, NH_3) *m/z* (%): 402 (M + 1, 100), 318 (17), 206 (16). *Mol. Wt.* calcd. for $C_{23}H_{31}NO_5$: 401.2202; found (hrms): 401.2204.

*(S)-O-Methylkreysigine (**14**)*

A solution of **12** (150 mg) in freshly distilled and deoxygenated trifluoroacetic acid (100 mL) was treated at 0°C under a nitrogen atmosphere, first with thallium(III) trifluoroacetate (260 mg) and then with boron trifluoride etherate (1 mL). The mixture was stirred for 8 h at 0°C and for an additional 20 h at room temperature. The mixture was then taken to dryness under reduced pressure and the residue treated with H_2O (30 mL). The resulting solution was made strongly alkaline with NH_3 and extracted with $CHCl_3$ (4 × 20 mL). The combined extract was dried over K_2CO_3 and then evaporated. The residual brown oil was purified by preparative layer chromatography on silica plates; 10% MeOH in $CHCl_3$ was used as developing agent. The main fraction eluted from the plates was **14**, obtained as a yellow oil (41 mg, 27%); $[\alpha]_D^{25}$ +68.1° (*c* 0.84, $CHCl_3$) (lit. (11) $[\alpha]_D^{21}$ +81° (*c* 0.43, $CHCl_3$)); ^1H nmr (90 MHz, $CDCl_3$) δ: 1.97–2.33 (2H, m, C-7 H's), 2.43 (3H, s, NCH_3), 2.60–3.40 (7H, m, C-4 H's, C-5 H's, C-6a H, C-8 H's), 3.55, 3.65, 3.84, 3.88, 3.92 (15H, 5s, 5 × OMe), 6.57, 6.70 (each 1H, s, C-3 H and C-9 H) (lit. spectrum (8, 11));

ms (EI) m/z (%): 399 (30), 384 (20), 368 (100). *Mol. Wt.* calcd. for $C_{23}H_{29}NO_5$: 399.2045; found (hrms): 399.2019.

(S)-Glaucine (4)

A solution of (*S*)-laudanosine (1*b*) (76 mg) (82% ee) in freshly distilled and deoxygenated trifluoroacetic acid (70 mL) was treated at 0°C under a nitrogen atmosphere with thallium(III) trifluoroacetate (117 mg) followed by $BF_3 \cdot Et_2O$ (0.6 mL). The temperature was maintained at 0°C for 3 h and the mixture, which was stirred throughout, was allowed to warm slowly to room temperature. The mixture was taken to dryness, the residue taken up in water (30 mL), the resulting solution made strongly alkaline with ammonia and then extracted with $CHCl_3$ (4 × 20 mL). The combined extract was dried over K_2CO_3, evaporated to dryness, and the residual oil chromatographed on a column of silica gel using 2% MeOH in $CHCl_3$. The oily residue (35.4 mg, 47%), obtained on evaporation of the eluant, crystallized on addition of ethyl acetate yielding (+)-glaucine as a colorless crystalline solid; mp 117–118°C; $[\alpha]_D^{25}$ +99.6° (*c* 0.89, $CHCl_3$) (lit. (13) mp 119–120°C (EtOAc); $[\alpha]_D$ +120° ($CHCl_3$)); ^1H nmr (90 MHz, $CDCl_3$) δ: 2.37–3.12 (7H, m, C-4 H's, C-5 H's, C-7 H's, C-6a H), 2.57 (3H, s, N—CH_3), 3.68, 3.90, 3.90, 3.98 (12H each, s's, 4 × OCH_3), 6.63, 6.81 (1H each, s's, C-3 H and C-8 H), 8.16 (1H, s, C-11 H) (lit. spectrum (14)); ms (EI) m/z (%): 355 (80), 354 (100), 340 (50), 324 (23), 206 (34). *Mol. Wt.* calcd. for $C_{21}H_{23}NO_4$: 355.1772; found (hrms): 355.1773.

Received March 31, 1987

JAHANGIR, MICHAEL A. BROOK, DAVID B. MACLEAN, and HERBERT L. HOLLAND. Can. J. Chem. **65**, 2362 (1987).

It is shown that 3,4-dihydroisoquinolines are activated toward nucleophilic attack by reaction with trimethylsilyl trifluoromethanesulfonate. The complex so formed reacts readily with the lithio derivative of 3-cyano-4-methyl-5-vinylpyridine, affording in a single step a tetracyclic amidine from which a lactam is obtained by hydrolysis. These reactions have been applied to the synthesis of the *Alangium* alkaloids, (±)-alangimaridine and alangimarine.

JAHANGIR, MICHAEL A. BROOK, DAVID B. MACLEAN et HERBERT L. HOLLAND. Can. J. Chem. **65**, 2362 (1987).

On démontre que les dihydro-3,4 isoquinoléines sont activées par rapport aux réactions nucléophiles avec le trifluorométhanesulfonate de triméthylsilyle. Le complexe qui se forme ainsi réagit facilement avec le dérivé lithien de la cyano-3 méthyl-4 vinyl-5 pyridine pour conduire en une seule étape à une amidine tétracyclique à partir de laquelle on peut obtenir une lactame par hydrolyse. On a appliqué ces réactions à la synthèse des alcaloïdes suivants de l'*Alangium* (±)-alangimaridine et alangimarine.

[Traduit par la revue]

Introduction

Alangium lamarckii Thw. has been used in Indian medicine for many years (2–4) and it has been claimed that the extracts of the plant are useful in the treatment of a large number of human disorders. Extensive investigation has resulted in the isolation of several biologically active alkaloids including emetine, cephaetine, and psychotrine (5). Recently, Pakrashi *et al.* (6–8) have isolated several new alkaloids from the seeds of *A. lamarckii*, namely, alangimaridine **1**, alangimarine **2**, isoalangimarine **3**, alamarine **4**, isoalamarine **5**, dihydroalamarine **6**, dihydroisoalamarine **7**, alangimarinone **8**, and alamaridine **9** (Fig. 1). These alkaloids are tetracyclic like the protoberberines but have a pyridine ring instead of the benzenoid D ring in the protoberberines; they possess the 8*H*-isoquino[2,1-*b*][2,7]naphthyridine ring system, an unusual ring system in natural products chemistry.

Ninomiya and co-workers (9) reported the first total synthesis in this class of alkaloids in their synthesis of alamarine **4** via a route involving enamide cyclization under both thermal and photochemical conditions. The enamide **10** when heated produced a mixture of two lactams, **11** (43%) and **12** (10%). On the other hand, irradiation of **10** gave the lactams **11** and **12** in 25 and 13% yields, respectively. Debenzylation and sodium borohydride reduction of the major product **11** gave (±)-alamarine **4** as shown in Scheme 1. Alamarine had previously been dehydrated to alangimarine **2** (6). In the past year two synthetic routes to (±)-alamaridine **9** have been reported (10, 11) but neither is applicable, without modification, to the preparation of alkaloids substituted at C-12.

The *Alangium* alkaloids bearing a substituent at C-12 may be considered to be related biogenetically to deacetylipecoside **15**, which in turn is derived from secologanin **13** and dopamine **14** (12–16). Deacetylipecoside **15**, through cyclization to alangiside **16** followed by hydrolysis, amination, and other unexceptional transformations, may be imagined to produce these alkaloids, as shown in Scheme 2. The *R* configuration is shown in the diagram but the absolute configuration of the alkaloids has not been established. It is also possible that alamaridine **9** is derived from deacetylipecoside **15** by ring closure between the isoquinoline nitrogen and the methine carbon of the vinyl group via the postulated intermediate **17**, followed by other transformations (Scheme 2). Biosynthetic studies have not been conducted on this new class of protoberberine analogues.

Here we report a new approach to the synthesis of those *Alangium* alkaloids bearing a vinyl substituent at C-12, which uses two readily available starting materials, namely, 3-cyano-4-methyl-5-vinyl pyridine **18** (17, 18) as its lithio derivative **18***a*, and substituted 3,4-dihydroisoquinolines.

Results and discussion

It has been shown (19) by us that the 8*H*-isoquino[2,1-*b*][2,7]naphthyridine ring system is formed in high yield by interaction of 3,4-dihydroisoquinolines **20** and the lithio derivative **19***b* of azaphthalide **19***a* (Scheme 3). This strategy was used to synthesize the ring system of alamaridine **9** with the methyl group of **9** being introduced in a subsequent step (11). The same approach was investigated for the synthesis of alkaloids **1–8** bearing substituents at C-12 but was abandoned because the azaphthalide **19***c* could not be prepared by us in good yield. In another approach, attempts to introduce a two-carbon unit at C-12 in **21** were also unsuccessful. Next, our attention was focussed on 3-cyano-4-methyl-5-vinylpyridine **18** as a potential precursor of rings C and D of the alkaloids **1–8** of Fig. 1. The compound readily formed an anion **18***a* in the presence of strong bases and it was considered that this anion might react with 3,4-dihydroisoquinolines in the same manner as the azaphthalide anion **19***b*, leading to formation of the appropriately substituted tetracyclic system. However, starting materials were recovered virtually quantitatively when the lithium derivative **18***a* and imine **20***a* were allowed to interact under a variety of reaction conditions. In other experiments (20) it was found that **18***a* added readily to iminium salts such as **22** but we were

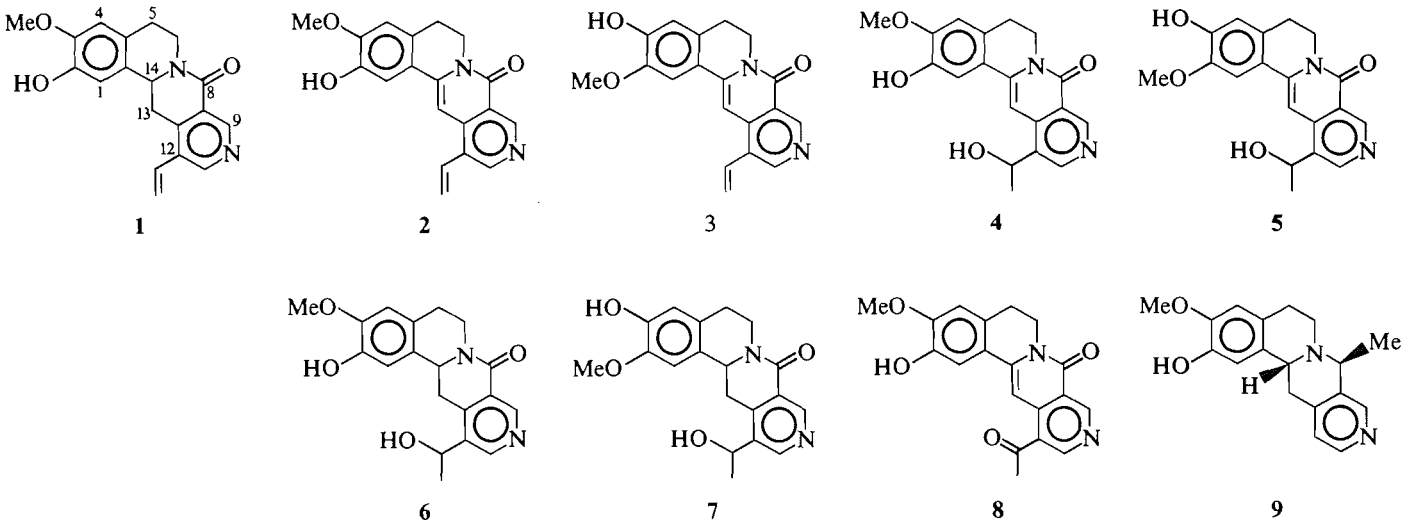

FIG. 1. Benzopyridoquinolizidine alkaloids of *Alanguim lamarckii*.

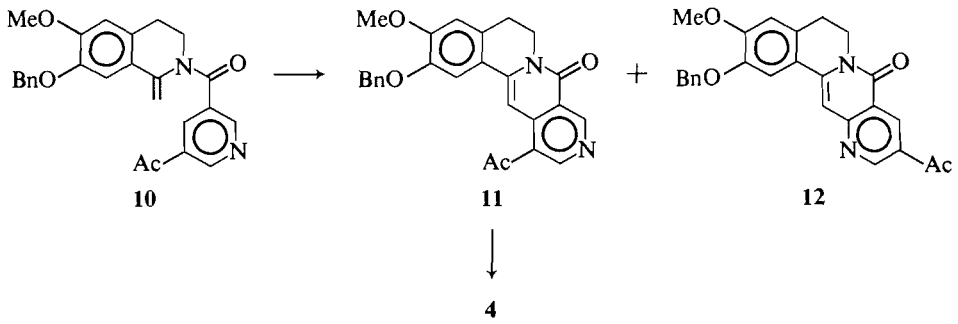

SCHEME 1

unable to find an alkyl group that could be removed from the resulting tertiary amines **23**. Had it been possible to convert the tertiary amines **23** to the corresponding secondary amines **24**, the latter would have been expected to react readily with the cyano function on the pyridine ring to yield the desired tetracyclic ring system (see Scheme 4).

It was apparent that a reagent was required that would activate an imine to nucleophilic attack and would be readily removed after the nucleophile had added. Eventually, we found that treatment of imines with trimethylsilyl trifluoromethanesulfonate (TMSOTf) prior to addition of the nucleophile achieved our purpose. A reaction occurred between the nucleophile and the imine–triflate complex that yielded a tetracyclic product without isolation of a tricyclic intermediate. Trimethylsilyl trifluoromethanesulfonate has been used previously as a powerful silylating agent for a wide range of active hydrogen compounds (21) and also for converting imines to the corresponding enamines (22, 23) in the presence of alkylamine bases. To our knowledge, its use to activate an imine toward nucleophilic addition has not been reported prior to its use by us (1, 11).

Treatment of 3,4-dihydroisoquinoline **20***a* with TMSOTf afforded a complex formulated as **25***a* (Scheme 5) to which the lithio derivative **18***a* was added dropwise at −78°C. When the addition was complete the mixture was stirred at −40°C for 4 h and then at 20°C for 12 h. The product of the reaction was a polar crystalline compound isolated in 87% yield. Its infrared spectrum displayed an absorption band at 1610 cm^{-1} indicative of an amidine function (>N—C=NH). The EI mass spectrum showed a molecular ion at m/z 335 of composition $C_{20}H_{21}N_3O_2$, as determined by high resolution mass spectroscopy. All the spectral evidence indicated that the product was a tetracyclic amidine of structure **26***a* (Scheme 5). The mode of cyclization is probably similar to that described elsewhere (19) for the reactions between lithium azaphthalide **19***b* and imines **20***a* and **20***b*. The exact role of the trimethylsilyl group in this reaction, except for activating the imine, has not been clarified but the reactions reported here did not proceed in the absence of this reagent. However, it seems likely that the trimethylsilyl group resides eventually on the amidine nitrogen atom and is lost on work-up. Hydrolysis of amidine **26***a* with 20% KOH solution (aqueous) in dioxane afforded (±)-*O*-methylalangimaridine **27***a* in 99% yield. The ^1H nmr spectrum of lactam **27***a*, except for the extra methoxyl signal, closely resembled that reported for alangimaridine **1** (7). Oxidation of **27***a* with iodine in refluxing methanol gave *O*-methylalangimarine **28** in 81% yield, whose spectral data were consistent with the proposed structure.

The synthesis of the *Alangium* alkaloids themselves was accomplished beginning with imine **20***b*, in which C-7 carries an *O*-benzyl group, and 3-cyano-4-methyl-5-vinylpyridine **18** as its lithio derivative. Condensation of the lithium salt **18***a* with the complex **25***b* afforded amidine **26***b* in 98% yield, which was then hydrolysed to the lactam **27***b* in 98% yield. Debenzylation of the protected phenol in **27***b* was readily achieved by heating it in ethanolic hydrochloric acid; racemic alangimaridine **1** was

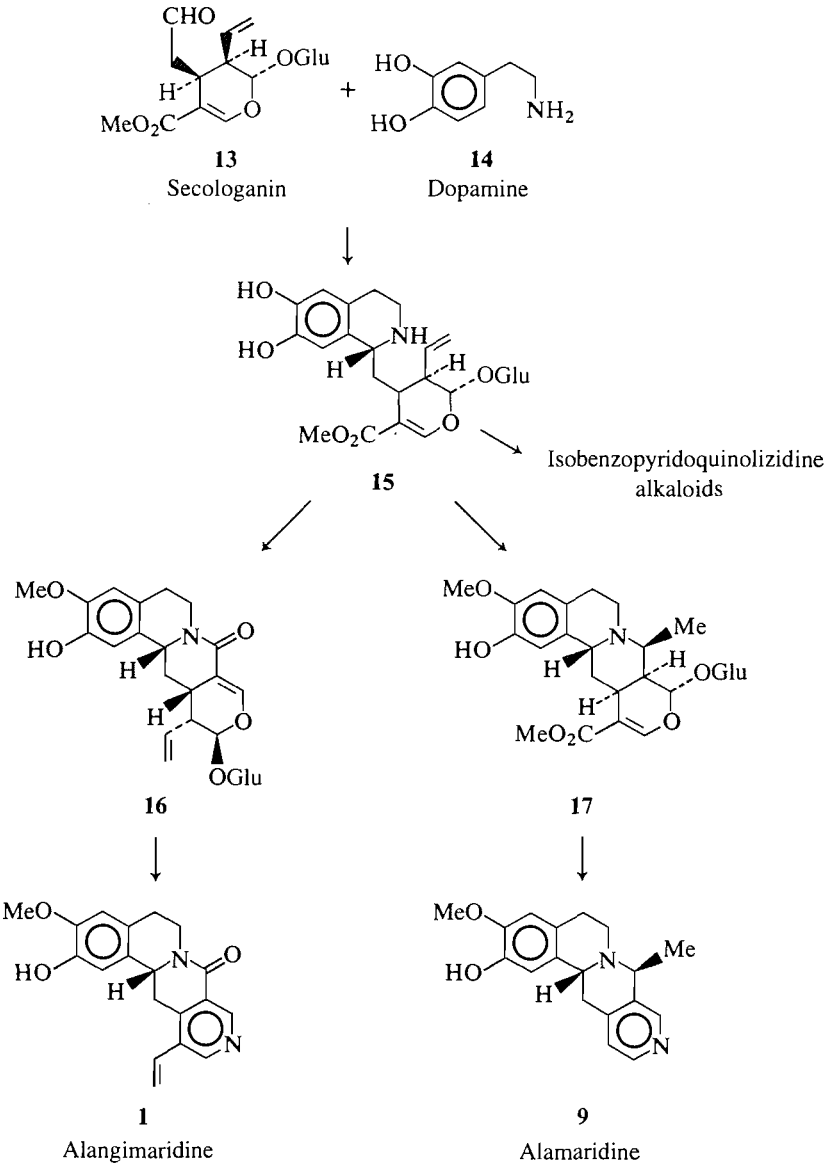
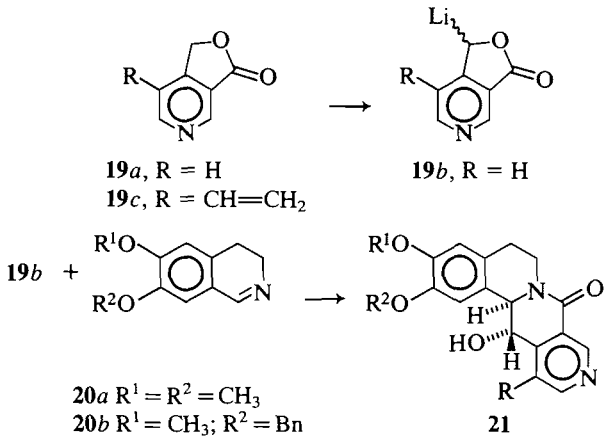


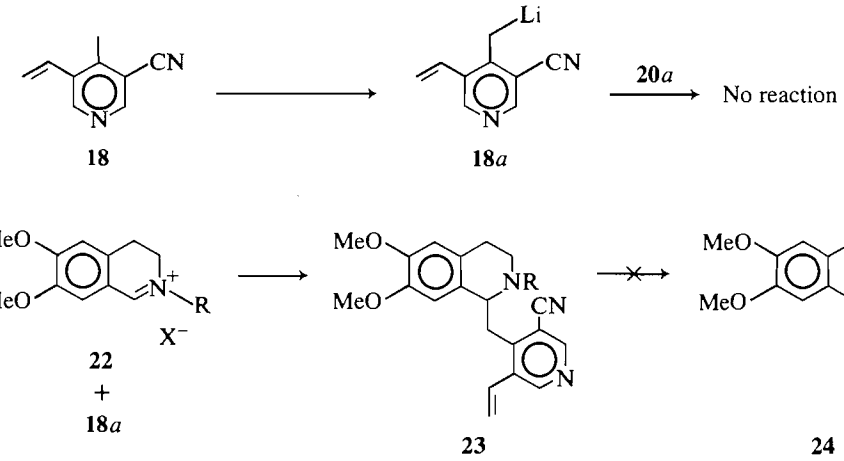
SCHEME 2

obtained in 97% yield (Scheme 5). The spectroscopic properties in solution of (±)-alangimaridine, prepared in this study, agree with those reported (7) for the natural product. The chemical shifts of the aliphatic protons in the ^{1}H nmr spectrum of **1**, assigned previously (7) in analogy with the ^{1}H nmr data reported for 8-oxotetrahydroberberines (24), were reconfirmed by high field (500 MHz) 2D ^{1}H nmr (COSY) spectroscopy. Dehydrogenation of **1** with iodine in methanol afforded alangimarine **2** in 80% yield. The ^{1}H nmr and infrared spectral data of the synthetic alangimarine were in agreement with those reported (7) for the natural alkaloid. (±)-*O*-Methylalangimaridine **27***a* and (±)-alangimaridine **1** on catalytic hydrogenation over 10% Pd–C afforded the corresponding 12-ethyl derivatives, **29***a* and **29***b*, respectively, in almost quantitative yields. Compound **29***b* has been prepared previously (7) and the spectroscopic properties of our sample agree with those previously reported (Scheme 6).

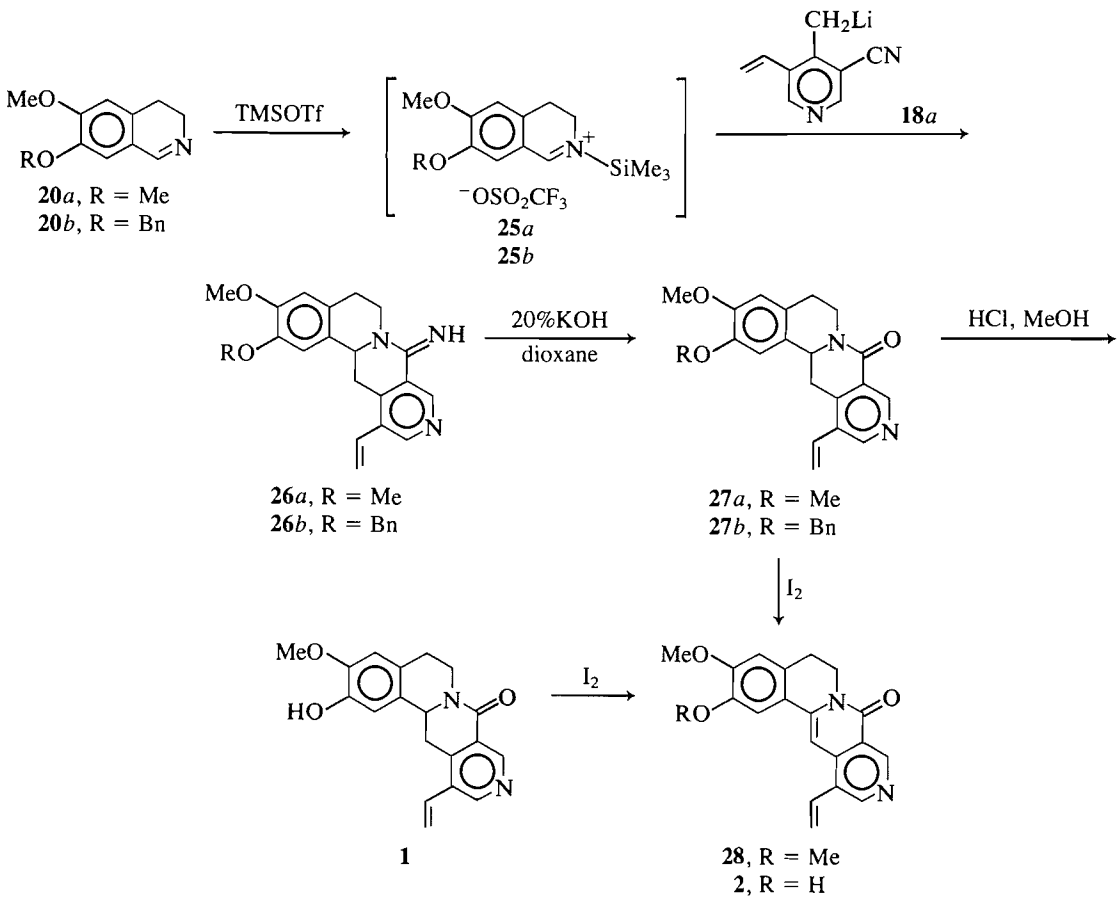


SCHEME 3

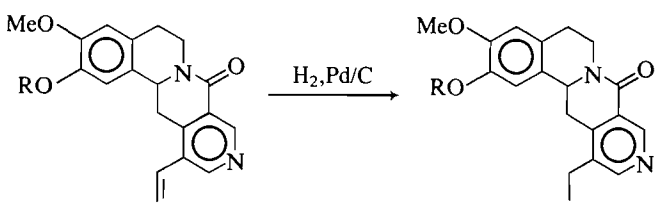
Examination of the ^{1}H nmr spectra of lactams **27***a*, **1**, **29***a*, and **29***b* revealed that the angular proton at C-14 was deshielded and appeared at or below δ 4.80, in comparison to the amidines **26***a* and **26***b* in which the chemical shifts of the protons at C-14 were at δ 4.49 and 4.56, respectively. Both in the lactams and amidines the C-6 axial proton was the most shielded among the aliphatic protons of the ring system. The large coupling constant for the C-14 proton ($J_{13ax,14} \approx 13$ Hz) in the lactams and the amidines clearly indicated that this proton has a *trans* diaxial relationship with an axial proton at C-13; thus the junction



SCHEME 4



SCHEME 5



SCHEME 6

of rings B and C approximates that of *trans*-quinolizidine. A comparison of the chemical shifts of C-9 H in the tetrahydrolactams with that in the corresponding 13,14-dehydrolactams **2** and **28** showed that C-9 H underwent deshielding by ca. 0.3 ppm with the oxidation of the C(13)—C(14) bond.

Under electron ionization conditions the molecular ion of amidine **26***a* was the base peak in the mass spectrum, while amidine **26***b* with an *O*-benzyl group had its base peak at m/z 91. The compounds showed strong $M - 1$ peaks arising presumably by loss of a hydrogen atom at C-14. Other major ions in the spectra probably result from a retro-Diels–Alder

opening of ring C. Ions at m/z 192 and 191 in **26***a* and at m/z 178 and 177 in **26***b* are derived from the isoquinoline moiety. Ions derived from ring C and D were also observed in both compounds; they appear in each case at m/z 144 and undergo further fragmentation through loss of HCN, affording ions at m/z 117.

The mass spectral fragmentation of the lactams **27***a*, **27***b*, **29***a*, and **29***b*, prepared in this study, resembles that of tetrahydroberberines (25). All lactams, except **27***b* with an *O*-benzyl group, had the molecular ions as the base peak and strong $M - 1$ ions. Other important fragment ions in the mass spectra may be attributed to the retro-Diels–Alder opening of ring C. Ions corresponding to the isoquinoline moiety and fragment ions derived from rings C and D were present in all five compounds. The latter fragment ions lose the elements of carbon monoxide to give further daughter ions. The mass spectra of the 13,14-dehydrolactams **2** and **28** did not exhibit significant fragmentation, in keeping with their aromatic character.

In this paper we have described a new approach to the synthesis of (±)-alangimaridine and alangamarine that should be adaptable with minor modification to the synthesis of the related alkaloids shown in Fig. 1. A key feature of the synthetic method is the activation of the imines **20** toward nucleophilic attack through formation of a complex between the imine and trimethylsilyl trifluoromethanesulfonate. The product of nucleophilic attack at the imine carbon atom undergoes reaction (without isolation of an intermediate) with the suitably disposed electrophilic centre (the CN group) present in the attacking nucleophile. Reactions of this type have potential in the synthesis of other nitrogen heterocycles. The scope of the reaction is currently under investigation.

Experimental

Apparatus, materials, and methods

The continuous wave ^{1}H nmr spectra were recorded on a Varian EM 390 spectrometer and the Fourier transform spectra on either a Bruker WP 80 (80 MHz), WM 250 (250 MHz), or WM 500 (500 MHz) spectrometer. Unless otherwise specified, the samples were dissolved in chloroform-*d* using tetramethylsilane (TMS) as internal standard. Chemical shifts, quoted as δ values, were measured in relation to TMS. The symbols s, singlet, d, doublet, t, triplet, q, quartet, br, broad, and m, multiplet, are used in reporting spectra. The ^{13}C nmr spectra were recorded at 62.9 MHz on a Bruker WM 250 FT or at 125.76 MHz on a WM 500 FT spectrometer at ambient temperature.

EI mass spectra were recorded at 70 eV with a source temperature of ca. 200°C either on a VG Micromass 7070 F mass spectrometer equipped with a data system comprised of a PDP 8A with VG 2000 software or a VG analytical ZAB E mass spectrometer equipped with a VG 11-250 data system. High resolution mass spectra (hrms) were recorded on either of the above instruments. CI mass spectra were recorded on a VG Micromass 7070 F mass spectrometer using NH_3 at ca. 1 Torr (1 Torr = 133.3 Pa) as reagent gas and DCI mass spectra were recorded under similar conditions on a VG analytical ZAB E mass spectrometer. Infrared spectra were run on a Perkin–Elmer 283 spectrometer in $CHCl_3$ solution or $CHCl_3$ film. Melting points were determined using a Gallenkamp apparatus and are uncorrected. Thin-layer chromatography (tlc) was performed using Polygram Sil G/UV_{254} and Polygram Alox N/UV_{254} plates. For flash column chromatography Kieselgel 60 (230–400 mesh) was used.

All reactions involving lithiation steps were carried out in flame-dried apparatus under a blanket of argon, using septa and syringes for transfer of reagents. Diisopropylamine and 1,1,1,3,3,3-hexamethyldisilazane were heated under reflux over calcium hydride and distilled onto activated molecular sieves (4A) for storage. THF was dried by distillation from Na/benzophenone under a nitrogen atmosphere just prior to use.

The following compounds were prepared using literature procedures, sometimes with minor modifications: 3,4-dihydro-6,7-dimethoxyisoquinoline (19), 7-benzyloxy-3,4-dihydro-6-methoxyisoquinoline (19), 3-cyano-4-methyl-5-vinylpyridine (17, 18). Trimethylsilyl trifluoromethanesulfonate was obtained commercially.

Condensation of 3,4-dihydroisoquinolines activated with trimethylsilyl trifluoromethanesulfonate with the lithium salt of 3-cyano-4-methyl-5-vinylpyridine ***18***a

*(a) 12-Ethenyl-5,6,13,14-tetrahydro-2,3-dimethoxy-8*H*-isoquino[2,1-*b*][2,7]naphthyridin-8-imine* ***26***a

A solution of 3,4-dihydro-6,7-dimethoxyisoquinoline **20***a* (0.61 g, 3.19 mmol) in dry THF (4 mL) was treated dropwise with TMSOTf (0.75 mL, 3.83 mmol), at −78°C under an argon atmosphere. The resulting cloudy suspension was stirred first at −78°C for 1 h, then at 0°C for an additional 2 h. Meanwhile a solution of *n*-BuLi (2.33 mL of a 1.55 *M* solution in hexane, 3.6 mmol) was added dropwise to a stirred solution of 1,1,1,3,3,3-hexamethyldisilazane (0.76 mL, 3.6 mmol) in THF (3 mL) at −78°C. The lithium derivative of hexamethyldisilazane (LHS) so generated was stirred for an additional 10 min at −20°C and then cooled to −78°C. A solution of 3-cyano-4-methyl-5-vinylpyridine **18** (0.432 g, 3.0 mmol) in THF (2 mL) was added dropwise to the above LHS solution at −78°C, and the red solution so generated was stirred for a further 20 min at −78°C.

The red anion solution was then added dropwise at −78°C to the imine–TMSOTf complex and, when the addition was complete, the mixture was stirred at −40°C for 4 h. The mixture was allowed to warm to room temperature and stirred for ca. 12 h. The reaction mixture was quenched with saturated NH_4Cl solution (1 mL, aq.) and the resulting mixture was evaporated, water added, and the contents extracted with $CHCl_3$; the $CHCl_3$ extract was dried (Na_2SO_4, anhydrous) and evaporated to dryness *in vacuo*. The crude product was filtered through a short neutral alumina column, eluting with CH_2Cl_2 to remove any starting materials, then with $CHCl_3$–MeOH (3:1), yielding **26***a* (0.87 g, 87%); mp 189–191°C (EtOAc); ir ($CHCl_3$, film), ν_{max}: 1610 cm^{-1}; ^{1}H nmr (500 MHz), δ: 2.76–2.82 (2H, complex m, C-6 H_{ax} and C-13 H_{ax} H's), 2.99–3.04 (2H, complex m, C-5 H's), 3.29 (1H, dd, J = 16.4 and 3.0 Hz, C-13 H_{eq}), 3.89 (3H, s, —OCH_3), 3.90 (3H, s, —OCH_3), 4.56 (1H, dd, J = 12.2 and 3.0 Hz, C-14 H), 4.81 (1H, m, C-6 H_{eq}), 5.54 (1H, d, J = 11.2 Hz, —CH=CH_2), 5.77 (1H, d, J = 17.6 Hz, —CH=CH_2), 6.66 (1H, s, C-4 H), 6.70 (1H, s, C-1 H), 6.83 (1H, dd, J = 17.6 and 11.2 Hz, —CH=CH_2), 8.71 (1H, s, C-11 H), and 9.03 (1H, s, C-9 H); ^{13}C nmr (125.76 MHz), δ: 29.2 (C-5), 35.9 (C-13), 39.8 (C-6), 54.1 (C-14), 56.1 (—OCH_3), 56.5 (—OCH_3), 119.8 (—CH=CH_2), 130.7 (—CH=CH_2), 109.4, 111.7, 147.0, and 148.6 (4 × ArCH's), 125.2, 127.5, 127.6, 131.2, 141.8, 148.2, and 148.3 (7 × ArC's), and 159.6 (>C=NH); ms (EI), m/z (%): 335 (100) $M^{+\cdot}$, 334 (24), 320 (41), 318 (5), 192 (24), 191 (13), 190 (14), 176 (37), 144 (10), 143 (39), 117 (13), and 90 (11). *Exact mass* calcd. for $C_{20}H_{21}N_3O_2$: 335.163; found (hrms): 335.163; calcd. for fragment ion $C_{19}H_{18}N_3O_2$ ($M - CH_3$): 320.140; found: 320.140; calcd. for fragment ion $C_9H_7N_2$: 143.061; found: 143.061.

*(b) 2-Benzyloxy-12-ethenyl-5,6,13,14-tetrahydro-3-methoxy-8*H*-isoquino[2,1-*b*][2,7]naphthyridin-8-imine* ***26***b

This condensation was carried out in a manner similar to that described previously for the conversion of **20***a* to **26***a*, using imine **20***b* (0.804 g, 3.03 mmol). The reaction mixture was processed in the usual manner and the crude product chromatographed on neutral alumina, eluting first with CH_2Cl_2 and then with increasing concentrations of MeOH, affording the amidine **26***b* (1.023 g, 83%); mp 218–221°C (dec.) (EtOH–EtOAc); ir ($CHCl_3$), ν_{max}: 1615 cm^{-1}; ^{1}H nmr (500 MHz), MeOH-d_4, δ: 2.90–3.04 (1H, m, C-6 H_{ax}), 3.17–3.44 (3H, complex m, C-5 and C-13 H_{ax} H's), 3.65–3.67 (1H, m, C-13 H_{eq}), 4.06 (3H, s, —OCH_3), 4.49 (1H, m, C-14 H), 4.96 (1H, m, C-6 H_{eq}), 5.30 and 5.34 (2H, ABq, J = 12.3 Hz, —OCH_2Ar), 5.37 (1H, d, J = 11.1 Hz, —CH=CH_2), 5.55 (1H, d, J = 17.3 Hz, —CH=CH_2), 6.90 (1H, s, C-4 H), 6.97 (1H, dd, J = 17.3 and 11.1 Hz, —CH=CH_2), 7.04 (1H, s, C-1 H), 7.45–7.72 (5H, complex m, aromatic H's), 9.06 (1H, s, C-11 H), and 9.18 (1H, s, C-9 H); ms (EI), m/z (%): 411 (7) $M^{+\cdot}$, 410 (2), 320 (95), 268 (1), 178 (2),

Hydrolysis of amidines ***26***a *and* ***26***b *to lactams* ***27***a *and* ***27***b

*(a) 12-Ethenyl-5,6,13,14-tetrahydro-2,3-dimethoxy-8*H*-isoquino-[2,1-*b*][2,7]naphthyridin-8-one* ***27***a

Amidine ***26****a* (250 mg) was dissolved in a mixture of dioxane (15 mL) and 20% KOH solution (10 mL, aq.) and the mixture was gently heated under reflux for 2 days. The solution was then evaporated to dryness *in vacuo*, acidified with concentrated HCl (aq.), and heated under reflux for an additional 30 min. Evaporation of the acidified solution was followed by basification with saturated Na_2CO_3 solution (aq.) and extraction with $CHCl_3$. The combined $CHCl_3$ extracts were washed with brine and dried over $MgSO_4$ (anhyd.). Removal of the solvent *in vacuo* and crystallization from EtOAc gave lactam ***27****a* (249 mg, 99.3%) as cubic crystals; mp 181–182°C; R_f 0.46 (alumina, 2% MeOH in $CHCl_3$), 0.14 (silica, 5% MeOH in $CHCl_3$); ir ($CHCl_3$, film), ν_{max}: 1650 cm^{-1}; ^1H nmr (500 MHz), δ: 2.76–2.82 (2H, complex m, C-6 H_{ax} and C-13 H_{ax} H's), 2.84–2.99 (2H, complex m, C-5 H's), 3.40 (1H, dd, J = 16.5 and 3.6 Hz, C-13 H_{eq}), 3.90 (3H, s, —OCH_3), 3.91 (3H, s, —OCH_3), 4.84 (1H, dd, J = 13.1 and 3.6 Hz, C-14 H), 4.97 (1H, m, C-6 H_{eq}), 5.56 (1H, d, J = 11.2 Hz, —CH=CH_2), 5.79 (1H, d, J = 17.6 Hz, —CH=CH_2), 6.71 (1H, s, C-4 or C-1 H), 6.72 (1H, s, C-1 or C-4 H), 6.86 (1H, dd, J = 17.6 and 11.2 Hz, —CH=CH_2), 8.77 (1H, s, C-11 H), and 9.19 (1H, s, C-9 H); ^{13}C nmr (125.76 MHz), δ: 29.1 (C-5), 34.5 (C-13), 38.7 (C-6), 54.2 (C-14), 56.1 (OCH_3), 56.5 (OCH_3), 119.8 (—CH=CH_2), 130.5 (—CH=CH_2), 109.1, 111.8, 149.3, and 150.1 (4 × ArCH's), 124.4, 126.9, 127.5, 130.5, 142.4, 148.3, and 148.4 (7 × ArC's), and 165.6 (>C=O); ms (EI), m/z (%): 336 (100) $M^{+\cdot}$, 335 (52), 321 (30), 307 (11), 305 (23), 192 (9), 191 (14), 190 (21), 176 (20), 145 (19), 117 (57), and 90 (22). *Exact Mass* calcd. for $C_{20}H_{20}N_2O_3$: 336.147; found (hrms): 336.149; calcd. for fragment ion $C_{11}H_{12}NO_2$: 190.087; found: 190.087; calcd. for fragment ion C_9H_7NO: 145.053; found: 145.052.

*(b) 2-Benzyloxy-12-ethenyl-5,6,13,14-tetrahydro-3-methoxy-8*H*-isoquino[2,1-*b*][2,7]naphthyridin-8-one* ***27***b

Hydrolysis of the amidine ***26****b* (250 mg) was achieved with 20% KOH solution (15 mL, aq.) in dioxane (25 mL) under the conditions described previously for the preparation of ***27****a* from ***26****a* with slight modification. The reaction mixture was heated under reflux for 2 days, the dioxane removed *in vacuo*, and the mixture diluted with water (50 mL). The product was extracted thoroughly with CH_2Cl_2 and, after successively washing the extract with water and brine, it was dried over $MgSO_4$ (anhyd.). Evaporation of the solvent *in vacuo* gave the lactam ***27****b* (246 mg, 98%); mp 175–177°C (EtOAc); R_f 0.53 (alumina, EtOAc); ir ($CHCl_3$, film), ν_{max}: 1655 cm^{-1}; ^1H nmr (500 MHz), $CDCl_3$ + MeOH-d_4, δ: 2.65–2.71 (1H, m, C-6 H_{ax}), 2.81–3.00 (3H, complex m, C-5 and C-13 H_{ax} H's), 3.17 (1H, dd, J = 16.7 and 3.8 Hz, C-13 H_{eq}), 3.93 (3H, s, —OCH_3), 4.80 (1H, dd, J = 13.1 and 3.8 Hz, C-14 H), 4.86–4.90 (1H, m, C-6 H_{eq}), 5.16 and 5.25 (2H, AB q, J = 12.5 Hz, —OCH_2Ar), 5.61 (1H, d, J = 11.7 Hz, —CH=CH_2), 5.81 (1H, d, J = 17.0 Hz, —CH=CH_2), 6.69 (1H, s, C-4 or C-1 H), 6.77 (1H, dd, J = 17.0 and 11.7 Hz, —CH=CH_2), 7.26 (1H, s, C-1 or C-4 H), 7.34–7.47 (5H, complex m, aromatic H's), 8.72 (1H, s, C-11 H), and 9.06 (1H, s, C-9 H); ms (EI), m/z (%): 412 (33) $M^{+\cdot}$, 411 (6), 321 (12), 176 (3), 145 (2), 117 (7), 91 (100), and 90 (6). *Exact Mass* calcd. for $C_{26}H_{24}N_2O_3$: 412.179; found (hrms): 412.178.

*(±)-Alangimaridine(12-ethenyl-5,6,13,14-tetrahydro-2-hydroxy-3-methoxy-8-isoquino[2,1-*b*][2,7]naphthyridin-8-one)* ***1***

A solution of *O*-benzyl lactam ***27****b* (50 mg) in EtOH (5 mL) and concentrated HCl solution (5 mL) was heated under reflux gently for 3 h under a nitrogen atmosphere. The solvent was removed *in vacuo*, the residue treated with water (10 mL), and the mixture basified with saturated $NaHCO_3$ solution (aq.). The resulting mixture was extracted with $CHCl_3$, and the $CHCl_3$ extract washed with brine and dried over Na_2SO_4 (anhyd.). Removal of the solvent and crystallization from MeOH–$CHCl_3$ gave colourless crystals of (±)-alangimaridine **1** (38 mg, 97.2%), mp 242–245°C; R_f 0.20 (silica, 10% MeOH in $CHCl_3$); ir ($CHCl_3$, film), ν_{max}: 1650 cm^{-1}; ^1H nmr (500 MHz), δ: 2.76–2.82 (2H, complex m, C-6 H_{ax} and C-13 H_{ax} H's), 2.94–3.00 (2H, complex m, C-5 H's), 3.40 (1H, dd, J = 16.5 and 3.8 Hz, C-13 H_{eq}), 3.92 (3H, s, —OCH_3), 4.81 (1H, dd, J = 13.1 and 3.8 Hz, C-14 H), 4.95 (1H, m, C-6 H_{eq}), 5.55 (1H, d, J = 11.1 Hz, —CH=CH_2), 5.73 (1H, s, exchanges with D_2O, phenolic OH), 5.77 (1H, d, J = 17.5 Hz, —CH=CH_2), 6.69 (1H, s, C-4 H), 6.81 (1H, s, C-1 H), 6.85 (1H, dd, J = 17.5 and 11.1 Hz, —CH=CH_2), 8.77 (1H, s, C-11 H), and 9.20 (1H, s, C-9 H); ^{13}C nmr (125.76 MHz), δ: 29.0 (C-5), 34.1 (C-13), 38.8 (C-6), 53.8 (C-14), 56.0 (—OCH_3), 119.8 (—CH=CH_2), 130.6 (—CH=CH_2), 111.0, 111.7, 149.1, and 149.9 (4 × ArCH's), 124.3, 126.6, 127.6, 130.3, 142.7, 144.8, and 145.8 (7 × ArC's), and 163.5 (>C=O); ms (EI), m/z (%): 322 (100) $M^{+\cdot}$, 321 (53), 307 (23), 305 (12), 291 (7), 293 (12), 178 (7), 177 (7), 176 (13), 162 (16), 145 (18), 117 (46), and 90 (28). *Exact Mass* calcd. for $C_{19}H_{18}N_2O_3$: 322.132; found (hrms): 322.131.

Oxidation of lactams ***27***a *and* ***1*** *to dehydrolactams* ***28*** *and* ***2***

*(a) 5,6-Dihydro-2,3-dimethoxy-8*H*-isoquino[2,1-*b*][2,7]naphthyridin-8-one* ***28***

A solution of lactam ***27****a* (50 mg) and iodine (100 mg) in EtOH (10 mL) was gently heated under reflux on a steam bath for 6 h. The progress of the reaction was monitored by tlc. When the reaction was complete, the solvent was evaporated *in vacuo* and 10% $Na_2S_2O_3$ solution (5 mL, aq.) was added to decompose excess iodine. The mixture was basified with saturated Na_2CO_3 solution (aq.) and the product was thoroughly extracted into $CHCl_3$. The combined $CHCl_3$ extracts were washed successively with 10% $Na_2S_2O_3$ solution and brine, and dried over Na_2SO_4 (anhyd.). Evaporation of the solvent gave dehydrolactam **28** (41 mg, 81%) as an amorphous solid, mp 145–150°C (dec.) ($CHCl_3$–MeOH); R_f 0.26 (alumina, 5% MeOH in $CHCl_3$); 0.60 (alumina, EtOAc); ir ($CHCl_3$, film), ν_{max}: 1650 cm^{-1}; ^1H nmr (500 MHz), δ: 2.97 (2H, t, J = 5.9 Hz, C-5 H's), 3.96 (3H, s, —OCH_3), 4.01 (3H, s, —OCH_3), 4.35 (2H, t, J = 5.9 Hz, C-6 H's), 5.59 (1H, d, J = 11.9 Hz, —CH=CH_2), 5.87 (1H, d, J = 17.5 Hz, —CH=CH_2), 6.77 (1H, s, C-4 H), 6.94 (1H, s, C-1 H); 7.15 (1H, dd, J = 17.5 and 11.9 Hz, —CH=CH_2), 7.27 (1H, s, C-13 H), 8.98 (1H, s, C-11 H), and 9.52 (1H, s, C-9 H); ms (EI), m/z (%): 334 (100) $M^{+\cdot}$ and 319 (55). *Exact Mass* calcd. for $C_{20}H_{18}N_2O_3$: 334.132; found (hrms): 334.132.

*(b) Alangimarine (12-ethenyl-5,6-dihydro-2-hydroxy-3-methoxy-8*H*-isoquino[2,1-*b*][2,7]naphthyridin-8-one)* ***2***

Oxidation of the lactam **1** (20 mg) with iodine (50 mg) in EtOH (20 mL) by the method described previously for the oxidation of ***27****a* to **28** gave the crude product, which was purified by flash column chromatography on silica gel eluting with 5% MeOH in $CHCl_3$. Crystallization from MeOH afforded yellow needles of **2** (17 mg, 86%); mp 245–247°C (dec.) (lit. (7) mp 247°C ($CHCl_3$–MeOH); R_f 0.35 (silica, 10% MeOH in $CHCl_3$); ^1H nmr (500 MHz), δ: 2.96 (2H, t, J = 6.3 Hz, C-5 H's), 3.98 (3H, s, —OCH_3), 4.35 (2H, t, J = 6.3 Hz, C-6 H's), 5.58 (1H, d, J = 11.1 Hz, —CH=CH_2), 5.84 (1H, d, J = 17.4 Hz, —CH=CH_2), 5.84 (1H, s, exchanges with D_2O, phenolic OH), 6.75 (1H, s, C-4 H), 6.98 (1H, s, C-1 H), 7.12 (1H, dd, J = 17.4 and 11.1 Hz, CH=CH_2), 7.42 (1H, s, C-13 H), 8.76 (1H, s, C-11 H), and 9.50 (1H, s, C-9H); ^{13}C nmr (125.76 MHz), δ: 28.1 (C-5), 39.8 (C-6), 56.3 (—OCH_3), 96.4, 110.1, 111.7, 119.1, 119.6, 122.6, 127.9, 129.0, 130.7, 139.5, 145.4, 148.2, 148.9, 150.9, and 150.9 (vinylic and aromatic carbons), 162.0 (>C=O); ms (EI), m/z (%): 320 (100) $M^{+\cdot}$ and 305 (66). *Exact Mass* calcd. for $C_{19}H_{16}N_2O_3$: 320.116; found (hrms): 320.115.

Hydrogenation of lactams ***27***a *and* ***1*** *to dihydro compounds* ***29***a *and* ***29***b

*(a) 12-Ethyl-5,6,13,14-tetrahydro-2,3-dimethoxy-8*H*-isoquino-[2,1-*b*][2,7]naphthyridin-8-one* ***29***a

A solution of lactam ***27****a* (100 mg) in EtOH (15 mL) containing 10% Pd–C (50 mg) was treated with H_2 in a Parr hydrogenator at ca. 25 psig at room temperature for 3 h. The reaction mixture was filtered through Celite to remove catalyst and the Celite thoroughly washed with $CHCl_3$. The filtrate and washings were evaporated to dryness *in vacuo*

and the residue crystallized from EtOH, yielding white cubic crystals of **29***a* (100 mg, 99%); mp 185–187°C; R_f 0.45 (alumina, EtOAc), 0.26 (silica, EtOAc); ir ($CHCl_3$, film), ν_{max}: 1650 cm^{-1}; ^1H nmr (500 MHz), δ: 1.26 (3H, t, J = 7.6 Hz, —CH_2CH_3), 2.73–2.81 (4H, complex m, C-6 H_{ax}, —CH_2—CH_3, and C-5 H_{ax} H's), 2.93–2.97 (2H, m, C-5 H_{ax} and C-13 H_{ax}), 3.31 (1H, dd, J = 16.4 and 3.5 Hz, C-13 H_{eq}), 3.91 (3H, s, —OCH_3), 3.92 (3H, s, —OCH_3), 4.84 (1H, dd, J = 13.1 and 3.5 Hz, C-14 H), 4.98 (1H, m, C-6 H_{eq}), 6.69 (1H, s, C-4 H), 6.72 (1H, s, C-1 H), 8.54 (1H, s, C-11 H), and 9.16 (1H, s, C-9 H); ^{13}C nmr (125.76 MHz), δ: 14.6 (—CH_2CH_3), 23.1 (—CH_2CH_3), 29.1 (C-5), 34.0 (C-13), 38.6 (C-6), 54.2 (C-14), 56.0 (2 × OCH_3), 109.2, 111.8, 148.2, and 152.1 (4 × ArCH's), 124.4, 126.9, 127.6, 135.0, 143.6, and 148.4 (ArC's),[3] and 163.6 (>C=O); ms (EI), m/z (%): 338 (100) $M^{+\cdot}$, 337 (76), 323 (61), 309 (37), 307 (50), 192 (8), 191 (27), 190 (37), 147 (34), 119 (63), 92 (24), and 91 (82). *Exact Mass* calcd. for $C_{20}H_{22}N_2O_3$: 338.163; found (hrms): 338.161.

*(b) 12-Ethyl-5,6,13,14-tetrahydro-2-hydroxy-3-methoxy-8*H*-isoquino[2,1-*b*][2,7]naphthyridin-8-one **29***b*

Hydrogenation of lactam **1** (10 mg) with 10% Pd–C (10 mg) in EtOH (15 mL) by the method described above for the hydrogenation of **27***a* gave compound **29***b* (10 mg, 99%), which crystallized as colorless crystals from MeOH; mp 228°C (lit. (7) mp 232°C (EtOH)); R_f 0.44 (silica, 10% MeOH in $CHCl_3$); ir ($CHCl_3$, film), ν_{max}: 1655 cm^{-1}; ^1H nmr (500 MHz), δ: 1.24 (3H, t, J = 7.7 Hz, —CH_2—CH_3), 2.71–2.79 (4H, complex m, —CH_2CH_3, C-5 H_{ax} and C-6 H_{ax} H's), 2.94–2.98 (2H, m, C-5 H_{eq} and C-13 H_{ax} H's), 3.33 (1H, dd, J = 16.4 and 3.6 Hz, C-13 H_{eq}), 3.92 (3H, s, —OCH_3), 4.80 (1H, dd, J = 13.3 and 3.6 Hz, C-14 H), 4.95–4.98 (1H, m, C-6 H_{aq}), 5.75 (1H, s, exchanges with D_2O, phenolic OH), 6.69 (1H, s, C-4 H), 6.81 (1H, s, C-1 H), 8.54 (1H, s, C-11 H), and 9.15 (1H, s, C-9 H); ^{13}C nmr (125.76 MHz), δ: 14.9 (—CH_2CH_3), 23.3 (—CH_2CH_3), 29.3 (C-5), 34.0 (C-13), 38.9 (C-6), 54.2 (C-14), 56.2 (—OCH_3), 111.1, 111.8, 126.7, 127.8, 130.6, 135.3, 142.8, 143.8, 148.4, 150.2, and 152.3 (aromatic carbons), and 163.5 (>C=O); ms (EI), m/z (%): 324 (100) $M^{+\cdot}$, 323 (68), 309 (31), 307 (14), 295 (19), 178 (3), 177 (11), 176 (15), 162 (26), 147 (23), 119 (30), 92 (8), and 91 (32). *Exact Mass* calcd. for $C_{19}H_{20}N_2O_3$: 324.147; found (hrms): 324.147.

C. TRINGALI, M. PIATTELLI, C. GERACI, G. NICOLOSI, and C. ROCCO. Can. J. Chem. **65**, 2369 (1987).

Two previously unreported antibiotic metabolites, 2′,3′,4″-triacetoxy-3,4,5′,6′-tetrahydroxy-*p*-terphenyl (**10**) and 2′,3′-diacetoxy-3,4,5′,6′,4″-pentahydroxy-*p*-terphenyl (**11**), have been isolated from the basidiomycete *Sarcodon leucopus*. Their structures have been determined by chemical transformations and spectral analysis, including heteronuclear two-dimensional nuclear magnetic resonance methods.

C. TRINGALI, M. PIATTELLI, C. GERACI, G. NICOLOSI et C. ROCCO. Can. J. Chem. **65**, 2369 (1987).

On a isolé deux nouveaux métabolites d'antibiotiques du basidiomycète *Sarcodon leucopus*; il s'agit du triacétoxy-2′,3′,4″ tétrahydroxy-3,4,5′,6′ *p*-terphényle (**10**) et du diacétoxy-2′,3′ pentahydroxy-3,4,5′,6′,4″ *p*-terphényle (**11**). On a déterminé leurs structures en faisant appel à des transformations chimiques et à des analyses spectrales, y compris des méthodes de résonance magnétique nucléaire hétéronucléaire en 2D.

[Traduit par la revue]

Introduction

Natural *p*-terphenyl derivatives occur in fungi mostly as 2,5-diphenyl-1,4-benzoquinones (1, 2). Fully aromatic *p*-terphenyl compounds from Basidiomycetes are less common and include protoleucomelone **1** from *Polyporus leucomelas* (3), the first to be isolated, dibenzoylleucoaurantiacin **2** from *Hydnum aurantiacum* (4), and 2′,3′,5′-trimethoxy-*p*-terphenyl **3** from *Peniophora gigantea* (5). *Aspergillus candidus*, a member of the Ascomycetes, has yielded terphenyllin **4** (6–8), deoxyterphenyllin **5** (9), 3-hydroxyterphenyllin **6** (10), 3,3″-dihydroxyterphenyllin **7** (11), and candidusin A (**8**) and B (**9**) (12, 13). Compounds **4** and **5** are reported to be active against HeLa cells, while **6–9** are effective inhibitors of sea urchin embryonic development.

The present paper describes the structure determination of two previously unreported bioactive *p*-terphenyl derivatives isolated from *Sarcodon leucopus* (Pers.) (Basidiomycetes).

The crude aqueous acetone extract from the fruiting bodies of *S. leucopus* possesses antimicrobic activity against both Gram-positive and Gram-negative bacteria. Activity-guided separation of the crude extract resulted in the isolation of two compounds, **10** and **11**, which accounted for most of the bioactivity. They gave phenolic reactions (ferric chloride and diazonium salts) and showed aromatic absorption in the uv spectrum. The ir spectrum displayed, in addition to benzenoid bands, absorptions associated with hydroxy (3420 cm^{-1}) and acetate (1760 cm^{-1}) groups. The empirical formulae, as established by exact mass measurement and nmr data, were found to be $C_{24}H_{20}O_{10}$ for **10** and $C_{22}H_{18}O_9$ for **11**. It is to be noted that in the mass spectrum of both compounds an ion was clearly discernible at 42 amu higher than the parent ion, which was explained as the result of an intermolecular transacetylation occurring in the mass spectrometer. Acetylation of both metabolites gave the same heptaacetate $C_{32}H_{28}O_{14}$. This result and considerations of the ^1H and ^{13}C nmr spectra (Tables 1, 2) allowed expansion of the molecular formulae to $C_{18}H_7(OH)_4(OAc)_3$ and $C_{18}H_7(OH)_5(OAc)_2$, respectively, and indicated a terphenyl as the parent hydrocarbon. The observation that the melting point of the heptaacetate closely compares to that reported for protoleucomelone **1** was suggestive of the identity of the two compounds and this, if confirmed, would have defined the carbon skeleton and, in addition, the oxygenation pattern in both **10** and **11**. Unfortunately, lack of spectral data about protoleucomelone as well as unavailability of a reference sample prevented us from clarifying this point. Formation of *p*-terphenyl by zinc-dust distillation of **10** settled the nature of the carbon skeleton, while as concerns further structural aspects of **10** and **11** we decided to rely mainly on their spectral properties.

The ^1H nmr spectrum of **10** displays, in addition to the resonances of the acetates, signals in the aromatic region due to strongly coupled spin systems. Two resonances centered at δ 7.38 and 7.12, respectively (2H each, N = 8.5 Hz), form an AA′BB′ system arising from the protons of a 1,4-disubstituted benzene ring; by comparison with the pertinent data for related compounds (**4** and **5**) (6–9), the former was assigned to the isochronous protons at the 2″ and 6″ positions, and the latter to the protons at the 3″ and 5″ positions. The rest of the spectrum was a three-spin system due to protons in a 1,4,5-trisubstituted aromatic ring.

The ^{13}C nmr spectrum of **10** contains 21 distinct resonances. Signals at 20.2 (2C), 21.1, 169.7, 169.8, and 170.7 ppm were readily assigned to three acetate groups. Based on a DEPT sequence, five of the remaining resonances could be associated with hydrogen-bearing carbons, four with quaternary carbons, and seven with O-substituted sp^2 carbons. One-bond H,C correlations were identified with signals at 121.7 (2C, C-3″ and C-5″) and 131.8 ppm (2C, C-2″ and C-6″), while chemical shift substituent effects allowed assignment of the remaining resonances arising from hydrogenated carbons (117.5 (C-2),

3′-OAc	1.95[d]	s		1.94[d]	s	
4″-OAc	2.30	s				

[a]Measured in $CDCl_3$–CD_3OD (7:3); chemical shifts (δ) are relative to CH_3OD at δ 3.30.
[b]*J* values are expressed in Hz.
[c]$N = J_{AB} + J_{AB'}$, with $J_{AB'} < 0.5$ Hz.
[d]Values with identical superscript within each column may be interchanged.

115.8 (C-5), and 122.4 (C-6) ppm. Confirmation was obtained from gated decoupled and H,C-COLOC spectra, as well as literature data for terphenyllin triacetate and 3-hydroxyterphenyllin (10). Assignment of the signals at 144.9 (C-3), 145.1 (C-4), and 150.5 (C-4″) ppm essentially followed from three-bond carbon–proton couplings. Resonances at 133.7, 133.8, 141.1, and 141.2 ppm, which appear as sharp singlets in the gated decoupled spectra, are due to oxygen-bonded carbons in the central ring. Finally, assignment of signals at 121.6 (C-4′), 123.1 (C-1′), 123.9 (C-1), and 130.8 (C-1″) ppm was based on J_{CH} values and carbon–proton shift correlations via two- and three-bond coupling.

The oxygenation pattern having been determined, the last point to be assessed was the location of the acetate groups. In the ^1H nmr spectrum of **10**, two of these groups resonate at higher field (δ 1.93 and 1.95) and, on the basis of literature data (14–16), must be located on the central ring, while the third appears at decidedly lower field (δ 2.30), indicating its location on an outer ring. When compound **10** was reacted with phenylboronic acid and the reaction mixture examined directly by mass spectrometry (attempts towards isolation of individual product(s) resulted in extensive hydrolytic removal of phenylboronate groups), a parent ion was observed at *m/z* 640, indicating the formation of a bis-phenylboronate (**12**). Therefore the novel fungal metabolite must have structure **10**.

The second compound, **11**, isolated from *S. leucopus*, possesses spectral properties very similar to those of **10**, the only obvious differences being associated with the presence of only two acetate groups, both resonating at high field (δ 1.92 and 1.94). Also in this case, reaction with phenylboronic acid yielded a bis-phenylboronate **13**, *m/z* 598 (as observed in the parent compound, in the mass spectrum of the reaction mixture a peak was discernible at 42 amu higher than the parent ion). Therefore the novel fungal metabolite was formulated as **11**.

The results obtained in the agar dilution test of compounds **10** and **11** against several Gram-positive and Gram-negative bacteria are reported in Table 3.

Experimental

Melting points were determined on a Kofler block and are uncorrected. Mass spectra were obtained at 70 eV with a Kratos MS-50S spectrometer. The ir and uv spectra were recorded with Perkin–Elmer

684 and Perkin–Elmer 330 spectrometers, respectively. Fruiting bodies of *Sarcodon leucopus* were collected on Mount Etna in November 1985.

*Isolation of compounds **10** and **11***

Fresh plant material (3.5 kg) was extracted three times with acetone–water (final concentration 70%). Bulk extracts were evaporated under reduced pressure to remove acetone and the residual aqueous suspension extracted five times with ether. The ether extracts were pooled, dried over Na_2SO_4, and taken to dryness to give a crude extract (11 g) that was chromatographed on an open column of silica gel (5 × 100 cm; a gradient of Et_2O in hexane followed by a gradient of MeOH in Et_2O as the eluents). Fractions of 50 mL were collected and pooled according to their tlc profiles. Compound **10** was eluted in fractions 39–43 and further purified by successive chromatographies on silica gel, using as solvent MeOH–CH_2Cl_2 1:24 vol/vol and then acetone–hexane 1:1 vol/vol, to give 70 mg of pure compound. Further chromatographic purification (silica gel, MeOH–CH_2Cl_2 1:12 vol/vol as the eluent) of fractions 45–55 gave pure **11** (185 mg).

2′,3′,4″-Triacetoxy-3,4,5′,6′-tetrahydroxy-p-*terphenyl (**10**)*: uv (EtOH) λ_{max} (ε): 204 (33 800), 270 (28 350) nm; ir (KBr): 3420, 3050, 2930, 1750, 1730, 1610, 1525, 1455, 1370, 1210, 1095, 1020, 980 cm^{-1}; hrms, m/z calcd. for $C_{24}H_{20}O_{10}$: 468.1056 (M^+); found: 468.1049 (15%), 510 ($M^+ + CH_2CO$, 5%), 426 ($M^+ - CH_2CO$, 66%), 384 ($M^+ - CH_2CO \times 2$, 100%), 342 ($M^+ - CH_2CO \times 3$, 46%), 326 (11%), 323 (11%), 57 (15%), 43 (48%). ^1H and ^{13}C data are given in Tables 1 and 2.

2′,3′-Diacetoxy-3,4,5′,6′,4″-pentahydroxy-p-*terphenyl (**11**)*: uv (EtOH) λ_{max} (ε): 205 (46 200), 265 (15 300) nm; ir (KBr): 3420, 3050, 2935, 1750, 1730, 1620, 1520, 1460, 1435, 1370, 1230, 1090, 1020, 980 cm^{-1}; hrms, m/z calcd. for $C_{22}H_{18}O_9$: 426.0951 (M^+); found: 426.0957 (6%), 468 ($M^+ + CH_2CO$, 15%), 385 (10%), 384 ($M^+ - CH_2CO$, 27%), 344 (6%), 343 (14%), 342 ($M^+ - CH_2CO \times 2$, 100%), 341 (10%), 340 (12%), 326 (12%), 324 ($M^+ - CH_2CO \times 2 - H_2O$, 5%), 323 (8%), 43 (35%). ^1H and ^{13}C data are given in Tables 1 and 2.

*Acetylation of compounds **10** and **11***

A solution of **10** (25 mg) in pyridine (0.5 mL) and acetic anhydride (1 mL) was stirred at room temperature for 1 h. Conventional work-up and flash chromatography (silica gel, acetone–hexane 3:7 vol/vol as the eluent) of the crude product provided the heptaacetate **1** (30 mg), mp 205–207°C (from acetone) (lit. (3) mp for protoleucomelone 204–205°C); uv (EtOH) λ_{max} (ε): 204 (52 600), 249 (19 100) nm; ir (KBr): 3020, 2400, 1780, 1520, 1460, 1440, 1375, 1215, 1100, 1030, 910 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3-CD_3OD$ 7:3) δ: 7.19, 7.24, 7.26 (H-2, H-5, H-6, ABC system), 7.37, 7.17 (H-2″, H-3″, H-5″, H-6″, AA′BB′ system, N = 8.5 Hz), 2.02, 2.07 (2s, 2′-, 6′-OAc and 3′-, 5′-OAc), 2.31, 2.33, 2.34 (3s, 3-, 4-, 4″-OAc); ^{13}C nmr (50.2 MHz, $CDCl_3-CD_3OD$ 7:3) δ: 130.0 (C-1), 125.6 (C-2), 142.4

(C-3), 142.8 (C-4), 123.7 (C-5), 128.2 (C-6), 129.7 (C-1′), 139.6 and 139.7 (C-2′, C-3′, C-5′, C-6′), 130.9 (C-4′), 129.1 (C-1″), 131.1 (C-2″, C-6″), 122.0 (C-3″, C-5″), 151.4 (C-4″), 168.5 (2 × $COCH_3$), 168.6 (2 × $COCH_3$), 169.0 (2 × $COCH_3$), 170.1 ($COCH_3$), 20.0 (4 × $COCH_3$), 20.5 ($COCH_3$), 20.6 ($COCH_3$), 21.1 ($COCH_3$) ppm; ms, *m/z*: 636 (M^+, 0.5%), 594 ($M^+ - CH_2CO$, 4%), 552 ($M^+ - CH_2CO \times 2$, 58%), 510 ($M^+ - CH_2CO \times 3$, 85%), 470 (73%), 468 ($M^+ - CH_2CO \times 4$, 100%), 428 (44%), 427 (84%), 426 ($M^+ - CH_2CO \times 5$, 58%), 386 (78%), 384 ($M^+ - CH_2CO \times 6$, 49%), 366 (17%), 344 (61%), 343 (29%), 342 (27%), 326 (12%), 325 (36%), 315 (17%), 46 (75%). Under the same experimental conditions **11** gave a compound indistinguishable (ms, uv, ir, nmr) from **1**.

*Zinc dust distillation of **10***

An intimate mixture of compound **10** (20 mg) and zinc dust (800 mg) was distilled in an open test tube. The sublimate was dissolved in hexane and purified by hplc (Whatman Partisil PXS 10/25 silica gel, hexane), to give *p*-terphenyl (2 mg), mp 210–211°C, undepressed on admixture with an authentic sample; uv (EtOH) λ_{max} (ε): 277 (26 900) nm; ms, *m/z*: 230 (100%), 228 (10%), 115 (12%), 101 (4%), 57 (11%), 43 (15%).

*Reaction of **10** and **11** with phenylboronic acid*

A solution of **10** (5 mg) and phenylboronic acid (3 mg) in acetone (0.5 mL) was refluxed for 4 h. After removal of the solvent, the residue was examined by mass spectrometry without any further purification. A parent ion at *m/z* 640 indicated the formation of a bis-phenylboronate; major fragments were observed at *m/z* 598 ($M^+ - CH_2CO$, 15%), 556 ($M^+ - CH_2CO \times 2$, 100%), 555 (53%), 514 ($M^+ - CH_2CO \times 3$, 75%), 513 (47%), 470 (50%), 469 (18%), 428 (22%), 427 (12%), 78 (19%), 44 (56%).

When **11** was reacted with phenylboronic acid under the same experimental conditions as above, mass spectral examination of the crude product gave evidence of a parent ion at *m/z* 598, indicating the formation of bis-phenylboronate also in this case; major ions were observed at *m/z* 640 ($M^+ + CH_2CO$, 16%), 556 ($M^+ - CH_2CO$, 60%), 555 (30%), 514 ($M^+ - CH_2CO \times 2$, 64%), 513 (36%), 78 (100%), 44 (76%), 43 (80%).

Proton and carbon nuclear magnetic resonance spectra

The nmr spectra were recorded at 200 MHz (^1H) and 50 MHz (^{13}C), respectively, using a Bruker AC-200 instrument equipped with a carbon-13–proton dual probehead, an Aspect 3000 data system, and a 160 MByte Disk cartridge. One-dimensional proton and carbon-13 Fourier transform nmr spectra with sweep widths and transmitter frequencies optimized for the lowest possible digital resolution (Hz/data point) were obtained from 32 K free induction decay signals. Gaussian resolution enhancements for proton nmr and exponential multiplication for carbon-13 nmr were applied before performing Fourier transformations; LB (line broadening) constants were adapted to the digital resolution. Coupled carbon-13 nmr spectra were obtained using the gated decoupling technique. Two-dimensional carbon-13–proton shift correlation was performed by polarization transfer via J_{CH}. Relaxation delays were 0.8 s; incremented delays of 1/8 W were adapted to the individual proton chemical shift ranges optimized as described previously. Polarization transfer delays ($1/2J_{CH}$ = 0.35 s and $1/^{2,3}J_{CH}$ = 0.1 s) were adapted to the expected averages of one-bond couplings (J_{CH} = 150 Hz) for CH correlations and two- or three-bond couplings ($^{2,3}J_{CH}$ = 5 Hz) for long-range CH correlations. The commercially available microprogram XHCORR for X–H shift correlation was used throughout, and 1024 × 256 data matrices were applied for the carbon and proton chemical shift domains. Shifted ($\pi/4$) sine squared shaping functions were applied before performing Fourier transformation in both domains.

Antibacterial activity

In the course of fractionation, antibacterial activity was followed by the paper disc – agar diffusion assay using *Staphylococcus aureus* as test organism. The minimum inhibitory concentrations (MICs) were determined by the conventional agar dilution method. All test strains were grown in Mueller Hinton medium incubated at 37°C for 18 h. Data of antibacterial activity are reported in Table 3.

Acknowledgements

FERNANDO MATA-PEREZ and JOAQUIN F. PEREZ-BENITO. Can. J. Chem. **65**, 2373 (1987).

The oxidation of methylamine by permanganate ion in aqueous phosphate buffers is autocatalyzed by a soluble form of colloidal manganese dioxide temporarily stabilized in solution by adsorption of phosphate ions on its surface. The dependence of the rate constants of both the noncatalytic and catalytic mechanisms on the concentrations of both methylammonium and hydroxyl ions and on temperature has been determined. The activation parameters have been obtained. Mechanisms in agreement with the experimental data are proposed.

FERNANDO MATA-PEREZ et JOAQUIN F. PEREZ-BENITO. Can. J. Chem. **65**, 2373 (1987).

L'oxydation de la méthylamine par l'ion permanganate, en solution dans des tampons de phosphates, est autocatalysée par une forme soluble du bioxyde de manganèse colloïdal qui est temporairement stabilisée en solution par adsorption des ions phosphates sur sa surface. On a déterminé les relations qui existent entre les constantes de vitesse, tant des mécanismes catalysés que ceux des mécanismes non-catalysés, et soit les concentrations tant des ions méthylammonium que des ions hydroxyles soit la température. On a obtenu les paramètres d'activation. On propose des mécanismes qui sont en accord avec les données expérimentales.

Introduction

Although some kinetic studies on the permanganate ion oxidation of tertiary (1, 2) and secondary (3) amines have been reported, little attention has been paid to the kinetic aspects of the oxidation of primary amines by permanganate ion, save for the case of benzylamine (4). On the other hand, the products from the oxidation of a wide variety of amines by permanganate ion are known (5–7).

We have now undertaken the kinetic study of the permanganate ion oxidation of methylamine in aqueous phosphate buffers. This reaction is clearly of the autocatalytic type.

Autocatalysis seems to be a rather general phenomenon for the oxidation of amines by permanganate ion (2–4, 8), but is by no means limited to amines, for many permanganate reactions have been found to be autocatalytic (9–27).

Despite the extensive occurrence of autocatalysis in permanganate reactions, there is not much information on the autocatalytic mechanism, since for the sake of simplicity the kinetic parameters of the autocatalytic pathway are, more often than not, ignored.

To compensate for that lack of information, in the work reported here a great deal of emphasis has been placed on the comprehension of both the noncatalytic and catalytic processes involved in the oxidation of methylamine by permanganate ion.

Experimental

The solvent used in all the experiments was triply-distilled water. The oxidant was potassium permanganate and the reductant (in great excess with respect to the oxidant) was methylamine in the chlorhydrate form.

A KH_2PO_4–NaOH buffer mixture was used with a double purpose: to stabilize temporarily in solution the Mn(IV) species generated as a reaction product, thus avoiding the appearance of a MnO_2 precipitate while the kinetic measurements were being taken (28), and to keep the pH of the medium constant. In the pH range 6–8 allowed by the buffer, the amine was present chiefly in the protonated form, since the pK_a corresponding to methylammonium ion is 10.62 (29).

In the experiments where the reductant concentration or the pH were changed, the ionic strength was held constant by addition of proper amounts of potassium chloride. The same electrolyte was used when the ionic strength of the medium was the factor to be changed.

The kinetic runs were followed by monitoring the disappearance of permanganate ion at 525 nm by means of a PE Coleman-55 spectrophotometer provided with a thermostated cell. The contribution from the reaction product to the total absorbance was discounted (30).

The pH's of the solutions were measured by means of a Radiometer pH-meter 51, and the temperature was controlled using a conventional thermostat.

In a typical experiment, two flasks, one of them containing 100 mL of a solution 10^{-3} *M* in potassium permanganate and the other containing the same volume of a solution 2.40 *M* in methylammonium chloride, were kept in a thermostatic bath at 25.0°C long enough to reach the thermic equilibrium. Both solutions were buffered at pH 8.0. Then the solution containing the organic substrate was added to the permanganate solution, the mixture was vigorously stirred, and an aliquot was extracted with the aid of a syringe and then injected into the thermostated cell. The absorbances at 525 nm were periodically taken until total permanganate consumption.

Results

A decrease in the absorbance at 525 nm and an increase at 420 nm (wavelength at which permanganate is transparent) were observed in all the experiments. The solutions passed successively through the following colours: purple (reactant), red (reactant + product), and brown-yellow (product). The spectrum recorded for the product solution when all the permanganate had been consumed showed a broad band with the absorbance continuously decreasing with increasing wavelength. Similar spectra were obtained in many permanganate reactions (2, 3, 27, 31–42). The solutions remained totally clear throughout the reaction, and a brown precipitate of managanese dioxide was observed the day after.

As illustrated by Fig. 1, all the reaction rate vs. time plots showed a definite bell-shaped profile, the rate having been calculated point by point from the experimental data as minus the derivative of the permanganate concentration with respect to time; i.e., the reaction is autocatalytic. Therefore two mechanisms have to be involved in the total process to account for both the acceleration and decay periods of the reaction

rate (43). This duality of mechanism must be reflected in the differential rate equation.

If we assume that the noncatalytic mechanism is first order in one of the reactants (permanganate ion), and the catalytic mechanism first order in both reactant and autocatalytic product since the kinetics were performed in great excess of the other reactant (methylamine), the differential rate law can be written as follows:

$$[1] \quad r = k_1[\mathrm{R}] + k_2[\mathrm{R}][\mathrm{P}]$$

where k_1 and k_2 are the pseudo rate constants corresponding to the noncatalytic and catalytic mechanisms, respectively.

Equation [1] can also be expressed in the following manner:

$$[2] \quad -\mathrm{d}c/\mathrm{d}t = k_1 c + k_2 c(c_0 - c)$$

c and c_0 being the permanganate concentrations at time t and at the beginning of the reaction, respectively.

The integral form of eq. [2] is

$$[3] \quad \ln [k_1 + k_2 c_0 - k_2 c)/c] = \ln (k_1/c_0) + (k_1 + k_2 c_0)t$$

This equation was successfully used for the kinetic study of the permanganate ion oxidation of dimethylamine (3) and trimethylamine (2) and was also proposed for the acid-catalyzed hydrolysis of esters (44).

By fitting the left-hand side of eq. [3] against time by the least-squares method a linear correlation is obtained, and from the intercept and the slope of that straight line the values of the rate constants can be derived. However, it is clear that the values of both k_1 and k_2 must first be known, to make that fit possible. This paradoxical situation has been resolved by means of an iterative procedure. The left-hand side of eq. [3] is fitted against time by the help of some trial values of the rate constants; from the intercept and the slope thus obtained, new values of k_1 and k_2 are inferred and the cycle is repeated until convergence is achieved.

Figure 2 shows an excellent agreement between eq. [3] and the experimental data for a typical kinetic run. The linear correlation coefficient associated with eq. [3] remained in all the cases within the limits 0.9992 and 0.99997.

Since the integral rate law (eq. [3]) is fulfilled, it follows that the kinetic order of permanganate ion in both mechanisms and that of the autocatalytic agent in the catalytic pathway are unity (see eqs. [1] and [2]).

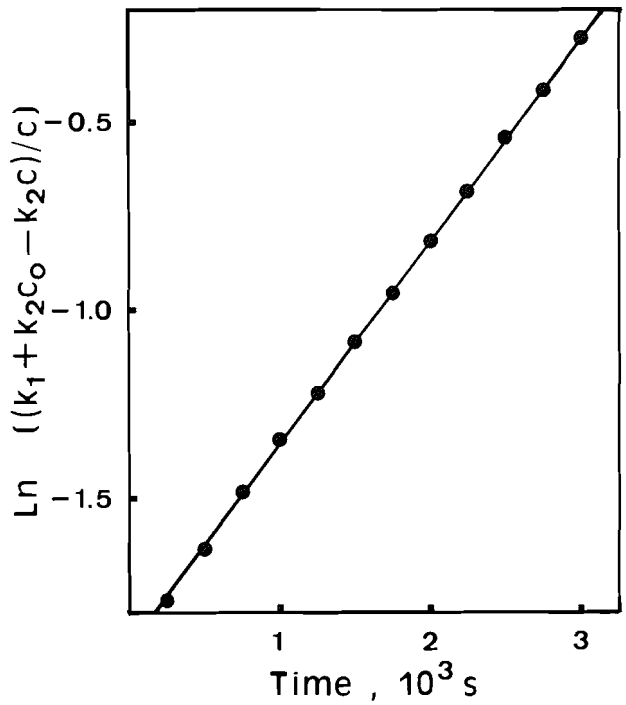

FIG. 2. Rate-law plot. Initial permanganate concentration, 5×10^{-4} *M*; methylammonium ion concentration, 1.20 *M*; ionic strength, 1.35 *M*; pH, 8.0; temperature, 25.0°C (r = 0.9999).

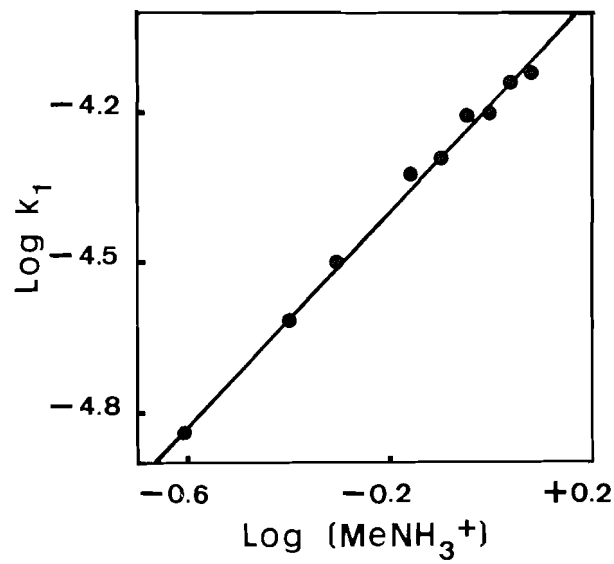

FIG. 3. Dependence of the rate constant of the noncatalytic mechanism on the methylammonium ion concentration. Initial permanganate concentration, 5×10^{-4} *M*; ionic strength, 1.35 *M* (KCl); pH, 8.0; temperature, 25.0°C (slope = 1.07, r = 0.998).

The values of the rate constants corresponding to different methylammonium ion concentrations have been determined. We can see in Fig. 3 that a log k_1 vs. log $[MeNH_3^+]$ plot is linear, the slope of that correlation being 1.07. Thus, the noncatalytic mechanism is first-order dependent on the substrate concentration. On the other hand, Fig. 4 indicates that there exists a linear relationship between $1/k_2$ and $1/[MeNH_3^+]$.

A plot of k_1 vs. $[OH^-]$ is also linear (see Fig. 5); since the intercept is different from zero, it follows that a log k_1 vs. log $[OH^-]$ plot is not linear. In the case of the catalytic

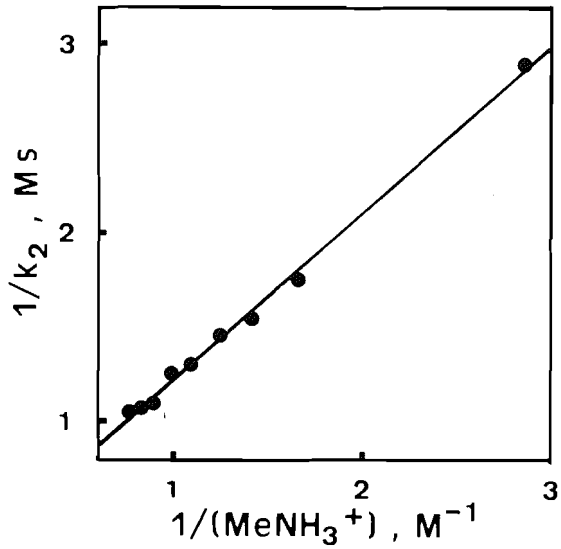

FIG. 4. Dependence of the rate constant of the catalytic mechanism on the methylammonium ion concentration. Initial permanganate concentration, 5×10^{-4} M; ionic strength, 1.35 M (KCl); pH, 8.0; temperature, 25.0°C ($r = 0.997$).

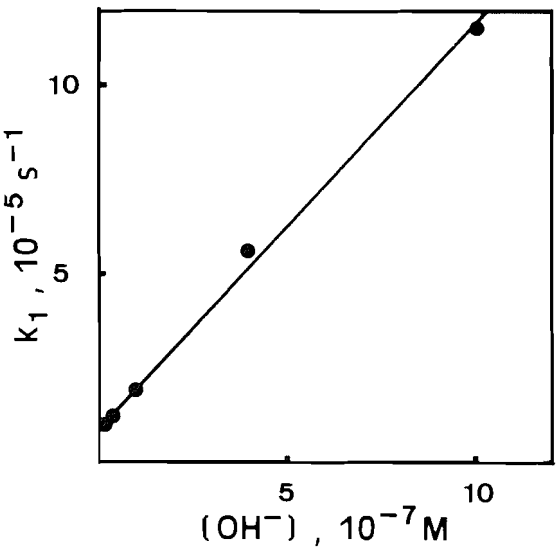

FIG. 5. Dependence of the rate constant of the noncatalytic mechanism on the hydroxyl ion concentration. Initial permanganate concentration, 5×10^{-4} M; methylammonium ion concentration, 0.30 M; ionic strength, 0.45 M (KCl); temperature, 50.0°C ($r = 0.999$).

mechanism linearity is found, however, in a correlation of the type $\log k_2$ vs. $\log [OH^-]$ (see Fig. 6).

The rate constants at several potassium chloride concentrations are given in Table 1. We can see that both k_1 and k_2 decrease as the ionic strength of the medium increases.

The values of k_1 and k_2 at different temperatures were also determined and are listed in Table 2. Both rate constants fulfill the Arrhenius equation, and the corresponding energies of activation are compiled in Table 3.

Discussion

As far as the noncatalytic mechanism is concerned, the following two rate-determining steps can be proposed:

[4] $CH_3NH_3^+ + OH^- \overset{\text{fast}}{\rightleftharpoons} CH_3NH_2 + H_2O$

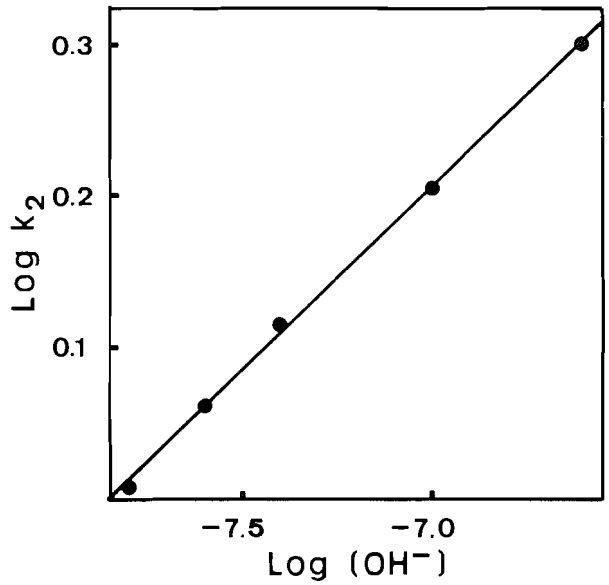

FIG. 6. Dependence of the rate constant of the catalytic mechanism on the hydroxyl ion concentration. Initial permanganate concentration, 5×10^{-4} M; methylammonium ion concentration, 0.30 M; ionic strength, 0.45 M (KCl); temperature, 50.0°C (slope = 0.24, $r = 0.999$).

TABLE 1. Dependence of the rate constants on the ionic strength[a]

Ionic strength (M)[b]	$10^5 k_1$ (s^{-1})	k_2 ($M^{-1} s^{-1}$)
0.65[c]	1.50	0.235
0.75	1.43	0.219

[5] $CH_3NH_2 + MnO_4^- \overset{\text{slow}}{\longrightarrow} CH_3NH_2^{+\bullet} + MnO_4^{2-}$

Accordingly, the noncatalytic portion of the total rate is

[6] $r_1 = k_5[MnO_4^-][MeNH_2]$

where k_5 is the rate constant associated with eq. [5]. Now, if the free and protonated forms of the amine are in equilibrium, we

[c]Activation parameters associated with rate constant k_5. From eqs. [12] and [13].

can also write:

[7] $r_1 = K_4k_5[MnO_4^-][MeNH_3^+][OH^-]$

K_4 being the equilibrium constant corresponding to eq. [4].

Equation [7] is in full agreement with the kinetic orders found for the oxidizing and reducing agents in the noncatalytic pathway (see eq. [2] and Fig. 3).

Moreover, Fig. 5 shows that the noncatalytic mechanism is first-order dependent on the hydroxyl ion concentration, as required by eq. [7]. Although the existence of an intercept different from zero suggests that the protonated form of the amine also has some reactivity toward permanganate ion, the small magnitude of that intercept indicates that this other modality of reaction is of very minor importance, the predominant oxidation being that of free methylamine by permanganate ion (see eq. [5]).

The experimental rate law found for the noncatalytic pathway in the permanganate ion oxidation of methylamine (see eq. [7]) is quite similar to those reported for the oxidation of dimethylamine (3) and of trimethylamine (2) by permanganate.

It has been observed that electrolyte additions slow down the reaction; this behavior is probably due to a decrease in equilibrium constant K_4 as the ionic strength of the medium increases, for eq. [4] implies the encounter of two ions with unlike charges.

We can easily see that eqs. [4] and [5] fully agree with the experimental results. However, it has been much discussed whether the oxidation of amines occurs through transfer of an electron, of a hydrogen atom, or of a hydride ion (45, 46). Obviously, from the kinetic data found for the reaction, the type of particle transferred to permanganate ion from methylamine does not directly follow, since the three kinds of transfer would lead to the same rate law (see eq. [7]).

The study of deuterium isotope effects reported in the literature indicates that the permanganate oxidation of benzylamine shows a primary isotope effect (4) and that of trimethylamine a secondary one (47). Therefore, one must conclude that in the first case the predominant oxidation mechanism is one of hydrogen-atom or hydride transfer, while in the second case the predominant oxidation mechanism is one of electron transfer. Consequently, it seems that oxidation of the amine by transfer of a hydrogen atom or a hydride ion from the α position in the substrate to permanganate ion is reserved for those amines (such as benzylamine) that would lead to a free radical (for hydrogen-atom transfer) or to a carbocation (for hydride transfer) highly stabilized by resonance. For those substrates (such as trimethylamine and methylamine) that do not lead to resonance stabilized products, electron transfer seems to be the main oxidation mechanism.

Moreover, a comparison of the rate constants given in the literature for the oxidation of dimethylamine (3) and trimethylamine (2) by permanganate ion in aqueous phosphate buffers with the data reported in this paper for the oxidation of methylamine reveals that the sequence of reactivity toward permanganate ion is

[8] trimethylamine > dimethylamine > methylamine

that is, the reactivity decreases as the ionization potential of the amine increases (48). Thus it does not seem unreasonable to assume that electron transfer is most likely the process involved (see eq. [5]).

From eqs. [2] ane [7] it follows that the pseudo rate constant of the noncatalytic mechanism is

[9] $k_1 = K_4k_5[MeNH_3^+][OH^-]$

By taking into consideration the identity:

[10] $K_4 = K_a/[H^+][OH^-]$

where K_a is the equilibrium constant for dissociation of methylammonium ion, eq. [9] can also be written as follows:

[11] $k_5 = k_1[H^+]/K_a[MeNH_3^+]$

Therefore, although the experimental activation parameters associated with k_1 are only apparent, the true activation parameters corresponding to eq. [5] can be derived from them by means of eq. [11].

If $\Delta H^1_{\ddagger}$ and $\Delta S^1_{\ddagger}$ stand for the activation parameters obtained from a plot of the data compiled in Table 1 according to the function $\ln(k_1[H^+]/[MeNH_3^+]T)$ vs. $1/T$, while ΔH^0 and ΔS^0 are the thermodynamic magnitudes corresponding to the methylammonium dissociation constant K_a (data available in the literature (49)), it follows from eq. [11] that the activation parameters associated with the electron-transfer step (eq. [5]) are given by the expressions:

[12] $\Delta H^5_{\ddagger} = \Delta H^1_{\ddagger} - \Delta H^0$

[13] $\Delta S^5_{\ddagger} = \Delta S^1_{\ddagger} - \Delta S^0$

The true values of the activation parameters derived from eqs. [12] and [13], as well as those necessary for their obtention, are listed in Table 4. We can see that the electron-transfer step (eq. [5]) only accounts for a small part of the experimental activation enthalpy found for k_1, but the same step accounts for a large portion of the experimental activation entropy.

Though no information concerning the noncontrolling steps can be inferred from the kinetic results, we can propose a reasonable scheme for the obtention of the reaction products from the intermediary species generated in eq. [5].

By analogy with the mechanism proposed for the permanga-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

nate ion oxidation of trimethylamine (47), the noncontrolling steps of the reaction could be the following:

[14] $CH_3NH_2^{+\cdot} \rightarrow {}^{\cdot}CH_2NH_2 + H^+$

[15] ${}^{\cdot}CH_2NH_2 + MnO_4^- \rightarrow CH_2{=}NH_2^+ + MnO_4^{2-}$

[16] $CH_2{=}NH_2^+ + H_2O \rightarrow CH_2O + NH_4^+$

[17] $3MnO_4^{2-} + 2H_2O \rightarrow 2MnO_4^- + MnO_2 + 4OH^-$

According to this mechanism, it is supposed that the cation radical generated in eq. [5] first suffers the loss of a proton (eq. [14]) to be then oxidized by permanganate ion (eq. [15]), so that methyliminium ion is formed. By hydrolysis of the latter (eq. [16]) formaldehyde and ammonium ion are formed, while manganese dioxide comes from dismutation of manganate ion (eq. [17]).

A number of reasons supporting this mechanism can be outlined. In the first place, imines are thought to be likely intermediates in the permanganate oxidation of amines (4).

On the other hand, ammonia is one of the products obtained from the permanganate degradation of primary amines, while aldehydes are obtained as reaction products from the oxidation of primary, secondary, and tertiary amines by aqueous potassium permanganate (5–7); in particular, formaldehyde was obtained from the permanganate oxidation of dimethylamine when this volatile product was rapidly distilled from the product mixture into 2,4-dinitrophenylhydrazine reagent (7), whereas under the experimental conditions of this work formaldehyde is expected to be readily oxidized by permanganate to formic acid and, further, to carbon dioxide (50).

Finally, manganate ion is known to disproportionate into permanganate ion and manganese dioxide in all but very basic aqueous media, the disproportionation being instantaneous in acid and neutral solutions (45), thus explaining the spectrophotometric detection of colloidal manganese dioxide at the end of the reaction between permanganate ion and methylamine. The same product was detected in many permanganate reactions carried out in aqueous media (42, 51) and in methylene chloride solutions (52).

As far as the catalytic pathway is concerned, it has been reported that a soluble form of colloidal manganese dioxide, temporarily stabilized in aqueous solution by adsorption of phosphate ions on its surface (42), is the actual autocatalytic agent for the permanganate ion oxidation of amines in aqueous phosphate buffers (3, 8). This soluble colloid is also responsible for the spectra recorded at the end of many permanganate oxidations (2, 3, 27, 31–42), and the recording of the same spectrum after completion of the permanganate–methylamine reaction allows its identification in our system as well. Therefore, once manganese dioxide has been formed through the noncatalytic mechanism (eq. [17]), the catalytic mechanism taking place on the colloid surface can be determined by the following equations:

[18] $MnO_2 + CH_3NH_3^+ \overset{\text{fast}}{\rightleftharpoons}$ adsorbate

[19] Adsorbate + $MnO_4^- \overset{\text{slow}}{\longrightarrow}$ products

In eq. [18] a fast equilibrium for adsorption of methylammonium ion on colloidal manganese dioxide has been assumed. In fact, manganese dioxide is known to strongly adsorb cations on its surface (53). Then, methylammonium ion thus adsorbed may suffer an oxidative attack by a permanganate ion from the double layer surrounding the colloidal particles (eq. [19]). As a result, the reaction products are formed.

Hence, the rate equation associated with the catalytic pathway is

[20] $r_2 = k_{19}[MnO_4^-][\text{adsorbate}]$

where k_{19} is the rate constant corresponding to eq. [19].

If the ratio between the adsorbate and manganese dioxide concentrations is given by the Langmuir equation (54) as a function of the concentration of methylammonium ion in solution:

[21] $[\text{adsorbate}]/[MnO_2] = a[MeNH_3^+]/(1 + b[MeNH_3^+])$

we can also write eq. [20] as follows:

[22] $r_2 = ak_{19}[MnO_4^-][MnO_2][MeNH_3^+]/(1 + b[MeNH_3^+])$

and, by comparing eqs. [2] and [22], the pseudo rate constant of the catalytic mechanism is

[23] $k_2 = ak_{19}[MeNH_3^+]/(1 + b(MeNH_3^+])$

Equation [23] is in agreement with the relationship between k_2 and $[MeNH_3^+]$ found in Fig. 4.

On the other hand, correlations similar to the one shown in Fig. 6 have been found for adsorption of cations on colloidal manganese dioxide, since it has been established that the logarithm of the ratio between the concentrations of cation adsorbed and manganese dioxide increases linearly with the pH of the medium (55, 56). From eqs. [21] and [23] it follows that the logarithm of k_2 must increase linearly with the pH of the solution or, in other words, with the logarithm of the hydroxyl concentration (see Fig. 6).

There are several possibilities to explain this behavior. In the first place, hydrated manganese dioxide may be regarded as an ion exchanger (57, 58), according to the equilibrium:

[24] $MnO_2{-}H_2O + CH_3NH_3^+ \rightleftharpoons MnO_2{-}OH^-{-}CH_3NH_3^+ + H^+$

whose equilibrium constant is

[25] $K_{24} = [\text{adsorbate}][H^+]/[MnO_2][MeNH_3^+]$

leading to the following expression for the rate constant (from eqs. [2], [20], and [25]):

[26] $k_2 = k_{19}K_{24}[MeNH_3^+]/[H^+]$

or, by using the definition of the water ionic product (K_w):

[27] $k_2 = k_{19}K_{24}[MeNH_3^+][OH^-]/K_w$

Equation [27] can indeed explain the log k_2 vs. log $[OH^-]$ linear relationship found in Fig. 6. However, the experimental value of the slope (0.24) is much lower than the kinetic order unity expected from eq. [27] for hydroxyl ion in the catalytic mechanism. Moreover, eq. [27] requires that k_2 be directly proportional to $[MeNH_3^+]$, in open disagreement with the experimental situation (see Fig. 4).

A second alternative might be given by the following equilibrium:

[28] $MnO_2 + nOH^- \rightleftharpoons MnO_2{-}(OH^-)_n$

where n is the number of hydroxyl ions linked to the colloid per manganese dioxide molecule. Hydroxyl ions are actually known to be bonded to colloidal manganese dioxide (59). Hence hydroxyl ions, instead of molecules of water (see eq. [24]), might be the real active points for adsorption of methylammonium ion on the surface of the colloidal particles:

[29] $MnO_2{-}(OH^-)_n + CH_3NH_3^+ \rightleftharpoons$ adsorbate

Accordingly, eq. [21] can be rewritten as

[30] $$[\text{adsorbate}]/[MnO_2{-}(OH^-)_n] = a[MeNH_3^+]/(1 + b[MeNH_3^+])$$

and, if the equilibrium constant associated with eq. [28] is called K_{28}:

[31] $$[MnO_2{-}(OH^-)_n] = K_{28}[MnO_2][OH^-]^n$$

Froms eqs. [2], [20], [30], and [31]:

[32] $$k_2 = ak_{19}K_{28}[OH^-]^n[MeNH_3^+]/(1 + b[MeNH_3^+])$$

This equation represents an improvement with respect to eq. [23], since eq. [32] takes into account the dependence of k_2 on the hydroxyl ion concentration. According to eq. [32], log k_2 must be linear when plotted against log $[OH^-]$ (see Fig. 6), the slope being the number of hydroxyl ions fixed on the colloid surface per MnO_2 molecule (see eq. [28]). The experimental fractionary value for that slope (0.24) is indeed logical, for only those molecules of manganese dioxide belonging to the colloid surface are available for complexation with hydroxyl ions.

Unfortunately, it has been reported that the number of OH^- ions linked to each MnO_2 molecule increases with the pH of the medium (55); thus n is at best an average value for the pH range used.

Finally, as a third alternative, Figs. 4 and 6 might be the result of consecutive adsorption equilibrium of hydroxyl and methylammonium ions on the surface of colloidal manganese dioxide. If adsorption of hydroxyl ion is best described by an isotherm of the Freundlich type (60), while adsorption of methylammonium ion is best accounted for by an isotherm of the Langmuir type (54), and if hydroxyl ions previously adsorbed are the active points for adsorption of methylammonium ion on the colloid surface, a situation such as the one made evident by Figs. 4 and 6 is perfectly consistent with theoretical considerations.

In conclusion, the experimental results seem to indicate that the catalytic pathway takes place by reaction between a permanganate ion from the solution and a methylammonium ion previously adsorbed on the surface of colloidal manganese dioxide, hydroxyl ions linked to the colloid surface being the active points for adsorption of the protonated form of the amine. This explanation is consistent with previous reports found in the literature (2, 3, 8).

Synthetic studies on cyathins. Synthesis of the ring system

DALE E. WARD
Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received April 3, 1987

DALE E. WARD. Can. J. Chem. **65**, 2380 (1987).

The tricyclic intermediate **4** has been converted into **2**, a compound that possesses the ring system and stereochemistry of the cyathins. The transformation was accomplished by the preparation of **11**, which underwent efficient base catalysed epimerization to give **12**. Functional group manipulation and selective oxidation provided keto-aldehyde **16**. Upon treatment with acid, **16** undergoes stereoselective aldol cyclization, transacylation, and hemiacetal formation to give **18**. Methylation under basic conditions provides **4**.

DALE E. WARD. Can. J. Chem. **65**, 2380 (1987).

On a transformé l'intermédiaire tricyclique en composé **2** qui possède le système cyclique et la stéréochimie des cyathines. On a effectué cette transformation en procédant à la préparation du composé **11** qui, sous l'influence des bases, subit ensuite une épimérisation efficace conduisant au produit **12**. La manipulation du groupement fonctionnel et une oxydation sélective conduisent au céto-aldéhyde **16**. Par traitement avec de l'acide, le composé **16** subit une cyclisation aldolique stéréosélective, une transacylation et la formation d'un hémiacétal conduisant au produit **18**. Sa méthylation, utilisant des conditions basiques, fournit le composé **4**.

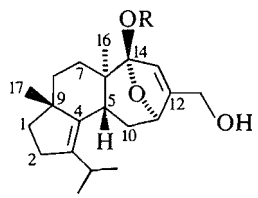
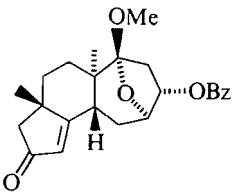
The cyathins (cf. cyathin A_3, **1***a*) are a unique family of diterpenoids produced by bird's nest fungi of the genus *Cyathus* (1). We have previously reported (2) on the preparation of the tricyclic compound **4** as an intermediate in our synthetic studies on cyathins. In this paper we describe the transformation of **4** into **2**, a compound that possesses the ring system and stereochemistry of the cyathins.



1*a* R = H, cyathin A_3
1*b* R = CH_3



2

The procedure for the preparation of **4** has been improved. Thus the 4:1 mixture of **3***a* and **3***b*, obtained as before (2), was oxidized with *m*-chloroperbenzoic acid in dichloromethane. The resulting mixture of epoxides was dissolved in tetrahydrofuran (THF) and the unsaturated ketone selectively reduced (3) with 9-borabicyclo[3.3.1]nonane (9-BBN). Excess borane was quenched by addition of methanol. After treatment with benzenethiol and base to induce epoxide ring opening, the resulting solution was refluxed with excess base to effect cyclization. Aqueous work-up provided an oil, which upon trituration with ether gave pure crystalline **4**. In this way, the mixture of photoadducts **3***a*,*b* could be converted into **4** in essentially "one pot" in 75% overall yield without the need of chromatography.

The cyathins possess a *trans* BC ring junction and thus we wished to epimerize the *cis*-6,6 ring junction in **4** to *trans*. We have previously (2) shown that **4** is the thermodynamically favored isomer. The major factor disfavoring the *trans* form is $A^{1,3}$ strain between the thiophenyl group and the C-13 methylene hydrogens. Thus the desulfurized derivative **5** (2) gives a 1:1.2 equilibrium mixture of *cis* and *trans* isomers after treatment with sodium methoxide in methanol. In an effort to improve on this ratio, we reasoned that if the C-8 carbonyl could be reduced to give the axial alcohol, the resulting 1,3 diaxial interaction between the C-8 -OH group and the C-13 methylene would further destabilize the *cis* form. To prevent any possible hydrogen bonding between a C-8 axial -OH group and the C-12 allylic alcohol, we sought to protect the latter.

Treatment of **4** with benzoic acid in the presence of triphenylphosphine and diethyl azodicarboxylate (4) gave the benzoate **6** with the desired (cf. C-11 in cyathin A_3) configuration at C-12. That inversion of configuration had indeed occurred in this reaction was readily demonstrated by direct benzoylation (benzoyl chloride, pyridine) of **4** to obtain a different benzoate. Reduction of **6** with sodium borohydride in methanol provided the mixture of alcohols **7**, which could be selectively oxidized by manganese dioxide to produce **8**. The presence of dichloromethane markedly reduced the rate of reduction of the unsaturated ketone with respect to the saturated one. Thus treatment of **6** with sodium borohydride in methanol–dichloromethane (1:1) at −78°C led exclusively to **8** in quantitative yield. The stereochemistry at C-8 was readily assigned by ^{1}H nmr spectroscopy; the C-8 hydrogen appears at δ 4.06 with equatorial–equatorial and equatorial–axial couplings (J = 2.5, 3 Hz). The attempted desulfurization of **8** with Raney nickel under a variety of conditions gave several products of which the desired **9** was, at best, a minor component. Alternatively, hydrolysis of **8** (NaOH, methanol) followed by treatment of the

SCHEME 1

resulting alcohol **10** with Raney nickel in methanol provided **11** in excellent yield. The role of the benzoate group in this reaction is unclear.

We were delighted to find that treatment of **11** with sodium hydroxide in refluxing methanol for 5 days led to a 95:5 (^{1}H nmr) mixture of **12** and **11** respectively. The stereochemistry was readily assigned by ^{1}H nmr. For **12**, the C-3 hydrogen appears at δ 5.82 and is coupled to the C-1 hydrogen (J = 1.5 Hz) whereas for **11**, the C-3 hydrogen appears at δ 6.0 as a singlet (2). While the rate of epimerization of **11** under these conditions is rather slow ($t_{1/2} \approx 24$ h), deuterium incorporation (NaOH, CH_3OD) at C-1 in **11** is complete within 4 h. The equilibrium ratio of **12** to **11** must be greater than 95:5 since a sample of pure **12** does not show epimerization (^{1}H nmr) after the same (NaOH, CH_3OH, reflux, 5 days) treatment. The separation of **12** from **11** is easily accomplished by trituration with ether, providing **12** in 65% overall yield from **4**.

With the four stereocenters of the cyathins in place in **12**, the next stage of our synthetic plan required deoxygenation at C-8 and cyclohexene ring expansion to produce the cyathin ring system.

The sterically hindered nature of the C-8 -OH group allowed the ready preparation (C_6H_5COCl, $(C_2H_5)_3N$, dimethylaminopyridine, 94%) of the monobenzoate **13**. Mesylation (CH_3SO_2Cl, C_5H_5N, 50°C), followed by elimination (DBU, toluene, 110°C) provided the triene **14**. The yield for the two steps was 76%. The disubstituted olefin could be selectively reduced using Wilkinson's catalyst under H_2 (50 psi; 1 psi = 6.9 kPa) for 48 h to give **15** in 92% yield.

The stage was set for ring expansion and towards this end a solution of **15** in 10% methanol in dichloromethane was "titrated" with O_3 at −78°C in the presence of Sudan III as indicator (5). The result was the selective oxidation of the isolated double bond to yield, after work-up, the sensitive keto-aldehyde **16**. While the presence of methanol was necessary for clean oxidation, there was a strong tendency for addition of methanol to the aldehyde to give varying mixtures of hemiacetals, acetal, and free aldehyde. This side reaction could be circumvented by the addition of a small amount of pyridine along with dimethyl sulfide (excess) at −78°C. Warming to room temperature and concentration provided **16** free from any hemiacetal or acetal. The benzoate group in **16** proved to be labile and all attempts at aldol cyclization led to hydrolysis and internal acetal formation to yield **17***a*. Structure **17***a* was assigned on the basis of its ^{1}H nmr spectrum. The most significant changes with respect to the spectrum of **16** are as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

follows: the aldehyde hydrogen is lost and a new one-hydrogen singlet appears at δ 5.32; the benzoate group is lost and the carbinol hydrogen is shifted upfield to δ 4.37; the acyl methyl group is shifted upfield to δ 1.45. The *exo* stereochemistry of the hemiacetal -OH group is assigned on the basis of the lack of coupling between the C-11 and C-12 (cyathin numbering) hydrogens (dihedral angle ≈ 90°).

Benzoate hydrolysis could be suppressed in favor of cyclization by treatment of **16** with dry *p*-toluenesulfonic acid in dry benzene (or toluene) at room temperature. In this way we could obtain a 3:1 mixture of **18** and **17***a* in 80% yield. Cyclization was always accompanied by transacylation; we were unable to detect the presence of any 11-benzoyloxy-12-hydroxy (cyathin numbering) compound in the reaction mixture. The driving force for this transacylation is, presumably, the formation of the stable internal hemiacetal. The ^{1}H nmr spectrum of **18** is fully assigned (with the exception of the C-7 and C-8 hydrogens) and is in complete accord with the indicated structure. The benzoyloxy group is assigned as *exo* due to the lack of coupling between the C-11 and C-12 hydrogens. Although the ^{1}H nmr spectrum of **18** exhibits sharp signals at room temperature, most of the resonances in the ^{13}C nmr spectrum could not be observed. This effect is due to hemiacetal–ketol interconversion. At −50°C all carbon resonances are observable and, significantly, C-14 appears at δ 108.6, indicating a predominance of the hemiacetal isomer. Interestingly, cyathin A_3 (**1***a*) shows broad signals in the ^{1}H nmr spectrum at room temperature while the ^{13}C nmr spectrum exhibits a set of signals for both the hemiacetal and ketol isomers (6).

In an effort to further characterize **18**, as well as to protect the hemiacetal, we attempted to prepare the corresponding methyl acetal **2**. In contrast to **1***a*, which readily forms **1***b* (**1***a*), we were unable to obtain **2** by treatment of **18** with methanol and acid under a variety of conditions. This result reflects the stability of the hemiacetal.[1] The preparation of **2** was finally accomplished by reaction of **18** with sodium hydride in the presence of iodomethane. With the exception of small changes in chemical shifts, the ^{1}H and ^{13}C nmr spectra of **2** are very similar to those of **18** and are fully consistent with the assigned structure.

Compound **2** possesses both the ring system and stereochemistry of the cyathins. While methods are available for introduction of a hydroxymethyl group at C-12 (7), the introduction of an isopropyl group at C-3 is not straightforward. Studies aimed at solving this problem are underway.

Experimental

All solvents except diethyl ether were distilled prior to use. ACS quality anhydrous diethyl ether was used without purification. Pyridine was distilled from CaH_2 and stored over molecular sieves, and THF was distilled under argon from potassium benzophenone ketyl. Unless otherwise noted, commercially available reagents were used as received.

Analytical thin-layer chromatography (tlc) was carried out on glass plates (70 × 20 or 70 × 50 mm) precoated (0.25 mm) with silica gel $60F_{254}$ (E. Merck, Darmstadt). Preparative thin-layer chromatography (ptlc) was carried out on glass plates (20 × 20 cm) precoated (0.25 mm) with the same adsorbent. Materials were detected by visualization under an ultraviolet (uv) lamp (254 or 350 nm), and (or) by spraying with a solution of phosphomolybdic acid (5%) containing a trace of ceric sulfate in aqueous sulfuric acid (5%, v/v), followed by charring on a hot plate. Flash column chromatography (8) was performed with Merck Silica Gel 60 (40–63 μm).

High resolution mass spectra (hrms) were recorded on an A.E.I. MS-50 mass spectrometer coupled to a DS 50 computer. Infrared (ir) spectra were recorded on a Nicolet 7199 FT interferometer on a Perkin–Elmer 781 infrared spectrophotometer. ^{1}H nuclear magnetic resonance (^{1}H nmr) spectra and ^{13}C nuclear magnetic resonance (^{13}C nmr) spectra were measured on a Bruker AM-300 spectrometer or a Bruker WH-400 spectrometer. For ^{1}H nmr, residual $CHCl_3$ in $CDCl_3$ was employed as the internal standard (assigned as 7.26 ppm downfield from tetramethylsilane (TMS)) and measurements are reported in ppm downfield from TMS (δ). For ^{13}C nmr, $CDCl_3$ was employed as the internal standard (assigned as 77.0 ppm downfield from TMS) and measurements are reported in ppm downfield from TMS (δ). The ^{1}H nmr assignments are made on the basis of chemical shift and multiplicity and, where necessary, confirmed by decoupling experiments. Coupling constants are reported to the nearest 0.5 Hz. The ^{13}C nmr assignments are made on the basis of chemical shift, multiplicity,[2] analogy with similar compounds (6), and consistency within the series of intermediates (9). Melting points were recorded on a Fisher–Johns melting point apparatus and are uncorrected.

cis-*12β-hydroxy-6β,9α,10-trimethyl-3-(phenylthio)tricyclo[7.4.0.0^{2,6}]-trideca-2,10-diene-4,8-dione* (**4**)

The 4:1 mixture of photoadducts **3***a* and **3***b* (1.009 g) was dissolved in CH_2Cl_2 (100 mL) and mCPBA (1.0 g) was added. The reaction was complete after 36 h (tlc: 5% CH_3OH in CH_2Cl_2), and $(CH_3)_2S$ (1 mL) was added. After 1 h the reaction mixture was washed with saturated $NaHCO_3$, dried with Na_2SO_4, and concentrated to give the mixture of epoxides (1.074 g, 100%). The epoxides were dissolved in dry THF (75 mL) and the solution was cooled in an ice bath. After addition of 9-BBN (0.5 *M* in THF, 9 mL) the solution was allowed to slowly warm to room temperature and the reaction was monitored by tlc (5% CH_3OH in CH_2Cl_2). After approximately 2 h starting material was consumed and CH_3OH (75 mL) was added. The solution was cooled in an ice bath and thiophenol (0.480 mL) and 2 *M* aqueous KOH (0.180 mL) were added. The solution was allowed to warm to room temperature and, after 14 h, 2 *M* aqueous KOH (5 mL) was added and the resulting solution was heated under reflux for 2 h. The reaction mixture was concentrated, diluted with water, and extracted (×3) with CH_2Cl_2. The combined CH_2Cl_2 layers were washed with dilute NaOH, water, dried (Na_2SO_4), and concentrated to give an oil, which upon trituration with ether provided crystalline **4** (mp 209–210°C, 845 mg, 78%).

cis-*12α-Benzoyloxy-6β,9α,10-trimethyl-3-(phenylthio)tricyclo-[7.4.0.0^{2,6}]trideca-2,10-diene-4,8-dione* (**6**)

The allylic alcohol **4** (845 mg) was dissolved in dry THF (100 mL), and triphenylphosphine (843 mg) and benzoic acid (424 mg) were added. Diethyl azodicarboxylate (0.61 mL) was added dropwise over 5 min, maintaining the reaction temperature at 15–20°C. After 1 h, CH_3OH (5 mL) was added and, after concentration, the reaction mixture was fractionated by flash column chromatography (gradient elution; 0–3% CH_3OH in CH_2Cl_2) to give the crude benzoate **6** (1.2 g). A sample further purified by ptlc (50% ethyl acetate – hexane) shows the following spectral characteristics: ir: 1710, 1263 cm^{-1}; ^{1}H nmr δ: 1.36 (s) and 1.39 (s) (C-6, 9 CH_3's), 1.84 (s, C-10 CH_3), 1.87 (dm, J = 14 Hz, C-13 αH), 2.05 (dt, J = 3.5, 14 Hz, C-13 βH), 2.56 (d, J = 13 Hz) and 3.00 (d, J = 13 Hz) (C-7 H's), 2.61 (AB quartet, C-5 H's), 4.24 (dd, J = 14, 3 Hz, C-1 H), 5.42 (m, C-12 H), 5.97 (d, J = 5.5 Hz, C-11 H), 7.2 (m, C_6H_5S-), 7.32, 7.52, 8.07 (m, C_6H_5CO-); ^{13}C nmr δ: 20.0 (q, C-16), 23.8 (q, C-15), 28.9 (q, C-14), 31.0 (t, C-13), 44.2 (d, C-1), 46.8 (t, C-7), 49.4 (s, C-6), 52.8 (s, C-9), 53.0 (t, C-5), 65.7 (d, C-12), 122.1 (d, C-11), 133.5 (s, C-3), 142.6 (s, C-10), 187.8 (s, C-2), 201.4 (s, C-4), 209.1 (s, C-8), 165.5, 135.2, 132.7, 130.1, 129.5, 128.9, 128.8, 128.1, 126.6 (C_6H_5CO-

[1]For acetal formation to occur, methanol must add to the (presumably protonated) carbonyl group. In **18**, methanol cannot compete with the addition of the C-11 -OH group to form the hemiacetal. By contrast, in **1***a*, the conformations of the hemiacetal and ketol isomers are different (6). Methanol can successfully add to the protonated ketol isomer to ultimately form **1***b*.

[2]Multiplicity was determined by *J*-moduation (10).

The crude diol **10** (945 mg) was dissolved in CH_3OH (100 mL) and W2 Raney Ni (5 mL) was added with stirring. After 1.5–2 h the mixture was filtered and concentrated to give crude diol **11** (601 mg). A sample further purified by ptlc (5% CH_3OH in CH_2Cl_2) shows the following spectral characteristics: ir: 3400 (br), 1692 (sh), 1675, 1606 cm^{-1}; ^{1}H nmr δ: 0.99 (s) and 1.56 (s) (C-6, 9 CH_3's), 1.75 (dm, *J* = 14 Hz, C-13 αH), 1.81 (s, C-10 CH_3), 1.82 (dd, *J* = 14.5, 3 Hz, C-7 H), 2.24 (dd, *J* = 14.5, 2.5 Hz, C-7 H), 2.34 (s, C-5 H's), 2.74 (dt, *J* = 14, 4 Hz, C-13 βH), 3.11 (dd, *J* = 14, 3 Hz, C-1 H), 3.96 (brs, C-8 H), 4.28 (m, C-12 H), 6.00 (m, C-11 H), 6.00 (s, C-3 H); ^{13}C nmr δ: 18.0 (q, C-16), 24.0 (q, C-15), 30.2 (q, C-14), 34.5 (t, C-13), 39.8 (t, C-7), 40.5 (d, C-1), 42.2 (s, C-9), 44.1 (s, C-6), 55.6 (t, C-5), 66.2 (d, C-12), 72.0 (d, C-8), 128.0 (d, C-11), 130.0 (d, C-3), 141.2 (s, C-10), 189.1 (s, C-2), 207.8 (s, C-4); hrms, *m/z* calcd. for $C_{16}H_{22}O_3$: 262.1569; found: 262.1560.

trans-*8β,12α-Dihydroxy-6β,9α,10-trimethyltricyclo[7.4.0.0^{2,6}]tri-deca-2,10-diene-4-one (12)*

The crude *cis* diol **11** (601 mg) was dissolved in CH_3OH (100 mL) and NaOH (1.5 g) was added. The resulting solution was heated under reflux for 5 days. Normal aqueous work-up leads to a poor recovery of product, therefore a nonaqueous work-up was utilized. The reaction mixture was made slightly acidic (pH ≈ 6) by addition of 6 *M* $HCl_{(aq)}$ and $NaHCO_3$ (1 g) was added. The mixture was concentrated to dryness and the resulting solid extracted with ether (impurities and *cis* diol **11** are removed), then with 20% CH_3OH in CH_2Cl_2 (×2). Concentration of the combined methanolic dichloromethane extracts provided essentially pure **12** (391 mg, 65% overall yield from **4**); ir: 3400 (br), 1692, 1672, 1611 cm^{-1}; ^{1}H nmr δ: 0.90 (s) and 1.47 (s) (C-6, 9 CH_3's), 1.71 (dt, *J* = 10, 13 Hz, C-13 αH), 1.80 (t, *J* = 1.5 Hz, C-10 CH_3), 1.85 (dd, *J* = 15, 3 Hz, C-7 H), 2.07 (dd, *J* = 15, 2.5 Hz, C-7 H), 2.18 (dddd, *J* = 12.5, 7, 1, 1 Hz, C-13 βH), 2.24 (d, *J* = 18 Hz) and 2.34 (d, *J* = 18 Hz) (C-5 H's), 3.23 (ddd, *J* = 13, 1.5, 1 Hz, C-1 H), 4.05 (brs, C-8 H), 4.45 (m, C-12 H), 5.53 (m, C-11 H), 5.83 (d, *J* = 1.5 Hz, C-3 H); ^{13}C nmr δ: 18.0 (q, C-16), 19.3 (q, C-15), 29.7 (q, C-14), 30.4 (t, C-13), 35.3 (d, C-1), 41.9 (t, C-7), 42.9 (s, C-6), 46.7 (s, C-9), 54.1 (t, C-5), 67.3 (d, C-12), 71.6 (d, C-8), 125.9 (d, C-3), 129.2 (d, C-11), 141.4 (s, C-10), 188.6 (s, C-2), 208.6 (s, C-4); hrms, *m/z* calcd. for $C_{16}H_{23}O_3$: 262.1569; found: 262.1555.

trans-*12α-Benzoyloxy-8β-hydroxy-6β,9α,10-trimethyltricyclo-[7.4.0.0^{2,6}]trideca-2,10-diene-4-one (13)*

The *trans* diol **12** (391 mg) was dissolved in CH_2Cl_2 (70 mL) and benzoyl chloride (0.5 mL), and triethylamine (1 mL) and *N,N*-dimethylaminopyridine (20 mg) were added. The reaction mixture was kept at 3°C for 16 h and CH_3OH (2 mL) was added. After 30 min the solution was concentrated and the resulting oil was fractionated by flash column chromatography (eluting first with CH_2Cl_2, then with ethyl acetate) to give the monobenzoate **13** (514 mg, 94%); ir: 3450 (br), 1710, 1700 (sh), 1674, 1614, 1269 cm^{-1}; ^{1}H nmr δ: 0.96 (s) and 1.50 (s) (C-6, 9 CH_3's), 1.84 (t, *J* = 1.5 Hz, C-10 CH_3), 1.87 (dd, *J* = 15, 3.5 Hz, C-7 H), 1.94 (ddd, *J* = 13, 12, 10 Hz, C-13 αH), 2.10 (dd, *J* = 15, 2.5 Hz, C-7 H), 2.25 (d, *J* = 18.5 Hz) and 2.35 (d, *J* = 18.5 Hz) (C-5 H's), 2.36 (dddd, *J* = 12, 7, 1, 1 Hz, C-13 βH), 3.38 (ddd, *J* = 13, 1.5, 1 Hz, C-1 H), 4.09 (dd, *J* = 3.5, 2.5 Hz, C-8 H), 5.59 (ddq, *J* = 2, 1, 1.5 Hz, C-11 H), 5.75 (dddq, *J* = 10, 7, 2, 1.5 Hz, C-12 H), 5.81 (d, *J* = 1.5 Hz, C-3 H), 7.35 (m), 7.58 (m), 8.07 (m) (C_6H_5CO-); ^{13}C nmr δ: 18.1 (q, C-16), 19.0 (q, C-15), 26.3 (t, C-13), 29.6 (q, C-14), 35.1 (d, C-1), 41.8 (t, C-7), 42.9 (s, C-6), 46.5 (s, C-9), 53.9 (t, C-5), 70.5 (d, C-12), 71.2 (d, C-10), 124.2 (d, C-11), 125.7 (d, C-3), 188.9 (s, C-2), 207.9 (s, C-4), 128.2 (d), 129.5 (d), 130.2 (s), 132.9 (d), 166.2 (s) (C_6H_5CO-); hrms, *m/z* calcd. for $C_{23}H_{26}O_4$: 366.1831; found: 366.1831.

trans-*12α-Benzoyloxy-6β,9α,10-trimethyltricyclo[7.4.0.0^{2,6}]tri-deca-2,7,10-triene-4-one (14)*

The benzoate **13** (514 mg) was dissolved in pyridine (50 mL) and the solution was heated to 50°C. Methanesulfonyl chloride (1.0 mL) was slowly added with a syringe pump over 10–15 h while monitoring the reaction by tlc (5% CH_3OH in CH_2Cl_2). When the reaction was completed the solution was concentrated from toluene, dissolved in ethyl acetate, washed with dilute HCl, saturated $NaHCO_3$, brine, dried over Na_2SO_4, and concentrated to give the crude mesylate (663 mg); ^{1}H nmr δ: 3.08 (s, -SO_2CH_3), 5.07 (dd, *J* = 3.5, 2.5 Hz, C-8 H). The mesylate was dissolved in toluene (50 mL), DBU (1.1 g) was added, and the solution was heated under reflux for 72 h. After dilution with ethyl acetate the solution was washed with dilute HCl, saturated $NaHCO_3$, brine, dried over Na_2SO_4, and concentrated to give an oil. Purification by flash column chromatography (30% ethyl acetate in hexane) gave the triene **14** (372 mg, 76%); ir: 1712, 1635, 1620, 1270 cm^{-1}; ^{1}H nmr δ: 1.04 (s) and 1.34 (s) (C-6, 9 CH_3's), 1.88 (t, *J* = 1.5 Hz, C-10 CH_3), 2.05 (dt, *J* = 9.5, 13 Hz, C-13 αH), 2.34 (d, *J* = 17.5 Hz) and 2.40 (d, *J* = 17.5 Hz) (C-5 H's), 2.41 (ddd, *J* = 13, 7, 2 Hz, C-13 βH), 3.11 (ddd, *J* = 13, 2, 1 Hz, C-1 H), 5.43 (dq, *J* = 2, 1.5 Hz, C-11 H), 5.64 (d, *J* = 10 Hz) and 5.94 (d, *J* = 10 Hz) (C-7, 8 H's), 5.75 (dddq, *J* = 9.5, 7, 2, 1.5 Hz, C-12 H), 5.83 (d, *J* = 1 Hz, C-3 H), 7.46 (m), 7.58 (m) and 8.09 (m) (C_6H_5CO-); ^{13}C nmr δ: 19.3 (q, C-16), 24.2 (q, C-15), 26.2 (t, C-13), 29.6 (q, C-14), 41.0 (d, C-1), 44.4 (s) and 45.7 (s) (C-6,9), 50.2 (t, C-5), 70.5 (d, C-12), 121.2 (d, C-11), 124.5 (d, C-3), 131.4 (d) and 131.7 (d) (C-7,8), 145.5 (s, C-10), 185.7 (s, C-2), 207.4 (s, C-4), 128.3 (d),

The diene **15** (218 mg) was dissolved in 10% methanolic dichloromethane (40 mL) containing a small amount (1–2 mg) of Sudan III and the resulting solution cooled to −78°C. A stream of ozone in air was bubbled through the solution until the red color was discharged. Argon was bubbled through the solution for 5 min. Pyridine (0.1 mL) and dimethyl sulfide (0.5 mL) were added and the solution kept at 3°C overnight. Concentration from xylenes (to remove pyridine and dimethyl sulfoxide) provided essentially homogeneous **16** (246 mg, quantitative); ir: 1705, 1620 cm^{-1}; ^{1}H nmr δ: 1.08 (s) and 1.22 (s) (C-6, 9 CH_3's), 1.82 (ddd, J = 14.5, 7.5, 1.5 Hz, C-10 H), 2.03 (ddd, J = 14.5, 10, 7.4 Hz, C-10 H), 2.23 (s, C-13 H's), 2.28 (s, C-1 H's), 3.41 (ddd, J = 10, 1.5 Hz, C-5 H), 5.23 (td, J = 7.5, 1 Hz, C-11 H), 6.10 (d, J = 1.5 Hz, C-3 H), 9.65 (d, J = 1 Hz, C-12 H); ^{13}C nmr δ: 14.6 (q, C-16), 23.6 (q, C-13), 25.4 (q, C-17), 28.1 (t, C-10), 32.2 (t, C-7), 35.7 (t, C-8), 38.1 (d, C-5), 43.3 (s, C-9), 52.0 (t, C-1), 55.5 (s, C-6), 77.5 (d, C-11), 128.3 (d, C-3), 186.6 (s, C-4), 197.4 (d, C-12), 206.2 (s, C-2), 211.0 (s, C-14), 165.8 (s), 133.6 (d), 133.1 (s), 129.8 (d) and 128.5 (d) (C_6H_5CO-); hrms, m/z calcd. for $C_{23}H_{26}O_5$: 382.1779; found: 382.1763.

*Preparation of acetal **2***[3]

The ketoaldehyde **16** (246 mg) was dissolved in benzene (40 mL) and water removed by azeotropic distillation under argon to give a dry solution (~20 mL). *p*-Toluenesulfonic acid (dihydrate, 250 mg) was suspended in toluene (40 mL) and water removed by azeotropic distillation under argon to give a dry solution (~20 mL). The two solutions were mixed under argon and allowed to stand for 48 h. The solution was washed with $NaHCO_{3(aq)}$, dried over Na_2SO_4, and concentrated to give an oil (249 mg), which consisted mainly of **18** and **17*a*** (3:1, ^{1}H nmr). Further purification by ptlc (5% CH_3OH in CH_2Cl_2) provided pure samples of **18**; ir: 3400 (br), 1705, 1620 cm^{-1}; ^{1}H nmr δ: 0.98 (s, C-16 H's), 1.32 (s, C-17 H's), 1.63 (ddd, J = 13, 4, 1.5 Hz, C-10 βH), 1.90 (ddd, J = 15, 3, 1.5 Hz, C-13 αH), 1.92 (td, J = 13, 3.5 Hz, C-10 αH), 2.29 (d, J = 18.5 Hz, C-1 H), 2.37 (d, J = 18.5 Hz, C-1 H), 2.56 (ddd, J = 13, 4, 1.3 Hz, C-5 H), 2.81 (brs, OH), 3.07 (dd, J = 15, 7.5 Hz, C-13 βH), 4.53 (dt, J = 3.5, 1.5 Hz, C-11 H), 5.27 (dd, J = 7.5, 3 Hz, C-12 H), 5.74 (d, J = 1.3 Hz, C-3 H), 7.45 (m, 2H), 7.59 (m, 1H) and 8.07 (m, 2H) (C_6H_5CO-); ^{13}C nmr (−50°C) δ: 11.6 (q, C-16), 25.9 (q, C-17), 26.1 (t, C-10), 28.1 (t, C-7), 35.2 (t, C-8), 38.1 (d, C-5), 40.1 (t, C-13), 43.1 (s, C-9), 45.2 (s, C-6), 52.1 (t, C-1), 77.4 (d) and 79.0 (d) (C-11,12), 108.4 (s, C-14), 125.7 (d, C-3), 187.8 (s, C-4), 208.9 (s, C-2), 128.3 (d), 128.7 (s), 129.6 (d), 133.5 (d), 166.4 (s) (C_6H_5CO-); hrms, m/z calcd. for $C_{23}H_{26}O_5$: 382.1779; found: 382.1768; and **17*a***; ^{1}H nmr δ: 0.87 (s, C-16 H's), 1.27 (s, C-17 H's), 1.46 (s, C-13 H's), 2.75 (brs, OH), 2.83 (ddd, J = 13.5, 4, 1.5 Hz, C-1 H), 4.33 (dd, J = 2.5, 2.5 Hz, C-11 H), 5.32 (brs, C-12 H), 5.71 (d, J = 1.5 Hz, C-3 H). In practice, the crude reaction mixture (249 mg) was dissolved in THF (25 mL), and iodomethane (0.5 mL) and NaH (50% in oil, ca. 100 mg) were added. After stirring for 1.5 h at room temperature, the reaction mixture was quenched with acetic acid, concentrated, diluted with ethyl acetate, washed with saturated $NaHCO_3$, dried over Na_2SO_4, and concentrated to give an oil. Purification by flash column chromatography (35% ethyl acetate in hexane) provided **2** (125 mg, 49% from **16**); ir: 1705, 1620 cm^{-1}; ^{1}H nmr δ: 0.92 (s, C-16 H's), 1.31 (s, C-17 H's), 1.61 (ddd, J = 13.5, 4, 1.5 Hz, C-10 βH), 1.92 (td, J = 13.5, 4 Hz, C-10 αH), 2.15 (ddd, J = 15, 2.5, 1.5 Hz, C-13 αH), 2.28 (d, J = 18.5 Hz, C-1 H), 2.35 (d, J = 18.5 Hz, C-1 H), 2.56 (ddd, J = 13.5, 4, 1.5 Hz, C-5 H), 2.60 (dd, J = 15, 7.5 Hz, C-13 βH), 3.40 (s, 3H, OCH_3), 4.48 (dt, J = 4, 1.5 Hz, C-11 H), 5.29 (dd, J = 7.5, 2 Hz, C-12 H), 5.73 (d, J = 1.5 Hz, C-3 H), 7.47 (m, 2H), 7.60 (m, 1H) and 8.07 (m, 2H) (C_6H_5CO-); ^{13}C nmr δ: 11.9 (q, C-16), 26.2 (q, C-17), 26.7 (t, C-10), 28.2 (t, C-7), 32.1 (t, C-13), 36.0 (t, C-8), 38.3 (d, C-5), 43.2 (s, C-9), 46.2 (s, C-6), 49.4 (q, OCH_3), 52.6 (t, C-1), 77.5 (d) and 78.8 (d) (C-11, 12), 111.2 (s, C-14), 125.9 (d, C-3), 186.7 (s, C-4), 207.4 (s, C-2), 128.5 (d), 129.6 (d), 129.9 (s), 133.3 (d), 166.4 (s) (C_6H_5CO-); hrms, m/z calcd. for $C_{24}H_{28}O_5$: 396.1936; found: 396.1932; and **17*b*** (32 mg, 17%); ir: 1700, 1620 cm^{-1}; ^{1}H nmr δ: 0.87 (s, C-16, H's), 1.29 (s, C-17 H's), 1.45 (s, C-13 H's), 1.54 (ddd, J = 13.5, 4, 2 Hz, C-10 βH), 1.89 (td, J = 13.5, 2.5 Hz, C-10 αH), 2.25 (d, J = 18 Hz) and 2.33 (d, J = 18 Hz) (C-1 H's), 2.83 (ddd, J = 13.5, 4, 1.5 Hz, C-5 H), 3.43 (s, OCH_3), 4.37 (dd, J = 2.5, 2 Hz, C-11 H), 5.02 (s, C-12 H), 5.70 (d, J = 1.5 Hz, C-3 H); ^{13}C nmr δ: 14.4 (q, C-16), 19.0 (q, C-17), 24.9 (q, C-13), 26.2 (t, C-10), 29.2 (t, C-7), 36.1 (t, C-8), 37.7 (d, C-5), 43.2 (s, C-9), 46.2 (s, C-6), 52.6 (t, C-1), 54.3 (q, OCH_3), 79.3 (d, C-11), 103.6 (d, C-12), 113.7 (s, C-14), 125.5 (d, C-3), 188.1 (s, C-4), 207.4 (s, C-2); hrms, m/z calcd. for $C_{17}H_{24}O_4$: 292.1674; found: 292.1662.

Chemoselective reaction of a sulfonate ester with methoxide ions in preference to benzyl mercaptide anions

RICHARD FRANCIS LANGLER[1] AND NANCY ANN MORRISON

Department of Chemistry and Chemical Engineering, Florida Institute of Technology, Melbourne, FL 32901-6988, U.S.A.

Received October 10, 1986[2]

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

RICHARD FRANCIS LANGLER and NANCY ANN MORRISON. Can. J. Chem. **65**, 2385 (1987).

Trifluoroethyl benzyl sulfide was prepared (in 2-propanol) and subsequently chlorinated as a further test of substituent electronegativity based regiochemical predictions. The initial attempt to prepare that sulfide by reaction of 2,2,2-trifluoroethyl methanesulfonate and benzyl mercaptide anions (in methanol) furnished benzyl methyl sulfide. Mechanistic possibilities are discussed in detail and some synthetic consequences of this novel reaction are presented.

RICHARD FRANCIS LANGLER et NANCY ANN MORRISON. Can. J. Chem. **65**, 2385 (1987).

On a préparé le sulfure de trifluoroéthyle et de benzyle (dans le propanol-2) et, dans le but de confirmer la corrélation qui existe entre l'électronégativité des substituants et les prédictions régiochimiques, on l'a ultérieurement soumis à une chloration. L'essai initial de préparer le sulfure par réaction du méthanesulfonate de trifluoro-2,2,2 éthyle avec les anions sulfures de benzyle (dans le méthanol) a conduit à la formation de sulfure de méthyle et de benzyle. On discute des diverses possibilités concernant le mécanisme et on présente quelques conséquences au niveau de la synthèse de cette nouvelle reaction.

[Traduit par la revue]

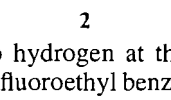
Introduction

Our longstanding interest in the chlorination of organosulfur compounds encompasses the regiochemical problem associated with sulfide chlorinations (*vide* eq. [1].) We have developed an

[1] $R^1CH_2SCH_2R^2 + Cl_2 \rightarrow R^1CH_2SCHClR^2 + R^1CHClSCH_2R^2$

1

approach (1, 2) that utilizes substituent electronegativities to successfully predict regiochemical results.[3] Our initial rationale (1) for employing substituent electronegativities to make such predictions was discredited by our own theoretical study (5). Upon completion of that work, we were left with the following positions: (*i*) according to our MNDO study of intermediate thionium ions **2**, phenyl was the best stabilizer and CF_3 was a



2

destabilizer (relative to hydrogen at the sp^2 carbon), so that chlorination of 2,2,2-trifluoroethyl benzyl sulfide **3**, ($R^1 = CF_3$, R^2 = Ph in **1**, eq. [1]) should occur at the benzylic carbon,[4] and (*ii*) according to substituent electronegativity predictions,[5] reaction should go exclusively into the trifluoroethyl group.

We resolved, at that time, to undertake the chlorinolysis of trifluoroethyl benzyl sulfide **3**, which we intended to prepare from trifluoroethyl methanesulfonate **4**.

Results and discussion

*Electrophilicity of **4** and the preparation of **3***

Our previous experience (8, 9) led us to treat 2,2,2-trifluoroethyl methanesulfonate **4** with the benzyl mercaptide anion in methanol as our first attempt to obtain **3**.

[2] $CF_3CH_2OSO_2CH_3 + PhCH_2SH \xrightarrow[CH_3OH]{CH_3ONa}$

4

$PhCH_2SCH_3$ + $PhCH_2SCH_2CF_3$

27% **3** (12.4%)

Several points arise from the results shown in eq. [2]. Firstly, this is clearly an unacceptable method for the preparation of **3**. However, the surprising formation of benzyl methyl sulfide does raise an interesting mechanism problem. Morever, in conjunction with the mechanism problem, the mass balance is very poor, suggesting the possibility of quantitative loss of a major product. We deal first with the origin of the benzyl methyl sulfide.

The simplest explanation for the formation of benzyl methyl sulfide, which involves what might be called an "ipso" attack, is shown as pathway *a* in Scheme 1. While we are unaware of any published precedent for nucleophilic attack at the carbon bearing sulfur in a sulfonate ester, we have observed analogous reactivity for some sulfonyl chlorides (8). Extension of this behavior to sulfonate esters would not appear to be a major step.

An alternative explanation for the formation of benzyl methyl sulfide involves attack by methoxide ions at sulfonyl sulfur (shown as pathway *b* in the scheme). Facile nucleophilic attack by an oxy-nucleophile at the sulfonyl sulfur of a sulfonate ester is readily illustrated by the following result.

[3] 
Under the same conditions, mercaptide anions attack the nitromesylate at carbon.

[4] 
Thus, the high chemoselectivity[6] postulated for the reactions

[1] Author to whom correspondence may be addressed.

[2] Revision received May 24, 1987.

[3] For recent reviews of this area see refs. 3 and 4.

[4] This expectation assumes that the favored pathway goes through the most stable thionium ion.

[5] Pauling electronegativity of phenyl is 2.41 (6) and Pauling electronegativity of trifluoromethyl is 3.46 (7).

[6] Of course, nucleophilic attack at the methylene carbon in **4** proceeds by an S_N2 process (see pathway *c* in the scheme). In eq. [4], the corresponding nucleophilic attack at the sp^2 carbon results in substitution by an addition–elimination sequence.

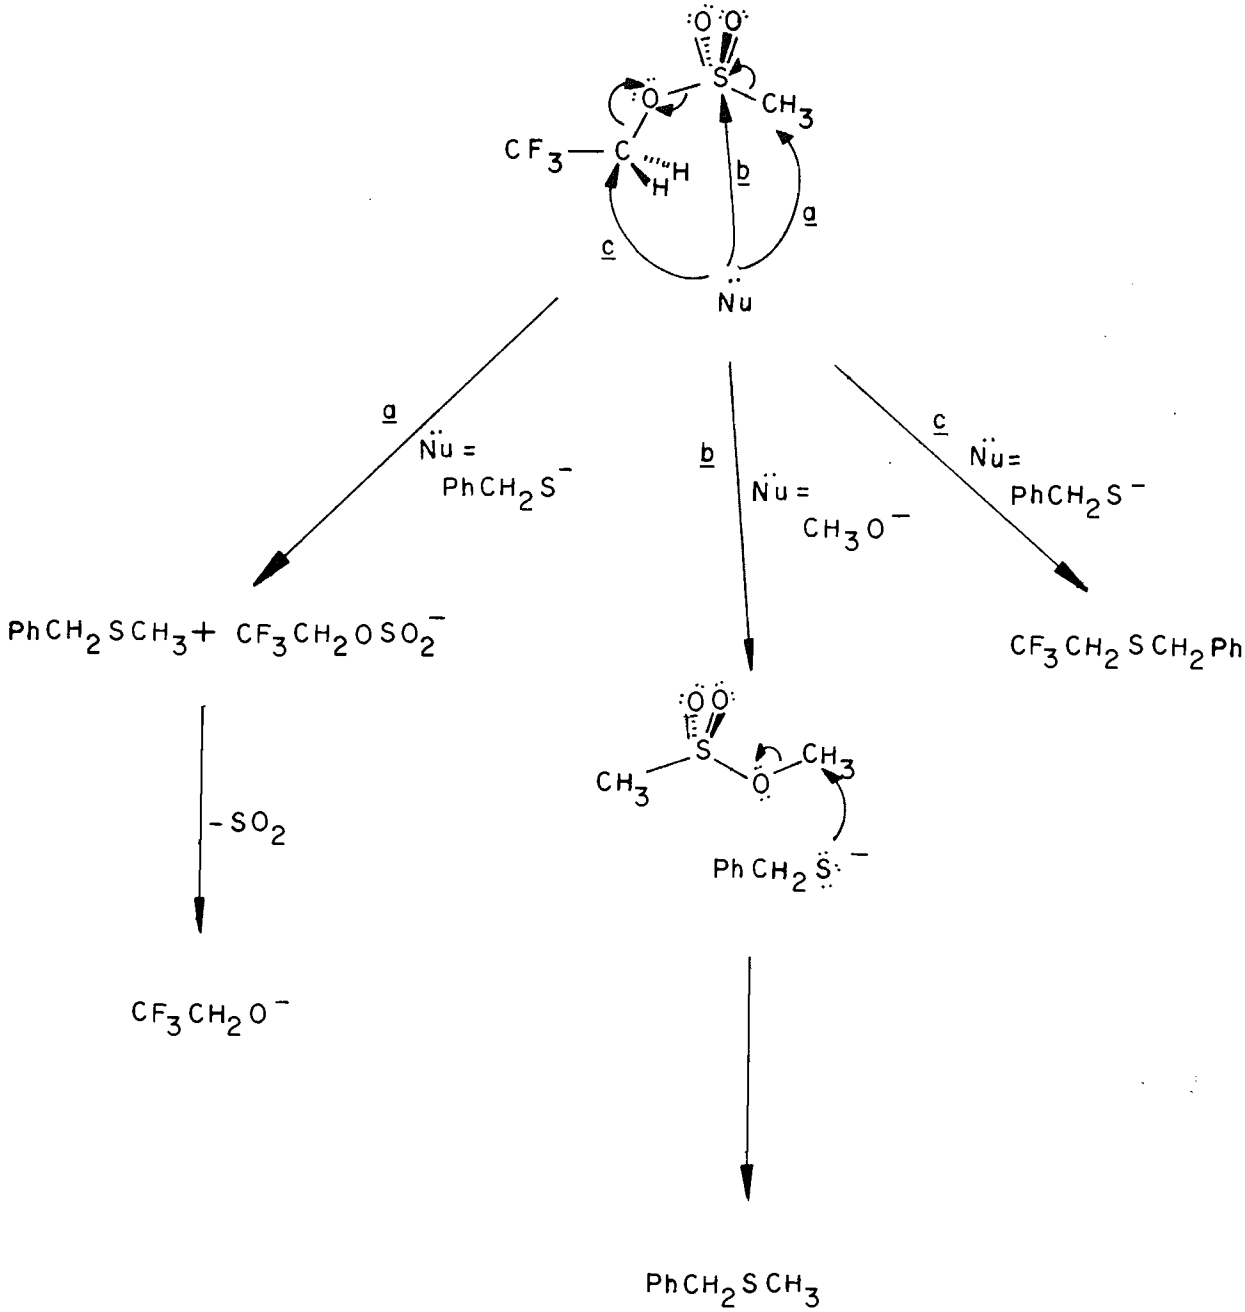

SCHEME 1

conducted in methanol (eq. [2]) can be observed in separate processes when the reactions are carried out in HMPA. HMPA, as expected, did not directly intervene in these reactions.

A simple test of the pathway by which benzyl methyl sulfide forms would involve replacing the methanol/methoxide of eq. [2] with isopropanol/isopropoxide. If the mechanism shown as pathway *a* in Scheme 1 is correct, there should be little change in the outcome of the reaction; in particular, the ratio of benzyl methyl sulfide to **3** should be essentially unchanged. However, if the pathway *b* mechanism is correct, isopropoxide ions would provide substantially greater steric hindrance, which should suppress attack at sulfonyl sulfur. This would enhance the yield of **3**. Of course, if the methyl group of benzyl methyl sulfide is derived from the methanol/methoxide, a change to isopropanol/isopropoxide would preclude formation of that sulfide. Equation [5] presents the results of this experiment.

$$[5]\quad CF_3CH_2OSO_2CH_3 + PhCH_2SH \xrightarrow[(CH_3)_2CHOH]{(CH_3)_2CHONa} \underset{\textbf{3}\ (57\%)}{PhCH_2SCH_2CF_3} + \underset{0\%}{PhCH_2SCH_3}$$

Thus the pathway *a* mechanism is ruled out and another reasonable preparation of **3**[7] has been developed. The somewhat surprising success of methoxide ions (in the pathway *b* mechanism) in a medium that must contain a substantial excess of mercaptide anions[8] leads to speculation about other processes

[7]Previous reports of the preparation of **3** may be found in ref. 10 and references therein.

[8]The pK_a of benzyl mercaptan is 12.0 (11*a*) and the pK_a of methanol is 15.5 (11*b*).

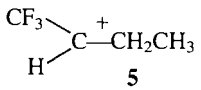
in which they might be involved. Methoxide ions could attack the methyl methanesulfonate formed *in situ* (see pathway *b*) to give dimethyl ether. The low-boiling ether would either be lost during the reaction or during work-up. The formation of dimethyl ether was confirmed as shown below.

[6] $\underset{\mathbf{4}}{CF_3CH_2OSO_2CH_3} \xrightarrow[CH_3OH]{CH_3ONa} CH_3OCH_3$

Corresponding conversions of alkoxide ions into symmetrical ethers have been reported by other workers (12*a*, *b*). Now it is clear what processes actually occurred when we carried out the eq. [2] reaction, although it was expected to proceed in a fashion similar to that shown in eq. [7] (taken from ref. 8).

[7] $PhSO_2(CH_2)_3OTs + PhCH_2SH \xrightarrow[CH_3OH]{CH_3ONa} PhSO_2(CH_2)_3SCH_2Ph$

One can begin to deal with an explanation for the unusual result shown in eq. [2] using Hard and Soft Acid and Base theory.[9] The hard base (alkoxide ion) should attack preferentially at the hard acid site (sulfonyl sulfur) and the soft base (mercaptide anion) should attack preferentially at the soft acid sites (sp^3 carbon), as observed. The unusual outcome of the reaction shown in eq. [2] would make sense if the rate of attack by mercaptide anion on the trifluoroethyl mesylate **4** was unusually slow (cf. eq. [7]). A rate retardation would necessarily be attributed to the trifluoromethyl group attached to the electrophilic carbon. Two possible origins for such an effect came to mind readily, viz: (*i*) a steric effect, or (*ii*) a field effect in which the negatively charged fluorine atoms repel approaching anionic nucleophiles. However, trifluoromethyl groups are believed to be only a little larger than methyl groups (14), which appears to rule out a steric argument. Field effects have been argued for the sulfonyl group. We have published results (15) that are inconsistent with this view for the sulfonyl group. Consequently, it is even less appealing to us as an explanation for a trifluoromethyl substituent effect. In connection with this point, we note that our MNDO gas phase results,[10] on the CF_3 containing systems **5** and **6**, show that the partial charge on fluorine is rather small (-0.17 in **5** and -0.23 in **6**) and is, to a first approximation, insensitive to demand for electron density.



5

6

Another view of this problem would suppose a rate acceleration for nucleophilic attack at the sulfonyl sulfur of **4** by methoxide ions. This view is supported by the pK_a of CF_3CH_2OH, which is 12.4 (17). The pK_a suggests that the trifluoroethoxy group is a significantly better leaving group than is an alkoxy group, thereby enhancing electrophilicity at the hard acid site.

We felt that the synthetic potential for pathway *b* chemistry was worth further exploration. Among many potential methodologies, this chemistry could offer "one-pot" methodologies for symmetric ethers and for sulfides. Equations [8] and [9] give preliminary results for each of these methodologies.

[8] $PhCH_2OH + CF_3CH_2OSO_2CH_3 \xrightarrow[(CH_3)_2CHOH]{(CH_3)_2CHONa} (PhCH_2)_2O$ 23%

[9] $PhCH_2OH + PhSH + PhOSO_2CH_3 \xrightarrow[(CH_3)_3COH]{(CH_3)_3COK} PhCH_2SPh$ 50%

Further results will be communicated in due course. We note, in connection with one-pot methodologies, the highly effective method for the conversion of alcohols to sulfides developed by Nakagawa, Aki, and Hata (18).

Chlorinolysis of 3

We have attempted to chlorinate **3** with sulfuryl chloride only to find no reaction. However, facile chlorination was accomplished with molecular chlorine.

[10] $\underset{\mathbf{3}}{PhCH_2SCH_2CF_3} + Cl_2 \xrightarrow{CCl_4} \underset{\mathbf{7}\ (100\%)}{PhCH_2SCCl_2CF_3}$

The result depicted in eq. [10] is consistent with the outcome expected on the basis of substituent electronegativity difference.[5] In accord with the conclusions reached from our earlier theoretical study (5), this result suggests that the major regioisomeric thionium ion **2** is not always the most stable one and that "sulfides which have substituents with high electronegativities follow an E_{1cb}-like mechanism". Equation [10] brings the total to 51 asymmetric sulfide chlorinations for which substituent electronegativities have been successful in anticipating the regiochemistry.

Conclusions

1. CF_3 is a better directing group than Ph in asymmetric acyclic sulfide chlorination reactions, as expected on the basis of ΔXp (substituent electronegativity difference) arguments.
2. Some sulfonate esters can induce alcohols to alkylate mercaptide anions (see eq. [2]). The reaction appears to involve two highly chemoselective steps: (*i*) nucleophilic attack by alkoxide ions (particularly primary ones) at sulfonyl sulfur, then (*ii*) mercaptide anion attack at carbon of the intermediate sulfonate ester.
3. High chemoselectivity in the nucleophilic substitutions on sulfonate esters suggests a variety of possible one-pot synthetic methods. Preliminary results show potential for such syntheses of sulfides and symmetric ethers.

Experimental

General

The ir spectra were recorded on a Perkin Elmer 237B grating spectrophotometer. The nmr spectra were obtained on a Varian EM360A instrument using TMS as the internal standard. Melting points were determined on a Mel-Temp capillary melting-point apparatus and are uncorrected.

Conversion of benzyl mercaptan to benzyl methyl sulfide

Sodium metal (1.204 g, 52.3 mmol) was dissolved in methanol (100 mL) and benzyl mercaptan (6.2 mL, 50 mmol) added. 2,2,2-Trifluoroethyl methanesulfonate **4** (8.900 g, 50 mmol) (19) was added and the reaction mixture refluxed for 20 h. Water (100 mL) was added and the resultant mixture washed with methylene chloride (three 100-mL aliquots). The combined organic layers were dried ($MgSO_4$) and concentrated. The residue was rectified at reduced pressure affording a mixture (4.5579 g, bp 106–112°C/50 Torr) (1 Torr = 133.3 Pa).

[9]For a discussion of sulfur nucleophiles and electrophiles in terms of HSAB theory see ref. 13.

[10]These calculations were carried out as part of a previously published study. Details may be found in that paper (16).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

A portion of the distillate (1.983 g) was chromatographed on silica gel (200 g) employing hexanes elution (100-mL fractions). Fraction 10 was concentrated, affording clean trifluoroethyl benzyl sulfide **3** (0.068 g, 0.33 mmol). Fractions 11–13 were combined and concentrated, affording more **3** (0.496 g) contaminated with benzyl mercaptan. Fractions 16–24 were combined and concentrated, affording benzyl methyl sulfide (0.8209 g, 6.09 mmol).

Chromatographed benzyl methyl sulfide (0.8209 g, 6.09 mmol) was oxidized by chromium trioxide (1.525 g, 15.2 mmol) in glacial acetic acid (50 mL) in the usual way (8). Benzyl methyl sulfone (0.362 g, 2.12 mmol) was obtained and recrystallized from methanol. It was identical to authentic material by ir, nmr, tlc, mp (123.5–124°C, lit. (20) mp 127°C), and mixture mp.

Preparation of p-*nitrophenyl methanesulfonate*

A solution of dry triethylamine (14.538 g, 143.9 mmol) and *p*-nitrophenol (19.999 g, 143.8 mmol) in dry pyridine (200 mL) was reacted with methanesulfonyl chloride (16.388 g, 143.7 mmol) in the usual way. The residue from routine work-up was recrystallized from methanol, affording clean *p*-nitrophenyl methanesulfonate (20.60 g, 94.9 mmol, 66%, mp 88–89°C). The sulfonate ester had R_f 0.81 on analytical tlc plates (0.5 mm silica gel thickness) when developed with chloroform; ir ($CHCl_3$): 1540, 1390, 1360, and 1170 cm^{-1}; uv (CH_3OH): 261 nm (ε 8 955); nmr ($CDCl_3$) δ: 8.30 (2H, d, J = 9 Hz), 7.36 (2H, d, J = 9 Hz), and 3.25 (3H, s). *Anal.* calcd. for $C_7H_7NO_5S$: C 38.70, H 3.24; found: C 38.66, H 3.19.

Reaction of p-*nitrophenyl methanesulfonate with phenoxide ions*

Phenol (2.1573 g, 22.9 mmol) in HMPA[11] (10 mL) was added dropwise to a slurry of sodium hydride (0.6111 g, 25.4 mmol) in HMPA (30 mL). Upon completion of the 5-min addition, the reaction mixture was stirred at ambient temperature for 1 h to permit complete evolution of hydrogen. *p*-Nitrophenyl methanesulfonate (5.0229 g, 23.1 mmol) was added and the reaction mixture stirred at ambient temperature for 18 h.

The reaction mixture was poured into water (400 mL) and 10% HCl (5 mL). The resultant mixture was washed with diethyl ether (three 100-mL portions). The ether was concentrated and the residue poured into water (100 mL). The aqueous layer was washed with diethyl ether (three 100-mL portions). The combined ether layers were washed with 2.5% sodium hydroxide (two 100-mL aliquots). The organic layer was dried ($MgSO_4$) and the solvent evaporated, affording crude phenyl methanesulfonate (3.3708 g, 19.5 mmol, 84%).

The crude mesylate was chromatographed on silica gel (400 g) employing chloroform elution (100-mL fractions). Fractions 12 and 13 were combined and concentrated, affording clean phenyl methanesulfonate (2.5932 g, 15.0 mmol). After recrystallization the methanesulfonate was shown to be identical to authentic material by ir, nmr, double-spotted tlc, mp (61–62°C), and mixture mp (60–61.3°C). Fractions 14 and 15 were combined, concentrated, and rechromatographed on silica gel (80 g) employing 1:1 chloroform – carbon tetrachloride elution (50-mL fractions). Fractions 8–12 were combined and concentrated, yielding more clean phenyl methanesulfonate (0.3802 g, 2.2 mmol).

Reaction of p-*nitrophenyl methanesulfonate with benzyl mercaptide anions*

Sodium hydride (0.3326 g, 13.8 mmol) was added to HMPA (30 mL). A solution of benzyl mercaptan (1.7 mL, 13.7 mmol) in HMPA (10 mL) was added dropwise over 10 min. The reaction mixture was stirred for an additional 10 min to permit complete evolution of H_2. The nitromesylate (2.9813 g, 13.7 mmol) was added and almost immediately the reaction mixture turned very deep red—almost black. The reaction mixture was stirred at ambient temperature for 2 h. Crude work-up followed the procedure used for reaction with phenoxide ions.

The residue was recrystallized from methanol, affording clean *p*-nitrophenyl benzyl sulfide (1.7561 g, 7.1 mmol, 52%, mp 119–119.5°C). The sulfide had R_f 0.46 on analytical tlc plates when developed with 3:1 carbon tetrachloride – chloroform; ir ($CHCl_3$): 1520 and 1350 cm^{-1}; nmr ($CDCl_3$) δ: 8.06 (2H, d), 7.30 (5H, s), 7.25 (2H, d), and 4.23 (2H, s). *Anal.* calcd. for $C_{13}H_{11}O_2NS$: C 63.65, H 4.51; found: C 63.46, H 4.48.

Preparation of 2,2,2-trifluoroethyl benzyl sulfide **3**

Small scale

Sodium metal (0.1233 g, 5.3 mmol) was reacted with 2-propanol (20 mL). Phenylmethanethiol (0.7 mL, 5.6 mmol) and the mesylate **4** (1.000 g, 5.6 mmol) (19) were added and the reaction mixture refluxed for 4 days. A standard extraction procedure furnished *crude product*. The crude was chromatographed on silica gel (100 g) employing hexanes for elution (100-mL fractions). Fractions 5–7 were combined and concentrated, furnishing benzylic sulfide **3** (0.660 g, 3.2 mmol, 57%) with known properties (10).

Large scale without chromatographic work-up

Reaction was carried out as outlined above using sodium metal (1.285 g, 55.8 mmol), phenylmethanethiol (7 mL, 56.4 mmol), and the trifluorosulfonate **4** (10.0145 g, 56.2 mmol) in 2-propanol (200 mL). The reaction mixture was refluxed for only 2 h. Upon completion of reflux, 3% sodium hydroxide (100 mL) was added and the reaction mixture refluxed for an additional hour. An extraction procedure furnished crude, which was added to pyridine (25 mL) and iodine (1 g) and stirred at ambient temperature for 5 min. Standard extraction furnished an organic layer, which was washed with 10% w/v sodium thiosulfate (two 50-mL aliquots). The solvent was evaporated and the residue rectified at reduced pressure, yielding **3** (6.131 g, 29.7 mmol, 52%, bp 112–120°C/35 Torr). The sulfide obtained this way is free of benzyl mercaptan and trifluoromesylate **4** but has a yellowish color.

Preparation of trifluoroethyl benzyl sulfone

The trifluorosulfide **3** (0.728 g, 3.5 mmol) in glacial acetic acid (5 mL) was added dropwise to a mixture of chromium trioxide (0.3556 g, 3.55 mmol) in glacial acetic acid (5 mL) and the oxidation carried out in the usual way (8). The crude sulfone (0.371 g, 1.5 mmol, 44%) was recrystallized from methanol, yielding clean trifluoroethyl benzyl sulfone (0.2601 g, mp 139–141°C). The sulfone had ir ($CHCl_3$): 1360 and 1145 cm^{-1}; nmr ($CDCl_3$) δ: 7.30 (5H, s), 4.26 (2H, s), and 3.50 (2H, q, J = 9 Hz). *Anal.* calcd. for $C_9H_9F_3O_2S$: C 45.37, H 3.80; found: C 45.59, H 3.76.

Reaction of trifluoroethyl mesylate **4** *with methoxide ions*

Sodium metal (1.0998 g) was dissolved in methanol (100 mL) and the trifluoroethyl mesylate (4.458 g) added. The reaction was refluxed for 0.5 h. Effluent gases were passed into a trap cooled with isopropanol/Dry Ice. Upon completion of the reflux, the trap contained dimethyl ether (0.7 mL), which was identical with authentic material by nmr.

Preparation of dibenzyl ether

Sodium metal (1.2953 g, 56.3 mmol) was dissolved in 2-propanol (100 mL) and benzyl alcohol (3.0337 g, 28.0 mmol) was added. 2,2,2-Trifluoroethyl methanesulfonate (4.9968 g, 28.0 mmol) (19) was added and the resultant mixture refluxed for 0.5 h. Acidification and extraction afforded a residue that was chromatographed on silica gel (400 g) employing chloroform elution (100-mL fractions). Fraction 12 was concentrated, affording a mixture of dibenzyl ether (0.056 g, 0.2 mmol) and benzyl trifluoroethyl ether (0.087 g, 0.4 mmol). Fractions 13–17 were concentrated and combined, affording clean dibenzyl ether (0.5775 g, 2.9 mmol). Dibenzyl ether had no OH stretch in the ir, and nmr ($CDCl_3$) δ: 7.33 (5H, s) and 4.53 (2H, s). Fractions 18–20 were concentrated and combined, yielding 2-propyl methanesulfonate (0.0754 g, 0.5 mmol). Further elution provided unchanged benzyl alcohol (1.0792 g, 9.9 mmol).

Preparation of benzyl phenyl sulfide

Potassium metal (1.0807 g, 27.7 mmol) was dissolved in *tert*-butanol (100 mL). Benzenethiol (1.5098 g, 13.7 mmol), benzyl alcohol (1.4935 g, 13.8 mmol), and phenyl methanesulfonate (2.3659 g, 13.7 mmol) were added. The reaction mixture was refluxed for 2 h.

[11] HMPA is hexamethylphosphoramide $[(CH_3)_2N]_3PO$. HMPA is toxic and carcinogenic (21).

Standard extraction gave crude, which was a mixture of ca. 2:1 benzyl phenyl sulfide – benzyl alcohol.

Half of the crude product was added to a mixture of chromium trioxide (1.9989 g, 19.9 mmol) in glacial acetic acid (50 mL). The reaction mixture was maintained at 90–100°C for 0.5 h. Standard extraction yielded clean benzyl phenyl sulfone (0.7770 g, 3.3 mmol). Upon recrystallization from methanol, the product was shown to be identical to authentic material by mp (147–149°C, lit. (ref. 20, p. 425) mp 148°C), ir, and nmr.

Chlorinolysis of **3**

Trifluoroethyl benzyl sulfide **3** (0.502 g, 2.4 mmol) was dissolved in carbon tetrachloride (5 mL), and Cl_2 (ca. 200 mL/min) was bubbled into the solution for 1 min. An nmr of the crude indicated that the reaction mixture was now ca. 28% monochlorosulfide and 72% dichlorosulfide **7**. Cl_2 was bubbled into the reaction mixture for another minute at the same rate. An nmr[12] of the crude indicated complete conversion of the starting material into the dichlorosulfide **7**.

The solvent was evaporated and the residue oxidized with chromium trioxide (0.6121 g, 6.1 mmol) in glacial acetic acid (30 mL) in the usual way (8). After recrystallization of crude dichlorotrifluorosulfone from methanol, clean sulfone (0.3497 g, 1.4 mmol, 58% after two steps, mp 78–79.5°C) was obtained. The product sulfone had R_f 0.26 on analytical tlc plates when developed with carbon tetrachloride; ir ($CHCl_3$): 1370 and 1170 cm^{-1}; nmr ($CDCl_3$) δ: 7.43 (5H, s) and 4.70 (2H, s). *Anal.* calcd. for $C_9H_7Cl_2F_3O_2S$: C 35.19, H 2.29, Cl 23.08, S 10.44; found: C 35.27, H 2.28, Cl 23.11, S 10.28.

Isolation, structure, and synthesis of combretastatin A-2, A-3, and B-2[1]

GEORGE R. PETTIT[2] AND SHEO BUX SINGH
Cancer Research Institute and Department of Chemistry, Arizona State University, Tempe, AZ 85287-1604, U.S.A.

Received May 8, 1987

GEORGE R. PETTIT and SHEO BUX SINGH. Can. J. Chem. **65**, 2390 (1987).

Further investigation of the South African tree *Combretum caffrum* (Combretaceae) for murine P388 lymphocytic leukemia (PS) cell-growth inhibitory substances has led to discovery of three new active constituents designated combretastatins A-2 (**5***a*, PS ED_{50} 0.027 μg/mL), A-3 (**5***b*, PS ED_{50} 0.026 μg/mL), and B-2 (**3***b*, PS ED_{50} 0.32 μg/mL). Both combretastatins A-2 and A-3 were found to markedly inhibit tubulin polymerization. The structure of each combretastatin was firmly established by a combination of high resolution (400 MHz) ^1H and ^{13}C nuclear magnetic resonance and mass spectral analyses followed by total syntheses. The conversion of methyl gallate (**7***b*) to combretastatin A-2 via intermediates **7***c* → **7***d* → **7***e* → **7***a* and **6***a* → **5***a* illustrates the practical synthetic route utilized for obtaining these substances. The Wittig reaction employed as the penultimate step in obtaining combretastatins A-3, afforded predominantly the natural *Z* isomer.

GEORGE R. PETTIT et SHEO BUX SINGH. Can. J. Chem. **65**, 2390 (1987).

Dans le but d'isoler de nouvelles substances inhibant la croissance des cellules (PS) de la leucémie lymphocytaire de la murine P388, on a procédé à une nouvelle investigation de l'arbre sud-africain *Combretum caffrum* (Combretaceae); cette étude a conduit à la découverte de trois nouveaux constituants actifs que l'on a appelés combrétastatines A-2 (**5***a*, PS ED_{50} 0,027 μg/mL), A-3 (**5***b*, PS ED_{50} 0,026 μg/mL) et B-2 (**3***b*, PS ED_{50} 0,32 μg/mL). On a trouvé que les combrétastatines A-2 ainsi que A-3 inhibent toutes les deux la polymérisation de la tubuline. On a fermement établi la structure de chacune des combrétastatines en faisant appel à une combinaison de résonance magnétique nucléaire ^1H et ^{13}C à haute résolution (400 MHz) et de spectrométrie de masse suivis de synthèses totales. La transformation du gallate de méthyle (**7***b*) en combrétastatine A-2 (via les intermédiaires **7***c* → **7***d* → **7***e* → **7***a* et **6***a* → **5***a*) illustre bien les voies pratiques de synthèse qui peuvent être utilisées pour obtenir ces substances. La réaction de Wittig, utilisée dans l'avant-dernière étape de la synthèse des combrétastatines A-3, fournit principalement l'isomère *Z* naturel.

[Traduit par la revue]

The plant family Combretaceae is comprised of 20 genera (600 species) growing in tropical and subtropical regions as shrubs and trees (2). The genus *Combretum* with 250 climbing or erect species is known for its medicinal properties in Africa and India (3).[3] In 1979 we began an investigation directed at discovering murine P-388 lymphocytic leukemia (PS system) inhibitory components of the South African tree *Combretum caffrum* (Eckl. and Zeyh) Kuntze (or as *Salicifolium* E. Mey), a valuable lead uncovered in the U.S. National Cancer Institute's (NCI) world-wide explorations (5). Eventually we succeeded in isolating combretastatin (**1**), which was found to significantly cause astrocyte reversal in the NCI astrocytoma bioassay (6) and inhibition of tubulin polymerization (7). Isolation of diphenylethanol **1** was followed by discovery of the principal PS in vivo active constituent of *Combretum caffrum* fractions, the powerful tubulin polymerization inhibitor combretastatin A-1 (**2**, ref. 8). Subsequently, we isolated from the same tree the PS cell-growth inhibitory combretastatin B-1 (**3***a*, ref. 8) and a series of phenanthrenes (cf. **4**, ref. 1) with analogous activity. We now report discovery of two new compounds closely related to combretastatin A-1 (**2**), designated combretastatins A-2 (**5***a*) and A-3 (**5***b*), which display significant PS cell-growth and tubulin inhibitory properties. Another constituent active against the PS cell line, named combretastatin B-2 (**3***b*), was also found in this productive plant.

The methylene chloride fraction (8) prepared from the original methylene chloride – methanol extract of *Combretum caffrum* stem wood (77 kg dry wt.) was employed as starting material for the present bioassay (PS) guided research. The active methylene chloride fraction was subjected to steric exclusion chromatography in methanol on Sephadex LH-20 to provide two active fractions (A and B of ref. 8). Several partition chromatography sequences of Sephadex LH-20, employing hexane–toluene–methanol (3:1:1) as solvent, afforded a set of active fractions that were further separated by ambient column and high performance silica gel chromatography, to yield combretastatin A-2 (**5***a*, NSC 383473, ED_{50} 0.027 μg/mL), combretastatin A-3 (**5***b*, NSC 382393, ED_{50} 0.026 μg/mL), and combretastatin B-2 (**3***b*, NSC 601287, ED_{50} 0.32 μg/mL). The structures of these interesting cell-growth inhibitory com-

pounds were unequivocally assigned as summarized in the sequel.

Both the ultraviolet and infrared spectra of combretastatins A-2, A-3, and B-2 suggested aromatic systems and this was further supported by high resolution electron impact mass spectra (hreims) that revealed the molecular formulae $C_{17}H_{16}O_5$, $C_{17}H_{18}O_5$, and $C_{17}H_{20}O_5$ respectively. The 400-MHz ^{1}H nmr spectrum of the A-2 (**5***a*) exhibited two methoxyl group protons (δ 3.750 and 3.870), methylenedioxy protons at δ 5.935 (supported by a ^{13}C nmr signal at δ 101.35 and ir band at 930 cm^{-1}), and signals integrating for 7 protons in the aromatic region. Two sets of relatively shielded AB spin systems appeared in the ^{1}H nmr spectrum totalling four protons. One of these sets appeared as a doublet at δ 6.458 (J = 1.32 Hz) with its counterpart at δ 6.483 (J = 1.32 Hz), typical of two *meta*-coupled aromatic protons. The other AB spin system showed doublets at δ 6.383 and 6.420 (J = 12.16 Hz each). Signals for the other three aromatic protons were split into an ABC system with J_{AC} = 0.0 Hz, typical of *ortho–ortho–meta* disposed aromatic protons. A relatively upfield one-proton doublet appeared at δ 6.732 (J_{AB} = 8.4 Hz), a downfield doublet of doublets and a doublet (one proton each) at δ 6.773 (dd, J_{BA} = 8.4 and J_{BC} = 2.0 Hz) and 6.875 (J_{BC} = 2.0 Hz). Another one-proton broad singlet resonated at δ 5.520 and disappeared upon D_2O exchange, suggesting the presence of a phenolic group. Confirmation of this observation was achieved by acetylation (**5***a* → **5***c*) and conversion to *p*-bromophenylcarbamate **5***d*.

When combretastatin A-2 was catalytically hydrogenated, the mass spectrum of the dihydro product (**3***c*) gave a relatively small molecular ion at m/z 302 and two major fragment ions at m/z 165 ($C_9H_9O_3$) and 137 ($C_8H_9O_2$), resulting from cleavage of the benzyl bond. The mass spectral analysis suggested presence of a methoxyl and methylenedioxy group in one aromatic ring and a methoxyl and hydroxyl group in the other. Examination of the ^{1}H nmr spectrum of the dihydro derivative **3***c* revealed the absence of doublets at δ 6.383 and 6.420. Instead a four-proton broad singlet was displayed at δ 2.78, typical of the benzyl protons of a bibenzyl unit. On this basis, combretastatin A-2 (**5***a*) was assumed to be a stilbene.

Interpretation of the ^{13}C nmr spectra (Table 1) of combretastatin A-2 (**5***a*), its acetate (**5***c*), and dihydro derivative (**3***c*) suggested that all contained (on the basis of chemical shift additive rules, ref. 9) a 3,4-methylenedioxy-5-methoxy substitution pattern in one phenyl ring and 3′-hydroxy-4′-methoxy substitution in the other. The 3′-hydroxy-4′-methoxy substitution pattern in the latter ring was further supported by an *ortho–para* shift of +8.3 ppm at C-2′, +5.0 at C-4′, and +6.5 at C-6′ in the ^{13}C nmr, as a result of acetylation. Once the substitution pattern in the aromatic rings was securely established, the geometry at the ethylene bridge was assigned as *Z* based on the olefin ^{1}H nmr coupling constant (J = 12.16 Hz). A coupling constant of 12.2 Hz was observed in the ^{1}H nmr spectrum of combretastatin A-1 and the *cis*-olefin geometry was independently proved by an X-ray crystal structure determination (8). Therefore, combretastatin A-2 was assigned structure **5***a* and this was unequivocally confirmed by total synthesis (*vide infra*).

The 400-MHz ^{1}H nmr spectra of combretastatin A-3 showed signals corresponding to 3-methoxy groups, and in general indicated that combretastatin B-2 was its dihydro derivative. Catalytic hydrogenation of A-3 to B-2 confirmed this relationship. The ^{1}H nmr spectrum of A-3 displayed two *meta*-coupled aromatic protons at δ 6.427 and 6.535 (J = 1.72 Hz each), and a set of ABC spin system protons with J_{AC} = 0 Hz. The most shielded doublet of this set appeared at δ 6.727 (J_{AB} = 8.4 Hz) and the relatively deshielded protons at δ 6.792 (dd, J_{BA} = 8.4 Hz) and 6.897 (d, J_{CB} = 2.0 Hz). The close proximity of their signals to those in combretastatin A-2 suggested a similar substitution pattern. The ^{1}H nmr spectrum also displayed a set of AB spin system protons at δ 6.380 and 6.439 (J = 12.2 Hz each) and two phenolic group protons at δ 5.514 and 5.679, which disappeared upon D_2O exchange. The assumption of two phenol groups in A-3 was confirmed by acetylation (**5***b*–**5***e*).

The mass spectrum of combretastatin B-2 showed a molecular ion at m/z 304 and two major fragments at m/z 167 ($C_9H_{11}O_3$) and 137 ($C_8H_9O_2$) arising from cleavage of the benzyl bond. In turn this suggested that one ring contained two methoxyl and one hydroxyl groups and the other one methoxyl and one hydroxyl group. The lack of an AB spin system with J = 12.2 Hz in the ^{1}H nmr spectrum of the combretastatin A-2 hydrogenation product (*vide supra*) and appearance of a four-proton broad singlet at δ 2.785 ppm was consistent with structure **3***b* for combretastatin B-2.

Finally, the substitution pattern in the aromatic rings of both A-3 (**5***b*) and B-2 (**3***b*) was established as 3-hydroxy-4,5-dimethoxy and 3′-hydroxy-4′-methoxy by application of chemical shift additive rules (9) in interpreting the ^{13}C nmr spectra (Table 1) of these substances and diacetate **5***c*. The assignments were further supported by the acetylation shifts seen in both the ^{13}C and ^{1}H nmr spectra. These shifts were similar to those appearing in the spectra of combretastatin A-2 acetate. Thus the structure of combretastatin A-3 was established as *Z*-stilbene **5***b* and combretastatin B-2 as bibenzyl **3***b*. The structures were confirmed (as summarized below) by unambiguous syntheses. Thus combretastatins A-2 and A-3 represent valuable new additions to the rare (heretofore, seven members) *cis*-stilbene family of plant biosynthetic products (10–12).

A very practical synthesis of combretastatin A-2 was achieved,

based on condensing the ylide from phosphonium bromide **6***a* with aldehyde **7***a*. Methyl gallate (**7***b*) proved to be a very effective starting point for a more convenient (cf. ref. 13) preparation of aldehyde **7***a*. Reaction of phenol **7***b* with aqueous sodium borate formed the *ortho*-borate ester and allowed specific methylation of the remaining hydroxy group using dimethylsulfate. Acid hydrolysis of the borate ester afforded 3,4-dihydroxy-5-methoxybenzoate (**7***a*, 84.5% yield). Conversion to the methylenedioxy derivative (**7***d*, 98% yield) was accomplished by fluoride-assisted methylenation with dibromomethane and cesium fluoride. Benzoate **7***d* was reduced with lithium aluminum hydride to benzyl alcohol **7***e* in 98% recovery. Oxidation of benzyl alcohol (**7***e*) with pyridinium chlorochromate (PCC) led to the required aldehyde (**7***a*) in 90% yield (73% overall).

Reaction of isovanillyl alcohol **6***b* with phosphorus tribromide in benzene–tetrahydrofuran yielded benzyl bromide **6***c*. The benzyl bromide (**6***c*) was unstable (more so in dichloromethane) and immediately converted to phosphonium bromide **6***a*. The ylide prepared (two equivalents of butyllithium in tetrahydrofuran) from phosphonium bromide **6***a* was treated with aldehyde **7***a* to yield a mixture of olefins **5***a* and **8***a* in 57% yield with a *Z*/*E* ratio of 1:16 (by ^1H nmr analysis). The isomers were separated by chromatography and the yield of *Z* isomer was increased by irradiating the *E* isomer in dioxane solution with long-wave (365 nm) uv light, to provide a *Z*/*E* ratio of 2.5:1.5. The *Z* isomer was identical with natural combretastatin A-2 (**5***a*), by both spectral and chromatographic comparisons. A route analogous to that used for A-2 (**5***a*) was adopted for synthesis of combretastatin A-3 (**5***b*). Therefore, benzoic acid **7***f* was converted to silyl ether **7***g* (14) and reduced to benzyl alcohol **7***h*. Reaction of benzyl alcohol **7***h* with phosphorus tribromide was followed by conversion of benzyl bromide **7***i* to phosphonium bromide **7***j*. The ylide prepared from bromide **7***j* upon reaction with aldehyde **6***d* yielded a mixture of olefins **5***f* and **8***b* in 82% yield with a *Z*/*E* ratio of 5:1 (by ^1H nmr). The geometrical isomers were separated using multiple development preparative layer chromatography. The major product, *Z* isomer **5***f*, was deprotected using tetrabutylammonium fluoride to afford combretastatin A-3 in 84% yield, identical (by tlc, ir, nmr) with the natural product.

The quite different olefin *Z*/*E* isomeric ratios obtained in the

Wittig reactions leading to A-2 and A-3 are noteworthy. In both the A-2 and A-3 syntheses, the *E* isomer(s) would normally be predicted as major product with a reaction performed in the presence of a lithium salt (15). However, in the synthesis of combretastatin A-3, the predominant product was the *Z* isomer. Apparently, the reaction is kinetically controlled due to the steric bulk (16) of the *tert*-butyldimethylsilyl group, thereby stabilizing the intermediate oxaphosphetane in the *erythro* (17) form to yield the *Z* isomer. Analogous results were realized in our parallel synthesis of combretastatin A-1 (8). Alternatively, the rate of dissociation to *cis*-stilbenes may be faster than reversal to the *threo*-oxaphosphetanes or starting ylides (18).

In experiments conducted by Dr. E. Hamel, both combretastatins A-2 and A-3 strongly inhibited tubulin polymerization (7, 8). Other biological studies with these new *cis*-stilbenes are in progress.

Experimental

Each of the synthetic intermediates was used as received from Sigma–Aldrich or from Lancaster Synthesis. All chromatographic solvents were redistilled. Sephadex LH-20 (particle size 25–100 μm) was obtained from Pharmacia Fine Chemicals AB (Uppsala, Sweden) and silica gel 60 (70–230 mesh) was supplied by E. Merck (Darmstadt, Germany). Analtech, Inc. (Newark, Delaware) silica gel GHLF U (0.25 mm layer thickness) was employed for thin-layer chromatograms and developed with an anisaldehyde – acetic acid or ceric sulfate – sulfuric acid spray reagent (heated at approximately 150°C for 5–10 min) and (or) by use of ultraviolet light.

In each of the synthetic procedures, solvent extracts of aqueous solutions were dried over anhydrous sodium sulfate. Ether refers to diethyl ether. Each pure specimen was colorless. The mutual identity of natural and synthetic specimens was established by comparison of infrared (NaCl plates) and ^{1}H nmr spectra combined with results from thin-layer chromatographic (tlc) comparisons in several solvents.

All melting points are uncorrected and were observed with a Kofler-type hot-stage apparatus. Ultraviolet spectra were obtained using a Hewlett–Packard model 8540A uv/vis spectrophotometer. Infrared spectra were measured with a Nicolet FT-IR model MX-1 unit and nuclear magnetic resonance spectra were obtained with a Bruker AM-400 instrument (deuteriochloroform as solvent and tetramethylsilane as the internal standard with chemical shifts recorded using the δ scale). The SFORD technique was used for determining multiplicities in ^{13}C nmr spectra. The mass spectral measurements were performed with a MS-50 instrument at the NSF Regional Facility, University of Nebraska, Lincoln, Nebraska. Elemental microanalyses were determined at MicAnal, Tucson, Arizona.

Plant taxonomy

Combretum caffrum (Eckl. and Zeyh.) Kuntze stem wood was collected (1979) and identified as part of the National Cancer Institute–U.S. Department of Agriculture research program directed by Drs. John Douros, Matthew I. Suffness, and James A. Duke.

Extract and solvent partition procedures

The stem wood (77 kg dry wt.) of *Combretum caffrum* was extracted with 1:1 methylene chloride – methanol and converted to a methylene chloride fraction that was partitioned between hexane and methanol–water (9:1) followed by adjustment to 3:2 methanol–water and extraction with methylene chloride as previously described (8). The methylene chloride fraction (827.9 g) from the solvent partitioning sequence was separated by steric exclusion chromatography on Sephadex LH-20 to obtain fractions A and B reported earlier (8).

*Isolation of combretastatin A-2 (**5**a), A-3 (**5**b), and B-2 (**3**b)*

Fraction A (28.6 g) was further separated on a column of Sephadex LH-20 (2.5 kg) by partition chromatography employing hexane–toluene–methanol (3:1:1) to furnish an active fraction (1.97 g, PS ED_{50} 1.8×10^{-2} μg/mL) that was redissolved in 3:1:1 hexane–toluene–methanol (20 mL), and the solution was filtered. The filtrate was chromatographed on a Sephadex LH-20 (200 g) column with the same solvent system. The resulting active fraction (1.35 g, PS ED_{50} 2.4×10^{-2} μg/mL) was dissolved in hexane – ethyl acetate (1:1, 5 mL) and chromatographed on a column (60 × 2.5 cm) of silica gel (60 g). Gradient elution, from 4:1 to 1:1 hexane – ethyl acetate, afforded in a 3:1 fraction the next PS (0.7 g, ED_{50} 1.0×10^{-2} μg/mL) active material. Rechromatography in acetone (2 mL) over a long column (100 × 1.2 cm) of silica gel (45 g) using the gradient hexane – ethyl acetate 9:1–4:1 yielded in a 4:1 fraction a pure specimen of combretastatin A-2 (**5***a*, 0.442 g, 5.74×10^{-4}% yield based on the dried plant, PS ED_{50} 2.7×10^{-2} μg/mL) as a viscous oil; R_f 0.46 (1:1 hexane – ethyl acetate); uv (CH_3OH) λ_{max} (ε): 223 (17 175), 303 (7190); ir ν_{max} (NaCl): 3490, 1508, 1452, 1440, 1427, 1272, 1196, 1129, 1114, 1085, 1042, 930 cm^{-1}; ^{1}H nmr (400 MHz): 3.750 (3H, s, OCH_3), 3.870 (3H, s, OCH_3), 5.520 (1H, s, OH, disappeared upon adding D_2O), 5.935 (2H, s, -OCH_2O-), 6.383 (1H, d, J = 12.16 Hz, -CH=CH-), 6.420 (1H, d, J = 12.16 Hz, -CH=CH-), 6.458 (1H, d, J = 1.32 Hz, H-2 or H-6), 6.483 (1H, d, J = 1.32 Hz, H-6 or H-2), 6.731 (1H, d, J = 8.4 Hz, H-5′), 6.773 (1H, dd, J = 8.4, 2.0 Hz, H-6′), 6.875 (1H, d, J = 2.0 Hz, H-2′); ^{13}C nmr (see Table 1); hreims (*m*/*z*): 300.1001 (100, M^+, calcd. for $C_{17}H_{16}O_5$: 300.0998), 285.0767 (4, $C_{16}H_{13}O_5$), 267.0666 (10, $C_{16}H_{11}O_4$), 239.0714 (17, $C_{15}H_{11}O_3$).

Active fraction B (30.6 g) was also separated in hexane–toluene–methanol (3:1:1) by partition chromatography on Sephadex LH-20 (2.5 kg). The PS active components were concentrated in two fractions: 8.11 g (PS, ED_{50} 2.7 μg/mL) and 1.57 g (ED_{50} 0.36 μg/mL). The latter fraction was chromatographed on a column (70 × 2.5 cm) of silica gel (70 g) and eluted with hexane – ethyl acetate (4:1–1:1). A fraction eluted with 4:1 hexane – ethyl acetate gave a pure specimen of combretastatin A-3 (**5***b*, 480.7 mg, 6.24×10^{-4}% yield, PS ED_{50} 2.6×10^{-2} μg/mL) as a viscous oil; R_f 0.40 (1:1 hexane – ethyl acetate); uv (CH_3OH) λ_{max} (ε): 251 (8090), 295 (8895); uv (CH_3OH + $NaOCH_3$) λ_{max}: 259 (9078), 279 (7383), 296 (7402); ir ν_{max} (NaCl): 3430, 1583, 1509, 1458, 1441, 1430, 1274, 1234, 1201, 1114, 1104 cm^{-1}; ^{1}H nmr (400 MHz): 3.668 (3H, s, OCH_3), 3.867 (3H, s, OCH_3), 3.886 (3H, s, OCH_3), 5.514, 5.680 (1H, each, brs, OH, D_2O exchanged), 6.381 (1H, d, J = 12.2 Hz, -CH=CH-), 6.427 (1H, d, J = 1.72 Hz, H-6), 6.439 (1H, d, J = 12.2 Hz, -CH=CH-), 6.535 (1H, d, J = 1.72 Hz, H-2), 6.72 (1H, d, J = 8.4 Hz, H-5′), 6.792 (1H, dd, J = 8.4 Hz, 2.0 Hz, H-6′), 6.897 (1H, d, J = 2.0 Hz, H-2′); ^{13}C nmr (refer to Table 1); hreims (*m*/*z*): 302.1156 (100, M^+, calcd. for $C_{17}H_{18}O_5$: 302.1154), 287.0919 (14, $C_{16}H_{15}O_5$), 269.0813 (14, $C_{16}H_{13}O_4$).

The active fraction weighing 8.11 g was chromatographed in ethyl acetate (20 mL) on a column of silica gel (200 g). Elution with hexane – ethyl acetate (3:1) and combination of earlier fractions furnished a 0.181-g fraction (PS, ED_{50} 0.19 μg/mL) that was further purified on a Whatman hplc column (500 × 10 mm) packed with Partisil (M-9). Elution with hexane-2-propanol (9:1) at a flow rate of 0.56 mL/min afforded pure combretastatin B-2 (**3***b*, 51.7 mg, 6.71×10^{-5}% yield, PS, ED_{50} 0.32 μg/mL) as another viscous oil; R_f 0.42 (1:1 hexane – ethyl acetate); uv (CH_3OH) λ_{max} (ε): 220 (22 902), 280 (6120); ir ν_{max} (NaCl): 3437, 1595, 1512, 1461, 1442, 1430, 1351, 1278, 1237, 1150 cm^{-1}; ^{1}H nmr (400 MHz): 2.785 (1H, brs, -CH_2—CH_2-), 3.819 (3H, s, OCH_3), 3.856 (3H, s, OCH_3), 3.866 (3H, s, OCH_3), 5.605, 5.748 (1H each, brs, OH, D_2O exchanged), 6.264 (1H, d, J = 1.88 Hz, H-6), 6.465 (1H, d, J = 1.88 Hz, H-2), 6.648 (1H, dd, J = 8.12, 2.0 Hz, H-6′), 6.760 (1H, d, J = 8.12 Hz, H-5′), 6.794 (1H, d, J = 2.0 Hz, H-2′); ^{13}C nmr (see Table 1); hreims (*m*/*z*): 304.1326 (30, M^+, calcd. for $C_{17}H_{20}O_5$: 304.1311), 167.0708 (100, $C_9H_{11}O_3$), 137.0604 (65, $C_8H_9O_2$).

*Acetylation of combretastatin A-2 (**5**a) and A-3 (**5**b)*

Both combretastatin A-2 (**5***a*, 12.0 mg) and combretastatin A-3 (**5***b*, 18.0 mg) were acetylated (separately) with acetic anhydride (1.0 mL) – pyridine (0.5 mL) at room temperature (72 h). Solvent was evaporated under a stream of nitrogen to afford acetate **5***c* and diacetate **5***e* as viscous oils; *combretastatin A-2 acetate* **5***c* displayed R_f 0.60 (1:1

hexane – ethyl acetate); ir ν_{max} (NaCl): 1767, 1510, 1430, 1264, 1199, 1127, 1112, 1086, 1042, 930, 773 cm^{-1}; ^1H nmr (400 MHz): 2.273 (3H, s, $COCH_3$), 3.731 (3H, s, OCH_3), 3.809 (3H, s, OCH_3), 5.940 (2H, s, $-OCH_2O-$), 6.410 (2H, s, -CH=CH-), 6.453 (1H, d, J = 1.1 Hz, H-2, or H-6), 6.473 (1H, d, J = 1.1 Hz, H-6 or H-2), 6.840 (1H, d, J = 8.56 Hz, H-5′), 6.977 (1H, d, J = 2.0 Hz, H-2′), 7.107 (1H, dd, J = 8.56, 2.0 Hz, H-6′); ^{13}C nmr (see Table 1); hreims (m/z): 342.1101 (59, M^+, calcd. for $C_{19}H_{18}O_6$: 342.1103), 300.0987 (100, $C_{17}H_{16}O_5$); *combretastatin A-3 diacetate* (**5***e*) showed R_f 0.54 (1:1 hexane – ethyl acetate); ir ν_{max} (NaCl): 1769, 1510, 1370, 1284, 1265, 1242, 1203, 1132, 1113, 1092 cm^{-1}; ^1H nmr (400 MHz): 2.270 (3H, s, $COCH_3$), 2.287 (3H, s, $COCH_3$), 3.675 (3H, s, OCH_3), 3.807 (3H, s, OCH_3), 3.813 (3H, s, OCH_3), 6.390 (1H, d, J = 12.2 Hz, -CH=CH-), 6.445 (1H, d, J = 12.2 Hz, -CH=CH-), 6.634 (1H, d, J = 1.76 Hz, H-6), 6.708 (1H, d, J = 1.76 Hz, H-2), 6.849 (1H, d, J = 8.46 Hz, H-5′), 7.037 (1H, d, J = 2.0 Hz, H-2′), 7.115 (1H, dd, J = 8.46, 2.0 Hz, H-6′); ^{13}C nmr (in Table 1); hreims (m/z): 386.1365 (71, M^+, calcd. for $C_{21}H_{22}O_7$: 386.1366), 344.1252 (56, $C_{19}H_{20}O_6$), 302.1146 (100, $C_{17}H_{18}O_5$).

*Hydrogenation of combretastatin A-2 (***5**a*) and combretastatin A-3 (***5**b*)

In separate experiments combretastatin A-2 (**5***a*, 12.0 mg) and combretastatin A-3 (**5***b*, 10 mg) in methanol (10 mL) and 5% Pd/C (10 mg) were each treated with a positive pressure of hydrogen at ambient temperature overnight. Catalyst was removed by filtering the solution and the product purified by preparative layer chromatography on regular (250 μm) Analtech plates with hexane – ethyl acetate (1:1) as mobile phase. The oily product from combretastatin A-3 was identical with natural *combretastatin B-2* while the dihydro product (*bibenzyl* **3***c*) from combretastatin A-2 (**5***a*) was a viscous oil exhibiting R_f 0.58 (1:1, hexane – ethyl acetate); ir ν_{max} (NaCl): 3478, 1633, 1590, 1510, 1451, 1441, 1429, 1274, 1194, 1129, 1089, 925 cm^{-1}; ^1H nmr (90 MHz): 2.78 (4H, s, $-CH_2CH_2-$), 3.86 (3H, s, OCH_3), 5.93 (2H, s, $-OCH_2O-$), 6.30 (H, d, J = 1.5 Hz, H-2 or H-6), 6.38 (1H, d, J = 1.5 Hz, H-6 or H-2), 6.63 (1H, dd, J = 8.2, 1.9 Hz, H-6′), 6.76 (1H, d, J = 8.2 Hz, H-5′), 6.77 (1H, d, J = 1.9 Hz, H-2′); ^{13}C nmr (entered in Table 1); hreims (m/z): 302.1149 (29, M^+, calcd. for $C_{17}H_{18}O_5$: 302.1154), 165.0547 (100, calcd. for $C_9H_9O_3$: 165.0552), 137.0597 (67, calcd. for $C_8H_9O_2$: 137.0603).

*Combretastatin A-2/3′-*O*-p-bromophenylcarbamate (***5**b*)

To a solution of combretastatin A-2 (**5***a*, 10 mg) in dry methylene chloride (1 mL) was added a solution of *p*-bromophenyl isocyanate (80 mg) in methylene chloride (1 mL). The mixture was stirred for 5 days at room temperature and heated at reflux for 24 h. The reaction mixture was cooled to room temperature and the solution filtered. The filtrate was concentrated and chromatographed (preparative layer) with hexane – ethyl acetate (1:1) as mobile phase. The band was eluted with acetone and crystallized from methylene chloride to afford an amorphous powder, mp 138–140°C; ir ν_{max} (NaCl): 3310, 1734, 1722, 1533, 1509, 1491, 1431, 1398, 1202, 1128, 1114, 924, 750 cm^{-1}; ^1H nmr (90 MHz): 3.75 (3H, s, OCH_3), 3.94 (3H, s, OCH_3), 5.93 (2H, s, OCH_2O), 6.43 (2H, brs, -CH=CH-), 6.48 (2H, AB_q, J = 1.1 Hz, H-2, H-6), 6.65–7.0 (3H, M, H-2′, -5′, -6′), 7.09 (1H, s, NH), 7.35 (2H, d, J = 8.5 Hz, ArH), 7.41 (2H, d, J = 8.5 Hz, ArH).

*Methyl 3,4-dihydroxy-5-methoxybenzoate (***7**c*)

Methyl gallate (**7***b*, 10 g, 54.3 mmol) was added to a solution of borax (80 g) in 800 mL of water with stirring (30 min). Dimethyl sulfate (30 mL) and a solution of sodium hydroxide (13 g in 50 mL of water) were added from two separate dropping funnels over 2.5 h and stirring was continued overnight. Concentrated sulfuric acid (50 mL) was added and stirring continued an additional hour. The product was extracted with chloroform (5 × 1 L and each time stirring the solution for 20 min). The combined chloroform extracts were washed with brine (500 mL), dried, and concentrated, and the residue crystallized from methanol–benzene to yield methyl ether **7***c* (9.1 g, 84.5%); mp 110–111°C (lit. (19) mp 112°C); ir ν_{max} (NaCl): 3380, 1700, 1696, 1611, 1436, 1341, 1314, 1229, 1204, 1089 cm^{-1}; ^1H nmr (90 MHz): 3.88 (3H, s, OCH_3), 3.94 (3H, s, OCH_3), 5.50–6.0 (2H, OH), 7.22 (1H, d, J = 1.8 Hz, ArH), 7.34 (1H, d, J = 1.8 Hz, ArH).

Under analogous experimental conditions but using continuous extraction with ethyl acetate in place of chloroform yielded a mixture of methyl gallate **7***c* (7.0 g) and 3-*O*-methyl gallic acid (1.4 g).

*Methyl 3,4-methylenedioxy-5-methoxybenzoate (***7**d*)

Cesium fluoride (24.5 g, 161.5 mmol) was added to a stirring solution of phenol **7***c* (7.3 g, 36.8 mmol) in dimethylformamide (90 mL) under argon. After stirring 20 min, dibromomethane (2.8 mL, 40.5 mmol) was added and the mixture heated for 2 h. The reaction was allowed to cool to room temperature. Ether (300 mL) was added and the ethereal solution was washed with cold water (3 × 50 mL), dried, and concentrated to afford methylenedioxy derivative **7***d* as a powder (7.62 g, 98% yield), which was recrystallized from acetone–hexane, mp 89–91°C; ir ν_{max} (NaCl): 1714, 1636, 1507, 1436, 1369, 1327, 1245, 1177, 1107, 1041 cm^{-1}; ^1H nmr (90 MHz): 3.89 (3H, s, OCH_3), 3.94 (3H, s, OCH_3), 6.06 (2H, s, $-CH_2-$), 7.21 (1H, d, J = 1.4 Hz, ArH), 7.33 (1H, d, J = 1.4 Hz, ArH); eims, m/z (rel. int.%): 210 (100, M^+), 179 (75, $M^+ - OCH_3$). *Anal.* calcd. for $C_{10}H_{10}O_5$: C 57.15, H 4.80; found: C 57.10, H 4.74.

*3,4-Methylenedioxy-5-methoxybenzyl alcohol (***7**e*)

Lithium aluminum hydride (0.50 g) was added to a stirred solution of methyl ester **7***d* (1.7 g) in ether–tetrahydrofuran (2:1, 50 mL). After stirring for 30 min, the reaction mixture was cooled to 5°C and saturated aqueous sodium sulfate was carefully added until a white solid appeared. The precipitate was collected by filtration, the solution was dried, and the solvent evaporated to give crystalline alcohol **7***e* (1.45 g, 98% yield). Recrystallization from ethyl acetate – hexane afforded an analytical sample melting at 66–67°C (lit. (4) mp 66°C); ir ν_{max} (NaCl): 3220, 1632, 1467, 1453, 1435, 1323, 1203, 1133, 1093, 1008, 918 cm^{-1}; ^1H nmr (90 MHz): 1.75 (1H, brs, OH), 3.90 (3H, s, OCH_3), 4.58 (2H, brs, $-CH_2OH$), 5.96 (2H, s, $-CH_2-$), 6.55 (2H, s, ArH).

*3,4-Methylenedioxy-5-methoxybenzaldehyde (***7**a*)

To a stirred yellow mixture of pyridinium chlorochromate (20) (1.72 g, 7.99 mmol) and anhydrous sodium acetate (0.655 g, 7.99 mmol) in methylene chloride CH_2Cl_2 (30 mL) was added at once a solution of benzyl alcohol **7***e* (1.32 g, 7.26 mmol) in methylene chloride (10 mol). The greyish solution, which formed immediately, was stirred for 2 h, and the reaction was monitored by tlc (1:1 hexane – ethyl acetate). After filtering the solution through a small silica column, colorless aldehyde **7***a* (1.18 g, 91% yield) was eluted with hexane – ethyl acetate (7:3). Recrystallization from acetone afforded needles, mp 132–133°C (lit. (13) mp 130–131°C, 129–130°C); ir ν_{max} (NaCl): 1694, 1676, 1622, 1508, 1474, 1451, 1362, 1325, 1134, 1190 cm^{-1}; ^1H nmr (90 MHz): 3.95 (3H, s, OCH_3), 6.09 (2H, s, $-CH_2-$), 7.04 (1H, d, J = 1.4 Hz, ArH), 7.12 (1H, d, J = 1.4 Hz, ArH), 9.78 (1H, s, -CHO).

*3-Hydroxy-4-methoxybenzyltriphenylphosphonium bromide (***6**a*)

A solution of phosphorus tribromide (8.51 mL) in a mixture of tetrahydrofuran–benzene (1:2, 330 mL) was added to a cool (0°C) solution of 3-hydroxy-4-methoxybenzyl alcohol (**6***b*, 6.13 g, 40 mmol) in the same solvent (75 mL) under argon. The colorless solution was stirred at room temperature for 2 h, poured onto ice water (100 mL), and extracted with ether (2 × 100 mL). The ethereal layer was washed once with water (50 mL) followed by brine (2 × 50 mL), dried, and evaporated to dryness to afford bromide **6***a* as an amorphous powder. A solution prepared from the crude bromide, anhydrous benzene (150 mL), and triphenylphosphine (15.72 g, 60 mmol) was stirred for 10 min at room temperature and heated at reflux for 2 h. On cooling to room temperature, a viscous oil separated. The upper solvent phase was decanted and the oil was crystallized from ethanol–ether to give bromide **6***a* as a powder (10.0 g, 52.4% from alcohol **6***b*); mp 262–264°C; ir ν_{max} (NaCl): 3158, 1604, 1589, 1527, 1512, 1437, 1279, 1255, 1128, 1111, 743 cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$ + D_2O): 3.77 (3H, s, OCH_3), 4.95 (2H, d, J_{PCCH} = 13.7 Hz, $-CH_2-$), 6.57 (2H, brs, ArH), 6.83 (1H, brs, ArH), 7.56–7.77 (15H, ArH). *Anal.* calcd. for $C_{26}H_{24}O_2PBr$: C 65.6, H 5.05, Br 16.67; found: C 64.50, H 5.07, Br 16.78.

*3'-Hydroxy-3,4-methylenedioxy-4',5-dimethoxy-(E)- and -(Z)-stilbene (**5**a and **8**a, combretastatin A-2 (**5**a), and E isomer (**8**a)*

Phosphonium bromide **6***a* (3.35 g, 7.0 mmol) was suspended in tetrahydrofuran (100 mL), stirred, and cooled to −50°C (under argon), and *n*-butyllithium (10 mL, 15 mmol) was added using a syringe and septum technique. The solution became deep red immediately and upon reaching room temperature was stirred 20 min prior to adding a solution of aldehyde **7***a* (1.15 g, 6.39 mmol) in tetrahydrofuran (30 mL). All the aldehyde was consumed in 30 min. Cold hydrochloric acid (1 *M*, 50 mL) was added followed by water (100 mL), and the product was extracted with ethyl acetate (3 × 100 mL) from the colorless solution. The ethyl acetate extract was washed with water (50 mL), brine (50 mL), dried, and the solvent evaporated. The crude product was chromatographed on a silica gel (50 g) column. Elution with hexane – ethyl acetate (17:3) afforded a mixture of *Z*- and *E*-stilbenes (1.09 g, 57% yield, ratio *Z*/*E* 1:16). Half of the product was rechromatographed on a longer silica gel column, and elution with hexane – ethyl acetate (9:1) provided first combretastatin A-2 (40 mg) as a viscous oil identical with natural combretastatin A-2 (**5***a*) and later the *E* isomer **8***a* (0.20 g) as needles from ethyl acetate – hexane, mp 145–150°C; ir ν_{max} (NaCl): 3490, 1622, 1509, 1463, 1440, 1429, 1319, 1279, 1263, 1254, 1133 cm^{-1}; ^1H nmr (400 MHz): 3.908 (3H, s, OCH_3), 3.941 (3H, s, OCH_3), 5.598 (1H, brs, OH), 5.978 (2H, s, $-OCH_2O-$), 6.629 (1H, d, J = 1.30 Hz, H-2 or H-6), 6.729 (1H, d, J = 1.30 Hz, H-6 or H-2), 6.825 (1H, d, J = 8.32 Hz, H-5'), 6.848 (2H, s, -CH=CH-), 6.945 (1H, d, J = 8.32, 2.0 Hz, H-6'), 7.113 (1H, d, J = 2.0 Hz, H-2'). *Anal.* calcd. for $C_{17}H_{16}O_5$: C 68.00, H 5.37; found: C 67.63, H 5.37.

Photochemical isomerization of E*-stilbene **8**a to combretastatin A-2 (**5**a)*

A solution of *E* isomer **8***a* (40 mg) in dioxane (30 mL) – water (1 mL) was stirred and irradiated (directly into the solution from above) with long-wavelength (365 nm) uv for 5 h. The ultraviolet source was an uv lamp used for visualizing tlc plates equipped with both short-wave (254 nm) and long-wave (365 nm) lamps. The solvent was removed and ^1H nmr examination of the residue revealed an isomeric mixture in the ratio *Z*/*E* of 2.5:1.5. Separation by chromatography on a silica gel column and elution with hexane – ethyl acetate (9:1) yielded combretastatin A-2 (15 mg).

*3-*tert*-Butyldimethylsilyloxy-4,5-dimethoxybenzyl alcohol (**7**h)*

Diisopropylethylamine (11.3 mL, 77 mmol) was added to a stirred solution of 3-hydroxy-4,5-dimethoxybenzoic acid (**7***f*, 5.0 g, 25 mmol) in dimethylformamide (50 mL, under argon) followed by addition of *tert*-butyldimethylsilyl chloride (8.32 g, 55 mmol), and the reaction mixture was stirred for 1 h. Ice (50 g) was added and the reaction mixture was extracted with ethyl ether (200 mL). The ethereal solution was washed with cold water (3 × 50 mL), sodium bicarbonate solution (10%, 50 mL), water (50 mL), dried, and solvent evaporated to yield *tert*-butyldimethylsilyl 3-*tert*-butyldimethylsilyloxy-4,5-dimethoxybenzoate (**7***g*) as a chromatographically homogeneous oil (10.4 g, 97% yield). Attempts at high vacuum distillation (100°C at 1.0 Torr; 1 Torr = 133.3 Pa) failed and resulted in desilylation. However, the oil showed the correct ir and ^1H nmr spectral data for silane **7***g*; ir ν_{max} (NaCl): 2932, 1700, 1590, 1420, 1350, 1254, 1230, 1221, 1118, 839, 775 cm^{-1}; ^1H nmr (90 MHz): 0.107 (6H, s, 2 × $SiCH_3$), 0.276 (6H, s, 2 × $SiCH_3$), 0.922 (18H, s, 6 × CH_3), 3.751 (3H, s, OCH_3), 3.790 (3H, s, OCH_3), 7.170 (2H, AB_q, J_{AB} = 1.5 Hz, ArH).

Silyl ester **7***g* (10.0 g, 23 mmol) was dissolved in ether (300 mL) and stirred (under argon) with lithium aluminum hydride (2.0 g) at room temperature for 1 h. Saturated ammonium chloride solution (ice-cold) was added and the ether layer separated. The aqueous phase was extracted with ether (3 × 200 mL) and the combined ether extract was washed with sodium bicarbonate solution, cold water, and dried. After solvent removal, the residual oil was found to be chromatographically homogeneous alcohol **7***h* (6.0 g, 86% yield); the oil distilled at 210°C (0.04 Torr) and displayed ir ν_{max} (NaCl): 3450, 2931, 1587, 1501, 1427, 1233, 1118, 1004, 837, 782 cm^{-1}; ^1H nmr (90 MHz): 0.201 (6H, s, 2 × CH_3), 1.026 (9H, s, 3 × CH_3), 1.716 (1H, t, J = 5.9 Hz, OH, D_2O exchanged), 3.794 (3H, s, OCH_3), 4.596 (2H, d, J = 5.9 Hz, $-CH_2OH$, collapsed to a broad singlet upon D_2O exchange), 6.510 (1H, d, J = 1.9 Hz, ArH), 6.610 (1H, d, J = 1.9 Hz, ArH). *Anal.* calcd. for $C_{16}H_{26}O_4Si$: C 60.39, H 8.78; found: C 60.06, H 8.78.

*3-*tert*-Butyldimethylsilyloxy-4,5-dimethoxybenzyltriphenylphosphonium bromide (**7**j)*

Before adding phosphorus tribromide (0.95 mL) in methylene chloride (5 mL) a solution of silyloxybenzyl alcohol **7***h* (6.0, 20 mmol) in methylene chloride (anhydrous, 100 mL) was stirred and cooled (−10°C, ice–salt bath) for 15 min. The mixture was stirred 10 min and 10% aqueous sodium bicarbonate solution (50 mL) was added (slowly). The methylene chloride layer was washed with cold water (2 × 50 mL), dried, and solvent evaporated to give 3-*tert*-butyldimethysilyloxy-4,5-dimethoxybenzyl bromide (**7***i*) as a colorless oil (6.4 g, 88% yield), homogeneous by tlc. While the product (**7***i*) was heat sensitive, and distillation was unsuccessful, it did give the correct spectral data for silane **7***i*; ir ν_{max} (NaCl): 2932, 1586, 1500, 1427, 1348, 1250, 1234, 1127, 1111, 838 cm^{-1}; ^1H nmr (90 MHz): 0.183 (6H, s, 2 × CH_3), 1.006 (9H, s, 3 × CH_3), 3.777 (3H, s, OCH_3), 3.855 (3H, s, OCH_3), 4.409 (2H, s, $-CH_2-$), 6.561 (2H, AB_q, J = 2.0 Hz, ArH); ms (*m*/*z*, rel. amt.) 362, 360 (40%, M^+), 305, 303 (80, $M^+ - C_4H_9$), 281 (60, $M^+ - Br$), 253 (75, $M^+ - Br - 28$), 209 (100, $M^+ - Br - C_5H_{12}$), 166 (45, $M^+ - Br - Si(CH_3)_2C(CH_3)_3$).

To a solution of bromide **7***i* (6.0 g, 16.6 mmol) in toluene (50 mL) was added (stirring) a solution of triphenylphosphine (4.36 g, 16.6 mmol) in toluene (10 mL). The mixture was heated to reflux for 15 min. When the clear solution started to become turbid, heating was discontinued and the mixture was stirred overnight at room temperature. The solid phosphonium bromide **7***j* (7.17 g, 69% yield) was recovered by filtration as a powder melting at 248°C; ir ν_{max}(NaCl): 2957, 1586, 1502, 1453, 1436, 1344, 1253, 1113, 836, 742, 721 cm^{-1}; ^1H nmr (90 MHz): 0.58 (6H, s, 2 × CH_3), 1.48 (9H, s, 3 × CH_3), 4.15 (3H, s, OCH_3), 4.32 (3H, s, OCH_3), 5.89 (2H, d, J_{PCH} = 14 Hz, CH_2), 6.71 (1H, t, J = 2.2 Hz, ArH), 7.36 (1H, t, J = 2.2 Hz, ArH), 8.23–8.45 (15H, ArH). *Anal.* calcd. for $C_{33}H_{40}BrO_3PSi$: C 63.56, H 6.46, Br 12.81; found: C 64.04, H 6.57, Br 12.47.

*Combretastatin A-3 (**5**b)*

Butyllithium (2.47 mL, 2.2 mmol) was added to a stirred and cooled (−10°C) suspension of phosphonium bromide **7***j* (1.31 g, 2.1 mmol) in tetrahydrofuran (100 mL). The orange-red solution was stirred at room temperature 10 min. Aldehyde **6***d* (0.532 g, 2.0 mmol) was added and stirring continued another 10 min while the red solution changed to yellow. A tlc examination (4:1, hexane – ethyl acetate) showed completion of reaction. Ice water (100 mL) was added and the product extracted with ether (3 × 100 mL). The ethereal solution was washed with water (100 mL), and concentrated to a gum, which upon silica gel column (40 g) chromatography and elution with hexane – ethyl acetate (97:3) afforded a mixture of 3,3'-bis-(*tert*-butyldimethylsilyloxy)-4',4,5-trimethoxy-(*Z*)- and (*E*)-stilbene (**5***f* and **8***b*) in a ratio of 5:1 (0.870 g, 82% yield). The isomers were separated by preparative layer chromatography on silica gel (20 × 20 cm, 500 μm, E-Merck plates) employing 19:1 hexane – ethyl acetate. The short uv positive upper band was the major product and elution with hexane – ethyl acetate yielded *Z* isomer **5***f* as an oil (423 mg); ir ν_{max} (NaCl): 2930, 1575, 1509, 1250, 1231, 1118, 838, 782 cm^{-1}; ^1H nmr (400 MHz): 0.070 (6H, s, 2 × CH_3), 0.105 (6H, s, 2 × CH_3), 0.932 (9H, s, 3 × CH_3), 0.958 (9H, s, 3 × CH_3), 3.666 (3H, s, OCH_3), 3.761 (3H, s, OCH_3), 3.774 (3H, s, OCH_3), 6.366 (1H, d, J = 12 Hz, -CH=CH-), 6.413 (1H, d, J = 1.84 Hz, H-6), 6.429 (1H, d, J = 12 Hz, -CH=CH-), 6.471 (1H, d, J = 1.84 Hz, H-2), 6.718 (1H, d, J = 8.3 Hz, H-5'), 6.778 (1H, d, J = 2.0 Hz, H-2'), 6.840 (1H, dd, J = 8.3, 2.0 Hz, H-6'). The lower long uv positive band was also eluted with hexane – ethyl acetate to give *E* isomer **8***b* as an oil (80 mg); ir ν_{max} (NaCl): 2930, 1578, 1509, 1427, 1272, 1251, 1117, 838, 782 cm^{-1}; ^1H nmr (400 MHz): 0.183 (6H, s, 2 × CH_3), 0.207 (6H, s, 2 × CH_3), 1.024 (9H, s, 3 × CH_3), 1.028 (9H, s, 3 × CH_3), 3.794 (3H, s, OCH_3), 3.823 (3H, s, OCH_3), 3.901 (3H, s, OCH_3), 6.626

(1H, d, J = 1.88 Hz, H-6), 6.693 (1H, d, J = 1.88 Hz, H-2), 6.800 (1H, d, J = 16.2 Hz, -CH=CH-), 6.825 (1H, d, J = 8.3 Hz, H-5′), 6.845 (1H, d, J = 16.2 Hz, -CH=CH-), 7.020 (1H, d, J = 2.1 Hz, H-2′), 7.047 (1H, dd, J = 8.3 Hz, 2.1 Hz, H-6′). *Anal.* calcd. for $C_{29}H_{46}O_5Si_2$: C 65.62, H 8.73; found: C 66.09, H 8.97.

To a stirred solution of silyl-*Z*-stilbene **5***f* (0.25 g, 0.47 mmol) in tetrahydrofuran (10 mL under argon) was added a 1 *M* tetrahydrofuran solution of tetrabutylammonium fluoride (1 mL, 1.0 mmol). Instantaneously the solution became yellow and reaction was complete as evidenced by tlc (hexane – ethyl acetate 3:2). Ice (5 g) – water (5 mL) was added to the mixture and the product extracted with ether (2 × 25 mL). The ethanol extract was washed with cold water (20 mL) and dried. After evaporation of solvent, the residue in 1:1 hexane – ethyl acetate was filtered through a pipette filled with silica gel (2 g) to afford combretastatin A-3 as an oil (0.13 g, 91% yield), homogeneous by tlc and identical with the natural product.

Enzymes in organic synthesis. 37.[1] Preparation and characterization of potential decalindione substrates of horse liver alcohol dehydrogenase

J. Bryan Jones and David R. Dodds

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received March 3, 1987

J. Bryan Jones and David R. Dodds. Can. J. Chem. **65**, 2397 (1987).

The preparations of ten decalindiones for investigation as substrates of horse liver alcohol dehydrogenase are reported. The structure characterizations include clarifications of some ambiguities in the decalin literature.

J. Bryan Jones et David R. Dodds. Can. J. Chem. **65**, 2397 (1987).

On a préparé dix décalinediones dans le but d'examiner leur comportement comme substrats de la déshydrogénase d'alcool provenant du foie de cheval. Les caractérisations de leurs structures a permis de clarifier quelques ambiguités que l'on retrouve dans la littérature relativement aux décalines.

The ability of enzymes to catalyze stereospecific transformations of symmetrical substrates into chiral synthons of value in asymmetric synthesis is now well established (2). Stereospecific oxidations of a broad structural range of meso diols catalyzed by horse liver alcohol dehydrogenase (HLADH) represent one of the most dramatic illustrations of this approach to chiral synthon preparation (3). The complementary process of chiron production via stereospecific reductions of symmetrical diketones is of equal asymmetric synthetic interest. As the first step in evaluating this aspect of HLADH stereospecificity we initiated an investigation of the enzyme's catalysis of the reductions of a series of the potential decalindione substrates **1**–**10** and oxidation of the meso diol **11**.

Each of the diones **1**–**11** possesses elements of rotational and (or) reflective symmetry, the respective symmetry elements being c_{2v} (**1**, **3**, **4**), i (**1**, **2**), σ_h (**1**, **4**), and σ_v (**1**, **4**–**11**). Decalins **1**, **4**–**10** are achiral, **2** and **11** are meso compounds, and **3** is a racemate.

This paper reports the preparation and characterization of **1**–**9** and **11**.

Results and discussion

Preparations and 2,6-decalindiones 1–3

This series was derived from 2,6-dihydroxynaphthalene as shown in Scheme 1.

Because hydrolysis of **12** gave both **13** and **1** in a ratio of 9:1, it was necessary to ketalize the mixture to achieve the isomer separation needed in the **13** → **2** steps. The mixture (equilibrium ratio β,γ:α,β of 1:2) of ethylenedioxymonoketals derived from **13** was readily purified into its components **14** and **15** by chromatography. Lithium in liquid ammonia reduction of **15**, followed by deketalization, yielded the desired dione **2**. Mild hydrolysis of **12** gave **1** containing 10% of **13**, and hydrogenation of **13** a 1:2 mixture of **3**:**2** even in the presence of acetic acid (4). These mixtures were readily purified by chromatography and recrystallization respectively.

Preparations of 2,7-decalindiones 4–9 and diol 11

The 2,7-decalindione **4** was obtained as shown in Scheme 2.

Unfortunately, all attempts to reduce **17** to the *trans*-2,7-dione **5** were unsuccessful. The ^{1}H nmr spectrum of **17** shows

SCHEME 2

only one singlet for the two olefinic protons, indicating that the enol hydroxyl proton is located between the two oxygen atoms of a fully conjugated system containing a delocalized negative charge. This situation would make reductions by the hydrogenation and dissolving metal reagents applied very difficult. Attempted reduction of **18** also failed (5). It was eventually necessary to adopt the lengthy route summarized in Scheme 3 to this compound.[2] The target dione **5** and its isomer **2** were produced in equal amounts by this method, but were readily separated. The *trans* ring junction of this series was further confirmed by hydrogenation of **20** to *trans*-2-decalone.

The *cis*-2,7-dione **6** was obtained in 65% yield by chromic acid oxidation of the diol product of high pressure hydrogenation of 2,7-dihydroxynaphthalene.

All of the C-4a substituted 2,7-diones **7–9** were derived from the same precursor **22** (Scheme 4). The bicyclic ester **21** was first observed (7) as a minor by-product, but by adding 1.5 equivalents of base, we were able to raise the yield to 36% (and occasionally 40%). Hydrogenation[3] of **21** gave mainly **22**, together with some of the hydrogenolysis product **23**. The relative ease of reduction of **21** is in sharp contrast to the resistance of **17** to the same transformations. Jones oxidation of **22** afforded the desired diketoester **7**. This was readily converted into the 4a-hydroxymethyl and 4a-methyl substrates **8** and **9** as shown.

On keeping samples of **8** under acidic conditions, up to 10% (by nmr) of the cyclic hemiketal **26** was detectable.

[2]This alternative 1,2-carbonyl shift method of Trost and Salzmann (6) was not satisfactory in this case.

[3]Attempted reduction of **21** with $LiAlH_4$, $NaBH_4$, or $Li/NH_3/EtOH$ gave only poor yields of multiproduct mixtures.

The ring junctions of all the saturated decalin derivatives of Scheme 4 are depicted in the *trans* configuration even though hydrogenation of α,β-unsaturated decalones usually results in *cis* ring junction formation (8). In this case the *trans* geometry is presumably sterically induced (9), with addition of hydrogen occurring from the direction opposite to that of the carboxyethyl group orientation. However, because of conflicting literature data (10), the *trans* nature of the ring junction was verified by the correlation outlined in the Scheme 5 conversions of **22** and **23** to the known (11) 4a-methyldecalone **28**. In addition, in view of the ambiguity in the ^{13}C nmr correlation of the ring junction literature data (12*a*) on *cis*- and *trans*-decalin systems, a further, unequivocal, synthesis of **28** was performed (Scheme 6) in which the *trans* ring junction is guaranteed by the lithium and liquid ammonia reduction of **29**. The samples of **28** from Schemes 5 and 6 were identical in every way. The α configuration of the hydroxyl group of **22** was then assigned from ^1H and ^{13}C nmr spectroscopy, which showed it to be equatorially oriented (12*b*).

Attempts to oxidize the hydroxydiketone **8** to the aldehyde **10** gave poor yields of complex mixtures. In contrast, oxidation of the triol **30** was successful but further oxidation of the initially formed aldehyde, via its hemiacetal form, during the reaction could not be prevented, resulting in the isolation of only the ketolactone **31** (Scheme 7). The dihydroxydecalin **11** was prepared by the method of Paquette *et al.* (13).

Evaluation of 1–9 and 11 as HLADH substrates

A reliable guide to the feasibility of preparative-scale HLADH-catalyzed reductions of new substrates is provided by comparison of their initial reduction rates with that of a standard reference ketone such as cyclohexanone (14). The rates of

reduction of **1**–**9** relative to that of cyclohexone, and of oxidation of **11**, are summarized in Table 1. Since HLADH-catalyzed reductions of ketones with relative rates of reduction >1% of that of cyclohexanone are preparatively viable (14), it is clear that the diones **1**–**6**, **8**, **9** are excellent candidates for such transformations. The full account[4] of their HLADH-catalyzed reductions will be reported shortly.

[4]A preliminary communication on some of these data has been published (15).

Experimental

All mp's were determined using an Electrothermal capillary melting point apparatus and are uncorrected. The ir spectra were recorded on films (for liquids) and KBr disks (for solids) with a Nicolet FT-IR spectrometer. The ^1H nmr spectra were recorded on a Varian T-60 instrument on $CDCl_3$ solutions with $(CH_3)_4Si$ as internal standard, and ^{13}C nmr data on a Varian CFT-20 machine with $CDCl_3$ solutions. Low and high resolution mass spectra were determined with Bell and Howell 21-490 and AEI MS3074 instruments respectively. Analytic glc was done with a Varian 2700 chromatograph with flame ionization

detection, and preparative glc with a Varian 920 instrument using thermal conductivity detection. Large-scale preparative lc was carried out using the Waters Prep LC 500 system.

*Bicyclo[4.4.0]dec-1-(6)-ene-3,8-dione (**1**)*

2,6-Dihydroxynaphthalene was converted (16) to 2,6-dimethoxynaphthalene, mp 148°C (lit. (16) mp 149°C), in 92% yield, and this material then reduced with Li/liq. NH_3 (17) to give an 89% yield of 2,6-dimethoxy-2,4,6,8-tetrahydronaphthalene (**12** (18)), mp 95–96°C; ir: 1220, 1390, and 1460 cm^{-1}; ^1H nmr δ: 2.70 (s, 8H), 3.60 (s, 6H), and 4.60 (s, 2H) ppm. The bis-enolether **12** (3.0 g, 15.6 mmol) was dissolved in MeOH (100 mL) containing 1 *M* aqueous oxalic acid (40 mL) (19). The mixture was stirred at 20°C for 1 h, then neutralized slowly with saturated aqueous $NaHCO_3$ and extracted with $CHCl_3$ (4 × 25 mL). The $CHCl_3$ solution was decolourized with charcoal, dried ($MgSO_4$), and rotoevaporated. The solid obtained was recrystallized from hexanes to give bicyclo[4.4.0]dec-1(6)-ene-3,8-dione (**1**, 1.6 g, 60% yield), mp 96°C; ir: 1230 and 1710 cm^{-1}; ^1H nmr δ: 2.60 (br, 8H) and 3.00 (s, 4H) ppm; ^{13}C nmr δ: 29.38, 37.75, 43.16, 126.15, and 208.65 ppm; ms *m/e*: 164. *Anal.* calcd. for $C_{10}H_{12}O_2$: C 73.15, H 7.37; found: C 73.22, H 7.41%.

trans-*Bicyclo[4.4.0]decane-3,8-dione (**2**)*

The bis-enolether **12** (5.0 g, 26 mmol) in THF (50 mL) and 1 *M* aqueous HCl (100 mL) was heated under reflux for 1 h (16) and then cooled and extracted with $CHCl_3$ (4 × 50 mL). The dried ($MgSO_4$) $CHCl_3$ extract was rotoevaporated to give **13** (containing 10% of **1** by ^1H nmr), which was purified by chromatography on silica gel ($CHCl_3$:hexanes:MeOH, 80:19:1 elution) to give bicyclo[4.4.0]dec-1(2)-ene-3,8-dione (**13**, 3.6 g, 85% yield), mp 91°C (lit. (16) mp 93.5°C); ir: 1680 and 1720 cm^{-1}; ^1H nmr δ: 1.60–3.10 (envelope, 11H) and 6.00 (s, 1H) ppm; ^{13}C nmr δ: 29.69, 30.95, 35.86, 36.44, 38.23, 45.11, 126.04, 161.67, 198.30, and 208.34 ppm.

The diketone **13** (1.6 g, 9.75 mmol) in dry benzene (50 mL) containing 1,2-ethanediol (550 μL, 9.75 mmol) and *p*-TsOH (50 mg) was refluxed in a Dean–Stark apparatus for 30 min (20). After all water had been removed, the reaction mixture was poured into saturated aqueous $NaHCO_3$ (200 mL) and extracted with diethyl ether (4 × 50 mL). The organic layer was dried ($MgSO_4$) and rotoevaporated and the residual oil obtained chromatographed on silica gel ($CHCl_3$:hexanes:MeOH, 80:19:1 elution) to give, first, 8-ethylenedioxybicyclo-[4.4.0]dec-1(6)-en-3-one (**14**, 400 mg, 20% yield); ir: 1080, 1610, and 1720 cm^{-1}; ^1H nmr δ: 1.10–2.70 (envelope, 12H), and 3.95 (s, 4H) ppm, and, second, 8,8-(ethylenedioxy)bicyclo[4.4.0]dec-1(2)-en-3-one (**15**, 800 mg, 40% yield), mp 73–74°C; ir: 1070 and 1680 cm^{-1}; ^1H nmr δ: 1.10–2.70 (envelope, 11H), 3.95 (s, 4H), and 5.90 (s, 1H) ppm; ^{13}C nmr δ: 29.06, 32.12, 34.09, 35.05, 36.33, 41.40, 64.40, 107.73, 124.76, 164.04, and 199.29 ppm. The monoketal **15** (600 mg, 2.9 mmol) in THF (20 mL) was added rapidly with stirring at −78°C to lithium (800 mg, 43 mmol) dissolved in liquid NH_3 (150 mL). After stirring the mixture for a further 20 min, solid NH_4Cl (15 g) was added, the ammonia allowed to evaporate, and the residue taken up in water (250 mL). Extraction with $CHCl_3$ (4 × 50 mL) and rotoevaporation of the dried ($MgSO_4$) extract gave 8,8-(ethylenedioxy)-*trans*-bicyclo[4.4.0]decan-3-one (540 mg, 90% yield); ir: 1080 and 1720 cm^{-1}; ^1H nmr δ: 0.90–2.70 (envelope, 14H) and 3.95 (s, 4H) ppm; ^{13}C nmr δ: 30.92, 32.88, 33.94, 38.59, 40.95, 41.91, 47.62, 64.26, 108.75, and 210.84 ppm. This ketal (535 mg, 2.55 mmol) in THF (50 mL) and 2 *M* aqueous HCl (50 mL) was heated at 50°C for 1 h. The cooled mixture was then extracted with $CHCl_3$ (4 × 50 mL) and the $CHCl_3$ solution washed with saturated aqueous $NaHCO_3$, dried (K_2CO_3), and rotoevaporated. The white solid obtained was recrystallized from hexanes to give *trans*-bicyclo[4.4.0]decane-3,8-dione (**2**, 280 mg, 65% yield), mp 138°C (lit. (21) 139°C); ir: 1320 and 1710 cm^{-1}; ^1H nmr δ: 1.10–2.90 (envelope, peaks at 1.90, 2.20, and 2.40) ppm; ^{13}C nmr δ: 32.73, 39.91, 41.08, 46.72, and 209.25 ppm; ms *m/e*: 166.

cis-*Bicyclo[4.4.0]decane-3,8-dione ((±)**13**)*

Bicyclo[4.4.0]dec-1(2)-ene-3,8-dione (**13**, prepared as above, 2.0 g, 12.2 mmol) in 95% aqueous EtOH (200 mL) containing 10% Pd/C (100 mg) was hydrogenated under H_2 (1 Torr; 1 Torr = 133.3 Pa) until 1 equiv. of H_2 was taken up. The solid product (1.85 g, 93% yield), mp 65°C, was recrystallized from hexanes to give, first, *cis*-bicyclo[4.4.0]decane-3,8-dione ((±)**3**, 600 mg, 33% yield), mp 73°C (lit. (21) mp 73°C); ir: 1710 cm^{-1}; ^1H nmr δ: 1.60–2.90 (envelope, peaks at 1.90, 2.30, and 2.55) ppm; ^{13}C nmr δ: 27.47, 36.15, 38.51, 44.21, and 209.40 ppm; ms *m/e*: 166. The mother liquors gave *trans*-bicyclo[4.4.0]decane-3,8-dione (**2**, 1.1 g, 60% yield), mp 139°C, identical with the sample prepared above.

*Bicyclo[4.4.0]dec-1(6)-ene-3,9-dione (**4**)*

(*a*) 2,7-Dihydroxynaphthalene was converted to 2,7-dimethoxynaphthalene, mp 138°C (lit. (22) mp 138°C), in 95% yield (23). This dimethyl ether was then reduced (17) in 98% yield to 2,7-dimethoxy-1,4,5,8-tetrahydronaphthalene (**16**), mp 66°C (lit. (17) mp 68.5–69.5°C). Hydrolysis of the bisenolether **16** with aqueous oxalic acid (19) gave a 50% yield of bicyclo[4.4.0]decane-3,9-dione (**4**), mp 59°C (lit. (19) mp 59.5–60.5°C); ir: 1630 and 1710 cm^{-1}; ^1H nmr δ: 2.55 (br s, 8H) and 2.80 (s, 4H) ppm; ^{13}C nmr δ: 29.76, 38.41, 43.23, 123.96, 129.37, and 208.63 ppm; ms *m/e*: 164.

(*b*) The bis-enolether **16** was hydrolyzed with 1 *M* aqueous HCl to give a 90% yield of bicyclo[4.4.0]deca-1(2),9(10)-diene-3,9-dione (**17**),[5] mp 178–179°C (lit. (19) mp 179°C); ir: 1530, 1595, and 2600–3400 cm^{-1}; ^1H nmr (DMSO-d_6) δ: 1.00–2.70 (9H, peak at 2.25), 5.55 (s, 2H), and 8.0 (br, 1H) ppm. This dienolone **17** (5.0 g, 30.5 mmol) in dry benzene (75 mL) containing 1,2-ethanediol (15 mL, 270 mmol) and *p*-TsOH (50 mg) was refluxed in a Dean–Stark apparatus for 3 h. Work-up in the usual way (see above) gave a yellow oil that was purified by chromatography on silica gel (EtOAc:hexanes, 3:2 elution) to give 3,9-bis-ethylenedioxybicyclo[4.4.0]dec-1(6)-ene[6] (**18**, 6.8 g, 92% yield), mp 47°C (lit. (14*b*) mp 45°C).

Treatment of the diketal **18** with aqueous oxalic acid (19) as described above gave **4** identical in all respects with the previous sample.

trans-*Bicyclo[4.4.0]decane-3,9-dione (**5**)*

Cyclohexanone and butadiene was condensed (24) to give, in 47% yield, *trans*-bicyclo[4.4.0]dec-8-en-2-one (**19**), bp 80°C (0.15 Torr), bp 112°C (14 Torr), mp 44°C (lit. (25) bp 112°C (14 Torr), mp 32–34°C); ir: 1430, 1600, 1650, and 1710 cm^{-1}; ^1H nmr δ: 1.50–3.00 (envelope with peak at 2.25, 12H) and 5.70 (s, 2H) ppm; ^{13}C nmr δ: 24.32, 25.92, 32.49, 40.01, 41.79, 50.15, 125.09, 125.76, and 211.67 ppm.

The basic method of Nakai and Mimara (26) was then followed. To a solution of *trans*-ketone **19** (5.05 g, 33.6 mmol) in dry EtOH (75 mL) was added tosylhydrazine (6.25 g, 33.6 mmol) and the reaction mixture refluxed for 1 h. The EtOH was rotary evaporated to give the product

[5]All attempts to reduce this compound failed.
[6]Attempted reductions of **18**, including the method of Whitesides and Ehman (5), were unsuccessful.

For personal use only.

tosylhydrazone as a solid foam (11.25 g, 100% yield), mp 137–139°C (dec.); ir: 1600, 1640, and 3240 cm^{-1}; ^1H nmr δ: 0.90–2.90 (envelope, 12H), 2.40 (s, 3H), 5.60 (s, 2H), and 7.00–8.00 (*para*-substituted phenyl, 4H) ppm; ^{13}C nmr δ: 21.47, 24.74, 26.19, 27.08, 32.73, 33.44, 39.11, 44.26, 124.95, 126.32, 128.10, 129.17, 135.27, 143.64, and 162.44 ppm (indicating only 1 product isomer); ms *m/e*: 318.

The above tosylhydrazone (10.57 g, 33.2 mmol) was taken up in a solution of THF (250 mL) and TMEDA (150 mL) at −35°C. To this was added *n*-BuLi (68 mmol), dropwise with stirring under argon. The resulting dark red solution was stirred at −35°C for 1 h and was then quenched with dimethyl disulphide (3.0 mL, 33.2 mmol). The reaction mixture was allowed to warm to 20°C and was then stirred for an additional 18 h. The resulting opaque, bright yellow, mixture was again cooled to −35°C and an additional aliquot of *n*-BuLi (33.2 mmol) added. *The reaction mixture was then allowed to stir at 20°C for another 24 h.* The dark mixture was then poured into saturated aqueous NH_4Cl (800 mL) and extracted with diethyl ether (6 × 100 mL). The organic layer was washed with 2 *M* aqueous HCl until the washings were acidic, then dried ($MgSO_4$) and rotoevaporated to a yellow oil. This was taken up in pentane (50 mL), filtered through a plug of alumina, and rotoevaporated to give *trans*-3-thiomethylbicyclo[4.4.0]deca-2,7-diene as a near-colourless oil (5.0 g, 85% yield); ir: 1440, 1630, and 1655 cm^{-1}; ^1H nmr δ: 1.00–2.40 (envelope, 10H), 2.30 (s, 3H), 5.20 (s, 1H), and 5.70 (s, 1H) ppm; ^{13}C nmr δ: 13.87, 29.73, 32.53, 35.96, 38.51, 122.48, 126.62, 126.91, and 133.62 ppm (indicating only 1 product isomer).

The above thiomethyl compound (4.95 g, 27.5 mmol) was dissolved in 75% aqueous CH_3CN (200 mL) and finely ground $HgCl_2$ (16.0 g, 59 mmol) added (27). The mixture was refluxed for 1 day, then cooled to 20°C, diethyl ether (800 mL) added, and the aqueous layer removed. The organic layer was washed with saturated aqueous $NaHCO_3$ until the aqueous washings were no longer turbid. The dried ($MgSO_4$) ether solution was then rotoevaporated to give a yellow crystalline solid that was chromatographed on silica gel (hexanes:diethylether:MeOH, 89:19:1 elution) to give *trans*-bicyclo[4.4.0]dec-8-en-3-one (**20**, 3.0 g, 77% yield), bp 55°C (0.05 Torr), mp 49–50°C; ir: 1440, 1645, and 1715 cm^{-1}; ^1H nmr δ: 1.10–2.60 (envelope, peaks at 1.90 and 2.40, 12H) ppm; ^{13}C nmr δ: 15.42, 31.57, 33.26, 36.29, 38.75, 41.09, 47.73, 125.11, 125.90, and 210.27 ppm; ms *m/e*: 150. *Anal.* calcd. for $C_{10}H_{14}O$: C 79.96, H 9.39; found: C 79.50, H 9.10%.

Catalytic hydrogenation of **20** gave *trans*-bicyclo[4.4.0]decan-3-one (*trans*-2-decalone), bp 70°C (1.5 Torr) (lit. (11, 29) bp 74–76°C (2 Torr)); ir: 1220, 1447, and 1715 cm^{-1}; ^1H nmr δ: 1.00–2.60 (envelope) ppm; ^{13}C nmr δ: 24.86, 25.36, 31.97, 32.87, 33.45, 40.69, 42.52, 47.65, and 209.15 ppm; ms *m/e*: 152.

A solution of 82% *m*-chloroperbenzoic acid (8.75 g, 41.6 mmol) in CH_2Cl_2 (60 mL) was added dropwise with stirring during 20 min to the ketone **20** (6.43 g, 41.6 mmol) in CH_2Cl_2 (100 mL) at 0°C. The mixture was then allowed to warm to 20°C and, after 10 min, was poured into 5% aqueous Na_2SO_3, and extracted with $CHCl_3$ (5 × 50 mL). The organic layer was washed successively with 5% aqueous $NaHCO_3$ (2 × 25 mL) and saturated aqueous NaCl (2 × 25 mL), then dried (Na_2SO_4) and rotoevaporated to yield a yellow oil (4.6 g); ir: 1720 and 1740 cm^{-1}; ^1H nmr δ: 1.10–2.60 (envelope), 3.10 (s), 3.90 (m), and 4.10 (m) ppm. These spectral data indicated the existence of the desired epoxide together with 15% lactone(s) due to Bayer–Villiger oxidation of the ketone.

The entire epoxide/lactone product mixture (4.6 g) was dissolved in dry THF (50 mL) and added dropwise with stirring to a solution of $LiAlH_4$ (2.0 g, 0.2 mmol) in dry THF (100 mL). The reaction mixture was refluxed for 4 h, then cooled to 20°C, and worked up using the standard aqueous base method (28) to give a poly-alcohol product as a viscous oil (4.5 g). This (4.4 g) was dissolved in acetone (200 mL), cooled to 0°C in an ice bath, and stirred vigorously while Jones reagent (20 mL, 80 mmol) was added dropwise during 20 min. After the addition was complete, the ice bath was removed, and the mixture stirred at 20°C for a further 2 h and then diluted with water (100 mL) and extracted with $CHCl_3$ (6 × 50 mL). The organic layer was washed with saturated aqueous $NaHCO_3$ and then dried ($MgSO_4$) and rotoevaporated to a yellow solid (3.1 g, 83% yield[7]); ^1H nmr δ: 0.90–2.50 (envelope) ppm (confirming the absence of lactone, aldehyde, or epoxide products).

This material was fractionally recrystallized from diethyl ether to yield *trans*-bicyclo[4.4.0]decane-3,8-dione (**2**, 900 mg, 20% yield from **20**), mp 140°C, identical with the previous sample. The mother liquors were chromatographically purified on silica gel (EtO_2:hexanes:MeOH, 80:19:1 elution) to give a white solid that was further purified by preparative gc (Carbowax 20M, 200°C) to give *trans*-bicyclo[4.4.0]-decane-3,9-dione (**6**) (**5**, 900 mg, 20% yield from **20**), mp 68°C; ir: 1710 and 1430 cm^{-1}; ^1H nmr δ: 1.20–2.60 (envelope) ppm; ^{13}C nmr δ: 31.73, 39.80, 40.67, 43.12, 47.68, and 208.90 ppm; ms *m/e*: 166. *Anal.* calcd. for $C_{10}H_{14}O_2$: C 72.26, H 8.49; found: C 72.04, H 8.35%.

cis-*Bicyclo[4.4.0]decane-3,9-dione (6)*

The method of Anderson and Barlow (29) was used to hydrogenate 2,7-dihydroxynaphthalene to the corresponding *cis*-decalin-2,7-diol, which was then oxidized (30) with Jones reagent to give a 65% yield of *cis*-bicyclo[4.4.0]decane (**6**), mp 64–65°C (lit. (29) mp 62–64°C); ir: 1710 cm^{-1}; ^1H nmr δ: 1.80–2.90 (envelope) ppm; ^{13}C nmr δ: 27.12, 32.83, 38.05, 39.13, 44.04, and 209.43 ppm; ms *m/e*: 166.

trans-*6-Carboethoxybicyclo[4.4.0]decane-3,9-dione (7)*

Using the basic method of Nasipur *et al.* (7), ethyl 2-methyl-4-oxo-2-cyclohexene-1-carboxylate (97.3 g, 0.53 mol) was added to a solution of sodium (18.5 g, 0.8 mol) in dry EtOH (350 mL) at 20°C during 30 min. The resulting orange anion solution was stirred for an additional 30 min, then neat ethyl-3-chloropropanoate (73.0 g, 0.53 mmol) was added with stirring during 30 min, and the resulting opaque mixture was stirred for a further 30 min. Sodium (6.5 g, 0.28 mol) in dry EtOH (150 mL) was added and the reaction mixture refluxed for 4.5 h. The orange mixture was cooled to 20°C and most of the EtOH was removed by rotoevaporation. The remaining dark orange residue was diluted with water (600 mL) and washed with diethyl ether (4 × 100 mL). The basic aqueous layer was then vigorously stirred and carefully acidified with 6 *M* aqueous HCl until a bright yellow precipitate appeared. This was collected by filtration and the aqueous filtrate extracted with $CHCl_3$ (4 × 100 mL). The $CHCl_3$ layer was washed with saturated aqueous NaCl (100 mL), dried ($MgSO_4$), and rotoevaporated to a yellow solid. This was combined with the previously collected yellow precipitate, washed with water (2 × 50 mL), and recrystallized from CH_3CN to afford 6-carboethoxybicyclo[4.4.0]deca-1,9-diene-9-ol-3-one (**21**, 42 g, 36% yield) as bright yellow crystals, mp 171°C (lit. (7) mp 171–172°C); ir: 1595, 1735, and 2600–3400 cm^{-1}; ^1H nmr (DMSO-d_6) δ: 1.10 (t, J = 6 Hz, 2H), 5.50 (s, 2H), and 10.50 (br s, 1H) ppm; ms *m/e*: 236. *Anal.* calcd. for $C_{13}H_{10}O_4$: C 66.09, H 6.83; found: C 66.17, H 6.85%.

The dienolone **21** (10.0 g, 42 mmol) and 11% Pd–C (500 mg) were suspended in diethyl ether (400 mL) and shaken under H_2 (2 atm) for 24 h, when H_2 uptake (2 equiv.) ceased. The catalyst was removed by filtration, the ether rotoevaporated, and the oily product purified by chromatography on silica gel ($CHCl_3$:MeOH, 99:1 elution) to give, first, *trans*-6-carboethoxybicyclo[4.4.0]decan-3-one (**23**, 1.3 g, 13% yield), mp 160°C; ir: 1190, 1440, and 1720 cm^{-1}; ^1H nmr δ: 1.00–2.60 (envelope, t at 1.30, J = 6 Hz, 17H), 2.60–3.30 (1H), and 4.30 (q, 2H, J = 6 Hz) ppm; ^{13}C nmr δ: 13.70, 22.75, 25.22, 28.66, 36.68, 38.51, 44.02, 44.71, 46.69, 59.68, 173.76, and 209.50 ppm; ms *m/e*: 224. *Anal.* calcd. for $C_{13}H_{20}O_3$: C 69.61, H 8.99; found: C 69.60, H 9.10%. Eluted second was *trans*-6α-carboethoxybicyclo[4.4.0]decan-3α-ol-9-one (**22**, 6.5 g, 65% yield), bp 85°C (0.15 Torr); ir: 1190, 1450, 1725, and 3400 cm^{-1}; ^1H nmr δ: 1.00–2.60 (envelope, t at 1.3, J = 7 Hz, 15H), 3.10 (br, 2H), 3.6 (br, 1H), and 4.2 (q, J = 7 Hz, 2H) ppm; ^{13}C nmr δ: 13.86, 32.06, 34.63, 35.81, 37.79, 38.39, 42.08, 44.38, 45.95, 60.22, 69.28, 173.73, and

[7]The material loss is due to removal of the lactone products as their carboxylate salts.

210.25 ppm; ms *m/e*: 240. *Anal.* calcd. for $C_{13}H_{20}O_4$: C 65.53, H 7.61; found: C 65.57, H 7.60%.

The above hydroxyketone **22** (7.6 g, 31.7 mmol) was dissolved in acetone (200 mL) at 0°C. To this was added, dropwise with vigorous stirring, Jones reagent (8.0 mL, 1.01 equiv.) and the reaction mixture stirred at 0°C for 2 h. The mixture was then diluted with water (300 mL) and extracted with $CHCl_3$ (5 × 100 mL). The organic layer was washed with saturated aqueous NaCl (100 mL), dried ($MgSO_4$), rotoevaporated, and Kugelrohr-distilled to give *trans*-6-carboethoxybicyclo[4.4.0]decane-3,9-dione (**7**, 6.3 g, 85% yield), bp 125°C (0.15 Torr), mp (recrystallized from pentanes) 83–84°C; ir: 1195 and 1720 cm^{-1}; ^1H nmr δ: 1.20–3.20 (envelope, t at 1.3, J = 7 Hz, 16H) and 4.30 (q, J = 7 Hz, 2H) ppm; ^{13}C nmr δ: 13.70, 34.87, 37.91, 42.71, 43.74, 45.50, 60.47, 172.91, and 207.54 ppm; ms *m/e*: 238. *Anal.* calcd. for $C_{13}H_{18}O_4$: C 65.53, H 7.61; found: C 65.57, H 7.60%.

trans-*6-Hydroxyethylbicyclo[4.4.0]decane-3,9-dione (8)*

trans-6-Carboethoxybicyclo[4.4.0]decane-3,9-dione (**7**, 8.8 g, 36.9 mmol) in dry MeOH (200 mL) containing trimethyl orthoformate (10 mL, 90 mmol) and *p*-TsOH (100 mg) was stirred at 25°C for 90 min. The mixture was then poured into saturated aqueous K_2CO_3 (500 mL), extracted with diethyl ether (5 × 100 mL), and the organic layers dried ($MgSO_4$) and rotoevaporated to give *trans*-6-carboethoxy-3,3,9,9-tetramethoxybicyclo[4.4.0]decane (12.3 g, quantitative yield); ir: 1050, 1100, 1455, and 1730 cm^{-1}; ^1H nmr δ: 1.00–2.10 (envelope, t at 1.20, J = 7 Hz, 13H), 3.15 (s, 6H), 3.20 (s, 6H), and 4.15 (q, J = 7 Hz, 2H) ppm; ^{13}C nmr δ: 14.17, 29.71, 33.36, 35.53, 36.63, 47.40, 59.86, 100.00, and 174.60 ppm.

The above diketal (7.5 g, 22.7 mmol) in dry THF (40 mL) was added dropwise with stirring at 20°C to $LiAlH_4$ (2.0 g, 53 mmol) in dry THF (200 mL) and the mixture refluxed for 3 h. The reaction mixture was then cooled to 20°C and worked up in the usual manner (28). After an additional 1 h of stirring, the quenched reaction mixture was allowed to settle and the inorganic salts removed by filtration and washed with THF (3 × 50 mL). Evaporation of the combined filtrate and washings left a white solid. This was recrystallized from diethyl ether to give *trans*-6-hydroxymethyl-3,3,9,9-tetramethoxybicyclo[4.4.0]decane (**24**, 6.3 g, 96% yield), mp 129–130°C; ir: 1100–1050, 1290, 1455, and 3500 cm^{-1}; ^1H nmr δ: 0.90–2.10 (envelope, 14H), 3.20 (s, 6H), 3.25 (s, 6H), and 3.70 (s, 2H) ppm; ^{13}C nmr δ: 28.16, 30.10, 34.48, 36.17, 36.71, 47.37, 57.00, and 100.20 ppm; ms *m/e*: 288. *Anal.* calcd. for $C_{15}H_{28}O_5$: C 62.47, H 9.79; found: C 62.37, H 9.70%.

The hydroxymethyldiketal **24** (5.6 g, 28.6 mmol) in THF (250 mL) and 6 *M* aqueous HCl (60 mL) was stirred at 25°C for 1 h. The mixture was then neutralized by the careful addition of solid $NaHCO_3$, and water added until the sediment dissolved. The aqueous mixture was extracted with CH_2Cl_2 (5 × 100 mL) and the organic extracts dried ($MgSO_4$) and rotoevaporated to give a solidifying oil (3.8 g, quantitative yield), which on recrystallization from diethyl ether yielded *trans*-6-hydroxymethylbicyclo[4.4.0]decane-3,9-dione (**8**, 3.6 g, 95% yield), mp 97.5°C; ir: 1045, 1720, and 3500 cm^{-1}; ^1H nmr δ: 1.00–3.20 (envelope, 14H) and 3.80–4.30 (br, 2H) ppm; ^{13}C nmr δ: 33.37, 36.43, 37.40, 43.12, 43.71, 58.21, and 209.8 ppm; ms *m/e*: 196. *Anal.* calcd. for $C_{11}H_{16}O_3$: C 67.32, H 8.22; found: C 67.12, H 8.24%.

On keeping, nmr solutions of **8** gradually developed signals due to formation of the internal hemiketal **26**; ^{13}C nmr δ: 30.57, 31.79, 32.18, 37.12, 38.29, 40.16, 43.44, 45.28, 69.50, 95.17, and 210.5 ppm.

trans-*6-Methylbicyclo[4.4.0]decane-3,9-dione (9)*

The general method of Ireland *et al.* (30) was applied. *trans*-6-Hydroxymethyl-3,3,9,9-tetramethoxybicyclo[4.4.0]decane (**24**, prepared above, 1.77 g, 6.14 mmol) was dissolved in dry THF (40 mL) and TMEDA (10 mL) at −78°C, and *n*-BuLi (1.1 equiv.) added dropwise with stirring. The mixture was stirred for 20 min and then bis(dimethylamino)phosphochloridate (4.5 mL, 30.73 mmol) was added. The mixture was allowed to warm to 25°C, at which temperature it was stirred an additional 2 h before being poured into saturated aqueous $NaHCO_3$ (300 mL), and shaken vigorously to hydrolyse the excess phosphochloridate. The aqueous solution was extracted with CH_2Cl_2 (5 × 75 mL), and the organic layers washed with saturated aqueous NaCl (2 × 100 mL), dried ($MgSO_4$), and rotoevaporated to give the phosphorylated product as a pale yellow oil (2.3 g, 88% yield); ir: 1090–1050, 1220, 1300, and 1450 cm^{-1}; ^1H nmr δ: 0.90–2.00 (envelope, 13H), 2.55 (s, 6H), 2.70 (s, 6H), 3.15 (s, 6H), 3.20 (s, 6H), and 4.00 (s, 2H) ppm.

This phosphorylation product (2.2 g, 5.2 mmol) in dry THF (25 mL) was added dropwise to lithium (350 mg, 50 mmol) in dry $EtNH_2$ (30 mL) cooled to 0°C. The blue reaction mixture was stirred for 1 h at 0°C and then quenched with water (100 mL). The $EtNH_2$ was allowed to evaporate and the remaining aqueous solution extracted with diethyl ether (5 × 50 mL). The organic layers were washed with saturated aqueous NaCl (50 mL), dried ($MgSO_4$), filtered through alumina, and rotoevaporated. The oily product was distilled to give *trans*-6-methyl-3,3,9,9-tetramethoxybicyclo[4.4.0]decane (**25**, 1.2 g, 85% yield), bp 100°C (0.15 Torr), mp 71–75°C; ir: 1050, 1110, and 1450 cm^{-1}; ^1H nmr δ: 0.90 (s, 3H), 1.00–2.00 (envelope, 13H), 3.15 (s, 6H), and 3.20 (s, 6H) ppm; ^{13}C nmr δ: 14.17, 28.22, 32.57, 34.56, 35.86, 36.70, 46.85, 46.90, and 99.97 ppm.

The diketal **25** (1.1 g, 4.1 mmol) in THF (125 mL) and 6 *M* aqueous HCl (25 mL) was stirred at 25°C for 2 h. The reaction mixture was carefully neutralized by the addition of solid $NaHCO_3$, then diluted with water until all the sediment dissolved, and extracted with diethyl ether (5 × 50 mL). The combined organic extracts were dried ($MgSO_4$), rotoevaporated, and the resulting white solid recrystallized from pentanes to give *trans*-6-methylbicyclo[4.4.0]decane-3,9-dione (**9**, 730 mg, quantitative yield), mp 114–115°C; ir: 1715 cm^{-1}; ^1H nmr δ: 1.30 (s, 3H), 1.60–2.10 (m, 5H), and 2.19–2.64 (envelope, 8H) ppm; ^{13}C nmr δ: 14.31, 32.46, 37.49, 39.14, 44.07, and 209.1 ppm; ms *m/e*: 188. *Anal.* calcd. for $C_{11}H_{16}O_2$: C 73.30, H 8.95; found: C 73.19, H 9.18%.

trans-*6-Methylbicyclo[4.4.0]decan-3-one (28)*

(a) From 22

trans-6α-Carboethoxybicyclo[4.4.0]decan-3α-ol-9-one (**22**, 2.5 g, 10.4 mmol) was dissolved in dry MeOH (125 mL) containing concentrated H_2SO_4 (100 μL). The reaction mixture was stirred at 20°C for 2 h and then poured into saturated aqueous K_2CO_3 (300 mL) and extracted with $CHCl_3$ (4 × 100 mL). The organic layer was dried (K_2CO_3) and rotoevaporated to give *trans*-6α-carboethoxy-9,9-dimethoxybicyclo[4.4.0]decan-3α-ol (2.9 g, 98% yield); ir: 1100–1050, 1725, and 3400 cm^{-1}; ^1H nmr δ: 1.00–2.20 (envelope, t at 1.1, J = 6 Hz, 17H), 3.15 (s, 3H), 3.20 (s, 3H), 3.60 (br, 1H), and 4.20 (q, J = 6 Hz, 2H) ppm.

The above dimethoxyketal (2.8 g, 9.8 mmol) in dry THF (50 mL) was added dropwise with stirring at 20°C to $LiAlH_4$ (2.0 g, 53 mmol) in THF (150 mL). The mixture was refluxed for 1 h, and then worked up in the standard way (28) to yield *trans*-6α-hydroxymethyl-9,9-dimethoxybicyclo[4.4.0]decan-3α-ol (**27**, 2.4 g, quantitative yield), mp 112–115°C; ir: 3400 cm^{-1}; ^1H nmr δ: 0.90–2.30 (envelope, 15H), 3.15 (s, 3H), 3.20 (s, 3H), and 3.80 (br, 3H) ppm; ^{13}C nmr δ: 28.01, 30.31, 30.86, 32.22, 35.00, 36.55, 37.08, 37.41, 38.62, 47.44, 57.65, 70.91, and 100.25 ppm.

Again using the basic method of Ireland *et al.* (30), the diol **27** (1.5 g, 6.15 mmol) was dissolved in a mixture of THF (40 mL) plus TMEDA (10 mL) and stirred at −78°C. To this was added *n*-BuLi (14.15 mmol) and the solution allowed to warm to 0°C. Bis(dimethylamino)phosphochloridate (9.0 mL, 30.75 mmol) was then added dropwise with stirring and the mixture stirred at 20°C for 2 h, then poured into 5% aqueous $NaHCO_3$ (300 mL), shaken vigorously to hydrolyse the remaining phosphochloridate, and extracted with CH_2Cl_2 (4 × 100 mL). The organic layer was washed with saturated aqueous NaCl (100 mL), dried ($MgSO_4$), and rotoevaporated to yield the phosphorylated product as a yellow oil (2.6 g, 83% yield); ir: 980, 1050, 1220, 1330, and 1450 cm^{-1}. This phosphorylated product (2.45 g, 4.94 mmol) in THF (30 mL) and *t*-BuOH (2.82 mL, 29.9 mmol) was then added dropwise with stirring to lithium (850 mg, 120 mol) in $EtNH_2$ at 0°C. The blue mixture was stirred at 0°C for 90 min, then

quenched with water (25 mL) and extracted with diethyl ether (4 × 50 mL). The ether solution was washed with saturated aqueous NaCl (100 mL), decolourized with charcoal, filtered through a plug of alumina, and rotoevaporated. The crude product was Kugelrohr-distilled to give *trans*-3,3-dimethoxy-6-methylbicyclo[4.4.0]decane (800 mg, 77% yield), bp 80–85°C (0.2 Torr); ir: 1050, 1105, and 1450 cm^{-1}; ^1H nmr δ: 1.05–2.00 (envelope, s at 1.05, 18H), 3.15 (s, 3H), and 3.20 (s, 3H) ppm; ^{13}C nmr δ: 14.78, 21.66, 26.49, 28.23, 33.09, 35.35, 37.82, 40.64, 46.99, and 100.42 ppm; ms *m/e*: 212.

The above dimethoxyketal (800 mg, 3.77 mmol) was dissolved in 90% formic acid (40 mL) containing water (5 mL), and THF was added until the hydrolysis mixture became clear. The solution was then stirred for 2 h at 20°C, water (250 mL) was added, and the solution was extracted with diethyl ether (5 × 100 mL). The organic layer was washed with saturated aqueous NaCl (2 × 100 mL), dried (K_2CO_3), and rotoevaporated to leave a pale yellow oil that was Kugelrohr-distilled to give *trans*-6-methylbicyclo[4.4.0]decan-3-one (**28**, 400 mg, 55% yield) (lit. (11) bp 130°C (15 Torr)); ir: 1450 and 1715 cm^{-1}; ^1H nmr δ: 1.05–2.60 (envelope, maxima at 1.05) ppm; ^{13}C nmr δ: 14.85, 21.54, 25.97, 28.94, 33.06, 38.19, 40.35, 44.67, 44.92, and 211.45 ppm. *Exact Mass* calcd. for $C_{11}H_{18}O$: 166.1358; found: 166.1351.

(b) From ***23***

trans-2-Carboethoxybicyclo[4.4.0]decan-3-one (**23**, 2.7 g, 12.1 mmol) in dry MeOH (150 mL) containing trimethyl orthoformate (2.0 mL, 18.0 mmol) and *p*-TsOH (100 mg) was stirred at 20°C for 2 h and then poured into saturated Na_2CO_3 (400 mL) and extracted with CH_2Cl_2 (4 × 100 mL). The organic layer was dried ($MgSO_4$) and rotoevaporated to yield *trans*-6-carboethoxy-3,3-dimethoxybicyclo[4.4.0]decane as a pale yellow oil (2.6 g, 80% yield); ir: 1050, 1195, 1445, and 1725 cm^{-1}; ^1H nmr δ: 0.90–2.10 (envelope, t at 1.30, J = 7 Hz, 18H), 3.15 (s, 3H), 3.20 (s, 3H), and 4.10 (q, 2H, J = 7 Hz) ppm; ms *m/e*: 270.

This ester ketal (2.5 g, 9.25 mmol) in dry THF (30 mL) was added dropwise with stirring to $LiAlH_4$ (1.5 g) in THF (100 mL). The mixture was then refluxed for 5 h and worked up as usual (28) to a clear, solidifying, oil, which was recrystallized from pentanes to give *trans*-6-hydroxymethyl-3,3-dimethoxybicyclo[4.4.0]decane (2.0 g, 95% yield), mp 83°C; ir: 1050, 1195, 1450, and 3400 cm^{-1}; ^1H nmr δ: 1.00–2.00 (envelope, 14H), 3.15 (s, 3H), 3.20 (s, 3H), and 3.80 (s, 2H) ppm; ^{13}C nmr δ: 21.28, 26.31, 27.87, 30.87, 34.05, 35.11, 37.04, 40.65, 47.21, 57.51, and 100.37 ppm; ms *m/e*: 228. *Anal.* calcd. for $C_{13}H_{24}O_3$: C 68.38, H 10.60; found: C 68.25, H 10.52%.

The Ireland (30) methodology was again applied to remove the hydroxyl function. The above hydroxymethyl ketal (1.5 g, 6.25 mmol) was dissolved in a mixture of THF (40 mL) and TMEDA (10 mL) and stirred at −78°C. To this solution was added *n*-BuLi (14.4 mmol). The resulting mixture was stirred at −78°C for a further 20 min and allowed to warm to 0°C. Bis(dimethylamino)phosphochloridate (9.1 mL, 5.0 equiv.) was added dropwise with stirring, and the mixture stirred at 25°C for a further 2 h and then poured into 5% aqueous $NaHCO_3$ solution (300 mL), shaken vigorously, and extracted with CH_2Cl_2 (4 × 75 mL). The organic layers were combined and washed with saturated aqueous NaCl (2 × 100 mL), dried ($MgSO_4$), and rotoevaporated to afford the phosphorylated product as a pale yellow oil (2.0 g, 64% yield); ir: 1050, 1220, 1300, and 1450 cm^{-1}; ^1H nmr δ: 0.90–2.00 (envelope, 15H), 2.55 (s, 6H), 2.70 (s, 6H), 3.15 (s, 3H), 3.20 (s, 3H), and 4.0 (s, 2H) ppm.

This phosphorylated product (1.5 g, 2.89 mmol) was taken up in dry THF (30 mL) and *t*-BuOH (2.1 mL, 23.1 mmol), and added with stirring to lithium metal (700 mg, 100 mmol) in dry $EtNH_2$ (30 mL) cooled at 0°C. The blue reaction mixture was stirred for an additional 90 min at 0°C and was then quenched with water (100 mL) and extracted with diethyl ether (5 × 50 mL). The organic layers were combined, washed with saturated aqueous NaCl (2 × 100 mL), decolourized with charcoal, filtered through an alumina plug, and rotoevaporated. Kugelrohr-distillation of the oily product gave *trans*-3,3-dimethoxy-6-methylbicyclo[4.4.0]decane (500 mg, 61% yield), bp 80–85°C (0.2 Torr), identical to the sample obtained in method (*a*) above. It was converted to **28** in 55% yield as described in (*a*) above.

(c) Via ***29***

Condensation of 2-methylcyclohexanone and methyl vinyl ketone by the method of Moss and Smudin (31) gave 6-methylbicyclo[4.4.0]-dec-1-en-3-one (**29**, 50% yield), bp 80–85° (0.25 Torr) (lit. (32) bp 82–83°C (0.7 Torr)); ir: 1620 and 1680 cm^{-1}; ^1H nmr δ: 1.30 (s, 3H), 1.40–1.60 (envelope, 12H), and 5.75 (s, 1H) ppm; ^{13}C nmr δ: 21.05, 21.32, 26.51, 31.99, 33.23, 35.18, 37.38, 40.87, 123.4, 169.1, and 197.9 ppm; ms, *m/e*: 164.

The α,β-unsaturated ketone **29** was reduced with lithium in liquid ammonia (11) to give a quantitative yield of **28**, identical with the samples obtained in routes (*a*) and (*b*) above.

trans-*6-Carboxybicyclo[4.4.0]decan-9-ol-3-one lactone* ***31***

trans-6α-Carboethoxybicyclo[4.4.0]decan-9α-ol-3-one (**22**, 2.0 g, 8.33 mmol) in dry THF (30 mL) was reduced with $LiAlH_4$ (1.0 g, 27 mmol) in dry THF (100 mL) in the usual (28) way to give *trans*-6α-hydroxymethylbicyclo[4.4.0]decane-3α,9-diol (**30**, quantitative yield), mp 165–169°C; ir: 1040 and 3350 cm^{-1}; ^1H nmr (DMSO-d_6) δ: 0.90–2.00 (envelope, 13H), 3.10–3.60 (envelope, 6H), and 3.80–4.50 (3H, all D_2O exchangeable) ppm.

The triol **30** (1.66 g, 8.3 mmol) was dissolved in DMF (100 mL) at 30°C (33) and Jones reagent (10 mL, 40 mmol) added dropwise with stirring during 30 min. The mixture was stirred for a further 3 h at 30°C, then cooled to 20°C, poured into water (300 mL), and extracted with diethyl ether (5 × 100 mL). The combined organic layers were decolourized with charcoal, dried ($MgSO_4$), and rotoevaporated to give *trans*-6α-carboxybicyclo[4.4.0]decan-9α-ol-3-one lactone (**31**, 1.3 g, 75% yield) as a colourless oil; ir: 1720–1740 cm^{-1}; ^1H nmr δ: 1.10–3.20 (envelope, 13H) and 4.80 (br, 1H) ppm; ^{13}C nmr δ: 25.64, 30.02, 31.29, 33.86, 37.97, 38.87, 41.23, 47.63, 75.10, 175.5, and 208.8 ppm; ms *m/e*: 194. *Anal.* calcd. for $C_{10}H_{14}O_3$: C 68.02, H 7.27; found: C 68.28, H 7.49%.

cis-*1,6-Bishydroxymethylbicyclo[4.4.0]dec-3-ene (**11**)*

This compound was prepared by the method of Paquette *et al.* (13) in 95% yield, mp 145–148°C (lit. (14) mp 147–149°C); ir: 660, 1020, 1470, 1660, and 3280 cm^{-1}; ^1H nmr (DMSO-d_6) δ: 1.40 (m, 8H), 2.00 (m, 4H), 3.40 (d, J = 4 Hz, 4H), 4.40 (t, J = 4 Hz, 2H), and 5.55 (br, 2H) ppm; ^{13}C nmr δ: 20.89, 30.33, 31.48, 38.64, 67.71, and 123.9 ppm.

Relative rates of HLADH-catalyzed reductions of ***1–9, 11***

The relative rates of reduction of **1–9**, **11**, and of the reference substrate cyclohexanone, were determined in the standard manner (34). The results are recorded in Table 1.

A conformational analysis of adriamycin based upon its ^{1}H nuclear magnetic resonance spectrum in various solvents

TIM ALLMAN AND R. E. LENKINSKI[1]

Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received March 2, 1987

TIM ALLMAN and R. E. LENKINSKI. Can. J. Chem. **65**, 2405 (1987).

The solution conformation of adriamycin was studied by ^{1}H nuclear magnetic resonance spectroscopy. The hydrochloride was found to be rigid on the nmr time scale in each of $CDCl_3$, DMF-d_7, and DMSO-d_6. The sugar and D rings were found to have the same conformations as were found previously by X-ray crystallography. Similar results were found for the free base in DMF-d_7 and $CDCl_3$ solutions although the free base was found to be conformationally mobile in acetone-d_6 and CD_3OD solutions.

TIM ALLMAN et R. E. LENKINSKI. Can. J. Chem. **65**, 2405 (1987).

Utilisant la résonance magnétique nucléaire du ^{1}H, on a étudié la conformation de l'adriamycine en solution. On a trouvé que, en solution tant dans le $CDCl_3$ que dans le DMF-d_7 ou le DMSO-d_6, le chlorhydrate est rigide par rapport à l'échelle de temps de la rmn. On a trouvé que le cycle D ainsi que les cycles des sucres adoptent les mêmes conformations que celles qui ont été observées antérieurement par diffraction des rayons-X. On a obtenu des résultats semblables avec la base libre en solution dans le DMF-d_6 ou dans le $CDCl_3$; toutefois, on a trouvé que, en solution dans l'acétone-d_6 ou dans le CD_3OD, la base libre est conformationnellement mobile.

[Traduit par la revue]

Introduction

The mode of action of adriamycin (Adm) in the inhibition of tumours is still unknown in detail although it is known that Adm binds strongly to DNA, probably by intercalation (1–4). Adm is also known to cleave DNA and a proposed mechanism involves the interaction of the charged amino group with the phosphate backbone of DNA. Since this interaction involves the nonrigid part of Adm, the conformation of Adm in solution is of interest. A number of investigators have used a variety of approaches in determining which of the many possible conformers is the most stable and which may be the "biologically active" conformer.

Although the X-ray crystal structure of neither Adm nor Adm·HCl has been reported, those of several similar compounds have been. Of most interest are the structures of daunomycin with butanol (5) and pyridine (1) of crystallization as well as the *N*-bromoacetyl derivative of daunomycin (6). In these studies the sugar ring was found to be turned back so that there are hydrogen bonds between the 9-OH and the glycosidic oxygen atoms. The internal conformations of the daunosamine ring and the D ring are as shown in Figs. 1 and 2 respectively.

Theoretical studies (7, 8) give a slightly different result. Although the rings themselves have the same conformations, a lower energy is calculated if the glycosidic linkage is twisted back so that there is a bifurcated hydrogen bond involving the 5-O atom, the 6-OH group, and the sugar ring O atom. In fact this describes the global minimum that was found on the potential energy surface but there is a local minimum at the crystal structure conformation as well.

The conformation found in solution is obviously of greater interest than that found in the solid state because it is when it is in solution that Adm is active. The only information about the solution conformation that is so far available comes from a study of the binding of Yb(III) to Adm in methanol. This study suggests that the conformation found in solution is nearly the same as the one calculated to have minimum energy (9).

The original report of the nmr spectra of daunomycin, of its agylcone, and of daunosamine (10) stands virtually alone in the literature. This may be because Adm has been studied almost exclusively in aqueous solution. Its ^{1}H nmr spectrum in water is poorly resolved and the appearance of the spectrum is highly dependent upon concentration, pH, and temperature. This is caused by the self-association of Adm in aqueous solution, and a study of this effect has appeared in the literature (11).

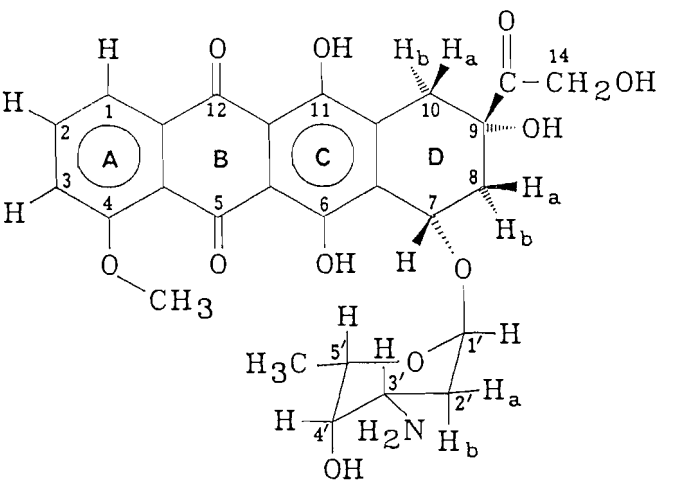

FIG. 1. Adriamycin. The portion of the molecule containing the A–D rings is referred to as the aglycone. The sugar ring is daunosamine. In daunomycin the 14-CH_2OH group is replaced by CH_3.

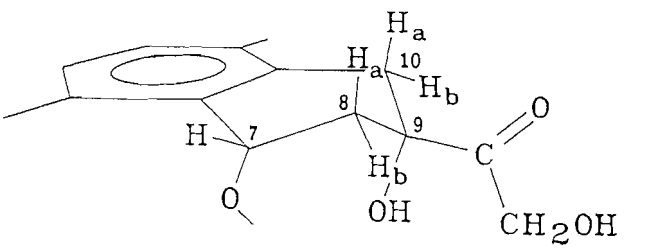

FIG. 2. The internal onformation of the D ring found in the crystal structures of related compounds. Note the planar "W" path connecting the 8b and the 10b protons.

Results

The ^{1}H nmr spectrum of daunomycin as well as several of its fragments and derivatives was first reported by Arcamone *et al.*

in 1970 (10). This was an excellent piece of work that proved the structure of daunomycin although these workers were severely limited by the instrumentation available at the time, two cw (continuous wave) instruments operating at 60 and 100 MHz. At these low fields there was much overlap of peaks and the spin systems were too strongly coupled for complete analysis. The present study carried out at 400 MHz was much easier in the analysis of the spectra because of the better chemical shift dispersion, better sensitivity, and the availability of two-dimensional (2D) experiments, which helped to determine the spin system connectivities and the nmr parameters. For each solvent, and for each of Adm and Adm·HCl where possible, a high resolution one-dimensional spectrum was run, followed by the COSY spectrum (to confirm the assignments) and the homonuclear *J*-resolved spectrum (to see the fine structure of the multiplets). The COSY spectrum of Adm in $CDCl_3$ is shown in Fig. 3 with a high resolution spectrum plotted above it.

Assignment of the spectra

Adm in $CDCl_3$

The spectrum of Adm in $CDCl_3$ is very well resolved and is typical of the spectra seen in most other solvents. This spectrum will be treated in detail with the assignment of the other spectra following from it. The complete set of ^1H nmr data is given in Table 1.

In the 1D spectrum the aromatic region appears as two doublets flanking a triplet and the doublets appear to have some fine structure. Examination of the appropriate slices in the *J*-resolved spectrum shows that the doublets are in fact doublets of doublets and the "triplet" is a doublet of doublets, with the two coupling constants being of similar size. The centre resonance is therefore assigned to the proton at position 2. It is split by couplings of 7.7 and 8.6 Hz to the 1 and 3 protons. The H1–H3 coupling constant is 1.1 Hz. The assignment of the resonance at 7.78 to the 3 proton follows from the COSY spectrum in which there is a cross peak connecting this resonance to the one at 4.04 δ (4-OCH_3). In fact, although this coupling is not resolved here, it is well resolved in the spectrum of Adm in acetone-d_6 and is about 0.5 Hz in magnitude.

The COSY spectrum shows correlations between the strongly coupled pair of resonances at 2.08 and 2.29 δ and the resonance at 5.03 δ. These can be assigned, followed Arcamone *et al.*, to the 8 protons and the 7 proton respectively. The strongly coupled resonances at 2.89 and 3.25 δ are assigned to the protons at position 10. Each of these resonances shows a large geminal coupling of 18.5 Hz and some fine structure. The COSY spectrum indicates that there is a scalar coupling between the resonances at 2.29 δ and 3.15 δ and which is found to be 2.5 Hz from the *J*-resolved spectrum. Such a large value could only arise from coupling along a W path and is strong evidence that the D ring has the puckered conformation shown in Fig. 2. There is also a small coupling of 0.8 Hz in the resonance arising from the 10a proton. No such correlation appears on the contour plot in Fig. 3 but examination of the appropriate f_1 slices on the computer display of the COSY spectrum showed a weak cross peak at 5.03 δ, the position of the resonance of the 7 proton.

The COSY spectrum is especially useful in the assignment of the resonances of the sugar protons. The 5′ methyl group and its geminal proton provide a starting point. The 5′ proton would be expected to be a 1:3:3:1 quartet while the methyl group should appear as a doublet. These are found at 3.97 and 1.29 δ respectively. Correlations in the COSY contour plot can then be traced out to give the following assignments: 4′(3.42), 3′(3.02), 2′(1.60 and 1.70), and 1′(5.45). The only large vicinal coupling seen in the sugar system is that between the 3′ proton and the 2′ proton at 1.70 δ. Models show that this must be a *trans* coupling to the 2′b proton (12–16). Assignment of the resonance at 1.60 δ to the 2′a proton follows from this.

The presence of this single $J_{axial-axial}$ in the sugar ring is strong evidence for the chair conformation shown in Fig. 1. There is also a W coupling seen between protons 2′a and 4′. Because this coupling is very sensitive to the planarity of its coupling path, it confirms the assignment of the chair conformation.

Adm·HCl in DMF

The ^1H nmr spectrum was analysed using the same techniques as was the spectrum of Adm in $CDCl_3$. The multiplets appear much the same as they do in the previous spectrum and analysis shows that, with the exception of the aromatic protons, the coupling constants are very similar. There are, however, some fairly large changes in the chemical shifts, especially those of the sugar protons. Examination of the data in Table 1 shows that the chemical shift differences are due largely to the different atomic charge distributions in the protonated and nonprotonated molecules. Comparison of the data for Adm and Adm·HCl in both methanol and DMF shows this effect clearly. It is greatest for the 3′ proton and diminishes with increasing distance from it. A similar trend is seen when the calculated atomic charges of the protonated and nonprotonated molecule are compared (8).

Adm·HCl in CD_3OD

The assignment of this spectrum follows directly from the previous discussion. The coupling constants show little change from their values in chloroform solution, indicating that there are no significant conformational changes and that the sugar ring is locked in its chair conformation.

Adm·HCl in DMSO-d_6

DMSO is the most viscous of all of the solvents employed in this study. The higher viscosity leads to broadening of the resonances and therefore there is somewhat greater uncertainty in the coupling constants. However, the large 2′a–3′ coupling as well as the 2′a–4′ W couplings show that the conformation of the sugar ring remains the same. The D ring also appears to have the same conformation as before because of the similarity of the spectra.

Often the rate of chemical exchange of exchangeable protons is decreased in DMSO to the extent that they can be seen in the ^1H spectrum. This was found to be the case and they were assigned from the COSY spectrum. However, attempts to obtain information about the orientation of the sugar ring with respect to the rest of the molecule by nOe (nuclear Overhauser enhancement) measurements on these exchangeable protons were unsuccessful.

Adm in $(CD_3)_2CO$

The spectrum of Adm in acetone appears markedly different. The large 2′b–3′ coupling constant has been reduced to 3.2 Hz while many of the small coupling constants have increased. No amount of twisting a model of the sugar ring could account for this because every chair or boat form has one pair of diaxial protons, which should give a large coupling constant. The ring must therefore be nonrigid although it is not clear why this is the case. The D ring, in contrast, has a spectrum very similar to that found in $CDCl_3$ and the presence of ^4J(8b–10b) shows that it is rigid. The resolution of the spectrum was very good and some very small couplings (<0.5 Hz) were seen in the 1′, 3′, and 5′

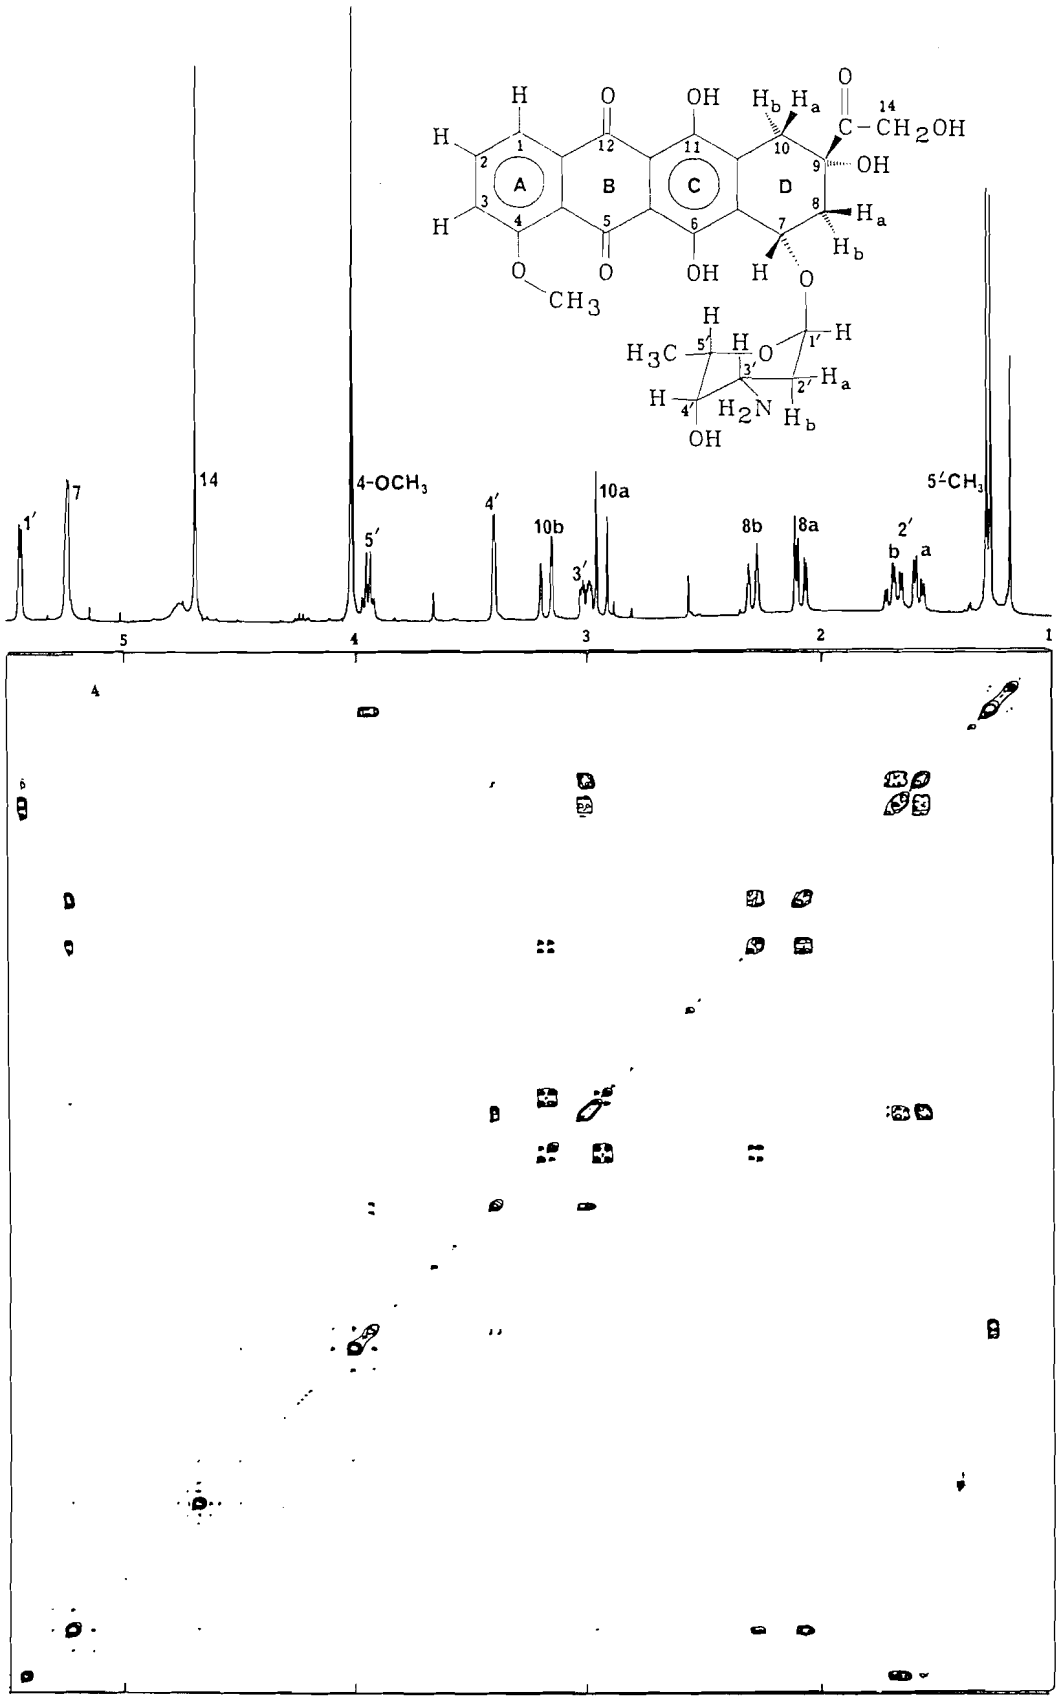

FIG. 3. The 400-MHz ^{1}H COSY spectrum of Adm in $CDCl_3$ in the region 5.5 δ to 0.0 δ with the 1D spectrum plotted above on the same scale. To improve legibility the aromatic portion is not shown. There is a cross peak (not shown) correlating the peaks at 7.32 δ and 4.02 δ. The presence of a cross peak indicates that the two resonances are scalar coupled.

multiplets but they could not be assigned. There was, however, a clearly resolved coupling of 0.5 Hz, connecting the 3 proton and the 4-OCH$_3$ protons.

Adm in CD_3OD

The spectrum of Adm·HCl in CD_3OD has much the same appearance as that of Adm in $CDCl_3$, indicating that in both cases the conformations are similar. However, the spectrum of Adm (the free base) in CD_3OD is quite different. The 2′ resonances are very close together, so close in fact that their separate nmr parameters could not be easily extracted although this could have been done with computer analysis. The 3′ resonance is different as well, containing two medium size couplings of 8.5 Hz rather than a large one and a small one. The

3′–4′ and 4′–5′ coupling constants are also significantly larger, each being 4.5 Hz.

Adm in DMF-d_7

The spectra of the protonated and nonprotonated molecules are virtually identical except for the deshielding of the protons caused by protonation. The sugar ring is therefore rigid and has the same conformation in both cases.

Discussion

Both crystal structures of daunomycin (5, 6) and the theoretical studies (7, 8) show that hydrogen bonding, both intramolecular and to the solvent molecules, is of great importance in determining the conformation of the molecule. It is probable that the internal conformation of the sugar ring is also stabilized by hydrogen bonding. Models show that interactions with the 5 and 6 oxygen atoms or the 9-OH group are not possible in any other chair or boat conformation.

It appears as well that the interactions that stabilize the conformation of the sugar ring are, at least partially, steric in origin. The methyl and amino groups are equatorial and therefore do not interfere. The hydroxyl group and the rest of the Adm molecule are axial but are on opposite sides of the ring. Hydrogen bonding must also play a role in stabilizing the puckered conformation of the D ring found both in the crystal and in solution. In fact the nmr results show that in each solvent this conformation is maintained even though there are marked solvent dependences in the sugar resonances.

The spectrum of Adm in methanol is quite different from that of Adm in acetone but it has the common feature that no single conformation can account for all of the magnitudes of all of the coupling constants simultaneously. It must be concluded, therefore, that the sugar ring is not rigid for the free base in these solvents. As well, because the measured nmr parameters of Adm in methanol are significantly different from those in acetone, it appears that the relative populations of the various conformers and perhaps the dynamic processes in the two solvents are quite different.

The results for the protonated and nonprotonated species in CD_3OD and DMF-d_7 clearly show the effects of protonation upon the chemical shifts of the sugar ring protons. As expected, the effect of the positive charge on the 3′ amino group is greatest for the 3′ proton and falls off with increasing distance. It would be interesting to compare the spectra of both Adm and Adm·HCl in all of the solvents but unfortunately the protonated species is insoluble in chloroform and acetone while Adm decomposes in DMSO.

Although it has been reported (11) that Adm shows no evidence for self-association in CD_3OD solution, a closer examination shows that this is not the case. Some preliminary data[2] indicate that the appearance of the ^1H nmr spectrum of Adm·HCl in methanol is both temperature and concentration dependent. The differences in the spectra of the protonated and nonprotonated forms as well as the presence of self-association of Adm in CD_3OD have important consequences with respect to the structure of adriamycin in aqueous solution. A high resolution spectrum of Adm can be obtained in D_2O only in acidic solutions (9) because the neutral species self-associates to form dimers. The reduced mobility of the dimer, its high formation constant, and the fact that it is in the fast exchange regime on the nmr time scale, all conspire to broaden the nmr resonances of Adm to the point that not much useful information can be obtained at physiologically important pH levels. The differences in conformation between Adm and Adm·HCl in CD_3OD could be looked upon as a "pH" dependence that is unobservable in D_2O but that may nonetheless exist. The conformational differences also cast doubt upon the notion that there is an "active" conformer. Adm in aqueous solution at physiological pH is partially deprotonated and therefore may be conformationally nonrigid here as well. The behaviour of Adm in methanolic solution as a function of its degree of protonation is under further investigation.

[2]T. Allman and R. E. Lenkinski, unpublished results. The spectrum of Adm·HCl in methanol at ambient temperature is sharp and shows no obvious effects that could be attributed to self-association. However, when the spectra were observed as a function of temperature below 0°C it was found that the spectra broadened as the temperature was decreased and as the concentration was increased. This mimics closely the behaviour of Adm in aqueous solution at higher temperatures.

Conclusion

We have shown that the appearance of the proton nmr spectrum of the sugar portion of adriamycin is dependent upon both the nature of the solvent and the state of protonation of the amino group. In most solvents the sugar ring is in the chair conformation in which the methyl group is equatorial. In these solvents there is no evidence for any interchange among other possible conformers although the free base in acetone and in methanol is conformationally mobile. It is interesting that there is evidence for only one conformation of the D ring. Overall, these results suggest that Adm has no strongly preferred conformation, making it likely that its interaction with DNA is controlled by intermolecular forces rather than intramolecular ones.

Experimental

Adm and Adm·HCl were prepared and purified as described elsewhere (17). All ^1H nmr spectra were recorded at the Southwestern Ontario NMR Centre on a Bruker WH-400 FT nmr spectrometer. Saturated solutions were prepared for the measurements in $CDCl_3$, $(CD_3)_2CO$, and CD_3OD. The solutions in the other solvents were approximately 10 mg L^{-1}.

2D nuclear magnetic resonance spectra

For the COSY spectra, 256 1K FIDs were acquired using the standard Bruker microprogram COSY.AU. A sine squared bell window function was applied in both dimensions before Fourier transformation. The magnitude spectrum was then symmetrized about the diagonal. The number of transients collected per FID varied depending upon the concentration of the sample but generally 16 to 64 were sufficient.

For the *J*-resolved spectra, 128 2K FIDs were acquired using the standard Bruker microprogram JRES.AU. The f_1 sweep width was ±28 Hz. The sine bell window function was applied in each dimension before transformation. A magnitude calculation was performed after which the spectra were tilted and then symmetrized about $f_1 = 0$ Hz.

1D nuclear magnetic resonance spectra

The 1D spectra were routinely acquired into 16 or 32K blocks and were Fourier transformed after the application of any of the standard window functions that was deemed to be necessary. Usually the window from 9.0 to 0.0 ppm was observed.

DOUGLAS M. TEMPLETON. Can. J. Chem. **65**, 2411 (1987).

The glycosaminoglycans are naturally occurring anionic polysaccharides whose polyelectrolyte properties and counterion interactions may underlie a number of biological activities. We have investigated the ability of the sulfated glycosaminoglycans to accelerate the reaction of $Br(NH_3)_5Co^{2+}$ with Hg^{2+}. Chondroitin sulfates A, B, and C, heparin, and heparan sulfates all accelerate this reaction to nearly the same extent, but do so at different optimal concentrations, above which inhibition is observed. This phenomenon of rate acceleration, sometimes called "polyelectrolyte catalysis", has previously been explained by a two-phase model, in which the reactant counterions are thought to equilibrate rapidly between the polymer domain and the bulk phase. Rate effects would then be due to higher local concentrations in the neighbourhood of the polymer. Our results show that this is an oversimplified view for the glycosaminoglycans. Rather, they demonstrate similar rate accelerations independent of net structural charge density. It is argued that counterion condensation, as described by Manning, reduces the surface potential of all glycosaminoglycans to nearly constant values. Different optimal concentrations of the glycosaminoglycans may arise in part from the unreactivity of a subpopulation of bound ions.

DOUGLAS M. TEMPLETON. Can. J. Chem. **65**, 2411 (1987).

Les glycosaminoglycanes sont des polysaccharides anioniques que l'on retrouve dans la nature dont les propriétés comme polyélectrolytes et les interactions contre-ioniques peuvent être à la base d'un grand nombre d'activités biologiques. On a étudié la facilité qu'ont des sulfates de glycosaminoglycanes d'accélérer la réaction du $Br(NH_3)_5Co^{2+}$ avec le Hg^{2+}. Les sulfates de chondritine A, B et C, l'héparine et les sulfates d'héparane accélèrent tous cette réaction de la même manière; toutefois, cette propriété n'est observée qu'à des concentrations optimales qui varient et au-dessus desquelles on observe une inhibition. Ce phénomène d'accélération des vitesses de réaction, qu'on appelle quelquefois «catalyse des polyélectrolytes», a été expliquée antérieurement par un modèle comportant deux phases; dans ce modèle, on suggère qu'il s'établit rapidement un équilibre entre les contre-ions réactifs du domaine du polymère et ceux de l'ensemble de la phase. Les effets sur les vitesses proviendraient alors de concentrations locales élevées autour du polymère. Nos résultats démontrent que cette théorie est trop simplifiée pour le glycosaminoglycanes. Nos résultats démontrent plutôt que les vitesses de réactions peuvent être accélérées de la même manière sans qu'il existe de densité nette de charge autour de la structure. On suggère donc que la condensation des contre-ions, telle que décrite par Manning, réduit le potentiel superficiel de tous les glycosaminoglycanes à des valeurs qui sont presque constantes. Il se peut donc que des concentrations optimales différentes de glycosaminoglycanes puissent provenir en partie du fait qu'une sous-population d'ions liés ne sont pas réactive.

[Traduit par la revue]

Introduction

Polyelectrolytes affect the solution properties of small ions having charges both similar (coions) and opposite (counterions) to those of the polyion. This is in large part due to electrostatic effects, which are manifest as forces concentrating counterions in the vicinity of the polymer while at the same time excluding coions from this region. Quantitative description of the concentration of counterions in the polymer domain has been approached with both Poisson–Boltzmann (1, 2) and Manning counterion condensation (3, 4) theories. Reactions in solution between small ions of like charge are in general slow, since the reactants exhibit mutual electrostatic repulsion. However, the rates of such reactions are frequently increased in the presence of polyelectrolytes of opposite charge to the reactants. This phenomenon has been called polyelectrolyte catalysis (5–8). It may be understood as arising from local concentration effects. Concentrations of both reactants are increased in the polymer domain, where the reaction then proceeds at increased rate. While this model may be of heuristic value, use of the term "catalysis" to describe the phenomenon is open to question, and has been rightly criticized (9, 10). Here we will recognize the fact that polyelectrolytes may well alter the equilibrium distribution of small ionic species, and will use the more neutral term of rate acceleration to describe the observed phenomenon.

[1]Correspondence should be sent to this address.

Acceleration of the rate of the reaction of bromopentammine Co(III) with mercuric ion,

$$Br(NH_3)_5Co(III)^{2+} + Hg^{2+} \rightarrow H_2O(NH_3)_5Co(III)^{3+} + HgBr^+$$

was studied in the presence of various ions and interpreted (11) in terms of the primary salt effect (12). Acceleration of this reaction by a biological polyelectrolyte was measured first in the presence of various polynucleotides (7) and later with chondroitin-4- and 6-sulfates (10). Booij (10) interpreted his results in terms of the two-phase model of Morawetz and Shafer (13). This model assumes that the reactants are distributed between two phases, the polymer domain with a potential ψ and the bulk solution. Rapid exchange is assumed between the phases, so that the equilibrium distribution is not affected by reaction, and the intrinsic rate constant is taken to be the same in both phases. This amounts to true catalysis and the faster rate of reaction is viewed as being due solely to the increased concentration of reactants in the polymer domain.

The glycosaminoglycans (GAGs) are a class of naturally occurring polysaccharides consisting of sulfated uronic acid – hexosamine disaccharide subunits. The exceptions are hyaluronic acid, which contains no sulfate, and keratan sulfate, in which the uronic acid is reduced to the corresponding polyol. In all cases some structural heterogeneity occurs along the length of the polymer chain, but individual GAGs are characterized by typical uronic acid – hexosamine disaccharides. Variation

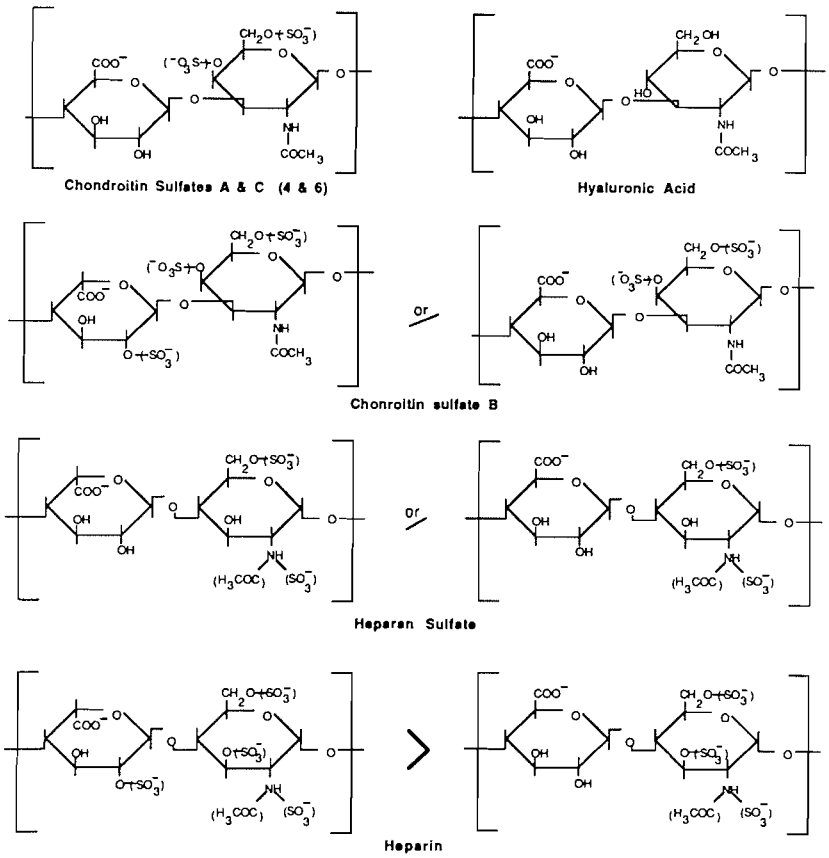

FIG. 1. Typical repeating disaccharide structures of the glycosaminoglycans used in the present study. Substituents in parentheses may alternatively be H. Iduronic acid predominates in heparin, which is also the most highly sulfated polymer of the group.

occurs in the stereochemistry of the C-5 carboxyl of the uronic acid (producing the C-5 epimers glucuronic and iduronic acid), in the extent of deacetylation of the amino group of the hexosamine, and in the degree and position of sulfation. The disaccharide structures of the GAGs used in the present study are given in Fig. 1. Clearly the GAGs are anionic polyelectrolytes with significant axial charge densities (*vide infra*). These vary from $\xi \simeq 0.7$ for hyaluronic acid to $2 < \xi < 3.5$ for various heparins (14, 15, and present work).

The electrostatic fields arising from these significant charge densities may underlie the wide range of biological functions of the GAGs. Thus electrostatic interactions have been implicated in such diverse processes as Ca^{2+} ion sequestration by chondroitins during bone mineralization (16), the anticoagulant activity of heparin (17), and the charge dependence of plasma solute filtration by the kidney (18). Our attempts to understand the latter phenomenon (19, 20) have led us to investigate the charge-dependent chemistry of these species. A number of investigators have studied metal ion binding to GAGs in isolation (21–25) and in tissue components (19). Another approach has been to study dye binding by GAGs (26), and it has been suggested that the well-known phenomenon of metachromasia may relate to the biological activity of some GAGs (17). Here we extend the work of Booij (10) to show that a wide range of GAGs from various sources exhibit polyelectrolyte rate acceleration of ionic reactions. Our results demonstrate that the two-phase model is unsuitable for describing the effects of GAGs. Significant ion binding modifies polymer charge densities, and can inhibit reaction by sequestering reactants in a manner dependent upon polymer concentration. The partitioning of ions between bulk and polymer domains is understood in terms of Manning's theory of counterion condensation (3, 4).

Theory

Two-phase model

In this model, a counterion partitions between the bulk phase and polyion domain according to the dimensionless parameter x where

$$[1] \quad x = \exp(-q\psi/kT)$$

where q is the charge on the electron, k Boltzmann's constant, and T the absolute temperature. ψ is the average potential experienced by a univalent counterion in the polymer domain. The volume of the polyion phase is approximated as that of a cylinder of radius r. If the structural radius R of the polymer is known, then the thickness ρ of the annulus in which reaction takes place can be calculated as

$$[2] \quad \rho = r - R$$

If [ua] is the concentration of uronic acid (equal to the concentration of disaccharide repeating units of the GAG polymer) in mol dm^{-3} and L is the length of the disaccharide, then with all lengths in m (metres) the volume of the polyion phase ϕ is given by

$$[3] \quad \phi = \pi r^2 LN[\text{ua}] \times 10^3$$

where N is Avogadro's number. Morawetz and Shafer (13) derived expressions for ϕ in terms of x, and for k/k_0 in terms of ϕ, where k and k_0 are the rates of the reaction in the presence and absence of polyelectrolyte, respectively. When the charges on both reactants are +2, these expressions reduce to (see

Appendix A of ref. 10)

[4] $\phi_{max} = x^{-2}$

and

[5] $(k/k_0)_{max} = x^2/4$

Equations [1] and [5] allow calculation of the effective potential from the observed rate acceleration, while eqs. [2], [3], and [4] determine the proximity of the reacting ions to the polymer.

Manning model

Partitioning of the divalent ions into the polymer domain can alternatively be described according to the empirical formulation of Manning (4), which gives the binding fraction f, defined as the fraction of polymer charge that remains uncompensated by counterion binding, by the discontinuous equation

[6] $f = (\xi Z)^{-1}, \xi > Z^{-1}$
$f = 1 \quad , \xi < Z^{-1}$

Z is the valence (charge) of the counterion and ξ is a dimensionless axial charge density given by

[7] $\xi = (q^2/4\pi\epsilon_r\epsilon_0 kT)(1/b)$
$= (\pounds/\epsilon_r T)(1/b)$

The term $(\pounds/\epsilon_r T)$ is the Landau length, where ϵ_r is the relative dielectric constant of the bulk medium and the constant $\pounds = q^2/4\pi\epsilon_0 k$. The permittivity of free space is ϵ_0 and b is the linear spacing between univalent charges on the polymer. Calculations throughout have been performed assuming T = 298 K and ϵ_r = 78.33 for water at 25°C. Note that this definition of f means that fractional charge reduction is $f - 1$, a value of $f = 1$ implies no counterion binding, and, for example, monovalent ions will not be effective in reducing polymer charge if $\xi < 1$.

In Manning's theoretical treatment of counterion condensation, the driving force for net binding may be considered to be the relief of electrostatic strain inherent in the polyion (e.g. see ref. 27). The nature of binding is not specified, all binding modes being equally effective in reducing polymer charge. Following Manning (4), we will consider binding to be either site specific or territorial. Site-specific binding refers to the complexation of counterions at fixed sites on the polymer. Territorial binding refers to all other binding modes, including, for example, metal ions concentrated in the neighbourhood of the polymer as described in double layer theory. It is only the total of both types of binding that must remain constant for counterions of a given valence, as indicated by eq. [6].

Poisson–Boltzmann model

The two-dimensional charge density per unit surface area, σ, of a cylinder of radius R and charge density ξ is given by (2)

[8] $\sigma = \xi/[2\pi R(\pounds/\epsilon_r T)]$

We will use this relation to calculate the surface potential ψ_0 of a GAG of known ξ, from the Gouy–Chapman equation, according to (28)

[9] $q\sigma/(8 \times 10^3 \cdot \epsilon_r\epsilon_0 NkTC_\infty)^{1/2} = \sinh [Zq\psi_0/2kT]$

where $\sinh(x) = \frac{1}{2}(e^x - e^{-x})$ and C_∞ is the molar concentration of counterion in the bulk solution (i.e., at an infinite distance from the polymer).

Relation of k/k_0 *to* ξ

From the above discussion it is apparent that, if the two-phase model applies, rate acceleration is related to ξ through the potential ψ that the structural charge density entails. In general,

[10] $\psi \propto -\xi/\epsilon_r$

where the proportionality term will be a function of distance from the polymer. This term has been given as $2K_0(\kappa d)$ where d is the distance from the polymer, K_0 is a zero'th order modified Bessel function of the second kind (10), and $1/\kappa$ is the Debye length defined as

[11] $1/\kappa = (8\pi \cdot 10^3 \cdot NC_\infty \pounds/\epsilon_r T)^{-1/2}$

Then for two polyions of the same signed charge and effective radius r (i.e., d constant), denoted by subscripts 1 and 2,

[12] $\psi_1/\psi_2 = \xi_1/\xi_2$

From eqs. [1], [4], and [11]

[13] $(k/k_0)_{max,1}/(k/k_0)_{max,2} = \exp[(-2q/kT)(\psi_1 - \psi_2)]$

and

[14] $\log (k/k_0)_{max,2} - \log (k/k_0)_{max,1} = 179(\psi_1 - \psi_2)$

at 25°C with ψ in volts.

Salt dependence of ion partitioning

We will consider the effects of a monovalent supporting electrolyte on the concentration of divalent counterions in the polymer domain. Because the surface potentials of the GAGs are sufficiently large ($\psi_0 < -60$ mV), linearization of the Poisson–Boltzmann equation is not justified, and the Debye–Hückel model is not valid (28). Equation [9] predicts a greater than second power dependence of ψ on ion charge. In symmetrical salts eq. [9] can be used to calculate the surface potential as a function of C_∞, from which $\psi(d)$ can be calculated according to ref. 28:

[15] $\psi(d) = (2kT/zq) \ln [(1 + \alpha e^{-\beta d})/(1 - \alpha e^{-\beta d})]$

where

$$\alpha = [\exp(zq\psi_0/2kT) - 1]/[\exp(zq\psi_0/2kT) + 1]$$

and

$$\beta = [(2q^2 C_\infty z^2)/(\epsilon_r\epsilon_0 kT)]^{1/2}$$

Here z is the valence of the electrolyte and ψ_0 is the surface potential at $d = 0$. Variation in C with distance is given by the Boltzmann relation

[16] $C(d) = C_\infty \exp[zq\psi(d)/kT]$

In mixed salts, a more general form of eq. [9] must be used, as derived by Grahame (29):

[17] $q\sigma = \{(2\epsilon_r\epsilon_0 kT)\Sigma_i C_{\infty,i} \exp(-z_i q\psi_0/kT) - 1\}^{1/2}$

where the summation is over all small ions i. In the Poisson–Boltzmann and Gouy treatments, then, the screening effects of a supporting electrolyte are understood through their concentration effects on surface potential, as revealed for example in eqs. [9] and [17] for a given structural charge density.

Salt effects on binding can also be accounted for in the Manning model. Equation [6] does not predict a concentration dependence for a single species of counterion, and this has been borne out over a wide range of conditions in polyelectrolyte solution (8). However, since the binding energy is related to the electrostatic potential in the polymer domain, a second ion will affect binding of the first if it is capable of modifying the

surface potential. In the presence of charge reduction by both monovalent and divalent ions, the contribution of each can be calculated from solution of the simultaneous equations

$$\ln [A(\theta_1/C_{\infty,1})] = -2\xi(1 - \theta_1 - 2\theta_2) \ln [1 - \exp(-b\kappa)]$$
$$\theta_2/C_{\infty,2} = A(\theta_1/C_{\infty,1})^2 \quad [18]$$

where θ_i is the extent of binding of counterions of valence i, defined as bound mole ratio per equivalent polyelectrolyte charge ($Z_i\theta_i = 1 - f_i$), and $A = e/10^3 \cdot V_p$ where V_p is the volume of the binding shell about the polymer in m^3 per mole of equivalent polyion charge and e is the base of the natural logarithms (2). Here the salt dependence of binding enters through the Debye length. Following Booij (10), we have performed most kinetic measurements at a calculated ionic strength of 0.020 *M* as a compromise between higher values, which would minimize polyelectrolyte effects by screening the polymer potential, and lower values, which would constitute a poorly controlled system. Under these conditions, the ratio of monovalent ions to divalent ions in the reaction mixture is greater than two orders of magnitude (see Methods), screening effects should be primarily due to the 1:1 salts, and the Gouy–Chapman potential should be a good approximation to the Grahame potential. The relationship between θ_2 and the observed rate of aquation depends both on the nature of binding and the reactivity of bound ions. To use eq. [18] to predict the observed ionic strength dependence of the acceleration, it will be necessary to consider the rate increase to be proportional to the increase in total concentration of divalent ions in the polymer domain, and to assume that the cobalt complex and mercuric ions are indistinguishable with respect to condensation, as implied by eq. [6].

Materials and methods

Chemicals

Chondroitin sulfates (ChS) Type A (whale cartilage), Type B (porcine skin), and Type C (shark cartilage), heparin (pig intestinal mucosa, grade I), hyaluronic acid (human umbilical cord, grade I), deoxyribonuclease I (crude, 460 Kunitz units/mg), ribonuclease (5× crystallized, 58 Kunitz units/mg), and calf thymus DNA (Type I, highly polymerized) were all obtained from Sigma Chemical Co., St. Louis, MO. The enzymes and hyaluronic acid were used without further purification. ChS(B) and heparin were purified by poly-L-lysine Sepharose chromatography. Some heparin was further fractionated by metal chelate affinity chromatography (MCAC). Chondroitin sulfates A and C were further purified by precipitation from 50 m*M* NaCl in 50 m*M* Tris-HCl, pH 7.4, with 1% cetylpyridinium chloride, redissolved in 2.5 *M* NaCl:methanol (2:1), precipitated with 5 volumes of 95% ethanol in the presence of 1% potassium acetate, dialysed extensively against deionized water, and lyophilized. $Hg(NO_3)_2$ (crystalline) was from Matheson, Coleman and Bell (Norwood, OH). $Br(NH_3)_5Co(III)\cdot Br_2$ was synthesized by the method of Diehl *et al.* (30), beginning with $CoCl_2\cdot 6H_2O$ (Anal R; BDH, Poole, UK). The product was recrystallized by dissolving 20 g in 400 mL H_2O with 20 mL NH_4OH, at 90°C. To the hot filtrate was added 36 mL of 48% HBr, and the solution was held over a steam bath for 2 h. On cooling, purple crystals were obtained ($\epsilon_{254} = 1.72 \times 10^4$ dm^3 mol^{-1} cm^{-1}). Heparan sulfates (HS) were isolated from beef lung as previously described (31), and eluted from poly-L-lysine Sepharose to yield two major fractions.

Chromatography

Cyanogen bromide activated Sepharose CL-4B was prepared and coupled with poly-L-lysine·HBr (D.P. 200; Sigma) as described (32) and poured into a 0.9 × 30 cm column. GAG samples were applied in Tris·HCl (50 m*M*, pH 7.5) and eluted with a linear gradient of NaCl (0–2 *M*, 200 mL) in the same buffer (33). Two major HS fractions eluted between the chondroitins and heparin, at 0.95 and 1.20 *M* NaCl. These are designated HS-I and HS-II respectively. MCAC was performed in disposable 10-mL plastic syringes containing iminodiacetic acid – Sepharose 6B (Pharmacia). The top two-thirds of the columns were charged with either Cu^{2+} or Ni^{2+}, and equilibrated with 50 m*M* phosphate buffer, pH 8.0. Heparin samples were loaded in this buffer, and eluted with a linear gradient of 50 m*M* phosphate (pH 8.0–pH 5.0, 200 mL). Most of the uronic-acid-positive material eluted as a single peak above pH 7. This fraction is designated non-metal-binding heparin (heparin-NMB). Less than 5% of the total uronic acid (also in polymer form) eluted as a second minor peak below pH 6. Heparin-NMB was further purified by dialysis against water, and lyophilized.

Biochemical procedures

Sulfated GAGs were estimated by the dimethylmethylene blue assay (31), using commercial heparin or chondroitin sulfates as standards, as appropriate. Uronic acid was measured by a scaled-down version of the carbazole assay (34), and sulfate by the rhodizonic acid procedure (35). For the sulfate determinations, triplicate samples were each divided in half, and one half was hydrolyzed with 1 *M* HCl (2 h, 100°C) before assay. The content of GAG sulfate ester was taken as the amount of sulfate released by hydrolysis, measured against standards of Na_2SO_4. Desulfation of ChS(A) was achieved by the method of Kantor and Schubert (36). Acetyl chloride was dissolved in methanol (0.5% by volume) and the solution let stand stoppered for 2 days. ChS(A) (100 mg) was suspended in 15 mL of this reagent, and stirred gently at room temperature for 48 h. The reagent was changed at 24 h. The product was collected by centrifugation, dialysed against water, and lyophilized. For nucleic acid digestions, 5–25 mg of GAG was dissolved in 10 mL sodium acetate buffer (0.125 *M*, pH 5.0, with 0.050 *M* $MgCl_2$) and incubated at 37°C for 48 h. Solutions of 1 mg deoxyribonuclease and 0.2 mg ribonuclease in 1 mL of the same buffer were added at 0 and 24 h. At 48 h the GAG solutions were placed in a boiling water bath for 10 min, the supernatant was cleared by centrifugation, and the GAGs were recovered by ethanol precipitation (5 vol 95% ethanol) in the presence of 1% potassium acetate.

Kinetic measurements

Water of 18 MΩ cm (Milli Q system; Millipore) was used for all solutions. Stock solutions of 1 m*M* $Br(NH_3)_5Co\cdot Br_2$ were prepared fresh each week and stored in the dark. For use each day, a 10-fold dilution was prepared, and the concentration determined from the absorbance at 254 nm. Water, $HClO_4$, $NaClO_4$, $Hg(NO_3)_2$, and the Co complex, all held at 25°C, were added in order to a quartz cuvette. The reaction was initiated by the addition of variable amounts of a GAG stock solution, which in each case was sufficient to make the final volume to 1.000 mL. Final concentrations were $[HClO_4] = 0.010$ *M*, $[Hg^{2+}] = 1.0 \times 10^{-4}$ *M*, and $[Co] = 1.0 \times 10^{-5}$ *M*. Sufficient $NaClO_4$ was added from an approximately 0.10 *M* stock solution to give a final ionic strength of 0.020 *M*, except in the ionic strength variation experiments, where variable amounts of perchlorate were used. The solution was mixed by inverting and the cuvette immediately placed in the spectrophotometer at 25 ± 0.1°C. Disappearance of the brominated Co complex was followed at 254 nm, and the initial rates were calculated assuming $\epsilon_{254} = 1.72 \times 10^4$ dm^3 mol^{-1} cm^{-1}. The pseudo-second-order rate constant k_2 was calculated according to $-d[Co]/dt = k_2[Hg][Co]$, where [Co] denotes the concentration of the brominated complex. The rate constant for aquation in the absence of GAG, $k_{2,0}$, was measured in duplicate at the beginning and end of each experiment, and the mean value used to calculate the $k_2/k_{2,0}$ ratios for that experiment. Over all experiments, a mean value of $k_{2,0} = (5.67 \pm 0.44) \times 10^4$ M^{-1} s^{-1} was found. Absorbance changes were recorded on a Perkin–Elmer Lambda 4C spectrophotometer, and analyzed in digitized form with Perkin–Elmer 7300 or 7700 computers. Each experiment consisted of concentration variation of a single GAG to encompass a maximum in the profile of $\log(k_2/k_{2,0})$ vs. [uronic acid]. Maximum rate acceleration and optimum GAG concentration were then found for the experiment from the derivative of a quadratic fit to

the profile ($R \geq 0.98$ in each case), and the values for these quantities are reported as the mean ± S.D. for several independent experiments.

Results

Chondroitin sulfate A enhances the rate of Hg^{2+}-induced aquation of bromopentammine $Co(III)^{2+}$ in 0.01 *M* perchloric acid at an ionic strength of $I = 0.020$ (Fig. 2). As the concentration of the polyelectrolyte is increased, the rate increases to a maximum, and declines thereafter. Similar behaviour is seen with ChS(B) and ChS(C) (not shown). A commercial preparation of heparin (Fig. 3), and heparan sulfates of two different compositions isolated from bovine lung (HS-I and HS-II), produce rate acceleration under similar conditions, and both show a concentration maximum for the effect. All GAGs show a concentration-dependent decrease above the maximum. At even higher concentrations, the reaction is inhibited relative to the rate of spontaneous hydrolysis in the presence of mercuric ion.

Because of microheterogeneity of these polymers, and the possibility that inhibition of the "uncatalyzed" reaction is due to site-specific binding of one or both ions by the GAG, the heparin sample was fractionated by metal chelate chromatography. On both Cu^{2+} and Ni^{2+} columns, a small fraction (<5%) of the total heparin was retained with higher affinity on the column (see Methods). The remaining heparin-NMB was also effective at enhancing the rate of the aquation reaction (Fig. 3), and was also capable of inhibiting the reaction at higher concentrations.

To demonstrate that the observed rate accelerations were due to the electrostatic fields generated by the charged functionality of the polyelectrolytes, two experiments were performed. First, the effect of hyaluronic acid on the reaction was investigated. This material is also a polymer of alternating hexosamine and uronic acid residues, but unlike the other GAGs contains no sulfate. Thus under the reaction conditions (well below the carboxyl pK_a), it is uncharged. No rate acceleration was seen with hyaluronic acid, and at increasing concentrations inhibition was noted (Fig. 4). Second, a sample of ChS(A) was desulfated by reaction with methanolic HCl. This produced a polymer with no detectable sulfate, and is also known to carboxymethylate uronic acid residues to a variable extent (36). When this desulfated chondroitin A was added to the reaction mixture, behaviour similar to hyaluronic acid was observed, i.e., no rate acceleration, and inhibition at higher concentrations (Fig. 4).

Quantitative comparison of the effects of the various polymers is achieved by determining the maximum rate acceleration produced by each, and the polymer concentration at which this maximum is reached. All sulfated GAGs give approximately the same degree of rate acceleration under a fixed set of conditions; however, they do so at quite different optimum concentrations (Table 1). From the two-phase model (eqs. [4] and [5]), the rate accelerations allow estimation of effective polymer radii and surface potentials (Table 1). For all sulfated GAGs, a mean value of $\log (k_2/\log k_{2,0}) = 1.55 \pm 0.07$ is found, corresponding to $\psi = -64 \pm 2$ mV. However, the effective polymer radius varies widely. Using published structural radii, the reaction annulus is seen to vary from 1.8 to 11.8 nm (Table 1). Under the assay conditions of 0.0197 *M* 1:1 salt, and ignoring the divalent reactants, the Debye length is 2.2 nm.

While relatively small changes in $\log (k_2/\log k_{2,0})$, and hence in the average potential ψ of the two-phase model, are observed, a much broader range of optimum GAG concentrations is seen. These range from 4.0×10^{-5} *M* for the heparin fractions to 1.6×10^{-3} *M* for the chondroitin sulfates, with intermediate values for the heparan sulfates. These concentrations are reflected in the reaction annuli. They follow the same order as the polymers' sulfate-to-uronic acid ratios, from which corresponding axial charge densities can be calculated using published structural information (Table 2). The mean repeat lengths for the fractionated lung heparan sulfates (HS-I and HS-II) have not been reported. However, if we assume both to have a disaccharide length of 0.93 nm, intermediate between heparin and the chondroitins, as reported for unfractionated heparan sulfate (14), then charge densities intermediate between heparin and the chondroitins are also calculated. The order of ξ values for all polymers follows their order of elution from the poly-L-lysine column, as expected (Fig. 5). The empirical relationship between ξ and $\log [ua]_{max}$ is shown (Fig. 6).

The surface potentials calculated from these structural charge densities by eqs. [8] and [9] (Table 3) are considerably larger

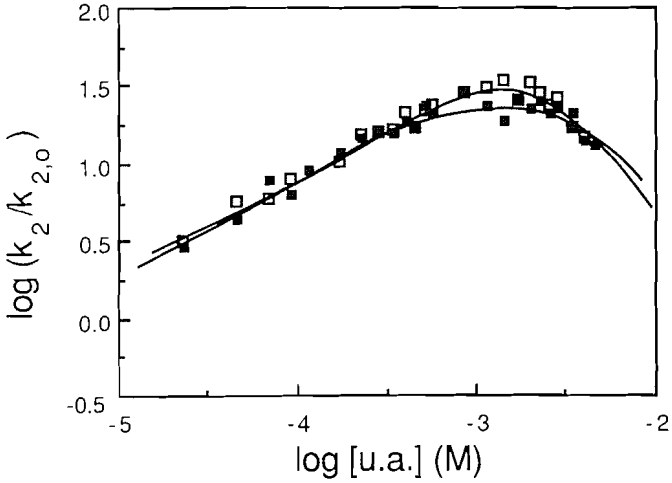

FIG. 2. Rate acceleration of the Hg^{2+}-induced aquation of $Br(NH_3)_5Co^{2+}$ in the presence of ChS(A). Polymer concentration is expressed as the molar concentration of uronic acid, [u.a.]. The reaction is carried out at 25°C in the presence of 1.0×10^{-4} *M* Hg^{2+}, 1.0×10^{-5} *M* Co(III) complex, and 0.010 *M* $HClO_4$, at an ionic strength of 0.020 adjusted with $NaClO_4$. The curves represent second-order polynomial fits to the data from two representative experiments (see Methods).

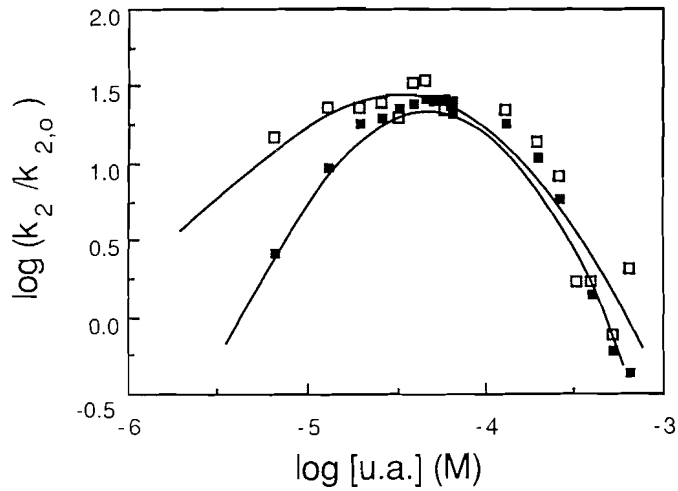

FIG. 3. Rate acceleration of the aquation reaction in the presence of native heparin (□) and the low affinity metal binding fraction heparin-NMB (■). Details are as in the legend to Fig. 2.

TABLE 1. Rate acceleration and two-phase parameters for the effect of the sulfated GAGs on the cobalt aquation reaction. The effective radii (r), reaction annulus (ρ), and average potential (ψ) are calculated from eqs. [1]–[5]. The partition factor x is as defined in eq. [1]. The mean $(k_2/k_{2,0})_{max}$ and $[ua]_{max}$ values are found from n independent experiments, such as those of Figs. 2 and 3. Values for ChS(B) are from a single experiment, since amounts of this material are limited

GAG	$\log (k_2/k_{2,0})_{max}$	$\log [ua]_{max}$ (M)	n	x	r (nm)	ρ (nm)	ψ (mV)
Heparin	1.7 ±0.3	−4.28±0.06	3	14.2	7.85	7.15	−68
Heparin-NMB	1.55±0.05	−4.49±0.02	2	11.9	11.8	11.1	−64
HS-II	1.54±0.02	−3.40±0.01	2	11.8	3.20	2.50	−63

ChS(A)	1.48±0.07	−2.83±0.02	4	11.0	1.76	1.06	−62
ChS(C)	1.55±0.05	−2.93±0.02	4	11.9	1.83	1.13	−64
ChS(B)	1.54	−3.2	1	11.8	2.50	1.80	−63

TABLE 2. Sulfate content and charge densities of the GAGs. Because each disaccharide contains one uronic acid residue, the SO_3^-/uronic acid ratio is the number of SO_3^- groups per disaccharide. Repeat lengths are mean published lengths of the disaccharide residues (14, 15, 23), and the value for our HS-I and HS-II is taken as the value reported for "heparan sulfate" (14). Charge spacings, b, and charge densities, ξ, differ between pH 2 and 5 due to deprotonation of the carboxyl group at the higher pH, which adds one negative charge per disaccharide

GAG	SO_3^-/uronic acid	Repeat length (nm)	pH ≃ 2		pH ≥ 5	
			b (nm)	ξ	b (nm)	ξ
Heparin	1.73±0.36	0.83	0.48	1.49	0.30	2.35
Heparin-NMB	1.73±0.36	0.83	0.48	1.49	0.30	2.35
HS-II	1.69	0.93	0.55	1.3	0.35	2.07

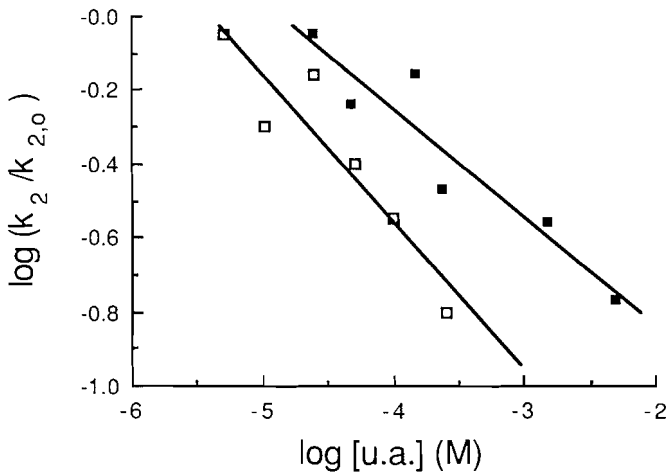

FIG. 4. Inhibition of the aquation reaction in the presence of hyaluronic acid (□) and chondroitin (desulfated ChS(A)) (■). Details are as in the legend to Fig. 2.

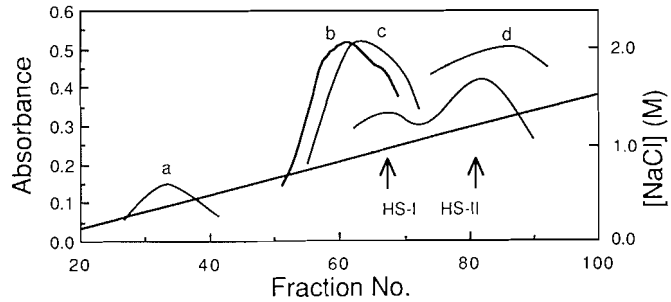

FIG. 5. Elution of glycosaminoglycans from a poly-L-lysine Sepharose CL-4B column with a linear gradient of NaCl in Tris·HCl (see Methods for details). Elution positions of standards of commercial hyaluronic acid (a), ChS(A) (b), ChS(C) (c), and heparin (d) are shown, along with those of the two components of bovine lung heparan sulfate, purified as described under Methods. The latter (HS I and II) are indicated by arrows on the figure; 1–5 mg of each glycosaminoglycan was loaded. Sulfated material was determined at 535 nm using the dimethylmethylene blue assay, as described in ref. 31, while hyaluronic acid was located by measuring its uronic acid content with the carbazole reaction, at 530 nm.

than the average potentials predicted by the two-phase model (Table 1). The potentials in Table 2 are calculated for both protonated and deprotonated carboxyl groups. In chondroitin sulfates, the carboxyl group pK_a at half ionization is about 3.8 (10), so under our experimental conditions (0.01 M $HClO_4$), ξ and ψ_0 values are due to sulfate groups alone.

Kinetic measurements at higher pH are not reported here since the Hg^{2+} ion hydrolyses to the unreactive $HgOH^+$ with a pK of 3.52 (37). We confirmed that at pH 5.5, $k_2 = k_{2,0} \simeq 0$. In the hope of investigating the reaction at higher pH, Cd^{2+} was substituted for Hg^{2+}. This choice was based on the significant stability constant of the $Cd(II)Br^+$ complex (log β_0 = 2 for

TABLE 3. GAG surface potentials. The surface charge density σ is calculated from eq. [8], assuming an average polymer radius of 0.7 nm for all GAGs. The Gouy–Chapman potentials, ψ_0^{G-C}, are calculated from eq. [9], taking into consideration only the 0.0197 *M* monovalent salts in the assay solution. The Grahame potentials, $\psi_0^{Grahame}$, from eq. [17], also include the 1.1×10^{-4} *M* divalent cations. The number of moles of divalent metal necessary to reduce ξ to $\xi_{net} = 0.5$ is calculated as $\frac{1}{2}$(uncompensated charge − net charge), where the charges are per disaccharide and net charge is given by eq. [7] with $\xi = 0.5$ and the repeat lengths of Table 3. All values are for pH ≃ 2, except for those in parentheses, which give data for hyaluronic acid at pH ≥ 5 for comparison

GAG	σ (m^{-2}, $\times 10^{-17}$)	ψ_0^{G-C} (mV)	$\psi_0^{Grahame}$ (mV)	Moles M^{2+}/mole u.a., at $\xi_{net} = 0.5$
Heparin	4.73	−115	−57	1.08
Heparin-NMB	4.73	−115	−57	1.08
HS-II	4.13	−108	−54	1.02
HS-I	3.49	−100	−50	0.89
ChS(A)	2.98	−92	−46	0.80
ChS(C)	2.73	−88	−44	0.74
ChS(B)	2.67	−87	−43	0.73
Hyaluronic acid	(2.10)	(−75)	(−37)	(0.12)

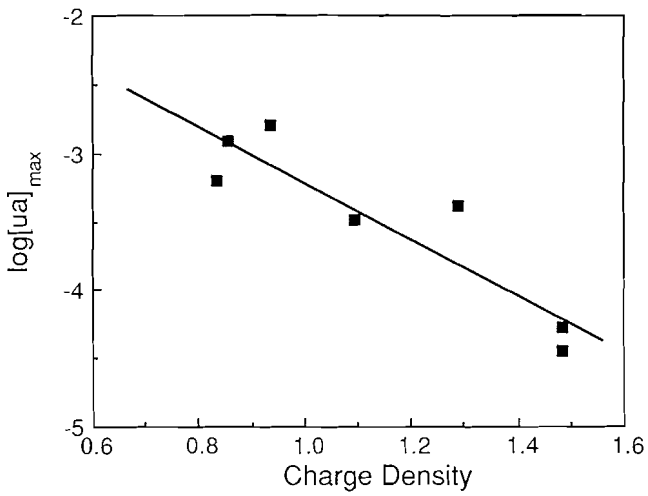

FIG. 6. Observed optimal concentrations of sulfated glycosaminoglycans as a function of linear charge density ξ. Polymer concentrations are expressed as molar concentrations of uronic acid monomers. Data are shown for heparin, heparin-NMB, HS-I, HS-II, ChS(A), ChS(B), and ChS(C). The glycosaminoglycans may be identified by their charge densities at pH ≃ 2, as given in Table 2.

$CdBr^+$ compared to $\log \beta_0 = 9$ for $HgBr^+$ (38)). No significant aquation was observed at either pH 2 or 5.5 with Cd.

No significant quantities of protein or nucleic acid were detected in any of the GAG samples, by absorbance at 280 and 260 nm. However, nucleic acids copurify with GAGs through many isolation steps based on charge properties, and because DNA has a high charge density of $\xi = 4.7$ (39), we were concerned that trace contamination with DNA could still interfere with the kinetic measurements. Indeed when DNA was substituted for GAG in a standard kinetic series (0.01 *M* $HClO_4$, $I = 0.020$), $\log (k_2/k_{2,0})_{max}$ was found to be 1.03 ± 0.02 at an optimum concentration of 1.3×10^{-4} *M* in nucleotide. Because contamination with DNA was therefore a valid concern, portions of solutions of heparin, HS-I, HS-II, and ChS(A) were used for kinetic measurements, then the remainder of the solutions were subjected to treatment with DNase and RNase and used for further kinetic measurements. No changes in the $\log (k_2/k_{2,0})_{max}$ values were found. Log $[ua]_{max}$ was increased by about 0.2 for both heparin and the more highly sulfated of the heparan sulfates, HS-II. It can be concluded that the kinetic parameters reported here are not in error due to the presence of any nucleic acid in the samples, and the increases in log $[ua]_{max}$ following enzyme treatment are probably due to some loss of labile sulfate esters in the more highly sulfated materials.

The ionic strength dependence of the reaction was investigated in the presence of a just suboptimal concentration (5.8×10^{-4} *M*) of ChS(A) (Fig. 7). We have calculated the effect of increasing monovalent salt concentration on the binding of divalent ions to the polymer, using both Poisson–Boltzmann and Manning models. For the former, the surface potential of ChS(A) is calculated from eq. [17] under the appropriate experimental conditions, using the structural parameters of Table 2. Then the concentration of bound divalent metal is found by integrating $C(d)$ (eq. [16]) over the binding shell of thickness d, with $\psi(d)$ given by eq. [15]. For the second approach, θ_2 is found within the binding shell by solving eqs. [18] with the appropriate structural parameters for ChS(A) at pH 2. In both cases, calculations have been performed for a binding shell of 1.06 nm (the reaction annulus calculated for ChS(A) from the two-phase model), or for a variable shell equal to the Debye length at each different concentration. All models show nearly similar dependence of divalent counterion binding on ionic strength (Fig. 7). The rate is assumed to be proportional to the square of the concentration of divalent ions in the polymer binding shell, with no distinction made between divalent species. For comparison with experiment, the proportionality constant is calculated at $I = 0.010$. The observed rate is much less sensitive to ionic strength than is predicted by either model (Fig. 7).

Discussion

A number of authors (15, 40) have considered that the polyelectrolyte properties of the GAGs might somehow account for their biological functions, but clear demonstration of this putative principal has remained elusive. In large part this is due to a lack of understanding of the very functions for which explanations are sought, and the teleological approach of deducing functions from polyelectrolyte properties has been favoured by some (14, 17). This potentially productive approach requires a detailed understanding of polyion–counterion interactions, and some important steps in this direction have been taken.

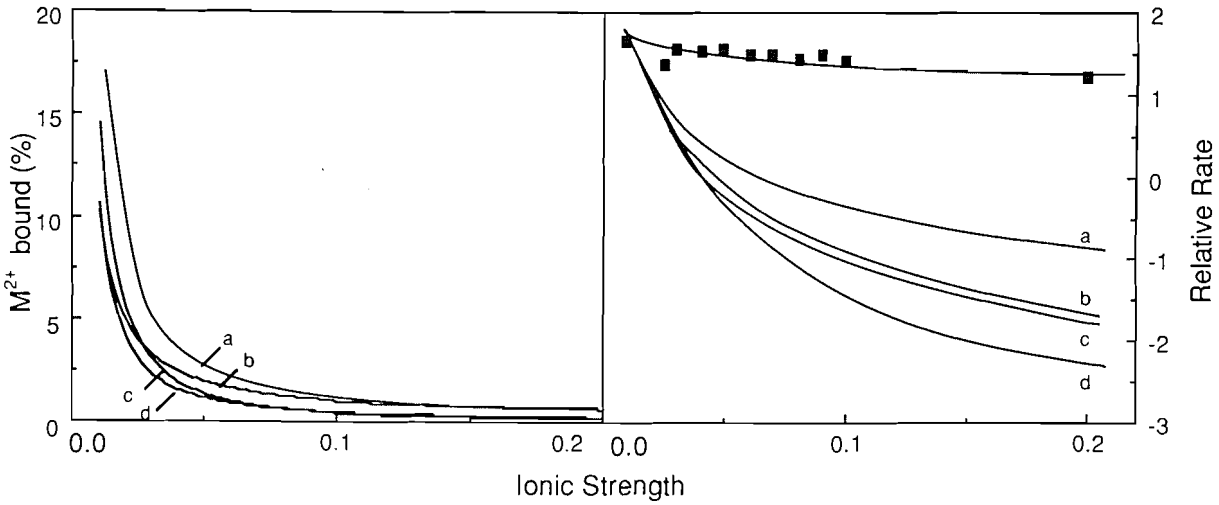

FIG. 7. Salt effects on the binding of divalent metals to ChS(A) (left panel) and on the relative rates of the aquation reaction in the presence of ChS(A) (right panel). Concentrations of Hg^{2+}, $Br(NH_3)_5Co^{2+}$, and $HClO_4$ are as in Fig. 2, and ionic strength is varied by the addition of $NaClO_4$. The concentration of uronic acid is 5.8×10^{-4} *M*. The left panel shows calculated curves for the binding of a divalent counterion, expressed as a percentage of total divalent cations present. Results are shown for the Poisson–Boltzmann model incorporating Grahame's equation, with a binding shell of 1.06 nm (b) or equal to the Debye length (a). Also shown are the predicted salt dependences of eq. [18] with a binding shell of 1.06 nm (d) or equal to the Debye length (c). The right panel shows the corresponding predictions of rate enhancement, based on k_2 proportional to $([M^{2+}]_{bound})^2$, for the same cases: Poisson–Boltzmann model with a binding shell of 1.06 nm (a) or equal to the Debye length (b), or eq. [18] with a binding shell of 1.06 nm (c), or equal to the Debye length (d). Rates are expressed as log $(k_2/k_{2,0})$, with the constant of proportionality calculated from the experimental value at $I = 0.010$. See text for details of all calculations. Experimentally determined values of log $(k_2/k_{2,0})$ are included for comparison (■).

The Manning counterion condensation model has been considered useful in describing self-diffusion of mono- and divalent ions in GAG solutions (15). While this provides a description of net binding, it does not allow distinction to be made between site-specific and territorial binding. The relative importance of these binding modes will depend on the nature of the counterion. Self-diffusion of ^{57}Co and Co^{2+} ion mobilities in ChS solutions allowed estimates of total condensed Co (41). These were compared with the site-bound fraction, deduced from the chemical shift changes in the ^1H nmr spectrum of H_2O, accompanying ion desolvation upon site binding. The net charge reduction was consistent with Manning theory. Site binding accounted for 40% of the total. Ca^{2+} and Sr^{2+} showed total binding similar to Co^{2+} in the ChS system. With the more highly sulfated heparin, Mg^{2+} bound to the extent predicted, while Ca^{2+} bound in excess of the theoretical prediction (24). If, as concluded by the authors, this is due to additional strong binding interactions in the Ca^{2+}-heparin system, then this would represent a departure from Manning behaviour. It would be interesting to distinguish site binding from territorial binding to substantiate this conclusion. Site-specific binding of Cu^{2+} to heparin, involving the carboxyl groups, has been observed in the circular dichroism spectrum (25). We have recently demonstrated that in an intact renal basement membrane, heparan sulfates account for the majority of divalent metal binding (19). Binding to these structures follows the Manning prediction (see ref. 20 for a preliminary report: full details will be published elsewhere). We can conclude at present that the Manning model is a useful starting point for the description of GAG–counterion interactions, that specific binding sites probably occur on all GAGs, and that the latter may be more important in the more highly sulfated materials.

Polyelectrolyte rate acceleration has previously been demonstrated with chondroitin sulfates A and C by Booij (10), who has discussed the phenomenon in terms of the two-phase model of Morawetz and Shafer (13). As explained above, this model assumes that the polyelectrolyte has no effect on the intrinsic rate constant and does not shift the position of equilibrium. At relatively low polymer concentrations, rate acceleration is due solely to an increased local concentration of reactants. At relatively high concentration, inhibition is due to effective separation of reactants (8). Short of detailed information on phase–phase exchange rates and intrinsic rate constants, applicability of the model can best be evaluated by testing its predictions for the relationship between ψ and rate acceleration.

The close similarity of the maximum accelerations for all polymers gives rise to closely similar effective potentials as calculated from the model. These are much closer than expected from structural information, and are more negative than even the surface charge densities predicted by the Grahame equation. Furthermore, even the small differences in the two-phase potentials predict larger differences in the maximum rates, if the assumptions inherent in eq. [12] are granted. For example, with a 6-mV difference between ψ[heparin] and ψ[ChS(A)], eq. [14] predicts a difference in maximum rates of nearly 12 times.

Clearly the assumptions of the two-phase model present an oversimplified explanation of the rate acceleration observed here for the series of GAGs. The similarity of all maximum rates supports a similar effective potential in all polymer solutions. This can only be reconciled with the known structures by assuming a reduction in ψ_0 by ion binding. Since all rates are measured in the same ionic environment, differences in screening by a double layer model cannot account for the different degrees of reduction. Rather, Manning's theory predicts that counterion condensation will reduce all polymer charge densities to $\xi_{net} = \min(\xi, N^{-1})$ (4). With divalent ions present, and all ξ's > 0.5, reduction to $\xi_{net} = 0.5$ is expected. This value predicts a Grahame potential (eq. [17]) of -31 mV

in a mixed salt solution of the composition used for the kinetic measurements at $I = 0.020$. The Gouy–Chapman potential (eq. [9]), considering monovalent salts only, is found to be −63 mV for a polyion radius of 0.7 nm. This latter value is only meaningful if we assume the charge-compensated polymer to behave as a discrete entity, which then is further screened, predominantly by the large excess of monovalent salt. Our data show the rate acceleration with ChS(A) to be much less sensitive to increases in monovalent salt than is to be expected from screening effects. This can be explained by eq. [6], since the structural charge density of the polymer is less than unity at the pH of the reaction. Only the divalent reactant counterions are effective in compensating polymer charge under these conditions. The net binding of divalent counterions required to reduce ξ from the structural value to ξ_{net} remains constant across the concentration range of monovalent ions, and this accounts for the relative insensitivity of such polyelectrolyte binding phenomena to salt effects (8).

The Gouy–Chapman potential calculated for $\xi = 0.5$ is in good agreement with the effective potentials predicted by the two-phase model. If the assumptions of the model are invalid, then this is coincidental. However, it may be consistently assumed that the charge-compensatory binding renders the ions unreactive, and the observed rate acceleration is due to the effects of the compensated polymer on the reaction of the residual reactants. Our failure to successfully predict the rate differences from eq. [14] could then be due to failure of eq. [12], which assumes that all reactions take place at the same distances from the polymers. Indeed quite dissimilar effective radii are calculated from the model. This may represent an over-interpretation of the data, since the small differences in effective potentials may not be significant.

More telling against the two-phase model are the predicted effective radii. While those calculated for the chondroitins seem reasonable, those for the more highly sulfated GAGs do not. It is unlikely that effective annuli several times thicker than the Debye length can have any meaning, since the potentials at such distances are very low. (At low surface potentials, ψ drops to $1/e$ of ψ_0 at the Debye length. At the ψ_0 values encountered here, the decrease of ψ with d is only slightly faster.) We are left with the conclusion that the model is inadequate for description of the results. In retrospect, this is not surprising, since some of the reactant ions are known to be bound to the GAGs, and to reduce their surface potentials. While the extent of site-specific binding of Hg^{2+} and the Co complex are not known, it is likely to be significant (*vide supra*). Such binding should invalidate the two main assumptions of the model, namely unaltered intrinsic rate constants and rapid exchange with the bulk phase.

At present, therefore, no theoretical description of the observed rate acceleration exists. A more complete description would consider the effects of potential on reaction rate. Detailed information on the speciation of all ions, as well as consideration of the discrete molecular nature of the solvent, would be required. The situation is further complicated by the fact that the observed rates are a composite of competing processes. Acceleration may take place due to local concentration effects and (or) changes in the free energies of the reactants in the polymer domain. Inhibition may result from binding of the reactants in unreactive form, and by separation of reactants by distinct polymers. The former cause of inhibition is likely more important for heparin, since binding of only about 30% of Hg^{2+} is necessary to reduce ξ to 0.5 at the optimum heparin concentration. However, all Hg^{2+} present would be necessary to so compensate ChS(C) at a uronic acid concentration of 4.3×10^{-4} *M*. This is only about a third of the optimum concentration of ChS(C), and with the chondroitin sulfates ion separation must be the more important cause of inhibition. The numbers of divalent ions which must bind, per disaccharide, to reduce the charge density of each GAG to 0.5, are included in Table 3.

We conclude that counterion condensation reduces all polymer charge densities to similar values and, under conditions where the volume of the polymer domain is not limiting, all GAGs achieve comparable rate accelerations as a consequence. However, at even higher polymer concentrations, two factors compete to inhibit the reaction. Those GAGs with higher charge densities may more effectively bind the reactant ions due to a greater density of potential binding sites. Those with lower charge densities eventually separate the reactive species. When these interpretations are borne in mind, the observed optimum concentrations may be useful in determining the relative sulfate-derived charge densities of unknown GAGs. Finally, under biological conditions, GAG concentrations are sufficiently low that bulk phase counterions may experience similar potentials from different classes of GAGs, if certain divalent ions are present to reduce charge densities by tight binding processes. This latter suggestion may have interesting consequences in vivo.

Conclusions

1. The GAGs are naturally occurring polyelectrolytes capable of effecting rate acceleration of ionic reactions in solution.
2. The two-phase model of polyelectrolyte catalysis is inadequate to describe the rate acceleration, probably due to significant site-specific binding to the GAGs.
3. All sulfated GAGs give similar rate accelerations, consistent with the description that counterion condensation reduces the charge density ξ of each to the same critical value, thereby producing similar surface potentials ψ_0.
4. Further investigation of these systems could yield insight into both the phenomenon of polyelectrolyte "catalysis" and the biological functions of GAGs.

Symbols

b	linear charge spacing
C_∞	bulk counterion concentration, at infinite distance from polymer
d	radial distance from polymer surface
f	ratio of uncompensated polymer charge to net structural charge
(k/k_0)	ratio of rate constant in the presence of a polyelectrolyte to that in its absence
k_2, $k_{2,0}$	pseudo-second-order rate constants, in presence and absence of a polyelectrolyte, respectively
k	Boltzmann's constant
L	length of repeating unit of a polymer; disaccharide length for a GAG
N	Avogadro's number
q	charge on the proton, in coulombs
r	effective radius of a polymer in the two-phase model
R	radius of a polymer treated as a cylinder
T	absolute temperature
x	phase partition in the two-phase model, given by $x = e^{-q\psi/kT}$
z	electrolyte valence
Z	formal charge on a counterion in the Manning model
ϵ_r	relative dielectric constant of a solvent
ϵ_0	permittivity of free space
ξ	dimensionless linear charge density
θ_i	bound mole ratio of counterions of valence i per equivalent polyelectrolyte charge
$1/\kappa$	Debye length
ρ	thickness of reaction annulus about a polyelectrolyte
σ	surface charge density in equivalents per unit area
ψ	electrostatic potential
ψ_0	surface potential of a polyelectrolyte
$\pounds/\epsilon_r T$	Landau length

The kinetics of cooxidation of several substituted phenyl methyl sulfoxides and oxalic acid with Cr(VI) have been carried out in the presence of perchloric acid. The reaction is first order each in sulfoxide, oxalic acid, Cr(VI), and H^+. The products of oxidation are sulfones and carbon dioxide. Electron-releasing groups in the phenyl ring accelerate the rate while electron-withdrawing groups retard it. The Hammett correlation yields a reaction constant of -0.927 ± 0.08 ($r = 0.994$) at 313 K. Addition of aluminium nitrate prevents the occurrence of cooxidation. Based on the kinetic information a suitable mechanism has been proposed. Diaryl sulfoxides behave in an analogous manner in the cooxidation.

C. Srinivasan, P. Pandarakutty Jegatheesan, S. Rajagopal et N. Arumugam. Can. J. Chem. **65**, 2421 (1987).

Opérant en présence d'acide perchlorique, on a mesuré les cinétiques de cooxydation de l'acide oxalique et de plusieurs phényl méthyl sulfoxydes substitués par le Cr(VI). La réaction est du premier ordre en sulfoxyde, en acide oxalique, en Cr(VI) et en H^+. Les produits d'oxydation sont les sulfones et le dioxyde de carbone. La présence sur le noyau phényle de groupements électrodonneurs provoque une augmentation de la vitesse de la réaction alors que les groupements électroaffinitaires la diminue. À 313 K, la corrélation de Hammett conduit à une constante de réaction de $-0{,}927 \pm 0{,}08$ ($r = 0{,}994$). L'addition de nitrate d'aluminium empêche la réaction de se produire. Sur la base des informations cinétiques, on propose un mécanisme approprié. Les sulfoxydes de diaryles se comportent d'une façon similaire lors de cooxydations.

Introduction

A dramatic rate acceleration was observed by Hasan and Roček (1) in the Cr(VI) oxidation of a mixture of isopropanol and oxalic acid compared to the Cr(VI) oxidations of either of the above substrates. They attributed this rate acceleration to the phenomenon called cooxidation wherein both substrates undergo oxidation simultaneously. On the other hand, oxalic acid acts as a catalyst in the Cr(VI) oxidations of iodide (2) and ferroin (3). Recently the mechanisms of oxidation of alkyl aryl sulfoxides (4) and diaryl sulfoxides (5) by Cr(VI) have been reported and therefore the study of the influence of oxalic acid on the rates of Cr(VI) oxidation of sulfoxides will be of particular interest. In this paper we wish to report the salient features of the Cr(VI) oxidation of sulfoxides in the presence of oxalic acid.

Experimental

Materials

Alkyl aryl sulfoxides were prepared by standard procedures (6) by the oxidation of the corresponding sulfides. The diaryl sulfoxides were obtained by the Friedel–Crafts reaction of substituted benzenes with thionyl chloride (7). 4,4′-Dinitrodiphenyl sulfoxide was prepared by the oxidation of the corresponding sulfide with hydrogen peroxide (8). These sulfoxides were purified by vacuum distillation/recrystallization from suitable solvents. The physical constants of the sulfoxides were found to agree with literature values. The tlc analysis of each sulfoxide proved the presence of a single entity, and no impurity peak appears in the ^1H nmr spectra.

Potassium dichromate (BDH, AR), oxalic acid (BDH, AR), 60% perchloric acid (E. Merck, GR), and sodium perchlorate (E. Merck, GR) were employed as such. Acetic acid was purified by refluxing with chromium trioxide (9).

Kinetics

Kinetic studies were carried out in 50% acetic acid – 50% water (v/v) and in 80% acetic acid – 20% water (v/v) mixtures in the case of alkyl aryl sulfoxides and diaryl sulfoxides respectively. The rate studies were performed under pseudo first-order conditions at constant ionic strength maintained by the addition of sodium perchlorate. Freshly prepared solutions of potassium dichromate and oxalic acid were used. The unreacted Cr(VI) was estimated iodometrically (10). Pseudo first-order rate constants were evaluated from the slopes of the plots of log $(a - x)$ vs. time by the method of least squares. Reactions were generally followed to >70% completion; reproducible results giving good first-order plots (correlation coefficient, $r > 0.995$) were obtained for duplicate runs in each sulfoxide. The second-order rate constants were obtained from $k_2 = k_1/[\text{sulfoxide}]$. The precision of the k values is given in terms of 95% confidence limits of the Student t test.

Product studies

A reaction mixture (under kinetic conditions) with methyl phenyl sulfoxide (MPSO) and oxalic acid (OxH_2) was allowed to stand overnight, neutralized with sodium carbonate, and extracted with ether. The solvent was removed after drying (anhydrous Na_2SO_4) and a solid was obtained. Its mp (88°C) corresponds to the mp of methyl phenyl sulfone (6). The ir spectrum of the product was superimposable on that of an authentic sample of methyl phenyl sulfone. The product, therefore, was methyl phenyl sulfone.

The liberation of carbon dioxide during the Cr(VI) oxidation of MPSO and OxH_2 was detected as described by Vogel (11). The generation of carbon dioxide is possible only if OxH_2 is oxidized and therefore the reaction is only a cooxidation process and not a catalytic one.

Results and discussion

Detailed kinetic studies on individual Cr(VI) oxidations of alkyl aryl sulfoxides (4), diaryl sulfoxides (5), and OxH_2 (12) have already been reported. For comparison, the individual oxidations of sulfoxides and oxalic acid were carried out under conditions similar to those employed in the cooxidation. It was found that with many of the substituted sulfoxides the reaction was too slow to measure. However, at 50°C the pseudo first-order rate constants for the individual oxidations of MPSO and OxH_2 by Cr(VI) were found to be 2.17×10^{-6} s^{-1} and 1.61×10^{-5} s^{-1} respectively. When a mixture of the two substrates was taken, the reaction proceeded at an impressively faster rate, the rate constant being 2.51×10^{-4} s^{-1}. These data indicate that, for the ternary system, the cooxidation is favoured over the individual oxidation as observed by Hasan and Roček (1) with other systems.

Table 1 records the dependence of the reaction rate on the concentrations of MPSO, Cr(VI), and OxH_2. That the cooxidation is first order each in Cr(VI), MPSO, and OxH_2 has been

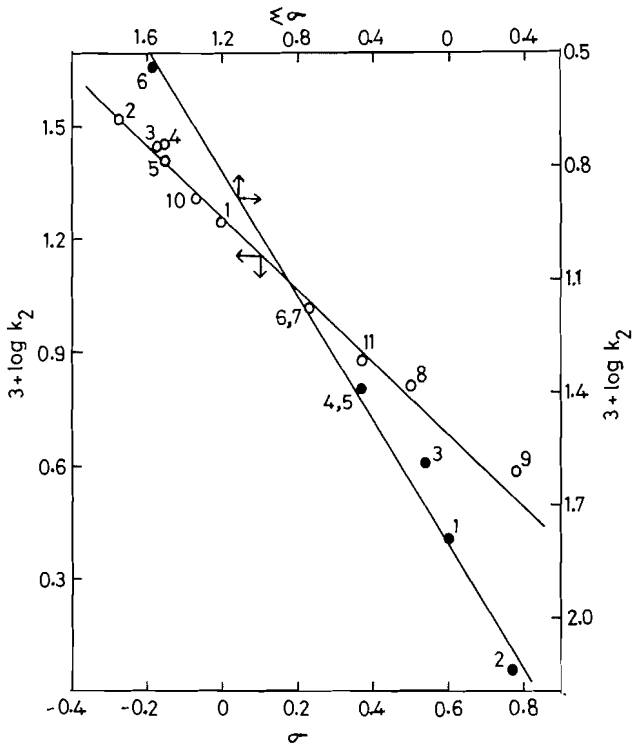

FIG. 1. Hammett plots at 40°C. ○: Substituted phenyl methyl sulfoxides (1. *p*-H, 2. *p*-OMe, 3. *p*-Me, 4. *p*-Et, 5. *p*-Pr^i, 6. *p*-Cl, 7. *p*-Br, 8. *p*-Ac, 9. *p*-NO_2, 10. *m*-Me, 11. *m*-Cl). ●: Substituted diphenyl sulfoxides (4-X-$C_6H_4)_2$ SO; X = H(1), Me(2), F(3), Cl(4), Br(5), NO_2(6).

established from the following observations: (*i*) constant k_1 values at different [Cr(VI)], constant k_2 values at various [MPSO], and constant k_3 values at different $[OxH_2]$; (*ii*) the linear plot of log k_1 against log [MPSO] with a slope of 0.976 ± 0.29 (r = 0.999, s = 0.009); and (*iii*) a slope of 1.09 ± 0.12 (r = 0.998, s = 0.018) in the double logarithmic plot of k_1 versus $[OxH_2]$. The oxidation rate increases markedly with acidity (cf. Table 2). A plot of log k_2 versus log $[H^+]$ passes through the origin with a slope of 1.02 ± 0.07 (r = 0.999, s = 0.007) showing a neat first-order dependence on $[H^+]$. The data in Table 2 show that a change in ionic strength (I) of the medium has no effect on rate and also the rate increases with decrease in polarity of the solvent.

The pseudo first-order rate constants for the cooxidation of MPSO in the absence of acrylamide and in the presence of 0.01 M and 0.05 M acrylamide are 1.76, 1.77, and 1.78 × 10^{-4} s^{-1} respectively. Thus acrylamide has no perceptible effect on the rate. This observation cannot be taken as evidence for the absence of free radicals. At high acidities it is rather not possible to detect free radicals as their own oxidation is catalyzed by acid (12). Similar results are obtained in the presence of free radical scavengers in the cooxidation of benzhydrol and oxalic acid with Cr(VI) (13).

It has been established that aluminium ions inhibit the Cr(VI) oxidation of OxH_2 by forming a complex with the latter (14). In the present system, also, when the reaction is performed in presence of aluminium nitrate the rate falls almost to the range obtained in the absence of OxH_2 (Table 3). This observation leads to the inference that complex formation between the oxidant and OxH_2 is indispensable for cooxidation to occur.

The effect of substituents on the rate of cooxidation was studied using several *meta*- and *para*-substituted phenyl methyl sulfoxides. Electron-releasing substituents accelerate the rate while electron-withdrawing groups retard it. A good Hammett correlation was obtained with a negative ρ value of −0.927 ± 0.08 (r = 0.994, s = 0.03 at 40°C) (see Fig. 1).

Mechanism

Chromic acid forms a cyclic 1:1 neutral complex, C_1, with OxH_2 (1). We propose that the complex C_1 reacts with a molecule of the sulfoxide producing another complex (C_2) in the rate-determining step. The complex C_2 on solvolysis yields the products sulfone, carbon dioxide, a $\cdot CO_2^-$ radical, and a Cr(III) species. The free radical can then undergo further oxidation with either free or complexed Cr(VI) producing carbon dioxide and Cr(V) (1) (shown in Scheme 1). This mechanism involves a two-electron oxidation of the sulfoxide part and a simultaneous one-electron oxidation of the OxH_2 part in the complex C_2. Because of the partial positive charge developed in the sulfur atom in C_2, the formation of C_2 will be favoured by electron-releasing substituents, leading to a negative ρ value.

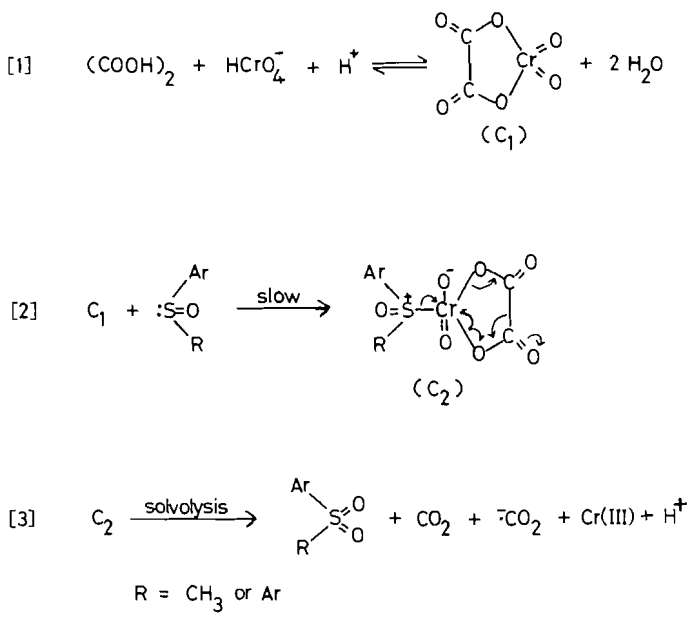
The rate law could be written as

$$-\frac{d[Cr(VI)]}{dt} = kK[ArSOR][OxH_2][H^+][Cr(VI)]$$

$$k_{obs} = kK[ArSOR][OxH_2][H^+]$$

Kinetic studies with diaryl sulfoxides

The kinetic behavior of diaryl sulfoxides is similar to that of



SCHEME 1

aryl methyl sulfoxides. The data in Table 1 clearly point out that the order with respect to diphenyl sulfoxide (DPSO), Cr(VI), and OxH_2 is unity in each case in the cooxidation of DPSO. The data in Table 2 also reveal that the effects of variations of $[H^+]$ and solvent composition on the rate of cooxidation of DPSO are analogous to those noticed for MPSO. These facts lead to the conclusion that the two series of sulfoxides follow the same reaction path.

In 4,4′-disubstituted diphenyl sulfoxides, electron-releasing substituents increase the rate while electron-withdrawing groups exert a retarding effect. An excellent Hammett correlation (Fig. 1) is obtained with a negative ρ value ($\rho = -0.820 \pm 0.11$, $r = 0.994$, $s = 0.06$ at 40°C).

Charge transfer complexes of diquat and paraquat with halide anions

S. G. BERTOLOTTI, J. J. COSA, H. E. GSPONER, AND C. M. PREVITALI

Departamento de Química y Física, Facultad de Ciencias Exactas Fisicoquímicas y Naturales, Universidad Nacional de Río Cuarto, 5800 Río Cuarto, Argentina

Received January 26, 1987

S. G. BERTOLOTTI, J. J. COSA, H. E. GSPONER, and C. M. PREVITALI. Can. J. Chem. **65**, 2425 (1987).

The association of methylviologen, 1,1′-dimethyl-4,4′-bipyridynium (PQ^{2+}), with halide and pseudo-halide ions was studied in water at 25°C by ultraviolet spectrophotometry. A charge transfer band could be observed in the region around 300 nm. From difference absorption measurements the first association constant (K_1) was obtained as 1.7 (Cl^-), 3.3 (Br^-), 3.9 (I^-), 0.7 (CN^-), and 2.0 (SCN^-) M^{-1}. Similar results were obtained for the dication, 6,7-dihydrodipyrido[1,2-*a*:2′,1′-*c*]pyrazinium (DQ^{2+}), with first association constants 3.3 (Cl^-), 4.1 (Br^-) and 4.6 (I^-) M^{-1}. First and second (K_2) association constants were also determined by a potentiometric technique using ion selective electrodes: $K_1 = 2.0\ M^{-1}$; $K_2 = 0.4\ M^{-1}$ for the system PQ^{2+}–Cl^- and $K_1 = 5.3\ M^{-1}$; $K_2 = 0.3\ M^{-1}$ for DQ^{2+}–Br^-.

S. G. BERTOLOTTI, J. J. COSA, H. E. GSPONER et C. M. PREVITALI. Can. J. Chem. **65**, 2425 (1987).

Faisant appel à la spectroscopie ultraviolette et opérant à 25°C, dans des solutions aqueuses, on a étudié les réactions d'association du méthylviologène, diméthyl-1,1′ bipyridinium-4,4′ (PQ^{2+}), avec divers ions halogénures et pseudo halogénures. On a observé une bande de transfert de charge dans la région de 300 nm. En se basant sur des mesures de différence d'absorption, on a obtenu les premières constantes d'association suivante (K_1) : 1,7 (Cl^-), 3,3 (Br^-), 3,9 (I^-), 0,7 (CN^-) et 2,0 (SCN^-) M^{-1}. On a obtenu des résultats similaires avec le dication, dihydro-6,7 dipyrido[1,2-*a*:2′,1′-*c*]pyrazinium (DQ^{2+}), alors que les premières constantes de vitesses sont : 3,3 (Cl^-), 4,1 (Br^-) et 4,6 (I^-) M^{-1}. Faisant appel à une technique potentiométrique utilisant des électrodes sélectives pour les ions, on a aussi déterminé les première et deuxième (K_2) constantes d'association : $K_1 = 2{,}0\ M^{-1}$ et $K_2 = 0{,}4\ M^{-1}$ pour le système PQ^{2+}–Cl^- et $K_1 = 5{,}3\ M^{-1}$ et $K_2 = 0{,}3\ M^{-1}$ pour DQ^{2+}–Br^-.

[Traduit par la revue]

Introduction

Paraquat, 1,1′-dimethyl-4,4′-bipyridinium dichloride ($PQCl_2$), and diquat, 6,7-dihydrodipyrido[1,2-*a*:2′,1′-*c*]pyrazinium dibromide ($DQBr_2$), are widely used as herbicides. They are inhibitors of electron transfer in both the cytochrome chain of mitochondria and the electron transfer chain of chloroplasts. Their use as electron relays in photochemical systems is of wide interest for solar energy conversion. It is known that they are able to form charge transfer complexes in the ground state with amines, phenols, hydroquinones, and sulfides (1), carboxylates (2), and transition metal complexes (3). However, besides this wide interest and usage, little is known about the interaction of the dications with halide anions in aqueous solutions.

Evidence of charge transfer complex formation of PQ^{2+} and DQ^{2+} with halide ions in the solid phase was given using ir spectroscopy (4). Also, the thermodynamic properties of aqueous solutions of paraquat were studied and the results suggested that, at high concentrations, this electrolyte behaves more like a 1:1 electrolyte than a 2:1 electrolyte (5).

The activity coefficients of paraquat and its mixtures with aqueous sodium chloride in the concentration range 0.1–4 molal were derived from isopiestic vapor pressure measurements (6). These results suggested that aqueous paraquat is similar in its electrochemical behavior to aqueous sulfuric acid solutions.

Conductivity measurements have been reported that indicate that the structurally similar compound, heptylviologen bromide, is completely dissociated in aqueous solution (7). However, reports based on absorption measurements and laser flash photolysis evidence (8), as well as conductance experiments (9), proposed that methylviologen is strongly associated with a chloride ion in aqueous solutions.

In view of the contradictory results given in the literature we decided to undertake a study of PQ^{2+} and DQ^{2+}–halide interaction, using ion selective electrodes and spectrophotometric techniques. In this report we present results for the association of PQ^{2+} and DQ^{2+} with chloride and bromide ions respectively. Our uv absorption results are coincident with those of Ebbesen and Ferraudi (8), but the potentiometric determinations afford a new interpretation, in terms of a weak two-step association.

Experimental

Paraquat was obtained by purification of the commercial herbicide Gramoxone through repeated recrystallization from water, ethanol, and ethanol–acetone mixtures. Diquat was prepared by refluxing a mixture of 2,2′-bipyridine and 1,2-dibromoethane (10). The yellow precipitate was filtered, washed with acetone, and recrystallized from acetone–water mixtures.

Sodium perchlorate, potassium nitrate, potassium cyanide, potassium thiocyanide, and potassium halides were Merck or Hopkins and Williams, analytical grade, and used without further purification.

The uv difference absorption measurements were obtained with a Cary 17 spectrophotometer in jacketed absorption cells at 25 ± 0.1°C. To an aqueous paraquat solution ($1.25 \times 10^{-4}\ M$ or $5 \times 10^{-4}\ M$) different potassium salts were added in varying concentrations, from 0.05 to 0.5 *M*. The reference cell was filled with $1.25 \times 10^{-4}\ M$ or $5 \times 10^{-4}\ M$ paraquat solution. At least eight runs were obtained for each anion. Some spectrophotometric measurements were also carried out in water–ethanol mixtures.

A potentiometric method was used for determination of free halide ion concentration. A bromide specific electrode (Orion model 94-35 A) or a chloride specific electrode (Orion model 94-17 A) with a double junction reference electrode (Orion model 92-02) was employed. The measurements were performed in a double-walled beaker maintained at 25 ± 0.1°C by water circulation. The electrodes were calibrated with standard solutions of 0.4 *M* total ionic strength, using sodium perchlorate or potassium nitrate as the inert electrolyte. Chloride ion measurements were done starting from a 0.2 *M* solution of $PQCl_2$ and then diluting it with a potassium nitrate or sodium perchlorate solution, with the condition that the total ionic strength was always 0.4 *M*. A similar procedure was used with $DQBr_2$.

Results and discussion

During the study of fluorescence quenching of 1-naphthylamine by paraquat in aqueous solutions (11) it was necessary to make corrections due to incident light absorption by the

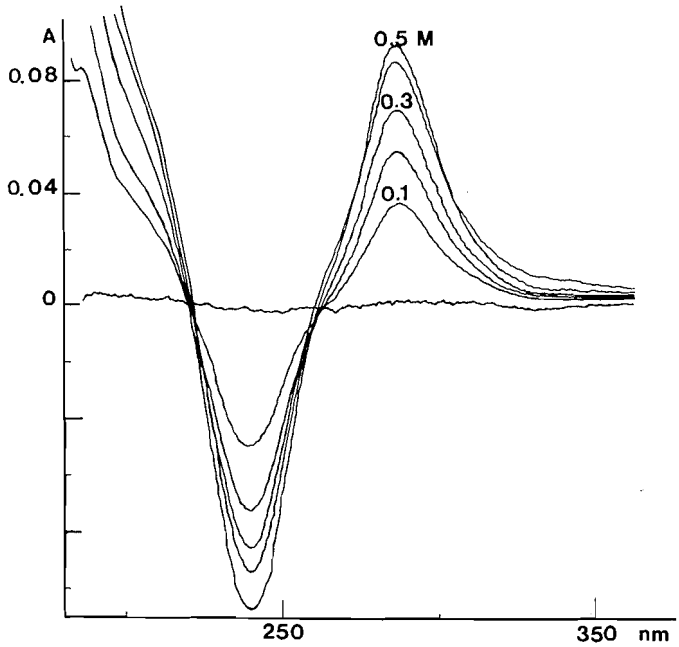

FIG. 1. The difference spectra of 1.25×10^{-4} *M* paraquat with an excess of potassium chloride.

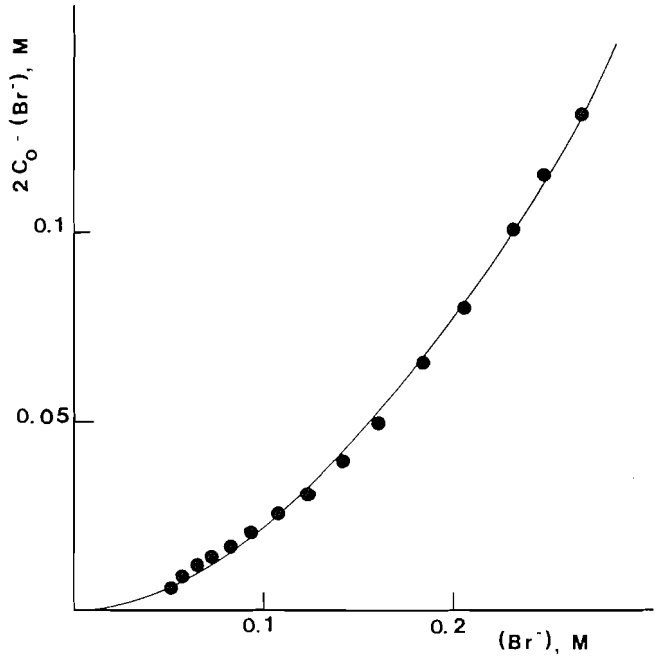

FIG. 2. Dependence of $2C_0 - [Br^-]$ vs. $[Br^-]$, experimental points by bromide selective electrode technique at 25°C, (—) line calculated according to eq. [6].

quencher at 320 nm. We found that paraquat did not obey Beer's Law at this wavelength in the concentration range 0.005–0.1 *M*. The positive deviation from Beer's Law suggested some kind of interaction between PQ^{2+} and chloride ions.

The absorption spectra of paraquat solutions containing any of the anions used in the present work confirmed that the absorption begins at longer wavelengths than those from either the potassium salt of the different anions studied or methylviologen perchlorate solutions. Therefore, difference spectra of dilute paraquat solutions, to which an excess of potassium halide was added, were obtained. As can be seen in Fig. 1 for the case of KCl, we found that the absorbance of the difference bands depends on chloride ion concentration.

Difference spectra with the addition pf potassium bromide, potassium iodide, potassium cyanide, and potassium thiocyanide were also obtained. With the exception of cyanide and thiocyanide, there is an approximately linear relationship between the wavenumber of the maxima in the difference spectra and the electronic affinity of the anions. This suggests that the difference band is of charge transfer type. Similar results were obtained with diquat solutions.

In the paraquat and diquat solutions the following association equilibria can be expected:

[1*a*] $B^{2+} + A^- \leftrightarrows BA^+ \qquad K_1$

[1*b*] $BA^+ + A^- \leftrightarrows BA_2 \qquad K_2$

where B^{2+} represents PQ^{2+} or DQ^{2+} and A^- stands for the different anions.

The equilibrium chloride and bromide concentrations were obtained by potentiometric measurements in aqueous solutions of paraquat and diquat, respectively, at different analytical concentrations, C_0. If it is assumed that the only equilibrium operating in the system is the first one, eq. [1*a*], the data for free ion and analytical concentration cannot be fitted with the resulting equation. Therefore the complete set, eqs. [1*a*] and [1*b*], was employed. The apparent equilibrium constants, K_1 and K_2, i.e., the equilibrium constants in terms of concentrations, were obtained using the following relationships:

[2] $[A^-] = [BA^+] + 2[B^{2+}]$

[3] $2C_0 = 2[BA_2] + [BA^+] + [A^-]$

Taking into account the A^- mass balance [3] and the equilibrium constants, we obtain:

$$[4] \quad [BA^+] = \frac{2C_0 - [A^-]}{1 + 2K_2[A^-]}$$

$$[5] \quad [B^{2+}] = \frac{2C_0 - [A^-]}{K_1[A^-]\{1 + 2K_2[A^-]\}}$$

then, replacing $[BA^+]$ and $[B^{2+}]$ in eq. [2]:

$$[6] \quad 2C_0 - [A^-] = \frac{K_1[A^-]^2 + 2K_1K_2[A^-]^3}{2 + K_1[A^-]}$$

Plots of $2C_0 - [A^-]$ versus $[A^-]$ are shown in Fig. 2 for aqueous solutions of diquat. Similar ones were obtained for paraquat. These plots can be fitted with K_1 and K_2 as adjustable parameters by a computer program. The values of the equilibrium constants obtained by this procedure are shown in Table 1 for diquat and paraquat.

The small differences between K_1 and K_2 can be taken as an indication that both charged groups in the molecule act almost independently of each other. This behaviour is similar to that observed in the dissociation of aliphatic organic diacids when both carboxylic groups are separated by a few carbon atoms.

These results were checked by a quantitative analysis of the difference spectra. The observed absorbance changes on addition of potassium salts to aqueous solutions of paraquat or diquat were treated by the Benesi–Hildebrand method, assuming that a 1:1 complex was formed, eq. [1*a*].

According to eqs. [1*a*] and [1*b*], a curvature could be expected in the Benesi–Hildebrand plots. However, under our

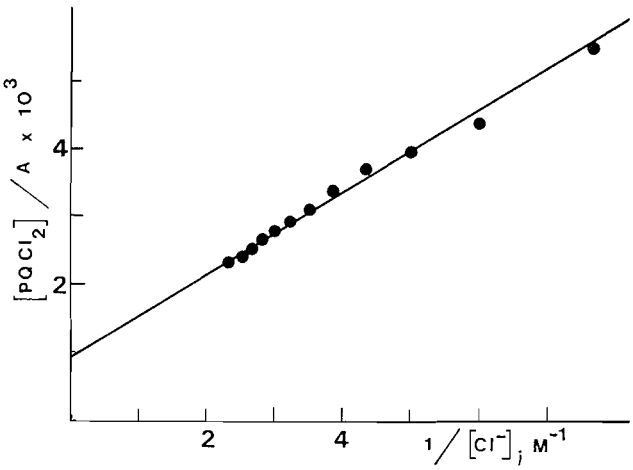

FIG. 3. Benesi–Hildebrand plot for PQ^{2+} – chloride ion. Paraquat, 1.25×10^{-4} M.

experimental conditions, deviation from a linear relationship was not observed (Fig. 3). If there was a compensating effect due to a change in the activity coefficient, we would expect a curvature in the Benesi–Hildebrand plot when the results are plotted against the chloride ion activity. However, this plot is also linear and it affords similar values of slope and intercept. The complex formation constants (K_1) and the difference of extinction coefficients ($\Delta\varepsilon$) at the maximum of the difference band were evaluated from the plots and they are given in Table 1. Although a departure from linearity could be expected according to the potentiometric results, we think that the failure to observe it is most probably due to the lack of sensitivity of the method. We assign the equilibrium constant obtained by this procedure to reaction [1*a*].

The K_1 values obtained are of the same order of magnitude as the equilibrium constant for the association between methylpyridinium and iodide (12). This is in agreement with the above conclusion that the two ammonium quaternary groups in these molecules behave almost independently.

The solvent effect on the charge transfer band observed in water–ethanol mixtures was a bathochromic shift when going to less polar solvents. Thus, for the complex of PQ^{2+} with bromide ion, the λ_{max} of the difference band are 297, 300, and 302 nm in pure water, 50%, and 75% of ethanol respectively. These results suggest the stabilization of the charge transfer state in going to less polar solvents, as was observed for other alkylpyridinium compounds (13).

The agreement between the values obtained by the two methods is satisfactory if it is realized that the experimental conditions are not exactly the same. The range of ionic strength used in the spectrophotometric method was 0.05–0.5 M. Nevertheless, the change in the activity coefficient of paraquat (6) is not high enough to invalidate the comparison of results obtained by both techniques.

In summary, we have shown that PQ^{2+} and DQ^{2+} associate with halide and pseudo-halide ions by a two-step equilibrium. This interaction is of an electron donor–acceptor type and a new charge transfer band, which manifests itself as a band in the difference spectra, is present in the electronic spectrum.

Contribution à l'étude des réactions d'alkylation et de polyalkylation de l'adamantane et de ses homologues

G. Molle, J. E. Dubois et P. Bauer[1]

Institut de topologie et de dynamique des systèmes de l'université Paris VII, Unité n° 34 associé au centre national de la recherche scientifique, 1 rue Guy de la Brosse, 75005 Paris, France

Reçu le 16 janvier 1987

G. Molle, J. E. Dubois et P. Bauer. Can. J. Chem. **65**, 2428 (1987).

Une méthode de préparation de dérivés alkylés de composés à structure cage est proposée. Elle repose sur la réaction de Grignard et le choix d'un solvant à haut point d'ébullition. La réaction a lieu à pression atmosphérique. Les méthylations de l'adamantane, du diamantane et de l'homoadamantane sont quantitatives. Avec d'autres groupes alkylants primaires les rendements sont supérieurs à 60%. La compétition entre la réaction d'alkylation et les réactions secondaires est discutée sur la base d'un mécanisme radicalaire.

G. Molle, J. E. Dubois, and P. Bauer. Can. J. Chem. **65**, 2428 (1987).

A method for preparing alkyl derivatives of cage-structure compounds is proposed. It relies on the use of Grignard reactions with a high boiling point solvent. The reactions take place at atmospheric pressure. Methylation of adamantane, diamantane, and homoadamantane occurs with quantitative yield. With other primary alkyl groups, yields are better than 60%. Competition between alkylation and secondary reactions is discussed on the basis of a free radical mechanism.

Introduction

Les dérivés de l'adamantane présentent un spectre très large d'applications pharmacologiques (1). L'introduction d'un groupe adamantyle sur certaines drogues peut accroître considérablement leur activité thérapeutique (2). Cette propriété est généralement attribuée au caractère lipophile très marqué de ce groupe.

Nos propres travaux sur les composés organométalliques à structure cage homologues de l'adamantane (3) ont montré que l'introduction de groupes méthyles sur les carbones apicaux de ces polycycliques exhaltait encore, dans de très larges proportions, ce caractère.

Malheureusement l'alkylation régiospécifique de l'adamantane et de ses homologues pose un certain nombre de problèmes (4–11) et ne conduit qu'à des mélanges de composés mono et polyalkylés généralement obtenus avec de faibles rendements.

Il est cependant possible de méthyler sélectivement l'adamantane (Ad—H) et ses homologues avec d'excellents rendements en utilisant les voies organométalliques (réactions [1] et [2] (12–14).

[1] $Ad—X + (CH_3)_3Al \rightarrow Ad—CH_3$

[2] $Ad—X + CH_3MgBr \rightarrow Ad—CH_3$

La voie organomagnésienne, développée pour la première fois par Schleyer et coll. (14), permet d'utiliser la plupart des réactifs de Grignard primaires mais s'effectue sous pression dans l'éther éthylique à 100°C ce qui n'est pas sans risque, la présence de peroxydes dans le milieu réactionnel pouvant dans ces conditions conduire à de violentes explosions. En outre, le rendement en produit alkylé chute d'une façon importante lorsque l'on dépasse le stade du bromure de méthylmagnésium (90% pour le méthyl-1 adamantane contre 39% pour l'éthyl-1 adamantane).

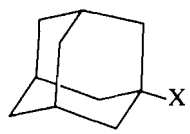
Le but de ce travail a donc été de rechercher des conditions opératoires qui permettent d'obtenir à pression atmosphérique, avec des rendements satisfaisants, des alkylations sélectives de l'adamantane et de ses homologues.

Résultats et discussion

Le fait qu'à 35°C dans l'éther éthylique la réaction d'alkylation entre les réactifs de Grignard et le bromo-1 adamantane n'ait pas lieu, alors qu'à 100°C sous pression les produits alkylés sont obtenus, tend à montrer que l'énergie d'activation de cette réaction est élevée et donc qu'à 35°C la formation de ces produits est pratiquement bloquée. Par contre il doit être possible de réaliser cette réaction, à pression atmosphérique, dans un solvant de polarité comparable mais ayant un point d'ébullition plus élevé. Des essais antérieurs (14) effectués avec le tétrahydrofuranne ou le dioxanne ont conduit à des échecs imputables, selon nous, à la trop grande basicité de ces solvants qui favorise la réaction de réduction des halogénures. L'utilisation d'un éther aliphatique tel que l'éther *n*-butylique (T_{eb} = 142°C), nous a paru plus appropriée.

1. Méthylation de l'adamantane

Les premiers essais réalisés, dans ce solvant avec l'iodo-1 adamantane **1**, le bromo-1 adamantane **2** et le chloro-1 adamantane **3** d'une part, et l'iodure ou le bromure de



1 X = I
2 X = Br
3 X = Cl

méthylmagnésium d'autre part conduisent à des rendements en méthyl-1 adamantane supérieurs à 85% (tableau 1).

Ces rendements deviennent même quantitatifs lorsque les dérivés chloré ou bromé de l'adamantane sont condensés sur le bromure de méthylmagnésium.

Avec l'iodure de méthylmagnésium, la formation de 10% environ de carbure de réduction (adamantane) est observée. Si un prélèvement est effectué dès l'addition de ce magnésien sur le bromure **2**, on constate après hydrolyse et analyse en chromatographie en phase vapeur (cpv), la présence de 100% de l'iodure **1** indiquant que l'alcoylation est précédée dans ce cas d'une réaction très rapide d'échange.

$$CH_3MgI + 2 \rightarrow 1 + CH_3MgBr$$

L'existence de cette réaction nous a donc conduit à rejeter les dérivés iodés dans la suite de ces travaux.

Une étude cinétique réalisée, à différentes températures, lors de la condensation du bromure **2** sur le bromure de méthylmagnésium dans l'éther *n*-butylique, montre que la réaction de méthylation de l'adamantane est d'ordre 2 et que l'énergie

TABLEAU 1. Rendements de la méthylation de l'adamantane

R—X	CH_3MgX	T (°C)	Rendement R—CH_3	Rendement R—H
1	CH_3MgI	105	86,5	13,5
2	CH_3MgI	105	90 (70)[a]	10
2	CH_3MgI	85	91	9
2	CH_3MgBr	85	>99 (83)[a]	—
3	CH_3MgBr	85	>99	—

CH_3MgBr = 2,3 *M*; CH_3MgI = 1,8 *M*; CH_3MgX/R—X = 2.
[a]Rendements obtenus par Schleyer et coll. (14).

TABLEAU 2. Constantes cinétiques de formation du méthyl-1 adamantane

R—X	T (°C)	$k \times 10^5$ (mol L^{-1} s^{-1})
2	70	5,8
2	80	16,2
2	85	26,4
2	90	46,8

CH_3MgBr = 2,2 *M*; CH_3MgBr/R—X = 2.

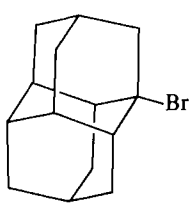
d'activation est de 26,5 kcal (tableau 2). L'extrapolation, à partir de cette valeur, de la constante cinétique à 35°C donne une valeur de $k = 7{,}1 \times 10^{-7}$ mol L^{-1} s^{-1} ce qui correspond à un temps de demi-réaction de l'ordre de 7 jours.

Ces résultats confirment notre hypothèse selon laquelle la température joue un rôle déterminant dans ce type d'alkylation et justifie donc pleinement notre choix d'un solvant ayant un point d'ébullition élevé tel que l'éther *n*-butylique.

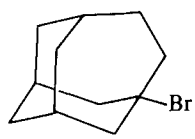
2. Méthylation des homologues de l'adamantane

L'extension de cette réaction à d'autres structures cage telles que le bromo-1 diamantane **4**, le bromo-3 homoadamantane **5** ou à des bromo-1 polyméthyladamantanes **6**, **7** et **8**, conduit à des résultats meilleurs que ceux obtenus dans l'éther éthylique sous pression à 100°C (tableau 3).

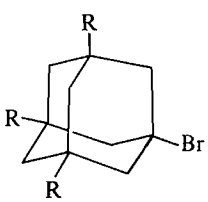
Tous les rendements sont supérieurs à 98%, avec un rapport RMgX/RX égal à 2, alors que ce même rapport est égal à 3,5 dans le protocole expérimental proposé par Schleyer et coll. (14).



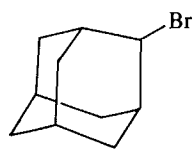
4



5



6 R = CH_3, H, H
7 R = CH_3, CH_3, H
8 R = CH_3, CH_3, CH_3



9

TABLEAU 3. Rendements des produits obtenus lors de la méthylation des homologues de l'adamantane dans l'éther *n*-butylique

R—X	T (°C)	R—CH_3	R—H
2	85	>99 (83)[a]	—
4	85	>99 (90)[a]	—
5	85	>99 (87)[a]	—
6	85	99	1
7	95	98 (92)[a]	2
8	105	>99	—
9	140	86	14

CH_3MgBr = 2,2 *M*; CH_3MgBr/RX = 2.
[a]Rendements obtenus par Schleyer et coll. (14) avec CH_3MgBr/RX = 3,5.

L'alkylation en position 2 de l'adamantane, à partir du dérivé bromé **9**, est beaucoup plus difficile et nécessite une température de 140°C, mais le rendement en méthyl-2 adamantane atteint alors 86%.

Les constantes cinétiques diminuent lorsque le nombre de groupes méthyle augmente sur le noyau (**2**, 26×10^{-5} mol L^{-1} s^{-1}; **6**, 10×10^{-5} mol L^{-1} s^{-1}; **8**, $4{,}8 \times 10^{-5}$ mol L^{-1} s^{-1}). Il est donc nécessaire pour les bromures **6**, **7** et **8** d'augmenter la température du milieu réactionnel de 85 à 105°C afin de limiter le temps de la réaction et la formation de produits secondaires.

3. Alkylation de l'adamantane

Tous les halogénures d'alkylmagnésium ont été synthétisés dans l'éther *n*-butylique puis condensés sur les halogénures **2** ou **3**. Les résultats sont réunis dans le tableau 4.

Si la condensation du bromure de méthylmagnésium sur le bromure **2** est quantitative, il n'en est pas de même pour le bromure d'éthylmagnésium. En effet le rendement en produit alkylé decroit dans ce cas à 66% (essai 1) pendant que le rendement en adamantane atteint 34%. Par contre l'augmentation de la chaine alkylée de l'organomagnésien n'influence pratiquement pas les rendements maximums obtenus puisqu'ils sont respectivement de 66, 61 et 62% pour l'éthyl, le *n*-butyl et le néopentyl-1 adamantane (essais 1, 5 et 7).

De plus les rendements en *n*-butyl-1 adamantane sont les mêmes que l'on fasse réagir le bromure **2**, sur le bromure de *n*-butylmagnésium (essai 3) ou le chlorure **3**, sur le chlorure de *n*-butylmagnésium (essai 5) avec des rapports R'MgX/RX égal à 2. Si ce rapport diminue, le rendement en *n*-butyl-1 adamantane chute à 38% (essai 4) avec les réactifs bromés mais reste sensiblement égal avec les chlorés (essai 6).

Il semblerait que la présence d'un hydrogène en β sur la chaîne aliphatique de l'organomagnésien soit responsable de la baisse de rendement constatée entre le bromure de méthylmagnésium et les autres réactifs de Grignard étudiés.

Pour vérifier cette hypothèse, nous avons synthétisé le bromure d'éthylmagnésium deutéré (C_2D_5MgBr) et condensé cet organomagnésien sur le bromure **2** (essai 2). Après hydrolyse du milieu réactionnel, une analyse effectuée par chromatographie en phase vapeur et par spectrométrie de masse donne 70% de rendement en éthyl-1 adamantane et montre que l'adamantane est deutéré à 90%.

La présence de *n*-octane semble indiquer que le magnésien qui ne conduit pas au produit alkylé attendu donne un produit de dimérisation.

Ainsi l'adamantane est vraisemblablement formé, au cours

TABLEAU 4. Rendements des réactions d'alcoylation de l'adamantane par voie magnésienne dans l'éther *n*-butylique

Essais	R—X	R'MgX	R'MgX/R—X	R—R'	R—H
1	**2**	C_2H_5MgBr	1,5/1	66[a]	34
2	**2**	C_2D_5MgBr	1,5/1	70	30
3	**2**	*n*BuMgBr	2/1	60[b]	40
4	**2**	*n*BuMgBr	1,2/1	38	62
5	**3**	*n*BuMgCl	2/1	61	39
6	**3**	*n*BuMgCl	1,2/1	62	38
7	**2**	tBuCH$_2$MgCl	3/1	62	38
8	**2**	Cyclohexyl-MgCl	2/1	20[c]	80
9	**2**	*t*BuMgCl	1,5/1	9[c]	91

T = 105°C; 1,5 < R'MgX < 1,7. Les dosages effectués après chaque essai montrent que R'MgX consommé = R—R' + R—H.

[a]85°C, $k = 1{,}33 \times 10^{-4}$ mol L^{-1} s^{-1}.

[b]Quand le rapport R'MgX/RX = 5, le rendement en R—R' = 59%.

[c]Ces produits non isolés ont été caractérisés par cpv et spectrométrie de masse.

de la réaction de réduction, par un transfert d'ion hydrure pouvant se concevoir selon un mécanisme à 6 centres du type :

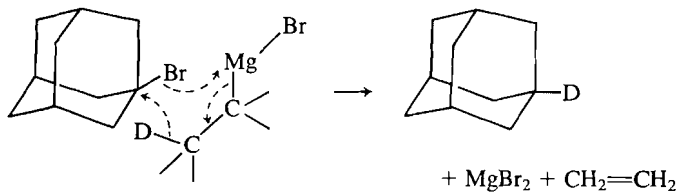


SCHÉMA 1

Cependant cette réaction secondaire de réduction est également observée lors de la condensation du bromure **2** sur le chlorure de néopentylmagnésium, bien que cet organomagnésien ne possède pas d'hydrogène en β (essai 7). Dans ce cas, outre 38% d'adamantane, une quantité importante de tétraméthyl-2,2,5,5 hexane est obtenue.

Si la présence de cet hydrocarbure n'est plus compatible avec un mécanisme à 6 centres, elle peut s'expliquer par contre par un mécanisme radicalaire faisant intervenir un transfert monoélectronique (SET) entre l'organomagnésien et le dérivé halogéné (schéma 2) (15).

Les rendements en produits d'alkylation sont toujours supérieurs à 60% pour les réactifs de Grignard primaires; ils chutent avec les organomagnésiens secondaires et tertiaires (essais 8 et 9) puisque les rendements en adamantane atteignent 80–90%.

Les échecs rencontrés surtout avec les organomagnésiens tertiaires pourraient alors s'expliquer par une diffusion hors de la cage de solvant des radicaux-anions tertiaires plus stables qui attaquent le solvant avant que la réaction d'alkylation n'ait lieu (16, 17).

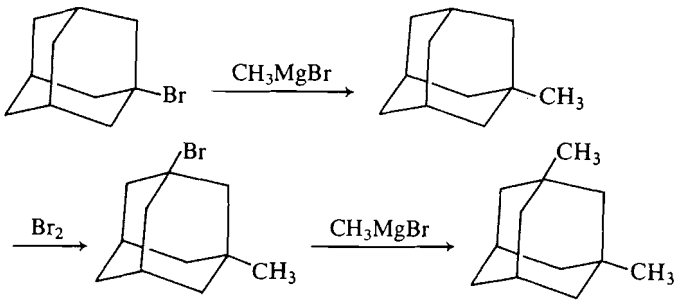
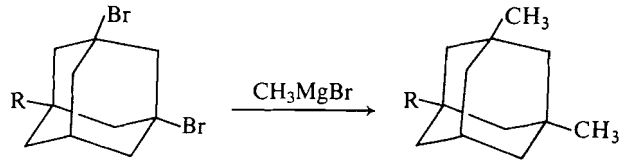
4. Polyalkylation de l'adamantane

La synthèse des dérivés polyalkylés s'effectue le plus souvent en plusieurs étapes :



Nous avons tenté la synthèse directe du diméthyladamantane à partir du dibromo-1,3 adamantane (schéma 3).

Les premiers essais effectués montrent (tableau 5) que le rendement en diméthyladamantane est limité à 52%, le reste étant constitué de 44% de méthyladamantane et 4% d'adamantane. Or nous avons montré précédement que la réaction de réduction n'avait pas lieu lors de la méthylation des bromures **2** et **4** puisque les rendements de la réaction d'alkylation sont quantitatifs (tableaux 1 et 3).



10 R = H
11 R = CH_3

SCHÉMA 3

Une deutérolyse effectuée au cours de la réaction montre que le méthyl-1 adamantane n'est pas deutéré. Il est donc très vraisemblablement formé, par diffusion du radical hors de la cage de solvant, lors de l'attaque du premier atome de brome (voie 1, schéma 4).[2]

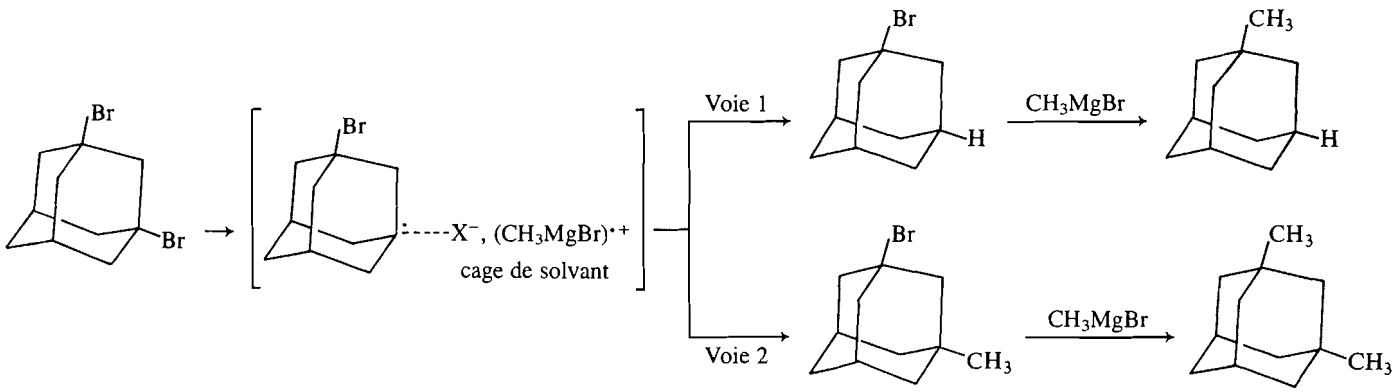


SCHÉMA 4

L'apport d'un groupe méthyle sur le noyau adamantyle conduit au même résultat (tableau 5). Dès lors on peut penser que c'est la présence de deux atomes de brome en position 1, 3 sur l'adamantane qui est responsable de la compétition entre les voies 1 et 2 du schéma 4. Cette situation est à l'origine d'une réaction secondaire qui conduit à la formation quantitative du dihydroadamantane lors de la réaction de ce dérivé dibromé avec le lithium (schéma 5) (19).

Pour vérifier ce point nous avons tenté la synthèse du 4,9-diméthyldiamantane à partir du 4,9-dichlorodiamantane

TABLEAU 5. Rendements de la méthylation des dérivés dihalogénés «cage» dans l'éther *n*-butylique à 140°C

RX_2	R—$(CH_3)_2$[a]	R—(CH_3)	RH
10	52[b]	44	4
11	51	46	3
12	97	3	—

CH_3MgBr = 2 *M*; CH_3MgBr/RX_2 = 2.

[a]Les rendements sont calculés par cpv et les produits caractérisés par spectroscopie de masse.

[b]Avec CH_3MgBr/RX_2 = 4 on obtient le même rendement.

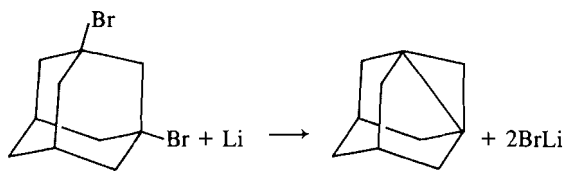

SCHÉMA 5

12, molécule dans laquelle les deux atomes de chlore sont beaucoup plus éloignés l'un de l'autre (schéma 6).

Dans ce cas on observe la formation de 97% de produit diméthylé, montrant ainsi que l'éloignement des deux atomes d'halogène élimine pratiquement la formation du produit monoalkylé.

Conclusion

Comme nous l'avions pressenti, l'utilisation d'un solvant à haut point d'ébullition nous a permis d'obtenir, à pression atmosphérique et avec des rendements parfois quantitatifs, les

2. À la température utilisée il ne nous a malheureusement pas été possible de mettre en évidence les produits intermédiaires : le bromo-1 adamantane et le méthyl-3 bromo-1 adamantane, puisque à cette température le temps de demi-réaction des voies 1 et 2 est de l'ordre de 7 s.

SCHÉMA 6

produits d'alkyation de l'adamantane et de certains de ses homologues.

L'emploi d'organomagnésiens constitue indiscutablement un progrès par rapport aux autres méthodes existantes.

Ces résultats ouvrent la voie à des études que nous comptons développer, sur le rôle de l'alkylation régiospécifique comme facteur activant le transfert de ces structures cage à travers les membranes biologiques.

Partie expérimentale

Généralités

Les points de fusion ont été déterminés sur un appareil automatique Mettler FP5. Les spectres infra-rouge ont été effectués sur un spectromètre Perkin Elmer 225 alors que les spectres de rmn ont été enrégistrés sur un appareil JEOL C 60 HL (le TMS étant pris comme référence). Les spectres de masse ont été obtenus avec un spectromètre JEOL JMS 200 connecté à un chromatographe JEOL GAS 20 K GLO et à un ordinateur JEOL Mass Data System.

Les analyses cpv ont été effectuées sur des colonnes Carbowax 20 M ou SE 30 placées sur un chromatographe Intersmat IGC 12 DFL relié à un intégrateur calculateur LTT ICAP 10. La chromatographie en phase liquide a été réalisée sur des colonnes en verre remplies d'alumine neutre (grade II) Merck en utilisant de l'éther de pétrole (30–60°C), du tétrachlorure de carbone et de l'éther éthylique comme éluants.

Réactifs

Le magnésium utilisé (Aldrich) contient 2000 ppm d'impuretés, principalement ferriques. L'éther *n*-butylique (Baker) est conservé sur sulfate de calcium anhydre et sa teneur en eau est inférieure à 40 ppm.

Les halogénures d'alkyles (Prolabo) sont préalablement distillés et stockés sur du carbonate de sodium à l'exception du bromure de méthyle gazeux (Matheson) qui est séché sur une colonne de chlorure de calcium avant introduction dans le milieu réactionnel. Le bromure d'éthyle deutéré est fourni par la Société Spin et Techniques. Les différents magnésiens sont filtrés sur cartouche d'alundum puis titrés par dosage acido-basique.

Les bromo-1 adamantane, bromo-2 adamantane, iodo-1 adamantane, bromo-1 diamantane, bromo-3 homoadamantane sont préparés selon les méthodes déjà décrites (20).

Les bromo-1 méthyl-3 adamantane et bromo-1 diméthyl-3,5 adamantane sont obtenus selon la méthode de Stetter et Wulff par bromation directe des méthyl-1 et diméthyl-3,5 adamantanes (21). Le bromo-1 triméthyl-3,5,7 adamantane est préparé par action du bromure de thionyle sur l'hydroxy-1 triméthyl-3,5,7 adamantane (22).

Synthèse des dihalogénures

Dans un tricol de 1 litre, muni d'un agitateur magnétique, d'un réfrigérant et d'une arrivée d'argon, sont introduits 40,8 g d'adamantane et 3 g de fer. À 0°C, sous agitation, sont ajoutés lentement 150 mL de brome. Un dégagement intense d'acide bromhydrique se produit. Dès que ce dégagement cesse, on monte la température à 25°C et l'agitation est maintenue 2 h, puis 200 mL de dibromoéthane sont ajoutés et la solution est versée doucement dans un bécher contenant un mélange de glace et de bisulfite de sodium. La phase organique est ensuite lavée à l'eau, puis neutralisée au bicarbonate et enfin rincée à nouveau à l'eau. La solution est séchée sur sulfate de sodium, filtrée puis évaporée à sec. La totalité du produit est reprise par 800 mL de méthanol. Après recristallisation, on obtient 75 g de dibromo-1,3 adamantane dont la pureté est de 99%. Le rendement est de 85%; F = 109,5°C (lit. (21) F 108°C).

Le dibromo-1,3 méthyl-5 adamantane est préparé selon le même mode opératoire. Le rendement est de 88%; F = 62°C.

Le dichloro-4,9 diamantane est préparé par action de l'acide chlorosulfonique sur le binor-S à basse température selon la méthode décrite par Blaney *et al.* (23).

Synthèse des halogénures d'alkylmagnésium

Dans un tricol de 1 L muni d'un agitateur et d'une garde de chlorure de calcium, on introduit 35 g de magnésium et 400 mL d'éther *n*-butylique anhydre. Après initiation du magnésium par quelques gouttes de dibromo-1,2 éthane, la température est abaissée à 5°C et on introduit l'halogénure. Au terme de la réaction le titre de la solution est déterminé par dosage acido-basique.

Alkylation des dérivés à structure cage

Synthèse du méthyl-1 adamantane

Dans un tricol de 100 mL muni d'un agitateur, d'un réfrigérant, et d'une ampoule d'addition, sont introduits, sous argon, 5 g de bromo-1 adamantane et 5 mL d'éther *n*-butylique préalablement séché sur fils de sodium. La température est portée à 105°C et 26 mL de bromure de méthylmagnésium (1,8 M) sont ajoutés goutte à goutte à raison de 2 gouttes par seconde. L'agitation à 105°C est maintenue 1 h. Après neutralisation du milieu réactionnel par HCl 1 M, la phase organique est lavée plusieurs fois à l'eau puis neutralisée au bicarbonate de sodium, avant d'être évaporée sous vide, en prenant les précautions nécessaires pour éviter une perte du produit par sublimation. Le méthyl-1 adamantane est ensuite purifié par cpl sur colonne d'alumine en utilisant le pentane comme éluant.

Les autres dérivés alkylés sont préparés selon la même méthode, seule la température du milieu réactionnel peut varier en fonction de la nature de l'organomagnésien ou du dérivé halogéné (voir les différents tableaux).

Les constantes cinétiques sont déterminées à partir des analyses chromatographiques et des dosages réalisés sur des prélèvements effectués au cours du temps.

Caractérisation des produits formés

Méthyl-1 adamantane : F = 104°C (lit. (14) F 102–103°C); rmn (CCl_4) : 0,8 (s, 3H), 1,47 (s, 6H), 1,70 (s, 6H), 1,92 (s, 3H) ppm; masse (75 eV) m/e (intensité relative) : 150 (15,7, M^+), 135 (100, $M^+ - CH_3$).

Diméthyl-1,3 adamantane : Eb = 204°C (lit. (24) Eb 204°C); rmn (CCl_4) : 0,79 (s, 6H), 1,17 (s, 2H), 1,38 (s, 8H), 1,56 (s, 2H), 1,99 (s, 2H) ppm; masse (75 eV) m/e : 164 (8,1, M^+), 149 (100, $M^+ - CH_3$).

Triméthyl-1,3,5 adamantane : Eb (760 Torr; 1 Torr = 133.3 Pa) = 210°C, Eb (0,7 Torr) = 40°C (lit. (22) Eb (19 Torr) 88°C); rmn (CCl_4) : 0,79 (s, 9H), 1,08 (s, 6H), 1,29 (s, 6H), 2,05 (s, 1H) ppm; masse (75 eV) m/e : 178 (3,3, M^+), 163 (100, $M^+ - CH_3$).

Tétraméthyl-1,3,5,7 adamantane : F = 67°C (lit. (25) F 66–67°C); rmn (CCl_4) : 0,80 (s, 12H), 1,0 (s, 12H) ppm; masse (75 eV) m/e : 192 (6,7, M^+), 177 (100, $M^+ - CH_3$).

Ethyl-1 adamantane : Eb = 229°C (lit. (24) Eb 219°C); rmn (CCl_4) : 0,77 (t, 3H), 1,05 (t, 2H), 1,42 (s, 6H), 1,67 (s, 6H), 1,95 (s, 3H) ppm; masse (75 eV) m/e : 164 (75, M^+), 135 (100, $M^+ - CH_2CH_3$).

Received December 22, 1986

M. Madalena Caldeira, M. Luísa Ramos, Nuno C. Oliveira, and Victor M. S. Gil. Can. J. Chem. **65**, 2434 (1987).

A proton, carbon-13, and vanadium-51 nuclear magnetic resonance study is reported on the number, stoichiometry, geometry, and relative stability of the complexes that form when vanadate(V) solutions are mixed with each one of the following organic α-hydroxyacids in the pH range ~2.5–~7: glycolic, lactic, chloro-3- and phenyl-3-lactic, mandelic, glyceric, and malic acids. The predominant complexes have 1:1 composition (almost certainly in a polymeric structure) in contrast with the 1:2 (metal:ligand) stoichiometry of the corresponding Mo(VI) and W(VI) complexes.

M. Madalena Caldeira, M. Luísa Ramos, Nuno C. Oliveira et Victor M. S. Gil. Can. J. Chem. **65**, 2434 (1987).

On rapporte une étude par résonance magnétique nucléaire du ^{1}H, du ^{13}C et du ^{51}V sur le nombre, la stoechiométrie, la géométrie et la stabilité relative des complexes qui se forment lorsqu'on mélange, à des pH allant de 2,5 à 7, des solutions de vanadate(V) avec l'un des acides α-hydroxylés suivants : acides glycolique, lactique, chloro-3 et phényl-3 lactiques, mandélique, glycérique et malique. Les complexes qui se forment d'une façon prépondérante ont une composition 1 : 1 (presque certainement dans une structure polymérique); ces résultats sont en opposition avec ceux obtenus avec le Mo(VI) et le W(VI) dont les complexes sont de composition 1 : 2 (métal : ligand).

[Traduit par la revue]

Introduction

The biological role of vanadium in living plant and animal tissues recognized in recent years (1) has lent additional importance to the coordination chemistry of this essential element in aqueous solution, a current field of research of great interest.

This paper deals with the complexes that form when vanadate(V) salts are mixed with α-hydroxycarboxylic acids, in aqueous solution, for various pH and concentration conditions. ^{1}H, ^{13}C, and ^{51}V nuclear magnetic resonance spectroscopy is used, since this technique proved to be quite successful in the study of complexation of metal oxoions (MoO_4^{2-}, WO_4^{2-}, UO_2^{2+}) with such ligands (2–6). Advantage is taken of the fact that, at room temperature, ligand exchange is usually sufficiently slow to enable distinct spectra to be obtained for free and bound ligand in the various complexes. Besides ^{1}H and ^{13}C spectra of the ligand, nmr spectra of the coordinated metal (^{51}V) are readily accessible, providing an additional contribution to the full characterization of those systems.

The following acids are used as ligands in this study:

A.	Glycolic acid	CH_2—OH—CO_2H
B.	(L)-Lactic acid	CH_3—CHOH—CO_2H
C.	(L)-Phenyllactic acid	C_6H_5—CH_2—CHOH—CO_2H
D.	(D,L)-Chlorolactic acid	CH_2Cl—CHOH—CO_2H
E.	(L)-Mandelic acid	C_6H_5—CHOH—CO_2H
F.	(D,L)-Glyceric acid	CH_2OH—CHOH—CO_2H
G.	(L)-Malic acid	CO_2H—CH_2—CHOH—CO_2H

Whereas the first five acids of the general formula R—CHOH—CO_2H can behave as bidentate ligands, the last two are potentially terdentate ligands.

The systems vanadate(V) + ligands A, B, E, G have previously been the objects of study by other techniques (potentiometry, conductimetry, spectrophotometry, cryoscopy) and we shall refer to each one in the discussion.

Experimental

Analytical grade ammonium vanadate(V) and commercially available hydroxycarboxylic acids were used (unavailability of the optically active forms in two cases and failure in attempts to resolve the racemic mixture precluded us from also using one of the optical isomers in such cases). To reduce the intensity of the OH nmr signal, the reactants were lyophilized from solution in deuterium oxide, and D_2O solutions were used throughout. Previous to use, lactic, chlorolactic, and glyceric acid solutions in D_2O were heated in boiling water for 2 h to accomplish depolymerization. The concentrations of the vanadate solutions were established by weight and the acid solutions were standardized by potentiometry. The pH was adjusted (cautiously, to reduce the possibility of drastic local disturbances of equilibria that may be slow to disappear) by addition of solutions of DCl and NaOD; the pH* values quoted are the direct pH-meter readings (room temperature) after standardization with aqueous (H_2O) buffers. Whenever necessary, the ionic strength was kept approximately constant by making the solution 1 *M* in KNO_3.

The ^{1}H, ^{13}C, and ^{51}V spectra were obtained on a Varian XL-200 nmr spectrometer. Except for some ^{1}H spectra (recorded at 2°C), all spectra were obtained at probe temperature (21 ± 1°C). The ^{13}C spectra were recorded using proton-decoupling techniques with suppression of the nuclear Overhauser effect; in this manner, temperature fluctuations of the sample were reduced to ca. ± 1°C. Dioxane and DSS were used as internal references for ^{13}C and ^{1}H shifts, respectively, whereas $VOCl_3$ was the external reference for ^{51}V shifts. Typically, spectral widths of 10 000 Hz, acquisition times of 1.5 s, pulse delays of 8–12 s, and 2000 pulses were used when recording ^{13}C spectra. For ^{51}V the corresponding values were 15 000 Hz, 0.5 s, 1 s, and 10–300 pulses.

Results and discussion

Proton, carbon-13, and vanadium-51 nmr spectra were obtained for D_2O solutions of various concentrations (in the range 0.01–1.0 *M* for ^{1}H spectra, 0.2–1.0 *M* for ^{13}C spectra, and 0.01–0.2 *M* for ^{51}V spectra), of different molar ratios (3:1 to 1:3 or 1:4) of the complexing species, and of different pH* values (2.5–7.5). Spectra were recorded after equilibration had been attained; in the case of vanadate(V) + lactic acid, the slowest system to reach equilibrium, this required up to ca. 2 days after addition of the reactants. The number and intensity of ligand (free and bound) signals and their changes with molar ratio and pH, together with the number and intensity of ^{51}V signals due to complexed vanadium, enabled the number of complexes to be established. In favourable cases, Job's plots based on ^{1}H spectral intensities gave direct stoichiometric information.

TABLE 1. ^{1}H, ^{13}C, and ^{51}V chemical shifts[a] for the system vanadate(V) + glycolic acid

		δ_H	δ_C	δ_V[b]
pH* = 3.1	Free species	4.28 (CH_2)	61.04 (CH_2)	−502.0
			179.37 (CO_2H)	−521.0
	Complex *a*	4.82 (CH_2)[c]	77.58 (CH_2)	−525.6
			182.55 (CO_2H)	
pH* = 5.0	Free species	4.02 (CH_2)	61.99 (CH_2)	−496.5
			181.21 (CO_2H)	−512.3
	Complex *a*	4.82 (CH_2)[c]	77.54 (CH_2)	−525.6
			182.80 (CO_2H)	
	Complex *b*	4.67 (CH_2)[c]	76.30 (CH_2)	−540.8
			183.12 (CO_2H)	

[a]δ values relative to DSS (^{1}H), TMS (^{13}C, using δ_C (dioxane) = 67.4), and external $VOCl_3$ (^{51}V).

[b]For free metal, main signals of $V_{10}O_{28}^{6-}$ only (dominant species in the pH range covered).

[c]At T = 275 K, to avoid interference of the OH peak.

The ^{13}C and ^{1}H chemical shifts observed for the ligand on complexation indicate the groups bound to the metal. Vicinal proton–proton coupling constants are measured in the case of acids C, D, F, G to give information on the conformation of the bound ligand. The ^{51}V line widths for the complexed species range from 240 to 480 Hz in comparison with 200–300 Hz for vanadate solutions.

We shall now present the results obtained with each acid as ligand, and compare with results in the literature, whenever available, provided by other techniques.

(a) Glycolic acid

Irrespective of the vanadate/glycolic acid molar ratio, at pH ≅ 3 only one complex is detected by ^{13}C and ^{51}V nmr, but additional weak signals in the proton spectrum are recorded, revealing the formation of minor species as well. At pH ≅ 5 two dominant complexes are detected and at pH around 7 complexation is almost nonexistent. Table 1 shows the chemical shifts for this system.

It is noted that the ligand ^{1}H and ^{13}C signals shift to high frequency on complexation and the large shifts observed for the CH_2 group (0.7–0.8 ppm for ^{1}H and 14–15 ppm for ^{13}C, at pH* = 5.0) are a clear indication of the involvement of the hydroxyl group in complexation, together with the carboxyl group. The vanadium signal shifts to low frequency by −13 and −28 ppm for the two complexes at pH* = 5.0 with respect to the low-frequency resonance of $V_{10}O_{28}^{6-}$, which is the dominant species in vanadate(V) solutions in similar conditions (7, 13).[1]

The promixity of the proton CH_2 signal of bound ligands to the residual OH resonance did not allow a sufficiently precise determination of the stoichiometry of the complexes by measuring intensity variations with metal:ligand molar ratio, but a rough indication can be obtained that *a* is an *n*:*n* species and *b* an *n*:*m* complex with $n \geqq m$. This is supported by a comparison of ^{13}C intensities for variable molar ratios.

Previous studies of this system were based on potentiometry, leading to the proposal of 4:2 and 2:2 complexes (8, 9) as well as 1:2 species, but only in an excess of glycolic acid (8), and on spectrophotometry, pointing to 1:2 complexation (10). On the other hand, solids of composition 1:2 and 1:1 have been synthesized from vanadyl acetate and glycolic acid (11).

[1]For a review on ^{51}V nmr parameters see ref. 16.

(b) Lactic acid

The results are very similar to those obtained with glycolic acid. Figure 1 shows the ^{51}V spectrum of a 0.20 *M*:0.20 *M* vanadate(V) + lactic acid solution at pH* = 5.2, the formation of a strong complex *a* and a weaker complex *b* being suggested. Figure 2 gives the corresponding proton spectrum, which shows the presence of two additional sets of signals (A_3X spectra) of bound ligand (complexes *c* and *d*). The chemical shifts oberved at pH* = 5.0 are given in Table 2 for complexes *a* and *b*. The Job's plots shown in Fig. 3 suggest that complex *a* is an *n*:*n* species. Complex *b* seems to have an identical composition, but due to the predominance of *a* no unambiguous stoichiometry can be directly inferred from the curve, in spite of the maximum at 1:1 (see discussion of V(V) + malic acid below).

The effect of pH on the formation of *a* and *b* is illustrated in Fig. 4 for two molar ratios.

The conclusion of predominant 1:1 complexation is at variance with a previous spectrophotometric study (10), which pointed to 1:2 complexation, and with a 2:1 complexation proposed on the basis of conductimetric measurements (12). It is also contrary to what happens with Mo(VI) and W(VI), which give 1:2 complexes (4).

(c) Chloro- and phenyl-lactic acids

At low pH, the formation of two complexes (*a* and *b*, *a* being more abundant) is detected with (D,L)-chlorolactic acid, possibly due to the use of the racemic mixture. With (L)-phenyllactic acid only one complex forms, irrespective of pH and concentration conditions. Tables 3 and 4 give the corresponding nmr parameters, including the proton coupling constants arising from ABX analysis of the spectra. At pH ≅ 5, the proton spectrum in the case of vanadate(V) + chlorolactic acid becomes too broad for a complete analysis; this is probably due to a faster exchange of bound ligand, simultaneous with the presence of a third species revealed by the ^{13}C spectra (chemical shifts, identical to those of complex *a* except for -*C*HOH- with a lower δ_C value, seem to suggest that the third complex forms an acid–base pair with complex *a* via deprotonation of the hydroxyl group in -CHOH-).

At pH* = 2.7, the concentrations of bound ligand for various metal:chlorolactic acid ratios are as follows:

	Concentration (*M*)	
V:acid	Complex *a*	Complex *b*
0.2 *M*:0.1 *M*	0.060	0.026
0.1 *M*:0.1 *M*	0.061	0.029
0.05 *M*:0.1 *M*	0.037	0.012

which suggests 1:1 complexation. In line with this, the Job's plot of Fig. 5 clearly shows that the complex with phenyllactic acid has *n*:*n* composition. Again, this is contrary to what happens with W(VI) or Mo(VI), which give 1:2 complexes (4).

Another important difference with respect to W(VI) and Mo(VI) is that phenyllactic acid undergoes a drastic conformational change upon binding to vanadium(V), as the vicinal proton coupling constants clearly show (Table 4). From a mean conformation for the free ligand having a *trans* and a *gauche* HH arrangement, the ligand shows a conformation close to **I** in the *n*:*n* complex with vanadium; the small vicinal couplings are only compatible with approximately *gauche* H atoms. (A similar conformation is assumed by the ligand in the

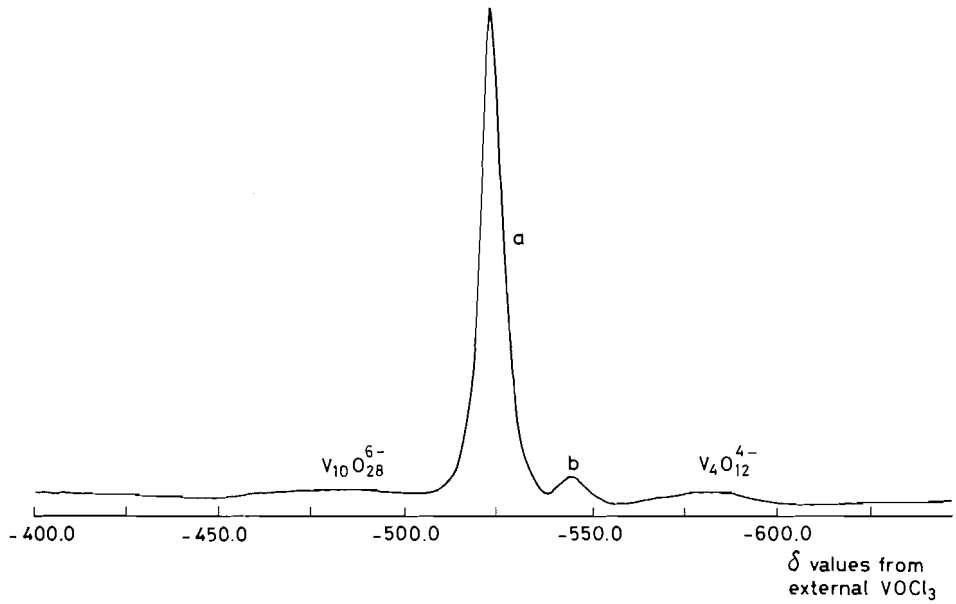

FIG. 1. The 52.6-MHz ^{51}V nmr spectrum of a 0.20 *M*:0.20 *M* D_2O solution of ammonium vanadate(V) and (L)-lactic acid (pH* = 5.2).

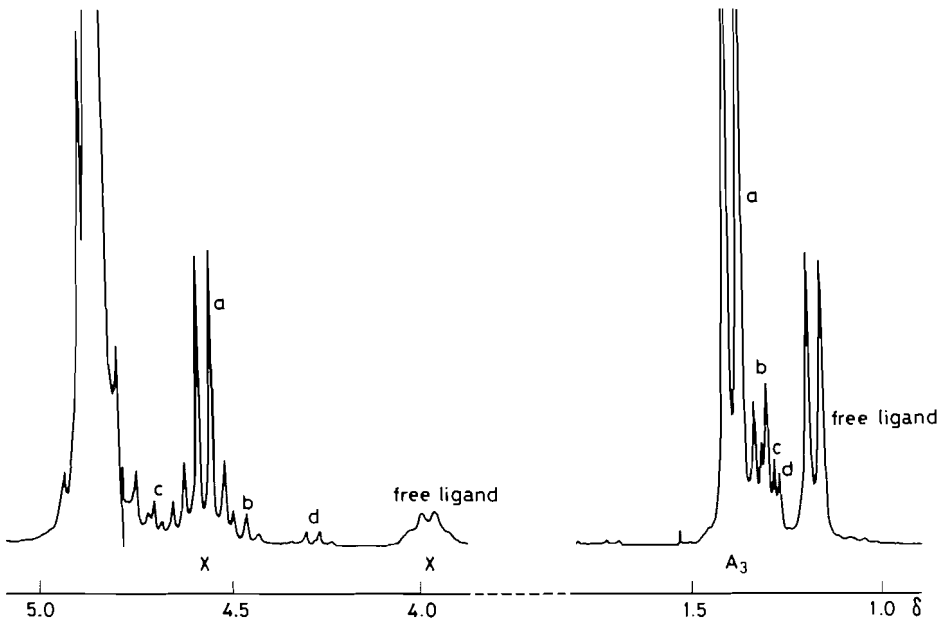

FIG. 2. The 200-MHz ^1H nmr spectrum of a 0.10 *M*:0.10 *M* D_2O solution of ammonium vanadate(V) and (L)-lactic acid (pH* = 5.2, 275 K).

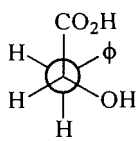

I

complexes of V(V) with chlorolactic acid.) The occurrence of conformation **I**, which is not favoured on grounds of group overcrowding in the ligand molecule, would be difficult to understand in the case of mononuclear 1:1 complex. We take this as an indication of a polymeric species being formed. Other data are, however, necessary before any nonspeculative proposal can be made about its structure.

(d) Mandelic acid

At pH ≅ 3 only one complex forms (complex *a*); at higher pH

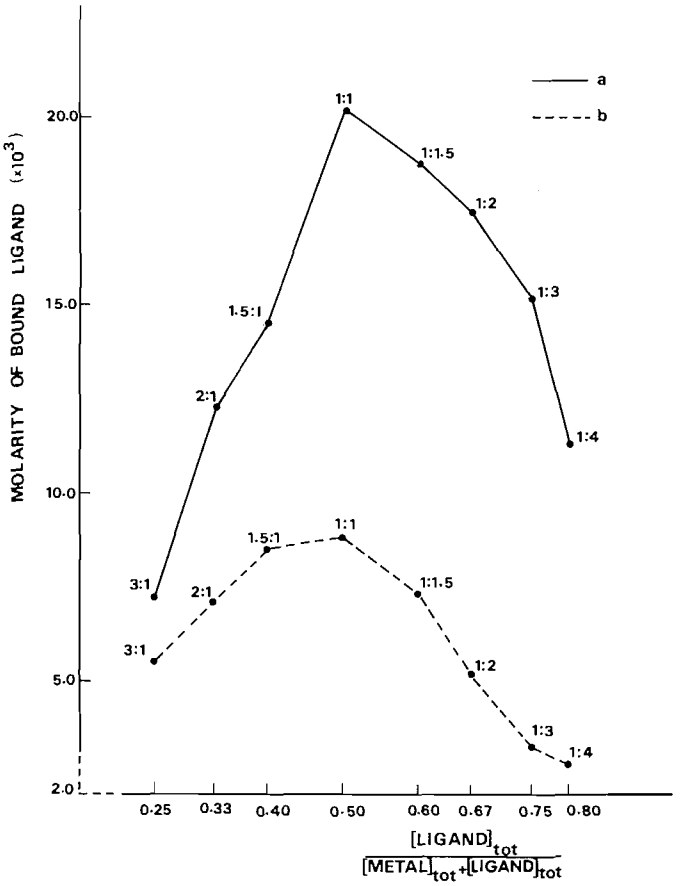

FIG. 3. Job's plots based on proton nmr spectral intensities for the system V(V) + (L)-lactic acid; total concentration of complexing species 0.080 *M* (D_2O solutions, 1 *M* in KNO_3, pH* = 5.0).

another complex (*b*) appears. Complex *a* is always dominant. This is an *n*:*n* species (as shown by a Job's plot at pH* = 2.9); *b* has a maximal concentration at 1.5:1 in a Job's plot at pH* = 5.1 but no direct conclusion on its composition can be obtained from this, because complex *a* dominates. The corresponding chemical shifts are as follows. Complex *a*: $\Delta\delta_{CHOH} = 0.53$, $\Delta\delta_{CHOH} = 14.00$, $\Delta\delta_{CO_2H} = 2.20$ relative to free ligand in the same conditions (pH* = 5.1, $\delta_{CHOH} = 5.02$, $\delta_{CHOH} = 75.99$, $\delta_{CO_2H} = 180.30$), and $\Delta\delta_V = -20.0$ relative to the low-frequency main peak of $V_{10}O_{28}^{6-}$. The equivalent values for complex *b* are, in the same order, 0.28, 12.60, 2.70, and −36.0.

The literature refers to 2:1 (12) and to 4:2, 2:2 (14, 15), and 1:2 (14) complexes on the basis of conductimetric (12, 14), spectrophotometric (14), cryoscopic (14), and potentiometric (15) studies.

(e) Glyceric acid

Two complexes form even at low pH, one (*a*) being always largely dominant. A Job's plot shows that this is an *n*:*n* complex. The corresponding spectral parameters are given in Table 5 for pH* = 3.2 (ABX proton spectrum). At this pH a full analysis of the proton spectrum of complex *a* is possible (not at pH* ≅ 5 due to overlap of the AB signals of the complex and the X signal of free ligand) but the free ligand spectrum is deceptively simple. Most of the signals of complex *b* are superimposed on those of *a*. It is clear that it is the α-hydroxyl group, rather than the β one, that is involved in complexation, together with the carboxyl group.

As for phenyllactic acid, there is a remarkable change in the vicinal HH coupling constants on complexation of glyceric acid

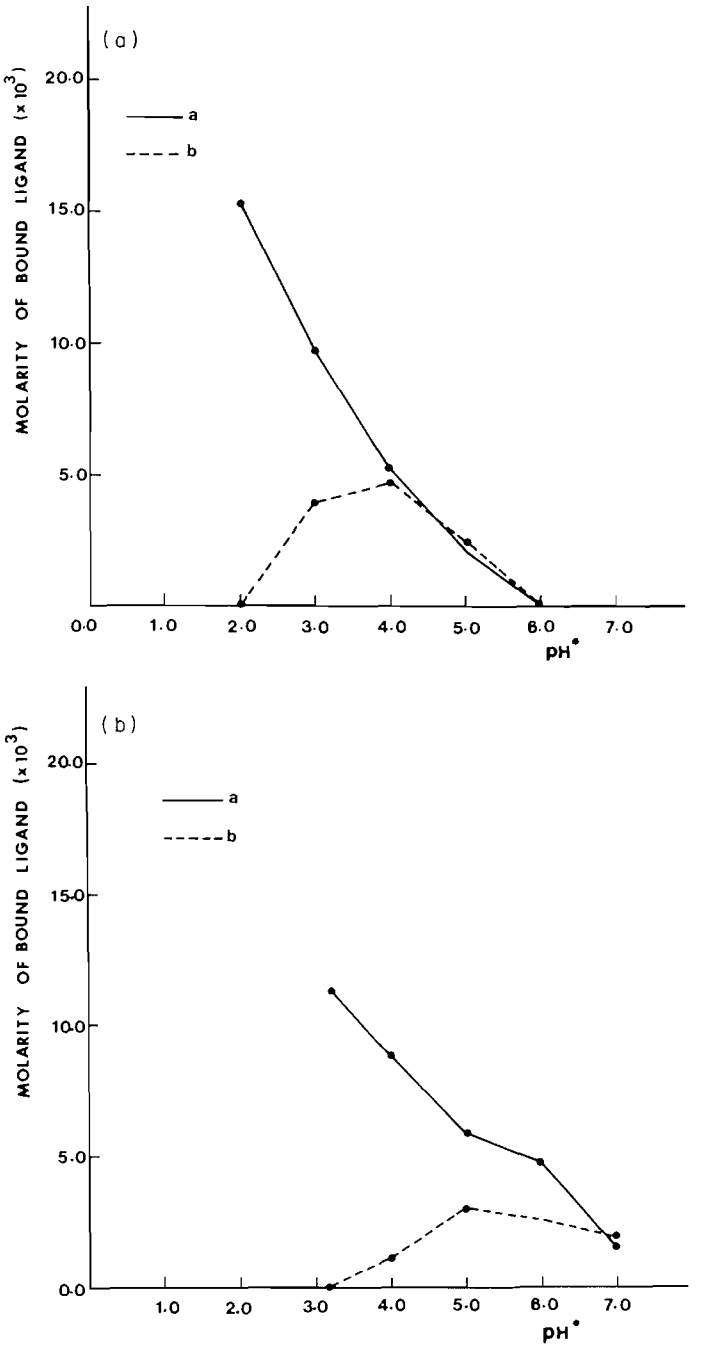

FIG. 4. Effect of pH on the concentration of the complexes V(V) + (L)-lactic acid; (*a*) 0.020 *M*:0.020 *M* (D_2O solution 1 *M* in KNO_3); (*b*) 0.020 *M*:0.040 *M* (D_2O solution 1 *M* in KNO_3).

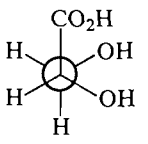
to vanadium(V): from a sum $J_{AX} + J_{BX} = 8.9$ Hz, which presupposes a *trans* and a *gauche* arrangement of the H nuclei, to a sum of 3.0 Hz, which requires a conformation close to **II** with two *gauche* arrangements. Again, this can only be understood in terms of a special polymeric *n*:*n* structure.



II

(f) Malic acid

Two complexes form in the pH range covered (2.0–6.5): a

complex *a*, which dominates up to pH* ≅ 4.2, and a complex *b*, which becomes the only one detected above pH* ≅ 5. The nmr parameters for pH* ≅ 4.8 are listed in Table 6. According to a Job's plot for pH* = 4.7 (for dilute solutions and in the presence of 1 *M* KNO_3 only complex *b* is detected), *b* is an *n*:*n* complex (Fig. 6). The same conclusion is reached for complex *a* from Job's curves obtained for pH* = 2.9 (Fig. 6): a clear maximum at 1:1 is observed for complex *a*, complex *b* having then only a small concentration. It is interesting to note that at this pH the maximal concentration of *b* occurs for a 2:1 ratio and not for the stoichiometric ratio 1:1 established when *b* is practically the only complex present (pH* ≅ 5). This is an illustration of one of the limitations of Job's continuous variations method: a maximum at the right stoichiometric ratio occurs only if the species is significantly dominant in those conditions. Thus we found no evidence for the 2:1 complexation previously

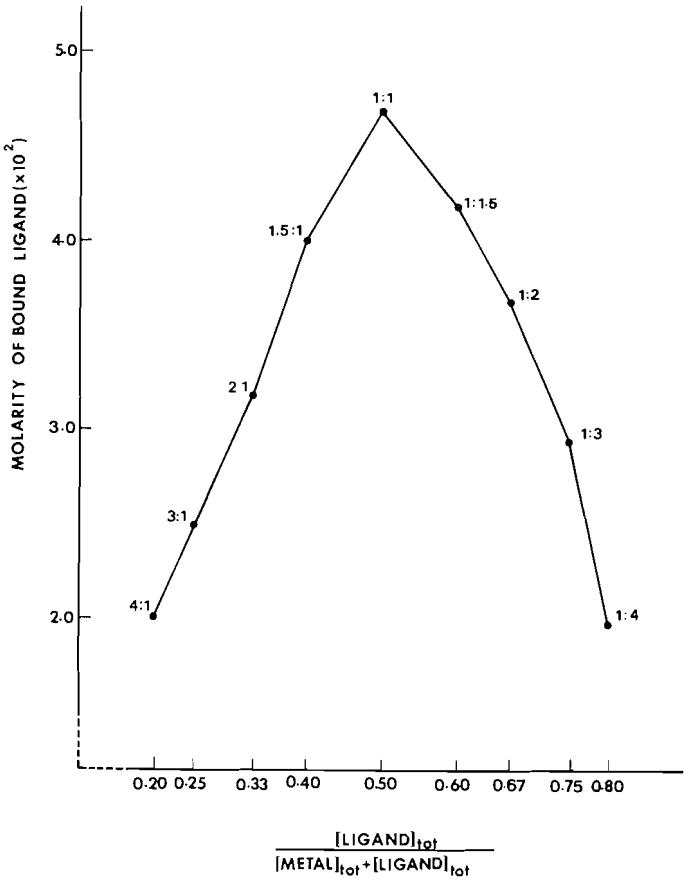

FIG. 5. Job's plots based on proton nmr spectral intensities for the system V(V) + (L)-phenyllactic acid; total concentration of complexing species 0.10 *M* (D_2O solutions, 1 *M* in KNO_3, pH* = 5.5, 275 K).

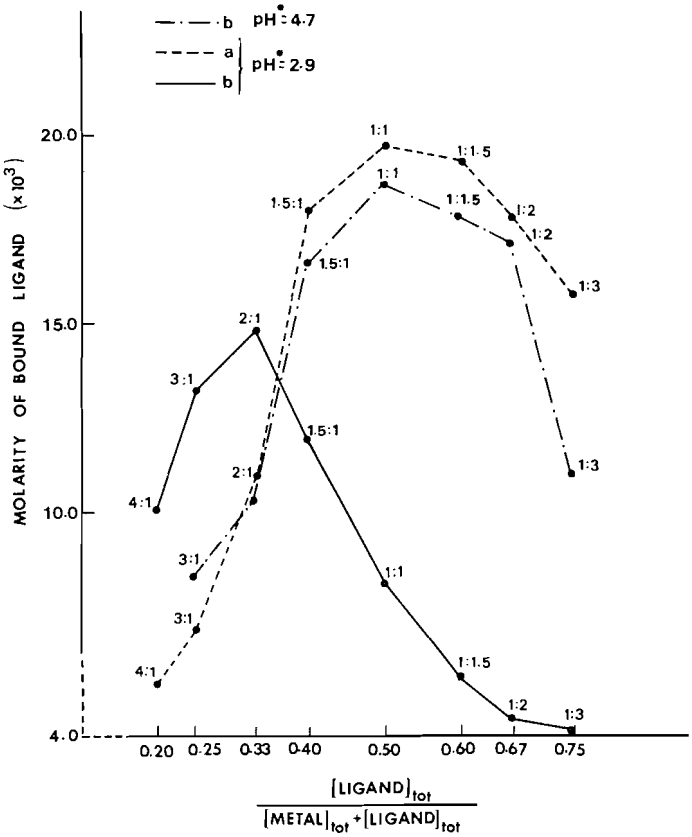

FIG. 6. Job's plots based on proton nmr spectral intensities for the system V(V) + (L)-malic acid; total concentration of complexing species 0.080 *M* (D_2O solutions 1 *M* in KNO_3).

proposed, together with 1:1 complexation, on the basis of a spectrophotometric, conductimetric, and cryoscopic study (14).

The carbon shifts for the carboxyl groups in complex *a* relative to free ligand in the same conditions (Table 6) clearly show that both groups are involved in chelation (together with the hydroxyl group). The situation is different for complex *b* where the ligand is bidentate (the β-carboxyl ^{13}C chemical shift is not significantly affected by complexation), as are the other ligands in this study.

In line with a terdentate function of malic acid in complex *a*, the vicinal coupling constants point to a conformation close to **III**, whereas in complex *b* the couplings presuppose a *trans* and a *gauche* arrangement of H atoms.

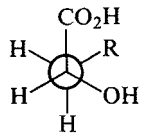
Conclusion

With the exception of (L)-phenyllactic acid, which forms only one strong complex with vanadium(V), all the other α-hydroxycarboxylic acids studied form two strong complexes and, in some cases, one or more minor species, in the pH range covered (~2.5–~7). The concentration of the dominant complex (complex *a*), in some cases the only one detected at pH ≅ 3, steadily decreases on increasing pH, while the concentration of the other (complex *b*) increases up to a point and then both become nearly zero for pH ≅ 6.5. In the case of malic acid as ligand, complex *b*, the least abundant in acidic medium, becomes the only complex detected at higher pH.

The acids act as bidentate ligands, but malic acid also has a terdentate function in complex *a*. The dominant complexes in all cases have *n*:*n* stoichiometry; the other strong complex is either *n*:*n* or *n*:*m* with $n > m$. With the possible exception of malic acid, mainly because of its terdentate function in complex *a*, the dominant *n*:*n* complexes are almost certainly polymeric, having the ligand in a conformation close to **IV** for R = ϕ, OH;



IV

this implies a drastic conformational change of the acid on complexation, which cannot easily be explained if the acid acted as a bidentate terminal ligand in a mononuclear complex. These results can be contrasted with those obtained for the corresponding W(VI) and Mo(VI) systems (4), in which the dominant complexation is 1:2 and no significant ligand conformational changes occur.

The tendency already noted with the proton and carbon chemical shifts in the tungsten and molybdenum complexes (4) is followed by vanadium, namely, the shifts on complexation decrease in the order W(VI) > Mo(VI) > V(V) for -C*H*OH-; they also decrease in that order for -*C*O_2H, but increase for -*C*HOH-.

Viscosity and density of isomeric butanol/water mixtures as functions of composition and temperature

P. CHANDANI SENANAYAKE, NORMAN GEE, AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 11, 1987

P. CHANDANI SENANAYAKE, NORMAN GEE, and GORDON R. FREEMAN. Can. J. Chem. **65**, 2441 (1987).

Viscosity and density of 27 binary mixtures of *sec*-, *iso*-, and *tert*-butanol with water were measured at $273 \leq T/K \leq 353$ and the results summarized using polynomials. At fixed T the density depended strongly but monotonically on mole fraction. The excess volume V^E was large and negative. In H_2O/*tert*-butanol as T increased V^E increased, while in H_2O/*sec*- or *iso*-butanol V^E decreased with increasing T. The excess viscosity was large and positive in all cases.

P. CHANDANI SENANAYAKE, NORMAN GEE et GORDON R. FREEMAN. Can. J. Chem. **65**, 2441 (1987).

Opérant à des températures allant de 273 à 353 K, on a mesuré les viscosités et les densités de 27 mélanges binaires d'eau avec les *sec*-, *iso*- et *tert*-butanols et on a résumé les résultats en utilisant des polynômes. A température constante, la densité dépend beaucoup de la fraction molaire, mais d'une façon monotone. La valeur du volume en excès V^E est importante et négative. Dans le mélange H_2O/*tert*-butanol, la valeur de V^E augmente avec une augmentation de la température; par ailleurs, dans les mélanges H_2O/*sec*- ou *iso*-butanol, les valeurs de V^E diminuent avec une augmentation de la température. Dans tous les cas, la valeur de la viscosité en excès est importante et positive.

Introduction

Studies of the reactivity of solvated electrons in hydroxylic solvents utilize values of the dynamic viscosity η in examining diffusion behavior (1–3). Values of η are sometimes not available and must be measured (3). During studies in mixtures of butanols and water (4) viscosity and density values were measured for 27 binary mixtures of water with *sec*-, *iso*-, or *tert*-butanol. The results are reported here.

Experimental

A. Materials

The butanols were obtained from BDH Chemicals: *sec*- (AnalaR, >99 mol%), *iso*- (OmniSolv, >99.0 mol%), and *tert*- (BDH Assured). They were further purified by (*a*) drying for 3 weeks on Davison 3A Molecular Sieves; (*b*) treated for one day at 323 K under argon (Liquid Carbonic Canada Ultra High Purity, >99.999 mol%) with sodium borohydride (~1 g/L); (*c*) fractionally distilled from the borohydride under argon through an 80 cm long by 2.3 cm diameter glass column packed with 3 mm glass helices, discarding the first 15% and last 35%; and (*d*) holding the collected 50% in an argon-pressured syphon system until use. The residual water content was determined by Karl Fischer titration to be 0.05 mol% in *sec*- and *iso*-butanol and 0.03 mol% in *tert*-butanol.

n-Butanol (Aldrich Gold Label, >99 mol%) was bubbled with Linde UHP argon and had 0.05 mol% water by Karl Fischer titration.

Ordinary distilled water was further purified in a SYBRON/Barnstead NANOpure II system.

Aldrich HPLC *n*-heptane (99.9 mol%) and Phillips Petroleum Research Grade *n*-pentane (99.93 mol%), *n*-hexane (99.99 mol%), methylcyclohexane (99.86 mol%) and *n*-octane (99.88 mol%) were (*a*) stirred with concentrated sulphuric acid for 1 day to remove olefins; (*b*) decanted and swirled for 10 min with Davison 5A Molecular Sieves; and (*c*) bubbled with Linde UHP argon.

B. Viscosity measurements

1. Calibration with water

The kinematic viscosity ν (m^2/s) was calculated from the efflux time t measured in Ubbelohde suspended level viscometers 0_c (Schott Geräte #24501-03) and I (Schott Geräte #24501-01). An optical meniscus detection system determined t in units of 0.01 s with a precision of ±0.009% (5).

Viscometer 0_c was calibrated by measuring t for water at $283.00 \leq T/K \leq 342.42$ and comparison with literature ν values using

$$[1] \qquad \nu = At - B/t$$

where A and B are the viscometer constants. Each t was the average of ~6 determinations. Values of ν were obtained from

$$[2] \qquad \nu = \eta/\rho$$

where the dynamic viscosities η (kg/m s = Pa s) were taken from a critical review (6), and ρ were from ref. 7*a*. Values of ν (m^2/s) calculated using $A = 2.8550 \times 10^{-9}\ m^2/s^2$ and $B = 2.2823 \times 10^{-6}\ m^2$ agreed with those in ref. 6 within an average deviation of 0.08%. Equation [1] is the usual calibration relation in the literature. However, the manufacturer's table of Hagenbach corrections to t (8) showed that it used

$$[3] \qquad \nu = Kt - K_E/t^2$$

where K and K_E are the constants instead of A and B. Equation [3] was also used in another work (9). Fitting our t values for water to literature values of ν (m^2/s) yielded $K = 2.8458 \times 10^{-9}\ m^2/s^2$ and $K_E = 3.4223 \times 10^{-4}\ m^2\ s$; however, the average deviation between ν calculated from eq. [3] and the literature values increased to 0.10%. Hence we calculated ν from measured t using eq. [1].

2. Calibration with organic liquids

To calibrate viscometer I water could not be used, because its ν values have too small a range. Organic liquids were used. Although suspended level viscometers were designed to minimize the surface tension effect (10), ref. 11 suggested that calibrating with water, which at 293 K has a surface tension $\sigma = 73 \times 10^{-3}$ N/m (7*b*), would give calibrating constants 1.2% lower than if hydrocarbons or alcohols were used ($\sigma \sim 20$ to 30×10^{-3} N/m (7*b*)). Such an effect was absent in ref. 9 where constants obtained by water calibration gave viscosities of toluene ($\sigma = 29 \times 10^{-3}$ N/m at 293 K (7*b*)) at $298 \leq T/K \leq 368$ agreeing within an average deviation of 0.15% of other values in the literature.

A surface tension effect would affect studies in alcohol–water mixtures as σ changes with composition (7*b*). The possibility of a surface tension effect in the viscometers was investigated by determining flow times t (each being the average of at least three measurements) of *n*-heptane, *n*-octane, and *n*-butanol in the water-calibrated viscometer 0_c. Densities ρ used to calculate the present η are the average of values cited in the viscosity literature sources (12–14). The η values (Table 1) are in general agreement with the rather scattered earlier works and do not support consideration of a surface tension effect in the present work.

At the same time that the organic solvent measurements were done in viscometer 0_c, viscometer I was filled with that solvent and stabilized in the same bath. To calibrate viscometer I, values were correlated by eq. [1]; the resulting $A = 1.0303 \times 10^{-8}\ m^2/s^2$ and $B = 2.3128 \times$

10^{-6} m^2 gave calculated ν values that agree with measured values, with an average deviation of 0.06%.

C. Density measurements

The liquid densities were determined from volume changes of a known mass of sample (15). Six Pyrex dilatometers, each consisting of two 1.000 mL pipettes sealed to a 10, 20, or 25 cm^3 bulb, were used. The two pipettes connected in parallel made the cell easier to clean and fill. The samples were sealed in the dilatometer using ground-glass-jointed caps and springs. The mass of sample was the difference between the filled and unfilled dilatometer, weighed at 294 ± 1 K on a Stanton Instruments Ltd. (model C.L.I.) analytical balance. Sample masses of ~9 to ~20 g were measured to 0.1 mg with a precision of ±0.1 mg as determined by repeated weighings of a given mass. The pipette scales were readable to 0.001 mL with a precision of ±0.001 mL. Each dilatometer was calibrated with water with the meniscus at positions covering the entire length of the pipette portion, and at $274.16 \leq T/K \leq 347.93$.

To estimate the reliability of the measurements, densities were measured in four liquids at 293.15 K and compared with values in the literature (Table 2). The percent deviation Δ

$$[4] \qquad \Delta = 100\left(1 - \frac{\text{lit.}}{\text{present}}\right)$$

varied from 0.09% to −0.11%. The reliability of the present densities is indicated by the average percent deviation,

$$[5] \qquad \Delta_{av} = \frac{100}{n}\sum_i |\Delta_i|$$

(n is the number of samples and subscript i denotes the ith sample) which for the liquids in Table 2 was 0.06%.

D. Temperature control

The viscometer or dilatometer was mounted in 4 L bath of light paraffin oil (Fisher Scientific) or of water. The bath was stirred using a propellor that was belt-driven by a Bodine Electric Company induction motor (model NSI-12) at about 1000 rpm. The temperature of the bath was regulated using a platinum resistance detector (Omega Engineering Inc. model TFD) in conjunction with a General Resistance Instruments temperature detector simulator (model RTD-100) in a Wheatstone bridge configuration with a Princeton Applied Research precision lock-in amplifier (model HR-8) as null detector. The lock-in amplifier in turn drove a power amplifier that controlled the heating rate of a Cenco 250 W knife heater. To get more rapid change in temperature, a 1000 W heater plugged into a standard Electrical Products voltage adjuster was used to raise the bath temperature towards the desired value, and then the lock-in amplifier controlled knife heater continued the approach toward constant temperature. At $273 \leq T/K \leq 300$ a Tecumseh (model AE 1343 AA) refrigeration unit pumped Freon-12 through a 5 cm × 10 cm expansion chamber outfitted with aluminum heat dissipation fins which was immersed in the bath, and supplied an ~45 W heat loss to the bath; the knife heater was used to balance this cooling and determined the final temperature.

The stability of the bath temperature was measured, using a second Omega FTD platinum resistance detector, to be ±0.002 K for >2 h. The bath temperature during viscosity or density measurements was recorded to 0.01 K with a Fluke 2189A platinum resistance thermometry system. The system consisted of a factory-matched Fluke 2180A digital thermometer and a Fluke Y2039 resistance temperature probe. Prior to use the system was adjusted at the ice point to 273.15 K; the accuracy at the ice point was ±0.01 K (16*b*). After all measurements were finished, the ice point check was repeated; the drift over the measurement period was less than 0.01 K. The uncertainty in temperature at ~353 K was about twice that at 273.15 K (16*a*). Hence, while the bath stability was ±0.002 K, the accuracy of temperature measurement was ±0.01 K near 273 K and ±0.02 K near 353 K.

E. Mixture composition

As in earlier work (1–3) the alcohol–water mixtures were prepared by volume measurement using pipettes cleaned by (*a*) washing with hot nitric acid; (*b*) many flushes with purified water; (*c*) *n*-hexane; (*d*) drying in an oven reserved for clean glassware. The pipette volumes were calibrated by weighing the delivered mass of water. Mole fractions were determined to ±0.0005.

Results

The density and viscosity of a mixture were measured at fixed mole fraction x as functions of temperature. More generally useful in thermodynamics are ρ and η at fixed T as functions of x. To convert the results the densities and viscosities were fitted with polynomials in temperature, and the fitting parameters were used to interpolate, typically less than 1 degree, to the desired temperatures used in Section D.

A. Temperature dependence of density

The experimental values of the densities ρ (kg/m^3) at the

[e]Average percent deviation of the calculated from the experimental densities.
[f]Largest magnitude of Δ_i.
[g]Reference 7*a*.

conditions listed in Table 3 were fitted to

$$[6] \quad \rho = a_0 + a_1 T + a_2 T^2$$

yielding the parameters values a_i (kg/m^3 K_i) in Table 3. Substituting the calculated ρ for lit. in eq. [4], the average percent deviation (eq. [5]) and largest value of Δ for each mixture fitting were obtained. Except for $x_w \geq 0.95$, a fit with $\Delta_{av} < 0.1\%$ was obtained using $a_2 = 0$. The quadratic term at $x_w \geq 0.95$ reflects the curvature of water density towards a maximum at 277.13 K (7*a*, 17).

Earlier composition studies often concentrate on the water-rich region (18*a*, 18*b*). To compare our results with literature values, densities were generated from eq. [6] and Table 3 at the temperature of the earlier study, for H_2O/*tert*-BuOH at 293.15 and 298.15 K, and for *sec*-BuOH/H_2O at 293.15 and 328.15 K, and then fitted to:

$$[7] \quad \rho\ (\text{kg/m}^3) = \sum_{j=0}^{7} c_j x^j$$

Tables of c_j are available from the Depository of Unpublished Data.[1] Our values were fitted by eq. [7] to $\Delta_{av} \approx 0.02\%$. The same calculated lines fitted literature values to typically <0.1% (11, 17, 19, 20), although one study at $x_w > 0.861$ (18*b*) differed from our and other (11, 19) data by ~0.4%.

B. Temperature dependence of viscosity

Viscosities of liquids (21) and gases (22) are often fitted to polynomials in ln T and powers of T. The present results are represented by:

$$[8] \quad \ln \eta = b_0 + b_1/T + b_2/T^2 + b_3/T^3$$

to ~0.1%. The fitting parameters b_i in K^{-i} were those in Table 4, giving η in 10^{-3} Pa s (= 10^{-2} Poise).

Discussion

The composition dependence of thermophysical properties of binary mixtures are often described in terms of properties that

for ideal mixtures have values Y_{ID} that are additive in mole fraction (18, 21, 23–26):

$$[9] \quad Y_{ID} = x_1 Y_1 + x_2 Y_2$$

where $x_1 + x_2 = 1$ and Y_i is the value for pure component i. The measured Y_{EXPTL} is then related to an excess Y^E where

$$[10] \quad Y^E = Y_{EXPTL} - Y_{ID}$$

A. Excess volume

For density the additive property is molar volume $V = M/\rho$, where M the molar mass for the mixture is $M_M = \sum_i x_i M_i$. The ideal mixture volume V_{ID} is $[(x_w M_w/\rho_w) + (x_A M_A/\rho_A)]$ in our work (subscript w refers to water and A to alcohol).

Example excess volumes V^E calculated by

$$[11] \quad V^E = \frac{M_M}{\rho_{EXPTL}} - V_{ID}$$

from densities obtained from [6] and parameters in Table 3 are compared to literature values (18*c*, 20) in Fig. 1. At 298.15 K the present and ref. 18*c* results in H_2O/*tert*-BuOH were in good agreement (Fig. 1*a*). Reference 18*c* results were expressed as

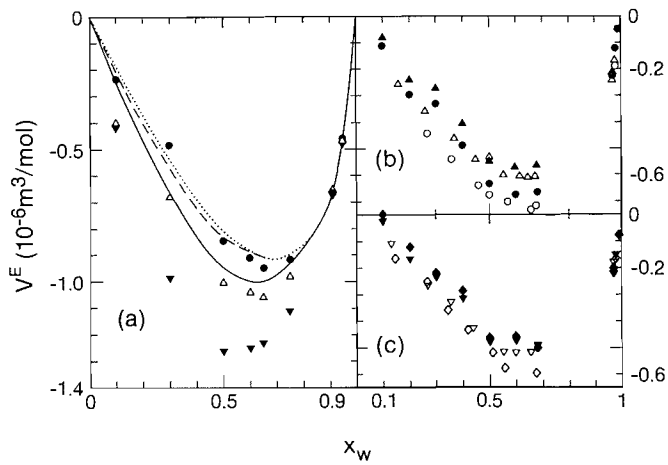

FIG. 1. Excess volume against mole fraction of water in (*a*) *tert*-BuOH at 298.15 K (●, ····), 313.15 K (△, - - -) and 353.15 K (▼, —); (●, △, ▼) are present results and lines are from ref. 18*c*. (*b*) and (*c*) *sec*-BuOH at 278.15 K (○, ●), 298.15 K (△, ▲), 328.15 K (▽, ▼), and 353.15 K (◇, ◆); solid symbols are present values and open symbols are from ref. 20.

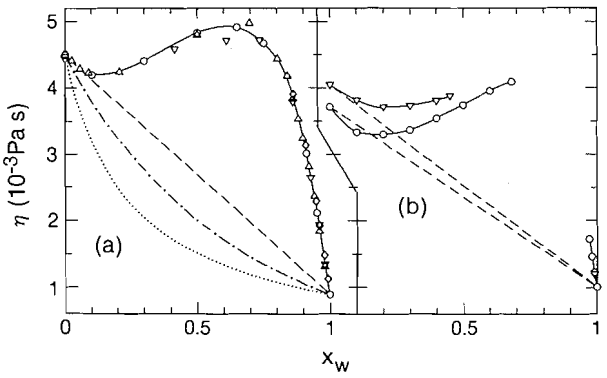

FIG. 2. Dynamic viscosity against mole fraction of water in (*a*) *tert*-BuOH at 298.15 K. η_{EXPTL} are ○ (present work), △ (ref. 11), ▽ (ref. 33), and ◇ (ref. 34). — is empirical; other lines are eq. [12] (· · · ·) and eq. [9] with $Y_i = \eta_i$ (----) or ϕ_i (· · · ·). (*b*) *sec*-BuOH (○) or *iso*-BuOH (▽) at 293.15 K. — is empirical and ---- are eq. [9] with $Y_i = \eta_i$.

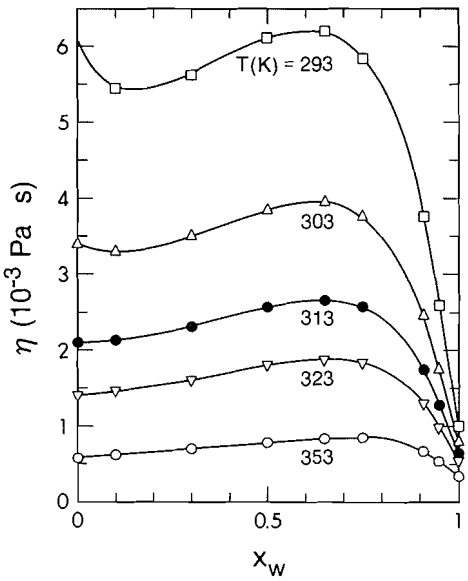

FIG. 3. .Effect of temperature on composition dependence of viscosity of *tert*-butanol/water mixtures. The value of η of pure supercooled *tert*-butanol at 293 K was obtained by extrapolation from higher temperatures.

line graphs and that same notation is used in Fig. 1*a*. The minimum in our V^E plot deepened with increasing temperature to a greater extent than indicated by ref. 18*c*, and the position of the minimum moved toward $x_w = 0.5$.

Figure 1*b* and 1*c* contain the comparison of H_2O/*sec*-BuOH results at 0.1 MPa (20). The V^E values decreased in magnitude as T increased from 278 to 328 K, but on further heating to 353 K remained approximately constant. In H_2O/*iso*-BuOH and H_2O/*sec*-BuOH V^E decreased with increasing T, which indicated that increasing thermal agitation of the molecules made these solutions less nonideal. Tables of V^E illustrating this point along with H_2O/*tert*-BuOH V^E are available from the Depository of Unpublished Data.[1]

B. Viscosity

The main problem in calculating an excess viscosity η^E is the lack of agreement about the form of the ideal mixture viscosity η_{ID}. The problem was examined in detail early in this century

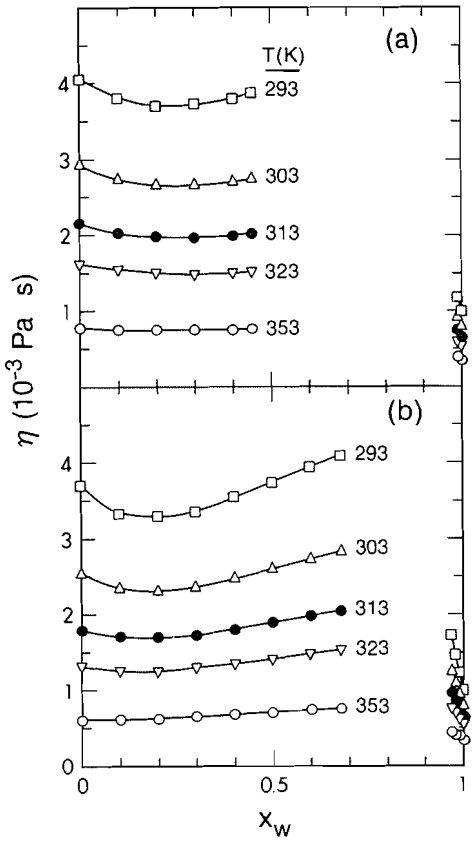

FIG. 4. Effect of temperature on composition dependence of viscosity of (*a*) *iso*-butanol/water; (*b*) *sec*-butanol/water.

(28) but is still apparent in the current literature (21, 23, 24, 27). While eqs. [9] and [10] could be used to define η^E (23, 29) the only mixture in which η could be described by eq. [9] appears to be $H_2O/HDO/D_2O$ (30), in which the components are quite similar. The most widely used relation appears to be that of Arrhenius (31) as modified by Kendall and Monroe from volume fraction to mole fraction (28), η_{AR}, that is eq. [9] with $Y_i = \ln \eta_i$,

$$[12] \quad \ln \eta_{AR} = x_1 \ln \eta_1 + x_2 \ln \eta_2$$

There is also disagreement about whether $[\ln \eta_{EXPL} - \ln \eta_{AR}]$ (21, 24, 30, 32) or $[\eta_{EXPTL} - \eta_{AR}]$ (27) is the more meaningful. Other models are power-root (28, 29) and fluidity $\phi \equiv 1/\eta$ equations (28, 33).

Example curves of η_{EXPTL} obtained from the measurements summarized by the parameters of Table 4 are shown in Fig. 2. For H_2O/*tert*-BuOH and H_2O/*sec*-BuOH the values of η_{EXPTL} in the mixtures near $x_w = 0.6$ were larger than in the pure components. The present values of η_{EXPTL} in H_2O/*tert*-BuOH are in good agreement with earlier values (11, 33, 34), except near $x_w = 0.65$ where refs. 11 and 33 differed by ~3% (Fig. 2). The relative viscosities in ref. 34 were multiplied by $\eta_w = 8.906 \times 10^{-4}$ Pa s for plotting in Fig. 2.

We tested eqs. [12] and eq. [9] with $Y_i = \eta_i$, and ϕ_i. In each case the calculated values were far from η_{EXPTL} (Fig. 2).

We also tested

$$[13] \quad \eta^P = x_1 \eta_1^P + x_2 \eta_2^P$$

with $P = 1/3$ (28), 1/2 (35), or 1/2.5 (36). The curves were intermediate to eq. [12] or [9] with $Y_i = \eta_i$ but all decrease monotonically with increasing x_w. The only clear conclusion

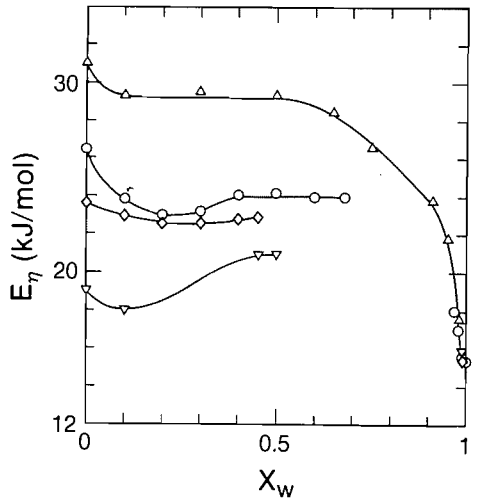

FIG. 5. Variation of energy of activation for viscous flow E_η with composition, over the range $298 < T/K < 353$. △, *tert*-butanol; ○, *sec*-butanol; ◇, *iso*-butanol; ▽, *n*-butanol (ref. 37).

from Fig. 2 is that regardless of the form for η_{ID} the present work indicates a large positive excess viscosity, consistent with stronger hydrogen bonding in the mixture than in the pure components, and consistent with the observed negative excess volume (Fig. 1).

Upon increasing the temperature the viscosities of the pure alcohols and the aqueous mixtures decreased more rapidly than did that of water. The *S*-shapes of the η against x_w curves decreased with increasing temperature (Figs. 3 and 4).

An average Arrhenius temperature coefficient of viscous flow, E_η, was obtained by fitting the measured viscosities over the temperature range $293 < T/K < 353$ to eq. [8] with $b_2 = b_3 = 0$. In this case $E_\eta = b_1 R$, where R is the gas constant. Values of E_η for binary mixtures of the four isomeric butanols with water are plotted in Fig. 5. The viscosity data for 1-butanol (37) have a lower precision (~1%) than those for the other isomers (~0.1%).

Addition of a small amount of water to a butanol disrupts the alcohol liquid structure and decreases the resistance to flow (Fig. 5). Addition of a small amount of a butanol to water stiffens the liquid structure and increases the resistance to flow. In the central composition region the viscosity and its temperature coefficient change relatively little, which probably indicates a relatively random fluid structure.

Allomerization of cholic acid and conversion to petromyzonol

XINGPEI ZHU,[1] ETCHRI AMOUZOU, AND STEWART MCLEAN
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received May 13, 1987

XINGPEI ZHU, ETCHRI AMOUZOU, and STEWART MCLEAN. Can. J. Chem. **65**, 2447 (1987).

Petromyzonol, a rare bile substance, has been prepared from an abundant starting material, cholic acid. The critical conversion, the inversion of the configuration at C-5, was accomplished by oxidizing a suitably protected derivative of cholic acid to a 1,4-dien-3-one, which was then stereoselectively reduced to methyl allocholate. In a single oxidation step, the 3-hydroxy steroid was converted to the dienone by Barton's procedure using a catalytic amount of benzeneseleninic anhydride and *m*-iodoxybenzoic acid as the stoichiometric oxidant. The stereoselective reduction employed two steps: hydrogenation of the dienone to the saturated ketone (5α) in the presence of the Wilkinson catalyst, followed by reduction of the ketone with K-Selectride. Finally, methyl allocholate was reduced to petromyzonol with lithium aluminum hydride.

XINGPEI ZHU, ETCHRI AMOUZOU et STEWART MCLEAN. Can. J. Chem. **65**, 2447 (1987).

On a préparé le pétromyzonol, une substance biliaire rare, à partir d'un produit de départ abondant, soit l'acide cholique. La conversion critique, l'inversion de la configuration en C-5, a été réalisée en oxydant un dérivé de l'acide cholique protégé d'une façon appropriée en diène-1,4 one-3 qui est ensuite réduite stéréosélectivement en allocholate de méthyle. En une seule étape d'oxydation et utilisant la technique de Barton qui fait appel à une quantité catalytique d'anhydride benzèneséléninique et à une quantité stoechiométrique d'acide *m*-iodoxybenzoïque comme oxydant, on transforme l'hydroxy-3 stéroïde en dièнone. La réduction stéréosélective implique deux étapes, soit l'hydrogénation, en présence de catalyseur de Wilkinson, de la diénone en cétone saturée (5α), puis la réduction de la cétone par du K-Selectride. Finalement, l'allocholate de méthyle est réduit en pétromyzonol par l'hydrure double de lithium et d'aluminium.

[Traduit par la revue]

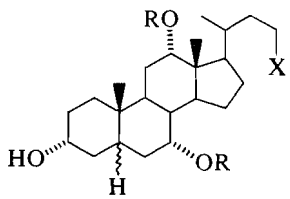
Petromyzonol (**1**) is a rare bile substance produced by the lamprey *Petromyzon marinus* L., but only in its larval form before it becomes parasitic (1). Petromyzonol is required for medical research on hepatic function, but supplies from natural sources are extremely limited.[2] A simple synthesis of petromyzonol from 3α,7α,12α-trihydroxy-5α-cholanic acid (allocholic acid, **2**) has been reported (1), but allocholic acid is, itself, not readily available, and was obtained in small amounts from certain lizards (family Iguanidae). However, its 5β epimer, cholic acid (**3**), is readily available and inexpensive,



1 5α; R = H; X = CH_2OH
2 5α; R = H; X = COOH
3 5β; R = H; X = COOH
4 5β; R = CHO; X = COOMe
8 5α; R = H; X = COOMe

and is, consequently, an attractive starting material for the synthesis of petromyzonol on a large scale. The key step in the synthesis is the inversion of configuration at C-5 (allomerization). Most allomerization procedures for bile acids depend on the oxidation of ring A to a 4-en-3-one and then stereoselective reduction to a 5α compound, generally by some variant of the Birch reduction (2). Most routes to the enone involve an elimination reaction of a 4-substituted ketone (e.g., dehydrobromination of the 4-bromo ketone). The presence of a 7α hydroxyl group (usually protected as an ester) introduces complications resulting from a facile further elimination to form the 4,6-dien-3-one (2, 3). In such cases, the use of selenium dioxide to oxidize the saturated ketone directly to the 4-en-3-one has been described (4), but later workers (2) report that the method is impractical for synthetic purposes.

The introduction by Barton *et al.* (5) of benzeneseleninic anhydride (BSA) as an oxidizing agent for steroidal ketones provided a number of operational advantages, and the method was improved further when it was shown that BSA could be used in catalytic amounts with *m*-iodoxybenzoic acid as the stoichiometric oxidant (6). (Since the reagent is reduced to *m*-iodobenzoic acid, which can be isolated and oxidized back to the iodoxy level with sodium hypochlorite, the only nonrecoverable oxidizing agent is common bleach.) With this reagent a 3-hydroxycholestane can be oxidized directly to the 1,4-dien-3-one in excellent yield without the necessity of isolating any intermediates.

Consequently, we prepared the 7,12 diformate of cholic acid (7) and converted it to its methyl ester (**4**). The catalytic BSA oxidation (6) of **4** was allowed to proceed as far as the 1,4-dien-3-one **5**, which was isolated in good yield (76%); stopping the oxidation at an earlier stage led to mixtures in which both isomeric enones were present. Removal of the formate groups provided the diol **6**, which was hydrogenated in the presence of chlorotris(triphenylphosphine)rhodium (Wilkinson's catalyst). The course of the reaction was followed by observing the amount of hydrogen consumed and the tlc characteristics of aliquots of the solution. It is subject to a number of experimental variables, including the batch of catalyst used, but it is clear that a rapid reduction is followed by a slower process that forms the saturated ketone; the concentration of this ketone in the mixture increases, but it begins to undergo further reduction before all of the partially reduced material has been converted to saturated ketone. For preparative purposes the hydrogenation was allowed to proceed until the first signs of overreduction appeared, and the products were then separated by chromatography. In this way the saturated 5α ketone **7** was isolated in yields of about 50%; the 5β isomer

7

could not be detected by tlc. It is apparent that the 7α hydroxyl group now provides a synthetic advantage; steroidal 4-en-3-ones are normally hydrogenated extremely slowly by the Wilkinson catalyst (8), but the catalyst can complex with the 7α hydroxyl group, and then delivery of hydrogen to the 4,5 double bond is accelerated and made highly stereoselective for the α face (9).

Reduction of the ketone **7** with potassium tri-*sec*-butylborohydride (K-Selectride) (10) at low temperature proceeded with very high stereoselectivity to provide the 3α hydroxyl group, and methyl allocholate (**8**) was isolated in 95% yield. Lithium aluminum hydride was used to reduce **8** to petromyzonol (**1**) in excellent yield.

The sequence described constitutes an experimentally useful procedure for the allomerization of common (5β) bile acids incorporating a 7α hydroxyl group (and an oxygen function at C-3). The oxidation sequence is carried out in a single operation and converts the 3-hydroxy compound directly to the dienone in very good yield. The 5α stereochemistry is established with high stereoselectivity in the hydrogenation step; the yield is good, and could effectively be improved by reprocessing partially reduced by-products. Both the yield and the stereoselectivity of the reduction with K-Selectride are excellent. The overall yield from cholic acid to petromyzonol was 32%.

Experimental

Melting points were determined on a Thomas–Kofler micro hot stage. A Perkin–Elmer 243B polarimeter was used. Infrared spectra were recorded on a Nicolet 5DX FTIR spectrometer (samples in KBr discs); the frequency of selected absorptions is reported. Ultraviolet spectra were recorded on a Cary 14 spectrometer; λ_{max} values (samples in 95% EtOH) are reported. Varian XL 400 and XL 200 nmr spectrometers were used. Unless otherwise indicated, samples were dissolved in $CDCl_3$ and reported data are for ^1H spectra at 400 MHz and ^{13}C spectra at 100 MHz; for ^1H spectra, only significant resolved signals are reported as δ_H values, followed in parentheses with an indication of the multiplicity (abbreviated), coupling constants (Hz) if determined, and the number of protons associated with the signal; for ^{13}C spectra, δ_C values are reported, followed in parentheses by a figure indicating the number of protons attached to the carbon as determined by spectral editing.

Methyl 3-oxo-7α,12α-dihydroxy-1,4-choladienate (6)

The 7,12 diformate of cholic acid (7) (1.00 g; 2.16 mmol) was dissolved in a minimum of methanol and treated with diazomethane in ether to provide the methyl ester **4**, which was isolated as a white foam; ^1H nmr (200 MHz): 8.04 (s, 1H), 7.98 (s, 1H), 5.13 (narrow m, 1H), 4.90 (narrow m, 1H), 3.64 (s, 3H), 3.45 (m, 1H), 0.76 (s, 3H), 0.68 (d, *J* 6.0, 3H), 0.57 (s, 3H). Hydroxy ester **4**, *m*-iodoxybenzoic acid (2.42 g, 8.69 mmol), and diphenyl diselenide (0.17 g, 0.54 mmol) were heated in refluxing toluene (50 mL) for 18 h (6). Solvent was removed, leaving a residue that was dissolved in ethyl acetate and extracted with aqueous sodium hydrogen carbonate. The ethyl acetate solution afforded a residue that was flash chromatographed (silica gel, 1:1 ethyl acetate – hexane) to afford the dienone **5** (0.75 g, 1.64 mmol), which, on recrystallization from hexane – ethyl acetate, formed white plates, mp 183–184°C; uv: 244 nm (ε 15 200); ir: 3037, 1730, 1708, 1658, 1622, 1602 cm^{-1}; ^1H nmr: 8.08 (s, 1H), 8.04 (s, 1H), 6.93 (d, *J* 8.4, 1H), 6.25 (dd, *J* 8.4, 1.6; 1H), 6.04 (narrow m, 1H), 5.30 (narrow m, 1H), 5.24 (narrow m, 1H), 3.65 (s, 3H), 1.23 (s, 3H), 0.90 (s, 3H), 0.89 (d, *J* 6.0, 3H). Deformylation was effected by stirring a solution at **5** in methanol with sodium carbonate (ca. 2 equiv.) at room temperature for 1 h. The diol **6** was isolated in quantitative yield and, after recrystallization from acetone, obtained as fine needles, mp 212–213°C; $[\alpha]_D^{22}$ +42.6° (*c* 0.75, $CHCl_3$); uv: 244 nm (ε 18 500); ir: 3500 (br), 1714, 1656, 1617, 1599; ^1H nmr: 7.01 (d, *J* 10.4, 1H), 6.21 (dd, *J* 10.4, 2.4; 1H), 6.06 (t, *J* 2.4, 1H), 4.05 (s, 2H), 3.65 (s, 3H), 1.20 (s, 3H), 1.00 (d, *J* 6.2, 3H), 0.76 (s, 3H); ^{13}C nmr: 186.0 (0), 174.8 (0), 165.8 (0), 156.0 (1), 127.4 (1), 126.7 (1), 72.2 (1), 69.4 (1), 51.5 (3), 46.7 (1), 46.5 (0), 43.1 (0), 41.6 (1), 40.7 (2), 39.9 (1), 37.8 (1), 35.1 (1), 31.0 (2), 30.8 (2), 29.8 (2), 27.3 (2), 23.3 (2), 18.0 (3), 17.1 (3), 12.5 (3). *Anal.* calcd. for $C_{25}H_{36}O_5$: C 72.11, H 8.65; found: C 72.11, H 8.43.

Methyl 3-oxo-7α,12α-dihydroxy-5α-cholanate (7)

A solution of chlorotris(triphenylphosphine)rhodium (640 mg; 0.69 mmol) in 25 mL of a 1:1 benzene–ethanol mixture was pretreated with hydrogen in a hydrogenation flask (8). A solution of the dienone **6** (600 mg; 1.44 mmol) in 25 mL of the same solvent was introduced into the flask and the reaction mixture was stirred vigorously. Aliquots were removed periodically and examined by tlc; optimal conversion was observed after about 25 h. Removal of the solvent then afforded a dark residue, which was dissolved in chloroform and passed through a short column of silica gel with elution by 19:1 chloroform–ethanol. The colorless product was rechromatographed on a silica gel column with elution by 4:1 ether–acetone. The saturated ketone 7 (300 mg; 0.72 mmol) was obtained as the major product; a small amount (30 mg) of overreduced material was isolated, and a fraction (150 mg) consisting of underreduced material was obtained. Recrystallization of 7 from aqueous acetone afforded white crystals, mp 150–152°C (lit. (4) mp 152–154°C); $[\alpha]_D^{23}$ +43° (*c* 2.0, MeOH) (lit. (4) $[\alpha]_D$ +45°); ir: 3405, 1732, 1712 cm^{-1}; ^1H nmr: 3.94 (narrow m, 1H), 3.82 (narrow m, 1H), 3.63 (s, 3H), 0.95 (s, 3H), 0.94 (d, *J* 6.0, 3H), 0.67 (s, 3H); ^{13}C nmr: 213.2 (0), 176.0 (0), 72.6 (1), 67.3 (1), 51.5 (3), 47.2 (1), 46.5 (0), 44.1 (2), 41.2 (1), 39.6 (1), 39.1 (1), 38.7 (1), 38.03 (2), 37.96 (2), 36.5 (2), 35.3 (0), 35.1 (1), 31.0 (2); 30.8 (2), 28.7 (2), 27.3 (2), 23.1 (2), 17.3 (3), 12.6 (3), 10.3 (3).

Methyl 3α,7α,12α-trihydroxy-5α-cholenate (8)

A solution of the ketone **7** (130 mg; 0.31 mmol) in 4 mL of dry tetrahydrofuran at −78°C under nitrogen was treated with 910 μL of 1.0 *M* K-Selectride (Aldrich Chemical Co.), and the reaction mixture was stirred for 5 h at −78°C and then allowed to warm to room temperature. The mixture was treated with 0.5 mL of 10% aqueous sodium hydroxide and 0.5 mL of 30% hydrogen peroxide followed by 5 mL of water. Extraction with ether provided triol **8** (126 mg; 0.30 mmol), which, on recrystallization from dichloromethane–methanol, formed white crystals, mp 226–228°C (lit. (4) mp 225–226°C); $[\alpha]_D^{23}$ +30° (*c* 1.5, MeOH) (lit. (4) $[\alpha]_D$ +28°); ^1H nmr: 4.03 (m, 1H), 3.94 (narrow m, 1H), 3.81 (m, 1H), 3.64 (s, 3H), 0.96 (d, *J* 6.1, 3H), 0.75 (s, 3H), 0.67 (s, 3H); ^{13}C nmr: 174.8 (0), 72.9 (1), 67.9 (1), 66.4 (1), 51.5 (3), 47.1 (1), 46.4 (0), 42.1 (1), 39.7 (1), 39.2 (1), 36.2 (2), 35.8 (0), 35.5 (1), 35.1 (2), 31.9 (1), 31.5 (2), 31.0 (2), 30.9 (2), 28.8 (2), 28.0 (2), 27.3 (2), 23.0 (2), 17.3 (3), 12.6 (3), 10.0 (3).

Petromyzonol (1)

A solution of **8** (24 mg; 0.057 mmol) in 1.5 mL of tetrahydrofuran was added dropwise with stirring to lithium aluminum hydride (8 mg; 0.21 mmol) in 1.5 mL of tetrahydrofuran. The mixture was heated to reflux for 1 h and then stirred for a further 12 h. Hydrolysis by aqueous Rochelle salt (11) with heating to reflux for 1 h and to 60°C for 3 h provided petromyzonol, which was purified by flash chromatography (silica gel, 17:3 chloroform–ethanol) and obtained as white crystals (20 mg; 0.050 mmol), mp 224–226°C (lit. (1) mp 229–231°C) undepressed on admixture with an authentic sample (mp 222–224°C); $[\alpha]_D^{23}$ +29.5° (*c* 1.5, EtOH) (lit. (1) $[\alpha]_D$ 27.5°); ^1H nmr (pyridine-d_5): 5.28 (br, 4), 4.28 (t, *J* 2.5, 1H), 4.24 (t, *J* 2.5, 1H), 4.10 (m, 1H), 3.86 (t, *J* 6.6, 2H), 2.98 (m, 1H), 2.73 (td, *J* 11.5, 7.4; 1H), 2.44

An asymmetrical disulfide-containing photoreactive heterobifunctional reagent designed to introduce radioactive labeling into biological receptors

GILLES DUPUIS

Department of Biochemistry, Faculty of Medicine, Université de Sherbrooke, Sherbrooke, Que., Canada J1H 5N4

Received October 22, 1986[1]

GILLES DUPUIS. Can. J. Chem. **65**, 2450 (1987).

The synthesis of succinimido 1-amino-(4-azidosalicyloyl)-3,4-dithio-5-carboxylate, a heterobifunctional photoaffinity labeling reagent, is described. The cross-linker possesses an asymmetrical disulfide bond, and a general method for generating a spacer arm bearing an asymmetrical or symmetrical disulfide bond is detailed. The heterobifunctional reagent has been obtained in a minimum of steps and intermediates have been characterized. It is further shown that the reagent can be trace-labeled with [^{125}I]-iodine and it has been used to modify phytohemagglutinin, a model protein. Upon irradiation, polymeric phytohemagglutinin derivatives are produced, as evidenced by electrophoretic analysis.

GILLES DUPUIS. Can. J. Chem. **65**, 2450 (1987).

On décrit la synthèse du succinimido amino-4 (azido-4 salicyloyl) dithio-3,4 carboxylate-5, un réactif de marquage photoaffinitaire hétérobifonctionnel. L'agent réticulant possède une liaison disulfure asymétrique et on décrit une méthode générale permettant de générer un bras d'espacement portant une liaison disulfure asymétrique ou symétrique. On a obtenu le réactif hétérobifonctionnel en faisant appel à un nombre minimal d'étapes et on a caractérisé les intermédiaires. On a de plus démontré que le réactif peut être marqué à l'état de traces avec de l'iode ^{125}I et on l'a utilisé pour modifier la phytohémaglutinine, une protéine modèle. Par irradiation, il y a formation de polymères dérivés de la phytohémaglutinine qui ont été mis en évidence par analyse par électrophorèse.

Introduction

Affinity labeling is a method that is increasingly used to study the molecular properties of biological receptors (1–4). In general, the strategy involves formation, under physiological conditions, of stable covalent bonds between the ligand and its receptor with the use of a cross-linking reagent. Initially, such cross-linkers were of the symmetrical type (5), but they are being largely replaced by the more versatile heterobifunctional reagents. These reagents are designed in such a manner that one of the functional groups serves to establish selectively a covalent bond with the ligand, while leaving the other function intact. This second reactive group is usually an aryl azide that can be light irradiated to generate a highly reactive nitrene (6, 7). Photoactivation of the ligand–receptor complex results in the formation of stable macromolecular species that can be analyzed by various methods. In this respect, electrophoretic analyses usually performed in the presence of sodium dodecylsulfate (SDS-PAGE)[2] have been mostly employed and have yielded valuable information concerning a variety of biological receptors (references cited in refs. 8 and 9). Such analyses can be greatly simplified if the cross-linked ligand–receptor complexes can be dissociated, as is the case of cross-linkers bearing a disulfide (4, 10–14), an azo or a *cis* glycol bond (15–17), or an ester linkage (18).

Most published reports have used radiolabeling of ligands to facilitate detection of the photolabeled complex. This approach presents disadvantages because some ligands are susceptible to denaturation during oxidative labeling (19) or may lack suitable chemical groups for introduction of label (20). Further, when cross-linked ligand–receptor complexes are dissociated by chemical treatments, radioactive label is no longer associated with the receptor, which then has to be detected by other means. A way of circumventing these problems is to use heterobifunctional reagents that bear a radioactive label. This approach has been used by Ji and Ji (21) who prepared several noncleavable aryl azido heterobifunctional reagents bearing [^{125}I]-substitution on the phenyl ring. Schwartz *et al.* (10) have also reported the synthesis and applications of a disulfide-containing heterobifunctional cross-linker that was asymmetrically [^{35}S]-labeled. Denny and Blobel (9) have described the synthesis and use of [^{125}I]-labeled *N*-4-(*p*-azido-*m*-phenylazo)benzoyl-3-aminopropyl-*N'*-oxysulfosuccinimide ester, a photoactivable heterobifunctional cross-linker that was initially synthesized by Jaffe *et al.* (15) and that can be cleaved by reduction of the azo bond. Recently, Schwartz (18) described a [^{125}I]-radiolabeled cross-linking reagent bearing an ester linkage in the spacer portion of the molecule.

In the present study, I report a facile synthesis of a reagent that possesses properties that make it highly suitable as a tool for study of biological receptors. The reagent embodies a reactive succinimidyl ester, a photolabile aryl azido group, and an easily reducible asymmetrical disulfide bond. Furthermore, the compound can be trace-labeled with 125-iodine, using the method of Bolton and Hunter (22). Photolysis of a model protein derivatized with the [^{125}I]-labeled reagent described here yields the expected products, as evidenced by electrophoretic analysis.

Results and discussion

Heterobifunctional reagent **4** was prepared according to the scheme outlined in Fig. 1. The synthetic route was designed to introduce radiolabel at the last step to minimize handling of radioactive intermediates. Discrete synthetic steps were as follows. 4-Azidosalicylic acid was obtained by a modification of the method of Husain *et al.* (23), by converting 4-aminosalicylic acid into the corresponding diazonium salt and reaction with sodium azide. The corresponding *N*-hydroxysuccinimido ester **1** was prepared in an 85% yield, by reaction of the azido

[1]Revision received June 2, 1987.

[2]The abbreviations used are: DCC, *N,N'*-dicyclohexylcarbodiimide; DCU, *N,N'*-dicyclohexylurea; DMF, *N,N*-dimethylformamide; DMSO, dimethylsulfoxide; TEA, triethylamine; THF, tetrahydrofuran; Su, succinimidyl; m, multiplet; d, doublet; s, singlet; SDS-PAGE, sodium dodecylsulfate-polyacrylamide gel electrophoresis; PHA, phytohemagglutinin from *Phaseolus vulgaris*.

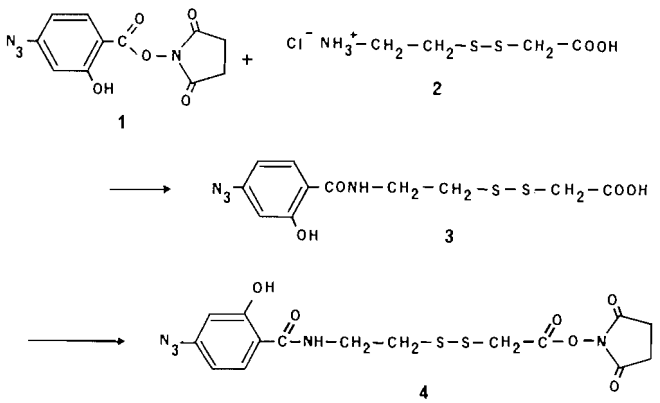

FIG. 1. Outline of the various synthetic steps used to prepare the heterobifunctional reagent **4** described in this study. Active ester **1** was allowed to react with amino acid **2** in the presence of 2 equivalents of triethylamine. Compound **3** was then converted into **4** by reaction with *N*-hydroxysuccinimide in the presence of DCC.

acid with *N*-hydroxysuccinimide in the presence of DCC according to Anderson *et al.* (24). Numerous published procedures were investigated to prepare asymmetrical disulfide **2**. For instance, controlled oxidation of a mixture (various molar ratios) of cysteamine hydrochloride and 2-mercaptoacetic acid, using H_2O_2 (25) or CNBr (26), gave **2** with poor yields. Similarly, attempts at disulfide exchange between cystamine dihydrochloride and 2-mercaptoacetic acid, in refluxing ethanol, met with little success. However, the procedure described by Schöberl and Gräfje (27), who used controlled oxidation of cystamine dihydrochloride with perbenzoic acid to the corresponding thiosulfinate, and reaction with 2-mercaptoacetic acid, proved to be satisfactory. Compound **2** was obtained after chromatographic purification, in a 45% yield, using *m*-chloroperbenzoic acid as oxidant.

Compound **3** was obtained as crystals and with a yield of 63%, by reaction of active ester **1** with asymmetrical disulfide **2**, in the presence of two equivalents of triethylamine. It was found necessary to use an aqueous DMF milieu to keep the amino component in solution. Compound **3** was easily converted into active ester **4** using the conditions described by Anderson *et al.* (24). Heterobifunctional reagent **4** was crystalline and obtained in a 71% yield. The desired product had the characteristics expected for a homogeneous product.

The ultraviolet spectrum of compound **4** is shown in Fig. 2. When aryl azido compound **4** was irradiated, a time-dependent change in its spectrum was observed. The decrease in optical density was interpreted as evidence for light-induced decomposition of **4**. Aryl azido compounds are known to decompose under light irradiation, initially giving nitrene species, followed by further reactions (2). Spectral recordings shown in Fig. 2 demonstrated that compound **4** behaves in a similar manner as other aryl azido compounds, namely, the reagents described by Ji and co-workers (28, 29), Chong and Hodges (30), Jaffé *et al.* (15), and by Dupuis and Radwan (31).

Ji and Ji (21) previously reported that salicylazido compounds can be iodinated by the procedure of Bolton and Hunter (22) if the conditions of reaction are carefully controlled. Using an organic solvent and a short time of reaction, these authors demonstrated that iodine-125 could be introduced on the aromatic ring without appreciable hydrolysis of the oxysuccinimidyl ester. This procedure was used to introduce [^{125}I]-labeling into compound **4**. Aryl azido compound **4**

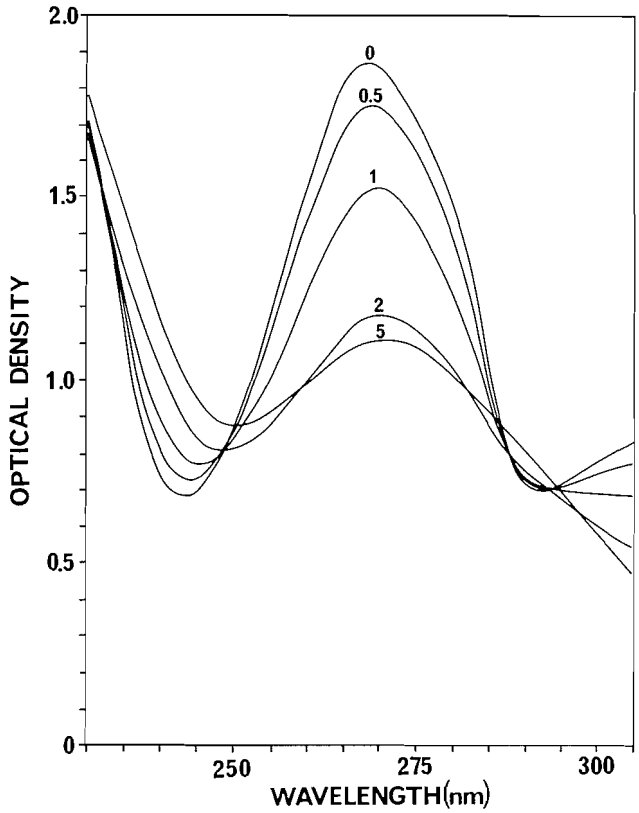

FIG. 2. Light-induced photodecomposition of cross-linking reagent **4**. The reagent was in an ethanolic solution and was irradiated for various periods of time (in minutes, as indicated) with an ultraviolet lamp as previously described (31).

was treated with one equivalent of chloramine T and Na[^{125}I] in acetone for 5–6 min at room temperature. Chloramine T/compound **4** molar ratios higher than unity led to labelled compounds that migrated in system III as multiple spots (autoradiography) with a main component of R_f^{III} 0.8, along with another spot of R_f^{III} 0.6. The fast moving compounds were thought to result from self-iodination of chloramine T. This interpretation was confirmed by allowing Na[^{125}I] to react with chloramine T under conditions described for labeling compound **4**. Chromatographic analyses (tlc) revealed (autoradiography) a profile of labeled products identical to the fast moving compounds (data not shown). Iodogen (32) behaved in a manner similar to chloramine T. The desired labeled compound **4** was freed of impurities resulting from self-iodination of chloramine T by purification on a silicic acid column. This procedure, however, did not resolve labeled and unlabeled reagents. Both compounds migrated on tlc plates at the same position as evidenced by a phenol-positive and light-sensitive spot that was superimposed on an intense radioactive spot (autoradiogram).

The use of compound **4** was investigated with a model protein. Phytohemagglutinin (PHA) from *Phaseolus vulgaris*, a tetrameric protein composed of noncovalently associated subunits (33), was allowed to react with the mixture of labeled and unlabeled heterobifunctional reagents under conditions similar to those described by Bolton and Hunter. It was found that the degree of PHA labeling was dependent on the concentration of lectin used. For instance, when the reaction was carried out at a 8 μM concentration (1 mg/mL) of PHA, the modified lectin had an activity of 3×10^5 cpm/mg.

For personal use only.

However, when the concentration of lectin was increased by a factor of five and two treatments with the mixture of reagents were done, the protein had an activity of 7×10^5 cpm/mg. SDS-PAGE analysis of the labeled protein showed the presence of a unique protein band of M_r 29 800 ± 1 500 daltons (data not shown). This value is in agreement with results reported for the PHA subunits (33). When the modified lectin was irradiated and the products were analyzed by SDS-PAGE, the autoradiograms (data not shown) revealed the presence of bands corresponding to PHA monomer (28 000 ± 2 000), dimer (64 000 ± 4 300), trimer (80 000 ± 5 400), and faint bands that remained on top of the gel and that probably were multimeric subunits (31).

Because the reagent described in this report possesses the essential feature of being cleavable by reduction, a number of reducing compounds were evaluated for their ability to break its disulfide bond. Whereas the heterobifunctional reagent, in methanolic solution, could be easily reduced (20 min treatment) by treatment with sodium borohydride, it was only partially reduced by Cleland's reagent (DL-dithiothreitol, DTT) or by 2-mercaptoacetic acid but was not cleaved by reaction with 2-mercaptoethanol. Efficiency of reduction was evaluated by tlc in system II. However, when the reagent was covalently bound to PHA, only DTT and 2-mercaptoethanol proved to be effective to reduce the cross-linker disulfide bond, as evidenced by electrophoresis.

Conclusion

The heterobifunctional cross-linker described in this study is easy to synthesize and can be readily [^{125}I]-labeled and freed of unwanted side products by a simple chromatographic procedure. The method of disulfide bond formation described here should be of general applicability for synthesis of either symmetrical or asymmetrical heterobifunctional reagents, varying in the length of the spacer. It can be argued that although disulfide-containing compounds are prone to sulfur exchange, they can be used with sulfhydryl or disulfide-containing proteins, under controlled conditions of pH (13, 34–36). Preliminary experiments suggest that reagent **4** is of general applicability for the study of peptide hormone-receptor (Dupuis and Lehoux, unpublished).

Experimental

Chemicals were obtained from Sigma Chemical Co. (St Louis, MO), Aldrich Chemical Co. (Milwaukee, WI), from Fisher Scientific Co., or from Canlab (Montreal). [^{125}I]-iodine was from Amersham (Oakville, Ontario). Petroleum ether was the fraction boiling at 55–110°C. All evaporations were performed under reduced pressure at 40–45°C, with a rotary evaporator. Melting points were determined in capillary tubes on a Tottoli apparatus and are not corrected. Elemental analyses were determined by Galbraith Laboratories (Knoxville, TN). The ^{1}Hmr spectra were recorded on a Varian T-60 spectrometer. Chemical shifts are presented in parts per million (δ) with reference to tetramethylsilane as an internal standard. Infrared (ir) spectra were determined with a Perkin–Elmer spectrometer, model 457. Ultraviolet spectra were recorded with a Perkin–Elmer Lambda 5 instrument.

Analytical thin-layer chromatographic (tlc) analyses were performed on 0.5 mm thick silica gel G (Sigma) plates and compounds were revealed by spraying with the Ellman reagent (37), ninhydrin (38), diazotized *p*-nitroaniline followed by sodium hydroxide (39), or by exposure to ultraviolet radiation. The following chromatographic systems were used: system I, 1-butanol – acetic acid – water (3:1:1); system II, benzene–chloroform – ethyl acetate – acetic acid (1:1:1:0.1), and system III, toluene–chloroform – ethyl acetate – acetic acid (1:1:1:0.1). Currix RP1 X-ray films (Agfa–Gevaert, Belgium) were used for autoradiographies.

Synthesis of compounds

Reactions involving aryl azido compounds were carried out under dim incandescent light.

4-Azidosalicylic acid

This compound was prepared by modification of a described procedure (23). 4-Aminosalicylic acid (20.6 g; 0.15 mol) was dissolved in concentrated H_2SO_4 (50 mL) and the solution added slowly to ice-cold water (300 mL). To the ice-cold suspension was added an aqueous solution (125 mL) of sodium nitrite (13.0 g; 0.18 mol), portionwise, over a period of 20 min. Crystalline urea was added to decompose excess nitrous acid, the solution was transferred to a 4-L beaker, and an aqueous solution (100 mL) of sodium azide (20.0 g; 0.18 mol) was slowly added at 0°C. After evolution of nitrogen ceased, the suspension was further stirred for 20 min at 0°C, in the dark. The azido compound was collected by filtration, washed with ice-cold water, and crystallized from aqueous ethanol. Yield, 16.0 g (67%); mp 197°C (dec.) (lit. (23) mp 193–195°C).

*Succinimido 4-azidosalicylate (**1**)*

4-Azidosalicylic acid (3.6 g; 0.020 mol) was dissolved in CH_2Cl_2 (50 mL) and DMF (50 mL) and *N*-hydrosuccinimide (2.5 g; 0.022 mol), recrystallized from ethyl acetate, was added. The solution was cooled in an ice bath and DCC (4.2 g; 0.020 mol) in DMF (10 mL) was added. The reaction was stirred overnight at 4°C and DCU was removed by filtration. Evaporation afforded a solid that crystallized from ethyl acetate – petroleum ether. Yield, 4.7 g (85%); mp 160–161°C; R_f^{II}, 0.7; ^{1}Hmr ($CDCl_3$/DMSO-d_6): 2.87s (4H, succinimidyl protons), 6.67m and 7.83d (3H, aromatic protons). *Anal.* calcd. for $C_{11}H_8N_4O_5$ (276.2): C 47.83, H 2.92, N 20.29; found: C 47.74, H 3.12, N 20.28.

*1-Amino-3,4-dithio-5-carboxylic acid (**2**)*

This compound was prepared by modification of a described procedure (27). Cystamine dihydrochloride (11.3 g; 0.050 mol) was dissolved in absolute methanol (500 mL), the solution cooled at 4°C, and a chloroform solution (150 mL) of 3-chloroperbenzoic acid (10 g; 0.058 mol) was added dropwise, at 4°C. The reaction was further stirred in the cold room overnight and for 2 additional hours at room temperature. The mixture was evaporated, treated with ether, and the solid was suspended in absolute methanol (300 mL). Freshly distilled 2-mercaptoacetic acid (9.2 g; 0.05 mol) in methanol (50 mL) was added, and the reaction was allowed to proceed, under stirring, for 2 h at room temperature. Evaporation gave an oil that was triturated with ether and crystals were obtained from ethanol–ether. These crystals were unreacted cystamine dihydrochloride (^{1}Hmr, tlc). The oily filtrate was evaporated on silica gel G 60 (Merck) and dried in a desiccator overnight. The solid was poured into a Mitchel–Miller column (Ace Glass, Vineland, NJ) (3 × 30 cm) containing silica gel G 60 and eluted with chloroform (400 mL), ethyl acetate (400 mL), and with 5% (500 mL), 10% (500 mL), and 25% methanol (1000 mL) in ethyl acetate. Compound **2** was located (tlc) in the 25% methanol eluates. Crystals were obtained from methanol – ethyl acetate. Yield, 4.6 g (45%); R_f^I, 0.5. Compound **2** was slightly contaminated with cystamine dihydrochloride (R_f^1, 0.1) and no satisfactory elemental analysis could be obtained; ^{1}Hmr ($CDCl_3$/DMSO-d_6): 3.10m (4H, —CH_2—CH_2—S) and 3.30s (2H, S—CH_2—COOH).

*N-(4-Azidosalicyloyl)-1-amino-3,4-dithio-5-carboxylic acid (**3**)*

Disulfide **2** (3.0 g; 14.6 mmol) was dissolved in 50% aqueous DMF (50 mL) and the solution cooled in an ice bath. The pH was adjusted to 7–8 (wet pHydrion paper) by addition of TEA. Active ester **1** in DMF (40 mL) was then added and the solution was stirred at room temperature while pH was maintained at 7–8 by addition of TEA. After 16 h, the mixture was evaporated and distributed between ethyl acetate and 1 *M* citric acid. The organic phase was washed with 1 *M* citric acid, water, dried, and evaporated. The solid crystallized from ether – petroleum ether or from aqueous methanol. Yield, 3.0 g (63%); mp 99–101°C; R_f^{II}, 0.6; ^{1}Hmr ($CDCl_3$/DMSO-d_6): 3.00m (2H, CH_2—COOH), 3.3m (4H, NH—CH_2—CH_2), 6.50m and 7.80d (3H, aromatic protons). *Anal.* calcd. for $C_{11}H_{12}N_4O_4S_2$ (328.4):

C 40.23, H 3.68, N 17.06, S 19.53; found: C 40.72, H 3.95, N 17.15, S 19.15.

Succinimido 1-amino-(4-azidosalicyloyl)-3,4-dithio-5-carboxylate (4)

Compound **3** (984 mg; 3.0 mmol) was dissolved in THF (10 mL), *N*-hydroxysuccinimide (380 mg; 3.3 mmol) was added, and the solution cooled in an ice bath. DCC (618 mg; 3.0 mmol) in THF (3 mL) was added and the mixture stirred for 30 min at 4°C and overnight at room temperature. DCU was filtered and the filtrate evaporated. Evaporation from petroleum ether afforded a solid that crystallized from ethyl acetate – petroleum ether. The molar extinction coefficient was 16 000, when measured in absolute ethanol at 271 nm. Yield, 0.9 g (74%); mp 137–138°C; R_f^{II}, 0.6; R_f^{III}, 0.6; ir (Nujol): 2100 (-N_3), 1730 (-*CO*—N-oxysuccinimidyl) and 1635 (-*CO*—NH) cm^{-1}; ^{1}Hmr ($CDCl_3$/DMSO-d_6): 2.87s (4H, succinimido protons), 3.10m (4H, NH—CH_2—CH_2), 3.83s (2H, CH_2—COOH), 6.50m and 7.77d (3H, aromatic protons). *Anal.* calcd. for $C_{15}H_{15}N_5O_6S_2$ (425.4): C 42.34, H 3.55, N 16.46, S 15.07; found: C 42.78, H 3.78, N 16.12, S 14.95.

[^{125}I]-labeling of compound 4

Compound **4** (11 mg; 25 μmol) was dissolved in acetone (1 mL) and 5 μL (500 μCi) of carrier-free Na[^{125}I] neutralized with 0.01 *M* HCl (5 μL) was added. A 50% aqueous solution of chloramine T (7 mg; 25 μmol) in acetone (1 mL) was added in one portion and the reaction was allowed to proceed for 6 min. The reaction mixture was added onto a dry column (1 × 25 cm) of silica gel G 60 and elution was done by percolating solvent mixture III. Fractions were collected automatically. Under these conditions, the desired compound was freed of Na[^{125}I] that was retarded and from iodinated side products that move ahead of labelled compound **4**. Radioactive **4** was obtained by pooling and evaporating (nitrogen stream) the appropriate fractions (tlc, system III). It had an R_f value of 0.6 in system III. The labeled reagent was kept in acetone at −20°C. Under these conditions, the reagent was stable for several weeks.

Derivation of phytohemagglutinin and photolysis

Purified (33) PHA (1 mg; 7.7 μmol) in 0.1 *M* sodium borate buffer, pH 8.3 (200 μL), was added to a tube (0.5 mL) containing the mixture of [^{125}I]-labeled and unlabeled compounds **4** (30×10^6 cpm) deposited on the walls of the flask by evaporation (stream of nitrogen) of an acetone solution. The mixture was stirred for 15 min at room temperature and then allowed to react for 15 min with a second portion of labeled reagent. The reaction mixture was diluted with 0.1 *M* phosphate buffer, pH 6.6 (700 μL), dialyzed against water (200 mL) containing 10 g of mixed-bed resin RG501-X8 (Bio-Rad) for 60 min at room temperature. The suspension was cleared by centrifugation. The modified lectin was irradiated for 15 min with an ultraviolet lamp (Black-Ray lamp, Ultra-Violet Products Inc., San Gabriel, CA) placed at 10 cm from the samples that were cooled with a stream of air. SDS-PAGE analysis was done as before (31).

The gas phase ion chemistry and proton affinity of hexamethyldisiloxane studied by high pressure mass spectrometry

XIAOPING LI AND JOHN ALFRED STONE
Chemistry Department, Queen's University, Kingston, Ont., Canada K7L 3N6

Received January 27, 1987

XIAOPING LI and JOHN ALFRED STONE. Can. J. Chem. **65**, 2454 (1987).

The ion chemistry of hexamethyldisiloxane ($(CH_3)_3SiOSi(CH_3)_3$, HMDS) has been studied under chemical ionization conditions at ion source temperatures of 300–600 K and pressures of 2–4 Torr. Highly exothermic proton transfer to HMDS from CH_5^+ and $C_2H_5^+$ leads mainly to loss of CH_3 but with decreasing exothermicity the yield of $HMDSH^+$ increases such that transfer from t-$C_4H_9^+$ ($\Delta H^0 = -7.5$ kcal mol^{-1}) yields almost exclusively $HMDSH^+$. Although $HMDSH^+$ transfers $(CH_3)_3Si^+$ rather than a proton to most reference bases, the proton affinity of HMDS has been determined from van't Hoff plots using the equilibrium method with methylaromatics as reference bases. PA(HMDS) = 203.4 kcal mol^{-1} is in excellent accord with an earlier estimate of 203 kcal mol^{-1} obtained by the bracketing method. The rate constants for these proton transfer reactions show very large negative temperature coefficients in the exothermic directions which are consistent with the reactions of charge delocalized ions and/or reactions in which considerable loss of rotational freedom occurs along the reaction coordinate. The rate constants in the reverse directions have a positive temperature coefficient only when the endothermicity is significant (>2.5 kcal mol^{-1}).

XIAOPING LI et JOHN ALFRED STONE. Can. J. Chem. **65**, 2454 (1987).

Opérant dans des conditions d'ionisation chimique, à des températures de la source ionique allant de 300 à 600 K et à des pressions de 2 à 4 Torr, on a étudié la chimie ionique de l'hexaméthyldisiloxane ($(CH_3)_3SiOSi(CH_3)_3$, HMDS). Les transferts de proton des cations CH_5^+ et $C_2H_5^+$ au HMDS sont très exothermiques et ils conduisent principalement à une perte de CH_3; toutefois, lorsque l'exothermicité diminue, le rendement en $HMDSH^+$ augmente d'une façon telle que le transfert du t-$C_4H_9^+$ ($\Delta H^0 = -7{,}5$ kcal mol^{-1}) conduit presqu'exclusivement au $HMDSH^+$. Pour la plupart des bases de référence, le $HMDSH^+$ transfère du $(CH_3)_3Si^+$ plutôt qu'un proton; malgré ce fait, on a déterminé l'affinité protonique du HMDS à partir des courbes de van't Hoff et en utilisant la méthode des équilibres des produits méthylaromatiques avec les bases de référence. La valeur de PA(HMDS) = 203,4 kcal mol^{-1} est en excellent accord avec une évaluation antérieure de 203 kcal mol^{-1} obtenue à l'aide de la méthode du "bracketing". Les constantes de vitesse pour ces réactions de transfert de proton présentent d'importants coefficients négatifs de température dans les directions exothermiques et ceux-ci sont en accord avec les réactions d'ions possédant des charges délocalisées et/ou des réactions dans lesquelles il se produit une importante perte de liberté rotationnelle le long des coordonnées de la réaction. Dans la direction inverse, les constantes de vitesse ne possèdent un coefficient de température positif que lorsque l'endothermicité est importante (>2,5 kcal mol^{-1}).

Introduction

There is a considerable body of qualitative information on the mass spectrometry and ion chemistry of silicon-containing compounds since derivatization of functional groups using silicon-containing reagents is a common method of increasing the volatility of compounds for gas chromatography/mass spectrometric analysis. In spite of this, quantitative thermochemical information on silicon-containing ions and indeed on organosilicon molecules is rudimentary to say the least. Even gas phase proton affinity values which are well established for organic molecules and an increasing number of organometallics, are almost non-existent for organosilicons.

Proton affinity measurements usually are most reliable when obtained by gas phase equilibrium methods, but such methods are often impossible with silicon compounds which, when protonated, show a propensity to engage in reactions competitive with proton transfer, usually the donation of a silicon-containing group. For this reason an early ion cyclotron resonance (ICR) study of proton transfer between trimethylsilyl-containing ethers and organic ethers used the double resonance technique to establish the preferred direction of proton transfer (1). Hexamethyldisiloxane (HMDS, $(CH_3)_3SiOSi(CH_3)_3$) was one of the compounds studied and, based on the results obtained, HMDS has subsequently been assigned a proton affinity (PA) of ~203 kcal mol^{-1} in a compendium of evaluated proton affinities (2).

The tendency for transfer of a silicon-containing group rather than the proton has been used to obtain both relative $(CH_3)_3Si^+$ affinities using ICR (3) and also absolute binding energies by the equilibrium method in a pulsed electron beam, high pressure ion source mass spectrometer (HPMS) (4). An interesting observation in the latter study was that the binding energies of $(CH_3)_3Si^+$ to aromatic hydrocarbons is considerably lower than that to bases such as aliphatic alcohols, esters, and ethers. Indeed, the $(CH_3)_3Si^+$ adducts of alcohols were found to transfer a proton rather than $(CH_3)_3Si^+$ to an aromatic. For example it was found that reaction [1a] rather than [1b] occurs between the $(CH_3)_3Si^+$ adduct of methanol and mesitylene.

$$[1a] \quad (CH_3)_3SiO(H)CH_3^+ + C_9H_{12} \longrightarrow (CH_3)_3SiOCH_3 + C_9H_{13}^+$$

$$[1b] \quad \not\longrightarrow (CH_3)_3SiC_9H_{12}^+ + CH_3OH$$

This suggested that it might be possible to set up proton transfer equilibria between aromatic hydrocarbons and silicon compounds of suitable proton affinities. This paper reports on such an experiment in which PA(HMDS) is determined. HMDS was chosen for this initial study for several reasons. It was one of the compounds in the original study (1) which has an estimated proton affinity in the range of readily available and suitably volatile methylaromatics. HMDS is also a very stable material which may be readily handled in our heated inlet system.

It was important initially to examine the ion chemistry of HMDS under high pressure ion source conditions to ascertain the optimal experimental parameters that will maximize proton transfer and minimize any competing reactions that might

TABLE 1. Fractional abundances of the major ions in the CI spectra of HMDS with different reagent gases

Reagent gas	Reagent ions	P (Torr)	T (K)	m/z 147	149	163	191	221	309
CH_4	CH_5^+, $C_2H_5^+$	4.1	591	0.386	0.213	0.176	0.010	0.224	0

detract from and perhaps negate proton affinity determinations by the equilibrium method.

Experimental

The pulsed electron beam, high pressure ion source mass spectrometer (HPMS) has been described previously (5).

Methane (Matheson 99.99%), ethane (Phillips Research Grade), and isobutane (Matheson 99.5%) were used as received. HMDS (Aldrich Chemical Co., Inc.) which had a stated purity of 98% + was also used as received; no peaks ascribable to impurities in this material were ever observed. The aromatic hydrocarbons 1,3-dimethylbenzene (DMB), 1,3,5-trimethylbenzene (MES), and 1,2,3,5-tetramethylbenzene (TMB) (Aldrich Chemical Co., Inc.) were of the highest purity available.

Gaseous samples, which were made up in a heated glass reservoir of 5 L volume, contained a reagent gas at ~700 Torr (1 Torr = 133.3 Pa) together with 0.05 mol% sulfurhexafluoride as an electron capture reagent, and a maximum of 0.1 mol% HMDS and/or any other reactants. In most experiments the reagent gas was a 9/1 methane/isobutane mixture. The choice of reagent gas did not affect the thermodynamic data obtained but the mixed reagent gas gave cleaner spectra and greater sensitivity. The gaseous sample was flowed into the ion source via a heated metering valve to give pressures in the range 2–4 Torr. Ion source temperatures were from 300 to 600 K.

Results and discussion

The chemical ionization (CI) mass spectra of HMDS

The CI spectra were very dependent on the reagent gas used and the ion source temperature. Typical spectra with methane and methane/10% isobutane as reagent gases are shown in Fig. 1 while Table 1 summarizes the major ions and their relative intensities obtained with several reagent gases and gas mixtures under a variety of ion source conditions.

Under methane CI conditions the reagent ions CH_5^+ and $C_2H_5^+$ appear to react with HMDS mainly by proton transfer to initially yield $HMDSH^+$ (m/z 163). A very small peak at m/z 191 containing two silicon atoms is probably the $C_2H_5^+$ adduct, $((CH_3)_2Si)_2OC_2H_5^+$). $HMDSH^+$ is never the major observable product, at high temperature m/z 147 dominates while at low temperature m/z 309 is the major product. The latter ion is completely absent at 582 K suggesting that it is possibly an ion–neutral association complex.

The normalized ion intensities plotted as functions of ion source residence times in Figs. 2 and 3 show that the major ion

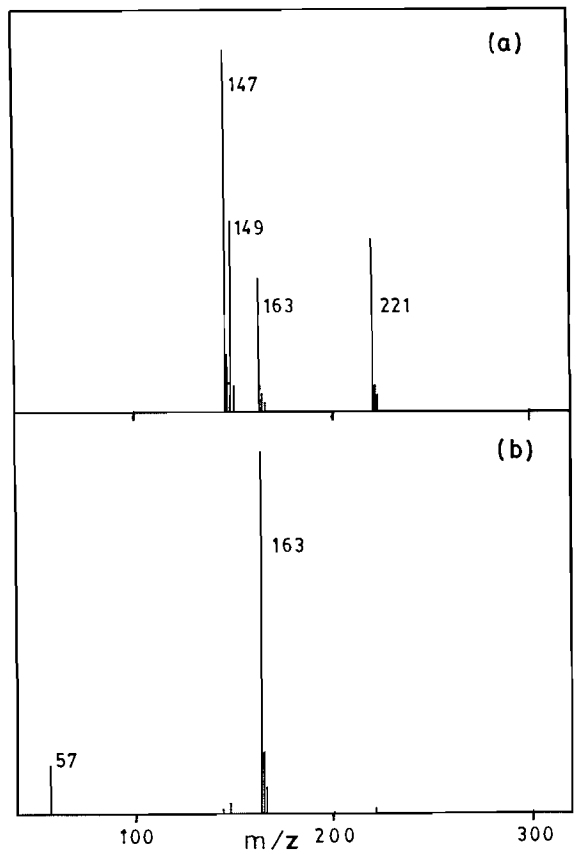

FIG. 1. Mass spectra: (*a*) CH_4/SF_6/HMDS (99.9/0.04/0.03) 4.1 Torr, 591 K; (*b*) CH_4/i-C_4H_{10}/SF_6/HMDS (85.4/14.6/0.04/0.03), 4.2 Torr, 593 K.

at short times, m/z 147, is very reactive. At 543 K (Fig. 2) it decays rapidly ($k \sim 3 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}) by reaction with HMDS to give m/z 221 and 149. m/z 309 also appears at short reaction time at this temperature and decays in parallel with m/z 147 after a very short time. This latter behaviour is independent of sample pressure in the temperature range 450–550 K. At lower temperatures when m/z 309 is the dominant ion at long reaction times the constant ratio of yields

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

of m/z 147 and 309 still exists, suggesting that they are in equilibrium (Fig. 3). Taking into account the number of silicon atoms in each ion as determined from the isotopic patterns then a plausible reaction scheme with CH_5^+ as protonating agent is:

[2] $(CH_3)_3SiOSi(CH_3)_3 + CH_5^+ \rightarrow [(CH_3)_3SiO(H)Si(CH_3)_3]^{+*} + CH_4$

[3a] $[(CH_3)_3SiO(H)Si(CH_3)_3]^{+*} \xrightarrow{M} (CH_3)_3SiO(H)Si(CH_3)_3^+$ (m/z 163)

[3b] $\rightarrow (CH_3)_3SiOSi(CH_3)_2^+ + CH_4$ (m/z 147)

[4] m/z 147 + $(CH_3)_3SiOSi(CH_3)_3 \rightarrow (CH_3)_3SiOSi(CH_3)_3 \cdot (CH_3)_3SiOSi(CH_3)_2^+$ (m/z 309)

[5] m/z 309 $\rightarrow$  + $(CH_3)_4Si$ (m/z 221)

Ion m/z 149 appears to be formed by the reaction of m/z 147 with adventitious water since the addition of extra water results in a significant increase in its yield. Ion m/z 149 is found as a prominent ion in the electron impact mass spectra of bistrimethylsilyl ethers ($(CH_3)_3SiO(CH_2)_nOSi(CH_3)_3$) (6). It was suggested that it arises by loss of methane from m/z 165, a common rearrangement ion in the spectra of these silyl ethers

[6] (m/z 165) (m/z 149)

Ion m/z 165 was not observed in any HMDS CI spectra which implies that the hydration of m/z 147 is sufficiently exothermic that the resulting m/z 165 has only a transitory existence.

The yields of $HMDSH^+$ (m/z 163) and $HMDS \cdot C_2H_5^+$ (m/z 191) are seen in Figs. 2 and 3 to change little with time, i.e. these ions are very unreactive towards HMDS.

Methane is obviously an unsatisfactory reagent gas for the preparation of $HMDSH^+$ in reasonable yield and in CI spectra not complicated by other silicon-containing ions. Since this behavior is presumably due to the high exothermicity of proton transfer (reaction [2]) the effect of reaction exothermicity on the decomposition of $HMDSH^+$ was studied by using mixed reagent gases. In methane/ethane mixtures the reagent ions are mainly $C_2H_5^+$, $C_3H_5^+$, and $C_3H_7^+$ while in methane/isobutane mixtures t-$C_4H_9^+$ is the only reagent ion. The results are summarized in Table 1.

The exothermicity of proton transfer may be calculated using PA(HMDS) = 203.4 kcal mol^{-1} obtained as described later. The values obtained for the different reagent ions are given in Table 2. Decomposition of the initially formed $HMDSH^+$ decreases with decreasing reaction exothermicity to such an extent that protonation by t-$C_4H_9^+$ at 4 Torr and 400 K leads exclusively to stabilized $HMDSH^+$. Even at 593 K only ~6% of the $HMDSH^+$ reacts further. A 9/1 methane/isobutane mixture was used in most of the subsequently described experiments.

Attempts to determine PA(HMDS) by studying proton transfer under equilibrium conditions with methane/isobutane mixtures and bases such as ethers, alcohols, and ketones were frustrated, as expected, by the preferred transfer of $(CH_3)_3Si^+$ rather than a proton. For example, diethyl ether formed $(C_2H_5)_2OSi(CH_3)_3^+$ rather than $(C_2H_5)_2OH^+$. However, proton transfer equilibrium measurements using HMDS and aromatic hydrocarbons were successfully accomplished.

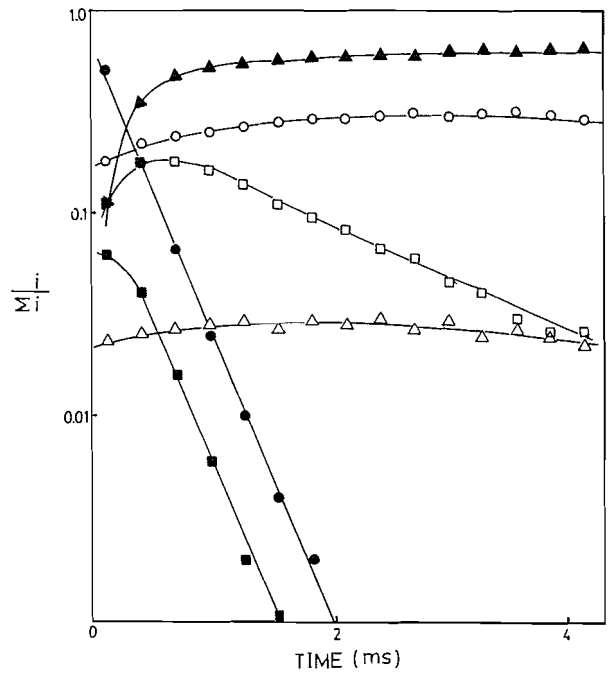

FIG. 2. Normalized ion intensities as functions of time after a 50 μs pulse of ionizing electrons for a mixture of CH_4/SF_6/HMDS 99.9/0.07/0.07 at 4.1 Torr and 543 K. ● $(CH_3)_5Si_2^+$ (m/z 147), ■ $(CH_3)_{11}Si_4O_2^+$ (m/z 309), ▲ $(CH_3)_7Si_3O_2^+$ (m/z 221), ○ $(CH_3)_6Si_2OH^+$ ($HMDSH^+$, m/z 163), □ $(CH_3)_4Si_2O_2H^+$ (m/z 149), △ $(CH_3)_6Si_2OC_2H_5^+$ (m/z 191).

Figure 4a shows the normalized yields of $HMDSH^+$ and $MESH^+$ in a HMDS/MES/CH_4/i-C_4H_{10} mixture after a 50 μs pulse of ionizing electrons. The constant ion currents after long reaction time, i_{HMDSH^+} and i_{MESH^+}, suggest that the following equilibrium has been attained.

[7] $MESH^+ + HMDS \rightleftharpoons MES + HMDSH^+$

That this was so was confirmed in the usual manner by showing that the variation of the concentration ratio of the neutrals [MES]/[HMDS] and ion source pressure had no effect on the computed equilibrium constant K.

[8] $$K = \frac{i_{HMDSH^+}}{i_{MESH^+}} \cdot \frac{[MES]}{[HMDS]}$$

K was measured over the temperature range 330–600 K; the results are shown in the van't Hoff plot of Fig. 5. Plots for reactions [9], [10], and [11] are also shown.

[9] $DMBH^+ + HMDS \rightleftharpoons DMB + HMDSH^+$

[10] $TMBH^+ + HMDS \rightleftharpoons TMB + HMDSH^+$

[11] $DMBH^+ + MES \rightleftharpoons DMB + MESH^+$

The thermodynamic data obtained from these plots which are shown in Table 3 are internally self consistent within the experimental error limits shown. The uncertainty in the ΔH^0 values is better than ±10% in all cases. This translates into a

$C_2H_5^+$	162.6	40.8
$C_3H_7^+$	179.5	23.9
$C_3H_5^+$	186.3	17.1
t-$C_4H_9^+$	195.9	7.5

[a]All proton affinity values are from ref. 2.
[b]PA(HMDS) = 203.4 kcal mol^{-1}, this work.

small uncertainty ($< \pm 0.2$ kcal mol^{-1}) when ΔH^0 is small but ± 0.3 kcal mol^{-1} for the two largest ΔH^0 values. In determining PA(HMDS), more weight is therefore placed on the small ΔH^0 values.

We have recently determined PA(MES) to be 201.0 ± 0.2 kcal mol^{-1} using ethylacetate (PA 200.7 kcal mol^{-1}) as reference (7). This value of PA(MES) compares well with the 200.7 kcal mol^{-1} in a table of evaluated proton affinities (2). This latter value, however, is obtained from the mean of two gas phase basicity values which differ by 2 kcal mol^{-1}. An ICR proton affinity value obtained at ~320 K is 199.7 kcal mol^{-1} (8) while an HPMS value obtained at ~520 K is 201.7 kcal mol^{-1} (9), in both cases a calculated entropy change based only on symmetry numbers was employed to obtain the proton affinity from the experimental basicity. There is a growing volume of evidence that such calculations are not valid for equilibria involving charge delocalized ions (2, 7, 10). The entropy changes in Table 2 are self consistent and are presumed

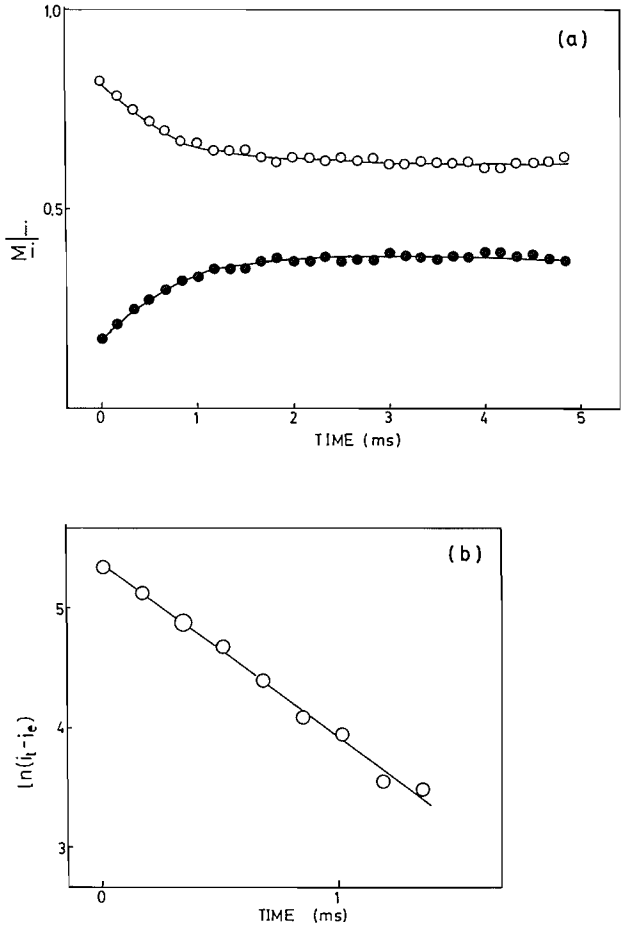

FIG. 4. (a) Normalized yields of MESH$^+$ ○ and HMDSH$^+$ ● as functions of time after a 50 μs pulse of ionizing electrons for a mixture of CH_4/i-C_4H_{10}/SF_6/MES/HMDS (91/9/0.04/0.34/0.053). (b) The kinetic plot for the approach to equilibrium in (a). The slope of the plot yields $k_{+7} + k_{-7}$. i_t and i_e are respectively the ion currents for MESH$^+$ at a time t and at equilibrium.

therefore to be reliable within the error limits given. It is noteworthy that the experimental entropy change for reaction [11] which involves two aromatic hydrocarbons differs by more than 2 cal K^{-1} mol^{-1} from the value calculated using symmetry number changes and is also of opposite sign. The calculated values for the other reactions are actually almost all in reasonable agreement with experiment, $DMBH^+$ + HMDS being the exception.

The data from Table 3 together with PA(MES) = 201.0 and PA(TMB) = 203.2 kcal mol^{-1} (7) yields PA(HMDS) = PA(MES) + 2.4 kcal mol^{-1} = 203.4 ± 0.4 kcal mol^{-1}. This value is in excellent agreement with the evaluated 203 kcal mol^{-1} (2) based on the original ICR result obtained from bracketing data viz. gas phase basicity, GB($(i$-$C_3H_7)_2O$) > GB(HMDS) > GB($(C_2H_5)_2O$). We could not confirm this ranking using HPMS because of the aforementioned problems with $(CH_3)_3Si^+$ transfer. Relative to MES, PA(DMB) is 194.9 ± 0.5 kcal mol^{-1}, a little lower than the evaluated value of 195.9 kcal mol^{-1} (2). The latter result is from an ICR determination at ~320 K and using calculated entropies (8).

An observation of significance in the ICR work (1) was that PA($((CH_3)_3C)_2O$) > PA(HMDS). Failure to observe proton transfer in the reverse direction i.e. from $HMDSH^+$ to $((CH_3)_3C)_2O$ was ascribed to a very slow reaction rate. Since no $((CH_3)_3C)_2O$ was available we attempted to prepare $((CH_3)_3C)_2OH^+$ by

reaction [12] with *i*-C_4H_{10} as the source of $(CH_3)_3C^+$.

[12] $(CH_3)_3C^+ + (CH_3)_3COH \rightleftharpoons (CH_3)_3CO(H)C(CH_3)_3^+$ (m/z 123)

No m/z 123 was observed even at 300 K, indicating a very weak (<15 kcal mol^{-1}) binding of cation and alcohol. It is therefore somewhat surprising that m/z 123 could be formed at low pressure under ICR conditions for the bracketing studies. The above ordering of the basicity values as determined by ICR is consistent with our observation that substitution of Si for C in $(CH_3)_3COH$ leads to a lowering of proton affinity in $(CH_3)_3SiOH$ (11).

The kinetics of proton transfer

The rate constants for both forward and reverse directions of reactions [7], [9], and [11] are readily determined by the methods which have been described previously in detail (7). Two methods may be used. The first involves treating the approach to equilibrium in the proton transfer reaction as a pseudo first order reversible reaction (12). Normalized data for reaction [7] are shown in Fig. 4(*a*) while in 4(*b*) is the appropriate kinetic plot which yields $(k_{+7} + k_{-7})$. Since the measured equilibrium constant $K = k_{+7}/k_{-7}$ the individual rate constants may be obtained. The rate constant in the forward direction may also be measured in the more usual manner by plotting log $(i/\Sigma i)$ vs. time, where the normalized ion current is that for the protonated species which decreases in intensity with time to attain equilibrium. Only the first few experimental points at low reaction time are used in such an analysis since it is only then that the reverse reaction is not significant. The results presented in Figs. 6, 7, and 8 show excellent agreement in rate constants obtained by the two methods. No kinetic data are obtainable for reaction [10] since $\Delta H^0 \sim 0$ and proton transfer equilibrium is attained during the ionizing electron pulse.

The collision rate constants k_c calculated for 300 K by the ADO theory of Su and Bowers (13) are (units 10^{-9} molecule^{-1} cm^3 s^{-1}) $MESH^+ + HMDS$, 1.4; $DMBH^+ + HMDS$, 1.4; and $DMBH^+ + MES$, 1.3. These values vary little with temperature since the molecular dipole moments are zero or very small. The experimental rate constants in the forward directions for reactions [9] and [11] are close to k_c at 300 K but decrease drastically with increase in temperature. The rate constant for reaction [7] is significantly less than k_c at 300 K and its value declines even more rapidly with increasing temperature than do those for the other two systems. These forward rate constants may be described by the equation $k = CT^n$ with $n = -6.7$, -5.9, and -3.3 for k_7, k_{11}, and k_9, respectively. These are very large negative temperature coefficients, comparable in magnitude with some found for exothermic hydride transfer in alkanes (14). The latter work showed that in general, for the reactions involving similar ions and neutrals, the value of n becomes more negative as the reaction exothermicity decreases.

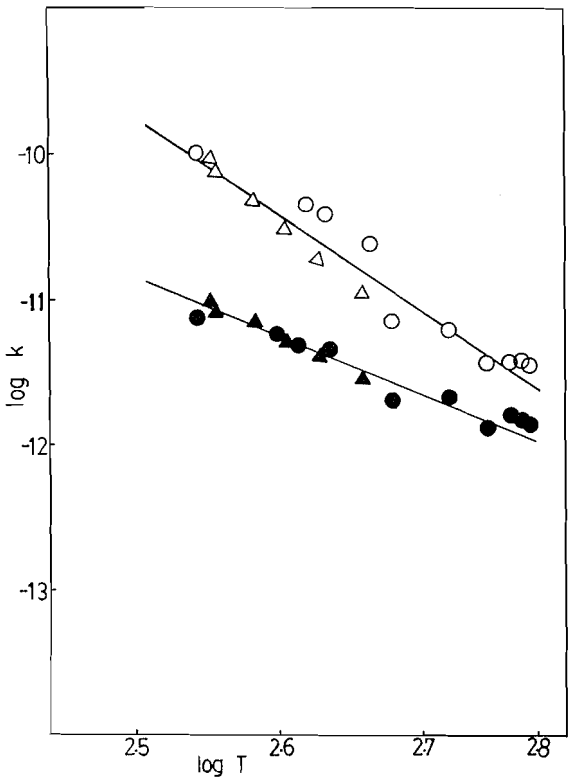

FIG. 6. The variations of the rate constants with temperature for reaction [7], $MESH^+ + HMDS \rightleftharpoons MES + HMDSH^+$. Open symbols $k_{forward}$, closed symbols $k_{reverse}$; circles, values obtained using the method illustrated in Fig. 5, triangles, values obtained from the initial slope of the decay of $MESH^+$.

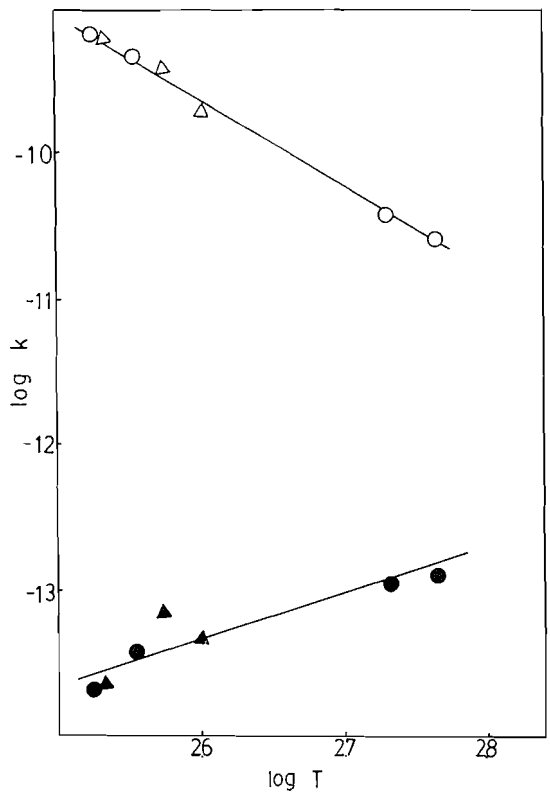

FIG. 7. The variations of the rate constants with temperature for reaction [9], $DMBH^+ + HMDS \rightleftharpoons DMB + HMDSH^+$. Upper curve $k_{forward}$, lower curve $k_{reverse}$; circles, values obtained using the method illustrated in Fig. 4, triangles, values obtained from the initial slopes of the decays of $DMBH^+$.

In like manner n for reaction [7] is more negative than n for the more exothermic reaction [9]. The value of n for reaction [11] does not fit this scheme, presumably because the neutral is MES rather than HMDS. In fact, the value is much more consistent with the lower values observed for proton transfer among aromatics where the value of n actually increases with increasing exothermicity (at least up to $\Delta H^0 \sim 5$ kcal mol^{-1}) (7). It is of significance that although each of the reactions [9] and [11] is exothermic by more than 6 kcal mol^{-1}, proton transfer is very inefficient at ~600 K.

The effect of temperature on the reverse, endothermic, proton transfer rate constants k_{-7}, k_{-9}, and k_{-11} are interesting for two reasons. In the first place two, k_{-9} and k_{-11}, have positive temperature coefficients, whereas k_{-7}, the rate constant for the least endothermic reaction has a negative temperature coefficient. Secondly the Arrhenius activation energies obtained from the temperature coefficients of k_{-9} and k_{-11}, 2.9 and 3.8 kcal mol^{-1}, respectively, are far less than the reaction endothermicities (6.1 and 8.0 kcal mol^{-1}). A similar observation was made in a study of slightly (<5 kcal mol^{-1}) endothermic proton transfer between methylbenzenes (7). For reactions such as these it is therefore not possible to obtain a measure of the reaction endothermicity from the experimental activation energy. It can be surmized from Figs. 6 and 7 that as the exothermicity of reaction involving proton transfer to HMDS from an aromatic decreases to around zero the temperature coefficients of the forward and reverse reactions will approach the same, high negative value.

Large temperature coefficients of rate constants for exothermic reactions are associated with internal barriers along the reaction coordinate, i.e., there is a maximum in the effective potential energy surface between reactants and products. The double-well theory of Farneth and Brauman (15) explains why an exothermic proton transfer reaction may be slow if the ion–molecule complex in the chemical transition state at the central barrier has a lesser density of states than it does at the centrifugal barrier for the collision. Once the collision complex (the stabilized form of which is a proton bound complex at the minimum of the first well) is formed, then return to reactants is entropically favoured. Kebarle (16) has shown that RRKM calculations do yield an appropriate negative temperature coefficient for such a model. In addition he also confirmed the validity of the suggestion of Meot-Ner (17) that an exothermic reaction may be inefficient in the forward direction if there is a considerable inhibition or even locking of external rotations on an otherwise relatively flat region of the potential energy curve along the reaction coordinate. Such would be the case when the proton is to be transferred to or from a fairly inaccessible site.

Protonated aromatics are ions in which the charge is considerably delocalized and some charge localization is probably required in the transition state at the central barrier for proton transfer (7). In addition a specific orientation of the aromatic rings will also be required implying a "tight" transition state. $HMDSH^+$ must also be a charge delocalized ion with electron transfer from Si to O as shown by its propensity to transfer $(CH_3)_3Si^+$.

HMDS has a Si—O—Si bond angle of 148 ± 3° as determined by electron diffraction in the gas phase (18) and 142.2° as determined by solid state X-ray crystallography (19). The gas phase results could be interpreted in terms of either a C_{2v} geometry or a structure with lower symmetry due to a staggering of the methyl groups. However, there are large

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12

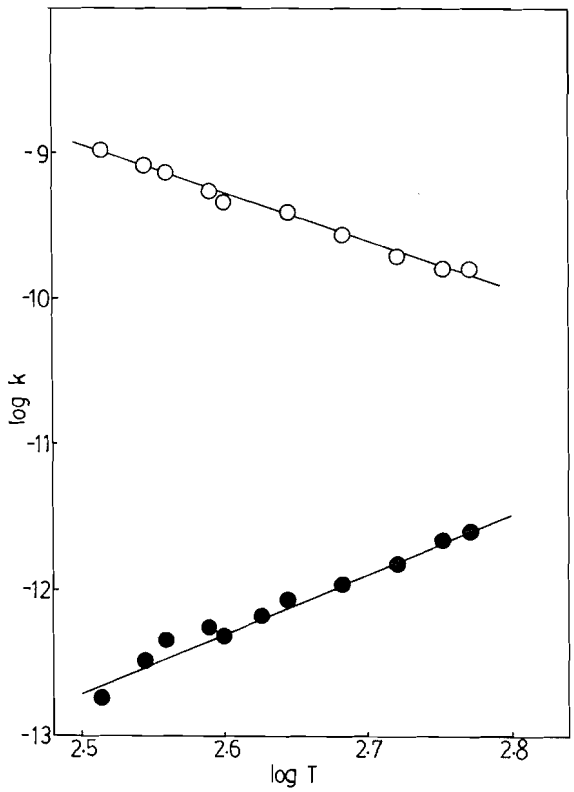

FIG. 8. The variations of the rate constants with temperature for reaction [11], $DMBH^+ + MES \rightleftharpoons DMB + MESH^+$. Upper curve $k_{forward}$, lower curve $k_{reverse}$.

amplitude motions, including twisting around the Si—O bonds (20). The very large Si—O—Si angle, which is much greater than the tetrahedral angle, will hinder access to oxygen in proton transfer. The molecular motions of HMDS along the reaction coordinate will be severely restricted as the chemical transition state is approached since not only will the external rotation of the molecule be limited but also the internal rotations of the $(CH_3)_3Si$ groups about the Si—O bonds and the CH_3 groups about the C—Si bonds will also be affected. The severe hindrance of all these rotational motions will result in large temperature coefficients for reactions involving proton transfer to or from HMDS.

The potential energy profile along the reaction coordinate in the double well potential model is defined by the depths of the two wells and the height of the central barrier. Data on the depths of the well can be obtained if the proton-bound complexes can be stabilized. Benzene forms a very weakly bonded (11 kcal mol^{-1}) proton bound dimer (21) but no aromatic proton bound dimer was observed in the present experiments. $(HMDS)_2H^+$ was not observed either in the presence or absence of aromatic and there was no evidence of a mixed dimer. Figures 2 and 3 show that $HMDSH^+$ is very unreactive towards HMDS and the non-observation of $(HMDS)_2H^+$ must therefore be due to its having only a transient existence before returning to reactants and not to its decomposition to products. Proton transfer between two HMDS molecules is probably very slow due to extreme steric constraints. In support of this contention is our inability to observe proton transfer from $HMDSH^+$ to the geometrically similar hexamethyldisilazane ($(CH_3)_3SiN(H)Si(CH_3)_3$) which has a proton affinity about 20 kcal mol^{-1} higher than HMDS.[1] When DMB is also present proton transfer is observed to occur, presumably via $DMBH^+$, although this ion was not observed. The protonated aromatic presumably can approach $HMDSH^+$ at right angles to the Si—O—Si axis without being sterically blocked whereas the large $(CH_3)_3Si$ groups in hexamethyldisilazane and $HMDSH^+$ prevent a sufficiently close encounter for measurable proton transfer in either a parallel or cruciform transition state.

[1]X. Li and J. A. Stone. Unpublished work.

Conclusions

The proton affinities of silicon compounds can be measured by the equilibrium method provided that the basicity of the competing base towards a silylium ion is low. The aromatic hydrocarbons possess the quality but their range of proton affinities does not extend very far above 200 kcal mol^{-1}. This means that aromatics may not be used to determine the proton affinities of the more basic organosilicon compounds, e.g., the silazanes. Preliminary results suggest that alkylamines may be satisfactory bases for HPMS equilibrium studies of such bases.

The preparation of esters of formic acid using boron oxide

CHARLES G. CARLSON, JUDITH E. HALL, YAN. Y. HUANG, SIRPA KOTILA,[1] ARVI RAUK, AND DONALD F. TAVARES[2]
Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received April 21, 1987

CHARLES G. CARLSON, JUDITH E. HALL, YAN. Y. HUANG, SIRPA KOTILA, ARVI RAUK, and DONALD F. TAVARES. Can. J. Chem. **65**, 2461 (1987).

Boron oxide has been found to act as an efficient reagent in the preparation of a number of formate esters by the direct esterification of formic acid with the alcohol. The reaction is most appropriate for primary and secondary alcohols, including unsaturated alcohols. The formate ester so produced is free of contamination by unreacted alcohol.

CHARLES G. CARLSON, JUDITH E. HALL, YAN. Y. HUANG, SIRPA KOTILA, ARVI RAUK et DONALD F. TAVARES. Can. J. Chem. **65**, 2461 (1987).

On a trouvé que l'oxyde de bore agit comme un réactif efficace pour la préparation d'un certain nombre d'esters formiques par l'estérification directe de l'acide formique avec l'alcool. La réaction est principalement appropriée pour les alcools primaires et secondaires, y compris les alcools qui ne sont pas saturés. Les esters formiques ainsi formés ne sont pas contaminés par l'alcool qui n'a pas réagi.

Introduction

The course of our research required the preparation of propargyl formate in high purity, free of contamination by unreacted alcohol or acid, conditions not readily achieved in most esterification procedures involving formic acid. Acid halides or anhydrides of formic acid are unstable or not readily available (1), although formyl fluoride has been used (2). Mixed formic/acetic anhydride prepared as a mixture of formic acid and acetic anhydride serves as a general reagent for the synthesis of a variety of formates (3) but suffers from the disadvantage that the product is usually contaminated with acetates except in the case of tertiary alcohols (3). The preparation of formate esters of high purity is also besieged by difficulties in isolation, which largely ensue from similarities in the boiling points of the components of the reaction and from the susceptibility of the formyl carbonyl group to undergo nucleophilic attack and decarbonylation. The preparation of esters such as allyl or propargyl formates may be further complicated by the sensitivity of the unsaturated moiety to strong acids and (or) bases.

Direct esterification of alcohols with carboxylic acids is a readily reversible process. The position of the equilibrium is particularly unfavourable in the case of formate esters (4). By way of example, propargyl formate has been prepared in 50% yield by reacting propargyl alcohol with a twofold excess of formic acid in refluxing dichloromethane for 14 h, followed by neutralization, a water wash, and distillation (5). Among the techniques to maximize the yield of the ester is the removal of the water by-product during the course of the reaction. Where the boiling points and solubilities of the reagents are suitable, this is most readily accomplished by carrying out the esterification in refluxing benzene in a Dean–Stark apparatus (5). For formates, this technique is foiled by the low solubility of formic acid in benzene and its consequent codistillation. Dichloromethane (6) and diisopropyl ether (1) are more suitable for formates but the azeotropic mixtures have a relatively low proportion of water, 1.5 and 3.6%, respectively. Alternatively, reagents may be introduced to complex the water of reaction (7, 8). Concentrated sulfuric acid is not appropriate since formic acid is unstable under these conditions. In an adaptation of the procedure of Heaton and Noller (9) for the preparation of propargyl formate, powdered calcium chloride was used to remove the water of reaction from a boiling equimolar mixture of alcohol and acid. The ester was isolated by a double distillation. The yield was not reported (10). We have adopted the same approach for the preparation of propargyl formate, using boron oxide B_2O_3 to trap the water of reaction. As the use of this reagent had not hitherto been reported in this capacity, we investigated the general synthetic utility of the reaction and report the results below.

Experimental

Materials and equipment

All materials were reagent grade and used without further purification except as noted. Specific sources were Fischer (formic acid, *p*-toluenesulfonic acid, 1-pentanol, 2-butanol, allyl alcohol, ethylene glycol, and methylene chloride); Aldrich (boron oxide, 1-hexanol, 1-adamantanol), Columbia Organic Chemicals (3-buten-2-ol, 3-butyn-1-ol); Lancaster (phthalic anhydride); BDH (Sicapent, benzyl alcohol); MCB (cyclohexanol). The ^1H and ^{13}C nmr spectra were obtained on a Varian XL-200 FT spectrometer, mass spectra on a Kratos MS80RFA mass spectrometer. Product purity was estimated by gas chromatography using an OV-17 column.

General procedure

A mixture of the alcohol (0.25 mol), anhydrous formic acid (11) (0.29 mol), boron oxide (0.09 mol), and *p*-toluenesulfonic acid (0.025 mol) in methylene chloride (50 mL) was refluxed with vigorous stirring. After 1 h, the reaction mixture was chilled in ice water and filtered. The filtrate was treated with anhydrous potassium carbonate, refiltered, and stirred for 1 h with phosphorus pentoxide[3] to remove any residual alcohol. Decantation through a short column of silica gel over diatomaceous earth and distillation of the resulting clear solution through a Vigreux column afforded clear colorless ester. The results for specific alcohols are further delineated below and collected in Table 1. Boiling points cited are uncorrected at 660 Torr (1 Torr = 133.3 Pa).

n-*Pentyl formate*

Ester of purity >99% isolated in 66% yield; ^1H nmr ($CDCl_3$) δ: 0.86 (t, 3H, J = 7.0 Hz), 1.29 (m, 4H), 1.62 (m, 2H), 4.12 (t, 2H, J = 6.7 Hz), 8.02 (s, 1H).

n-*Hexyl formate*

Ester of 99.6% purity could be isolated in 74% yield; ^1H nmr ($CDCl_3$) δ: 0.86 (t, 3H, J = 6.6 Hz), 1.29 (m, 6H), 1.63 (m, 2H), 4.13 (t, 2H, J = 6.7 Hz), 8.04 (s, 1H).

[g]No solvent was used.
[h]Principal impurity is the alcohol, ~3%.
[i]4 Torr.

2-Propenyl formate (allyl formate)

Collection of all material boiling in the range 42–80°C afforded the ester in 96% yield as 41% w/w solution in CH_2Cl_2. The 78–80°C fraction is 98% chemically pure and corresponds to a yield of 31%. Because of the severe entrainment of the solvent in this case, the experiment was repeated using diethyl ether as solvent, and in the absence of solvent. In ether, ester of 96% chemical purity could be isolated in 39% yield. In the absence of solvent, >99% pure ester was obtained in 36% yield; ^{1}H nmr ($CDCl_3$) δ: 4.68 (d, 2H, J = 5.7 Hz), 5.42–5.26 (m, 2H), 6.01–5.85 (m, 2H), 8.11 (s, 1H). These results are in agreement with the data reported in the literature (12).

2-Propynyl formate (progargyl formate)

Ester of >99% purity could be isolated in 81% yield; ^{1}H nmr ($CDCl_3$) δ: 2.55 (t, 1H, J = 2.5 Hz), 4.78 (d of d, 2H, J = 2.5 Hz and J = 0.9 Hz), 8.09 (t, 1H, J = 0.9 Hz). These results agree with data previously reported (13).

3-Butynyl formate

Ester of 99.7% purity could be isolated in 75% yield; ^{1}H nmr ($CDCl_3$) δ: 2.02 (t, 1H, J = 2.6 Hz), 2.53 (t of d, 2H, J = 6.7 Hz and J = 2.6 Hz), 4.25 (t, 2H, J = 6.7 Hz), 8.05 (s, 1H); ^{13}C nmr ($CDCl_3$): 18.7 (CH_2), 61.4 (CH_2O), 70.1 (≡CH), 79.6 (≡C—), 160.5 (OC(O)H) ppm; ms m/e: 98 (missing), 55 (10), 53 (17), 52 (100), 51 (21), 50 (19), 43 (13), 40 (48), 39 (60), 38 (17), 37 (10), 31 (73). *Anal.* calcd. for $C_5H_6O_2$: C 61.22, H 6.16; found: C 61.28, H 6.37.

Benzyl formate

Ester of 100% purity could be isolated in 82% yield; ^{1}H nmr ($CDCl_3$) δ: 5.22 (s, 2H), 7.40 (s, 5H), 8.16 (s, 1H). These results agree with data previously reported (14).

Ethylene glycol diformate

The reaction was carried out as described above with the exception that the quantities of formic acid, boron oxide, *p*-toluenesulfonic acid, and methylene chloride were doubled. Diester of 100% purity was obtained in 48% yield; ^{1}H nmr ($CDCl_3$) δ: 4.36 (s, 4H), 8.04 (s, 2H). These results are in agreement with data previously reported (15).

1-Methylpropyl formate (*sec*-butyl formate)

Ester of 99% purity could be isolated in 35% yield or in 51% yield as 75% w/w solution in CH_2Cl_2; ^{1}H nmr ($CDCl_3$) δ: 0.89 (t, 3H, J = 7.5 Hz), 1.23 (d, 3H, J = 6.3 Hz), 1.57 (m, 2H), 4.95 (hextet, 1H, J = 6.4 Hz), 8.04 (s, 1H).

Cyclohexyl formate

Ester of 97% purity could be obtained in 52% yield; ^{1}H nmr ($CDCl_3$) δ: 1.20–1.90 (br m, 10H), 4.86 (br m, 1H), 8.02 (s, 1H). These data are in agreement with previously reported values (14).

1-Methyl-2-propenyl formate

Ester of 97% purity could be isolated in 58% yield, or obtained in 77% yield as a 70% w/w solution in methylene chloride; ^{1}H nmr ($CDCl_3$) δ: 1.33 (d, 3H, J = 6.6 Hz), 5.20 (m, 2H), 5.44 (quintet, 1H, J = 6.6 Hz), 5.83 (m, 1H), 8.04 (s, 1H); ^{13}C nmr ($CDCl_3$): 19.9 (CH_3), 70.9 (CH), 116.4 (=CH_2), 137.0 (=CH), 160.4 (OC(O)H) ppm; ms m/e: 100 (missing), 72 (14), 73 (52), 57 (99), 55 (85), 54 (55), 53 (34), 51 (13), 50 (13), 45 (34), 44 (33), 43 (100), 41 (14), 39 (85), 32 (14), 31 (17). *Anal.* calcd. for $C_5H_8O_2$: C 59.98, H 8.05; found: C 59.18, H 8.29.

2-Methyl-2-propyl formate (*tert*-butyl formate)

The reaction was slower than with the other alcohols. The reaction mixture was refluxed for 1.75 h and left to stand at room temperature overnight. Ester of 93% purity could be isolated in 10% yield, or obtained in 20% yield as a 53% solution in methylene chloride (analysis by gc using OV-1 column); ^{1}H nmr ($CDCl_3$) δ: 1.46 (s, 9H), 7.98 (s, 1H). These data agree with those previously reported (16).

1-Adamantyl formate

The quantities of the general procedure were scaled to 0.17 mol of 1-adamantanol. An equilibrium mixture (36% conversion to ester) was achieved after 3 h refluxing. After treatment with potassium carbonate, the filtrate was concentrated, yielding a crop of needle-like crystals of 1-adamantanol. The mother liquor, consisting of ester/alcohol in 4:1 ratio in CH_2Cl_2, was chromatographed on a silica column with hexane as eluent. Distillation afforded ester of 100% purity in 14% yield (bp 105°C at 4 Torr); ^{1}H nmr ($CDCl_3$) δ: 1.67 (m, 6H), 2.12 (m, 6H), 2.19 (br s, 3H), 8.08 (s, 1H). These data agree with those previously reported (17).

Results and discussion

Boron oxide, B_2O_3, seems not to have been used in direct esterification reactions, which formally could proceed as follows:

$$3ROH + 3R'COOH + B_2O_3 \rightarrow 3R'COOR + 2B(OH)_3$$

Several observations support the notion that boron oxide, in the

presence of free alcohol, may serve the triple role of providing the alkoxy group, trapping the water of reaction, and acting as a Lewis acid catalyst in esterification reactions. Firstly, boron oxide reacts readily with alcohols to yield alkyl borates (alkoxy boranes), whose composition depends on the relative amounts of B_2O_3 and alcohol. When the stoichiometry is 1:3, the following reaction, which yields soluble trialkyl borates (trialkoxy boranes) and insoluble boric acid, dominates (18):

$$B_2O_3 + 3ROH \rightarrow B(OR)_3 + B(OH)_3$$

Indeed, a slurry of boron oxide in methylene chloride removes approximately three quarters of an equivalent amount of propargyl alcohol from solution by chemisorption on the solid and in the form of soluble borate esters within 10 min. Secondly, trialkyl borates, $(RO)_3B$, have been used in a variety of esterifications, although not in the preparation of formates and not of esters of propargyl alcohol (ref. 18, pp. 137–138, and refs. 19–21).

$$(RO)_3B + 3R'COOH \rightarrow 3R'COOR + B(OH)_3$$

In our hands, tripropargyl borate (23) reacted with three molar equivalents of formic acid in methylene chloride to give propargyl formate in 52% yield after distillation. A moderate enhancement of the rate of reaction is observed, compared to the direct esterification without boron species present. Thirdly, boron oxide has been used as a drying agent for formic acid (11, 19). As a bonus, boron oxide is relatively inexpensive, and may also be conveniently prepared by dehydration of inexpensive boric acid (24).

While the exact nature of the participation of the boron species has not yet been elucidated, the intermediacy of the free alcohol is implicated (19–21), and the observed enhancement of the rate of the reaction suggests a role as catalyst.

The results of the reaction with a range of primary, secondary, and tertiary alcohols, some unsaturated, are shown in Table 1. Esters of high chemical purity are obtained from the primary and secondary alcohols. Both tertiary alcohols required a substantially longer reaction time and could be isolated only in low yields. *tert*-Butyl alcohol is decomposed to a large extent under the conditions of the reaction. Phenol did not react. The distillation of many of the esters is hampered by entrainment of the solvent, methylene chloride. In the worst case, allyl formate of purity >98% could only be isolated in 31% yield by careful fractionation, while almost 96% of the theoretical amount of the ester could be recovered as a solution in methylene chloride if separation was not attempted. Yields and product purities (determined by gc analysis) are reported in two ways in the table. In the first column, the maximum yield of ester of highest purity is reported. The minor impurity is a trace of methylene chloride in most cases. In the second column, the total amount of ester recovered, and the composition of the total amount of material distilling above 42°C, is reported. The only components of the distillate are ester and solvent. Two of the compounds, the formate esters of but-3-en-2-ol and but-3-yn-1-ol, have apparently not been previously reported.

In summary, the reaction time is less than an hour if a catalytic amount of *p*-toluenesulfonic acid is added. Isolation is by distillation, after treatment of the filtered reaction mixture with potassium carbonate and phosphorus pentoxide. The product is uncontaminated by formic acid, unreacted alcohol, or water. The short reaction time, availability and cost of materials, and the purity of the product, offer distinct advantages of this method over other preparations of these formates. The method is not suitable for the preparation of tertiary alcohols, for which the mixed formic/acetic anhydride method is preferred (3).

Ion-pair interactions between the methyl tris(1-pyrazolyl)gallato molybdenum, tricarbonyl anion, $[MeGapz_3]Mo(CO)_3^-$, and the Na^+ cation, and the reactivity of the anion toward RX molecules (where RX = HCl, DBr, MeI, or EtBr)

EMMANUEL C. ONYIRIUKA AND ALAN STORR[1]

Chemistry Department, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received March 19, 1987

EMMANUEL C. ONYIRIUKA and ALAN STORR. Can. J. Chem. **65**, 2464 (1987).

Ion-pair interactions between the carbonylate anion, $[MeGapz_3]Mo(CO)_3^-$, and the Na^+ cation in THF solution have been demonstrated using ir spectroscopy. The carbonylate ion has been protonated and the resulting hydride, $[MeGapz_3]Mo(CO)_3H$, characterized. The reaction of MeI with $[MeGapz_3]Mo(CO)_3^-$ proceeds via a detectable σ-methyl derivative to the η^2-acyl complex $[MeGapz_3]Mo(CO)_2(\eta^2\text{-COMe})$, whereas an analogous reaction using EtBr leads to the formation of an unstable σ-ethyl derivative, $[MeGapz_3]Mo(CO)_3Et$, with no evidence for the (η^2-COEt) insertion product.

EMMANUEL C. ONYIRIUKA et ALAN STORR. Can. J. Chem. **65**, 2464 (1987).

Faisant appel à la spectroscopie infrarouge, on a démontre que, en solution dans le THF, il existe des interactions entre paires d'ions de l'anion carbonylate $[MeGapz_3]Mo(CO)_3^-$ et du cation Na^+. On a protoné l'ion carbonylate et on a caractérisé l'hydrure $[MeGapz_3]Mo(CO)_3H$ qui en résulte. La réaction du MeI avec l'anion $[MeGapz_3]Mo(CO)_3^-$ se produit par l'intermédiaire d'un dérivé σ-méthyle que l'on peut détecter et elle conduit au complexe η^2-acyle $[MeGapz_3]Mo(CO)_2(\eta^2\text{-COMe})$; par ailleurs, une réaction analogue impliquant le EtBr conduit à la formation d'un dérivé σ-éthyle instable, le $[MeGapz_3]Mo(CO)_3Et$, et on n'a pas pu détecter la formation du produit d'insertion (η^2-COEt).

Introduction

The uninegative, tridentate, six-electron donor ligand, $MeGapz_3^-$, shows many similarities to the cyclopentadienyl, Cp^-, ligand (1). It is also closely related in properties to the $RBpz_3^-$ ligands (R = H, alkyl, aryl, or pyrazolyl), introduced some time ago by Trofimenko (2). For example, all three ligand systems yield $LMo(CO)_3^-$ (L = $RBpz_3$, $MeGapz_3$, or Cp), anions on reaction with $Mo(CO)_6$ or $(MeCN)_3Mo(CO)_3$. Differences in behaviour between the ligand systems, however, are sometimes observed. Thus, the reaction of the above $LMo(CO)_3^-$ anions with allyl halides gives directly the η^3-allyl complexes $LMo(CO)_2(\eta^3\text{-allyl})$ when L = $RBpz_3$ or $MeGapz_3$, whereas the reaction first gives a σ-allyl derivative, $CpMo(CO)_3(\sigma\text{-allyl})$ when L = Cp, and only upon uv irradiation does the decarbonylation reaction occur to yield the η^3-allyl derivative $CpMo(CO)_2(\eta^3\text{-allyl})$ (3–5). The present paper details further the properties of the $[MeGapz_3]Mo(CO)_3^-$ and $[MeGa(3,5\text{-diMepz})_3]Mo(CO)_3^-$ anions and compares and contrasts, where appropriate, their behaviour with similar complexes containing $RBpz_3^-$ or Cp^- ligands.

Experimental

Starting materials

Ph_3AsHCl (Strem Chemicals), Et_4NCl (Eastman Organic Chemicals), EtBr (Allied Chemicals), HCl (Matheson), DBr (Merck Sharpe and Dohme), and MeOH (Fisher Scientific) were used as supplied. The ligand salts, $Na^+MeGapz_3^-$ (1) and $Na^+MeGa(3,5\text{-diMepz})_3^-$ (6) were prepared as previously described. MeI (Fisher Scientific) was dried by distillation from P_2O_5 and $(MeCN)_3Mo(CO)_3$ was prepared according to a literature method (7). Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free dry nitrogen or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over Na/benzophenone, benzene by refluxing over potassium, CH_2Cl_2 by refluxing over CaH_2, and hexanes by refluxing over $CaSO_4$.

Preparation of $Na^+[MeGapz_3]Mo(CO)_3^-$ and $Na^+[MeGa(3,5\text{-diMepz})_3]Mo(CO)_3^-$

$$Na^+MeGapz_3^- + (MeCN)_3Mo(CO)_3 \xrightarrow{THF} Na^+[MeGapz_3]Mo(CO)_3^- + 3MeCN$$

A 30 mL aliquot of the gallate ligand solution in THF containing ~0.51 mmol $Na^+MeGapz_3^-$ was added to a stirred solution of $(MeCN)_3Mo(CO)_3$ (0.154 g, 0.510 mmol) in the same solvent. The reaction mixture was stirred until the ν_{CO} bands characteristic of the $(MeCN)_3Mo(CO)_3$ starting material had disappeared. The volatiles were then allowed to evaporate to leave the $Na^+[MeGapz_3]Mo(CO)_3^-$ salt as an amber-colored solid. The $Na^+[MeGa(3,5\text{-diMepz})_3]Mo(CO)_3^-$ salt was prepared by a similar method. Both salts were very air-sensitive and satisfactory elemental analyses could not be obtained. However, solution ir and ^1H nmr spectra for the two salts were recorded.

For $Na^+[MeGapz_3]Mo(CO)_3^-$: ir (THF) ν_{CO} 1895s, 1775s, 1720s; (CH_2Cl_2) ν_{CO} 1888s, 1760br cm^{-1}. ^1H nmr (d_6-acetone, 80 MHz) 9.58s (Ga—Me), 3.83t (pz—H^4), 2.35d (pz—H^5), 2.00d (pz—H^3). ($J_{HCCH} \approx 2$ Hz for pz protons; $\tau_{(CH_3)_2CO} = 7.89$ ppm).

For $Na^+[MeGa(3,5\text{-diMepz})_3]Mo(CO)_3^-$: ir (THF) ν_{CO} 1890s, 1765s, 1710s; (CH_2Cl_2) ν_{CO} 1885s, 1745 br cm^{-1}. ^1H nmr (d_6-acetone, 80 MHz) 9.54s (Ga—Me), 7.78 (pz—Me^5), 7.19s (pz—Me^3), 4.38s (pz—H^4).

Preparation of $Et_4N^+[MeGapz_3]Mo(CO)_3^-$

$$Na^+[MeGapz_3]Mo(CO)_3^- + Et_4NCl \xrightarrow[MeOH]{THF} Et_4N^+[MeGapz_3]Mo(CO)_3^- + NaCl$$

Et_4NCl (0.169 g, 1.02 mmol), dissolved in ~5 mL MeOH, was added to an equimolar amount of the carbonylate salt $Na^+[MeGapz_3]Mo(CO)_3^-$ prepared as a THF solution as described above. The resulting cloudy yellow solution was stirred for ~1 h. The yellow precipitate formed was then collected and dried *in vacuo* to give the desired product, $Et_4N^+[MeGapz_3]Mo(CO)_3^-$ in 40% yield. This salt, like the corresponding Na^+ salt, is unstable in air: ir (THF) 1890s, 1765 br; (CH_2Cl_2) 1890s, 1760 br; (Nujol) 1885s, 1752s, 1730s cm^{-1}.

^{1}H nmr (d_6-acetone, 270 MHz): 9.57s (Ga—Me), 3.81t (pz—H^4), 2.27d (pz—H^5),1.92d (pz—H^3), 8.57br (N—CH_2—CH_3), 6.41br (N—CH_2—CH_3).

Preparation of $HAsPh_3^+[MeGapz_3]Mo(CO)_3^-$ and $HAsPh_3^+[MeGa(3,5\text{-}diMepz)_3]Mo(CO)_3^-$

$$Na^+[MeGapz_3]Mo(CO)_3^- + HAsPh_3Cl \xrightarrow[\Delta]{THF} HAsPh_3^+[MeGapz_3]Mo(CO)_3^- + NaCl$$

To a stirred THF solution of $Na^+[MeGapz_3]Mo(CO)_3^-$ (0.85 mmol) was added solid $HAsPh_3Cl$ (0.29 g, 0.85 mmol). The resulting mixture was refluxed overnight, after which the solution was cooled and the solvent removed *in vacuo*. The resulting yellow residue was extracted with benzene and filtered. Golden-yellow needles of the desired salt $HAsPh_3^+[MeGapz_3]Mo(CO)_3^-$ were obtained as a benzene solvate on slow evaporation of the solvent. The salt $HAsPh_3^+[MeGa(3,5\text{-}diMepz)_3]Mo(CO)_3^-$ was prepared in a similar manner, with the exception that the extraction and recrystallization procedure was carried out with CH_2Cl_2/hexane solvents. Both the salts obtained are considerably more air-stable than the corresponding Na^+ or Et_4N^+ salts.

Anal calcd. for $HAsPh_3^+[MeGapz_3]Mo(CO)_3^- \cdot \frac{3}{4}C_6H_6$; C 51.26, H 3.91, N 10.11; found: C 51.44, H 3.54, N 9.94. Infrared (CH_2Cl_2) ν_{CO} 1890s, 1750br; (THF) ν_{CO} 1890s, 1755br; (Nujol) ν_{CO} 1885s, 1760s, 1735s cm^{-1}. ^{1}H nmr (d_6-acetone, 80 MHz) 9.56s (Ga—Me), 3.83t (pz—H^4), 2.35d (pz—H^5), 1.98d (pz—H^3), 2.05br (As—*Ph*), 2.58s (As—H).

Anal calcd. for $HAsPh_3^+[MeGa(3,5\text{-}diMepz)_3]Mo(CO)_3^-$: C 51.83, H 4.67, N 9.81; found: C 52.23, H 4.80, N 9.72. Infrared (CH_2Cl_2) ν_{CO} 1885s, 1740br; (THF) ν_{CO} 1885s, 1750br cm^{-1}. ^{1}H nmr (d_6-acetone, 80 MHz) 9.55s (Ga—Me), 7.80s (pz—Me^5), 7.21s (pz—Me^3), 4.38s (pz—H^4), 2.09br (As—*Ph*), 2.61s (As—H).

Preparation of $[MeGapz_3]Mo(CO)_3H$

$$Na^+[MeGapz_3]Mo(CO)_3^- + HCl \xrightarrow{THF} [MeGapz_3]Mo(CO)_3H + NaCl$$

An equimolar amount of HCl gas (0.50 mmol) was condensed onto a THF solution containing the $Na^+[MeGapz_3]Mo(CO)_3^-$ salt (0.50 mmol). The reaction mixture was warmed to room temperature and the resulting orange solution was stirred for ~2 h. The solvent was then removed *in vacuo*, and the resulting residue extracted with hexane. The product hydride was obtained from the hexane filtrate as an air-sensitive orange solid in ~60% yield.

Anal calcd. for $[MeGapz_3]Mo(CO)_3H \cdot \frac{1}{2}C_6H_{14}$: C 37.67, H 3.92, N 16.48; found: C 37.21, H 3.62, N 16.41. Infrared (C_6H_{14}) 1952w, 1928s, 1908s, 1808s cm^{-1}. ^{1}H nmr (d_6-acetone, 300 MHz), 9.90s (Ga—Me), 3.60t (pz—H^4), 2.50d (pz—H^5), 2.16d (pz—H^3), 18.50s (Mo—*H*).

Attempts to prepare the corresponding deuteride, $[MeGapz_3]Mo(CO)_3D$, using DBr gas were only partially successful. A sticky orange solid was isolated that displayed three strong ν_{CO} bands at 1935, 1910, and 1840 cm^{-1} together with a weak band at 1380 cm^{-1} (assigned to $\nu_{Mo—D}$) in its ir spectrum in benzene solution.

Preparation of $[MeGapz_3]Mo(CO)_2(\eta^2\text{-}COMe)$

$$Na^+[MeGapz_3]Mo(CO)_3^- + MeI \xrightarrow{THF} [MeGapt_3]Mo(CO)_2(\eta^2\text{-}COMe) + NaI$$

To a THF solution of the carbonylate salt was added an excess of MeI in the same solvent. The resulting dark orange–red reaction mixture was stirred for ~4 days, after which the solvent and unreacted MeI were removed under vacuum. The resulting dark-red residue was extracted with CH_2Cl_2 and the solution filtered. An equal volume of hexane was added to the filtrate and the mixed solvents then allowed to evaporate. Air-sensitive, brick-red crystals of the product were obtained in ~30% yield.

Anal calcd. for $[MeGapz_3]Mo(CO)_2(\eta^2\text{-}COMe)$: C 34.95, H 3.12, N 17.48; found: C 35.10, H 3.16, N 17.15. Infrared (CH_2Cl_2) 1980s, 1855s, 1570w cm^{-1}. ^{1}H nmr (d_6-acetone, 80 MHz) 9.30s (Ga—Me), 3.63t 3.53t (pz—H^4), 2.46d 2.24d (pz—H^5), 2.06d 1.95d (pz—H^3), 6.60s (—CO*Me*). The mass spectrum of the compound displayed prominent signals due to the P^+, $P - Me^+$, $P - CO^+$, $P - CO - Me^+$, and $P - 2CO^+$, $P - 2CO - Me^+$, $P - 3CO^+$, $P - 3CO - Me^+$ ions (P^+ = parent ion).

Preparation of $[MeGapz_3]Mo(CO)_3Et$

$$Na^+[MeGapz_3]Mo(CO)_3^- + EtBr \xrightarrow{THF} [MeGapz_3]Mo(CO)_3Et + NaBr$$

An excess of EtBr in THF was added to a THF solution of the carbonylate salt (~0.68 mmol). The mixture was stirred at room temperature for ~1 day and then at reflux temperatures for a further short period. Solvent removal, followed by extraction with benzene and recrystallization from CH_2Cl_2/hexane yielded the product as a reddish-brown solid in low yield.

Anal calcd. for $[MeGapz_3]Mo(CO)_3Et$: C 36.39, H 3.44, N 16.98; found: C 36.55, H 3.28, N 16.63. Infrared (CH_2Cl_2) 1970s, 1930s, 1820s: 1890s, 1755br cm^{-1}. ^{1}H nmr (d_6-acetone, 270 MHz) 9.53s (Ga—Me), 3.81 (pz—H^4), 2.36 (pz—H^5), 1.97 (pz—H^3), 8.15br (Mo—CH_2—CH_3), 6.32br (Mo—CH_2—CH_3).

Results and discussion

The $[MeGapz_3]Mo(CO)_3^-$ and $[MeGa(3,5\text{-}diMepz)_3]Mo(CO)_3^-$ carbonylate anions have been isolated as their sodium (Na^+), tetraethylammonium (Et_4N^+), and triphenylarsonium ($HAsPh_3^+$) salts. The ir spectra of the salts in the carbonyl stretching region of the spectrum were found to be solvent and cation dependent, suggestive of ion-pair interactions in some cases. The phenomenon of ion-pair interactions between cations of Groups 1 or 2 and transition metal carbonylate anions has been well documented (8, 9). For example, the crystal structures of $[CpMo(CO)_3^-]_2Mg^{2+} \cdot 4(C_5H_5N)$ (10) and $[\{Co(salen)\}_2Na^+Co(CO)_4^- \cdot THF]$ (11) have indicated ion-pair interactions to exist between the carbonylate anions and the cations in these complexes. Generally transition metal carbonylate anion – alkali or alkaline earth cation interactions are found to occur quite extensively in basic, low polarity, donor solvents such as THF. The first ir spectroscopic evidence for this type of ion pairing in solvents of moderate polarity was reported some time ago by Edgell *et al.* (12). Since that report and subsequent work on the $Na^+Co(CO)_4^-$ salt (13), analyses of ν_{CO} ir stretching frequencies in THF solutions have successfully revealed alkali metal cation interactions with the carbonylate anions $CpFe(CO)_2^-$ (14, 15) and $CpM(CO)_3^-$ (M = Cr, Mo, or W) (16).

In the present study the ir spectra of the $M^+LMo(CO)_3^-$ salts (where M = Na, Et_4N, or $HAsPh_3$ and L = $MeGapz_3$ or $MeGa(3,5\text{-}diMepz)_3$) in CH_2Cl_2 solution displayed two strong ν_{CO} bands consistent with the symmetrical C_{3v} structure (A_1 + E modes) expected for the free carbonylate anions. However, in THF solution three strong ν_{CO} bands were observed for the Na^+ salts. Representative solution ir spectra in the ν_{CO} region of the spectrum for the $M^+[MeGapz_3]Mo(CO)_3^-$ salts are shown in Fig. 1. The presence of three strong ν_{CO} bands for the $Na^+[MeGapz_3]Mo(CO)_3^-$ salt in THF suggests that the C_{3v} symmetry of the unperturbed anion has been reduced to C_s symmetry ($2A' + A''$ modes) by an ion-pair interaction with the Na^+ cation (see Fig. 2). A listing of the ν_{CO} values for the $M^+LMo(CO)_3^-$ salts (Table 1) reveals the presence of a low-frequency band for the $Na^+LMo(CO)_3^-$ salts in THF which

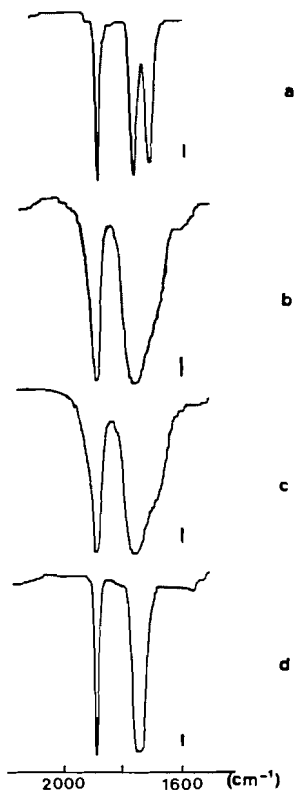

FIG. 1. Infrared spectra of $M^+[MeGapz_3]Mo(CO)_3^-$ salts in the ν_{CO} region: (*a*) $M^+ = Na^+$ in THF, (*b*) $M^+ = Na^+$ in CH_2Cl_2, (*c*) $M^+ = Et_4N^+$ in CH_2Cl_2, (*d*) $M^+ = HAsPh_3^+$ in CH_2Cl_2.

we assign to the A' (contact) vibration. Thus in the type of ion pairing proposed, substantial π-electron drift towards the CO group involved in the interaction is expected to occur (17). This is shown schematically in Fig. 3. In Fig. 3*a*, *c* the Na^+ cation is positioned for maximum interaction with both the σ and π electron density on the CO ligand. Whether this arrangement or the alternate linear arrangement (Fig. 3*b*) holds, the interaction would reduce the bond order for the CO involved, and hence lower its ν_{CO} stretching frequency.

The solution ir spectrum of the $Et_4N^+[MeGapz_3]Mo(CO)_3^-$ salt in THF displays one strong, sharp band at $\sim 1890\ cm^{-1}$ and a second continuous broad band with two or more maxima centred at $\sim 1765\ cm^{-1}$. Again, perturbation of the carbonylate anion by the Et_4N^+ cation might be occurring in the THF

solvent. Interestingly an X-ray crystal structure of the related $Me_4N^+CpCr(CO)_3^-$ complex (18) has revealed some electrostatic interaction between the Me_4N^+ cation and the $CpCr(CO)_3^-$ anion. The ν_{CO} values for the $Na^+[MeGapz_3]Mo(CO)_3^-$ salt in THF (1895, 1775, 1720 cm^{-1}) compare favorably with the ν_{CO} values reported independently for the $Na^+CpMo(CO)_3^-$ salt (1893, 1775, 1749 cm^{-1} in pyridine (10), and 1899, 1796, 1743 cm^{-1} in THF (16)).

The ^1H nmr spectra of the salts studied in this work all showed the three pyrazolyl groups of the gallate ligands to be equivalent, with no evidence of any asymmetry of the type indicated by the ν_{CO} ir measurements. This is to be expected since oxygen-17 and carbon-13 nmr spectral studies have indicated that the lifetime of the similar $CpMo(CO)_3^-\ldots Na^+$ interactions in the related $Na^+CpMo(CO)_3^-$ salt solution is considerably shorter than the time scale of the nmr experiment (9, 16).

The reactivity of the carbonylate anion, $[MeGapz_3]Mo(CO)_3^-$, towards a variety of RX species has been probed. It had been reported earlier that acidification of the $[RBpz_3]Mo(CO)_3^-$ anions (R = H or pz) with acetic acid yields the corresponding $[RBpz_3]Mo(CO)_3H$ acids (19). Similarly, the weak acid, $CpMo(CO)_3H$, is readily obtained by protonation of the $CpMo(CO)_3^-$ anion with acetic acid (3). Consequently, the preparation of $[MeGapz_3]Mo(CO)_3H$ was attempted initially by the acidification of the $Na^+[MeGapz_3]Mo(CO)_3^-$ salt with glacial acetic acid. However, incomplete protonation of the carbonylate anion was indicated by solution ir and ^1H nmr measurements. The subsequent use of hydrogen chloride as the protonating agent was more successful and an orange-yellow, air-sensitive, solid of the correct formulation, $[MeGapz_3]Mo(CO)_3H$, was obtained in good yield. This compound displayed three strong ν_{CO} bands at 1928, 1908, and 1808 cm^{-1} and a weak ν_{Mo-H} vibration at 1952 cm^{-1} in its hexane solution ir spectrum. The assignment of the Mo—H vibration was confirmed by preparing the corresponding deuteride, $[MeGapz_3]Mo(CO)_3D$, which also gave three strong ν_{CO} bands (1935, 1910, 1845 cm^{-1}) in addition to a weak band at ~1380 cm^{-1}, assigned to the ν_{Mo-D} vibration.

The ^1H nmr spectrum of $[MeGapz_3]Mo(CO)_3H$ in d_6-acetone solution displayed one set of signals for the pyrazolyl ring protons (indicating equivalent pyrazolyl-ring environments) and a Mo—*H* signal at 18.5 τ. This result is contrary to the ir data, which showed three ν_{CO} bands, consistent with a C_s symmetry and inequivalent pyrazolyl rings for the complex. It is probable that stereochemical non-rigidity is being displayed by the hydride complex in solution. Thus, assuming the solid to possess a 3:4 piano-stool structure similar to that demonstrated recently in the crystal structure determination of the analogous compound $(\eta^5\text{-}C_5Me_5)Mo(CO)_3H$ (20), a rapid equilibration (on the nmr time scale) of the position of the three CO ligands and the hydrido ligand in the basal plane of the molecule would account for the ^1H nmr result. A similar equilibration process has been suggested for the closely similar complexes, $[HBpz_3](Mo(CO)_3X$ (X = H, Br, I) (21) and is thought to involve an intermediate C_{3v} arrangement with the X atom along the B···Mo axis. An alternative explanation of the ^1H nmr spectrum could involve a rapid rotation of the $MeGapz_3$ moiety about the Ga···Mo axis, which would also result in equalizing the environments of the pyrazolyl groups. The Mo—H signal for the $[MeGapz_3]Mo(CO)_3H$ complex (18.5 τ) appeared at a considerably higher field position than those reported for $CpMo(CO)_3H$ (12.8 τ (3)) and $[HBpz_3]Mo(CO)_3H$ (13.3 τ (19), 13.02 τ (21)). This large upfield shift is difficult to rationalize but the $MeGapz_3^-$ ligand is known to be a better electron donor than either the $HBpz_3^-$ or Cp^- ligands (1) and thus is likely to produce a more electron-rich Mo centre with concomitant increased shielding at the Mo—H proton.

An earlier report suggested that the reaction of MeI with the anion $[HBpz_3]Mo(CO)_3^-$ gave the σ-methyl derivative, $[HBpz_3]Mo(CO)_3Me$ (19). Recently, however, Curtis *et al.* communicated that the product of the above reaction was in fact an η^2-acyl complex, $[HBpz_3]Mo(CO)_2(\eta^2\text{-}COMe)$, no detectable quantities of the σ-methyl derivative being observed in solution. ^1H nmr and ir evidence for the η^2-acyl complex in solution was further substantiated by a solid state X-ray crystal structure determination (22, 23). Generally, metal η^2-acyl complexes are of interest since it is thought possible that such species may play an important role in the metal catalyzed hydrogenation of CO (24–26). The reaction of MeI with the anion $[MeGapz_3]Mo(CO)_3^-$ was carried out firstly to determine if a σ-methyl derivative could be detected and secondly to probe further this novel class of η^2-acyl molybdenum compounds. The reaction itself, in THF, was very slow and incomplete. Even after four days, the solution ir spectrum showed the three ν_{CO} bands due to the presence of unreacted carbonylate anion. However, in addition to these bands, three new ν_{CO} bands at 1970, 1920, and 1855 cm^{-1} were observed. These we assign to the presence of the σ-methyl complex $[MeGapz_3]Mo(CO)_3Me$ in THF solution.

Upon work-up of the reaction mixture brick-red crystals were isolated that displayed two strong ν_{CO} bands at 1980 and 1855 cm^{-1} and a weak band at 1570 cm^{-1} (CH_2Cl_2 solution). This pattern is consistent with the η^2-acyl formulation, $[MeGapz_3]Mo(CO)_2(\eta^2\text{-}COMe)$, for the complex (27, 28), the positions of the bands being closely similar to those reported for the $[HBpz_3]Mo(CO)_2(\eta^2\text{-}COMe)$ compound (1983, 1856, 1570 cm^{-1}) (22). It is interesting to speculate why a σ-methyl derivative is observed in our reaction, whereas Curtis *et al.* reported no detectable σ-methyl complex in the reaction involving the analogous boron-containing compound. Wax and Bergman have shown similar CO insertion reactions to be "solvent catalyzed" (29). Thus the use of the poorly coordinating solvent, THF, in our reaction sequence may have allowed the detection in solution of the σ-methyl derivative $[MeGazp_3]Mo(CO)_3Me$ whereas the use of the highly coordinating acetonitrile reaction medium by Curtis *et al.* (22, 23) may have promoted the rapid formation of the $[HBpz_3]Mo(CO)_2(\eta^2\text{-}COMe)$, thus preventing detection of the σ-methyl intermediate.

The ^1H nmr spectrum of the $[MeGapz_3]Mo(CO)_2(\eta^2\text{-}COMe)$ complex in d_6-acetone is as expected for the η^2-acyl formulation. Thus the pyrazolyl ring protons appear in the predicted 2:1 intensity ratio and the η^2-CO*Me* signal is displayed as a sharp singlet at 6.60 τ. The transformation of the σ-methyl complex, $[MeGapz_3]Mo(CO)_3Me$, to the η^2-acyl complex $[MeGapz_3]Mo(CO)_2(\eta^2\text{-}COMe)$ observed in the present study and the even more facile sequence reported for the analogous pyrazolylborate compound (22, 23) has no counterpart in cyclopentadienyl molybdenum chemistry.

The reaction of the $[MeGapz_3]Mo(CO)_3^-$ anion with EtBr afforded the metal–alkyl bonded $[MeGapz_3]Mo(CO)_3Et$ derivative in low yield. The red–brown compound decomposes slowly on storage and solutions of the complex are even less stable than the solid. Thus, the solution ir spectrum of the complex in CH_2Cl_2 shows three ν_{CO} bands at 1970, 1930, and 1820 cm^{-1} due to the ethyl complex, in addition to two ν_{CO} bands at 1890 and 1755 cm^{-1}, which increase in intensity

with time, assigned to the anion $[MeGapz_3]Mo(CO)_3^-$. It is interesting that the ir spectrum of the closely related $[HBpz_3]Mo(CO)_3Et$ complex, reported earlier by Trofimenlo (19), displayed five ν_{CO} bands (1980, 1960, 1850, 1835, and 1816 cm^{-1}, Nujol), a pattern that again may be indicative of some decomposition of this ethyl compound. The ir spectra of related cyclopentadienyl analogues are interesting in that they display only two ν_{CO} bands, $CpMo(CO)_3Et$ (2016, 1932 cm^{-1}, CCl_4 (3)) and $CpCr(CO)_3Et$ (2012, 1933 cm^{-1}, pentane (30)). The crystal structure of the $CpMo(CO)_3Et$ complex (31) has revealed a 3:4 piano-stool arrangement in the solid state and if this structure persists in solution an accidental coincidence of two ν_{CO} bands must occur in the ir spectra. The three ν_{CO} bands assigned to the $[MeGapz_3]Mo(CO)_3Et$ complex are consistent with a C_s symmetry ($2A' + A''$ modes) or a 3:4 piano-stool arrangement in solution. To explain the room-temperature ^1H nmr spectrum of the complex, which indicates equivalent environments for the three pyrazolyl rings, a fluxional process similar to that suggested earlier for the $[MeGapz_3]Mo(CO)_3H$ complex and that interchanges the Et and 3CO ligands via an average C_{3v} arrangement, could be operative.

No evidence for CO insertion into the Mo—Et bond to form an η^2-COEt complex was observed for the $[MeGapz_3]$-$Mo(CO)_3Et$ compound. It is not clear at this stage why an acyl derivative was obtained with MeI but not with EtBr. In general the rate of an alkyl to acyl conversion reaction is known to be dependent on the strengths of the M—C (alkyl) and M—CO bonds in the starting alkyl complex (32) and a recent thermodynamic study (33) might lead one to predict a more facile acyl formation should occur with the Mo—Et derivative. Perhaps the ready decomposition of the $[MeGapz_3]Mo(CO)_3Et$ complex precludes the formation of an η^2-COEt derivative.

Complexes of the dimethylgallium-1-pyrazolyl-*o*-aminophenolato ligand, $[Me_2Ga(pz)(o\text{-}NH_2C_6H_4O)]^-$. Formation and crystal structure of the molybdenum amidine complex, $Mo(CO)_2Br(\eta^3\text{-}C_3H_5)[\eta^2\text{-}HN{=}CMe(pz)]$ (where pz = pyrazolyl, $N_2C_3H_3$)

Received March 11, 1987

G. D. Gracey, Steven J. Rettig, Alan Storr, and James Trotter. Can. J. Chem. **65**, 2469 (1987).

The synthesis, characterization, and structures of complexes containing the *o*-aminophenolato ligand are detailed. A novel molybdenum amidine complex is also described. Crystals of (*o*-aminophenolato)dimethylgallium are monoclinic, a = 10.1970(9), b = 9.7597(7), c = 18.778(2) Å, β = 100.810(7)°, Z = 8, space group $C2/c$, those of bis(dimethylgallium-1-pyrazolyl-*o*-aminophenolato)nickel(II) benzene solvate are monoclinic, a = 20.491(1), b = 11.789(1), c = 15.789(1) Å, β = 103.413(7)°, Z = 4, space group $C2/c$, and those of η^3-allyl(bromo)[2-(1-pyrazolyl)ethylidenamino]dicarbonylmolybdenum(II) are monoclinic, a = 11.0278(4), b = 8.4461(2), c = 15.3747(5) Å, β = 109.208(3)°, Z = 4, space group $P2_1/c$. The structures were solved by conventional heavy atom methods and refined by full-matrix least-squares procedures to R = 0.030, 0.053, and 0.038 for 1980, 1684, and 1901 reflections, respectively. Reaction of the $[Me_2Ga(pz)(OC_6H_4NH_2)]^-$ ligand, L^-, with $[Re(CO)_4Cl]_2$ results in the formation of $LRe(CO)_3$ whose physical properties indicate a *fac* arrangement of the organogallate ligand.

G. D. Gracey, Steven J. Rettig, Alan Storr et James Trotter. Can. J. Chem. **65**, 2469 (1987).

On décrit la synthèse, la caractérisation et les structres des complexes contenant le ligand *o*-aminophénolato. On décrit aussi un nouveau complexe amidine du molybdène. Les cristaux du (*o*-aminophénolato) diméthyl gallium sont monocliniques avec a = 10,1970(9), b = 9,7597(7) et c = 18,778(2) Å, β = 100,810(7)°, Z = 8 et groupe d'espace $C2/c$; par ailleurs, ceux du bis(diméthyl gallium parazolyl-1 *o*-aminophénolato) nickel(II) solvaté par le benzène sont monocliniques avec a = 20,491(1), b = 11,789(1) et c = 15,789(1) Å, β = 103,413(7)°, Z = 4, et groupe d'espace $C2/c$ et ceux du η^3-allyl (bromo) [(pyrazolyl-1)-2 éthylidènamino] dicarbonyl molybdène(II) sont monocliniques avec a = 11,0278(4), b = 8,4461(2) et c = 15,3747(5) Å, β = 109,208(3)°, Z = 4 et groupe d'espace $P2_1/c$. On a résolu les structures par les méthodes conventionnelles aux atomes lourds et on les a affinées par les méthodes des moindres carrés (matrice entière) jusqu'à des valeurs respectives de R de 0,030, 0,053 et 0,038 pour 1980, 1684 et 1901 réflexions indépendantes. La réaction du ligand $[Me_2Ga(pz)(OC_6H_4NH_2)]^-$, L^-, avec le $[Re(CO)_4Cl]_2$ conduit à la formation du $LRe(CO)_3$ dont les propriétés physiques suggèrent une arrangement *fac* du ligand organogallate.

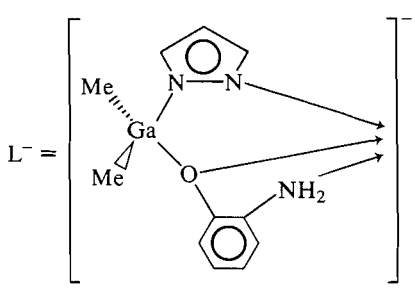
Introduction

In our continuing investigations of the reactivity of organogallium species with "active" hydrogen compounds, and of the synthesis of anionic pyrazolylgallate ligands (1 and references therein), our attention has recently focussed on *o*-aminophenol and *o*-aminothiophenol as molecules of potential interest. Both of these compounds react readily with Me_3Ga with elimination of methane and the formation of metallocyclic gallium compounds, one of which has now been structurally characterized, $Me_2Ga(OC_6H_4NH_2)$. Further, the *o*-aminophenol molecule has been successfully incorporated into the tridentate ligand system **1**. This ligand has been used to prepare a bis-ligand nickel



1

complex, L_2Ni, and also the rhenium tricarbonyl compound $LRe(CO)_3$. The X-ray crystal structures of the L_2Ni complex and of the molybdenum amidine complex $Mo(CO)_2Br(\eta^3\text{-}C_3H_5)[\eta^2\text{-}HN{=}CMe(pz)]$ are reported.

Experimental

Starting materials

Air-sensitive materials were handled in a nitrogen atmosphere. Tetrahydrofuran (THF), benzene, and CH_2Cl_2 were dried by refluxing over Na/benzophenone, potassium, and CaH_2, respectively, followed by distillation. $[Re(CO)_4Cl]_2$ (2), $(MeCN)_3Mo(CO)_3$ (3), $Mo(MeCN)_2(\eta^3\text{-}C_3H_5)(CO)_2Br$ (4), and Me_3Ga (5) were prepared by literature methods.

Preparation of $[Me_2Ga(XC_6H_4NH_2)]$ (where X = O or S)

$$o\text{-}HOC_6H_4NH_2 + Me_3Ga \xrightarrow[\Delta]{THF} Me_2Ga(OC_6H_4NH_2) + CH_4$$

To a solution of Me_3Ga (0.574 g, 5.00 mmol) in THF was added 2-aminophenol (0.546 g, 5.00 mmol) in the same solvent. The reaction mixture was refluxed overnight and the solvent then removed under vacuum. The crude material isolated was recrystallized from benzene to yield colorless crystals of the desired product in high yield. *Anal.* calcd. for $Me_2Ga(OC_6H_4NH_2)$: C 46.20, H 5.82, N 6.74; found: C 46.27, H 5.87, N 6.79. ^1H nmr (C_6D_6, 400 MHz, δ(C_6H_6) = 7.16 ppm) δ −0.12 s ($GaMe_2$), 2.44 s br (NH_2), 6.45 dd (J = 7.0, 1.5 Hz), 6.53 td (J = 7.0, 1.5 Hz), 7.06 td (J = 8.0, 1.5 Hz), 7.14 d (J = 8.0 Hz) (ring protons). The X-ray crystal structure of this compound is described below.

The analogous $Me_2Ga(SC_6H_4NH_2)$ complex was obtained in a similar manner using 2-aminothiophenol (0.37 g, 2.96 mmol) in the reac-

tion with trimethylgallium (0.34 g, 2.96 mmol). Colorless, needle-like crystals were obtained from benzene in good yield. *Anal.* calcd. for $Me_2Ga(SC_6H_4NH_2)$: C 42.90, H 5.40, N 6.25; found: C 42.72, H 5.40, N 6.16. ^{1}H nmr (C_6D_6, 400 MHz) δ −0.11 s ($GaMe_2$), 2.60 s br (NH_2), 6.20 dd (J = 7.0, 2.0 Hz), 6.64 td (J = 8.0, 2.0 Hz), 6.78 td (J = 7.0, 2.0 Hz), 7.60 dd (J = 7.0, 2.0 Hz) (ring protons).

Preparation of $Na^+[Me_2Ga(pz)(OC_6H_4NH_2)]^-$ (Na^+L^-)

An equimolar amount of 2-aminophenol (1.466 g, 13.40 mmol) in THF was added to a THF solution of $Na^+Me_3Gapz^-$ (6) and the mixture refluxed for ~2 days. The resultant clear solution was cooled and made up to a standard volume with THF and this solution stored under a nitrogen atmosphere for use in subsequent reactions.

Preparation of $[Me_2Ga(pz)(OC_6H_4NH_2)]_2Ni$ (L_2Ni)

$$NiBr_2 + 2Na^+L^- \xrightarrow[rt]{THF} L_2Ni + 2NaBr$$

To a stirred slurry of $NiBr_2$ (0.118 g, 0.54 mmol) in THF was added a two molar equivalent of a THF solution of the ligand Na^+L^-. The reaction mixture was stirred for ~3 days and the solvent was then removed *in vacuo*. The residue was extracted with benzene and the solvent allowed to evaporate from the filtered solution. Purple, needle-like crystals of the product L_2Ni were obtained in approximately 60% yield as a benzene solvate. *Anal.* calcd. for $[Me_2Ga(pz)(OC_6H_4NH_2)]_2Ni\cdot 2C_6H_6$: C 53.03, H 5.50, N 11.00; found: C 52.68, H 5.51, N 11.08. The X-ray crystal structure of this complex is described below.

Preparation of $[Me_2Ga(pz)(OC_6H_4NH_2)]Re(CO)_3$ ($LRe(CO)_3$)

$$[Re(CO)_4Cl]_2 + 2Na^+L^- \xrightarrow[\Delta]{THF} 2LRe(CO)_3 + 2CO + 2NaCl$$

A two molar equivalent of the Na^+L^- ligand in THF solution was added to $[Re(CO)_4Cl]_2$ (0.450 g, 0.67 mmol) in the same solvent. The mixture was refluxed overnight and the solvent removed *in vacuo*. The residue was recrystallized from benzene to yield small colorless crystals of the product in good yield. *Anal.* calcd. for $[Me_2Ga(pz)(OC_6H_4NH_2)]Re(CO)_3$: C 30.84, H 2.77, N 7.71; found: C 31.00 H 2.80, N 7.74. ^{1}H nmr (C_6D_6, 80 MHz) δ −0.24 s, 0.45 s ($GaMe_2$), A = 2.79, B = 2.45 (J = 12.0 Hz) (NH_2). Ir (CH_2Cl_2 solution) ν_{CO} 2032, 1908, 1891 cm^{-1}.

Attempted preparation of $[Me_2Ga(pz)(OC_6H_4NH_2)]Mo(CO)_2(\eta^3\text{-}C_3H_5)$ ($LMo(CO)_2(\eta^3\text{-}C_3H_5)$)

[i] $$(MeCN)_3Mo(CO)_3 + Na^+L^- \xrightarrow{THF} Na^+LMo(CO)_3^- + 3MeCN$$

[ii] $$Na^+LMo(CO)_3^- + xsC_3H_5Br \xrightarrow{THF} LMo(CO)_2(C_3H_5) + NaBr + CO$$

$(MeCN)_3Mo(CO)_3$ (1.01 g, 3.48 mmol) in THF was reacted with a

*Refined as 50% O, 50% N.

one molar equivalent of the Na^+L^- ligand solution in the same solvent. The mixture was stirred overnight and then an excess of allyl bromide was added. The reaction mixture was stirred for an additional 2 days after which the solvent was removed under vacuum and the residue extracted with benzene solvent. Slow evaporation of the solvent from the filtrate yielded a yellowish brown oily solid. Evidence from ir, mass spectral, and ^{1}H nmr data clearly indicated the desired complex to be present in the oily solid, but satisfactory elemental analytical data could not be obtained. Attempts to obtain ^{1}H nmr spectra of the oily solid in d_6-acetone resulted in complete dissolution of the material, followed almost immediately by the deposition of a reddish-orange crystalline material. This air-stable solid was shown subsequently to be a molybdenum amidine complex. *Anal.* calcd. for $Mo(CO)_2Br(\eta^3\text{-}C_3H_5)[\eta^2\text{-}HN{=}CMe(pz)]$: C 31.43, H 3.14, N 11.00; found: C 31.53, H 3.22, N 10.68. Ir (KBr disc) ν_{CO} 1938, 1845 cm^{-1}, $\nu_{C=N}$ 1657 cm^{-1}, ν_{NH} 3340 cm^{-1}. The X-ray crystal structure of this complex is described below.

Spectra

Infrared spectra were recorded on a Perkin-Elmer 598 spectrometer, ^{1}H nmr spectra were recorded on Bruker WP-80 and Bruker WH-400 MHz instruments using FT techniques. Mass spectra were recorded on a Kratos AES MS 50 mass spectrometer. Elemental analyses were preformed by Mr. P. Borda of the UBC microanalytical laboratory.

Crystal structure analyses

Crystallographic data for $Me_2Ga(OC_6H_4NH_2)$, $[Me_2Ga(pz)(OC_6H_4NH_2)]_2Ni \cdot 2C_6H_6$, and $Mo(CO)_2Br(\eta^3\text{-}C_3H_5)[\eta^2\text{-}HN{=}CMe(pz)]$ appear in Table 1. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections with 2θ = 28–43, 25–32, and 81–97°, respectively, for the three compounds. The intensities of three standard reflections were measured each hour of X-ray exposure time during the data collections. For $[Me_2Ga(pz)(OC_6H_4NH_2)]_2Ni$ and $Mo(CO)_2Br(\eta^3\text{-}C_3H_5)[\eta^2\text{-}HN{=}CMe(pz)]$ only small random fluctuations were noted and for $Me_2Ga(OC_6H_4NH_2)$ the intensities of the check reflections decreased uniformly to final values 0.95 times the initial values. The data for $Me_2Ga(OC_6H_4NH_2)$ were scaled accord-

For personal use only.

ingly. Data for the three compounds were reduced[2] and corrected for absorption.

The structures were solved by conventional heavy-atom methods, the metal and halogen atoms being positioned from the Patterson functions and the remaining atoms from subsequent difference maps. The centrosymmetric space group $C2/c$ was indicated by E-statistics and Patterson functions for $Me_2Ga(OC_6H_4NH_2)$ and L_2Ni, imposing crystallographic C_2 symmetry on molecules of the latter. The O and N atoms of the *o*-aminophenolato ligand in $Me_2Ga(OC_6H_4NH_2)$ were found to be disordered over the two positions X(1) and X(2), both positions being refined as 50% O and 50% N. Unbalanced thermal parameters resulted from both possible ordered structures in $C2/c$ and the disorder persisted when the structure was refined in the noncentrosymmetric space group Cc. Non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included as fixed contributors to the structure in calculated positions (N—H = 0.92, C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å, $U_H \propto U_{\text{bonded atom}}$) for $[Me_2Ga(pz)(OC_6H_4NH_2)]_2Ni$. Hydrogen atoms associated with the disordered NH_2 group in $Me_2Ga(OC_6H_4NH_2)$ were also fixed in idealized positions while all remaining hydrogen atoms in $Me_2Ga(OC_6H_4NH_2)$ and $Mo(CO)_2Br(\eta^3\text{-}C_3H_5)[\eta^2\text{-}HN{=}CMe(pz)]$ were refined with isotropic thermal parameters. Neutral atom scattering factors and anomalous scattering corrections (Mo, Ga, Ni, and Br) were taken from ref. 7. Isotropic type I extinction corrections (Thornley–Nelmes definition of mosaic anisotropy, Lorentzian distribution) were applied for $Me_2Ga(OC_6H_4NH_2)$ and $Mo(CO)_2Br(\eta^3\text{-}C_3H_5)[\eta^2\text{-}HN{=}CMe(pz)]$ (8–10), the final values of g being $4.1(2) \times 10^4$ and $0.43(2) \times 10^4$, respectively.

Final positional and isotropic thermal parameters (U_{eq} = 1/3 trace diagonalized U) appear in Table 2. Bond lengths, bond angles, and intra-annular torsion angles are given in Tables 3–5, respectively. Calculated hydrogen atom parameters for $[Me_2Ga(pz)(OC_6H_4NH_2)]_2Ni$, anisotropic thermal parameters, bond lengths, and angles involving hydrogen, a complete listing of torsion angles (Tables 6–10), and measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

Results and discussion

Alkane elimination from trimethylgallium compounds and compounds containing active hydrogen has been well documented (1). The reaction of *o*-aminophenol and *o*-aminothiophenol with trimethylgallium followed the expected pattern to produce metallocyclic compounds incorporating the "Me_2Ga" moiety. The $Me_2Ga(XC_6H_4NH_2)$ (where X = O or S) complexes produced both displayed ^1H nmr spectra which indicated two equivalent Ga–Me groups and two equivalent N—H protons in the molecules. A planar structure of aromatic ring carbons and the Ga, N, and X atoms is consistent with this data. The mass spectra of the two complexes displayed prominent signals due to the parent monomer ions (P^+) with the most intense peaks being due, in each case, to the $P - Me^+$ ions. The solid state structure of $Me_2Ga(OC_6H_4NH_2)$ is shown in Fig. 1 and consists of individual monomer units linked to neighboring units by a network of N—H···O hydrogen bonds shown in Fig. 2 (X(1)—H(X1a)···X(2) ($1/2 - x$, $y - 1/2$, $1/2 - z$); X(1)—H(X1b)···X(1) ($-x$, y, $1/2 - z$); and X(2)—H(X2a)··· X(1) ($1/2 - x$, $1/2 + y$, $1/2 - z$); H···X = 2.17, 2.09, 2.09 Å; X···X = 3.009(3), 3.002(4), 3.009(3) Å; X—H···X = 152, 172, 173°; respectively). With but few exceptions (11), similar "Me_2Ga" systems have been shown by X-ray crystallographic analyses to dimerize in the solid state via the formation of four-membered $(Ga—O)_2$ rings, giving distorted trigonal bipyramidal arrangements about each five-coordinate gallium atom (12–18). As a result of the disordering of the *o*-aminophenolato ligand, the two Ga—X distances most likely represent averages of the actual Ga—N and Ga—O distances. Assuming that the Ga—O distance in $Me_2Ga(OC_6H_4NH_2)$ is the same as that in $[Me_2Ga(pz)(OC_6H_4NH_2)]_2Ni$ (1.941(4) Å), a Ga—N distance of 2.06 Å can be approximated for $Me_2Ga(OC_6H_4NH_2)$. These values are similar to the Ga—O and Ga—N distances of 1.917(4) and 2.064(8) Å in the tetrahedral complex $Me_2GaOCH_2CH_2NH_2$ (19). The aromatic ring in $Me_2Ga(OC_6H_4NH_2)$ is planar to within experimental error and the five-membered chelate ring has a flattened Ga-envelope conformation.

The reaction of the ligand **1** with $[Re(CO)_4Cl]_2$ resulted in a good yield of the rhenium tricarbonyl product $[Me_2Ga(pz)(OC_6H_4NH_2)]Re(CO)_3$. The arrangement of the tridentate ligand in this complex has been shown by ir and ^1H nmr data to

*Here and elsewhere in this report primed atoms have coordinates related to those in Table 2 by the symmetry operation: $-x$, y, $1/2 - z$.

be exclusively *facial*. Thus three strong ν_{CO} bands occur in the ir spectrum whereas for a *mer* arrangement of the unsymmetrical ligand two weak ν_{CO} bands and one strong ν_{CO} band would be predicted (20). The ^1H nmr spectrum of the complex in C_6D_6 solvent is also consistent with a *fac* arrangement of the organogallate ligand. Thus the $GaMe_2$ grouping gives rise to two sharp singlets at ~0 δ whereas for a *mer* arrangement of the ligand a plane of symmetry in the molecule would render the two GaMe groups equivalent and hence lead to one signal in this region of the spectrum. The AB quartet pattern observed for the —NH_2 grouping is also consistent with a *fac* but not a *mer* arrangement of the tridentate ligand. The mass spectrum of the $LRe(CO)_3$ complex confirms the monomeric nature of the compound in the gas phase. The parent monomer ion (P^+)

pattern was observed together with prominent signals due to the $P - Me^+$ and $P - 3CO^+$ ions.

The reaction of the Na^+L^- ligand with anhydrous $NiBr_2$ has demonstrated the ability of the Ni(II) ion to accommodate two of the gallate ligands in a monomeric pseudo-octahedral complex, viz. L_2Ni. The nature of the purple crystalline product has been confirmed by elemental analysis, mass spectrometry, and X-ray crystallographic analysis. The elemental analysis indicated the presence of two benzene solvate molecules per L_2Ni molecule in the crystals and these were subsequently located in the X-ray analysis. The mass spectrum confirmed the monomeric nature of the complex in the vapor phase with weak signals due to the P^+ ion and strong signals due to the $P - Me^+$ and $P - 2Me^+$ ions being observed. The X-ray analysis of the L_2Ni complex, $[Me_2Ga(pz)(OC_6H_4NH_2)]_2Ni\cdot 2C_6H_6$, showed the ligands to be coordinated in a meridional fashion. A previous publication has documented the structures of both the *mer* and *fac* isomers of the related complex $[Me_2Ga(pz)(OCH_2CH_2NH_2)]_2Ni$ (21) and has also described how the two isomers can be interconverted by an adroit choice of recrystallization solvents. The present L_2Ni complex crystallized solely as the *mer* isomer and all attempts to convert this to the *fac* isomer proved unsuccessful. The structure of the molecule is shown in Fig. 3 and clearly establishes the tridentate chelating nature of the organogallate ligand **1**.

The crystal structure of $[Me_2Ga(pz)(OC_6H_4NH_2)]_2Ni\cdot 2C_6H_6$ consists of well-separated complex and solvent molecules. The L_2Ni molecule has crystallographic C_2 symmetry, each meridionally coordinated ligand forming a system of four fused rings which is planar to within ±0.26 Å. The pyrazolyl and phenyl rings are planar to within experimental error while the five-membered NiOGaNN and NiOCCN chelate rings have flattened Ga- and N-envelope conformations, respectively (see Table 5). The Ni—O, Ni—N(pz), and Ni—N(am) bond lengths of 2.049(3), 2.057(5), and 2.143(5) Å in $[Me_2Ga(pz)(OC_6H_4NH_2)]_2Ni$ are similar to the corresponding mean values of 2.040(3), 2.092(6), and 2.147(5) Å observed for *mer*-$[Me_2Ga(pz)(OCH_2CH_2NH_2)]_2Ni$ (21). Corresponding bond angles about Ni in the two compounds differ by a maximum of 1.7(3)°. Distances and angles involving gallium are normal.

Attempts to prepare the $LMo(CO)_2(\eta^3\text{-}C_3H_5)$ complex did not lead to a pure product. A crude material was obtained

which displayed two strong ν_{CO} bands in its ir spectrum and a ^1H nmr pattern which indicated the presence of the complex with the L ligand facially coordinated. The mass spectrum of the product material also gave evidence for the presence of the $LMo(CO)_2(\eta^3\text{-}C_3H_5)$ complex with prominent signals due to P^+ and derivative ions being observed. Perhaps of more interest was the formation of the molybdenum amidine complex $Mo(CO)_2Br(\eta^3\text{-}C_3H_5)[\eta^2\text{-}HN{=}CMe(pz)]$ on treating the crude material with d_6-acetone. The X-ray structure of this complex is described below and the molecular arrangement is shown in Fig. 4. The structure represents the second of its type, a previous publication (22) having detailed the structure of the ruthenium cation $[Ru(CO)H[HN{=}CMe(Me_2pz)](PPh_3)_2]^+$. An earlier paper by Jones *et al.* (23) had suggested the existence of a similar Ru amidine cation $[Ru(\eta^6\text{-}C_6H_6)[HN{=}CMe(Me_2pz)](Me_2pzH)]^{2+}$ based primarily on ir and nmr data. It was suggested in both of these publications that the coordinated amidine ligand resulted from the addition of a dimethylpyrazole, Me_2pzH, unit across the C≡N bond of a coordinated MeCN molecule. A similar mechanism in the present case would suggest the presence of coordinated MeCN in the brown oily solid produced in the attempted preparation of the $LMo(CO)_2(\eta^3\text{-}C_3H_5)$ complex. A pyrazole molecule could conceivably originate from the ligand, L. It is not clear at this time what role the d_6-acetone plays in promoting the formation of the molybdenum amidine complex but we are planning further investigations in this area. The $\nu_{C=N}$ frequency of 1657 cm^{-1} observed for the Mo complex compares closely with the two $\nu_{C=N}$ values (1645, 1650 cm^{-1}, respectively) quoted for the Ru cations.

The molecular structure of $Mo(CO)_2Br(\eta^3\text{-}C_3H_5)[\eta^2\text{-}HN{=}CMe(pz)]$ consists of discrete monomeric units associating into centrosymmetric dimeric species (Fig. 5) via N—H···Br hydrogen bonding interactions (N(3)—H(N3)···Br($1-x$, $1-y$, $1-z$), H···Br = 2.65(10), N···Br = 3.416(7) Å, N—H···Br = 172(10)°). These dimer units are linked to one another by a pair of possible weak hydrogen bonds [C(6)—H(6)···Br($1-x$, $1/2+y$, $1/2-z$) and C(8)—H(8)···O(1) ($1-x$, $y-1/2$, $1/2-z$), H···A = 2.67(8) and 2.43(8), C···A = 3.535(9) and 3.35(1) Å, C—H···A = 137(6) and 164(6)°, respectively). The coordination geometry about Mo is irregular pseudo-octahedral if the η^3-allyl ligand is considered to occupy one coordination site. The geometry of the HN=CMe(pz) ligand is similar to, but more accurately determined than that of the related HN=CMe(Me_2pz) ligand in the Ru cation (22). The N(3)—C(9) distance of 1.257(10) Å is consistent with a C=N double bond and is not significantly different from the corresponding distance of 1.30(4) Å in the Ru cation. The pyrazolyl ring is planar to within experimental error while the five-membered chelate ring is slightly, but significantly, non-planar (maximum deviation from the mean plane = 0.023(7) Å). The Mo—N(amidine) bond, *trans* to the allyl ligand (2.179(7) Å), is significantly shorter than the Mo—N(pz) bond (2.239(6) Å). The Mo—Br distance of 2.707(1) Å is longer than other Mo(II)—Br distances reported for 6- and 7-coordinate complexes which range from 2.629 to 2.680 Å (24–27), possibly as a result of the hydrogen bonding. Other bond lengths in the complex are as expected.

The microwave spectrum and structure of bromine thiocyanate, BrSCN

H. M. JEMSON, W. LEWIS-BEVAN, AND M. C. L. GERRY[1]

Department of Chemistry, The University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received February 2, 1987

H. N. JEMSON, W. LEWIS-BEVAN, and M. C. L. GERRY. Can. J. Chem. **65**, 2478 (1987).

The microwave spectra of ^{79}BrSCN and ^{81}BrSCN have been measured and analysed to give rotational, centrifugal distortion, and Br quadrupole coupling constants. The molecule has been shown unambiguously to be BrSCN rather than BrNCS. A harmonic force field has been determined from combined vibrational and distortion data. With structural parameters for the SCN chain transferred from $S(CN)_2$, both effective and ground state average values for the BrS length and BrSC angle have been estimated. The Br quadrupole tensor has been diagonalized, and the BrS bond is shown not to be bent.

H. N. JEMSON, W. LEWIS-BEVAN et M. C. L. GERRY. Can. J. Chem. **65**, 2478 (1987).

On a mesuré les spectres de micro-ondes du ^{79}BrSCN et du ^{81}BrSCN et on les a analysés pour obtenir les constantes de couplage de rotation, centrifuge et quadrupolaire du Br. On a démontré sans ambiguités que la molécule est bien BrSCN et non pas BrNCS. On a déterminé un champ de force harmonique à partir des données combinées de la vibration et de la distortion. En se basant sur les paramètres structuraux du transfert en chaîne du SCN à partir du $S(CN)_2$, on a évalué les valeurs moyennes tant efficace qu'à l'état fondamental de la longueur de la liaison BrS et de l'angle BrSC. On a diagonalisé le tenseur quadrupolaire du Br et on démontre que la liaison BrS n'est pas recourbée.

[Traduit par la revue]

Introduction

Thiocyanates, which possess the SCN moiety, have rather interesting structural properties. The group is ambidentate, and can bond to the remainder of the molecule at either the S or N atom to form, respectively, thiocyanates or isothiocyanates. There seems to be no *a priori* indication whether a molecule has a thiocyanate or isothiocyanate configuration. The H- and SiH_3-derivatives, for example, are isothiocyanates, HNCS (1) and SiH_3NCS (2). The methyl derivatives can exist in both forms, CH_3NCS and CH_3SCN (3), as can the cyano derivatives, $S(CN)_2$ (4) and NCNCS (5). Of the possible chlorine derivatives, only the thiocyanate, ClSCN, is known (6).

There have been several studies of bromine thiocyanate, BrSCN, in solution (7–10). In common with other halogen thiocyanates, it is prepared by the following scheme (7):

[1] $Pb(SCN)_2 + Br_2 \rightarrow (SCN)_2 + PbBr_2$

[2] $(SCN)_2 + X_2 \rightarrow 2XSCN$

where X is a halogen, including Br. Bromine thiocyanate undergoes addition reactions with alkenes. However, the reaction products are not unique, with both bromothiocyanato and dibromo derivatives being formed (8). It has also been used as a reagent in thiocyanation reactions (11, 12). Both infrared solution studies (10) and chemical studies (7–9) suggest that the bromine is linked via the S atom.

The only previous study of gas phase bromine thiocyanate was of its photoelectron spectrum by Frost *et al.* (13). This sprectrum was found to parallel that of chlorine thiocyanate, ClSCN. Since the configuration of the latter was found from its microwave spectrum to be indeed ClSCN (6), it seemed likely that the configuration of the bromine derivative would be the same. The aim of the present study was to confirm that this is indeed the case, and to measure the spectroscopic constants and structural parameters of the molecule.

Experimental methods

Bromine thiocyanate was prepared according to the method of Frost *et al.* (13). Freshly prepared AgSCN was loosely packed with glass wool in a U-tube, and dried under vacuum for several hours at 100°C. The solid sample was then cooled to room temperature and Br_2 vapour was added to it.

The reaction products depended on the pressure of Br_2 used and the way it came in contact with the solid. If Br_2 was simply passed through the solid sample the spectrum of $S(CN)_2$ was observed, along with some lines of SO_2 and HNCS. However, when Br_2 was passed over AgSCN at low pressure (with one end of the U-tube closed), so that the gaseous reaction products reacted with more Br_2, the spectrum of bromine thiocyanate appeared almost immediately. Its formation was entirely analogous to its formation in solution.

[3] $2AgSCN + Br_2 \rightarrow (SCN)_2 + 2AgBr$

[4] $(SCN)_2 + Br_2 \rightarrow 2BrSCN$

The microwave spectrum was observed in a conventional 100 kHz Stark modulated spectrometer, in the frequency range 8–54 GHz. The microwave source was a Watkins-Johnson 1291A Synthesizer in the range 8–18 GHz, extended to 54 GHz with Honeywell SpaceKom 14-27 and T-K_a3 multipliers. Throughout the study a flow system was used, in which the products of the reaction described above were passed immediately into the spectrometer's six foot X-band Stark cell, held at room temperature. Measurement accuracies are believed to be better than ±0.03 MHz.

Results

Assignment and analysis of the spectrum

Initial predictions of the rotational constants of both BrSCN and BrNCS were made by transferring parameters from related molecules. For BrSCN the BrS bond length was taken from S_2Br_2 (14) and the SCN parameters from $S(CN)_2$ (4); the BrSC angle was taken to be the same as the CSC angle in $S(CN)_2$ (4). For BrNCS the BrN length was transferred from BrNCO (15), as was the BrNC angle, increased by 7° following other isocyanates and isothiocyanates (3, 16); the parameters of the NCS chain were those of HNCS (16). In the two cases the molecule was predicted to be a planar near-symmetric prolate rotor, but with considerably different rotational constants.

The observed spectrum contained a series of strong *a*-type R branch clusters, along with reasonably intense *b*-type transitions. The spacing of the *a*-type R branches was found to be ~3500 MHz, in reasonable agreement with the predicted (B_0 + C_0) of BrSCN. The observed *b*-type transitions also fol-

lowed quite closely the pattern predicted for BrSCN. It followed that this configuration was probably the correct one.

All transitions showed quadrupole hyperfine splitting due to the Br nucleus ($I = 3/2$). Rough predictions of the coupling constants were made using those of ClSCN (6), scaled by the ratios of the quadrupole moments, and were used in first order predictions of the hyperfine patterns; these were an invaluable aid in the assignments. No ^{14}N hyperfine structure was observed for any transitions.

Significant perturbations of the hyperfine structure from the first order patterns were observed. This is not surprising, since the off-diagonal coupling constant χ_{ab} was expected to be large: with the BrS bond expected to be on or near the principal quadrupole axis, the angle between it and the a-inertial axis was anticipated to be ~33°. Also, several near-degeneracies of the type $\Delta F = 0$; $\Delta J = 0, \pm 1, \pm 2$; K_aK_c = eo ↔ oo, oe ↔ ee, were found, and transitions involving these levels were significantly shifted from their first order positions.

The analysis of the BrSCN spectrum required use of our global least-squares fitting procedure, which simultaneously produced rotational, centrifugal distortion and Br quadrupole coupling constants, including χ_{ab}. This procedure was used earlier for BrNCO (15) and INCO (19), which also have large perturbations in their hyperfine structure.

A bootstrap procedure was used to analyse the spectrum. Initial assignments were made to a-type R branch $K_a = 0$ and asymmetry split $K_a = 1$ transitions. Transitions from one asymmetry branch of the $K_a = 2 \leftarrow 1$ b-type Q branch ($J_{2,J-2}$–$J_{1,J-1}$) were also assigned; Fig. 1 shows the $13_{2,11}$–$13_{1,12}$ transition for both isotopes. These were used to obtain preliminary rotational and quadrupole constants, which were in turn used for further predictions. As further transitions were assigned they were included in successive fits, with the distortion constants now also released. Ultimately the assigned transitions included $K_a = 0$, 1, 2, and 3 a-type R branches for $J = 6$ to 12. The b-type transitions included, besides the branch mentioned above,

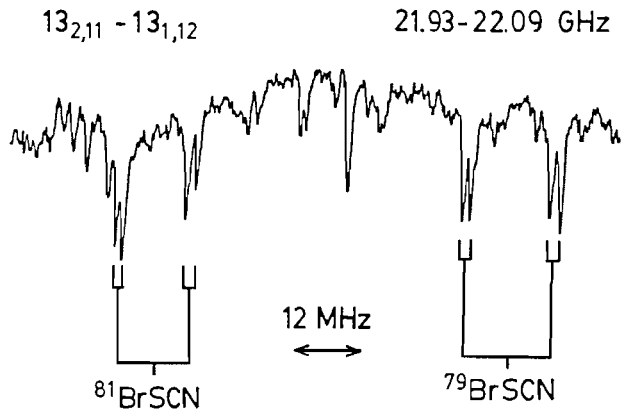

FIG. 1. The transition $13_{2,11}$–$13_{1,12}$ of ^{79}BrSCN and ^{81}BrSCN.

lines from the sub-branches $J_{3,J-3}$–$J_{2,J-2}$ and $J_{4,J-4}$–$J_{3,J-3}$; these sub-branches, which initially extend to low frequency, were easily assigned at the point where they change direction to higher frequency. An example for $J_{3,J-3}$–$J_{2,J-2}$, is in Fig. 2. Some Q branches of the series $J_{3,J-2}$–$J_{2,J-1}$, as well as some $K_a = 1 \leftarrow 0$ and $0 \leftarrow 1$ R branches, were measured to complete the analysis.

The final constants are given in Table 1. Along with rotational and Br quadrupole constants all five quartic centrifugal distortion constants (obtained in terms of Watson's A-reduction (18)) have been measured. The frequencies of all measured transitions are in Tables 2 and 3; they were weighted in the fits according to their resolvability and to whether they are partially overlapped by other transitions. These tables also contain residuals obtained when χ_{ab} is included in their calculation and when it is omitted; the latter approximates a first-order prediction. Comparison of the two sets of residuals indicates several important near degeneracies affecting primarily the a-type transitions. The closest near degeneracies separate the (unsplit)

55/2–55/2	0.500	41838.727	0.121	0.118
57/2–57/2	0.500	41839.301	0.014	−0.041

[a]Measurements were weighted according to $1/\sigma^2$, where σ is the uncertainty in the measurements. Unit weight corresponded to an uncertainty of 0.03 MHz.

[b]Observed frequency minus the frequency calculated using the constants in Table 1.

9_{19} and 8_{27} levels by ~265 MHz for ^{79}BrSCN and ~407 MHz for ^{81}BrSCN, which in turn produce shifts in transitions involving 9_{19} of up to ~30 MHz in ^{79}BrSCN and up to ~13 MHz for ^{81}BrSCN. Table 4 indicates some of the closest near degeneracies.

Harmonic force field and structure

Despite having rotational constants for only ^{79}BrSCN and ^{81}BrSCN, we can make some deductions about the structure. In the first place, comparison of the observed rotational constants with those predicted for BrSCN and BrNCS (Table 5) indicates clearly that the molecule is the former, the thiocyanate, with Br bonded to S. Secondly, the inertial defects (Table 1) are small and positive, and essentially the same for both isotopes, consistent with a planar structure. This is confirmed by the ratio of the out-of-plane quadrupole constants $\chi_{cc}(^{81}\text{Br})/\chi_{cc}(^{79}\text{Br}) = 0.8335$, which is very close to the ratio of the quadrupole moments of the two nuclei (0.8353).

Because of the limited isotopic data only a partial set of bond lengths and angles could be obtained. These we have chosen to be the Br—S length and BrSC angle. The SCN parameters were held fixed at their values in $S(CN)_2$, in which the SCN chain is bent by 5° (4). Ground state effective (r_0) values of the two unknowns were estimated by a least-squares fit to the observed rotational constants. The results are in Table 6, along with a comparison with corresponding parameters of similar molecules. Uncertainties were estimated by varying each of the assumed parameters in turn within reasonable limits: r(SC) by 0.012 Å (to include the value assumed for CH_3SCN (3)), r(CN) by 0.003 Å (since little variation is reported in the literature (4)), and <(SCN) by 5°, to include a linear structure. Remarkably little variation in the derived parameters was found. The positions of the atoms in the inertial axis system of ^{79}BrSCN are shown in Fig. 3.

In order to evaluate ground state average (r_z) parameters it was first necessary to obtain a harmonic force field, using infrared data from the literature and the centrifugal distortion constants measured in the present work. Infrared data are, however, rather sparse, with wavenumbers of only four of the six normal modes being reported (10); these were obtained for BrSCN in solution (10), and the measurements were not made below 350 cm^{-1}. However, in the present work we were able to observe rotational transitions of molecules in the first excited state of the lowest frequency mode; from relative intensity measurements we estimate it to be at 154 ± 30 cm^{-1}.

The internal coordinates and structure used in the force field

[b]Defined as a torsion, for which **B** matrix elements are (rad Å^{-1}): Br, −0.465; S, −6.136; C, 16.503; N, −9.902.
[c]Numbers in parentheses are one standard deviation in units of the last significant figures. All other force constants were constrained to zero.

analysis are given in Table 7. All the in-plane coordinates are conventional valence coordinates. The out-of-plane coordinate we have defined as a torsion; from its **B**-matrix elements given in Table 7 it is clear that it is nevertheless essentially an SCN out-of-plane bend. We were thus able to assume that the in-plane and out-of-plane bending wavenumbers have the same value. The structure was the r_0 structure derived above.

As a starting point to the determination we estmated the SBr stretching constant to be the same as the SCl stretching constant in SCl_2 (23), and the in-plane S—C≡N constants to be the same as those of $S(CN)_2$ (4). Least-squares fits were then made to the wavenumbers and distortion constants, using first of all a diagonal force field (which gave a reasonable fit) and then including off-diagonal constants. An excellent fit was obtained including the single off-diagonal constant f_{14}, the interaction constant between the BrS stretch and the BrSC bend. The wavenumbers were assigned uncertainties of 20 cm^{-1} for ν_1 and ν_6, 30 cm^{-1} for ν_5 and 10 cm^{-1} for the remainder; the distortion constants were given uncertainties of 5%; the data were weighted as (uncertainty)$^{-2}$. The resulting force constants are in Table 7, and the goodness of the fit is indicated in Table 8. It is clear that the approximate force field obtained is very reasonable.

To evaluate the r_z parameters the harmonic parts of the α-constants were subtracted off the ground state rotational constants for the two isotopes. The resulting ground state average values are in Table 5. A least-squares fit was then made to the BrS length and BrSC angle of ^{79}BrSCN, with the remaining parameters fixed at their r_z values in $S(CN)_2$ (4). The small variation of r_z (BrS) with isotope was estimated with a Morse potential, using a = 1.542 Å^{-1} (24). The results are also in Table 6; the derived values are very similar to the corresponding r_0 values.

Discussion and conclusions[2]

This work has confirmed unambiguously that bromine thiocyanate, like chlorine thiocyanate before it, is a thiocyanate, of formula BrSCN, rather than an isothiocyanate, of formula BrNCS. Very reasonable values for the BrS bond length and BrSC angle have been obtained (Table 6): the BrS length is similar to that found in other molecules, and to the sum of the single bond radii (22), and the BrSC angle is ~99°, in common with other molecules containing the —SCN group. The similarity between the r_0 and r_z parameters is reasonable for a molecule containing entirely heavy atoms. The need to assume some structural parameters, as well as the uncertainties in the derived values, would be reduced with further isotopic substitutions, such as of ^{34}S for ^{32}S. This substitution is usually done using natural abundances; unfortunately the observed signal-to-noise ratios (Figs. 1 and 2) were too low for transitions of the ^{34}S species (~4% abundant) to be identified.

The harmonic force field obtained is remarkably good, especially considering the paucity and relatively poor quality of the infrared data. It is particularly interesting to note that it gives a

θ_{za} (deg)[b]	33.12 (2)	33.05 (4)

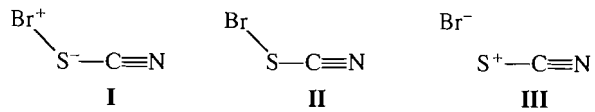
[a]Numbers in parentheses are one standard deviation in units of the last significant figures.
[b]θ_{za} is the angle between the z-principal axis and the a-inertial axis.

calculated inertial defect of 0.436 amu Å^2 for both isotopic species, in very good agreement with the observed values near 0.448 amu Å^2. The major contributor to this is, however, the lowest frequency mode, for the approximate formula $\Delta = 4K/\omega$, with $K = h/8\pi^2$ (25). and assuming $\omega = 154 \pm 30\,cm^{-1}$, gives $\Delta = 0.438 \pm 0.08$ amu Å^2, in comparable agreement with experiment.

The Br quadrupole coupling tensors were diagonalized to give the principal values. These results are in Table 9. The angle between the z-principal axis and the a-inertial axis is also given there. It is 33.1°, slightly smaller than the angle between the Br—S bond and the a-axis (34.4°). In terms of simple bonding theories the difference is probably not significant, and the maximum electron density can be taken to lie along the BrS internuclear axis. However, it is interesting that the difference is very similar to those found for BrNCO (15), INCO (17) and ClHCCO (26). It is not immediately clear what the cause of the difference is, or even if it is significant.

The difference ($\chi_{xx} - \chi_{yy}$) is an indication of the π character of the BrS bond. Using well known equations (27) this is estimated to be ~5%, with more electron density in the Br $4p_y$ (out-of-plane) orbital than in the $4p_x$ orbital. The cause of this is unclear. One possibility is an in-plane π bond, with electron density donated from the Br atom to the S atom (presumably d-orbitals) (form **I** below).

The degree of ionic character, i.e., the contribution of form **III**, was also calculated from the quadrupole constants. Its



I II III

value came to 9%. Evidently the BrS bond is predominantly (~85%) covalent, in keeping with the comparable electronegativities of Br and S.

Coupled transport of iodide ions during interdiffusion of aqueous HCl and NaOH

DEREK G. LEAIST
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received April 29, 1987

DEREK G. LEAIST. Can. J. Chem. **65**, 2489 (1987).

Stokes diaphragm cells have been used to study multicomponent diffusion in aqueous HCl–NaOH–NaI mixtures at 25°C. The nine quaternary diffusion coefficients for the mixture containing 0.025 mol L^{-1} of each electrolyte are reported. The measured coefficients are used to analyze coupled transport of iodide ions generated by interdiffusion of aqueous HCl and NaOH. The analysis shows that the gradient in concentration of NaOH is twice as effective at producing flow of iodide ions relative to the HCl gradient, and that the NaI gradient substantially alters the rates of diffusion of HCl and NaOH components. Equations are developed for predicting multicomponent transport coefficients that describe coupled transport of ions driven by interdiffusion of strong acids and bases.

DEREK G. LEAIST. Can. J. Chem. **65**, 2489 (1987).

On a utilisé des cellules à diaphragme de Stokes pour étudier la diffusion à plusieurs composantes dans des mélanges aqueux de HCl/NaOH/NaI, à 25°C. On rapporte les neuf coefficients de diffusion quaternaire pour le mélange contenant 0,025 mol L^{-1} de chacun des électrolytes. On a utilisé les coefficients ainsi déterminés pour analyser les transports couplés d'ions iodures qui sont provoqués par l'interdiffusion du HCl et du NaOH aqueux. L'analyse démontre qu'un gradient en concentration de NaOH est deux fois plus efficace qu'un gradient en concentration de HCl pour produire un écoulement des ions iodures; par ailleurs, le gradient de NaI affecte d'une façon importante les vitesses de diffusion des composantes HCl et NaOH. On a développé les équations nécessaires pour prédire les coefficients de transport dans des systèmes à plusieurs composantes qui décrivent le transport couplé des ions qui est provoqué par de l'interdiffusion d'acides forts et de bases fortes.

[Traduit par la revue]

1. Introduction

When a pH gradient is formed in a mixed electrolyte solution, the resulting flow of hydrogen or hydroxyl ions can produce large and potentially useful coupled flows of other ions (1). Recently, for example, interdiffusion of aqueous hydrochloric acid and sodium hydroxide was used to concentrate sodium(1), copper(2), and chromium(3) ions by transporting them against their concentration gradients, from regions of low concentration into regions of higher concentration. Separation of specific ions can be achieved by maintaining pH differences across liquid membranes that contain mobile carrier compounds which bind and transport selected ions (1–3).

Coupled transport of ions is often described by numerically solving the Nernst–Planck equations (4, 5)

$$[1] \qquad j_i = -D_i\nabla c_i + (z_i c_i D_i F/RT)E$$

where j_i, c_i, z_i, and D_i are the molar flux densities, concentrations, valences, and diffusion coefficients of the various ions, F is the Faraday, and E is the diffusion-induced electric field. Because ideal solutions are assumed, Nernst–Planck equations are accurate only for very dilute electrolyte solutions. If association or dissociation reactions occur, the diffusion coefficients and concentrations of certain species may be difficult to determine.

These limitations can be overcome by using multicomponent Fick equations (6, 7).

$$[2] \qquad J_i = -\sum_{k=1}^{n} D_{ik}\nabla C_k$$

Here, J_i and C_i denote the molar flux densities and concentrations of neutral solute components, such as HCl and NaOH, coefficient D_{ik} measures the flux of component i produced by the gradient in component k. Because concentrations of solute components can be measured by conventional analytical techniques, reliable values of D_{ik} can be determined by standard experimental procedures (2, 9), regardless of the number of components or reaction equilibria. The D_{ik} coefficients include the effects of the electric field implicitly. Consequently, separate calculation of E is not required. Moreover, the D_{ik} coefficients incorporate non-ideal transport behavior.

In the work reported here, multicomponent diffusion coefficients are measured for aqueous HCl–NaOH–NaI mixtures, and Fick equations are used to analyze coupled transport of iodide ion during interdiffusion of aqueous hydrochloric acid and sodium hydroxide.

2. Experimental

Diffusion in aqueous HCl(C_1)–NaOH(C_2)–NaI(C_3) mixtures was measured at 25°C by using Stokes magnetically stirred diaphragm cells. Rates of diffusion of each electrolyte were followed by determining concentration changes after diffusion for a timed interval between upper and lower solution compartments through liquid held in the pores of a sintered Pyrex disc. Details of cell construction have been reported (7, 10).

The cells were filled with the appropriate initial solutions, stirred for about 2 h to establish steady-state diffusion, then reloaded with fresh solutions and stirred for 0.5 to 4 days. At the end of a run, 10 mL samples of the upper and lower solutions were titrated against 0.1 mol L^{-1} silver nitrate. A silver indicator electrode with calomel reference and sodium sulfate bridging electrolyte was used. The volumes of titrant required to reach the first and second endpoints (11) gave the concentrations of iodide (C_3) and total halide ($C_1 + C_3$), respectively, and hence the concentrations of the HCl (C_1) and NaI components (C_3). Separate 10 mL samples of solution were titrated against standardized NaOH or HCl to determine the concentration of excess acid or base ($|C_1 - C_2|$), and hence the concentration of the NaOH component (C_2). The endpoint was detected with a glass electrode. Measured values of C_1, C_2, and C_3 were reproducible within ±0.5, 0.6, and 0.2 mmol L^{-1}, respectively.

The diaphragm cells were calibrated at frequent intervals by diffusing 0.5 mol L^{-1} KCl into pure water. Cell constants, β (2000 – 2500 m^{-2}), were computed from the relation

$$[3] \qquad \Delta C(t) = \Delta C(0)\exp(-\beta\bar{D}t)$$

where $\Delta C(t)$ is the concentration of KCl in the lower solution less the concentration in the upper solution at time t. Values of $\bar{D}$, the integral

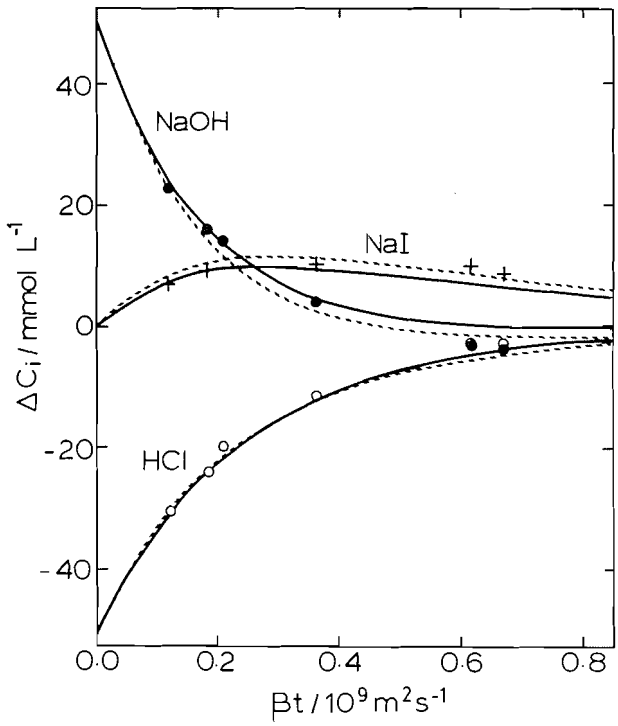

FIG. 1. Comparison of measured and predicted concentration differences during interdiffusion of 50 mmol L^{-1} NaOH + 25 mmol L^{-1} NaI solution (lower compartment) and 50 mmol L^{-1} HCl + 25 mmol L^{-1} NaI solution (upper compartment) at 25°C. Solid curve: eqs. [6] and measured $\bar{D}_{ik}$ values (Table 1). Dashed curve: eqs. [6] and predicted $\bar{D}_{ik}$ values (eqs. [11]).

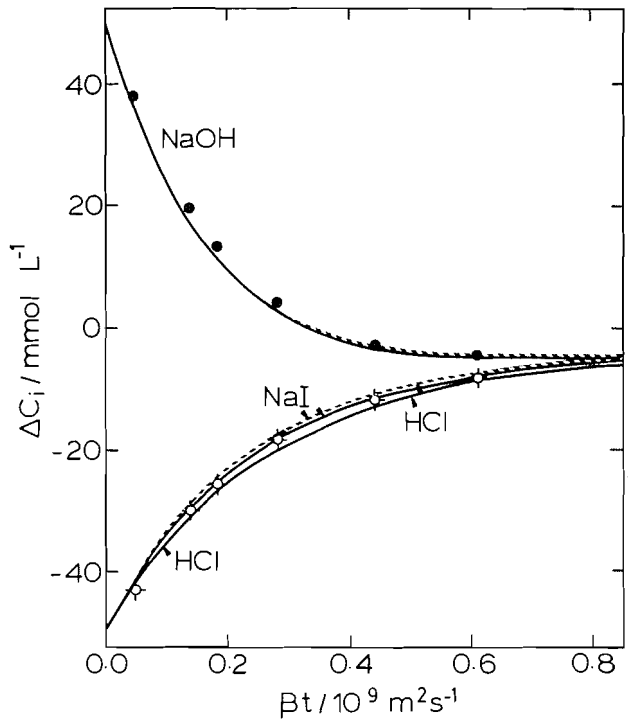

FIG. 2. Comparison of measured and predicted concentration differences during interdiffusion of 50 mmol L^{-1} NaOH and 50 mmol L^{-1} HCl + 50 mmol L^{-1} NaI.

diffusion coefficient for aqueous KCl, were interpolated from the data reported by Woolf and Tilley (12).

Reagent grade $AgNO_3$, KCl, and NaI were dried in a vacuum oven at 110°C. Solutions of the salts were prepared with de-ionized, distilled water in calibrated volumetric flasks. Stock solutions of NaOH were prepared by dilution of filtered saturated solutions, then standardized against dried potassium hydrogen phthalate. The NaOH solutions were used to standardize HCl solutions which were prepared by dilution of concentrated reagent grade acid.

3. Results and discussion

Three sets of experiments were performed at the mean cell composition: 25 mmol L^{-1} HCl + 25 mmol L^{-1} NaOH + 25 mmol NaI.

In the first set of experiments, 50 mmol L^{-1} NaOH + 25 mmol L^{-1} NaI, initially in the lower compartment, diffused into 50 mmol L^{-1} HCl + 25 mmol L^{-1} NaI, in the upper compartment. The results of these experiments are shown in Fig. 1 where the measured differences in component concentrations across the cell diaphragms are plotted against βt. Notice that interdiffusion of HCl and NaOH components causes the NaI component to diffuse into the NaOH solution, co-current to the flow of HCl. For values of βt less than about 0.3×10^9 s m^{-2}, iodide ions are driven "up" the iodide gradient. For larger values of βt, however, the gradients in HCl and NaOH decay sufficiently to allow backflow of iodide ions into the upper compartment.

When aqueous HCl and NaOH interdiffuse, an electric field is generated to maintain electroneutrality in the solutions by slowing down the highly mobile H^+ and OH^- ions (7). The electric field should drive I^- ions into the NaOH solution, which is consistent with the observed behaviour.

The binary diffusivity of aqueous HCl (13, 14) is significantly larger than the binary diffusivity of NaOH (15). In the solutions under discussion, however, the HCl and NaOH components have similar apparent diffusivities since ΔC_1(HCl) and ΔC_2(NaOH) decay at similar rates.

In this second set of experiments, 50 mmol L^{-1} NaOH solution diffused into 50 mmol L^{-1} HCl + 50 mmol L^{-1} NaI solution. The results are shown in Fig. 2. In these experiments the NaI component diffuses more rapidly than the HCl component. This result is unexpected since the binary diffusivity of aqueous HCl (13, 14) is nearly twice that of NaI (16).

Figure 3 shows the results of the final set of experiments in which 50 mmol L^{-1} NaOH + 50 mmol L^{-1} NaI solution diffused into 50 mmol L^{-1} HCl solution. Because the HCl and NaOH gradients tend to drive the NaI component back into the NaOH solution, the NaI component diffuses relatively slowly in these experiments. Study of Figs. 2 and 3 shows that diffusion of the NaOH component counter-current to NaI is almost twice as rapid as diffusion of NaOH co-current to NaI. Counter-current flow of NaI also speeds up diffusion of the HCl component, but to a lesser extent.

Measured $\bar{D}_{ik}$ coefficients

Although five different solute species (H^+, Cl^-, Na^+, OH^-, and I^-) diffuse in the HCl–NaOH–NaI solutions, electroneutrality and local equilibrium of the rapid $H^+ + OH^- = H_2O$ reaction reduce to three the number of independent solute flows. Consequently, isothermal diffusion in the solutions can be described by quaternary Fick equations (eqs. [2] with $n = 3$).

In order to provide a comprehensive description of the diffusion behavior, including the rate of diffusion of each electrolyte and its ability to produce coupled flows of the other electrolytes, all nine quaternary diffusion coefficients were measured. The coefficients were determined at the average

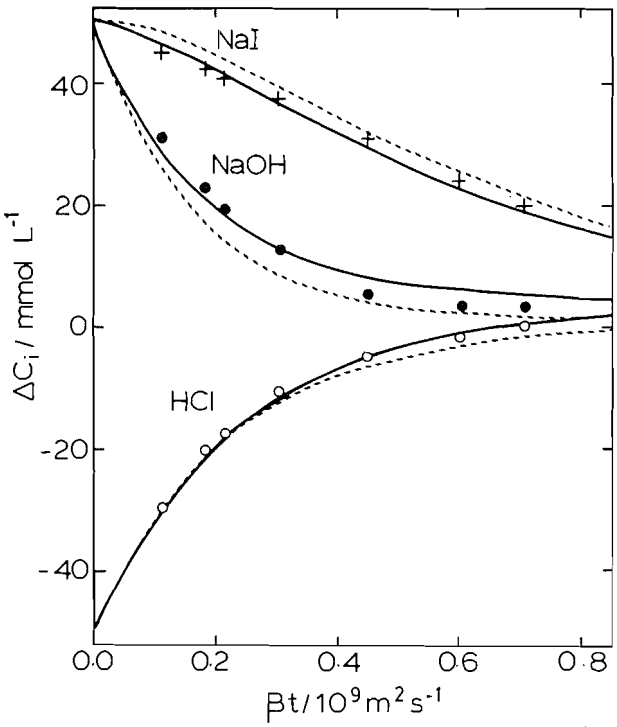

FIG. 3. Comparison of measured and predicted concentration differences during interdiffusion of 50 mmol L^{-1} NaOH + 50 mmol L^{-1} NaI and 50 mmol L^{-1} HCl.

cell composition 25 mmol L^{-1} HCl + 25 mmol L^{-1} NaOH + 25 mmol L^{-1} NaI by using Kosanovich and Cullinan's matrix procedure (9). First, data from three runs, each with different initial solutions but identical values of βt, were used to evaluate the 3 × 3 matrix **Q**

$$[4] \qquad \mathbf{Q} = [\Delta_1 C(0)\ \Delta_2 C(0)\ \Delta_3 C(0)] \times [\Delta_1 C(\beta t)\ \Delta_2 C(\beta t)\ \Delta_3 C(\beta t)]^{-1}$$

where $\Delta_i C(\beta t)$ designates the 3 × 1 column vector of component concentration differences at time t from the ith run. Integral values of D_{ik} were then calculated from the relation (9)

$$[5] \qquad \bar{\mathbf{D}} = \mathbf{P} \begin{pmatrix} \ln Q^{(1)} & 0 & 0 \\ 0 & \ln Q^{(2)} & 0 \\ 0 & 0 & \ln Q^{(3)} \end{pmatrix} \mathbf{P}^{-1}/\beta t$$

where $Q^{(i)}$ are the eigenvalues (17) of Q and the columns of **P** are the corresponding eigenvectors.

At a given mean cell composition, three runs are sufficient to determine the values of $\bar{D}_{ik}$. For improved precision, however, two additional runs were performed. The duration of each run was adjusted to give $\beta t = 0.1850 \times 10^9$ s m^2. This value was chosen so that concentration differences decayed by factors of about e^{-1} from initial values. The measured values of $\bar{D}_{ik}$ are listed in Table 1. These values were obtained by substitution of ΔC_i data from runs 1, 2, 3 or 1, 4, 5 (Table 2) into eqs. [4] and [5], then averaging the two sets of $\bar{D}_{ik}$ values.

Cross-coefficients $\bar{D}_{31}$ and $\bar{D}_{32}$, which measure the coupled flows of NaI produced by the gradients in HCl(1) and NaOH(2) components, are positive and negative, respectively. This indicates iodide ions are transported "down" HCl gradients and "up" NaOH gradients, in accordance with the behavior shown in Fig. 1. Because the magnitude of $\bar{D}_{32}$ is twice that of $\bar{D}_{31}$, NaOH gradients are twice as effective at transporting iodide compared to HCl gradients. This result is surprising since ternary diffusion experiments have shown that HCl gradients (18) produce larger coupled flows of ions than do NaOH gradients (19).

TABLE 1. Comparison of measured and predicted quaternary diffusion coefficients for 25 mmol L^{-1} HCl(1) + 25 mmol L^{-1} NaOH (2) + 25 mmol L^{-1} NaI(3) in aqueous solution at 25°C[a]

	Value	
$\bar{D}_{ik}$	Measured	Predicted
$\bar{D}_{11}$	3.01±0.16	3.24
$\bar{D}_{12}$	−1.08±0.11	−1.37
$\bar{D}_{13}$	−0.36±0.12	−0.16
$\bar{D}_{21}$	−1.83±0.16	−2.63
$\bar{D}_{22}$	4.19±0.12	4.32
$\bar{D}_{23}$	−0.85±0.12	−0.34
$\bar{D}_{31}$	0.66±0.14	1.15
$\bar{D}_{32}$	−1.31±0.10	−1.32
$\bar{D}_{33}$	2.16±0.10	1.88

[a] D_{ik} in units of 10^{-9} m^2 s^{-1}.

TABLE 2. Initial and final cell concentration differences used to calculate quaternary diffusion coefficients[a,b]

	Value				
Parameter	Run 1	Run 2	Run 3	Run 4	Run 5
$\Delta C_1(0)$	−50.0	−50.0	0.0	−50.0	50.0
$\Delta C_2(0)$	50.0	50.0	−50.0	50.0	0.0
$\Delta C_3(0)$	0.0	50.0	−50.0	−50.0	50.0
$\Delta C_1(\beta t)$	−24.0	−20.5	−9.0	−25.6	31.0
$\Delta C_2(\beta t)$	15.8	22.7	−29.4	13.4	13.1
$\Delta C_3(\beta t)$	9.2	42.4	−40.5	−25.7	31.4

[a] $\beta t = 0.1850 \times 10^9$ s m^{-2}.
[b] ΔC_i in units of mmol L^{-1}.

As mentioned earlier, the NaOH and HCl components have larger apparent diffusivities when they diffuse "up" the NaI gradient. This behavior is supported by the negative values which were determined for coefficients $\bar{D}_{13}$ and $\bar{D}_{23}$. Because $\bar{D}_{23}$ is larger than $\bar{D}_{13}$, the effect is more pronounced for the NaOH component.

A more quantitative test of the multicomponent description of the behavior shown in Figs. 1–3 can be obtained by comparing the measured concentration differences with values calculated from integrated Fick equations (20, 21). Integration of eqs. [2] for diaphragm cell diffusion gives (21)

$$[6] \qquad \Delta C_i(t) = \sum_{p=1}^{3} \sum_{q=1}^{3} A_{ip} B_{pq} \Delta C_q(0) \exp(-\beta \bar{\mathbf{D}}^{(\mathbf{P})} t)$$

where the columns of **A** are eigenvectors of $\bar{\mathbf{D}}$, $\mathbf{B} = \mathbf{A}^{-1}$, and $\bar{\mathbf{D}}^{(\mathbf{P})}$ are the eigenvalues of $\bar{\mathbf{D}}$.

The solid curves shown in Figs. 1–3 give component concentration differences that were calculated from eqs. [6] together with the experimental diffusion coefficients listed in Table 1. The measured and calculated values of $\Delta C_i(\beta t)$ are in very close agreement. The small discrepancies which are observed may be due to the concentration dependence of the integral diffusion coefficients, $\bar{D}_{ik}$. Values of $\bar{D}_{ik}$ represent averages of differential coefficients, $\bar{D}_{ik}$, taken over the range

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

composition between upper and lower solutions (7, 20). As a result, values of $\bar{D}_{ik}$ vary with time during each run, and a single set of $\bar{D}_{ik}$ values cannot give exact predictions of $\Delta C_i(\beta t)$ for all values of βt.

By using run combinations 1, 2, 3 and 1, 4, 5 to determine values of $\bar{D}_{ik}$, the average of the initial ($\beta t = 0$) final ($\beta t = 0.1850 \times 10^9\ m^2\ s^{-1}$) concentration differences are -18, 17, and 2 mmol L^{-1} for components HCl, NaOH, and NaI. These average differences correspond roughly to typical differences shown in Figs. 1–3. This helps to reduce the deviations between measured and calculated values of $\Delta C_i(\beta t)$. We will return to this point later in the discussion.

Predicted D_{ik} *coefficients*

A detailed interpretation of multicomponent diffusion in dilute electrolyte solutions can be made by tracing values of the D_{ik} coefficients back to the concentrations and mobilities of the various diffusing ions. The flux densities of the ions, j_i, can be expressed as (6)

$$[7] \qquad j_i = -\sum_{k=1}^{s} l_{ik} \nabla \tilde{\mu}_k$$

where $\nabla \tilde{\mu}_k$ are gradients in electrochemical potential of the ions and l_{ik} are ionic transport coefficients. At low ionic strengths it is a good approximation to neglect off-diagonal l_{ik} coefficients and write (22)

$$[8] \qquad l_{ii} = c_i u_i = c_i D_i / RT$$

where c_i, u_i, and D_i are the concentrations, absolute mobilities, and diffusivities of the ions, R is the gas constant, and T is the temperature.

This approximation can be used to estimate the Onsager coefficients of the components, L_{ik}, which are defined by flow equations (6)

$$[9] \qquad J_i = -\sum_{k=1}^{n} L_{ik} \nabla \mu_k$$

in which $\nabla \mu_k$ are the gradients in chemical potential of the neutral solute components. The multicomponent diffusion coefficients can then be estimated by using the identity (6)

$$[10] \qquad D_{ik} = \sum_{m=1}^{n} L_{im} \mu_{mk}$$

where $\mu_{mk} = \partial \mu_m / \partial C_k$. Details of the procedure for estimating values of D_{ik} are given in the Appendix.

Figure 4 shows values of D_{ik} that were predicted for compositions 50 mmol L^{-1} HCl + $(1 - x)$50 mmol L^{-1} NaOH + 25 mmol L^{-1} NaI, with $0 \leq x \leq 1$. Similar compositions are encountered along the diffusion path when 50 mmol L^{-1} NaOH + 50 mmol L^{-1} NaI solution diffuses into 50 mmol L^{-1} HCl + 25 mmol L^{-1} NaI solution, for example. The sharp changes in the diffusion coefficients at the equimolar HCl–NaOH composition closely resembles the behavior discussed previously for aqueous HCl–NaOH mixtures (7).

In order to compare measured and predicted values of the multicomponent diffusion coefficients, it is necessary to convert the predicted differential D_{ik} values to integral $\bar{D}_{ik}$ values. This is accomplished by using the expressions (7, 20)

$$[11] \qquad \bar{D}_{ik} = \int_0^1 D_{ik} \mathrm{d}\xi$$

$$[12] \qquad \xi = (C_i - \bar{C}_{iU})/(\bar{C}_{iL} - \bar{C}_{iU})$$

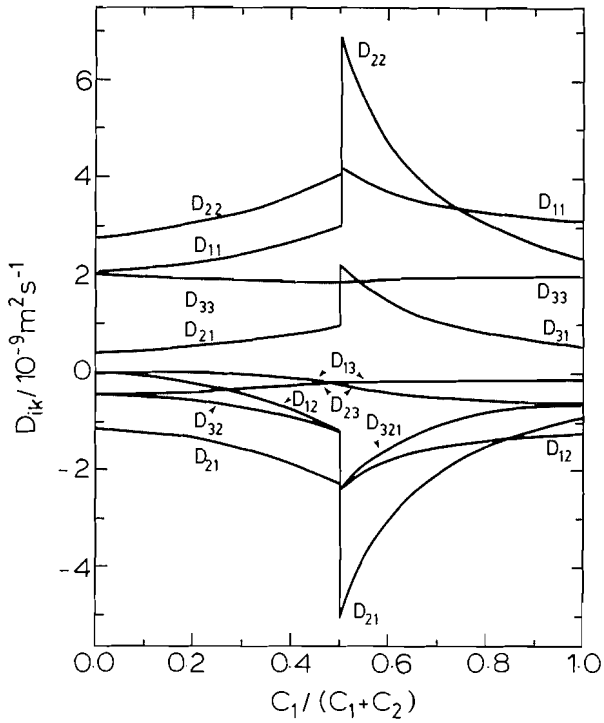

FIG. 4. Predicted values of the quaternary diffusion coefficients for aqueous HCl (50 mmol L^{-1}) – NaOH ($(1 - x)$50 mmol L^{-1}) – NaI(25 mmol L^{-1}) mixtures at 25°C with $0 \leq x \leq 1$ ($x = C_1/(C_1 + C_2)$).

where $\bar{C}_{iU}$ and $\bar{C}_{iL}$ denote mean component concentrations in the upper and lower solutions, the average of the concentrations at the beginning and end of a run for each compartment.

By averaging over run combinations 1, 2, 3 and 1, 5, 6 (Table 1), the values 34.2, 16.6, 23.9 and 15.8, 33.4, 26.1 mmol L^{-1} were obtained for $\bar{C}_{1U}$, $\bar{C}_{2U}$, $\bar{C}_{3U}$ and $\bar{C}_{1L}$, $\bar{C}_{2L}$, $\bar{C}_{3L}$, respectively. Numerical integration between these limits according to eqs. [11] and [12] gave the predicted integral values shown in Table 2. Except for the value of $\bar{D}_{21}$, which is too large, the predicted integral coefficients are in reasonable agreement with the experimental results.

To test the ability of predicted diffusion coefficients to account for the behavior shown in Fig. 1, values of $\bar{D}_{ik}$ were calculated by numerical integration of $\bar{D}_{ik}$ values from 37.5 mmol L^{-1} HCl + 12.5 mmol L^{-1} NaOH + 25 mmol L^{-1} NaI to 12.5 mmol L^{-1} HCl + 37.5 mmol L^{-1} NaOH + 25 mmol L^{-1} NaOH. These limits were obtained by averaging initial ($t = 0$) and final ($t \rightarrow \infty$) concentrations in the upper and lower cell compartments, respectively. The dashed curves shown in Fig. 1 were calculated by substitution of these $\bar{D}_{ik}$ into eqs. [6]. The dashed curves shown in Figs. 2 and 3 were obtained by similar procedures. The agreement between measured and predicted values of $\Delta C_i(\beta t)$ is almost as good as the agreement which was obtained by using experimental $\bar{D}_{ik}$ values.

The predicted values of each $\bar{D}_{ik}$ coefficient used in Figs. 1–3 differed by only $0.10 \times 10^{-9}\ m^2\ s^{-1}$ or less, which is within the present experimental error. Therefore it is a good approximation to treat integral coefficients as constants, even though the differential D_{ik} values show large variations along the diffusion path (7). This is an important result because it means that solutions to the multicomponent diffusion equations can be approximated reliably by convenient analytical expressions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12

without resorting to numerical methods, such as finite difference approximations.

In conclusion, this study has shown that multicomponent diffusion equations provide an accurate and detailed description of coupled diffusion during interdiffusion of a strong acid and base. The present work can be extended to weak electrolyte mixtures in which the diffusing species form ion associates.

Appendix

Expressions for the quaternary diffusion coefficients of aqueous HCl(C_1)–NaOH(C_2)–NaI(C_3) mixtures can be obtained by an extension of the procedure used for ternary HCl–NaOH mixtures (7).

The ions will be designated by subscripts: 1 = Cl^-, 2 = Na^+, 3 = H^+, 4 = OH^-, and 5 = I^-. The flux of the HCl component (total HCl) equals the flux of the Cl^- ions, and the flux of the NaI component equals the flux of I^- ions. Also, the total flux of Na^+ ions less the flux of Na^+ ions due to the NaI component gives the flux of the NaOH component (total NaOH).

[A13] $J_1(\mathrm{HCl}) = j_1(\mathrm{Cl}^-)$

[A14] $J_2(\mathrm{NaOH}) = j_1(\mathrm{Na}^+) - j_5(\mathrm{I}^-)$

[A15] $J_3(\mathrm{NaI}) = j_5(\mathrm{I}^-)$

The gradients in the chemical potentials of the components equal the sums of the gradients in the electrochemical potentials of the constituent ions, and hence

[A16] $\nabla\mu_1(\mathrm{HCl}) = \tilde{\mu}_1(\mathrm{Cl}^-) + \tilde{\mu}_3(\mathrm{H}^+)$

[A17] $\nabla\mu_2(\mathrm{NaOH}) = \tilde{\mu}_2(\mathrm{Na}^+) + \tilde{\mu}_4(\mathrm{OH}^-)$

[A18] $\nabla\mu_3(\mathrm{NaI}) = \tilde{\mu}_2(\mathrm{Na}^+) + \tilde{\mu}_5(\mathrm{I}^-)$

Electroneutrality and local equilibrium of the $H^+ + OH^- = H_2O$ reaction provide the following constraints.

[A19] $j_1(\mathrm{Cl}^-) + j_4(\mathrm{OH}^-) + j_5(\mathrm{I}^-) = j_2(\mathrm{Na}^+) + j_3(\mathrm{H}^+)$

[A20] $\nabla\tilde{\mu}_3(\mathrm{H}^+) + \nabla\tilde{\mu}_4(\mathrm{OH}^-) = 0$

Excess HCl ($C_1 > C_2$)

In mixtures containing excess HCl over NaOH, negligible amounts of OH^- ions are present

[A21] $c_4(\mathrm{OH}^-) = 0$

[A22] $j_4(\mathrm{OH}^-) = 0$

and $c_1(\mathrm{Cl}^-) = C_1$, $c_2(\mathrm{Na}^+) = C_2 + C_3$, $c_3(\mathrm{H}^+) = C_1 - C_2$, $c_4(\mathrm{OH}^-) = K_w/(C_1 - C_2) \cong 0$, and $c_5(\mathrm{I}^-) = C_3$. Upon substitution of eqs. [A13]–[A22] into eqs. [9] and elimination of any two of the five $\nabla\tilde{\mu}_i$, the following expressions are obtained

[A23] $L_{11} = l_{11}(l_{22} + l_{33} + l_{55})/H$

[A24] $L_{12} = L_{21} = l_{11}(l_{22} + l_{55})/H$

[A25] $L_{13} = L_{31} = -l_{11}l_{55}/H$

[A26] $L_{22} = (l_{11} + l_{33})(l_{22} + l_{55})/H$

[A27] $L_{23} = L_{32} = -l_{55}(l_{11} + l_{33})/H$

[A28] $L_{33} = l_{55}(l_{11} + l_{22} + l_{33})/H$

where H is an abbreviation for

[A29] $H = l_{11} + l_{22} + l_{33} + l_{55}$

Differentiation of the expressions for the chemical potentials of the components

[A30] $\mu_1(\mathrm{HCl}) = \mu_1^0 + RT \ln [(C_1 - C_2)C_1y_1y_3]$

[A31] $\mu_2(\mathrm{NaOH}) = \mu_2^0 + RT \ln [(C_2 + C_3)K_w(C_1 - C_2)^{-1}y_2y_4]$

[A32] $\mu(\mathrm{NaI}) = \mu_3^0 + RT \ln [(C_2 + C_3)C_3y_2y_5]$

gives

[A33] $\mu_{11}/RT = C_1^{-1} + (C_1 - C_2)^{-1} + G$

[A34] $\mu_{12} = \mu_{21} = (C_2 - C_1)^{-1}$

[A35] $\mu_{13} = \mu_{31} = G$

[A36] $\mu_{22} = C_2 + C_3$

[A37] $\mu_{23}/RT = \mu_{32}/RT = (C_2 + C_3)^{-1}$

[A38] $\mu_{33}/RT = C_3^{-1} + (C_2 + C_3)^{-1} + G$

where G stands for

[A39] $G = -S_f I^{1/2}/(1 + I^{1/2})^2$

These expressions were obtained by assuming that the ionic activity coefficients, y_i, are given by the semi-empirical relation (23)

[A40] $\ln y_i = -S_f z_i^2 I^{1/2}/(1 + I^{1/2})$

where I is the ionic strength in units of mol L^{-1} ($I = C_1 + C_3$ in this case) and $S_f = 1.17$ for aqueous solutions at 25°C.

The predicted values of the D_{ik} shown in Fig. 4 were obtained by substitution of eqs. [A23]–[A29] for the L_{im} coefficients and eqs. [A33]–[A39] for the μ_{mk} derivatives into eqs. [10]. The calculations employed ionic diffusivities $D_1(Cl^-) = 2.03 \times 10^{-9}$, $D_2(Na^+) = 1.33 \times 10^{-9}$, $D_3(H^+) = 9.31 \times 10^{-9}$, and $D_5(I^-) = 2.05 \times 10^{-9}$ m^2 s^{-1} which were obtained from published limiting molar ionic conductivities (24), λ_i^0, by using the relation $D_i = \lambda_i^0 RT/(z_i F)^2$.

If activity coefficient terms are dropped, the expressions for the D_{ik} coefficients simplify remarkably to give the following limiting expressions

[A41] $D_{11} = (1 - t_1)D_1 + t_1 D_3$

[A42] $D_{12} = t_1(D_2 - D_3)$

[A42] $D_{13} = t_1(D_2 - D_5)$

[A44] $D_{21} = (t_2 + t_5)(D_1 - D_3)$

[A45] $D_{22} = (1 - t_2 - t_5)D_2 + (t_2 + t_5)D_3$

[A46] $D_{23} = (1 - t_2 - t_5)(D_2 - D_5)$

[A47] $D_{31} = t_5(D_3 - D_1)$

[A48] $D_{32} = t_5(D_2 - D_3)$

[A49] $D_{33} = (1 - t_5)D_5 + t_5 D_2$

where t_i denotes the limiting transference number of ion i

[A50] $t_i = c_i z_i^2 D_i/\Sigma c_k z_k^2 D_k$

Excess NaOH ($C_2 > C_1$)

Expressions for the transport coefficients of the alkaline mixtures can be obtained by replacing l_{33} (for H^+ ions) with l_{44} (for OH^- ions), and permuting subscripts 1 and 2 on L_{ik} and μ_{ik} in eqs. [A23]–[A29] and eqs. [A33]–[A39]. The corresponding limiting expressions for the D_{ik} coefficients can be obtained by replacing D_3 with D_4 and permuting subscripts 1 and 2 on the D_{ik} in eqs. [A41]–[A50]. At 25°C the limiting value of $D_4(OH^-)$ is 5.28×10^{-9} m^2 s^{-1} (24).

Charge distributions and chemical effects. XLIII. Bond dissociation energies and radical formation

SÁNDOR FLISZÁR AND CAMILLA MINICHINO[1]

Département de Chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Qué.), Canada H3C 3J7

Received April 2, 1987

SÁNDOR FLISZÁR and CAMILLA MINICHINO. Can. J. Chem. **65**, 2495 (1987).

The problem of bond dissociation, $R_1R_2 \rightarrow R_1\cdot + R_2\cdot$, is addressed from the viewpoint that the fragments, R_1 and R_2, may not be individually electroneutral in the host molecule, whereas the corresponding radicals certainly are. The mutual charge neutralization of R_1 by R_2 during the cleavage of the bond linking R_1 to R_2 is described by an expression featuring only molecular ground-state properties. This expression translates directly into a new energy formula for the dissociation energy, $D^*(R_1R_2) = \epsilon(R_1R_2) + CNE - E^*_{nb} + RE(R_1) + RE(R_2)$, where both the molecule and the radicals are taken at their potential minimum. The charge neutralization energy, CNE, profoundly affects the relationship between the dissociation (D^*) and contributing bond energy (ϵ), i.e., the energy in the unperturbed molecule. Nonbonded interactions between R_1 and R_2, E^*_{nb}, are almost negligible. The reorganizational energy, RE, measures the energy difference between $R\cdot$ and the corresponding electroneutral group found in the symmetric molecule RR. Numerical applications to alkanes reveal an important cancellation of individual CNE terms accompanying the mutual charge neutralization of alkyl groups during the cleavage of CC bonds, i.e., $CNE - E^*_{nb} \simeq 0$. Theoretical ϵ_{CC}'s lead to valid CC bond dissociation energies. In CH bond dissociations, on the other hand, the sum $\epsilon_{CH} + CNE$ remains nearly constant although individual ϵ_{CH}'s may differ from one another by as much as 6 kcal mol^{-1}. The appropriate approximation, $D^*_{CH} \simeq$ constant + RE, shows in what manner charge neutralization energies disguise genuine contributing CH bond energies to create a perception of seemingly constant CH bond contributions.

SÁNDOR FLISZÁR et CAMILLA MINICHINO. Can. J. Chem. **65**, 2495 (1987).

La dissociation d'un lien, $R_1R_2 \rightarrow R_1\cdot + R_2\cdot$, est décrite en tenant compte que dans la molécule les fragments R_1 et R_2 ne sont pas habituellement électriquement neutres à titre individuel, tandis que les radicaux correspondants le sont certainement. On déduit une équation pour l'énergie de neutralisation de charge, ENC, décrivant la neutralisation de R_1 par R_2. Il en découle une formule pour l'énergie de dissociation, $D^*(R_1R_2) = \epsilon(R_1R_2) + ENC - E^*_{nl} + RE(R_1) + RE(R_2)$, la molécule et les radicaux étant pris à leur minimum de potentiel, où $\epsilon(R_1R_2)$ est l'énergie de lien (qui dépend des charges) dans la molécule non perturbée. La contribution des interactions entre atomes non liés, E^*_{nl}, est pratiquement négligeable. L'énergie de réorganisation, RE, mesure la différence d'énergie entre $R\cdot$ et le groupement électriquement neutre qui lui correspond, tel qu'il est trouvé dans la molécule symmétrique RR. L'étude des alcanes révèle que $ENC - E^*_{nl} \simeq 0$ lors du clivage des liens CC. L'utilisation des énergies ϵ_{CC} théoriques permet une bonne évaluation des énergies de dissociation D^*_{CC}. D'autre part, la somme $\epsilon_{CH} + ENC$ est pratiquement constante pour les liens CH en dépit d'importantes variations individuelles des énergies de lien ϵ_{CH}. L'approximation $D^*_{CH} \simeq$ constante + RE indique bien comment l'énergie de neutralisation de charge, ENC, déguise les liens CH en les faisant paraître comme s'ils étaient tous de même énergie dans les molécules non perturbées.

[Traduit par la revue]

The concept of chemical bond is fundamental to chemistry. Its energetic aspects are at the center of this study, both for non-reacting molecules and for molecules undergoing bond cleavage.

Under laboratory conditions, molecules contain vibrational, translational, and rotational energies which are not fairly partitionable among chemical bonds. For convenience, our analysis considers the molecules at their potential minimum, i.e., with reference to their hypothetical vibrationless state at 0 K; the role of vibrational energies is treated as a separate problem. The measure for what holds the atoms together in a molecule is thus offered by the difference

ΔE^*_a = energy of all the isolated ground-state atoms minus the ground-state energy of the molecule

which is the energy required for breaking up that molecule into its constituent atoms. The atomization energy, ΔE^*_a, includes the annihilation of all interactions between atom pairs which are not chemically bonded to one another in the conventional sense, ΔE^*_{nb}, and the destruction of all chemical bonds ij, represented by their energies ϵ_{ij}, i.e.,

$$[1] \quad \Delta E^*_a = \sum_{i<j} \epsilon_{ij} + \Delta E^*_{nb}$$

It turns out that nonbonded interactions are minor (1, 2), ~0.02–0.05% of ΔE^*_a, so that the study of ΔE^*_a essentially reduces to a consideration of bond energies, $\Delta E^*_a \simeq \sum_{i<j} \epsilon_{ij}$.

We must now become familiar with the precise meaning of ϵ_{ij}. It represents the part of the total atomization energy which is contributed by a particular ij bond. This contribution is dictated by actual properties in the molecule (internuclear distance and local charge density) and should not be mistaken for the energy required to break that bond. Indeed, bond dissociation energies depend also on electronic rearrangements, such as making sure that electroneutral fragments are formed during the cleavage of a bond, and on important structural changes in polyatomic fragments. For example (1, 2), ϵ_{CH} is 104.86 kcal mol^{-1} for the CH bond in methane, in which H carries a partial charge. The actual cleavage of this bond, however, requires $D^*_{CH} = \sim 111.4$ kcal mol^{-1} and results in a neutral H atoms and a methyl radical which differs considerably from the original CH_3 group in CH_4. D^*_{ij}, expressed for a molecule and its fragments at their potential minimum, is

$$[2] \quad D^*_{ij} = \Delta E^*_a(R_iR_j) - \Delta E^*_a(R_i\cdot) - \Delta E^*_a(R_j\cdot)$$

where R_iR_j is the molecule and $R_i\cdot$, $R_j\cdot$ are the free radicals produced upon cleavage of the ij bond. The link between D^*_{ij} and ϵ_{ij} is one of the topics covered in this study.

The bond dissociation energy, D^*_{ij}, can be obtained from

experiment; it bears an important part in problems of chemical reactions. The contributing bond energy, ϵ_{ij}, on the contrary, can only be calculated. Of course, it has to satisfy eq. [1]. Moreover, if it is to offer a realistic understanding of the nature of chemical bonding, ϵ_{ij} should be rooted in, and derivable from, quantum theory, as opposed to purely empirical sets of bond energies constructed solely with eq. [1] in mind and involving as many parameters as required to do the job.

Let us now examine a point of utmost importance regarding theoretical bond energies. Reference energies, ϵ^0_{ij}, can be deduced (1, 2) from appropriately selected reference molecules, e.g., $\epsilon^0_{CC} = 69.633$ and $\epsilon^0_{CH} = 106.806$ kcal mol^{-1} for the ethane CC and CH bonds, respectively. A transfer of bond energies (like the ϵ^0_{CC} and ϵ^0_{CH} energies deduced for ethane) from one molecule to another implies the transfer of the bond-forming atoms as they are in the molecule for which they were derived. Such a transfer, involving invariant "local" electron populations, cannot (as a rule) describe an electroneutral molecule (1, 2). For example, if the ethane C and H net charges are 0.0351 and −0.0117 e, respectively, a methane "molecule" constructed from these "atoms" would carry a negative charge of −0.0117 e. Clearly the simple transfer of selected reference bond energies ϵ^0_{ij} would not satisfy the requirement for molecular electroneutrality. The appropriate charge renormalization accompanying the use of reference bond energies ϵ^0_{ij} leads to a description of ϵ_{ij} featuring net atomic charges, namely (1, 2),

$$[3] \quad \epsilon_{ij} = \epsilon^0_{ij} + a_{ij}\Delta q_i + a_{ji}\Delta q_j$$

Here we have ϵ^0_{ij} for a reference bond with net charges q^0_i and q^0_j at atoms i and j, respectively, whereas ϵ_{ij} corresponds to modified charges, $q_i = q^0_i + \Delta q_i$ and $q_j = q^0_j + \Delta q_j$. The a_{ij} and a_{ji} parameters, "measuring" the changes in bond energy accompanying unit charge variations at atoms i and j, respectively, are derived from theory. Typical values are, for alkanes, $a_{CC} = -0.488$, $a_{CH} = -0.247$, and $a_{HC} = -0.632$ kcal mol^{-1} me^{-1} (1 me = 10^{-3} e). The remarkable feature is that eq. [3] describes equally well the CH bonds of methane (1, 2), ethylene (3*a*), and benzene (3*b*) or the CC single bonds of ethane, propene (3*b*), biphenyl (3*b*), butadiene (3*b*), etc. The sum of these bond contributions, i.e., from eq. [1],

$$[4] \quad \Delta E^*_a = \sum_{i<j} \epsilon^0_{ij} + \sum_i \sum_j a_{ij}\Delta q_i + \Delta E^*_{nb}$$

is in all cases to its experimental counterpart, within ~0.23 kcal mol^{-1} (average deviation). Briefly, theoretical bond energies offer a consistent and quite general description of molecular energies on a conceptually simple basis, eq. [3].

Our approach differs considerably in conceptual content from earlier descriptions of alkanes (4*a*) and alkyl radicals (4*b*), in a strategy postulating electrostatic interactions between net charges, $E^{el} = \Sigma_{i<j} q_i q_j / r_{ij}$. For the alkanes, all H charges were empirically fixed at 58.1 me, with C carrying the neutralizing negative charge. This is clearly at odds with theoretical charge analyses. Still, with the aid of two additional empirical parameters, this scheme permitted evaluation of standard enthalpies of formation for the alkanes, essentially because it discriminates primary, secondary, etc., C atoms. Similarly, experimental results of seven alkyl radicals were also well reproduced (4*b*), with the introduction of four new empirical parameters in addition to those used for the alkanes. This sort of empirical duplication of experimental results is, unfortunately, not informative as regards the formal relationship between a bond dissociation energy and the energy of that bond in the unperturbed ground-state molecule. Our energy calculations, eq. [4], involve only theoretical charges, ϵ^0_{ij} and a_{ij} results.

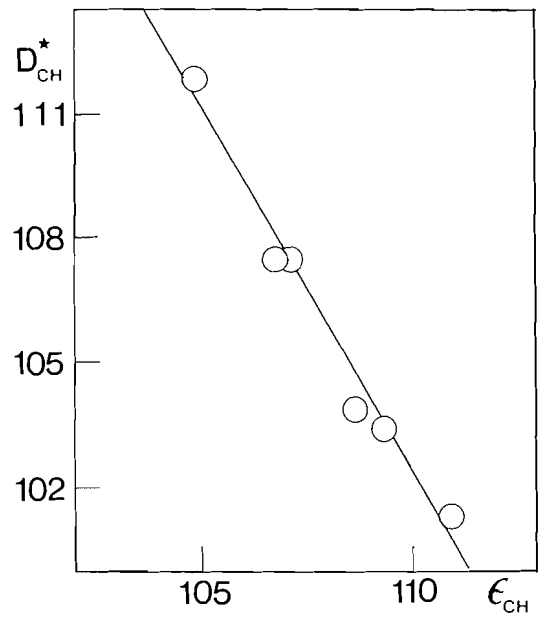

FIG. 1. Alkanes: a comparison between CH dissociation and theoretical contributing bond energies, eq. [3], in kcal mol^{-1}. The D^*_{CH} values were derived from experimental results by Castelhano and Griller (5).

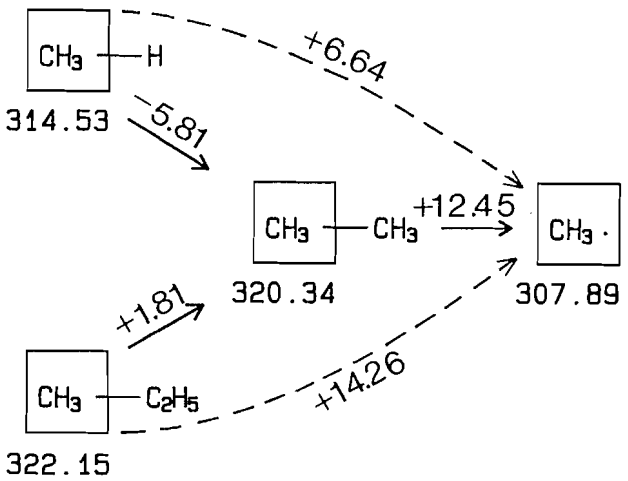
Now we come to the problems. The comparison between dissociation (D^*_{CH}) and contributing (ϵ_{CH}) bond energies in alkanes is intriguing (Fig. 1). It suggests that those CH which contribute larger ϵ_{CH}'s to thermochemical stability are easier to break, certainly a point requiring clarification. In addition, Sanderson's claim (6) that all contributing CH bond energies are equal should be examined. On one hand, this claim is diametrically opposed in conceptual content to the basic tenet embodied in our description of bond energies, namely, the preservation of molecular electroneutrality. Still, on the other hand, it deserves more than passing attention because of the undisputed success of Sanderson's approach — a success largely responsible for an interesting clash of opinions.

We feel that a patient processing of general theory, rather than an accumulation of empirically generated data, should offer better insight into the energetics governing free radical formation and explain the apparent discrepancies in the interpretation of bond energies. We have opted for a fresh start, in a perspective developed from a theoretical description of chemical bonds, aimed at a general description relating dissociation energies, D^*_{ij}, and contributing bond energies, ϵ_{ij}. Numerical examples are presented for alkanes.

Theory

At the center of our description of bond energies, electroneutrality constraints are important in two ways. (*i*) For ground-state molecules, the description of contributing bond energies featuring their dependence on the charges at the bond-forming atoms, eq. [3], is rooted in the conservation of molecular electroneutrality. (*ii*) In dissociation processes, $R_1R_2 \rightarrow R_1\cdot + R_2\cdot$, the individual fragments (R_1 and R_2) may not be electroneutral while they are part of the host molecule whereas the corresponding radicals certainly satisfy electro-



SCHEME 1. Calculated ΔE^*_a energies, eq. [4], for the methyl fragments found in methane, ethane, and propane and for the methyl radical (experimental value), in kcal mol^{-1}. The ΔE^*_a's (indicated under the corresponding boxes) illustrate how non-electroneutral CH_3 fragments (those of CH_4 and C_3H_8) compare with the electroneutral CH_3 of ethane and with the radical $CH_3\cdot$.

neutrality. This charge reneutralization represents the clue toward a realistic description of dissociation energies — a clue which can be exploited in two ways.

Our first strategy is illustrated by a numerical example, worked out for methyl groups (Scheme 1), but its conceptual content applies to any group R. Here we calculate the energies of all the bonds occurring in CH_3 and include the corresponding nonbonded contributions following eq. [1]. This gives $\Delta E^*_a(CH_3)$. Clearly, $\Delta E^*_a(CH_3)$ is deduced in the usual way (1, 2) from the appropriate atomic charges. The latter depend on what is attached to CH_3 and so does $\Delta E^*_a(CH_3)$. Thus all the CH_3 groups differ in energy from one another, and we know by how much. Therefore, it suffices to know how anyone differs from the radical $CH_3\cdot$ in order to gain the same information for the other CH_3 groups. A convenient reference is the electroneutral CH_3 of ethane, a choice which permits one to associate energy changes with charge neutralization — hence the term CNE = charge neutralization energy. The methyl of CH_4, for example, is electron deficient by 9.05 me (1, 2). When recovering that charge, its energy decreases by CNE = -5.81 kcal mol^{-1} (meaning that ΔE^*_a increases by that amount). Similarly, when the CH_3 of propane restores its electroneutrality by losing its excess electronic charge, 2.65 me (1, 2), its energy increases by CNE = $+1.81$ kcal mol^{-1}.

At this point we have acknowledged CNE as a useful concept permitting one to go from any R, described by $\Delta E^*_a(R)$, to the corresponding electroneutral R^0, described by $\Delta E^*_a(R^0)$. It suffices to know once and for all how R^0 differs from the radical $R\cdot$, i.e., the reorganization energy

$$[5] \quad RE = \Delta E^*_a(R^0) - \Delta E^*_a(R\cdot)$$

In order to learn how any R differs in energy from $R\cdot$. Having now secured this idea, there is a better way of exploiting it.

Two radicals are formed in any dissociation $R_1R_2 \rightarrow R_1\cdot + R_2\cdot$. For the problem at hand, it is more convenient to consider them jointly rather than proceeding *via* calculations of the individual CNE's, i.e., $\Delta E^*_a(R_1) - \Delta E^*_a(R_1{}^0)$ and $\Delta E^*_a(R_2) - \Delta E^*_a(R_2{}^0)$. If the portions of $\Delta E^*_a(R_1R_2)$ associated with R_1 and R_2 *as they exist in the molecule* are $\Delta E^*_a(R_1)$ and $\Delta E^*_a(R_2)$, respectively, their sum $\Delta E^*_a(R_1) + \Delta E^*_a(R_2)$ differs (in principle) from that of the corresponding electroneutral fragments, $\Delta E^*_a(R_1{}^0) + \Delta E^*_a(R_2{}^0)$. The difference between these sums is CNE, i.e.,

$$[6] \quad \Delta E^*_a(R_1) + \Delta E^*_a(R_2) = \Delta E^*_a(R_1{}^0) + \Delta E^*_a(R_2{}^0) + CNE$$

The individual ΔE^*_a's can be deduced from eq. [4]. However, this involves calculations for all the bonds found in R_1 and R_2, leaving out the only one of interest, namely, the bond linking R_1 with R_2 which is undergoing dissociation. Reverting now to a more practical strategy, we start with the energy of the molecule $\Delta E^*_a(R_1R_2)$, suppress the bond linking R_1 and R_2 and overcome the nonbonded interaction between R_1 and R_2 by supplying $\epsilon(R_1R_2) + \Delta E^*_{nb}(R_1\cdots R_2) = \epsilon(R_1R_2) - E^*_{nb}(R_1\cdots R_2)$. The energy balance gives

$$[7] \quad \Delta E^*_a(R_1R_2) - [\epsilon(R_1R_2) - E^*_{nb}(R_1\cdots R_2)] = \Delta E^*_a(R_1) + \Delta E^*_a(R_2)$$

and, using eq. [6],

$$[8] \quad CNE = \Delta E^*_a(R_1R_2) - \epsilon(R_1R_2) + E^*_{nb}(R_1\cdots R_2) - \Delta E^*_a(R_1{}^0) - \Delta E^*_a(R_2{}^0)$$

The $\Delta E^*_a(R^0)$'s are simply deduced from an application of eq. [7] to symmetric molecules RR, i.e.,

$$[9] \quad \Delta E^*_a(R^0) = \tfrac{1}{2}[\Delta E^*_a(RR) - \epsilon(RR) + E^*_{nb}(R\cdots R)]$$

Equation [8] enables the calculation of CNE energies from molecular ground-state properties. More importantly, it is the key equation for the description of bond dissociation energies. Indeed, using the definition of $D^*(R_1R_2)$, eq. [2], and that of reorganizational energy, eq. [5], it follows from eq. [8] that

$$[10] \quad D^*(R_1R_2) = \epsilon(R_1R_2) + CNE - E^*_{nb}(R_1\cdots R_2) + RE(R_1) + RE(R_2)$$

This energy formula is general and suffers from no approximations in that all the appropriate bonded and nonbonded contributions are taken care of. It is seen that CNE, eq. [8], is not just a correction term. Quite on the contrary, this particular form of electroneutrality constraint is all that is required for deducing the relationship between bond dissociation and contributing bond energies.

Numerical applications: the alkanes

Thermochemical data

Extensive studies, which are well reviewed (7), have dealt with the heats of formation of alkyl radicals. Two sets of experimental results are indicated in Table 1. Although some measurements were carried out in solution, they can be regarded as being equivalent to gas-phase data to a good approximation, for reasons given in detail elsewhere (5, 8). The sum of zero-point (ZPE) and heat content ($H_T - H_0$) energies, at 298.15 K, are also reported.

The atomization energies are conveniently deduced from the formula, valid for non-linear molecules,

$$[11] \quad \Delta E^*_a = \sum_i n_i[\Delta H_f(A_i) - \tfrac{5}{2}RT] + ZPE + (H_T - H_0) - \Delta H_f$$

where the $\Delta H_f(A_i)$'s are the standard enthalpies of formation of gaseous atoms (170.89 for C and 52.09 kcal atg^{-1} for H) (15). For all practical purposes, theoretical ΔE^*_a values for the

t-$C_4H_9\cdot$	9.4	10.3	9.0	75.04	1199.16

[a]Set 1 is taken from ref. 5. Set 2 is a critical selection given in ref. 9. The ZPE + $(H_T - H_0)$ energies, at 298.15 K, are based on experimental and calculated fundamental frequencies (10–12) giving, in the harmonic oscillator approximation, 20.74 ($CH_3\cdot$), 39.15 ($C_2H_5\cdot$), and 74.97 kcal mol^{-1} (t-$C_4H_9\cdot$). It is fortunate that ZPE + $(H_T - H_0)$ energies can be constructed to a good approximation by means of additivity rules (2). Theoretical foundation for this additivity, which has a long history (13), has been established (14). Present data suggest that ZPE + $(H_T - H_0)$ energies of alkyl radicals R· are systematically lower by 8.85 kcal mol^{-1} than those of their parent hydrocarbon RH. The values of the latter (2) are reported in Table 2. The $\Delta E^*_a(R\cdot)$ results were deduced from eq. [11].

hydrocarbons (1, 2), eq. [4], are the same as those deduced from eq. [11]. (Selected examples are given in Table 2.) In contrast, the study of radicals by means of eq. [4] is presently not feasible because of our lack of knowledge regarding their charges. SCF results would not provide adequate information: only charges obtained after configuration interaction would be suitable (16). Hence we resort to eq. [11] for the radicals — a task requiring a balanced selection of $\Delta H_f(R\cdot)$ values.

With the experimental data of Table 1, we obtain two sets of $\Delta E^*_a(R\cdot)$ values. From the ΔE^*_a's of the parent hydrocarbons (Table 2), we now deduce the corresponding D^*_{CH} energies, eq. [2]. (Those of Fig. 1 are for set 1.) The correlations with ϵ_{CH} bond energies (Appendix 1) are $D^*_{CH} = 296.98 - 1.77\epsilon_{CH}$ and $D^*_{CH} = 294.70 - 1.75\epsilon_{CH}$ kcal mol^{-1} from sets 1 and 2, respectively. While the correlation derived from set 1, including $CH_3\cdot$ and t-$C_4H_9\cdot$, exhibits a small and uniform scatter about the correlation line (ave. dev. $\simeq 0.38$), with set 2 the correlation is generally excellent (ave. dev. $\simeq 0.26$ kcal mol^{-1}) except for $CH_3\cdot$ and t-$C_4H_9\cdot$ which deviate by ~ 1.3 kcal mol^{-1} from the correlation line. Tentatively assuming the approximate validity of this type of empirical correlation, back calculation of $\Delta H_f(R\cdot)$ yields virtually the same results using either of these correlation lines. This strategy suggests a balanced set of $\Delta H_f(R\cdot)$ values. Of course, not too much weight should be attached to this particular selection, but it seems reasonable to expect that it would confine any scatter about the true $\Delta H_f(R\cdot)$ values within acceptable limits — a view supported by recent experimental data (5, 17) and critical review of earlier work (18). The corresponding $\Delta E^*_a(R\cdot)$ values are indicated with a precision which is not warranted by our actual knowledge. They are used here primarily in order to facilitate recalculations without being continually bothered by rounding-off errors. None of the conclusions reached in this paper critically depends on the assumed precision of the data given in Table 1.

As regards the correlation $D^*_{CH} = 295.91 - 1.76\epsilon_{CH}$ kcal mol^{-1} between dissociation and intrinsic bond energies (Table 3), a point must be made concerning radicals like $CH_3CH_2CH_2\cdot$, $C_3H_7CH_2\cdot$, and $(CH_3)_2CHCH_2\cdot$. Here we ask which of the non-equivalent CHa or CHs bonds of the parent hydrocarbon is involved (Table 4). It turns out that it is systematically the weaker of the two possible CH bonds that obeys the correlation with D^*_{CH}. Cyclohexane follows the same pattern. For the equatorial CH bond, $\epsilon_{CH} = 109.28$, we obtain D^*_{CH}(equat.) = 103.58 kcal mol^{-1}. Equation [2] and $\Delta E^*_a(C_6H_{12})$, Table 2, gives $\Delta E^*_a(C_6H_{11}\cdot) = 1657.22$ and, finally, $\Delta H_f(C_6H_{11}\cdot) = 14.6$ kcal mol^{-1}. For the axial CH bond, 111.28 kcal mol^{-1}, we find $\Delta H_f(C_6H_{11}\cdot) = 11.1$ kcal mol^{-1}. The experimental result (19)[2] is $\Delta H_f(C_6H_{11}\cdot) = 14.4 \pm 0.4$ and Allinger's calculation (21) indicates 14.01 kcal mol^{-1}. Again, it is the weaker CH bond, the equatorial one, which obeys the correlation. Hence, pending the physical explanation, when the choice between non-equivalent bonds is immaterial as regards the final products, Fig. 1 should not mislead us into concluding that the stronger bond is fated to break.

Nonbonded interactions and reorganizational energies

For nonbonded interactions we use Del Re's approximation (22)[3]

$$[12] \quad E^*_{nb} = \frac{1}{2}\sum_{k,l}\frac{q_k q_l}{r_{kl}}$$

which has recently received (3) indirect, but welcome, support as to its validity in σ systems. Equation [12] expresses Coulomb interactions between net charges of nonbonded atoms k and l at a distance r_{kl}. For the problem at hand, we are primarily interested in $E^*_{nb}(R_1\cdots R_2)$ interactions between the atoms of R_1 and those of R_2 in molecules R_1R_2 (Table 5). Negative terms are attractive. This portion of the total nonbonded interactions measures what holds R_1 and R_2 together in addition to the chemical bond joining these groups.

These results are used in calculations of $\Delta E^*_a(R^0)$, eq. [9], and reorganizational energies, eq. [5], which are reported in Table 6.

The stage is set. Now we can examine the relative importance of the various terms contributing to the dissociation of chemical bonds in saturated hydrocarbons.

Leading terms governing CC and CH bond dissociations

Let us begin with the CC bonds. Equation [1] and Tables 5 and 6 yield the CNE results which are indicated in Table 7 along with additional $\Delta E^*_a(R_1R_2)$ and ϵ_{CC} input data for a representative selection of molecules.

The CNE terms are generally small, particularly for relatively similar R_1 and R_2 partners, because charge neutralization between alkyl groups benefit from important compensations. (Citing propane as an example, experiment (23), arguments invoking inductive effects (1, 2, 24) and theoretical charge analyses (1, 2) all say the same thing, namely, that each methyl group carries an excess negative charge, −2.65 me in our calculation (1, 2). This excess charge is necessarily transferred back to the ethyl moiety when the CC bond dissociates, reducing the ΔE^*_a energy of the CH_3 part from 322.15 to 320.34 and increasing that of C_2H_5 from 610.81 to 612.78 kcal mol^{-1}, for

[2]This result is deduced from the activation energy for the gas-phase photobromination of cyclohexane, $E_{Br} = 11.53 \pm 0.32$ kcal mol^{-1}, and the Evans–Polanyi type equation (18a, 20), $E_{Br} = 0.87[DH^{298}(CH) - 82.7]$ kcal mol^{-1}, relating E_{Br} and dissociation enthalpies of CH bonds.

[3]Note that $\Delta E^*_{nb} = (0 - E^*_{nb}) = -E^*_{nb}$ because all ΔE^*'s are defined for "atoms minus molecule".

	CH equatorial	31.86	−14.34	109.28

a small total change − CNE = −0.16 kcal mol^{-1}).[4] As a consequence, we can approximate eq. [10] as follows

$$[13]\quad D^*_{CC} \simeq \epsilon_{CC}(R_1R_2) + RE(R_1) + RE(R_2) + 0.33 \text{ kcal mol}^{-1}$$

where the constant (0.33) is the average of the CNE and nonbonded contributions evaluated for all the 36 molecules constructed from the 8 alkyl groups considered here. The associated error (standard deviation = 0.26 kcal mol^{-1}) is acceptable. Briefly, CNE and nonbonded terms are minor contributors to the dissociation of CC bonds. This is no longer true for CH bonds (Table 8).

The CNE part accompanying CH dissociations is not only quantitatively important, but also produces an interesting effect. Indeed, CNE compensates to a large extent differences existing between ϵ_{CH} energies: ϵ_{CH} + CNE is nearly constant for all C(sp^3)—H bonds on one hand, and also for C(sp^2)—H bonds, on the other. Hence, incorporating also the small nonbonded interactions into this approximation, we rewrite eq. [10] as follows

$$[14]\quad D^*_{CH} \simeq \text{constant} + RE$$

where the constant, 98.40 or 102.65 kcal mol^{-1} for C(sp^3)

[4]Note that CNE includes the changes in nonbonded interaction energies accompanying the redistribution of electronic charge.

[a] For **10**–**17**, the results under the heading ϵ_{CH} + CNE include $E^*_{nb}(R\cdots H)$, eq. [10]. The corresponding $\Delta E^*_a(R^0)$ values, eq. [8], are not corrected for $E^*_{nb}(R\cdots R)$, a circumstance introducing a small imprecision, <0.1 kcal mol^{-1}. The ϵ_{CH} results in parentheses (and, thus, the companion CNE results) are somewhat uncertain (≤0.3 kcal mol^{-1}) because of uncertainties affecting calculated H net charges. The $\Delta E^*_a(RH)$ values are from ref. 2 (**10**, **11**, **13**–**16**) and ref. 3*b* (**12**, **17**). The $\Delta E^*_a(RR)$ and ϵ_{CC} results for use in eq. [9] are (25), in kcal mol^{-1}, ΔE^*_a = 1593.9, ϵ_{CC} = 74.00 (1,5-hexadiene, for **10**); ΔE^*_a = 2180.99, ϵ_{CC} = 72.93 (1,7-octadiene, for **11**); ΔE^*_a = 1009.9, ϵ_{CC} = 90.81 (1,3-butadiene, for **13**); ΔE^*_a = 1603.57, ϵ_{CC} = 90.44 (*E*,*E*-2,4-hexadiene, for **14**); ΔE^*_a = 2195.98, ϵ_{CC} = 89.63 (2,5-dimethyl-2,4-hexadiene, for **15**); ΔE^*_a = 1603.0, ϵ_{CC} = 91.33 (2,3-dimethyl-1,3-butadiene, for **16**) and (3*b*) ΔE^*_a = 3203.0, ϵ_{CC} = 74.26 (1,2-diphenylethane, for **12**); ΔE^*_a = 2612.8, ϵ_{CC} = 84.94 (biphenyl, for **17**).

and C(sp^2)—H bonds, respectively, represents the average value of ϵ_{CH} + CNE − $E^*_{nb}(R\cdots H)$. The ϵ_{CH}'s examined here range from 104.86 (CH_3—H) to 110.89 kcal mol^{-1} (t-C_4H_9—H) for C(sp^3)—H bonds and from 105.72 (ethylene) to 113.54 kcal mol^{-1} (benzene) for C(sp^2)—H bonds. These are the theoretical bond energies satisfying $\Delta E^*_a \simeq \Sigma\epsilon_{ij}$. CNE disguises them in such a way that, when viewed from the perspective of dissociation energies, all CH bonds involving the same type of C are perceived as if they were equal in energy, to a good approximation. This result explains the nature of "constant CH bond energies" and vindicates Sanderson's ideas (6) concerning their use in problems of bond dissociation along the lines expressed by eq. [14]. As regards the CC bonds, however, eq. [13] commands the use of genuine ϵ_{CC}'s, whose values range from 69.63 to ~74.5 kcal mol^{-1} for the alkanes studied in this paper.[5] Their validity is illustrated by the quality of calculated D^*_{CC}'s (Table 7).

A clarification concerning reorganization energies can now be given — a problem conveniently approached by an examination of CH bonds which are not equivalent in the hydrocarbon, but whose dissociation yields the same final products.

[5] These conclusions also hold for dissociation enthalpies, $DH(R_1—R_2) = \Delta H_f(R_1\cdot) + \Delta H_f(R_2\cdot) - \Delta H_f(R_1R_2)$. Indeed, eqs. [2] and [11] lead to

$$DH(R_1 - R_2) = D^*(R_1 - R_2) + Z(R_1\cdot) + Z(R_2\cdot) - Z(R_1R_2)$$

where Z stands for ZPE + H_T − H_0. For the alkanes, taking advantage of the approximation $Z(R\cdot) \simeq Z(RH) - 8.85$ (Table 1) and (2) $Z(R_2R_2) \simeq Z(R_1H) + Z(R_2H) - 11.48$ kcal mol^{-1}, it follows from eqs. [13] and [14] that

$$DH(C—C) \simeq \epsilon_{CC} + RE(R_1\cdot) + RE(R_2\cdot) - 5.9$$

$$DH(C—H) \simeq 91.0 + RE \text{ kcal mol}^{-1}$$

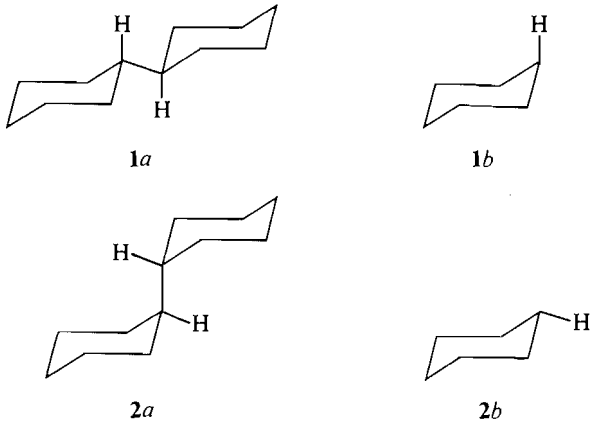

SCHEME 2. The equatorial–equatorial and axial–axial conformations of bicyclohexyl and the corresponding cyclohexyl fragments.

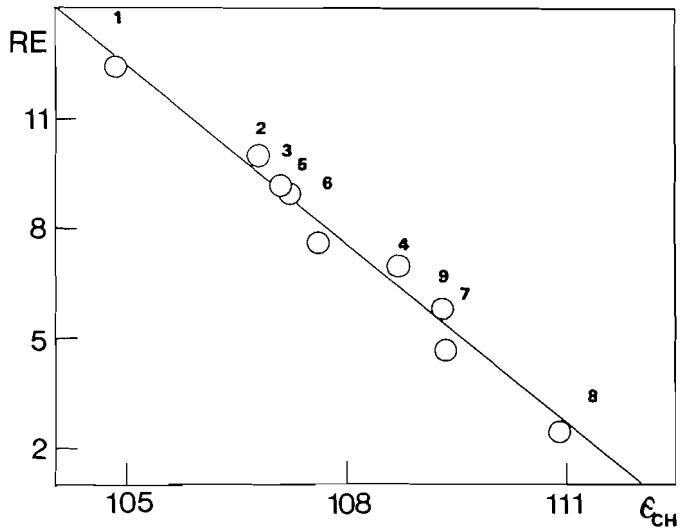

FIG. 2. A comparison between reorganizational energies, eq. [5], and theoretical CH bond energies, eq. [3], in kcal mol^{-1}. The numbering refers to that given in Table 6.

Analysis of the reorganizational energy

Let us first describe the cyclohexane system which is used as an example. Following eq. [9], the appropriate reference state R^0 is defined with respect to bicyclohexyl. The equatorial–equatorial conformation, **1***a*, is preferred over the axial–axial form **2***a* because of the four additional butane–*gauche* interactions occurring in the latter. As a consequence, **1***a* and **2***a* define reference states **1***b* and **2***b*, respectively, where $\Delta E^*_a(\mathbf{2}b) < \Delta E^*_a(\mathbf{1}b)$ (Scheme 2).

Using now eq. [14] and the definition of RE, eq. [5], we write

$$[15] \quad D^*_{CH} \simeq [98.40 - \Delta E^*_a(R\cdot)] + \Delta E^*_a(R^0)$$

A cyclohexyl radical formed from cyclohexane would not remember whether it has been formed via removal of an equatorial CH bond (corresponding to $R^0 = \mathbf{1}b$) or through abstraction of an axial CH bond (with $R^0 = \mathbf{2}b$). The term in brackets is the same in either event and we are treacherously led to think that a smaller D^*_{CH} would result if an axial rather than an equatorial CH bond was broken, because $\Delta E^*_a(\mathbf{2}b) < \Delta E^*_a(\mathbf{1}b)$. The error is that this reasoning overlooks the energy required in the process $\mathbf{1}a \rightarrow \mathbf{2}a \rightarrow \mathbf{2}b$, i.e., more precisely, the energy difference $\Delta E^*_a(\mathbf{1}b) - \Delta E^*_a(\mathbf{2}b)$ which has to be added in the computation of D^*_{CH}. Finally, D^*_{CH} is the same (or nearly so) for the dissociation of an axial or an equatorial CH bond of cyclohexane, depending on whether the ϵ_{CH} + CNE − $E^*_{nb}(R\cdots H)$ part of eq. [14] remains exactly the same in both cases.

This example illustrates the following points, equally valid for other molecules. (*i*) *The appropriate R^0 for use in the definition of RE is that deduced from eq. [9] with reference to the RR molecule at its energy minimum.* This defines the "most stable R^0". Any arbitrary selection of a "less stable R^0" reduces $\Delta E^*_a(R^0)$ in eq. [5] but, on the other hand, introduces an additional term in the calculation of D^*, namely the energy supplied in going from R^0 to the "less stable R^0". (*ii*) When non-equivalent CH bonds of a hydrocarbon can dissociate to give the same final products, *the RR molecule at its energy minimum is that constructed by replacing the weaker CH bond of RH by the appropriate CC bond linking R with R.* (For example, the CC bond between R and R replaces the equatorial CH bond of cyclohexane, the CH_s bond of propane or *n*-butane, or the CH_a bond of isobutane.) *The "most stable R^0" thus mimics the topology resulting from the abstraction of the weaker CH bond of RH* which, in quite an indirect way, is promoted to play the pivotal role in comparisons between D^*_{CH} and ϵ_{CH} energies. (*iii*) In this vein, *our earlier observation that the empirical D^*_{CH} vs. ϵ_{CH} correlation holds for the weaker bond suggests that its approximate validity is somehow linked to the implicit use of the correct R^0. A preferential cleavage of the weaker bond should not be inferred because either bond is capable of dissociating with the same D^*_{CH}, or nearly so,* although the corresponding ϵ_{CH}'s may differ significantly from one another. (*iv*) It follows that any attempt at interpreting D^*_{CH} in terms of ϵ_{CH} alone is doomed to failure. *The reason for the existence of a correlation between D^*_{CH} and ϵ_{CH} energies is given by eq. [14] and the approximate linear decrease of reorganizational energies for increasingly larger ϵ_{CH}* bond energies (Fig. 2).

In closing, let us examine a physical aspect concerning the energy involved in going from R^0 to the radical at its energy minimum. R^0 has certainly proved its merits as a convenient computational reference but, as such, does not exist as an isolated chemical species. The counterpart of R^0, considered now as an isolated species, is written R. Its geometry is that of R^0, i.e., that found in the molecule RR, and differs from that of the genuine radical R·. The change in geometry from R to R· is accompanied by an energy lowering — the relaxation energy $E(R\cdot) - E(R)$. On the other hand, bond formation to give RR also lowers the energy of this group of atoms, by $E(R) - E(R^0)$. The reorganizational energy is thus $RE = [E(R) - E(R^0)] + [E(R\cdot) - E(R)] = E(R\cdot) - E(R^0)$. The energies of R^0 and R· are readily derived from the basic equation $E = \Sigma_i E_i^{atom} - \Delta E^*_a$. The energies of R were deduced from LCAO-X_α calculations using in each case the α value which reproduces exactly $E(R\cdot)$ — an approach yielding energies of comparable quality, at the level of experimental accuracy (26) (Appendix 3). The results indicated in Table 9 are self-explanatory as regards $E(R) - E(R^0)$ and the relaxation energy $E(R\cdot) - E(R)$. It is $\Delta E^*_a(R)$ which offers the most interesting features.

Indeed, the $\Delta E^*_a(R)$ of CH_3 corresponds to CH bond energies virtually equal to ϵ_{CH} + CNE − $E_{nb}(R\cdots H)$. The results obtained for ethyl propyl, isopropyl and *tert*-butyl are equally intriguing in that their average bond energies, $\Delta E^*_a(R)/n$ with n = total number of bonds, also reflect the same regularity, as if all CH and CC bonds of R were equal in energy. These novelties seem to convey a message worth further studies.

TABLE 9. Analysis of the reorganizational energies, kcal mol^{-1}, except E(R)[a]

R	E(R), au	E(R) − E(R^0)	E(R·) − E(R)	ΔE^*_a(R)	ΔE^*_a(R)/n	ϵ_{CH} + CNE − E^*_{nb}
CH_3	−39.8279	24.10	−11.67	296.25	98.75	99.01
C_2H_5	−79.1485	24.85	−14.81	587.91	97.99	97.76
n-C_3H_7	−118.4777	21.08	−11.91	884.97	98.33	98.22
i-C_3H_7	−118.4805	19.95	−12.93	886.74	98.53	97.62
t-C_4H_9	−157.8073	19.31	−16.85	1182.29	98.52	98.41

[a]The geometries assumed for the RR molecules, defining those of R, are experimental results obtained for ethane (27), butane (28), hexane (29), 2,3-dimethylbutane and 2,2,3,3-tetramethylbutane (30). The total number of bonds in each R is n.

Conclusions

Our description of bond dissociation energies bears clear similarities with Sanderson's ideas, namely, that a dissociation energy is given by the contributing bond energy ϵ plus the appropriate reorganizational energies. The new aspects introduced by the present treatment lie (*i*) in the use of theoretical, charge-dependent, bond energies, eq. [3], which are a requirement in order to ensure molecular electroneutrality, (*ii*) in the convenient use of electroneutral reference states for defining reorganizational energies, and (*iii*) with the unavoidable introduction of a new term, the charge neutralization energy, which accounts for the fact that individual molecular fragments may not be electroneutral while they are part of the host molecule whereas the corresponding radicals certainly satisfy electroneutrality. Explicit consideration of this constraint leads directly to a general energy formula describing bond dissociation.

Numerical applications to alkanes reveal the minor role played by Coulomb interactions between nonbonded atoms. In the dissociation of carbon–carbon bonds, the mutual neutralization of charge by alkyl groups results in an important mutual cancellation of the individual energy terms associated with this neutralization. The net effect is usually small. As a consequence, the cleavage of CC bonds is primarily governed by the contributing bond energy plus the reorganizational energies of the radicals, in general accord with current views supported by Sanderson's work. The quality of our theoretical bond energies is well reflected in the quality of calculated dissociation energies. In the dissociation of carbon–hydrogen bonds, on the other hand, charge neutralization energies are entirely responsible for a peculiar perception of "seemingly constant contributing CH bond energies", leaving the reorganizational energy as the sole term regulating the dissociation of a CH bond. That this is true, at least to a good approximation, is known from Sanderson's work. Our calculations now reveal that, in fact, it is the sum of the genuine contributing bond energy plus the charge neutralization energy which remains nearly constant for CH bonds. Ultimately, this is what matters for the final result. The contributing CH bond energies, however, still obey the basic tenet, namely the preservation of molecular electroneutrality, responsible for charge-dependent bond energies. It is comforting to witness that, at times, conflicting ideas can be reconciled. In the present case, explicit consideration of charge neutralization constraints did the job.

Acknowledgements

The present work is part of a continuing effort conducted with the Chemistry Department, Università di Napoli, Italy. We thank the Italian Authorities and particularly Professor Giuseppe Del Re for promoting this cooperation and for the extraordinary hospitality extended to one of us (S.F.). We also thank Professors G. Del Re, V. Barone and D. Salahub for helpful discussions, Drs. J. Andzelm and M. Comeau for assistance, and the Natural Sciences and Engineering Research Council of Canada for financial support.

Appendix 1

Atomic charges were deduced from a Mulliken-type analysis allowing for an uneven partitioning of overlap populations between dissimilar atoms (1, 2, 16, 31). For the alkanes, using STO-3G Mulliken charges (32) derived will full geometry and scale factor optimizations (31), this analysis gives (1, 2) (in me) $q_C = (35.1/69.4)\ (q_C^{\text{Mulliken}} + 30.12N_{CH})$ and $q_H = (35.1/69.4)(q_H^{\text{Mulliken}} - 30.12)$, where N_{CH} = number of H atoms attached to C. The ethane net charges, $q^0_C = 35.1$ and $q^0_H = -11.70$ me, serve as references in calculations of $\Delta q_C = q_C - q^0_C$ and $\Delta q_H = q_H - q^0_H$, for use in eq. [3]. With these charges and the appropriate parameters (1, 2), eq. [3] becomes (in kcal mol^{-1})

$$\epsilon_{CH} = 106.806 - 0.247\Delta q_C - 0.632\Delta q_H$$

$$\epsilon_{CC} = 69.633 - 0.488\Delta q_{Ci} - 0.488\Delta q_{Cj}$$

For Δq_C, we can use the accurate relationship (2, 31*a*)

$$\Delta q_C = -0.148\delta_C \text{ me}$$

where δ_C is the ^{13}C nmr shift relative to ethane. The ϵ_{CC} results (Tables 6 and 7) were deduced from nmr data reported by Lindeman and Adams (33) and by Stothers (34) for bicyclohexyl.

Appendix 2

The ΔE^*_a results for alkanes with 6 or more C atoms (Tables 6 and 7) were deduced from an accurate approximation (2, 35) incorporating nonbonded contributions,

$$\Delta E^*_a \simeq 710.54(1 - m) + 290.812(n - 2 + 2m) + 0.03244\Sigma N_{CC}\delta_C + 0.05728\Sigma\delta_C \text{ kcal mol}^{-1}$$

where n = number of C atoms, m = number of cycles, and N_{CC} = number of CC bonds formed by the atom whose nmr shift is δ_C relative to ethane. This form of eq. [4], where the H charges are taken care of by charge normalization, is known to agree with experimental results, eq. [11], within 0.23 kcal mol^{-1} (average deviation). Smaller molecules were calculated with explicit consideration of nonbonded terms (1, 2). The appropriate nmr data were taken from literature (33, 34).

Appendix 3

The LCAO-Xα calculations (Table 9) were performed by means of the programs developed by Dunlap *et al.* (36). Huzinaga's (9*s*5*p*) basis (37) was used for the ground-state carbon and hydrogen was described by a (5*s*) basis obtained from Dunning's (3*s*) basis set (38). Auxiliary (9*s*5*p*3*d*) exchange and density functions were selected for carbon and (5*s*5*p*) for hydrogen. Bond-centered *s* functions were also used, as suggested by Dunlap *et al.* (26). For each radical R· we have determined the α value reproducing the total energy corresponding to the ΔE^*_a(R·) of Table 1. The same α was used for the calculation of R in the geometry of the molecule RR. This strategy allows valid energy comparisons between R·, R, and R^0 which are on the same footing as regards their quality (26).

Infrared spectra of unannealed and of annealed $Cu_4(OH)_6(NO_3)_2$

ETALO A. SECCO[1] AND GLEN G. WORTH[2]
Chemistry Department, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received March 24, 1987

ETALO A. SECCO and GLEN G. WORTH. Can. J. Chem. **65**, 2504 (1987).

The infrared spectra over the range 4000–150 cm^{-1} of $Cu_4(OH)_6(NO_3)_2$ along with site group and factor group analysis are reported for the first time. The observed absorption frequencies associated with OH and NO_3 modes show distinct individual spectral features in the unannealed and annealed $Cu_4(OH)_6(NO_3)_2$. Three distinct types of OH groups involving different degrees of H-bonding are evident. The multiple frequencies involving Cu—O—H bending modes further reflect the varying degrees of H-bonding and OH coupling in $Cu(OH)_4O_2$ and $Cu(OH)_5O$ entities paralleling their behavior in $Cu_4(OH)_6SO_4$. The NO_3 internal optic modes' activities, fundamentals along with overtones and combination bands, illustrate distinct interaction effects (OH and Cu) with respect to specific modes relative to halo-nitrates with same site symmetry. The presence of CuO in the sample after the anneal effected a striking change in ν_3. The Cu—O, O—Cu—O, and OH torsional mode frequencies show consistent behavior with $Cu_4(OH)_6SO_4$.

ETALO A. SECCO et GLEN G. WORTH. Can. J. Chem. **65**, 2504 (1987).

On a déterminé pour la première fois le spectre infrarouge du $Cu_4(OH)_6(NO_3)_2$ de 4000 à 150 cm^{-1} et on présente une analyse par groupe de position d'atomes et par groupe de facteurs. Les fréquences d'absorption observées pour les modes associés avec OH et NO_3, présentent des caractéristiques spectrales individuelles et distinctes pour les $Cu_4(OH)_6(NO_3)_2$ qu'ils soient sous forme d'anneau ou pas. On a mis en évidence trois groupes distincts de groupements OH impliquant divers degrés de liaisons-H. Les fréquences multiples impliquant les modes de déformation de l'angle Cu—O—H sont d'autres reflets des divers degrés de liaison-H et de couplage OH dans les entités $Cu(OH)_4O_2$ et $Cu(OH)_5O$ et ceux-ci sont parallèles à leur comportement dans le $Cu_4(OH)_6SO_4$. Les modes d'activité optique interne du NO_3, tant au niveau fondamental qu'au niveau des bandes harmonique ou de combinaison, illustrent les effets d'interactions distinctes (OH et Cu) par rapport aux modes spécifiques relatifs au halo-nitrates avec le même site de symétrie. La présence de CuO dans l'échantillon après l'annelation provoque un changement important dans ν_3. Les fréquences du mode de torsion Cu—O, O—Cu—O et OH présentent un comportement systématique dans le $Cu_4(OH)_6SO_4$.

[Traduit par la revue]

Introduction

The polyatomic species NO_3 can undergo various steps of reduction from its isolated point group symmetry of D_{3h} to the low site symmetry C_s in a crystalline lattice (1–3). This reduction in symmetry permits an insight into the intra-molecular effects as reflected on the internal and external optic modes of NO_3 by the surrounding molecular units or environment. Recent spectroscopic studies on crystalline Ag_2BrNO_3 and Ag_2ClNO_3 (3) provided additional information relating the magnitude of site and correlation field effects on the normal modes of NO_3 relative to $AgNO_3$ and KNO_3(II). The infrared spectra of NO_3 in Ag_2BrNO_3 and Ag_2ClNO_3 showed features more in common, to a first approximation, with $AgNO_3$ than with KNO_3(II) of same site symmetry. The interplay of other factors, e.g. dipolar coupling, etc. (4, 5) along with site symmetry contribute to specific spectroscopic properties.

The availability of the compound $Cu_4(OH)_6(NO_3)_2$ of known crystal structure presents another opportunity to observe the spectroscopic properties of NO_3 with same site symmetry C_s (1, 3) in another crystalline environment. These results can provide meaningful data for theoretical lattice or vibrational dynamics analysis using the dipolar coupling model. The prospect of obtaining useful correlations relating H-bonding effects in $OH...ONO_2$ relative to $OH...OSO_3$ as observed for $Cu_4(OH)_6SO_4$-type compounds (6) along with comparing the spectroscopic properties of OH in entities of identical coordination, viz. $Cu(OH)_4O_2$ and $Cu(OH)_5O$ in $Cu_4(OH)_6SO_4$, is another incentive for the infrared study of $Cu_4(OH)_6(NO_3)_2$. Furthermore, the infrared spectra of $Cu_4(OH)_6(NO_3)_2$ annealed just prior to the onset of decomposition might provide an insight into the elementary step leading to decomposition, viz. $Cu_4(OH)_6(NO_3)_2 \rightarrow 4CuO + 3H_2O + 2NO_2 + (1/2)O_2$.

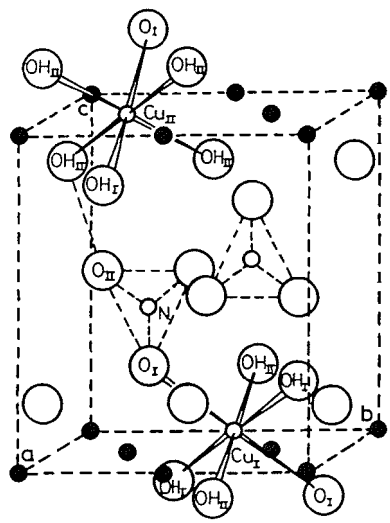

FIG. 1. Unit cell structure of $Cu_4(OH)_6(NO_3)_2$ taken from ref. 7. The filled circles ● represent the remaining Cu atoms along with Cu_I and Cu_{II} associated with the unit cell. Interatomic distances (Å): $Cu_I—Cu_I = Cu_{II}—Cu_{II} = 3.03$, $Cu_I—Cu_{II} = 3.17$, $Cu_I—OH_{II} = 2.08$, $Cu_I—OH_I = 2.00$, $Cu_{II}—OH_{II} = 2.05$, $Cu_{II}—OH_I = 2.27$, $Cu_I—O_I = 2.35$, $Cu_{II}—O_I = 2.18$, $OH_{II}—OH_{II} = 3.03$, $OH_{II}—OH_I = 4.97$, $OH_{II}—O_I = 2.60–2.46$, $OH_I—O_{II} = 2.94–2.78$, N—N = 4.01, N—O = 1.21–1.30, O—O = 2.10–2.25.

Structure of $Cu_4(OH)_6(NO_3)_2$

The structural assignment of basic copper nitrate, $Cu_4(OH)_6(NO_3)_2$, is monoclinic with space group $P2_1/m$-C_{2h}^2 (7). Using the notation given for the first setting of the C_{2h}^2 space group

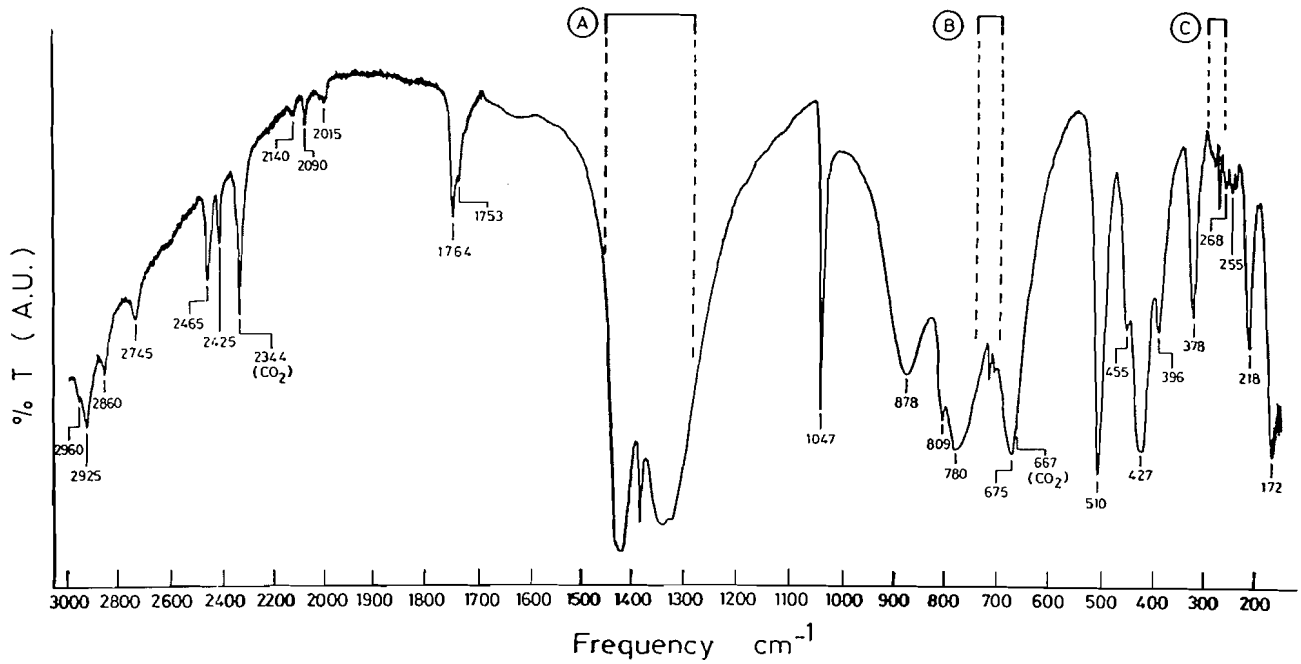

FIG. 2. Infrared spectrum of unannealed $Cu_4(OH)_4(NO_3)_2$ in KBr matrix for region 3000–150 cm^{-1}.

in the International tables for X-ray crystallography (8), we find that only the 2e sites (Wyckoff notation) with C_s symmetry are occupied. The unit cell containing one molecular or formula unit with dimensions, $a_0 = 5.57_6$ Å, $b_0 = 6.05_0$ Å, $c_0 = 6.89_6$ Å, $\beta = 94° 30'$ shown in Fig. 1 is taken from Nowacki and Scheidegger (7). The appropriate interatomic distances are noted in the caption of Fig. 1. The H atom of OH, not shown, forms Cu—O—H bond angle of 118°.

The disposition of the OH groups, their orientations and their intermolecular distances as presented in Fig. 1, suggests three classes of OH entities. The first class is essentially "free" OH with very weak H-bonding represented by OH_I and OH_{II} from Cu_{II} in $Cu_{II}(OH)_5O$ entity projecting out of the O_I—Cu_{II}—OH_{II} plane. The second and third classes are classified as varying degrees of H-bonded OH based on interatomic distances represented by $OH_{II}\ldots O_{II}$ = 2.46–2.60 Å, and $OH_I\ldots O_{II}$ = 2.78 Å.

Figure 1 shows the Cu to have a slightly distorted octahedral coordination with four equal coplanar Cu—OH bonds and two Cu—O bonds. Both oxygens in one pair of Cu_I—O are from the NO_3, i.e. $2O_I$ to form the entity $Cu_I(OH)_4O_2$. The second pair involves one oxygen from NO_3, i.e. O_I and the other oxygen from OH_{II} to form the entity $Cu_{II}(OH)_5O$. The coordination and spatial arrangements with respect to Cu and OH are identical to those in $Cu_4(OH)_6SO_4$ (6, 9). The octahedra are linked to form "layers" parallel to the [001] plane which are held together by H-bonds via NO_3 which are effectively normal to the layer planes.

Factor group analysis of $Cu_4(OH)_6(NO_3)_2$

A unit cell of $Cu_4(OH)_6(NO_3)_2$ containing 24 atoms gives rise to 72 degrees of freedom involving Cu ion motion, OH group external and intramolecular motions, and nitrate external and intermolecular motions. A free nitrate ion belongs to the molecular point group D_{3h} with irreducible representations for internal modes $\Gamma_{int} = A_1' + A_2'' + 2E'$ which correspond to the internal normal modes $\nu_1, \nu_2, \nu_3, \nu_4$, respectively. The low site symmetry C_s of the NO_3 in the cell removes all the degeneracies of the D_{3h} representations to yield nondegenerate A' and A'' representations. From correlation procedure (10) each site group A' representations is found to transfer to $A_g + B_u$ and each A'' to $B_g + A_u$ in the factor group C_{2h}. The number of irreducible representations of the modes for NO_3 is determined to be $4A_g + 4B_u + 2A_u + 2B_g$ for internal vibrational modes and 12 similar representations for translational and rotational modes or external modes. The remaining representations are identified with 6 internal modes for OH, 12 Cu—O—H bending modes, 6 Cu—O stretching modes, 12 O—Cu—O angle deformation modes, and 12 modes for Cu ion motion.

Experimental

$Cu_4(OH)_6(NO_3)_2$ was prepared according to the accepted procedure by the action of moderately concentrated solution of $Cu(NO_3)_2$ on CuO in a stoppered flask with constant stirring at ~100°C for 10 days, and analyzed as described (11, 12).

The infrared transmission spectra were recorded with a Perkin-Elmer 180 spectrophotometer using both the standard compressed KBr disc sample and the Nujol mull sample between polyethylene windows. The observed absorption frequencies were reproducible within 2 cm^{-1} for all of the overlapping spectral regions using both sample techniques. The stock sample was maintained in oven at 150°C before using. Spectra recorded for the undried sample maintained at room temperature showed no discernible difference with the dried sample spectra.

$Cu_4(OH)_6(NO_3)_2$ was annealed in two ways: (*i*) The sample contained in a pyrex tube was heated in a drying oven at 160°C up to 66 h. The sample color transformed from its initial light blue through grey–blue to eventually dark brown. The residue at different stages was used in both the Nujol mull and the KBr disc. The recorded spectra at each stage were indistinguishable from the unannealed sample spectra. (*ii*) The sample was compressed in a KBr matrix to form the disc. The KBr disc sample was annealed in a high temperature cell attachment at 190°C for 3 h. The disc color was dark brown similar to the 66 h at 160°C residue and its spectrum was recorded at room temperature.

Results and discussion

The recorded spectra for the unannealed $Cu_4(OH)_6(NO_3)_2$ are presented in Figs. 2, 3, and 4*a* and interpreted with respect to OH and NO_3 optic modes. Portions of the spectrum of the KBr disc sample annealed at 190°C for 3 h exhibiting different spectral features relative to Figs. 2 and 3 are presented in Fig. 4.

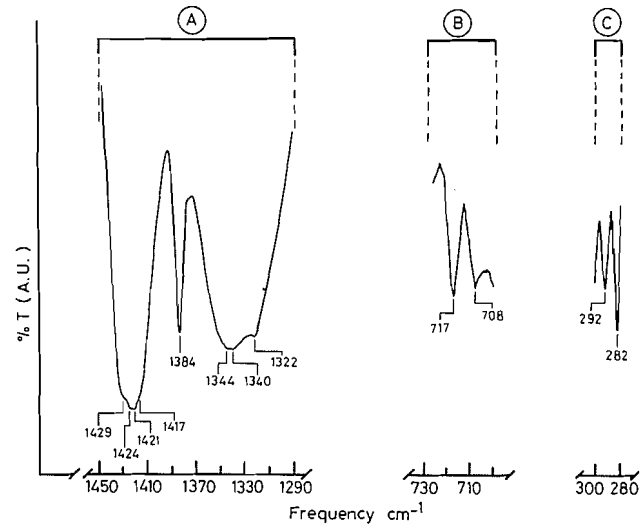

FIG. 3. Expanded portions of spectrum of Fig. 2, A, B, C.

The spectra intensities are given in arbitrary units (A.U.). No HOH bending absorption was observed.

OH absorption

The fundamental vibration frequency for OH occurs over the range 3600–3200 cm^{-1} depending on the degree of H-bonding. Tarte (12) reported the frequencies 3543, 3522, and 3428 cm^{-1} for $Cu_4(OH)_6(NO_3)_2$ whereas we record the frequencies 3550, 3475, and 3415 cm^{-1} as given in Fig. 4*a*, broken line.

The three frequencies indicate three distinct classes of hydroxy groups in the solid structure. The sharp peak at 3550 cm^{-1} is assigned to very weak H-bonded OH identified as OH_I and OH_{II} in $Cu_{II}(OH)_5O$ with interatomic distances of 2.94 and 3.03 Å. The 3550 cm^{-1} frequency is in excellent agreement with values reported for OH groups with no substantial H-bonding in lanthanide (Gd, Nd) basic nitrates (13). The shoulder at 3475 cm^{-1} and the broad band centred at 3415 cm^{-1} are consistent with different degrees of hydrogen bonding expected with OH...O separations ranging from 2.46 to 2.78 Å. These OH...O distances and their OH frequencies are in contrast with those observed for $Cu_4(OH)_6SO_4$ (6), viz. 3572–3596 cm^{-1} at 2.96 and 3.14 Å, 3396 cm^{-1} at 2.87 Å, and 3272 cm^{-1} at 2.65 Å. The distinct differences may be interpreted in terms of (*i*) weaker H-bonding in $OH...ONO_2$ relative $OH...OSO_3$ or (*ii*) non-linear or out-of-plane OH...O configuration in $OH...ONO_2$.

The absorption frequencies 878, 780, 675 cm^{-1} are assigned to Cu—O—H deformation modes paralleling the assignment of 990, 878, 780 cm^{-1} in $Cu_4(OH)_6SO_4$ (6). These assignments are based on the deuterium shift and these frequencies are within ± 2 cm^{-1} of the values reported by Tarte (12). Again the Cu—O—H bending mode frequencies reflect the varying degrees of H-bonding in the OH groups with the highest frequency associated with the strongest H-bridge, viz. 878 cm^{-1}. The fact that the relative magnitude of the shift of the bending mode frequencies, $\Delta\nu_b/\nu_b$, is larger than that of the O—H stretching mode frequencies, $\Delta\nu_s/\nu_s$, by a factor ~4, usually $\Delta\nu_b/\nu_b < \Delta\nu_s/\nu_s$ implies that the bending modes involve coupling in the coordinated units, i.e. $Cu(OH)_4O_2$ and $Cu(OH)_5O$, described above. The Cu—O—H bending mode frequencies show the same separation of ~100 cm^{-1} in both hydroxycompounds with an apparent correlation between the strength of the H-bonded OH and frequency shift. That is, ν_b = 780 cm^{-1} with ν_s = 3550–3596 cm^{-1} for very weak H-bridging and ν_b = 880 vm^{-1} with ν_s = 3400–3470 cm^{-1} for medium strength H-bridging. The extreme frequencies, however, 990 cm^{-1} in $Cu_4(OH)_6SO_4$ and 675 cm^{-1} in $Cu_4(OH)_6(NO_3)_2$ may reflect on the nature of the $Cu(OH)_5O$ entity. $Cu(OH)_5O$ shows five equal Cu—OH distances, ± 0.05 Å, in both compounds but the Cu—O distance is 2.52 Å in the sulphate and 2.18 Å in the nitrate. The assignment of the bands 255–292 cm^{-1} to OH torsional modes parallels the assignment in $Cu_4(OH)_6SO_4$-type compounds (6).

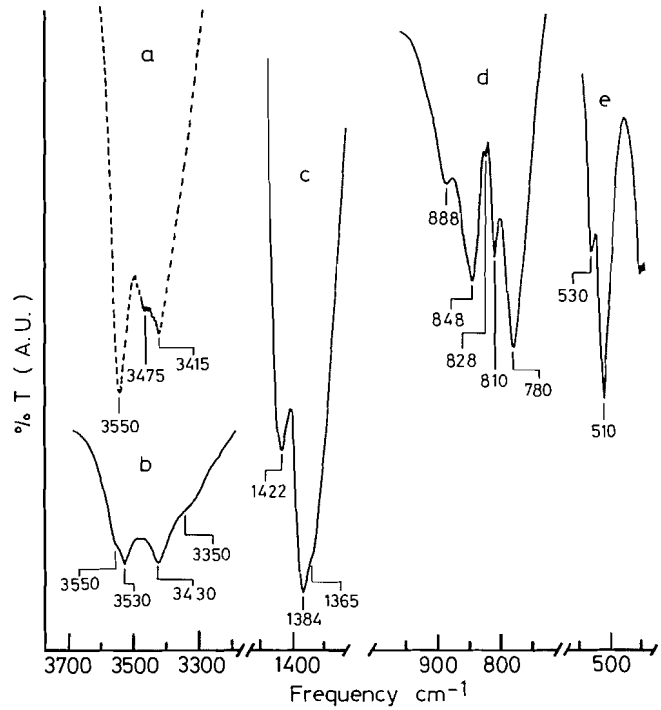

FIG. 4. Portions of infrared spectra of (*a*) unannealed $Cu_4(OH)_6(NO_3)_2$ for region 3700–3200 cm^{-1} and (*b*), (*c*), (*d*), (*e*) annealed $Cu_4(OH)_6(NO_3)_2$ in compressed KBr matrix at 190°C for 3 h.

NO_3 absorption

The reported fundamental vibration frequencies for NO_3 of D_{3h} symmetry (14) are ~1050 (A_1'), ~830 (A_2''), ~1400 (E'), and ~700 (E') where E' and A_2'' are infrared active modes. In the crystal all the fundamental vibration modes for NO_3 of reduced symmetry have been observed in the infrared (1–3) over a range of values, viz. $\nu_1(A_1')$ 1040–1067, $\nu_2(A_2'')$ 801–839, $\nu_3(E')$ 1313–1432, and $\nu_4(E')$ 702–741 cm^{-1}.

The recorded spectra for $Cu_4(OH)_6(NO_3)_2$ over the 3000–150 cm^{-1} region are given in Figs. 2 and 3 with the frequencies noted on the spectra. These frequencies with their assignments along with those of Ag_2BrNO_3, Ag_2ClNO_3, and $AgNO_3$ for comparison purposes are tabulated in Table 1. All the internal optic modes predicted by factor group analysis for NO_3 are observed and identified. It is not possible to interpret all the spectral features with a high degree of confidence but a number of definitive assignments along with comparisons, correlations, and tentative assignments can be made.

The relatively strong sharp $\nu_1(A_1')$ and $\nu_2(A_2'')$ singlet peaks at 1047 cm^{-1} and 809 cm^{-1}, respectively, are in strong contrast to the weak doublets and weak multiplets of their analogous modes in Ag_2BrNO_3 and Ag_2ClNO_3 (3).

The clearly resolved doublet of equal intensities for $\nu_4(E')$ at 708 and 717 cm^{-1} is in obvious contrast to the multiplets of

[a]Reference 3.

varying intensities observed for Ag_2BrNO_3, Ag_2ClNO_3, and $AgNO_3$.

The multiplet structure of $\nu_3(E')$ with 8 identifiable frequencies far exceeds the maximum of 4 possible frequencies permitted by factor group analysis and reported for Ag_2BrNO_3. The 8 frequencies can be interpreted in terms of splitting in E' for each of 2 NO_3, i.e. 4 possible modes with each giving rise to splitting. Such an interpretation raises some questions. Does this splitting involve LO-TO modes and/or varying degrees of dipolar coupling? Can such splitting be specific to $\nu_3(E')$ and not $\nu_4(E')$ or is the multiplet in $\nu_4(E')$ too weak to be detected? Or are these extra features artifacts originating in a superimposed reflectivity component in the matrix?

The appearance of numerous overtone and combination bands assigned to NO_3 is in striking contrast to their absence in spectra of related nitrate compounds. The Nujol bands, viz. 2960, 2925, 2860 cm^{-1}, are included as a point of caution and to illustrate the sensitivity of the instrument in detecting Nujol presence in KBr ground in a mortar previously used to make a Nujol mull after being scrupulously cleaned. The sharp peak at 2344 cm^{-1} and spike at 667 cm^{-1} due to ν_3 and ν_2 of CO_2, respectively, serve as internal references.

The frequencies for the external and lattice modes of NO_3 are also presented in Table 1 along with those observed for Ag_2BrNO_3 and Ag_2ClNO_3. The frequencies and spectra profiles are comparable in both the hydroxy- and halonitrates but the relatively stronger peak intensities ($\times 10$) are evident in $Cu_4(OH)_6(NO_3)_2$ spectra.

TABLE 2. Remaining observed frequencies in $Cu_4(OH)_6(NO_3)_2$

$Cu_4(OH)_6(NO_3)_2$	$Cu_4(OH)_6SO_4$[a]	Assignment
328, 305	338, 318	ν_s(Cu—O)
292, 282, 268, 255	289, 260, 254	OH torsion
218, 172	228, 172	ν_b(O—Cu—O)

[a]Reference 6.

Table 2 contains the Cu—O stretching, O—Cu—O bending and OH torsional mode frequencies for $Cu_4(OH)_6(NO_3)_2$ and $Cu_4(OH)_6SO_4$. The consistency and agreement between these values and the Cu—O—H bending frequencies of both compounds support the structure and bonding character in the common coordinated units of $Cu(OH)_4O_2$ and $Cu(OH)_5O_2$.

Annealed $Cu_4(OH)_6(NO_3)_2$ in compressed KBr matrix

Most of the absorption frequencies and band profiles recorded in this spectrum are consistent with the spectrum of the unannealed sample spectrum. The portions of this spectrum exhibiting distinctly different or additional features are presented in Fig. 4.

The OH stretch frequency region, Fig. 4*b*, shows a definite change in the band profile along with lower frequency displacements of 20–80 cm^{-1}. The strong Cu—O—H bending mode at 878 cm^{-1} has shifted to 848 cm^{-1} leaving a weaker remnant at 888 cm^{-1} while the 778 cm^{-1} Cu—O—H bending frequency remains unaltered, Fig. 4*d*, suggesting a structural or coordination change in either $Cu(OH)_4O_2$ or $Cu(OH)_5O$.

Figure 4*d* shows $\nu_2(NO_3)$ at 810 cm^{-1} along with a weak satellite at 828 cm^{-1}. In Fig. 4*e* the NO_3 external mode at 510 cm^{-1} is accompanied by a weak satellite at 530 cm^{-1}. Both satellites appear ~20 cm^{-1} above its respective parent peak.

The most striking spectral change is identified with $\nu_3(NO_3)$, Fig. 4*c*. Its two main peaks at 1422 and 1384 cm^{-1} with shoulder at 1365 cm^{-1} are in strong contrast with the comple multiplet observed in the unannealed spectrum.

Due to the lack of information on the exact composition of th sample it is not possible to interpret these spectral feature with confidence. However, the dark brown color betray the presence of CuO from partial decomposition rather tha interaction with KBr. These modified spectral features sugges that CuO molecularly dispersed throughout the undecompose $Cu_4(OH)_6(NO_3)_2$ can affect specific fundamental modes o neighboring species.

Reçu le 9 janvier 1987

S. ZAYDOUN, M. SAIDI IDRISSI et C. GARRIGOU-LAGRANGE. Can. J. Chem. **65**, 2509 (1987).

Les spectres de vibration du méthyl-4 triazole-1,2,4, de son chlorhydrate et de quelques uns de leurs homologues deutériés ont été examinés entre 4000 et 200 cm^{-1}. Une attribution de la plupart des modes fondamentaux a été proposée et l'effet de la protonation sur les fréquences des vibrations normales a été expliqué.

S. ZAYDOUN, M. SAIDI IDRISSI, and C. GARRIGOU-LAGRANGE. Can. J. Chem. **65**, 2509 (1987).

Vibrational spectra of 4-methyl-1,2,4-triazole, its hydrochloride salt, and some of their deuterated homologs have been studied from 4000 to 200 cm^{-1}. An attribution of most of the fundamental modes is proposed, and the effect of protonation on fundamental frequency values is explained.

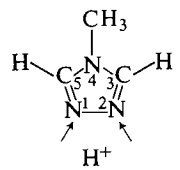
Introduction

Le triazole-1,2,4 et ses dérivés jouent un rôle biologique important aussi bien dans le domaine de l'agronomie qu'en pharmacologie (1–4). Leurs sels sont des fongicides actifs (5). Depuis plusieurs années, nous nous intéressons à l'étude de ces composés. Ainsi, dans un précédent travail (6), nous avons examiné les spectres vibrationnels des triazoles-1,2,4 méthylés en position 1 qui représentent des formes «bloquées» correspondant au {1*H*} triazole-1,2,4. En vue de compléter cette étude, nous présentons ici une analyse des spectres vibrationnels du méthyl-4 triazole-1,2,4 (Me4 TA) découlant de la forme {4*H*}. Ce composé a un caractère basique et joue un rôle de donneur d'e^- dans une interaction donneur–accepteur. Nous nous sommes donc également intéressés à son chlorhydrate, afin de noter l'influence de la protonation sur les vibrations fondamentales de la base.



Deux sites de protonation équivalents correspondant aux deux azotes «pyridiniques» sont probables pour ce composé.

Nos résultats précédents (7) et le présent travail montrent que seule la monoprotonation est possible dans le cas des systèmes triazoliques-1,2,4.

I. Partie expérimentale

Le Me4 TA a été préparé en utilisant la méthode de Freund (8). Il a été purifié par chromatographie sur colonne de silice en utilisant un mélange benzène–chloroforme comme éluant.

L'homologue C-deutérié $Me4D_2$-3,5 TA a été obtenu en dissolvant la base dans D_2O et en portant la solution placée dans un tube scellé à 120°C pendant 2 h.

La pureté du Me4 TA ainsi que l'échange hydrogène–deutérium ont été contrôlés par rmn.

Les chlorhydrates de méthyl-4 et de méthyl-4 dideutério-3,5 triazoliums-1,2,4 (Me4 TAH^+ et $Me4D_2$-3,5 TAH^+) ont été obtenus par passage d'un courant de gaz chlorhydrique HCl sec dans une solution de la base dans le chloroforme anhydre. Le sel formé précipite, il est séparé par filtration et séché sous vide. Le Me4 TAH^+ et son dérivé N-deutérié (Me4 TAD^+) ont également été préparés par addition d'une solution aqueuse de HCl ou DCl à la base et par évaporation de l'eau sous vide.

Les dosages du carbone, de l'hydrogène, de l'azote et du chlore pour le Me4 TAH^+ ont donné les résultats suivants :

	% C	% H	% N	% Cl
Exp.	30,39	5,07	33,58	29,10
Calc.	30,13	5,02	35,15	29,71

Les spectres ir ont été enregistrés à l'aide d'un spectromètre Perkin–Elmer 577. Les solides ont été étudiés en suspension dans le Nujol ou dans le Fluorolube, entre des fenêtres de NaCl (4000–600 cm^{-1}) et de silicium ou de polyéthylène (600–200 cm^{-1}).

Les spectres Raman des composés en solution aqueuse ont été obtenus avec un appareil Coderg PH 1, la raie excitatrice étant la raie à 514,5 nm d'un laser spectra physics à gas argon ionisé.

II. Résultats et discussion

II.1. Dénombrement des modes normaux de vibration

En l'absence de données cristallographiques, nous supposons que le cycle triazole garde sa planéite dans le Me4 TA et le Me4 TAH^+ comme pour le triazole-1,2,4 (9) et que ces composés possèdent au plus la symétrie ponctuelle C_s. Dans cette hypothèse, les 27 vibrations fondamentales du Me4 TA peuvent se classer en $18A'$ $(2\nu_{CH} + 2\delta_{CH} + 7R + \nu_{N-CH_3} + \delta_{N-CH_3} + \nu_s + \nu'_s + \delta_s + \delta'_s + r_\parallel)^1$ et $9A''$ $(2\gamma_{CH} + 2R + \gamma_{N-CH_3} + \nu_a + \delta_a + r_\perp + t_{CH_3})^1$ toutes actives en ir et en Raman.

Pour le Me4 TAH^+, trois nouveaux mouvements de vibration sont introduits par addition d'un proton à la molécule (ν_{NH}, δ_{NH}, γ_{NH}).

II.2. Analyse des spectres vibrationnels

Les spectres ir des Me4 TA et Me4 TAH^+ et de leurs homologues deutériés sont représentés sur la figure 1. Les spectres Raman des dérivés hydrogénés sont donnés sur la figure 2. Les attributions des vibrations fondamentales du squelette et du groupement CH_3 sont rassemblées dans les tableaux 1 et 2.

Nous discuterons séparément les vibrations du noyau et celles des groupements exocycliques.

Vibrations des groupements C—H

On relève sur le spectre ir des Me4 TA et Me4 TAH^+ entre

1. La notation utilisée pour désigner les vibrations du noyau est celle précédemment décrite pour le triazole-1,2,4 (10). Pour le groupement CH_3, on a adopté la notation de Forel (11).

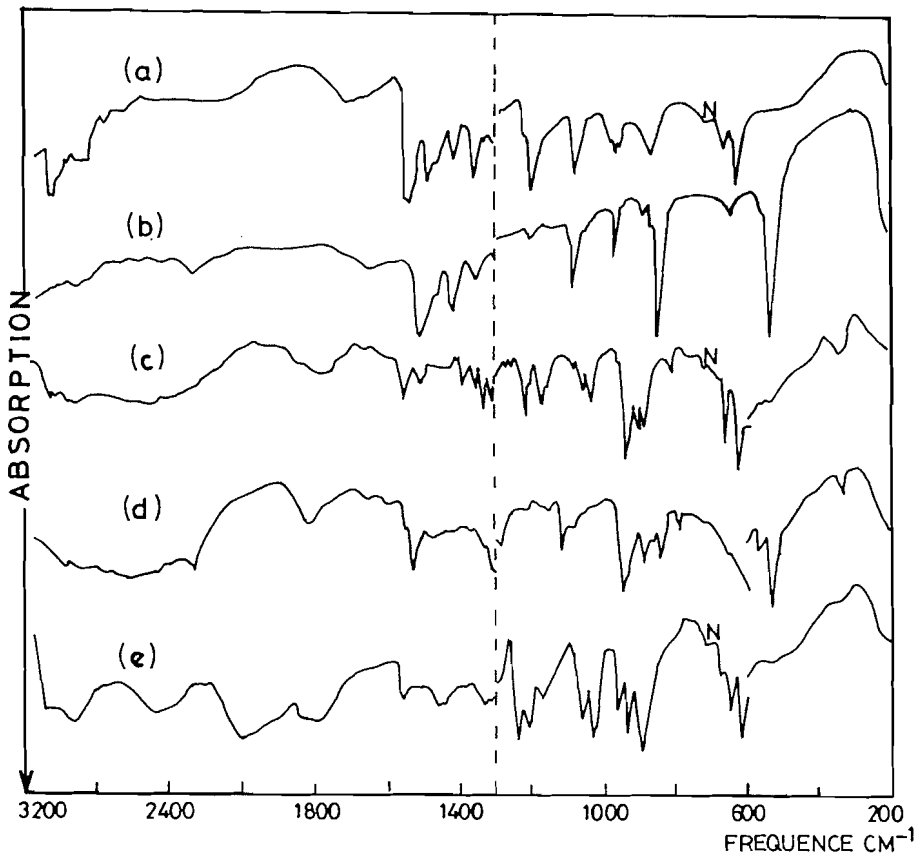

FIG. 1. Spectres infrarouges des (a) Me4 TA, (b) Me4D_2-3,5 TA, (c) Me4 TAH$^+$, (d) Me4D_2-3,5 TAH$^+$ et (e) Me4 TAD$^+$ à l'état solide entre 3200 et 200 cm^{-1}.

3150 et 3020 cm^{-1} trois absorptions situées vers 3110, 3095 et 3055 cm^{-1}. Aux deux premières correspondent en Raman des raies d'intensités moyenne et faible (figure 2). Nous les attribuons aux vibrations de valence ν_{CH} faisant intervenir leurs mouvements en phase et en opposition de phase (tableau 1). Sur le spectre ir de leurs homologues C-deutériés, elles sont remplacées par les deux bandes situées vers 2290 et 2240 cm^{-1} (figure 1). La bande faible vers 3060 cm^{-1} qui disparait par C-deutériation peut correspondre à une harmonique ou combinaison faisant intervenir le vibrateur C—H.

Les bandes observées vers 1210 et 1190 cm^{-1} sur le spectre ir du Me4 TA à l'état solide sont attribuées aux deux vibrations de déformation dans le plan δ_{CH}. En effet, la deutériation spécifique sur le carbone fait disparaître la première et diminuer considérablement l'intensité de la seconde (figure 1). Cette dernière, qui persiste sur le spectre ir du Me4D_2-3,5 TA, ne correspond pas à un reste de produit hydrogéné mais plutôt au mode R_4 superposé au mode δ_{CH} dans la molécule hydrogénée.

La comparaison des spectres ir du Me4 TAH$^+$ et du Me4D_2-3,5 TAH$^+$ (figure 1) nous permet d'attribuer la bande à 1178 cm^{-1} du premier à l'une des deux vibrations δ_{CH}. Le comportement semblable des deux bandes du Me4 TAH$^+$, obtenues à 1218 cm^{-1} et 1089 cm^{-1} par deutériation sur le carbone, et le fait que le spectre Raman du cation non deutérié présente deux raies d'intensité moyenne et forte, respectivement, et polarisées, nous incitent à attribuer celles-ci aux modes couplés $R_4 + \delta_{CH}$. Les vibrations δ_{CD} sont observées dans les composés C-deutériés vers 880 et 840 cm^{-1} (tableau 1, figure 1).

Par analogie avec le méthyl-1 triazole (6), la bande large et

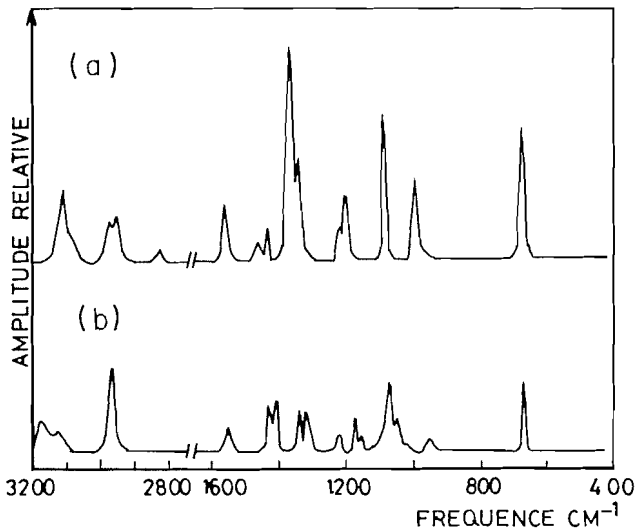

FIG. 2. Spectres Raman des (a) Me4 TA et (b) Me4 TAH$^+$ en solution aqueuse entre 3200 et 400 cm^{-1}.

dissymétrique située vers 870 cm^{-1} sur le spectre ir du Me4 TA (figure 1) est attribuée aux deux modes γ_{CH} superposés. Par contre, dans le cas du Me4 TAH$^+$, deux bandes sont vues à 902 et 889 cm^{-1}, correspondant aux deux vibrations γ_{CH}. L'apparition de ces deux bandes est vraisemblablement due au fait que les deux vibrateurs C—H sont dans un environnement différent.

Deux bandes γ_{CD} apparaissent sur les spectres ir des deux

molécules $Me4D_2$-3,5 TA et $Me4D_2$-3,5 TAH^+ vers 560 et 520 cm^{-1}.

Vibrations du noyau

Les mouvements de vibration dans le plan du noyau triazolique, R_1–R_7, donnent lieu à des absorptions auxquelles correspondent des raies de diffusion d'intensité moyenne à forte. À la bande ir à 1354 cm^{-1} observée sur le spectre du Me4 TA à l'état solide correspondent deux raies à 1361 et 1338 cm^{-1}, polarisées sur le spectre Raman de la solution aqueuse (figure 2), et deux bandes à 1360 et 1350 cm^{-1} sur le spectre ir du Me4 TA en solution dans le chloroforme deutérié. La forte intensité de la première raie nous incite à l'attribuer au mode R_3 (tableau 1).

Le tableau 1 montre que les modes R_4 et δ_{CH} sont superposés. En effet, une modification du spectre ir dans la région 1300–1100 cm^{-1} par deutériation sur le carbone est observée (figure 1).

Deux bandes intenses entre 1600 et 1500 cm^{-1} existent sur le spectre ir du cation Me4 TAH^+. L'absorption intense relevée vers 1570 cm^{-1} à laquelle correspond une raie Raman polarisée est attribuée au mode R_1 (figures 1 et 2, tableau 1). La bande située à 1525 cm^{-1} est très perturbée par la deutériation sur l'atome d'azote. Elle pourrait correspondre à une combinaison faisant intervenir le vibrateur N—H. Remarquons que le mode R_1 subit une augmentation en fréquence par protonation. Cela peut s'expliquer par l'effet électronique dû à la présence de la charge positive sans exclure un léger couplage avec le mode δ_{NH}. En effet, R_1 baisse légèrement en fréquence par N-deutériation.

Les vibrations R_2 et R_3 sont situées vers 1390 et 1315 cm^{-1} et sont abaissées par rapport au Me4 TA. L'examen des spectres du cation N-deutérié permet de conclure que ces abaissements de fréquence sont dus à une intéraction de ces modes avec la vibration δ_{NH}.

Le mode R_4 est situé vers 1218 cm^{-1}; un fort couplage a été noté pour ce mouvement avec l'une des vibrations δ_{CH} (cf. vibrations des groupements C—H).

À la vibration R_5 correspond l'absorption à 1062 cm^{-1}. La fréquence de ce mode n'est pas modifiée par N-deutériation, ce qui permet de penser que l'abaissement de sa fréquence par protonation est vraisemblablement dû à la modification de la densité de charge dans le noyau.

Les modes R_6 et R_7 sont situés à 1041 et 940 cm^{-1}; leur comportement vis à vis de la protonation est différent. La N-deutériation met en évidence une interaction de R_7 avec δ_{NH}.

Les vibrations de type A″ sont souvent faibles en Raman. Dans le cas du Me4 TA, elles n'ont pas été observées. Nous les avons donc situées à partir du spectre ir en nous basant sur la méthode des suites et la deutériation sur le carbone. Ainsi, les bandes observées vers 670 et 630 cm^{-1} sont attribuées, comme

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

dans les systèmes triazoliques déjà examinés (6), aux deux vibrations du cycle R_8 et R_9. Elles sont peu déplacées par protonation (tableau 1).

Vibrations du groupement N—CH_3

Le spectre Raman des Me4 TA et Me4 TAH^+ présente une raie forte et polarisée vers 660 cm^{-1} attribuable à la vibration de valence $\nu_{N—CH_3}$ (figure 2, tableau 1). L'absorption correspondant à ce mode est, comme dans le cas du méthyl-1 triazole (6), superposée à celle assigné à R_8 et située vers 670 cm^{-1} (figure 1, tableau 1). La vibration $\delta_{N—CH_3}$ n'a pas été localisée. Le mode $\gamma_{N—CH_3}$ n'est pas observé car il est situé en dessous de 200 cm^{-1}.

Vibrations du groupement méthyle

On observe sur le spectre ir du Me4 TA un massif situé entre 3010 et 2800 cm^{-1} dont l'aspect ressemble à ceux observés pour le méthyl-4 dibromo-3,5 triazole[2] et le méthyl-4 bromo-3 triazole (6). Nous avons attribué la bande de plus haute fréquence à la vibration ν'_s car il lui correspond une raie moins intense que celle correspondant à la vibration ν_s. La bande ir vers 2820 cm^{-1} est attribuable, par analogie avec d'autres composés hétérocycliques méthylés (13), à une combinaison $\delta_a + \delta_s$ ou $\delta'_s + \delta_s$. Les bandes vers 2900 et 2705 cm^{-1} peuvent correspondre, comme dans le toluène (14, 15), aux harmoniques $2\delta_a$ et $2\delta_s$, respectivement.

Dans le cas du dérivé protoné, le massif ν_{NH} masque en ir les vibrations de valence ν_{CH_3}. Les attributions que nous proposons sur le tableau 2 sont donc bassées sur les spectres Raman et sur les spectres ir des systèmes N-deutériés.

Par analogie avec les attributions déjà proposées pour les vibrations du méthyle dans plusieurs dérivés triazoliques N-méthylés (6), nous situons les modes δ'_s et δ_a vers 1480 et 1450 cm^{-1}, respectivement (tableau 2). La vibration δ_s est localisée vers 1350 cm^{-1}. On attribue l'épaulement relevé vers 1060 cm^{-1} au mouvement $r_\perp$ et la bande observée vers 950 cm^{-1} au mode $r_\parallel$. Les fréquences de ces vibrations sont peu perturbées par la protonation sur l'azote.

La vibration de torsion t_{CH_3} est attendue en dehors de notre domaine d'étude (13, 15).

Vibrations du groupement N—H

Les spectres ir des chlorhydrates sont caractérisés par l'existence d'un massif large, intense et riche en sous-maximums qui s'étend de 3200 à 1950 cm^{-1} (figure 1). Son centre de gravité est situé vers 2600 cm^{-1}. La deutériation sur l'azote provoque son déplacement vers 2010 cm^{-1}. Ce massif est attribuable comme dans les chlorhydrates d'halogéno triazoliums-1,2,4 (7) à la vibration ν_{NH} du vibrateur N—H introduit par la protonation; il est engagé dans une liaison hydrogène forte de type $NH^+ \ldots Cl^-$ avec l'anion, comme en témoigne sa fréquence de vibration. Cependant, une association de type $NH^+ \ldots IN$ ne peut pas être exclue. Les sous-maximums observés peuvent s'expliquer, comme dans le cas des ions pyridinium (16) et imidazolium (12) par l'existence d'une résonance de Fermi entre la vibration fondamentale ν_{NH} et des harmoniques ou des combinaisons binaires. La structure du massif ν_{ND} est moins complexe que celle du massif ν_{NH} du fait que ces deux massifs apparaissent dans deux régions différentes du spectre qui ne font pas appel aux mêmes combinaisons et harmoniques.

2. M. Saidi Idrissi. Travaux non publiés.

Aucune raie correspondant à la vibration ν_{NH} n'est observée en diffusion.

Les spectres ir présentent également dans cette région un massif moins large et moins intense que le premier, sous la forme d'un triplet et centré vers 1800 cm^{-1} (figure 1). La deutériation sur l'azote ne modifie ni son aspect ni la fréquence du centre de gravité.

L'absorption relevée à 1163 cm^{-1} sur le spectre ir du Me4 TAH^+ est attribuée au mode δ_{NH}, car elle disparait lors de la N-deutériation.

La bande située vers 940 cm^{-1} est assignée au mode γ_{NH} superposé à la vibration R_7 dans ce système. En effet, l'aspect de cette bande est modifié considérablement sur le spectre ir du cation Me4 TAD^+, qui présente en plus une bande à 650 cm^{-1} attribuable au mode γ_{ND} (figure 1).

Conclusion

L'analyse des spectres vibrationnels du méthyl-4 triazole et de son homologue deutérié nous a permis de proposer une attribution de la plupart des modes fondamentaux de cette molécule. La protonation du méthyl-4 triazole-1,2,4 aboutit à la fixation d'un seul proton sur l'un des azotes pyridiniques. L'étude des spectres vibrationnels du chlorhydrate obtenu montre que l'addition d'un proton provoque des variations de fréquence de la plupart des vibrations fondamentales. Les spectres des cations deutériés nous ont permis d'expliquer ces variations par deux causes :

(*i*) Couplage des mouvements de vibration avec le nouveau vibrateur N—H.

(*ii*) Modification de la répartition de la densité de charge électronique due à la présence d'une charge positive sur le cycle.

C. T. YIM and D. F. R. GILSON. Can. J. Chem. **65**, 2513 (1987).

The orientational order parameters of monochlorobenzene have been determined, as functions of temperature and concentration, in two nematic solvents, EBBA and ZLI-1132. There are significant differences in the orientation of the solute molecule in the two solvents as reflected in the values of corresponding potential energy parameters as well as in the concentration dependence of the order parameters. These differences are caused mainly by a stronger interaction between the aromatic ring and the solvent ZLI-1132, since the change in the potential function terms for chlorobenzene parallel those for unsubstituted benzene. Attempts to correlate the orientation potential with molecular polarizability and molecular shape lead to the conclusion that neither of these properties plays a dominant role in determining the potential.

C. T. YIM et D. F. R. GILSON. Can. J. Chem. **65**, 2513 (1987).

On a déterminé les paramètres d'ordre orientationnel du monochlorobenzène, en fonction de la température et de la concentration, dans deux phases nématiques, soit le EBBA et le ZLI-1132. Il y a des différences importantes dans l'orientation de la molécule de soluté dans les deux solvants; ces différences sont mises en évidence par les paramètres d'énergie potentielle correspondants à chacun des solvants ainsi que par le fait que les paramètres d'ordre varient avec la concentration. Ces différences proviennent principalement d'une interaction plus forte entre le cycle aromatique et le solvant ZLI-1132; en effet, le changement dans les termes de la fonction de potentiel du chlorobenzène est parallèle à celui observé dans le benzène qui n'est pas substitué. On a effectué des essais dans le but d'établir une corrélation entre le potentiel d'orientation et la polarisabilité moléculaire et la forme moléculaire; on en déduit que ni l'une ni l'autre de ces propriétés ne joue un rôle dominant dans la détermination du potentiel.

Introduction

Liquid crystals are now commonly used in display devices (1, 2). Recent developments in this area utilize the ability of the anisotropic solvent to orient dichroic dye molecules to improve contrast or add colour properties. In these applications, the degree of orientation of the solute molecule in the liquid crystal solvent is of considerable importance. The measurement of both solute and solvent orientation parameters also provides experimental data essential for the understanding of anisotropic intermolecular interactions and for testing the theories of ordered phases.

The elements of the ordering matrix for fairly simple molecules can be easily obtained from the analysis of the high resolution nmr spectrum of the solute molecule dissolved in a nematic liquid crystal solvent (3). The spectrum of the solute is dominated by the direct intramolecular dipolar couplings and may contain many lines. This direct intramolecular dipolar coupling is a function of both the internuclear distance and the average orientation of the internuclear vector with respect to the external magnetic field. Analysis of the spectrum therefore leads to information about both the geometry of the solute molecule and its orientation in the solvent. A large number of molecules have been studied by this method. However, in most of these studies the attention has been focused solely on the molecular structure, while the orientational order parameters have been treated as a "by-product" of lesser significance. Saupe has shown that calculation of the orientation parameters by a simple bond additive model gave approximate agreement with the experimental values for several fluoro- and chlorobenzenes (4, 5), and later studies have attempted to correlate the available orientation data with molecular shape (6), polarizability (7, 8, 10, 11), moments of inertia (9), repulsive forces (10, 11), and by empirical relationships (12). Recently, a few studies have been reported that specifically investigate the orientation of the solute molecule as a function of temperature and concentration in different types of nematic solvents (10, 11, 13–20). Attempts have also been made to relate the temperature and concentration dependence of the order parameters to reduced variables (13, 14).

The solute order parameters are entirely determined by the orientation dependent part of the intermolecular interaction potential. In its simplest form, the effective pseudopotential experienced by a solute molecule can be written as

$$[1] \quad V = -kT(a[1]\cos^2\theta_1 + a[2]\cos^2\theta_2 + a[3]\cos^2\theta_3)$$

where θ_i are the Euler angles specifying the orientation of the molecule-fixed 1,2,3-axial system to the director of the liquid crystal solvent, and the constants $a[i]$ characterize the interaction energy along the corresponding axis. These constants reflect both solute and solvent contributions. If the solute molecule is rigid, as in the case discussed in the present work of a planar aromatic molecule, then eq. [1] can be further simplified to a two-parameter equation. For example, if the 3-direction is taken as the long molecular axis and the 2-axis to be perpendicular to the aromatic ring,[1] Fig. 1, then the equation can be rewritten (15, 6) as

$$[2] \quad V(\theta,\phi) = -kTQ(\sin^2\theta\cos^2\phi + R\cos^2\theta)$$

where

$$Q = (a[1] - a[2])$$

[1] In refs. 6 and 15 the axes are labelled differently, with the 3-axis perpendicular to the ring and the 2-axis the long molecular axis.

and

$$R = (a[3] - a[2])/(a[1] - a[2])$$

and θ and φ are the polar and azimuthal angles, respectively. If dispersion forces play an exclusive role in determining the orientation, then the parameter R should be constant for a given solute molecule, leaving Q as the only term involving the solvent contribution. Attention is usually focused on the parameter R, which measures the relative strength of interaction along the two principal axes within the plane of the aromatic ring, and the experimental values for several different solutes have been compared with those calculated for various different molecular properties (6, 10, 11, 15, 17).

An alternative approach is possible, whereby the relative orientations can be compared by substituting the following parameters:

$$A = a[3] - (1/2)(a[1] + a[2])$$

$$B = (a[1] - a[2])/(2a[3] - a[1] - a[2])$$

and eq. [1] is rewritten as

$$[3] \quad V(\theta,\phi) = -kTA(\cos^2\theta + B\sin^2\theta\cos 2\phi)$$

Equation [3] is essentially the same as that derived by Emsley *et al.* (18). Provided that the potential function is determined by dispersion forces only, then the parameter B should be independent of temperature and solvent and dependent only on the anisotropy of polarizability of the solute molecule. Of course, eqs. [2] and [3] are equivalent and the parameters therein are related:

$$Q = 2AB$$

$$R = (1/2B) + 0.5$$

In this study we will adopt the second form, i.e., eq. [3], as the orientation potential.

In the present paper we report the results of an investigation of the temperature and concentration dependence of the orientational order of monochlorobenzene in two different nematic solvents: EBBA and ZLI-1132. This molecule has been studied previously (21–24), but not specifically in terms of its orientation in thermotropic liquid crystal solvents.

Experimental

Two liquid crystal solvents were used: (*a*) ZLI-1132, a mixture of cyanophenylcyclohexanes and cyanobiphenylcyclohexanes, which was supplied by BDH Chemicals Ltd., and (*b*) EBBA (*N*-(*p*-ethoxybenzylidine)-*p'*-*n*-butylaniline), which was synthesized and purified by literature methods (25).

Chlorobenzene (Fisher Scientific, bp 131.5–131.7°C) was used without further purification. Samples of various concentrations were prepared by weighing appropriate amounts of solute and solvent into nmr tubes and then sealing under vacuum. The concentrations of the samples studied are listed in Table 1.

The proton nmr spectra were recorded on Varian XL-200 and XL-300 spectrometers, without deuterium lock. The sample temperatures were calibrated against the proton chemical shift difference in an ethylene glycol sample. The spectra were recorded using a 5-μs pulse, an acquisition time of 1.5 s, and a spectral width of 5–12 kHz, and between 64 and 192 free induction decays were accumulated to obtain an acceptable signal-to-noise ratio, depending on the concentration. The spectral analyses were performed with a modified LAOCN 3 program using either an IBM PC or Olivetti M-24 microcomputer.

Results and discussion

The optimized geometry was obtained by fitting to the dipolar coupling constants obtained from room temperature spectra,

TABLE 1. Concentration dependence of the nematic to isotropic transition temperature and the average A' and B parameters for chlorobenzene dissolved in ZLI-1132 and EBBA

Solvent	Concentration (mol%)	$T_{N\rightarrow I}$ (K)	A' ($\times 10^{-21}$ J/mol)	B
ZLI-1132	15.5	326.2	10.8	0.591
	7.1	336.9	11.5	0.605
	2.9	341.4	11.8	0.602
	1.1	344.0	12.1	0.607
EBBA	12.7	325.3	6.87	0.249
	7.2	338.0	7.66	0.255
	3.8	346.0	8.17	0.262
	2.2	349.0	8.28	0.263

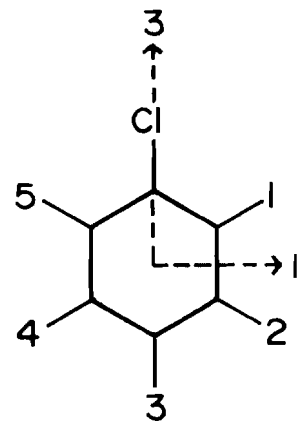

FIG. 1. Coordinate system and atomic labelling for chlorobenzene.

and the same geometry was used for analyzing the spectra recorded at other temperatures. For chlorobenzene in EBBA the geometry found is in agreement with that of Jacobsen and Schaumburg (22). The optimized geometry in ZLI-1132 is slightly different: specifically, the relative internuclear distances between H2 and H3 and between H2 and H4 are longer, and between H1 and H5 shorter, when compared with the corresponding values in EBBA (see Fig. 1 and Table 2). Vibrational effects were ignored in calculating the order parameters. Emsley *et al.* (18) have examined the effect of vibrational averaging on the derived values of order parameters and concluded that the effect is small and can be neglected in studying the orientation behavior and its variation with temperature.

Since chlorobenzene possesses two perpendicular planes of symmetry, only two of the five independent elements of the Saupe order matrix are required, and these are conveniently expressed as S_{33}, and $(S_{11} - S_{22})$. They can be obtained from the orientation potential via the expressions:

$$S_{33} = (3/2Z)\int\int(\cos^2\theta\exp\{-V(\theta,\phi)/kT\}\sin\theta\,d\theta d\phi) - (1/2)$$

$$S_{11} - S_{22} = (3/2Z)\int\int(\sin^2\theta\cos 2\phi\exp\{-V(\theta,\phi)/kT\} \times \sin\theta\,d\theta\,d\phi)$$

where

$$Z = \int\int\exp\{-V(\theta,\phi)/kT\}\sin\theta\,d\theta\,d\phi$$

Here the 3-axis is taken as the long molecular axis and the 2-axis to be perpendicular to the ring plane, Fig. 1. At any one temperature, the values of S_{33} and $S_{11} - S_{22}$ are sufficient

r_{24}	4.322	4.299	4.302

*Assumed.

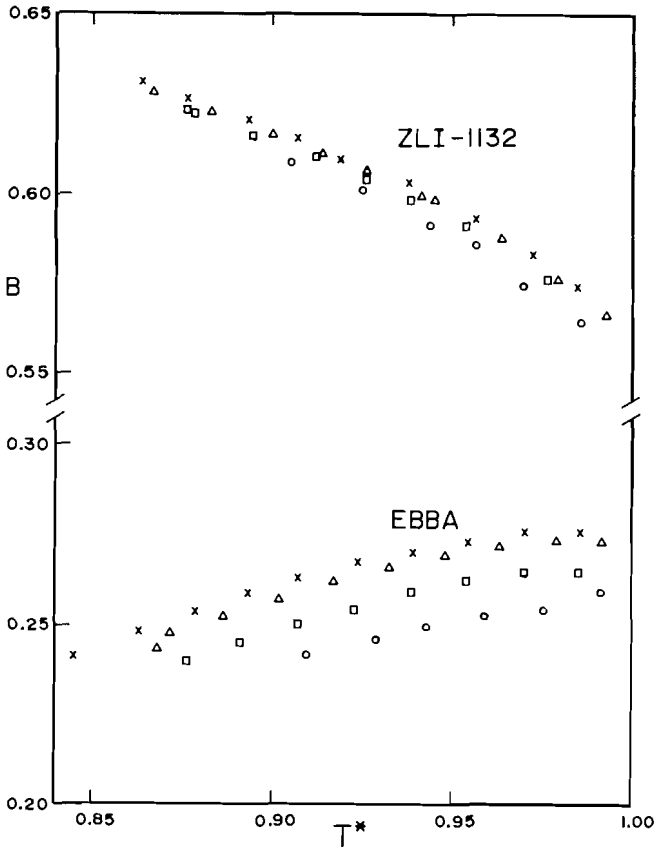

FIG. 2. Dependence of the parameter B on reduced temperature. Concentrations (in mol%) in ZLI-1132: ○, 15.5; □, 7.1; △, 2.9; ×, 1.1; and in EBBA: ○, 12.7; □, 7.2; △, 3.8; ×, 2.2.

to determine the parameters A and B in eq. [3]. The values of B so obtained are plotted against reduced temperature, T^* ($= T/T_{N\rightarrow I}$), in Fig. 2. The most obvious feature of these plots is the strong solvent dependence of B (or R in eq. [2]). Figure 2 also shows that there is a significant variation of B with both temperature and concentration. For chlorobenzene in EBBA, the value of B tends to increase with increasing temperature, while in ZLI-1132 it tends to decrease. This is in conflict with the theory, which predicts that B should be a molecular property and independent of temperature and solvent.

The average B values for each concentration are listed in Table 1. To eliminate the concentration dependence, the average B value was plotted against concentration and extrapolated to give B_0, i.e., the B value at infinite dilution, and these values are given in Table 3. For comparison, the B(pol) and B(vdW), which are calculated using polarizability (26) and van der Waals dimensions respectively, are also listed. Even if allowance is made for the uncertainties in these calculated

TABLE 3. Potential energy parameters B_0, A_0, and A_0B_0

Benzene	1.0	—	—	7.23	7.23
EBBA					
Chlorobenzene	0.267	0.486	0.437	8.66	2.31
Benzene	1.0	—	—	2.88	2.88

quantities, it is obvious there is little or no agreement with the experimental values. Therefore we conclude that neither of these properties plays a dominant role in determining the orientation behavior of chlorobenzene in the two solvents, in agreement with the results of Emsley *et al.* on the orientation of perdeuterated anthracene (20). Jokisaari and co-workers observed that, for the three solutes *ortho*- and *meta*-difluorobenzene (11, 17) and monoiodobenzene (10), similar R values are observed in solvents ZLI-1132 and ZLI-1167, and they suggested that dispersion forces are decisive in determining the solute order in these two solvents. However, variations in the solvent and temperature dependence of B and (or) R have been reported for numerous other cases (10, 11, 15–20) and specific solute–solvent interactions have been invoked to explain the observed behaviour. In their study of the orientation of perdeuterated anthracene, Emsley *et al.* (20) used six different solvents. This is the most extensive study reported so far on the effect of solvent on orientation, and yet there was no obvious correlation between the orientation and the nature of the solvent. Neither dispersion nor repulsion forces appeared to dominate. A qualitative improvement, leading to the correct temperature variation, was obtained by extending the potential function to include a fourth-rank term.

As expected, the values of A, derived by fitting the experimental order parameters, are temperature and concentration dependent. The measurements of the orientation are, of course, made at constant pressure and not at constant density, and, within the framework of the mean field theory of Maier and Saupe, the term kTA in eq. [3] is expected to be dependent on both the solvent order and on the average intermolecular separation (27, 28). Both are temperature dependent, and to include this eq. [3] is rewritten:

$$[5]\quad V(\theta,\phi) = -(A'SV_m^{-\gamma})(\cos^2\theta + B\sin^2\theta\cos 2\phi)$$

with the substitution $kTA = A'(SV_m^{-\gamma})$, where S is the solvent order, V_m is the molar volume, and the exponent γ specifies the volume dependence. A' is expected to be a constant for a given solvent–solute pair.

Experimental data on both solvent order parameters and densities are available and we will take advantage of the fact that the order parameter of the solvent is a function of reduced temperature and is, therefore, independent of the solute and its concentration (29, 30). For EBBA, the order parameters were obtained from wide-line nmr spectra[2] and the specific volumes have been measured by Bahadur and Chandra (32). For ZLI-1132, both the specific volume and order parameter data have been reported by Bahadur *et al.* (33). The dipolar splitting of the nmr absorption can be related directly to the order parameter, since it depends upon the *ortho* proton distance and

	(V)		2.29		3.84

*(N) and (V) stand for Neugebauer's and Vuks approach respectively.

orientation, but in the case of ZLI-1132, the order parameters were determined from refractive index measurements and this approach is subject to some controversy (34–38). It is claimed (34–37) that the method due to Neugebauer (39) is superior to that proposed by Vuks (40), but, in the present work, we have evaluated the A' values for ZLI-1132 based on order parameter data derived by both methods (33). The dependence of parameter A' on the volume is introduced into eq. [5] by assuming different fixed values of the exponent γ: $\gamma = 0$ (no volume dependence), $\gamma = 2$ (attractive forces), and $\gamma = 4$ (repulsive forces). The molar volume is assumed to behave in the same fashion as the order parameter, i.e., dilute solution and pure solvent will have the same volume at the same reduced temperature. The A_0 values (the A' at infinite dilution) are then obtained by extrapolation.

The results for both solvent systems are presented in Table 4. Since the values cannot be compared directly for different γ values, the A_0 values are given relative to that of benzene in EBBA. The results for chlorobenzene/ZLI-1132 clearly show that values derived for the two sets of order parameters differ only slightly, but the different volume dependence does affect the results; an increase in γ from 2 to 4 decreases the A_0 values in ZLI-1132 by 5% relative to those in EBBA. An attempt to find the "best" values of γ, by varying the exponent to yield A' values of least variance, gave exponents of 1 and 5 for ZLI-1132, using data from Neugebauer's and Vuks' approaches, respectively, and zero for EBBA. Clearly, the available data on the order parameters and molar volumes of nematic solvents are not precise enough to draw definite conclusions regarding the volume dependence, but, in spite of these uncertainties, a constant relative A_0 value is obtained.

Since neither the use of different sets of order parameters nor the different volume dependence has a significant effect, any set of A' and A_0 values can be used for further discussion of the orientation behaviour. For simplicity, we have chosen the values that are obtained assuming $\gamma = 0$, and, for ZLI-1132, using the order parameters from Neugebauer's approach. In Table 1 the resulting average A' is listed for each of the systems studied. The corresponding values of A_0, A_0B_0, and those of unsubstituted benzene[3] are given in Table 3.

The term A_0 corresponds to a potential energy difference between orientations of the solute molecules with axis-3 parallel and perpendicular to the liquid crystal director, while A_0B_0 corresponds to the difference between axis-1 and axis-2 oriented parallel to the director (see eqs. [2] and [3]). The larger A_0 and A_0B_0 values observed in ZLI-1132 imply a stronger interaction, which causes the chlorobenzene molecules to correlate their orientations with those of host molecules more effectively in ZLI-1132 than in EBBA. For solutions of different concentrations of the same solute, a plot of the order parameter of the liquid crystal solvent vs. reduced temperature, T^*, results in a universal curve (29), but attempts to show that the solute order behaves in much the same way led to contradictory conclusions (13, 14). The present results for chlorobenzene are plotted as a function of reduced temperature T^* in Fig. 3. In both solvents the results do show a small but definite concentration dependence, which is larger in EBBA than in ZLI-1132.

The variation of the nematic to isotropic transition temperature with concentration has been considered as an indication of solute–solvent compatibility (42, 43). The slopes of the $T_{N\rightarrow I}$ vs. concentration (mole fraction) plots are 133 and 216 K mol^{-1} for chlorobenzene in ZLI-1132 and in EBBA, respectively, and clearly demonstrate that chlorobenzene molecules are more capable of correlating their molecular orientations with those of ZLI-1132 than with EBBA, and hence are less effective in disordering this solvent.

A comparison of these energy parameters for chlorobenzene and benzene indicates that the replacement of a C—H by C—Cl on the benzene ring increases A_0 by approximately the same amount in both solvents. The changes in A_0B_0 are much smaller; in ZLI-1132 this quantity remains almost unchanged. The difference in A_0B_0 values of chlorobenzene in the two solvents is reasonably close to the corresponding difference for unsubstituted benzene (5.08 vs. 4.35×10^{-21} J/mol), therefore chlorine substitution is not the major contributor to the differences in orientation in these two solvents. The data in Table 3 further show that the larger B for chlorobenzene in ZLI-1132 is mainly due to the potential energy parameter A_0B_0. The contribution of A_0 is relatively small and tends to reduce the difference in B values in the two solvent systems. The strong solvent dependence of B is largely due to the difference in the contribution of the benzene ring to the total interaction energy. This may be interpreted as an indication that specific solute–solvent interactions are important in determining orientation order, in particular, the preferred location of the solute molecule at a given region of the solute.

The physical properties of a number of cyano-containing nematic liquid crystals, such as cyanobiphenyls, cyanophenylcyclohexanes, and cyanocyclohexylcyclohexanes, have been interpreted in terms of an antiparallel molecular association or correlation (44, 45). The association leads to the formation of dimers and involves both polar and apolar interactions. On the other hand, dielectric measurements have indicated that there is little dipole–dipole correlation in MBBA (31). It seems reasonable to assume that the same type of interaction exists between the aromatic moiety of the chlorobenzene molecules and the cyanophenyl group of ZLI-1132. The interaction restricts the orientation freedom of the ring plane with respect to the director, and is, therefore, responsible for the observed difference in A_0B_0 values in the two solvents.

In their recent studies of a series of molecules with C_3 or higher symmetry, dissolved in these same two solvents, Burnell and co-workers (41) concluded that the ordering of the solutes involves both the size and shape of the solute and the interaction of the molecular quadrupole moment with the solvent electric

field gradient. This model predicts that an aromatic ring system should interact more strongly with the solvent ZLI-1132, which is in agreement with the present results.

It is shown that $^{1}H-^{13}C$ shift-correlated two-dimensional spectra obtained for polarization transfer via two-bond and three-bond $^{13}C-^{1}H$ coupling can, in conjunction with related experiments, be used to assign unambiguously the molecular skeletons of two of the less common triterpenes, moretenone and 3-acetylaleuritolic acid. It is concluded that this is a technique of considerable generality for assigning structures of triterpenes and is more reliable than alternative approaches such as mass spectral fragmentation patterns. It has the additional benefit of simultaneously providing reliable ^{13}C and ^{1}H spectral assignments for these compounds.

STEWART MCLEAN, MARION PERPICK-DUMONT, WILLIAM F. REYNOLDS, HELEN JACOBS et SAGAR SINGH LACHMANSING. Can. J. Chem. **65**, 2519 (1987).

On a démontré que si on utilise les spectres de correlation homonucléaire bidimensionnels $^{1}H-^{13}C$, optimisés pour le transfert de polarisation par le biais de couplages $^{13}C-^{1}H$ à travers deux ou trois liaisons, de concert avec des expériences qui leurs sont reliées, on peut attribuer d'une façon qui n'est pas ambigue le squelette moléculaire de deux des triterpènes les moins communs, soit la moréténone et l'acide acétoxy-3 aleuritolique. On conclut que cette technique est très générale pour l'attribution de structures de triterpènes et qu'elle est plus sure que d'autres approches comme les patrons de fragmentation en spectrométrie de masse. De plus, cette technique fournit de même coup des attributions sures pour les spectres en résonance magnétique nucléaire du ^{13}C et du ^{1}H de ces composés.

Triterpenoid derivatives are among the most common natural products isolated from plants (1). However, they are particularly difficult to characterize because of their extremely complex spectra, the large number of possible isomers, and the relative similarities of physical and spectral properties for different isomers. Mass spectral fragmentation patterns have been used for assigning molecular skeletons of triterpenes (2). However, as will be shown below, this is not a completely reliable technique. Consequently, there is an obvious need for an unambiguous technique for assigning structures of the less common triterpenes.

We have recently shown that two-dimensional $^{1}H-^{13}C$ shift-correlated nmr spectra optimized for polarization transfer between protons and carbons separated by two or three bonds (3–5) provide a reliable and relatively sensitive technique for total assignment of ^{13}C and ^{1}H spectra of known triterpenes (6). In this report, we demonstrate how the same approach can be used to assign the molecular structures and spectra of two uncommon triterpenoid derivatives, moretenone and 3-acetylaleuritolic acid. It is concluded that this is a technique of considerable generality for assigning structures of triterpenes.

Results and discussion

The two compounds mentioned above were isolated during the course of a detailed phytochemical investigation of *Maprounea guianensis* Aubl. (Euphorbiaceae). This plant has a reputation in Guyana as a medicinal agent (7) while the related *M. africana* has been shown to produce triterpenes with cytotoxic activity (8). Both crystalline components were isolated from the $CHCl_3$ extract of stem bark of *M. guianensis* (see Experimental). Their structural and spectral characterization is discussed below.

Characterization of moretenone

Low resolution mass spectrometry indicated a molecular weight of 424 for the first compound. The ^{1}H nmr spectrum showed six methyl singlets in the range of δ 0.69–1.08. A further slightly broadened methyl peak was observed at δ 1.68 along with a pair of weakly coupled olefinic protons at δ 4.68 and δ 4.70, indicating the presence of an isopropenyl group. No other ^{1}H signals were observed below δ 2.55. The infrared spectrum showed a strong band at 1700 cm^{-1} while the ^{13}C spectrum showed a peak at δ 218, both indicative of a carbonyl group. Normal and DEPT-edited (9) ^{13}C spectra indicated the presence of seven CH_3 groups, eleven CH_2 groups (one olefinic), five CH groups, and seven nonprotonated carbons. Allowing for one oxygen from a carbonyl group, this corresponds to an empirical formula of $C_{30}H_{48}O$, i.e., a molecular weight of 424.

A preliminary search of the literature revealed that one common triterpene, which had the correct empirical formula and which contained the anticipated functional groups, was lupenone, **1** (1). However, comparison of our ^{13}C spectral data with those reported by Wenkert *et al.* for lupenone (10) showed a number of significantly different chemical shifts, particularly for carbons assigned by Wenkert to rings D and E and the isopropenyl group. This suggested that our compound was an isomer of **1**, most likely involving structural differences in ring E. A further literature search revealed no compound with ^{13}C spectral data that were in agreement with our data.

2

To elucidate the structure of this triterpene, three $^1H-^{13}C$ shift-correlated 2D nmr spectra were obtained. The first was a standard experiment with delay times optimized for $^1J_{CH}$ (11), which established connectivities between directly bonded carbons and hydrogens (Table 1). The next two experiments used delay times optimized for two-bond and three-bond $^1H-^{13}C$ couplings. They were obtained using the pulse sequence XCORFE (5). The first of the two experiments was optimized for couplings involving methyl protons ($^2J_{CH} \simeq {}^3J_{CH} \simeq 4.5$ Hz) (12). Cross-peaks involving methyl protons are particularly useful in triterpenes since the methyl groups are strategically located around the periphery of these molecules (e.g., see **1**), providing a network of two-bond and three-bond connectivities, which effectively tie the molecule together.

Results of this experiment are summarized in Table 1 with typical cross-sectional plots through specific ^{13}C frequencies shown in Fig. 1. The methodology used for making spectral assignments was similar to that described in detail by Reynolds *et al.* (6). The starting point was two methyl groups (δ_H 1.03, δ_C 26.5 and δ_H 1.08, δ_C 21.1), which showed cross-peaks with each other. This is only consistent with the presence of a *gem*-dimethyl group (6), assigned as C-23 and C-24, by analogy with **1**. In support of this assignment, both methyl protons gave additional cross-peaks with the carbonyl carbon (C-3), a quaternary carbon at δ 47.4 (C-4), and a methine carbon at δ 54.9 (C-5). The latter carbon showed an additional cross-peak with the methyl ^1H signal at δ 0.93_5, assigned as H-25 (see Fig. 1*a*).

The patterns of cross-peaks due to H-25, H-26, and H-27, as well as the chemical shifts and numbers of attached protons for carbons showing cross-peaks with these methyl protons, indicated that the structures of rings A, B, and C were identical to that shown in **1**. For example, the methine carbon at δ 49.7 (C-9) shows cross-peaks with methyl ^1H signals assigned as H-25 and H-26 (see Fig. 1*b*), as expected for **1**. However, the methine carbon assigned as C-13 showed both the expected cross-peak with H-27 and an additional cross-peak at δ 0.69 assigned to H-28 (Fig. 1*c*). This indicates that this methyl group must be bonded to C-18 (see **2**), rather than to C-17 as in **1**. The remaining cross-peaks for H-28 (see Table 1) were consistent with this assignment.

The key remaining uncertainty is the location of the isopropenyl group. The remaining methine group (δ_H 2.25, δ_C 47.9) was assigned as the point of attachment of the isopropenyl group, based on the characteristic allylic shift of the ^1H signal and an observed cross-peak of this carbon to the methyl ^1H signal at δ 1.68. This methine group was assigned as C-21, based on a second XCORFE spectrum with delay times optimized for $^nJ_{CH}$ couplings involving CH and CH_2 protons. A value of 0.062 s was chosen for the fixed delay, T_1, prior to polarization transfer. This corresponds to an optimum of $^nJ_{CH} = 8$ Hz, approximately the maximum expected value for this type of coupling (12). Results of this experiment are summarized in Table 1 with key cross-sectional spectra shown in Fig. 2. The XCORFE sequence allows distinction between $^1H-C-^{13}C(H)$ and $^1H-C-C-^{13}C(H)$ cross-peaks since the former show vicinal coupling along the f_1 (^1H) frequency axis while the latter are fully ^1H-decoupled (5). The only limitation is the f_1 data point resolution (8 Hz in this case). Peaks with vicinal couplings larger than 8 Hz appear as doublets or multiplets, peaks with couplings of ca. 8 Hz appear as broad singlets, while peaks with smaller couplings are not significantly broadened beyond the data point resolution. Bearing this in mind, a cross section through the unassigned methylene carbon at δ 27.3 shows broad ^1H peaks at δ 2.25 and δ 1.05 and a sharper peak at δ 1.51 (Fig. 1*d*). The former corresponds to the allylic methine proton while the latter two are due to the previously assigned C-19 methylene protons. Therefore, the δ 27.3 carbon must be flanked by C-19 and the allylic methine carbon, i.e., it is C-20, while the isopropenyl group must be bonded to C-21 (see **2**). The stereochemistry at C-21 was deduced from the observation of a 12-Hz coupling between H-21 and H-17, indicating an *anti* orientation for these hydro-

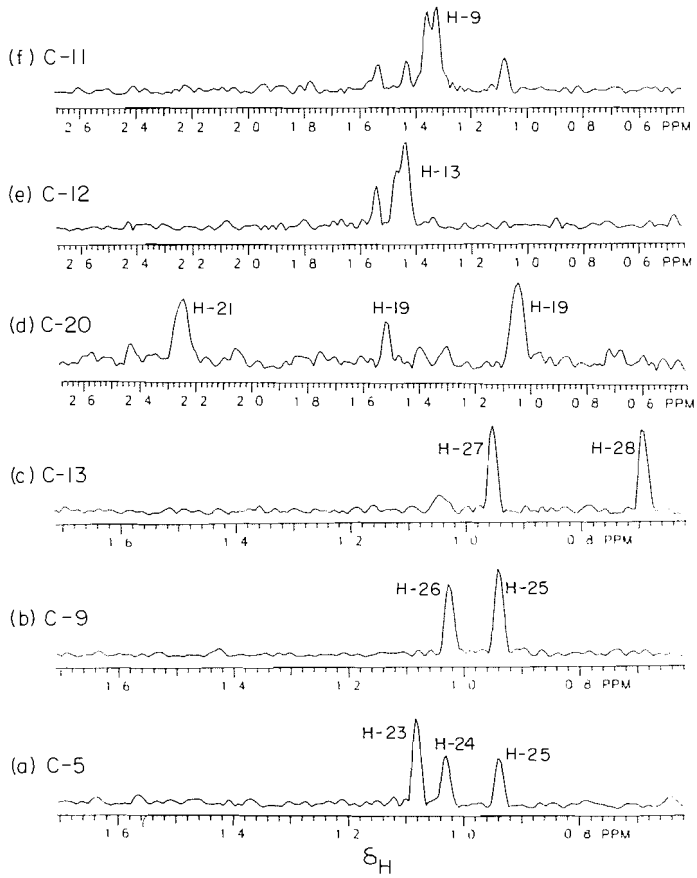

FIG. 1. Typical cross-sectional plots through specific ^{13}C (f_2) frequencies from XCORFE spectrum for **2**, illustrating two- or three-bond connectivities to the labelled ^1H (f_1) signals. Spectra 1(a)–(c) are from the XOCORFE spectrum optimized for polarization transfer from CH_3 groups, while 1(d)–(f) are from the spectrum optimized for polarization transfer from CH and CH_2 groups.

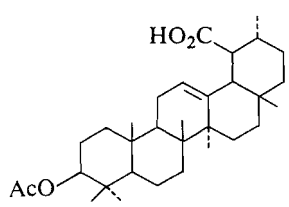
gens. Remaining carbon assignments were straightforward from the second XCORFE spectrum. For example, C-12 and C-11 were assigned on the basis that their cross sections (Figs. 1*e* and 1*f*) showed, respectively, doublets for H-13 and H-9.

A further search of the literature revealed that **2** (with the illustrated stereochemistry) has been assigned by Lavie *et al.* to moretenone, a constituent of *Euphorbia lateriflora* (13). There have been no subsequent reports of the isolation of moretenone from other plant sources. The physical constants and ^1H spectral data for our compound are in good agreement with those reported for moretenone (13) while differing significantly from those reported for hopenone, the C-21 epimer of **2** (14).

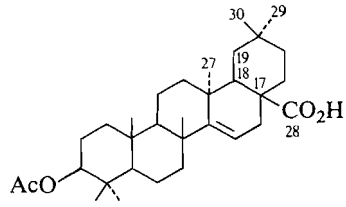
Characterization of 3-acetylaleuritolic acid

The second compound had physical and spectral properties, including mass spectral fragmentation patterns, which were very similar to those reported for 3-acetylmaprounic acid, **3**, which had been isolated from *M. africana* (8). In view of the similar plant source, we initially assumed that our compound was **3**. However, DEPT-edited ^{13}C spectra indicated two fewer methine carbons than **3** plus an additional quaternary carbon and an additional methylene carbon, i.e., our compound must be an isomer of **3**.

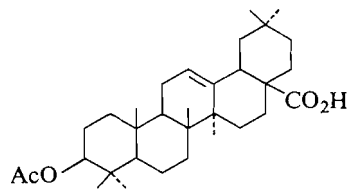
Consequently, we undertook a set of experiments similar to



3



4



5

those used for **2**, to elucidate the structure of the second compound. The ^1H–^{13}C shift-correlated spectrum in $CDCl_3$ showed that two methyl ^1H signals (corresponding to carbons at δ 15.6 and δ 26.1) overlapped at $\delta\ 0.95_5$. A second spectrum in C_6D_6 showed overlap of a different pair of methyl ^1H signals (corresponding to carbons at δ 16.5 and δ 28.6) at $\delta\ 0.93_5$. However, comparison of the two spectra indicated that all methyl ^1H signals should be resolved in ca. 75% C_6D_6:25% $CDCl_3$ solvent mixture. This was in fact observed (see Fig. 2). Consequently this solvent mixture was used to obtain an XCORFE spectrum with delay times optimized for polarization transfer from methyl protons (Fig. 2). Results are summarized in Table 2.

Analysis of the cross-sectional spectra indicated the presence of two *gem*-dimethyl groups. One of these groups showed additional cross-peaks with a quaternary carbon and two methylene carbons while the second showed additional cross-peaks with a quaternary carbon and two methine carbons. One of the methine carbons (δ 80.5) has a chemical shift characteristic of a carbon bearing an oxygen substituent, while the second (δ 55.7) shows an additional cross-peak with a third methyl ^1H signal. This indicates a structure for ring A similar to **3** with the second *gem*-dimethyl group being C-23 and C-24 and the third methyl ^1H signal corresponding to H-25. Analysis of other cross-peaks involving H-25 and H-26 suggests that ring B is also identical to **3**. However, cross-peaks involving H-26 and H-27 revealed key differences in rings C and D. In structure **3**, both H-26 and H-27 should show cross-peaks with two quaternary carbons, C-8 and C-14. In fact, the only carbon that shows cross-peaks with both of these ^1H signals is the nonprotonated olefinic carbon (δ 160.8). The only location of C-27 and the double bond that is consistent with this observation is that shown in **4**. H-27 also shows cross-peaks with a quaternary carbon (δ 37.5), a methine carbon (δ 41.7), and a methylene carbon (δ 33.5), respectively assigned as C-13, C-18, and C-12. The carboxyl group must be bonded to a quaternary carbon to give the correct numbers of different types of carbons. Since C-18 is a methine carbon, the CO_2H group must be bonded to C-17. Finally, a direct ^1H–^{13}C shift-correlated experiment plus a ^1H COSY-45 spectrum (15) in combination with the XCORFE spectrum allowed location of the remaining *gem*-dimethyl group at C-20 rather than C-21. The first spectrum established the direct bond between C-18 and the methine proton at δ 2.28. The ^1H COSY spectrum showed that this proton was coupled to protons at δ 1.09 and δ 1.24

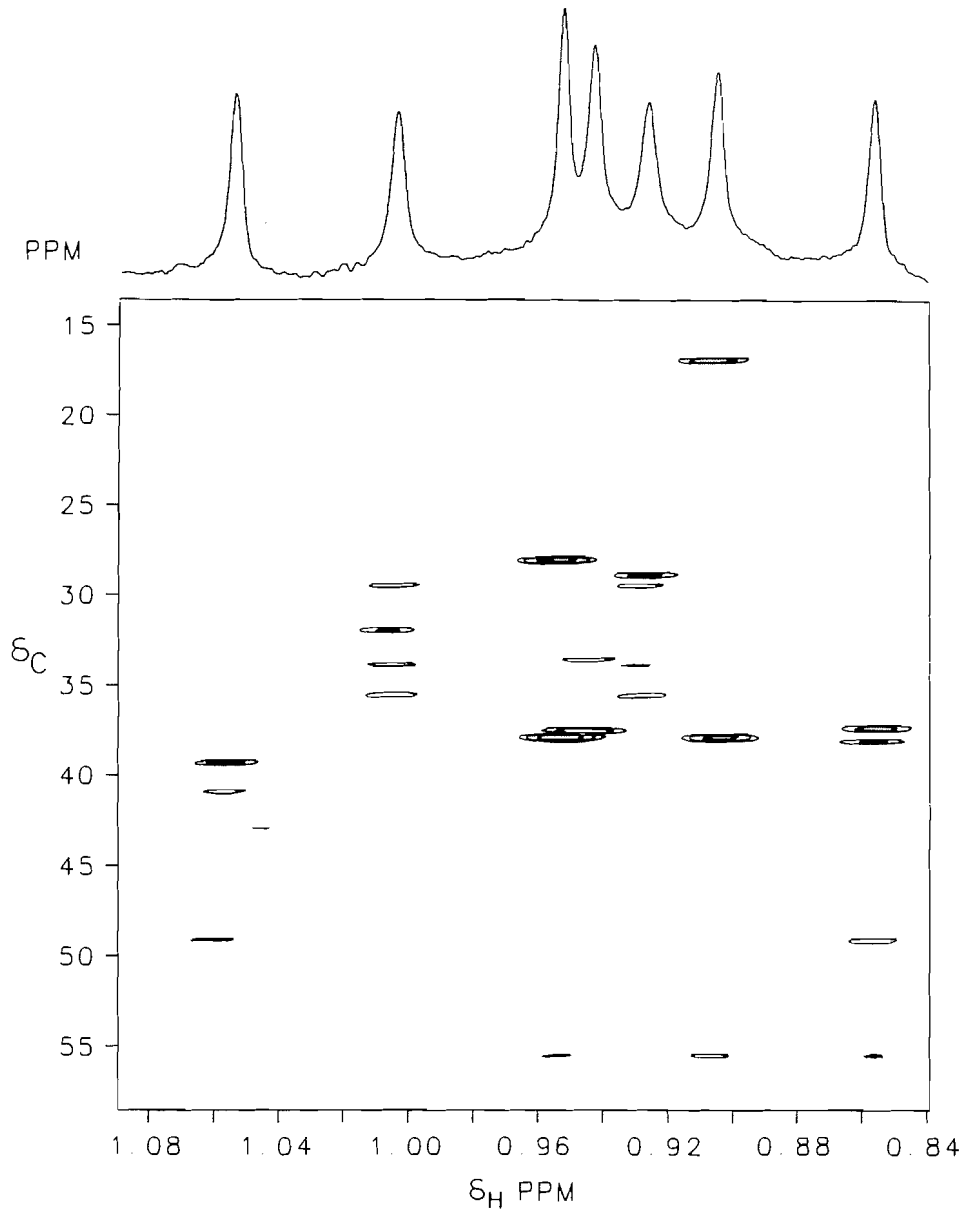

FIG. 2. Contour plot of XCORFE spectrum of **4** in 75% C_6D_6:25% $CDCl_3$. ^1H spectrum along the top shows the resolution of ^1H signals in this solvent pair.

while the direct shift-correlated experiment showed that the latter two protons were directly bonded to the carbon at δ 35.5. Thus this must be C-19. Since this carbon showed cross-peaks in the XCORFE spectrum with the two remaining *gem*-dimethyl ^1H signals, these methyl groups must be bonded to C-20. The remaining methylene carbon showing cross-peaks to these methyl protons (δ 33.8) is thus assignable as C-21.

Because of the limited amount of sample available (16 mg), it was not feasible to obtain a second XCORFE spectrum optimized for CH and CH_2 proton polarization transfer.[2] Fortunately, however, the remaining carbons (C-2, C-6, C-11, C-16, and C-22) could all be assigned from the above-mentioned combination of ^1H COSY and direct ^1H–^{13}C shift-correlated spectra. Assignments are given in Table 2. The ^1H-COSY spectra were much more informative for **4** than for **2**. This was due to the larger number of resolved ^1H signals for **4**, reflecting the larger number of functional groups in this compound.

There has been considerable confusion in the literature regarding the structure and ^{13}C spectral assignments for 3-acetyl-aleuritolic acid, **4**. This compound appears to have been first isolated by Misra and Khastigar (16), albeit with significantly different physical properties (e.g., mp 278–281°C). Subsequently, a compound (mp 301–302°C), isolated from *Phytolacca americana*, was assigned structure **4** by Woo and Wagner, mainly on the basis of mass spectral fragmentation patterns (17). They claimed that their compound was identical to that of Misra and Khastigar (based on mixture melting points) and also to a compound previously isolated by Burke and Le Quesne from *P. americana* and assigned structure **5**, also on the basis of mass spectral fragmentation patterns (18). To eliminate any possible doubts, we obtained a sample of the compound believed to be methyl aleuritolate from Professor Le Quesne and also

[2]This experiment is considerably lower in sensitivity than that involving polarization transfer from methyl protons (see ref. 6).

TABLE 2. Assigned ^{13}C and ^{1}H chemical shifts for **4** and observed $^{13}C-^{1}H$ cross-peaks used in making the assignments[a]

Carbon	n_H	δ_C ($CDCl_3$)[b]	δ_H ($CDCl_3$)	C—H connectivities

[a] See Table 1 for an explanation of column headings.

[b] Values in parentheses are for 75% C_6D_6:25% $CDCl_3$ mixture used for XCORFE experiment. Assignments in $CDCl_3$ were confirmed from a separate set of direct and indirect shift-correlated spectra.

[c] Proton cross-peaks in ^{1}H COSY-45 spectrum.

[d] Values in parentheses are $^{1}H-^{1}H$ coupling constants (Hz) in cases where these are clearly resolved. The $^{1}H-^{1}H$ coupling for H-3 in **4** and in methyl aleuritolate (see footnote *b*, Table 3) confirms the β orientation of the OR function in these compounds.

[e] The spectra provide no direct method for distinguishing C-29 from C-30 since they are present as a *gem*-dimethyl pair. Thus these assignments may be reversed.

converted part of our sample of **4** to this derivative. The two samples gave exactly identical ^{1}H and ^{13}C spectra (see Table 3), confirming their identity. ^{13}C and ^{1}H spectra were assigned using a combination of 2D experiments similar to that used for **4**. Thus we are confident that all compounds discussed above in this paragraph are identical. It may also be significant that the ^{1}H spectral data for **4** and for methyl aleuritolate are indistinguishable from those reported, respectively, for 3-acetylmaprounic acid **3** and methyl maprounate (8), while the mass spectral fragmentation patterns for **3** and **4** are also indistinguishable. A reinvestigation of the structure of **3** would appear to be justified.

Finally, Carpenter *et al.* have assigned the ^{13}C spectrum of **4** (19) by comparison with previously assigned spectra for oleanic acid derivatives (20). Comparison with our spectral data confirms that the compound isolated by Carpenter is identical to our sample. However, there are 11 misassignments in the earlier spectral assignments (19). This reinforces our earlier remarks concerning the unreliability of assigning spectra from model compounds (21) and the desirability of having more reliable techniques for ^{13}C spectral assignment (6, 21).

Consideration of the generality of indirect $^{13}C-^{1}H$ shift-correlated spectra for assigning structures of triterpenes

In this investigation $^{13}C-^{1}H$ shift-correlated spectra optimized for $^{n}J_{CH}$ couplings ($n = 2$ or 3) involving methyl protons have been used in conjunction with other two-dimensional (2D) nmr spectra to assign skeletal structures for two of the less common triterpenes. The first, moretenone, has been reported from only one other plant source, while the structure of the second, 3-acetylaleuritolic acid, has been in dispute. In a previous investigation, we have used a similar approach to assign ^{13}C and ^{1}H spectra of our other triterpenes (6). While these were all known compounds, the spectral data would have been sufficient to assign structures had these been unknown. Since all triterpene derivatives have a number of strategically located methyl groups (1), this approach should be generally applicable for assigning structures of this type of molecule.

[a] ^{13}C chemical shifts (δ scale).

[b] ^{1}H chemical shifts (δ scale). Values in parentheses are $^{1}H-^{1}H$ coupling constants (in Hz) for protons where couplings are clearly resolved.

There are only three apparent limitations, all of which can be overcome. First, while the shift-correlated spectra provide no direct stereochemical information, this can be deduced either (as in this case) from vicinal $^{1}H-^{1}H$ couplings or from nuclear Overhauser enhancement measurements. Second, it is essential to have resolved methyl ^{1}H signals. As shown above, this can be achieved by judicious choice of solvent or solvent mixture. The final problem is one of sensitivity. After determining the correct solvent mixture, the three 2D spectra used to determine the structure of **4** were obtained in 26 h, using 16 mg of sample. While this represents a great sensitivity improvement over the alternative approach of 2D $^{13}C-^{13}C$ connectivity experiments (22), even greater sensitivity would be desirable. Subsequent work in our laboratory has shown that independent optimization of all three delay times can further increase sensitivity by, on average, a factor of two (23). For example, this allowed us to determine the XCORFE spectrum of methyl aleuritolate (optimized for polarization transfer from methyl protons) in 15 h, using only 5 mg of sample. However, an even more promising approach would be to use $^{1}H-^{13}C$ shift-correlated spectra obtained with ^{1}H detection since this provides one order of magnitude further increase in sensitivity (24).

Mass spectral fragmentation patterns have, in the past, been widely used for assigning structures of triterpenes (2). However, as discussed above, structures **3**, **4**, and **5** have been assigned to three different triterpene samples with very similar physical properties, including mass spectral fragmentation patterns. It has been subsequently shown that at least two of the three compounds are identical. It is this sort of ambiguity which leads us to search for a more reliable technique for structure assignment of triterpenes. We believe combinations of 2D nmr experiments of the kind used above provide this technique. Furthermore, they have the additional advantage of providing reliable ^{13}C and ^{1}H spectral assignments (6).

Experimental

General experimental procedures

Melting points were determined on a Thomas–Kofler micro hot stage. Infrared spectra were measured on a Nicolet 5DX FTIR spectrometer with samples in $CHCl_3$. Nuclear magnetic resonance spectra were obtained on a Varian XL-400 spectrometer. Mass spectra were obtained at 70 eV on a Bell and Howell CEC 21-490 mass spectrometer. Optical rotations were measured on a Perkin–Elmer 243B polarimeter.

Plant material

Maprounea guianensis was collected near the Soesdyke–Linden highway, Demerara, in May 1984. Voucher specimens are deposited in the Herbarium of the University of Guyana and at the Institute of Systematic Botany, University of Utrecht, Netherlands.

Extraction and isolation

Dried and ground bark (1.36 kg) was exhaustively extracted with cold $CHCl_3$ to afford a gum (10 g). The gum was shaken with a mixture of 9:1 MeOH–H_2O and hexane; a residue (4.4 g) remained undissolved. The material (1.9 g) obtained from the hexane solution was chromatographed on a column of silica gel; elution was first with hexane and then hexane–EtOAc of increasing polarity, and progress was monitored by tlc. Moretenone (115 mg) was the only identifiable constituent isolated. The residue (4.4 g) from the partitioning experiment was dissolved in $CHCl_3$ and chromatographed on a silica gel column with elution by hexane–EtOAc, EtOAc, then EtOAc–MeOH. This chromatography provided moretenone and 3-acetylaleuritolic acid. The MeOH aqueous fraction from the partitioning experiment also contained moretenone and 3-acetylaleuritolic acid.

Moretenone

Moretenone, **2**, recrystallized from Me_2CO, was obtained as needles, mp 194–197°C; $[\alpha]_D$ 52.5° (*c* 0.2, $CHCl_3$); ir: 1700, 1635, 881 cm^{-1}; ms M^+ 424 (lit. (13) mp 202–203°C; $[\alpha]_D$ 53° ($CHCl_3$); ir: 1710, 1640, 885 cm^{-1}; ms M^+, 424).

3-Acetylaleuritolic acid

3-Acetylaleuritolic acid, **4**, recrystallized from hexane–EtOAc, mp 297–300°C; $[\alpha]_D$ 24.3° (*c* 0.14, $CHCl_3$); ir: 3500, 1733, 1688 cm^{-1}; ms M^+, 498 (2%), 248 (31%), 234 (100%), 189 (77%) (lit. (17) mp 301–302°C; $[\alpha]_D$ 23.1° ($CHCl_3$); ir: 1735, 1689 cm^{-1}).

A sample of **4** was refluxed with K_2CO_3 in MeOH. Solvent was removed under reduced pressure and the residue was partitioned between EtOAc and 1 *M* aqueous HCl. The EtOAc solution afforded a solid, which was dissolved in Et_2O and treated with CH_2N_2. The product was chromatographed on silica gel and the fraction obtained, mp 200–203°C, was identical to the methyl aleuritolate supplied by Professor Le Quesne.

Two-dimensional nuclear magnetic resonance spectra

Experimental parameters are similar to those detailed by Reynolds *et al.* (6). However, due to the smaller amounts of sample available (36 mg for **2**, 16 mg for **4**), shorter ^{1}H relaxation delays (0.5 s) were used along with more transients per time increment (256 transients for **2**, 800 transients for **4**), to increase the signal-to-noise as much as possible for XCORFE experiments.

Received March 9, 1987

J. ALAN CREIGHTON and MICHAEL J. TAYLOR. Can. J. Chem. **65**, 2526 (1987).

The title dications are prepared in a single step by the reaction of *N,N,N',N'*-tetramethyl-1,2-diaminoethane (tmen) with the halogenoalkanes CH_2X_2 (X = Cl, Br, or I) or CH_2XCH_2X (X = Cl or Br), respectively. These bulky dications are useful for the precipitation of complex ions from solution, and show selectivity for doubly-charged anions. Tmen also reacts with CBr_4 to yield a dibromo-imidazolidinium heterocyclic dication, whereas reaction with $CHBr_2CHBr_2$ produces the dihydrobromide of tmen. Vibrational and nmr spectra are reported, and the protons of the CH_2 group between the two quaternary nitrogen atoms of the tetramethylimidazolidinium dication are shown from the nmr data to possess acidic character.

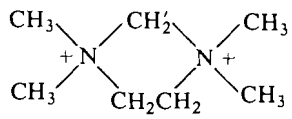
J. ALAN CREIGHTON et MICHAEL J. TAYLOR. Can. J. Chem. **65**, 2526 (1987).

On a préparé les dications mentionnés dans le titre en une seule étape, en faisant réagir le *N,N,N',N'*-tétraméthyl diamino-1,2 éthane (tmen) respectivement avec les halogénoalcanes CH_2X_2 (X = Cl, Br ou I) ou CH_2XCH_2X (X = Cl ou Br). Ces dications très encombrants sont utiles pour provoquer la précipitation d'ions complexes à partir de solutions et ils présentent une sélectivité pour les anions doublement chargés. Le tmen réagit aussi avec le CBr_4 pour donner le dication hétérocyclique dibromo-imidazolidinium; par ailleurs, la réaction avec le $CHBr_2CHBr_2$ fournit le dibromhydrate du tmen. On rapporte les spectres de vibration et rmn; la rmn démontre que les protons du groupement CH_2 entre les deux atomes d'azote quaternaires du dication tétraméthylimidazolidinium possèdent un caractère acide.

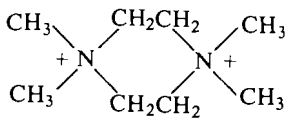
[Traduit par la revue]

Introduction

The reaction of *N,N,N',N'*-tetramethyl-1,2-diaminoethane (tmen) with dichloromethane to form the cyclic 1,1,3,3-tetramethylimidazolidinium dication **1** has recently been reported (1). We have independently encountered the same reaction while attempting to use tmen and CH_2Cl_2 as a mixed solvent, which deposited crystals of the dichloride of **1** in a surprisingly rapid reaction. We have therefore investigated more fully the reaction of tmen with various halogenomethanes, and have also studied the similar reaction of tmen with the 1,2-dihalogenoethanes to give dihalide salts of the 1,1,4,4-tetramethylpiperazonium dication **2**. A separate report gives the structure of **2** in



1



2

the salt $[C_8H_{20}N_2][InBr_5(H_2O)].H_2O$ (2), while the structure of **1** in the diiodide salt has already been determined crystallographically by Khan, Peppe, and Tuck (1). Our interest in such bulky dications is because of their potential use as counterions for the crystallization of large anions, especially those with a double negative charge (3, 4).

Quaternisation reactions of *N,N,N',N'*-tetramethyl-α,ω-diaminoalkanes with α,ω-dibromoalkanes have been previously investigated as a route to linear and cyclic polymeric quaternary ammonium cations (5, 6). However, the use of this type of reaction for the synthesis of cyclic quaternary ammonium cations does not seem to have been noted and the conventional route to such cyclic cations has been by *N*-methylation of the parent heterocycles with bromomethane or iodomethane (Menschutkin reaction) (4, 7). A low-yield synthesis of the dibromide of **2** by reaction of vinylidenebis(dimethylamine) with 1,2-dibromoethane has also been published (8).

Our investigations of the tetramethylimidazolidinium cation have also revealed that the protons of carbon atom 2 (H' in the structural formula of **1**) are appreciably acidic, and the reactivity at this carbon atom is thus a further interesting aspect of this cation.

Experimental

Preparative and spectral data

1,1,3,3-Tetramethylimidazolidinium salts

For the preparation of the dichloride salt of **1** excess dichloromethane was used as the reaction medium, and a 1:3 molar ratio of tmen to CH_2Cl_2 was found to be optimal. With this molar ratio roughly a 50% yield of the dichloride precipitated after 1 week at room temperature, whereas with methanol as the solvent it was shown by nmr spectroscopy that there was no reaction between tmen and CH_2Cl_2 (1:1) at room temperature after 1 week. It was normally possible to use reagent-grade tmen and CH_2Cl_2 without further purification, but with one batch of tmen there was no reaction with CH_2Cl_2 until after the tmen had been purified by distillation. The reaction of CH_2Br_2 or CH_2I_2 with tmen is more rapid than that of CH_2Cl_2, and precipitation of the dibromide or diiodide salt was roughly 70% complete after stirring these liquids in 3:1 mole ratio for 1 week at room temperature. The crystalline products were washed with dry ether and dried *in vacuo*. The dichloride salt was noticeably deliquescent. *Anal.* calcd. for $[C_7H_{18}N_2]Cl_2$: C 41.8, H 9.02, N 13.9; found: C 41.3, H 9.64, N 13.7. *Anal.* calcd. for $[C_7H_{18}N_2]Br_2$: C 29.0, H 6.26, N 9.66; found: C 28.6, H 6.76, N 9.42. *Anal.* calcd. for $[C_7H_{18}N_2]I_2.0.75CH_2I_2$: C 15.9, H 3.36, N 4.79; found: C 15.9, H 3.59, N 4.72. are very soluble in water and their solutions immediately precipitate silver halides on treatment with silver nitrate solution. Their identification as dihalide salts of **1** was confirmed by ^1H and ^{13}C nmr data (^1H: see ref. 1. ^{13}C: δ = 55.5, CH_3; 63.0, CH_2CH_2; 89.4, NCH_2N) recorded from their solutions in D_2O. The quantity of CH_2I_2 contained in the iodide salt is probably not stoichiometrically significant, being that remaining after partial loss of CH_2I_2 during drying *in vacuo* from a weakly-bound halide ion – iodoalkane crystalline adduct (9).

Vibrational spectroscopic data for **1**; Raman (cm^{-1}): 330w, 435w, 485m, 562m, 595w, 770vs (ring mode), 865m, 900w, 930m, 940w, 975m, 995w, 1020m, 1045vw, 1115w, 1155w, 1203m, 1250w, 1280m, 1340w, 1380w, 1405w, 1445m, 1480w, 2850w, 2900m, 2950s, 2980w, 3015vs. The infrared spectrum consisted of bands coincident with the Raman data.

1,1,4,4-tetramethylpiperazonium salts

Dihalide salts of **2** were prepared by reaction of tmen with 1,2-dichloroethane or 1,2-dibromoethane. Equimolar quantities (0.05 mol) of tmen and CH_2XCH_2X (X = Cl or Br) in 5 mL methane + 5 mL dimethylformamide as solvent were allowed to react for several days at room temperature. The solid product was washed with dry ether; yield 70%. No recrystallisation was necessary. *Anal.* calcd. for $[C_8H_{20}N_2]Cl_2$: C 44.7, H 9.37, N 13.0; found: C 44.5, H 9.83, N 12.8. *Anal.* calcd. for $[C_8H_{20}N_2]Br_2$: C 31.6, H 6.63, N 9.21; found: C 31.7, H 7.09, N 9.20. The identification of these products as dihalide salts of **2** was confirmed by nmr data (1, 5): ^1H: δ = 3.4, NCH_3; 4.0 ppm, NCH_2CH_2N; ^{13}C: δ = 54.1, CH_3; 57.5 ppm, CH_2. Vibrational spectroscopic data for **2** comprise Raman: 280m, 340m, 455m, 485m, 520w, 707vs (ring mode), 815m, 894m, 954s, 998w, 1034m, 1075vw, 1120w, 1210m, 1230m, 1285m, 1313m, 1343w, 1390w, 1410w, 1455m, 1490w, 2860w, 2935m, 2960s, 2995m, 3005vs; infrared: 265w, 360w, 455m, 632m, 735w, 870s, 920vs, 970s, 1022s, 1050w, 1060s, 1135m, 1200m, 1214s, 1308s, 1330w, 1400m, 1475m, 3010m (regions 1400–1450 and 2850–3000 cm^{-1} masked by Nujol absorption).

Complex anion salts of 1

To illustrate the use of these cations for the precipitation of doubly-charged complex anions, solutions of the dichloride of **1** in hot ethanol were mixed in 1:1 mole ratio with hot ethanolic solutions of $CoCl_2 . 6H_2O$ or $CuCl_2 . 2H_2O$ to precipitate $[C_7H_{18}N_2][CoCl_4]$ or $[C_7H_{18}N_2][CuCl_4]$ in high yield. The colours of these solids, respectively blue and yellow, were characteristic of the $[CoCl_4]^{2-}$ and $[CuCl_4]^{2-}$ ions, and it was also possible to characterise further the copper compound by obtaining its Raman spectrum using 647.1 nm excitation. This showed bands at 276s, 238w cm^{-1}, close to published wavenumbers 276, 232 cm^{-1} of the two bands of the $[CuCl_4]^{2-}$ ion observed in the Raman spectrum of the salt $[(CH_3)_4N][CuCl_4]$ (10). *Anal.* calcd. for $[C_7H_{18}N_2][CoCl_4]$: C 25.4, H 5.48, N 8.46; found: C 25.0, H 5.47, N 8.65. *Anal.* calcd. for $[C_7H_{18}N_2][CuCl_4]$: C 25.1, H 5.41, N 8.35; found: C 24.1, H 5.50, N 8.40. A similar reaction using $NiCl_2 . 6H_2O$ precipitated the $[NiCl_4]^{2-}$ salt of **1**, with the characteristic lilac colour of this anion, if the ethanol solvant was dry. *Anal.* calcd. for $[C_7H_{18}N_2][NiCl_4]$: C 25.4, H 5.49, N 8.47; found: C 25.7, H 5.27, N 8.67. If the ethanol was not dry, however, a green solid precipitated. The same green product resulted from standing $[C_7H_{18}N_2][NiCl_4]$ in moist air, and from the resulting 15.6% weight gain (constant weight), and on the basis of CHN analyses, this product is formulated as $[C_7H_{18}N_2][NiCl_4(H_2O)_2] . H_2O$. *Anal.* calcd.: C 21.8, H 6.29, N 7.28; found: C 22.1, H 6.37, N 7.45; calcd. weight increase on gaining $3H_2O$, 16.3%.

The dication **1** is also effective for the precipitation of doubly charged complex anions from aqueous solutions, and thus the tetrabromozincate salt was obtained as small, well-shaped crystals on adding an aqueous solution of the dibromide of **1** to an aqueous solution of $ZnBr_2$. *Anal.* calcd. for $[C_7H_{18}N_2][ZnBr_4]$: C 16.3, H 3.52, N 5.44; found: C 16.2, H 3.56, N 5.49. Strong bands in the ir spectrum at 220 cm^{-1}, and in the Raman spectrum at 175 cm^{-1} confirmed the presence of the $[ZnBr_4]^{2-}$ ion (11). Crystalline hexahalogenostannate salts were obtained similarly by adding the aqueous solution of the appropriate dihalide of **1** to either $SnCl_4$ in 6 ml L^{-1} HCl or $SnBr_4$ in 4 mol L^{-1} HBr. *Anal.* calcd. for $[C_7H_{18}N_2][SnCl_6]$: C 18.2, H 3.93, N 6.07; found: C 17.9, H 3.99, N 6.05. *Anal.* calcd. for $[C_7H_{18}N_2][SnBr_6]$: C 11.5, H 2.48, N 3.85; found: C 12.2, H 2.95, N 2.78. The ir and Raman spectra of these salts showed the known vibrational bands of the $[SnCl_6]^{2-}$ and $[SnBr_6]^{2-}$ ions (11) together with the bands of the dication **1**.

1,1,3,3-Tetramethyl-2,2-dibromo-imidazolidinium dibromide

The reaction of tmen with CBr_4, which in principle could result in a *spiro*-tetracation, has also been investigated. On mixing tmen with CBr_4 (1:1) in acetonitrile solution at room temperature a white solid precipitated over the course of several hours. This solid was observed to lose CBr_4 on standing in air, and it thus has a rather variable composition, depending on the washing and drying procedure. The microanalyses for two separate preparations were as follows. *Anal.* calcd. for $[C_7H_{16}N_2Br_2]Br_2 . 0.75CBr_4$: C 13.4, H 2.32, N 4.02; found: C 12.9, H 2.35, N 4.07. *Anal.* calcd. for $[C_7H_{16}N_2Br_2]Br_2 . 0.2CBr_4$: C 16.8, H 3.14, N 5.45; found: C 16.4, H 3.17, N 5.46. The Raman and far-infrared spectra of this product contained bands close to but not coincident with the vibrational bands of free CBr_4, as shown in Table 1. Similar small shifts from the free CBr_4 frequencies have previously been found in crystalline adducts of CBr_4 with tetra-alkylammonium halides (9) (see Table 1), and these adducts were shown to involve a halide ion – CBr_4 interaction (9), which persists in solution in dichloromethane or acetonitrile (12). Thus it is clear that the product precipitated from the reaction of tmen with CBr_4 is also a bromide ion – CBr_4 adduct. The formulation of the cation as 1,1,3,3-tetramethyl-2,2-dibromo-imidazolidinium was confirmed from the microanalyses and the ^1H nmr spectrum (D_2O solution), which showed two resonances at δ = 3.22, 3H; 3.70 ppm, 1H. The initially white solid decomposed slowly, becoming dark brown after several hours.

Reaction of N,N,N′,N′*-tetramethyl-1,2-diaminoethane with 1,1,2,2-tetrabromoethane*

Either five- or six-membered cyclic dications may be envisaged to result from the reaction of tmen with $CHBr_2CHBr_2$, and therefore

equimolar amounts of these reactants in carbon tetrachloride solution were allowed to react. Some crystalline solid had formed after 1 h, and this change was accompanied by the growth of a sharp peak in the nmr spectrum of the solution at $\delta = 7.1$ ppm, attributable to $CHBr{=}CBr_2$. The solid was identified from its nmr spectrum in D_2O solution as the dihydrobromide of tmen, $[(CH_3)_2HNCH_2CH_2NH(CH_3)_2]Br_2$ (^1H nmr data: $\delta = 2.93$, 3H: 3.60 ppm, 1H), which was identical with that of a sample prepared by reacting tmen with hydrobromic acid. Hence in this case the quaternization of the diamine to form a cyclic cation is supplanted by a reaction in which the diamine abstracts hydrogen halide from the halogenoalkane.

Discussion

Preparative and nmr data

Quaternary ammonium cations have been used extensively as counterions for the crystallisation of bulky anions, but little use appears to have been made of quaternary ammonium dications for this purpose. Where such dications have been synthesized, such as that derived by methylation of both nitrogen atoms in 1,4-diazabicyclooctane, the usual procedure has been to prepare the diiodide salt using iodomethane as methylating agent, and where the salt of a different anion is required, to obtain this by anion-exchange in aqueous solution (13). It is therefore of considerable advantage for the preparation of water-sensitive chloro-complexes that the dichloride of **1** can be prepared directly in an anhydrous state by such a simple and convenient reaction. As expected, the preparations of the halogeno-metallate salts reported here show the particular effectiveness of **1** and **2** as counterions for the precipitation of bulky anions which bear a 2− charge. In this respect the precipitation of the $[InBr_5(OH_2)]^{2-}$ salt is of particular note, since it is obtained from an aqueous solution containing a mixture of anionic species (14), this 2− ion containing one ligand water molecule so as to maintain the characteristic six-coordination of indium shown also in $[InBr_6]^{3-}$ and $[InBr_4(OH_2)_2]^-$ (2).

The high δ values of the ^1H and ^{13}C resonances of the NCH_2N group of **1** indicate that these atoms are considerably deshielded and suggest that the protons concerned might be appreciably acidic. This has been confirmed by showing that these hydrogen atoms undergo exchange by deuterium on the addition of OD^- or tmen as base to a solution of **1** in D_2O, the NCH_2N proton resonance at 5.4 ppm diminishing rapidly, while the signals from the other proton-containing groups were unchanged. The resulting spectrum (^1H, $\delta = 4.5$ (NCH_2CH_2N), 3.6 ppm (NCH_3)) was identical with that of the deuterated form of **1** obtained by the reaction of tmen with CD_2Cl_2. No similar exchange was observed on treating **2** with base in D_2O solution, showing that the acidic character of the methylene protons is a characteristic of the $^+NCH_2N^+$ group. This finding raises the possibility that with deprotonation **1** may act as a nucleophile or potential ligand, leading perhaps to the formation of metal–carbene complexes, or that **1** may yield a stable nitrogen ylide under strongly basic conditions.

Benzophenone-photosensitized autoxidation of linoleate in solution and sodium dodecyl sulfate micelles

LAWRENCE ROSS COATES BARCLAY,[1] KIMBERLY ANN BASKIN, STEVEN JEFFREY LOCKE, AND TANYA DIANE SCHAEFER
Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received April 7, 1987

LAWRENCE ROSS COATES BARCLAY, KIMBERLY ANN BASKIN, STEVEN JEFFREY LOCKE, and TANYA DIANE SCHAEFER. Can. J. Chem. **65**, 2529 (1987).

Diffusion studies show that benzophenone (BP), linoleic acid, and methyl linoleate partition completely into the micelles of phosphate buffer/0.10 *M* SDS. Water-soluble compounds 4-sulphomethylbenzophenone, sodium salt (BP^-), azobis(2-amidinopropane·HCl) (ABAP) and 2,5,7,8-tetramethyl-6-hydroxychroman-2-carboxylate (Trolox) show partial partitioning into the micelles. BP- and BP^--photosensitized oxidation of linoleic acid in 0.50 *M* SDS exhibited characteristics of free radical chain reactions including: (*1*) inhibition by phenolic antioxidants, (*2*) no retardation by singlet oxygen quenchers, and (*3*) the formation of conjugated hydroperoxides with *cis,trans* to *trans,trans* ratios of geometrical isomers typical of autoxidation. Quantitative kinetic studies of the order in substrate, RH, and the rate of chain initiation, R_i, show that the classical rate law, $-d[O_2]/dt = k_p/2k_t^{1/2}[RH]R_i^{1/2}$ applies to BP-photoinitiated autoxidation of linoleic acid in SDS and the oxidizability ($k_p/2k_t^{1/2} = 4.42 \times 10^{-2}\ M^{-1/2}\ s^{-1}1/2$) is the same as that found with a thermal initiator. The rotating sector method gave absolute rate constants for linoleic acid autoxidation in 0.50 *M* SDS for propagation ($k_p = 36.2\ M^{-1}\ s^{-1}$) and termination ($2k_t = 3.52 \times 10^5\ M^{-1}\ s^{-1}$), significantly lower than values in polar organic solvents; attributed to solvation of polar peroxyls in aqueous SDS. Depressed inhibition rate constants (k_{inh}) for α-tocopherol, Trolox, and pentamethylhydroxychroman (PMHC) in 0.50 *M* SDS compared to k_{inh} in *tert*-butyl alcohol are attributed to hydrogen bonding effects on the peroxyl radicals and on the inhibitors.

LAWRENCE ROSS COATES BARCLAY, KIMBERLY ANN BASKIN, STEVEN JEFFREY LOCKE et TANYA DIANE SCHAEFER. Can. J. Chem. **65**, 2529 (1987).

Des études de diffusion démontrent que la benzophénone (BP), l'acide linoléique et le linoléate de méthyle se repartissement complètement dans les micelles du tampon de phosphate/0,10 *M* SDS. Les composés qui sont solubles dans l'eau, comme le sel de sodium de la sulfo-4 méthylbenzophénone (BP^-), l'azobis (amidino-2 propane·HCl) (ABAP) et le tétramethyl-2,5,7,8 hydroxy-6 chromanecarboxylate-2 (Trolox), ne se répartissent que partiellement dans les micelles. L'oxydation photosensibilisée par le BP ou le BP^- de l'acide linoléique dans du SDS à 0,50 *M* présente les caractéristiques des réactions radicalaires en chaînes, y compris : (*1*) l'inhibition par les antioxydants phénoliques, (*2*) le fait que les pièges à oxygène singulet ne retardent pas la réaction et (*3*) la formation d'hydroperoxydes conjugués contenant des rapports des isomères géométriques *cis,trans* à *trans,trans* qui sont typiques d'auto-oxydations. Des études cinétiques quantitatives de l'ordre en substrat, RH, et en vitesse d'initiation de chaîne, R_i, démontrent que l'équation de vitesse classique, $-d[O_2]/dt = k_p/2k_t^{1/2}[RH]R_i^{1/2}$ s'applique à l'auto-oxydation photo-initiée par le BP de l'acide linoléique dans le SDS et que la facilité d'oxyder ($k_p/2k_t^{1/2} = 4{,}42 \times 10^{-2}\ M^{-1/2}\ s^{-1/2}$) est la même que celle qui a été observée avec un initiateur thermique. Utilisant la méthode du secteur tournant, on a déterminé les vitesses absolues pour la propagation ($k_p = 36{,}2\ M^{-1}\ s^{-1}$) et pour la terminaison ($2k_t = 3{,}52 \times 10^5\ M^{-1}\ s^{-1}$) de la réaction d'oxydation de l'acide linoléique dans du SDS à 0,50 *M*; ces valeurs sont beaucoup plus basses que celles observées dans des solvants organiques polaires et on attribue ces différences à la solvatation des radicaux peroxyles polaires par le SDS aqueux. Les constantes d'inhibition de vitesse (k_{inh}) que l'on observe pour l'α-tocophérol, le Trolox et le pentaméthylhydroxychromane (PMHC), dans le SDS à 0,50 *M*, sont faibles par rapport à la valeur de k_{inh} que l'on observe dans l'alcool *tert*-butylique; on attribue ces différences à des effets de liaisons hydrogènes sur les radicaux peroxyles et sur les inhibiteurs.

[Traduit par la revue]

Introduction

The photosensitized action of oxygen on biological systems (the photodynamic effect) results in a number of known detrimental effects including membrane damage, protein damage, mutagenesis, and skin cancer (1–3). The possible involvement of singlet oxygen in the photoxidation of biological systems has attracted great interest (1–3) and even some application; as in photodynamic therapy (1).

The variety of examples in the literature where singlet oxygen is reported to be involved in photosensitization processes in model membrane environments such as phospholipid bilayers (4–9) and various types of micelles (10–22) usually involve a dye or porphyrin as sensitizer. These reports were most concerned with the detection of singlet oxygen but little attention was focused on the fate of an oxidizable substrate in these studies in microenvironments.

This investigation examines in detail the photo-oxidation of the linoleate chain in an aqueous sodium dodecyl sulfate (SDS) micellar system containing a simple aromatic ketone (benzophenone) as sensitizer. The results reported herein will show that (*1*) the benzophenone-sensitized oxidation of linoleate in 0.50 *M* SDS proceeds by a free-radical chain autoxidation reaction (Type I) rather than a reaction involving singlet oxygen (Type II); (*2*) the classical rate law

$$[1] \qquad \frac{-d[O_2]}{dt} \quad \frac{k_p[RH]R_i^{1/2}}{(2k_t)^{1/2}}$$

well known for autoxidation in homogeneous solution (23–25), is applicable to this system where RH is the linoleate concentration in the micellar phase, k_p and $2k_t$ are the chain propagation and bimolecular termination rate constants, respectively, and R_i is the rate of free radical chain initiation measured by the inhibitor method (26) using phenolic antioxidants; (*3*) the products of autoxidation of linoleate show the same trend with linoleate micellar concentration for photoinitiation with

benzophenone as that found with lipid-soluble and water-soluble thermal azo initiators, and (*4*) this ketone-sensitized micellar system provides a very useful model microenvironment for *quantitative* kinetic studies of the substrate oxidizability ($k_p/2k_t^{1/2}$) and this system has important advantages for the precise determination of the absolute rate constants for chain propagation, termination, and inhibition for autoxidation of the linoleate chain.

Results

1. Partition coefficients between buffer and 0.10 M *SDS*

Whereas a previous study on thermally initiated autoxidation of linoleic acid in SDS micelles *assumed* that the substrate partitioned completely into the micellar phase (27), it was important for this quantitative study to actually determine the partition coefficients of this and other pertinent compounds between SDS micellar and phosphate buffer phases. For this purpose, we used a variation of the simple method to measure diffusion coefficients (28). The procedure and results of this study are outlined in Table 1.

TABLE 1. Distribution coefficients of organic compounds between phosphate buffer (0.01 *M*, pH 7.0) and SDS (0.10 *M*) at 25°C[a]

Compound[b]	$D \times 10^5$ cm^2 s^{-1}		
	Buffer	SDS	f[c]
Linoleic acid	0.556 ± 0.032	0.158 ± 0.013	0.952
Methyl linoleate	[d]	0.192 ± 0.012	1.0
Benzophenone	0.833 ± 0.014	0.166 ± 0.004	0.960
BP^-	0.666 ± 0.013	0.473 ± 0.044	0.366
ABAP	0.592 ± 0.013	0.180 ± 0.010	0.907
DBHN	1.013 ± 0.020	0.224 ± 0.016	0.902
Trolox	0.621 ± 0.063	0.531 ± 0.031	0.186
PMHC	0.685 ± 0.019	0.185 ± 0.001	0.914
α-Tocopherol	[d]	[e]	1.0[d]
Anthracene	[d]	0.140 ± 0.025	1.0[d]
Phenanthrene	[d]	0.138 ± 0.005	1.0[d]

[a]Diffusion coefficients were calculated from the equation (58): $D = 0.2310r^2t_r/(W_{1/2})^2$ where r is the radius of the tube, t_r is the retention time of the solute, and $W_{1/2}$ is the width of the dispersion curve at half height. The distribution coefficient, f, is then calculated from the equation $D = fD_m + (1 - f)D_w$ (28) where D and D_w are the diffusion coefficients of a solute in 0.10 *M* SDS and buffer, respectively, and D_m is the diffusion coefficient of the micelles (see footnote *d*).

[b]Concentrations of the injected samples were less than 10^{-3} *M* and the detector wavelength was such that the absorbance of the stock solution was at least 0.5.

[c]The deviation is estimated to be 5–10%.

[d]Solubility was too low for measurement. These were taken as "tracer" compounds and their average $D = D_m$ (28).

[e]Eluted peaks were not Gaussian.

2. Inhibition studies with phenolic antioxidants

Experiments were conducted on the effects of the known efficient phenolic antioxidants (29), α-tocopherol (E), 2,2,5,7,8-pentamethyl-6-hydroxychroman (PMHC), and 2,5,7,8-tetramethyl-6-hydroxychroman-2-carboxylate (Trolox) on the ketone-sensitized oxidation of linoleic acid in SDS micelles. Typical oxygen uptake traces showing the inhibition periods for these antioxidants in reactions initiated by benzophenone and by the sodium salt of 4-sulphomethylbenzophenone (BP^-) are illustrated in Fig. 1 A and B, respectively.

The relative effectiveness of the three antioxidants, E, PMHC, and Trolox, was also measured in a qualitative manner for the photoinitiated oxidation of methyl linoleate in SDS micelles. Typical traces illustrated in Fig. 2 show the relatively poor antioxidant activity of vitamin E *in this system*. Similar results (not shown) were obtained when the water-soluble thermal initiator azobis(2-amidinopropane) hydrochloride (ABAP) was used to initiate autoxidation of methyl linoleate in SDS micelles. This latter system appears to be inhomogeneous (see Discussion); therefore, subsequent quantitative studies were conducted with linoleic acid in SDS.

3. Singlet oxygen quenchers

The inhibition studies with phenolic antioxidants indicate that linoleate undergoes reaction by a free-radical chain autoxidation under our conditions. Nevertheless, a few experiments were carried out with known singlet oxygen quenchers in the aqueous and micellar phases to determine whether they had any effect on the autoxidation. Sodium azide (5×10^{-3} *M*) had no effect on the rate of oxygen uptake and this concentration of azide added with α-tocopherol did not affect the typical induction period observed for this inhibitor (Fig. 1*A*). Similarly, diphenylisobenzofuran (DPBF) did not affect the rate of oxygen uptake in concentrations of 8.2×10^{-4} *M* in the micellar phase and did not affect the length of the induction period of α-tocopherol (1.17×10^{-4} *M*).

Irradiation of aqueous SDS micellar solutions containing methylene blue is a known method to generate singlet O_2 in the aqueous phase (14, 20, 22). The effect of the free-radical trap, Trolox, on an irradiated micellar solution containing methylene blue showed a very interesting contrast with its inhibiting action in the BP-sensitized experiments. In the presence of aqueous $^1O_2$, Trolox caused a rapid upsurge in the rate of oxygen consumption which is more pronounced with increased Trolox. Similarly, injection of α-tocopherol (8.5×10^{-4} *M*) did not cause an induction period. HPLC analysis indicated consumption of E with time, presumably due to attack by singlet oxygen in the micellar phase. These results are attributed to a rapid chemical reaction between singlet oxygen and the inhibitors (30, 31). On the other hand, ground state O_2 shows a low reactivity toward the tocopheroxyl radical (32).

4. Product studies

The products of autoxidation of linoleate are known to be conjugated diene 9- and 13-hydroperoxide positional isomers, having the *trans,trans* and *cis,trans* configuration (33). Reaction of linoleate with singlet oxygen yields a different mixture with approximately equal amounts of two conjugated (9- and 13-) and two non-conjugated (10- and 12-) hydroperoxides (34). In other words, the products from the $^1O_2$ reaction are not controlled by abstraction of the reactive allylic hydrogens as is the case for the autoxidation procedure. Porter and co-workers (35–39) have conducted a detailed study of the products formed in autoxidation of linoleic acid in solution and from phospholipid emulsions using a lipid-soluble initiator (e.g. di-*tert*-butylhyponitrite, DBHN). As a result, they developed a mechanism for lipid peroxidation which involves a competition between H-atom abstraction and β-scission of peroxyl radicals to account for the dependence of the relative amounts of the kinetic (*cis,trans*) and thermodynamic (*trans,trans*) products on the hydrogen atom donating ability, i.e. linoleate concentration, of the medium.

In order to determine if the Porter mechanism for linoleate autoxidation is applicable to oxidations conducted in aqueous SDS micelles, we investigated the dependence of the ratio of the various oxidation products as a function of micellar linoleate

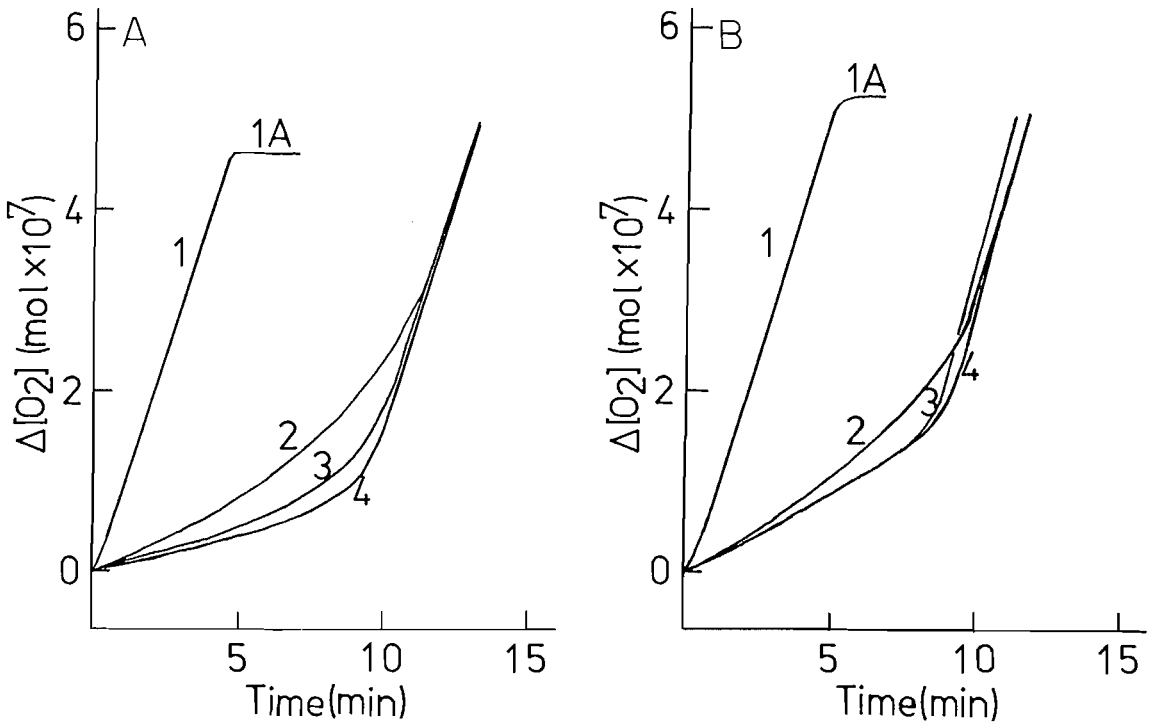

FIG. 1. (*A*) Autoxidation of linoleic acid (6.43×10^{-5} mol) in 2.00 mL of 0.50 *M* SDS (pH 7.0) at 30°C, photoinitiated by benzophenone (2.82×10^{-6} mol): *1*, uninhibited reaction (1A: lamp off); *2*, inhibited with α-tocopherol (1.67×10^{-8} mol); *3*, inhibited with Trolox (1.66×10^{-8} mol); *4*, inhibited with PMHC (1.62×10^{-8} mol). (*B*) Autoxidation of linoleic acid (4.83×10^{-5} mol) in 1.50 mL of 0.50 *M* SDS (pH 7.0) at 30°C, photoinitiated by BP^- (2.07×10^{-6} mol): *1*, uninhibited reaction (1A: lamp off); *2*, inhibited with α-tocopherol (3.75×10^{-8} mol); *3*, inhibited with Trolox (3.83×10^{-8} mol); *4*, inhibited with PMHC (3.88×10^{-8} mol).

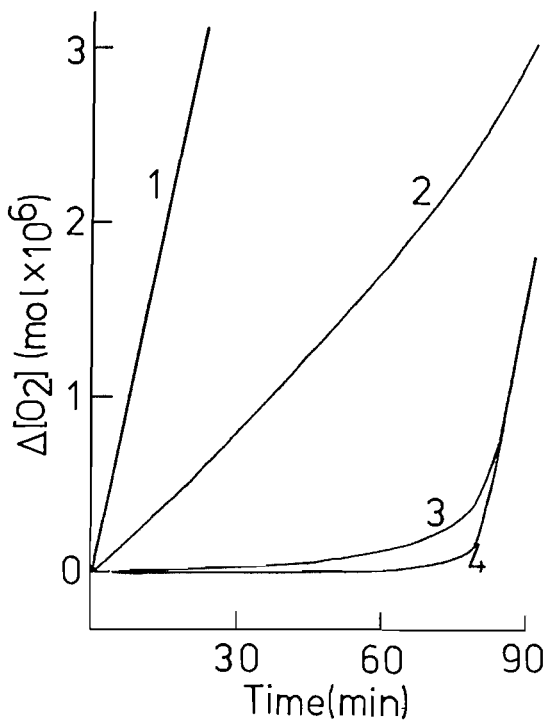

FIG. 2. Autoxidation of methyl linoleate (1.21×10^{-4} mol) in 2.00 mL of 0.50 *M* SDS (pH 7.0) at 30°C, photoinitiated by benzophenone (1.10×10^{-6} mol): *1*, uninhibited reaction; *2*, inhibited with α-tocopherol (3.70×10^{-8} mol); *3*, inhibited with Trolox (3.65×10^{-8} mol); *4*, inhibited with PMHC (3.60×10^{-8} mol).

concentration. Oxidations initiated by both water-soluble and lipid-soluble azo compounds (ABAP and DBHN, respectively) and water- and lipid-soluble benzophenones were studied. In all four cases, the products separated by HPLC (following reduction and methylation) were the alcohols known to form by free-radical autoxidation; namely **1**–**4** (Scheme 1).

The analytical data for the products of micellar linoleate autoxidations when thermally initiated by the azo compounds, ABAP and DBHN, are outlined in Table 2 while those for reactions photoinitiated by the benzophenones (BP and BP^-) are given in Table 3.

HPLC analyses were also undertaken to determine the fate of benzophenone during prolonged irradiation. A typical sample containing 1.54×10^{-4} *M* BP in 0.50 *M* SDS, saturated with O_2 *but without linoleic acid*, gave >95% recovery of benzophenone with only traces of benzhydrol and benzopinacol after $2\frac{1}{4}$ h of irradiation at full lamp intensity. Also, there was no observed uptake of oxygen during the experiment. Similar results were obtained when the experiment was carried out in the presence of linoleic acid (0.46 *M*). After $2\frac{1}{4}$ h of irradiation, greater than 90% of the BP remained while approximately 2.5% of the initial amount was accounted for by benzhydrol and a trace of benzopinacol. During the course of a typical kinetic autoxidation experiment (the equivalent of 2–3 h of continuous irradiation at full lamp intensity) essentially all of the benzophenone is recovered.

5. Kinetic results

In order to determine if the classical rate law (eq. [1]) is applicable to these photo-oxidations in SDS micelles, the

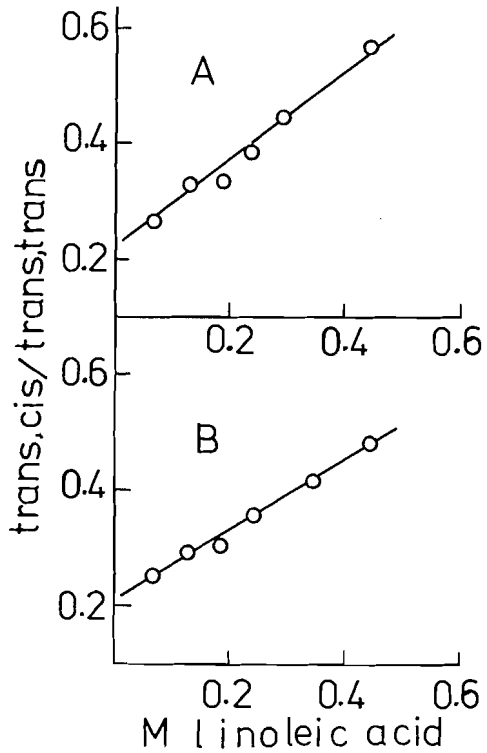

FIG. 3. Concentration dependence of product ratios (*trans,cis/trans,trans*) of hydroxy fatty esters derived from autoxidation of linoleic acid in 0.50 *M* SDS (pH 7.0) at 30°C. Values taken from Table 2. *A*, Initiation by DBHN (1.03×10^{-5} mol); *B*, initiation by ABAP (2.67×10^{-5} mol).

dependence of the rate of oxygen uptake on micellar linoleic acid concentration was measured at five concentrations over the range 0.0630 *M* to 0.459 *M* and the dependence of the rate of O_2 consumption with variation in R_i was measured by the application of five different lamp intensities at each linoleic acid concentration. The results of these experiments are summarized in Table 4.

The absolute rate constants for chain propagation, k_p, and termination, $2k_t$, were measured by the rotating sector method (40, 41).

The separation of the absolute rate constants for chain propagation and termination involves measurement of the lifetime, τ, of the reaction chain. The chain lifetime is defined by the equation

$$[2] \quad \tau = (2k_tR_i)^{1/2}$$

where R_i is the rate of photoinitiation. A sectored disc is placed in the light path between the lamp and the reaction vessel and the rate of oxygen consumption is measured at various rotation speeds of the disc. If the ratio of dark to light periods is r, the rate at fast speeds is

$$[3] \quad R_f = K[I/(r + 1)]^{1/2}$$

where $KI^{1/2}$ is the oxidation rate at a steady light intensity, I. At slow rotation speeds, the rate is

$$[4] \quad R_s = KI^{1/2}/(r + 1)$$

At intermediate sector rotation speeds, the reaction rate has a complicated dependence on the duration of the light flash, λ, and the lifetime of the reaction chain. The value of λ is

SCHEME 1

determined by the rotation speed of the sector

$$[5] \quad \lambda = \frac{r + 1}{\text{slow speed (rpm)}}$$

Under steady illumination, the rate of oxygen consumption, R_0, can be represented by the classical rate law:

$$[1a] \quad R_0 = k_p[\text{RH}]\left(\frac{R_i}{2k_t}\right)^{1/2}$$

Burnett and Melville (40) have given values of the ratio R_λ/R_0 in terms of λ/τ for various values of r. As a result, $2k_t$ can be readily obtained from eq. [2] once the R_i has been measured. Substitution of R_i and $2k_t$ into eq. [1*a*] yields k_p. To improve the accuracy of the measurements, we used the modification (41) of finding a particular λ by varying the sector speed to obtain a rate midway between R_f and R_s and then repeatedly measured R_0 and R_λ.

In the above discussion it has been assumed that chain termination is a bimolecular process. First order chain termination, which can be represented as

$$[6] \quad \text{ROO}\cdot \rightarrow \text{inactive products}$$

causes a reduction in the value of R_f/R_0. The measured ratio enables determination of a quantity, γ, by means of the following expression:

$$[7] \quad \frac{R_f}{R_0} = \frac{\{(\gamma^2 r + 1)/(r + 1)\}^{1/2}\gamma}{1 - \gamma}$$

TABLE 2. Product ratio distribution for autoxidation of linoleic acid in 0.50 *M* SDS (pH 7.0) at 30°C; initiated by azo intiators

[c]One experiment.

where γ is defined as $k_x/(k_x^2 + 8k_tR_i)^{1/2}$. For a particular γ, the value of R_λ/R_0 yields a second quantity m, defined as

$$[8] \quad m = \frac{\lambda(k_x^2 + 8k_tR_i)^{1/2}}{2}$$

The rate constant for first order termination, k_x is readily calculated from γ and m:

$$[9] \quad k_x = \frac{2\gamma m}{\lambda}$$

The rate constants for bimolecular termination and chain propagation are then obtained from the following expressions:

$$[10] \quad 2k_t = \frac{m^2}{\lambda^2 R_i} - \frac{k_x^2}{4R_i}$$

and

[b]The transmittance was controlled by inserting neutral density filters into the light path.

$$[11] \quad k_p = \frac{R_0 2(2k_t)\gamma}{[RH]k_x(1 - \gamma)}$$

The absolute rate constants were determined in two organic solvents, acetonitrile and *tert*-butyl alcohol, by photoinitiation with benzophenone as well as the more conventional azobiscyclohexylnitrile (ACHN) (41). For each solvent, reasonably good agreement was obtained by the two methods, as illustrated in Table 5.

The rotating sector method was applied to a series of autoxidations of linoleic acid in aqueous SDS micelles with benzophenone as sensitizer. The absolute rate constants so determined are reported in Table 6.

Equation [12] is the rate equation for inhibited autoxidations,

$$[12] \quad \frac{-d[O_2]}{dt} = \frac{k_p[RH]R_i}{nk_{inh}[ArOH]}$$

where the stoichiometric factor $n = 2$ for the phenolic antioxidant (ArOH) used. Since the k_p is now known for our conditions we were able to determine inhibitor rate constants, k_{inh}, for the termination of peroxyls via the process,

$$ROO\cdot + ArOH \rightarrow ROOH + ArO\cdot$$

in homogeneous solution and in SDS micelles. Some typical value are shown in Table 7.

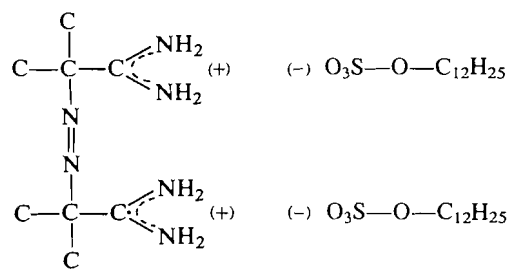
Discussion

1. Partitioning of substrates, initiators and antioxidants between the aqueous and micellar phases

The partition coefficient determinations (Table 1) reveal that the diffusion coefficients for anthracene and phenanthrene approach a limiting value, indicative of localization within micelles. As such, these highly hydrophobic compounds are said to act as "tracers" of the micellar diffusion and the average value of their diffusion coefficients is assigned to D_m (28). From the table it can also be seen that linoleic acid is completely (within experimental error) in the micellar phase. The diffusion coefficient for methyl linoleate in 0.10 M SDS is similar to that for the "tracer compounds". This and the fact that the ester has such poor solubility in the buffer used (precluding measurement of D) lead to the conclusion that both linoleates partition entirely into the micellar phase. Subsequent calculations assume this to be the case.

The partitioning of the initiators employed in this study provides some very interesting results. Benzophenone resides in the micellar phase ($f = 0.96$) while its water-soluble derivative BP^- partitions considerably ($f = 0.37$) into the micelles of 0.10 M SDS. It has been suggested earlier that BP^- was "essentially" in an aqueous environment in the presence of 0.2 M SDS from spectroscopic properties (42). It is our conclusion that the determination of diffusion coefficients provides a more sensitive quantitative measurement of partitioning than do spectroscopic methods.

The behaviour of the azo initiator, ABAP, appears to be very surprising. It is readily soluble in water (aqueous solutions of 1 M or more are easily prepared), but it partitions to the extent of 91% into 0.1 M SDS. We speculate that this may be due to electrostatic interactions between the positive amidino groups of ABAP and the anionic surface of the micelle, such as shown below



This model implies that ABAP *may* be associated with the surface of the micelles. Such electrostatic interactions could account for the unusual observation that ABAP decomposes three times *less rapidly* in 0.50 M SDS than in water or in liposome dispersions (43). We suggest that these dipolar

[a]Initial linoleic acid concentration was 0.420 *M* in both TBA and CH_3CN and 0.238 *M* (in the micellar phase) for 0.50 *M* SDS.

[b]Inhibition rate constants were determined for at least four points along each induction period where the chain length was in the range 2–9. The variation is shown for each induction period. The method of calculation of ref. 29 was used.

[c]The calculation for k_{inh} assumes that α-T, PMHC, and Trolox partition completely into the micellar phase in 0.50 *M* SDS (see text).

interactions act to inhibit cleavage of the molecule and reduce the rate of nitrogen liberation.

Trolox is an effective antioxidant in either organic solvents (29) or aqueous systems (43, 44). As shown in Table 1, it partitions significantly (19%)[2] into the micellar phase and its versatility as an antioxidant is undoubtedly due to this partitioning action between the two phases.

2. Product studies with azo and benzophenone initiators. The mechanism for benzophenone-initiated oxidations

The photosensitized reaction of oxygen with an organic substrate may be initiated by hydrogen abstraction from the substrate by the sensitizer triplet followed by free radical autoxidation (Type I mechanism). Alternately, the Type II process involves initial energy transfer from the sensitizer to form singlet oxygen which can react with the hydrogen donor in a variety of ways (such as the ene reaction with olefins), usually distinct from the free radical route. These two reaction types have been studied extensively and reviewed (2, 3). Product studies provide one method of distinguishing Type I from Type II (*vide supra*).

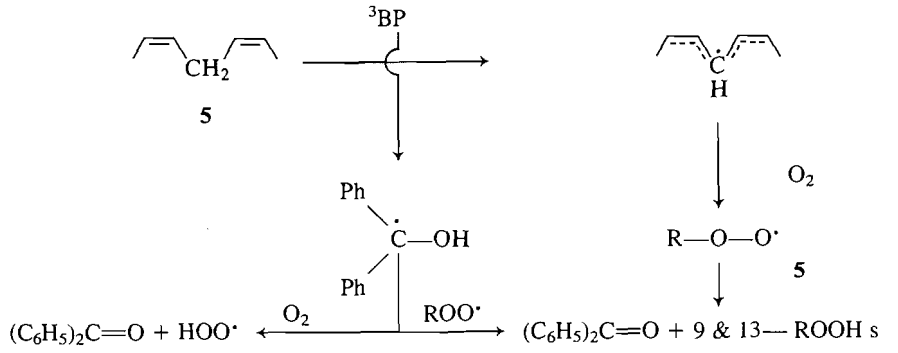
In Fig. 3 *A* and *B* are shown plots of the dependence of the ratio of *cis,trans*-substituted hydroperoxides (**1** + **2**) to *trans,trans* products (**3** + **4**) as a function of micellar linoleic acid concentration for thermal initiation by DBHN and ABAP, respectively. Good linear correlations were obtained with both lipid-soluble DBHN and water-soluble ABAP. Since ABAP is associated with the micellar phase, it most likely forms initiating peroxyls in (or near) the same region as DBHN.

Plots of *cis,trans/trans,trans* product ratios for oxidations photoinitiated by benzophenone and BP^- are shown in Fig. 4 *A* and *B*, respectively. These plots show that the ratio of kinetic (*c,t*) to thermodynamic (*t,t*) products shows a linear dependence on linoleate concentration remarkably similar to that found for the thermal azo initiators. These results are entirely consistent with the free radical autoxidation (Type I) mechanism for linoleate oxidations in micellar SDS whether thermally initiated (by DBHN or ABAP) or photoinitiated (by BP or BP^-).

At least two important factors operate to account for the occurrence of Type I mechanism in our system. (*1*) One important competition which controls whether initiation occurs by Type I (radical chain) or Type II (singlet O_2) is between substrate and oxygen for the triplet sensitizer (2). Allylic hydrogens are known to be effective quenchers of benzophenone triplets by hydrogen abstraction (45) and the doubly allylic hydrogens in linoleate are readily abstracted. (2) While singlet oxygen is known to form in micelles by various photosensitization methods (10–22) and its lifetime is "longer" (53 μs, ref. 17) in SDS, peroxyl radicals have lifetimes orders of magnitude longer. Furthermore, termination of linoleate peroxyls is very much retarded in the presence of SDS micelles (*vide infra*). As a result of these factors, $^1O_2$ quenchers such as azide and DPBF had no effect on our reactions and the peroxyl radicals carried a chain reaction as proposed in Scheme 2.

The recycling of benzophenone as initiator is an interesting characteristic of our system. This could occur via some chain

[2]This higher partition fraction over that reported (2%) is probably related to the higher SDS concentration used here compared to only 0.0150 *M* used earlier (44).



SCHEME 2

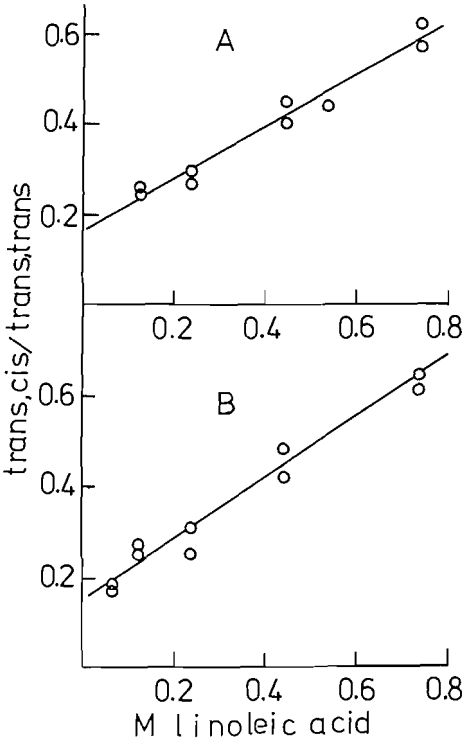


FIG. 4. Concentration dependence of product ratios (*trans,cis/trans,trans*) of hydroxy fatty esters derived from autoxidation of linoleic acid in 0.50 *M* SDS (pH 7.0) at 30°C. Values taken from Table 3. *A*, Photoinitiated by benzophenone (5.48×10^{-7} mol); *B*, photoinitiated by BP$^-$ (5.49×10^{-7} mol).

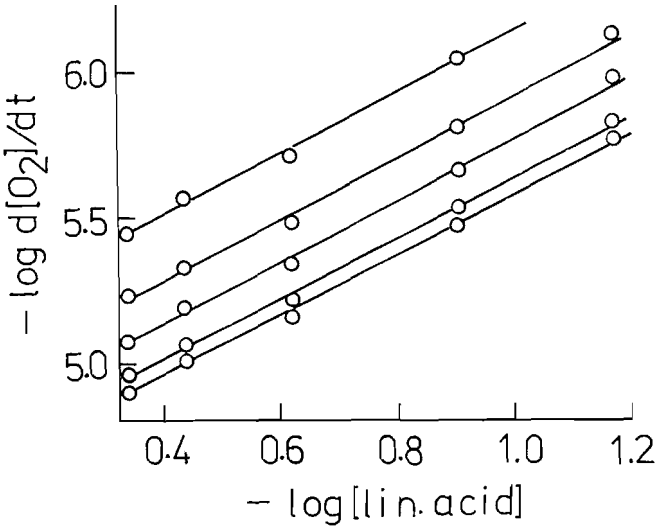

FIG. 5. Kinetic order plots for autoxidation of linoleic acid in 0.50 *M* SDS (pH 7.0) at 30°C; photoinitiated by benzophenone (1.13×10^{-2} *M*). Rate of oxygen consumption as a function of substrate concentration at five different light intensities. Values taken from Table 4.

termination by H-atom transfer from the ketyl radical to peroxyl or possibly to oxygen, a known reaction in homogeneous solution (46).

3. Kinetics for benzophenone-initiated autoxidation. Medium effects on rate constants of autoxidation and inhibition

The benzophenone-sensitized autoxidation has very significant advantages over the usual azo initiators for these quantitative measurements. Evolution of nitrogen and consumption of oxygen from the latter require large corrections to the measured rates in microenvironments (47), and such corrections are difficult to make for photo-decomposition of azo initiators since the necessary rate constants are unknown. In addition, azo initiators give thermal (dark) rates of autoxidation which can cause large errors in determinations of rate constants. These limitations do not occur in benzophenone-sensitized autoxidations; there is no dark rate and no gas is absorbed/produced when BP is irradiated in oxygenated 0.50 *M* SDS.

Log plots of the oxygen uptake for benzophenone-initiated reactions in SDS micelles are shown in Fig. 5 over a 7.3-fold change in linoleate concentration and for the five different light intensities used. Excellent linear correlations were obtained in all cases and the order in linoleate is essentially unity (1.02–1.06). Plots of the kinetic order in light transmittance shown in Fig. 6 for these conditions also exhibit linear correlations. The reaction order with respect to the rate of free radical chain initiation (R_i) obtained from the slopes vary somewhat, 0.627 to 0.540 with linoleate concentration. This is attributed to some first order chain termination[3] of peroxyls accompanying the usual bimolecular termination at low concentration. Subsequent kinetic measurements of rate constants were made at intermediate concentration (0.238 *M*) where the classical rate law for autoxidation (eq. [1]) is followed.[4]

The absolute rate constants for chain propagation, k_p, and termination, $2k_t$, for autoxidation of linoleate in two polar solvents, *tert*-butyl alcohol and acetonitrile (Table 5), provide

[3]Others (41) have postulated first order termination of peroxyls but the detailed mechanism is not known.

[4]The probability of simultaneously generating two radicals in the micelle is nil. In these and other related free radical reactions in SDS micelles (27, 44, 51), the fact that bimolecular termination occurs also implies that the radicals in question (e.g. linoleoylperoxyl) diffuse rapidly between micelles to allow radical recombination.

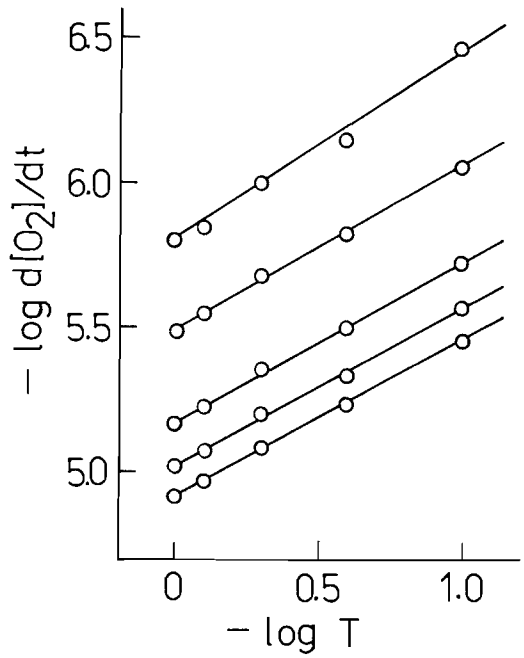

FIG. 6. Kinetic order plots for autoxidation of linoleic acid in 0.50 *M* SDS (pH 7.0) at 30°C; photoinitiated by benzophenone (1.13×10^{-2} *M*). Rate of oxygen consumption as a function of light intensity at five substrate concentrations. Values taken from Table 4.

basic data for comparison with the values obtained in micelles. As observed earlier by Howard and Ingold (48), the effect of an increase in solvent polarity is mainly on the rate of chain *termination*, which is decreased because the solvent stabilized polar peroxyl radicals (48) are destroyed in this step. Our finding that the $2k_t$ is lower in CH_3CN ($4.16 \pm 0.30 \times 10^6$ M^{-1} s^{-1}) than in *tert*-butyl alcohol ($17.2 \pm 2.7 \times 10^6$ M^{-1} s^{-1}) is consistent with the effect of the more polar solvent to decrease the termination rate.

Kinetic data for benzophenone-initiated autoxidation of linoleate (Table 6) indicate that the substrate oxidizability obtained by this method ($4.42 \pm 0.46 \times 10^{-2}$ $M^{-1/2}$ $s^{-1/2}$) is the same as that obtained earlier (4.48×10^{-2} $M^{-1/2}$ $s^{-1/2}$) using a thermal azo initiator in 0.50 *M* SDS (27).

Significant differences are shown in the absolute rate constants in micelles compared to those in organic solvents. The chain propagating rate constant in SDS (36.2 ± 4.8 M^{-1} s^{-1}) is one-half that found in acetonitrile. The effect on the $2k_t$ is more dramatic; the value in 0.50 *M* SDS ($2k_t = 3.52 \pm 0.90 \times 10^5$ M^{-1} s^{-1}) being reduced by at least an order of magnitude. We suggest that these effects on the rate constants are due, at least in part, to the polarity of peroxyl radicals.[5] Once formed, the radical centre would rapidly move to the micelle-aqueous interface where the polar environment of the aqueous buffer would substantially lower the $2k_t$ by strongly solvating the radicals by polar and hydrogen bonding interactions (50),[6] in this case of the resonance-stabilized peroxyls:

$$R{-}\ddot{O}{-}\ddot{O}\cdot \Longleftrightarrow R{-}\overset{(+)}{\dot{O}}{-}\overset{(-)}{\ddot{O}}\!: \quad \cdots \quad H{-}OH$$

Such solvation effects would also account for the lower k_p observed since the reactivity of the peroxyls would thereby be suppressed.

[5]The dipole moment of a peroxyl radical was found to be 2.4 D (49).

[6]In addition, the fact that a radical must exit a micelle in order to terminate with one in another micelle can be a controlling factor (51).

Values for inhibitor rate constants (k_{inh}) are of interest because they are an indication of the antioxidant activity. Accurate determinations are reported for various phenolic antioxidants in chlorobenzene solution (29). However, other reported values for k_{inh} in different solvents (52) and in micelles (44) can be quite unreliable because they are based on values of k_p measured in solution under different conditions. Evaluation of k_{inh} in microenvironments such as micelles and bilayers are of particular interest because they have implications for the effectiveness of antioxidants as biomembrane protectors. It is reported that the antioxidant properties of α-tocopherol and PMHC are similar within micelles and liposomes but that the phytyl side chain of α-tocopherol suppresses its transfer between liposomes (53).

Our values of k_{inh} reported in Table 7 are corrected for the k_p applicable for the medium in which the determination was made. Rather large errors are associated with these numbers (see Table 7), but they are sufficiently reliable to determine the effect of a micellar environment compared to a polar organic solvent, which is our main objective. To a certain extent, it is also possible to compare the activities of the three antioxidants in the same medium. The k_{inh} for α-tocopherol is retarded by a factor of 14 on changing from solution ($k_{inh} = 23 \pm 1.2 \times 10^4$ M^{-1} s^{-1} in *tert*-butyl alcohol) to micelles ($k_{inh} = 1.69 \pm 1.0 \times 10^4$ M^{-1} s^{-1}). This supports the proposal that diffusion of this lipophilic phenol between micelles is a limiting factor in antioxidant activity (44). The overall result of the micelles is a change in the relative activities of the three antioxidants. In 0.50 *M* SDS, PMHC and Trolox are now approximately twice as active as E; whereas in homogeneous alcohol solution, E and PMHC have the same activity, within experimental error, followed by Trolox. The absence of a definite induction period when α-tocopherol is used with methyl linoleate dispersed in SDS micelles (Fig. 2) can now be understood in terms of the reduced mobility of this inhibitor between micelles combined with a lack of homogeneity in such a system. It was suggested that methyl linoleate may "pool" (54) or form a heterogeneous microemulsion (55) in detergents (56) so that exchange of E between droplets is limiting. This demonstrates the importance of selecting the model system for quantitative study with considerable care.

Our actual values of k_{inh} are significantly different from values known in less polar solvents (e.g. α-tocopherol, $k_{inh} = 320 \times 10^4$ M^{-1} s^{-1} in chlorobenzene (29)). We suggest that a polar protic solvent (TBA) reduces the k_{inh} substantially by solvation of the polar peroxyl radicals. Trolox shows a further reduction in k_{inh} on changing from TBA ($k_{inh} = 14.7 \pm 1.3 \times 10^4$ M^{-1} s^{-1}) to more polar acetonitrile ($k_{inh} = 10.6 \pm 1.3 \times 10^4$ M^{-1} s^{-1}) most probably due to solvent effects on the peroxyl radical reactivity. The overall drop in activity of the three antioxidants observed in aqueous SDS micelles is attributed to a combination of strong hydrogen bonding aqueous solvent effects on the polar peroxyl radicals, and the effect water may have of tying up the electron lone pairs on the oxygen *para* to the phenolic hydroxyl group of the antioxidants. This latter hydrogen bonding would reduce the reactivity of the phenolic hydrogen by damping the stereoelectronic effect (29) exerted by the lone pairs on the para oxygen.

Experimental

1. Distribution coefficients

(1) Materials and preparation

The buffer used for diffusion coefficient measurements was 0.005 *M*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

each of NaH_2PO_4 and Na_2HPO_4 (pH 7.0) in glass-distilled water containing 1×10^{-5} *M* EDTA. Stock 0.10 *M* SDS was prepared in this buffer. Anthracene (Eastman-Kodak) and phenanthrene (Fisher) were each recrystallized from ethanol.

Dilute solutions (generally less than 10^{-3} *M*) of the various compounds were prepared in both buffer and 0.10 *M* SDS by vortex-stirring and sonication (except DBHN and ABAP solutions). The solution concentration was such that it gave an absorbance between 0.5 and 1.5 at λ_{max} as measured in a 1.0 cm cell with a Varian Cary 219 spectrophotometer. Because of poor solubility, methyl linoleate was dissolved in 0.30 *M* SDS prior to determination of its diffusion coefficient in 0.10 *M* SDS. Also, the poor water solubility of linoleic acid necessitated the addition of sufficient aqueous NaOH to increase the pH of the injected buffer sample to 8.5.

(2) Apparatus

The Taylor diffusion apparatus used in this study is based on the design of Burkey *et al.* (28). Using a Spectra Physics SP8000 HPLC pump, the solvent was pumped at constant flow (0.2 mL/min) through 10 m of stainless steel tubing (0.03 in. i.d., Chromatographic Specialities) which was enclosed in the HPLC oven and thermostatted at 25 ± 0.1°C. A Nupro CA relief valve was placed in-line between the pressure transducer and injector of the HPLC to provide adequate back pressure (800–1200 psi) for effective flow referencing while not interfering with solute diffusion. The sample was loaded into a 10 μL loop and injected into the diffusion apparatus. Solute dispersion was detected at (or near) λ_{max} with a Schoeffel SF 770 variable wavelength detector and recorded on a Varian CDS 401 data system.

2. Autoxidations

(1) Materials and preparations

(a) Phosphate buffer

Solutions were prepared in 0.05 *M* of each of NaH_2PO_4 and Na_2HPO_4 (pH 7.0) in glass distilled water containing 1×10^{-4} *M* EDTA. Prior to use, the buffer was passed through a column of Chelex 100 (50–100 mesh) (BioRad) to remove traces of heavy metal ions (57).

(b) Solvents

Hexane, methanol, and acetonitrile were of HPLC grade and purchased from Caledon or Anachemia. *tert*-Butyl alcohol was purified by distillation.

(c) Sodium dodecyl sulfate

Electrophoresis purity SDS was purchased from BioRad. Stock solutions of 0.50 *M* SDS were prepared in the 0.10 *M* phosphate buffer (pH 7.0) described above.

(d) Linoleic acid, methyl linoleate

Linoleic acid and methyl linoleate were purchased from Nu-Chek Prep, Inc. (>99%). The lipids were found to be free of hydroperoxide by periodic TLC analysis on silica gel with *N,N*-dimethyl-*p*-phenylenediamine spray.

(e) Initiators

Di-*tert*-butylhyponitrite was synthesized and stock solutions were prepared in 0.50 *M* SDS as reported earlier (54). Azobis(2-amidinopropane·HCl) and azobiscyclohexylnitrile were obtained from Polysciences, Inc. and stored at −30°C. Benzophenone (Fisher) was recrystallized from pentane, while 4-sulphomethylbenzophenone, sodium salt (a gift from Dr. J. C. Scaiano) was used as received. Stock solutions of ABAP were prepared in phosphate buffer. BP and BP^- were dissolved in 0.50 *M* SDS by vortex-stirring and sonication. For autoxidations carried out in homogeneous solution, benzophenone and ACHN were readily dissolved in either *t*-butanol or CH_3CN. All initiator solutions were stored at 4°C.

(f) Inhibitors

For micellar autoxidations, the following procedure was used: Stock solutions of α-tocopherol (Eastman-Kodak) were prepared in 0.50 *M* SDS as previously described (27) while solid PMHC (a gift from Dr. G. W. Burton) was readily dissolved in SDS. Standard solutions of Trolox, a gift from Hoffman-LaRoche, were prepared in argon-degassed phosphate buffer. Stock solutions of PMHC, α-T and Trolox were also prepared in *t*-butanol or acetonitrile, as required. All inhibitor solutions were stored under argon and at 4°C.

(g) Quenchers

Solutions of 1,3-diphenylisobenzofuran (Aldrich) were prepared in 0.5 *M* SDS by vortex-stirring and sonication. Sodium azide and 1,4-diazabicyclo[2.2.2]octane (DABCO, Aldrich, 97%) were dissolved in argon-degassed buffer. All quencher solutions were stored refrigerated and under argon.

(2) Autoxidation procedure

Autoxidations were carried out at 30°C and 760 mm Hg of O_2 using a sensitive automatic recording gas absorption apparatus similar to that described (47). For DBHN-initiated autoxidations, a 2.00 mL aliquot of DBHN in 0.50 *M* SDS was added to a calibrated reaction cell, followed by the appropriate amount of linoleic acid and isomolar NaOH. The cell and contents were then attached to the gas absorption apparatus and the rate of O_2 consumption measured. For the ABAP-initiated autoxidations, typically 100 μL of 0.4 *M* ABAP solution in buffer was added to 2.00 mL of 0.50 *M* SDS in a calibrated cell. The cell and contents were attached to the apparatus and allowed to shake for up to 1 h (before the addition of linoleic acid and NaOH) to permit solubilization of the ABAP.

In a typical photoinitiated run, a 2.00 mL aliquot of benzophenone in the appropriate solvent (or BP^- in 0.50 *M* SDS) was added to a calibrated reaction cell followed by the desired amount of linoleic acid (and NaOH for micellar autoxidations). The cell and contents were then attached to the apparatus and shaken to thermally equilibrate. The reaction was initiated by irradiation through Pyrex with a 200 W super pressure mercury lamp, the intensity of which was monitored using fiber optics sampling of the light beam and a phototube detector. Various additives were added to the reaction mixtures from precision syringes. The extent of oxidation was generally less than 10%.

(3) Absolute rate constants

Two 45° sectors were cut from each of two discs of blackened metal with dimensions such that $r = 3$. The discs were placed back-to-back between the light source and the gas absorption apparatus equipped with a shutter. The disc nearest the lamp was driven by an electric motor through a series of gears which could be changed to provide nine different rotation speeds from 0.286 to 4.20 rpm. The disc nearer the oxidation apparatus was driven through gears which enabled rotation speeds of 700 to 2400 rpm.

The reaction order with respect to the rate of photoinitiation was determined by measuring the rate of oxygen consumption when the reaction mixture was exposed to irradiation of different intensities. A series of neutral density filters of known transmittance (Ealing Scientific) was placed in the light path, the shutter opened and the rate of oxidation measured on a strip chart recorder.

The parameter γ was determined by measuring R_f/R_0. This ratio is measured three times using the rates obtained at 2400 rpm (R_f) and steady illumination (R_0).

The next step involved a preliminary measurement of R_λ/R_0 for several of the possible slow sector speeds, λ. From ref. 40, it can be shown that for a sector with $r = 3$, the rotating sector method is most accurate when $m = 3.70$. Using the sector rotation speed which produces m nearest to 3.70, the ratio R_λ/R_0 was determined twice by alternately measuring R_λ and R_0. The R_i was then measured by the addition of an aliquot of Trolox solution (in the appropriate solvent). This process was repeated until at least four values of R_λ/R_0 (i.e. m) and two values of R_i have been determined. From this the absolute rate constants are then calculated according to eqs. [9]–[11].

HPLC analyses

(1) Linoleate autoxidation products

After 5% oxidation (as measured by the consumption of O_2), 5 mL of 10 m*M* PPh_3 was added to a 500 μL aliquot of the reaction mixture followed by the addition of 50 mL of methanol/water (50/50). The aqueous solution was extracted twice with diethyl ether; 35 and 15 mL. The combined extracts were dried over Na_2SO_4 and then treated with excess CH_2N_2 in ether at 0°C. The solution was gently warmed to room

temperature to remove excess diazomethane. Samples were then stored at −30°C until required for analysis.

Immediately prior to analysis by HPLC, the solvent was removed at reduced pressure, followed by pumping at <0.25 mm Hg for at least 30 min. The residue was brought up in 2 mL of HPLC solvent: hexane/2-propanol/acetone (992/4/4). Brief centrifugation was usually necessary to remove excess solid PPh_3. Separation of the four methyl hydroxylinoleates was achieved using a Waters 5100 HPLC pump fitted with a 30 cm × 10 μm Apex silica column (Jones Chromatography). With a flow rate of 1.6 mL/min, the products were detected by monitoring eluent absorption at 234 nm with a Schoeffel SF 770 variable wavelength detector. Identification of the four compounds was achieved by cross-comparison of an autoxidation product mixture from our lab with a reference mixture obtained and analyzed (39) under similar conditions in the laboratories of Dr. N. A. Porter of Duke University.

Relative amounts of the four hydroxylinoleates were determined by correcting the peak areas, as reported by a Varian CDS 401 data system, for the appropriate molar absorptivity (33): 13-*c*,*t* (λ_{max} 236, ϵ = 27 200); 13-*t*,*t* (λ_{max} 233 nm, ϵ = 30 500); 9-*c*,*t* (λ_{max} 236 nm, ϵ = 28 300); 9-*t*,*t* (λ_{max} 233 nm, ϵ = 31 600).

(2) Benzophenone product analysis

A 100 μL aliquot was removed from the reaction mixture and added to 1 mL of methanol/water (50/50). After vortex-stirring for 15 s, the aqueous solution was extracted twice with 1 mL of HPLC solvent: hexane/2-propanol/acetone (992/4/4). Following brief centrifugation, the organic layers were removed. To 500 μL of the combined extracts was added 25 μL of 2.82×10^{-3} *M* *p*-methoxyacetophenone (the internal standard) in hexane. The sample was eluted using the Waters 5100 pump and the Apex silica column. To aid in separation, the solvent was pumped at 0.8 mL/min for 10 min, then increased to 1.6 mL/min for the remainder of the analysis. The eluent was monitored at 225 nm with the Schoeffel SF 770 detector.

(3) α-Tocopherol analysis

A 250 μL aliquot of the reaction mixture (initially 3.94×10^{-5} *M* α-T) was removed from the reaction vessel and added to 500 μL of absolute ethanol in a small test tube. After vortex-stirring for 15 s, the solution was extracted twice with 250 μL of hexane. Brief centrifugation was necessary to aid separation of the two layers. To 250 μL of the combined hexane extracts was added 10 μL of the internal standard solution, 9.28×10^{-4} *M* PMHC in hexane. Analysis was performed by injecting 50 μL of the resulting solution onto the Apex silica column with the solvent; hexane/2-propanol (99/1) flowing at 0.9 mL/min. The column effluents were monitored at 220 nm with the Schoeffel SF 770.

Received May 12, 1987

LAWRENCE ROSS COATES BARCLAY, KIMBERLY ANN BASKIN, DAVID KONG, and STEVEN JEFFREY LOCKE. Can. J. Chem. **65**, 2541 (1987).

Kinetics of autoxidation of bilayer mixtures of oxidizable dilinoleoylphosphatidylcholine (DLPC) with saturated phospholipids as solvents (dimyristoyl-, DMPC, and dipalmitoyl-phosphatidylcholine, DPPC) follow the classical rate law of autoxidation: $-d[O_2]/dt = k_p/2k_t^{1/2}[RH]R_i^{1/2}$. The kinetic order in substrate [RH] was found to be unity for peroxidation initiated by a lipid-soluble initiator, azobis-2,4-dimethylvaleronitrile (ADVN), and by the water-soluble azobis(2-amidinopropane·HCl) (ABAP). The kinetic order in rate of chain initiation, R_i, was found to be one-half for both initiation by ADVN, photochemically decomposed, and by ABAP. The oxidizability of unilamellar DLPC liposomes ($k_p/2k_t^{1/2} = 0.232\ M^{-1/2}\ s^{-1/2}$) is twice that of multilamellar DLPC ($k_p/2k_t^{1/2} = 0.116\ M^{-1/2}\ s^{-1/2}$). Analysis of the hydroperoxides formed during ABAP-initiated autoxidations of mixed DLPC + DPPC liposomes showed a linear trend between the ratio of *cis,trans* to *trans,*trans geometrical isomeric hydroperoxides and [DLPC], consistent with the peroxidation mechanism proposed for homogeneous systems. ^{31}P nmr spectra of mixed bilayers were used to distinguish between heterogeneous and homogeneous mixtures of DLPC + DPPC. Such spectra taken at various stages of oxidation indicate that the bilayer structure of DLPC is preserved at least to the 10% extent of oxidation used in kinetic studies. At much higher oxidative conversion, the spectra indicate changes in lamellar structures.

LAWRENCE ROSS COATES BARCLAY, KIMBERLY ANN BASKIN, DAVID KONG et STEVEN JEFFREY LOCKE. Can. J. Chem. **65**, 2541 (1987).

La cinétique de l'auto-oxydation de mélanges en double couches de dilinoléoylphosphatidylcholine (DLPC) oxydables avec des phospholipides saturés comme solvants (dimyristoyl-, DMPC et dipalmitoylphosphatidylcholine, DPPC) répond à une loi de vitesse classique pour une auto-oxydation : $-d[O_2]/dt = k_p/2k_t^{1/2[RH]}R_i^{1/2}$. On a trouvé que l'ordre en substrat [RH] est égal à un pour la peroxydation initiée par un initiateur lipo-soluble, l'azo bis(diméthyl-2,4 valéronitrile) (ADVN) et par l'initiateur soluble dans l'eau, azo bis(amidino-2 propane·HCl) (ABAP). On a trouvé que l'ordre en initiation de chaînes, R_i, est égal à une demi pour les initiations tant par l'ADVN décomposé d'une façon photochimique que par l'ABAP. La facilité d'oxyder les liposomes DLPC unilamellaires ($k_p/2k_t^{1/2} = 0{,}232\ M^{-1/2}\ s^{-1/2}$) est deux fois plus grande que celle du DLPC multilamellaire ($k_p/2k_t^{1/2} = 0{,}116\ M^{-1/2}\ s^{-1/2}$). Une analyse des hydroperoxydes qui se forment au cours des auto-oxydations initiées par l'ABAP de mélanges de liposomes de DLPC + DPPC a permis de montrer qu'il existe une tendance linéaire entre le rapport des isomères géométriques *cis,trans* et *trans,trans* des hydroperoxydes et la [DLPC]; ce résultat est en accord avec le mécanisme de peroxydation proposé pour des systèmes homogènes. On a utilisé les spectres rmn du ^{31}P des doubles couches pour établir une distinction entre les mélanges homogènes et hétérogènes du DLPC + DPPC. De tels spectres, déterminés à divers stages de l'oxydation, indiquent que la structure en double couche du DLPC est maintenue au moins jusqu'au 10% d'oxydation utilisé pour les études cinétiques. A des taux d'oxydation plus élevés, les spectres indiquent qu'il s'est produit des changements dans les structures lamellaires.

[Traduit par la revue]

Introduction

Autoxidation of unsaturated biomembrane lipids disrupts important structural and functional properties of membranes and is associated with important pathological events (1, 2) including the action of foreign toxic substances (3). Several groups have recently developed an increased interest in the *quantitative* study of autoxidation of biologically significant systems such as phospholipids in bilayers and lipids in micelles (4–31).

Most of the attention of these groups has been centred on the mechanism and activity of antioxidants (9–22), the dynamics of free radical initiation (23–26), and elucidation of the autoxidation chain mechanism from studies of trends in formation of the hydroperoxide products (27–31). We have shown that quantitative kinetic studies can be carried out in bilayers and micelles using both lipid-soluble and water-soluble initiators and inhibitors (7). This has facilitated applications to quantitative studies on natural biological fluids (32, 33). It would appear from our initial studies in bilayers (4, 5) that the kinetics of autoxidation in this phase follow the same classical rate law well known for autoxidation of organic substrates in homogeneous solution (34–37); namely, that the rate of oxygen uptake is first order in concentration of substrate (RH) and one-half order in the rate of chain initiation (R_i) as indicated in eq. [1]:

$$[1] \quad \frac{-d[O_2]}{dt} = \frac{k_p[RH]R_i^{1/2}}{2k_t^{1/2}}$$

For systems which obey eq. [1], the susceptibility of substrates to undergo autoxidation, known as *oxidizability* $k_p/(2k_t)^{1/2}$, follows from eq. [2]:

$$[2] \quad \frac{k_p}{2k_t^{1/2}} = \frac{-d[O_2]/dt}{[RH]R_i^{1/2}}$$

We have recently demonstrated that the autoxidation of linoleic acid in sodium dodecyl sulfate micelles obeys eq. [1] (8).

While it seems to be assumed that the autoxidation of unsaturated lipids in membranes follows the same classical rate law, i.e. eq. [1] (38), there are very significant deficiencies in our basic knowledge of the kinetics of membrane autoxidation. For example, the kinetic orders with respect to substrate and the rate of chain initiation have not been adequately determined in

bilayers. Our earlier studies (4, 5) did show that the calculated oxidizability of egg lecithin bilayers, thermally initiated by di-*tert*-butylhyponitrite (DBHN) was "constant" for different amounts of initiator in the bilayer. On the other hand, it is also important to determine the kinetic order in substrate, RH, by employing bilayers with varying amounts of oxidizable and inert phosphatidylcholine. Obviously, *the concentration of oxidizable lipid in a single pure PPC is a fixed value*, independent of the amount used. Therefore, it is not sufficient to simply determine the effect on the rate of oxidation by varying the total amount of the sample PPC in the "aqueous emulsion" as reported (39) since this does not really vary the substrate concentration in the bilayer. Furthermore, mixtures of lipids provide a better model for a biological membrane than does a single lecithin (40).

Although the water-soluble initiator azobis(2-amidinopropane·hydrochloride) (ABAP) has been very useful in micelle and bilayer autoxidations (7, 41), both kinetic and PPC product studies are lacking for ABAP-initiated autoxidations. In order to evaluate important kinetic properties of bilayers, such as the oxidizability, a complete verification of eq. [1] is required for both water-soluble and lipid-soluble initiators. With such an objective in mind, we now report on a comprehensive quantitative investigation of bilayer autoxidation; including the following studies. (*1*) The kinetic order in oxidizable substrate, [RH], is determined by using a mixed bilayer system composed of variable amounts of non-oxidizable (saturated) dipalmitoylphosphatidylcholine, DPPC, or dimyristoylphosphatidylcholine, DMPC, mixed with the oxidizable (unsaturated) dilinoleoylphosphatidylcholine, DLPC. The effect of variation of [RH] on the rate of oxygen uptake is determined by changing the relative amounts of the two lipids in the mixture. This study is completed for a lipid-soluble initiator azobis-2,4-dimethylvaleronitrile (ADVN) and the water-soluble ABAP. (*2*) The kinetic order in the rate of chain initiation is determined for initiation in the aqueous phase by varying [ABAP] for neat DLPC and for mixtures of DLPC and DPPC. The kinetic order with respect to the R_i for DLPC autoxidations initiated by photochemically decomposed ADVN (in the bilayer) is determined by measuring the rate of O_2 consumption as a function of light intensity. (*3*) Quantitative studies of the hydroperoxides formed from ABAP-initiated autoxidation of mixtures of DLPC and DPPC are completed in order to determine whether the products and the variation in product distribution with [DLPC] are similar to those observed for autoxidations initiated in the bilayer lipid phase. The object of this study is to determine whether the mechanism for peroxidation as outlined in references 27–31 is also applicable to autoxidations initiated in the aqueous phase. (*4*) Some results are reported on ^{31}P nmr spectra of bilayers. The objectives of these studies are to determine whether (*a*) evidence of the homogeneity of the DLPC and DPPC mixed bilayers can be obtained from the spectra and (*b*) the process of oxidation alters the bilayer structure of the PPCs (multilamellar and unilamellar) as characterized by their ^{31}P nmr spectra. In this study, it was important to determine whether the integrity of the bilayer structure is retained during the usual extent of oxidation (5–10%) in our kinetic and product studies. There is widespread interest in the effects of lipid peroxidation on the structures and properties of phospholipid membranes (42–47) and pathological effects, such as "leak formation" in animal erythrocytes (48–54). To our knowledge, however, there is no evidence that relates the extent of peroxidation (as measured in a *quantitative* kinetic manner) to effects on membrane structure.

Results

1. The kinetic order in oxidizable substrate for mixed bilayers

(a) With a lipid-soluble initiator (ADVN)

Known amounts of DLPC mixed with DMPC as "solvent", containing the initiator ADVN, were prepared above the phase transition temperature, T_t.[2] Data for the rates of oxygen consumption, the measured rates of chain initiation and the oxidizabilities are given in Table 1. The data were obtained over a six-fold range of DLPC concentration. A chain length, ν, in excess of 20 was maintained even at low DLPC and a constant value (within experimental error) of the oxidizability ($k_p/2k_t^{1/2} = 0.116 \pm 0.013\ M^{-1/2}\ s^{-1/2}$) was maintained throughout. The kinetic order in DLPC concentration was found to be 1.05 ± 0.03.

(b) With a water-soluble initiator (ABAP)

It was desirable to carry out experiments using DLPC mixed with DPPC since the latter commonly occurs in natural biomembranes (56). Since DPPC has a T_t of 41°C (55) and mixing in the gel phase is "constrained" (40, 56), preparations were kept above this T_t throughout to maximize random mixing of the two phospholipids. In addition, the mixtures were extruded through a French pressure cell to produce unilamellar liposomes (20, 57). The use of unilamellar liposomes avoids the problem of inhomogeneous distribution of the initiator, reported in other studies (58) when ABAP was added to multilamellar liposomes *after sample preparation*.[3] Kinetic data obtained with these unilamellar DLPC liposomes are outlined in Table 2. A chain length in excess of 20 was achieved over the six-fold range in [DLPC] with $k_p/2k_t^{1/2} = 0.232 \pm 0.034\ M^{-1/2}\ s^{-1/2}$. The kinetic order in bilayer DLPC concentration was found to be 1.07 ± 0.06.

Some experiments were also carried out by adding the initiator, ABAP, with the aqueous buffer *before* preparing the DLPC unilamellar liposomes. The oxidizability ($k/2k_t^{1/2} = 0.239 \pm 0.031\ M^{-1/2}\ s^{-1/2}$) obtained under such conditions is similar to that reported above for experiments with ABAP added after liposome formation.

2. The kinetic order in rate of chain initiation (R_i)

(a) With a lipid-soluble initiator (ADVN)

Under ideal conditions, the rate of oxygen consumption by the organic substrate is expected to be proportional to the $R_i^{1/2}$ and therefore to the square root of the light intensity for reactions where a photochemically decomposed initiator is employed. At 30°C, the thermal decomposition of ADVN in DLPC is slow. Consequently, the kinetic order with respect to the R_i was determined by measuring rates of O_2 uptake at six different light intensities for the ADVN photoinitiated autoxidation of DLPC. From the results given in Table 3, the kinetic order in light intensity was 0.503 ± 0.032.

(b) With a water-soluble initiator (ABAP)

The reaction order with respect to the concentration of

[2]DMPC did not absorb oxygen in the presence of ADVN in blank runs. The T_t of DMPC is 23°C (55); the T_t of DLPC is not known, but it is assumed to be below our conditions used.

[3]We also found that α-tocopherol sequestered in our unilamellar liposomes gave distinct inhibition periods using our procedure. This contrasts sharply with the behaviour in multilamellar samples (58).

[f]See footnote *e*, Table 1.

water-soluble ABAP was measured conveniently by simply adding measured amounts of aqueous ABAP to DLPC and measuring the effect on the rate of oxygen consumption. Typical data for such experiments are given in Table 4. The kinetic order in [ABAP] was 0.524 ± 0.056 and 0.431 ± 0.054 for two runs, 1 and 2, with liposomes of neat DLPC. A more extensive study was carried out on a mixture of DLPC and DPPC (duplicated) giving a kinetic order of 0.538 ± 0.016.

3. *Quantitative studies of oxidation product formation from mixed DLPC + DPPC bilayers with a water-soluble initiator (ABAP)*

The products of autoxidation of linoleate are known to be the 9- and 13-hydroperoxy substituted 9-*cis*,11-*trans*; 9-*trans*,11-*trans* and 10-*trans*,12-*cis*; 10-*trans*,12-*trans* octadecadienoates which are usually analyzed by reduction and conversion to the corresponding hydroxymethyl esters as shown in Scheme 1.

Very significant information has been provided on the mechanism of autoxidation of unsaturated lipids by Porter and co-workers (27–31) through a detailed study of the dependence of the *cis,trans* to *trans,trans* ratio of geometrical isomers on the hydrogen atom donating ability of the medium. The study was also applied to the autoxidation of methyl linoleate in micelles (59) and to aqueous dispersions of lecithins (27, 29). It was most important to determine whether the same trend in product formation is observed when autoxidation is initiated in the aqueous phase. For this purpose, we undertook some studies of the dependence of the *cis,trans* to *trans,trans* product ratios on the concentration of DLPC bilayers formed from mixtures of DLPC and DPPC. The results are summarized in Table 5. The results for the product analysis from the autoxidation of 1-palmitoyl-2-linoleoylphosphatidylcholine (PLPC) are included since this is regarded as the ideal 1:1 mixture of palmitoyl and linoleoyl chains.

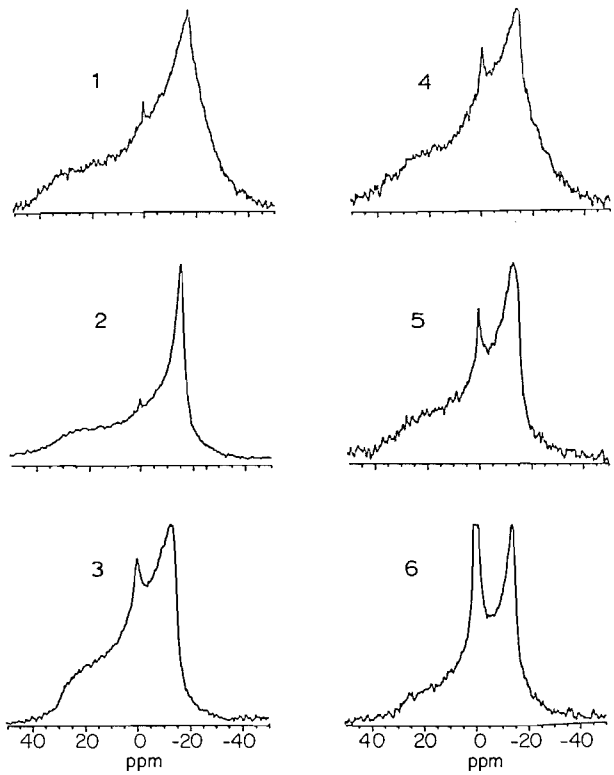

FIG. 1. ^{31}P nmr spectra of multilamellar phosphatidylcholine liposomes (0.1 mmol) in 2.00 mL of THAM buffer (pH 7.0). *1*, dipalmitoylphosphatidylcholine (DPPC) at 30°C; *2*, DPPC from *1*, at 45°C; *3*, dilinoleoylphosphatidylcholine; *4*, equimolar mixture of DLPC + DPPC, prepared (vortexed) and run at 30°C; *5*, mixture from *4*, spectrum repeated at 45°C; *6*, mixture of DLPC + DPPC prepared above 45°C (see text) and run at 45°C. The same spectrum results when run again at 30°C.

4. ^{31}P nmr spectra and autoxidation of bilayers

(a) ^{31}P nmr of DLPC and DPPC mixtures

Our kinetic and product studies and results of others (27, 29) tend to indicate that mixtures of DLPC and DPPC will form homogeneous bilayers under appropriate conditions; e.g. above their phase transition temperatures. Nevertheless, it was desirable to obtain some independent evidence on the nature of our mixtures. For this purpose we explored the application of ^{31}P nmr to mixtures of DLPC and DPPC prepared under various conditions. Some typical spectra are shown in Fig. 1 for DPPC (below and above T_t), DLPC and mixtures prepared below (30°C) and above (45°C) the T_t of DPPC.

(b) ^{31}P nmr spectra and oxidation of bilayers

Under controlled conditions, multilamellar and unilamellar liposomes (prepared from several unsaturated PPCs) were oxidized to known extents of peroxidation and their ^{31}P nmr spectra monitored during the process. Autoxidation was stopped by adding Trolox, known to be an effective antioxidant under these conditions (7) and then the ^{31}P spectra were run. Typical spectra illustrating the effects of peroxidation on multilamellar (DLPC) and unilamellar liposomes (egg lecithin, ELPC) are shown in Fig. 2.

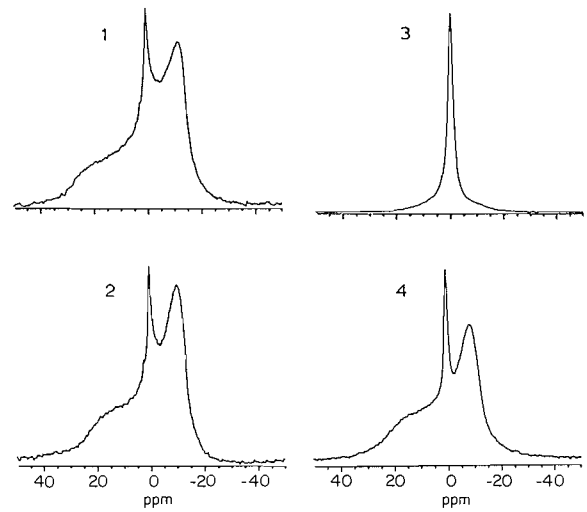

FIG. 2. ^{31}P nmr spectra of phosphatidylcholine liposomes (0.1 mmol) in 2.0 mL of THAM buffer (pH 7.0) at 40°C. *1*, multilamellar DLPC, purified by HPLC; *2*, oxidized DLPC, 60% conversion of active methylene groups; *3*, unilamellar egg lecithin; *4*, egg lecithin from *3*, after >30% oxidation.

Discussion

1. The kinetics and mechanism of autoxidation in bilayers

Rate measurements on *mixed bilayers* with various known concentrations of oxidizable DLPC with an inert PPC provide a very satisfactory method for establishing the kinetic order of oxygen uptake with substrate concentration. The results obtained with initiation by lipid-soluble ADVN in mixtures of DLPC and DMPC (Table 1) gave a good linear correlation for the order plot as shown in Fig. 3, when corrected for slight variations in the R_i. The kinetic order was unity (1.05), within experimental error, over a six-fold range of DLPC concentration and the oxidizability remained essentially constant at $k_p/2k_t^{1/2} = 0.116\,M^{-1/2}\,s^{-1/2}$.

Homogeneous mixtures of DLPC + DPPC (*vide infra*) were prepared above the phase transition temperature of DPPC. The kinetic order in DLPC was again found to be unity (1.07), within experimental error, for this system using the water-soluble initiator, ABAP. The data of Table 2 give a reasonably good correlation for the kinetic order plot shown in Fig. 4. The oxidizability of *unilamellar* DLPC was found to be $0.232\,M^{-1/2}\,s^{-1/2}$.[4]

In order to study the kinetic order with respect to the rate of chain initiation one could prepare bilayers with different (but known) concentrations of the initiator. However, due to the instability of thermal initiators such as ADVN, a study of this type with mixed bilayers is experimentally difficult (5) because significant amounts of the initiator decompose during bilayer formation. Fortunately, other studies have shown that the photocatalytic decomposition of an azo initiator could be carried out in bilayer dispersions (62). The dependence of the rate of O_2 consumption on the R_i for 0.05 *M* ADVN in multilamellar DLPC liposomes was followed by varying the light intensity. This gave a linear plot (Fig. 5) with a resulting kinetic order with respect to the R_i of one-half.

The kinetic order for the R_i for autoxidations initiated by ABAP was determined for bilayers of neat DLPC and mixtures of DLPC + DPPC. The latter study is considered to be the more significant. A plot of the order in [ABAP] gave an excellent

[4]We have recently determined the oxidizability of unilamellar 1-palmitoyl-2-linoleoylphosphatidylcholine (PLPC) to be $0.118\,M^{-1/2}\,s^{-1/2}$, which is consistent with these results since PLPC has one oxidizable chain.

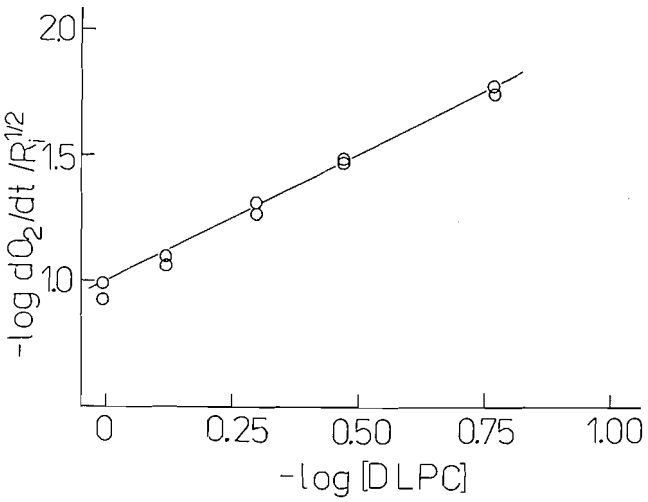

FIG. 3. Kinetic order plot for the autoxidation of mixed bilayers of DLPC + DMPC, initiated by lipid-soluble ADVN. Data taken from Table 1.

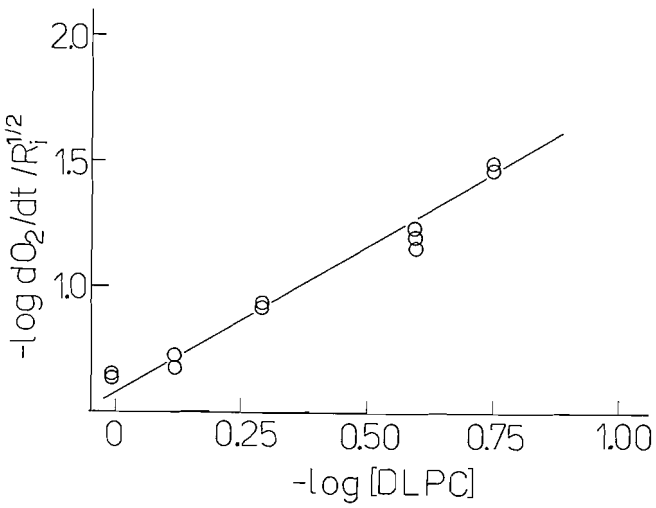

FIG. 4. Kinetic order plot for the autoxidation of mixed bilayers of DLPC + DPPC, initiated by water-soluble ABAP. Data taken from Table 2.

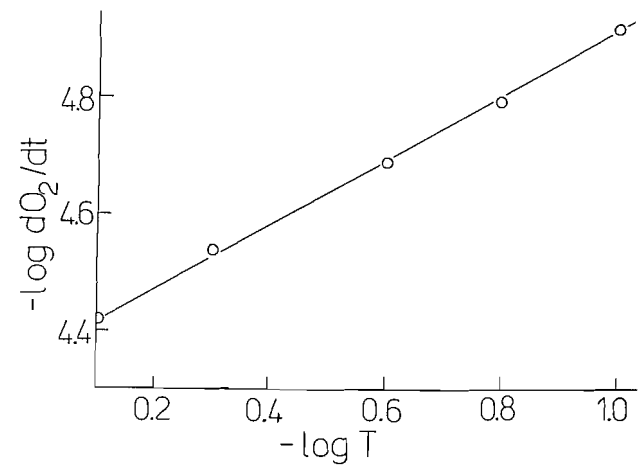

FIG. 5. Kinetic order plot of oxygen consumption as a function of light intensity for autoxidation of DLPC liposomes initiated by ADVN. Data taken from Table 3.

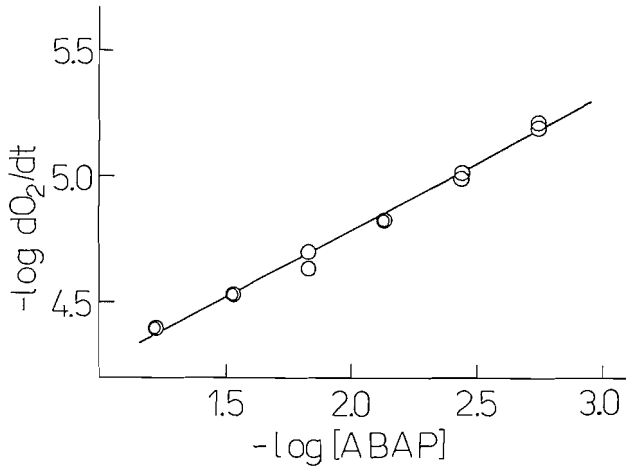

FIG. 6. Kinetic order plot of oxygen consumption with concentration of the water-soluble initiator, ABAP, for autoxidation of mixed bilayers of DLPC + DPPC. Data taken from Table 4, runs 3(a) and 3(b).

linear correlation (Fig. 6) for two runs with a kinetic order of 0.538 in the R_i.

Overall our results show that bilayer autoxidations initiated by either a lipid-soluble initiator (ADVN) or by water-soluble ABAP give rates of oxygen consumption which are first order in concentration of oxidizable substrate and half order in the R_i. This represents the first complete study showing that the classical autoxidation kinetics (eq. [1]) are applicable to PPCs as model biomembranes. Furthermore, these classical kinetics are applicable to water-soluble as well as lipid-soluble initiators. Certain interesting questions, however, remain to be answered: *(1) Why is a unilamellar system more susceptible to autoxidation than a multilamellar system?* and *(2) How does initiation with a water-soluble initiator result in the observed classical kinetics in the bilayers?*

We have not yet a satisfactory answer to question (1). However, we suspect that the higher oxidizability of unilamellar vesicles (ULV) ($k_p/2k_t^{1/2} = 0.232\,M^{-1/2}s^{-1/2}$) as compared to multilamellar vesicles (MLV) ($k_p/2k_t^{1/2} = 0.116\,M^{-1/2}s^{-1/2}$) is related to different "packing" of the lipid chains in ULV compared to those in the larger MLV systems (56). At constant R_i, identical samples of DLPC gave a higher rate of oxidation when prepared as ULV as compared to MLV. We therefore speculate that the higher oxidizability for unilamellar systems could arise from an increase in the rate of chain propagation,[5] perhaps due to a higher local concentration of oxidizable methylene groups.

In order to fully address question (2), we first examine the results of the analysis of linoleate oxidation products from mixed DLPC + DPPC bilayers when oxidation was initiated by water-soluble ABAP. A plot of the ratio of geometrical isomers (*c,t*/*t,t*) shows a linear relationship with the bilayer concentration of DLPC (Fig. 7) and the result from PLPC correlates within experimental error. In other words, the product distribution depends directly on the hydrogen atom donating ability of the medium; in this case the DLPC concentration in the bilayer. Furthermore, we found that the yield of products from addition at the C-9 position (isomers **1** + **3** = 48.9 ± 1.5%) is the same,

[5]Preliminary measurements on sonicated (unilamellar) DLPC liposomes indicate that the k_p term is higher than that for multilamellar DLPC (62).

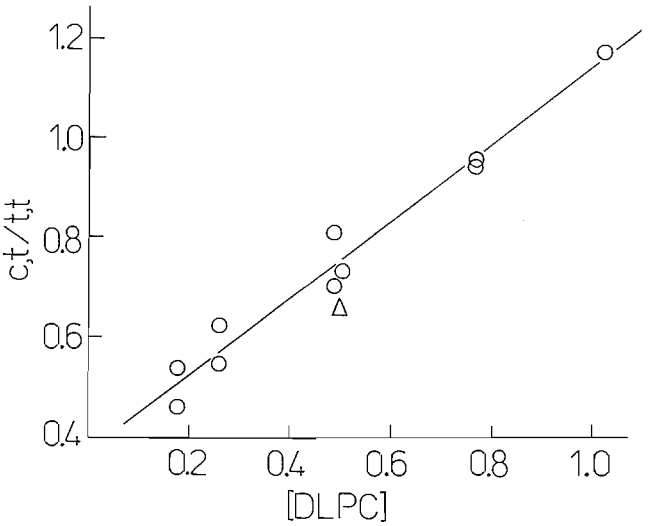

FIG. 7. Concentration dependence of the product ratios (*cis,trans/trans,trans*) of hydroxy linoleate esters derived from the autoxidation of mixtures of DLPC + DPPC. [DLPC] is the substrate concentration in the total (reaction) volume of DLPC + DPPC. The result from PLPC is shown as Δ.

within experimental error, as that for the products resulting from addition at the C-13 position (isomers **2** + **4** = 51.2 ± 1.5%). These results mean that the "Porter Mechanism" for lipid peroxidation is entirely applicable to autoxidations initiated by a water-soluble initiator. This mechanism (27, 28) involves H-atom abstraction to give a resonance-stabilized pentadienyl radical, addition of oxygen at either position 9 or 13 to give initial *c,t* and *t,c* peroxyl radicals (kinetically controlled), respectively. These radicals may abstract a hydrogen atom to produce the 9 or 13 hydroperoxide or undergo isomerization to a thermodynamically favored conformation followed by β-scission of O_2. Subsequent addition of O_2 produces *trans,trans* peroxyl radicals which may abstract a H-atom to give *trans,trans* hydroperoxides, the thermodynamic products.

These results of kinetic and product studies imply that the water-soluble initiator, ABAP, or peroxyl radicals derived thereof, "penetrate" the hydrophobic region of the bilayers sufficiently[6] to provide effective H-atom abstraction from the reactive methylene group at C-12. Mechanisms have been proposed for *trans*-bilayer transport of polar solutes. For example, inverted micelles (lipidic particles) (64–66) could form around ABAP near the membrane surface and transport it into the lipid phase.

2. ^{31}P nmr evidence of bilayer mixing and effect of oxidation

It is well known that the ^{31}P nmr spectra of multilamellar and large unilamellar PPC bilayers exhibit broad, asymmetrical line shapes due to restricted anisotropic motion of the phospholipid molecules. In these systems, the typical high field peak and low field shoulder result in a "chemical shift anisotropy" (CSA) of about −40 ppm (66). It also has been shown that line widths and line shapes can give information on the overall particle size of PPC vesicles (67).

Our ^{31}P nmr spectra provide some independent evidence on the nature of the mixtures of DLPC + DPPC. Below its T_t, DPPC exhibits a rather broad, structureless signal (Fig. 1, No. 1, CSA = 63 ppm) which appears to characterize its gel state. Above its T_t, the spectrum changes to give a sharper peak and a shoulder (No. 2, CSA = 48 ppm). Similarly, DLPC (No. 3) which is above its T_t shows the typical peak and shoulder (CSA = 45 ppm).[7] The spectrum of an equimolar mixture of DLPC + DPPC prepared by vortex-stirring of the two at 30°C (No. 4) appears identical to that of DPPC alone at 30°C. At 45°C the latter spectrum changes into a spectrum typical of the liquid crystal state (No. 5, CSA = 53 ppm) but the spectrum reverts back to that like No. 4 on cooling the sample to 30°C again. These results indicate that a heterogeneous mixture of DPPC and DLPC is present and that there is some segregation of the DLPC and DPPC from mixtures prepared under these conditions.[8]

A significant change is observed in the spectra when a film of DLPC and DPPC is converted into a bilayer above the T_t (e.g. above 45°C). Now the spectrum (No. 6, CSA = 46 ppm) is the same at 45°C and 30°C (not shown). This is taken as evidence that the DLPC and DPPC have been homogeneously mixed under these conditions. This ^{31}P nmr method has only been applied to 1:1 mixtures of the two phospholipids. We believe it is reasonable to assume that homogeneous mixtures also result at lower DLPC concentrations provided the temperature during liposome preparation and use remains above their T_t. ^{31}P nmr spectra show that phosphatidylethanolamines are miscible above their gel-liquid T_t (68).

A number of physical transformations are reported to accompany peroxidation of liposomes and thereby alter their ^{31}P nmr spectra. These changes include a decrease in PPC vesicle size (46), promotion of phase changes from bilayer to hexagonal phase in phosphatidylethanolamines (42), and enhancement of rapid transbilayer (flip-flop) movement of phospholipids which may cause non-bilayer structures (48). In addition, small unilamellar DPPC vesicles can fuse spontaneously below the T_t (69) and Ca^{2+} may cause "fast" fusion of egg lecithin – phosphatidic acid mixed vesicles (70). Despite these complications, some important conclusions can be made from our ^{31}P nmr spectra at various oxidation stages, as measured by the moles of oxygen consumed per reactive methylene group (DLPC) or per mole of lipid (ELPC). ^{31}P nmr spectra of liposomes of purified DLPC (Fig. 2, No. 1, CSA = 45 ppm) were not changed significantly after 10% oxidative conversion of the reactive methylene groups. By 60% conversion, there was a noticeable reduction in the chemical shift anisotropy (No. 2, CSA = 37 ppm). If the oxidative process causes an increase in bilayer fluidity or a decrease in the size of the liposomes (67), there could be increased motional averaging of the phosphorous-containing head group causing the observed decrease in the CSA.

Some spectral studies beginning with unilamellar vesicles which are subjected to peroxidation indicate that very significant changes can occur. A typical example is shown for egg lecithin in Fig. 2, Nos. 3 and 4. The initial unoxidized sample shows a ^{31}P spectrum with a single band attributed to smaller

[6]We have not measured the partition coefficient of ABAP between water and bilayers; however, we find that it partitions readily into 0.10 *M* SDS since $f = 0.91$ using the diffusion coefficient procedure (63).

[7]The narrower peaks which appear in most of the spectra near 0 ppm are probably due to smaller, possibly unilamellar, particles. Their proportion increases in samples prepared above the T_t (e.g. Fig. 1, No. 6).

[8]However, a referee points out that the spectrum of this mixture is expected to be dominated by the more fluid phase DLPC because of the short T_2 value of gel-state lipids.

particles, presumably unilamellar vesicles. The signal broadened as the oxidation proceeded, such that by 30% oxidative conversion the spectrum showed a signal with CSA = 34 ppm. Prolonged oxidation results in a spectrum typical of multilamellar systems (No. 4, CSA = 37 ppm). Control samples shaken under argon did not show these significant changes in their ^{31}P nmr spectra.

From these preliminary ^{31}P nmr results we conclude that: (*1*) during oxidation the bilayers retain their structural integrity to at least 10% conversion of the active methylene groups (the maximum in our kinetic studies) and (*2*) at high oxidative conversion (e.g. above about 30%), very significant changes occur. Large multilamellar liposomes appear to change to smaller average sizes while unilamellar systems are converted to multilamellar or much larger unilamellar liposomes.

Experimental

1. Materials and preparations

(a) Buffers: Phosphate buffer for autoxidation kinetic studies was prepared from 0.05 *M* each of NaH_2PO_4 and Na_2HPO_4 (pH 7.0) in glass-distilled water containing 1×10^{-4} *M* Na_2EDTA. The buffer was passed through Chelex 100 (50–100 mesh, BioRad) to remove traces of heavy metal ions. Dispersions for nmr studies were prepared in 0.054 *M* THAM (Fisher) buffer adjusted to pH 7.0 with HCl and containing 1×10^{-4} *M* Na_2EDTA.

(b) Reagents: The initiators were purchased from Polysciences and stored as the solid at −30°C. Solutions of known concentration were prepared in buffer (ABAP) and in methylene chloride or chloroform (ADVN) and stored at 4°C. Stock solutions of the inhibitor, 2,5,7,8-tetramethyl-6-hydroxychroman-2-carboxylate (Trolox) were prepared in known concentrations in the appropriate buffer shortly before use. Organic solvents used were of HPLC grade.

(c) PPCs and HPLC purification: DLPC and DMPC were purchased from Avanti Polar Lipids and DPPC was obtained from Sigma. PLPC was synthesized in the laboratory of N. A. Porter by known procedures (71). Stock solutions of DLPC in methanol (40 mg/mL) and PLPC in methanol/cyclohexane (80/20, 40 mg/mL) were prepared. Phospholipid purification was achieved by recycle HPLC using a 10 × 250 mm Vydac reverse phase column (C_{18}, 10 μm). The sample was eluted with mixed solvent: methanol/water/cyclohexane (90/10/5) pumped at 9.0 mL/min by a Waters Model 510 EF pump. Approximately 1% of the column effluent was passed through a Schoeffel SF 770 variable wavelength detector where its absorbance at 210 nm was measured. Hydroperoxide impurities eluted as a series of three peaks 2–10 min after injection of solution containing 80 mg of crude phospholipid. After the hydroperoxides were removed, the PC which had a broad elution pattern (12–30 min after injection) was recycled through the column. The purified phospholipid was then collected in an argon-filled flask at 0°C in the dark. The solvent (>200 mL) was removed by rotary evaporation at reduced pressure at 20–30°C in the dark, followed by pumping at <0.5 mm Hg to constant weight. Stock solutions of the purified lipids were then prepared in either degassed methanol (DLPC) or methylene chloride (PLPC) and stored at −30°C in the dark. The phospholipid purity was determined by spotting on silica TLC plates and development with hexane/2-propanol/acetone (992/4/4). Small traces of hydroperoxides were detected as pale pink spots with *N,N*-dimethyl-*p*-phenylenediamine dihydrochloride spray (1.5 g in methanol/water/acetic acid (128/25/1)). The phospholipid was detected with either 3.5% molybdatophosphoric acid spray (BDH) or molybdenum blue spray reagent (Sigma).

(d) Mixtures of PPCs: Homogeneous mixtures of DLPC + DPPC were prepared by slow evaporation of mixtures of known amounts from chloroform solution at 55–60°C on a water bath under a stream of argon. Final traces of solvent were removed under reduced pressure at 60°C; always keeping the sample above the phase transition temperature of DPPC. A similar procedure for DLPC + DMPC mixtures was used at 45°C. In this case, the required amount of initiator (ADVN) was added to the organic solvent containing the phospholipids. Multilamellar vesicles were prepared by vortex-stirring the film of PPCs with buffer, followed by ten freeze–thaw cycles of the aqueous dispersion by cooling in liquid nitrogen. Unilamellar vesicles were prepared by passing the multilamellar liposomes three times through a warmed French pressure cell under argon at 20 000 psi (20, 57).

2. Kinetic studies

Autoxidations were carried out at 45°C under 760 mm Hg of oxygen using a sensitive pressure transducer and an automatic recording apparatus modified from that described earlier (5, 62). The present experiments required precise measurements of rates of oxygen uptake on mixtures containing relatively small amounts of unsaturated phospholipids. In order to obviate baseline drift encountered earlier (5) due to vapour pressure of the solvent, we used a specially constructed stainless steel dual channel apparatus which has been described elsewhere (72). One channel was connected to a reaction vessel containing only the solvent used (in this case aqueous buffer); the other to a calibrated vessel containing the prepared sample in buffer. This new procedure automatically compensates for the vapour pressure due to solvent, essentially eliminating error or lag time due to baseline drift.

3. Autoxidation product analysis

Phospholipid samples were prepared as described above for kinetic experiments. After 5% oxidation, a 100 μL aliquot of the reaction mixture was added to 1 mL of 10 m*M* Ph_3P in methanol and the solution mixed. Transesterification of the phospholipid was accomplished by the addition of 1.5 mL of 0.45 *M* KOH in methanol. The mixture was stirred and then allowed to stand for 15 min at room temperature. The solution was treated with 1 mL of 1.0 *M* NH_4Cl and then extracted with 1.0 mL of HPLC solvent (*vide infra*) with brief centrifugation to aid the separation.

Separation of the four methyl hydroxylinoleates was achieved using a Waters 510 EF pump fitted with 4 × 300 mm Apex silica (10 μm) column (Jones Chromatography). With a flow rate of 1.6 mL/min, the products were detected at 234 nm with a Schoeffel SF770 variable wavelength detector. Relative amounts of the four hydroxylinoleates were determined by correcting the peak areas, as reported by a Varian CDS 401 data system, for the appropriate molar absorptivity (73): 13-*c,t* (λ_{max} 236 nm, ϵ = 27 200); 13-*t,t* (λ_{max} 233 nm, ϵ = 30 500); 9-*c,t* (λ_{max} 236 nm, ϵ = 28 300); 9-*t,t* (λ_{max} 233 nm, ϵ = 31 600).

4. ^{31}P nmr spectra

^{31}P nmr spectra were determined on bilayer dispersions containing approximately 0.1 mmol of total phospholipid in 2 mL of 0.054 *M* THAM buffer (pH 7.0). A Nicolet 360 NB FT NMR spectrometer was used at 146.15 MHz employing two-level broadband decoupling with a 90° pulse of 25 μs and decoupling power of 10 W for data acquisition and 2 W during magnetization recovery times. A delay time of 4 s was used between pulses.

An oxidation apparatus was installed adjacent to the nmr facility so that samples could be examined immediately after various stages of oxidation. Trolox[9] was added to the sample to terminate the oxidation and the samples purged with argon before ^{31}P nmr spectra were determined. Generally, 2500–4000 acquisitions were necessary to obtain satisfactory spectra. Samples of mixed bilayers (DLPC + DPPC) and those passed through the French pressure cell were similarly prepared immediately before ^{31}P nmr analysis.

Sodium and potassium phenoxide, in the presence of one equivalent of dicyclohexano-18-crown-6 (*cis–anti–cis* isomer) and dibenzo-18-crown-6, form complexes that have a ratio of 1:1:1 (crown:salt:phenol) in ethereal solvents containing excess phenol. On the other hand, complexes having 1:1:2 ratios (crown:salt:phenol) are obtained under the same conditions when the macrocycle is 18-crown-6 or dicyclohexano-18-crown-6 (*cis–syn–cis* isomer). When only one equivalent of phenol is present, then 1:1:1 complexes are obtained with 18-crown-6 and dicyclohexano-18-crown-6 (*cis–syn–cis* isomer). No complexes containing only the metal salts were isolated from these solutions. The infrared spectral data obtained from the complexes show that the phenol hydroxyl hydrogens in the complexes form either strong or very strong hydrogen bonds. The nuclear magnetic resonance chemical shifts of the phenol protons in the complexes have been obtained from deuterated dimethoxyethane solutions. Comparisons are made with the chemical shifts of the phenol hydroxyl protons obtained from the corresponding solutions containing only the equivalent salt/phenol solutions.

ANDRÉ RODRIGUE, JOHN W. BOVENKAMP, MICHAEL P. MURCHIE, GERALD W. BUCHANAN et SUZANNE FORTIER. Can. J. Chem. **65**, 2551 (1987).

Dans des solvants éthérés contenant un excès de phénol, les phénolates de sodium ou de potassium, en présence d'un équivalent de dicyclohexano-18-couronne-6 (isomère *cis–anti–cis*) et de dibenzo-18-couronne-6, forment des complexes dans lesquels le rapport couronne:sel:phénol est 1:1:1. Par ailleurs, lorsqu'on travaille dans le mêmes conditions mais que le macrocycle est la 18-couronne-6 ou la dicyclohexano-18-couronne-6 (isomère *cis–syn–cis*), il se forme des complexes dans lesquels le rapport couronne:sel:phénol est 1:1:2. Lorsqu'on n'utilise qu'un seul équivalent de phénol, il se forme des complexes dans lesquels le rapport est 1:1:1, même avec la 18-couronne-6 et le dicyclohexano-18-couronne-6 (isomère *cis–syn–cis*). À partir de ces solutions, on n'a pas pu isoler de complexes ne contenant que des sels métalliques. Les données infrarouges obtenues à partir de ces complexes démontrent que les hydrogènes hydroxyliques du phénol des complexes forment des ponts hydrogènes qui sont soit forts ou très forts. Utilisant des solutions dans du diméthoxyéthane deutéré, on a pu déterminer les déplacements chimiques en résonance magnétique nucléaire des protons des phénols des complexes. On a fait une comparaison avec les déplacements chimiques des protons hydroxyliques des phénols dans des solutions correspondantes ne contenant que du phénol et le sel équivalent.

[Traduit par la revue]

Introduction

Since the isolation of the first alkali metal complexes of macrocyclic ethers (1), there has been a great deal of interest in complexes containing neutral molecules that can engage in hydrogen bonding. Pedersen (2) showed that macrocyclic ethers complexed thiourea in ratios of macrocycle to thiourea of 1:1–1:6, depending on the macrocycle used. When salts such as potassium or sodium thiocyanate were present in the reaction mixture, the complexes were found to contain one molecule of the salt and one or more molecules of thiourea. Hilgenfeld and Saenger (3) have published the crystal structure of the 1:1:1 complex of dibenzo-18-crown-6·potassium iodide·thiourea. Interestingly, it was found that the thiourea neither participates in the complexation of the metal ion, nor does it have any contact with the polyether ligand. Instead, it forms polymeric chains coupled by hydrogen bonding. The iodide is coordinated to the cation and is also hydrogen bonded to the thiourea chain. Polymeric chains involving coupling by hydrogen bonding will be discussed further (*vide infra*). Many other examples of the incorporation of neutral hydrogen bonding molecules into complexes with macrocyclic ethers have been reported in the literature (see ref. 4 for a review).

In our earlier work (5–9) we reported studies on the complexes of 18-crown-6 macrocyclic ethers with sodium and potassium salts. These complexes were obtained by precipitation from ethereal solvents. Depending on the macrocycle, the cation, and the anion of the salt used in the complexation reaction (5), the resulting complexes were found to have host:guest ratios of 1:1, 1:2, or 1:3. The complexes were studied using X-ray diffraction techniques (6), variable temperature ^{13}C nmr spectroscopy (7, 8), and CPMAS ^{13}C nmr (9). In our first attempt to prepare a suitable crystal of the 1:2 complex of DC-18-crown-6(B)·2KOPh for X-ray diffraction study,[2] rigorous anhydrous conditions were not used. Under these

conditions, the actual crystal that was analyzed by X-ray diffraction was shown to have the unexpected 1:1:1 composition: DC-18-crown-6(B)·KOPh·HOPh (*vide infra*).[3] This result led to the work reported in the present paper.

There have been some reports of neutral substituted phenols being incorporated into complexes. For example, Poonia and Truter (10) report the synthesis of 2(benzo-15-crown-5)·K(2-nitrophenolate)·(2-nitrophenol). Poonia (11) has also synthesized complexes of benzo-15-crown-5 and dibenzo-30-crown-10 containing sodium and potassium salts and one or more molecules of 2-nitrophenol, 2,4-dinitrophenol, or 2,4,6-trinitrophenol. More recently (12), it has been shown that 3-nitrophenol can be incorporated into a complex without a salt being present. The complex was 18-crown-6·$2H_2O$·2(3-nitrophenol). To the best of our knowledge, no macrocyclic ether/salt complexes have previously been reported in which phenol itself has been incorporated.

In this paper we report a systematic study of the complexes formed when four different 18-crown-6 macrocyclic ethers were reacted with phenol in the presence of either sodium or potassium phenoxide. The use of phenol in conjunction with the sodium and potassium phenoxide salts was a deliberate choice. It was felt that this could lead to complexes with a high degree of symmetry.

The synthetic aspects, as well as the results of infrared and solution proton nmr studies are reported here. In an accompanying paper (13), the crystal structures of two of the complexes (**5** and **12**) are presented. The second accompanying paper (14) reports a high resolution ^{13}C CPMAS (cross-polarization magic angle spinning) study on the solids of three configurationally isomeric dicyclohexano-18-crown-6 ethers, as well as on three complexes derived therefrom. One of the solid complexes studied by this technique was **5**.

Results and discussion

As has been discussed previously (5), salts like sodium and potassium phenoxide form aggregates in ethereal solvents like DME, diethyl ether, and THF. The degree of association of ion pairs depends on the solvent and on the size, charge density, and hardness of both the cation and the anion (15, 16). In the absence of phenol, it has been shown that 18-crown-6 forms a 1:1 complex with KOPh when precipitated from a DME solution (5). Although we have not yet been successful in growing a suitable crystal of this complex for an X-ray diffraction structure determination, it is very likely that the 18-crown-6 macrocycle has broken up the aggregates to complex a contact ion pair. It has been shown that a dimer of KOPh is complexed in the 1:2 complex of DC-18-crown-6(B)·2KOPh and a tetramer of NaOPh is complexed in the 1:2 complex of DC-18-crown-6(A)·2NaOPh (5, 6).

In ethereal solutions of sodium and potassium phenoxide that also contain phenol (like those used in the present paper), very different aggregates are expected. The aggregates will now contain phenol, which will be coordinated to the anions with strong or very strong hydrogen bonds (*vide infra*) (see ref. 17 for a review on strong and very strong hydrogen bonding). Berny and Perrin (18, 19) have added KOPh to a benzene solution of phenol to obtain KOPh·3HOPh (mp 135°C) and, by adding potassium to a benzene solution of phenol, have isolated KOPh·2HOPh (mp 142°C). Hanson, McCulloch, and McInnes (20) have isolated a complex with the structure $[(C_6H_5OH)_4][C_6H_5O^-][Me_4N^+]$. The phenoxide oxygen was shown to be hydrogen bonded to three phenol molecules while the fourth phenol was hydrogen bonded to the oxygen of one of the three phenolic hydroxyls.

Interestingly, when larger cations such as Et_4N^+ and n-Bu_4N^+ were used, fewer phenols were found in the isolated complexes (3 and 2 molecules, respectively (20)). It can thus be expected that, in our ethereal solutions of NaOPh and KOPh, aggregates of the salts with phenol will be formed and that these will be broken up by the macrocycles as the cations are complexed.

The compositions of the complexes obtained by precipitation from ethereal solvents are shown in Table 1. The anhydrous solvent or solvent mixtures used in the complexation reactions are shown in Table 2. It was necessary to use mixtures of ethereal solvents for some of the complexation reactions to obtain the yields of the precipitated complexes shown in Table 2. A satisfactory elemental analysis has been obtained for each of the complexes (see Experimental). Also, integrated proton nmr spectra were in agreement with the ratios for the complexes shown in Table 1.

Section A of Table 1 gives the crown:salt:phenol ratios of the complexes obtained when one equivalent of macrocycle is added to a solution of the appropriate ethereal solvent containing one equivalent of phenoxide salt and three equivalents of phenol. Under these conditions, both 18-crown-6 and DC-18-crown-6(A) give complexes with 1:1:2 crown:salt:phenol ratios (**1**–**4**). By contrast, the other two macrocycles (DC-18-crown-6(B) and DB-18-crown-6) give complexes that contain only one molecule of phenol (**5**–**8**).

Section B of Table 1 shows the ratios obtained when one equivalent of 18-crown-6 and DC-18-crown-6(A) are reacted with one equivalent of salt in the presence of only 1.05 equivalents of phenol. Instead of the 1:1:2 crown:salt:phenol ratios obtained when 3 equivalents of phenol were used, the precipitated complexes have 1:1:1 ratios (**9**–**12**).

None of the macrocycles formed complexes with the salts only. Without exception, the complexes isolated contained either one or two molecules of phenol. It is interesting to note from Table 1 that, when phenol is present, the crown:salt:phenol ratio for a particular macrocycle is independent of whether the cation is K^+ or Na^+. Thus, the same ratio of 1:1:2 is obtained with 18-crown-6 when either KOPh (see **1**) or NaOPh (see **2**) is present in the reaction mixture. The same is true throughout Table 1 (e.g., compare **3** and **4**, **5** and **6**, etc). This is frequently not the case in the absence of phenol. 18-Crown-6, for example, gives a 1:1 host:guest complex with KOPh but a 1:3 host:guest complex with NaOPh (for this and other examples, see ref. 5).

One of the accompanying papers (13) reports the crystal structure determinations of two of the 1:1:1 complexes (**5** and **12**). For complex **5**, it has been found that the K^+ cation sits on a center of symmetry, in the center of the cavity formed by the six crown ether oxygens. The potassium is also coordinated to two phenol/phenoxides, one on each side of the crown cavity. Groups of phenol/phenoxide–potassium–phenol/phenoxide are linked by the hydrogen atoms to form a chain: $K^+\cdots O\cdots H\cdots O\cdots K^+$. The crystal structure of **12** is very different. In this case, the macrocyclic ring is distorted to accommodate the sodium ion. The phenol/phenoxide units are coordinated to the cation on only one side of the cavity, with one of the oxygens being coordinated to the cation and, at the

[3]Under rigorously anhydrous conditions, suitable crystals of the expected 1:2 complex were obtained for X-ray diffraction study (6).

TABLE 1. The complexes and their crown:salt:phenol ratios

Number	Macrocycle	Salt	Melting point (°C)	Crown:salt:phenol ratio
	Section A. Complexes from solutions with a 1:1:3 ratio[a]			
1	18-Crown-6	K^+OPh^-	80–82	1:1:2
2	18-Crown-6	Na^+OPh^-	82–83.5	1:1:2
3	DC-18-crown-6(A)	K^+OPh^-	84.5–86.5	1:1:2
4	DC-18-crown-6(A)	Na^+OPh^-	74–75	1:1:2
5	DC-18-crown-6(B)	K^+OPh^-	149–151	1:1:1
6[b]	DC-18-crown-6(B)	Na^+OPh^-	110–113 145–150	1:1:1
7	DB-18-crown-6	K^+OPh^-	176.5–178	1:1:1
8[b]	DB-18-crown-6	Na^+OPh^-	172–175 220–225	1:1:1
	Section B. Complexes from solutions with a 1:1:1.05 ratio[c]			
9	18-Crown-6	K^+OPh^-	113–113.5	1:1:1
10	18-Crown-6	Na^+OPh^-	96.8–97	1:1:1
11	DC-18-crown-6(A)	K^+OPh^-	102–103	1:1:1
12	DC-18-crown-6(A)	Na^+OPh^-	112.5–114.5	1:1:1

[a]The initial reaction solution had the macrocycle, metal phenoxide, and phenol in a 1:1:3 molar equivalent ratio, respectively.

[b]Two distinct mp ranges were observed. With complex **6**, the solid melts between 110 and 113°C until at 113°C the material in the tube is 80% liquid. The amount of solid then increases until melting again begins at 145°C and is complete at 150°C. Complex **8** also has two melting point ranges. It is apparent that at the first mp the original complex is broken up and a higher mp material is formed in each case.

[c]The initial reaction solution contained one equivalent each of macrocycle and metal phenoxide and 1.05 equivalents of phenol.

TABLE 2. Ethereal solvents[a] used in the complexation reactions and the yields obtained

Complex no.	Solvent used	Yield (%)	Complex no.	Solvent used	Yield (%)
1	Ether (50 mL)	86	**7**	DME (10 mL) + ether (20 mL)	92
2	Ether (40 mL)	93	**8**	THF (20 mL) + ether (20 mL)	81
3	Ether (30 mL)	88	**9**	DME (5 mL) + ether (50 mL)	81
4	Ether (30 mL)	70	**10**	THF (5 mL) + ether (30 mL)	84
5	DME (10 mL) + ether (15 mL)	75	**11**	Ether (30 mL)	70
6	Ether (20 mL)	68	**12**	DME (5 mL) + ether (20 mL)	78

[a]DME = 1,2-dimethoxyethane; THF = tetrahydrofuran; ether = diethyl ether.

same time, hydrogen bonded to the phenol hydrogen. We are currently attempting to grow crystals of the 1:1:2 complexes (**1–4**) for X-ray diffraction structure determinations.

Infrared spectra of the complexes

Infrared spectra were obtained using Nujol mulls of the complexes. We will discuss here only the peaks attributable to the phenol hydroxyl hydrogens in the spectra in the 1650–2800 cm^{-1} region (see Table 3). Additional information is difficult to extract because of the complexity of the spectra between 600 and 1650 cm^{-1} and the very large peaks due to CH stretching vibrations between 2800 and 3100 cm^{-1}.

Hadzi and Bratos (21, 22; see ref. 17 for a summary) recognized three types of spectra for hydrogen bonding systems: (*i*) the weak interaction in which the peaks are not far removed from the nonassociated AH spectrum; (*ii*) the stronger hydrogen bond that gives a very broad band absorbing at 1600–3000 cm^{-1} with three discernible maxima, which he called an ABC band; and (*iii*) very strong hydrogen bonds, which give a very broad band below 1600 cm^{-1}. None of the infrared spectra for **1–12** showed any peaks at wave numbers above 3100. Thus, all of the hydrogen bonds in the complexes are either strong (type (*ii*)) or very strong (type (*iii*)). By contrast, the Nujol mull of phenol itself shows a broad hydrogen bonding band with a maximum at about 3180 cm^{-1} (ref. 23 reports a value of 3200 cm^{-1}). In Hadzi's classification this represents type (*i*) hydrogen bonding.

The discussion of the infrared spectral information in Table 3 can be divided into three parts: that of **1–4**, **5–8**, and **9–12**. The 1:1:2 complexes **1–4** all show a broad band with two maxima in the 1650–2800 cm^{-1} region (see Fig. 1 and Table 3). Thus, this represents type (*ii*) hydrogen bonding (strong). The infrared spectrum of 18-crown-6·NaOPh·2HOPh (**2**) shown in Fig. 1 is typical for these complexes. Hadzi's spectra (21) showed a characteristic trio of bands near 2800, 2500, and 1900 cm^{-1}. Because of the very large peak due to CH stretching vibrations in our spectra between 2800 and 3100, nothing can be said about a potential third maximum expected in this region.

In contrast to **1–4**, the infrared spectra of the 1:1:1 complexes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

TABLE 3. Hydrogen bonding information from infrared spectra of **1–12**

Complex no.	ν_{OH} bands in the 1650–2800 cm^{-1} region[a] (cm^{-1})	Complex no.	ν_{OH} bands in the 1650–2800 cm^{-1} region[a] (cm^{-1})
1	Maxima at 1820 and 2480	**7**	No Peaks
2	Maxima at 1880 and 2480	**8**	No Peaks
3	Maxima at 1820 and 2540	**9**	No Peaks
4	Maxima at 1880 and 2600	**10**[b]	Maxima at 1850 and 2510
5	No peaks	**11**	No Peaks
6	No peaks	**12**	No Peaks

[a]At wave numbers between 2800 and 3100, hydrogen bonding information is lost due to the very large CH stretching vibrations. Thus, nothing can be reported on the potential third maxima expected in this region (21).

[b]The magnitude of the ν_{OH} peak found for **10** is weak compared to those for **1–4**.

5–8 do not show any peaks in the 1650–2800 cm^{-1} region attributable to hydrogen bonding, indicating that very strong hydrogen bonding must occur in these complexes. The spectrum of **5** (DC-18-crown-6(B)·KOPh·HOPh) shown in Fig. 2 is representative. The very broad bands expected below 1600 cm^{-1} for very strong hydrogen bonding are difficult to identify due to the complexity of the spectrum in this region (see Fig. 2). The presence of very strong hydrogen bonding in **5** is in agreement with the crystal structure where the distance between the oxygens in the O···H···O unit is 2.48 Å (13).

Of the complexes **9–12**, only **10** exhibits strong hydrogen bonding (type (*ii*)) while **9**, **11**, and **12** have no peaks attributable to strong hydrogen bonding in the 1650–2800 cm^{-1} region and thus very strong hydrogen bonding must be involved. The crystal structure of **12** shows a PhO···H···OPh anion that is coordinated to the cation via one of the oxygens on the unhindered side of the DC-18-crown-6(A) macrocycle (13). The O···H···O distance of 2.47 Å is indicative of a very strong hydrogen bond. It is expected that the same type of hydrogen bonding and association to the cation will be present in **11**, especially since the phenolic proton chemical shift is significantly further downfield in **11** as expected (*vide infra*). Complexes **9** and **10** are the only K^+/Na^+ pair of complexes in the table that show different types of hydrogen bonding, with **9** exhibiting very strong and **10** strong hydrogen bonding. Unfortunately, X-ray diffraction data on **9** and **10** are not available to explain this difference.

Nuclear magnetic resonance chemical shifts of the phenol hydroxyl protons

The chemical shift of protons involved in hydrogen bonding has frequently been used as an indication of the strength of the hydrogen bond. Whereas weak hydrogen bonding results in only a slight downfield shift, stronger hydrogen bonding results in large downfield shifts, sometimes below 20 ppm (17). Jones and Dyer (24) found the proton chemical shift for the lithium, sodium, and potassium salts of $H(CF_3CO_2)_2^-$ in trifluoroacetic acid solutions to be 15.73, 16.94, and 19.17 ppm, respectively. One of the main conclusions of ref. 24 is that the presence of a cation near the $H(CF_3CO_2)_2^-$ anion causes the downfield shift of the proton to be smaller and dependent on the distance separating the two ions. As noted for trifluoroacetic acid solutions (24), the most upfield shift is found for the smaller, more electronegative cations, which would be expected to associate more strongly with the anion. The findings of Jones and Dyer (24) apply directly to the interpretation of the phenolic hydroxyl proton chemical shifts found in this work.

Table 4 gives the chemical shifts of the phenolic protons of **1–4**, **6**, and **8–12** as obtained from deuterated DME solutions (**5** and **7** were insoluble in this solvent). Table 4 also includes the chemical shift values found for deuterated DME solutions containing only the sodium or potassium phenoxide salts with phenol being present in the ratios of 1:1–1:4 (salt:phenol). The concentration of all solutions in Table 4 was 0.07 molar for the complexes in Section A, as well as for NaOPh and KOPh in the mixtures in Section B.

Fujio and Tsuno (25) have determined the hydroxyl chemical shifts of *m*- and *p*-substituted phenols in acetonitrile and carbon tetrachloride in the presence of benzyltri-*n*-butylphosphonium chloride. It was found that hydrogen bonding to the chloride anion shifted the hydroxyl proton signals significantly downfield with the largest shift difference being about 5.5 ppm. In our case, in DME-d_{10} the largest downfield shift difference in the absence of a macrocycle is 8.4 ppm (Table 4, Section B) for the solution containing phenol and one equivalent of KOPh.

Phenol itself has a chemical shift for the OH proton of 7.57 ppm in DME-d_{10}. A 1:1 solution of NaOPh:HOPh has an OH chemical shift of 11.02 ppm. With two and three equivalents of phenol in the solution only slight changes in chemical shifts to 11.19 and 11.10 ppm, respectively, occur. The presence of a fourth equivalent of phenol causes an upfield shift to 10.73 ppm. The relatively constant chemical shift for NaOPh solutions containing one, two, and three phenols is consistent with the cation making less contact with the anion, as the number of phenol equivalents increases, and with the effective charge on the anion consequently increasing. As a result, the chemical shift does not move upfield as would be expected. In the crystal structure of $[(C_6H_5OH)_4][C_6H_5O^-][Me_4N^+]$, three phenols are hydrogen bonded to the anion oxygen whereas the fourth phenol is hydrogen bonded to one of the other phenol oxygens (20). If this type of structure occurs in our solutions, then the upfield shift in the solution with four equivalents of phenol is readily explained.

The potassium phenoxide/phenol solutions exhibit different behaviour. The solution with one equivalent of each has an OH chemical shift of 16.00 ppm, a downfield shift more than twice as large as that found for the corresponding NaOPh solution (relative to phenol itself). Thus, as expected from the work of Jones and Dyer (24) discussed above, the potassium cation is less associated with the anion than is the smaller sodium cation. Only upfield shifts were found in solutions of potassium phenoxide containing 2, 3, and 4 equivalents of phenol.

The chemical shifts in Table 4 for the complexes are interesting from several points of view. Without exception, the

NaOPh + 2HOPh	11.19 ± 0.04	KOPh + 2HOPh	13.49 ± 0.05
NaOPh + 3HOPh	11.10 ± 0.16	KOPh + 3HOPh	12.19 ± 0.23
NaOPh + 4HOPh	10.73 ± 0.09	KOPh + 4HOPh	11.15 ± 0.09

[a]Relative to internal TMS. The values shown are the average chemical shifts obtained from three different solutions except for **9** and **10** where four solutions were used. Standard deviations are shown.

[b]The concentration of the complexes (Section A) was 0.07 molar and the concentration of NaOPh and KOPh in the solutions of Section B was also 0.07 molar.

[c]Complexes **5** and **7** were not sufficiently soluble in DME-d_{10}.

chemical shifts for the phenol protons in the complexes (Section A) are downfield relative to those found for the corresponding phenol/phenoxide solutions (Section B). This is as expected since the contact of the anion and the cation should be reduced by the complexation of the cation by the macrocycle. These differences in chemical shift are much greater for the sodium complexes (differences range from 2.34 to 3.98 ppm) than for the potassium complexes (differences range from 0.51 to 0.84 ppm). This simply reflects the fact that, for the solutions in Section B, the sodium cations were much more closely associated with the anions than were the potassium cations in the corresponding solutions. It is to be noted from Table 4 that, for pairs of complexes where the same macrocycle is used but different phenoxide salts (e.g. **1** and **2**, **3** and **4**, etc.), the potassium salts have chemical shifts that are downfield to those of the corresponding sodium salts. This is in agreement with the findings of ref. 24 (*vide supra*).

The largest chemical shifts in Section A of Table 4 are exhibited by **9–12**. It is known that, in **12**, only one of the oxygens of the $PhO^- \cdots H^+ \cdots OPh^-$ unit is coordinated to the cation (13). Thus, a larger effective charge (and consequently a larger chemical shift) would likely result when compared to that for structures similar to **5** (13) where all of the oxygens are coordinated to the cation. The fact that the chemical shift for **11**, which involves the larger K^+ (which should be complexed more strongly by the cavity of the DC-18-crown-6(A) macrocycle), is further downfield by 1.75 ppm is an indication that the phenol/phenoxide orientation found in **12** could also be present in **11**. The chemical shifts for the **9** and **10** pair are very close to those for **11** and **12**, respectively.

When the chemical shifts for complexes **9–12** are compared to those of the corresponding complexes containing two molecules of phenol (**1–4**), it is seen that the chemical shifts for the potassium complexes are downfield by about 2.7 ppm and those for the sodium complexes are downfield by about 1.4 ppm. It is to be noted that the chemical shifts of the 1:1:1 complexes of **6** and **8** (14.40 and 14.20 ppm, respectively) are upfield by about 0.6–0.8 ppm to the 1:1:1 complexes **10** and **12**, which also involve the sodium cation. Interestingly, the crystal structure of complex **5** (a member of the series **5–8**) shows all of the oxygens of the phenol/phenoxide units to be coordinated to the encapsulated cations. If this type of structure is present in **6** and **8** then this would explain the upfield shift compared to **10** and **12**. It is not expected that the complexes have dissociated to any significant extent in the dry DME-d_{10} solutions used, since these complexes were obtained from ethereal solutions in the first place. From the available data, however, we cannot be certain that, even in these relatively nonpolar solutions, a proportion of the complexes has not dissociated.

It is interesting to note that relatively large downfield shifts have also been found for the OH chemical shifts of adducts of phenol with neutral bases. Thus, Eyman and Drago (26) report a value for the adduct of phenol and pyridine of 10.88 ppm in methylene chloride at 30°C.

Experimental

Commercial anhydrous diethyl ether was dried over sodium wire. Reagent grade 1,2-dimethoxyethane and tetrahydrofuran were distilled from lithium aluminum hydride using a Stedman column and a variable take-off still head. Phenol was sublimed under vacuum prior to use. Potassium and sodium phenoxide were prepared as before (5). Isomers A and B of DC-18-crown-6 were separated from the commercial mixture by the method of Izatt *et al.* (27); mp 60.2–61.2°C (lit. (27) mp 61–62°C) and mp 81.5–82.5°C (lit. (27) mp 83–84°C), respectively. DB-18-crown-6 was recrystallized from toluene; mp 161.5–163°C (lit. (28) mp 164°C and (29) mp 162.5–163.5°C). Commercial 18-crown-6 was precipitated as the acetonitrile complex (30) and the acetonitrile was removed under vacuum; mp 40.5–41.0°C (lit. (1) mp 39–40°C).

Great care was taken throughout this work to protect the samples from atmospheric moisture. All complexation reactions, the preparation of Nujol mulls, and the preparation of samples for nmr were carried out in a Dri-Lab (Vacuum Atmospheres) under an argon atmosphere.

Synthesis of complexes 1–8

Phenol (0.0051 mol) and the appropriate phenoxide salt (0.0017 mol) were stirred in dry ethereal solvent for 15 min. The macrocyclic ether was added (0.0017 mol) and, after a stirring period of 1 h, the

precipitated complex was collected by filtration and washed with dry diethyl ether. The complex was then subjected to high vacuum (<0.001 Torr; 1 Torr = 133.3 Pa) at 56°C overnight.

Table 2 gives the volume of the ethereal solvent or solvent mixture used and the yield of each complex obtained. Table 5 gives the elemental analyses for complexes **1–12**. All complexes were colourless salts.

*Synthesis of complexes **9–12***

The same procedure was used as described above except that only 1.05 equivalents of phenol were used instead of three equivalents.

The complexes with 1:1:1 ratios could be recrystallized from the same solvent or mixture of solvents used to form the complex. The only exception was the complex DC-18-crown-6(B)·NaOPh·HOPh (**6**). In this case, recrystallization gave DC-18-crown-6(B)·2NaOPh (see ref. 5 for the synthesis of this complex) as the precipitated product.

Complexes with 1:1:2 ratios could not be recrystallized from the solvents in which they were formed. The precipitated products from the recrystallizations had crown:salt:phenol ratios between 1:1:1 and 1:1:2. However, the products obtained directly from the complexation reactions gave satisfactory elemental analyses, good mp's, and integrated proton nmr spectra in agreement with the ratios shown in Table 1.

Infrared spectra of the complexes

A Perkin–Elmer infrared spectrophotometer (model 283) was used. Spectra were obtained on Nujol mulls of the complexes using ZnSe optically flat windows (25 mm diameter × 2 mm thick).

Nuclear magnetic resonance spectra of the complexes and phenol/phenoxide solutions

Proton magnetic resonance spectra were obtained at 200.058 MHz on a Varian XL-200 spectrometer using a 5-mm computer-switchable probe. Chemical shifts are relative to internal TMS. The 1,2-dimethoxyethane-d_{10} was dried over activated molecular sieves. A spectrum of the dried solvent was run at high amplitude and compared with that of the undried solvent to ensure that the trace of water present initially had been removed. We have found that even a trace of water can cause a 1-ppm or more upfield shift of the phenol hydroxyl proton peak.

Received February 9, 1987

MARIE E. FRASER, SUZANNE FORTIER, MARY K. MARKIEWICZ, ANDRÉ RODRIGUE, and JOHN W. BOVENKAMP. Can. J. Chem. **65**, 2558 (1987).

The crystal structures of the 1:1:1 complexes of dicyclohexano-18-crown-6 (isomer B) with potassium phenoxide and phenol, and of dicyclohexano-18-crown-6 (isomer A) with sodium phenoxide and phenol have been determined. The potassium phenoxide complex crystallizes in space group *Pnca* with $a = 14.150(3)$, $b = 23.794(6)$, $c = 9.491(1)$ Å, and $Z = 4$. The sodium phenoxide complex crystallizes in space group *Pbca* with $a = 21.201(4)$, $b = 24.406(6)$, $c = 12.492(3)$ Å, and $Z = 8$. Both structures were solved by direct methods and refined by full matrix least-squares calculations to residuals, R, of 0.059 for the potassium phenoxide complex, and 0.069 for the sodium phenoxide complex. In the potassium phenoxide complex, the cation sits on a centre of symmetry, in the centre of the cavity formed by the crown ether in its regular conformation. The potassium is coordinated to all six crown oxygens as well as to two phenol/phenoxides, one on each side of the crown. Groups of phenol/phenoxide–potassium–phenol/phenoxide are linked by the hydrogen atoms to form a chain: $K^+ \ldots O \ldots H \ldots O \ldots K^+$. The distance between the oxygens of the phenol/phenoxides is short, 2.48(1) Å. The hydrogen was initially located halfway between the two oxygens, on a 2-fold axis special position. Inspection of the difference Fourier map and refinement on the hydrogen position revealed, however, the presence of statistical or dynamical disordering. In the sodium phenoxide complex, the hexaether adopts an irregular conformation. The distances between the sodium and the crown oxygens range from 2.45 to 2.89 Å, while a distance of 2.363 Å is found with the phenoxide oxygen. Strong hydrogen bonding is found between the oxygens of the phenol and phenoxide. The O....O distance is 2.471(4) Å.

MARIE E. FRASER, SUZANNE FORTIER, MARY K. MARKIEWICZ, ANDRÉ RODRIGUE et JOHN W. BOVENKAMP. Can. J. Chem. **65**, 2558 (1987).

On a déterminé les structures cristallines des complexes 1:1:1 du dicyclohexano-18-couronne-6 (isomère B) avec le phénolate de potassium et le phénol et du dicyclohexano-18-couronne-6 (isomère A) avec le phénolate de sodium et le phénol. Le complexe du phénolate de potassium cristallise dans le groupe d'espace *Pnca*, avec $a = 14,150(3)$, $b = 23,794(6)$ et $c = 9,491(1)$ Å et $Z = 4$. Le complexe du phénolate de sodium cristallise dans le groupe d'espace *Pbca*, avec $a = 21,201(4)$, $b = 24,406(6)$ et $c = 12,492(3)$ Å et $Z = 8$. On a résolu les deux structures par des méthodes directes et on les a affinées par les méthodes des moindres carrés jusqu'à des valeurs résiduelles, R, de 0,059 pour le complexe du phénolate de potassium et de 0,069 pour le phénolate de sodium. Dans le complexe du phénolate de potassium, le cation se trouve sur un centre de symétrie, au centre de la cavité qui est formée par l'éther couronne dans sa conformation régulière. Le potassium est coordonné aux six oxygènes de la couronne ainsi qu'à deux phénol/phénolate, un de chaque côté de la couronne. Les groupements phénol/phénolate–potassium–phénol/phénolate sont liés par des atomes d'hydrogènes qui forment une chaîne : $K^+ \ldots O \ldots H \ldots O \ldots K^+$. La distance entre les oxygènes du phénol/phénolates est courte, 2,48(1) Å. Au début de l'affinement, l'hydrogène se trouve à mi-chemin entre les deux oxygènes, dans une position spéciale sur un axe binaire. Une inspection de la carte différentielle de Fourier et un affinement sur la position de l'hydrogène révèle toutefois la présence d'un désordre statistique ou dynamique. Dans le complexe du phénolate de sodium, l'éther couronne adopte une conformation irrégulière. Les distances entre le sodium et les oxygènes de l'éther varient de 2,45 à 2,89 Å et on trouve une distance de 2,363 Å avec l'oxygène du phénolate. On trouve qu'il existe une forte liaison hydrogène entre les oxygènes du phénol et le phénolate. La distance O....O est égale à 2,471(4) Å.

[Traduit par la revue]

Introduction

The first ternary crown ether complexes were reported in 1971 by Pedersen (1) who obtained these 1:1:1 complexes by reaction of alkali metal thiocyanate and iodide complexes of benzo-15-crown-5 and dibenzo-18-crown-6 with thiourea in methanol. Although the exact nature of the complexes could not be established, ultraviolet spectroscopy indicated that the complexation of the metal ion in the 1:1:1 complex of dibenzo-18-crown-6, potassium thiocyanate, and thiourea was essentially the same as in the 1:1 complex of dibenzo-18-crown-6 and potassium thiocyanate. It was thus concluded that, at least in this 1:1:1 complex, the thiourea had no significant effect. This was later confirmed in the 1:1:1 complex of dibenzo-18-crown-6, potassium iodide, and thiourea, for which a crystal structure determination was reported (2). In this structure, thiourea does not participate in the coordination of the metal ion nor does it have any contact with the crown ligand. Instead, it contributes to the stabilization of the anion by forming polymeric hydrogen-bonded sheets.

In the present paper, the crystal structures of two new ternary crown ether complexes, the 1:1:1 complexes of DC-18-crown-6 (isomer B), potassium phenoxide, and phenol and DC-18-

crown-6 (isomer A), sodium phenoxide, and phenol are presented. These structural results are compared to those reported in a previous publication (3) on the 1:2 host:guest complexes of DC-18-crown-6 (isomers A and B) with sodium and potassium phenoxide.

Experimental

The synthetic method used for the preparation of the two complexes has been described in a previous publication (4).

The crystal of DC-18-crown-6 (isomer B)·KOPh·HOPh was grown during an attempt to obtain suitable crystals of DC-18-crown-6 (isomer B)·2KOPh from a large amount of 1,3-dioxolane by slow evaporation of the solvent in an argon atmosphere. The solvent used was not totally anhydrous. Subsequently DC-18-crown-6 (isomer B)·KOPh·HOPh was obtained by reacting DC-18-crown-6 (isomer B) with a solution containing one equivalent of KOPh and an excess of phenol (4). Both samples had the same melting point of 149–151°C.

The crystal of DC-18-crown-6 (isomer A)·NaOPh·HOPh was obtained from a solution of DC-18-crown-6 (isomer A)·NaOPh·2HOPh in a mixture of tetrahydrofuran – diethyl ether (volume ratio of 2 to 15). The solution was slowly evaporated to dryness in an argon atmosphere. Under these conditions the complex containing two molecules of phenol gave crystals of the complex containing only one molecule of phenol. The crystallized complex had a melting point of 112.5–114.5°C.

Pertinent data about the crystals used and the measurement of diffraction intensities are summarized in Table 1. For the Na^+ complex, the crystal used in the diffraction experiment was mounted inside a glass capillary in an oxygen-free atmosphere. For the K^+ complex, the crystal was mounted in the usual manner, at the tip of a glass fibre. The intensity data were collected on an Enraf– Nonius CAD-4 diffractometer using graphite monochromated radiation, MoKα (λ = 0.71073 Å), for the K^+ complex, and CuKα (λ = 1.5418 Å), for the Na^+ complex. In each case, intensities were collected by the θ/2θ scanning procedure and three reflections were measured after every 7200 s of exposure time to check on the stability of the crystals. No evidence of crystal decay was detected for the K^+ complex. For the Na^+ complex, a 5.5% loss in intensity was observed and a linear decay correction was applied. A numerical absorption correction was also applied to the Na^+ complex intensity data. The minimum, maximum, and average transmissions were found to be 0.7014, 0.9249, and 0.8770 respectively. For both complexes, the data were corrected for Lorentz and polarization effects. The structures were solved by direct methods using the program MULTAN80 (5). For the K^+ complex, 14 of the 24 hydrogen atoms in the asymmetric unit, including the phenol hydrogen, were found in the difference Fourier map; the remaining 10 were calculated. For the Na^+ complex, the positions of all the hydrogen atoms were found in the maps. The structures were refined by full matrix least squares using all reflections with $I \geqslant 3\sigma(I)$. Anisotropic temperature factors were used for the non-hydrogen atoms. Isotropic temperature factors were used for the phenol hydrogens whose positions were also refined. The remaining hydrogen atoms were assigned temperature factors equal in magnitude to the equivalent isotropic values of their parent atoms and were included in the calculations, but neither their positions nor their temperature factors were refined. The function minimized was $\Sigma w||F_o| - |F_c||^2$, where $w = 1/\sigma^2(|F_o|)$. A correction for isotropic secondary extinction effect was included in each refinement. The scattering factors were taken from Cromer and Waber (6). All calculations were done on a PDP 11/23 computer using the Enraf–Nonius SDP program package (7).[2]

Results and discussion

The 1:1:1 complex of DC-18-crown-6 (isomer B) with potassium phenoxide and phenol

An ORTEP (8) drawing of the complex showing the atom numbering scheme is given in Fig. 1. The fractional coordinates and equivalent isotropic temperature factors of the non-hydrogen atoms are presented in Table 2. Oxygen–potassium bond lengths and angles appear in Table 4, average and range in the

bond lengths and angles of the host and of the phenol/phenoxide are given in Table 5, macrocyclic ring torsion angles appear in Table 6.

Host geometry and conformation

In the present crystal structure, the *cis–anti–cis* isomer of DC-18-crown-6 has a crystallographic centre of symmetry. The crown oxygens form a nearly regular hexagon and thus outline a circular cavity. The hexaether is found in the regular conformation with all torsion angles about C—C bonds synclinal and

those about C—O bonds antiplanar. As shown in Table 5, bond lengths and angles are in the expected range. The cyclohexyl ring is found in the chair conformation with an average absolute torsion angle value of 56.2°.

Host–guest interactions

The potassium ion sits on the crystallographic centre of symmetry of the hexaether, in the ideal nesting position. The average distance of 2.81 Å between the potassium and the crown oxygens is identical to the value observed in the KNCS complex of 18-crown-6 (9) in which the metal ion is also found in the ideal nesting position. The longer distance of 3.103 Å, observed between the potassium and the phenol/phenoxide oxygens, compares also with the value of 3.19 Å found between the potassium and each terminal atom, N or S, in the KNCS complex of 18-crown-6 (9). It is interesting to compare the complexation of the potassium ion in the present structure to that found in the 1:2 host:guest complex of DC-18-crown-6 (isomer

[a]The primed atoms are related to the unprimed atoms by the following symmetry operation: $-x, -y, -z$.

B) with potassium phenoxide (3). In the latter complex, the potassium ions are pulled out of the approximate plane defined by the crown oxygens by a distance of 1.678 Å. Each of the potassium ions is coordinated to four crown oxygens with an average K....O distance of 2.87 Å, and to the oxygens of the two phenoxide groups with an average distance of 2.60 Å. These differences clearly show the important role played by hydrogen bonding in the structural characteristics of these host–guest complexes. In the 1:1:1 complex, groups of phenol/phenoxide–potassium–phenol/phenoxide are linked by the hydrogen atoms to form a chain: $K^+...O...H...O...K^+$. The anion is stabilized by hydrogen bonding, which facilitates complexation of the metal ion by the hexaether ligand. As a result, the ligand is left in the regular conformation with its guest in the ideal nesting position. In the 1:2 complex, on the other hand, the hard anions are strongly associated with the potassium ions and are able to pull them out of the crown cavity. The net result is an unusual 1:2 host:guest structure with a distorted hexaether ligand.

The role played by the phenol in the present structure is similar to that played by thiourea in the 1:1:1 complex of dibenzo-18-crown-6, potassium thiocyanate, and thiourea (2). The phenol stabilizes the anion through hydrogen bonding. As a result the complexation of the potassium ion by the hexaether ligand is essentially the same as was found when the counterion was the soft SCN^- anion (9).

Hydrogen bonding

The phenol hydrogen was initially located on the twofold axis special position of space group *Pnca*, thus exactly halfway between the two oxygens of the phenol/phenoxide groups. Close inspection of the difference Fourier map section defined by the O···H···O plane shows clearly, however, elongation of the hydrogen peak towards the oxygens, which suggests the presence of statistical or dynamical disordering. This is also supported by the refinement on the hydrogen position, which converges with the hydrogen being distributed on either side of the twofold axis. The hydrogen bond is strong, as can be seen from the short O···O distance of 2.48(1) Å (10, 11). With the hydrogen distributed on either side of the twofold axis, O—H distances of 0.77(6) and 1.76(7) Å are found and the O—H—O angle is 156(8)°.

The 1:1:1 complex of DC-18-crown-6 (isomer A) with sodium phenoxide and phenol

An ORTEP (8) drawing of the complex showing the atom numbering scheme is given in Fig. 2. The fractional coordinates and equivalent isotropic temperature factors of the non-hydrogen atoms are presented in Table 3. Oxygen–sodium bond lengths and angles appear in Table 4, average and range in the bond lengths and angles of the host and of the phenol and phenoxide are given in Table 5, macrocyclic torsion angles appear in Table 6.

Host geometry and conformation

As can be seen from Fig. 2 and from Table 6, the conformation of the host, the *cis–syn–cis* isomer of DC-18-crown-6, is irregular with several of the torsion angles about the C—O bonds deviating severely from the expected range. Four of the crown oxygens, O(3), O(9), O(12), and O(18) define an approximate plane that is at a distance of 1.139(3) Å from the sodium ion. The remaining two oxygens, O(6) and O(15), are folded out of the plane, towards the Na^+ ion. Distortion of the 18-crown-6 macrocycle to accommodate the sodium ion was also found in the hydrated sodium thiocyanate complex of 18-crown-6(9) and in the 1:2 host:guest complex of DC-18-crown-6 (isomer A) and sodium phenoxide (3). In each case, the distortion is due to crown oxygens folding out of the macrocycle approximate plane towards the cation guest. In the hydrated thiocyanate sodium complex of 18-crown-6, one oxygen is out of the plane, while in the 1:2 host:guest complex of DC-18-crown-6 (isomer A) and sodium phenoxide, two adjacent oxygens are involved in the distortion. In the present complex, the distortion is caused by two opposite oxygen atoms folding out of the macrocycle approximate plane.

As shown in Table 5, bond lengths and angles are in the expected range. The cyclohexyl rings are found in the chair conformation with average absolute torsion angle values of 57.3° and 56.6°.

Host–guest interactions

The sodium ion is coordinated to all six oxygens of the crown ligand. The sodium crown oxygen distances range from

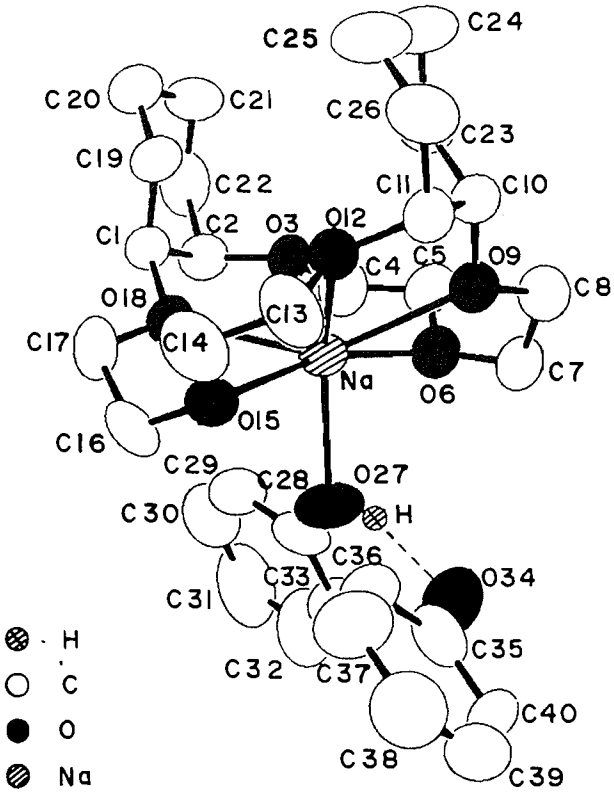

FIG. 2. ORTEP diagram and numbering scheme for the 1:1:1 complex of DC-18-crown-6 (isomer A), sodium phenoxide, and phenol.

2.452(4) to 2.886(4) Å with an average value of 2.608 Å. These distances are relatively long but are in the range of values observed in other 18-crown-6 complexes with sodium ion guests (12, 13). A distance of 2.363(3) Å is found between the sodium and the phenoxide[3] oxygen, while the phenol oxygen is found at a distance of 4.106(3) Å from the sodium. As in the potassium complex, the anion is stabilized by the phenol through hydrogen bonding.

In the 1:2 host:guest complex of DC-18-crown-6 and sodium phenoxide, on the other hand, the two sodium ions are strongly associated with the phenolate anion. One sodium is coordinated to only one crown oxygen at a distance of 2.425 Å and to three phenoxide oxygens at an average distance of 2.23 Å. The second sodium is coordinated to all six crown oxygens at distances ranging from 2.358 to 2.842 Å, with an average value of 2.55 Å, and to one phenoxide oxygen located at a distance of 2.323 Å.

Hydrogen bonding

A strong hydrogen bond is found between the phenol and phenoxide oxygens. The O...O distance is 2.471(3) Å and the O—H, O...H distances are found to be 1.35(4) and 1.38(4) Å. The O—H—O angle, at a value of 130(3)°, shows a strong deviation from linearity that is unusual for a hydrogen bond of this strength (10, 11). This result, however, must be taken with caution in view of the imprecision associated with the hydrogen position, as apparent in the large values of the standard deviation.

[3]From the O—H distances, it is not possible to distinguish the phenol from the phenoxide oxygen. We are using the term phenoxide oxygen to refer to the oxygen that is coordinated to the sodium ion.

Conclusions

Several factors contribute to the structural characteristics of host–guest complexes. It is well known that ligand and salt (both cation and anion), as well as solvent parameters, play a role in the structural features of these complexes (14). In the present paper, two examples are given of complexes in which hydrogen bonding is seen to have a marked effect. In particular, comparison of the present 1:1:1 complexes of DC-18-crown-6 (isomers A and B) with sodium and potassium phenoxide and phenol with the 1:2 complexes of DC-18-crown-6 (isomers A and B) with sodium and potassium phenoxide shows that stabilization of the anion by hydrogen bonding affects the cation–anion interaction as well as the ligand – metal ion complexation and, in turn, the ligand conformation.

High resolution ^{13}C CPMAS spectra for three configurationally isomeric dicyclohexyl-18-crown-6 ethers and three complexes derived therefrom are presented. Spectra are consistent with conformationally locked crown ether structures at 298 K. Data are discussed in terms of the symmetry properties of the macrocycles and stereochemical effects on ^{13}C chemical shifts in the solid phase. For the complex of 18-crown-6 with NaSCN and H_2O, a single line is observed at 298 K. Temperature reduction removes the chemical shift averaging as the different torsional angles of the solid crown ether undergo distortions that become slow on the nuclear magnetic resonance timescale.

G. W. BUCHANAN, M. Z. KHAN, J. A. RIPMEESTER, J. W. BOVENKAMP et A. RODRIGUE. Can. J. Chem. **65**, 2564 (1987).

On rapporte les CPMAS du ^{13}C à haute résolution de trois éthers dicyclohexyl-18-couronnes-6 qui sont configurationnellement isomères. Les spectres sont en accord avec des structures d'éthers couronnes qui seraient conformationnellement figées à 298 K. On discute des données en fonction des propriétés de symétrie des macrocycles et des effets stéréochimiques, dans la phase solide, sur les déplacements chimiques en résonance magnétique nucléaire du ^{13}C. À 298 K et dans le H_2O, on n'observe qu'une seule bande pour le complexe de l'éther 18-couronne-6 avec le NaSCN. Une diminution de la température élimine les déplacements chimiques moyens alors que les différents angles de torsion de l'éther couronne solide subissent des distorsions qui deviennent lentes sur l'échelle de temps de la résonance magnétique nucléaire.

[Traduit par la revue]

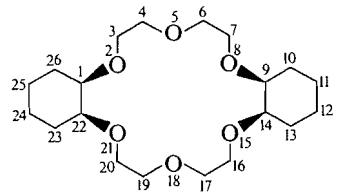
Introduction

In the past two years, several attempts have been made to apply solid phase ^{13}C nmr spectroscopy via the CPMAS (cross-polarization magic angle spinning) technique, to the stereochemical analysis of crown ethers and their complexes (1–3). The success of such efforts, however, depends greatly on the quality of spectra obtained. In the first report by Belton *et al.* involving dibenzo-30-crown-10, dibenzo-24-crown-10, and benzo-15-crown-5 systems, resolution of 0.1 ppm was obtained (1) at 75.5 MHz with high signal-to-noise ratios.

Unfortunately, this was followed by publication of 75.5-MHz spectra of inferior quality by Tabeta and Saito (2), which led to some erroneous conclusions regarding the stereochemical features of two dicyclohexyl-18-crown-6 isomers. Our early communication in the field (3) illustrated some high resolution ^{13}C spectra at 45.3 MHz for one isomer of dicyclohexyl-18-crown-6 and two complexes thereof.

Presently we report results of our studies on three configurationally isomeric dicyclohexyl-18-crown-6 ethers and some unique complexes with alkali metal phenoxides and phenol. Specifically the free *cis-syn-cis* (**1**), *cis-anti-cis* (**2**), and *trans-syn-trans* (**3**) isomers depicted below have been examined.

In addition, the 1:2 complex of **1** with sodium phenoxide, the 1:2 complex of **2** with potassium phenoxide, and the 1:1:1 complex of **2** with phenol and phenoxide have been studied. One complex of 18-crown-6 has also been included. Conclusions regarding symmetry are compared with those from X-ray data and stereochemical features of ^{13}C shieldings in solids are discussed.



Results and discussion

Free crown ethers

The 45.3-MHz ^{13}C CPMAS spectra of **1**, **2**, and **3** are presented in Fig. 1. For **1**, which is also known as isomer A, there are seven resolved carbon resonances in the 19–32 ppm region, corresponding to non-oxygenated carbons, with one instance of peak overlap. This indicates the absence of any symmetry in the crystal structure of **1**, since eight non-oxygenated carbons would be expected in such a case. By contrast, Tabeta and Saito (2) report just two resolved resonances in this region. An examination of their published spectra indicates that the ^1H decoupling power employed appears to be only about 50% of that required for adequate removal of all ^{13}C–^1H coupling effects. Hence the published spectra (2)

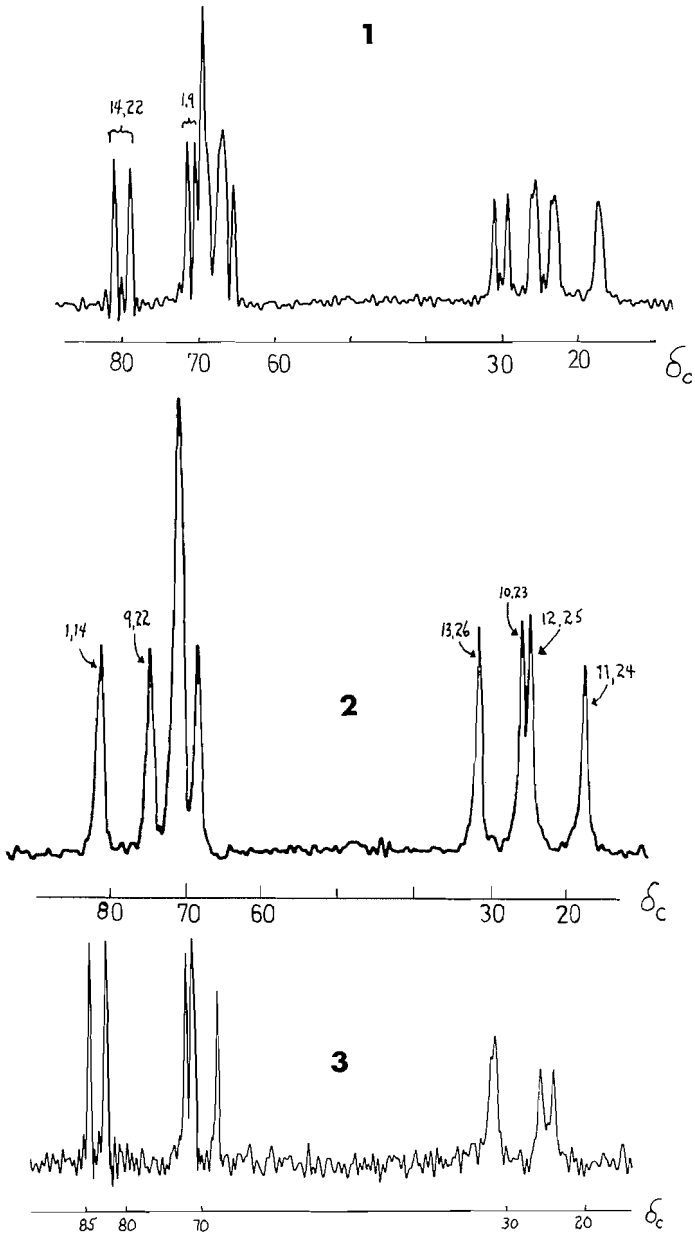

FIG. 1. The 45.3-MHz ^{13}C CPMAS spectra of *cis-syn-cis* (**1**), *cis-anti-cis* (**2**), and *trans-syn-trans* (**3**) dicyclohexano-18-crown-6 ethers.

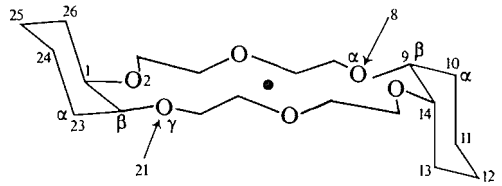
appear as broad multiplets that are barely visible above the baseline noise in many cases.

Further evidence for the complete lack of symmetry in **1** comes from the observation of two resonances at 81.2 and 79.0 ppm arising from the cyclohexyl methine carbons bearing equatorial oxygen. Similarly the lines at 70.5 and 71.5 ppm are due to their axially oxygenated counterparts. A preliminary report of the X-ray structure of **1** has been communicated by Dalley *et al.* (4). There is distortion in the central cavity of the molecule as reflected in the oxygen–oxygen contact distances, leading to complete loss of symmetry. Somewhat surprisingly, this point was not emphasized by the authors at the time.

By contrast, it was found (4) that the *cis-anti-cis* isomer (**2**), also known as isomer B (B′ polymorph), shows no distortions in the macrocyclic cavity and there is a crystallographic centre of symmetry.

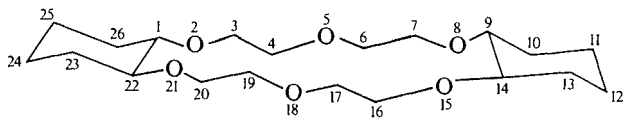
The ^{13}C CPMAS spectrum is consistent with a conformationally locked crown ether in which there is a centre of symmetry



and the asymmetric unit is half the molecule. In such a structure, one would expect to observe 10 ^{13}C resonances in the absence of any accidental peak overlap. The spectrum (Fig. 1) shows four non-oxygenated carbons, with the symmetry equivalent C-11,24 resonance at highest field (19.6 ppm) due to the γ-*gauche* relationship with the axial O-8 and O-21 sites respectively (5). Appearing at 26.6 ppm is the resonance due to the C-12,25 pair, which are *trans*-γ to the equatorial O-15 and O-2 sites respectively. This assignment is made by analogy with the spectrum observed in solution at 183 K (6) where ring inversion is effectively stopped on the nmr timescale. Ring carbons which are β to equatorial oxygen, i.e., C-13 and C-26, give rise to the line at 33.0 ppm, so that the remaining resonance at 27.2 must be due to C-10,23.

In the oxygenated carbon region, the intensities are in the ratio of 1:3:1:1 with two instances of peak overlap. The resonance at 81.1 ppm arises from C-1,14, which bear equatorial oxygens. The corresponding carbons C-9,22, bonded to axial oxygens, appear at 75.0 ppm. Interestingly, in the solid there is no evidence for minor conformations of **1** or **2**, in contrast to their behaviour in solution (5, 6). The chemical shifts in the solid are, however, within 1–2 ppm of those found for the major conformation in solution at 183 K where ring inversion is slow on the nmr timescale (6).

For the *trans-syn-trans* isomer **3** below (7), no X-ray data are available. The CPMAS spectrum shows four non-oxygenated carbons in the range of 23.5–31.6 ppm and six resonances (allowing for one peak overlap) in the 67.8–84.6 ppm range. These results indicate that the asymmetric unit in the crystal of **3** is one-half the molecule, which could arise due to a centre of symmetry or a C_2 axis most likely passing through the O-5 and the O-18 atoms of the macrocycle.



3

Interestingly, the highest field resonance of **3** is at 23.5 ppm, whereas **1** and **2**, which both possess a *cis* linkage, have resonances near 19.5 ppm. In **3** there are only *trans*-γ interactions involving the C-11, -12, -24, and -25 sites whereas in **1** and **2** there are an equal number of *trans*-γ and *gauche*-γ interactions experienced by these sites. It is well known (5) that *gauche*-γ interactions involving carbon and oxygen induce upfield shifts of 4–6 ppm at the carbon relative to the corresponding *trans*-γ interactions, so that the result is consistent with the all-*trans* stereochemistry of **3**. Similarly the C-1, -9, -14, -22 resonances appearing at 82.4 and 84.6 ppm are downfield of those for corresponding carbons of **1** and **2** since there are only β-equatorial effects of oxygen present in **3**.

Complexes

The ^{13}C CPMAS spectra of the three dicyclohexyl-18-crown-6 complexes examined are illustrated in Fig. 2.

*(i) The 1:2 complex of **1** with sodium phenoxide*

Preparation and characterization of this complex were reported

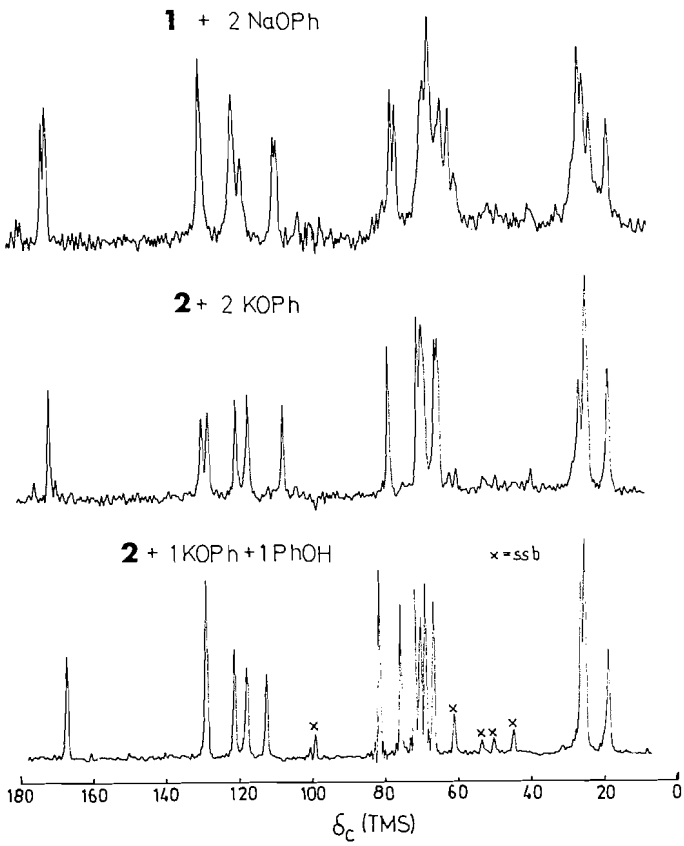


FIG. 2. The 45.3-MHz ^{13}C CPMAS spectra of complexes of **1** and **2**.

recently (8) and its X-ray structure has been published (9). The X-ray results indicate an irregular macrocyclic ring conformation in which no elements of symmetry exist. The solid phase ^{13}C spectrum reflects this despite several instances of peak overlap. For example there are two resonances near 82 ppm indicating that the cyclohexyl carbons bearing equatorial oxygens are different, as they were in free **1**, which lacks any elements of symmetry.

From inspection of the aromatic region one can draw some conclusions regarding the phenoxide environment. There are seven clearly visible lines in the range of 110–180 ppm with several instances of accidental peak overlap. This includes two resonances for oxygenated aromatic carbon near 178 ppm. Hence the two phenoxide rings must be in different environments in the crystal structure. Such a conclusion is in accord with the X-ray data (9).

*(ii) The 1:2 complex of **2** with potassium phenoxide*

The ^{13}C CPMAS spectrum of this complex (8) has just one resonance near 81 ppm, indicative of a single type of equatorially oxygenated cyclohexyl carbon. Allowing for two instances of peak overlap there are a total of 10 resonances in the aliphatic region, which suggests an element of symmetry must be present in the crown ether (either a centre or a plane).

In addition, there are six aromatic carbon resonances with no apparent peak overlap in the 110–180 ppm range. This suggests that the two phenoxide moieties are present in the crystal such that they are equivalent, but that the magnetic environment of each of the aromatic carbons is unique. These conclusions are in agreement with the recently completed X-ray study (9) on this novel structure. In the absence of X-ray data, an alternative rationale for the observed carbon nonequivalence could have been that the chemically equivalent (in solution) C-2,6 and C-3,5 sites are rendered magnetically nonequivalent in the solid by crystal packing forces. Such effects have been observed earlier for benzo-15-crown-5 ether (1).

*(iii) The 1:1:1 complex of **2** with phenol and potassium phenoxide*

The spectrum for this material (10) in Fig. 2 shows six clear resonances in the saturated oxygen-bearing carbon range of 60–82 ppm and three in the 20–35 ppm region. Assuming one instance of peak overlap in the latter group of lines, it therefore appears that there is an asymmetric unit of one-half a molecule for the crown ether itself in this complex. X-ray data (11) indicate that there is a centre of symmetry in the crown ether portion of this complex, in agreement with the nmr results.

In addition, there are five distinct resonances resolved in the aromatic region of 110–170 ppm. Given one instance of peak overlap near 130 ppm, one is forced to conclude that the aromatic rings of the phenoxide and phenol are equivalent in the crystal, but each aromatic unit lacks any symmetry elements, so that six ^{13}C resonances result. As shown by Figs. 1 and 2 of an accompanying paper (11), the hydroxyl proton and the potassium ion are situated so that they are equally "shared" between the oxygenated aromatic rings, rendering the latter equivalent.

In this complex, the aromatic carbon bearing oxygen resonates about 5 ppm upfield of those for the complexes involving only phenoxide. This is consistent with the approximately 50% phenolic character at this site. In solution, C-1 of phenol resonates ca. 12 ppm upfield of that for phenoxide (12, 13) and similar differences appear to exist in the solid.

(iv) The 1:1 complex of 18-crown-6 with H_2O and NaSCN

Finally, we have recorded the ^{13}C CPMAS spectrum of the complex of 18-crown-6 with NaSCN and one equivalent of water. In this spectrum at 298 K there is a single broad line at 68.6 ppm for the crown ether carbons. The linewidth at half-height is about 360 Hz, however, which is at least an order of magnitude greater than that normally seen in the spectra of these materials.

Results of the X-ray crystallographic analysis (14) indicate that there is a highly distorted crown structure in this complex, so that there is a complete lack of symmetry. The macrocyclic cavity adopts a conformation in which five approximately coplanar oxygen atoms surround the sodium ion. The remaining oxygen of the crown ether and a water molecule complete the distorted pentagonal bipyramidal coordination of the cation. It was found that the vibrational ellipsoids of the carbons in the irregular part of the macrocycle are large and anisotropic, suggesting that internal motions of the molecule are occurring to a substantial extent.

Accordingly we have recorded the ^{13}C CPMAS spectrum of this complex at lower temperatures in an attempt to slow down these internal motions sufficiently to produce resolvable signals for the macrocyclic carbons. As the spectra in Fig. 3 illustrate, partial success has been achieved with resolution of 7 out of the possible 12 resonances expected for the completely nonaveraged situation.

The chemical shifts for the 18-crown-6 carbons at 233 K range from 63.9 to 73.0 ppm. It is likely that these shift differences arise primarily from differences in the torsional angles present at each carbon, since it is well known (15) that ^{13}C shieldings are profoundly affected by *gauche* vs. *trans* torsional arrangements (or γ effects) depicted below. Carbons at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12

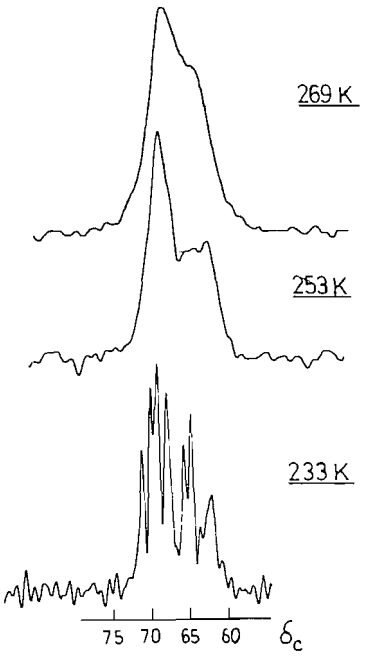

FIG. 3. The 45.3-MHz ^{13}C CPMAS spectra of the $NaNCS \cdot H_2O$ complex of 18-crown-6 as a function of temperature.

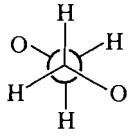
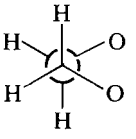
the termini, as well as at the central positions of the *gauche* arrangements are generally shifted upfield by 4–6 ppm relative to their counterparts in *trans* orientations.

From the X-ray data for this complex (14), one can group the carbons of 18-crown-6 into four general classes based on the number of *gauche*- and *trans*-type networks in which each is involved. There are 4 carbons (Class 1), which partake in 1 *gauche* and 3 *trans* interactions. Class 2 contains 5 carbons, which are involved in 2 *trans* and 2 *gauche* effects, while Class



trans



gauche

3 contains 2 carbons, which experience 1 *trans*, 2 *gauche*, and one 115° torsional geometries. Finally, Class 4 has just one carbon, which experiences no *trans* effects, 3 *gauche* effects, and one dihedral angle of 115°.

For the reasons outlined above, Class 1 carbons will resonate at lowest field while there will be a steady progression to higher field for Classes 2, 3, and 4 respectively. Since there is a difference of 2 *gauche* effects between Class 1 and Class 4, the total range of chemical shifts expected is 8–10 ppm. This agrees with experimental observations. Also the asymmetry in the spectrum at 233 K reflects, at least to a first approximation, the relative populations of Classes 1–4.

In conclusion, it is apparent that solid phase ^{13}C nmr represents a valuable addition to the available methods for examining crown ether stereochemistry, especially for the determination of asymmetric units in the crystal. The low temperature results reflect the potential of this technique for the observation of individual carbon environments that are not detectable in solution.

Experimental

Spectra

A Bruker CXP-180 spectrometer was employed to obtain the spectra at 45.3 MHz. Cross-polarization times of 2–5 ms were used with rf field amplitudes being 60 kHz. Normally 400–800 scans were accumulated. Sweep width was 20 kHz with a 4-s recycle time. Typically 2K data points were collected and FID's were zero filled to 8K before Fourier transformation. Magic angle spinning rates of ca. 3 kHz were achieved by using Kel-F spinners of the Andrew-Beams type. For the low temperature spectra, recycle times of 30–40 s were used due to the long ^1H T_1's. A probe supplied by Doty Scientific with spinners of a double air-bearing design was employed.

Materials

Compounds **1** and **2** were available from earlier work (5). The literature procedure (7) was followed for the preparation of **3**. Methods for preparation of phenoxide complexes have been reported (8). Synthesis of the 1:1:1 complex of **2** is reported in an accompanying paper (10) and the $NaSCN \cdot H_2O$ complex of 18-crown-6 has been described earlier (14).

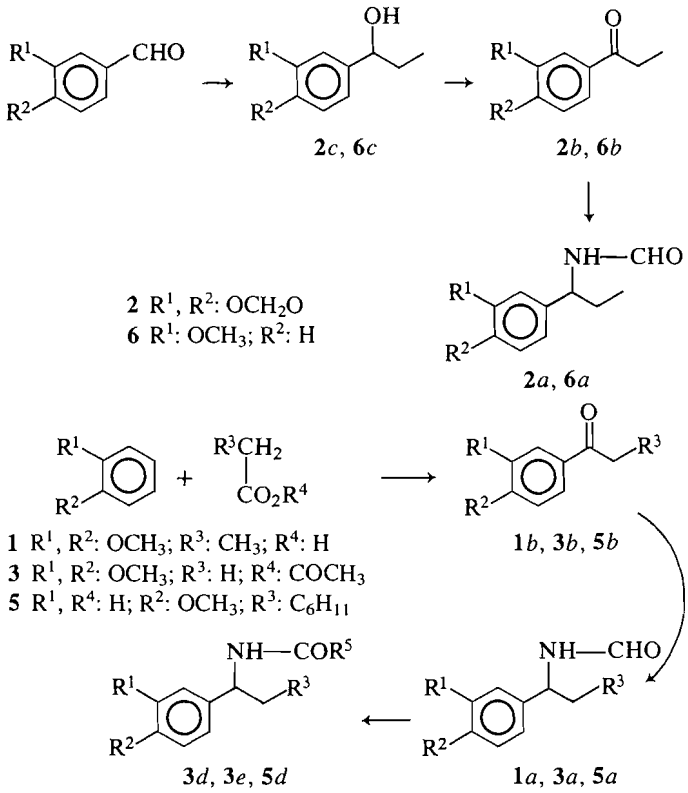
Phenylindanes were obtained from the reaction of *N*-acyl-1-arylalkylamines with polyphosphoric ester (PPE). *cis*-1-Methyl-3-(3,4-dimethoxyphenyl)-5,6-dimethoxyindane was synthesized to determine which stereoisomer was produced by *N*-formyl and *N*-acetyl-1-(3,4-dimethoxyphenyl)ethylamine with PPE. Nuclear magnetic resonance specra (^{1}H and ^{13}C) of several mono-, 1,3-di-, and 1,2,3-tri-substituted indanes were fully analyzed to provide information on steric interactions and conformation of the cyclopentene ring. Possible cyclodimerization pathways are proposed.

ELBA N. ALESSO, DORA G. TOMBARI, GRACIELA Y. MOLTRASIO IGLESIAS et JOSÉ M. AGUIRRE. Can. J. Chem. **65**, 2568 (1987).

On a obtenu des phénylindanes par la réaction de *N*-acyl arylalkyl-1 amines avec l'ester polyphosphorique (EPP). On a réalisé la synthèse du méthyl-1 (diméthoxy-3,4 phényl)-3 diméthoxy-5,6 indane afin de déterminer quel stéréoisomère est formé par la réaction du EPP avec les *N*-formyl et *N*-acétyl (diméthoxy-3,4 phényl)-1 éthylamines. Dans le but d'obtenir des informations sur les interactions stériques et la conformation du noyau cyclopentène, on a complètement analysé les spectres en résonance magnétique nucléaire du ^{1}H et du ^{13}C de plusieurs indanes mono-, di-1,3 et tri-1,2,3 substitués. On propose divers mécanismes possibles pour la cyclodimérisation.

[Traduit par la revue]

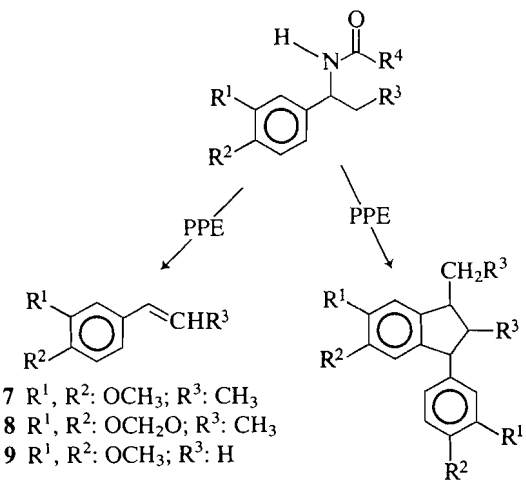
In previous work (1) polyphosphoric ester (PPE) has been found to act as a highly effective desamidation agent on *N*-acyl-1,2-diarylethylamines to produce *trans*-stilbenes. However, in some special cases, indane-type derivatives were obtained along with the *trans*-stilbenes.



SCHEME 1

Reactions of *N*-acyl-1-arylalkylamines, prepared as illustrated in Scheme 1, with PPE in chloroform–ether solution, were attempted in order to learn more about the reaction scope and the nature of the products, including their stereochemistry. As shown in eq. [1] and outlined in Table 1, amides **1***a*, **2***a*, **3***a*, **3***d*, and **3***e* rendered indanes **7**, **8**, and **10** as major products, whereas amides **5***a*, **5***d*, and **6***a* gave only the styrenes, which were detected as their bromo derivatives. Cyclodimerization thus depends essentially on the degree of aryl ring substitution.

[1]



Catalyzed dimerization of isohomogenol and isosafrol has been reported (2) to give the 1,2-*cis*-2,3-*trans*-(α-racemate) diisohomogenol **7** and diisosafrol **8** as major products, with the all *trans*-(γ-racemate) isomers as minor products. Amides **1***a* and **2***a* rendered only the α-racemate. Likewise, **3***a*, **3***d*, and **3***e* gave a stereoisomer of **10** as the major product, with traces of the other one.

Having isolated and purified the two possible stereoisomers of **10**, a synthetic sample of the *cis*-indane **10** was then prepared

*Detected as bromo derivative.

following Scheme 2 reactions (3, 4). An alternative synthesis of compound **10** (Scheme 3) was attempted using indanone **15**, as reported by Feeman and Amstutz (6), but cyclization of **14** was unsuccessful after boiling in phosphorus oxychloride solution for 3 min. Instead, **15** was obtained by using PPA (polyphosphoric acid). The cyclized product was a colourless solid, mp 75°C, characterized by its spectral data.

Spectral data for the synthetic sample allowed direct identification of the minor **10** isomer as the *cis* isomer. Comparison of 80-MHz spectra enabled the following conclusions to be drawn:

1. Stereochemical assignments of indane **10** are further supported by the H-2a and H-2b chemical shifts, whose variation over a 1.1-ppm range in the *cis* isomer is attributable to the diverse degrees of H-2a shielding by the C-1 methyl and C-3 aryl groups. In the *trans* isomer these two protons are collapsed in a complex multiplet and appear at intermediate field. The observed difference in chemical shift between the geminal protons in the *cis* isomer is not unexpected when the cyclopentene ring conformation is locked (7).

2. Strikingly, H-4 in either stereoisomer is clearly shielded in comparison to the same proton in 5,6-dimethoxyindane **16**. The minimal H-4 chemical shift difference observed (Δ = 0.1 ppm) between the two stereoisomers **10** and 3-(3,4-dimethoxyphenyl)-5,6-dimethoxyindane **17** seems attributable to the similar *pseudo*-equatorial C-3 aryl group position, with the aryl group at right angles to the plane of the indane nucleus, the only conformation in which the C-3 aryl group is close enough to H-4 to exert a shielding effect (8).

3. The observed shielding effect of H-3 (Δ = 0.20 ppm) between the *cis* and *trans* isomers of **10** is not unexpected, given the strong H-3 *pseudo*-axial – CH_3 *pseudo*-axial repulsion leading to considerable van der Waals deshielding (7) of H-3 in the *trans* isomer.

4. The different displacement of the C-1 methyl group signal in either stereoisomer is indicative (9) of the different angle subtended by the aromatic ring plane and defined by the bonds joining C-1 and the methyl group (10). Preliminary data on H-4 in *cis*- and *trans*-**10** support the *pseudo*-equatorial position of the C-3 aryl group, so it is reasonable to assume that equilibria must be shifted in the direction of the conformers shown in Fig. 1. Besides, on comparing the methyl group shift in 5,6-dimethoxy-1-methylindane **18** and the chemical shifts of the same group in *cis*- and *trans*-**10**, it proves quite similar to that of the *trans* isomer. It could thus be expected that the

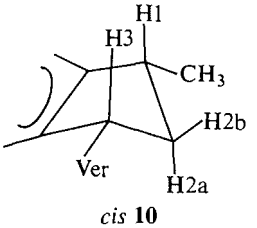
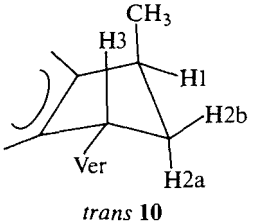
CH_3	1.36	1.26

methyl group in **18** would preferably be in the *pseudo*-axial position. Dreiding models indicate that the H-3 *pseudo*-axial to CH_3 *pseudo*-axial distance is greater than the CH_3 *pseudo*-equatorial to H-7 distance.

The ^{13}C chemical shifts for seven indanes are given in Table 2. Cyclopentene ring carbon shifts were determined by means of model values and APT (Attached Protons Test) experiments. Besides evaluating substitution effects on ^{13}C nmr shielding data, steric factors and epimeric shift differences were compared with results obtained from substituted cyclopentanes (11). To start with, the ^{13}C signal was compared for C-3 in **18** versus C-1 in **16**. The former compound shows a larger shielding than the latter (Δ = 1.72 ppm). Although the steric origin of γ effects in indane seems unquestionable, this effect is minor when compared to the same effect exerted by the introduction of an



cis **10**

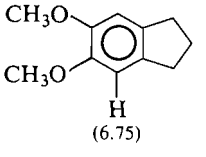


trans **10**

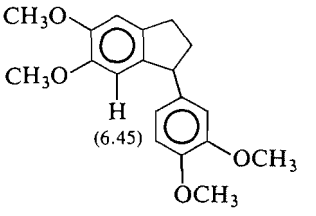
Ver = 3,4-dimethoxyphenyl

FIG. 1

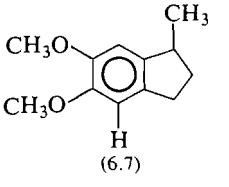
axial methyl group in cyclohexane, and may be ascribed to reduced steric interaction in the indane system due to less ring puckering. Moreover, C-3 in the *trans* isomer is shielded by 1 ppm in comparison to the *cis* isomer. In the epimeric indanes, C-3 shielding variations arise from the γ effect of equatorial versus axial methyl groups (12, 13). The ^{13}C signals from C-2 show greater shielding for the *trans*-**10** than for the *cis*-**10** epimer (Δ = 1.61 ppm). In methylindane **18**, the β effect is



16



17



18

9.18 ppm, greater than for an axial methyl group in cyclopentane or cyclohexane. This feature may also be associated with less ring puckering. The C-1 shielding variation in stereoisomers **10** is rather small (Δ = 0.12 ppm), in agreement with Roberts and co-workers (11), who considered that the α effect in substituted cyclopentanes is hardly influenced by steric hindrance (Table 2).

Lastly, ^{13}C nmr data for diisosafrol closely agree with those for diisohomogenol (10), lending further support to the conclusion that diisosafrol and diisohomogenol obtained by PPE desamidation share the same stereochemistry.

To clarify feasible cyclodimerization pathways, it was therefore of interest to determine whether *trans*-styrenes and

N-acyl-1-arylalkylamines having the same aryl ring substitution produce the same indanes, given the fact that *trans*-styrenes were isolated when unfavourably substituted aryl groups were present in the starting amides. When 1,2-(methylenedioxy)-*trans*-4-propenylbenzene, synthesized by a Wittig reaction, and amide **2***a* were likewise treated with PPE, only the α stereoisomer of indane **8** was obtained, clearly indicating that cyclodimerization involves the common intermediary **21** (Scheme 4). However, the yield from amide **2***a* was significantly higher than from the styrene (78 versus 20%), which may be accounted for by assuming that **21** might have been formed by routes a and (or) b from the amide, as well as by route c from the styrene. It is thus evident that the monomeric cations formed by pathways a and c are identical but differ in formation capability.

The existence of nitrilium ions **22** was supported by the isolation of benzonitrile as one of the reaction products from amide **3***e*. These ions are the most commonly invoked intermediaries in the mechanism of the Bischler–Napieralski synthesis and von Braun amide degradation reaction (14, 23).

Experimental

Infrared spectra were obtained on a Shimadzu IR 440 spectrometer. The ^1H and ^{13}C spectra were recorded on a Bruker WO 80 SYFT or a Varian FT 80 A spectrometer with $CDCl_3$ as solvent. Both spectra were referenced to internal Me_4Si and are reported on the δ scale. Mass spectra were recorded on a Varian Mat Mod CH7 A instrument. Elemental analyses were carried out in our laboratories using a Colemann Analyzer. Melting points (uncorrected) were obtained on a Thomas Hoover apparatus. Polyphosphoric ester (PPE) was prepared by the method of Pollmann and Schramm (15). Polyphosphoric acid was prepared by heating P_2O_5 (100 g) with H_3PO_4 (85%, 120 g) during 4 h at 120°C. Formamide was prepared by heating $(NH_4)_2CO_3$ (80 g) with HCOOH (80 g) during 1 h at 160°C.

1-(3,4-Methylenedioxyphenyl)-1-propanol **2**c

Ethyl bromide (0.5 mL) was added to a mixture of 10.7 g (0.44 g-atom) of Mg and 80 mL of dry ether. After starting the stirring, a solution of 48 g of ethyl bromide in 100 mL of ether was slowly added to the mixture (over 2 h). To the freshly prepared ethyl Grignard reagent was added dropwise 19.5 g (0.13 mol) of 3,4-dimethylenedioxybenzaldehyde in 20 mL of ether. When the addition was complete, the mixture was heated gently under reflux for 1 h and allowed to cool to room temperature. The mixture was hydrolyzed with saturated aqueous NH_4Cl and the aqueous layers were extracted with ether. The ethereal solution was dried ($MgSO_4$) and concentrated *in vacuo* to yield an oil, which was purified by dry column chromatography (silica gel). Elution with cyclohexane yielded the desired product. Yield 82%; ir (neat): 3450 (O—H) cm^{-1}; ^1H nmr: 0.85 (t, 3H, CH_3), 1.65 (m, 2H, CH_2), 2.15 (s, 1H, O*H*), 4.40 (t, 1H, C*H*), 5.9 (s, 2H, OCH_2O), 6.75 (m, 3H, Ar). *Anal.* calcd. for $C_{10}H_{12}O_3$: C 66.72, H 6.72; found: C 66.65, H 6.70.

1-(3-Methoxyphenyl)-1-propanol **6**c

This alcohol was prepared by the same procedure as described for **2***c* and isolated as an oil using a dry column (silica gel) with benzene as eluent. Yield 69.2%; ir (neat): 3480 (O—H) cm^{-1}; ^1H nmr: 0.86 (t, 3H, CH_3), 1.65 (m, 2H, CH_2), 2.75 (s, 1H, O*H*), 3.70 (s, 3H, OCH_3), 4.40 (t, 1H, C*H*), 6.7–7.2 (m, 4H, Ar). *Anal.* calcd. for $C_{10}H_{14}O_2$: C 72.35, H 8.50; found: C 72.40, H 8.52.

1-(3,4-Methylenedioxyphenyl)-1-propanone **2**b

A mixture of 7 g (0.070 mol) of chromium trioxide in 10 mL of water was immersed in an ice bath and 11.2 g of concentrated (18 *M*) H_2SO_4 followed by 20 mL of water was added cautiously with manual stirring. The solution was cooled to 0–5°C. The cooled oxidation reagent was added with vigorous stirring to a solution of 18 g (0.1 mol) of alcohol in 60 mL of acetone, cooled to 0–5°C at such a rate as to maintain the temperature of the reaction mixture at about 20°C. The stirring was continued for 3 h after the addition was completed. Sodium bisulfite was added and the mixture was extracted with chloroform and acetone. The extracts were combined, washed sucessively with saturated sodium bicarbonate solution and water, and dried ($MgSO_4$). The solvent was removed and the residue was chromatographed on a dry column (silica gel) with benzene as eluent. Yield 64.06% of a white solid, mp 36–37°C; ir (mull): 1670 (C=O) cm^{-1}; ^1H nmr: 1.21 (t, 3H, CH_3), 2.90 (c, 2H, CH_2), 6.00 (s, 2H, OCH_2O), 6.8 (d, 1H, Ar-5), 7.40 (d, 1H, Ar-2), 7.55 (dd, 1H, Ar-6). *Anal.* calcd. for $C_{10}H_{10}O_3$: C 67.47, H 5.66; found: C 67.37, H 5.63.

1-(3-Methoxyphenyl)-1-propanone **6**b

This ketone was prepared by the same procedure as described for **2***b* and isolated as an oil using a dry column (silica gel) with benzene as eluent (16). Yield 77.7%; ir (neat): 1660 (C=O) cm^{-1}; ^1H nmr: 1.23 (t, 3H, CH_3), 2.95 (c, 2H, CH_2), 3.85 (s, 3H, OCH_3), 6.95–7.90 (m, 4H, Ar).

1-(3,4-Dimethoxyphenyl)-1-propanone **1**b

A mixture of recently prepared polyphosphoric acid (220 g), veratrole (0.20 mol), and propionic acid (0.20 mol) was stirred during 4 h at 70–80°C. Water was added and the mixture was extracted with $CHCl_3$, and the organic phase was washed with NaOH solution (10%) and water. The chloroform solution was dried over Na_2SO_4 and evaporated to dryness. The residue was crystallized from methanol. Yield 55%, mp 58–59°C (EtOH) (lit. (17*a*) mp 58–59°C).

1-(3,4-Dimethoxyphenyl)ethanone **3**b

This ketone was prepared by using a modification of the procedure described before, using acetic anhydride as the electrophilic reagent. It was isolated as an oil and was purified by distillation at 160°C and 10 Torr (1 Torr = 133.3 Pa). Yield 69%, mp 48–49°C (lit. (17*b*) mp 49–51°C).

1-(4-Methoxyphenyl)-2-cyclohexylethanone **5**b

This ketone was prepared in an analogous manner to **1***b*. The residue was crystallized from EtOH–H_2O. Yield 85%, mp 44–45°C (lit. (18) mp 43°C).

N-*1-(3,4-Dimethoxyphenyl)propylformamide* **2**a

A mixture of 1.78 g (0.01 mol) of the ketone **2***b* and 15 mL of freshly prepared formamide was heated at 180–190°C for 8 h. The water formed was removed during the reaction. The reaction mixture was diluted with water and extracted twice with $CHCl_3$. The combined organic layers were dried (Na_2SO_4) and finally the solvent was removed *in vacuo*. The amide was isolated as an oil using dry column (silica gel) with benzene–ethanol (95:5) as eluent. Yield 52.2%; ir (neat): 3352 (N—H), 1660 (C=O) cm^{-1}; ^1H nmr: 0.85 (t, 3H, CH_3), 1.75 (m, 2H, CH_2), 4.75 (m, 1H, C*H*), 5.85 (s, 2H, OCH_2O), 6.40 (m, 1H, N*H*), 6.75 (s, 3H, Ar), 8.10 (s, 1H, C*H*O). *Anal.* calcd. for $C_{11}H_{13}NO_3$: C 63.82, H 6.33, N 6.77; found: C 63.70, H 6.30, N 6.79.

The following compounds were prepared in a manner similar to that described for **2***a*.

N-*1-(3-Methoxyphenyl)propylformamide* **6**a

Isolated as an oil using dry column (silica gel) and benzene–ethanol (95:5) as eluent. Yield 85%; ir: 3345 (N—H), 1665 (C=O) cm^{-1}; ^1H nmr: 0.90 (t, 3H, CH_3), 1.76 (m, 2H, CH_2), 3.75 (s, 3H, OCH_3), 4.85 (m, 1H, C*H*), 6.5 (s, br, 1H, N*H*), 6.6–7.25 (m, 4H, Ar), 8.1 (s, br, 1H, C*H*O). *Anal.* calcd. for $C_{11}H_{15}NO_2$: C 68.45, H 7.83, N 7.26; found: C 68.50, H 7.78, N 7.30.

N-*1-(3,4-Dimethoxyphenyl)propylformamide* **1**a

Isolated as an oil using a dry column (silica gel) and benzene as eluent. Yield 58%; ir: 3350 (N–H), 1680 (C=O) cm^{-1}; ^1H nmr: 0.90 (m, 3H, CH_3), 1.80 (m, 2H, CH_2), 3.85 (s, 6H, OCH_3), 4.83 (m, 1H, C*H*), 6.1 (s, br, 1H, N*H*), 6.77 (s, 3H, Ar), 8.10 (s, br, 1H, C*H*O). *Anal.* calcd. for $C_{12}H_{17}NO_3$: C 64.63, H 7.68, N 6.28; found: C 64.66, H 7.71, N 6.30.

N-*1-(3,4-Dimethoxyphenyl)ethylformamide* ***3***a

Yield 52%, mp 115–116°C (benzene); ir: 3250 (N—H); 1685 (C=O) cm^{-1}; ^1H nmr: 1.47 (d, 3H, CH_3), 3.82 (s, 6H, OCH_3), 5.05 (m, 1H, C*H*), 6.1 (s, br, 1H, N*H*), 6.84 (s, 3H, Ar), 8.1 (s, br, 1H, C*H*O). *Anal.* calcd. for $C_{11}H_{15}NO_3$: C 63.21, H 7.23, N 6.70; found: C 63.35, H 7.30, N 6.75.

N-*1-(4-Methoxyphenyl)-2-cyclohexylethylformamide* ***5***a

Yield 55%; mp 66–68°C (benzene); ir: 3350 (N—H), 1660 (C=O) cm^{-1}; ^1H nmr: 0.75–1.9 (m, 13H, CH_2—C_6H_{11}), 3.70 (s, 3H, OCH_3), 5.10 (dd, 1H, C*H*), 5.90 (s, br, 1H, N*H*), 6.85 (d, 2H, Ar-3,5), 7.15 (d, 2H, Ar-2,6), 8.05 (s, br, 1H, C*H*O). *Anal.* calcd. for $C_{16}H_{23}NO_2$: C 73.62, H 8.88, N 5.37; found: C 73.70, H 8.91, N 5.50.

N-*1-(3,4-Dimethoxyphenyl)ethylacetamide* ***3***d

A mixture of 1.5 g of ***3a***, 25 mL of HCl (δ 1.19), and 75 mL of water was heated under reflux for 1 h. After cooling, the clear solution was extracted with ether and the aqueous solution was made strongly alkaline with 20% NaOH solution. The resulting solution was extracted with ether. The ether layers were washed (H_2O) and dried ($MgSO_4$). Evaporation left the crude amine, which was converted to its acetyl derivative in the usual way. Yield 67%; ir: 3250 (N—H), 1640 (C=O) cm^{-1}; ^1H nmr: 1.35 (d, J = 6 Hz, 3H, CH_3), 1.86 (s, 3H, CH_3), 3.73 (s, 6H, OCH_3), 4.95 (m, 1H, C*H*), 6.10 (s, br, 1H, N*H*), 6.72 (s, 3H, Ar). *Anal.* calcd. for $C_{12}H_{17}NO_3$: C 64.63, H 7.68, N 6.28; found: C 64.69, H 7.71, N 6.32.

N-*1-(4-Methoxyphenyl)-2-cyclohexylethylacetamide* ***5***d

This acetamide was prepared from ***5a*** in an analogous manner to ***3d***. Yield 73%, mp 131–133°C (EtOH); ir: 3230 (NH), 1650 (C=O) cm^{-1}; ^1H nmr: 1–2.05 (m, 13H, CH_2—C_6H_{11}), 2.15 (s, 3H, CH_3), 4.0 (s, 3H, OCH_3), 5.25 (dd, 1H, C*H*), 6.0 (s, br, 1H, N*H*), 6.90 (d, 2H, Ar-3,5), 7.35 (d, 2H, Ar-2,6). *Anal.* calcd. for $C_{17}H_{25}NO_2$: C 74.24, H 9.16, N 5.09; found: C 74.36, H 9.13, N 5.16.

N-*1-(3,4-Dimethoxyphenyl)ethylbenzamide* ***3***e

This compound was prepared by hydrolysis of ***3a*** and then the amine was treated with benzoyl chloride in dry pyridine to give white crystals, mp 123–124°C (EtOH–H_2O). Yield 84%; ir: 3310 (NH), 1640 (C=O) cm^{-1}; ^1H nmr: 1.6 (d, 3H, CH_3), 3.85 (s, 6H, OCH_3), 5.30 (m, 1H, C*H*), 6.45 (s, br, 1H, N*H*), 6.85 (d, 2H, Ar), 6.90 (s, 1H, Ar), 7.45 (m, 3H, Ar), 7.80 (m, 2H, Ar). *Anal.* calcd. for $C_{17}H_{19}NO_3$: C 71.64, H 6.72, N 4.92; found: C 71.70, H 6.70, N 4.96.

1,3-Bis-(3,4-dimethoxyphenyl)-1-butanone ***12***

A solution of chalcone **11**, 3.28 g (0.01 mol), in anhydrous benzene was added slowly to a 100% excess of methyl magnesium iodide containing 0.1 mol of cuprous chloride (19). During the addition, the temperature of the reaction mixture was maintained at 0–5°C. After addition was complete, the reaction mixture was stirred for an additional 30 min, then the temperature was allowed to rise. Finally, the mixture was refluxed for 1 h. The reaction mixture was decomposed by pouring it into cracked ice mixed with acetic acid. The solution was filtered, the benzene layer was separated, and the aqueous layer was extracted with methylene chloride. The combined organic layers were dried ($MgSO_4$) after being washed with aqueous bicarbonate and water. The solvent was finally evaporated and the extract was purified by column chromatography (silica gel) with benzene as eluent. The ketone was obtained as colourless crystals from acetone. Yield 52%, mp 94–95°C; ^1H nmr: 1.3 (d, J = 6.7 Hz, 3H, CH—CH_3), 3.0–3.5 (m, 3H, C*H*—CH_2), 3.84, 3.86, 3.92 (s, 12H, OCH_3), 6.82–7.6 (m, 6H, Ar). *Anal.* calcd. for $C_{20}H_{24}O_5$: C 69.83, H 7.03; found: C 69.82, H 7.09.

cis-*3-(3,4-Dimethoxyphenyl)-1-methyl-5,6-dimethoxyindane* ***10***

A solution of the ketone **12** (1.97 mol) in 0.9 mL of 85% phosphoric acid was added slowly with vigorous stirring to 0.9 mL of concentrated H_2SO_4 at 0°C. The reaction mixture was heated at 60–70°C for 30 min at which time the colour changed from yellow to red. The crude product was obtained by pouring the reaction mixture into ice water. The solid was dissolved in methylene chloride and the solution shaken exhaustively with a solution of NaOH (2%), then with water. Drying and evaporation of the solvent yielded the indene **13**, which was used without any other purification. Hydrogenation of 0.0026 mol of **13** in 6 mL of ethyl acetate with 5.3 mg of platinum dioxide at room temperature and 40 psi (1 psi = 6.9 kPa) for 2 h afforded a pale yellow oil. Yield 82%; ^1H nmr: 1.36 (d, 3H, CH_3), 1.60 (m, 1H, H-2a), 2.70 (m, 1H, H-2b), 3.2 (m, 1H, H-1), 3.70, 3.80, 3.86, 3.90 (s, 12H, OCH_3), 4.14 (m, 1H, H-3), 6.45 (s, 1H, Ar-4), 6.6–6.75 (m, 4H, Ar); ms: M^+ 328 (100%); *m/e*: 313 (62%), 297 (89%), 191 (15%), 190 (36.7%), 175 (28%), 165 (18%), 164 (19%), 159 (21%), 149 (16.1%).

trans-*3-(3,4-Dimethoxyphenyl)-1-methyl-5,6-dimethoxyindane* ***10*** (ref. 1): ms: M^+ 328 (100%); *m/e*: 313 (37%), 297 (6.25%), 191 (9.8%), 190 (36.7%), 175 (21.4%), 165 (3.9%), 164 (8.1%), 149 (25.4%).

3-(3,4-Dimethoxyphenyl)-5,6-dimethoxyindanone ***15***

A mixture of 2.3 g (6.6 mmol) of **14** and 23 g of freshly prepared PPA was heated with stirring for 8 h at 100–110°C. The mixture was cooled and the excess of PPA was destroyed by addition of water. The crude product was extracted with methylene chloride and the organic layer was washed with water and NaOH (5%). The organic extract was dried ($MgSO_4$) and after removal of the solvent it was purified by column chromatography (silica gel) using methylene chloride as eluent. Recrystallization from acetone gave 1.3 g of nearly colourless solid. Yield 51.2%, mp 74–75°C (lit. (6) mp 124–125°C); ^1H nmr: 2.55 (dd, J_{gem} = 20 Hz, J_{vic} *cis* = 4 Hz, 1H, H-2b), 3.20 (dd, J_{gem} = 20 Hz, J_{vic} *trans* = 8 Hz, 1H, H-2a), 3.75, 3.80, 3.90 (s, 12H, OCH_3), 4.4 (dd, J_{vic} *trans* = 8 Hz, J_{vic} *cis* = 4 Hz, 1H, H-3), 6.5–6.75 (m, 4H, Ar), 7.20 (s, 1H, Ar-7). *Anal.* calcd. for $C_{19}H_{20}O_6$: C 69.57, H 6.15; found: C 69.35, H 6.18.

cis-*3-(3,4-Dimethoxyphenyl)-1-methyl-5,6-dimethoxyindane* ***10***

A solution of the indanone **15** (300 mg, 0.97 mol) in anhydrous benzene was added to a 100% excess of methyl magnesium iodide in anhydrous ether. During the addition the temperature of the reaction was maintained at 5–10°C. After addition was complete the mixture was refluxed on a water bath for 2 h; the organic solution was poured into a mixture of acetic acid, water, and crushed ice. The organic layer was separated and the aqueous solution was extracted with two portions of ether. The combined organic extracts were washed with a dilute solution of sodium bicarbonate, followed by water, and finally were dried ($MgSO_4$). The solvent was evaporated and the residue was purified by preparative tlc, using plates of silica gel with fluorescent indicator and benzene–ethanol (9:1) as eluent. Without further purification the indene was hydrogenated in a manner similar to indene **13**. Yield 53%. This material was identical (ir, nmr) with that prepared by the alternative method.

5,6-Dimethoxyindane ***16***

This compound was obtained from the 5,6-dimethoxyindanone (5) and zinc amalgam (20). Yield 71%, mp 50°C (lit. (21) mp 50°C); ^1H nmr: 2.05 (q, 2H, CH_2), 2.80 (t, 4H, CH_2), 3.80 (s, 6H, OCH_3), 6.75 (s, 2H, Ar).

3-(3,4-Dimethoxyphenyl)-5,6-dimethoxyindane ***17***

This compound was prepared from **15** according to the literature experimental procedure (6). Yield 83%, mp 84–85°C (EtOH) (lit. (5) mp 85.0–86.8°C); ^1H nmr: 2.50 (m, 2H, CH_2), 2.85 (m, 2H, CH_2), 3.75, 3.83, 3.90 (s, 12H, OCH_3), 4.20 (m, 1H, C*H*), 6.45 (s, 1H, Ar-7), 7.25 (m, 4H, Ar).

1-Methyl-5,6-dimethoxyindane ***18***

The 5,6-dimethoxyindanone (280 mg, 1.35 mmol) dissolved in anhydrous benzene was added drop by drop to an excess of methyl Grignard reagent (6.75 mol) at 0–5°C. After addition was complete the mixture was refluxed for 2 h. The reaction mixture was decomposed by pouring it into cracked ice mixed with acetic acid and methylene chloride. The combined organic layers were dried ($MgSO_4$) after

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

being washed with aqueous bicarbonate and water. The solvent was finally evaporated and the residue, without further purification, was hydrogenated in a similar manner to indene **13** and crystallized from benzene–hexane to afford colourless crystals. Yield 78%, mp 88–89°C; ^{1}H nmr: 1.25 (d, 3H, CH_3), 1.65 (m, 1H, CH_2-2), 2.25 (m, 1H, CH_2-2), 2.75 (m, 2H, CH_2-3), 3.10 (m, 1H, C*H*), 3.73, 3.80 (s, 6H, OCH_3), 6.65, 6.70 (s, 2H, Ar). *Anal.* calcd. for $C_{12}H_{16}O_2$: C 75.06, H 8.40; found: C 74.93, H 8.30. For the indene, ^{1}H nmr: 2.12 (d, 3H, CH_3), 3.22 (s, br, 2H, CH_2), 3.80, 3.85 (s, 6H, OCH_3), 6.05 (m, 1H, C*H*), 6.8 (s, 1H, Ar-4), 6.93 (s, 1H, Ar-7).

General procedure for the cyclodimerization reaction with PPE (ref. 1)

A solution of amide or styrene (1 mmol) and PPE (2.56 g) in chloroform–ether was warmed at 80°C for 8 h. After removing the solvent *in vacuo*, water and methylene chloride were added to the crude product. The organic layer was separated, then washed with NaOH (5%) and water. The organic extract was dried ($MgSO_4$) and the solvent was removed. Chromatography of the crude product on alumina column (eluent benzene–hexane) afforded the indanes.

1-Ethyl-2-methyl-3-(3,4-dimethoxyphenyl)-5,6-dimethoxyindane 7

Only the α isomer was obtained from the amide **1***a*. Yield 56%, mp 104–105°C (lit. (2) mp 104–106°C). The ^{1}H nmr of this material was identical with that prepared by an alternate method (2).

1-Ethyl-2-methyl-3-(3,4-methylenedioxyphenyl)-5,6-methylenedioxyindane 8

Only the α isomer was obtained from the amide **2***a*. Yield 78%, mp 92–93°C (lit. (2) mp 92–93°C). The ^{1}H nmr of this material was identical with that prepared by an alternate method (2). From the isosafrol the α isomer was obtained in 20% yield.

trans-*1-Methyl-3-(3,4-dimethoxyphenyl)-5,6-dimethoxyindane 10*

This isomer was obtained from the amides **3***a*, **3***d*, and **3***e* in 56, 50, and 57% yield respectively, mp 118–119°C.

trans-*1-Methoxy-4-(2-cyclohexylethenyl)benzene 19*

This compound was obtained from the amides **5***a* and **5***d*, mp 39–40°C (EtOH); ^{1}H nmr: 1.1–1.9 (m, 11H, C_6H_{11}), 3.79 (s, 3H, OCH_3), 5.99 (dd, J = 15.2 Hz, J = 6.4 Hz, 1H, C*H*—C_6H_{11}), 6.31 (d, J = 15.2 Hz, 1H, C*H*-Ar), 6.81 (d, J = 8.8 Hz, 2H, Ar-3,5), 7.25 (d, J = 8.8 Hz, 2H, Ar-2,6). *Anal.* calcd. for $C_{15}H_{20}O$: C 83.40, H 9.33; found: C 83.25, H 9.38.

1,2-Dibromo-1-(3-bromo-4-methoxyphenyl)-cyclohexylethene

Bromine (0.5 mL) was added, dropwise, to a solution of *trans*-styrene (0.2 mL) in CCl_4 (1 mL). The solid obtained was filtered and washed with cold MeOH. Recrystallization from methanol gave white crystals, mp 87–88°C; ^{1}H nmr: 1.2–1.9 (m, 11H, C_6H_{11}), 3.85 (s, 3H, OCH_3), 3.90–4.25 (m, 2H, C*H*-Br), 6.95 (d, J = 6 Hz, 1H, Ar-5), 7.20 (dd, J = 6 Hz, J = 1.2 Hz, 1H, Ar-6), 7.45 (d, J = 1.2 Hz, 1H, Ar-2). *Anal.* calcd. for $C_{15}H_{19}Br_3O$: C 39.59, H 4.21; found: 39.61, H 4.25.

1,2-Dibromo-1-(2-bromo-5-methoxyphenyl)propane 20

The crude product of the reaction of **6***a* with PPE was treated with bromine and carbon tetrachloride. The bromine derivative was isolated as an oil by preparative tlc on silica gel with fluorescent indicator and benzene as solvent; ^{1}H nmr: 2.00 (d, J = 6.4 Hz, 3H, CH_3), 3.80 (s, 3H, OCH_3), 4.55 (m, 1H, C*H*Br), 5.50 (d, J = 12 Hz, 1H, C*H*Br), 6.7 (dd, J_{H3-H4} = 8 Hz, J_{H4-H6} = 3 Hz, 1H, Ar-4), 7.03 (d, J = 3 Hz, 1H, Ar-6), 7.40 (d, J = 8 Hz, 1H, Ar-3). *Anal.* calcd. for $C_{10}H_{11}Br_3O$: C 31.03, H 2.87, Br 61.96; found: C 31.10, H 2.89, Br 61.78.

Conformational analysis of 3-substituted-2,3,4,5-tetrahydro-1-benzoxepin by ^1H and ^{13}C nuclear magnetic resonance

A. LACHAPELLE AND M. ST-JACQUES[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Qué.), Canada H3C 3J7

Received May 5, 1987

A. LACHAPELLE and M. ST-JACQUES. Can. J. Chem. **65**, 2575 (1987).

2,3,4,5-Tetrahedro-1-benzoxepin (**8**) and its 3-substituted derivatives (**9–13**) have been studied by ^1H and ^{13}C dynamic nuclear magnetic resonance in a few solvent systems. The results show that, while **8** and its methyl derivative **9** exist solely in chair forms (*C* for **8** and C_e:C_a (96:4) for **9**), the twist-boat (*TB*) conformation contributes significantly to the conformational equilibria of the derivatives 3-methoxy **10** (C_a:C_e:*TB*, 70:20:10), 3,3-dimethyl **11** (*C*:*TB*, 90:10), 3,3-methylmethoxy **12** (C_a:C_e:*TB*, 89:4:7), and 3,3-dimethoxy **13** (*C*:*TB*, 92:8). The analysis of several factors (steric, electrostatic, and electronic) on the conformational behaviour of these molecules shows why the *TB* form is a viable conformational alternative to destabilized chair forms in this benzoxepin system.

A. LACHAPELLE et M. ST-JACQUES. Can. J. Chem. **65**, 2575 (1987).

Faisant appel à la résonance magnétique nucléaire dynamique du ^1H et du ^{13}C, on a étudié la tétrahydro-2,3,4,5 benzoxépine-1 (**8**) ainsi que ses dérivés portant des substituants en position 3 (**9–13**), dans divers solvants. Les résultats démontrent que, alors que **8** et son dérivé méthylé **9** existent uniquement dans des formes chaises (*C* pour **8** et C_e:C_a (96:4) pour **9**), la conformation bateau croisé (*BC*) apporte une contribution importante à l'équilibre conformationnel des dérivés méthoxy-3 (**10**) (C_a:C_e:*BC*, 70:20:10), diméthyl-3,3 (**11**) (*C*:*BC*, 90:10), méthyl-3 méthoxy-3 (**12**) (C_a:C_e:*BC*, 89:4:7) et diméthoxy-3,3 (**13**) (*C*:*TB*, 92:8). Une analyse de l'influence de plusieurs facteurs (stérique, électrostatique et électronique) sur le comportement conformationnel de ces molécules démontre pourquoi la forme *BC* est une alternative conformationnelle viable pour les formes chaises déstabilisées de ce système benzoxépine.

[Traduit par la revue]

Over the last two decades, various studies of substituted six-membered ring heterocycles (tetrahydropyran (1), 1,3-dioxane (2), etc...) have revealed the importance of steric and electrostatic effects on conformational stability. While most molecules investigated were shown to exist as chair forms, only extremely crowded derivatives were found (3) to adopt predominantly the twist-boat (*TB*) form, in order to minimize the strong nonbonding interactions. Recent work by St-Jacques and co-workers (4, 5) showed that replacement of the 5- or 2-methylene groups in the 1,3-dioxane **1** ring by an *ortho*-benzo group, leading to 2,3-dihydro-2,4-benzodioxepin **2** and to 2,3-dihydro-1,5-benzodioxepin **5**, stabilizes the *TB* conformation significantly (about 20% is detected for both compounds in CHF_2Cl between −100 and −150°C). Furthermore, *TB* stabilization is increased substantially by substitution at the 3-position with a *gem*-dimethyl group (as in **3** or **6**) or with a polar methoxy group (as in **4** or **7**).

Because both series of molecules contain interactions involving two ring oxygen atoms, we wished to characterize the effect of only one oxygen atom in the seven-membered ring. We therefore report a high-field ^1H and ^{13}C nmr (1D and 2D) investigation of molecules **8–13**, containing a single oxygen adjacent to the aromatic ring, whose results contribute to understanding the various factors (steric, stereoelectronic, electrostatic, etc...) favouring the twist form.

Results

The ^1H and ^{13}C nmr spectra of all six compounds (**8–13**) studied were obtained at different temperatures between −5 and −125°C. Three different solvent systems were used: a polar CHF_2Cl–CD_2Cl_2 (80:20) mixture for both ^1H and ^{13}C spectra and less polar combinations such as CF_2Cl_2–acetone-d_6 (94:6) for ^1H and CH_3OCH_3–CD_2Cl_2 (80:20) for ^{13}C spectra. All pertinent nmr parameters are summarized in Tables 1 and 2.

The ^{13}C spectra of **8** in both the polar and the less polar solvent systems revealed no spectral modifications upon lowering the temperature. Aliphatic carbon atoms were identified through selective proton irradiations at −120°C while the aromatic carbon signals were assigned using aromatic carbon chemical shifts of a similar molecule (6) (4,5-dihydro-1,3-benzodioxepin **14**). The observed signals were attributed to the chair (*C*) form, as will be further discussed in the next section.

The 400.13-MHz ^1H spectra of **8** in both solvent systems, however, showed one spectral modification on going from −10 to −125°C, as illustrated in Fig. 1. At −10°C, the aliphatic region consists of four multiplets corresponding to the four methylene groups of the molecule. The most deshielded one (3.90 ppm) can easily be assigned to H-2, because of the

[a]All spectra were taken on a Bruker WH-400 spectrometer operating at 400.13 MHz for solutions containing tetramethylsilane as internal standard and 20% CD_2Cl_2 (for CHF_2Cl) or 6% acetone-d_6 (for CF_2Cl_2) for locking purposes.

[b]The aromatic signals are not reported here because of solvent (CHF_2Cl) overlapping peaks. All aromatic signals for compounds **8–13** appear between 6.85 and 7.10 ppm in the CF_2Cl_2/acetone-d_6 solvent system.

[c]The symbols *C*, C_e, C_a, and *TB* refer to conformations defined in the text.

[d]Multiplicity of the signal could not be resolved due to peak overlapping.

[e]These signals were not identified, either because of peak overlapping or too small signal-to-noise ratio.

[f]Precise integration of the signals was not possible due to peak overlapping.

For personal use only.

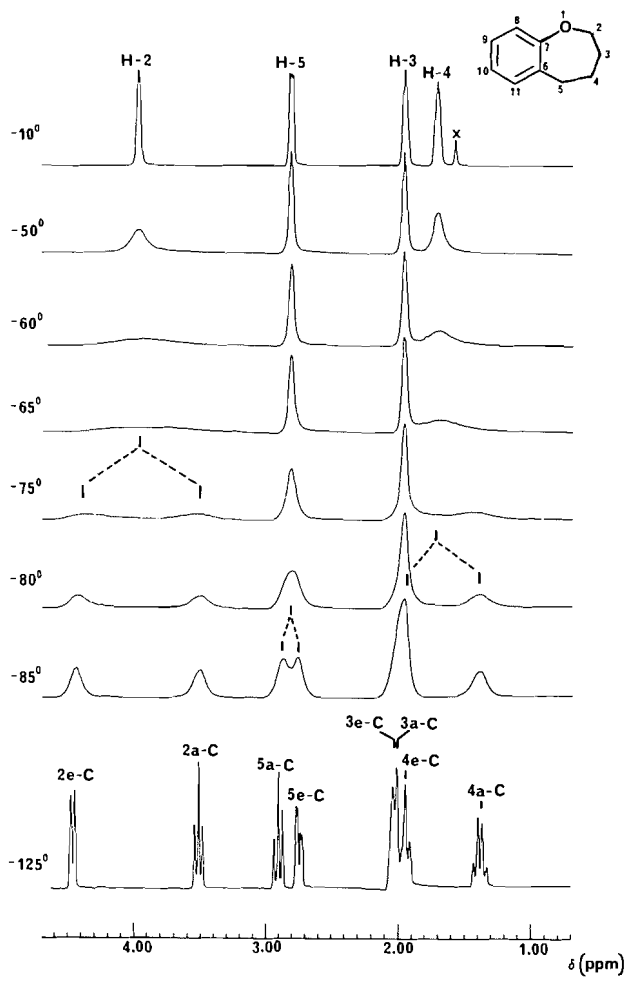

FIG. 1. Aliphatic portion of the 400.13-MHz ^{1}H nmr spectra of **8** in CHF_2Cl–CD_2Cl_2 (80:20) at several temperatures. The numbers and letters over the signals at −120°C refer to the position and the orientation of the protons, as well as to the nature of the ring conformation, as described in the text. "X" denotes an impurity, while broken lines link together exchanging protons.

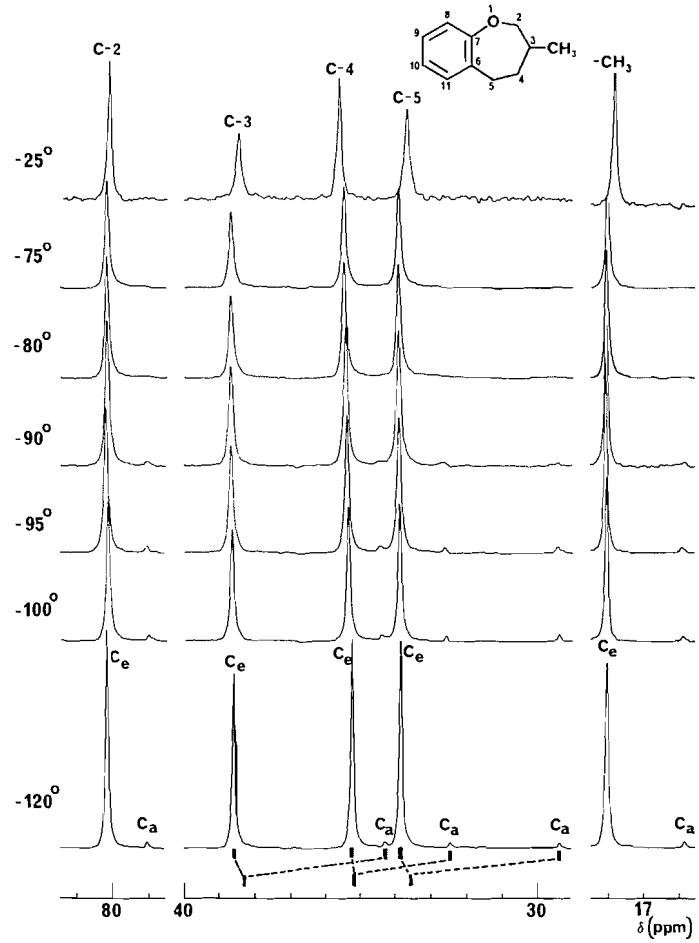

FIG. 2. Aliphatic portion of the 100.62-MHz ^{13}C nmr spectra of **9** in CHF_2Cl–CD_2Cl_2 (80:20) at several temperatures. C_e and C_a refer to conformations described in the text.

deshielding effect of the oxygen atom. Irradiation of that multiplet permits the identification of the H-3 multiplet, and subsequent irradiations readily identify the H-4 and H-5 multiplets. Each signal broadens at lower temperatures to give, at −120°C, five distinct signals, each integrating for one proton, and a multiplet at 2 ppm integrating for three other protons. The deshielded doublet at 4.46 ppm can readily be identified as 2e-*C*,[2] showing only one strong geminal coupling ($^2J_{HH}$ = −12.2 Hz) with 2a-*C*, as confirmed by selective irradiation of the doublet at 4.46 ppm, which transformed the triplet at 3.51 ppm (2a-*C*) into a doublet. The shielded quartet at 1.38 ppm could be assigned to either 3a-*C* or 4a-*C*, but since irradiation of the 2a-*C* resonance left that signal unperturbed, it is unequivocally identified as 4a-*C*. Subsequent irradiations established the identity of all the other aliphatic resonances (Table 2).

The 100.62-MHz ^{13}C spectra of **9** (R = H, R′ = CH_3) in both solvent systems showed one spectral change upon lowering the temperature. As shown in Fig. 2, the aliphatic portion of the ^{13}C spectrum of **9** in CHF_2Cl at −25°C consists of five peaks, of which the C-3 signal could easily be identified by an off-resonance experiment. While the deshielded C-2 carbon can be readily assigned, the C-4 and C-5 signals were identified by selective proton irradiation of 4a-*C*, at −25°C. Finally, the aromatic carbon chemical shifts were assumed to exhibit the same order as in the parent compound **8**, as reported in Table 1.

All aliphatic carbon signals broaden at low temperatures to give, at −120°C, two sets of signals of unequal intensities (97:3 in CHF_2Cl–CD_2Cl_2 shown in Fig. 2 and 96:4 in CH_3OCH_3–CD_2Cl_2), which can be assigned to the C_e (major set) and C_a forms (minor set), as will be discussed in the next section. The aromatic signals of the minor set cannot be detected either because of low signal-to-noise ratio (quaternary carbons) or overlap with the major set (protonated aromatic carbons).

The 400.13-MHz ^{1}H spectrum of **9**, at −10°C, in CHF_2Cl–CD_2Cl_2, consists of eight distinct signals that could be assigned by comparison with proton chemical shifts of the parent compound **8** (at −120°C), and by selective irradiation of the methyl doublet at 1.11 ppm, leading to the identification of H-3. All signals broaden slightly as the temperature is lowered to give, at −125°C, in addition to eight intense signals corresponding to the C_e form, a very weak doublet at 1.28 ppm, which can be associated with the C_a form (see next section). The other resonances of the minor form either overlap with the

[2]Protons are identified by a symbol composed of two parts: the first one gives the position and orientation of the proton while the second part specifies the nature of the ring conformation. Thus 2e-*C* refers to the 2-equatorial proton of the chair form.

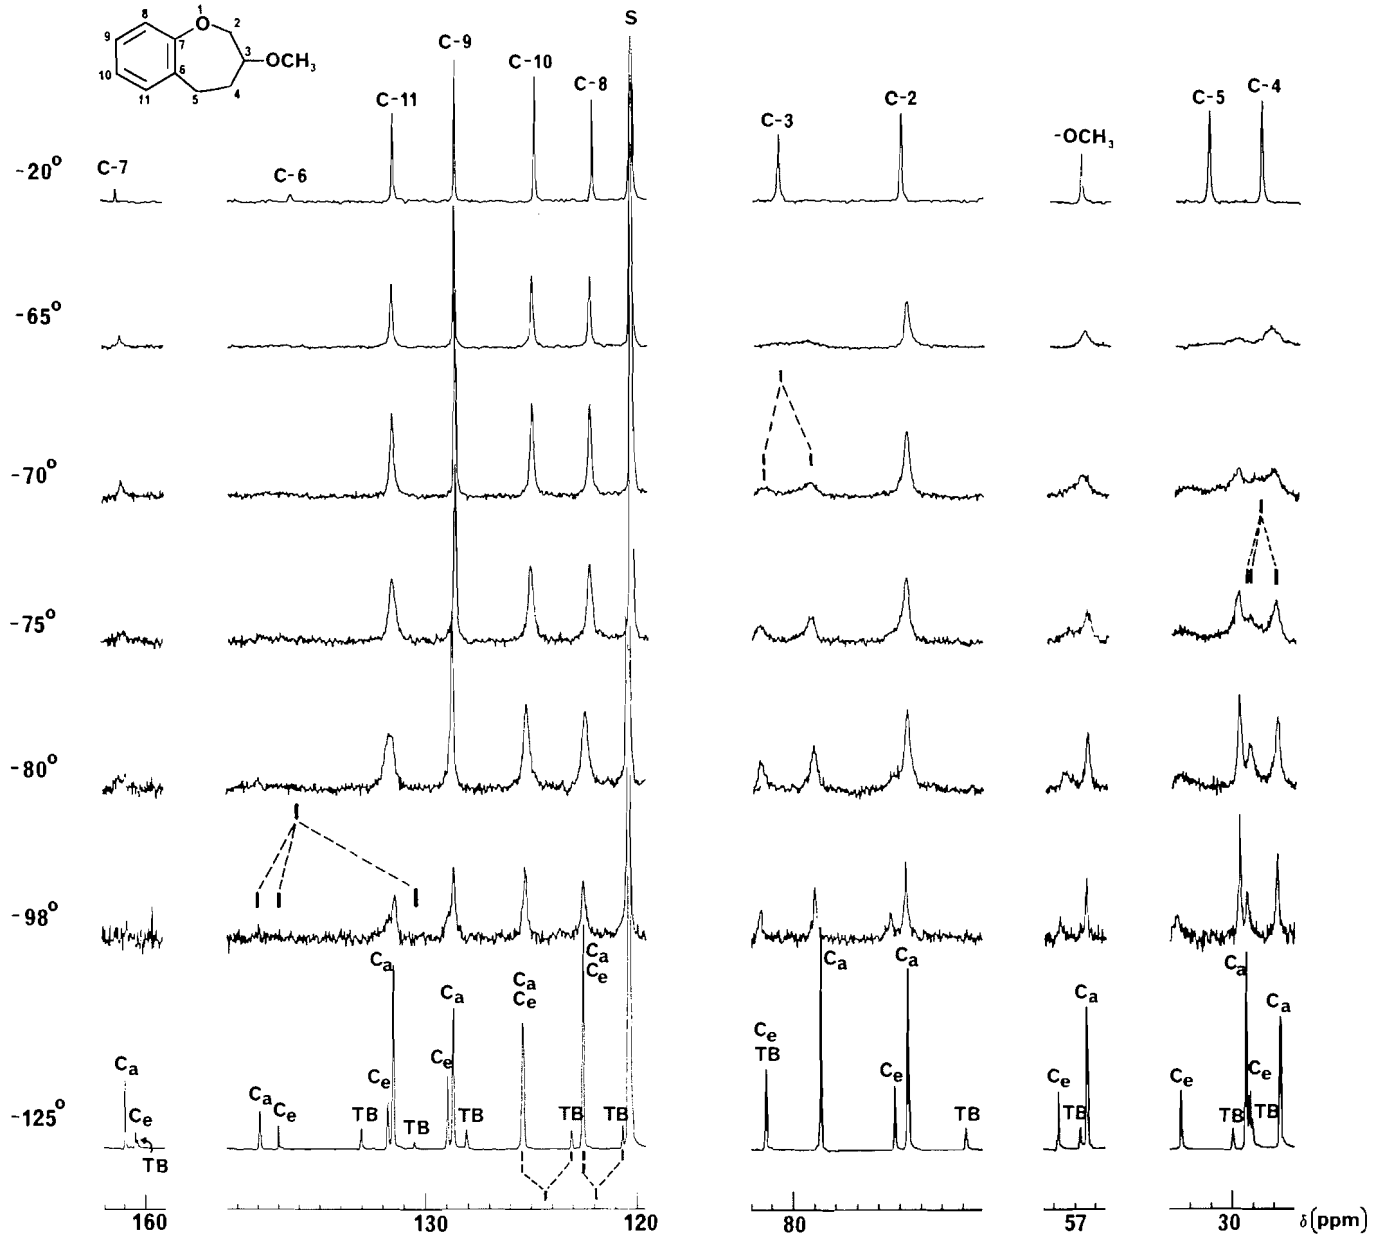

FIG. 3. The 100.62-MHz ^{13}C nmr spectra of **10** in CHF_2Cl–CD_2Cl_2 (80:20) at several temperatures. C_a, C_e, and *TB* refer to conformations described in the text. "S" defines a solvent (CHF_2Cl) line, while broken lines link together signals corresponding to the same carbon atom position.

intense signals or cannot be clearly distinguished from the background noise in that solvent system. However, a better signal-to-noise ratio is observed in the ^1H spectrum of **9** in CF_2Cl_2–acetone-d_6 at $-120°C$, and allows the identification of 2e-C_a and 2a-C_a as doublets. Other weak resonances appear in the spectrum, but they could not be correlated precisely with the remaining protons of the C_a form.

In contrast, both ^{13}C and ^1H spectra of compound **10** (R = H, R′ = OCH_3) exhibit spectacular changes (Figs. 3 and 4) as the temperature is lowered. At $-20°C$, the ^{13}C spectrum of **10** in the polar CHF_2Cl–CD_2Cl_2 solvent system shows five resonances for the aliphatic carbons and six resonances for the aromatic carbons. All aromatic signals can be easily assigned through direct comparison with those of the parent molecule **8** (see Table 1). The oxygen-bound carbon atoms, namely C-2, C-3, and the methoxy carbons, can be differentiated by an off-resonance proton decoupling experiment, while C-4 and C-5 were identified through selective proton irradiations.

All signals of **10** broaden at lower temperatures to give, at $-125°C$ (Fig. 3), three different sets of carbon resonances, integrating for 70:20:10. The intensity ratio is associated to the C_a, C_e, and *TB* forms respectively, as will be discussed in the next section. Integration shows that the tall signal at 122.54 ppm contains two superimposed signals, one for the C_a form (70%) and one for the C_e form (20%). A change for the less polar solvent system (CH_3OCH_3–CD_2Cl_2) modifies the relative intensities of the sets at $-125°C$ (44:50:6 for C_a, C_e, and *TB* respectively). The nmr parameters characteristic of each form are summarized in Table 1.

The ^1H spectrum of **10** in CHF_2Cl–CD_2Cl_2, at $-10°C$, shows seven aliphatic signals integrating each for one proton and a taller methoxy signal (Fig. 4). The two most deshielded

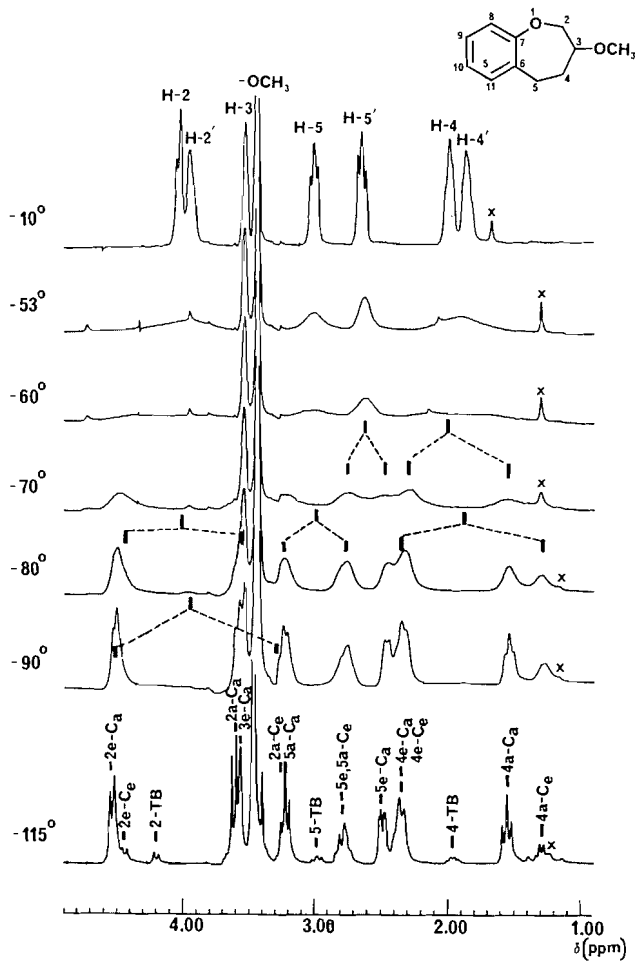

FIG. 4. Aliphatic portion of the 400.13-MHz ^{1}H nmr spectra of **10** in CHF_2Cl–CD_2Cl_2 (80:20) at several temperatures. The numbers and letters refer to the position and the orientation of the protons, while C_e, C_a, and *TB* refer to conformations described in the text. "X" identifies an impurity.

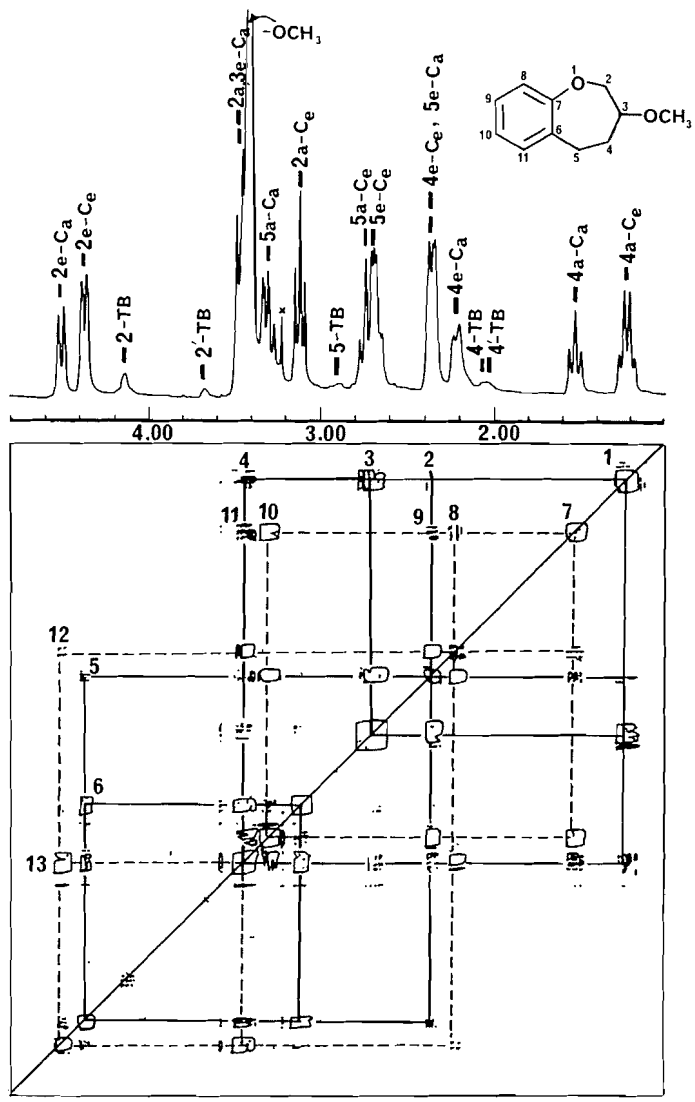

FIG. 5. Proton (^{1}H) 2D-homonuclear COSY spectrum, with double quantum filtering of the aliphatic signals of **10**, in CF_2Cl_2–acetone-d_6 (94:6), at −120°C. The numbers and letters refer to the position and the orientation of the protons, while C_a, C_e, and *TB* refer to conformations described in the text.

signals can be attributed to the 2-protons next to the oxygen atom. The other resonances given in Table 2 were assigned by double irradiations. All those signals broaden at lower temperatures to give, at −115°C, three sets of signals in a ratio 70:20:10, as also found in the ^{13}C spectrum. The signals of the major C_a form (70% of the total spectrum) were assigned without much difficulty through double irradiations and by comparison with previous proton patterns of chair forms (as for compounds **8** and **9**). Thus, it was found that 3e-C_a overlaps with the most shielded line of the triplet (3.59 ppm) corresponding to 2a-C_a. Identification of the C_e (20%) and *TB* (10%) proton resonances is difficult in that solvent system because of their low abundance and possible overlap with the major peaks. However, a change to the less polar CF_2Cl_2–acetone-d_6 solvent system increases the amount of C_e form appreciably (44:50:6 for C_a:C_e:*TB*) and facilitates the assignation of its resonances.

Unequivocal assignations of C_a and C_e resonances of **10** in the CF_2Cl_2–acetone-d_6 mixture at −120°C are possible using the 2D-COSY technique, with double quantum filtering (7) to remove as much as possible the interference caused by the intense methoxy signal, as shown in Fig. 5.

The 2D contour plot consists of correlation peaks appearing either *on* or *off* the diagonal line (lower left to upper right); the diagonal peaks arise from individual protons whose chemical shifts and multiplicities are obtained directly from the 1D spectrum above, while the off-diagonal peaks relate two diagonal peaks through coherence transfer via *J* coupling. Unequivocal identification of a "base" diagonal peak for each conformation is the starting point that enables us to sort out the chemical shifts of all coupled protons to this base peak and, hence, to secure the position of all resonances for each conformation.

For example, the quartet at 1.19 ppm is unambiguously assigned to 4a-C_e, since 4a-protons in chair forms of this system always appear as the most shielded protons in the ^{1}H nmr spectrum (Table 2). Now, correlations 2, 3, and 4, on the same horizontal line as the diagonal peak 1, correspond to protons in the C_e conformation coupling with 4a-C_e. Thus, correlation peak 4 can confidently be attributed to 3a-C_e (methine proton at 3.40 ppm), while correlation 2 identifies 4e-C_e (2.31 ppm), since protons at position 4 in both **8** and **9** were shown (Table 2) to be more shielded than the benzylic protons (position 5). Additional evidence for this last assignment is given by the presence of correlation 5 between the 2e-C_e proton (character-

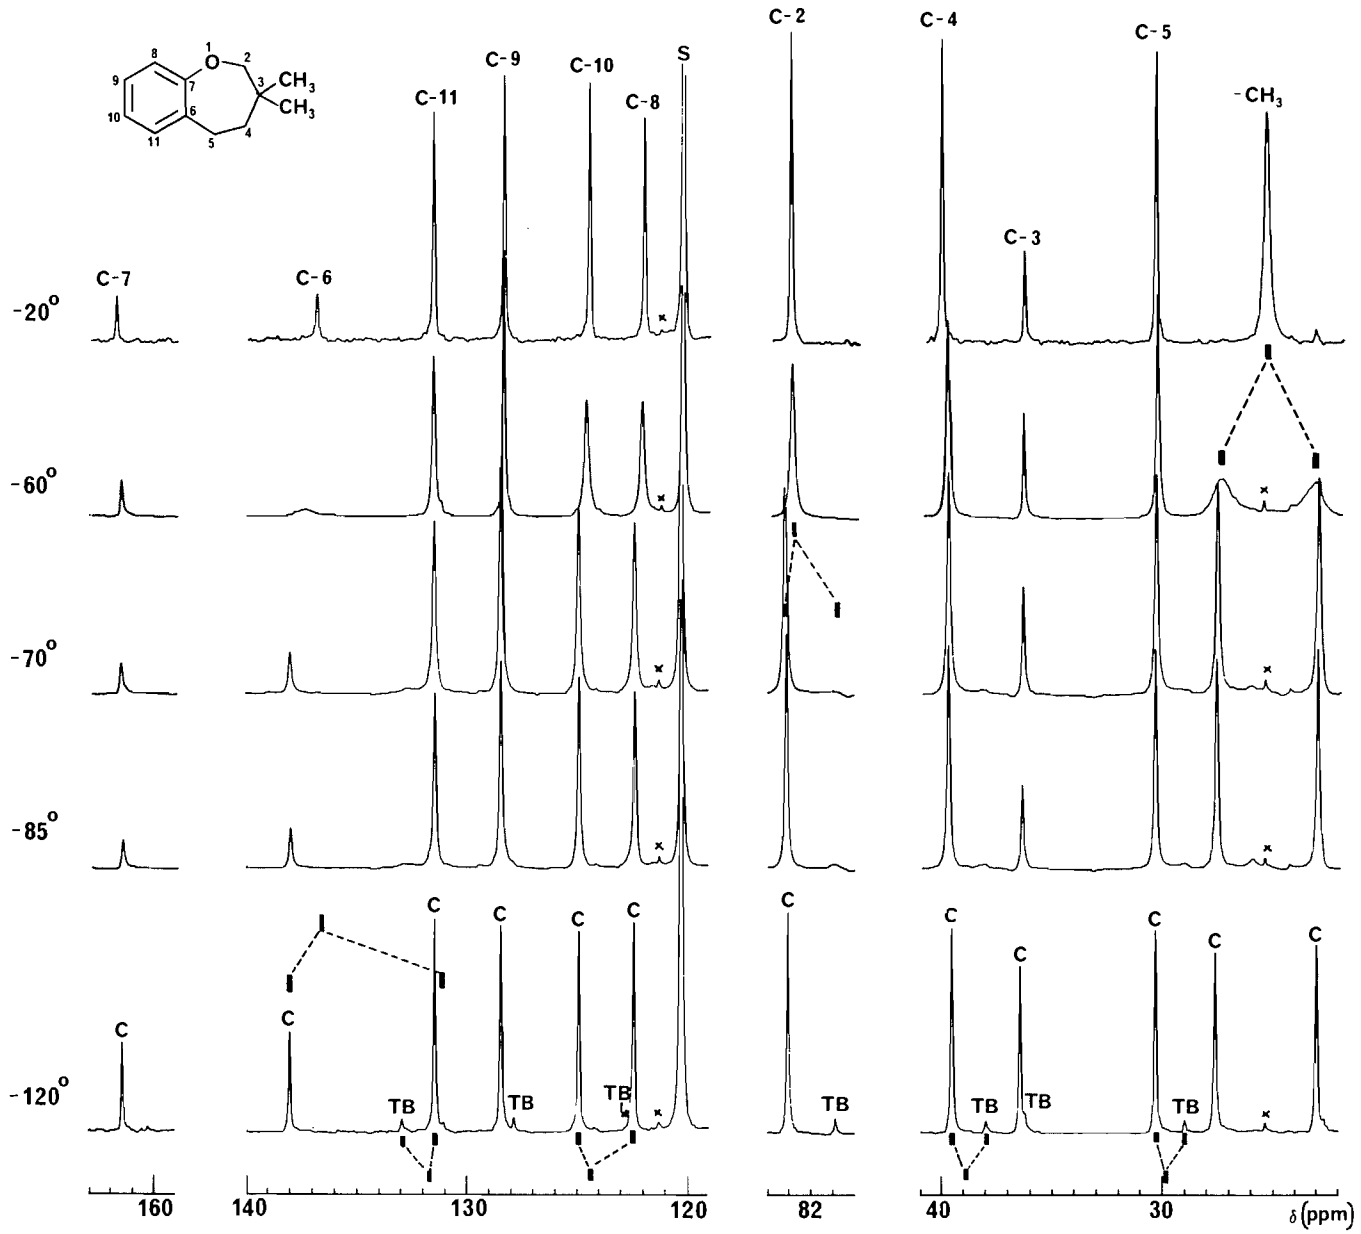

FIG. 6. The 100.62-MHz ^{13}C nmr spectra of **11** in CHF_2Cl–CD_2Cl_2 (80:20) at several temperatures. *C* and *TB* refer to conformations described in the text. Broken lines link together signals corresponding to the same carbon atom position. "S" defines a solvent (CHF_2Cl) line, while "X" denotes an impurity.

istically the most deshielded seven-membered ring proton in this system) and the 4e-C_e proton (diagonal peak 14). Correlation peak 5 arises from "W"-coupling between 2e-C_e and 4e-C_e, which cannot exist between 2e-C_e and either 5e-C_e or 5a-C_e. Correlation peak 3, together with careful integration of the 1D spectrum, can then be attributed to the two benzylic protons (5a-C_e and 5e-C_e). Finally, the diagonal peak 15 belongs to 2a-C_e, a triplet at 3.11 ppm, since correlation peak 6 relates it to the 2e-C_e proton via geminal coupling.

Signals of the less abundant C_a form can be identified through a similar procedure in which the 4a proton (4a-C_a) is taken as a reference point (base peak 7 on the diagonal). Figure 5 shows four off-diagonal correlation peaks (numbered 8, 9, 10, and 11) related horizontally by dotted lines to base peak 7. Correlation peak 8 is attributed to 4e-C_a (broad doublet at 2.18 ppm), since it can explain correlation peak 12 relating it to 2e-C_a (diagonal peak 16) via W-coupling. All other signals assigned in Fig. 5 were identified by straightforward analysis of the 2D spectrum and by direct comparison with the low temperature ^1H nmr spectrum of the same compound at −115°C, in CHF_2Cl–CD_2Cl_2 (80:20), shown in Fig. 4. For example, the presence of the 2a-C_a proton at 3.42 ppm (diagonal peak 17) is confirmed by the presence of correlation 13, which relates it to 2e-C_a via geminal coupling.

Correlation peaks for the minor *TB* resonances were not observed in the 2D-COSY spectrum of Fig. 5; these signals were assigned by direct comparison with *TB* resonances in the ^1H spectrum of **10** at −115°C, in CHF_2Cl–CD_2Cl_2 (80:20), shown in Fig. 4.

Changes were also observed in the ^{13}C and ^1H spectra of compound **11** (R = R′ = CH_3), on going from −10 to −120°C. As seen in Fig. 6, the ^{13}C spectrum of **11**, in CHF_2Cl–CD_2Cl_2

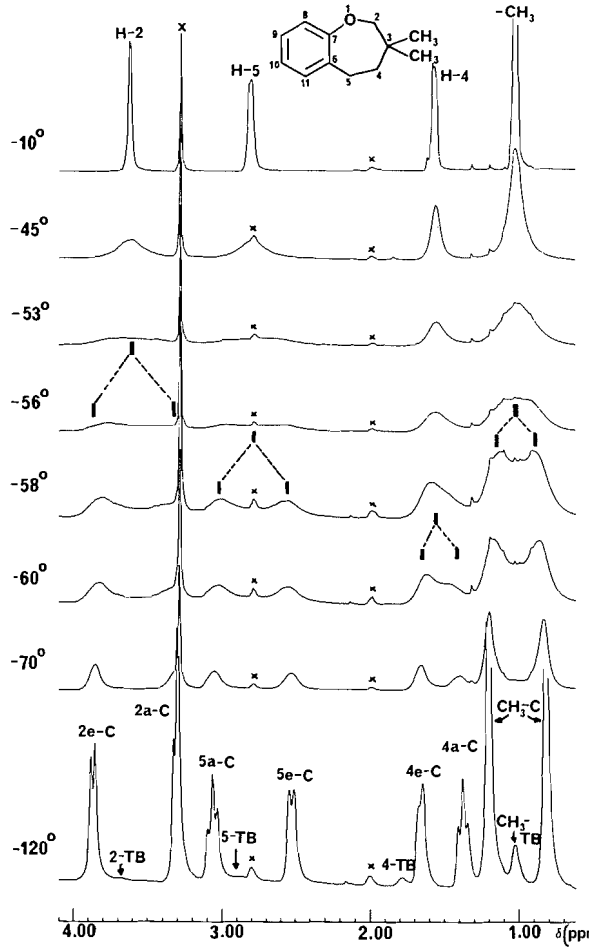

FIG. 7. Aliphatic portion of the 400.13-MHz ^{1}H nmr spectra of **11** in CHF_2Cl–CD_2Cl_2 (80:20) at several temperatures. The numbers and letters refer to the position and the orientation of the protons, while *C* and *TB* refer to conformations described in the text. Broken lines link together exchanging protons, while "X" denotes an impurity.

(80:20) at −15°C, consists of 11 signals, which were readily assigned by off-resonance experiments and by using the known substituent chemical shift (SCS) effect of a *gem*-dimethyl group on a chair form (8). The methyl carbon signal at 25.59 ppm shows appreciable broadening at that temperature, and coalesces at lower temperature to give, at −60°C, two distinct broad signals corresponding to axial and equatorial methyl groups on the chair conformation. A broad signal corresponding to the methyl groups of the twist-boat conformation is also apparent at −80°C near 26.5 ppm. All other carbon resonances also broaden at lower temperature to give, at −120°C, two sets of signals (integration = 90:10) assigned to the chair (*C*) and the twist-boat (*TB*) conformations, as will be discussed in the next section. Minor *TB* signals for quaternary carbons C-6 and C-7 could not be distinguished from the base line, while that of C-8 was hidden under the large solvent (CHF_2Cl) line. A decrease in the polarity of the solvent mixture (CH_3OCH_3–CD_2Cl_2, 80:20) only led to small variations in the relative populations of the two conformations (*C*:*TB*, 89:11).

The partial ^{1}H spectrum of **11** at −10°C in CHF_2Cl–CD_2Cl_2 (Fig. 7) shows four distinct broad signals corresponding to the three methylene groups and to the *gem*-dimethyl moiety. All these signals broaden as the temperature is lowered to give, at −120°C, two sets of signals with unequal intensities (90:10), as was also noted in the ^{13}C spectrum and assigned to the chair (*C*) and twist-boat (*TB*) conformations. Precise assignment of the individual ^{1}H resonances is done by direct comparison with the analogous signals observed for the parent compound **8** at the same temperature. The doublet corresponding to 2a-*C* (3.31 ppm) partially overlaps with an impurity line, but its presence is unambiguously ascertained by selective decoupling of the 2e-*C* doublet (3.87 ppm). The minor set consists of only two detectable aliphatic signals at 1.02 and 1.79 ppm, which are assigned respectively to the methyl groups and to H-4. Better signal-to-noise ratio in the less polar CF_2Cl_2–acetone-d_6 (94:6) mixture allowed the detection at −120°C of the two other missing *TB* signals, namely those for H-5 (2.8 ppm) and for H-2 (3.5 ppm).

Appreciable variations (shown in Figs. 8 and 9) also occur in the ^{13}C and ^{1}H spectra of **12** (R = CH_3, R′ = OCH_3) in CHF_2Cl–CD_2Cl_2 (80:20) as the temperature is lowered. The ^{13}C spectrum of **12** at −20°C, for example (Fig. 8), shows 12 resonances, most of which are assigned by techniques mentioned earlier. The most deshielded signal in the 25–35 ppm region is assigned to C-4 because of the known downfield β-effect created by the introduction of the methyl group at the 3-position (*5a,b*). Lowering the temperature broadens all the signals, although the C-9 and methoxy resonances remain sharper at −70°C. Further cooling produces, at −95°C, three sets of signals of unequal intensities (89:4:7) for the C-4, C-5, methyl, and methoxy resonances: these sets are assigned respectively to the C_a, C_e, and *TB* conformations, as will be discussed in the next section. Signals for the least stable of the three conformations (C_e) could, however, not be detected for all the other carbon atoms, which show only two signals.

The assignment of individual aromatic carbon atoms for the *TB* set is possible through direct comparison with aromatic *TB* resonances of **10** and **11**; this procedure allows the detection of the C-8 (*TB*) signal under the solvent (CHF_2Cl) line near 120 ppm. Finally, the identification of the C-2 and C-3 *TB* signals is done using the known intimate relation between the coalescence temperature for a given dynamic process and the chemical shift difference between the two exchanging sites (9). Extensive broadening at −70°C for the C-2 and C-3 resonances, for example, compared to that observed for the methoxy signal, corresponds to a larger chemical shift difference between C_a and *TB* signals than for the methoxy case. This deduction leads to the assignment of the small 79.77-ppm signal to C-3 of *TB* and the signal at 76.52 ppm to C-2 of *TB*, in line with trends observed in C_a and *TB* signals of the monomethoxy derivative **10**.

The partial ^{1}H spectrum of **12** (Fig. 9) in CHF_2Cl–CD_2Cl_2 (80:20) at −15°C shows six multiplets, corresponding to the six aliphatic protons of the aliphatic portion of the molecule, and two singlets corresponding to the methoxy and methyl groups. All those resonances broaden as the temperature is lowered to give, at −115°C, a major set of signals that could be easily analyzed through selective irradiations; this set is attributed to the C_a conformation, in agreement with the ^{13}C spectrum of the same molecule at −95°C. A minor set of resonances is also detected and attributed to the *TB* form, but clear identification of individual resonances is possible only by considering the signals in the fast exchange limit (−10°C) as somewhat weighted averages of signals appearing in the slow exchange limit

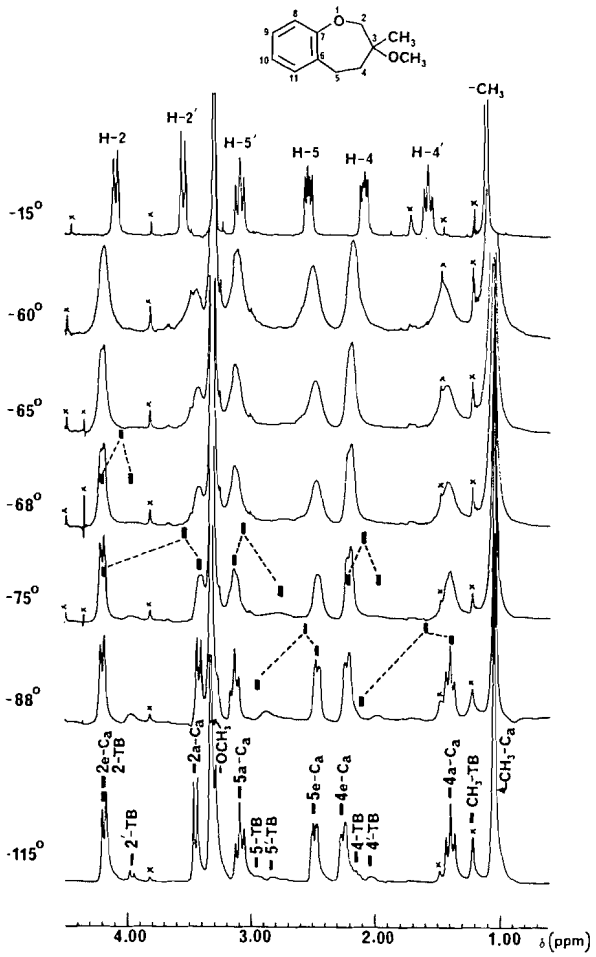

FIG. 9. Aliphatic portion of the 400.13-MHz ^{1}H nmr spectra of **12** in CHF_2Cl–CD_2Cl_2 (80:20) at several temperatures. Numbers and letters over the signals refer to the position and to the orientation of the protons, while C_a and *TB* correspond to conformations described in the text. "X" denotes an impurity.

(−110°C). Observation, for example, of the 2a-C_a signal, at −115°C, at higher field than the H-2′ signal at −15°C, points to a corresponding signal at lower field, which was detected as a broad peak around 4.1 ppm. Other minor resonances were assigned in the same fashion. Changing the solvent medium to a less polar combination only resulted in a small change of population for the three conformers present, namely C_a (85); *TB* (7) and C_e (8).

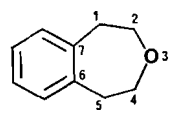
Finally, significant changes were also observed in the ^{13}C and ^{1}H nmr spectra of **13** (R = R′ = OCH_3) upon temperature lowering. For example, the ^{13}C spectrum of **13** in CHF_2Cl–CD_2Cl_2 (80:20) (Fig. 10) at −25°C shows 10 of the 11 signals of the molecule, which were assigned through direct comparison with the ^{13}C spectrum of **12** at −20°C. All those signals broaden as the temperature is lowered, although the phenomenon is much more pronounced for signals corresponding to C-6, C-8, C-9, C-11, C-2, and C-4. At −110°C, two sets of signals of different intensities (89:11) are detected; they are attributed respectively to the chair (*C*) and twist-boat (*TB*) conformations, as will be discussed in the next section. Again, lowering the polarity of the solvent mixture only resulted in a small population variation of *C* and *TB* forms (94:6).

The partial ^{1}H nmr spectrum of **13** in CHF_2Cl–CD_2Cl_2 (80:20), at −10°C (Fig. 11) shows three broad multiplets for the three methylene groups of the molecule and one singlet for the methoxy groups. All signals coalesce as the temperature is lowered, and split at −120°C into two sets of unequal intensities (92:8) assigned to the chair (*C*) and twist-boat (*TB*) forms, as previously deduced by ^{13}C. Careful integration of all aliphatic signals shows the presence of only three broad *TB* resonances, corresponding each to two protons, which could mean that the pseudorotation ($TB \rightleftharpoons TB^*$) process is still relatively rapid at that temperature (−120°C).

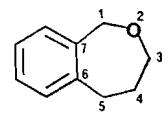
Discussion

Conformations of the seven-membered ring in compounds 8–13

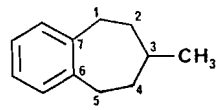
Previous investigations (4–6, 10, 11) of various heterocyclic compounds of the benzocycloheptene family have demonstrated the frequent existence of two seven-membered ring geometries for such molecules, namely the chair (*C*) and the twist-boat (*TB*) conformations. However, as was the case for benzocycloheptene itself (12*a*), only the chair form has been detected (10*a*, 12*b*) by dynamic nmr for the unsubstituted benzoxepins **15** and **16**. The absence of a ^{13}C spectral change for **8** (in both polar and nonpolar solvent systems) confirms the existence of a single chair (*C*) conformation for that molecule. The $C \rightleftharpoons C^*$ conformational inversion possible for **8** is revealed by the ^{1}H spectral modification from which an activation barrier of 9.2 ± 0.3 kcal mol^{-1} is estimated (13). This value is comparable to those observed for the same process in **15** (9.5 ± 0.2 kcal mol^{-1}) (12*b*) and in **16** (9.4 ± 0.3 kcal mol^{-1}) (10*a*).



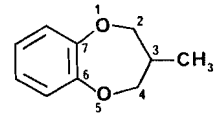
15



16



17



18

The presence of two sets of carbon resonances in the ^{13}C nmr spectrum of **9** (R = H, R′ = CH_3), at −120°C, reveals the presence of two distinct conformations at that temperature. The identification of these conformations makes use of experimental methyl substituent effects (α, β, and γ) (14) for **9** compared with those obtained for the chair forms of two model compounds 3-methylbenzocycloheptene **17** (15) and 3-methyl-1,5-benzodioxepin **18** (5*b*). The major set of signals of **9** gives ^{13}C methyl chemical shift effects (β (on C-2) = +5.10 ppm, β (on C-4) = +8.30 ppm, and γ (on C-5) = −1.47 ppm) similar to those found for an equatorial methyl group on the chair conformation of **18** (β (on C-2) = +5.11 ppm) (5*b*) and of **17** (β (on C-4) = +7.80 ppm and γ (on C-5) = −1.24 ppm) (15), in agreement with a C_e (chair with an equatorial methyl) form for **9**. A similar treatment for the minor set of signals relates it to the C_a (axial methyl) conformation, because the β-effect observed on C-2 (+3.99 ppm) agrees fairly well with that of an axial methyl group on the chair form of **18** (β (on C-2) = +4.07 ppm) (5*b*). The presence of a strongly shielding γ-effect (−5.95 ppm) noted for the weaker C-5 resonance of **9** corroborates this C_a assignment.

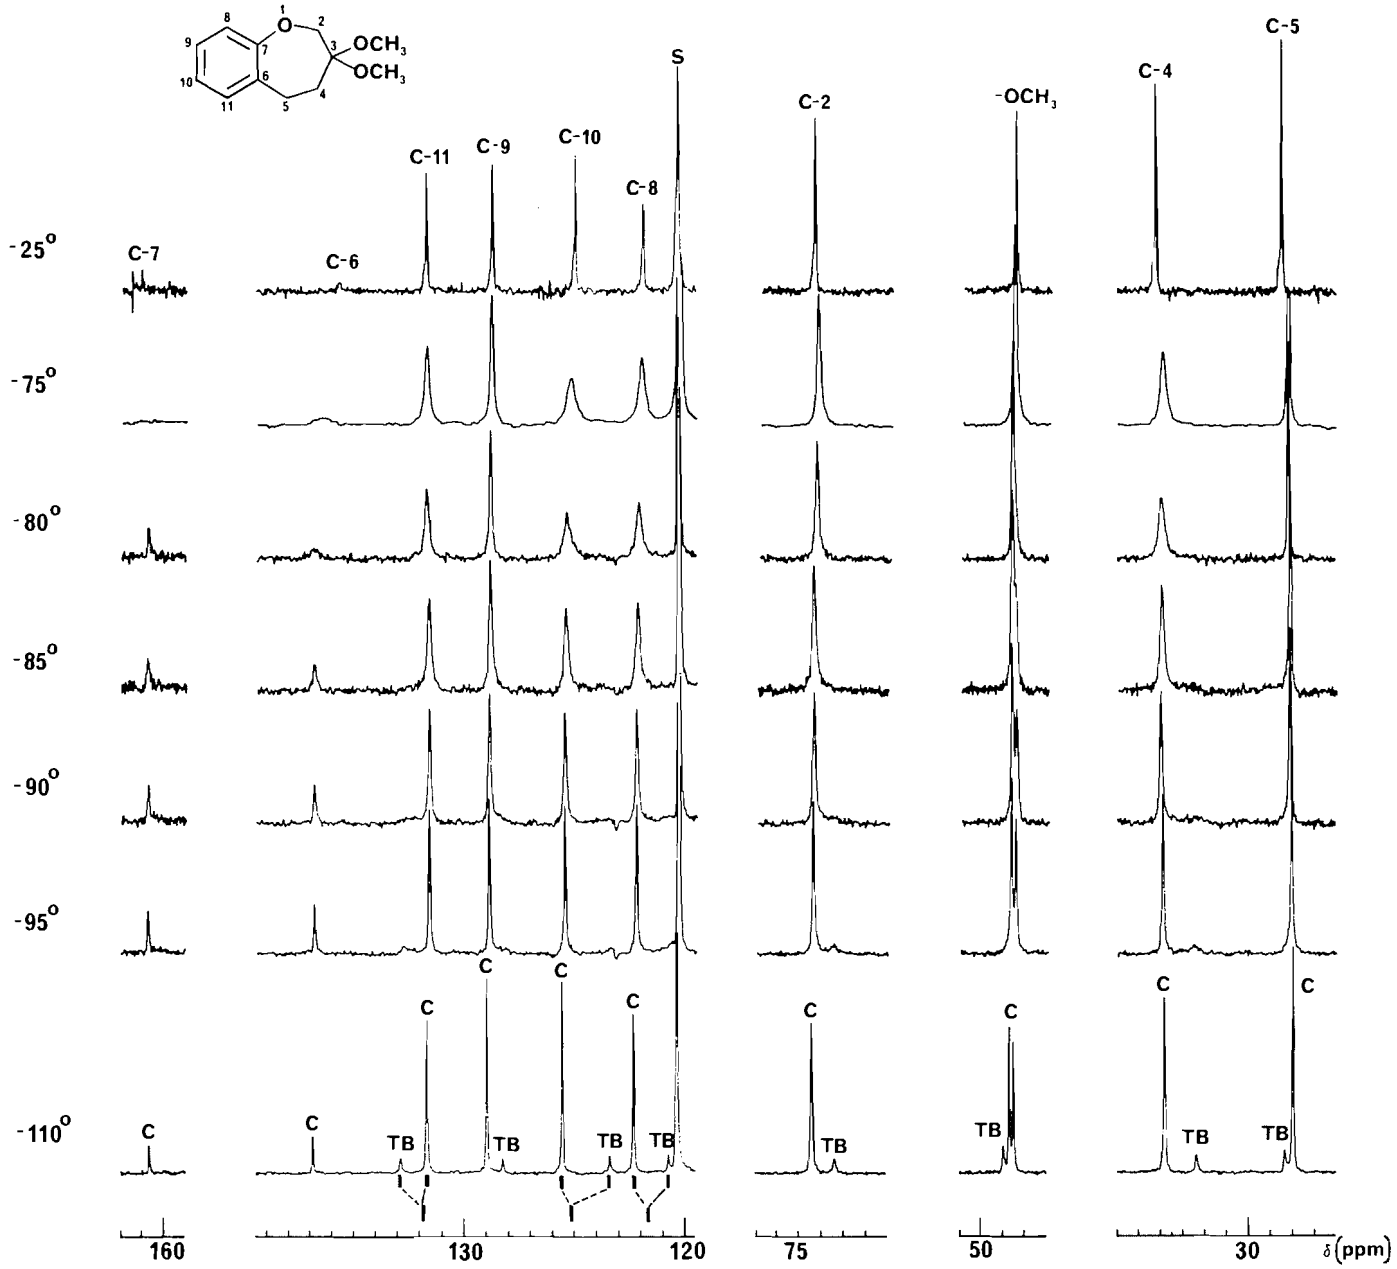


FIG. 10. The partial 100.62-MHz ^{13}C nmr spectra of **13** in CHF_2Cl–CD_2Cl_2 (80:20) at several temperatures. *C* and *TB* refer to conformations described in the text. Broken lines link together signals corresponding to similar carbon atom positions.

Similarly, at −120°C, the chemical shift difference between the geminal protons at the 2-position in **18** was found (5*b*) to be quite sensitive to the methyl orientation on the chair conformation (equatorial $\Delta\delta$ = 0.97 ppm and axial $\Delta\delta$ = 0.46 ppm). The observation of similar chemical shift differences for the two sets of signals of **9** (major $\Delta\delta$ = 0.90 ppm and the minor $\Delta\delta$ = 0.40 ppm) therefore supports the above conformational assignments.

The above method must be used with great caution for derivatives **10–13** because additional factors, such as solvation owing to the presence of a polar substituent and ring deformation resulting from increased substitution, could lead to misleading results, especially for the identification of twist-boat conformations, because no reference *TB* signal is detected in the low-temperature nmr spectra of the parent compound **8**. More reliable conformational assignments can be obtained using the chemical shifts of the protonated aromatic carbons C-8 to C-11 as "conformational probes".

^{13}C chemical shifts are known to be quite sensitive to small changes in local environments (14). Analysis of Dreiding models for the chair and the twist-boat conformations for compounds **8–13** shows that interactions of the phenolic-type oxygen atom with the aromatic ring are significantly different in the *C* and *TB* conformations. Because changes in orientation of the substituents at the distant 3-position should not affect aromatic chemical shifts significantly for a particular ring geometry, those signal positions should reflect mainly on the geometry of the seven-membered ring.

The usefulness of the aromatic carbons as a probe is illustrated by analysis of the low-temperature ^{13}C spectrum

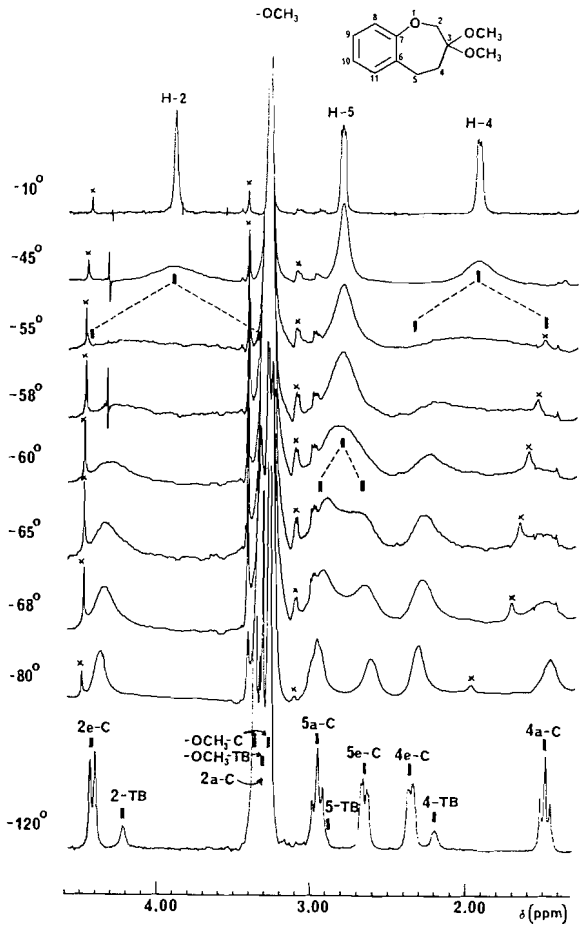

FIG. 11. Aliphatic portion of the 400.13-MHz ^{1}H nmr spectra of **13** in CHF_2Cl–CD_2Cl_2 (80:20) at several temperatures. Letters and numbers over individual signals describe the position and the orientation of the corresponding protons. *C* and *TB* refer to conformations described in the text. "X" denotes an impurity.

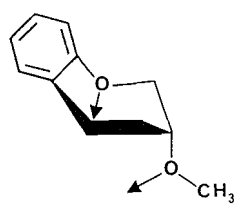
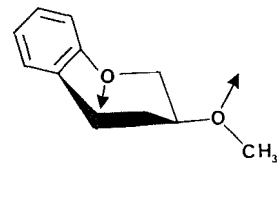
of the monomethoxy derivative **10**. The examination of the 120–135 ppm aromatic region in Table 1 shows that of the three resonances for each carbon, the two more intense (70% and 20% of the total signal intensity) have chemical shifts similar to those observed for the chair conformation of the parent compound **8** as well as the monomethyl derivative **9**. These signals, then, most probably belong to the two possible chair conformations C_a and C_e. Now, the association of each of the chair forms to the appropriate set of resonances can be done through the analysis of the C-6 and C-7 signals. For example, the fact that the less shielded C-6 and C-7 signals belong to the most intense set (70%) relates them to the C_a form, since axial methoxy groups are known (5*b*, 15) to have a less pronounced shielding δ-effect than equatorial ones. This assignment is corroborated by the observations of the 4a proton resonance as a triplet for this set in the ^{1}H spectrum of **10** at −120°C, owing to strong couplings with both H-4e and H-5a.

Finally, population variations induced by changing the polarity of the solvent are in line with the above identification of the C_e and C_a signals. Existing knowledge (16) holds that increasing the solvent dielectric constant should stabilize the more polar conformation, because of better solvation and attenuation of unfavorable dipole–dipole interactions. Precise dipole moment determination for the C_a and C_e conformations of **10** is not feasible because many geometrical variables (exact lone-pair locations, bond lengths, etc...) are unknown for this system. Only a qualitative assessment of the relative dipole moments of the two conformations can be utilized throughout this work. Such an analysis, applied previously to the 1,5-benzodioxepin family (5*b*), considered only the C—O bonds and the lone pairs of the oxygen atom as major contributors to the resultant dipole moment of the molecule. The resulting dipoles about each oxygen atom are represented as arrows bisecting the lone pairs and the C—O—C angle in structures **19** and **20**, and pointing towards the negative end of the dipole.



19 (C_a)



20 (C_e)

The dipole orientations of the methoxy group on both the C_a and C_e conformations do not have a fixed spatial direction and are represented as the mean of the most probable rotamers.

The relative orientations of the two resulting dipoles clearly indicate that C_a (**19**, with dipoles pointing in the same direction) should be more polar than C_e (**20**, with dipoles oriented in opposite directions). Such a conclusion is then consistent with the association of the major set of resonances in CHF_2Cl with C_a, since lowering the solvent polarity actually reduces the population of this form from 70% (in CHF_2Cl) to 44% (in CF_2Cl_2).

Association of the minor (10%) set of ^{13}C resonances of **10** in CHF_2Cl to the twist-boat (*TB*) family is straightforward from the chemical shift analysis of the aromatic carbons, which are quite distinct from those observed for the chair form of **8** as well as **9**. All *TB* resonances for those carbon atoms (except C-11) are more shielded than their chair counterpart. Indeed, the shielding is quite spectacular for the quaternary C-6 resonance, for which a chemical shift difference of more than 7 ppm is observed between the C_a and the *TB* signals (Table 1). Such a difference can be rationalized by the fact that C-6 is *ortho* to the phenolic oxygen and lone-pair delocalization contributes appreciably to its electron density. Because a change from the *C* to the *TB* geometry alters the angular relationship about the phenolic oxygen bonds, the extent of electron delocalization is modified. This change then gives rise to the dramatic upfield displacement of the C-6 chemical shift.

Now, two *TB* conformations are possible for **10** depending on the orientation of the methoxy group, namely TB_g (**21**) and TB_a (**22**). In **21**, the external C—O bond is *gauche* (g) to the internal C—O bond while in **22**, it is *anti* (a). Observation of only one set of *TB* carbon resonances in the ^{13}C spectrum of **10**, at −120°C, suggests either the predominance of one of these conformations or a rapid equilibrium of the two forms. The absence of suitable ^{13}C reference chemical shifts for those *TB* conformations unfortunately restricts the use of ^{13}C parameters in this pursuit.

The multiplicity of the ^{1}H *TB* signals for **10** at −120°C (in CHF_2Cl) is useful to sort out the various conformational possibilities, since H-2a′ and H-4a′ should show characteristic coupling patterns for each form (the prime indicates pseudo-axial orientation in *TB*). For example, Dreiding models of the two *TB* forms (see also projections **23** and **24**) reveal that the 2a′

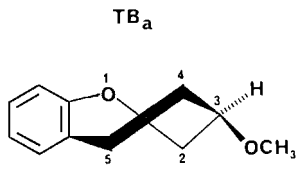
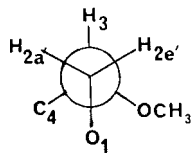
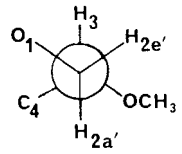
21



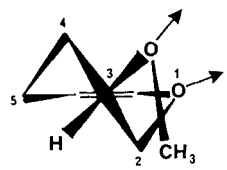
22



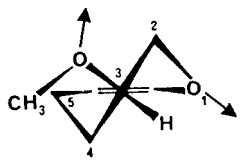
23



24



25



26

proton should give rise to a triplet due to strong coupling with H-2e′ and H-3 for TB_a, while in TB_g it should give a doublet (strong coupling with H-2e′ only).

The observation that the *TB*-2a′ signal is a doublet (4.19 ppm) in the ^{1}H nmr spectrum of **10** therefore suggests a predominant TB_g conformation. This conclusion is corroborated by the appearance of the H-4a′ as a quartet (1.95 ppm) (strong couplings with the 4e′, 3, and 5a′ protons). Exact determination of the TB_g:TB_a ratio cannot, however, be deduced from such an approach (since the *TB* geometries described are flexible enough to be distorted significantly in solution).

The TB_g predominance over TB_a can also be appreciated from the effect produced by a change in the solvent polarity. Table 2 shows that substitution of the polar CHF_2Cl–CD_2Cl_2 mixture by the less polar CH_3OCH_3–CD_2Cl_2 system reduces the relative populations of the *TB* and C_a forms relative to C_e, inferring roughly similar dipole moments for the *TB* and C_a conformations. Structures **25** and **26** confirm that a similar resultant orientation of internal dipole moments exists in both C_a and TB_g conformations (**19** and **25**), in agreement with the observed solvent effect.

The evaluation of the conformational preferences of compounds **11** (R = R′ = CH_3), **12** (R = CH_3; R′ = OCH_3), and **13** (R = R′ = OCH_3) is rather straightforward through the use of the aromatic ^{13}C signals as probes. Thus, the similar aromatic resonances observed for the chair form of the unsubstituted compound **8** and of **11**, **12**, and **13** clearly indicate a predominance of the chair (*C*) conformation in all three cases. The presence of two sets of chair resonances in the low temperature ^{13}C nmr spectrum of the methylmethoxy derivative **12** refers to different spatial arrangements of the substituents at the 3-carbon, namely to C_a and C_e conformations, as defined earlier in the text. Previous studies (2*a*) on the analogous 5,5-methylmethoxy-1,3-dioxane compound showed that the methyl group appears at higher field in the ^{1}H nmr spectrum when in an equatorial position than in an axial one. Assuming the same order in the seven-membered ring, the methyl group on the major chair conformation of **12** should be equatorial, since no methyl signals at higher field can be detected in the low temperature ^{1}H nmr spectra of that compound. The exact position of this major methyl signal (1.05 ppm) can also be used as an indication of its equatorial orientation since it correlates fairly with the ^{1}H nmr chemical shift (1.04 ppm) of the equatorial methyl group in the similar C_a conformation of 5-methyl-5-methoxy-1,5-benzodioxepin (5*b*).

Aromatic signals for the *TB* conformations of all three disubstituted compounds (e.g., **11**, **12**, and **13**) were identified by comparison with those of the monomethoxy derivative **10**. Finally, two *TB* forms (TB_g and TB_a, as defined in the text for **10**) are possible in solution for **12**, but careful analysis of the experimental results could not establish their individual relative contribution to the conformational equilibrium of the molecule.

Origin of the conformational preferences

Benzocycloheptene, the basic carbon framework of this study, was shown, by ^{1}H nmr spectroscopy (12*a*), to exist solely in the chair form (*C*), as predicted from theoretical calculations by Favini and Nava (17). Further studies (4, 5) demonstrated that the introduction of two oxygen atoms at either the 1,5 or the 2,4 position stabilizes the twist-boat conformation (*TB*) relative to the chair (*C*) conformation, due to more favorable dipolar as well as electronic or stereoelectronic interactions between both oxygen atoms.

Such a stabilization is, however, not apparent a priori for compound **8**, in which only one benzylic CH_2 group is replaced by an oxygen atom. Qualitative assessment of the various parameters involved can be achieved through the use of a phenomenological approach described by Kaloustian (16) and Zefirov (18). This method defines the total energy (*E*) of a conformer as the sum of energies relating to structural (E_{ST}), dipolar (E_D), and solvent (E_S) interactions. Therefore, the energy difference (ΔE) between two conformers corresponds to the sum of the differences in each sub-term, as described in eq. [1]:

$$[1]\quad \Delta E_{(C/TB)} = \Delta E_{ST}(C/TB) + \Delta E_D(C/TB) + \Delta E_S(C/TB)$$

In benzocycloheptene, the large energy difference (ΔE) between the *C* and *TB* conformations is attributed mainly to the ΔE_{ST} sub-term (notably to the van der Waals interactions and to the torsional strain, which both favor the *C* form). The introduction of an oxygen atom next to the benzene ring to give compound **8** should raise the contribution of the other ΔE sub-terms, since significant dipolar interactions are created. However, the overall effect of these changes on $\Delta E(C/TB)$ cannot be determined experimentally since no *TB* signal is detected in the low temperature ^{1}H and ^{13}C nmr spectra of **8**.

The presence of a methyl group at the 3-position as in **9** does not significantly perturb the conformational behavior of the seven-membered ring, since only chair conformations (C_e (major) and C_a (minor)) are detected in the low temperature nmr spectra of **9**. The presence of minor C_a signals is not unexpected for **9**, since replacement of a benzylic methylene group of benzocycloheptene by an oxygen atom is expected to reduce the 1,3-diaxial interactions that would characterize an axial methyl group. By comparison, no C_a form is detected for 5-methylbenzocycloheptene **17** (15). A similar increase in the amount of the C_a form upon substituting methylene groups by oxygen atoms was noted for methyl derivatives of the analogous saturated six-membered ring system (19).

In contrast, the change from a methyl group at the 3-position

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

to a polar methoxy group (compound **10**) brings radical changes to the conformational equilibrium of the system. The earlier analysis of the dipole orientations in the possible chair conformations of **10** (structures **19** and **20**) showed that the C_a conformer should have a greater dipole moment than C_e. The predominance of the C_e conformation for **10** in a relatively nonpolar medium (CH_3OCH_3–CD_2Cl_2, 80:20) can thus be explained by the less destabilizing dipolar interactions (E_D term less positive) in that conformation. Increasing the polarity of the medium (CHF_2Cl–CD_2Cl_2, 80:20) reverses the relative conformational stabilities, as C_a becomes the predominant conformation in solution. Increased solvation (E_S term more negative) and decreased dipolar interactions (E_D term less positive) should stabilize the C_a form relative to the C_e form. Finally, effective overlap between bonding σ and antibonding σ^* orbitals (the so-called "attractive *gauche* effect" (20)) should also stabilize the C_a form, although the quantitative assessment of the effect of this factor on the conformational equilibrium is beyond the scope of this study.

Quite interestingly, *TB* signals are detected in the low temperature nmr spectra of compound **10**, indicating that the introduction of a methoxy group at the 3-position is much more stabilizing for the *TB* form than for the *C* form. This observation is compatible with the great flexibility of the twist-boat conformation, which allows structural distortions in order to minimize the total energy of the conformer through reduced dipolar interactions or better orbital overlap. A similar observation (10*a*) was made upon introduction of a methoxy group at the 3-position of 2,3,4,5-tetrahydro-2-benzoxepin (**16**).

Two twist-boat conformations (TB_g and TB_a, as defined earlier by structures **21** and **22**) are possible in solution for **10**; the predominance of the TB_g conformer, at least in the polar solvent system (CHF_2Cl–CD_2Cl_2), can be rationalized through consideration of dipolar and orbital interactions in both *C* and *TB* conformations. The examination of Dreiding models described in the preceding section indicates similar spatial *gauche* arrangements for the —O—C—C—O— fragment in both TB_g and C_a, whereas an *anti* arrangement exists in both TB_a and C_e. Therefore, on a qualitative basis, the stabilizing factors shown previously to favor C_a over C_e in a polar medium should also favor TB_g over TB_a.

The presence of two geminal substituents at the 3-position as in compounds **11**, **12**, and **13** also stabilizes the *TB* form relative to the *C* form. In the case of the dimethyl derivatives **11**, it results in large part from destabilizing 1,3-diaxial CH_3–H interactions on the chair form, which can be alleviated by placing these substituents in the sterically less demanding isoclinal positions of the *TB* form.

A combination of factors governing conformational preferences in both the monomethyl (**9**) and the monomethoxy (**10**) derivatives can then be used to analyse the methylmethoxy (**12**) case. As expected, C_a (axial methoxy and equatorial methyl groups) is the predominant conformation of **12** in solution, for it combines the favorable arrangements of the C_a form of **10** and the C_e form of **9**. Furthermore, *TB* signals are detected in solution for **12**. Because the addition of a 3-methyl group does not change significantly the *C*:*TB* ratio from that observed for **10**, the origin of the relative stabilization of the *TB* form for **12** should be related to that for compound **10**.

Finally, the presence of only 8% of *TB* form in solution for the dimethoxy derivative **13** indicates that the addition of a second methoxy group at the 3-position of **10** does not change significantly the *C*:*TB* ratio of this system. The observation of similar *TB* populations for both the dimethyl (**11**) and the dimethoxy (**13**) derivatives also suggests that increased dipolar interactions in the latter must be compensated for by reduced 1,3-diaxial steric interactions, in the chair as well as in the twist-boat conformations. This result also apparently implies that the effect of geminal disubstitution at the 3-position on the $C \rightleftharpoons TB$ conformational equilibrium is relatively independent of the nature (polar or nonpolar) of the substituting groups.

Experimental

All syntheses requiring anhydrous conditions were performed under argon with techniques described elsewhere (21). Anhydrous solvents were obtained by distilling over various drying agents: $LiAlH_4$ for ether, sodium–benzophenone for tetrahydrofuran, $CaCl_2$ for benzene and xylene, and Mg for methanol. Flash chromatography was performed on 230–400 mesh silica gel (Merck) under standard conditions described by Still *et al.* (22). Preparative vapor phase chromatography was performed on a Varian model 920 apparatus using a 5 ft. × 3/8 in. stainless steel column containing 30% SE-30(P-HMDS) on Chromosorb-P. The sample to be purified is vaporized at 200°C in the injection port, passed through the separating column on a stream of helium gas (carrier gas), detected at 200°C by thermal conductivity, and condensed in an acetone – Dry Ice bath. Column temperatures and retention times are specified when necessary.

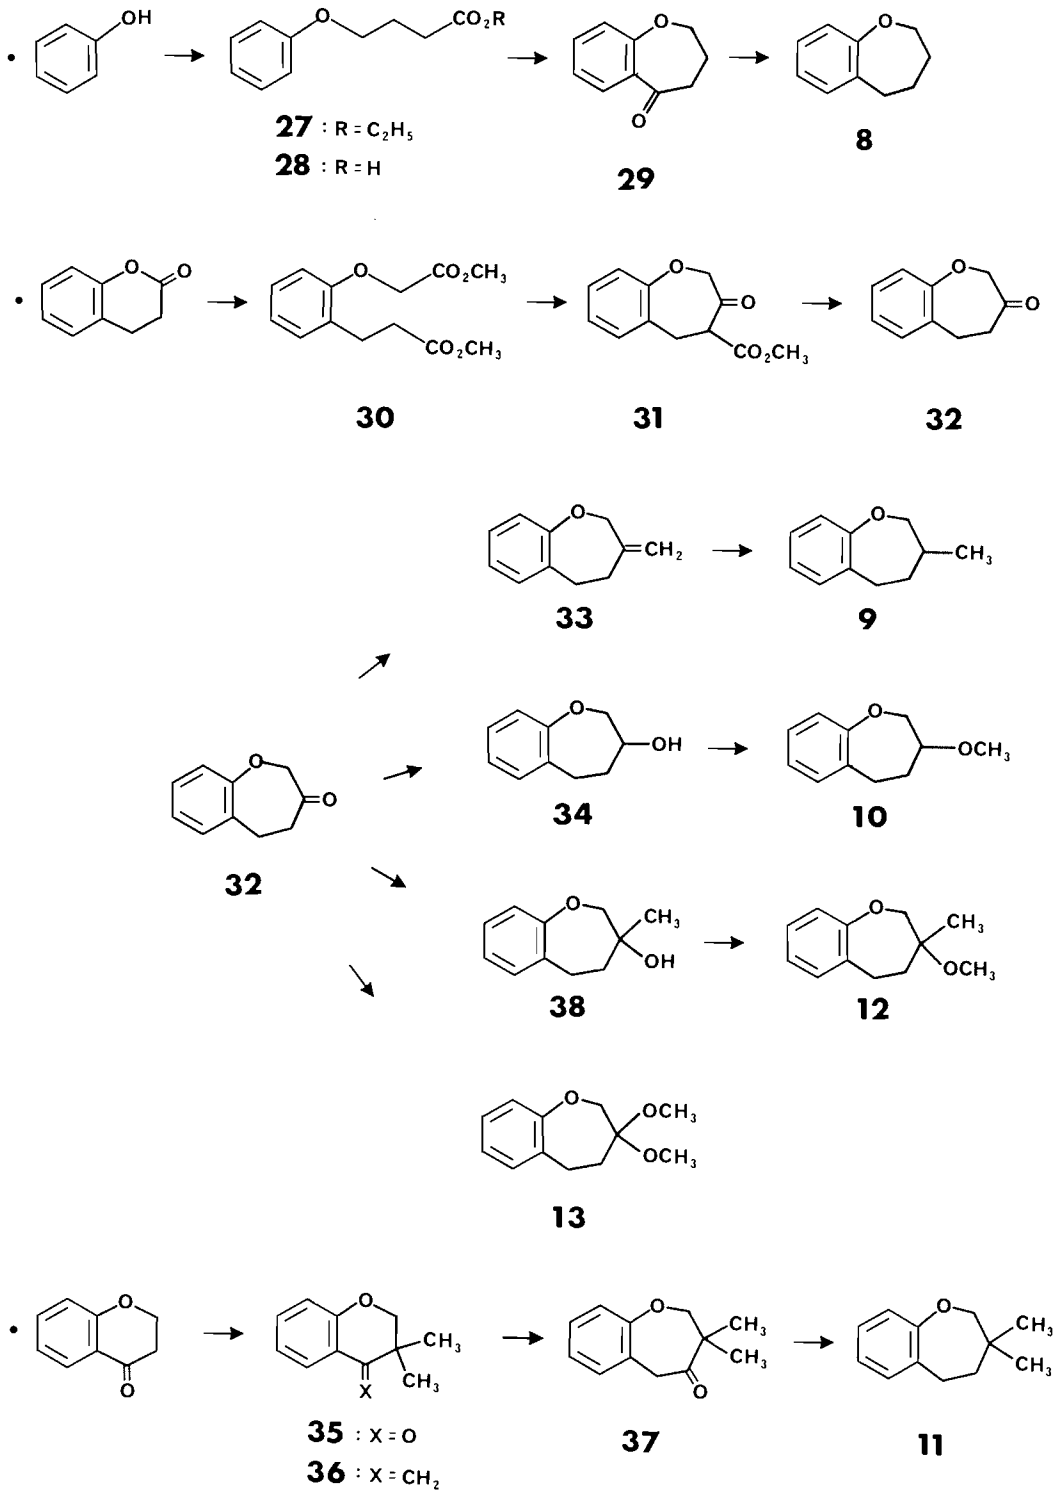
Melting points were determined on a Thomas–Hoover (Unimelt) apparatus and were not corrected. Boiling points were determined by either simple or bulb-to-bulb (Kugelrohr) distillation for which the temperature reported represents the lowest one at which the vapors condensed on the receiving bulbs. Infrared spectra were taken on a Perkin–Elmer (Model 783) spectrometer. Low resolution mass spectra were recorded at 70 eV, in the chemical ionization mode, on a V.G. Micromass (Model 12-12) spectrometer, while those at high resolution were recorded at 70 eV, in the electron impact mode, on a modified MS-9 spectrometer. Routine ^1H nmr spectra were taken on a Bruker WH-90 spectrometer; solutions were typically 5% (w/v) $CDCl_3$ containing Me_4Si as internal reference. The following abbreviations are used to describe the signal multiplicity: s: singlet; d: doublet; t: triplet; q: quartet; m: multiplet; br: broad.

The variable temperature ^1H nmr spectra at 400.13 MHz and the ^{13}C nmr spectra at 100.62 MHz were obtained using a Bruker WH-400 spectrometer equipped with a B-VT-1000 variable temperature unit. Calibration using a copper–constantan thermocouple inside a solvent-containing nmr tube indicates that the temperatures reported are precise within ±3°C.

Proton samples in standard 5-mm tubes (degassed and sealed) were studied as 0.20 *M* solutions in either CHF_2Cl–CD_2Cl_2 (80:20) or CF_2Cl_2–acetone-d_6 (94:6) solvent systems containing a small amount of TMS. The following instrumental parameters are typical: flip angle, 15°; SW (scan width), 4500 Hz; number of scans, 100–1000. Gaussian multiplication was applied on all FID's. Data size was 8K (AQ (acquisition time), 0.91 s) for low temperature spectra (−100 to −125°C), and 16 and 32K (AQ, 1.81 and 3.64 s) for all others (+10 to −100°C). All 8 and 16K FID's were zero filled to 32K prior to the Fourier transformation.

Carbon-13 samples in standard 10-mm tubes (degassed and sealed) were studied as 0.40 *M* solutions in either CHF_2Cl–CD_2Cl_2 (80:20) or CH_3OCH_3–CD_2Cl_2 (80:20) solvent systems, containing a small amount of TMS. The following instrumental parameters are typical: flip angle, 60–70°; SW, 18 000 Hz; relaxation delay, 0.20 s; number of scans, 100–3000. Gaussian multiplication was applied on all FID's; data size, 16K (AQ, 0.46 s), zero filled to 32K prior to Fourier transformation.

Conformation populations derived from integration of proton signals represent averages of five integrations for a defined set of signals, while reliable integrations from carbon-13 spectra were obtained using a 0.1–0.2 s delay between pulses and by comparing results with at least two other sets of carbon resonances of the same compound. All integration figures are therefore precise within 2%.



SCHEME 1

The rate constant for **8** was determined by nmr at the coalescence temperature using the equation $\pi((\Delta\nu)^2 + 6J^2)^{1/2}/\sqrt{2}$ for singlet to AB spectral change. The free-energy barrier for this compound was calculated from standard equations (13) using a transmission coefficient of one (*vide infra*).

The two-dimensional (2D) ^{1}H nmr COSY experiment with double quantum filtering (7) was performed using the standard Bruker hardward and software (COSYDQF.AU). The pulse sequence utilized was D1–90°–D0–D2–90°–D3–90°–D2–FID, with the following delays: D1, 0.6 s; D2, 5 μs; D3, 5 μs. A spectral width of 2200 Hz and quadrature detection were used to collect a 97 FID × 2K data matrix (zero filled to 1K × 2K) using 96 scans; digital resolution was then 2.14 Hz/point. A sine bell square function was applied in both dimensions and absolute display was used.

Compounds **8–13** were obtained by multistep synthesis from commercially available products, as described in Scheme 1.

γ-Phenoxybutyric acid ethyl ester 27

To 150 cm^3 of a 1.05 *M* sodium ethoxide solution in ethanol (10.75 g of sodium in 150 cm^3 of ethanol) was added with stirring, at 40°C, 40.00 g (0.425 mol) of phenol in four portions, over a period of 2 h. γ-Chlorobutyric acid ethyl ester (Aldrich, 64.01 g, 0.425 mol) was

For personal use only.

then added dropwise during 2 h, and the resultant cloudy solution was refluxed for 16 h. The solution was then cooled to room temperature, filtered on sintered glass, and evaporated under reduced pressure; the residue was dissolved in 300 cm^3 of ether, and this organic phase was washed successively by 3 × 75 cm^3 10% NaOH and by 3 × 75 cm^3 brine. The organic phase was then separated, dried over anhydrous magnesium sulfate, and filtered on sintered glass. Evaporation under reduced pressure yielded an oil, which was distilled under reduced pressure (120–125°C/0.5 Torr; 1 Torr = 133.3 Pa) (lit. (23) bp 170–173°C/25 Torr) to give 53.29 g (60% yield) of a clear and pleasant smelling oil whose ^1H nmr spectrum agreed with the proposed structure; ^1H nmr (90 MHz, $CDCl_3$) δ: 1.24 (t, 3H, CH_3), 2.09 (m, 2H, —CH_2—), 2.50 (t, 2H, —CH_2—CO—), 3.98 (t, 2H, —O—CH_2—), 4.13 (q, 2H, —CO—O—CH_2—), 6.83–7.36 (m, 4H, arom. protons).

γ-Phenoxybutyric acid ***28***

A quantity of 50.00 g (0.240 mol) of **27** was mixed, at room temperature, with 75.00 g (1.34 mol) of KOH and 350 cm^3 of absolute ethanol in a one-necked round-bottomed flask, and the resulting solution was stirred during 1.5 h. A white precipitate gradually appeared as the reaction proceeded; the mixture was then filtered on sintered glass, and the recovered white solid was dissolved in 600 cm^3 H_2O. The resulting solution was made acidic (pH 3) by slow addition of concentrated HCl, which precipitated the desired acid. Filtration on a Büchner funnel and drying over $CaCl_2$ for 24 h afforded 36.3 g (84% yield) of a white fluffy solid, whose melting point (63.0–64.0°C) agrees fairly well with that reported in the literature (62–63°C (ref. 24)); ^1H nmr (90 MHz, $CDCl_3$) δ: 2.12 (m, 2H, —CH_2—), 2.59 (t, 2H, —CH_2—CO—), 4.01 (t, 2H, —O—CH_2—), 6.84–7.38 (m, 4H, arom. protons), 10.01 (br, 1H, —COOH, exchangeable with D_2O).

*2,3-Dihydro-1-benzoxepin-5(4*H*)-one* ***29***

This compound was prepared by cyclization of γ-phenoxybutyric acid **28** with polyphosphoric acid, as described by Fontaine (25). A 65% yield of the desired ketone was thus obtained as a clear and dense oil, whose boiling point (120.8–125.0°C/1 Torr) is similar to that reported (106°C/2 Torr) (ref. 26), while its ^1H nmr spectrum (in $CDCl_3$) is identical with the one already published (25).

2,3,4,5-Tetrahydro-1-benzoxepin ***8***

To 12.21 g of zinc powder (Aldrich) in a 250-cm^3 three-necked flask, were added 1.12 g (0.004 mol) of mercuric chloride (Aldrich), 12.0 cm^3 of distilled water, and 1.1 cm^3 of concentrated HCl; the mixture was stirred at room temperature for 1 h, and then allowed to settle for 10 min. The Zn–Hg amalgam was ready for use after decanting the milky liquid phase. To that amalgam were added 9.6 cm^3 of distilled water, 21.6 cm^3 of concentrated HCl, and 6.0 g of ketone **29**. The mixture was then allowed to cool and filtered through a Büchner funnel; the solid particles were crushed on the filter and thoroughly washed with water (150 cm^3) and ether (200 cm^3). The organic layer from the filtrate was then separated and the aqueous layer extracted with 2 × 100 cm^3 ether. The combined organic phases were washed with 5 × 75 cm^3 of a saturated $NaHCO_3$ solution, dried on $MgSO_4$, filtered on a Büchner funnel, and evaporated under reduced pressure to give 3.90 g of a yellow oil. Distillation on a Kugelrohr apparatus (145°C/0.7 Torr) yielded a clear oil, which was flash-chromatographed on silica gel using dichloromethane–hexane (10:90) as eluant. The first compound eluted was identified as 2,3-dihydro-1-benzoxepin (oil), R_f 0.19 (CH_2Cl_2–hexane, 10:90); ^1H nmr ($CDCl_3$) δ: 2.66 (2H, m, H-3), 4.23 (2H, t, H-2), 5.99 (1H, td, H-4), 6.34 (1H, td, H-5), 6.88–7.25 (4H, m, arom. protons), while the more polar compound was the desired benzoxepin **8** (oil, 1.42 g, 26% yield). An analytically pure sample could be obtained from a preparative gc experiment (column temperature, 140°C; gas flow rate, 30 cm^3 min^{-1}; retention time, 3.0 min). The ^{13}C and ^1H nmr spectra described in Tables 1 and 2 confirm the identity of **8**. *Exact Mass* calcd. for **8** (EI ms), $C_{10}H_{12}O$, *m/e*: 148.0888; found: 148.0882.

2-(Carbomethoxyethyl)-phenoxyacetic acid methyl ester ***30***

In a 300-cm^3 three-necked flask containing 120 cm^3 of a sodium methylate solution (prepared from 6.6 g of sodium and 120 cm^3 of anhydrous methanol) was added dropwise, under argon, 35.9 cm^3 (42.0 g) of dihydrocoumarin (Aldrich). The resulting solution was refluxed for 45 min, followed by the dropwise addition to this refluxing solution of 29.5 cm^3 (47.67 g; 1.1 equiv.) of bromomethylacetate (Aldrich) and the cloudy solution was kept at reflux for another 16 h; it was then cooled, filtered on sintered glass, and evaporated under reduced pressure. The residue was dissolved in ether (200 cm^3) and washed successively with 3 × 50 cm^3 10% NaOH and 3 × 50 cm^3 brine. The organic phase was then dried on $MgSO_4$, filtered on a Büchner funnel, and evaporated under reduced pressure. The oily yellowish liquid obtained was distilled under vacuum (162–168°C/1.3 Torr) to give 56.00 g (78% yield) of **30** as a pleasant smelling oil; ir (neat): 1720 (C=O; ester) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.56–3.08 (4H, m, Ph—*CH_2*—*CH_2*—$COOCH_3$), 3.63 and 3.75 (6H, s, 2 × -OCH_3), 4.64 (2H, s, —O—CH_2—), 6.65–7.23 (4H, m, arom. protons); ms (EI): 252 ($M^{+\cdot}$) (25), 192 (100).

*4-Carbomethoxy-3,4-dihydro(2*H*)-1-benzoxepin-3-one* ***31***

The procedure described here is a slightly modified version of the one presented in a U.S. patent (26). To 16.44 g of a 50% (w/w) dispersion of NaH in mineral oil, in 300 cm^3 of anhydrous THF, was added dropwise, under argon, a solution of 40.00 g of **30** in 200 cm^3 of anhydrous THF. The rate of addition was chosen to maintain gentle boiling without external heating. The greenish solution thus obtained was then refluxed for 16 h. After cooling, it was poured in 1.0 dm^3 of ice water, stirred for 0.5 h, and acidified to pH 2 with concentrated HCl. The organic layer was removed and the aqueous phase was extracted with 4 × 100 cm^3 ether; the combined organic phases were washed with brine (4 × 100 cm^3), dried on anhydrous $MgSO_4$, filtered on a Büchner funnel, and evaporated under reduced pressure to give a red oily liquid. Distillation at 140–144°C under 1 Torr yielded 20.05 g (57% yield) of a thick yellow oil. The ^1H nmr spectrum of this substance indicates the presence of the 4-carbomethoxy derivative **31** as the major product; ir (neat): 1720 and 1740 (C=O; ketone and ester) cm^{-1}; ^1H nmr ($CDCl_3$) (400.13 MHz) δ: 3.32 (1H, dd, H-5), 3.47 (1H, dd, H-5), 3.69 (1H, t, H-4), 4.55 (2H, AB pattern, —O—CH_2—), 7.00–7.25 (4H, m, arom. protons); ^{13}C nmr (100.62 MHz, $CDCl_3$) δ: 29.93 (C-5), 52.48 (C-4), 54.59 (—OCH_3), 78.30 (—O—CH_2—), 121.53, 124.71, 128.16, 131.00 (arom. protonated carbons), 157.31 (quaternary arom. carbon), 169.50 (C=O; ester), 205.74 (C=O; ketone); *Exact Mass* calcd. for **31** (EI ms), $C_{12}H_{12}O_4$, *m/e*: 220.0736; found: 220.0742.

*3,4-Dihydro-2*H*-1-benzoxepin-3-one* ***32***

A quantity of 18.00 g of **31**, together with 60 cm^3 of absolute ethanol and 60 cm^3 of 5% HCl, was mixed in a 300-cm^3 round-bottomed flask and refluxed with stirring for 16 h. The solution was then cooled, poured into 200 cm^3 of brine water, and extracted with ether (4 × 150 cm^3); the organic phases were then dried on $MgSO_4$, filtered on a Büchner funnel, and evaporated under reduced pressure to yield 12.68 g (95% yield) of a slightly yellow liquid. The product was used as such for further experiments. Analytically pure **32** could be obtained by vacuum distillation (160–163°C/1 Torr; lit. (27) bp 100–105°C/0.5 Torr); ir (neat): 1720 (C=O; ketone) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.80–3.20 (4H, m, Ar—*CH_2*—*CH_2*—), 4.50 (2H, s, —O—CH_2—), 6.97–7.28 (4H, m, Ar); ms (CI): 163 ($M^{+\cdot}$ + 1) (100).

*3,4-Dihydro-2*H*-1-benzoxepin-3-methylene* ***33***

To 5.26 g (15 mmol) of methyltriphenylphosphonium bromide in 60 cm^3 of anhydrous THF, at 0°C, was added dropwise, under argon, 8.7 cm^3 (15 mmol) of *n*-BuLi (1.6 *M* in hexane). The solution turned orange as the addition proceeded. After stirring at 0°C for 30 min, a solution of 1.43 g (9 mmol) of **32** in 20 cm^3 of anhydrous THF was added dropwise. The solution was stirred for 2 h at 0°C, then allowed to warm to room temperature, and stirred for another 16 h. The solution was then poured in 300 cm^3 of pentane, and filtered through a 3 cm thick silica bed, using pentane as a washing solvent (200 cm^3). The filtrate was evaporated under reduced pressure to yield 1.11 g (78% yield) of **33** as a yellow oil. The product was used as such

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

without further purification; ^{1}H nmr ($CDCl_3$) δ: 2.40–2.92 (4H, m, —CH_2—CH_2—), 4.40 (2H, s, —O—CH_2—), 4.97 (2H, s, C=CH_2), 6.98–7.25 (4H, m, arom. protons).

2,3,4,5-Tetrahydro-3-methyl-1-benzoxepin ***9***

Hydrogen (1 atm (101.3 kPa)) was bubbled through a stirred solution of **33** (0.95 g) in 50 cm^3 of absolute ethanol containing 200 mg of 10% Pd/C, during 48 h. The solution was then filtered through Celite and the solids washed with 100 cm^3 EtOH; the filtrate was evaporated under reduced pressure, yielding a yellow oil that was purified by flash chromatography on silica gel, using dichloromethane–hexane (25:75) as eluant. The first compound eluted (major component) proved to be the desired **9** (420 mg; 43% yield), as a colorless liquid (bp (Kugelrohr) 59°C/1.1 Torr). The ^{13}C and ^{1}H nmr spectra are described in Tables 1 and 2; ms (CI): 163 ($M^{+\bullet}$ + 1) (36), 147 (10), 71 (100). *Exact Mass* calcd. for $C_{11}H_{14}O$, *m/e*: 162.1045; found: 162.1055.

The minor compound (more polar) was identified as (3-methylbutyl)-phenol: ^{1}H nmr ($CDCl_3$) δ: 0.95 (6H, d, 2 × CH_3), 1.26–1.60 (3H, m, —*CH_2*—*CH*—), 2.62 (2H, t, Ar—*CH_2*—), 4.78 (1H, s, phenolic OH), 6.70–7.23 (4H, m, arom. protons).

2,3,4,5-Tetrahedro-1-benzoxepin-3-ol ***34***

To 3.00 g of $LiAlH_4$ in 20 cm^3 of anhydrous ether was added dropwise, under argon, a solution of 4.00 g of **32** in 10 cm^3 of ether. The exothermic reaction brought the solution to reflux, maintained by external heating for an additional hour, after which the solution was cooled and treated carefully with 10% NaOH. The organic layer was separated and the aqueous phase extracted with ether (3 × 50 cm^3). The combined organic layers were dried on sodium carbonate, filtered, and evaporated under reduced pressure to give 2.50 g (62% yield) of **34** as a white, fluffy solid (mp 87–91°C; lit. (27) mp 86–88°C); ^{1}H nmr ($CDCl_3$) δ: 1.87–2.00 (2H, m, H-4), 2.38 (1H, br, —OH, exchangeable with D_2O), 2.65–3.03 (2H, m, H-5), 3.99 (2H, s, H-2), 4.01 (1H, br s, H-3), 6.92–7.17 (4H, m, arom. protons).

2,3,4,5-Tetrahedro-3-methoxy-1-benzoxepin ***10***

To 351 mg of NaH (50% dispersion in mineral oil, washed with hexane) in 20 cm^3 of anhydrous THF, was added dropwise, under argon, a solution of 1.00 g of **34** in 10 cm^3 of anhydrous THF. The solution was stirred at room temperature for 15 min and then 5 cm^3 (13 equiv.) of CH_3I was added dropwise. The resulting red solution was stirred at room temperature for 48 h, during which period a white precipitate appeared. This pinkish solution was filtered on sintered glass and the filtrate evaporated under reduced pressure; the residue was dissolved in 10 cm^3 of CCl_4 and filtered. The filtrate was again evaporated under reduced pressure to give 1.04 g (96% yield) of a yellow oil, identified as **10** by its ^{1}H and ^{13}C nmr spectra (Tables 1 and 2). Analytically pure **10** could be obtained by preparative gc (column temperature, 100°C; He flow rate, 60 cm^3/min; retention time, 6.0 min). *Exact Mass* calcd. for $C_{11}H_{14}O_2$, *m/e*: 178.0994; found: 178.0993.

2,3-Dihydro-3,3-dimethyl-1-benzopyran-4-one ***35***

This compound was prepared from dihydro-2,3-chromanone-4 (Aldrich) by following the general procedure described by Klemm *et al.* (28), with modifications proposed later by Zimmermann and Factor (29). A 39% yield of the desired product was obtained upon distillation (98.0°C/2.5 Torr (lit. (28) bp 88–89°C/1 Torr). The ^{1}H nmr spectra of **35** was found to be similar to the one described in ref. 29.

2,3-Dihydro-3,3-dimethyl-4-methylene-1-benzopyran ***36***

To 20.33 g (57 mmol) of methyltriphenylphosphonium bromide (Aldrich) in 300 cm^3 of anhydrous THF was added dropwise, under argon, at 0°C, 35.4 cm^3 (57 mmol) of a 1.55 *M* *n*-BuLi solution in hexane, and the resulting solution was stirred at 0°C for an additional half hour. A solution of 6.00 g (34 mmol) of the ketone **35** in 60 cm^3 of anhydrous THF was then added dropwise; the resulting mixture was warmed to room temperature and stirred for 36 h; it was then poured in 500 cm^3 of pentane followed by filtration on a silica gel pad (3 cm thick), which was washed several times with pentane (total volume of washing solvent: 500 cm^3). The filtrate was evaporated under reduced pressure to give a residual yellow oil, which was vacuum distilled to give 4.57 g (77% yield) of the desired olefin **36** (bp 76.0–80.0°C/1.0 Torr); ir (neat), ν: 1600, 1640 (C=C) (cm^{-1}); ^{1}H nmr ($CDCl_3$) δ: 1.16 (s, 6H, 2 × CH_3), 3.81 (s, 2H, -CH_2-), 5.02, 5.48 (2s, 2H, =CH_2), 6.79–7.62 (m, 4H, arom. protons); ms (CI), *m/e*: 175 ($M^{+\bullet}$ + 1) (100), 174 ($M^{+\bullet}$) (75), 159 (15). *Exact Mass* calcd. for $C_{12}H_{14}O$, *m/e*: 174.1045; found: 174.1022.

2,3,4,5-Tetrahedro-3,3-dimethyl-1-benzoxepin-4-one ***37***

This compound was prepared by a ring expansion of **36** mediated by thallium(III) nitrate, as described by Taylor *et al.* (30). To a stirred solution of 10.63 g (24 mmol) of thallium(III) nitrate in 90 cm^3 methanol was added as rapidly as possible a solution containing 4.17 g (24 mmol) of ketone **36** in 90 cm^3 methanol. The resulting mixture rapidly turns red as a voluminous white precipitate (probably thallium(I) nitrate) appears; it is stirred for an additional 3 min, then poured into 200 cm^3 chloroform. The solution is then filtered on sintered glass and the filtrate washed successively with 3 × 100 cm^3 of a saturated $NaHCO_3$ solution and with 3 × 10 cm^3 brine. The organic phase is then dried on $MgSO_4$, filtered on a Büchner funnel, and evaporated under reduced pressure to give a yellow oil, which, by vacuum distillation, yields the desired seven-membered ring ketone **37** as a clear yellow oil (3.88 g; 85% yield); bp (Kugelrohr) 100°C/1.5 Torr; ir (neat), ν: 1740 (C=O) (cm^{-1}); ^{1}H nmr ($CDCl_3$) δ: 1.24 (s, 6H, 2 × CH_3), 3.95, 4.08 (2s, 4H, 2 × -CH_2-), 6.86–7.26 (m, 4H, arom. protons). *Exact Mass* calcd. for $C_{12}H_{14}O_2$ (EI ms), *m/e*: 190.0994; found: 190.0953.

2,3,4,5-Tetrahedro-3,3-dimethyl-1-benzoxepin ***11***

This compound was prepared by a Zn–Hg/HCl Clemmensen reduction similar to that described for compound **8**. The crude product was purified by flash chromatography on silica gel using CH_2Cl_2–hexane (5:95) as eluent. The first fractions gave dihydro-2,3-dimethyl-3,3-benzoxepin-1, identified by its ^{1}H nmr spectra ($CDCl_3$) δ: 1.12 (s, 6H, 2 × -CH_3), 3.88 (s, 2H, -CH_2-), 5.70, 6.13 (AB, 2H, —CH=CH—), 6.93–7.11 (m, 4H, arom. protons). Subsequent fractions yielded pure **11** (692 mg, 25%) as a clear oil; R_f 0.17 (CH_2Cl_2–hexane, 5:95); bp (Kugelrohr) 80°C/1.6 Torr. The ^{13}C and ^{1}H nmr spectra are described in Tables 1 and 2. *Exact Mass* calcd. for **11** (ms), $C_{12}H_{16}O$, *m/e*: 176.1201; found: 176.1209.

2,3,4,5-Tetrahedro-3-methyl-1-benzoxepin-3-ol ***38***

To 270 mg (11 mmol) of magnesium turnings and an iodine crystal in 5 cm^3 of anhydrous ether was slowly added dropwise, under argon and with stirring, a solution of 1.2 cm^3 of CH_3I (19 mmol) in 10 cm^3 of anhydrous ether; the rate of addition was adjusted to maintain the solution to reflux (addition period, 0.5 h) and the solution was then stirred for an additional 30 min. To this mixture was added a solution of 1.50 g (9 mmol) of ketone **32** in 10 cm^3 of anhydrous ether and the resulting solution was stirred at room temperature for 16 h, during which period a white precipitate gradually appeared. The milky solution was then neutralized with 50 cm^3 of a 10% NH_4Cl solution followed by the addition of 50 cm^3 of ether. The organic phase was washed with 3 × 50 cm^3 brine, and the combined aqueous phases were backwashed with 3 × 50 cm^3 ether. The combined ethereal phases were dired over Na_2CO_3, filtered, and the solvent was evaporated under reduced pressure to yield 1.60 g (97% yield) of a yellow oil whose ^{1}H nmr spectrum is similar to the one described in the literature (31). The product was used as such, without further purification, for the next step.

2,3,4,5-Tetrahedro-3-methyl-3-methoxy-1-benzoxepin ***12***

This compound was obtained by methylation of the tertiary alcohol **38** using the procedure described earlier for the formation of the monomethoxy derivative **10**. Distillation of the crude product under reduced pressure gave 1.03 g (73% yield) of **12**, as a slightly yellow oil (bp 98–100°C/0.5 Torr). The ^{13}C and ^{1}H nmr spectra are described in Tables 1 and 2. *Exact Mass* calcd. for **12** (EI ms), $C_{12}H_{16}O_2$, *m/e*: 192.1150; found: 192.1151.

2,3,4,5-Tetrahedro-3,3-dimethoxy-1-benzoxepin ***13***

A mixture of 1.00 g (6 mmol) of ketone **32**, 6.8 cm^3 (62 mmol) of trimethylorthoformate (Aldrich), 25 mg (0.2 mmol) of *p*-toluene-

sulfonic acid, and 175 cm^3 of anhydrous methanol was refluxed and stirred, under argon, for 16 h. The resulting solution was afterwards brought back to room temperature, and evaporated under reduced pressure to distill off the methanol. The residue was dissolved in 125 cm^3 of benzene and washed successively with 2×50 cm^3 of a 20% NaOH solution and with 2×50 cm^3 brine after which the organic phase was separated, dried on K_2CO_3, filtered, and evaporated under reduced pressure to yield a yellow oil, which gave pure **13** (1.10 g; 86% yield) when distilled on a Kugelrohr apparatus. Crystallization occurred on standing for 24 h at 0°C (white crystals, mp 60.0–62.0°C). The ^{13}C and ^1H nmr spectra are described in Tables 1 and 2. *Exact Mass* calcd. for **13** (EI ms), $C_{12}H_{16}O_3$, *m/e*: 208.1099; found: 208.1099.

Ion–ion–solvent interactions in aqueous ionic cosolvent systems. II. Single-ion transfer free energies and entropies using tetraphenylarsonium tetraphenylborate reference electrolyte assumption in aqueous sodium nitrate solvent system

SIBAPRASAD RUDRA, HIMANSU TALUKDAR, AND KIRON K. KUNDU[1]
Physical Chemistry Laboratories, Jadavpur University, Calcutta – 700 032, India

Received February 19, 1987

SIBAPRASAD RUDRA, HIMANSU TALUKDAR, and KIRON K. KUNDU. Can. J. Chem. **65**, 2595 (1987).

Single-ion tranfer free energies $\Delta G_t^0(i)$ and entropies $\Delta S_t^0(i)$ of some electrolytes from water to 1, 2, and 4 *m* aqueous $NaNO_3$ solvents have been determined at 25°C using the widely used tetraphenylarsonium tetraphenylborate (Ph_4AsBPh_4) reference electrolyte assumption, after due modification for this solvent system. The required ΔG_t^0 and $T\Delta S_t^0$ values of Ph_4AsPi, $KBPh_4$, KPi, AgPi, $PbPi_2$, Ag_2CrO_4, and AgCl where Pi = picrate, were determined by measuring solubilities at 15–35°C of the solutes except AgCl, the values of which were determined from emf measurements. Analysis of $\Delta G_t^0(i)$ and $T\Delta S_t^0(i)$ values of the ions as well as their respective true interaction effects, $\Delta G_{t,tr.int}^0(i)$ and $T\Delta S_{t,tr.int}^0(i)$ as obtained after correcting for their cavity effects $\Delta G_{t,cav}^0(i)$ and $T\Delta S_{t,cav}^0(i)$ estimated by the scaled particle theory (SPT) and Born-type electrostatic effects, $\Delta G_{t,Born}^0(i)$ and $T\Delta S_{t,Born}^0(i)$ computed by simple Born equation, reveals that the behaviour of the ions in this ionic cosolvent system is chiefly guided by one or several effects of ion–ion–solvent, Born and cavity forming interactions. Moreover, a rational explanation has been offered to explain the observed mirror-image entropic behaviour of simple cations and anions in light of Kundu *et al.*'s four-steps transfer process.

SIBAPRASAD RUDRA, HIMANSU TALUKDAR et KIRON K. KUNDU. Can. J. Chem. **65**, 2595 (1987).

Opérant à 25°C et utilisant l'hypothèse du tétraphénylborate de tétraphénylarsonium (Ph_4AsBPh_4), un électrolyte de référence fréquemment utilisé, et après avoir fait les modifications appropriées pour le système de solvant, on a mesuré les énergies $G_t^0(i)$ et les entropies $\Delta S_t^0(i)$ libres de transferts mono-ioniques de quelques électrolytes de l'eau vers des solutions aqueuses 1, 2 et 4 *m* en $NaNO_3$. On a déterminé les valeurs requises de ΔG_t^0 et ΔS_t^0 du Ph_4AsPi, du $KBPh_4$, du KPi, du AgPi, du $PbPi_2$, du Ag_2CrO_4 et du AgCl (dans lesquels Pi = picrate) en mesurant leurs solubilités à des températures allant de 15 à 35°C; dans le cas du AgCl, on a déterminé ces valeurs à partir de mesures de fem. Une analyse des valeurs de $\Delta G_t^0(i)$ et $T\Delta S_t^0(i)$ des ions ainsi que de leurs effets respectifs d'interaction réelle, $\Delta G_{t,ver.int}^0(i)$ et $T\Delta S_{t,ver.int}^0(i)$, obtenues après avoir corrigé les effets de cavités $\Delta G_{t,cav}^0(i)$ et $T\Delta S_{t,cav}^0(i)$ qui ont été évalués par la théorie de la particule scalaire (TPS) et par les effets électrostatiques du type de Born, $\Delta G_{t,Born}^0(i)$ et $T\Delta S_{t,Born}^0(i)$, calculés par l'équation simple de Born, révèle que le comportement des ions dans ce système de cosolvant ionique résulte principalement d'un ou de plusieurs effets ion/solvant ionique ainsi que d'interactions de Born qui se produisent dans la cavité. De plus, utilisant le processus de transfert en quatre étapes proposé par Kundu et ses collaborateurs, on offre une explication rationnelle du comportement entropique d'image miroir qui a été observé avec des cations et des anions simples.

[Traduit par la revue]

Introduction

In the previous paper (1) we have reported for the first time the transfer thermodynamics of HCl and the related "ion–ion–solvent" interactions and solvent structuredness in 1, 2, and 4 *m* $NaNO_3$ solutions taking each composition as an individual solvent and taking the infinitely dilute solution of solutes in each solvent as the standard state, exactly similar to what is being done in aquo-organic solvent systems. As a part of our comprehensive studies and especially for better understanding of the individual ion behaviour in this solvent system, we are now reporting free energies of transfer, ΔG_t^0, and also entropies of transfer, $T\Delta S_t^0$, of some electrolytes and their constituent ions from water to the aqueous mixtures of 1, 2, and 4 *m* $NaNO_3$ at 25°C taking each composition as the individual solvent referred to above. These are determined by the widely used tetraphenylarsonium tetraphenylborate (Ph_4AsBPh_4) reference electrolyte (RE) assumption (2) which has been duly modified in the aquo-ionic solvent system as discussed later on.

Since the solubility of this RE itself is too low to be determined accurately in this ionic cosolvent system $\Delta X_t^0(Ph_4AsBPh_4)$ (X = G and S) values were obtained indirectly by relation [1]

$$[1] \quad \Delta X_t^0(Ph_4AsBPh_4) = \Delta X_t^0(Ph_4AsPi) + \Delta X_t^0(KBPh_4) - \Delta X_t^0(KPi)$$

where Pi = picrate. ΔX_t^0 values of the salts Ph_4AsPi, $KBPh_4$, and KPi were determined by solubility measurements (3, 4) at different temperatures. Moreover, to help determine $\Delta X_t^0(i)$ values for Cl^- and hence H^+ from $\Delta X_t^0(HCl)$ values reported in the previous paper, ΔX_t^0 values of AgPi have been determined by measuring the solubility of the compound spectrophotometrically and that of AgCl by emf measurements of cell [A] (5) at different temperatures

$$[A] \quad Ag/AgNO_3(m), NaNO_3 + water//AgCl, KCl(m), NaNO_3 + water/Ag$$

using 0.1 *m* NH_4NO_3 as the salt bridge in the respective solvent system.

Moreover, in order to facilitate understanding of the behaviour of divalent cations and anions in this solvent we have also determined ΔX_t^0 values of Ag_2CrO_4 and $PbPi_2$ from solubility measurements at different temperatures. Also, to verify the validity of the emf method adopted for AgCl, the solubilities of Ag_2CrO_4 were determined from emf measurements at 25°C using cell [B]

$$[B] \quad Ag/AgNO_3(m), NaNO_3 + water//Ag_2CrO_4, K_2CrO_4(m), NaNO_3 + water/Ag$$

Experimental

Sodium nitrate and other salts used were of AR quality. The method of preparation of $NaNO_3$ solutions has been described (1). Methods of

[b]Electromotive force method.

preparation and purification of the salts Ph_4AsPi, $KBPh_4$, and KPi as well as the procedure for the determination of saturated solubilities of Ph_4AsPi and $KBPh_4$ in these solvents by spectrophotometric measurements were essentially similar to those described earlier (3–5). AgPi and $PbPi_2$ were prepared from $AgNO_3$ and $Pb(NO_3)_2$, respectively, by a process similar to that adopted for KPi. As the solubilities of these salts are rather large, we determined them spectrophotometrically at different "ionic strengths" using up to 0.15 *m* $KClO_4$ as the inert electrolyte and each composition of the solvent system as the standard reference state. The solubilities thus obtained at different "ionic strengths" arising from the added inert electrolyte and the saturated solutions of the respective salts were then extrapolated to "zero ionic strength" of the same at each solvent composition, which gives the solubilities of salts in the respective solvent composition. Notably, in view of the fact that in our treatment the salt solutions are assumed to be in their respective standard reference states, the "ionic strength" at any composition of the salt solution does not vary significantly due to small addition of $KClO_4$ and the effect of involved activity coefficient term is always small and disappears upon extrapolation to zero "ionic strength".

Ag_2CrO_4 was prepared by mixing equivalent amounts of $AgNO_3$ and K_2CrO_4 and washed several times with triple distilled water. Its solubilities were measured spectrophotometrically at the wavelength 364 nm where the molar extinction coefficient is 3490. The dilution of the aliquot of the saturated solution of each salt was made with triple distilled water. The appropriately diluted solutions were analyzed spectrophotometrically using a Perkin-Elmer (model 200) spectrophotometer. Constancy of two or three successively measured concentrations of each of the solutions to within ±1% was taken as the criterion for the attainment of the saturated solubility of the salts. At least two sets of measurements were made for all the solutes and the results were found to agree to within ±1%. Emf measurements of cell [A] and cell [B] were made by a Leeds and Northrup K_3-potentiometer and a Cambridge moving coil galvanometer. Ag/Ag^+ electrodes were prepared by electrochemical deposition of Ag on Pt-wire base from $K[Ag(CN)_2]$ solution using 5 mA current for 10–15 min. Electrodes having less than ±0.1 mV asymmetry potential were used. The emf's of cell [A] and cell [B] were measured for different molalities of KCl and K_2CrO_4 equilibrated with solid AgCl and Ag_2CrO_4, respectively, so as to determine pK_{sp} at "zero ionic strength."

Results

The observed saturated solubilities (S) in mol dm^{-3} at different temperatures for the salts Ph_4AsPi, $KBPh_4$, KPi, AgPi, Ag_2CrO_4, and $PbPi_2$ in different compositions of aqueous $NaNO_3$ solvent and also in water are given elsewhere.[2] Assuming that the salts are completely ionized the thermodynamic solubility products K_{sp} of the salts Ph_4AsPi, $KBPh_4$, KPi, AgPi, Ag_2CrO_4, and $PbPi_2$ were computed on the molar scale by relation [2]

$$[2] \quad pK^c_{sp} = -\log (\nu_+^{\nu_+} . \nu_-^{\nu_-}) S^{\nu_+ + \nu_-}$$

where ν_+ and ν_- represent the number of cation and anion, respectively, of the electrolyte. The corresponding mean molar activity coefficients $\gamma_\pm$ of the salts have been neglected for low soluble salts like $KBPh_4$, Ph_4AsPi, Ag_2CrO_4 and that of KPi, $PbPi_2$, and AgPi have been accounted for by determining the solubilities at zero "ionic strength" referred to above, by the usual extrapolation procedure. pK^c_{sp} values thus obtained at different temperatures are listed in Table 1. Estimated uncertainties in pK_{sp} values are within ±0.01.

[2]A complete set of the data referred to above may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The free energies of solution of the salts (ΔG_s^0) on the molar scale were calculated for each solvent using relation [3]

$$[3] \quad \Delta G_s^0 = 2.303RT\mathrm{p}K_{sp}^c$$

and were fitted by the method of least squares to an equation of form [4]

$$[4] \quad \Delta G_s^0 = a + bT + cT \ln T$$

where T is the absolute temperature. The values of the coefficient, a, b, and c thus obtained are listed in Table 2. These values when applied to eq. [4] reproduce ΔG_s^0 values to within ±0.02 kJ mol^{-1}. The standard free energies of transfer ΔG_t^0 from water to the solvents were computed at 25°C on the mole fraction scale using relation [5]

$$[5] \quad \Delta G_t^0 = (a_s - a_w) + (b_s - b_w)T + (c_s - c_w)T \ln T + \text{scale effect}$$

where the scale effect is $\nu RT \ln M_w d_s / M_s d_w$. The subscripts s and w represent the quantities for solvent and water, respectively. M represents the appropriate molar mass of the solvent, and d is the density of the solvent (1), T = 298.15 K and $\nu = (\nu_+ + \nu_-) = 2$ for 1:1 electrolyte and 3 for 2:1 or 1:2 electrolyte.

The corresponding standard entropies of transfer were computed from eq. [6]

$$[6] \quad \Delta S_t^0 = (b_w - b_s) + (c_w - c_s) + (c_w - c_s) \ln T - \text{scale effect}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

where the scale effect is $[\nu R \ln M_w d_s/M_s d_w + \nu RT(\mathrm{d} \ln d_s/\mathrm{d}T - \mathrm{d} \ln d_w/\mathrm{d}T)]$, temperature coefficient of the density being obtained from ref. 1. ΔG_t^0 and ΔS_t^0 values thus obtained are given in Table 2.

Assuming negligible junction potential across the salt bridge the emf (E_A) of cell [A] is given by [7]

$$[7] \quad E_A = \frac{RT}{F} \ln (a_{Ag^+})_l/(a_{Ag^+})_r$$

where the subscripts l and r refer to the left and right hand half cells, respectively. This E_A is related to K_{sp} of AgCl by [8]

$$[8] \quad pK'_{sp} = \frac{E_A \cdot F}{2.303RT} - \log (m_{Ag^+})_l - \log (m_{Cl^-})_r = pK_{sp} + 2 \log (\gamma_\pm) = pK_{sp} + f(\mu)$$

which has been obtained as a result of the experimental condition for that $(m_{Ag^+})_l = (m_{Cl^-})_r$ and hence assuming that $(\gamma_{Ag^+})_l = (\gamma_{Cl^-})_r = (\gamma_\pm)$.

The pK_{sp} values at infinite dilution were then determined by extrapolating the function of the observed linear plots pK'_{sp} defined by eq. [8], against the ionic strength μ to $\mu = 0$. The pK_{sp} values thus obtained on molal scale, pK^m_{sp} are reported in Table 1. Moreover, to verify the pK^m_{sp} values of AgCl obtained by this method, the pK^m_{sp} values of Ag_2CrO_4 were also determined at 25°C by the method using cell [B]. The pK^m_{sp} values of Ag_2CrO_4 thus obtained on the molal scale were then transformed to the molar scale. Notably, the pK^c_{sp} values of Ag_2CrO_4 obtained both by emf and spectroscopic methods are in fair agreement to within the limit ±0.02 as presented in Table 1. Evidently uncertainties to liquid junction potential are within experimental error.

The free energies of solution (ΔG^0_s) on the molal scale of AgCl were calculated using eq. [3] and fitted by the method of least squares to eq. [4]. ΔG^0_t(AgCl) and ΔS^0_t(AgCl) values on mole fraction scale were then calculated using [5] and [6], respectively, with the scale effect as $\nu RT \ln M_w/M_s$ for eq. [5] and $\nu R \ln M_w/M_s$ for eq. [6]. Those values are listed in Table 2. The estimated uncertainties in ΔG^0_t and ΔS^0_t for the different salts are ±0.03 kJ mol^{-1} and ±2 J K^{-1} mol^{-1}, respectively.

The transfer free energies of the relevant individual ions $\Delta G^0_t(i)$ were then computed by use of TATB assumption which has been widely used not only in pure solvents but also in various aquo-organic solvents because of its intrinsic merits (6). True, there might be some doubts on the validity of this assumption for the mixed solvents as there might be preferential solvation of cations or anions by the components of the mixed solvents. But whether that "preferential" solvation will really affect the relative solvation of these big Ph_4As^+ and Ph_4B^- ions is indeed highly questionable. However, in our aquo-ionic cosolvent system, because of the possible difference in Ph_4B^-–Na^+ and Ph_4As^+–NO_3^- interactions we have calculated our data in the following way. Since

$$[9] \quad {}_s\bar{X}^0(Ph_4AsBPh_4)^N = \Delta X^0_t(Ph_4AsBPh_4)^N + {}_w\bar{X}^0(Ph_4AsBPh_4)^N$$

$$[10] \quad {}_w\bar{G}^0(Ph_4AsBPh_4)^N = {}_w\bar{G}^0(Ph_4AsBPh_4)^c + 2RT \ln 1000\, d_w/M_w$$

and

$$[11] \quad {}_w\bar{S}^0(Ph_4AsBPh_4)^N = {}_w\bar{S}^0(Ph_4AsBPh_4)^c - 2R \ln 1000\, d_w/M_w - 2RT(\mathrm{d} \ln d_w/\mathrm{d}T)$$

where the superscripts N and c refer to mole fraction and molar scales, respectively, we have obtained the values of ${}_s\bar{G}^0(Ph_4AsBPh_4)^N$ by use of eqs. [9] and [10] as ${}_w\bar{G}^0(Ph_4AsBPh_4)^c$ is obtained by use of [4] in pure water. Similarly ${}_s\bar{S}^0(Ph_4AsBPh_4)^N$ is obtained using eqs. [9] and [11] and the temperature derivative of eq. [4] for pure water.

Now assuming that Ph_4B^-–Na^+ and Ph_4As^+–NO_3^- interactions are governed chiefly by coulombic interaction we have,

$$[12] \quad \frac{{}_s\bar{G}^0(Ph_4B^-)}{{}_s\bar{G}^0(Ph_4As^+)} = \frac{Ne^2[\epsilon_s(r_{Ph_4B^-} + r_{Na^+})]^{-1}}{Ne^2[\epsilon_s(r_{Ph_4As^+} + r_{NO_3^-})]^{-1}} = \frac{r_{Ph_4As^+} + r_{NO_3^-}}{r_{Ph_4B^-} + r_{Na^+}} = 1.05$$

taking $r_{Ph_4B^-} = r_{Ph_4As^+} = 0.420$ nm (7), $r_{Na^+} = 0.097$ nm (8), and $r_{NO_3^-} = 0.124$ nm (9). As TATB reference electrolyte assumption is also likely to be true regardless of temperatures, then as per above-noted assumption we have

$$[13] \quad \frac{{}_s\bar{S}^0(Ph_4B^-)}{{}_s\bar{S}^0(Ph_4As^+)} = \frac{-Ne^2[\epsilon_s\theta_s(r_{Ph_4B^-} + r_{Na^+})]^{-1}}{-Ne^2[\epsilon_s\theta_s(r_{Ph_4As^+} + r_{NO_3^-})]^{-1}} = \frac{r_{Ph_4As^+} + r_{NO_3^-}}{r_{Ph_4B^-} + r_{Na^+}} = 1.05$$

where θ_s^{-1} is given by $-\mathrm{d} \ln \epsilon_s/\mathrm{d}T$. Thus from eqs. [12] and [13] we get

$$[14] \quad \frac{{}_s\bar{X}^0(Ph_4B^-) + {}_s\bar{X}^0(Ph_4As^+)}{{}_s\bar{X}^0(Ph_4As^+)} = 2.05$$

or

$${}_s\bar{X}^0(Ph_4As^+) = \frac{1}{2.05}\,{}_s\bar{X}^0(Ph_4BAsPh_4)$$

and

$$[15] \quad {}_s\bar{X}^0(Ph_4B^-) = 1.05\,{}_s\bar{X}^0(Ph_4As^+)$$

The required values were therefore obtained by

$$[16] \quad \Delta\bar{X}^0_t(Ph_4B^-) = {}_s\bar{X}^0(Ph_4B^-) - {}_w\bar{X}^0(Ph_4B^-)$$

and

$$[17] \quad \Delta\bar{X}^0_t(Ph_4As^+) = {}_s\bar{X}^0(Ph_4As^+) - {}_w\bar{X}^0(Ph_4As^+)$$

The transfer free energies and entropies of the relevant individual ions, $\Delta X^0_t(i)$ were then computed by use of additivity relations. The results thus obtained for the solvents are presented in Table 3. The estimated uncertainties of the values are within ±0.1 kJ. Notably, as would be discussed later, the observed $\Delta S^0_t(i)$ values especially for small sized cations and anions, are very much similar to those observed in various aquo-organic solvents. And this seemingly suggests that TATB method is not only valid in aquo-organic solvents but also in aquo-ionic cosolvent systems like this, provided reasonable modification is made for the latter, as has been done in the present case.

Discussion

Free energies of transfer

ΔG^0_t–composition profiles for the salts and HCl are illustrated in Fig. 1. From this figure it appears that whilst the salts AgPi and $PbPi_2$ are increasingly destabilized and KPi, Ph_4AsPi, and HCl are increasingly destabilized after an initial stabilization up to 1–2 *m* $NaNO_3$, the salts AgCl, Ag_2CrO_4, and $KBPh_4$ are, however, increasingly stabilized with the increased

[a]The required diameters of the solvent constituents and the values of the scale effect $RT \ln V_w/V_s$ are taken as given in ref. 1, $\alpha = -d \ln d_s/dT$, also taken from the same paper, and those for the solute species $b_{Ph_4B^-} = 0.84$ nm (7), $b_{Pi} = 0.72$ nm as tentatively taken to be equal to that of pNA given in ref. 13(*b*), $b_{Cl^-} = 0.362$ nm (32), $b_{K^+} = 0.270$ nm (32), $b_{H_3O^+} = 0.276$(1), $b_{Ag^+} = 0.252$ nm (32), $b_{Pb^{2+}} = 0.240$ nm (8), $b_{CrO_4^{2-}} = 0.320$ nm (9).

[b]The required radii of the ionic species are obtained from the corresponding diameters of the species as indicated in *a* and that of H^+ as equal to 0.276 nm (1).

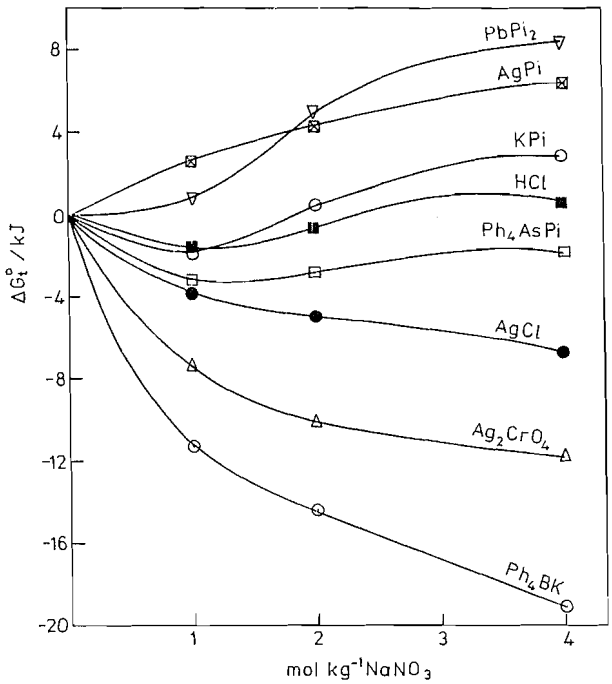

FIG. 1. Variation of ΔG_t^0 of different electrolytes with molality of $NaNO_3$ in aqueous $NaNO_3$ solutions.

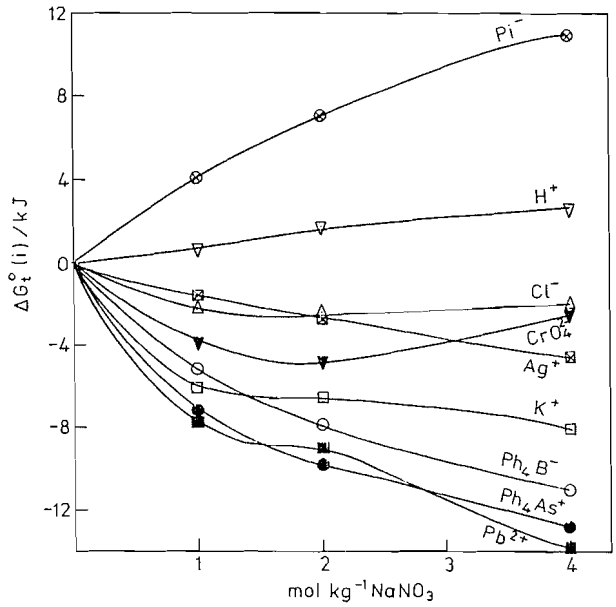

FIG. 2. Variation of $\Delta G_t^0(i)$ of different ions with molality of $NaNO_3$ in aqueous $NaNO_3$ solutions.

molality of $NaNO_3$. But as indicated in our previous paper for HCl (1), the behaviour of these salts like the acid HCl is also likely to be chiefly guided by the combined effects of "ion–ion–solvent" interactions of the cations and anions of the solutes with the oppositely charged ionic constituents of the ionic cosolvent $NaNO_3$ and the possible repulsive interactions between the similarly charged ions (1) besides the destabilizing Born-type electrostatic interactions arising from the difference of the dielectric constant of solvent (10, 11). Thus a discussion of $\Delta G_t^0(i)$ values of single ions rather than those of the electrolytes should be more informative regarding the involved ion–ion–solvent interactions and the $\Delta G_t^0(i)$–composition profiles for single ions are illustrated in Fig. 2. Significantly enough, $\Delta G_t^0(i)$–composition profiles for anions like Cl^- and CrO_4^{2-} show an upward trend after passing through a shallow minimum around 1–2 *m* $NaNO_3$ while those for Pi^- and Ph_4B^- move increasingly upward and downward, respectively, right from the beginning. But while $\Delta G_t^0(i)$ values for cations like Ag^+, K^+, and Pb^{2+} are more or less increasingly negative those for H^+ are increasingly positive. Evidently the behaviour of Ph_4B^- or H^+ seems to be "odd man out" in the respective cases.

As per discussion in our previous paper (1), transfer energetics ΔX_t^0 (X = G, H, and S) can be taken to compose of cavity forming effect $\Delta X_{t,cav}^0$, Born-type electrostatic effect $\Delta X_{t,Born}^0$ and the true interaction effect $\Delta X_{t,tr.int}^0$ i.e.

$$[18]\quad \Delta X_t^0(i) = \Delta X_{t,cav}^0 + \Delta X_{t,Born}^0(i) + \Delta X_{t,tr.int}^0(i)$$

Thus the discussion of true transfer free energies of ions $\Delta G_{t,tr.int}^0(i)$ rather than $\Delta G_t^0(i)$ should be more informative. Consequently we have tentatively computed $\Delta G_{t,Born}^0(i)$ and $\Delta G_{t,cav}^0(i)$ terms for the different ions by the simple Born equation (10) and scaled particle theory (SPT) (12), respectively, as per formulations described and referred to in the previous papers (1, 13). These and the required solvent and solute parameters are given in Table 3. The values of $\Delta G_{t,Born}^0(i)$ and $\Delta G_{t,cav}^0(i)$ and also $\Delta G_{t,tr.int}^0(i)$ so obtained are given in Table 3 and depicted in Fig. 3.

Significantly enough, in the case of small sized ions like Cl^-, H^+, Ag^+, and K^+ the cavity effect is smaller and in fact gets nullified to a larger extent by the opposing Born effect. In the case of bivalent ions like Pb^{2+} and CrO_4^{2-} $\Delta G_{t,tr.int}^0(i)$–composition profiles become more negative than the $\Delta G_t^0(i)$–composition profiles, indicating larger stabilization of these ions due to true interaction effects.

As indicated in the previous paper (1), consequent to the assumed standard state in this ionic cosolvent system $\Delta G_{t,tr.int}^0(i)$ values of the transferred small-sized ions are likely to be chiefly guided by the ion–ion–solvent interactions with the constituent ions of the ionic cosolvent $NaNO_3$ relative to that in water. Various spectroscopic (14–16) and other evidences (17) indicate that in the solvent composition up to 1.5 *m* $NaNO_3$ the prevalent ionic species are $(Na^+)_{aq}$ and NO_3^-.

The observed stabilization of Cl^- or CrO_4^{2-} in this region therefore suggests that the resulting attractive interaction of these ions and $(Na^+)_{aq}$ over the repulsive interaction of Cl^- or CrO_4^{2-} and NO_3^- exceeds the Cl^-–H_2O or CrO_4^{2-}–H_2O interaction in pure water. This is probably due to the fact that H_2O molecules in the hydration cosphere round Na^+ have more protonic character (δ^+) than that in pure water and hence are likely to induce more "acid–base" type (18) short range interaction with Cl^- or CrO_4^{2-} ion than that in pure water. The observed more downward trend of CrO_4^{2-} than that of Cl^- indicates that CrO_4^{2-} interacts more strongly with $(Na^+)_{aq}$ due to its doubly charged character.

On the other hand, the observed increased stabilization of cations such as Ag^+, K^+, and Pb^{2+} suggests that the attractive interactions between these ions and the unhydrated NO_3^- are so strong that these seemingly overcome the combined opposite effects of Born-type electrostatic and weak cation–$(Na^+)_{aq}$ repulsive interactions. The observed larger stabilization of the divalent Pb^{2+} than the univalent Ag^+ and K^+ is evidently the result of its more attractive interaction with NO_3^- ion. The observed increased destabilization of H^+ is, however, indicative of the resultant effect of smaller attractive interactions between H_3O^+ (rather than bare proton) with delocalised (δ^+) charge on 3-H atom, and NO_3^- and the destabilizing repulsive interactions of H_3O^+ with $(Na^+)_{aq}$ bearing more protonic

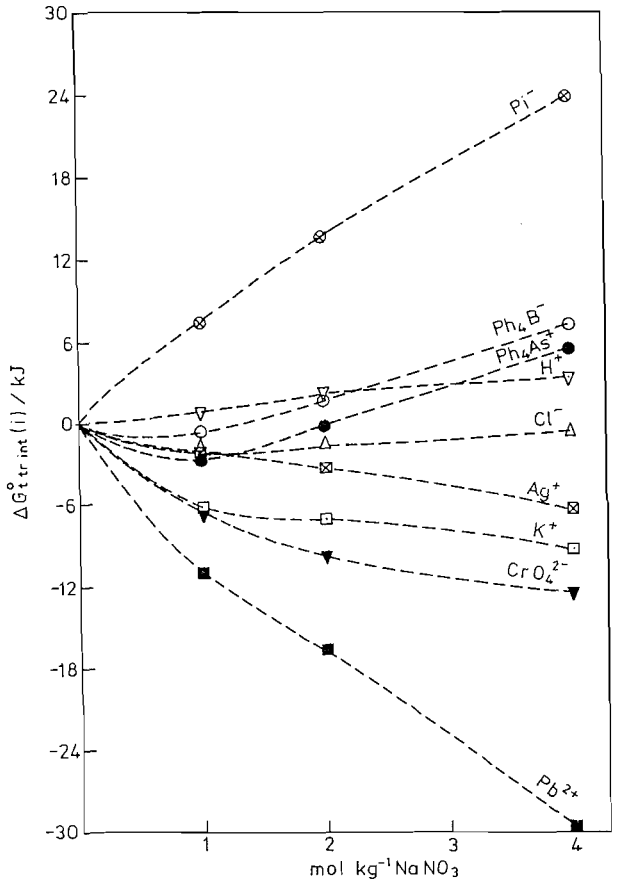

FIG. 3. Variation of $\Delta G^0_{t,tr.int}(i)$ of different ions with molality of $NaNO_3$ in aqueous $NaNO_3$ solutions.

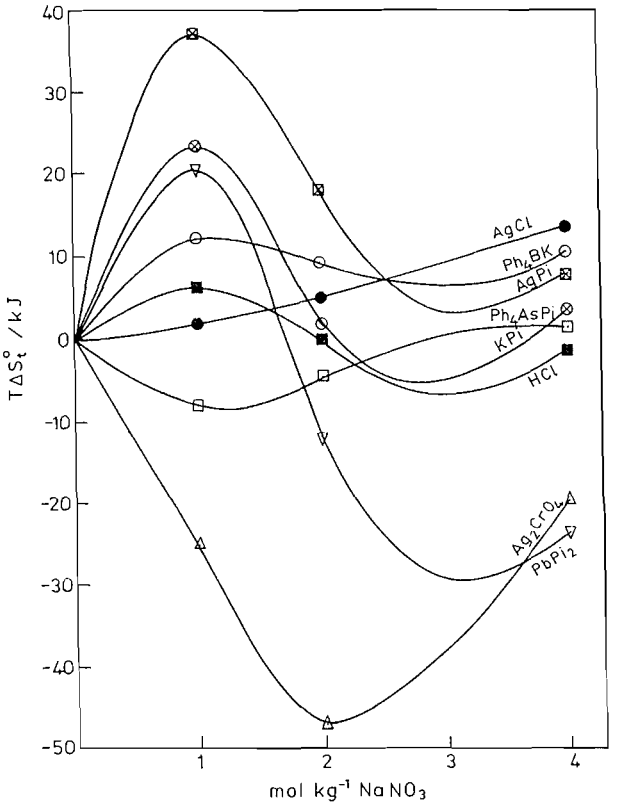

FIG. 4. Variation of $T\Delta S^0_t$ of different electrolytes with molality of $NaNO_3$ in aqueous $NaNO_3$ solutions.

character of H_2O molecules in the hydration cosphere around Na^+. More importantly, the effect of structural propensity of H_3O^+ in 3-D structures in pure water also augments largely the observed destabilization of H_3O^+ in these aqueous $NaNO_3$ solutions. All this explains the odd-man-out behaviour of H^+ compared to other cations.

From Figs. 2 and 3 it appears that while $\Delta G^0_t(i)$–compositions for Ph_4B^- and Ph_4As^+ become increasingly negative, $\Delta G^0_{t,tr.int}(i)$–composition profiles become increasingly positive after passing through a shallow minimum around 1 *m* $NaNO_3$. This implies that the observed stabilization of Ph_4B^- and Ph_4As^+ as reflected in $\Delta G^0_t(i)$ values, is dictated by the pronounced cavity effect, since the solvation of large hydrophobic molecular ions is always associated with the creation of cavity inside the bulk of the solvent (7, 12, 19, 20) and that the salting-out of these hydrophobic Ph_4B^- and Ph_4As^+ ions become increasingly predominant with the increased proportion of the ionic cosolvent $NaNO_3$, as expected from the larger hydrophobic effect in salt solution than in water.

Similarly, the relative positions of $\Delta G^0_t(i)$ and $\Delta G^0_{t,tr.int}(i)$–composition profiles for Pi^- are also indicative of the fact that the pronounced cavity-effect partly opposes the "true interaction" effects of the species. The latter effects are largely guided by the "salting-out" effect on the hydrophobic parts of the species overcoming the relatively smaller stabilization effect of the anionic features of Pi^- in this ionic cosolvent system compared to that in pure water. Moreover, the pronounced H-bonding stabilization of Pi^- through three NO_2 groups in water also contribute to the observed destabilization of Pi^- in the salt solutions.

Notably, the observed near invariance of $\Delta G^0_{t,tr.int}(i)$ values of the smaller ions beyond 1.5 *m* $NaNO_3$ is indicative of the effect of constitutional features of the aqueous ionic cosolvent system beyond 1–15 *m* as obtained from various spectroscopic evidences (14–16) indicated earlier (1). Evidently, the solvent separated ion-pairs (SSIP) present beyond 1.5 *m* $NaNO_3$ diminish the intensity of cation–anion or anion–cation attractive interactions to a large extent particularly for the small sized cations and anions.

Entropies of transfer

Figure 4 depicts the $T\Delta S^0_t$–composition profiles of some salts at 25°C. Strikingly enough, $T\Delta S^0_t$–composition profiles of AgPi, KPi, $PbPi_2$, and $KBPh_4$, unlike that of AgCl, pass through a maximum whilst those of Ph_4AsPi and Ag_2CrO_4 pass through a minimum around 1–1.5 *m* $NaNO_3$. Since the discussion of $T\Delta S^0_t(i)$ values of single ions rather than those of the electrolytes should provide more information on solvent structuredness, $T\Delta S^0_t(i)$–composition profiles for the ions are illustrated in Fig. 5. Significantly enough, $T\Delta S^0_t(i)$–composition profiles for all cations pass through a maximum whilst those for all anions pass through a minimum. Pi^- is seemingly the odd-man-out as its profile passes through a slight maximum.

Notably, the observed mirror-image behaviour of $T\Delta S^0_t(i)$ for these small hydrophilic cations and anions may lead one to wonder if it is due to the possible uncertainties of the involved modification of the RE assumption. But the fact that similar type of behaviour has also been observed in the aqueous mixtures of Bu^{t}OH (21), DMSO (4*b*, 22), ACN (4*d*, 23), DMF (24), MeOH (25), urea (26), and glycerol (26) lead us to believe that as in aquo-organic solvents, the basic RE assumption and its modification for the present solvent system are free from uncertainties. Notably, Marcus (6), Juillard *et al.* (21), and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12

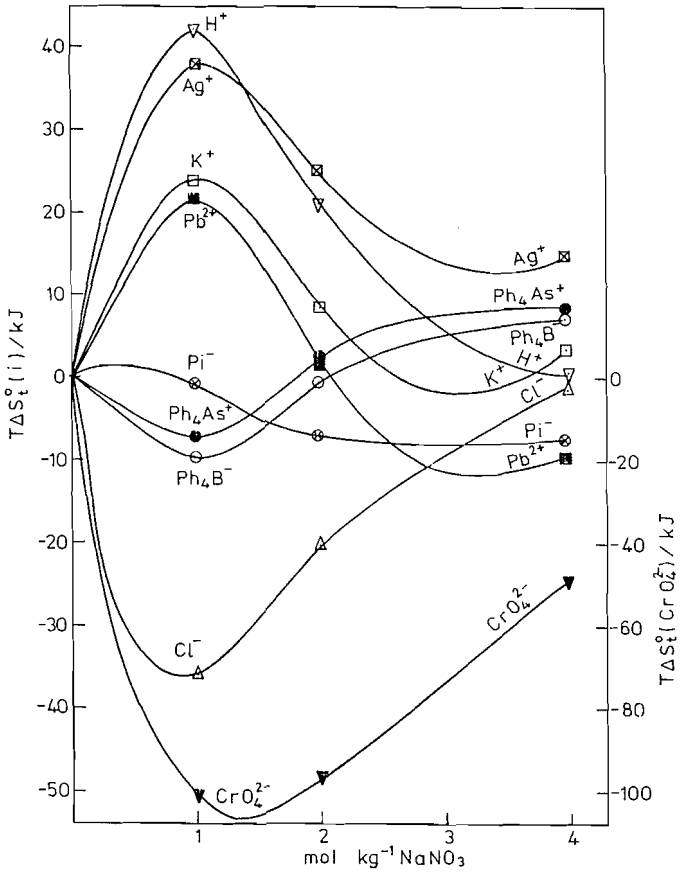

FIG. 5. Variation of $T\Delta S_t^0(i)$ of different ions with molality of $NaNO_3$ in aqueous $NaNO_3$ solutions.

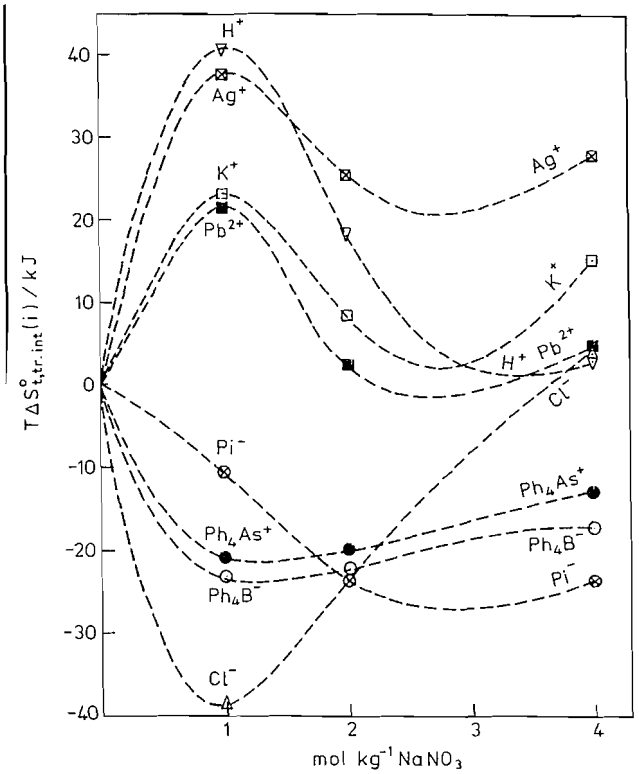

FIG. 6. Variation of $T\Delta S^0_{t,tr.int}(i)$ of different ions with molality of $NaNO_3$ in aqueous $NaNO_3$ solutions.

Abraham *et al.* (25) also indicated that the widely used RE assumption for $\Delta G_t^0(i)$ at 25°C should be equally true irrespective of temperatures and hence $T\Delta S_t^0(i)$ data for the individual ions should be no less meaningful.

But the question why cations and anions show opposite behaviour in $T\Delta S_t^0(i)$–composition profile is not yet accounted for satisfactorily. Indeed the cationic behaviour in some cosolvent systems (21, 23, 25) has been adduced in light of the effects of structural changes of the solvents, relative hydration/solvation and preferential solvation of the cations, solvent sorting in the coordination sphere of the cations (23*b*), no tangible explanation has yet been offered for the anions.

Thus before we analyse the implications of the observed maxima and minima in this solvent system let us make at least a tentative estimate of (*a*) the Born-type electrostatic contribution, $\Delta S^0_{t,Born}(i)$ with the help of the simple Born equation as described in our previous paper (27) and (*b*) the cavity effect term $\Delta S^0_{t,cav}(i)$ through SPT using the formulations described in our previous papers (13). Since the required temperature coefficients of dielectric constants ($\theta^{-1} = -d \ln \epsilon / dT$) are not known at different compositions for the solvent system, we have tentatively obtained them by assuming $(\theta_s)_{NaNO_3} = (\theta_s)_{NaCl}$ in the corresponding compositions for NaCl. θ_s values for different molalities of NaCl system are obtained from the slope of the observed linear plots of ln ϵ_s vs. T, ϵ_s values being obtained from Akhadov's monograph (28). The values of $\Delta S^0_{t,Born}(i)$, $\Delta S^0_{t,cav}(i)$, and $\Delta S^0_{t,tr.int}(i)$ so obtained are given in Table 3. The latter values are also illustrated in Fig. 6. Significantly enough there are little differences between $T\Delta S_t^0(i)$ and $T\Delta S^0_{t,tr.int}(i)$–composition profiles for most of the ions save Pi^- and Ph_4B^-/Ph_4As^+ which become fairly more negative.

Following Kundu *et al.*'s four-step transfer process (27*b*, 29) and the discussion in our previous paper (1), we may try to explain the observed results for different cations and anions as follows. It is well known that due to low ionic force field hydrophilic anions like Cl^- are generally less hydrated and often designated as structure breakers (17). As a result ΔS_1^0 the entropy change accompanying step 1, i.e., breaking down of hydration sphere round the anions is more or less fairly small. However, the secondary solvation zone (SSZ) is fairly large in these cases, $|-\Delta S_2^0|$, the entropy change, accompanying step 2, i.e., the formation of three dimensional (3D) ice-like water structure out of the released disordered water molecules from the SSZ, is largely negative. The net contributions ($\Delta S_1^0 - \Delta S_2^0$) are therefore likely to be largely negative for different anions.

Now at initial compositions, i.e., below 1.5 *m* $NaNO_3$ the prevalent ionic species are free $(Na^+)_{aq}$ and NO_3^- (14–17). Since the anions are likely to be stabilized by $(Na^+)_{aq}$, as indicated earlier, the entropy change ΔS_3^0 associated with the step 3, i.e. the breakdown of the relevant structure of the solvents or of the solvating species in the solvent, would be zero. Also, as the anions are likely to induce more order by restricting the translation degree of freedom of $(Na^+)_{aq}$ round the added anions, $|-\Delta S_4^0|$ the entropy change in the step 4, i.e., for the formation of ion–ion solvated species with the incoming ions in $NaNO_3$ solution, will be increasingly negative. This is also true for overall contributions ($\Delta S_1^0 - \Delta S_2^0$) + ($\Delta S_3^0 - \Delta S_4^0$) or $\Delta S^0_{t,tr.int}(i)$, as have been observed for the anions like Cl^-.

But after about 1.5 *m* $NaNO_3$ where the ionic species are being increasingly replaced by solvent-separated ion-pairs

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

(SSIP), ΔS_3^y would be more and more positive for breaking down the SSIP first to free NO_3^- and $(Na^+)_{aq}$ and then to free NO_3^- and Na^+ especially when water content diminishes at still higher concentration of $NaNO_3$. Evidently at higher $NaNO_3$ compositions while ΔS_3^0 will be increasingly positive, ΔS_4^0 will be increasingly less negative and thus $(\Delta S_3^0 - \Delta S_4^0)$ increasingly positive. Consequently the opposing effects of $(\Delta S_1^0 - \Delta S_2^0)$ and $(\Delta S_3^0 - \Delta S_4^0)$ will result in a minimum in $\Delta S_{t,tr.int}^0(i)$–composition profiles for the anions as have been observed. The observed relative position of the said profile for CrO_4^{2-} also conforms to the effect of divalent character of CrO_4^{2-} as compared to the monovalent Cl^-.

On the other hand, the relative positions of the composition profiles of $T\Delta S_t^0(i)$ and $T\Delta S_{t,tr.int}^0(i)$ for Pi^- suggest that the cavity effect plays an important role (also see Table 3). Moreover, the essentially similar nature of the latter profile with that of Cl^- or CrO_4^{2-} is indicative of the fact that entropic contributions of the characteristic features of the hydrophilic anions as discussed above are somewhat subdued by the opposing hydrophobic effects of the aromatic ring of Pi^-. In the cases of Ph_4B^- and Ph_4As^+, cavity effect of course plays an important role (see Table 3 and Fig. 6). As their solvation is chiefly guided by water molecules rather than $(Na^+)_{aq}$ or NO_3^-, respectively, their initial downward trends followed by the upward bent are also indicative of the fact that $NaNO_3$ is a 3D structure breaker up to about 1.5 *m*, thus causing the observed downward trend (13, 29). Since the water molecules are increasingly engaged for the SSIP, they impart the observed upward trends in $T\Delta S_t^0$ at higher compositions.

On analyzing the cations we find that, unlike the anions, $T\Delta S_t^0(i)$ and $T\Delta S_{t,tr.int}^0(i)$–composition profiles pass through maxima around 1–1.5 *m* $NaNO_3$ and their relative order is $H^+ > Ag^+ > K^+ > Pb^{2+}$. In view of the fact that small hydrophilic cations like these are usually largely hydrated, ΔS_1^0 values are expected to be large positive quantities. Since $|-\Delta S_2^0|$ is the entropy change accompanying the formation of 3D water structure by the water molecules set free in step 1, it would be smaller than the corresponding ΔS_1^0. This is because in step 1 we have to dismantle larger order induced by ionic force field around these cations, while in step 2 ordering is induced by the weaker H-bonding interactions around the central water molecules. As a result the difference $(\Delta S_1^0 - \Delta S_2^0)$ is a large positive quantity characteristic to the cations concerned.

Now in the initial compositions of the aqueous $NaNO_3$ solvent system, where prevalent NO_3^- ions are free to "solvate" the added cations, $\Delta S_3^0 = 0$. However, electrostatic interactions between cations and NO_3^- ions cause ΔS_4^0 to be increasingly negative. Consequently, the negative $(\Delta S_3^0 - \Delta S_4^0)$ would increasingly nullify the positive $(\Delta S_1^0 - \Delta S_2^0)$. Beyond about 1.5 *m* $NaNO_3$ where the free ions are gradually replaced by SSIP, $(Na^+)_{aq}NO_3^-$, and NO_3^- side being relatively free as compared to $(Na^+)_{aq}$ of the SSIP, added cations are likely to interact directly with the SSIP through the NO_3^- ions causing ΔS_3^0 to be zero and ΔS_4^0 to be increasingly negative. Consequently the difference $(\Delta S_3^0 - \Delta S_4^0)$ will ultimately overcome the positive contribution of $(\Delta S_1^0 - \Delta S_2^0)$ and thus result in a maximum in $T\Delta S_{t,tr.int}^0$–composition profile, as observed.

The observed relative positions of the $\Delta S_{t,tr.int}^0(i)$–composition profiles of cations around the maximum, viz. $H^+ > Ag^+ > K^+ > Pb^{2+}$ are also fairly in conformity with the relative hydration of these cations. In fact, of all these cations H^+ is highly hydrated because it easily fits in the water lattice and also facilitates to form not only H_3O^+ but also $H_9O_4^+$ (30), as detected in the gas phase from mass spectra by Kebarle (31). The crystallographic radius of Ag^+ (0.126 nm) (32) is not much smaller than that of K^+ (0.135 nm) (32) and the remarkably enhanced maximum for Ag^+ compared to K^+ is the reflection of larger hydration of Ag^+ than K^+. This is evident from the viscosity *B*-coefficients (17); $B_{Ag^+} = 0.089$ vs. $B_{K^+} = 0.007$ and also from the hydration numbers (*n*) obtained by the mobility method (33): $n_{Ag^+} = 2.4$ compared to that for $n_{K^+} = 1.00$. Similarly, although Pb^{2+} is doubly charged and is likely to be highly hydrated, due to the screening effect on nuclear charge by the surrounding multi-electron atmosphere in the outer orbits, the effective force field and hence the hydration is likely to be fairly small compared to other bivalent cations like Mg^{2+}, Ca^{2+} etc. In fact, while the hydration number as obtained by acidity function method (34) for $n_{Mg^{2+}} = 7.4$, $n_{Ba^{2+}} = 6.6$, $n_{Sr^{2+}} = 5.8$, and $n_{Pb^{2+}} = 1.9$. All these values thus reflect smaller hydration of Pb^{2+} compared to that of other bivalent cations. This result seemingly substantiates the observed relative position of $T\Delta S_{t,tr.int}^0$–composition profile of Pb^{2+} compared to the monovalent cations studied here.

Conclusions

The results of the present study reveal that the entropic contributions of the ionic constituents of electrolytes like MX (X = Cl and the like, and M = H, K, and the like) in this ionic cosolvent system behave, on the one hand, almost opposite to each other, while on the other hand, exactly similar to that observed in some aqueous nonionic cosolvent systems referred to earlier. Moreover, since $\Delta S_t^0(i)$ is guided by the ion–ion–solvent interactions of the oppositely charged constituents of the ionic cosolvent, rather by water molecules, neither the transfer entropies of the electrolytes nor those of their ionic constituents would directly or unambiguously reflect the structuredness of the solvents. Consequently, $\Delta S_t^0(HX)$ or rather $\Delta S_{t,tr.int}^0(HX)$ in aqueous ionic cosolvent systems which are usually considered 3D water structure breakers (17), can be hardly used to provide the desired extra confidence to its use as a structural probe for aquo-organic solvents, as envisaged by us earlier (1).

Received March 23, 1987

This paper is dedicated to the memory of Professor Karel Wiesner

JOHN A. FINDLAY, MAHESH JASEJA, and JEAN-ROBERT BRISSON. Can. J. Chem. **65**, 2605 (1987).

The structure of forbeside C, a saponin from the starfish *Asterias forbesi*, has been deduced totally by nuclear magnetic resonance methods applied to the undegraded molecule. Using principally 2D-COSY, HCORR, RCT, and 1D-nOe experiments, forbeside C is shown to be the hydrate of the monosodium salt of 6α-*O*-{β-D-fucopyranosyl(1→2)-*O*-β-D-fucopyranosyl(1→4)-*O*-[β-D-quinovopyranosyl(1→2)]-*O*-β-D-quinovopyranosyl(1→3)-*O*-6-deoxy-β-D-*xylo*-hexos-4-ulopyranosyl}-20S-hydroxy-3β-sulfo-oxy-5α-cholest-9(11)-en-23-one, the structure reported previously for ovarian asterosaponin **1**.

JOHN A. FINDLAY, MAHESH JASEJA et JEAN-ROBERT BRISSON. Can. J. Chem. **65**, 2605 (1987).

Appliquant des méthodes de la résonance magnétique nucléaire à la molécule qui n'a pas été dégradée, on a déterminé la structure du forbeside C, une saponine provenant de l'étoile de mer *Asterias forbesi*. Faisant principalement appel à des expériences de COSY-2D, HCORR, RCT et d'eOn-1D, on a démontré que le forbeside C est l'hydrate du monosel de sodium de la *O*-{β-D-fucopyrannosyl(1→2)-*O*-β-D-fucopyrannosyl(1→4)-*O*-[β-D-quinovopyrannosyl(1→2)]-*O*-β-D-quinovopyrannosyl(1→3)-*O*-désoxy-6 β-D-*xylo*-hexosulo-4 pyrannosyl}-6α hydroxy-20(S) sulfoxy-3β 5α-cholestène-9(11) one-23, la structure qui avait été rapportée antérieurement pour l'astérosaponine ovarienne **1**.

[Traduit par la revue]

Recently, we reported (1) the structures of the major saponins, forbeside A and forbeside B, from the starfish *Asterias forbesi* (Desor). We have now assigned the structure **1** to a third saponin, forbeside C, from the same source. As in the case of the major saponins, the structure of forbeside C has been deduced entirely by nmr methods and corroborated, in part, by FAB mass spectrometric data.

The ^{1}H nmr spectrum of forbeside C in pyridine-d_5/D_2O (5:1) at 500 MHz shows, in the downfield region, five anomeric sugar proton signals as doublets at δ 5.108 (7.9 Hz), δ 5.057 (7.9 Hz), δ 4.997 (8.0 Hz), δ 4.947 (7.7 Hz), and δ 4.838 (7.7 Hz). The high coupling constant values are consistent only with the β configuration for all anomeric linkages. The region δ 3.5–4.5 ppm shows the overlapping resonances of the oligosaccharide ring protons. Five sugar methyl doublets at δ 1.828 (6.1 Hz), δ 1.770 (6.5 Hz), δ 1.724 (6.1 Hz), δ 1.482 (6.2 Hz), and δ 1.445 (6.2 Hz) attest to the presence of five deoxy sugars. The rest of the signals in the upfield region δ 0.90–2.90 ppm are assigned to the aglycone moiety. The signals of the five aglycone methyl groups are easily recognizable, three of them are tertiary (δ 0.99 s, δ 0.95 s, δ 1.67 s) and are assigned to C18, C19, and C21 protons, respectively. Isopropyl doublets appear at δ 0.94 and δ 0.92, corresponding to the C26 and C27 methyls. In addition, doublets are observed at δ 2.95 and δ 2.80 for the C22 methylene protons and two overlapping AB quartets are observed at δ 2.53, corresponding to the C24 protons. A broad signal for the olefinic proton at C11 is clearly seen at δ 5.20 and a multiplet at δ 4.89 for the C3α

[a]From comparison with forbeside A and forbeside B data (1).
[b]From ^{1}H–^{13}C correlation using CHORTLE technique.

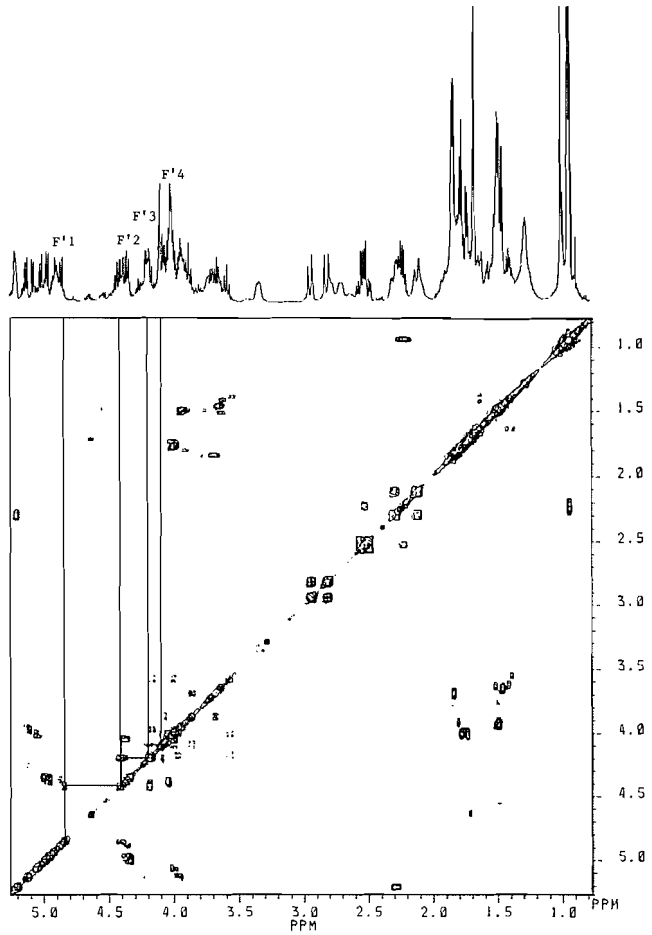

FIG. 1. 2D-nuclear proton correlation (COSY) spectrum (δ 0.95–5.15) of forbeside C.

proton. These findings indicate the presence of a thornasterol A aglycone moiety (1, 2). This was confirmed by ^{13}C nmr spectroscopy. The ^{13}C signals (Table 1) of the aglycone of forbeside C are virtually coincident with those of forbeside A (1) and consistent with those of thornasteroside A (3). The ^{13}C nmr spectrum also shows five anomeric carbon signals at 106.4, 105.8, 104.5, 103.5, and 102.3 ppm and five sugar methyls at 18.0, 18.0, 16.9, 16.6, and 13.4 ppm, consistent with the presence of five deoxy sugars in the oligosaccharide moiety. Distortionless enhancement by polarization transfer (DEPT) (4) analysis showed the absence of methylene carbons (-CH_2-) in the region 60–65 ppm. Thus, a preliminary review of nmr data indicated that forbeside C features a pentasaccharide chain attached to thornasterol A at position C6. With the aid of ^{1}H–^{13}C correlation spectra using "CHORTLE" (5) technique, all the proton resonances of the thornasterol A aglycone could be identified in the ^{1}H nmr spectrum of forbeside C. The assignments are listed in Table 1.

The complete structure of the oligosaccharide chain was determined by two-dimensional nuclear proton correlation (2D-COSY) (6), relayed coherence transfer (2D-RCT) (7), one-dimensional nuclear Overhauser enhancement (nOe) (8) difference spectroscopy, spin simulation, and heteronuclear ^{13}C–^{1}H correlation (HCORR) spectroscopy. The carbon and proton chemical shifts and coupling constant values of the oligosaccharide moiety of forbeside C are summarized in Table 2.

The anomeric doublet at δ 4.838 is designated as F′1, and the others are designated as F″1, Z1, Q″1, and Q′1 sequentially downfield.

From the 2D-COSY spectrum (Fig. 1), the anomeric proton signal for F′1 at δ 4.838 is coupled to the F′2 proton signal at δ 4.408 and, continuing this J-connectivity path, it was possible to locate F′3 at δ 4.182, and F′4 at δ 4.081. These assignments are confirmed by the 2D-RCT spectrum (Figs. 2*a*,*b*), which also shows that the signal at δ 4.081 (F′4) correlates with the signals at δ 3.927 and δ 1.482. Since the doublet at δ 1.482 belongs to the F′6 methyl, the signal at δ 3.926 is assigned to F′5. In the 2D-COSY spectrum the correlation between the F′4 and F′5 protons is not apparent since the $J_{4,5}$ coupling value is very small. Furthermore, the irradiation of the F′1 proton signal (δ 4.838) in the nOe difference spectrum (Fig. 3) induces substantial enhancements at δ 4.182 (F′3), δ 3.927 (F′5), and δ 3.565, the site of interglycosidic linkage. From the COSY spectrum (Fig. 1) and nOe spectra (Fig. 3), it is clear that the $J_{3,4}$ coupling value is small. From the J values in Table 2, which were refined by spin simulation (Fig. 4), it is evident that F′ must be a β-fucose unit.

Similarly, from the second anomeric doublet F″1 (δ 4.947), the J-connectivity pathway can be traced out from the 2D-COSY spectrum (Fig. 1) identifying all the couplings belonging to the sugar network F″, i.e., F″2 at δ 4.365, F″3 at δ 4.036, F″4 at δ 3.997, F″5 at δ 3.639, and F″6 at δ 1.455. The small couplings as observed from F″3/F″4, F″4/F″5 cross peaks and

the $J_{(AB)}$ values of each of the proton couplings derived by spin simulation show sugar F″ to be a β-fucose unit.

The irradiation of the F″1 proton signal (δ 4.947) in the nOe difference spectrum (Fig. 3) causes marked enhancements of signals at δ 4.036 (F″3) and δ 3.639 (F″5), and also a substantial enhancement at δ 4.407, showing the site of interglycosidic linkage at the neighbouring sugar unit to be F′2.

From the 2D-COSY spectrum (Fig. 1) one can trace out the *J*-connectivity pathway starting from Q″1 at δ 5.057 to Q″6 at δ 1.828, thus assigning all the ring protons in sugar Q″. Irradiation at δ 5.057 (Q″1) (Fig. 3) induces enhancements at δ 4.075 (Q″3) and δ 3.675 (Q″5) and a marked enhancement at δ 3.961 (Q′2), the site of interglycosidic linkage to the neighbouring sugar Q′.

The last anomeric doublet at δ 5.108 (Q′1) is seen coupled to a signal at δ 3.961 (Q′2) in the 2D-COSY spectrum (Fig. 1) and, continuing this pathway, the protons Q′3, Q′4, Q′5, and Q′6 are identified at δ 3.961, δ 4.165, δ 3.565, δ 3.997, and δ 1.724, respectively. The nOe difference spectrum (Fig. 3) shows enhancement at δ 4.165 (Q′3) and δ 3.997 (Q′5) in agreement with the assigned quinovose structure.

In the 2D-COSY spectrum (Fig. 1) the anomeric doublet for sugar Z at δ 4.997 (Z1) is seen to be coupled to the signal at δ 4.328 (Z2) but this latter proton has no further coupling partner. Also, one can see the remaining methyl doublet at δ 1.770 (Z6) coupled to the signal at δ 3.993 (Z5), which in turn shows no further coupling partner. The 2D-RCT spectrum (Fig. 2) gives no evidence of proton substitution at Z3 and Z4.

The proton chemical shifts obtained from the 2D-COSY and 2D-RCT experiments and coupling constant information for various sugar protons were refined by spin simulation (Fig. 4) until excellent agreement between experimental and calculated spectra was obtained (Table 2). This confirmed the absence of signals due to proton substitution at Z3 and Z4.

The sequencing of the sugars was completed with the help of 1D nOe difference spectroscopy (Fig. 3) by irradiating each of the anomeric signals separately. The nOe data for the oligosaccharide chain is summarized in Table 3. Thus, the positions of three interglycosidic linkages, their preferred conformations, and the position of attachment of sugar Z to the aglycone were readily revealed from inter-residue nOe. However, irradiation of signal Q′1 did not reveal the location of interglycosidic

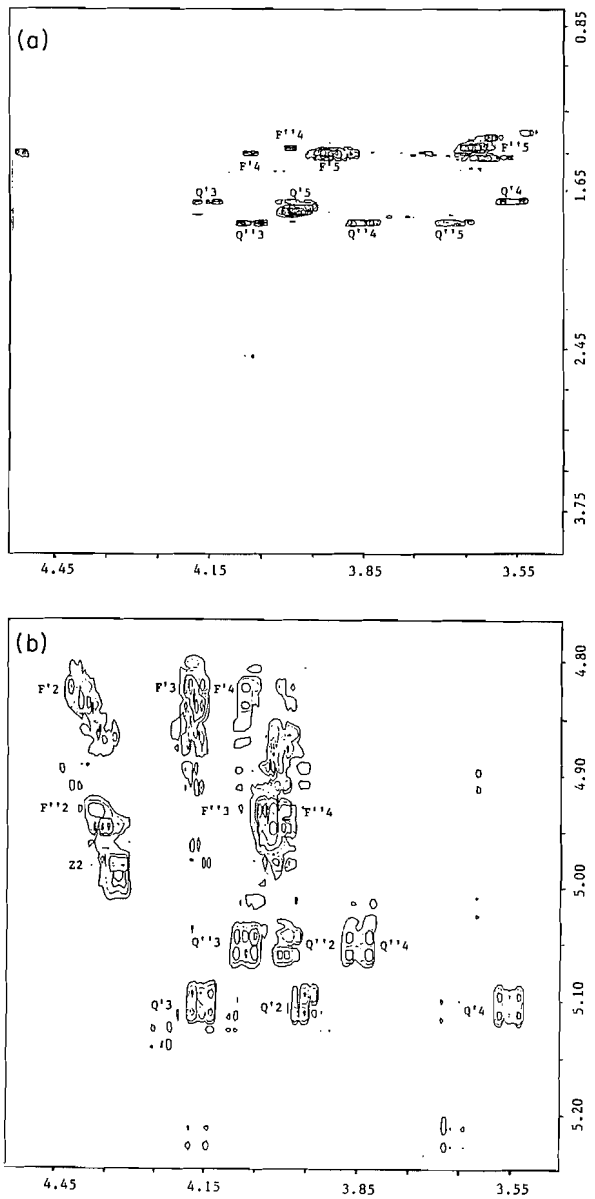

FIG. 2. (*a*) 2D-Relayed coherence transfer (RCT) spectrum (δ 3.45–4.55/δ 0.85–3.85) of forbeside C. (*b*) 2D-Relayed coherence transfer (RCT) spectrum (δ 3.45–4.55/δ 4.75–5.25) of forbeside C.

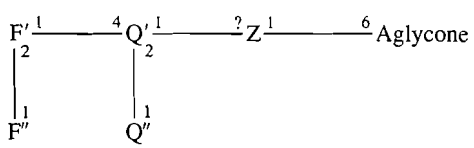
linkage to sugar Z, implying that this site on Z was substituted by either a deuterium (D_2O) exchangeable hydrogen or no hydrogen. Alternatively, the transglycosidic nOe may be negligible for reasons of conformation. The sequencing of the sugars as deduced from nOe data can be summarized as follows:



Corroboration of the location of the interglycosidic linkages comes from the ^{13}C shift data (Table 2) since the chemical shifts of carbons involved in the interglycosidic linkages invariably occur at lower field than when simply hydroxylated. Thus Q′ is seen to be linked at C2 and C4 since their signals, 83.4 and 84.8 ppm, respectively, are substantially downfield from the

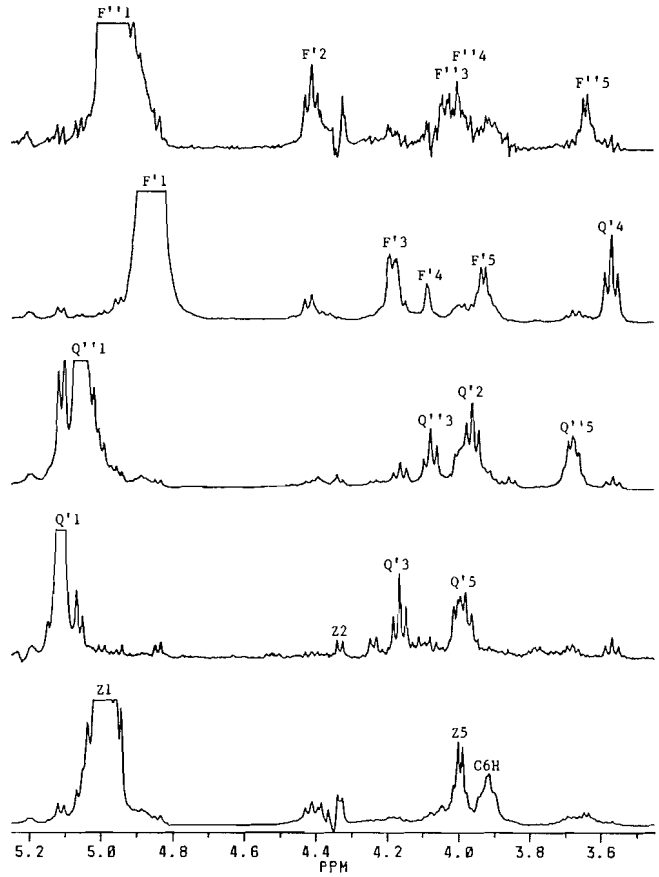


FIG. 3. The nOe difference spectra for forbeside C.

corresponding signals in Q″ (i.e., 76.0 and 75.5, respectively). Similarly F′ must be linked at C2 since its chemical shift, 81.6 ppm, is 7.3 ppm lower than its counterpart in F″. Thus the ^{13}C nmr data fully support this assigned sequence and also allow insight into the connectivity of Q′ to Z. The signal at δ 92.7 for the fully substituted carbon in the ^{13}C spectrum (pyridine-d_5/D_2O, 5:1) of forbeside C must belong to either Z3 or Z4 since all other signals are satisfactorily accommodated. Furthermore, it is evident that, in this medium, one of the sugar Z carbons (Z3 or Z4) fails to give rise to a discernible ^{13}C signal.

This dilemma was overcome by assigning the δ 92.7 signal to a *gem* diol carbon at C4. The inclusion of an extra oxygen atom is in full agreement with the molecular ion from positive ion FAB (fast-*atom bombardment*) mass spectral data (*vide infra*). The placement of the *gem* diol at C4 allows for the exchange of C3H for deuterium via the anticipated C4 *gem* diol ⇌ C4 ketone + water equilibrium in pyridine-d_5/D_2O. In confirmation of these assignments, recovery of the nmr sample followed by equilibration in pyridine-d_5/H_2O (5:1) for seven days afforded a ^{13}C nmr spectrum featuring an additional methine signal at 90.3 ppm. Therefore the interglycosidic linkage must be at C3, the carbon that gives rise to the elusive 90.3-ppm signal and whose hydrogen is D_2O exchangeable. This lower field chemical shift is in accord with expectation.

To determine the relative configuration of C3H in sugar Z, the 2D-COSY spectrum of forbeside C was recorded in pyridine/H_2O (5:1) and it showed the Z3 proton at δ 4.073 coupled with a large (9.0 Hz) coupling constant to Z2 at δ 4.328. Sugar Z is, therefore, a β-linked 6-deoxy-*xylo*-4-hexulose unit in hydrated form.

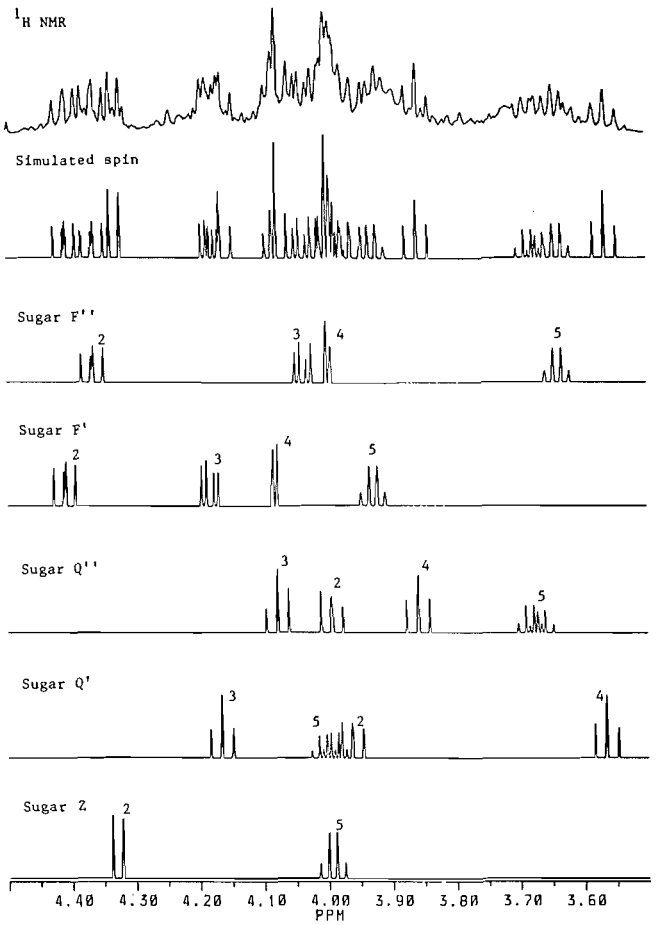

FIG. 4. Spin simulation of the ^{1}H nmr spectra for the sugar moiety of forbeside C.

TABLE 3. The nOe data for forbeside C obtained from nOe difference spectroscopy

Irradiation at ^{1}H (ppm)	nOe enhancements at ^{1}H shift: Intraresidual 1–3	Axial–axial 1–5	Interresidual through glycosidic bond to
4.997 (Z1)	—	3.993	(C_6 of aglycone) 3.93
5.108 (Q′1)	—	3.997	—
5.057 (Q″1)	4.075	3.675	3.961 (Q′2)
4.838 (F′1)	4.182	3.927	3.565 (Q′4)
4.947 (F″1)	4.036	3.639	4.408 (F′2)

The positive ion FAB mass spectrum (Fig. 5) of forbeside C exhibits prominent ions at m/z 1303.3 (M + Na), 1281.2 (M + H), 1201.5 (M + H + Na − $NaSO_3$), and 1183.5 (M + H + Na − $NaSO_3$ − H_2O), confirming the elemental composition $C_{57}H_{93}NaO_{28}S$, while other ions provide corroboration of aspects of the oligosaccharide chain as shown in Scheme 1. Thus cleavage of the oligosaccharide moiety furnishes an ion m/z 769, which is subject to further fragmentation corresponding to loss of one or two sugars by fission on each side of the glycosidic oxygens.

Thus, assuming D-family sugars, forbeside C possesses structure **1**, the hydrate of the monosodium salt of 6α-*O*-{β-D-fucopyranosyl(1→2)-*O*-β-D-fucopyranosyl(1→4)-*O*-[β-D-quinovopyranosyl(1→2)]-*O*-β-D-quinovopyranosyl(1→3)-*O*-6-deoxy-β-D-*xylo*-hexos-4-ulopyranosyl}-2OS-hydroxy-3β-sulfo-oxy-5α-cholest-9(11)-en-23-one. This same structure has been assigned to ovarian asterosaponin **1** from the starfish *Asterias amurensis* by Ikegami and co-workers (9) and was deduced principally from examination of various hydrolysis and degradation products. It has also been found by Itakura and

Experimental

Forbeside C

Forbeside C (30 mg) was obtained via fractionation of crude saponin (3 g) obtained from specimens of *Asterias forbesi* (Desor) (collected in Passamaquoddy Bay, August 1984) as previously described (1). This saponin was obtained as a glassy solid (mp 180–182°C uncorrected).

Nuclear magnetic resonance spectra

The nmr spectra were recorded on a Bruker AM-500 spectrometer at 300 K using forbeside C (25 mg) in 0.5 mL of pyridine-d_5/D_2O (5:1) unless otherwise indicated.

All one-dimensional and two-dimensional nmr experiments were performed using the standard pulse sequences provided by Bruker (DISNMRP).

One-dimensional nuclear Overhauser enhancement difference experiments

The 1D-nOe difference experiments were performed as previously described (11). However, instead of irradiation at a single frequency of the whole multiplet, each line in the multiplet was sequentially irradiated 100 ms for a total time of 1 s per multiplet (12). A line broadening factor of 2 Hz was used prior to Fourier transformation to improve signal-to-noise ratio.

2D-COSY and 2D-RCT experiments

2D-COSY and 2D-RCT experiments were performed using the standard pulse sequences. The initial matrix of 256 × 2048 data points over a sweep width of 5.4 ppm in both dimensions was zero-filled to 1024 × 2048 points for a final resolution of 2.6 Hz/point. Sine-bell functions were used for resolution enhancement. Magnitude calculations and symmetrization about the diagonal were used to represent the data. For the two-step RCT experiment, a delay of 32 ms was used.

The heteronuclear $^{13}C-^{1}H$ correlation

The heteronuclear $^{13}C-^{1}H$ correlation was done by a least-squares analysis of the ^{13}C intensities as a function of proton evolution times according to Pearson (5). Five evolution times of 0.16, 0.4, 1.0, 2.4, and 3.2 ms were used.

Spin simulations

The spin simulations were done using the Bruker programme PANIC. A linewidth of 0.5 Hz was used in all cases.

[2]Larry Calhoun and John A. Findlay, unpublished results.

Fast-atom bombardment (FAB) mass spectra

The FAB mass spectra were obtained on VG 7070E and VG ZAB-SE mass spectrometers employing xenon as an ionizing gas, accelerating voltages of 5 and 10 kV, respectively, and "MAGIC BULLET" was used as matrix (13).

Received May 20, 1987

GORDON S. BATES, MICHAEL D. FRYZUK, and CHARLES STONE. Can. J. Chem. **65**, 2612 (1987).

The facile preparation of 2-trialkylstannyl-1,3-butadienes and 2-phenylseleno-1,3-butadiene by reaction of 2-(1,3-butadienyl)magnesium chloride with trialkylstannyl chlorides and phenylselenium chloride, respectively, is reported. The Diels–Alder reactivity of these dienes with a variety of activated dienophiles is also described. Finally, a novel transmetallation of tin, in vinyl stannanes, to selenium by use of phenylselenium chloride is outlined.

GORDON S. BATES, MICHAEL D. FRYZUK et CHARLES STONE. Can. J. Chem. **65**, 2612 (1987).

On rapporte une méthode facile de préparer les trialkylstannyl-2 et phénylséléno-2 butadiènes-1,3 qui implique la réaction du chlorure du butadiène-1,3 yle-2 magnésium avec les chlorures soit de trialkylstannyles soit de phénylsélénium. On décrit aussi la réactivité de ces dienes, dans la réaction de Diels–Alder, avec divers diénophiles activés. Enfin, on décrit une nouvelle réaction de transmétallation de l'étain, dans des stannanes de vinyles, vers le sélénium du chlorure de phénylsélénium.

Introduction

As part of our interest in the Diels–Alder reactivity of 1,3-dienes with metalloid (1) or transition metal substituents, we have examined the synthesis of 2-substituted 1,3-butadienes of the formula **1** (ML_n = metalloid or transition metal complex). Our rational approach was to use the readily available, inexpensive starting material chloroprene **2**, and examine its conversion to **1** via the Grignard reagent **3**. It had been reported that attempts to prepare **3** from chloroprene gave polymers; however, the preparation of this Grignard reagent could be achieved from the less accessible 4-chloro-1,2-butadiene (2). More recently, a modification was published that allows **3** to be prepared directly from **2** by first activating the magnesium (3). We have used this procedure to prepare 2-trialkylstannyl-1,3-butadienes **4** and 2-phenylseleno-1,3-butadiene **5** in a one-step, facile synthesis. While our work was in progress, reports on alternative syntheses and Diels–Alder reactivity of **4** and **5** were communicated. A "tin-cupration" of 2-butyne-1,4-diol followed by "silyl-cupration" generated **4***a* in reasonable yield (4), while an equally elaborate Wurtz-type coupling yielded **4***b* (5). The preparation and isolation of **5** have never been reported to our knowledge, although the synthesis of the SO_2-masked derivative **6** has been recently described along with a study of its Diels–Alder reactivity (6).

In this paper we describe the following: (*i*) full details for the one-pot synthesis of **4** and **5**, (*ii*) cycloaddition reactions of these dienes with a variety of dienophiles, and (*iii*) the first example of transmetallation from tin to selenium.

Results and discussion

Synthesis of dienes

Chloroprene **2** is readily converted to the corresponding Grignard reagent **3** by activating the magnesium with 1–3 mol% anhydrous $ZnCl_2$ and small amounts of 1,2-dibromoethane. In this fashion, 0.25–0.60 *M* solutions of **3** in tetrahydrofuran (THF) can be obtained. The subsequent reaction with the commercially available stannyl halides and phenylselenium chloride provides for the convenient, one-pot preparation of the dienes **4** and **5** on a multi-gram scale (see eq. [1]). Diene **5**, previously uncharacterized due to its ready polymerization (6), was isolated and found to be stable for long periods at low temperature (−20°C).

Diels–Alder reactions

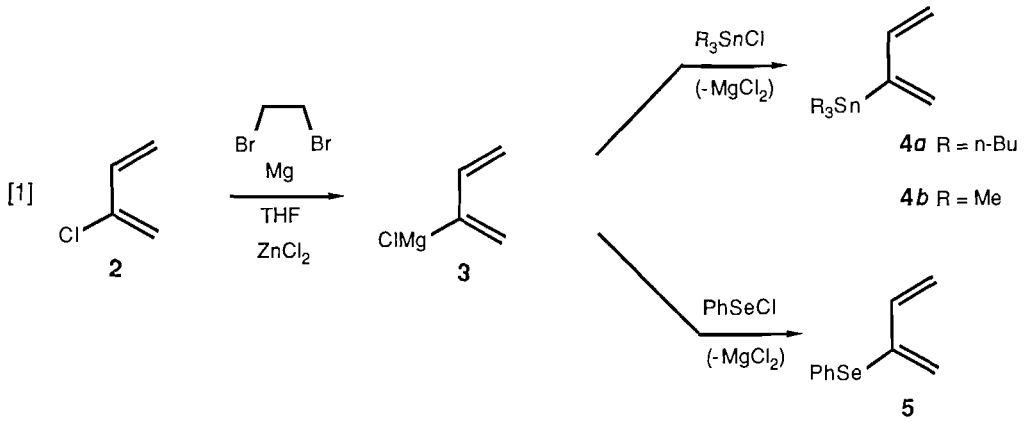
Reaction of 2-trialkylstannyl-1,3-butadienes **4** with a variety of activated dienophiles leads to the preparation of substituted cyclohexenes containing a vinyl stannane functionality. This latter functionality has been shown to have great synthetic potential via transition metal catalysed cross-coupling with vinyl halides (7) and vinyl triflates (8). The results of the preparation of such trialkylstannyl-substituted cyclohexenes **7–11** are summarized in Table 1. In general, the reactions proceeded smoothly at elevated temperatures to give good yields of the Diels–Alder cycloadducts. However, reaction of **4***a* with maleic anhydride for extended periods of time at room temperature gave the best yields of cycloadduct **7**. In the work-up of **9**, by column chromatography on silica gel, enolization took place producing small quantities of the corresponding hydroquinone. Hydroquinone production was also observed when reaction times in excess of 12 h were used. Similar results were noted in the preparation and work-up of **14** (see Table 2), albeit to a lesser extent.

The trialkylstannane substituted diene allows for facile reaction with electron-deficient dienophiles, as is evidenced by its ready cycloaddition with dimethyl acetylenedicarboxylate. Extended periods (several days) of reflux in toluene with diphenylacetylene, an electron-rich dienophile, led only to isolation of starting materials.

In an attempt to determine the directing effect of the stannyl

TABLE 1. Reaction of 2-trialkylstannyl-1,3-butadienes **4***a*/**4***b*

Entry	Dienophile	Conditions	Products	Yields
1		$PhCH_3$, room temp., 2 days	 **7**	75%
2		$PhCH_3$, reflux, 8 h	 **8**	90%
3		$PhCH_3$, reflux, 5 h	 **9**	69%
4	$MeO_2CC{\equiv}CCO_2Me$	$PhCH_3$, reflux, 18 h	 **10**	71%
5		$PhCH_3$, reflux, 18 h	 **11a** **11b** 2 : 1	72%



moiety, the reaction of **4***b* with methyl acrylate at reflux in toluene was examined. In analogy to results previously observed in cycloaddition reactions of silylbutadienes (9), the stannyl moiety was found to exhibit only a weak directing effect, resulting in a 2:1 mixture of *para*:*meta* regioisomers **11***a*:**11***b*.[3] Other workers have shown (4*b*) that the use of 15% $AlEt_2Cl$ in the reaction of **4***a* with ethyl acrylate gave a 10:1 ratio of *para*:*meta* regioisomers.

The assignment of **11***a* (*para*) as the major regioisomer is based on much literature precedent, both theoretical and experimental (6, 10). Attempts to separate mixtures of **11***a*/**11***b* using column chromatography proved difficult; however, an enriched 7:1 (**11***a*:**11***b*) mixture was obtained. It was hoped that by use of ^1H nmr NOEDIFF (nuclear Overhauser effect difference) spectroscopy (11), on this enriched mixture, more physical evidence for the assignment of the major regioisomer

[3]The best yields of **11***a*/**11***b* were obtained by use of several equivalents of freshly distilled methyl acrylate containing 2 mol% (based on diene) 2,6-di-*tert*-butyl-4-methylphenol (BHT).

TABLE 2. Reaction of 2-phenylseleno-1,3-butadiene **5**

Entry	Dienophile	Conditions	Products	Yields
1		$PhCH_3$, room temp., 2 days	 **12**	70%
2		$PhCH_3$, reflux, 8 h	 **13**	76%
3		$PhCH_3$, reflux, 2 h	 **14**	64%
4	$MeO_2CC{\equiv}CCO_2Me$	$PhCH_3$, reflux, 18 h	 **15**	81%
5		$PhCH_3$, reflux, 18 h	 **16a** **16b** 4:1	90%

could be achieved. Unfortunately, the results of such experiments at 400 MHz were equivocal.

The results of the cycloaddition reactions of the phenylseleno diene **5** with a variety of activated dienophiles are outlined in Table 2. The reaction of **5** at room temperature with maleic anhydride and at elevated temperature with less activated dienes yielded cycloadducts **12–16**.[4]

The synthetic utility of the vinyl selenide functionality is realized most readily in its role as a masked carbonyl (12). Other uses involve cross-coupling reactions with Grignard reagents in the presence of nickel-phosphine catalysts (13) and oxidative cleavage with hydrogen peroxide (14). Evidence that the selenenyl substituted diene permits facile reaction with electron-deficient dienophiles is seen in the ready formation of **12–16** and in its total lack of reactivity with diphenylacetylene.

Regiochemical investigation of the Diels–Alder reactivity of **5** involved reaction with methyl acrylate at reflux in toluene. A 4:1 mixture[5] of *para*:*meta* regioisomers was obtained in excellent chemical yield. This result was in complete agreement with published data, based on theoretical calculations, on the products obtained by reaction of **6** with ethyl acrylate (6). The results of our study show that, in reaction with methyl acrylate, the selenenyl moiety has a greater directing effect than the stannyl substituent.

Transmetallation from tin to selenium

Other results from our laboratory (1) have shown that addition of phenylselenium chloride (PhSeCl) to solution of zirconium dienyl complexes results in smooth transmetallation from zirconium to selenium with immediate discharge of the deep red colour of PhSeCl. A similar result was obtained when the stannyl diene **4***b* was reacted with PhSeCl at room temperature (see eq. [2]). Work-up of the reaction mixture yielded a yellow oil that had identical spectral data to diene **5**, indicating that the transmetallation reaction had proceeded without rearrangement. In an attempt to gain further comparative information on the reaction of the dienes **4***a* and **5** with methyl acrylate, a solution of PhSeCl was added to a 2:1 *para*:*meta* mixture of the Diels–Alder adducts **11***a*/**11***b*. Stirring the mixture overnight at room temperature caused discharge of the deep red colour of the PhSeCl, which on work-up yielded a 2:1 *para*:*meta* mixture of **16***a*/**16***b* as determined by ^1H nmr (see eq. [3]). This result indicates that the major regioisomer formed in reaction **4***b* and **5**, with methyl acrylate, was the same in each case.

Transmetallation of tin in vinyl stannanes has precedence in

[4]Addition of 2 mol% (based on diene) BHT was used in all reactions of **5**.

[5]No attempt was made to separate this mixture.

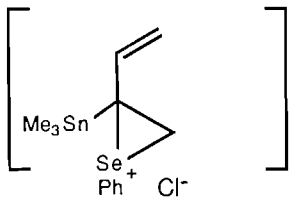
reactions at low temperature with alkyl lithium reagents (15), and in coupling reactions catalysed by palladium complexes (7). Stereoselective transmetallation from mercury to selenium by reaction of vinyl mercuric compounds with PhSeCl has also been observed (16).

The reaction of vinyl stannanes with PhSeCl is analogous to a previously reported reaction in which iodine is used to cleave the tin–carbon bond producing a vinyl iodide (17). Much work has already been done on the mechanism of areneselenenyl chloride addition to alkenes. Schmid and Garratt (18) have proposed three possible mechanisms, which differ only in the relative amount of carbon–selenium bond making and selenium–chlorine bond breaking leading up to the formation of the seleniranium ion. In our system, collapse of seleniranium ion **17** to give diene **5** could proceed via attack of chloride at the



17

least-substituted carbon or at tin, followed by elimination of Me_3SnCl.[6] No spectroscopic evidence for the formation of allenic species was observed.

This transmetallation reaction appears to be general for vinyl stannanes. It exhibits interesting chemoselectivity as shown in eq. [2], with no products of addition to the isolated double bond being observed. To our knowledge, this is the first example of transmetallation from tin to selenium. Further studies in this area will involve investigation of the stereochemistry of this metal-transfer reaction.

Experimental

The ^1H nmr spectra were recorded on a Bruker WH-400 equipped with Aspect 2000 computer software. Signal positions are given in delta (δ) with reference to C_6D_5H at 7.15 ppm. Infrared spectra were run on a Nicolet 5D-X spectrophotometer. Low resolution and high resolution mass spectra (hrms) were determined on a Kratos MS-50 spectrometer. Gas–liquid chromatography was performed on a Hewlett–Packard model 5880a gas chromatograph using a 12 m × 0.2 mm column (Carbowax 10M). Column chromatography was carried out using Merck Kieselgel 60 (230–400 mesh ASTM). For thin-layer chromatography (tlc) silica gel 13181 (Eastman chromagram) sheets were used. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia.

Dry solvents were used in all experiments. Tetrahydrofuran (THF) and toluene were dried by refluxing over and then distilling from sodium-benzophenone ketyl. All Diels–Alder reactions were carried out in the absence of light. In addition, reactions of **5** and reactions involving methyl acrylate contained 2 mol% (based on diene) 2,6-di-*tert*-butyl-4-methylphenol (BHT). No microanalysis is given for previously prepared compounds. For cycloadduct **9**, satisfactory microanalysis could not be obtained; instead, hrms is given for the hydroquinone. Grignard reagent **3** was prepared according to Method A in ref. 3.

*2-Tri-*n*-butylstannyl-1,3-butadiene,* ***4****a*

Tri-*n*-butyltin chloride (14.64 g, 45 mmol) dissolved in 25 mL THF was added dropwise, at room temperature, to a stirred solution of Grignard **3** (75 mL, 45 mmol; 0.6 *M* solution in THF) under nitrogen. The mixture was stirred at room temperature for a further 6 h, and then 10 mL of water was added to decompose any unreacted Grignard reagent. At this stage most of the THF was evaporated, leaving a white slurry that was extracted with 3 × 100 mL portions of diethyl ether. The ether layer was washed with 2 × 100 mL portions of aqueous 2 *M* potassium fluoride to remove any unreacted n-Bu_3SnCl. Finally, the organic layer was washed with 2 × 100 mL water and dried over anhydrous $MgSO_4$. Evaporation of the solvent and distillation under high vacuum yielded one fraction (40–50°C/10^{-3} Torr; 1 Torr = 133.3 Pa) of a colourless liquid **4***a* (10.9 g, 71%).

Spectroscopic data for **4***a* were consistent with those reported in ref. 4*a*.

2-Trimethylstannyl-1,3-butadiene, ***4****b*

Trimethyltin chloride (6.0 g, 30 mmol) dissolved in 25 mL THF was added dropwise, at room temperature, to a solution of Grignard **3** (50 mL, 30 mmol; 0.6 *M* in THF) under nitrogen. The mixture was stirred at room temperature for a further 6 h. The work-up was identical to that described for **4***a*. Distillation, at reduced pressure, yielded **4***b* (4.35 g, 65%) as a colourless liquid, distilling at 42°C/11 Torr.

Spectroscopic data for this compound were identical to those reported in ref. 5.

2-Phenylseleno-1,3-butadiene, ***5***

Phenylselenium chloride (4.78 g, 25 mmol) dissolved in 25 mL THF was added dropwise, at room temperature, to a stirred solution of Grignard **3** (100 mL, 25 mmol; 0.25 *M* in THF) under nitrogen. The deep red colour of the PhSeCl dissipated immediately on addition to **3**; the reaction was then stirred at room temperature for a further hour. The work-up was identical to that described for **4***a*, with the omission of the aqueous KF washings. After drying the organic layer, evaporation of the solvent yielded a yellow oil. Distillation of the latter under high

[6]A similar argument is put forward to explain the stereospecific cleavage of an E/Z mixture of $PhCH{=}CHSnMe_3$ by Br_2 (19).

vacuum (10^{-3} Torr) gave a pale yellow oil **5** (3.66 g, 70%); ν_{max} (film): 1620, 1572, 1477, 1439, 1214, 914, and 735 cm^{-1}; δ (C_6D_6, 400 MHz): 5.00 (1H, d, J = 10.5 Hz), 5.34 (1H, s), 5.53 (1H, s), 5.62 (1H, d, J = 17 Hz), 6.24 (1H, dd, J = 10.5 Hz, 17 Hz), 6.94 (3H, m), and 7.44 (2H, m). *Anal.* calcd. for $C_{10}H_{10}Se$: C 57.43, H 4.82; found: C 57.66, H 4.81.

Preparation of ***7***

A solution of **4***a* (500 mg, 1.46 mmol) and maleic anhydride (143 mg, 1.46 mmol) in 2 mL of toluene was stirred at room temperature under nitrogen for 48 h. The solvent was evaporated and the residue was purified directly by column chromatography (eluent: ether/petroleum ether 1:2) yielding **7** (482 mg, 75%) as a white solid.

Spectroscopic data for **7** were identical to those reported in ref. 4*a*.

Preparation of ***8***

A solution of **4***a* (500 mg, 1.46 mmol) and *N*-phenylmaleimide (252 mg, 1.46 mmol) in 3 mL of toluene was refluxed for 8 h. The solvent was evaporated and the residue was subjected to column chromatography (eluent: ether/petroleum ether 1:3), which yielded **8** (675 mg, 90%) as a yellow oil; ν_{max} (film): 1779, 1712, 1499, 1456, 1378, 1190, 1171, and 690 cm^{-1}; δ (C_6D_6, 400 MHz): 0.90 (15H, m), 1.29 (6H, m), 1.48 (6H, m), 1.84 (1H, m), 1.99 (1H, m), 2.53 (2H, m), 2.63 (1H, dd, J = 6 Hz, 15 Hz), 2.85 (1H, d, J = 15 Hz), 6.01 (1H, m), 7.00 (1H, m), 7.15 (2H, m), and 7.41 (2H, m). *Anal.* calcd. for $C_{26}H_{39}NO_2Sn$: C 60.49, H 7.61, N 2.71; found: C 60.60, H 7.79, N 2.60.

Preparation of ***9***

A solution of **4***a* (500 mg, 1.46 mmol) and benzoquinone (158 mg, 1.46 mmol) in 3 mL toluene was refluxed under nitrogen for 5 h. The solvent was evaporated and the residue was purified by column chromatography (eluent: dichloromethane) to give **8** as a yellow oil (453 mg, 69%); ν_{max} (film): 1684, 1602, 1260, 1090, and 850 cm^{-1}; δ (C_6D_6, 400 MHz): 0.90 (15H, m), 1.32 (6H, m), 1.32 (6H, m), 1.54 (6H, m), 1.84 (1H, m), 2.17 (1H, m), 2.39 (1H, m), 2.57 (1H, m), 2.63 (1H, m), 2.70 (1H, m), 5.72 (1H, m), and 6.05 (2H, s). From the chromatography of **9** a white solid (53 mg, 8%) was obtained, Spectroscopic data, as follows, indicated that this solid was the hydroquinone of **9**; ν_{max} (Nujol): 3286, 1625, 1595, 1311, 1242, 992, 807, and 743 cm^{-1}; δ (C_6D_6, 400 MHz): 0.93 (9H, t, J = 7 Hz), 0.99 (6H, t, J = 8 Hz), 1.37 (6H, m), 1.58 (6H, m), 3.27 (2H, m), 3.63 (2H, m), 3.83 (2H, br s, δ was concentration dependent and signal disappeared on D_2O exchange), 6.06 (1H, m), 6.10 (1H, d, J = 8.5 Hz), and 6.22 (1H, d, J = 8.5 Hz); *m/e* (relative intensity) with ^{120}Sn: 395 (14.3), 338 (6.4), 281 (13.4), 161 (98.1), 147 (70.0), and 56 (93.1). *Mol. Wt.* calcd. for $C_{18}H_{27}O_2Sn$ ($M - n$-Bu)$^+$: 395.1033; found (hrms): 395.1027.

Preparation of ***10***

A solution of **4***a* (500 mg, 1.46 mmol) and dimethyl acetylene dicarboxylate (207 mg, 1.46 mmol) in 3 mL toluene was refluxed overnight under nitrogen. The solvent was evaporated and the residue was purified by column chromatography (eluent: ether/petroleum ether 1:7) to give **10** (503 mg, 71%) as a colourless liquid; ν_{max} (film): 1736, 1726, 1668, 1618, 1434, 1261, and 1065 cm^{-1}; δ (C_6D_6, 400 MHz): 0.91 (15H, m), 1.32 (6H, m), 1.51 (6H, m), 2.93 (2H, m), 3.27 (2H, m), 3.42 (3H, s), 3.45 (3H, m), and 5.63 (1H, m). *Anal.* calcd. for $C_{22}H_{38}O_4Sn$: C 54.46, H 7.89; found: C 54.61, H 7.87.

Preparation of ***11***a/***11***b

A solution of **4***b* (1.73 g, 7.98 mmol) and methyl acrylate (3.43 g, 39.92 mmol) in 10 mL toluene was refluxed overnight under nitrogen. The solvent and excess methyl acrylate were evaporated and the residue was subjected to column chromatography (eluent: ether/petroleum ether 1:20) yielding **11***a*/**11***b* (1.74 g, 72%). Capillary glc and ^1H nmr indicated that the regioisomers **11***a*/**11***b* were present in a 2:1 ratio. The following data were obtained for this mixture: ν_{max} (film): 1737, 1618, 1437, 1166, and 767 cm^{-1}; δ (C_6D_6, 400 MHz): 0.07 (9H, s), 1.67–2.54 (7H, m), 3.36 and 3.37 (3H, 2 singlets; **11***a* and **11***b*, respectively), and 5.75 (1H, m). *Anal.* calcd. for $C_{11}H_{20}O_2Sn$: C 43.61, H 6.65; found: C 43.91, H 6.80.

Preparation of ***12***

A solution of **5** (750 mg, 3.59 mmol) and maleic anhydride (351 mg, 3.59 mmol) in 3 mL toluene was stirred at room temperature for 48 h under nitrogen. A mass of white crystals gradually deposited from solution. Low temperature recrystallization of this material (from ether/petroleum ether) yielded pure **12** (771 mg, 70%); ν_{max} (Nujol): 1845, 1780, 1245, 1010, and 942 cm^{-1}; δ (C_6D_6, 400 MHz): 1.42 (1H, m), 1.76 (1H, m), 2.04 (1H, m), 2.11 (2H, m), 2.37 (1H, m), 5.61 (1H, m), 6.97 (3H, m), and 7.33 (2H, m). *Anal.* calcd. for $C_{14}H_{12}O_3Se$: C 54.74, H 3.94; found: C 54.56, H 3.92.

Preparation of ***13***

A solution of **5** (1.00 g, 4.78 mmol) and *N*-phenylmaleimide (829 mg, 4.78 mmol) in 3 mL toluene was refluxed for 8 h under nitrogen. The solvent was evaporated and the residue was chromatographed (eluent: ether/petroleum ether 1:3) to give **13** as a yellow oil (1.39 g, 76%); ν_{max} (film): 1960, 1882, 1782, 1715, 1597, 1575, 1384, 1180, and 745 cm^{-1}; δ (C_6D_6, 400 MHz): 1.75 (1H, m), 2.08 (1H, m), 2.40 (2H, m), 2.49 (1H, m), 2.78 (1H, m), 5.92 (1H, m), and 6.98–7.50 (10H, m). *Anal.* calcd. for $C_{20}H_{17}NO_2Se$: C 62.83, H 4.48, N 3.66; found: C 62.91, H 4.63, N 3.80.

Preparation of ***14***

A solution of **5** (657 mg, 3.14 mmol) and benzoquinone (340 mg, 3.14 mmol) in 2 mL toluene was refluxed for 2 h under nitrogen. Upon cooling the reaction to room temperature a white solid deposited. After evaporation of the bulk of the solvent the residue was dissolved in CH_2Cl_2 and passed through a short column (2 cm × 2 cm) of silica to remove small traces of a highly coloured material. Removal of the solvent and recrystallization from toluene/petroleum ether yielded a white solid **14** (638 mg, 64%); ν_{max} (KBr): 1676, 1598, 1577, 1475, 1435, 1263, and 737 cm^{-1}; δ (C_6D_6, 400 MHz): 1.68 (1H, m), 2.05 (1H, m), 2.17 (1H, m), 2.41 (2H, m), 2.59 (1H, m), 5.87 (1H, m), 5.92 (1H, s), 5.93 (1H, s), 7.00 (3H, m), and 7.47 (2H, m). *Anal.* calcd. for $C_{16}H_{14}O_2Se$: C 60.58, H 4.45; found: C 60.56, H 4.52. Purification of **14** using long columns of silica (> 10 cm × 2 cm) led to significant decomposition, as well as formation of small quantities (generally <3%) of what appeared to be the corresponding hydroquinone. The ^1H nmr data of the latter are as follows: δ (C_6H_6, 400 MHz): 3.21 (2H, m), 3.58 (2H, m), 3.77 and 3.90 (2 broad singlets, δ was concentration dependent; signals disappeared on D_2O exchange), 6.08 (1H, d, J = 8.5 Hz), 6.13 (1H, d, J = 8.5 Hz), 6.20 (1H, m), 6.93 (3H, m), and 7.46 (2H, m).

Preparation of ***15***

A solution of **5** (1.00 g, 4.78 mmol) and dimethyl acetylene dicarboxylate (680 mg, 4.78 mmol) in 3 mL toluene was refluxed overnight under nitrogen. The solvent was evaporated and the residue subjected directly to column chromatography (eluent: ether/petroleum ether 1:7), yielding **15** as a yellow oil (1.36 g, 81%); ν_{max} (film): 1731, 1669, 1640, 1578, 1434, 1263, 1064, 742, and 689 cm^{-1}; δ (C_6D_6, 400 MHz): 2.78 (2H, m), 3.16 (2H, m), 3.27 (3H, s), 3.41 (3H, s), 5.80 (1H, m), 6.96 (3H, m), and 7.42 (2H, m). *Anal.* calcd. for $C_{16}H_{16}O_4Se$: C 54.71, H 4.59; found: C 55.00, H 4.67.

Preparation of ***16***a/***16***b

A solution of **5** (1.30 g, 6.22 mmol) and methyl acrylate (1.60 g, 18.66 mmol) in 3 mL toluene was refluxed overnight under nitrogen. The solvent was evaporated and the resulting yellow liquid was distilled, under high vacuum (10^{-3} Torr), to yield a pale yellow oil (1.65 g, 90%). All data reported are for the 4:1 mixture of *para*:*meta* regioisomers **16***a*/**16***b*, the ratio having been determined by ^1H nmr and capillary glc; ν_{max} (film): 1738, 1578, 1475, 1437, 1169, 1020, 738, and 692 cm^{-1}; δ (C_6D_6, 400 MHz): 1.46–2.71 (7H, m), 3.23 and 3.30 (3H, 2 singlets; **16***b* and **16***a*, respectively), 6.00 and 6.03 (1H, 2 multiplets), 6.97 (3H, m), 7.44 and 7.47 (2H, 2 multiplets). *Anal.* calcd. for $C_{14}H_{16}O_2Se$: C 56.96, H 5.46; found: C 56.71, H 5.49.

Reaction of **4**b *with phenylselenium chloride*

To a solution of **4***b* (200 mg, 0.92 mmol) in 1 mL toluene was added, dropwise, a toluene solution of phenylselenium chloride (176 mg,

0.92 mmol). On addition, the deep red colour of the PhSeCl dissipated immediately. The mixture was stirred overnight at room temperature, after which 75 mg of KF and 3 mL of THF were added to destroy the Me_3SnCl by-product. After a further 2 h at room temperature, the resulting slurry was filtered through a short column of basic alumina. Evaporation of the solvent yielded a yellow oil (164 mg, 85%), spectroscopic data for which were identical to those reported for the phenylseleno diene **5**.

Reaction of ***11****a*/***11****b with phenylselenium chloride*

To a solution of **11***a*/**11***b* 2:1 *para*:*meta* (150 mg, 0.50 mmol) in 1 mL toluene was added a solution of phenylselenium chloride (95 mg, 0.50 mmol). The mixture was stirred overnight at room temperature during which time the deep red colour of the mixture had changed to a bright yellow. The reaction work-up was identical to that described above. A yellow oil (122 mg, 84%) was isolated whose spectroscopic data were consistent with those reported for **16***a*/**16***b*, with ^{1}H nmr and capillary glc indicating a *para*:*meta* ratio of 2:1.

Received December 23, 1986[1]

FRANK E. HRUSKA, RUDY SEBASTIAN, ANDRÉ GRAND, LUCIENNE VOITURIEZ, and JEAN CADET. Can. J. Chem. **65**, 2618 (1987).

X-ray crystallography was used to determine the structure of (−)*cis*(5*R*,6*S*)-5,6-dihydroxy-5,6-dihydrothymidine, a γ-radiation induced product of thymidine. The crystals belong to the orthorhombic space group $P2_12_12_1$ and have cell dimensions a = 8.420(1) Å, b = 10.422(1) Å, and 13.552(1) Å. The half-chair pucker of the 5,6-saturated pyrimidine ring is similar to that observed for the isolated base with the *cis* configuration, and is described by the Cremer–Pople parameters Q = 0.48 Å, θ = 62°, and φ = 272°. The conformation about the *N*-glycosyl bond is *anti*; the χ angle (−111.6(5)°) lies at one extreme of the range previously seen for nucleosides (−180 to −115°). The pucker $^2T_1$ of the sugar (P = 151.2°; τ_m = 36.5°) contrasts with the O4′-*endo* type of pucker seen in 5,6-dihydrothymidine ($^0T_4$) and (5*S*)-5-hydroxy-5,6-dihydrothymidine ($^0T_1$). The conformation about the C4′—C5′ bond is *gauche*$^+$. The solid state structure is similar to that determined in aqueous solution by ^{1}H nmr.

FRANK E. HRUSKA, RUDY SEBASTIAN, ANDRÉ GRAND, LUCIENNE VOITURIEZ et JEAN CADET. Can. J. Chem. **65**, 2618 (1987).

On a utilisé la diffraction des rayons-X pour déterminer la structure de la (−)-dihydroxy-5,6 dihydro-5,6 thymidine-(5*R*,6*S*)-*cis*, un produit de la thymidine induit par les radiations-γ. Les cristaux appartiennent au groupe d'espace orthorhombique $P2_12_12_1$, avec a = 8,420(1), b = 10,422(1) et c = 13,522(1) Å. La forme demi-chaise de la pyrimidine saturée en 5,6 est semblable à celle qui a été observée avec la base isolée ayant la configuration *cis*; on peut décrire cette demi-chaise par les paramètres de Cremer-Pople Q = 0,48 Å, θ = 62° et φ = 272°. La conformation de la liaison *N*-glycosyle est *anti*; l'angle χ (−111,6(5)°) se trouve à la limite extrême de la fourchette qui avait été observée antérieurement avec les nucléosides (−180° à −115°). La conformation $^2T_1$ du sucre (P = 151,2° et τ_m = 36,5°) est en opposition avec le type de conformation *endo*-O4′ que l'on a observé dans la dihydro-5,6 thymidine ($^0T_4$) et dans l'hydroxy-5 dihydro-5,6 thymidine-(5*S*) ($^0T_1$). La conformation autour de la liaison C4′—C5′ est *gauche*$^+$. La structure observée à l'état solide est semblable à celle qui a été déterminée en solution aqueuse, par rmn du ^{1}H.

[Traduit par la revue]

Introduction

The free radical reactions in γ-irradiated, aerated or oxygen-free, aqueous solutions of thymine (Thy) (or thymidine (dThd)) leads to, *inter alia*, the *cis*- and *trans*-5,6-dihydroxy-5,6-dihydrothymine derivatives (1, 2). These thymine diols (or glycols) are a major class of base damage in DNA exposed to ionizing radiation or near-ultraviolet light (3–5), and to certain oxidants (4). The biological significance of these damaged bases is evidenced by the presence of *N*-glycosylase activities which lead to their excision (6). The addition of the hydroxyl groups to the thymine base, with the concomitant 5,6-saturation of the ring, should have important effects on its base stacking and hydrogen bonding properties. At present only limited information is available on the effects of 5,6-saturation of pyrimidine rings on ordered nucleic acids (7). Our understanding of the effects of thymine diol formation on the physical properties and biological behavior of DNA would be furthered by the availability of the precise structural details provided by X-ray diffraction. However, such data have been reported (8) for only a single base, the *cis*-5,6-dihydroxy-5,6-dihydrothymine, and no data are available at the nucleoside level. Cadet and Teoule (9) have prepared the four isomers of 5,6-dihydroxy-5,6-dihydrothymidine; a ^{1}H nmr study of their conformational properties followed (10). The present work describes our crystallographic study of the (−)(5*R*,6*S*) thymidine glycol (*cis* configuration for the two hydroxyl groups) (Fig. 1). Our data are compared with those for other crystalline 5,6-saturated pyrimidine derivatives and with the nmr solution data.

[1]Revision received May 25, 1987.

Experimental

The (−)(5*R*,6*S*) isomer of 5,6-dihydroxy-5,6-dihydrothymidine (**I**) was prepared according to the literature (10) and was crystallized from a saturated aqueous solution. A crystal with dimensions 0.2 mm × 0.2 mm × 0.3 mm was chosen for data collection on an experimental ENRAF-NONIUS CAD4 diffractometer.

$C_{10}H_{16}N_2O_7$ F_w = 276.248

Orthorhombic, $P2_12_12_1$; a = 8.420(1), b = 10.422(1), c = 13.522(1) Å; V = 1186.6 Å^3; Z = 4; ρ_c = 1.547 g cm^{-3}; μ = 0.799 cm^{-1}; MoK$_\alpha$: 0.71069 Å (monochromatized); 20°C; scan mode: ω; scan rate: 1° min^{-1}; max shift/esd final cycle 0.42.

The intensities of the reflections were corrected for Lorentz and polarization factors but not for absorption. The structure was solved by direct methods using MULTAN (11). An *E*-map based on 190 phased reflections with $E > 1.6$ revealed the positions of all non-hydrogen atoms. The structure was refined by least-squares XFLSN methods (12) with 985 reflections (of 1250 unique data) for which $|F_o| > 2.5\sigma(F_o)$. The refinement of 169 variables yielded values of R = 0.091 and R_w = 0.081 ($R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $R_w = [\Sigma w(|F_o| -$

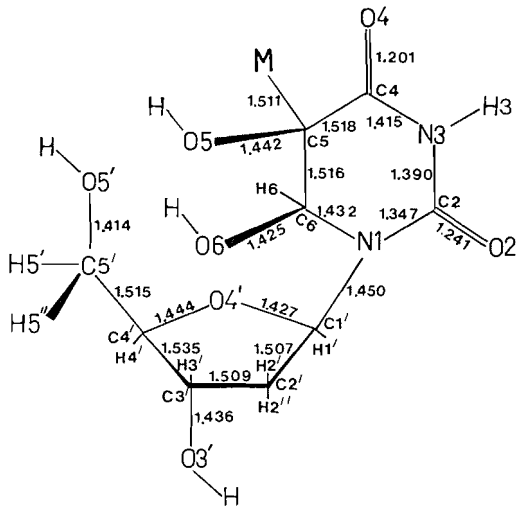

FIG. 1. Structure of (−)*cis*(5*R*,6*S*)-5,6-dihydroxy-5,6-dihydrothymidine (**I**) and bond lengths (Å) involving the heavy atoms. The estimated standard deviations are less than 0.009 Å.

$|F_c|)^2/\Sigma w|F_o|^2]^{1/2}$) for non-hydrogens only. (The weights were based on counting statistics.) The positions of all hydrogen atoms were determined from a difference Fourier map and were fixed in subsequent cycles of refinement. In the final stages of refinement non-hydrogen atoms were assigned anisotropic temperature factors whereas the hydrogens were assumed to have isotropic thermal motions ($B = 5$ Å^2). The refinement converged at $R = 0.061$ and $R_w = 0.047$. The final Fourier difference map shows no electron density larger than 0.4 e Å^{-3}. The choice of the proper enantiomorph was based on the known D configuration of the 2-deoxyribose unit.

Further data are provided in Table 1 (atomic coordinates), Fig. 1 (bond lengths), Table 2 (bond angles), Table 3 (torsion angles), Table 4 (Cremer–Pople (CP) parameters (13) for the pyrimidine ring), and Table 5 (hydrogen bond geometries). A stereoscopic view of the packing is shown in Fig. 2. The molecules represented by the symbols **I**, **II**, etc. are given in a footnote of Table 4. Lists of anisotropic temperature parameters and of final hydrogen coordinates (unrefined) are available.[2]

Results and discussion

Structure of the pyrimidine ring

The bond lengths and bond angles of **I** are given in Fig. 1 and Table 2, respectively. Figure 3 shows a comparison of the bond lengths and bond angles of the 5,6-saturated pyrimidine rings of **I** and **II**. (**II** is the free thymine diol base with the *cis* configuration of the hydroxyl groups (8).) The bond lengths and endocyclic bond angles of **I** and **II** are similar. Significant differences are noted in some of the exocyclic angles at C5 and C6.

Figure 3 also provides a comparison of **I** and an "average" thymine base which allows us to assess the effect of 5,6-saturation on the geometry of the pyrimidine ring. The data for the thymine base are the averages of six sets of literature values (14–18) used previously (19). Relative to the thymine base, **I** shows a large extension at C5—C6 (0.18 Å), and smaller extensions of C4—C5 (0.08 Å) and N1—C6 (0.05 Å), a reflection of the loss of π-electron density due to 5,6-saturation (20). The N1—C2 and C2—O2 bonds are, respectively, shortened and extended by 0.03 Å; a similar trend has been observed in other 5,6-saturated pyrimidines (21, 22) and attributed to stronger conjugation of the lone electron pair on N1 with the C2—O2 carbonyl group.

The pyrimidine ring of **I** exhibits an approximate half-chair conformation (Figs. 2, 4). The best contiguous four-atom plane is defined by the N1, C2, N3, and C4 atoms; their average displacement from this plane is 0.04 Å. The C5 and C6 atoms are displaced respectively 0.28 Å to the left and 0.42 Å to the right of the plane, with left and right displacements defined by Fig. 5. (When **I** is viewed in its *anti* conformation about the *N*-glycosyl bond, left and right represent displacements towards

the O4′ and C2′ sides of the sugar, respectively.) Following Hruska *et al.* (23), we can denote this as a $_5H^6$ pucker (H means half chair with C6 showing the greater displacement to the right of the four-atom plane, and C5 the lesser displacement to the left). In this conformation the 5-methyl and 6-hydroxyl groups occupy pseudoaxial positions whereas the 5-hydroxyl group is pseudoequatorial and *gauche* to the 6-hydroxyl (see Fig. 2 and torsion angles in Table 3*b*). Note in the tabulation of torsion angles (Table 3*a*,*b*) that the substituent atoms on the C5—C6 fragment are oriented only 5° (average) from the classically-staggered saturated system (±60°, 180°).

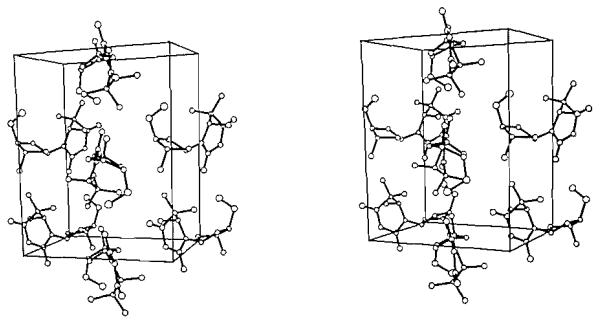

FIG. 2. Stereoscopic packing diagram. The hydrogen atoms and hydrogen bonds are not shown.

The overall conformation of the pyrimidine base is similar in **I** and **II**, that is, the attachment of the sugar has little effect on the base pucker. The endocyclic torsion angles of **I** (Table 3*a*) differ from those of **II** (8) by 3° (average) and by no more than 6° (at N3—C4). This similarity is also apparent in their CP parameters (Table 4) which indicate the extent of puckering (*Q*, the total puckering amplitude) and the mode of puckering (θ and φ, the angular descriptors) (13).

For comparison with **I** and **II**, Table 4 provides CP data for other 5,6-saturated pyrimidine nucleosides. Molecules lying in the "northern" CP hemisphere (N(CP)) ($0° < \theta < 90°$) have *Q* values in the range 0.45 ± 0.04 Å. The diols **I** and **II** show the most pronounced extent of puckering (largest *Q*), presumably a reflection of the presence of three bulky groups (methyl and hydroxyl) on the C5—C6 fragments. **III** (5*S*-5-hydroxy-5,6-dihydrothymidine), which lacks a 6-hydroxyl group, has a smaller *Q* (0.44 Å) as do the remaining N(CP) entries (**IV–VIII**)

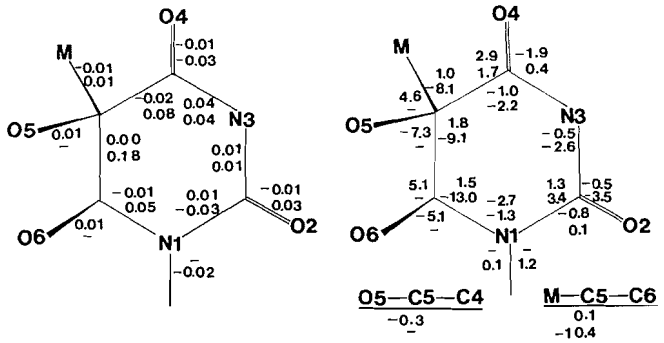

FIG. 3. Left. Differences between the bond lengths (Å) of the *cis* thymidine diol (**I**) and the *cis* thymine diol (**II**) (top number) and an "average" thymine base (bottom number). Right. Similar comparison of bond angles. Data for **I**: Fig. 1 and Table 2; for **II**, ref. 8; for the average thymine: refs. 14–18. See text for details. A positive number means that the bond length or angle is larger in **I**.

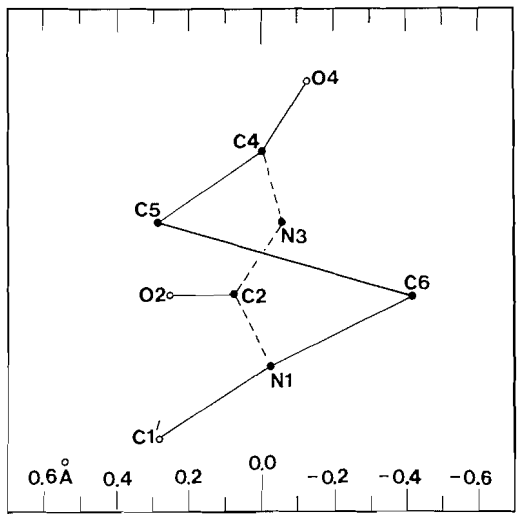

FIG. 4. Schematic view of the base from its front edge (C5—C6) to its back edge (C2—N3) which illustrates the ring puckering. Solid circles: ring atoms; open circles: atoms directly bonded to the ring. The horizontal axis gives deviations (Å) to the left (positive) and to the right (negative) of the best four-atom plane, N1—C2—N3—C4.

which are not substituted on C5—C6. The θ and φ entries for **I**–**VIII** lie in the narrow ranges 63 ± 4° and 274 ± 9°, respectively.

Table 4 lists four nucleosides with 5,6-saturated pyrimidine rings in the "southern" CP hemisphere (S(CP)) (90° < θ < 180°). **IX** (5,6-dihydrothymidine) and **X** (molecule **2** of 5,6-dihydrouridine) have Q values (0.45 Å, 0.49 Å) similar to those of the N(CP) entries, whereas those of the two rings of the thymine photodimer (**XI** and **XII**) are significantly reduced (0.31 Å, 0.24 Å). The S(CP) entries lie in a narrow range of θ values (119 ± 5°), but have a larger range of φ values (114 ± 27°).

At present no crystallographic data are available for the three isomers of **I** having the 5*R*–6*R*, 5*S*–6*R*, or 5*S*–6*S* configurations at C5 and C6. A ^{1}H nmr study of the four thymidine diols in aqueous solution has been reported (10) but it provided no information about the pyrimidine ring pucker since no vicinal pair of protons is located on the ring. However, our crystal structure of **I** (in conjunction with molecular models) suggests that the favored conformation is that which places the 6-hydroxyl in a pseudoaxial orientation, and thereby minimizes crowding between this group and the 5-hydroxyl and 5-methyl groups. On this basis we expect an N(CP) pucker to be favored by the 5*S*–6*S* isomer and an S(CP) pucker by the 5*R*–6*R* and 5*S*–6*R* isomers.

The N*-glycosyl bond (*χ,χ′*)*

The N1—C1′ bond length of **I** (Fig. 1) and the bond angles involving the N1—C1′ bond (Table 2*b*,*d*) are similar to those of the other 5,6-saturated pyrimidine-2′-deoxynucleosides, **III** (26) and **IX** (27). The χ(O4′—C1′—N1—C2) and χ′(O4′—C1′—N1—C6) torsion angles (Table 3) show that **I** has the *anti* conformation about the *N*-glycosyl bond. The χ angle (−111.6°) lies at one extreme of the range of χ angles seen for nucleosides (−180 – −115°) (28). It is noteworthy that the two 2′-deoxyribonucleosides with N(CP) puckers of the saturated pyrimidine ring (**I**, **III**) have similar χ(−111.6°, −110.6°) and χ′(67.6°, 68.7°) angles, even though the 6-OH of **I** is replaced by a hydrogen in **III**. On the other hand, molecule **IX**, a 2′-deoxyriboside with an S(CP) pucker of the pyrimidine ring, has significantly different χ(−117.3°) and χ′(52.8°) angles. (χ and χ′ for **IX** were calculated by G. I. Birnbaum from data in ref. 27; data for **III** in ref. 26). A similar (but less pronounced) trend is noted for the two independent molecules of the *riboside*, 5,6-dihydrouridine; the N(CP) molecule (**V**) and the S(CP) molecule (**X**) have χ′ angles of 65.6 and 57.3°, respectively (averages of data from Suck *et al.* (29) and Sundaralingam *et al.* (30)).

With an N(CP) pucker and χ′ = 67.6° in **I**, H6 occupies a pseudoequatorial position on the left face of the pyrimidine ring (left and right defined in Fig. 4), and is positioned over the sugar ring as shown in Fig. 5*a*. A close contact is made between this hydrogen and O5′ (2.191 Å separation). The 6-OH group occupies a pseudoaxial position on the right face, and is located off the sugar ring on the C2′ side. As noted in the previous section, the 5*S*–6*S* isomer of **I**, is expected to favor an N(CP)

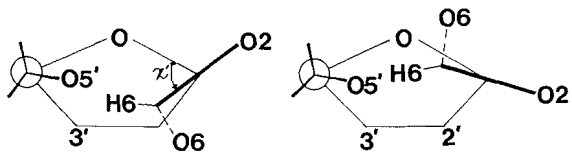

FIG. 5. Left (*a*): view of **I**, the 5*R*,6*S* thymidine diol which shows the position of the pseudoequatorial H6 and pseudoaxial 6-OH relative to the sugar ring. A similar arrangement of these atoms is postulated in the text for the 5*S*,6*S* diol. Right (*b*): approximate positions predicted for the pseudoequatorial 6H and pseudoaxial 6-OH of the 5*R*,6*R* and 5*S*,6*R* diols.

pucker, and thus the disposition of its H6 and 6-OH should be similar to that noted in **I** (Fig. 5*a*). On the other hand, the 5*R*–6*R* and 5*S*–6*R* isomers are expected to favor the S(CP) pucker (see previous section). Examination of molecular models leads us to predict that the pseudoequatorial H6 (on the right face) will lie over the sugar ring (Fig. 5*b*) whereas the pseudoaxial 6-OH (on the left face) will lie off the ring on the O4′ side.

The sugar geometry

The bond lengths (Fig. 1) and bond angles (Table 2) of the sugar moiety of **I** are not unusual. The furanose ring adopts an S-type pucker (31) with a phase angle of pseudorotation (P) of 151.2° ($^2T_1$) and a maximum amplitude of pucker (τ_m) of 36.5°. The pucker of dThd is not very different: P = 187.5° ($_3T^2$) and τ_m = 38.2° (18, 32). In contrast **III** and **IX** (the other 2′-deoxyribosides with 5,6-saturated bases) are located in the O4′-*endo* quadrant of the pseudorotational cycle: P = 95.5° ($^0T_1$) and 84.4° ($^0T_4$), respectively (26, 31). Furthermore, **IX** shows a considerable flattening of the ring (τ_m = 31.6°) whereas **III** does not (τ_m = 37.4°) (26, 31).

The conformation of **I** about the C4′—C5′ bond (γ) is *gauche*$^+$ (γ = 39.1°). This angle falls just outside of the lower extreme of γ values observed for S-type nucleosides (28). *Anti*-2′*endo* deoxynucleosides such as dThd show a slight bias for the *trans* over the *gauche*$^+$ γ torsion angle (32). Considering the other 2′-deoxyribosides, we note that **III** is also *gauche*$^+$ (γ = 49.4°) (25) whereas **IX** shows disorder at the C4′—C5′ bond (2:1 *trans*:*gauche*$^+$ distribution) (27).

Comparison with solution

A ^{1}H nmr study of **I** as well as of its 5*R*–6*R*, 5*S*–6*R*, and 5*S*–6*S* isomers has appeared (10). Each of the four isomers prefers the *anti* conformation in aqueous solution. Evaluation of the C4′—C5′ orientation according to Haasnoot *et al.* (33) gives the following narrow ranges of populations: *gauche*$^+$ (47 ± 2%); *trans* (37 ± 2%); *gauche*$^-$ (16 ± 2%). No significant effect of the configuration at C5 and C6 is apparent; the bias towards the *gauche*$^+$ rotamer and the minimal contribution from *gauche*$^-$ are standard features of normal 2′-deoxyribosides (34). Like most 2′-deoxyribosides, the four diols show a bias towards the S(2′*endo*) type of sugar pucker, the pucker of I in the crystal state. However, this bias is slightly stronger in the 6*S* pair of isomers (70% *S*) than in the 6*R* pair (60% *S*).

Hydrogen bonding and molecular packing

The molecular packing of **I** can be seen in three dimension in Fig. 2. No strong intramolecular hydrogen bonds are found though a close contact is made between H6 and O5′ (2.191 Å). The packing is stabilized by two strong and three weak hydrogen bonds in the networks N3—H3···O6—H···O5′—H···O2 and O5—H···O3′—H···O4′. Thus all potential donors are involved. The O3′, O5′, and O6 donor atoms also serve as acceptors but N3 and O5 do not. It is interesting that O2 participates in a weak bond, and O4 does not participate at all. In contrast with **I**, the 5-OH of the free base (**II**) serves as both a donor and an acceptor, whereas the 6-OH serves only as a donor; both keto groups of **II** serve as acceptors (8). No base stacking interactions occur in **I**.

Enthalpies of interaction of nonpolar solutes with nonpolar solvents. The role of solute polarizability and molar volume in solvation

RICHARD FUCHS, ERIC J. CHAMBERS, AND W. KIRK STEPHENSON
Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.

Received January 20, 1987

RICHARD FUCHS, ERIC J. CHAMBERS, and W. KIRK STEPHENSON. Can. J. Chem. **65**, 2624 (1987).

Heats of solution of 10 nonpolar solutes (carbon tetrachloride, perfluoroheptane, diiodomethane, benzene, hexane, decane, hexadecane, cyclohexane, toluene, and mesitylene) in 11 nonpolar solvents (heptane, cyclohexane, carbon tetrachloride, benzene, carbon disulfide, diiodomethane, toluene, mesitylene, tetrachloroethylene, 1,1,2-trichlorotrifluoroethane, and hexadecane) have been combined with solute heats of vaporization to give enthalpies of transfer from vapor to solvent ($\Delta H(v \rightarrow S)$). The heat of vaporization of diiodomethane has been measured (11.70 ± 0.01 kcal/mol). Correlations of the form $\Delta H(v \rightarrow S) = a + b\text{MMR} + c\text{MV}$ describe the solvent–solute interaction enthalpies with high precision (correlation coefficients 0.991–0.999). Earlier correlations with only the molar refraction are limited to solutes of similar refractive index. In each solvent $\Delta H(v \rightarrow S)$ becomes more exothermic with an increase in the solute molar refraction term, and less exothermic with an increase in the solute molar volume term. These terms represent solvent–solute dispersion interaction enthalpies, and solvent cavity formation enthalpies, respectively.

RICHARD FUCHS, ERIC J. CHAMBERS et W. KIRK STEPHENSON. Can. J. Chem. **65**, 2624 (1987).

On a combiné les chaleurs de solution de 10 solutés non-polaires (chlorure de carbone, perfluoroheptane, diiodométhane, benzène, hexane, décane, hexadécane, cyclohexane, toluène et mésitylène) dans 11 solvants non-polaires (heptane, cyclohexane, tétrachlorure de carbone, benzène, disulfure de carbone, diiodométhane, toluène, mésitylène, tétrachloroéthylène, trichloro-1,1,2 trifluoroéthane et hexadécane) avec les chaleurs de vaporisation des solutés et on en a déduit les enthalpies de transfert de la vapeur au solvent ($\Delta H(v \rightarrow S)$). On a mesuré la chaleur de vaporisation du diiodométhane (11,70 ± 0,01 kcal/mol). Les corrélations de la forme $\Delta H(v \rightarrow S) = a + b\text{MMR} + c\text{MV}$ décrivent les enthalpies d'interaction solvant–soluté avec une grande précision (coefficients de corrélation 0,991–0,999). Des corrélations antérieures avec uniquement la réfraction molaire sont limitées à des solutés d'indices de réfraction semblables. Dans chacun des solvants, la valeur du $\Delta H(v \rightarrow S)$ devient plus exothermique avec une augmentation du terme de la réfraction molaire du soluté et moins exothermique avec une augmentation du terme du volume molaire du soluté. Ces termes représentent respectivement les enthalpies d'interaction de dispersion solvant–soluté et les enthalpies de formation de la cavité du solvant.

[Traduit par la revue]

In an interesting series of recent articles Solomonov and coworkers (1–3) suggested that solvation enthalpies ($\Delta H(v \rightarrow S)$) of a variety of organic solutes in polar and nonpolar solvents depend (in a given solvent) on the molar refractions (MR = $(((n^2 - 1)/(n^2 + 2)) \times$ molar volume) of the solutes, and in many cases are independent of solute dipolarity. Molar refraction may reasonably be taken as a measure of the capability of each solute to undergo dispersion interactions with a particular solvent. By contrast, correlations of solvation enthalpies (4–9) with the Taft–Kamlet π^* solvatochromic parameter (10, 11) imply the importance of polar (dipolarity–polarizability) interactions. Although π^* values were designed as *solvent* parameters, the role of the *solute* π^* in solvation has also been demonstrated (12). For the "select solvent set" of nonaromatic and nonhalogenated solvents π^* is approximately linear with the dipole moment μ (13), and dispersion interactions are believed to be relatively constant. We are therefore presented with two quite different viewpoints of the factors involved in solvation in organic solutions. Resolution of this question will be important in the treatment of future data, and in our understanding of the intermolecular forces operative.

In the present study we begin an examination of molar refraction correlations with the simplest possible systems, nonpolar solutes in nonpolar solvents. We will consider whether, in the absence of polar effects, MR is a general predictor of relative solvation enthalpies of solutes.

Dissolution of a gaseous species in a liquid is an exothermic process, a result of solvent–solute dispersion interactions. However, there is an endothermic contribution to $\Delta H(v \rightarrow S)$, the enthalpy of formation of cavities within the solvent structure, required to accommodate the dissolving solute molecules. If ΔH_{cav} is dependent (in a given solvent) on solute molar volume (MV), then $\Delta H(v \rightarrow S)$ might be expected to be correlated with both MR and MV

$$\Delta H(v \rightarrow S) = a + b\text{MR} + c\text{MV}$$

where coefficient b is negative and c is positive. However, this results in two MV terms

$$\Delta H(v \rightarrow S) = a + b\left[\frac{n^2 - 1}{n^2 + 2}\right]\text{MV} + c\text{MV}$$

Most of the organic liquid solutes considered by Solomonov *et al.* (1) have refractive indices of 1.4–1.5, and polarizability functions (PF) $((n^2 - 1)/(n^2 + 2))$ of 0.24–0.29. With PF nearly constant it would be unlikely that correlations with MR and (MR + MV) could be distinguished. We will therefore include in the present study solutes of extremely low (1.26) and extremely high (1.74) refractive index (PF = 0.16–0.40). Throughout this study we assume that polar interactions make a negligible contribution to the interactions of slightly polar diiodomethane ($\mu = 1.10$), and that the solvation enthalpies of perfluoroheptane are not appreciably affected by the presence of an isomeric impurity. We will also consider a modified molar refraction (MMR) based on an alternative polarizability function: $\text{MMR} = ((n^2 - 1)/(2n^2 + 1))(\text{MV})$, which might provide a better measure of dispersion interactions.

Experimental

Solutes and solvents were commercial samples in excess of 99% purity, and were dried with 4A molecular sieve. An exception was perfluoroheptane (3M Co.), which was fractionally distilled through a 200 plate Teflon spinning band column to give material consisting

[e]$\Delta H(v \rightarrow S)$ of octane.

of 65% perfluoro-*n*-heptane, 34% perfluoromethylhexane, and the remainder other C-7 perfluoroalkanes + homologs. The calorimetric procedure (25.0°C) was previously described (4), except the calorimeter remained sealed at all times, and sample addition (10, 20, or 50 μL syringe) was made through a Teflon-faced septum.

The heat of vaporization of diiodomethane at 25.0°C was measured by evaporation of 100 μL samples into a slow nitrogen stream, using a vaporization calorimeter and technique reported previously (14).

Results and discussion

The measured heats of solution (kcal/mol at 25.0°C) are listed in Table 1. Calculated solvation enthalpies ($\Delta H(v \rightarrow S) = \Delta H_s - \Delta H_v$) are listed in Table 2. Table 3 presents the molar refraction, modified molar refraction, and molar volume of each solute.

Based on Solomonov's correlations (1–3) we should expect similar solvation enthalpies in a particular solvent for various solutes with similar molar refractions. It is important to estab-

TABLE 3. Properties of nonpolar solutes

Solute	n_D	MV (cm^3)	MR (cm^3)	MMR (cm^3)
Hexane	1.3751	130.5	29.89	24.31
Decane	1.4113	194.9	48.43	38.79
Hexadecane	1.4345	292.9	76.36	60.57

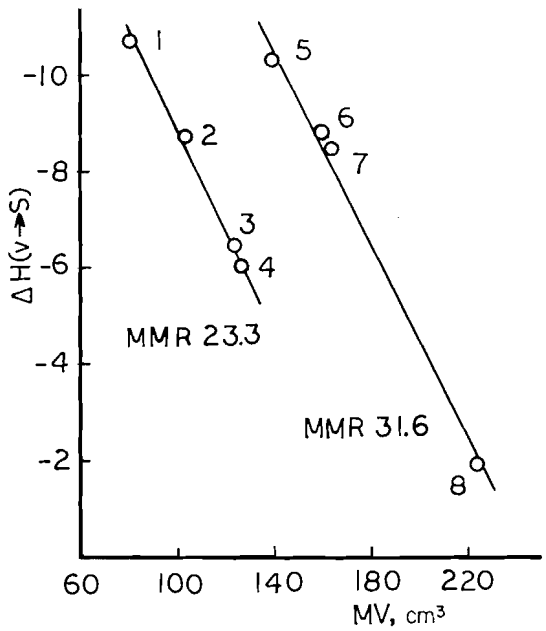

FIG. 1. The effect of molar volume on solvation enthalpies in benzene for solutes of the same modified molar refraction. Points are *1*, diiodomethane; *2*, $C_6H_5C_{0.81}H_{2.62}$; *3*, $C_{3.9}H_{8.8}CH{=}CH_2$, *4*, $C_{5.72}H_{13.44}$ alkane; *5*, mesitylene; *6*, $C_{6.13}H_{13.26}CH{=}CH_2$, *7*, *n*-octane; and *8*, perfluoroheptane.

lish whether molar volume separately influences $\Delta H(v \rightarrow S)$. Experimentally, the problem is to find a varied series of solutes with the same molar refraction. We make use of the observation that $\Delta H(v \rightarrow S)$ of alkanes (5) is linear with carbon number (and MR) (as are values for monoalkylbenzenes and for the series benzene, toluene, and mesitylene), and use Solomonov's interpolative procedures (1) to estimate $\Delta H(v \rightarrow S)$ of alkanes, alkenes, and alkylbenzenes of intermediate carbon number and chosen molar refraction. Figure 1 is a plot of $\Delta H(v \rightarrow$ benzene) vs. MV for (*1*) four solutes with modified molar refractions of 31.6 cm^3 and molar volumes of 138.9–223.9 cm^3, and (*2*) four solutes with MMR = 23.3 cm^3 and MV = 80.7–126.2 cm^3. Both groups show a strong decrease in solvation with increasing molar volume (Group 1: $\Delta H(v \rightarrow Bz) = -10.73$ to -1.97 kcal/mol; Group 2: -10.76 to -6.07 kcal/mol). The same trend is observed with other solvents. It is apparent that molar refraction alone does not properly predict solvation enthalpy when a series of solutes of greatly differing molar volume (and refractive index) is considered.

In correlations of $\Delta H(v \rightarrow S)$ of solutes with molar refraction and molar volume the results with MMR are somewhat better than those with MR, and the former are reported below. In Solomonov-type correlations with molar refraction only, MR is somewhat superior to MMR. Equations in MR are listed below for comparison with the two parameter correlations. The number of solutes, n, correlation coefficient, r, and uncertainties in the coefficient a, b, and c are furnished for each equation. All solutes for which $\Delta H(v \rightarrow S)$ is listed in Table 2 are included in the correlations.

In diiodomethane

[1] $\Delta H(v \rightarrow S) = (-2.1739 \pm 0.1525) - (1.0255 \pm 0.0226)MMR + (0.1778 \pm 0.0044)MV$
$n = 7, \quad r = 0.9992$

[2] $\Delta H(v \rightarrow S) = (3.5237 \pm 2.5615) - (0.1118 \pm 0.0625)MR$
$n = 7, \quad r = 0.6244$

In benzene

[3] $\Delta H(v \rightarrow S) = (-1.9448 \pm 0.1922) - (0.7607 \pm 0.0156)MMR + (0.1073 \pm 0.0028)MV$
$n = 10, \quad r = 0.9987, \quad$ std. error $= 0.2212$

[3a] $\Delta H(v \rightarrow S) = (-1.690 \pm 0.378) - (0.4970 \pm 0.0198)MR + (0.07884 \pm 0.00437)MV$
$n = 10, \quad r = 0.9950$

[4] $\Delta H(v \rightarrow S) = (-2.0239 \pm 2.4308) - (0.1820 \pm 0.0602)MR$
$n = 10, \quad r = 0.7300$

[5] $\Delta H(v \rightarrow S) = (-2.4077 \pm 0.8813) - (0.1850 \pm 0.0212)MR$
$n = 8, \quad r = 0.9628$

[6] $\Delta H(v \rightarrow S) = (-1.9928 \pm 0.2222) - (0.7740 \pm 0.0504)MMR + (0.1101 \pm 0.0101)MV$
$n = 8, \quad r = 0.9981$

In heptane

[7] $\Delta H(v \rightarrow S) = (-0.4519 \pm 0.4005) - (0.6406 \pm 0.0325)MMR + (0.0664 \pm 0.0058)MV$
$n = 10, \quad r = 0.9948$

[8] $\Delta H(v \rightarrow S) = (-0.45178 \pm 1.4490) - (0.2411 \pm 0.0359)MR$
$n = 10, \quad r = 0.9216$

In carbon disulfide

[9] $\Delta H(v \rightarrow S) = (-1.2639 \pm 0.1825) - (0.6960 \pm 0.0297)MMR + (0.0879 \pm 0.0057)MV$
$n = 10, \quad r = 0.9985$

[10] $\Delta H(v \rightarrow S) = (-2.1493 \pm 0.7438) - (0.2017 \pm 0.0190)MR$
$n = 10, \quad r = 0.9664$

In carbon tetrachloride

[11] $\Delta H(v \rightarrow S) = (-1.4826 \pm 0.2292) - (0.6757 \pm 0.0186)MMR + (0.0803 \pm 0.0033)MV$
$n = 10, \quad r = 0.9981$

[12] $\Delta H(v \rightarrow S) = (-1.5103 \pm 1.7903) - (0.2120 \pm 0.0444)MR$
$n = 10, \quad r = 0.8606$

In mesitylene

[13] $\Delta H(v \rightarrow S) = (-1.0398 \pm 0.1479) - (0.7460 \pm 0.0120)MMR + (0.0933 \pm 0.0021)MV$
$n = 10, \quad r = 0.9993$

[14] $\Delta H(v \rightarrow S) = (-1.0623 \pm 2.0183) - (0.2263 \pm 0.0500)MR$
$n = 10, \quad r = 0.8470$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12

In toluene

[15] $\Delta H(v \rightarrow S) = (-1.6014 \pm 0.1241) - (0.7551 \pm 0.0101)MMR + (0.1005 \pm 0.0018)MV$
$n = 10, \quad r = 0.9995$

[16] $\Delta H(v \rightarrow S) = (-1.6516 \pm 2.2279) - (0.2045 \pm 0.0552)MR$
$n = 10, \quad r = 0.7947$

In cyclohexane

[17] $\Delta H(v \rightarrow S) = (-0.5780 \pm 0.4792) - (0.6829 \pm 0.0423)MMR + (0.0784 \pm 0.0074)MV$
$n = 11, \quad r = 0.9901$

[18] $\Delta H(v \rightarrow S) = (-0.9527 \pm 1.5758) - (0.2189 \pm 0.0404)MR$
$n = 11, \quad r = 0.8740$

In tetrachloroethylene

[19] $\Delta H(v \rightarrow S) = (-0.9512 \pm 0.2698) - (0.7055 \pm 0.0219)MMR + (0.0855 \pm 0.0039)MV$
$n = 10, \quad r = 0.9976$

[20] $\Delta H(v \rightarrow S) = (-0.9816 \pm 1.8544) - (0.2242 \pm 0.0460)MR$
$n = 10, \quad r = 0.8651$

In 1,1,2-trichlorotrifluoroethane

[21] $\Delta H(v \rightarrow S) = (-1.5331 \pm 0.2135) - (0.4829 \pm 0.0183)MMR + (0.0435 \pm 0.0034)MV$
$n = 10, \quad r = 0.9980$

[22] $\Delta H(v \rightarrow S) = (-1.233 \pm 0.7477) - (0.2171 \pm 0.0188)MR$
$n = 10, \quad r = 0.9714$

In hexadecane

[23] $\Delta H(v \rightarrow S) = (-0.6256 \pm 0.0881) - (0.5458 \pm 0.0137)MMR + (0.0487 \pm 0.0026)MV$
$n = 9, \quad r = 0.9998$

[24] $\Delta H(v \rightarrow S) = (-0.8786 \pm 0.3431) - (0.2427 \pm 0.0084)MR$
$n = 9, \quad r = 0.9958$

One may conclude from eqs. [1]–[24] that correlations of $\Delta H(v \rightarrow S)$ with both MMR and MV are far superior to correlations with MR alone. In all solvents the latter predict values of $\Delta H(v \rightarrow S)$ which are insufficiently exothermic for solutes of high refractive index, and too exothermic for solutes of low n_D. These are the solutes which, for a given molar refraction, have particularly small and large molar volumes, respectively. If the extreme solutes are omitted, correlations with MR improve (eq. [5] vs. eq. [4]), but are still not comparable to the two parameters correlation (eq. [3]). If C_7F_{16} and CH_2I_2 are omitted the two parameter correlations are not greatly improved (eq. [6] vs. eq. [3]). The intercept and coefficients (a, b, c) are only slightly affected. These observations indicate that the two extreme solutes are not "forcing" the correlation. Solvation enthalpies can also be estimated from the Hildebrand-Scatchard equation

$$\Delta H(v \rightarrow S) = (-2\delta_H{}^B\delta_H{}^A MV^B)((\delta_H{}^A)^2 MV^B) - RT$$

where $\delta_H{}^A$ and $\delta_H{}^B$ represent the Hildebrand solubility parameters of the solvent and solute, respectively. Solomonov obtained poor results by this method (1). The correlation of calculated H.–S. solvation enthalpies with our experimental values for 10 solutes in benzene is poor ($r = 0.934$, std. error = 1.45 kcal/mol).

In equations of the form $\Delta H(v \rightarrow S) = a + b\text{MMR} + c\text{MV}$ which solvent properties determine the coefficients, b and c? Because b and c are related ($r = 0.987$) correlations of b with polarizability functions, and c with Hildebrand δ^2 (or δ)

$$b = (0.279 \pm 0.092) - (4.551 \pm 0.413)((n^2 - 1)/(2n^2 + 1)) \qquad r = 0.976$$

$$c = -(0.023 \pm 0.008) + (0.148 \pm 0.010)(\delta_H{}^2/100) \qquad r = 0.987$$

for eight of the solvents (CS_2, C_2Cl_4, hexadecane omitted) suggest, but do not prove, that solvent capability for dispersion interactions, and solvent cohesiveness and cavity formation enthalpy are principal factors determining b and c, respectively.

Synthesis of ^{31}P nmr spectroscopic study of $[Ag(\mu\text{-}R_2PCH_2PR_2)_3Ag]^{2+}$ (R = Me or Ph). Observation of an intramolecular "end-over-end" exchange of bridging $R_2PCH_2PR_2$ [1]

PHILIP A. W. DEAN,[2] JAGADESE J. VITTAL, AND RADHEY S. SRIVASTAVA[3]
The Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received April 21, 1987

PHILIP A. W. DEAN, JAGADESE J. VITTAL, and RADHEY S. SRIVASTAVA. Can. J. Chem. **65**, 2628 (1987).

Reaction of $AgAsF_6$ with $R_2PCH_2PR_2$ (R = Ph or Me) in a 2:3 ratio in $MeNO_2$ or Me_2CO produces the new compounds $[Ag_2(R_2PCH_2PR_2)_3](AsF_6)_2$, which have been isolated in good yield. The analogous ^{107}Ag-enriched compounds are produced using $^{107}AgAsF_6$. The 2:3 compounds have interesting variable temperature ^{31}P nmr spectra which have been studied in detail using the ^{107}Ag-enriched compounds. The ^{31}P nmr spectra of $[^{107}Ag_2(Ph_2PCH_2PPh_2)_3](AsF_6)_2$:$[^{107}Ag_2(Me_2PCH_2PMe_2)_3](AsF_6)_2$ mixtures at ambient probe temperature show the formation of the mixed ligand binuclear cations $[^{107}Ag_2(Ph_2PCH_2PPh_2)_{3-x}(Me_2PCH_2PMe_2)_x]^{2+}$ (x = 1 or 2). By analogy, the two parent complexes also contain binuclear cations, and the limiting low temperature ^{31}P nmr spectra of these can be interpreted in terms of the manxane structure, $[^{107}Ag(\mu\text{-}R_2PCH_2PR_2)_3{}^{107}Ag]^{2+}$. With increase in temperature, the ^{31}P nmr spectra of the parents provide evidence for an intramolecular exchange process which is faster for R = Ph than for R = Me and which is shown to involve "end-over-end" exchange of bridging $R_2PCH_2PR_2$. This type of exchange has not been observed previously for these ligands. With Me_2CO as solvent, an approximate value of the enthalpy of activation for exchange is 59 kJ mol^{-1} for $[^{107}Ag(\mu\text{-}Ph_2PCH_2PPh_2)_3{}^{107}Ag]^{2+}$ and 50 kJ mol^{-1} for $[^{107}Ag(\mu\text{-}Me_2PCH_2PMe_2)_3{}^{107}Ag]^{2+}$.

PHILIP A. W. DEAN, JAGADESE J. VITTAL et RADHEY S. SRIVASTAVA. Can. J. Chem. **65**, 2628 (1987).

La réaction du $AgAsF_6$ avec le $R_2PCH_2PR_2$ (R = Ph ou Me), dans un rapport de 2 à 3, dans le $MeNO_2$ ou le Me_2CO, conduit à la formation des nouveaux produits $[Ag_2(R_2PCH_2PR_2)_3](AsF_6)_2$ qui ont été isolés avec de bons rendements. On a préparé les produits analogues enrichis en ^{107}Ag en utilisant du $^{107}AgAsF_6$. Les spectres rmn du ^{31}P, à température variable, des composés 2:3 sont intéressants et on les a étudiés en détail en utilisant les composés enrichis en ^{107}Ag. Les spectres rmn du ^{31}P, à la température ambiante, de mélanges de $[^{107}Ag_2(Ph_2PCH_2PPh_2)_3](AsF_6)_2$:$[^{107}Ag_2(Me_2PCH_2PMe_2)_3](AsF_6)_2$ montrent qu'il y a formation de cations binucléaires à ligands mixtes du type $[^{107}Ag_2(Ph_2PCH_2PPh_2)_{3-x}(Me_2PCH_2PMe_2)_x]^{2+}$ (x = 1 ou 2). Par analogie, les deux complexes parents contiennent aussi des cations binucléaires et les spectres rmn du ^{31}P aux limites de la basse température peuvent être interprétés en fonction de la structure du manxane, $[^{107}Ag(\mu\text{-}R_2PCH_2PR_2)_3{}^{107}Ag]^{2+}$. Par augmentation de la température à laquelle on détermine les spectres rmn du ^{31}P des composés parents, on obtient des indications à l'effet qu'il se produit un processus d'échanges intramoléculaires qui est plus rapide avec les produits RPh qu'avec les produits RMe et on démontre de plus que ce processus implique un échange "tête à queue" du ligand $R_2PCH_2PR_2$ qui sert de pont. Ce type d'échange n'avait pas été observé antérieurement avec ces ligands. Avec le Me_2CO comme solvant, la valeur approximative de l'enthalpie d'activation est de 59 kJ mol^{-1} pour le $[^{107}Ag(\mu\text{-}Ph_2PCH_2PPh_2)_3{}^{107}Ag]^{2+}$ et de 50 kJ mol^{-1} pour le $[^{107}Ag(\mu\text{-}Me_2PCH_2PMe_2)_3{}^{107}Ag]^{2+}$.

Introduction

A variety of stoichiometries and structures are known for complexes of silver(I) with bis(diphenylphosphino)methane (dppm) and related 1,1-ditertiaryphosphinoalkanes. For the 2:1 Ag:L complexes $(Ph_2PCHRPPh_2)(AgO_2CR')_2$ (R = H or Me; R' = Me, Et, *i*-Pr, and Ph) in solution, the bridging bidentate nature of the ligands has been demonstrated using ^{1}H and ^{31}P nmr spectroscopy (1). The $Ag(\mu\text{-dppm})Ag$ unit has been established (2) in the cluster $[Ag_2Ru_4(\mu_3\text{-}H)_2(\mu\text{-dppm})(CO)_{12}]$ and its occurrence in $(dppm)(AgNO_3)_2$ has been postulated (3). From an nmr study (1) and an X-ray structural study (4), the ligands also occupy bridging bidentate positions in the 2:2 complexes $[Ag(\mu\text{-}Ph_2PCHRPPh_2)_2Ag](BF_4)_2$ (R = H or Me) and $(Ag_2(dppm)_2(NO_3)_2)$, respectively. In addition, a wide range of related heterometallic binuclear complexes containing the skeleton $M(\mu\text{-}Ph_2PCH_2PPh_2)_2Ag$ have been described (5). X-ray analysis of the 3:3 compound of AgBr with dppm has revealed the ligand-bridged trimeric structure $[Ag_3(\mu\text{-dppm})_3(\mu_3\text{-}Br)_2]Br$ (6). The same technique was used to characterize a 4:4 cation in $[\{Ag_2(dppm)_2\}_2(NO_3)_2](PF_6)_2$ (4). In this cation two $Ag(\mu\text{-dppm})_2Ag$ subunits are evident. The complex $(dppm)(AgO_3SMe)$ is trimeric in $CHCl_3$ (7), and so might have a dppm-bridged structure. In contrast, the 1:2 complex $(dppm)_2(AgO_3SMe)$ is monomeric in $CHCl_3$ (7); its structure is unknown.

To our knowledge, there has been no report of a 2:3 Ag:L silver(I) complex with a ligand of the general type $R_2PCH_2PR_2$. We describe here the ready synthesis of two such complexes, one with dppm and one with $Me_2PCH_2PMe_2$ (dppm). These are shown by nmr spectroscopy to contain $[Ag(\mu\text{-}R_2PCH_2PR_2)_3Ag]^{2+}$, analogous to the cation $[Au(\mu\text{-dmpm})_3Au]^{2+}$ for which structural data were reported very recently (8). The new silver complex with dppm is isoelectronic with $Pd_2(dmpm)_3$. The palladium complex is of unknown structure but it is thought likely (9) to have the same structure as $[Pt(\mu\text{-dppm})_3Pt]$ which has been fully characterized both in solution and in the solid state (9).

The ^{31}P nmr spectra of both new silver complexes exhibit interesting temperature dependence. This has been studied in detail and provides evidence for a novel intramolecular exchange process.

Experimental

Materials and general procedures

Isotopically-enriched silver metal (98.22% ^{107}Ag) from Oak Ridge National Laboratory, and natural silver of 99.999% purity (Alfa) were

[1]Presented in part at the 67th Canadian Chemical Conference and Exhibition, Montreal, June, 1984. Abstract IN 12-10.

[3]On leave from 1983 to 1985 from Department of Chemistry, M. G. Degree College, Gorakhpur 273001, India.

converted into the corresponding silver hexafluoroarsenates by treatment with AsF_5 in SO_2 (10). 1,2-Bis(dimethylphosphino)methane was the gift of Professor R. J. Puddephatt and Mr. R. Ramachandran of this Department. All other chemicals were of reagent grade and were used as received from commercial sources. All solvents were dried over 3A Molecular Sieves and thoroughly deoxygenated in a flow of Ar before use. Silver hexafluoroarsenate was handled in a glove box under an atmosphere of dry nitrogen.

Carbon, hydrogen, silver, and phosphorus microanalyses were performed by Analytische Laboratorien, Gummersbach, West Germany.

Synthesis

The following syntheses were performed under an atmosphere of Ar gas. However, the air-sensitivity of the compounds described here, once they are formed, does not seem to be high.

$[Ag_2(dppm)_3](AsF_6)_2$ (1). A solution of $AgAsF_6$ (0.499 g, 1.68 mmol) in 5 mL of $MeNO_2$ was added with stirring to a solution of dppm (0.990 g, 2.58 mmol) in 10 mL of $MeNO_2$. The light yellow solution was filtered and the solvent was removed *in vacuo*. The crude product was recrystallized from warm acetone and dried under vacuum. Yield 1.25 g (85%). *Anal.* calcd. for $C_{75}H_{66}Ag_2As_2F_{12}P_6$: C 51.57, H 3.81, Ag 12.35, P 10.64; found: C 51.48, H 3.98, Ag 12.20, P 10.70. ^1H nmr (CD_3NO_2, 294 K): δ_H 3.77 (s, CH_2), 7.15–7.43 (phenyl H atoms).

$[Ag_2(dmpm)_3](AsF_6)_2$ (2). Starting from $AgAsF_6$ (0.509 g, 1.71 mmol) and dmpm (0.35 g, 1.7 mmol), this compound was prepared and purified in a manner identical to that used for **1**. Yield 0.67 g (78%). *Anal.* calcd. for $C_{15}H_{42}Ag_2As_2F_{12}P_6$: C 17.98, H 4.23, Ag 21.53, P 18.55; found: C 17.97, H 4.12, Ag 21.30, P 18.69. ^1H nmr (CD_3NO_2, 294 K): δ_H 1.57 (CH_3), 2.24 (CH_2, septet, J_{obs} = $(1/3)[^2J(^{31}P—^1H) + ^4J(^{31}P—^1H)]$ = 3.0 Hz).

$[^{107}Ag_2(dppm)_3](AsF_6)_2$ (1) and $[^{107}Ag_2(dmpm)_3](AsF_6)_2$ (2*).* These compounds were prepared in the same way as **1** and **2**, but starting with $^{107}AgAsF_6$.

Nuclear magnetic resonance spectra

All nmr samples were prepared on a mass of solute/volume of solvent basis. The tube size was 5 mm od for measurement of proton spectra on a Varian XL-200 spectrometer system and for measurement of ^{13}C and some of the ^{31}P spectra on a Varian XL-300 Spectrometer System. In these cases the deuterated solvent was the ^2D field/frequency lock substance. Some of the ^{31}P nmr spectra were measured on the XL-200 spectrometer using protiated solvents and no field/frequency lock. (Field drift $\ll$ 1 Hz/day.) Samples for measurements at or below ambient probe temperature were then contained in 10 mm od nmr tubes, while samples which would be measured at elevated temperatures were contained in sealed 9 mm od standard wall tubes that were a tight sliding fit inside a standard thin-walled 10 mm od nmr tube.

References used were internal TMS for ^1H and ^{13}C nmr spectra and external 85% H_3PO_4 (by sample interchange) for ^{31}P nmr. In the last case no corrections for volume susceptibility difference were made.

Probe temperatures were measured by means of a calibrated thermocouple probe in a stationary dummy sample of the appropriate solvent for ambient probe temperature or below, or of ethylene glycol for elevated temperatures.

Simulation of nuclear magnetic resonance spectra

Spectra were simulated using a version of LAOCN3 (11) adapted locally[4] to run on a Victor 9000 computer. This adaptation can handle up to an 8-spin system.

Results and discussion

When progressive amounts of $Ph_2PCH_2PPh_2$ are added to $AgAsF_6$ in $MeNO_2$ or Me_2CO, ^{31}P nmr shows that at Ag:dppm = 2:1 the known (1) complex $[Ag(\mu\text{-dppm})Ag]^{2+}$ is formed quantitatively. Additional amounts of dppm up to Ag:dppm = 1:1 lead to quantitative formation of $[Ag(\mu\text{-dppm})_2Ag]^{2+}$, which is also known (1, 4). The 2:2 complex in the presence of further dppm reacts quantitatively to give a third species that has not been noted previously. From the composition of the solution together with integration of the ^{31}P nmr spectrum, it is evident that this species has a 2:3 stoichiometry, and indeed analytically pure $Ag_2(dppm)_3(AsF_6)_2$ (**1**) is isolable in good yield from solutions that contain it (see Experimental section). This 2:3 complex seems to have escaped attention in previous work (1, 4), perhaps because a restricted range of compositions was investigated. Addition of more dppm to the 2:3 compound does not produce further silver complexes. Indeed, the ^{31}P nmr spectrum shows signals from the 2:3 complex and free dppm. A 1:2 complex might have been anticipated from the earlier isolation of $(dppm)_2(AgO_3SMe)$ (7).

By substitution of Me_2PCH_2PMe for dppm it was possible to produce the 2:3 compound $Ag_2(dmpm)_3(AsF_6)_2$ (**2**) quantitatively in $MeNO_2$ or Me_2CO solution. Again this new compound was isolated in good yield (see Experimental section).

The variable temperature ^{31}P nmr spectra of **1** and **2** show interesting changes. As an example, Fig. 1 shows the ^{31}P nmr spectra of **2** in Me_2CO at ambient probe temperature and reduced temperature. At 295 and 213 K these spectra are centered at −20.7 and −20.0 ppm, respectively. The spectra of **1** are generally similar[5] and centered at 5.9 and 5.0 ppm at 295 and 213 K, respectively. Three things are immediately evident from the spectra: (*i*) from the similarity of the spectra at reduced temperature the cations in **1** and **2** must have the same structure; (*ii*) the complexes contain symmetrical spin systems, judging from the symmetrical if complicated spectra obtained at low temperature; and (*iii*) there is the onset of an exchange process as the temperature is increased to ambient probe temperature. As exemplified by the 213 K spectrum in Fig. 1, the ^{31}P nmr spectra at reduced temperature show the expected couplings to ^{109}Ag and ^{107}Ag. These isotopes both have spin, $I = \frac{1}{2}$, and their natural abundances are 48.18 and 51.82%, respectively (12). The largest doublet separation in each low temperature spectrum is a result of coupling to ^{109}Ag and the smallest of coupling to ^{107}Ag. At 213 K the ratio of the largest to smallest doublet separations is (358 ± 1 Hz)/(310 ± 1 Hz) (= 1.15) for **1**, and (368 ± 1 Hz)/(319 ± 1 Hz) (= 1.15) for **2**, both identical with $\gamma(^{109}Ag)/\gamma(^{107}Ag)$ which is 1.150 (12). In each spectrum at 213 K there is a third doublet with an intermediate coupling, 334 ± 1 Hz for **1** and 343 ± 1 Hz for **2**, providing evidence that the cations have a polynuclear structure. From the formulae of **1** and **2** a binuclear structure is the simplest possibility. In a dimeric Ag_2 complex the statistical (13) fractional populations of the $(^{109}Ag)_2$, $(^{109}Ag)(^{107}Ag)$, and $(^{107}Ag)_2$ isotopomers are 0.232, 0.499, and 0.269, respectively. In order of increasing separation, the approximate relative intensities of the three major doublets are 1.3:2.0:1 in the spectrum of **1*** at 213 K, and 1.5:2.2:1 in the spectrum of **2*** at 213 K. These are in fair agreement with expectation for a binuclear complex. However, since these are previously unreported complexes, further proof of their structure seemed desirable. The occurrence of three isotopomers with comparable populations makes the detailed interpretation of the spectra of **1** and **2** a difficult task. To

[4]We thank Dr. R. H. Hill, previously of this Department, for making available to us his adaptation which could handle up to seven spins and which we modified to handle up to eight spins.

[5]Copies of these spectra may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1S 0S2.

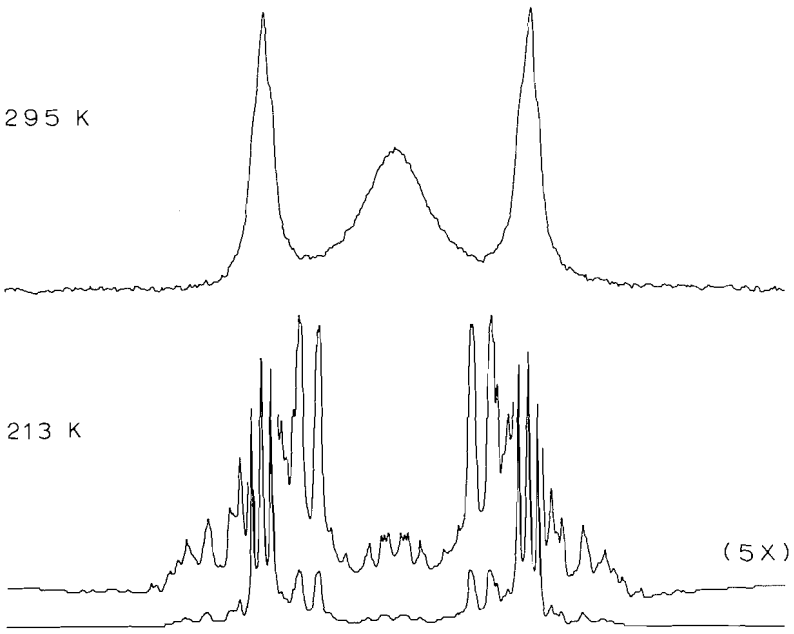

FIG. 1. The 80.98 MHz ^{31}P nmr spectra at 213 and 295 K of $[Ag(\mu\text{-dmpm})_3Ag](AsF_6)_2$ (**2**) (0.01 mol/L of acetone). The spectra are 1000 Hz wide and have been plotted using a 1 Hz exponential line broadening. The lower spectrum is shown with a 5× vertical expansion.

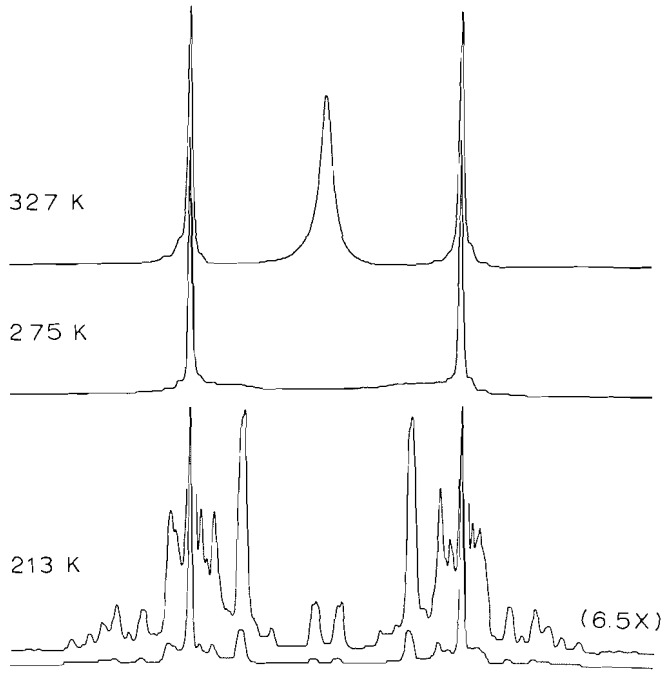

FIG. 2. Representative variable temperature ^{31}P nmr spectra of $[^{107}Ag(\mu\text{-dmpm})_3{}^{107}Ag](AsF_6)_2$ (**2***) (0.01 mol/L of acetone). The spectra are 750 Hz wide and were plotted using a 1 Hz (bottom) or 2 Hz (middle and top) exponential line broadening. The bottom spectrum is shown with a 6.5× vertical expansion.

simplify this problem the ^{107}Ag-enriched complexes **1*** and **2***, containing 98.2% ^{107}Ag were synthesized and studied.

Representative variable temperature ^{31}P nmr spectra, those of **2*** in Me_2CO, are shown in Fig. 2. The spectra of **1*** exhibit parallel behaviour.[5] In each case the most noticeable feature of the limiting low temperature spectrum is the intense doublet that was associated above with coupling to ^{107}Ag. At 213 K, the doublet is centred at $\delta_P = 4.9$ and has a separation of 310 ± 1 Hz for **1***. For **2*** under the same conditions the corresponding values are $\delta_P = -20.0$ and a separation of 318 ± 1 Hz. It is most significant that for both complexes *this doublet is retained when the effects of exchange on the spectra become evident as the temperature is raised*. This shows that the exchange process that is occurring is *intramolecular*. At a phenomenological level, it is very useful to have only the simpler part of the spectrum, the intense doublet, unaffected as the temperature is raised. As a result of this behaviour, the ^{31}P nmr spectra of **1***:**2*** mixtures at ambient or higher temperature both allow a chemical proof of the dimeric structure and give an indication of the type of exchange process that occurs in the complexes.

In **1***:**2*** mixtures, only two new species are formed. Figure 3(*a*) shows the ^{31}P nmr spectrum at 304 K of a solution in which **1***:**2*** = 1.9:1. In this spectrum, a sharp doublet of triplets of relative intensity 2 is observed at $\delta_P = 6.4$ ppm, in the dppm-on-^{107}Ag region. By comparison with the spectrum of **1*** itself, the large doublet splitting of 305 ± 1 Hz must be associated with coupling to ^{107}Ag. The smaller splitting of 56 ± 1 Hz between the components of the triplets also occurs in the dmpm-on-^{107}Ag region (see following) and so is $^{31}P—^{31}P$ coupling. In the dmpm-on-^{107}Ag region there is a doublet of quintets of relative intensity 1 centered at $\delta_P = -20.4$ ppm. Again the large doublet splitting, 327 ± 1 Hz, must be associated with coupling to ^{107}Ag, while the quintets show the 56 Hz $^{31}P—^{31}P$ coupling. In both regions the sharp signals are accompanied by broader resonances from the parts of the spectrum that are affected by the exchange process that is known to be occurring at this temperature (see above). The relative intensities of the sharp signals in the two regions together with their multiplicities show that the new species must contain two dppm ligands and one dmpm. Taken with the known overall stoichiometries of **1*** and **2*** it is evident that the new complex must be binuclear and of composition $[^{107}Ag_2(dppm)_2(dmpm)]^{2+}$.

The second binuclear complex with mixed ligands is formed in **2***-rich mixtures of **1*** and **2***. Figure 3(*b*) presents the ^{31}P nmr spectrum at 295 K of a mixture in which **1***:**2*** = 1:2.4. This shows the doublet spectrum of **2***. Also in the dmpm-on-^{107}Ag region, at $\delta_P = -20.6$ ppm, there can be seen sharp

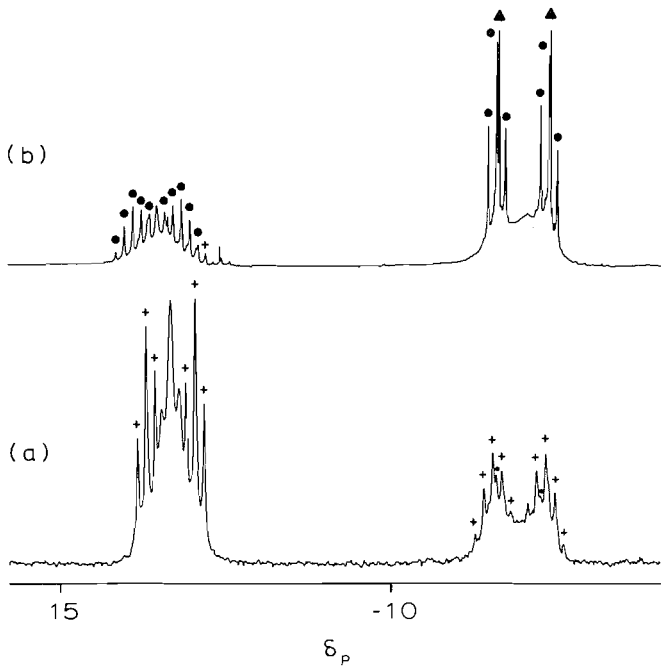

FIG. 3. The 80.98 MHz ^{31}P nmr spectra of **1***:**2*** mixtures (total concentration 0.01 mol/L of acetone), showing the sharp resonances of $[^{107}Ag(\mu\text{-dppm})_{3-x}(dmpm)_x{}^{107}Ag]^{2+}$. (*a*) **1***:**2*** = 1.9:1; (*b*) **1***:**2*** = 1:2.4. Spectrum (*a*) was recorded using a 2 Hz exponential line broadening, spectrum (*b*) using 1 Hz. Key: + = $[^{107}Ag(\mu\text{-dppm})_2(dmpm)^{107}Ag]^{2+}$; ○ = $[^{107}Ag(\mu\text{-dppm})(\mu\text{-dmpm})_2{}^{107}Ag]^{2+}$; △ = $[^{107}Ag(\mu\text{-dmpm})_3{}^{107}Ag]^{2+}$.

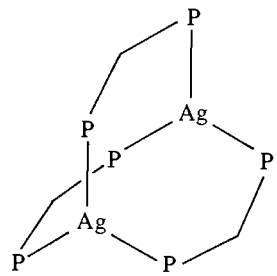
signals (once more there occur accompanying broad signals) due to the new complex. The observed pattern is a doublet of triplets of relative intensity 2, with a 321 ± 1 Hz doublet splitting from ^{107}Ag and a 52 ± 1 Hz ^{31}P—^{31}P coupling within the triplets. The other sharp part, occurring in the dppm-on-^{107}Ag region, is a doublet of quintets of relative intensity 1 centered at δ_P = 7.4 ppm, and having a 302 ± 1 Hz coupling to ^{107}Ag and the same 52 Hz ^{31}P—^{31}P coupling. Following our previous reasoning, this second new complex is clearly binuclear $[^{107}Ag(dppm)(dmpm)_2]^{2+}$.

With the occurrence of the two binuclear mixed ligand complexes proven, it is clear that **1*** (and **1**) and **2*** (and **2**) must also be binuclear. The two complexes with mixed ligands are then formed by simple ligand redistribution, as in eq. [1].

$$[1]\quad [^{107}Ag_2(dppm)_3]^{2+} + [^{107}Ag_2(dmpm)_3]^{2+} \rightleftharpoons [^{107}Ag_2(dppm)_{3-x}(dmpm)_x]^{2+}$$

The symmetries of the limiting low temperature ^{31}P nmr spectra of **1*** (and **1**) and **2*** (and **2**) (see above) are quite consistent with the complexes having the "manxane" structure **I**.[6] With such a structure, **1*** and **2*** will have ^{31}P nmr spectra that are the A part of an AA′A″A‴A⁗A⁗′XX′ spectrum. In such spectra, the A part is symmetrical and contains a doublet with half the total intensity and a separation of $(J(A—X) + J(A—X'))$ (14). Thus $(^1J(^{107}Ag—^{31}P) + {}^3J(^{107}Ag—^{31}P))$ = 310 Hz in **1***, and 318 Hz in **2***. The other half of the intensity in the A part of the spectrum occurs as an AA′A″BB′B″ subspectrum. By trial and error, a convincing simulation[7] of the 213 K ^{31}P nmr spectrum of **1*** was obtained using $^1J(^{107}Ag—^{31}P)$ = 309 Hz, $^2J(^{31}P—Ag—^{31}P)$ = 100 Hz, $^2J(^{31}P—C—^{31}P)$ = 148 Hz, and $^4J(^{31}P—Ag—P—C—^{31}P)$ = 3 Hz. Evidently $^3J(^{107}Ag—^{31}P)$ is small, approximately 1 Hz. Similarly, the ^{31}P nmr spectrum of **2*** at 213 K was satisfactorily reproduced with the three non-zero coupling constants $^1J(^{107}Ag—^{31}P)$ = 317 Hz, $^2J(^{31}P—Ag—^{31}P)$ = 115 Hz, and $^2J(^{31}P—C—^{31}P)$ = 141 Hz. Here both $^3J(^{107}Ag—^{31}P)$ and $^4J(^{31}P—Ag—P—C—^{31}P)$ must be very small. For **1***, the smallness of $^3J(^{107}Ag—^{31}P)$ is consistent with results for other complexes with the Ag(μ-dppm)Ag unit (1, 2), while the values found for $^2J(^{31}P—C—^{31}P)$, $^2J(^{31}P—M—^{31}P)$, and $^4J(^{31}P—^{31}P)$ are comparable to those reported for [Pt(μ-dppm)$_3$Pt] (9). Also, the values found for $^1J(^{107}Ag—^{31}P)$ in **1*** and **2*** are in the range reported (15) for monomeric tris(phosphine) complexes, $Ag(PR_3)_3X$ (X = weakly coordinating anion), adding strong support to the proposed structure **I**. For the complexes $[Ag(\mu\text{-dppm})_nAg]^{2+}$, $^1J(^{107}Ag—^{31}P)$



I

varies with *n* in the order 1 > 2 > 3 (ref. 1 and see above), as expected if the couplings vary with the 5*s* character of the hybrid orbitals of the silver atom, i.e. are dominated by the Fermi contact mechanism. We note that the values of $^2J(^{31}P—^{31}P)$ obtained for **1*** and **2*** are roughly twice the values found for the ^{31}P—^{31}P couplings in the ^{31}P nmr spectra of $[^{107}Ag_2(dppm)_{3-x}(dmpm)_x]^{2+}$ (x = 1 or 2) at ambient probe temperature (see above). However, the couplings found for the complexes with mixed ligands are the exchange-average of $^2J(^{31}P—^{31}P)$ and $^4J(^{31}P—^{31}P)$ (see below) and as just described the four-bond coupling is small.

It is now possible to account for the reduced temperature ^{31}P nmr spectra of **1** and **2** (see Fig. 1). These spectra are composites: they contain the two different AA′A″A‴A⁗′A⁗⁗XX′ spectra of the isotopomers $[^{107}Ag(\mu\text{-L—L})_3{}^{107}Ag]^{2+}$ and $[^{109}Ag(\mu\text{-L—L})_3{}^{109}Ag]^{2+}$, and spectrum of the isotopomer $[^{107}Ag(\mu\text{-L—L})_3{}^{109}Ag]^{2+}$ which will be of the type AA′A″A‴A⁗′A⁗⁗MX or AA′A″BB′B″B‴MX depending on whether the isotope effect is or is not negligible. The relative intensities are those of the combinations $^{107}Ag_2$, $^{109}Ag_2$, and $^{107}Ag^{109}Ag$, i.e. 0.269, 0.232, and 0.499 (see above).

There remains the nature of the intramolecular exchange process that occurs in the 2:3 complexes as the temperature is raised. It is clear from the exchange-averaged spectra of

[6]The CH_2 signals in the ^1H nmr spectra of **2** and **2*** in CD_3NO_2 at ambient probe temperature are consistent with a manxane structure also. These signals are *septets*. In the manxane structure the apparent coupling in the expected septet is $(1/3)[^2J(^{31}P—^1H) + 2^4J(^{31}P—^1H)]$.

[7]For speed and ease of computation the spectra were simulated as the appropriately weighted composite of two A_3 subspectra and an AA′A″BB′B″ subspectrum. The last of these results from complexes in which the spins of Ag are opposed. The form of the centre of the six-spin subspectrum, in particular, is very sensitive to the values chosen for the various coupling constants. It should be noted, however, that the combination of coupling constants obtained by trial and error may not be unique.

$[^{107}Ag(\mu\text{-dppm})_{3-x}(\mu\text{-dmpm})_x{}^{107}Ag]^{2+}$ ($x = 1$ or 2) (see Fig. 3 and the discussion above) that this process renders both ends of the bridging ligands equivalent on a time-average. Thus the process must involve overall "end-over-end" ligand exchange as shown in reaction [2]. This type of intramolecular exchange

[2] 
does not seem to have been observed previously for a bridging dppm. However, intramolecular "end-over-end" exchange of η^1-dppm is well-established. (See, for examples, refs. 5*a* and 16.) A plausible mechanism for the exchange is via the short-lived complex $[Ag(\mu\text{-dppm})_2Ag(\eta^2\text{-dppm})]^{2+}$, as shown in reaction [3].[8]

[3] 
For the exchange process shown in reaction [2], the $[^{107}Ag(\mu\text{-L—L})^{107}Ag]^{2+}$ complexes with different combinations of ^{107}Ag nuclear spins count as different sites. The possible combinations of silver spins are αα, ββ, and αβ/βα with relative populations 1, 1, and 2, respectively. When the spins are αα or ββ, the exchange process does not result in a change of site for the two ^{31}P nuclei that interchange places. On the other hand when the silver spins are αβ/βα, the two ^{31}P nuclei on the ligand undergoing exchange do change sites (and hence resonance frequencies) as a result of the exchange, and thus their resonances collapse together as the exchange rate becomes appreciable on the nmr timescale. Therefore, exactly half of the total intensity in the ^{31}P nmr spectra of **1*** and **2*** should remain sharp during the end-over-end exchange process,[9] while the other half should collapse together and eventually become a singlet when the exchange rate becomes fast enough. This is just what is observed in the variable temperature spectra of **1*** and **2***, as exemplified in Fig. 2. The same explanation accounts for the spectra of the complexes $[^{107}Ag(dppm)_{3-x}(dmpm)_x{}^{107}Ag]^{2+}$ ($x = 1$ or 2) at ambient probe temperature (see Fig. 3). Here the exchange in the complexes with αα or ββ spins of silver causes averaging of ^{31}P—^{31}P couplings but not of different sites (i.e. resonance frequencies). In complexes with opposed silver spins, both averaging of coupling constants and site exchange (at an intermediate rate) occur, and this accounts for the broad signals seen in Fig. 3(*a*) and (*b*). Similarly, the couplings to $^{109/107}Ag$ persist in just half the intensity of the spectra of **1** and **2** at 295 K, while the other half of the intensity is in the form of a single broad resonance (e.g. Figs. 1 and 2). Again this observation is quite consistent with the occurrence of the intramolecular exchange process shown in reaction [2].

After the complicated subspectrum[7] of the Ag(α)Ag(β)/Ag(β)Ag(α) spin isomers of **1*** and **2*** has collapsed to a single line, it seems reasonable that the behaviour of this line should be just that expected for exchange between two different equally populated sites, i.e. the α and β spins of silver. In this region of exchange-narrowing, the exchange rate is inversely proportional to $(\Delta\nu_{1/2}(\text{excess}))^{-1}$ (17). In the present case $\Delta\nu_{1/2}(\text{excess}) = [\Delta\nu_{1/2}(\text{collapsed singlet}) - \Delta\nu_{1/2}(\text{uncollapsed doublet})]$.[10] Thus from an Eyring plot of $\ln [\Delta\nu_{1/2}(\text{excess}) \times T]^{-1}$ vs. $1/T$, for the region of exchange-narrowing, it is possible to obtain the enthalpy of activation, $\Delta H^{\ddagger}$, for the exchange process shown in reaction [2]. From a regression analysis of the Eyring plot, $\Delta H^{\ddagger}$ for intramolecular ligand exchange in **1*** in Me_2CO is found to be 58.7 ± 1.4 kJ mol^{-1} (from five points covering the temperature range −4.1 to 22.4°C; the correlation coefficient is 0.999). The same approach (with four points covering the range 36.0–54.4°C; the correlation coefficient is 0.999) yields 49.9 ± 1.5 kJ mol^{-1} for $\Delta H^{\ddagger}$ for exchange in **2*** in Me_2CO. The standard deviations from such Eyring plots can be serious underestimates (18).[11] With the small temperature range that could be used here, and the consequent small number of points collected, the values of $\Delta H^{\ddagger}$ should be taken as approximate. However, the relative values of $\Delta H^{\ddagger}$, **1*** > **2***, together with the observed rates of exchange, **1*** > **2***, suggest that there is a difference in the entropies of activation between **1*** and **2*** that favours the intramolecular ligand exchange in **1***.

[8] We find that the ^{31}P nmr spectrum of $[^{107}Ag(\mu\text{-dppm})_2{}^{107}Ag]^{2+}$ does not show evidence for the same type of exchange that occurs in **1***. Possibly two anchored bridging ligands are necessary before end-over-end exchange can occur. Alternatively, as suggested by one of the referees, stronger ligand binding in the 2:2 complex makes it less susceptible to the initial dissociative rupture required for a process like [3].

[9] *General* broadening can occur if there is *inter*molecular ligand exchange. This is clearly the case for the dppm complex around ambient probe temperature.

[10] Use of this difference minimizes the effect of any general broadening.

[11] We thank a referee for drawing our attention to this point.

LYNN M. MIHICHUK, CAROLYN L. GIESINGER, BEVERLY E. ROBERTSON, and RICHARD J. BARTON. Can. J. Chem. **65**, 2634 (1987).

(L—L)W(CO)$_4$ (L—L = $(CH_3)_2AsC(CF_3)=C(CF_3)As(CH_3)_2$) is oxidized by I_2 to yield the seven-coordinate complex (L—L)W(CO)$_3I_2$ which reacts with monodentate phosphines or phosphites to form (L—L)W(CO)$_2I_2$P (P = phosphine or phosphite). Crystals of (L—L)W(CO)$_2I_2P(OCH_3)_3$ are monoclinic, space group $P2_1/c$, a = 15.711(3), b = 13.134(2), c = 13.800(3) Å, β = 111.81(2)° with Z = 4. The structure was solved from a Patterson map and anisotropically refined by least squares to a conventional R value of 0.039 using 3737 independent reflections. The crystal structure showed the tungsten atom to be seven-coordinate with a geometry most closely approximated by a capped octahedral environment, the capping group being a carbonyl moiety ([W—C] = 1.95(1) Å). The capped face consists of the carbon atom ([W—C] = 1.98(1) Å) of the remaining carbonyl, an arsenic atom ([W—As] = 2.556(1) Å), and the phosphorus atom ([W—P] = 2.466(3) Å). The W—As bond *trans* to a phosphite group is longer (by 0.050(2) Å) than the W—As bond *trans* to an iodine atom. ^{1}H nmr data indicate the complex to be fluxional at 298 K and rigid at lower temperatures, the data at lower temperatures being consistent with the configuration found in the crystal. The nmr data at lower temperatures suggest two exchange processes are occurring; one which averages two sets of As—CH_3 groups and another process which averages all four As—CH_3 groups.

LYNN M. MIHICHUK, CAROLYN L. GIESINGER, BEVERLY E. ROBERTSON et RICHARD J. BARTON. Can. J. Chem. **65**, 2634 (1987).

L'oxydation du (L—L)W(CO)$_4$ (L—L = $(CH_3)_2AsC(CF_3)=C(CF_3)As(CH_3)_2$) par du I_2 conduit à un complexe hepta-coordonné (L—L)W(CO)$_3I_2$ qui réagit avec les phosphines ou les phosphites monodentates pour former (L—L)W(CO)$_2I_2$P (P = phosphine ou phosphite). Les cristaux de (L—L)W(CO)$_2I_2P(OCH_3)_3$ sont monocliniques, groupe d'espace $P2_1/c$ avec a = 15,711(3), b = 13,134(2) et c = 13,800(3) Å, β = 111,81(2)° et Z = 4. On a résolu la structure par une carte de Patterson et on l'a affinée d'une façon anisotrope par la méthode des moindres carrés jusqu'à une valeur conventionnelle de R de 0,039 pour 3737 réflexions uniques. La structure cristalline démontre que l'atome de tungstène est hepta-coordonné avec une géométrie qui se rapproche beaucoup d'un environnement octaédrique cappé, dans lequel le groupe qui agit comme cap est une portion carbonyle ([W—C] = 1,95(1) Å). La face cappée comporte l'atome de carbone ([W—C] = 1,98(1) Å) de l'autre carbonyle, un atome d'arsenic ([W—As] = 2,556(1) Å) et l'atome de phosphore ([W—P] = 2,466(3) Å). La liaison W—As est *trans* par rapport à un groupement phosphite et elle est plus longue (par 0,050(2) Å) que la liaison W—As qui est *trans* par rapport à un atome d'iode. Les données relatives à la rmn du ^{1}H indiquent que le complexe est fluxionnel à la température ambiante (298 K) et qu'il est rigide à des températures plus basses; les données obtenues à des températures plus basses sont en accord avec la configuration trouvée dans le cristal. Les données de la rmn à basse température suggèrent qu'il y a deux processus d'échanges qui sont impliqués; un fait que la position des deux ensembles de groupements As—CH_3 devient moyenne et un autre processus provoque une moyenne des quatre groupements As—CH_3.

Introduction

The relevant seven-vertex polytopal polyhedra are the pentagonal bipyramid (D_{5h}), the monocapped octahedron (C_{3v}) and the quadrilaterally monocapped trigonal prism (C_{2v}). X-ray crystallographic studies of seven-coordinate complexes of transition metal carbonyls have shown that they generally adopt either of the latter two types of geometry (1–4). However, the actual structures seldom match the ideal polyhedral arrangements but various criteria have been proposed to aid in the assignment of the most appropriate description to an experimentally determined coordination polyhedron (5–7).

Another phenomenon commonly associated with seven coordination is fluxional behavior (8), which results in the room temperature nmr spectra often not being consistent with the X-ray crystal structure. Variable-temperature nmr studies may provide the appropriate data representative of the slow-exchange limit. Previous work in the area of seven coordination by one of us described the fluxional behavior of a series of related complexes utilizing ^{1}H, ^{19}F, and ^{31}P nmr studies (9). However, no crystallographic studies were available, making the assignment of the static structure and the discussion of the exchange processes uncertain! We are now compiling structural data (10) in order to better understand the behavior of these complexes and to elucidate the mechanism of the ligand motion, which is generally poorly understood in seven coordination. In view of the fluxional phenomenon we thus believe that spectroscopic assignment of seven-coordinate complexes should be substantiated with a crystallographic structural analysis.

In this paper we describe the synthesis, X-ray structure, and fluxional behavior of the seven-coordinate complex $(CH_3)_2AsC(CF_3)=C(CF_3)As(CH_3)_2W(CO)_2I_2P(OCH_3)_3$.

Experimental section

A. General comments

All preparations were carried out under an argon atmosphere using standard Schlenk techniques. The ligand *cis*-2,3-bis(dimethylarsino)-1,1,1,4,4,4-hexafluorobut-2-ene, (L—L), and the complex (L—L)W(CO)$_3I_2$ were prepared as previously described (9, 11).

^{1}H nmr data were obtained using a Perkin-Elmer R12-B nmr spectrometer. Chemical shifts are reported in parts per million from internal Me_4Si for ^{1}H. Low temperature ^{1}H nmr data were obtained using a Bruker HX-90 NMR spectrometer with $CFCl_3$ as solvent. Infrared spectra were recorded using a Beckman IR-12 spectrophotometer.

B. Preparation of (L—L)W(CO)$_2$I$_2$P(OCH$_3$)$_3$

A solution of (L—L)W(CO)$_3$I$_2$ (0.196 g, 2.17 × 10^{-4} mol) and P(OCH$_3$)$_3$ (0.035 g, 2.82 × 10^{-4} mol) in 35 mL degassed benzene was refluxed for 21.5 h. The benzene was removed under reduced pressure and recrystallization from dichloromethane–hexane solution yielded yellow crystals of (L—L)W(CO)$_2$I$_2$P(OCH$_3$)$_3$; 0.146 g, 69%; mp 136–138°C; ir (CH$_2$Cl$_2$) ν(CO) 1953, 1874 cm^{-1}; ^{1}H nmr (CDCl$_3$) δ 3.87 (d, 9H, P(OCH$_3$)$_3$, J_{P-H} = 10.5 Hz), 2.16 (s, 12H, As(CH$_3$)$_2$).

C. X-ray structure analysis

A yellow plate of (L—L)W(CO)$_2$I$_2$P(OCH$_3$)$_3$ with approximate dimensions 0.09 × 0.2 × 0.35 mm was mounted on a modified Picker FACS-1 four-circle diffractometer. Intensity data were collected using the NRCC diffractometer control system (12).

The effects of absorption were corrected using the Gaussian method and the XTAL system of programs (13). Scattering factors were also assigned by XTAL. Dispersion corrections for the tungsten, iodine, arsenic, and phosphorus atoms were taken from the International tables for X-ray crystallography, Vol. IV (14).

The structure was solved by applying the Patterson method followed by use of electron density and difference Fourier maps. It was refined by full-matrix least squares applied to the structure amplitudes using anisotropic temperature factors. The hydrogen atoms were not located.

Table 1 contains crystallographic experimental data, Tables 2 and 3 contain atomic and thermal parameters and important bond lengths and bond angles, respectively.[2] The atomic labelling is given in Fig. 1 and a stereoscopic view of the molecule with thermal ellipsoids represented at 50% probability is shown in Fig. 2. Figure 3 shows the torsional angles in the five-membered ring of the chelate ligand and their estimated standard deviations for the title compound and the related complex (L—L)W(CO)Br$_2$[P(OCH$_3$)$_3$]$_2$ (10). Figure 4 shows an enantiomeric inversion pathway to partially explain the fluxional behavior of the title compound.

[2]Tables of observed and calculated structure factor amplitudes, anisotropic temperature factors and additional bond lengths and angles may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a]$U_{eq} = (1/3) \sum_{i=1}^{3} \sum_{j=1} [U_{ij} a_i^* a_j^* (\mathbf{a}_i \cdot \mathbf{a}_j)]$. Values listed are multiplied by 10^2.

Results and discussion

The tungsten atom is seven-coordinate with the coordination sphere containing the two arsenic atoms of the L—L ligand, two iodine atoms, the two carbon atoms of the carbonyl groups, and the phosphorus atom of the trimethyl phosphite group. The coordination polyhedron about the tungsten atom for the title compound is similar to that of (L—L)W(CO)Br$_2$[P(OCH$_3$)$_3$]$_2$ (10). In order to compare the two compounds we have used the δ parameters of Porai-Koshits and Aslanov (15), as calculated by Muetterties and Guggenberger. However, we have modified the experimentally determined polyhedron by moving each ligand along its radius vector to the surface of a unit sphere. The modified coordination polyhedron in both compounds is intermediate between the monocapped octahedron (C_{3v}) and the quadrilaterally monocapped trigonal prism (C_{2v}). The δ values which are most sensitive to changes in polyhedral shape and which are best used to compare experimentally determined polyhedra with the relevant polytopes are the three δ values for the edges which form the capped face in the monocapped

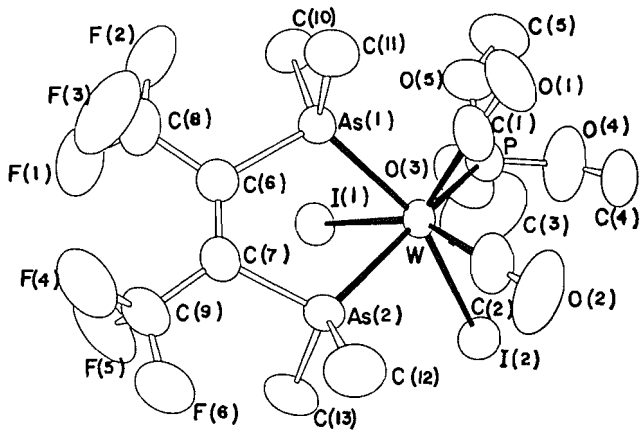

FIG. 1. Atomic labelling for $(CH_3)_2AsC(CF_3)=C(CF_3)As(CH_3)_2$-$W(CO)_2I_2P(OCH_3)_3$.

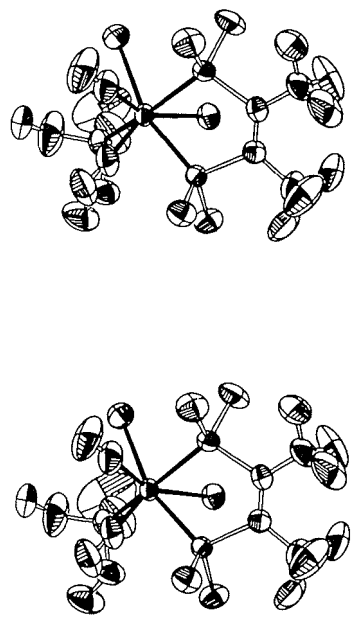

FIG. 2. Stereoscopic view of the molecule with thermal ellipsoids represented at 50% probability.

octahedral description. These three δ values are (24.2°, 24.2°, 24.2°), (7°, 16°, 23°), (4°, 8°, 30°), and (0°, 0°, 41.5°) for the idealized monocapped octahedron, (L—L)$W(CO)_2I_2P(OCH_3)_3$, (L—L)$W(CO)Br_2[P(OCH_3)_3]_2$, and the idealized monocapped trigonal prism, respectively. The compound reported here is marginally better described as a distorted capped octahedron, while (L—L)$W(CO)Br_2[P(OCH_3)_3]_2$ is marginally better described as a monocapped trigonal prism (10).

These small differences are readily attributed to the lesser bulk of the second carbonyl group, which replaces a $P(OCH_3)_3$ ligand and the greater radius of I(1) which replaces Br(1) in (L—L)$W(CO)Br_2[P(OCH_3)_3]_2$.

In the capped octahedral description, the capping atom is the C(1) carbonyl group. In the capped trigonal prism description I(1) is the capping atom. In both compounds the bidentate ligand bridges an edge joining the capped trilateral face of the octahedron to the trilateral face formed by the remaining three ligands, and an edge of the capped quadrilateral face of the trigonal prism which joins the two trilateral faces of the prism.

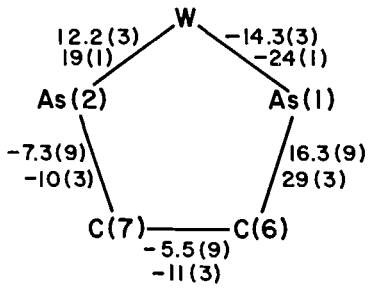

FIG. 3. Schematic diagram showing the torsional angles in the five-membered ring of the chelate ligand and their estimated standard deviations (in brackets) for the title compound (top numbers) and the related complex (L—L)W(CO)Br_2[$P(OCH_3)_3$]$_2$ (bottom numbers).

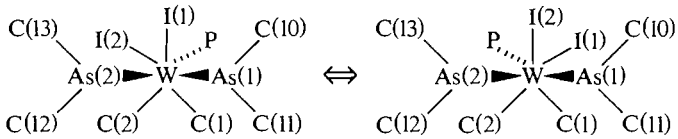

FIG. 4. Schematic diagram showing an enantiomeric inversion pathway for the molecule.

Kepert (16) reports this as the normal configuration for polyhedra with one bidentate ligand with a *bite* on the unit sphere greater than 1.20. The *bite* on the unit sphere for the iodine and bromine compounds are 1.23 and 1.25, respectively.

The stereochemistry of seven-coordinate complexes, in particular substituent site preferences, have been discussed by Hoffmann *et al.* (17). For d^4 cations containing molybdenum or tungsten, Hoffmann *et al.*, from considerations of bond energies, conclude that in the monocapped octahedron description, strong π-acceptors such as the carbonyl substituent will prefer to occupy the three vertices of the capped face over the capping vertex itself, with the three vertices of the uncapped face least preferred. However, from simple steric considerations ligands with a small radius, such as a carbon atom, should prefer vertices with a minimum number of neighboring vertices; i.e. the capping vertex would be most preferred and the vertices of the capped face least preferred.

Hoffmann *et al.* conclude that strong π-donors, such as the halides would prefer the vertices of the uncapped face of the monocapped octahedron. From simple steric considerations, these large ligands would be expected to occupy the vertices of the capped face, each of which has five neighboring vertices.

If we consider both polyhedra from the point of view of the monocapped trigonal prism, Hoffmann *et al.* conclude that the acceptors would prefer either the vertices of the quadrilaterally capped face or the vertices of the opposite edge over the vertex of the capping vertex. They conclude that the π-donors would prefer the capping vertex of the monocapped trigonal prism. From simple steric considerations, the vertices of the capped quadrilateral face would be preferred.

A detailed analysis of the stereochemistry of (L—L)W-$(CO)_2I_2P(OCH_3)_3$ and (L—L)W(CO)Br_2[$P(OCH_3)_3$]$_2$ from the point of view of the monocapped octahedron and from the point of view of the monocapped trigonal prism shows that it is generally consistent with these considerations, but when steric and bond energy preferences are in conflict it is not possible to predict which will prevail.

The puckering of the ring is qualitatively the same in both compounds, as shown in Fig. 3, but of lesser magnitude in the compound reported here. The ring puckering parameters, according to the method of Cremer and Pople (18), are $q = 0.26$ and $\phi = 10.1°$, compared to $q = 0.43$ and $\phi = 13.2°$ for (L—L)W(CO)Br_2[$P(OCH_3)_3$]$_2$. These parameters imply a moderate degree of puckering, intermediate between twist and envelope conformation. The greater degree of puckering in the bromine complex is primarily due to the greater bulk of the second phosphite group.

Significant shortening of the W—As bonds from a predicted value of 2.73 Å (4) to the experimental values of 2.556(1) and 2.606(1) Å is a result of double-bond character in the W—As bonds caused by $d\pi$–$d\pi$ back donation from the tungsten atom. The lengths of the two W—As bonds are also significantly different from each other which can be explained by a consideration of their respective *trans* ligands. The I(2) atom *trans* to As(1) is not as strong a $d\pi$ acceptor as the P atom *trans* to As(2), resulting in greater back donation to As(1). This results in a shortening of the W—As(1) bond compared to the W—As(2) bond, the difference being 0.050(2) Å.

Fluxional behavior of (L—L)W(CO)$_2$I$_2$P(OCH$_3$)$_3$

The observation of a single As—CH_3 resonance in the room temperature ^{1}H nmr spectrum of the title compound is not consistent with the structure in the solid state and this led us to variable-temperature nmr studies. The static structure consistent with the solid-state structure is frozen out at 216 K. The solid-state structure shows all four As—CH_3 groups to be chemically nonequivalent and thus four resonances are found at 2.09, 2.39, 2.97, and 3.09. As the temperature is increased, the four peaks broaden and coalesce into two peaks with coalescence temperatures of 218 K for the two lower field peaks and 224 K for the two higher field peaks; as the temperature is further increased the two peaks broaden and coalesce into a single peak with a coalescence temperature of 239 K. The single resonance line becomes very sharp at 298 K indicative of a fast-exchange limiting spectrum. Thus the ^{1}H nmr results suggest that there are two exchange processes occurring; one process which averages two pair of As—CH_3 groups (process 1) and another process which averages all four As—CH_3 groups (process 2). Using the relationships $k = \pi\Delta\nu/\sqrt{2}$ and $k = (k_BT/h)\exp(-\Delta G^{\ddagger}/RT)$ (19) values of $\Delta G^{\ddagger} = 46.6 \pm 0.3$ kJ mol^{-1} for process 1 and 48.3 ± 0.3 kJ mol^{-1} for process 2 are obtained.

There exists the possibility that the changes in the nmr spectra may be associated with only one process. We had hoped to obtain $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values using the value of $\Delta G^{\ddagger}$ calculated from the variable temperature ^{19}F nmr spectra. However, the ^{19}F nmr spectra showed further complications due to the presence of an A_3B_3 spin system at lower temperatures. We intend to pursue these phenomena by investigating other related seven-coordinate complexes using ^{1}H, ^{13}C, ^{19}F, and ^{31}P nmr spectroscopy.

If we assume the model involving two exchange processes for the related complex (L—L)W(CO)Br_2[$P(OCH_3)_3$]$_2$, there is only evidence for process 2. At room temperature two As—CH_3 resonances are observed which remain sharp at 223 K. Thus it was not possible to obtain a low-temperature slow-exchange limiting spectrum consistent with the solid-state structure. With increased temperatures the two resonances broaden, collapse, and coalesce into a single line with a coalescence temperature of

343 K. At the coalescence temperature a value of 70.8 kJ mol^{-1} for $\Delta G^{\ddagger}$ is obtained.[3]

Therefore, our proposed mechanism must account for the fact that process 2 occurs at a temperature approximately 80° higher in the bromo complex than in the iodo complex, and, given that in the bromo complex the two As—CH_3 resonances remain sharp down to 223 K, and give no indication of the onset of a transition at a lower temperature, process 1 occurs at a lower temperature in the bromo complex than in the iodo complex.

A seven-vertex polyhedron with the C_{2v} symmetry required to produce a single As—CH_3 resonance, and which is consistent with the stoichiometry of (L—L)$W(CO)_2I_2P(OCH_3)_3$ is the pentagonal bipyramid with the (L—L) ligand, the phosphite ligand and either the two iodine atoms or two carbonyl groups in the equatorial plane. The adoption of a C_{2v} pentagonal bipyramidal geometry at higher temperatures would involve a rearrangement, not a coalescence phenomenon such as that observed. Furthermore, the equatorial plane of a pentagonal bipyramid would seem to be unreasonably crowded.

Other explanations of the nmr spectra must involve equilibration of the As—CH_3 resonances through fluxional behavior of the remaining ligands. The mechanism must also explain the intermediate spectra which shows a doublet resonance.

Process 1, the transition to the intermediate state with an activation energy of 46.6 kJ mol^{-1} might involve a random scrambling of the atoms I(2), C(1), C(2), and P, leaving the atom I(1) rigidly held in the "pocket" of the chelate ring. This would equilibrate the atoms C(11) and C(12) as one pair and the atoms C(10) and C(13) as the other pair. Process 2, the coalescence to a single resonance, with an activation energy of 48.3 kJ mol^{-1} would then involve the addition of the atom I(1) to the random scrambling motion.

Alternatively, process 1 may involve a scrambling of the atoms I(1), I(2), C(1), C(2), and P that is not completely random. The doublet resonance state would exist if the scrambling motion did not permit an enantiomeric inversion. This would equilibrate the atoms C(10) and C(12) as one pair and the atoms C(11) and C(13) as the other pair. An enantiomeric inversion of the $W(CO)_2I_2P(OCH_3)_3$ portion of the molecule would then result in the coalescence of the nmr spectrum to one As—CH_3 resonance. Examination of Fig. 2 suggests that the enantiomeric inversion might be accomplished by a mirror operation on the atoms I(1), I(2), and the $P(OCH_3)_3$ group as illustrated in Fig. 4.

In both proposed models for the fluxional behavior process 2 might be expected to be controlled primarily by the overall degree of crowding of the ligands. Specifically, the presence of the extra phosphite ligand in the bromo complex forces the chelate ligand to enclose the Br(1) atom more completely in its pocket than is the I(1) atom enclosed in the iodo complex. This effect is evident in Fig. 2. It is also illustrated by the observation that the puckering parameter in the bromo complex is 1.65 times that for the iodo complex and the Br(1) atom is 2.60 Å from the W, As(1), As(2) plane compared to 2.81 Å for the I(1) atom. Therefore the activation energy for process 2 may be raised by the presence of the second phosphite group in the bromo complex, which restricts the motion of the halogen atom in the pocket of the chelate ring, either in a random scrambling or in a mirror inversion with the other halogen atom.

However, the greater radius of the iodine atom over that of the bromine atom would also contribute to the overall crowding of the complex and we would expect that in a complex with one phosphite and two bromine ligands, process 2 would occur at a lower temperature than in (L—L)$W(CO)_2I_2P(OCH_3)_3$. This expectation is consistent with results obtained for a related complex, (L—L)$Mo(CO)_2Br_2P(OCH_3)_3$ (9). Assuming a similar structure as the title compound, but with molybdenum replacing tungsten and bromine replacing iodine a single As—CH_3 resonance is observed at room temperature which remains sharp down to 193 K. The reason that process 1 occurs at a lower temperature in the bromo complex than in the iodo complex is not clear, but it presumably involves the relative radius of the halogen atoms.

We have tried unsuccessfully to synthesize the complex (L—L)$W(CO)I_2[P(OCH_3)_3]_2$ to compare its anticipated dynamic behavior to (L—L)$W(CO)Br_2[P(OCH_3)_3]_2$ and further illustrate the steric effect of the halogens.

[3]This value was obtained at a field strength of 60 MHz.

Phase diagram and heat of fusion of succinonitrile–phenanthrene system have been studied. Heat of mixing, entropy of fusion, and excess thermodynamic functions such as h^E, s^E, and g^E have also been calculated. The results have been explained on the basis of cluster formation and the interactions among the components forming the eutectic melt. Solid–liquid and liquid–liquid interfacial energies calculated from the heats of fusion of the pure components suggest the validity of Cahn wetting condition and predict the monotectic solidification morphology in the present system.

U. S. Rai, O. P. Singh et Narsingh B. Singh. Can. J. Chem. **65**, 2639 (1987).

On a étudié le diagramme de phase et la chaleur de combustion du système succinonitrile/anthracène. On a aussi calculé la chaleur de mélange, l'entropie de fusion et les fonctions thermodynamiques en excès. On explique les résultats en faisant appel à la formation d'agrégats et en faisant intervenir les interactions entre les composants qui forment un mélange eutectique. Les énergies interfaciales solide/liquide et liquide/liquide, calculées à partir des chaleurs de fusion des composants à l'état pur, suggèrent d'une part que la condition de mouillage de Cahn est valide et, de plus, elles prédisent la morphologie de solidification monotectique qu'on retrouve dans le présent système.

Introduction

In the recent past the chemistry of eutectic (1–3) and monotectic systems (4) has been a field of active investigation due to their unusual physical properties not normally shown by the parent components. The metallic eutectics constitute an interesting area of investigation in metallurgy and material science, but they require complicated experimental techniques. Due to low transformation temperature, ease in purification, transparency, and wider choice of material, organic eutectics have attracted the attention of a number of research groups (5–7). Apart from these, the small density difference of the two components forming the organic eutectics minimises the density-driven convection effects on solidification. Succinonitrile (SCN), a material of low entropy of fusion, simulates the metallic solidification and phenanthrene (Ph), a material of high entropy of fusion, simulates nonmetallic solidification. As such, the SCN–Ph system can be chosen as a suitable analogue of Al–Si (metal–nonmetal) system for direct observation on solidification. The results of linear velocity of crystallization, diffusion coefficient measurement, and microstructure of succinonitrile–phenanthrene system were reported by Singh and co-workers (8). In the present article the data on phase diagram, heats of fusion, and interfacial energy have been discussed in detail. Making use of the heats of fusion some excess thermodynamic functions such as g^E, s^E, and h^E and entropy of fusion and heat of mixing have been calculated. The results have been analysed in light of cluster formation and interactions among the components forming the eutectic melts. The interfacial energies which decide the mode of solidification of monotectic alloys have been calculated from the heats of fusion data.

Experimental

Phase diagram

The phase diagram of the SCN–Ph system was determined by thaw–melt method (9, 10). The mixtures of different compositions were prepared by weighing phenanthrene and succinonitrile in a long-necked test tube which was sealed before the melting of any of the components. The test tube was immersed in an oil bath to ensure complete melting. The test tube was taken out and shaken periodically to mix the liquids. At this state, we could find out that both liquids had a miscibility gap and the melting point of the mixture could not be determined by taking a small amount of solid mixtures as there was always the possibility of the heavier component settling down. The thaw temperature, melt temperature, and temperature of complete miscibility were observed by immersing the same sealed test tube in which the mixtures were prepared in a bath.

Heats of fusion

Heats of fusion for SCN, Ph, and their eutectic were determined using a Perkin-Elmer DSC-2 with computer-aided data requisition and analysis by differential scanning calorimeter. Whenever a transition such as melting, boiling, dehydration, or crystallization occurs in the sample material, an endothermic or exothermic reaction takes place. The change in power required to maintain the sample holder at the same temperature as that of the reference holder during transition is recorded from the peak obtained in the pattern. The chart abscissa indicates the transition temperature and the peak area indicates the total energy transfer to or from the sample. In the present system under investigation all runs were carried out with a range of 2 m cal s^{-1}, chart speed of 5 mm min^{-1}, and chart range of 10 mV. The heating rate was 1.25 K min^{-1} and the sample weight range was 5–10 mg for each estimation.

Interfacial energies

Solid–liquid and liquid–liquid interfacial energies are required to verify the theory of monotectic solidification in SCN–Ph system. Measurement of solid–liquid interface energy is extremely difficult and unfortunately, the reported data show wide variation. Only few workers like Glicksman *et al.* (11) and Jones and Hardy (12) have claimed suitable values which are well within 10% of total error. Fortunately, these values lie between the theoretically predicted values by Spapen (13). Glicksman has shown that solid–liquid interface energy is given by a fraction of the heat of fusion of the molecules on unit area of the surface. A similar method of calculation was adopted to obtain solid–liquid interface energies in the SCN–Ph system. Liquid–liquid interfacial energy was calculated by a method reported earlier (14).

Results

The enthalpy of fusion, the values of $\ln \gamma_i^l$ and $\partial \ln \gamma_i^l / \partial T$ at the eutectic temperature, the excess thermodynamic functions for the eutectic, the entropy of fusion of succinonitrile–phenan-

Discussion

Phase diagram

The phase diagram of the SCN–Ph system is shown in Fig. 1 which clearly shows that Ph forms a monotectic (0.225 mole fraction of SCN) and a eutectic (0.975 mole fraction of SCN). Monotectic (15) is another important three-phase reaction of the eutectic class in which one liquid phase decomposes with decreasing temperature into a solid phase and a new liquid phase

$$L_2 \rightleftharpoons S_2 + L_1$$

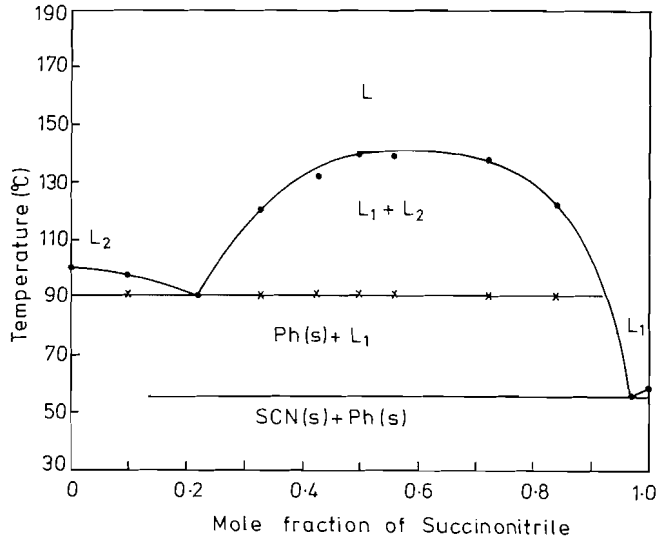

FIG. 1. Phase diagram of the SCN–Ph system.

Over a certain composition range, the two liquids are mutually immiscible and they constitute individual phases. The boundary of the $L_1 + L_2$ field is the limit of liquid immiscibility. The field of $L_1 + L_2$ may be regarded as being made up of an infinite number of tie-lines. The tie-lines connect the two liquid phases L_1 and L_2, the composition of each liquid phase varies with temperature. With increasing temperature the tie-lines become progressively shorter until the ultimate tie-line, at the top of the area, has zero length. This is known as critical point where the two liquid phases, having identical composition, become indistinguishable. The temperature corresponding to this point is known as consolute temperature and it is found to be 49°C above the monotectic horizontal in the SCN–Ph system. Above the critical temperature, there is complete miscibility in the liquid state, i.e., there is only one liquid phase called L in the entire composition range. At the invariant monotectic temperature L_2 (liquid rich in Ph), L_1 (liquid rich in SCN), and solid Ph are in equilibrium.

Thermochemical studies

The heats of fusion of pure components and eutectic are reported in Table 1. For the purpose of comparison, the heat of fusion of eutectic was calculated, using mixture law, and is given in the same table. In order to assess the nature of interaction between the components forming the eutectic melts, the activities of components and their excess thermodynamic functions were also calculated, and the results are given in the Tables 2 and 3, respectively.

(a) Heat of fusion of eutectic

If an eutectic is a simple mixture of two components, involving neither heat of mixing nor any type of association in the melt, heat of fusion may simply be given by the mixture law:

$$[1] \quad (\Delta_f h)_e = x_1 \Delta_f h_1^0 + x_2 \Delta_f h_2^0$$

where x and $\Delta_f h^0$ are mole fraction and heat of fusion, respectively, of the component indicated by the subscript. But when a solid eutectic melts, there is a considerable possibility of association and heat of mixing, both causing violation of the mixture law. Besides the heat of mixing, another factor, the interfacial tension, may also affect the magnitude of the heat of fusion. The comparison of the experimental value (vide Table 1) of heat of fusion with that calculated from eq. [1] indicates that the calculated value is lower than the experimental value. This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

difference may be attributed to the formation of a quasieutectic (16) structure of the eutectic melt. During cluster formation, there may be liberation of heat which will lower the actual value of the heat content of the eutectic. The cluster formation will be favoured due to the molecular association by certain weak intermolecular forces.

(b) Entropy of fusion and excess thermodynamic functions of eutectics

The deviation from ideal behaviour can best be expressed in terms of excess thermodynamic functions which gives the quantitative nature of molecular interactions. These functions are also of much use in the development of statistical theories based on fluid models. The difference between the thermodynamic function of mixing for a real system and the corresponding value for an ideal system at the same temperature and pressure is called excess thermodynamic function. This quantity represents the excess of a given thermodynamic property of the solution over that in the ideal solution and can be expressed as follows:

$$[2] \quad Y^{E} = \Delta Y_{mix}(\text{real}) - \Delta Y_{mix}(\text{ideal})$$

where Y can be taken as any of the thermodynamic functions.

Theoretical studies (17, 18) on the entropy of fusion and calculation of some excess thermodynamic functions of eutectics predict the structure, stability, and ordering in the eutectic melts. The excess thermodynamic functions and entropy of fusion of eutectics are given in Tables 3 and 4, respectively. The entropy of fusion, ΔS, has been calculated from the following relation:

$$[3] \quad \Delta S = \Delta_f h/T$$

where $\Delta_f h$ is the heat of fusion and T is the fusion temperature. The positive entropy of fusion in the system studied indicates an increase in the randomness of the system during melting.

To understand the nature of interaction between the components forming the eutectic, some thermodynamic functions such as the excess free energy, g^E, excess enthalpy of mixing, h^E, and excess entropy of mixing, s^E, have been calculated by the procedure below.

The eutectic temperature and composition can be determined from the phase diagram of a system. Using eutectic temperature and composition, one can calculate the excess thermodynamic function with eqs. [4] to [6].

$$[4] \quad g^{E} = RT(x_1 \ln \gamma_1^1 + x_2 \ln \gamma_2^1)$$

$$[5] \quad s^{E} = -R(x_1 \ln \gamma_1^1 + x_2 \ln \gamma_2^1 + x_1 T\frac{\partial \ln \gamma_1^1}{\partial T} + x_2 T\frac{\partial \ln \gamma_2^1}{\partial T}$$

$$[6] \quad h^{E} = -RT^2\left(x_1\frac{\partial \ln \gamma_1^1}{\partial T} + x_2\frac{\partial \ln \gamma_2^1}{\partial T}\right)$$

The activity coefficient, γ_i, of component i present in the system is given by

$$[7] \quad -\ln x_i^1\gamma_i^1 = \frac{\Delta_f h_i^0}{R}(T^{-1} - T_i^{0-1})$$

where x_i^1, γ_i^1, $\Delta_f h_i^0$, and T_i^0 are the mole fraction, activity coefficient, heat of fusion, and melting temperature of component i, respectively; R is the gas constant; and T is the melting temperature of the system. The values of $\partial \ln \gamma_i/\partial T$ can be determined by the slope of the liquidus curve in the phase diagram, using eq. [8] obtained after differentiating eq. [7].

$$[8] \quad x_i\frac{\partial \ln \gamma_i^1}{\partial T} = x_i\frac{\Delta_f h_i^0}{RT^2} - \frac{\partial x_i}{\partial T}$$

The liquidus curves in the phase diagram are virtually straight lines in the region of eutectic composition. The value of $\partial x_i/\partial T$ can be calculated as

$$[9] \quad x_i = \alpha + \beta T$$

where α and β are constants and $\beta = \partial x_i/\partial T$.

It is evident from the Table 3 that the value of excess thermodynamic functions are all negative. The value of excess free energy is a measure of the departure (19) of the system from ideal behaviour. Thus, it reveals some interaction among the components of the system in the present investigation. The negative value of excess enthalpy and excess entropy correspond to excess free energy, and are measures of excess enthalpy of mixing and excess entropy of mixing, respectively, and thereby suggest an appreciable interaction among the two components of the eutectic. Similar results were reported (20) in the case of *m*-aminophenol–pyrogallol system in which excess free energy, g^E, excess entropy, s^E, and excess enthalpy, h^E, are -478.0, -11.1, and $-1044.0\ \text{J mol}^{-1}$, respectively.

The activity coefficients of components 1 and 2 for the present system were computed from eq. [7] and are given in Table 2. In each case, the activity coefficient is not equal to unity and therefore it is not possible to predict the eutectic composition and temperature.

(c) Heat of mixing

The heat of mixing, ΔH_m, of a eutectic can be very easily calculated by following equation, and thereby an insight into the structure (21) of melt in binary eutectics may be obtained:

$$[10] \quad \Delta H_m = (\Delta_f h)_{exp} - \Sigma x_i \Delta_f h_i^0$$

where $(\Delta_f h)_{exp}$ is the heat of fusion of the system determined experimentally, x_i, and $\Delta_f h_i^0$ are the mole fraction and heat of fusion, respectively, for component i. The heat of mixing of eutectic in the present system was calculated using eq. [10] and was found to be 5.995 kJ/mol. In the present system, eutectic composition is far from equimolar composition and the enthalpy of mixing is reasonably high. The eutectic point is shifted towards the component of lower melting temperature. Recently, Singh and co-workers (16) have reported that eutectic composition is connected with enthalpy of mixing in a definite manner. This type of behaviour was observed by Zalkin (22, 23) in the metallic system and he explained the eutectic structure on the basis of colloidal theory. Thermochemical studies suggested that structure of eutectic melts depends on the sign and magnitude of enthalpy of mixing, ΔH_m. Based on the above observations, three different structures have been suggested; quasieutectic for $\Delta H_m > 0$, clustering of molecules for $\Delta H_m < 0$, and molecular solution for $\Delta H_m = 0$. The magnitude of enthalpy of mixing indirectly gives (24) an idea about the composition of eutectics in a system. In the present system, the value of ΔH_m is highly positive which suggests firstly that the eutectic is on one side of the phase diagram and there is miscibility gap in the system, and secondly that the structure is of quasieutectic type.

Interfacial energies

The influence of surface energy on monotectic solidification morphology is discussed in this section. In the last few years, several articles have been published (25, 26) which explain various interesting phenomena during the solidification of a monotectic alloy. Specifically, the role of wetting in a phase

separation process has been the subject of great discussion. The wetting (26) condition is given as:

$$[11] \quad \gamma_{SL_2} < \gamma_{SL_1} + \gamma_{L_1L_2}$$

where γ is the interface energy between the faces denoted by the subscripts. Two important views have been put forward: (*a*) if the minor component wets the wall of the container in preference to the major component, the separation is possible by capillarity because the minor component easily spreads on the wall of the container, (*b*) at the monotectic temperature, if there is perfect wetting, a film of the liquid of the first component intrudes between its own solid and liquid of the second. As the temperature goes below the critical temperature $\gamma_{L_1L_2}$ increases more rapidly than γ_{SL_2}. This increases the critical wetting condition. In case the critical wetting temperature is below the monotectic temperature, the liquid of the first component will intrude between the growing solid and liquid of the second component. This will tend to push the liquid ahead of the growth front with a force determined by the disjoining pressure.

In order to check the validity of Cahn (26) wetting condition and to predict the mode of solidification morphology, in the present system, the interfacial energies were calculated at the monotectic temperature and results are included in Table 5. It is evident from the numerical values of interfacial energies that Cahn's wetting condition given by eq. [11] is obeyed in the present system. If we apply the wetting idea, the Ph–SCN liquid wets the solidified Ph perfectly and SCN-rich droplets will be surrounded by the SCN–Ph liquid. In this situation there is the possibility of capillary instabilities (27). Accordingly, if the cell depths are greater than the droplet circumference, capillary instabilities will develop SCN droplets and they will pinch off into spheres, Ph-rich liquid solidifies behind these spheres afterwards. Repetition of this process produces a very well arranged array of spheres (8). At low growth rates, droplets will not have enough time to develop capillary instabilities. These SCN droplets get surrounded by solidified Ph in such a way that cylindrical rods of SCN freeze as the solidification proceeds further.

Bis(pentafluorophenyl)tellurium difluoride crystallizes, in the space group *Cc*, as a molecular solid in which pairs of crystallographically independent molecules are linked by two weak secondary Te···F interactions. ($C_{12}F_{12}Te$; a = 11.088(6), b = 20.040(10), c = 13.208(5); β = 109.07(4); U = 2774; Z = 8; fw = 499.7). The structural model was refined by full-matrix least-squares methods to a final residual of R_1 = 0.035 for 1621 observed reflections. The stereochemistry of the primary bonding about Te is ψ-trigonal bipyramidal as for other R_2TeX_2 species and is compared with that of diphenyltellurium difluoride. Differences in the stereochemistry of the primary bonding about tellurium can be attributed to the influence of the more electron-withdrawing C_6F_5 group, and relates to the different secondary bonding and the crystal packing. ^{125}Te nmr coupling constants, $J_{^{125}Te-^{19}F}$, are reported for this and two related compounds. Previous ^{125}Te Mössbauer data is discussed in the light of the structure.

J. ARAMINI, R. J. BATCHELOR, C. H. W. JONES, F. W. B. EINSTEIN et R. D. SHARMA. Can. J. Chem. **65**, 2643 (1987).

Le difluorure du bis(pentafluorophényl)tellure qui cristallise dans le dans le groupe d'espace *Cc* est un solide moléculaire dans lequel des paires de molécules qui sont cristallographiquement indépendantes sont liées par deux interactions Te···F secondaires et faibles. ($C_{12}F_{12}Fe$; a = 11,088(6), b = 20,040(10), c = 13,208(5); β = 109,07(4); U = 2774; Z = 8; fw = 499,7). On a affiné la structure par les méthodes des moindres carrés (matrice entière) jusqu'à une valeur finale de R_1 = 0,035 pour 1621 réflexions observées. La stéréochimie de la liaison primaire autour du Te est ψ-trigonale bipyramidale comme dans le cas des autres espèces R_2TeX_2 et elle se compare à celle du difluorure du diphényltellure. On peut attribuer les différences dans la stéréochimie de la liaison primaire autour du tellure à l'influence du groupement C_6F_5 qui est plus électroaffinitaire et on peut les relier à la liaison secondaire différente et à l'entassement du cristal. On rapporte les constantes de couplage, $J_{^{125}Te-^{19}F}$, de ce composé et de deux autres composés apparentés. En se basant sur la structure qui a été déterminée, on discute de données de Mössbauer du ^{125}Te qui ont été publiées antérieurement.

[Traduit par la revue]

Introduction

The diorganyltellurium dihalides R_2TeX_2, X = Cl, Br, or I, are found to occur as molecular solids in which some weak intermolecular secondary bonding takes place (1). The molecules have an irregular trigonal bipyramidal stereochemistry with *trans*-axial halogens. The only diorganotellurium difluoride whose structure has been reported previously is that of diphenyltellurium difluoride (2), which, like the other dihalides, exhibits a ψ-tbp stereochemistry. The other tellurium fluorides for which crystal structures have been determined are TeF_4 (3) and $C_2F_5TeF_3$ (4). These compounds crystallize as *cis*-μ-bridged infinite chain polymers having ψ-octahedral stereochemistry about tellurium.

In the present work we report the X-ray crystal structure of bis(pentafluorophenyltellurium difluoride), the first perfluorinated difluoride for which the structure has been determined. A recent ^{125}Te Mössbauer spectroscopic investigation (5) of $(C_6F_5)_2Te$ and its dihalides $(C_6F_5)_2TeX_2$, X = F, Cl, or Br, showed these compounds to have very different quadrupole splittings from the corresponding phenyl compounds and this could be interpreted as evidence for the greater electronegativity of the C_6F_5 ligand compared with C_6H_5. Alternatively, the Mössbauer data could be interpreted as evidence for a somewhat different coordination geometry about the tellurium in the perfluorinated compounds than that in the phenyl compounds and the determination of the X-ray crystal structure of $(C_6F_5)_2TeF_2$ was undertaken to resolve this question.

The ^{125}Te solution nmr spectra for $(C_6F_5)_2Te$ and its dihalides have also previously been studied and compared with those of the corresponding phenyl compounds (5). In the present paper we also report the ^{125}Te—^{19}F coupling constants for $(C_6F_5)_2TeF_2$, $(C_6H_5)_2TeF_2$, and $(C_6F_5)_2Te$ and these constants are discussed.

Experimental

Crystals of $(C_6F_5)_2TeF_2$ (5) were obtained from chloroform solution by slow evaporation of the solvent. Crystal data, acquisition, and refinement details are given in Table 1. Cell parameter determination and data acquisition were performed at 20°C using an Enraf-Nonius CAD-4F diffractometer and Mo K_α radiation, graphite monochromated. Standards were measured every hour of acquisition time and showed no systematic variation in intensity.

Data reduction, including Lorentz and polarization corrections, was applied to the raw data. No absorption correction was applied, which may result in possible errors of ±4% in F_{obs}. Systematic absences in the diffractometer data coincided with those for the space groups $C2/c$ and Cc. Intensity statistics favoured the choice of the non-centrosymmetric space group Cc. This choice was subsequently confirmed by the successfully refined structure.

The structural solution was arrived at by the heavy atom method using Patterson and Difference Fourier syntheses. Full-matrix least-squares refinement of 329 variables for 1621 observed reflections, included anisotropic thermal parameters for the Te and F atoms. The x and z coordinates of Te(1) were fixed to define the origin. Seven poorly centered, high angle reflections with poor agreement were excluded from the refinement. No extinction correction was deemed necessary.

The programs used for data reduction and structure refinement were from the NRC VAX Crystal Structure System (6) and used scattering factors and anomalous dispersion corrections for neutral atoms from International tables (7). Plots were generated by the program SNOOPI (8). The final positional and isotropic thermal parameters are given in Table 2. Tables of anisotropic thermal parameters and of calculated and observed structure factors and σ values for the 1628 observed reflections are deposited as supplementary information and are available upon request.[2]

ρ_{obsd} = 2.38 g cm^{-1} (floatation)	U = 2774 Å^3
ρ_{calcd} = 2.393 g cm^{-1}	μ(Mo K_α) = 22.83 cm^{-1}
Crystal dimensions (mm) 0.15 × 0.25 × 0.30	
Temperature = 20°C	
Radiation: Mo K_α, graphite monochromator, 0.71069 Å	
Scan mode: Ω-2θ	Max. 2θ: 45°
Scan width:[a] 0.85° + 0.35 tan θ	Reflections: 1806 (h, k, $\pm l$)
Scan speeds: 3.3–0.78° min^{-1}	1628 ($I \geq 2.5\sigma$)
	7 (rejected)
	Variables: 329
$R_f = \Sigma(\lvert F_o\rvert - \lvert F_c\rvert)/\Sigma\lvert F_o\rvert = 0.035$	
$R_{wf} - [\Sigma w(\lvert F_o\rvert - \lvert F_c\rvert)^2/\Sigma(wF_o^2)]^{1/2} = 0.046$	
$w = [\sigma^2(F) + 0.0002F^2]^{-1}$	
Maximum shift/error 0.01	Goodness of fit = 2.1[b]
Final difference: highest peak 0.86(10) e Å^{-3} 0.914(18) Å from Te(1)	

[a]Background intensities were measured by extending the scans by 25% of the scan width on either side.

[b]Goodness of fit = $\Sigma w(\lvert F_o\rvert - \lvert F_c\rvert)^2$/degrees of freedom.

The ^{125}Te nmr spectra were recorded on a Bruker WM400 spectrometer at 126.24 MHz and ambient temperature using the methods previously described (5). A sample spectrum showing the tellurium fluorine couplings is given in Fig. 2.

Results and discussion

The structure of bis(pentafluorophenyl)tellurium difluoride (Fig. 1) appears to be a molecular solid in which pairs of crystallographically independent molecules are mutually linked by secondary Te···F interactions. Each of the two independent molecules displays the approximate ψ-trigonal bipyramidal geometry typical of R_2TeX_2 species, having pseudo-*trans*-axial fluorine atoms while the pentafluorophenyl groups and, presumably, the formally non-bonding pair of electrons on tellurium occupy the equatorial plane. Each molecule is distorted from the ideal trigonal bipyramidal geometry because of the greater stereochemical influence of the non-bonding pair of electrons as evidenced by the F—Te—F and C—Te—C bond angles. These and other bond angles, as well as selected bond distances, are given in Table 3.

One other R_2TeF_2 crystal structure is known, that of diphenyltellurium difluoride (2). This structure and that of the title compound may be compared in terms of the bonding and geometry about tellurium. Both molecules of $(C_6F_5)_2TeF_2$ and that of $(C_6H_5)_2TeF_2$ display the usual ψ-trigonal bipyramidal geometry of R_2TeX_2 species. The primary Te—F bond lengths range from 1.932(11) to 1.990(11) Å for $(C_6F_5)_2TeF_2$, as compared to 2.006(2) Å for $(C_6H_5)_2TeF_2$. The Te—C distances are not significantly different in the two compounds; $(C_6F_5)_2TeF_2$, 2.064(16) to 2.157(19); $(C_6H_5)_2TeF_2$, 2.115(3) Å. The F—Te—F bond angles are more acute in the molecules of $(C_6F_5)_2TeF_2$, 164.0(5) and 161.5(5)°, than in $(C_6H_5)_2TeF_2$, 173.1(1)°, while the C—Te—C bond angles are more obtuse in $(C_6F_5)_2TeF_2$, 102.0(6)° and 104.1(6)°, as compared to 96.9(1)° for $(C_6H_5)_2TeF_2$. The average C—Te—F bond angle is 85.7° for $(C_6F_5)_2TeF_2$. All eight values which give rise to this average are smaller than the value for $(C_6H_5)_2TeF_2$, 87.6(1)°, seven of them significantly. The fact that the F—Te—F bond angle is smaller in $(C_6F_5)_2TeF_2$ than in $(C_6H_5)_2TeF_2$, together with the observation that the C—Te—C bond angle is larger, suggests that the non-bonding pair of electrons on tellurium has a larger stereochemical influence in $(C_6F_5)_2TeF_2$ than in $(C_6H_5)_2TeF_2$.

The above observations may be directly or indirectly attributable to the greater electron-withdrawing power of the C_6F_5 group compared to C_6H_5. The effect of crystal packing and secondary bonding forces and the interrelationship between these and the much stronger primary bonds in determining the net geometry about tellurium is, however, a moot point. In the structure of the title compound there are obvious correlations between secondary interactions and the primary bond lengths. In $(C_6F_5)_2TeF_2$ each tellurium atom has only one secondary contact to a fluorine on an adjacent molecule, whereas in $(C_6H_5)_2TeF_2$ each tellurium atom has two such interactions (symmetry equivalent). One feature of this is that in $(C_6H_5)_2TeF_2$ every fluorine atom is involved in a secondary interaction, though weak, 3.208(2) Å. In $(C_6F_5)_2TeF_2$, on the other hand, there are both Te—F···Te interactions as well as purely terminal Te—F bonds. The secondary Te···F interactions in $(C_6F_5)_2TeF_2$, 2.952(11) Å and 2.846(11) Å, are considerably shorter than that in $(C_6H_5)_2TeF_2$, although still quite weak (estimated bond valences 0.05 and 0.07).[3] This appears to be consistent with a possible correlation between secondary bond length and the number of such interactions to Te.

The primary Te—F bonds in $(C_6F_5)_2TeF_2$ range from 1.932(11) to 1.990(11) Å as compared to 2.006(2) Å in $(C_6H_5)_2TeF_2$. The variation in Te—F bonds, while crystallographically significant, does not appear to reflect chemical differences beyond the overall shortening on changing from C_6H_5 to C_6F_5 substituents.

The geometries and dimensions of the C_6F_5 groups are not significantly different from those previously reported (10).

[3]Bond valences calculated by the empirical method proposed by Brown and Altermatt (9). Using the same method a Te(IV)···F separation of 3.52 Å (the sum of the Van der Waals radii) corresponds to a bond valence of .011.

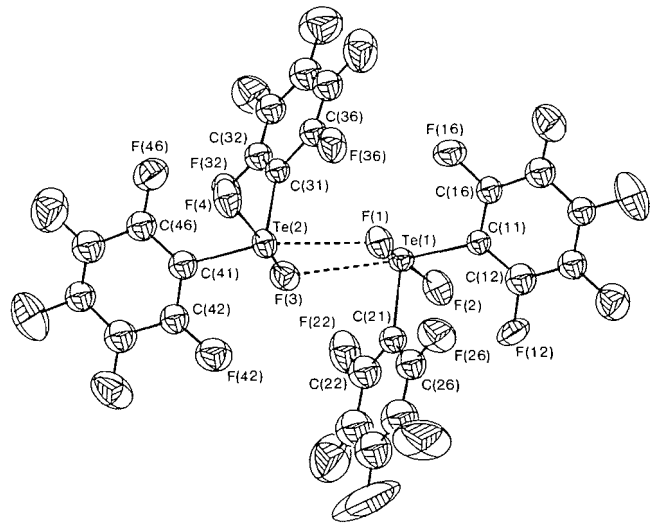

FIG. 1. Molecular structure of $(C_6F_5)_2TeF_2$.

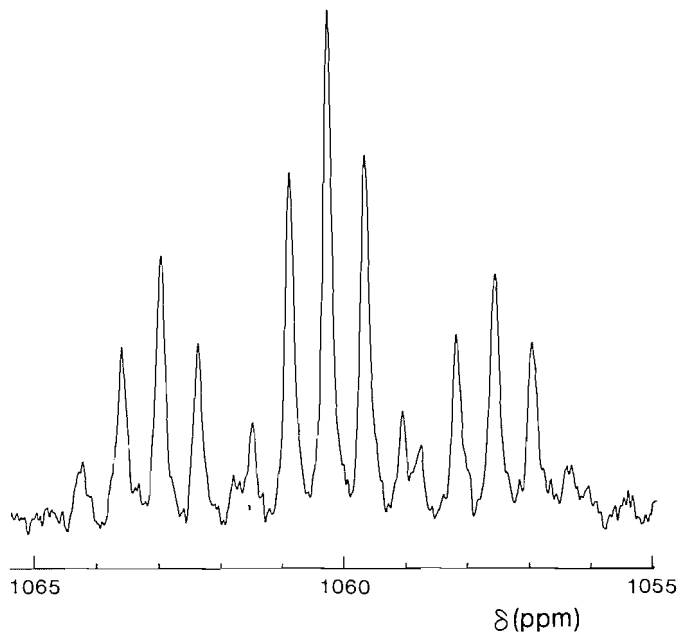

FIG. 2. ^{125}Te nmr spectrum of $(C_6F_5)_2TeF_2$ measured in $CDCl_3$ solution at ambient temperature.

Mössbauer data

With regard to the Mössbauer data, the ^{125}Te Mössbauer quadrupole splitting is smaller in $(C_6F_5)_2TeF_2$ (8.78(8) mm s^{-1}) than in $(C_6H_5)_2TeF_2$ (10.4(1) mm s^{-1}). If the non-bonding electrons were dominant in determining the magnitude of the quadrupole splitting in these compounds, i.e., if the principal component of the electric field gradient tensor was in the direction of the non-bonding pair, then we would have anticipated that the quadrupole coupling in $(C_6F_5)_2TeF_2$ would be larger than that in $(C_6H_5)_2TeF_2$, the non-bonding pair being more stereochemically active in the former than the latter. It appears then that the electric field gradient is not determined by the stereochemically active lone pair or the small changes in coordination about the tellurium but is in fact dominated by the difference in tellurium *p*-orbital populations between the axial Te—F bonds and the equatorial Te—C bonds. This difference must then be smaller in $(C_6F_5)_2TeF_2$ than in the diphenyl compound, presumably as a result of the difference in electronegativity of the C_6H_5- and C_6F_5-ligands, i.e., the more electronegative C_6F_5-ligand withdraws more electron density from tellurium in the equatorial plane than does C_6H_5- and $(C_6F_5)_2TeF_2$ yields a smaller Δ value.

The question as to the role that the tellurium non-bonding pair may play in determining the quadrupole couplings in Te(IV) compounds of the type R_2TeX_2 is one which has been difficult to answer. Because of the broad natural linewidth of the ^{125}Te Mössbauer transition and the small magnetic moments of the

nuclear states involved, it is not possible to determine the signs of the quadrupole coupling constants for ^{125}Te, a measurement which would clarify, for example, whether or not the principal component of the electric field gradient lies in the direction of the non-bonding pair. The X-ray structural data, together with the relative magnitudes of the quadrupole splittings, has answered this question for $(C_6H_5)_2TeF_2$ and $(C_6F_5)_2TeF_2$, following the arguments outlined above.

Nuclear magnetic resonance data

The ^{125}Te nmr chemical shifts for $(C_6F_5)_2TeF_2$ (1060 ppm) and $(C_6H_5)_2TeF_2$ (1125 ppm) are very similar. There are no alkyl- or aryltellurium(IV) fluorides with which to compare these shifts but they are similar to those of TeF_4 (1316 ppm) and TeF_3^+ (1381 ppm) (11) where the shifts are relative to neat Me_2Te. The Te(VI) phenyltellurium fluorides have shifts ranging from 659 ppm for $(C_6H_5)_2TeF_2$ to 805 ppm for $(C_6H_5)_2TeF_4$ (12), while in $Te(OTeF_5)_4$ the central Te(IV) has a shift of 1104 ppm and the ligand Te′(VI) a shift of 868 ppm (11) at 297 K. Assuming that that ^{125}Te nmr chemical shifts are dominated by the Ramsey paramagnetic shielding term, these trends correspond to less shielding at Te(IV) than at Te(VI).

The shifts for $(C_6F_5)_2TeX_2$ (X = F, Cl, Br) have been compared with those of $(C_6H_5)_2TeX_2$ in ref. 5, as have those of $(C_6F_5)_2Te$ and $(C_6H_5)_2Te$.

The $^1J_{^{125}Te—^{19}F}$ coupling constants observed for $(C_6F_5)_2TeF_2$

TABLE 4. ^{125}Te nmr data for $(C_6F_5)_2TeF_2$, $(C_6H_5)_2TeF_2$, and $(C_6F_5)_2Te$

Compound	δ^a (ppm)	$^1J_{^{125}Te-^{19}F}$ (Hz)	$^3J_{^{125}Te-^{19}F}$ (Hz)
$(C_6F_5)_2TeF_2$	1060.3	342	77
$(C_6H_5)_2TeF_2$	1125.1	548	
$(C_6F_5)_2Te$	298.0		50

[a] δ, measured in $CDCl_3$ solution with respect to neat Me_2Te at ambient temperature.

(342 Hz) and $(C_6H_5)_2TeF_2$ (548 Hz) are significantly smaller than those for TeF_3^+ (2905 Hz) or for $TeF_2(OTeF_5)_2$, where $^1J_{^{125}Te-^{19}F}$ = 2736 Hz and $^1J_{^{125}Te'-^{19}F}$ = 3724 (equatorial) or 3656 (axial) (11). In $(C_6H_5)_2TeF_4$ the corresponding coupling constant was 3000 Hz (12). These data can be understood assuming that the coupling constants are dominated by the Fermi contact term and hence the *s*-character in the Te—F bond. In $(C_6H_5)_2TeF_2$ and $(C_6F_5)_2TeF_2$ the axial F—Te—F linkage may be viewed as a $3c$—$2e$ bond in which a tellurium $5p$ orbital is dominant. This would be consistent with the relatively large Te—F bond length. The small $^1J_{^{125}Te-^{19}F}$ values would result from the small amount of *s*-character in the Te—F bonds. In comparison, for the other cases noted above a considerable amount of *s*-character would be anticipated in the Te—F bonds resulting in the much larger coupling constants.

However, the fact that $(C_6F_5)_2TeF_2$ has a smaller $^1J_{^{125}Te-^{19}F}$ coupling constant than $(C_6H_5)_2TeF_2$ is less readily rationalised. The F—Te—F bond angle is more acute in the former than the latter and the Te—F bond length is marginally smaller, suggesting a greater *s*-character in the Te—F bond.

The $^3J_{^{125}Te-^{19}F}$ coupling constants in $(C_6F_5)_2TeF_2$ (77 Hz) and $(C_6F_5)_2Te$ (50 Hz) are somewhat larger than those observed in $Te(OTeF_5)_4$ ($^3J_{^{125}Te-^{19}F}$ = 31.8 Hz) (11), reflecting a greater covalency and a greater *s*-character in the F—C—C—Te linkage. The Te—F coupling pattern observed in Fig. 2 reflects a 1:2:1 triplet, from the directly coupled axial fluorines, of 1:4:6:4:1 quintets arising from the three-bond coupling to the four equivalent fluorines of the pentafluorophenyl rings.

S. P. MALLELA, K. LEE, P. F. GEHRS, J. I. CHRISTENSEN, J. R. SAMS, and F. AUBKE. Can. J. Chem. **65**, 2649 (1987).

The synthesis of a series of hetero-bimetallic fluorosulfate bridged coordination polymers of the type $M(II)Sn(SO_3F)_6$, with M(II) = Mn, Fe, Co, Ni, or Cu, by interaction of the metal bisfluorosulfate with the strong fluorosulfate acceptor $Sn(SO_3F)_4$ in fluorosulfuric acid is described. Subsequent solvolysis of either stoichiometric 1:1 mixtures of $M(SO_3F)_2$ and $Sn(SO_3F)_4$ or the bimetallic polymer $M(II)Sn(IV)(SO_3F)_6$ in an excess of trifluoromethyl sulfuric acid affords the corresponding SO_3CF_3-bridged polymers of the composition $M(II)Sn(SO_3CF_3)_6$ with M(II) = Mn, Fe, Co, Ni, or Cu. The new compounds are characterized by infrared and ^{119}Sn Mössbauer spectroscopy.

S. P. MALLELA, K. LEE, P. F. GEHRS, J. I. CHRISTENSEN, J. R. SAMS et F. AUBKE. Can. J. Chem. **65**, 2649 (1987).

On décrit la synthèse d'une série de polymères de coordination pontés de fluorosulfates hétérobimétalliques du type $M(II)Sn(SO_3F)_6$, dans lesquels M(II) = Mn, Fe, Co, Ni ou Cu et qui sont produits par une interaction entre le bisfluorosulfate métallique et l'accepteur fluorosulfate puissant $Sn(SO_3F)_4$, dans l'acide fluorosulfurique. La solvolyse subséquente, soit des mélanges stoechiométriques 1:1 de $M(SO_3F)_2$ et $Sn(SO_3F)_4$ ou du polymère bimétallique $M(II)Sn(IV)(SO_3F)_6$, dans un excès d'acide trifluorométhylsulfurique conduit aux polymères pontés SO_3CF_3 correspondants, de composition $M(II)Sn(SO_3CF_3)_6$, dans lesquels M(II) = Mn, Fe, Co, Ni ou Cu. On a caractérisé les nouveaux produits par spectroscopies infrarouge et de Mössbauer du ^{119}Sn.

[Traduit par la revue]

Introduction

The first two examples of sulfonate bridged polymers of the type $M^{II}M^{IV}(SO_3X)_6$ with X = F or CF_3 were discovered and identified by us some time ago, $Sn(SO_3CF_3)_3$, where ^{119}Sn Mössbauer spectra suggested formulation as a mixed valency compound $Sn^{II}Sn^{IV}(SO_3CF_3)_6$ (2), and $Pd(SO_3F)_3$, with formulation as $Pd^{II}Pt^{IV}(SO_3F)_6$ based on magnetic susceptibility measurements (3).

Both compounds may be viewed as homo-bimetallic sulfonates with the metal in the 2+ and 4+ oxidation states. Subsequently the first hetero-bimetallic fluorosulfates, $Pd^{II}Pd^{IV}(SO_3F)_6$ and $Pd^{II}Sn^{IV}(SO_3F)_6$ (4), were obtained with identification relying again on magnetic susceptibility studies, ligand field and vibrational spectra. The ir spectra for the Pd(II)–Sn(IV) complex were distinctly different from those previously reported for salts of the type $M'_2[Sn(SO_3F)_6]$, with M' = K, Cs, NO, and ClO_2 (5), and an "aniso bidentate" bridging function of the fluorosulfate group, with strong bonding to Sn(IV) and weak coordination to Pd(II), producing an octahedral environment for both metallic centers was suggested (4). The polymeric nature was deduced from the lack of solubility in strongly ionizing HSO_3F, which is in contrast to high solubility and weakly basic behavior found for the $M'_2[Sn(SO_3F)_6]$ salts (5) as well as for $Ba[Pt(SO_3F)_6]$ (6).

The magnetic and spectroscopic study on the Pd^{II}—M^{IV} fluorosulfates and a parallel investigation of the corresponding silver(II) salts, $Ag^{II}Sn(SO_3F)_6$ and $Ag^{II}Pt(SO_3F)_6$ (6), suggested a magnetically dilute environment for the paramagnetic ions Ag^{2+} and more surprisingly Pd^{2+}, where an $^3A_{2g}$ ground state is rather uncommon and only encountered in PdF_3 (7–9) or related fluoro complexes. The study of Pd(II) fluorosulfate complexes suggested a closer approach to a bare Pd^{2+} ion for M^{IV} being Sn rather than Pt or Pd (4).

The objective then became to study a wider range of divalent metal ions in such a magnetically dilute environment produced by weakly coordinated fluorosulfate and trifluoromethyl sulfates. Metal ions from the 3*d* series became interesting because a number of detailed magnetic susceptibility studies on some of the divalent metal sulfonates such as $Co(SO_3F)_2$ (10), $Co(SO_3CF_3)_2$, $Cu(SO_3F)_2$ (11*a*), $Fe(SO_3F)_2$ (11*b*), and $Fe(SO_3CF_3)_2$ (11*c*) had been reported. An infrared study on a wide range of metal bisfluorosulfates (12) and a general synthetic route to such metal fluorosulfates via the solvolysis of the corresponding benzoates in HSO_3F (12) provided a good basis as well.

More recent work from our laboratory provided additional encouragement: metal oxidation by $S_2O_6F_2$ in HSO_3F as solvent represented a simple and facile general route to both $Sn(SO_3F)_4$ (13) and $Pt(SO_3F)_4$ (14), and the conversion of the more readily accessible fluorosulfates into the corresponding trifluoromethyl sulfates by solvolysis in excess HSO_3CF_3 was systematically explored (15). The preparation of one of the desired bimetallic polymers, $Mn^{II}Sn(SO_3CF_3)_6$, was quoted as an example (15). The general preparative route, SO_3X-abstraction (X = F or CF_3) by strong acceptors according to:

$$[1]\quad M^{II}(SO_3X)_2 + M^{IV}(SO_3X)_4 \xrightarrow{HSO_3X} M^{II}M^{IV}(SO_3X)_6$$

with M^{IV} = Sn or Pt and X = F or CF_3 had been explored most recently in attempts to stabilize the divalent cations Sn^{2+} and $(CH_3)_2Sn^{2+}$ in this manner (16). The potential of this general route had been demonstrated by the successful isolation of $HgSn(SO_3F)_6$, obtained from $Hg(SO_3F)_2$ (12, 17) and $Sn(SO_3F)_4$ (13, 18).

It was decided to use only $Sn(SO_3F)_4$ and $Sn(SO_3CF_3)_4$ as acceptors for the following reasons: (*i*) previous work discussed above (4, 6) had established $Sn(SO_3F)_4$ as a stronger acceptor than $Pt(SO_3F)_4$. (*ii*) ^{119}Sn Mössbauer spectra would allow us to monitor the abstraction reaction. (*iii*) The $Sn(SO_3X)_6$ moiety, X = F or CF_3, transparent in the visible – near ir region, would permit observation of ligand field bands in this region, while ligand-to-metal charge transfer bands are observed for platinum(IV) fluorosulfate complexes (14). (*iv*) The small but

measurable TIP (temperature independent paramagnetism) contributions found in otherwise diamagnetic Pt(IV) compounds (14) would require correction in a magnetic study. (*v*) Finally, only $Pt(SO_3F)_4$ appears to have been reported so far, but not $Pt(SO_3CF_3)_4$.

The present study reports the synthesis, analysis, ^{119}Sn Mössbauer spectra and infrared spectra for the complete series $M^{II}Sn^{IV}(SO_3X)_6$ where M^{II} = Mn, Fe, Co, Ni, and Cu, and X = F or CF_3. Extension to the corresponding Cr^{II} compounds is explored and additional synthetic routes are discussed.

Experimental

Metalfluorosulfates $M^{II}(SO_3F)_2$ (M = Mn, Fe, Co, Ni, and Cu) were prepared by solvolysis of the corresponding benzoates in HSO_3F and identified by their infrared spectra (12). The benzoates were obtained from Dr. R. C. Thompson of this Department, whose help is gratefully acknowledged. $Sn(SO_3F)_4$ was prepared as described earlier (13). Technical grade fluorosulfuric acid was doubly distilled at atmospheric pressure in a counter stream of dry nitrogen. Trifluoromethyl sulfuric acid (3M Co.) was freshly distilled from concentrated H_2SO_4 in a stream of dry nitrogen before each reaction.

A Perkin Elmer 598 grating infrared spectrophotometer was used with samples pressed between AgCl or AgBr windows (Harshaw Chemicals).

The ^{119}Sn Mössbauer spectra were recorded in transmission mode with a constant acceleration spectrometer of conventional design. Pulses were accumulated in a Tracor-Northern TN-1706 multichannel analyser, whence the data were transmitted via an IBM PC to the mainframe computer for curve fitting. The latter was accomplished using a standard non-linear regression programme with no constraints imposed on the fitting parameters (19). In every case, the spectra were satisfactorily fitted to a single Lorentzian line whose full width at half maximum did not exceed 1.34 mm s^{-1}. The Doppler velocity scale was calibrated using an iron foil absorber and ^{57}Co source. Isomer shifts are reported relative to $BaSnO_3$ at 77 K.

All reactions were performed in Pyrex reaction vials of about 40 mL capacity, fitted with Kontes Teflon stem valves and equipped with Teflon coated spin bars. Volatile materials were handled by using vacuum-line techniques. Solids were handled in a Vacuum Atmospheres Corp. Dri Lab, Model No. HE-43-2, filled with purified dry nitrogen and equipped with a Dri-Train Circulating unit, Model No. HE-92-B.

All reactions were followed by weight. Vacuum filtration of moisture-sensitive material was performed in an apparatus described by Shriver (20). Chemical analysis was carried out by Analytische Laboratorium, Gummersbach, West Germany. The carbon content was determined by Mr. P. Borda of this Department.

General procedure for the synthesis of M(II)[Sn(SO$_3$F)$_6$]

To an equimolar mixture of $M(II)(SO_3F)_2$ and $Sn(SO_3F)_4$ approximately 10 mL HSO_3F were distilled *in vacuo*. In no instance was complete dissolution of the fluorosulfates noted during reaction. The product isolation was accomplished by vacuum filtration and subsequent repeated washing with doubly distilled HSO_3F. The product was dried *in vacuo*, usually at ~40°C, and manipulated inside the dry box.

For the syntheses of compounds of the type $M(II)[Sn(SO_3CF_3)_6]$ two alternative approaches were used: The solvolysis of $M(II)[Sn(SO_3F)_6]$ in HSO_3CF_3 and the co-solvolysis of $M(II)(SO_3F)_2$ and $Sn(SO_3F)_4$ in HSO_3CF_3.

Details of this general reaction type have been reported earlier (15).

Individual preparations, specific details

(i) MnSn(SO$_3$F)$_6$: To $Mn(SO_3F)_2$ (336 mg, 1.33 mmol) and $Sn(SO_3F)_4$ (691 mg, 1.34 mmol) ~10 mL of HSO_3F were distilled. The reaction mixture was heated at 60°C for 5 days. The white hygroscopic product did not decompose or melt below 310°C.

(ii) CuSn(SO$_3$F)$_6$: To $Cu(SO_3F)_2$ (593 mg, 2.27 mmol) and (1167 mg, 2.27 mmol) $Sn(SO_3F)_4$ ~15 mL HSO_3F were distilled. The reaction mixture was heated to ~70°C for 6 days. The product was dried *in vacuo* at ~40°C for 2 days. The white hygroscopic product did not decompose or melt below 300°C.

(iii) NiSn(SO$_3$F)$_6$: $Ni(SO_3F)_2$ (333 mg, 1.296 mmol) were mixed with (668 mg, 1.297 mmol) $Sn(SO_3F)_4$ and ~15 mL HSO_3F were added. The reaction mixture was subsequently heated to ~60°C for 4 days. The yellow color of $Ni(SO_3F)_2$ changed to light yellow during the reaction. The product was dried *in vacuo* at 40°C for 2 days. The light yellow hygroscopic solid did not decompose or melt below 310°C.

(iv) CoSn(SO$_3$F)$_6$: To $Co(SO_3F)_2$ (375 mg, 1.46 mmol) and $Sn(SO_3F)_4$ (751 mg, 1.46 mmol) ~15 mL HSO_3F were distilled and the mixture kept for 2 days at room temperature. The purple color of $Co(SO_3F)_2$ gradually turned to light purple as the reaction proceeded. The light purple hygroscopic solid did not decompose or melt below 300°C.

(v) FeSn(SO$_3$F)$_6$: $Fe(SO_3F)_2$ (194 mg, 0.76 mmol) and $Sn(SO_3F)_4$ (393 mg, 0.76 mmol) were stirred in ~5 mL HSO_3F at 60°C for 7 days. The resulting white hygroscopic product turned to very light green at 265°C on heating.

(vi) FeSn(SO$_3$CF$_3$)$_6$: To $Fe(SO_3F)_2$ (641 mg, 2.52 mmol) and $Sn(SO_3F)_4$ (1229 mg, 2.52 mmol) ~15 mL of HSO_3CF_3 were distilled. The reaction mixture was then gradually heated to 70°C for 12 days. The hygroscopic solid did not decompose or melt below 330°C.

(vii) CoSn(SO$_3$CF$_3$)$_6$: $Co(SO_3F)_2$ (360 mg, 1.40 mmol) and $Sn(SO_3F)_4$ (721 mg, 1.40 mmol) plus 10 mL HSO_3CF_3 were gradually heated to 70°C for 11 days; the pink color of $Co(SO_3F)_2$ gradually turned to light pink during the reaction. The light pink product did not decompose or melt below 300°C.

(viii) NiSn(SO$_3$CF$_3$)$_6$: $Ni(SO_3F)_2$ 360 mg, (1.40 mmol) and 721 mg (1.40 mmol) of $Sn(SO_3F)_4$ were transferred into a reaction vial in the drybox. Excess (~10 mL) HSO_3CF_3 were distilled onto it and the resultant mixture was heated at 70°C for 10 days. The yellow color of $Ni(SO_3F)_2$ gradually turned to light yellow. The product was finally dried *in vacuo* at ~40° for 2 days. The light yellow, hygroscopic solid did not melt or decompose below 300°C.

(ix) CuSn(SO$_3$CF$_3$)$_6$: For method (*a*) 944.6 mg of $CuSn(SO_3F)_6$ were solvolysed in excess (10 mL) HSO_3CF_3 at 60°C for 8 days. The synthesis of $MnSn(SO_3CF_3)_6$ in a similar manner was reported previously (15) by this method. (*b*) To an equimolar mixture of $Cu(SO_3F)_2$ (395 mg, 1.51 mmol) and $Sn(SO_3F)_4$ (778 mg, 1.51 mmol) about 10 mL HSO_3CF_3 were distilled. Stirring was continued at ~60°C for 11 days. The white hygroscopic solid (1625 mg, 1.5 mmol) did not decompose or melt below 300°C.

Results and discussion

(a) Synthesis

The general synthetic route to the bimetallic fluorosulfates is in principle adopted from the reported preparations of $AgPt(SO_3F)_6$ (6), $PdPt(SO_3F)_6$ (4), and $PdSn(SO_3F)_6$ (4). There are important differences: $Pt(SO_3F)_4$ is sufficiently soluble to allow its dissolution in HSO_3F prior to reaction and there are distinct color changes, and precipitation, during the reaction which make it rather easy to judge its completion.

This is somewhat more difficult with $Sn(SO_3F)_4$. The bulk of the materials remain solid throughout and color changes as observed e.g., for the reaction of cobalt and nickel fluorosulfate are very subtle. These color changes are sufficient to reduce the reaction times for the preparations of $NiSn(SO_3F)_6$ and $CoSn(SO_3F)_6$ to 4 and 2 days, respectively. Heating to ~60–70°C is found to be advantageous.

Reaction times and conditions chosen for the remaining three preparations in the absence of any noticeable changes during the reactions are intended to allow completion of the abstraction reaction within a sufficiently large time limit.

The abstraction reaction with $Sn(SO_3F)_4$ as acceptor and $M(SO_3F)_2$ as donor may be viewed as an acid–base reaction in HSO_3F, in spite of the apparent lack of solubility of both reactants. However, for the reaction to occur at all, some limited

solubility of the two reactants at the reaction temperature is required.

An alternate, more convenient and direct route to bimetallic fluorosulfates, the simultaneous or successive oxidation of both metals by $S_2O_6F_2$, exemplified by the preparation of $AgSn(SO_3F)_6$ (6):

$$[2]\quad Ag + Sn + 3S_2O_6F_2 \xrightarrow{HSO_3F} AgSn(SO_3F)_6$$

is not feasible on two accounts: (*i*) tin is oxidized within 12 h at room temperature (13), however, the transition metals are found to react either not at all or extremely slowly and often only incompletely, even at elevated temperatures, and (*ii*) some of all five *d*-block metals may possibly be partly oxidized beyond the 2+ oxidation state. Recently the synthesis of $Mn(SO_3F)_3$ by metal oxidation has been reported (21).

Some effort has been expended to include $CrSn(SO_3F)_6$ in this study. However, the solid product of the reaction between $Cr(SO_3F)_2$ and $Sn(SO_3F)_4$ has been found to contain only small amounts of tin(II) and tin(IV) according to its Mössbauer spectrum. The bulk was identified as $Cr(SO_3F)_3$ by its infrared spectrum (22). It is suggested that oxidation of $Cr(SO_3F)_2$ rather than complexation, has occurred according to:

$$[3]\quad 2Cr(SO_3F)_2 + Sn(SO_3F)_4 \xrightarrow{HSO_3F} 2Cr(SO_3F)_3 + Sn(SO_3F)_2$$

with the reduced product $Sn(SO_3F)_2$ fairly soluble in HSO_3F (16).

This result is not surprising. Of the reduction potentials ϵ^0 (23) in aqueous medium for the M^{2+}/M^{3+} couples, with M ranging from Cr to Cu in the 3*d* series, only the ϵ^0 value for Cr^{2+}/Cr^{3+}, +0.41 V is positive, and hence oxidation of Cr^{2+} by Sn(IV) is likely. Redox potentials ϵ^0 are strictly valid in aqueous medium only, but our observation points to a comparable situation in HSO_3F, favoring oxidation over complexation for Cr^{2+} only.

The Mössbauer data, summarized in Table 2 and to be discussed later, provide the most unambiguous evidence for a successful complexation. Analytical data, listed in Table 1, confirm the suggested overall composition and are valuable because they rule out unexpected side reactions, such as hydrolysis or partial product decomposition. The thermal behaviour of the fluorosulfato complexes is inconsistent with the presence of mere mixtures of the starting materials. Polymeric $Sn(SO_3F)_4$ is found to have rather sharp decomposition points at +196°C (13) or +216°C (18), depending on the method of preparation used. None of the reaction products melt or decompose below 300°C.

Conversion of the $MSn(SO_3F)_6$ compounds into the corresponding trifluoromethyl sulfates proceeds for the most part very cleanly and completely as is evident from the analytical data in Table 1. Only in the case of $NiSn(SO_3CF)_6$ do the analytical data indicate an incomplete conversion, even after prolonged reaction times and a reaction temperature of 70°C. A similar situation was found previously for polymeric $Hg(SO_3F)_2$ (15). It is not immediately obvious why $NiSn(SO_3F)_6$ should be so difficult to convert to the corresponding SO_3CF_3 compound. It appears to make very little difference whether a stoichiometric mixture of $M(SO_3F)_2$ and $Sn(SO_3F)_4$ or the bimetallic $MSn(SO_3F)_6$ are used as starting materials as exemplified by two different preparations of $CuSn(SO_3CF_3)_6$.

The reason for a complete conversion is seen in a degradation of HSO_3F, initially formed in the solvolysis reaction, by an excess of HSO_3CF_3 to form a number of fairly volatile products such as CO_2, COF_2, SO_2, CF_3SO_3F, $CF_3SO_3CF_3$, and SiF_4 which seemingly do not interfere in the product isolation. However, the formation of SiF_4, a secondary product from the reaction of HF with glass, suggests the formation of water as well. It is therefore not surprising that in products of the conversion reaction, micro analysis and ir spectra will indicate the presence of variable amounts of water in the trifluoromethyl sulfates obtained, and careful drying *in vacuo* at ~40°C is needed.

The evolution of volatile by-products during the conversion reaction results in a rather slight pressure increase over the reaction mixture, insufficient to reliably estimate when a reaction is complete. As a precaution rather long reaction times of up to 12 days are chosen with reaction temperatures usually at ~70°C.

The resulting products, like their SO_3F counterparts, are seemingly insoluble in the parent acid and are usually stable at least up to 300°C. For polymeric $Sn(SO_3CF_3)_4$, depending on the method of preparation lower melting points, 225–227°C (2) and 235°C (15), respectively, are reported.

In summary, it appears that the general synthetic routes described here can be extended to a wider range of bimetallic polymers of the general type $M^{II}M^{IV}(SO_3X)_6$ with X = F or CF_3 than had been reported previously (2–4, 6, 16). The synthetic approach is successful as long as the $M(SO_3X)_2$ precursors are readily obtainable and will not reduce the M^{IV} species. Besides the reduction of Sn^{IV} by Cr^{II} described here, we have previously noted a similar redox-reaction between Sn^{II} and Pt^{IV} (16).

Infrared spectra

The infrared spectra obtained on solid films pressed between AgCl or occasionally AgBr windows resulted in rather broad bands. The band positions are tabulated for $M^{II}Sn(SO_3F)_6$ in Table 3 and for $M^{II}Sn(SO_3CF_3)_6$ in Table 4, together with an approximate band description for the fluorosulfates. The spectra of the fluorosulfate complexes are less complicated than those of their trifluoromethyl sulfate analogues and permit comparison with published data on $PdSn(SO_3F)_6$ (4), $AgSn(SO_3F)_6$ (6) and the ionic salts $K_2[Sn(SO_3F)_6]$ (5).

Comparison to published infrared data for either $Sn(SO_3F)_4$ (18) or $M(SO_3F)_2$ (12) with M = Fe, Co, or Ni is difficult even for the fluorosulfates, due to the complex spectra obtained. However, both the positions of the band centers and the band intensities differ markedly in the SO_3-stretching range; e.g. very strong bands at 1260 cm^{-1} and strong sharp bands at 1120 cm^{-1} noted for $M(SO_3F)_2$ (12) are absent in the spectra reported here or are slightly shifted and of very low intensity. The band center at ~1400 cm^{-1} of the rather intense SO_3 stretch of highest frequency differs also from the reported strong band at 1438 cm^{-1} in the infrared spectrum of $Sn(SO_3F)_4$. Additional but admittedly subtle differences are also noted in the SF-stretching range, while the rather narrowly spaced deformation modes provide little useful information in this regard.

For all bimetallic fluorosulfate stannates, the bands due to the three expected S—O stretching vibrations are found at ~1400, ~1200, and ~1025 cm^{-1} with little variations noted for the five new complexes. Pronounced band-splittings of 10 to 20 cm^{-1} are observed only for $CuSn(SO_3F)_6$ and appear to be caused by a distorted environment around the Cu^{2+} ion. Even more pronounced splitting of the three fundamentals are reported for $AgSn(SO_3F)_6$ (6), and even ν_{SF} shows a splitting of 30 cm^{-1} for this compound. Assuming the distortions to be due to the Jahn–Teller effect in both instances, this effect is more pronounced for Ag^{2+}.

Additional, weaker band features in the SO_3 stretching region at ~1270, ~1150, and ~1105 cm^{-1} are common to all five new complexes and found for $PdSn(SO_3F)_6$ (3) as well, but are not observed for $K_2[Sn(SO_3F)_6]$ (5) or $Ba[Sn(SO_3F)_6]$ (16).

Spectral features found for the ionic hexakis (fluorosulfato) stannates, which differ from the spectra of the bimetallic polymers are briefly summarized: (*i*) the observed spectra are considerably simpler, (*ii*) principle bands in the SO_3F stretching region are shifted to lower frequencies by ~20 to 30 cm^{-1}, and (*iii*) a skeletal ν_{SnO} at 620 cm^{-1} is unsplit and a SO_3F wagging mode at ~455 is absent.

The features found for the bimetallic polymers are consistent with monodentate —OSO_2F groups, strongly bonded to tin and coordinated more weakly to M^{2+} through a second oxygen, where M is a transition metal. This bonding type has been described previously as "aniso bidentate bridging" (4, 16).

The general impression that band positions, intensities, and shapes for the bimetallic fluorosulfate complexes are relatively independent of the divalent cation, with distortions around M^{2+} barely detectable, is reinforced by the infrared spectra for the series $M^{II}Sn(SO_3CF_3)_6$ listed in Table 4. For the mixed valency compound $Sn^{II}Sn^{IV}(SO_3CF_3)_6$ (2) a similar band pattern is reported, some small frequency shifts not withstanding. Incomplete conversion to $NiSn(SO_3CF_3)_6$ suggested by the analytical data is not evident from the infrared data, which compare well with those for the other compounds. Band splittings due to Jahn–Teller distortions of the Cu^{2+} ion as had been found for $CuSn(SO_3F)_6$, but are not observed for the SO_3CF_3 analogue. This is presumed to be due to both extensive vibrational mixing between SO_3 and CF_3 modes and the near coincidence of their bands, which results in greater complexity and makes it more difficult to detect possible distortions reflected in the SO_3 vibrations around Cu^{2+}.

A detailed band description is rather problematic on account of this vibrational mixing and only a few tentative suggestions are made. It appears reasonable in view of assignments proposed for the SO_3F-series, to attribute three band features at 1370–1360, ~1200, and 980–960 cm^{-1} to the three SO_3 stretching modes, shifted by ~10 to ~40 cm^{-1} to lower frequencies for the SO_3CF_3 compounds, which would imply a similar coordination mode for the sulfonate groups. From this follows assignment of bands at ~1230, 1120, and ~1070 cm^{-1} as primarily caused by CF_3 stretching vibrations.

A rather sharp medium intensity band at 775 cm^{-1} is found in all spectra. This band is strongly Raman active (2, 15) and found in a very narrow frequency range for SO_3CF_3 compounds. Not surprisingly, bands at 640–630 cm^{-1}, attributed predominantly to Sn—O skeletal vibrations, are found for both series of compounds in the same frequency range with rather similar band shapes and relative intensities.

All these features point to a strong structural similarity between the two series of compounds. Due to the spectral complexity of the SO_3CF_3 vibrations, it is not quite as easy as had been for the fluorosulfates to differentiate between true compounds and mere mixtures, but a careful comparison to ir spectra of previously (2) and recently (15) reported Sn^{IV}—SO_3CF_3 derivatives reveals several differences both in band position and intensity patterns.

^{119}Sn Mössbauer spectra

In previous ^{119}Mössbauer spectra studies of hexakis(fluorosulfato)stannate(IV) derivatives $R_2[Sn(SO_3F)_6]$ with monovalent cations ($R = K^+, Cs^+, NO^+, ClO_2^+, Br(SO_3F)_2^+$) (1, 5) single-line absorptions with $\delta = -0.27 \pm 0.04$ mm s^{-1} (at ~80 K, relative to $BaSnO_3$) and line widths from 1.1 to 1.4 mm s^{-1} have been observed. These results were interpreted (5, 22) as indicating a regular, or nearly regular, octahedral environment about tin(IV). The corresponding $M[Sn(SO_3F)_6]$ salts with the divalent cations $M = Hg^{2+}, Sn^{2+}, Ba^{2+}, Pd^{2+}$ were also found (4, 16) to exhibit unsplit resonances with isomer shifts again in the region of -0.27 mm s^{-1}. In all instances where $Sn(SO_3F)_4$ was used as starting material, its doublet with $\Delta E_a = 1.34$ mm s^{-1} (18) had collapsed to a single line on complexation.

On the other hand, the ^{119}Sn Mössbauer spectrum of $Ag[Sn(SO_3F)_6]$ exhibits (6) a quadrupole splitting of 0.53 mm s^{-1} and a slightly more positive isomer shift of -0.21 mm s^{-1}. Two reasonable explanations of the distorted environment of tin in this complex are (*i*) diminished ionic character due to the strongly polarizing Ag^{2+} ion, and (*ii*) a Jahn–Teller distortion of the Ag^{2+} ion transmitted to tin via bridging fluorosulfate groups. Either of these effects would be consistent with the more positive isomer shift, but comparison with $Hg[Sn(SO_3F)_6]$, where the small Hg^{2+} ion is also strongly polarizing and which shows a narrow single-line absorption, suggests that the quadrupole splitting in the silver complex is most likely a result of Jahn–Teller distortion of the Ag^{2+} ion (6).

The present results (Table 2) for the 3*d* transition metal derivatives $M[Sn(SO_3F)_6]$ and $M[Sn(SO_3CF_3)_6]$ (M = Mn, Fe, Co, Ni, Cu) are interesting in that in every case the ^{119}Sn Mössbauer spectrum consists of a single line of width 1.06–1.33 mm s^{-1}. We might well have expected to observe quadrupole splitting in the two Cu^{2+} complexes arising from Jahn–Teller distortion of the d^9 cations. However, neither the line widths nor the isomer shifts are exceptional for the copper salts, and it seems that any distortion due to the Jahn–Teller effect is not being effectively relayed to the tin site via bridging sulfonate groups. Another possibility is that of a dynamic Jahn–Teller distortion that is too rapid to be observed on the Mössbauer time scale.

In neither the $M[Sn(SO_3F)_6]$ nor the $M[Sn(SO_3CF_3)_6]$ series of compounds is there a discernible trend in either isomer shift or line width as the electronic configuration of the cations changes from d^5 to d^9. In each series the isomer shifts are identical within experimental error, although on average the values for the trifluoromethyl sulfates are approximately 0.02–0.03 mm s^{-1} more positive than those for the fluorosulfates. This difference is barely large enough to be significant, but is consistent with previously reported isomer shift differences in the following pairs of complexes where X = F, CF_3: $Sn(SO_3X)_4$ (2), $Sn[Sn(SO_3X)_6]$ (anionic species (16)), and $(CH_3)_2Sn[Sn(SO_3X)_6]$ (anionic species (16)). If these differences are indeed genuine, they indicate a very slightly more positive effective nuclear charge on tin in the fluorosulfate derivatives.

Finally, it should be noted that all the new derivatives show weak but resolvable Mössbauer spectra at room temperature. This fact presumably reflects the bridging function of the SO_3X^- (X = F, CF_3) moieties and significant covalent cation–anion interactions, without however, causing more than a minor perturbation of the near-spherical charge distribution at tin in the anions.

Conclusions

Metal bis(fluorosulfates), $M(SO_3F)_2$ with M = Mn, Fe, Co, Ni, or Cu react with $Sn(SO_3F)_4$ in fluorosulfuric acid at

reaction temperatures of 25 to 70°C to give bimetallic coordination polymers. Solvolysis of these SO_3F-containing polymers in trifluoromethylsulfuric acid leads to the corresponding $MSn(SO_3CF_3)_6$ compounds.

Characterisation is based on chemical analysis, vibrational spectra, and on single line ^{119}Sn Mössbauer spectra at 298 and 80 K. A common structural type, involving octahedral environments for both tin and the transition metal ion is suggested in all instances except for possible Jahn–Teller distortions for Cu^{2+}. The suggested anisobidentate bridging mode for the fluorosulfate group — strong oxygen bonding to tin and weak coordination to M^{2+} — should provide a magnetically dilute environment for the paramagnetic M^{2+} ions and a detailed magnetic study involving both sets of compounds is presently underway.

Acknowledgements

Financial support by the Natural Sciences and Engineering Research Council of Canada in the form of operating grants (to J.R.S. and F.A.) and summer student scholarships (to P.F.G. and K.L.) is most gratefully acknowledged. We are thankful to Mrs. L. Sallos for recording the Mössbauer spectra, Mr. P. Borda for chemical analysis (carbon) and great patience, and to Professor R. C. Thompson for many helpful discussions.

Interactions between cations and sugars. III. Free energies, enthalpies, and entropies of association of Ca^{2+}, Sr^{2+}, Ba^{2+}, La^{3+}, Gd^{3+} with D-ribose in water at 25°C

ALFREDO MAESTRE ALVAREZ,[1] NICOLE MOREL-DESROSIERS, AND JEAN-PIERRE MOREL[2]

Laboratoire d'Etude des Interactions Solutés–Solvants, U.A. au C.N.R.S. n° 434, Université de Clermont-Ferrand 2, 63170 Aubière, France

Received March 3, 1987

ALFREDO MAESTRE ALVAREZ, NICOLE MOREL-DESROSIERS, and JEAN-PIERRE MOREL. Can. J. Chem. **65**, 2656 (1987).

The standard enthalpies of transfer of ribose and arabinose from water to aqueous solutions of electrolytes ($CaCl_2$, $SrCl_2$, $BaCl_2$, $LaCl_3$, and $GdCl_3$) have been measured at 25°C. A method is described to calculate from these data the equilibrium constant and the enthalpy for the association between the cations and the complexing isomers of ribose. Mean values relative to these isomers are given: the constants vary from 2.0 to 4.3 and the enthalpies from −5.9 to −17.9 kJ mol^{-1} for the different cations studied. The thermodynamic properties of association are not related to the size nor to the charge of the complexed cation in a simple way. On the other hand, the enthalpies of reaction are linearly correlated to the entropies of reaction.

ALFREDO MAESTRE ALVAREZ, NICOLE MOREL-DESROSIERS et JEAN-PIERRE MOREL. Can. J. Chem. **65**, 2656 (1987).

Les enthalpies standard de transfert du ribose et de l'arabinose entre l'eau et les solutions aqueuses d'électrolytes ($CaCl_2$, $SrCl_2$, $BaCl_2$, $LaCl_3$ et $GdCl_3$) sont mesurées à 25°C. Une méthode est décrite qui permet, à partir de ces grandeurs, de calculer la constante d'équilibre et l'enthalpie de la réaction d'association entre les cations et les formes isomères complexantes du ribose. Des valeurs moyennes relatives à ces isomères sont données (les constantes varient de 2,0 à 4,3 et les enthalpies de −5,9 à −17,9 kJ mol^{-1}) pour les différents cations étudiés. Les grandeurs thermodynamiques de la réaction d'association ne sont pas reliées de façon claire à la taille ou à la charge du cation complexé. Cependant, pour la série des cations étudiés, il existe une corrélation linéaire de pente unité entre les enthalpies et les entropies de réaction.

Introduction

Recently, we have reported the thermodynamic properties characterizing the reaction of association of the cation Ca^{2+} with the suitably positioned sequences of hydroxyls of ribose in aqueous solutions (1, 2). Values of the constant of this equilibrium, mainly determined by nmr data, had already been proposed (3–5). Our value (1) was evaluated from the electrochemically measured free energies of transfer of $CaCl_2$ from water to aqueous solutions of ribose and arabinose (taken as the reference pentose which characterizes the non-specific interactions between the sugar and the electrolyte). By using a liquid membrane electrode selective to Ca^{2+} ions (ORION 93-20) it was possible to perform very sensitive emf measurements and the results obtained showed to be in satisfactory agreement with those published previously (4, 6).

To have a better understanding of the association process between the cations and the complexing sequences of hydroxyls (*axial–equatorial–axial* for the pyranose forms and *cis–cis* for the furanose forms), we felt it was necessary to study the association of ribose with other cations. It is known, for instance, that the other alkaline-earth cations (3, 7) and some trivalent cations like La^{3+} (4, 7, 8) are notably associated with ribose or other sugars and derived species in aqueous solutions. Unfortunately, our potentiometric method cannot be used with these species because of the lack of sensitive selective electrodes; in particular, some attempts with a liquid membrane electrode selective to divalent cations (ORION 93-32) have shown that the electrode is not sufficiently sensitive and that the results are not reproducible (the involved emf are of the order of a few mV and should be known to better than 0.05 mV). On the other hand, it is known that some calorimetric methods can lead simultaneously to the association constant and to the enthalpy of reaction. We have thus tried to apply such a method to the determination of the free energies and enthalpies of association of ribose and arabinose with Ca^{2+} (for which we have comparative results and can thus check the validity of the method), Sr^{2+}, Ba^{2+}, La^{3+}, and Gd^{3+} in aqueous solutions at 25°C.

Theoretical relations

The standard enthalpy of transfer of a sugar S at infinite dilution from water to a solution of electrolyte E at molality m_E corresponds to the difference between the enthalpies of dilution of a concentrated solution of the sugar in water and in the electrolytic solution (2)

$$[1] \quad \Delta_t H_S^\theta(m_E) = \Delta_{dil} H_S(m_S, m_E) - \Delta_{dil} H_S(m_S)$$

The final concentration in sugar, m_S, must be the same for both dilution processes and sufficiently low. This enthalpy of transfer can be expressed as a power series in concentration of the electrolyte (2)

$$[2] \quad \Delta_t H_S^\theta(m_E) = 2\nu h_{SE} m_E + 3\nu^2 h_{SEE} m_E^2 + \ldots$$

where h_{SE}, h_{SEE}, ... are parameters characteristic of the pair, triplet, and higher-order interactions between the sugar and the electrolyte and ν is the number of ions into which E dissociates. Similarly, the standard enthalpy of transfer of the electrolyte E from water to the solution of sugar at molality m_S can be written

$$[3] \quad \Delta_t H_E^\theta(m_S) = \Delta_{dil} H_E(m_E, m_S) - \Delta_{dil} H_E(m_E) = 2\nu h_{SE} m_S + 3\nu h_{SSE} m_S^2 + \ldots$$

with the following correspondence

$$[4] \quad \left(\frac{\partial \Delta_t H_E^\theta}{\partial m_S}\right)_{m_S=0} = \left(\frac{\partial \Delta_t H_S^\theta}{\partial m_E}\right)_{m_E=0} = 2\nu h_{SE}$$

The pair interaction parameter h_{SE} is a mean parameter characterizing the interactions between all the sugar-ion pairs. For an electrolyte like $CaCl_2$, for instance, $\nu = 3$ and it follows that

$$[5] \quad 3h_{SE} = h_{SCa^{2+}} + 2h_{SCl^-}$$

[1]On leave of absence from the Facultad de Farmacia, Universidad de Sevilla, España.

For personal use only.

By comparing ribose (R), which can interact specifically with Ca^{2+} through the suitably positioned sequences of hydroxyls, with arabinose (A), which is taken as the reference pentose since it does not show specific interactions with this cation, we get (1)

$$[6] \quad 2\nu(h_{RE} - h_{AE}) = 2h_{RCa^{2+}}$$

where $h_{RCa^{2+}}$ characterizes only the specific interaction between Ca^{2+} and ribose. The point particularly interesting is that the pair interaction parameters are related to the thermodynamic properties of association (1, 2, 9). For instance, the parameters relative to the pair RCa^{2+} are related to the properties of the reaction

$$[7] \quad R_{(aq)} + Ca^{2+}{}_{(aq)} = RCa^{2+}{}_{(aq)}$$

characterized by the equilibrium constant β_1. It can be shown (1, 9) that the pair interaction parameter relative to the free energy, $g_{RCa^{2+}}$, that we have measured in a previous work (1) corresponds to

$$[8] \quad -2g_{RCa^{2+}} = RT\beta_1$$

from which it follows that

$$[9] \quad 2h_{RCa^{2+}} = \beta_1 \Delta_R H^\theta$$

where $\Delta_R H^\theta$ is the standard enthalpy of reaction [7]. If relation [2] is restricted to the first-order term in m_E and is successively applied to S ≡ R and S ≡ A we get

$$[10] \quad \delta\Delta_t H^\theta = \Delta_t H_R{}^\theta(m_E) - \Delta_t H_A{}^\theta(m_E) = 2h_{RCa^{2+}} m_E = \beta_1 \Delta_R H^\theta m_E$$

and, from the known β_1 and $h_{RCa^{2+}}$, $\Delta_R H^\theta$ may be estimated. In fact, relations [2] and [4] are not exactly linear with m_E and it is important to understand what is the origin of the second-order term. Rigorously, it can be shown from the equations relating the coefficients of the power series in m_E to the constants of the successive equilibria corresponding to the formation of pairs, triplets, etc... (see, for example, ref. 9) that the coefficient of the second-order term (g_{SEE} in the present case) is related to the two successive association constants β_1 and β_2. The deviation from linearity of relation [2] thus results from the formation of the triplet SEE ($RCa^{2+}Ca^{2+}$ in the present case) which is characterized by the constant β_2, on the one hand, and from the formation of the complex SE itself (reaction [7] characterized by the constant β_1) when m_E is large, on the other hand. Although both reasons can be put forward in the general case, it is obvious that in the present study the formation of the triplet $RCa^{2+}Ca^{2+}$ is totally unlikely. As regards the second reason, let us explain its origin. Considering only reaction [7] and taking into account the assumption relative to the non-specific interactions, we may write

$$[11] \quad \delta\Delta_t H^\theta(m_E) = \alpha(m_E)\Delta_R H^\theta$$

where α, which is a function of m_E, is the extent of association of ribose with Ca^{2+} (reaction [7]). α is generally calculated from β_1, m_R, and m_E but at infinite dilution of ribose it reduces to

$$[12] \quad \alpha(m_E) = \beta_1 m_E/(1 + \beta_1 m_E)$$

The first-order assumption would simply lead back, by introduction of $\alpha(m_E) = \beta_1 m_E$ into [11], to relation [10]. In the general case,

$$[13] \quad \delta\Delta_t H^\theta(m_E) = \frac{\beta_1 m_E}{(1 + \beta_1 m_E)}\Delta_R H^\theta$$

which can be written

$$[14] \quad \frac{\delta\Delta_t H^\theta(m_E)}{m_E} = \beta_1 \Delta_R H^\theta - \beta_1 \delta\Delta_t H^\theta(m_E)$$

It is thus possible to get simultaneously the association constant β_1 and the enthalpy of reaction $\Delta_R H^\theta$ from the sole determination of the enthalpies of transfer at different m_E.

Experimental

D-Arabinose and D-ribose (Fluka puriss.) were dried under vacuum, stored in a desiccator, and used as such. The solutions of $CaCl_2$, $SrCl_2$, $BaCl_2$ (Merck pro analysi), $LaCl_3$ (Fluka puriss.), and $GdCl_3$ (Prolabo rectapur) were titrated by EDTA. All solutions were prepared by weight from triply distilled water degassed prior to use.

The enthalpies of dilution were measured with a LKB 8700 calorimeter by using the classical ampoule breaking technique. The measurements were carried out at 25.00 ± 0.01°C.

Results

The concentrated (0.650 mol kg^{-1}) solutions of ribose and arabinose in water have been diluted to a final molality of 0.0200 mol kg^{-1}. It follows that the enthalpies of dilution of these two sugars in pure water are, respectively,

$$\Delta_{dil}H_R = -0.14 \text{ kJ mol}^{-1}$$

$$\Delta_{dil}H_A = -0.12 \text{ kJ mol}^{-1}$$

By introducing into relation [1] these data and the enthalpies of dilution in the electrolytic solutions of various molalities, we get the standard enthalpies of transfer of ribose and arabinose given in Table 1. In the particular case of $CaCl_2$, the enthalpies of transfer of the electrolyte from water to the solutions of sugar have also been studied in order to check the reciprocity postulated in relation [4]. The initial concentration of $CaCl_2$ is 0.650 mol kg^{-1} and it is diluted to a final molality of 0.0200 mol kg^{-1}. However, since the heat of dilution of $CaCl_2$ varies noticeably with concentration, it is necessary to correct for the fact that the final concentration in pure water is not exactly the same as that in the sugar solution in order to get the enthalpies of transfer of $CaCl_2$ reported in Table 1 (it was not necessary to make such a correction to get the enthalpy of transfer of ribose since the enthalpy of dilution of the sugar is not so much concentration dependent). By plotting $\delta\Delta_t H^\theta/m_E$ versus $\delta\Delta_t H^\theta$ we can evaluate β (corresponding to the β_1 of the theoretical section since the formation of the triplet is unlikely) and $\Delta_R H^\theta$ as shown in relation [14]. The plots obtained, for instance, with the data of $SrCl_2$ and $BaCl_2$ are shown in Fig. 1. The vertical bars indicate the estimated uncertainties of the $\delta\Delta_t H^\theta/m_E$ values. The sets of β and $\Delta_R H^\theta$ values (in kJ) thus obtained are (0.86, −15.1), (1.87, −5.9), (1.60, −5.9), (1.20, −9.2), and (1.78, −17.9) for the cations Ca^{2+}, Sr^{2+}, Ba^{2+}, La^{3+}, and Gd^{3+}, respectively. The uncertainties are not easy to evaluate but we can estimate that β is determined to ±0.2 and $\Delta_R H^\theta$ to ±0.5 kJ.

Discussion

The β and $\Delta_R H^\theta$ values we get here are overall values characteristic of the association of all the complexing forms of ribose. This comes from the fact that solutions of ribose present anomeric and conformational equilibria and that only the isomers which have suitably positioned sequences of hydroxyls can specifically interact with the cation. The existence of these equilibria makes it necessary to specify clearly which processes are involved in the course of the measurement.

[a] m, in mol kg^{-1}; $\Delta_t H^\theta$, in kJ mol^{-1}.

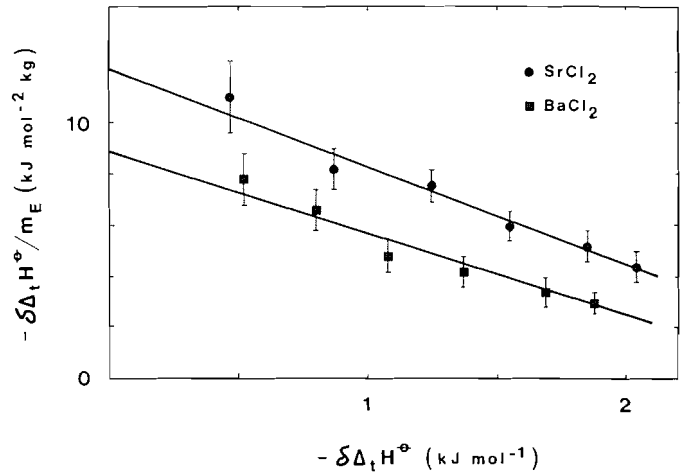

FIG. 1. Determination of β and $\Delta_R H^\theta$ for $SrCl_2$ and $BaCl_2$ ($\delta\Delta_t H^\theta/m_E$ in kJ mol^{-2} kg and $\delta\Delta_t H^\theta$ in kJ mol^{-1}).

If we let $[R_i]$ be the concentration of the isomer R_i and m_R be the total analytical concentration of pure ribose we may write

$$[15] \quad [R_i] = r_i m_R$$

r_i, the fraction of the isomer R_i in solution at equilibrium, can be considered as a thermodynamic constant if the concentrations of the studied solutions are low enough to be assimilated to activities. The two conformers of the α-pyranose ($r_a = 0.22$), the 1C4 conformer of the β-pyranose ($r_b = 0.14$), and the α-furanose ($r_c = 0.07$) bear a sequence of hydroxyls suitably positioned for association with Ca^{2+}. The r_i values given in parentheses have been determined by Angyal (10) at 31°C; they do not differ very much from those found at 40°C (11). Each of the active isomers is characterized by its complexation constant

$$[16] \quad \beta_i = \frac{[R_i M^{z+}]}{[R_i][M^{z+}]}$$

From nmr measurements, it is possible to determine the constants relevant to each isomer. At 31°C, Angyal (3) has found $\beta_a = 4.6$, $\beta_b = 1.2$, and $\beta_c = 5.0$ for the isomers indicated above, respectively. Lenkinski and Reuben (4) have found $\beta_a = 3.4$, $\beta_b = 0.8$, and $\beta_c = 5.3$ at 27°C. The constant β_b relevant to β-pyranose is not known with good accuracy (4). In fact, only the 1C4 conformer of β-pyranose is active and when $CaCl_2$ is added the equilibrium between the two conformers is displaced in favour of the 1C4 form. If we consider that the β_b value given above reflects the sum of the concentrations of both conformers, we then understand why it is much smaller than the constant of α-pyranose; but if we take into account the fact that the 1C4 conformer represents only 25% of β-pyranose (11) we calculate for the active isomer a constant which is close to the α-pyranose one (see below). We thus notice that all the active isomers of ribose form with Ca^{2+} complexes of comparable stabilities.

Our method does not allow differentiation between the isomers but gives an overall constant which has the advantage of being determined at sufficiently low concentration to be considered as a real thermodynamic constant. This overall constant may be written

$$[17] \quad \beta = \frac{\sum_i [R_i M^{z+}]}{[M^{z+}][R]}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.166.140.6 on 09/07/12
For personal use only.

where R_i is an active isomer and [R] is the total concentration of all the forms, active or not, of the free ribose. It can easily be shown that

$$[18] \quad \beta = \sum_i r_i \beta_i$$

Considering the values given above, we may assume that all the β_i constants are identical and may define a mean association constant $\overline{\beta}_i$ such that

$$[19] \quad \beta = \overline{\beta}_i \sum_i r_i$$

with $\sum_i r_i = 0.22 + 0.14 + 0.07 = 0.43$ (the r_b value given in our previous work (1) was wrong). We find $\beta = 0.86$ whereas from Lenkinski and Reuben's values, which are the most precise nmr-determined values at a temperature close to 25°C, we get $\beta = 0.22 \times 3.4 + 0.14(0.8 \times 4) + 0.07 \times 5.3 = 1.56$. The agreement is not perfect since the mean association constant deduced from nmr data is almost twice the one we get from calorimetry. Let us notice, however, that our value is in excellent agreement with the electrochemically determined one (1). In fact, the nmr method necessitates to work on concentrated solutions (0.634 *M* in ribose and up to 2.76 *M* in $CaCl_2$ (4)) and thus leads to apparent constants which can differ noticeably from thermodynamic constants.

If we examine the variations of the enthalpies of transfer of ribose with m_{CaCl_2} and of $CaCl_2$ with m_R we observe, as in a previous work (2), that both curves almost overlap over the studied concentration range. This means that the triplets $RCa^{2+}Ca^{2+}$ and $RRCa^{2+}$ do not participate to these processes. For both transfers, the deviation from linearity is solely due to the variation of the extent of association.

What do the values of $\Delta_R H^\theta$ deduced from the extrapolation of the straight lines of Fig. 1 represent? The β_1 which appears in the relation between $\delta\Delta_t H^\theta(m_E)$ and $\Delta_R H^\theta$ [13] corresponds to the overall association constant defined by [19]. Accordingly, the plots of Fig. 1 lead to a mean enthalpy of association of the metal cation with the different complexing isomers of ribose (let us notice also that $2h_{RCa^{2+}}/\beta_1$ leads directly to $\Delta_R H^\theta$, as shown by relation [9], whereas we had mistakenly said in our previous paper (2) that it was leading to $\sum_i r_i \Delta_R H^\theta$). The thermodynamic properties for the association of different cations with a complexing isomer of ribose are given in Table 2.

Some interesting observations can be made regarding these data:

(*a*) although always small, the association constants vary noticeably from one cation to the other;

(*b*) *neither the charge nor the size of the cation is determinant of the value of the association constant:* in fact, it appears, on the one hand, that the extent of association of cations of similar size but differently charged is not proportional to the valence of the ion (divalent strontium is more associated than trivalent lanthanum) and, on the other hand, that the extent of association of like-valence ions is not clearly related to the size of the ion (within the divalent cations strontium is more associated than smaller calcium whereas within the trivalent cations gadolinium is more associated than larger lanthanum);

(*c*) the enthalpy of reaction is favourable to the association process but is largely compensated by an unfavourable entropy of reaction which thus leads to small association constants.

Figure 2 shows that there is a good linear correlation of slope close to unity between $\Delta_R H^\theta$ and $T\Delta_R S^\theta$ and that it extrapolates

TABLE 2. Thermodynamic properties of association of ribose with different cations in water at 25°C

[b] Association constant: mean value for the whole of the complexing forms.
[c] kJ mol^{-1}.

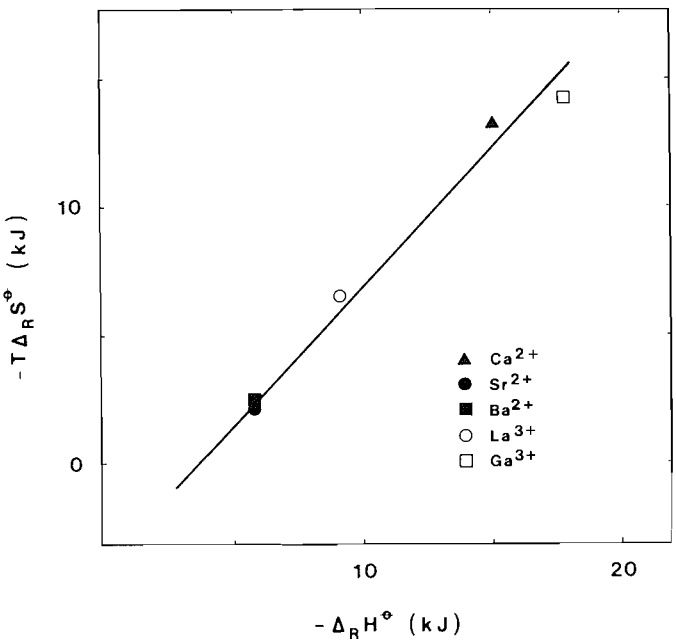

FIG. 2. Correlation between the entropies and the enthalpies (kJ mol^{-1}) of association of ribose with Ca^{2+}, Sr^{2+}, Ba^{2+}, La^{3+}, and Gd^{3+} in water at 25°C.

to $T\Delta_R S^\theta = 6$ kJ. The existence of such a correlation indicates that the association phenomenon is essentially controlled by the hydration of the different species involved in the process. This implies, in fact, the replacement of the water molecules solvating the ion by the three hydroxyls of the complexing forms of the sugar. During this process, which corresponds to a reorganization of the hydration spheres of the cation and of the sugar, the nature of the interactions involved is not fundamentally modified. The fact that the straight line of Fig. 2 does not pass through the origin is not easy to interpret but it is not a pronounced effect.

Conclusion

By using a calorimetric method, we have determined the equilibrium constants and the enthalpies of the reaction of association of Ca^{2+}, Sr^{2+}, Ba^{2+}, La^{3+}, and Gd^{3+} with ribose. We get mean values relative to the whole of the isomers of the sugar which present sequences of three hydroxyls in a position suitable for complexation (*axial–equatorial–axial* for the pyranose forms and *cis–cis* for the furanose forms).

We show that the values of the stability constant and of the enthalpy of association are not related to the size nor to the charge of the complexed cation in a simple way. The existence of a linear correlation of slope close to unity between the enthalpies and the entropies of reaction indicates that the process is essentially controlled by the hydration of the species.

WARREN HIRSCH, CAROL DIMARTINI, VOJTECH FRIED, and WILLIAM LING. Can. J. Chem. **65**, 2661 (1987).

The complexation of aqueous ammonia with α, β, and γ cyclodextrins has been monitored by pH measurements at (23 ± 1)°C. A mathematical model has been developed yielding reproducible equilibrium association constants for the formation of these complexes. The constants are quite large, suggesting the possibility of hydrogen bond formation.

WARREN HIRSCH, CAROL DIMARTINI, VOJTECH FRIED et WILLIAM LING. Can. J. Chem. **65**, 2661 (1987).

Opérant à 23 ± 1°C et faisant appel à des mesures de pH, on a déterminé les taux de complexation de l'ammoniac aqueux avec les cyclodextrines α, β et γ. On a développé un modèle mathématique qui permet de reproduire les constantes d'équilibre d'association pour la formation de ces complexes. Les constantes sont assez élevées et elles suggèrent la possibilité de formation de ponts hydrogènes.

[Traduit par la revue]

Introduction

The cyclic oligosaccharides α, β, and γ cyclodextrin (cyclohexaamylose, cycloheptaamylose, and cyclooctaamylose) have been the subject of much intensive research (1, 2). The above cyclodextrins are structured in doughnut shapes which are composed of six, seven, or eight glucose units, respectively. Some reasons for the interest in the cyclodextrins are their ability to mimic enzymes, their catalytic ability, and their ability to form inclusion complexes in aqueous solution with molecules and anions. The relatively large interior of the cyclodextrins allow suitably sized molecules or anions to get trapped within the cavity, conformational changes perhaps aiding the process (3–5). The pH change of systems of acids and their anionic conjugate bases upon cyclodextrin addition has provided much information on stability constants (6, 7). Possible binding forces within these inclusion complexes may involve hydrophobic, Van der Waals, hydrogen bonding, or dipole interaction (1, 2, 6). In the present work, the complexation of an electrically neutral base, ammonia, has been studied by a novel pH method since there is a scarcity of information on the inclusion of this type of guest.

Experimental section

The α, β, and γ cyclodextrins, obtained from Aldrich Inc., were used as received. Information on the water contents was obtained from the manufacturer. Hydration did not affect the calculated results within experimental error. Solutions of cyclodextrins were prepared by dissolving weighed portions in volumetric flasks. The ammonia was reagent grade, from Baker Chemical Company. Distilled, degassed water was used to prepare the desired solution concentrations. Solutions were freshly prepared before a series of measurements were made. The solutions of known concentration, which were prepared by dilution of the reagent, showed pH values equal to the calculated values within experimental error. Therefore, no purification was deemed necessary.

A Beckman model Φ 43 pH meter accurate to ±0.01 pH unit was employed. The meter was calibrated with two primary standard buffers, tetraborate (pH 9.18) and phosphate (pH 7.41), before each series of readings were taken. The combined AgCl/glass electrode was rinsed with distilled water and blotted dry with clean tissue before use. pH measurements were made at the room temperature: (23 ± 1)°C. Some measurements were made with a combined glass–calomel electrode to insure that complexation of AgCl by the very dilute ammonia solutions was negligible. Aqueous ammonia was introduced into a modified graduated cylinder equipped with a side-arm sealed with synthetic rubber. The initial pH was recorded. Cyclodextrin solutions were added to the ammonia solution in several 1 mL portions by hypodermic syringe. The pH electrode fit tightly within the cylinder to prevent escape of ammonia. After each addition, the solution was stirred manually and the stable pH was recorded; then additional cyclodextrin was added to the solution. At least three aliquots of cyclodextrin were added in each experiment. Not less than five such experiments were performed for each cyclodextrin.

Results

Computerized linear least square plots were prepared for the pH of the aqueous ammonia–cyclodextrin solutions vs. $v/(V + v)$, where the V represents the initial volume and the v represents the volume of aqueous cyclodextrin (Cy) of known molar concentration (about 10^{-3} M) added in millilitre (see Tables 1–3). The correlation coefficients of these empirical plots were all close to one.

Calculations of K_{CyNH_3} were based on the predicted values for the pH of the last point on each plot and for the intercept (pure NH_3(aq)).

The following equations describe the equilibria occurring in the solutions being studied as well as the charge and mass balance.

[1] $NH_3 + H_2O \rightleftarrows NH_4^+ + OH^-$

with

$$K_b = \frac{(NH_4^+)(OH^-)}{(NH_3)} = 1.74 \times 10^{-5} \text{ (at 23°C)} \quad (8)$$

[2] $Cy + NH_3 \rightleftarrows CyNH_3$

with

$$K_{CyNH_3} = \frac{(CyNH_3)}{(Cy)(NH_3)}$$

where $(CyNH_3)$ is the molar concentration of the cyclodextrin–ammonia complex.

[3] $F_{NH_3} = (NH_3) + (NH_4^+) + (CyNH_3)$

where F_{NH_3} represents the total molar concentration of ammonia.

[4] $F_{Cy} = (Cy) + (CyNH_3)$

where F_{Cy} is the total molar cyclodextrin concentration.

[5] $K_w = (H^+)(OH^-)$

[6] $(NH_4^+) + (H^+) = (OH^-)$

from electroneutrality.

Gelb and co-workers report the existence of complexes formed between OH^- and α and β Cy, each with formation constants ≈ 50 (6). The concentrations of these complexes were found to be too small to affect eqs. [4] and [6], and hence the K_{CyNH_3} values within experimental error.

F_{NH_3} was obtained from the predicted initial value of (OH^-), employing eqs. [1], [5], and [6] and the dilution factor $V/(V + v)$. Next, (NH_3) and (NH_4^+) were obtained from the same equations using the value for (OH^-) for the predicted last point in each plot. Then, $(CyNH_3)$ was obtained from eq. [3] and after determining F_{Cy} from the concentration of Cy titrant and the dilution factor $v/(V + v)$, (Cy) was obtained from eq. [4]. Finally, K_{CyNH_3} was obtained for each run from eq. [2]. The average results of the runs and their standard deviations are listed in Table 4.

TABLE 4. Formation constants for cyclodextrin–ammonia complexes in aqueous solutions

Cyclodextrin	K_{CyNH_3} at (23 ± 1)°C
α	$(6.1 \pm 0.9) \times 10^4$
β	$(1.5 \pm 0.3) \times 10^4$
γ	$(2.2 \pm 0.8) \times 10^4$

The preceding model equations assume a 1:1 molecular ratio of NH_3 to Cy in each complex. This assumption seems warranted under the experimental conditions, i.e. $F_{Cy} > F_{NH_3}$. Moreover, the constancy of the calculated equilibrium constants between the runs, which employed different values for F_{Cy} and F_{NH_3}, seems to justify the assumption. Since the ionic strength of these dilute solutions was very low, activity coefficients are assumed to be unity.

The model equations assume that the ammonium cation is not included at all by the cyclodextrins. As a test of this assumption, the other assumptions above, and the validity of the method in general, aniline solutions were reacted with aqueous β cyclo-

For personal use only.

dextrin, monitoring the pH as with ammonia above. The results of six trials using three separate cyclodextrin concentrations yield a formation constant for the inclusion complex (at 23°C) of 46 ± 8. This value is in good agreement with a literature value of 50 ± 3, which was obtained by uv–visible absorption spectrophotometry (9).

Discussion of results

The interactions of α, β, and γ cyclodextrins with aqueous ammonia produced significant pH decreases. The decrease in pH can be attributed to the formation of the inclusion complex $CyNH_3$. The decrease suggests that an ammonia molecule is being trapped inside the cavity of the cyclodextrins, and is not free to react with water. Hence, the solution becomes less alkaline. As the Cy concentration increases in the solution, the molar concentration of free ammonia decreases resulting the noted pH decreases. The binding constants of α, β, and γ cyclodextrins were $(6.1 \pm 0.9) \times 10^4$, $(1.5 \pm 0.3) \times 10^4$, and $(2.3 \pm 0.8) \times 10^4$, respectively. All three of the binding constants are quite large compared to those of acids and their anions, which were explained by dipole forces (6, 7). However, previous experiments (10, 11) have obtained binding constants in the order of magnitude of 10^4.

While there is about a four-fold decrease in the binding constant in going from the α to the β form, the constants for the β and γ are indistinguishable within experimental error. Apparently, the "tightness of fit" effect is not very important and after a certain ring size becomes negligible.

Gelb and associates (7) determined ΔS^0 and ΔH^0 for the complexation of 28 different guests by Cy, utilizing the temperature dependencies of the formation constants. For these guests, which were quite diverse in nature (anions, aliphatic and aromatic carboxylic acids, and other small organic molecules such as alcohols), the following empirical relationship was determined from a linear least-squares plot of ΔH^0 vs. ΔS^0

$$[7] \quad \Delta H^0 = (410 \pm 15)\Delta S^0 - (1.2 \pm 0.2) \times 10^3$$

where the units for ΔH^0 are cal mol^{-1} and those for ΔS^0 are cal mol^{-1} K^{-1}. However, there is apparently a scarcity of data on electrically neutral bases such as ammonia. Assuming that eq. [7] holds true for NH_3, since

$$[8] \quad \Delta G^0 = -RT \ln K = \Delta H^0 - T\Delta S^0$$

one calculates from Table 4 that for the α Cy–NH_3 complex,

$$\Delta G^0 = -6.49 \text{ kcal mol}^{-1}$$

$$\Delta S^0 = -46 \text{ cal mol}^{-1} \text{ K}^{-1}$$

$$\Delta H^0 = -20 \text{ kcal mol}^{-1}$$

The very large negative ΔH^0 in conjunction with only a small "tightness of fit" effect suggest that the intermolecular forces are strong and short range. Therefore, we suspect that hydrogen bonds augment the dipole forces postulated by Gelb *et al.* (7). In particular, the lone pair of NH_3 may hydrogen bond with —OH groups in the ring while its hydrogens may interact with —O— in the ring. Gelb *et al.* explain the fact that their standard entropy changes are consistently quite negative by conformational changes in the ring. This idea has also been advanced by others (5), and probably occurs with NH_3. The previous experiments (10, 11) which yielded binding constants of the order 10^4 involved the inclusion of the phenolphtalein and oxalate anions, respectively. Both of these contain —O's which may hydrogen bond to —OH groups in the Cy ring.

The reactions of the chromate, dichromate, and permanganate ions with 100% sulfuric acid and dilute oleum

R. J. GILLESPIE AND R. KAPOOR
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received November 18, 1986[1]

R. J. GILLESPIE and R. KAPOOR. Can. J. Chem. **65**, 2665 (1987).

Solutions of potassium chromate and potassium dichromate in 100% sulfuric acid and dilute oleum have been investigated by cryoscopic and conductimetric methods. It is shown that they both react to give the compound $CrO_2(HSO_4)_2$. The absorption spectra of solutions of potassium chromate and dichromate in 100% sulfuric acid are very similar to the spectra of species of the type CrO_2X_2. Potassium permanganate dissolves in 100% sulfuric acid to give green solutions which are shown to contain $MnO_3 \cdot SO_4H$. The formation of this compound has been further confirmed by conductimetric measurements in dilute oleum. The absorption spectra of these green solutions are also consistent with the formation of a species of the type MnO_3X.

R. J. GILLESPIE et R. KAPOOR. Can. J. Chem. **65**, 2665 (1987).

Faisant appel à des méthodes cryoscopiques et conductimétriques, on a étudié des solutions de chromate et de bichromate de potassium dans l'acide sulfurique à 100% et dans de l'oléum dilué. On a démontré que chacun de ces composés réagit pour donner le composé $CrO_2(HSO_4)_2$. Les spectres d'absorption des solutions de chromate et de bichromate de potassium dans l'acide sulfurique à 100% sont très semblables à ceux des espèces du type CrO_2X_2. Le permanganate de potassium dissout dans l'acide sulfurique à 100% pour donner des solutions vertes et on a démontré qu'elles contiennent du $MnO_3 \cdot SO_4H$. On a de plus confirmé la formation de ce composé à l'aide de mesures conductimétriques dans l'oléum dilué. Les spectres d'absorption de ces solutions vertes sont aussi en accord avec la formation d'une espèce du type MnO_3X.

Ever since the discovery of the NO^+ and NO_2^+ cations (1) there has been considerable speculation about the existence of other similar oxocations and there have been a number of studies which had the objective of establishing the existence of such ions. The existence of the dioxochlorine cation ClO_2^+ has been certainly established by X-ray crystallography and other studies on its salts with the anions AsF_6^- (2), SbF_6^-, and $Sb_3F_{16}^-$ (3). Although evidence has also been presented for ions that may be written as IO^+, IO_2^+ (4, 5), and AsO^+ (6), it is very probable that in fact they exist only in solvated forms even in highly acidic media, or as polymeric chains in the solid state. There is even less evidence for other oxocations. For example, phosphoric acid is converted to $H_4PO_4^+$ in solution in 100% sulfuric acid and PO_2^+ ion is not formed (7). Ammonium metavanadate and vanadium pentoxide have been shown to be solvolyzed to $OV(HSO_4)_3$ in 100% sulfuric acid and there is no evidence for the oxocation VO_2^+ as a discrete species (7) although it is known in strongly solvated forms such as $[VO_2(H_2O)_4]^+$ (8). The existence of other oxometal cations such as TiO^{2+}, ZrO^{2+}, and MoO_2^{2+} as discrete species has also not been established although they are known when they are coordinated with ligands to give anionic species.

In this paper we report a study of the possible formation of the oxocations of Cr(VI) and Mn(VII) in which we investigated the species formed by some of their compounds when they are dissolved in 100% sulfuric acid and dilute oleum.

Chromium(VI) compounds

Hayek and Engelbrecht (9) reported the formation of $CrO_2(SO_4)_2$ by the reaction of chromyl chloride, CrO_2Cl_2, with SO_3. Woolf (10) suggested that this compound is an ionic CrO_2^{2+} salt, i.e., $(CrO_2)^{2+}S_2O_7^{2-}$. Yatsimirskii and Vasil'eva (11) postulated the formation of $H_2Cr_2O_7$, and $H_2Cr_4O_{13}$ and other related compounds in solutions of chromates in 50–80% sulfuric acid. Symons and co-workers (12), from their study of the absorption spectrum of potassium chromate in 100% sulfuric acid, tentatively suggested that chromyl ion, CrO_2^{2+}, is formed in these solutions. But later Mishra and Symons (13) reported the conductivities of solutions of potassium chromate in 100% sulfuric acid. Their results are consistent with the formation of $CrO_2(OH)(HSO_4)$,

$$K_2CrO_4 + 4H_2SO_4 \rightarrow 2K^+ + CrO_2(OH)(HSO_4) + H_3O^+ + 3HSO_4^-$$

and are not in such good agreement with the formation of CrO_2^{2+}. However, the conductivity results alone are not sufficient to establish the mode of ionization unambiguously. We now report the results of cryoscopic and conductimetric measurements on solutions of potassium chromate and potassium dichromate in 100% sulfuric acid and dilute oleum.

Solutions in 100% H_2SO_4

Some difficulty was experienced in the preparation of solutions of potassium chromate and dichromate in 100% sulfuric acid. If the mixture was not vigorously stirred immediately after addition of the solute to 100% sulfuric acid a yellow solid compound separated out, which was insoluble even on heating. The identity of this solid could not be established with certainty, since it was very difficult to filter a significant amount from the sulfuric acid solution. It seems likely that this solid is CrO_3 which is insoluble in 100% sulfuric acid even at high temperatures. However, if the sulfuric acid was vigorously stirred on addition of the solute a clear solution was obtained. The results of the cryoscopic and conductimetric studies on these solutions are given in Table 1. We obtained a value of $\gamma = 4$ from the conductivity data rather than $\gamma = 3$ as reported by Mishra and Symons (13) and a value of $\nu = 9.0$.[2] Possible modes of ionization are

$$[1a] \quad K_2CrO_4 + 2H_2SO_4 \rightarrow 2K^+ + H_2CrO_4 + 2HSO_4 \qquad \nu = 5; \gamma = 2$$

[1]Revision received July 2, 1987.

[2]γ is the number of moles of HSO_4^- formed by one mole of the solute and ν is the total number of moles of ions and molecules produced in solution by one mole of the solute (1).

	1.2	9.872	9.2	1.5000	
	1.6	9.668	9.1	1.7000	4.0
	2.0	9.461	9.1	1.9040	
	2.4	9.255	9.0	2.1090	
	2.8	9.048	8.9	—	
	3.2	8.828	8.9	—	
$K_2Cr_2O_7$	0.2			1.0675	
	0.4			1.1400	
	0.6			1.2350	
	0.8			1.3525	
	1.0			1.4725	5.0
	1.2			1.5950	
	1.4			1.7125	
	1.6			1.8350	
	1.8			1.9500	
	2.0			2.0675	

[2a] $K_2CrO_4 + 3H_2SO_4 = 2K^+ + H_3CrO_4^+ + 3HSO_4^-$ $\quad \nu = 6; \gamma = 3$

[3a] $K_2CrO_4 + 6H_2SO_4 = 2K^+ + CrO_2^{2+} + 2H_3O^+ + 6HSO_4^-$ $\quad \nu = 11; \gamma = 6$

[4a] $K_2CrO_4 + 9H_2SO_4 = 2K^+ + CrO^{4+} + 3H_3O^+ + 9HSO_4^-$ $\quad \nu = 15; \gamma = 9$

[5a] $K_2CrO_4 + 4H_2SO_4 = 2K^+ + CrO_2(OH)(HSO_4) + H_3O^+ + 3HSO_4^-$ $\quad \nu = 7; \gamma = 3$

[6a] $K_2CrO_4 + 7H_2SO_4 = 2K^+ + CrO(SO)_4)_2 + 3H_3O^+ + 5HSO_4^-$ $\quad \nu = 11; \gamma = 5$

[7a] $K_2CrO_4 + 5H_2SO_4 \rightarrow 2K^+ + CrO_2(SO_4) + 2H_3O^+ + 4HSO_4^-$ $\quad \nu = 9; \gamma = 4$

[8a] $K_2CrO_4 + 6H_2SO_4 \rightarrow 2K^+ + CrO_2(HSO_4)_2 + 2H_3O^+ + 4HSO_4^-$ $\quad \nu = 9; \gamma = 4$

These results support the formation of $CrO_2(HSO_4)_2$ or $CrO_2(SO_4)$ in sulfuric acid (eqs. [7a] and [8a]). It is not possible to distinguish between these two possibilities on the basis of the cryoscopic and conductimetric results because they differ only by a solvent molecule, but it is very probable that the compound formed in a large excess of sulfuric acid is $CrO_2(SO_4H)_2$.

The conductivity results on solutions of potassium dichromate in 100% sulfuric acid (Table 1) can be accounted for by a reaction similar to that proposed for potassium chromate, namely

$$K_2Cr_2O_7 + 9H_2SO_4 \rightarrow 2K^+ + 2CrO_2(HSO_4)_2 + 3H_3O^+ + 5HSO_4^- \qquad \gamma = 5$$

For the formation of $CrO_2(OH)(HSO_4)$ as suggested by Mishra and Symons (13),

$$K_2Cr_2O_7 + 5H_2SO_4 = 2K^+ + 2CrO_2(OH)(HSO_4) + H_3O^+ + 3HSO_4^-$$

a γ value of 3 would be expected.

Solutions in dilute oleum

Further evidence for the ionization of potassium chromate and dichromate in sulfuric acid has been obtained by conductimetric titrations in dilute oleum at 25°C, the results of which are shown in Table 2 and Fig. 1.

The reaction of potassium chromate with dilute oleum can be conveniently considered to take place in two stages: first the reaction of potassium chromate with 100% H_2SO_4

$$K_2CrO_4 + 4H_2SO_4 = 2K^+ + 2HSO_4^- + CrO_2(HSO_4)_2 + 2H_2O$$

followed by the reaction of $H_2S_2O_7$ with H_2O and HSO_4^-. Two moles of $H_2S_2O_7$ are needed to react with two moles of H_2O and $2(1/0.56)$ moles of $H_2S_2O_7$ are needed to react with two moles of HSO_4^- to give a conductivity minimum (14). Thus a conductivity minimum in the titration of n_a moles of $H_2S_2O_7$ with n_b moles of K_2CrO_4 will be obtained at the ratio

$$n_b/n_a = 1/[2 + 2(1/0.56)] = 0.18$$

which is very close to the experimental value of 0.19.

Addition of potassium dichromate to dilute oleum gives a minimum at $r_{min} = n_b/n_a = 0.16$ (Table 2 and Fig. 1). The reaction of potassium dichromate in 100% sulfuric acid can be written as

$$K_2Cr_2O_7 + 6H_2SO_4 = 2K^+ + 2HSO_4^- + 2CrO_2(HSO_4)_2 + 3H_2O$$

Thus the minimum in the conductivity curve for this reaction would be expected at

$$n_b/n_a = 1/[3 + 2(1/0.56)] = 0.15$$

where n_b and n_a are the molalities of potassium dichromate and initial acid, respectively.

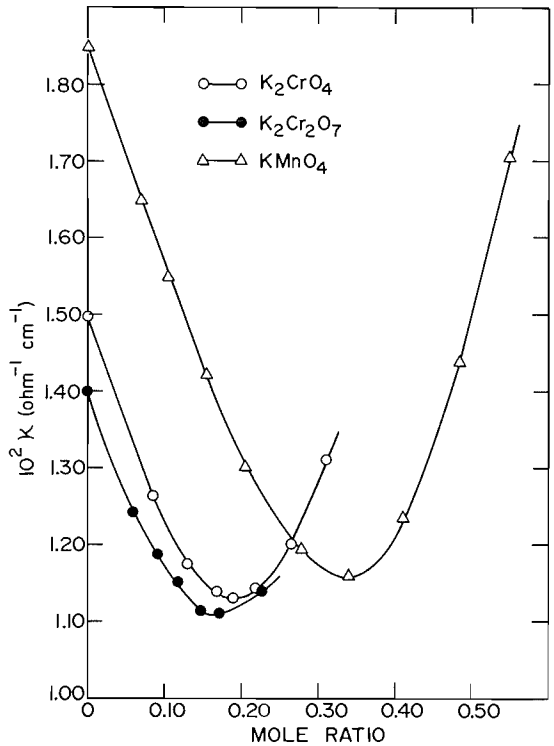

FIG. 1. Conductivities of solutions of potassium chromate, potassium dichromate, and potassium permanganate in dilute oleum.

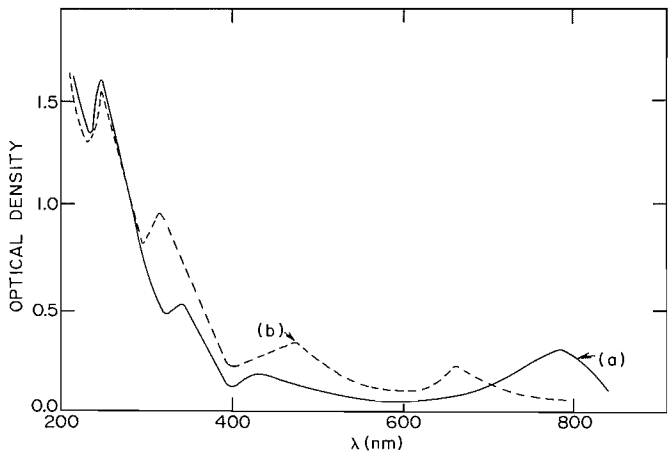

FIG. 2. Absorption spectra of a solution of (*a*) potassium chromate/potassium dichromate, and (*b*) potassium permanganate in 100% sulfuric acid.

Absorption spectra

The visible and ultraviolet absorption spectra of solutions of potassium chromate and potassium dichromate in 100% sulfuric acid have been studied and a typical spectrum is given in Fig. 2. Absorption maxima occur at 250, 340, 420, and 780 nm. The solutions obey Beer's law and the values for the molar extinction coefficients are given in Table 3.

It is seen that both potassium chromate and potassium dichromate give the same absorption spectrum and the values for the molar extinction coefficient for $K_2Cr_2O_7$ are twice those observed for K_2CrO_4. This strongly suggests that both these compounds give the same species in 100% sulfuric acid.

TABLE 3. Absorption maxima for solutions of potassium chromate and potassium dichromate in 100% sulfuric acid

K_2CrO_4		$K_2Cr_2O_7$	
λ (nm)	ϵ	λ (nm)	ϵ
250	5 500	250	11 000
340	1 400	340	2 750
420	300	420	600
780	400	780	780

It has been pointed out that the ultraviolet and visible spectrum of Cr^{VI} in 72% perchloric acid is close to that expected for H_2CrO_4 (12) and resembles the spectrum of CrO_2Cl_2 (15). The spectrum obtained for potassium chromate and dichromate in 100% sulfuric acid (Fig. 2) is similar to that reported by Mishra and Symons (13) and is very similar to that of CrO_2Cl_2. The similarity between these spectra strongly suggests that they all arise from species of the type CrO_2X_2. It is concluded that in 72% $HClO_4$ chromate is converted to $CrO_2(OH)_2$ while in 100% H_2SO_4 both chromate and dichromate are converted to $CrO_2(HSO_4)_2$.

Potassium permanganate

It has been known for a long time that the dissolution of a small amount of potassium permanganate in concentrated sulfuric acid produces a green solution (16). Franke (17) suggested that the green colour was due to $(MnO_3)_2SO_4$, but he gave no direct evidence for this species.

Symons and co-workers (12), from their study of the absorption spectrum of potassium permanganate in 100% sulfuric acid, postulated that the green species is permanganic acid. Royer (18) has studied the conductivity and freezing point of $KMnO_4$ in slightly aqueous sulfuric acid. He explained his results in terms of the formation of the permanganyl ion, MnO_3^+, according to the following equation

$$KMnO_4 + 3H_2SO_4 \rightarrow K^+ + MnO_3^+ + H_3O^+ + 3HSO_4^- \quad \nu = 6; \gamma = 3$$

He also suggested that the absorption spectrum of the green species was consistent with the formation of the planar MnO_3^+ ion.

Subsequently Mishra and Symons (13) studied the behaviour of $KMnO_4$ in 100% sulfuric acid. They obtained a γ value of 2.0–2.2 and taking into account the average of Royer's ν values, which is in fact closer to 5 than 6, they proposed the reaction

$$KMnO_4 + 3H_2SO_4 \rightarrow K^+ + MnO_3{\cdot}SO_4H + H_3O^+ + 2HSO_4^- \quad \nu = 5; \gamma = 2$$

These authors also carried out a conductimetric titration of $KMnO_4$ in dilute oleum and found $r_{min} = n_{KMnO_4}/n_a = 0.28$, although as we shall show the above equation would predict a conductivity minimum at $r_{min} = 0.36$.

Because the previous cryoscopic and conductimetric work did not lead to unambiguous conclusions, we made some further studies on solutions of $KMnO_4$ in 100% sulfuric acid and dilute oleum.

0.04	9.385	4.9	1.900	
0.05	9.075	4.9	2.170	2.0
0.06	8.780	4.9	2.430	
0.07	8.475	4.9	2.710	

TABLE 5. Conductivities of solutions of potassium permanganate in dilute oleum

$r = \frac{n_b}{n_a}$	$10^2\ \kappa$ ($ohm^{-1}\ cm^{-1}$)
Initial molality of $H_2S_2O_7$ = 0.185	
0.000	1.848
0.069	1.648
0.105	1.550
0.154	1.421
0.206	1.303
0.274	1.196
0.341	1.162
0.411	1.236
0.484	1.437
0.550	1.706

Potassium permanganate dissolves both in 95% and 100% sulfuric acid to give green solutions which if they are less concentrated than 0.05 molal are reasonably stable for about 24 h. More concentrated solutions were less stable, becoming turbid after 3–4 h, and eventually depositing MnO_2 with the evolution of oxygen gas.

The results of the cryoscopic and conductimetric studies are given in Table 4. Possible reactions are

[1b] $KMnO_4 + H_2SO_4 = K^+ + HMnO_4 + HSO_4^-$ $\quad \nu = 3; \gamma = 1$

[2b] $KMnO_4 + 2H_2SO_4 = K^+ + H_2MnO_4^+ + 2HSO_4^-$ $\quad \nu = 4; \gamma = 2$

[3b] $KMnO_4 + 3H_2SO_4 = K^+ + MnO_3^+ + H_3O^+ + 3HSO_4^-$ $\quad \nu = 6; \gamma = 3$

[4b] $KMnO_4 + 3H_2SO_4 = K^+ + MnO_3SO_4H + H_3O^+ + 2HSO_4^-$ $\quad \nu = 5; \gamma = 2$

It is clear from Table 4 that the results are consistent with the formation of MnO_3SO_4H (eq. [4b]).

The results of a conductimetric titration of $KMnO_4$ in dilute oleum at 25°C are given in Table 5 and Fig. 1. If there are initially n_a moles of $H_2S_2O_7$, and n_b moles of $KMnO_4$ are added to give a conductivity minimum and assuming ionization according to eq. [4b]

$$n_b/n_a = 1/(1 + 1/0.56) = 0.36$$

at the conductivity minimum. The experimental value of $n_b/n_a = 0.36$ is in good agreement with the value calculated on the basis of eq. [4b] above although the value of Mishra and Symons of $n_b/n_a = 0.28$ is not in such good agreement with our experimental value or the calculated value. If the product of the ionization had been the MnO_3^+ ion a conductivity minimum would have been expected at

$$n_b/n_a = 1/[1 + (2/0.56)] = 0.22$$

The previous evidence did not clearly establish the mode of ionization of $KMnO_4$ but our new results confirm the suggestion of Mishra and Symons that it ionizes according to eq. [4b] above.

Absorption spectra

The visible and ultraviolet absorption spectrum of green solutions of potassium permanganate in 100% sulfuric acid is shown in Fig. 2. Four absorption maxima were found at 250, 310, 460, and 650 nm. The solutions obey Beer's law and the values for the molar extinction coefficient are given in Table 6. The spectrum is very similar to that observed for CrO_3Cl^- and CrO_3F^- (12, 15), and is also in accord with the changes expected in going from MnO_4^- (symmetry T_d) to the MnO_3X species (symmetry C_{3v}). This is consistent with the other evidence that the green species is $MnO_3 \cdot SO_4H$.

Experimental section

The freezing-point depression and electrical conductivities of solutions were measured by methods described previously (19–21). Potassium chromate, potassium dichromate, and potassium permanganate were (BDH, AnalaR) samples and were kept over P_4O_{10} in a desiccator before use.

The preparation of the 100% sulfuric acid solvent has been described previously (19, 20). Oleums of known composition were obtained by distilling sulfur trioxide into a weighed amount of 100% sulfuric acid.

The reaction between SnX_2 (X = Cl, Br, I), 1,10-phenanthroline (phen) and $Y_4C_6O_2$ (Y = Cl, Br) yields $Y_4C_6O_2SnX_2$.phen with the *o*-quinone being converted to the corresponding catecholate anion. Reactions in which phen is replaced by $Me_2NC_2H_4NMe_2$ (tmen) are more complex, and the products depend in part on the solvent. These products include $Cl_4C_6O_2SnCl_2$.tmen, and products arising from solvation by ROH (R = CH_3, C_2H_5). An X-ray crystallographic study of $(tmenH)_2[Sn(O_2C_6Cl_4)_3]$ shows that the anion contains a six-coordinate tin atom bonded to substituted catecholate anions. Hydrogen-bonding between cation and anion appears to be an important factor in the stability of the lattice.

THEODORE A. ANNAN, RAJ K. CHADHA, DENNIS G. TUCK et KATHERINE D. WATSON. Can. J. Chem. **65**, 2670 (1987).

La réaction du SnX_2 (X = Cl, Br, I) phénanthroline (phen) avec le $Y_4C_6O_2$ (Y = Cl, Br) conduit au $Y_4C_6O_2SnX_2$.phen alors que la *o*-quinone est transformée en anion catécholate correspondant. Les réactions dans lesquelles le phen est remplacé par le $Me_2NC_2H_4NMe_2$ (tmen) sont plus complexes et la nature des produits dépend du solvant. Parmi ces produits, on retrouve le $Cl_4C_6O_2SnCl_2$.tmen et des produits qui proviennent de la solvatation par ROH (R = CH_3, C_2H_5). Une étude par diffraction des rayons-X du $(tmenH)_2[Sn(O_2C_6Cl_4)_3]$ démontre que l'anion contient un atome de Sn(IV) qui est hexacoordonné et qui est lié aux anions catécholates substitués. Les liaisons hydrogènes entre le cation et l'anion semblent être des facteurs importants dans la stabilité du réseau.

[Traduit par la revue]

Introduction

Although there is considerable literature on the reactions between *ortho*-quinones and transition metal ions, the corresponding oxidations of lower state Main Group metals have not been widely studied. In recent work, we have investigated the reaction of indium(I) halides (InX) in non-aqueous media with a variety of substituted *o*-quinones to give the corresponding XIn^{III}(catecholate) species. Electron spin resonance spectroscopy shows that these redox reactions proceed via one-electron, rather than two-electron, processes (1). We now report the results of a parallel preparative study of the reaction between stannous halides (SnX_2) and the tetrahalogeno-substituted *o*-quinones $Y_4C_6O_2$ (X = Cl, Br) to give the corresponding catecholate $Y_4C_6O_2SnX_2$, which were isolated as the adducts with bidentate neutral donors. During an investigation of the possible insertion of indium(I) chloride into the Sn—X bond of one of these products, we recovered the rearranged product $(tmenH)_2[Sn(O_2C_6Cl_4)_3]$ (tmen = *N,N,N',N'*-tetramethylethanediamine), whose structure was determined by X-ray crystallography.

Experimental

General

Tin(II) halides (Alfa), tetrahalogeno-*o*-quinones, 1,10-phenanthroline (phen), and tmen (Aldrich) were used as supplied. Solvents were dried by conventional methods, and stored over drying agents. All reactions were carried out in an atmosphere of dry nitrogen.

Tin analysis was by atomic absorption spectrophotometry, and microanalysis was carried out by Guelph Chemical Laboratory. Total halogen analysis of reaction products by the Oakdale–Thompson method proved unreliable, and the presence of the *o*-quinone in acidified aqueous solution prevented the use of the Volhard method. Proton nmr spectra were recorded on a Varian EM 360 instrument, and ^{13}C spectra on a General Electric GN 300 instrument at Wayne State University, Detroit, MI. Mass spectrometry was carried out on a Varian MAT CH-5DF instrument operating in the electron impact or field desorption modes. Infrared spectroscopy involved the use of samples in KBr discs with a Nicolet 5DX instrument.

Preparative

(*a*) A solution of $SnCl_2$ (0.39 g, 2 mmol) and tetrachloro-*o*-quinone (0.50 g, 2 mmol) in acetone (50 mL) was stirred mechanically for 1 h at room temperature to give a yellow–orange solution. Addition of phen (0.31 g, 2 mmol) precipitated $Cl_4C_6O_2SnCl_2$.phen in quantitative yield. Later work showed that the synthesis is more conveniently carried out by refluxing equimolar quantities of $SnCl_2$, $Cl_4C_6O_2$ (or $Br_4C_6O_2$), and phen in acetone for 1 h, and this technique was used in the preparation of analogous compounds listed in Table 1, since direct reaction at room temperature is unsatisfactory with $SnBr_2$ or SnI_2. The yellow–orange solids were collected, washed successively with acetone (2 × 20 mL) and *n*-pentane (20 mL), and dried *in vacuo*.

(*b*) $Cl_4C_6O_2SnI_2$.phen can also be prepared by refluxing tin metal (0.4 g, 2.4 mmol), iodine (0.86 g, 3.4 mmol calculated as I_2), and $Cl_4C_6O_2$ (0.83 g, 3.4 mmol) in toluene (50 mL) for 3 h, by which time the tin had dissolved to give a light green solution. An equimolar quantity of phen was then added, and refluxing stopped. The mixture was stirred for 1 h as it cooled; the orange solid which formed was then collected and washed as described above.

(*c*) $SnCl_2$ (0.39 g, 2 mmol) was suspended in toluene (50 mL) containing an equimolar quantity of $Cl_4C_6O_2$ (0.5 g), and tmen (0.35 g, 3 mmol) added to the red solution. The mixture was stirred at room temperature for 16 h, and then filtered, to give an off-white solid which

was washed with toluene and then *n*-pentane, and dried *in vacuo*. This solid was identified as $Cl_4C_6O_2SnCl_2$.tmen on the basis of metal analysis, infrared and ^1H nmr spectroscopy. Repetition of this procedure with $Br_4C_6O_2$ in place of the tetrachloro-*o*-quinone gave as the final insoluble product a beige-coloured solid which contained tmen and the $Br_4C_6O_2^{2-}$ ligand, but did not correspond analytically to $Br_4C_6O_2SnCl_2$.tmen (calcd Sn 16.3%; found Sn 24.7%). ^1H nmr, singlets at 2.72 and 3.33 ppm from Me_4Si, in d_6-dmso.

(*d*) A mixture of $SnCl_2$ and $Cl_4C_6O_2$ (quantities as in (*c*)) was dissolved in acetone, and tmen (0.35 g, 3 mmol) added; the solution darkened in colour, and a slight cloudiness developed. After 1 h, the now pale yellow solution was filtered to remove a white solid, and the solution evaporated *in vacuo* to yield crystals of $Cl_4C_6O_2SnCl_2$.tmen. The white solid collected by filtration contained Sn (32%) and $Cl_4C_6O_2$, but no tmen. This material was not investigated further.

(*e*) Stannous chloride (0.56 g, 3.0 mmol) was dissolved in dry methanol (50 mL), and tmen (0.35 g, 3.0 mmol) added dropwise to the stirred solution. The slight cloudiness disappeared on warming the solution. A methanol solution of $Cl_4C_6O_2$ (0.73 g, 3.0 mmol in 50 mL) was added dropwise over 1 h. Some slight precipitation was obvious at this point, and on refluxing over 4 h considerable quantities of solid were thrown down. This solid was collected, washed with hot methanol (2 × 20 mL), and dried *in vacuo*. This material was identified as $Cl_4C_6O_2SnCl_2$.tmen.$2CH_3OH$ (A) on the basis of metal analysis (Table 1), infrared and ^1H nmr spectroscopy (Table 5). Yield 0.87 g. No spectroscopic or weight changes were detected after heating the substance *in vacuo* (60°C, 6 h).

The filtrate from this reaction was taken to dryness *in vacuo*, giving a mixture of colourless and yellow powders. The former was found to be insoluble in most common organic solvents, and the compounds were separated by treatment with hot acetonitrile. The insoluble colourless solid (weight 0.24 g) was identified as the salt $(tmenH_2)Cl_2$ (B) (analysis: found Cl 37.4, calcd 37.5%). ^1H nmr in D_2O showed singlets at 3.7 (4H) and 3.0 (12H) ppm from internal sodium 3-(trimethylsilyl)propionate. The molar conductivity of a m*M* solution in H_2O was 209 $ohm^{-1}\ mol^{-1}\ cm^2$, slightly less than the classical value of 240 $ohm^{-1}\ mol^{-1}\ cm^2$ for 2:1 electrolytes.

The acetonitrile extract of the above solid mixture was subsequently taken to dryness *in vacuo*. Analysis and spectroscopy showed that this compound is $Cl_4C_6O_2Sn(OCH_3)_2$ (C).

The total mass of products A, B, and C was 1.72 g, to be compared with 1.64 g of reactants used. After making appropriate allowance for the MeOH and MeO incorporated into A and C, the mass balance accounts for 94% of the starting materials.

(*f*) Stannous chloride (0.50 g, 2.6 mmol) and $Cl_4C_6O_2$ (0.65 g, 2.6 mmol) were dissolved in dry ethanol (50 mL), and 0.4 mL (2.6 mmol) of tmen added to the pale yellow solution. An instant opalescence was followed by the formation of a white precipitate. The mixture was refluxed for 12 h under nitrogen, after which the precipitate was collected by filtration, washed with hot ethanol (2 × 20 mL) and dried overnight *in vacuo*. This solid is $Cl_4C_6O_2SnCl_2$.tmen.C_2H_5OH. The filtrate was treated by the method described above for the methanol solution, and the products identified were $(tmenH_2)Cl_2$ and $Cl_4C_6O_2Sn(OC_2H_5)_2$.

(*g*) The compound $(tmenH)_2[Sn(O_2C_6Cl_4)_3]$ was produced in the course of an unsuccessful attempt to insert indium(I) chloride into a Sn—Cl bond of $Cl_4C_6O_2SnCl_2$. Tin(II) chloride (0.39 g, 2 mmol) and $Cl_4C_6O_2$ (0.5 g, 2 mmol) were stirred together in methanol (25 mL), and the resultant solution added dropwise to a solution of InCl (0.31 g, 2 mmol) in 50 mL tmen/toluene (1:50) at −40°C (cf. ref. 3). The mixture was stirred for 1 h to give a clear solution, after which the cooling bath was removed, and stirring continued for 1 h as the solution reached room temperature (~25°C). After filtration to remove impurities, the solution was evaporated *in vacuo*; the resultant solid was recrystallized from methanol, and the crystals washed with *n*-pentane and dried *in vacuo*. Analysis, spectroscopy, and a subsequent X-ray crystallographic study showed that this product is $(tmenH)_2[Sn(O_2C_6Cl_4)_3]$.

X-ray crystallographic analysis

A single crystal of $(tmenH)_2[Sn(O_2C_6Cl_4)_3]$ (**1**) was mounted along the largest dimension, and the cell parameters obtained from 15 strong reflections with $15° < 2\theta < 30°$. Data were collected on a Syntex $P2_1$ diffractometer following the procedure described previously (4). The intensities of three monitored reflections did not change significantly during data collection. The data were corrected for Lorentz and polarization effects; no absorption correction was deemed necessary because of the low absorption coefficient. Details of the X-ray data collection are given in Table 2.

The systematic absences (hkl, $h + k = 2n + 1$; $h0l$, $l = 2n + 1$) indicated the space groups $C2/c$ or Cc. The former was used and later assumed to be correct because of the successful refinement of the structure. Computation was carried out on the University of Manitoba Computer Services Department's Amadahl 580/5850 mainframe computer. The position of the tin atom was obtained from a sharpened Patterson synthesis using SHELX, 1976, and was found to be on a twofold axis. The positions of remaining non-hydrogen atoms were determined from a difference Fourier map. The structure was refined anisotropically using full-matrix least-squares methods, and the refinement converged at $R = (\Sigma||F_o| - |F_c||/\Sigma|F_o|) = 0.0369$. Hydrogen atoms were included in subsequent refinement in ideal positions (C—H 0.95 Å and CCH 109.5°), leading to the final values $R = 0.0324$ and $R_w = [E_w\Delta^2/\Sigma_w F_o^2]^{1/2} = 0.0378$. The function $(|F_o| - |F_c|)^2$ was minimized during least-squares refinement; in the final cycles, a weighting scheme of the form $w = 1/[\sigma^2(F) + pF]^2$ was employed, with a final p value of 0.0011. No evidence of secondary extinction was found.

[a] U_{eq}^* is calculated from the refined anisotropic thermal parameter $U_{eq} = \frac{1}{3}\Sigma_i\Sigma_j U_{ij} a^*_i a^*_j a_i \cdot a_j$.

Sources of scattering factors and computer programs have been given elsewhere (4). The final atomic coordinates for non-hydrogen atoms are given in Table 3 and important distances and angles in Table 4. List of structure factors, anisotropic thermal parameters, and fractional coordinates for hydrogen atoms are available as deposited material.[1] The structure of the $[Sn(O_2C_6Cl_4)_3]^{2-}$ anion is shown in Fig. 1, and the crystal packing of $(tmenH)_2[Sn(O_2C_6Cl_4)_3]$ in the unit cell in Fig. 2.

Results and discussion

Preparative

The six compounds $Y_4C_6O_2SnX_2$.phen (X = Cl, Br, I; Y = Cl, Br) are the result of adduct formation by the dihalogenotin(IV)catecholate species, which are themselves generated by the redox reaction

[1] 
The products were characterized by elemental analysis, and by infrared and ^{1}H nmr spectroscopy, all of which confirmed the presence of the neutral donor and the catecholate ligands, and also demonstrated the absence of the original *o*-quinone (no ν(C=O) at 1700 cm^{-1}). In three cases, the molar mass of the product was confirmed by field desorption mass spectrometry, with the manifold of peaks from the molecular ion appearing as the most abundant species. The values given in Table 1 correspond to the most intense line in the manifold, and in each case computer simulation of the isotopic distribution within the manifold agreed with the experimental results. Similar determinations could not be carried out for the other products because of the limitations imposed by the m/e range of the mass spectrometer.

Reaction [1] is formally equivalent to oxidative addition. Given our results on indium(I) systems, and the work on transition metals such as the copper complexes of semiquinones (5), it seems very probable that reaction [1] actually proceeds

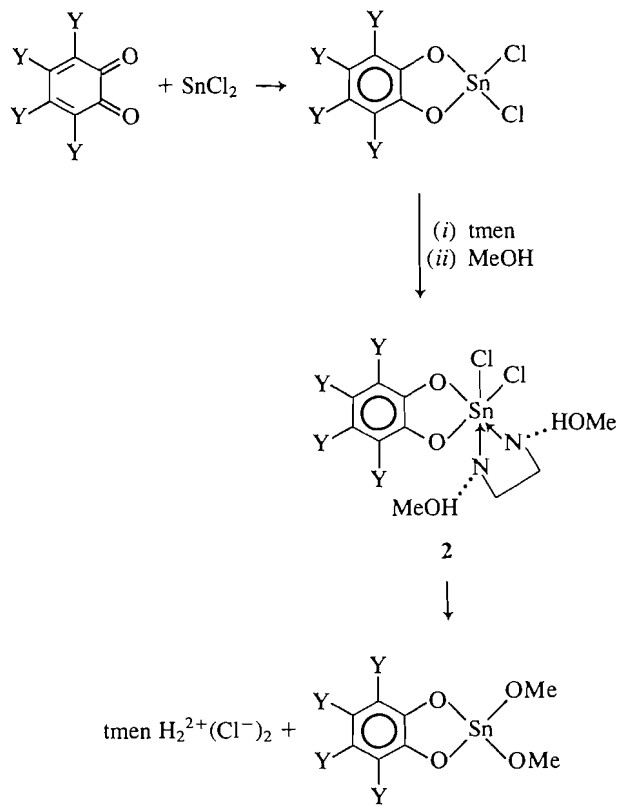
via successive one-electron transfers, but the experimental conditions of these systems did not permit detailed studies by esr spectroscopy. It is clear that the mechanism proposed to account for the insertion of InX into M—M and M—X bonds (6, 7) cannot apply in the case of eq. [1], since neither the ground state nor any readily accessible excited state of the quinone can act as an electron pair acceptor, but a detailed discussion of this point must await further investigations of related systems.

The $Y_4C_6O_2SnX_2$ molecules identified as the primary product in eq. [1] are clearly Lewis acids, in keeping with the presumption that the coordination number at tin is four. The adducts formed with 1,10-phenanthroline are thermally stable, and only slightly soluble in most common organic solvents. The tmen derivatives of $Cl_4C_6O_2SnCl_2$ are more labile, and the reactions leading to these compounds merit some discussion. The preparations in either toluene or acetone give the expected 1:1 adduct, but in methanol or ethanol the product is solvated by strongly bound ROH which is probably hydrogen-bonded either to a chloride ligand or to an oxygen atom of the catecholate ligand. The other products obtained from this reaction mixture are the salt $(tmenH_2)Cl_2$ and the tin alkoxide derivatives $Cl_4C_6O_2Sn(OR)_2$. On the basis of the experimental evidence, we suggest that the reaction sequence is



This sequence implies that the difference between CH_3OH and C_2H_5OH resides in the composition of the solvate **2** formed in the second step. The formation of such solvates, and the subsequent intramolecular reaction, are common features of tin(IV) chemistry. The products $Cl_4C_6O_2Sn(OR)_2$ may be stabilized by intermolecular Sn...O bonding.

The unexpected formation of the $[Sn(O_2C_6Cl_4)_3]^{2-}$ anion took place during experiments designed to investigate the insertion of InCl into the Sn—Cl bond of $Cl_4C_6O_2SnCl_2$, following earlier work on such insertion reactions between InX and Ph_3SnX (7). The following sequence is in keeping with the known reactions of SnX_2 and $Cl_4C_6O_2$ (= Q), as demontrated in this work, and of InX and InX_3.

The structure of $(tmenH)_2[Sn(O_2C_6Cl_4)_3]$ (1)

The crystal structure of **1** confirms the presence of the anionic triscatecholato complex of tin(IV). The $tmenH^+$ cations show no unusual stereochemical features except that there is clear evidence of hydrogen-bonding at Cl(1) of two $Cl_4C_6O_2^{2-}$ ligands, with Cl(1)---H—N = 2.626 Å, and N(2)—H---Cl(1) = 144.8° (Fig. 2). There are no significant non-bonded distances involving the hydrogen atoms of the cation (Cl(1)—

[a]Results from ref. 14.

H(12A) = 2.936 Å; Cl(2)—H(13A) = 2.908 Å; Cl(4)—H(13B) = 2.953 Å; Cl(5)—H(11) = 3.052 Å; Cl(5)—H(13A) = 2.901 Å; Cl(6)—H(16A) = 2.943 Å). It seems reasonable to conclude that the hydrogen-bonding is responsible in part for the stability of the crystals isolated.

The bond distances observed in the $[Sn(O_2C_6Cl_4)_3]^{2-}$ anion (Fig. 1) are typical of those reported for other tin(IV) complexes. The average Sn—O bond length is 2.062(3) Å, in good agreement with the values reported for $CF_3CO_2^-$ ligands coordinated to octahedral tin(IV) in the complex $[Sn^{II}Sn^{IV}O(O_2CCF_3)_4]_2$ (range 2.040(6)–2.070(7) Å) (8). Some older results include $Sn(OCCH_3)_4$ (mean *r*(Sn—O) = 2.22, range 2.13–2.29 Å) (9) and $[Sn^{II}Sn^{IV}(O_2CC_6H_4NO_2\text{-}o).THF]_2$ (mean *r*(Sn—O) at octahedral tin(IV) = 2.059, range 2.047(6)–2.067(7)) (10); the latter paper reviews earlier results for Sn^{IV}—O bonds in a variety of stereochemistries. In the present structure, the Sn—O_6 kernel is distorted octahedral, with the average O—Sn—O bite angle = 81.5(2)°.

The coordinated $Cl_4C_6O_2$ ligands are aromatic, with planar hexagonal C_6 rings, with *r*(C—C)(av) = 1.400(9) Å, and C—C—C(av) = 120.0(7)°. The C—Cl distances are typical of those in aromatic compounds, as are the C—O values, but these bonds (av. 1.336(5) Å) are significantly longer than the average of 1.29 Å found in a variety of transition metal complexes of the 3,5-di-*tert*-butyl-*o*-semiquinato ligand (11, 12), thus confirming that the reduction of the $Cl_4C_6O_2$ ligand has indeed proceeded beyond the semiquinone state to the dianion. In summary, there is ample confirmation from the crystallographic results that the reaction product in this case is a tin(IV)—catecholate derivative. The remaining features of the structure do not call for any comment.

Spectroscopic results

The most informative region of the infrared spectra is the ν(C=O) mode, which occurs at ~1700 cm^{-1}, vs, in both tetrahalogeno-*o*-quinones. This band is absent in all the tin compounds prepared in this work, being replaced by ν(C—O) vibrations at 1430m + 1240s cm^{-1}, indicating the presence of the *o*-$Cl_4C_6O_2^{2-}$ ligand.

The ^1H nmr spectra have been noted in the Experimental

Section and are tabulated in Table 5. The ^{13}C spectra of those products which are sufficiently soluble for such measurements are summarized in Table 6. Significant changes occur in the ^{13}C resonance spectrum of $Cl_4C_6O_2$ following reduction from the quinone to the catechol form, and these same changes are apparent in the spectra of the neutral adducts with tmen or phen, and in the $[Sn(O_2C_6Cl_4)_3]^{2-}$ anion, again confirming the presence of the reduced form in each of these species. Smaller changes are observed in the spectrum of tmen or phen upon coordination, or on formation of the protonated species. It is rather surprising that $tmenH^+$ cation shows two sets of resonances, and we conclude that the hydrogen-bonding evident in the solid state (Fig. 2) persists in solution, thus removing the degeneracy observed in the spectrum of the free ligand.

In general, we conclude that the spectroscopic evidence is exactly congruent with that from X-ray crystallography, and shows clearly that the reaction of SnX_2 with the tetrahalogeno-*o*-quinones is an oxidative addition process to give the appropriate tin(IV) species.

Electrocatalytic reduction of molecular oxygen by mononuclear and binuclear cobalt phthalocyanines

MICHAEL R. HEMPSTEAD,[1] A. B. P. LEVER,[1] AND CLIFFORD C. LEZNOFF
Department of Chemistry, York University, North York, Ont., Canada M3J 1P3

Received March 25, 1987

MICHAEL R. HEMPSTEAD, A. B. P. LEVER, and CLIFFORD C. LEZNOFF. Can. J. Chem. **65**, 2677 (1987).

Investigations of the electrocatalytic activity of mononuclear and binuclear cobalt phthalocyanines for the reduction of molecular oxygen established that the latter compounds are more effective catalysts than the corresponding mononuclear species. A correlation between the half-bandwidths for the Q band of these species and their catalytic efficiency, expressed as a kinetically-limited current, suggests that the increase in activity may be attributed to electronic coupling between the phthalocyanine rings.

MICHAEL R. HEMPSTEAD, A. B. P. LEVER et CLIFFORD C. LEZNOFF. Can. J. Chem. **65**, 2677 (1987).

Des études sur l'activité électrocatalytique des phtalocyanines de cobalt mononucléaires et binucléaires pour la réduction de l'oxygène moléculaire ont permis d'établir que les derniers composés sont des catalyseurs plus efficaces que les espèces mononucléaires correspondantes. Une corrélation entre les demi-largeurs des bandes Q de ces espèces et leur efficacité catalytique, exprimée sous la forme de courant limite cinétique, suggère que l'augmentation de l'activité peut être attribuée au couplage électronique entre les cycles phtalocyanines.

[Traduit par la revue]

Introduction

If a fuel cell is to operate efficiently, a catalyst must be embedded in the cathode to accelerate the reduction of oxygen gas. This catalyst must be capable of withstanding the operating conditions of the fuel cell (strong acid or base, fairly high temperatures), for long periods of time, without loss of activity. Platinum is commonly used as a fuel cell catalyst, but is expensive, representing some 10% of the total fuel cell cost. Catalysts which are more effective and less expensive are needed, if fuel cell applications are to become viable.

Many mononuclear metal porphyrins act as electrocatalysts (1–21) but the work of Collman and Anson (22–28) and Chang and co-workers (29–35) has revealed that certain binuclear porphyrins are much more effective. Similarly, mononuclear phthalocyanines of iron and cobalt are effective (36–50), but some ill-characterised "dimeric" and polymeric phthalocyanines appear more effective (51–62). Savy and co-workers (54–56) performed ESCA, esr, Mössbauer and optical spectroscopic studies to establish correlations between the spectroscopic properties of polymeric and monomeric iron phthalocyanines and the electrocatalytic activity of these species towards oxygen reduction. We consider here a correlation between the optical spectra of a series of well-characterized mono- and binuclear cobalt phthalocyanines and their electrocatalytic activity.

The binuclear porphyrins studied by Collman and Anson are too fragile for long-term use under fuel cell conditions and therefore our studies have been directed towards thermally more stable binuclear phthalocyanine compounds. We have recently reported (63–65) a series of binuclear phthalocyanine complexes of the general formula [M—tri(neopentoxy)phthalocyanine]$_2$(bridge) where the bridge may contain 1, 2, 4, or 5 atoms, and where M may be H_2, Cu, or Co. The three neopentoxy groups are randomly distributed in the 4 or 5 positions of the three unbridged benzene rings, providing solubility in many organic solvents, e.g., toluene, *o*-dichlorobenzene, and dichloroethane, but generally not acetone and ethanol.

Of relevance to this presentation are the following species, with their abbreviations (the number in parentheses is the number of bridging atoms connecting the two phthalocyanine rings): CoTNPc, 2,9,16,23-tetraneopentoxyphthalocyanatocobalt(II). This is the mononuclear control molecule. O(1)[CoTrNPc]$_2$, bis-2-(9,16,23-trineopentoxyphthalocyaninylcobalt(II))ether; two phthalocyanine rings linked by a single oxygen (ether) bridge. C(2)[CoTrNPc]$_2$, 1,2-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninylcobalt(II))ethane; two phthalocyanine rings linked by an ethane —CH_2CH_2— bridge. Cat(4)[CoTrNPc]$_2$, 1,2-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxycobalt(II))benzene; two phthalocyanine rings linked by a catechol —O—C_6H_4—O— bridge. EtMeO(5)[CoTrNPc]$_2$, 1,3-bis-2′-(9′,16′,23′-trineopentoxyphthalocyaninoxycobalt(II))-2-ethyl-2-methylpropane; two phthalocyanine rings linked by a —$OCH_2C(Et)(Me)CH_2O$— bridge.

Earlier investigations of the metal-free analogues of these species (66) established properties of these compounds which are relevant to the observations reported here. These properties are as follows. (*i*) In condensed phases (frozen solution glass, Nujol mull, etc.), these complexes may exhibit *inter*molecular aggregation. In dilute solution, $<5 \times 10^{-5}$ *M*, *inter*molecular aggregation is generally absent (67). (*ii*) Some binuclear phthalocyanines may close upon themselves ("clamshell" behaviour) to aggregate via cofacial *intra*molecular aggregation. Specifically, of the metal-free species, only Cat(4)[TrNPcH$_2$]$_2$ and EtMeO(5)[TrNPcH$_2$]$_2$ are capable of such *intra*molecular aggregation. Such species exist in a dynamic equilibrium with "open" conformations. (*iii*) The electronic spectra of the metal-free species show evidence of the coupling of the transition moments on each phthalocyanine ring (66). Thus direct through space coupling is observed in the cofacial conformations, giving rise to a blue shift in the Q and Soret absorptions. However, a blue shift is also observed in the other metal-free species, as a consequence of coupling through space (or through the bridge) in "open", non-aggregated conformations.

Note that electronic coupling is more readily detected in the electronic spectra of binuclear phthalocyanine species, relative to comparable porphyrin species, because the visible region transition moments are much larger in the former case (68).

Experimental

The species Co(II)TNPc (64), EtMeO(5)[Co(II)TrNPc]$_2$ (64), C(2)[Co(II)TrNPc]$_2$ (65), Cat(4)[Co(II)TrNPc]$_2$ (65), and O(1)-[Co(II)TrNPc]$_2$ (69) were prepared by literature routes. Aldrich Gold

Label *o*-dichlorobenzene (DCB) was used without further purification and Fisher certified 1 *N* sodium hydroxide was diluted as required for the aqueous studies. Water was purified by double-distillation over $KMnO_4$ followed by passage through a Barnstead organic removal cartridge and two Barnstead mixed resin ultrapure cartridges. Stress-annealed pyrolytic graphite (SAPG) and ordinary pyrolytic graphite (OPG), obtained from Union Carbide, were used as electrode materials. The graphite was mounted in Teflon to expose a circular area of 0.490 cm^2 for the SAPG electrode and 0.493 cm^2 for the OPG electrode. Before each experiment, the OPG electrode surface was cleaned by successive polishings with 1.0 μm, 0.3 μm, and 0.05 μm alumina (Linde) suspended in water on Metron polishing cloth. Argon gas (Linde) was purified by passage through heated copper filings, anhydrous $CaSO_4$ (Drierite), molecular sieves (BDH Type 3A), and glass wool. Oxygen gas (Linde) was purified by passage through anhydrous $CaSO_4$, NaOH pellets (AnalaR analytical grade), anhydrous $CaSO_4$, molecular sieves, and glass wool. Tetrabutylammonium perchlorate (TBAP) (Eastman Kodak) was recrystallized from absolute ethanol and dried in a vacuum oven at 50°C for 2 days. Potential scans were performed with a Pine Instruments RD3 potentiostat and the rotation studies with a Pine Instruments PIR rotator. The cell for the adsorption experiments employed a medium frit to separate a silver wire quasi-reference electrode from the main chamber containing the OPG working electrode and a platinum wire counter electrode. The cell for the aqueous studies comprised a separate chamber for each electrode with a Luggin capillary extending from the reference chamber to the proximity of the OPG surface. For all aqueous experiments, the potential was measured versus a saturated calomel electrode (sce).

Phthalocyanine solutions were prepared in DCB with 0.1 *M* TBAP as supporting electrolyte, such that the concentration was ca. 10 μ*M* with respect to the TNPc unit. These solutions were purged with argon for about an hour before scanning the working electrode at a rate of 100 mV/s over the range 0.00 to +1.00 V versus the silver wire. Adsorbed layers on OPG or SAPG electrodes were obtained by cycling until the anodic and cathodic peak currents associated with the adsorbed species remained constant over 5 min of continuous scanning. When this condition was satisfied, the adsorbed layer was assumed to have reached a steady coverage. Scans at various rates were then recorded to determine the surface coverage (*vide infra*).

The catalytic efficiency of the various phthalocyanine compounds was investigated with the adsorbed species on the OPG electrode. This modified electrode was removed from the phthalocyanine solution, washed with ethanol, then with water, and finally placed in the cell for the aqueous studies. The 0.10 *M* NaOH solution in this cell had been purged with oxygen for several hours to ensure saturation. The electrode was then scanned over the range 0.00 to −1.00 V versus sce at a rate of 10 mV/s for rotation rates ranging from 400 to 10 000 rpm. After each scan, the electrode was held at 0.00 V for 1 min to permit the rotation rate to be changed for the next scan.

Results

(I) Adsorption studies

Some preliminary adsorption experiments were performed on a SAPG electrode to determine the electronic nature and orientation of the adsorbed species. The cyclic voltammograms for a solution of 2.5×10^{-5} *M* CoTNPc in DCB and 0.1 *M* TBAP studied at a SAPG working electrode, as shown in Fig. 1, display two couples in close proximity. Following deconvolution of these waves,[2] a plot (Fig. 2*A*) of cathodic peak current, $i_{p,c}$, versus scan rate, ν, for couple I ($R = 0.999$) and a

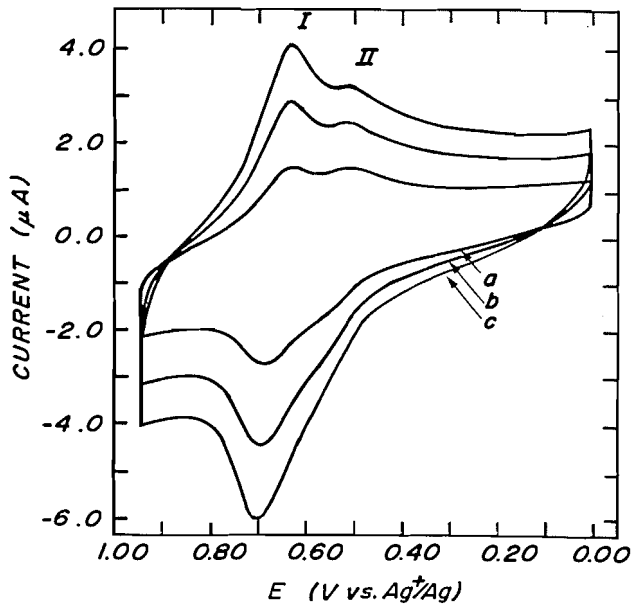

FIG. 1. Cyclic voltammograms at scan rates of (*a*) 50 mV/s, (*b*) 100 mV/s, and (*c*) 150 mV/s for 2.5×10^{-5} *M* CoTNPc in DCB and 0.1 *M* TBAP under argon at a SAPG working electrode. Couples I and II are both associated with the $[Co(II)TNPc(-1)]^+/Co(II)TNPc(-2)$ process. The nature of these couples is investigated more fully in Fig. 2.

plot (Fig. 2*B*) of $i_{p,c}$ versus $\sqrt{\nu}$ for couple II ($R = 0.998$) indicated that these couples were adsorption and diffusion processes (71), respectively. From the relative positions of couples I and II, it follows that the adsorbed species binds most strongly in the reduced form associated with couple II (72), although the presence of a reductive adsorption wave indicates that the oxidized form associated with this couple also binds to the electrode. Couple II is associated with the ligand process $[Co(II)TNPc(-1)]^+/Co(II)TNPc(-2)$ (73) and therefore CoTNPc binds to the graphite surface most strongly as $Co(II)TNPc(-2)$. The binding between the CoTNPc and the SAPG electrode can be explained by π−π interactions between the phthalocyanine ring and the graphite lattice, if the CoTNPc is adsorbed flat to the SAPG surface. This mode of adsorption has also been suggested in a similar investigation (41) by Yeager and co-workers who studied cobalt tetrasulphonate phthalocyanine (CoTSPc).

In addition to the electronic nature and orientation of the adsorbed molecule, the extent of coverage of the catalyst on the electrode surface must be known. Quantitative analysis requires the selection of an appropriate adsorption isotherm to describe the cyclic voltammetric response of the adsorbate. An adsorption isotherm describes the relationship between the concentrations of the adsorbate in the adsorption layer and in the bulk phase from which the adsorption takes place. Appropriate isotherms may also yield information about interactions between molecules in the adsorption layer.

The Langmuir isotherm was used to analyse the adsorption of CoTNPc on a SAPG electrode. This isotherm applies to systems in which there are no interactions between the adsorbed molecules (72). For systems which satisfy these conditions, the value of n may be calculated from the peak-width-at-half-height, $W_{1/2}$, from the expression

$$[1] \quad n = \frac{2RT}{W_{1/2}F} \ln (3 + 2\sqrt{2})$$

[2]The cathodic waves for these couples were deconvoluted by subtracting the background from a neat DCB solution to obtain a baseline followed by construction of a symmetric wave about the peak of couple I. The contribution of the symmetric wave in the region of mixed currents was subtracted from the observed response to obtain the current associated with couple II. Complete details of this deconvolution are described in ref. 1.

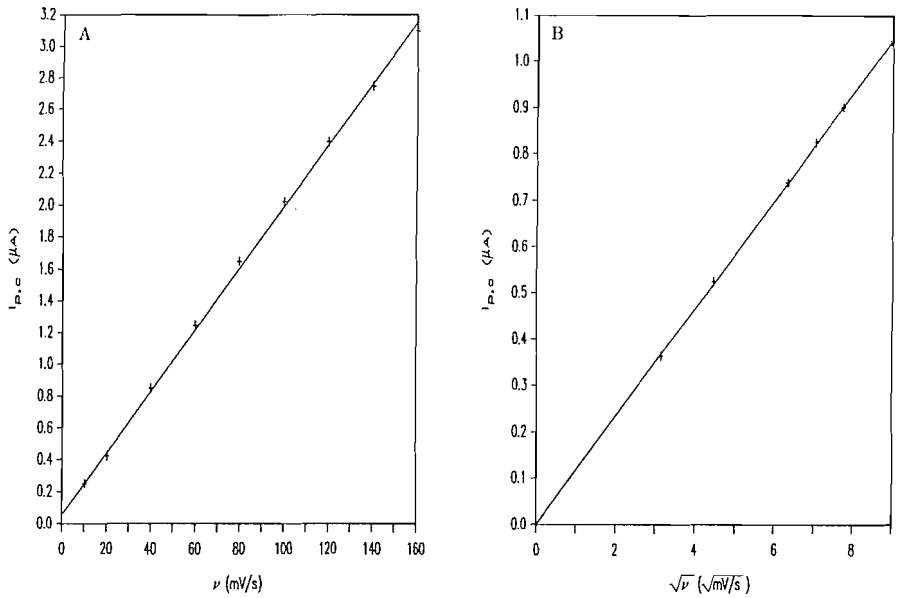

FIG. 2. Plots of the dependence of cathodic peak current with scan rate for (*A*) couple I and (*B*) couple II, as designated in Fig. 1 (2.5×10^{-5} *M* CoTNPc in DCB and 0.1 *M* TBAP at a SAPG working electrode).

The average value of n calculated in this fashion was 1.00 ± 0.02 in excellent agreement with our expectation of a one-electron process. By calculating the charge under the adsorption peak and assuming the area of a phthalocyanine molecule, A_{pc}, is 200 Å^2 (41), the coverage of CoTNPc on a SAPG electrode was determined to be about 0.30 ± 0.1 monolayers. This low level of coverage is consistent with another study (41) in which CoTSPc adsorbed on SAPG to the extent of 0.4 monolayers.

Since a coverage of between one and two monolayers was desired for these oxygen reduction studies, SAPG was not used for these investigations. (Recent studies have established a method for obtaining a coverage of one monolayer on SAPG which will be employed in later investigations.) Yeager and co-workers (42) found that CoTSPc could be adsorbed on OPG to about four times the coverage on SAPG; the greater adsorption on the OPG electrode was attributed to a higher density of surface defects assumed to be critical to adsorption (74). Adsorption experiments with CoTNPc and an OPG electrode did show enhanced adsorption, as shown in Fig. 3. This increased adsorption affects the cyclic voltammograms in many ways. The most readily apparent effect is the loss of the diffusion wave which had been observed in conjunction with an adsorption wave when using SAPG. Since the adsorption wave overwhelms the diffusion wave under the conditions employed for this experiment (71), later calculations of surface coverage disregard contributions from diffusion and treat this as a pure adsorption process. The other noticeable effect in Fig. 3 is the large peak separation observed at higher scan rates. This probably arises from the larger currents observed in this scan and the high *iR* drop in these DCB solutions.

The adsorption studies with the OPG electrode were analysed with the Langmuir isotherm which gave an average n value of 0.72 ± 0.04, suggesting that the use of the Langmuir isotherm was not appropriate for this system. An alternate choice, the Frumkin isotherm (75–78) is useful for systems in which there are interactions between adsorbed molecules. A recent investigation (78) of several isotherms suggests that the Frumkin isotherm is most appropriate for electrochemical processes involving the adsorption of organic compounds. According to the Frumkin isotherm, the peak current and the value of n are

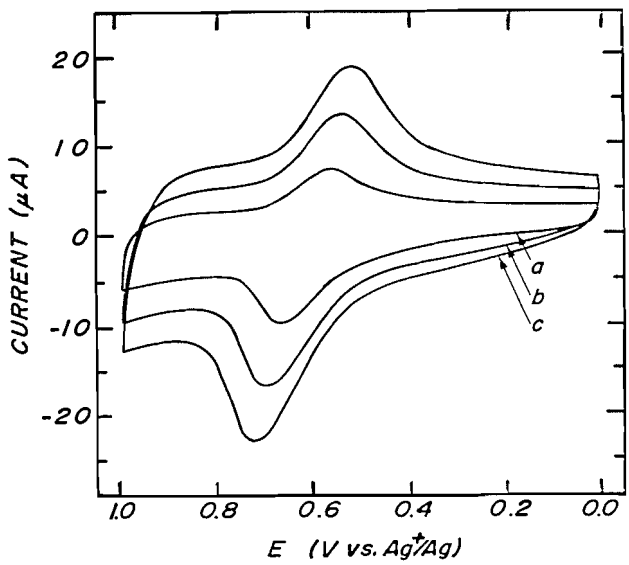

FIG. 3. Cyclic voltammograms at scan rates of (*a*) 50 mV/s, (*b*) 100 mV/s, and (*c*) 150 mV/s for 1.0×10^{-5} *M* TNPcCo in DCB and 0.1 *M* TBAP at an OPG working electrode. The waves shown here are associated with the $[Co(II)TNPc(-1)]^+/Co(II)TNPc(-2)$ couple.

given by the expressions (77)

$$[2] \quad i_p = \frac{n^2F^2A\Gamma\nu}{RT(4 - 2r\Gamma)}$$

$$[3] \quad n = \frac{2RT}{W_{1/2}F}\left[\ln P - r\Gamma\frac{P-1}{P+1}\right]$$

where r is an interaction parameter (cm^2/mol), Γ is the surface concentration of the adsorbed species (mol/cm^2), and P is given by

$$[4] \quad P = 3 - r\Gamma + (r^2\Gamma^2 - 6r\Gamma + 8)^{1/2}$$

Repulsive interactions are denoted by negative values of r while stabilizing interactions are denoted by positive values of r. If the interactions between adsorbed molecules are repulsive, the wave broadens and the peak decreases, but if the interactions

TABLE 1. Average values of θ and $r\Gamma$ for an OPG electrode modified with CoTNPc or one of its binuclear derivatives

Compound	θ	$r\Gamma$
CoTNPc	1.4 ± 0.4	−0.77 ± 0.14
O(1)[CoTrNPc]$_2$	1.3 ± 0.4	−1.36 ± 0.11
C(2)[CoTrNPc]$_2$	1.8 ± 0.1	−0.87 ± 0.13
Cat(4)[CoTrNPc]$_2$	2.2 ± 0.2	−0.88 ± 0.06
EtMeO(5)[CoTrNPc]$_2$	2.2 ± 0.4	−0.85 ± 0.01

are attractive, the wave narrows and the peak increases. If the interaction parameter is zero, then the Frumkin isotherm expressions simplify to those given by the Langmuir isotherm.

The cyclic voltammograms from the adsorption studies on OPG displayed waves which were broader and more rounded than those observed for the SAPG experiments. This change in waveshape indicates that at these higher coverages, repulsive interactions exist between molecules adsorbed on the electrode surface. The voltammograms which had been analysed by the Langmuir isotherm to give an average n value of 0.72 ± 0.04 when analysed by the Frumkin isotherm yielded 0.93 ± 0.03 in much better agreement with the expected value of unity.

Average values of the dimensionless parameters $r\Gamma$ and the average surface coverage, θ (where $\theta = \Gamma A_{pc}$), are presented in Table 1 for an OPG electrode modified with CoTNPc or one of its binuclear derivatives. The surface coverage calculations for the binuclear compounds used the same area approximation per phthalocyanine unit as had been used for CoTNPc since these calculations were designed to estimate the number of cobalt atoms on the electrode surface, not the number of phthalocyanine molecules. As a means of clarifying this point, consider the following example. If a value of 2.0 is calculated for θ, this could indicate that the electrode is covered by two monolayers of the mononuclear species, two layers of a binuclear species in an "open" configuration, or one layer of a binuclear species in a cofacial configuration. Consideration of steric restraints in these molecules and the behaviour of these species in solution is required to infer the manner in which these molecules adsorb on the electrode surface.

The θ value of 1.4 ± 0.4 for CoTNPc-modified OPG electrodes is most likely indicative of a coverage of one monolayer. The reported θ may be somewhat high as it is based on the geometric area of the electrode and does not account for the inherent roughness of the surface. It is improbable that a second layer forms on the surface since none of the adsorbate is lost after washing and transferring to an aqueous solution. A weakly bound second layer of CoTSPc on OPG has been reported (74), but it was readily removed by washing.

The average coverage for the molecule O(1)[CoTrNPc]$_2$ was 1.3 ± 0.4, which is quite similar to that found for CoTNPc. The adsorption of O(1)[CoTrNPc]$_2$ was anticipated to be similar to that of CoTNPc because this binuclear species can only exist in an "open" conformation. The O(1)[CoTrNPc]$_2$ molecule would adsorb with one ring flat on the OPG surface while the other ring lies at some oblique orientation. The ring in the oblique orientation would give this surface a highly disordered structure and, from the $r\Gamma$ value in Table 1, it would appear that it also leads to abnormally high repulsive interactions.

The remaining binuclear phthalocyanines have average θ values near two. If these molecules adsorbed on to the electrode surface in an "open" conformation then a θ value near two would not be expected since, as noted earlier, the π–π

TABLE 2. Half-bandwidths of the Q band for CoTNPc and its binuclear derivatives as Co(III) and also as Co(I)[a]

Compound	Half-bandwidths (cm^{-1}) Co(III)	Co(I)
CoTNPc	680	660
C(2)[CoTrNPc]$_2$	765	735
Cat(4)[CoTrNPc]$_2$	800	775
EtMeO(5)[CoTrNPc]$_2$	785	775
O(1)[CoTrNPc]$_2$	1000	920

[a]These half-bandwidths were calculated from the spectra obtained by bulk electrolysis of DCB solutions containing these species along with an excess of tetrabutylammonium-hydroxide and 0.1 *M* TBAP (80).

interactions which arise between the first and second layer of phthalocyanine molecules adsorbed on the electrode surface are too weak to stabilize a second layer. It would therefore appear that most of these binuclear species adsorb on to the electrode surface in some sort of cofacial arrangement. This configuration is easily obtained by Cat(4)[CoTrNPc]$_2$ and EtMeO(5)[CoTrNPc]$_2$, but the stacking of C(2)[CoTrNPc]$_2$ would necessitate that the phthalocyanine rings in the second layer lie above a surface bound ring of an adjacent C(2)[CoTrNPc]$_2$ molecule. The values of $r\Gamma$ reported for these binuclear compounds are fairly consistent and are quite similar to the value of −0.7 reported by Collman and Anson (28) for one of their cofacial cobalt porphyrins. It has been suggested that the source of repulsions observed for flatly adsorbed aromatic molecules such as these, is the parallel orientation of their dipoles (79).

Another interesting feature of these adsorption studies is illustrated in Fig. 4. The cyclic voltammograms for O(1)[CoTrNPc]$_2$ and Cat(4)[CoTrNPc]$_2$ display one adsorption wave for the [Co(II)TrNPc(−1)]$^+$/Co(II)TrNPc(−2) couple, just like that observed for the adsorption of CoTNPc on OPG (see Fig. 3). However, the cyclic voltammograms for C(2)[CoTrNPc]$_2$ and EtMeO(5)[CoTrNPc]$_2$ display two couples in the same potential region. Plots of i_p versus ν for the two couples are linear, thus both couples arise from adsorption processes. Frumkin isotherm analysis yielded values of n close to unity which, when combined with the potential of these couples, suggests that these couples are both associated with the [Co(II)TrNPc(−1)]$^+$/Co(II)TrNPc(−2) process. The origin of these two adsorption processes may be explained in terms of the electronic coupling inherent in these binuclear compounds.

The theory of intramolecular coupling in these binuclear phthalocyanines has been presented elsewhere (66). In solution, these binuclear species are expected to exist in a dynamic equilibrium between various conformations, dependent upon the nature of the bridge since, in some cases, steric effects may provide barriers to free rotation. Therefore, the electronic absorption spectrum of a solution of one of these binuclear species would represent the summation of the spectra of a mixture of these conformers. The coupling in these species resulted in a blue-shifted Q band which was also broadened, the degree of this broadening being a qualitative measure of the degree of electronic coupling in these binuclear species.

The half-bandwidths of the five phthalocyanine species investigated in this study are presented in Table 2 (80). The relative extent of coupling in these compounds, as established

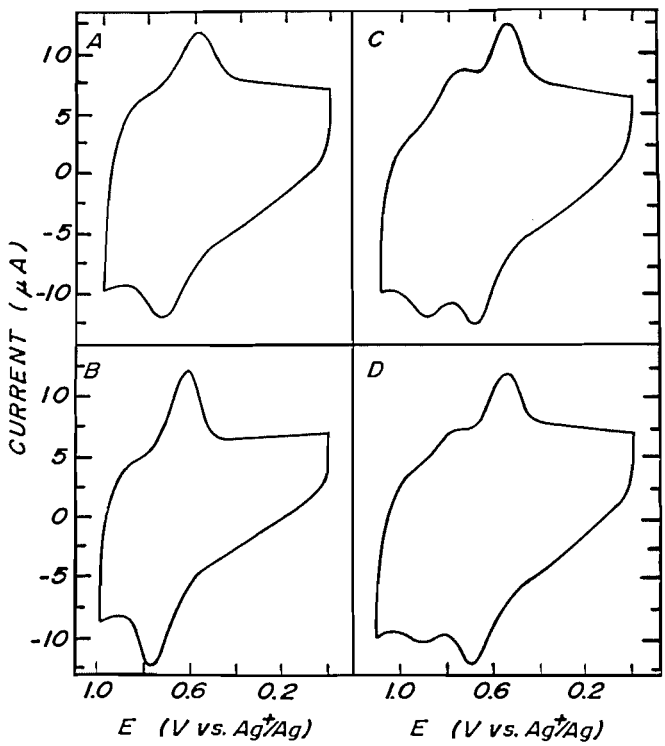

FIG. 4. Cyclic voltammograms displaying adsorption features of (*a*) O(1)[TNPcCo]$_2$, (*b*) Cat(4)[TNPcCo]$_2$, (*c*) C(2)[TNPcCo]$_2$, and (*d*) EtMeO(5)[TNPcCo]$_2$. All voltammograms were recorded at a scan rate of 100 mV/s for a binuclear concentration of ca. 5 μM in DCB and 0.1 *M* TBAP. The waves shown here are associated with the [Co(II)TNPc(−1)]$^+$/Co(II)TNPc(−2) couple.

by these half-bandwidths, is as follows:

[5] O(1)[CoTrNPc]$_2$ > EtMeO(5)[CoTrNPc]$_2$ ≃ Cat(4)[CoTrNPc]$_2$ > C(2)[CoTrNPc]$_2$ > CoTNPc

Cyclic voltammograms of each of the binuclear species are presented in Fig. 4. In the voltammograms of C(2)[CoTrNPc]$_2$ and EtMeO(5)[CoTrNPc]$_2$, two adsorption waves are observed which arise from two distinct redox couples in close proximity. Similar voltammograms have been reported previously (28, 81) but, in these earlier reports, both of the redox processes could be observed when the species was in solution, not bound to the electrode surface. For each of the adsorbed binuclear species, one phthalocyanine ring lies on the electrode surface while the other ring is not in contact with it. The two redox couples, therefore, are regarded to arise from the bound Pc ring, and the bridged Pc ring which is not bound directly to the electrode. In solution, only one redox process is observed, common to both rings. In the more highly coupled species, namely O(1)[CoTrNPc]$_2$ and Cat(4)[CoTrNPc]$_2$, electron transfer across the bridge to the outer phthalocyanine ring is facile and therefore only one redox couple is observed. However, electron transfer across the saturated C(2)[CoTrNPc]$_2$ and EtMeO(5)[CoTrNPc]$_2$ bridges is inhibited and therefore the redox potential for the outer phthalocyanine ring could differ from that of the inner phthalocyanine ring. Although the O(1)[CoTrNPc]$_2$ bridge is, technically, also a saturated bridge, it is apparent from the half-bandwidth studies mentioned above, that electron transfer across this bridge is permissible. This proposal could explain the differences between the cyclic voltammograms given in Fig. 4, although further study would be necessary to establish the source of this behaviour conclusively.

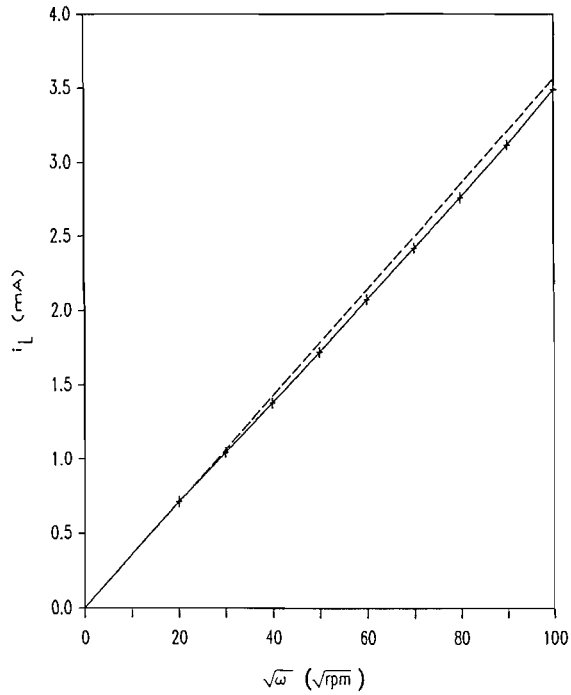

FIG. 5. Levich plot of the diffusion-limited O_2 reduction current at a CoTNPc-modified OPG electrode. The dashed line is the response predicted by eq. [6] and the solid line is the fit through the experimental data denoted by + signs.

(II) Oxygen studies

The catalytic properties of these phthalocyanine species were investigated by means of rotating disc electrode (RDE) studies. The diffusion-limited current for such an experiment, expressed in mA, is described by the expression (82)

$$[6] \quad i_L = 1000nAFC\left(\frac{2\pi\upsilon\omega}{60}\right)^{1/2} \times \left[\frac{0.62048S^{-2/3}}{1 + 0.2980S^{-1/3} + 0.14514S^{-2/3}}\right]$$

where υ is the kinematic viscosity (cm^2/s), ω is the rotation rate (rpm), S is the Schmidt number ($S = \upsilon/D$), A is the electrode area (cm^2), F is Faraday's constant, and C is the concentration of O_2 (mol/cm^3). A Levich plot (i_L versus $\omega^{1/2}$) of the diffusion-limited O_2 reduction current at a CoTNPc-modified OPG electrode is shown in Fig. 5. In the calculation of i_L for this Levich plot, the diffusion coefficient and concentration of O_2 were taken as 1.67×10^{-5} cm^2/s (42) and 1.38×10^{-6} mol/cm^3 (83), respectively, the kinematic viscosity was estimated at 9.97×10^{-3} cm^2/s (84), the Schmidt number was calculated to be 597, and the value used for n was two. The good agreement between the calculated diffusion-limited current and the experimentally observed limiting current suggests that O_2 is undergoing a two-electron reduction to peroxide rather than a four-electron reduction to water. Further evidence for this two-electron reductive pathway will be presented later.

If an electrode process is hindered by a kinetic step, a plot of i_L, or i, versus $\omega^{1/2}$ deviates from the linear relationship given in eq. [6] (71). The effect of this kinetic step on the current that flows in the potential region of mixed diffusion-kinetic control for a first-order process under steady-state conditions is given by the expression (85–88):

$$[7] \quad 1/i = 1/i_k + 1/i_L$$

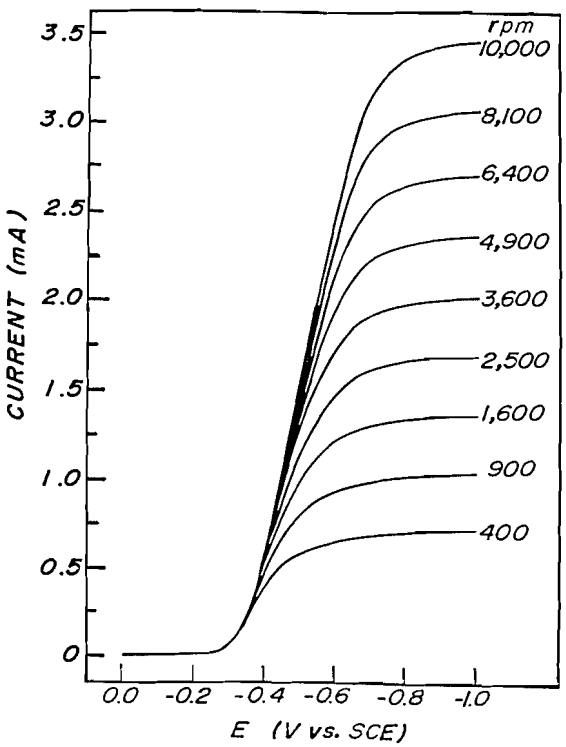

FIG. 6. Reduction of molecular oxygen at a rotating OPG electrode modified CoTNPc in an O_2-saturated 0.10 M NaOH solution.

in which i_k is the kinetically-limited current. A plot of $1/i$ versus $1/\omega^{1/2}$, known as the Koutecky–Levich plot, establishes this kinetically-limited current which is equivalent to the current that would flow if the concentration of O_2 at the electrode surface could be maintained at its bulk concentration during the reduction process. Therefore, i_k at a given potential is directly proportional to the maximum rate at which O_2 can be reduced to peroxide at the catalyst-modified electrode at that potential (89).

The reduction of O_2 at an OPG electrode modified with CoTNPc is shown in Fig. 6. These scans were recorded at 10 mV/s, but may be considered to be steady-state curves since no hysteresis was observed between the forward and reverse scans. Following the procedures presented by Frumkin and Tedoradse (90), Koutecky–Levich plots at −0.450 V, −0.500 V, −0.550 V, and −0.600 V were constructed. Koutecky–Levich plots of O_2 reduction at −0.450 V for OPG electrodes modified with CoTNPc and each of its binuclear derivatives are given in Fig. 7. The scatter for Koutecky–Levich plots was small ($R > 0.999$) and the n values calculated from the slopes of these plots (Table 3) were consistent with a two-electron process yielding peroxide as the reduction product. The different intercepts for the Koutecky–Levich plots illustrate that the catalytic activity of these species differ. The kinetically-limited currents for oxygen reduction are presented in Table 4. These kinetically-limited currents have been normalized to the CoTNPc data to rank the catalytic efficiency of the binuclear species and these normalized kinetically-limited currents are presented in parentheses in Table 4.

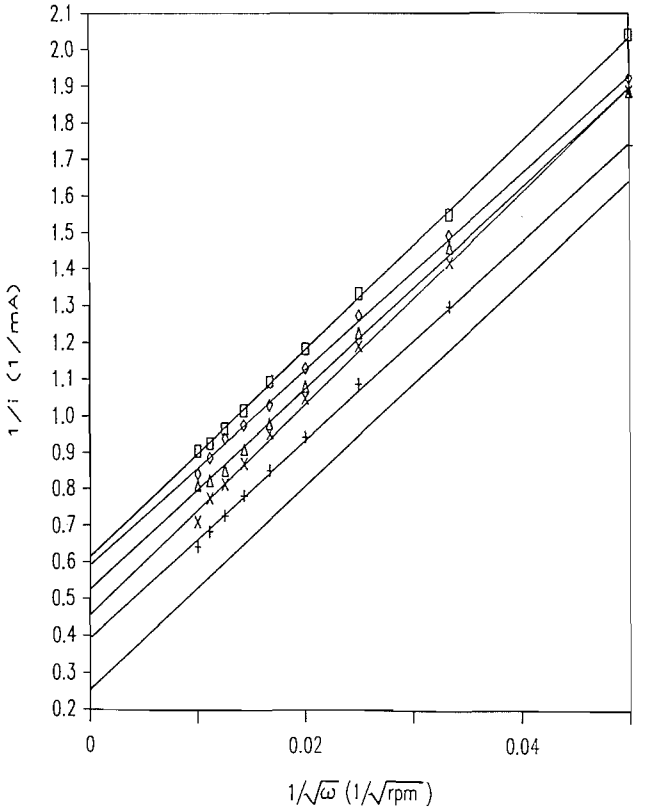

FIG. 7. Koutecky–Levich plots for the reduction of molecular oxygen in 0.10 *M* NaOH at −0.450 V versus sce on OPG electrodes modified with □, CoTNPc; +, O(1)[CoTrNPc]$_2$; ◇, C(2)[CoTrNPc]$_2$; △, Cat(4)[CoTrNPc]$_2$; or ×, EtMeO(5)[CoTrNPc]$_2$. A theoretical two-electron line is shown at the bottom of the graph for comparison.

The standard deviation for the average normalized kinetically-limited currents is less than 15% which though somewhat large, is similar to the deviation reported in another study (91). These normalized currents indicate the reactivities of these species towards oxygen reduction are as follows:

[8] O(1)[CoTrNPc]$_2$ > EtMeO(5)[CoTrNPc]$_2$ ≃ Cat(4)[CoTrNPc]$_2$ > C(2)[CoTrNPc]$_2$ > CoTNPc

It is surely significant that this ranking is the same as given for the electronic coupling of these species.

Although the binuclear CoTNPc compounds have shown increased activity towards the electrocatalytic reduction of molecular oxygen, the potential at which this process occurs in pH 13 NaOH solution is approximately the same as that for CoTSPc under the same conditions (41), and rather too negative to be practical for a fuel cell catalyst. Present studies are being directed towards the shifting of the molecular oxygen reduction potential to more positive values by performing these experiments under acidic conditions, and also to devise conditions under which the direct four-electron reduction process will be favoured.

Summary

In basic media, binuclear cobalt phthalocyanines were shown to be more active towards the electrocatalytic reduction of molecular oxygen than the corresponding mononuclear species. The increased activity of these binuclear compounds has been attributed to the increased electronic coupling between the phthalocyanine rings of these species. Current studies include CoPc species showing a much greater degree of intramolecular coupling than observed here (92). A mechanistic study of CoTNPc over the pH range 1 to 13 will also be reported shortly.

Structure of kerlinic acid from *Salvia keerlii*. Chemical correlation with melisodoric acid[1]

LYDIA RODRÍGUEZ-HAHN,[2] ADRIANA GARCÍA, BALDOMERO ESQUIVEL, AND JORGE CÁRDENAS
Instituto de Química, Universidad Nacional Autónoma de México, Circuito Exterior, Ciudad Universitaria, Coyoacán 04510, México, D.F.

Received March 11, 1987

LYDIA RODRÍGUEZ-HAHN, ADRIANA GARCÍA, BALDOMERO ESQUIVEL, and JORGE CÁRDENAS. Can. J. Chem. **65**, 2687 (1987).

The structure of kerlinic acid, a *neo*-clerodane diterpenoid isolated from *Salvia keerlii* (Labiatae), was deduced from spectral data and chemical correlation with melisodoric acid.

LYDIA RODRÍGUEZ-HAHN, ADRIANA GARCÍA, BALDOMERO ESQUIVEL et JORGE CÁRDENAS. Can. J. Chem. **65**, 2687 (1987).

En se basant sur des données spectrales et sur une corrélation chimique avec l'acide mélisodorique, on a déduit la structure de l'acide kerlinique, un diterpénoïde de la famille du *néo*-clérodane qui a été isolé du *Salvia keerlii* (Labiatae).

[Traduit par la revue]

Introduction

Plants of the Labiatae family have attracted much attention due to a variety of biological activities and medicinal properties attributed to them (1). The bi- and tricyclic diterpenoids isolated from plants of this family have shown antifeedant (2), antitumor, antibacterial, or antifungal properties (3, 4).

Salvia L. is the largest genus of the Labiatae family with over 900 species widespread all over the world. This genus has been divided into four Subgenera (*Sclarea*, *Salvia*, *Leonia*, and *Calosphace*), according to morphological characteristics. In México *Salvia* L. is represented by almost 300 species all of which belong to *Salvia* subgenus *Calosphace* (5, 6). In recent years we have undertaken a systematic study of the Mexican *Salvia* spp. We have found that the diterpenoid content of the *Salvia* species studied depends on the section to which it belongs (7–11). Over 80% of the diterpenoids isolated up to now from Mexican *Salvia* spp. are *neo*-clerodane diterpenoids (10–12, 14).

Some years ago (12) we described the structural elucidation of melisodoric acid **1***a*, a clerodane diterpenoid isolated from *Salvia melissodora* Lag. *Salvia melissodora* has been classified in the section *Scorodonia* (S. subgenus *Calosphace*) (5). Melisodoric acid and some of its derivatives showed antifeedant activity (M. Taboada, personal communication). We have been trying to find an adequate natural source of melisodoric acid and have studied different populations of *S. melissodora* and of *S. keerlii* Bentham (*S.* section *Scorodonia*), a species botanically related to *S. melissodora* (5, 6).

A phytochemical study of *S. keerlii* collected in Oaxaca (México) yielded (13) two *neo*-clerodane diterpenoids, kerlin and kerlinolide. Herein we describe the isolation and structural elucidation of kerlinic acid **2***a*, the main diterpenoid constituent of a population of *S. keerlii* collected in a semiarid region near Querétaro (México).

Results and discussion

Kerlinic acid **2***a*, $C_{20}H_{28}O_4$, showed in the ir spectrum the presence of a hydroxyl group (3500 cm^{-1}), a carboxyl function (3200–2700, 1670 cm^{-1}), and a furan ring (1560, 1510, and 870 cm^{-1}). The ^1H nmr spectrum of **2***a* (Table 1) confirmed the presence of a β-substituted furan ring. A multiplet at δ 5.6 was ascribed to the H-3 vinylic proton, which was shown to be coupled to the vinylic methyl group bound to C-4 by double resonance experiments. A double doublet at δ 3.45 (1H, J = 4 and 10 Hz) was assigned to the geminal proton of a secondary hydroxyl group. It also showed signals due to a tertiary, a secondary, and a vinylic methyl group. Treatment of **2***a* with ethereal diazomethane gave the methyl ester **2***b*. Acetylation (Ac_2O, py) of **2***b* gave the acetate derivative **2***c* whose ^1H nmr spectrum (Table 1) showed the acetate geminal proton at δ 4.75 (dd, J = 4 and 10 Hz).

c R = Me, R′ = Ac
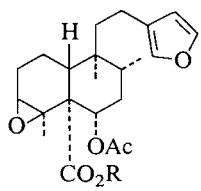
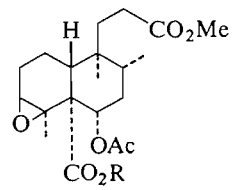
d R = H, R′ = Ac



3 R = Me



4 R = Me

The resemblance of the spectral data of kerlinic acid to those of melisodoric acid, **1***a*, suggested structure **2***a* for the former. To prove the structural relationship between kerlinic acid **2***a* and melisodoric acid **1***a*, we decided to transform it into the dimethyl ester derivative **4**, which had been previously (12) obtained from melisodoric acid.

Treatment of **2***c* with one equivalent of *m*-chloroperbenzoic acid gave mainly polar products and recovered starting material after 24 h of reaction. The polar products were isolated and characterized as a mixture of the 3,4-epoxy-hydroxy lactones **5** and **6**. Treatment of **2***c* with three equivalents of *m*-chloroperbenzoic acid gave the 3,4-epoxy-hydroxy lactones **5** and **6** in 90% yield as a crystalline mixture that could not be resolved. Their structures were deduced from the spectral data. The mixture showed hydroxyl absorptions in the ir spectrum at 3583 and 3480 cm^{-1} and a band at 1766 cm^{-1} that was attributed to

*Run at 80 MHz in $CDCl_3$ using TMS as internal standard. Coupling constants in Hz are in parentheses.

the α,β-unsaturated γ-lactone function. In the ^{1}H nmr spectrum (Table 1), H-3 was observed as a broad doublet (J = 4 Hz) at δ 2.95. Two multiplets at δ 6.8 and 6.2 were ascribed to the H-14 of **5** and **6** respectively. A broad singlet at δ 5.8 was assigned to H-15 of **5** and a singlet at δ 5.97 to H-16 of **6**.

Manganese dioxide oxidation of the mixture of hydroxy lactones gave the epoxy anhydride **7**. The anhydride moiety was evidenced by the ir bands at 1843 and 1775 cm^{-1} and a triplet (1H, J = 2 Hz) at δ 6.55 in the ^{1}H nmr spectrum (Table 1) ascribed to H-14.

Ozonolysis of the mixture of 3,4-epoxy-hydroxy lactones **5** and **6**, followed by oxidative treatment of the ozonide and esterification with ethereal diazomethane, gave the dimethyl ester **4** identical (see Experimental) to the product previously obtained from melisodoric acid (12). Reduction of the hydroxy lactones **5** and **6** with sodium borohydride (14) gave a mixture of 3,4-epoxy lactones **8** and **9** in a 4:3 ratio. The presence of product **8** in the mixture was proved by comparison of its ^{1}H nmr spectrum with that of the product obtained by epoxidation of melisodoric acid acetate methyl ester **1***c* (12). In this way, the structural correlation between kerlinic acid **2***a* and melisodoric acid **1***a* was established.

The stereochemistry proposed for kerlinic acid **2***a* rests on a careful analysis of the ^{13}C nmr data of **2***a* and some of its derivatives (Table 2). Recently (15) the ^{13}C chemical shifts of the pendant methyl groups in a clerodane skeleton have been proposed as a useful tool to distinguish between *cis* and *trans* A/B ring junctions. In *cis*-clerodanes the equatorial C-20 resonates at δ 21–29; a chemical shift of δ 17–19 is expected for the axial C-20, and about δ 15 for the equatorial C-17 in *trans-neo*-clerodanes. In the ^{13}C nmr spectra of **2***a* and its

*Recorded at 20 MHz. Chemical shifts in δ values from TMS. SFORD multiplicities in parentheses.

†The methyl signals were assigned by selective decoupling experiments.

derivatives (Table 2), C-20 and C-17 resonate at δ 15–16. These chemical shifts indicate an axial orientation for C-20, an equatorial orientation for C-17, and a steroidal A/B *trans* ring junction for kerlinic acid **2***a*.

The coupling constants observed for H-6 in the ^{1}H nmr spectrum of kerlinic acid **2***a* and its derivatives (Table 1) indicate an axial–axial and axial–equatorial interaction of this proton with H-7α and H-7β, hence the C-6 hydroxyl group is α-equatorially oriented.

The β-orientation proposed for the 3,4-epoxide in **5** and **6** was deduced from the upfield shift observed for C-10 in these products with respect to the chemical shift of C-10 in compounds **2***a*–**2***d* (Table 2). The application of the Tori (16) equation was not useful in our case.

In the structural elucidation of melisodoric acid (12), its relative stereochemistry was not ascertained. The chemical correlation established between **2***a* and **1***a*, mainly the formation of product **4** with the same optical rotation (see Experimental) from both acids, allowed us to assign the stereochemistry shown in **1***a* for melisodoric acid.

In a series of papers on the chemistry of the diterpenoid constituents of *Solidago* species, McCrindle *et al.* (17) described the *m*-chloroperbenzoic acid epoxidation reaction of a number of furyl olefins, in which the furyl 3,4-epoxides were obtained in 10–50% yields. In some examples they describe the formation of polar compounds whose structures were not analysed. We think that those polar compounds were the corresponding hydroxy lactone derivatives formed by attack of the *m*-chloroperbenzoic acid on the β-substituted furan ring present in all the products described.

Experimental

Melting points are uncorrected. The uv spectra were run in methanol solutions, and the ir spectra were recorded in chloroform solutions. Mass spectra were obtained by direct inlet at 70 eV. The ^{1}H nmr spectra were obtained at 80 MHz in $CDCl_3$ solutions with TMS as internal standard, the ^{13}C nmr spectra at 20 MHz, also in $CDCl_3$ solutions with TMS as internal standard. Assignments of ^{13}C nmr chemical shifts were made with the aid of off-resonance, noise-decoupled, APT and gated decoupling ^{13}C nmr spectra.

Plant material was collected in August 1985, 15 km SW of Querétaro, México, and the voucher specimen (MEXU 211417) was deposited at the Herbarium of the Instituto de Biología, UNAM.

Isolation of kerlinic acid **2**a

Dried aerial parts of *S. keerlii* (1.7 kg) were extracted with acetone (10 L) for 1 week. The solvent was removed under reduced pressure and the gummy residue obtained (140 g) was chromatographed over silica gel (1 kg, deactivated with 5% H_2O). Elution with light petroleum – EtOAc (9:1) gave kerlinic acid **2***a* (11 g, 0.68% dry weight), mp 183–185°C from acetone – light petroleum; $[\alpha]_D^{25}$ −236.8 (*c* 0.19, $CHCl_3$); λ_{max}: 205 nm (14 500); ν_{max}: 3500, 3200–2500, 1670, 1560, 1510, 870 cm^{-1}; ^{1}H nmr, see Table 1; *m/z*: 332 (M^+, 8), 314 (2), 270 (7), 189 (2), 175 (30), 105 (43), 95 (30), 81 (100%). *Anal.* calcd. for $C_{20}H_{28}O_4$: C 72.26, H 8.49; found: C 71.65, H 8.43.

Kerlinic acid methyl ester **2**b

Kerlinic acid **2***a* (1 g) in ethyl ether was treated with ethereal diazomethane solution in the usual manner. The crude product obtained was passed through SiO_2 to yield kerlinic acid methyl ester **2***b* (850 mg) as an oily product; ν_{max}: 3510, 1690, 1560, 1090, 1060, 870 cm^{-1}; ^{1}H nmr, see Table 1; *m/z*: 346 (M^+, 30), 328 (2), 296 (10), 269 (20), 173 (30), 105 (25), 95 (25), 91 (35), 81 (100%) ($C_{21}H_{30}O_4$ requires M^+, 346).

Kerlinic acid methyl ester acetate **2**c

Treatment of kerlinic acid methyl ester **2***b* (450 mg) with Ac_2O (1 mL) in pyridine (1 mL) at 90°C gave the acetate derivative **2***c* after chromatography over SiO_2. The acetate **2***c* showed mp 107–108°C from light petroleum; ν_{max}: 1720, 1650, 1495, 870 cm^{-1}; ^{1}H nmr, see Table 1; *m/z*: 388 (M^+, 8), 328 (9), 314 (5), 296 (20), 269 (25), 233 (40), 173 (58), 105 (45), 95 (30), 81 (100%), 43 (90) ($C_{23}H_{32}O_5$ requires M^+, 388).

Epoxidation of **2**c

The acetate **2***c* (100 mg) in dry carbon tetrachloride (5 mL) was treated with *m*-chloroperbenzoic acid (75 mg) at room temperature with stirring for 4 h. Water was added and the reaction mixture extracted twice with dichloromethane. The organic solution was washed with saturated aqueous $NaHCO_3$ solution and brine, dried, and the solvent removed under reduced pressure. The crude product obtained was chromatographed over SiO_2. Elution with light petroleum gave the epoxide **3** (5 mg), mp 107–111°C, from light petroleum; ν_{max}: 1732, 1560, 873 cm^{-1}; ^{1}H nmr, see Table 1; *m/z*: 404 (M^+, 8), 309 (35), 249 (50), 217 (25), 289 (31), 175 (8), 105 (10), 95 (25), 81 (80), 43 (100%) ($C_{23}H_{32}O_6$ requires M^+, 404). Elution with light petroleum – EtOAc (1:1) gave the hydroxy lactones **5** and **6** (65 mg).

Preparation of hydroxy lactones **5** *and* **6**

To a cooled (ice bath) solution of the acetate **2***c* (250 mg) in dichloromethane (10 mL), *m*-chloroperbenzoic acid (388 mg) was added. The reaction mixture was warmed to room temperature and stirred for 8 h. Water was added and extracted with EtOAc. The organic solution was washed with saturated aqueous $NaHCO_3$ solution and brine, dried, and the solvents removed under reduced pressure. The solid product obtained was recrystallized from acetone – light petroleum to yield a 2:3 mixture of the hydroxy lactones **5** and **6** (225 mg); mp 198–200°C; λ_{max}: 206 nm (10 400); ν_{max}: 3583, 3540, 1766, 1730, 1650, 1248, 864 cm^{-1}; ^{1}H nmr, see Table 1; ^{13}C nmr, see Table 2; *m/z*: 436 (M^+, 2), 377 (10), 344 (15), 277 (15), 259 (10), 249 (15), 217 (35), 189 (15), 161 (19.5), 91 (25.8), 43 (100%) ($C_{23}H_{32}O_8$ requires M^+, 436).

Treatment of the acetate **2***c* with *m*-chloroperbenzoic acid following Wiesner conditions (14) gave the hydroxy lactones **5** and **6** in a 1:1 ratio (mp 176–178°C).

Manganese dioxide oxidation of the hydroxy lactones **5** *and* **6**

The hydroxy lactones mixture (25 mg) in dichloromethane was treated with manganese dioxide (250 mg) stirring at room temperature for 5 h. The reaction mixture was filtered through Celite, the solvent removed, and the residue chromatographed over SiO_2. The crystalline anhydride **7** showed mp 146–150°C from light petroleum; λ_{max}: 204 nm (9000); ν_{max}: 1843, 1775, 1731, 1641, 897 cm^{-1}; ^{1}H nmr, see Table 1; *m/z*: 403 ($M^+ - 31$, 2), 375 ($M^+ - 59$, 35), 359 (50), 342 (22), 315 (15), 275 (12), 217 (18), 189 (8), 161 (15), 119 (19), 105 (22), 97 (8), 91 (26), 43 (100%) ($C_{23}H_{30}O_8$ requires M^+, 434); by chemical ionization *m/z*: 435 ($M^+ + 1$, 12), 463 ($M^+ + 29$, 5).

Preparation of the dimethyl ester derivative **4**

The hydroxy lactones (100 mg) in dichloromethane (20 mL) were treated with ozone at −70°C. The reaction mixture was warmed to room temperature and treated with a saturated aqueous solution of $NaHCO_3$ (0.5 mL), and hydrogen peroxide (30%, 0.2 mL) in MeOH, for 2 h, then acidified and extracted with EtOAc. The organic solution was washed with brine, dried, and the solvent removed. The oily product obtained was treated with ethereal diazomethane solution and passed through SiO_2 gel to yield the dimethyl ester **4**, mp 92–94°C, $[\alpha]_D^{25}$ −29.4° (*c* 0.17, $CHCl_3$), identical (mp, mmp, ir) to the product obtained from melisodoric acid (12), $[\alpha]_D^{25}$ −29°.

Sodium borohydride reduction of the hydroxy lactones (ref. 14)

The hydroxy lactones (**5** and **6**, 60 mg) in dichloromethane at 0°C were treated with sodium borohydride (60 mg) and methanol (0.1 mL). The reaction mixture was stirred for 1 h at room temperature, acidified, and extracted with EtOAc, washed with brine, dried, and the solvent removed. The crude reaction product was chromatographed over SiO_2 to yield the mixture of lactones **8** and **9** in 4:3 ratio, mp 145–148°C (**8** showed (12) mp 168–170°C). Attempts to obtain pure **8** and **9** were unsuccessful, as use of silver nitrate impregnated SiO_2 preparative plates produced decomposition; ν_{max}: 1784, 1749, 1615, 1602, 1246 cm^{-1}; ^{1}H nmr, see Table 1; *m/z*: 420 (M^+, 1), 389 (2), 360 (12), 328 (20), 301 (30), 261 (40), 189 (50), 119 (80), 91 (87), 79 (78), 55 (100%) ($C_{23}H_{32}O_7$ requires M^+, 420).

Acknowledgements

We thank Dr. T. P. Ramamoorthy (Instituto de Biología, UNAM) for the classification of the plant and for fruitful discussions, and Miss E. Argüelles for her help in the collection of the plant material. We also thank Messrs. R. Villena, M.

Torres, H. Bojórquez, L. Velasco, and R. Gaviño for technical assistance. We are very grateful to Dr. L. A. Maldonado for drawing our attention to Professor Wiesner's work. This work was supported in part by CONACyt, México (Project PCCBBNA 021142).

^{15}N nuclear magnetic resonance spectra of nucleoside compounds. Reflection of modifications at N1 and N^6 of adenosine derivatives

JUN UZAWA AND KENTARO ANZAI[1]

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351, Japan

Received May 1, 1987

JUN UZAWA and KENTARO ANZAI. Can. J. Chem. **65**, 2691 (1987).

^{15}N nuclear magnetic resonance spectra of adenosine derivatives were taken at the natural abundance level, and the reflection of structural modifications on the spectra was considered on the basis of the electronic behaviour of the molecules.

JUN UZAWA et KENTARO ANZAI. Can. J. Chem. **65**, 2691 (1987).

Opérant au niveau de l'abondance naturelle, on a déterminé les spectres en résonance magnétique nucléaire du ^{15}N de dérivés de l'adénosine; on a observé des variations dans les spectres qui résultaient de modifications de structure et on les a considérées en fonction du comportement électronique des molécules.

Introduction

Several papers have been published regarding the ^{15}N nmr spectra of nucleosides (1). We would like to present here the ^{15}N nmr spectra of some adenosine derivatives to cast light on the spectral changes caused by structural modifications at N1 and N^6 of adenosine.

Results and discussion

Morris (2) has presented a method of taking ^{15}N nmr spectra at the natural abundance level, using INEPT (insensitive nuclei enhanced by polarization transfer). To assign the signals of nitrogen unambiguously, Bax, Niu, and Live (3) have adopted the selective INEPT, including the use of refocussed pulse sequence and broad band proton decoupling. If a compound has several nitrogen atoms whose $^nJ_{N,H}$ values are similar, as in the case of polypeptides (3), the selective INEPT would be effective because a τ value can be chosen unequivocally based on a J value. A preliminary study has suggested that the nitrogen atoms in adenosine have $^2J_{N,H}$ values ranging widely (8–15 Hz), and setting a τ value based on a $^2J_{N,H}$ value seems to be difficult. Deviation from the optimum τ values ($\tau = 1/4J$) causes, if the refocussing period is included in the sequence, the decrease of the S/N ratio (4). Thus, we adopted the basic INEPT pulse sequence,[2] and τ values were chosen experimentally to reach analyzable spectra (Table 1). The assignment of nitrogen resonance signals in adenine compounds at the natural abundance level was accomplished as follows: selective irradiation[3] at the H-2 resonance resulted in the appearance of two antiphase doublets assignable to N1 and N3 (8). In the same manner the signals of N7 and N9 were observed by irradiating the H-8 signal. Distinction between N1 and N3 signals was accomplished by the method of Städeli, Bigler, and Philipsborn (5), which included the combination of INEPT with selective ^{1}H decoupling. Because of the coupling (<2 Hz) between N1 and one (two) hydrogen(s) at N^6, the N1 signal was broader than the N3 signal, being sharpened by weak irradiation[4] at the N^6-H resonance during the time of acquisition.

The position of protonation on adenosine was determined to be N1, based on the fact that addition of an acid causes upfield shifts of the N1 signal without affecting the other nitrogen signals (6). From a different viewpoint this experiment seems to illustrate the localization of positive charge without perturbing the π-electron sextet, which would have caused upfield shifts of other N atoms.

To extend the above reasoning, the ^{15}N nmr spectra of compounds having various functional groups at N1 of adenosine ($\gtrless$N→O, $\gtrless$N$^+$—OR, $\gtrless$N$^+$—R, $\succ$N—R) were inspected. Unexpectedly, adenosine **1** and adenosine *N*-oxide **15** were found to have almost the same ^{15}N chemical shifts, giving no information about the position of oxygen. Wasylishen and Schaefer (7) reported that protonation of azines was accompanied by the decrease of $^2J_{N,H}$ and, in fact, a small value of $^2J_{N1,H\text{-}2}$ (4.9 Hz) in **15** compared to **1** (16 Hz) was observed. Other N1-modified derivatives of adenosine showed a $^2J_{N1,H\text{-}2}$ value of 8.8 Hz, compared to a value of 16 Hz in N^6-substituted adenosine derivatives.

The introduction of positive charge at N1 seemed not to affect the π-electron sextet, as was shown by the ^{15}N chemical shifts of **11**, **12**, and **13**.

We previously reported that zinc bromide coordinates at N1 and N7 to the same extent, as is known by upfield shifts of the ^{15}N signals (9). The present study revealed that both $^2J_{N1,H\text{-}2}$ and $^2J_{N7,H\text{-}8}$ were not altered by coordination of the zinc cation until a salt concentration of 0.5 equivalents,[5] in spite of large upfield shifts of the N1 and N7 signals (N1, $\Delta\delta$ 24; N7, $\Delta\delta$ 18).

The fact that the resonance signal of N7 in **6** was at high field compared to **7** ($\Delta\delta$ 5) led us to the assumption that the bulkiness of the di-*p*-methoxytrityl group at N6 in **6** forced hydrogen bonding between N^6*H* and N7. In the case of 7-deazaadenosine compounds **19** and **20**, the ^{13}C chemical shifts of C7 were similar (**19**, δ_{C7} 100.0; **20**, δ_{C7} 100.5).

Effects of the substituents at N^6 seemed to be explicable by Hammett's rule: electron-releasing alkyl and electron-withdrawing acyl or trityl groups exerted opposite effects on the electron densities at N^6, N1, and N3. The ^{15}N chemical shifts of N7 and N9 were not altered, showing that the nature of 10π-electron aromatics could hardly be attributed to adenine compounds. Modifications of the imidazole ring as were seen in 8-bromoadenosine and 7-deazaadenosine did not alter the ^{15}N chemical shifts of N^6, N1, and N3.

In conclusion, although recent advances in nmr techniques enable us to take ^{15}N nmr spectra at the natural abundance level, the procedure for taking the spectra is still less accessible than for ^{1}H and ^{13}C nmr measurements. However, the laboriousness of taking the spectra may be balanced by the information obtained about the electronic states of nitrogen (lone-pair existence, metal coordination, protonation, and salt formation). Thus, detailed information about the structure of nitrogen compounds is made available, as exemplified in this paper.

Experimental[6]

^{15}N nuclear magnetic resonance measurements

The ^{15}N nmr spectra were recorded on a JEOL FX-100 spectrometer at 10.10 MHz; τ value, 25 ms or 2.8 ms; proton pulse width, 240 μs or 11 ms (for selective INEPT); repetition time, 1.8 s; 15 000–125 000 transients; sample concentration, 0.6–0.1 mol in DMSO-d_6; ^{15}N chemical shifts were measured relative to external standard of aqueous $^{15}NH_4NO_3$.

N^6,5′-O-Bis(4,4′-dimethoxytrityl)-2′,3′-O-isopropylideneadenosine (7)

The isolation of 5′-*O*-(4,4′-dimethoxytrityl)-2′,3′-*O*-isopropylideneadenosine from the reaction mixture of **3** (1.04 g, 5 mmol) and 4,4′-dimethoxytrityl chloride (1.8 g, 5.3 mmol) in pyridine (50 mL) as the main product (yield 1.6 g, 53%) has been reported (9). The presence of two minor products was observed on tlc and the less polar one was isolated by silica gel chromatography (4:1 C_6H_6–EtOAc), yield 370 mg (8%), mp 104–108°C (ligroin); ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 3.72 and 3.76 (2s, 6H, $2CH_3O$). *Anal.* calcd. for $C_{55}H_{53}N_5O_8$: C 72.43, H 5.86, N 7.68; found: C 72.78, H 5.94, N 7.38.

8-Bromo-9-(2′,3′-O-isopropylidene-β-D-ribofuranosyl)-1-methyladeninium iodide (12)

A solution of **4** (386 mg, 1 mmol) and CH_3I (1 mL) in DMF (20 mL) was left standing at room temperature for 5 days. The solvent was removed by evaporation to obtain a solid, which was dissolved in hot PrOH. A powder decomposing in the range 290–300°C separated when this solution was left in a refrigerator, yield 405 mg (77%); ^{1}H nmr data (100 MHz, DMSO-d_6) δ: 1.40 and 1.62 (2s, 6H, two isopropylidene methyls), 3.84 (s, 3H, N1-methyl), 6.14 (d, 1H, H-1′, J = 3 Hz), 8.16 and 8.68 (2s, 2H, H-8 and H-2). *Anal.* calcd. for $C_{14}H_{19}N_5O_4BrI$: C 31.83, H 3.63, N 13.26, I 24.03; found: C 32.08, H 3.68, N 13.44, I 23.64.

8-Bromo-2′,3′-O-isopropylidene-N^6-methyladenosine (5)

A solution of **7** (528 mg, 1 mmol) in 0.1 *M* NaOH (20 mL) was left standing at room temperature overnight to give a precipitate, which was crystallized from toluene, yield 300 mg (75%), mp 175–177°C; ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 1.43 and 1.72 (2s, 6H, two isopropylidene methyls), 3.40 (d, 3H, $HNCH_3$, J = 5 Hz), 6.10 (d, 1H, H-1′, J = 4 Hz), 8.35 (s, 1H, H-2). *Anal.* calcd. for $C_{14}H_{18}N_5O_4Br$: C 42.15, H 4.52, N 17.46; found: C 42.10, H 4.45, N 17.46.

2′,3′-O-Isopropylidene-1-methyladenosine (14)

This compound has already been synthesized (10) and the following is our method of preparation. The adeninium iodide **11** (449 mg, 1 mmol) was dissolved in 0.3 *M* NaOH (40 mL) and the product was immediately extracted with $CHCl_3$. The solvent was removed by evaporation and the residue was crystallized from toluene, yield 370 mg (87%), mp 180–181°C; ^{1}H nmr data (100 MHz, $CDCl_3$) δ: 1.42 and 1.68 (2s, 6H, two isopropylidene methyls), 3.60 (s, 3H, $=N—CH_3$), 5.81 (d, 1H, H-1′, J = 3 Hz), 7.72 and 7.80 (2s, 2H, H-8 and H-2). *Anal.* calcd. for $C_{14}H_{19}N_5O_4$: C 52.33, H 5.92, N 21.80; found: C 52.27, H 5.94, N 21.73.

5′-O-Trityltubercidin (19) and N^6,5′-O-ditrityltubercidin (20)

To a solution of **18** (2.66 g, 10 mmol) in pyridine (50 mL) was added trityl chloride (5.57 g, 20 mmol) portionwise. After leaving it at room temperature for 2 days, the solution was poured into an ice-cooled solution of $NaHCO_3$. The products were extracted with $CHCl_3$ and separated on a silica gel column. Compound **20** was eluted with EtOAc and obtained as a glass from EtOAc–ligroin, yield 1.63 g (22%); uv λ_{max} (MeOH): 283 nm (ε 17 600); ^{1}H nmr data (100 MHz, DMSO-d_6) δ: 3.2 (m, 2H, H-5′), 6.10 (d, 1H, H-1′, J = 4 Hz), 7.76 (s, 1H, H-2), 8.1 (s, 1H, NH, quenched with D_2O); ^{13}C nmr data (25 MHz, DMSO-d_6) δ: 87.3 (C1′), 73.7 (C2′), 70.3 (C3′), 82.4 (C4′), 64.1 (C5′), 149.9 (C2 and C4), 104.9 (C5), 155.4 (C6), 100.5 (C7), 121.6 (C8), 86.1 (Ph_3C—O), 70.3 (Ph_3C—N), 143.6 (phenyl C1 of Ph_3C—O), 145.4 (phenyl C1 of Ph_3C—N). *Anal.* calcd. for $C_{49}H_{42}N_4O_4$: C 78.37, H 5.64, N 7.46; found: C 78.15, H 5.42, N 7.22.

Compound **19** was eluted with 9:1 EtOAc–MeOH. The crystals precipitated during concentration of the eluate were washed with benzene, yield 2.9 g (57%), mp 210–212°C ($CHCl_3$–benzene); uv λ_{max} (MeOH): 270 nm (ε 13 500); ^{1}H nmr data (100 MHz, DMSO-d_6) δ: 3.2 (m, 2H, H-5′), 6.14 (d, 1H, H-1′, J = 4 Hz), 8.10 (s, 1H, H-2), 7.05 (s, 2H, NH_2, quenched with D_2O); ^{13}C nmr data (25 MHz, DMSO-d_6) δ: 87.3 (C1′), 73.7 (C2′), 70.4 (C3′), 82.2 (C4′), 64.0 (C5′), 151.8 (C2), 150.3 (C4), 102.8 (C5), 157.5 (C6), 100.0 (C7), 121.3 (C8), 86.1 (Ph_3C—O), 143.6 (phenyl C1 of Ph_3C—O). *Anal.* calcd. for $C_{30}H_{27}N_4O_4$: C 70.99, H 5.36, N 11.04; found: C 70.69, H 5.22, N 10.89.

[6]For the preparation of **13**, **15**, and **16** see refs. 11, 13, and 14, respectively. The present authors have reported the synthesis of **6**, **8**, **9**, **10**, and **17** (9, 12).

M. AGORRODY, E. MONTAUDON et B. MAILLARD. Can. J. Chem. **65**, 2694 (1987).

Les additions radicalaires de composés donneurs d'hydrogène ZH aux peroxydes δ-insaturés conduisent à des éthers cycliques à 5 ou 6 chaînons, avec des rendements compris entre 40 et 70%, selon la substitution de la double liaison.

M. AGORRODY, E. MONTAUDON, and B. MAILLARD. Can. J. Chem. **65**, 2694 (1987).

Free radical additions of hydrogen donors of type ZH to δ-unsaturated organic peroxides give 5- or 6-membered cyclic ethers in yields varying from 40 to 70%, depending on the substitution of the double bond.

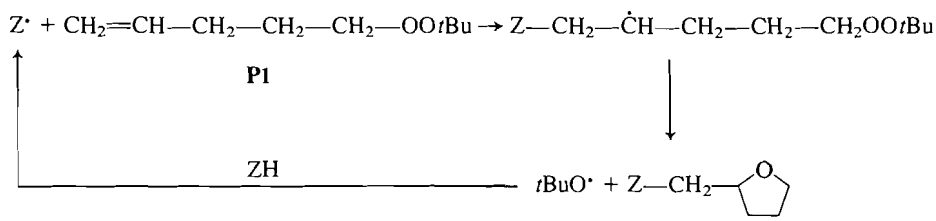
Dans un travail précédent (1), il a été montré que le peroxyde de *tert*-butyle et de pentène-4 yle, **P1**, se comporte comme ses homologues inférieurs, le peroxyde d'allyle et de *tert*-butyle et le peroxyde de *tert*-butyle et de butène-3 yle, et subit une décomposition induite au cours de sa thermolyse dans des solvants bons donneurs d'hydrogène.

La phase de propagation de cette décomposition induite en chaîne est la suivante :



Le rendement obtenu en (tétrahydrofuryl-2 méthyl)-2 tétrahydrofuranne lors de cette étude préliminaire (1), où le solvant est le THF, est de 50%. Ceci laisse présager que ces réactions peuvent constituer une voie d'accès facile à des tétrahydrofurannes fonctionnels substitués en 2. Notre travail, dont le but est d'explorer les possibilités synthétiques de la décomposition induite de peroxydes δ-insaturés, se limitera uniquement à la recherche et à la séparation des éthers cycliques. Une définition préalable des modalités permettant d'atteindre les meilleurs rendements est indispensable.

1. Détermination des conditions optimales

L'expérience acquise conduit à opérer dans des conditions d'additions radicalaires afin d'éviter la disparition du peroxyde par thermolyse. L'amorceur et les paramètres qui ont donné les meilleurs résultats lors de la décomposition de peroxydes allyliques (2) et homoallyliques (3) sont les suivants : chauffage en présence de peracétate de *tert*-butyle (PA) à 110°C durant 12 h.

Les premiers essais ont mis en évidence l'influence primordiale des proportions relatives **P1**/PA sur les rendements de la réaction. En effet, au-dessous d'une certaine valeur de ce rapport, la décomposition de **P1** est incomplète. Ce facteur doit être déterminé en premier lieu.

*1.1. Rapport molaire **P1**/PA*

Le solvant utilisé pour cette étude est le cyclohexane. Le rapport molaire cyclohexane/**P1** est arbitrairement fixé à 100/1. Les rendements en (cyclohexylméthyl)-2 tétrahydrofuranne sont rassemblés dans le tableau 1.

L'examen de ce tableau impose d'utiliser un rapport molaire **P1**/PA égal à 2 si l'on veut que la décomposition de **P1** soit complète. Cette proportion d'amorceur est beaucoup plus importante que celle déterminée dans le cas d'autres dérivés peroxydiques : en effet, avec le peroxyde d'allyle et de *tert*-butyle (2), le peroxyde de butène-3 yle et de *tert*-butyle (3), un rapport molaire peroxyde/PA de 10 est suffisant. La nécessité d'utiliser ici davantage d'amorceur traduit l'intervention d'une réaction en chaîne très courte. Ce résultat est surprenant si l'on considère que les décompositions induites des trois modèles cités s'effectuent avec le même mécanisme en trois étapes.

Précisons que si, dans l'étude des peroxydes de butényle (3), le rapport peroxyde/PA utilisé était de 1/0,5 et non de 1/0,1, ce choix avait été établi non pas à partir du peroxyde de butène-3 yle et de *tert*-butyle mais à partir du peroxyde de méthyl-4

TABLEAU 1. Addition radicalaire du cyclohexane à **P1** (110°C; 12 h). Influence du rapport molaire **P1**/PA

Rapport molaire **P1**/PA	1/0,1	1/0,2	1/0,3	1/0,5	1/0,75	1/1
Rendement (%)[a]	43[b]	49[b]	63[b]	70	65	60

[a]Déterminé relativement au peroxyde mis en jeu par dosage du produit brut en cpg.
[b]Présence de peroxyde **P1** qui n'a pas réagi.

TABLEAU 2. Additions radicalaires à **P1** (110°C; 12 h). Influence du rapport molaire ZH/**P1** sur les rendements en tétrahydrofurannes substitués en 2

	Rendement (%)[b]		
	ZH		
ZH/**P1**[a]	Cyclohexane	Propionate de méthyle	Chlorure de méthylène
100/1	62	75	46
50/1	70	58	42
20/1	51	35	32

[a]Rapport molaire **P1**/PA = 1/0,5.
[b]Déterminé relativement au peroxyde **P1** mis en jeu par analyse du produit réactionnel brut en cpg.

pentène-3 yle et de *tert*-butyle, afin de pouvoir effectuer des comparaisons dans toute cette série : en effet, le peroxyde disubstitué sur le carbone sp^2 terminal nécessitait, lui et lui seul, un tel taux d'amorceur.

1.2. Rapport molaire optimal ZH/P1

La détermination du «meilleur» rapport molaire ZH/**P1** a été réalisée à partir des essais décrits dans le tableau 2.

On observe que, si l'on excepte le cas du cyclohexane, le rendement maximum en tétrahydrofuranne substitué correspond à un rapport ZH/**P1** = 100. Ces proportions seront retenues et utilisées pour tous les solvants et tous les peroxydes étudiés dans cette série.

Les additions radicalaires de solvants ZH aux peroxydes δ-éthyléniques seront donc réalisées en présence de peracétate de *tert*-butyle dans les conditions suivantes : rapport molaire ZH/peroxyde/PA = 100/1/0,5; 110°C; 12 h.

2. Additions radicalaires au peroxyde de *tert*-butyle et de pentène-4 yle, P1

La réaction a été effectuée dans divers solvants, fonctionnels ou non : dichlorométhane, cyclohexane, propionate de méthyle, acétonitrile, dioxanne-1,4, acide propionique, anhydride propionique, acétone, dans les conditions déterminées dans le paragraphe précédent.

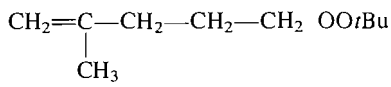
Les rendements en produits isolés relativement au peroxyde mis en jeu dans la réaction sont rassemblés dans le tableau 3.

Dans la majorité des cas, un seul tétrahydrofuranne substitué est identifié; seul le propionate de méthyle fait exception.

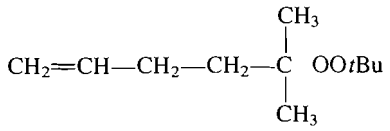
Les rendements en hétérocycles oxygénés, **1***x*, compris entre 40 et 70% sont relativement bons, bien que légèrement inférieurs à ceux obtenus à partir du peroxyde d'allyle et de *tert*-butyle (2); ils confèrent donc à la méthode un intérêt synthétique.

3. Additions radicalaires aux peroxydes δ-éthyléniques

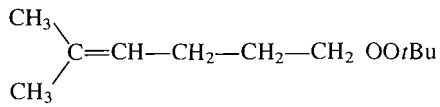
Compte-tenu de la potentialité synthétique de l'addition radicalaire de dérivés à hydrogène mobile ZH au peroxyde **P1**, nous avons préparé les peroxydes **P2**, **P3**, **P4**, dans le but de déterminer l'influence des substituants présents sur ou au voisinage des deux fonctions réactives sur le cours de la réaction.



P2



P3



P4

Nous allons essayer d'interpréter les résultats enregistrés avec chacun des peroxydes sur la base du mécanisme en deux étapes établi dans le cas du peroxyde **P1** (1).

3.1. Additions radicalaires au peroxyde P2

Le tableau 4 regroupe les résultats obtenus à partir du peroxyde **P2**.

La comparaison des résultats des peroxydes **P1** et **P2** montre que l'on peut classer les solvants ZH en deux catégories, une augmentation du rendement étant observée avec la première (dichlorométhane, acétonitrile, propionate de méthyle, acide propionique, acétone), alors que pour la seconde, il n'y a que peu de variation (cyclohexane) ou diminution (dioxanne).

Si l'on se réfère au caractère polaire des radicaux issus de ces deux catégories de solvants — électrophile pour la première, nucléophile pour la seconde — on est tenté d'attribuer cette différence de résultats à l'étape d'addition; en effet, la nature du radical additionné ne devrait avoir aucune influence sur l'étape de substitution homolytique intramoléculaire.

3.2. Additions radicalaires au peroxyde P3

Le tableau 5 regroupe les résultats obtenus à partir du peroxyde **P3**.

De la comparaison des résultats obtenus avec les peroxydes **P1** et **P3**, il ressort que la substitution des deux hydrogènes en α de la liaison peroxydique par deux groupements méthyle est sans effet majeur sur la formation de tétrahydrofuranne et n'entraîne une diminution du rendement nette que dans le seul cas du dioxanne.

3.3. Additions radicalaires au peroxyde P4

Le tableau 6 regroupe les résultats obtenus à partir de ce peroxyde.

Le peroxyde **P4** conduit à des tétrahydropyrannes alors que les peroxydes **P1**, **P2**, **P3** sont des précurseurs de tétrahydrofurannes. Ce résultat est conforme aux règles gouvernant la réactivité et la régiosélectivité de l'étape d'addition, à savoir : l'orientation de l'addition d'un radical à une double liaison est contrôlée par la substitution de cette dernière.

Lorsque le substrat ZH est le cyclohexane, l'hétérocycle attendu ne semble pas se former; une partie du peroxyde **P4** est

récupérée après réaction, indiquant que l'addition du radical cyclohexyle à la double liaison ne se fait pas, vraisemblablement pour des raisons stériques.

Les rendements en hétérocycles formés à partir du peroxyde **P4** sont plus faibles que dans le cas du peroxyde **P1**. Aucune comparaison directe ne peut être effectuée, puisque les chaînes séparant le centre radicalaire de la liaison peroxydique n'ont pas la même longueur.

Conclusion

L'addition radicalaire de composés donneurs d'hydrogène au peroxyde de *tert*-butyle et de pentène-4 yle conduit avec des rendements intéressants à des tétrahydrofurannes substitués en 2 par un groupement fonctionnel ou non. La ramification de la chaîne du peroxyde ne semble pas être un obstacle au succès de la réaction.

Notre méthode permet de synthétiser aisément et avec de bons rendements : (*i*) certains tétrahydrofurannes substitués en 2 à partir du peroxyde de *tert*-butyle et de pentène-4 yle; (*ii*) certains tétrahydrofurannes-2,2 disubstitués à partir de peroxydes d'alkyl-4 pentène-4 yle et de *tert*-butyle; (*iii*) certains tétrahydrofurannes-2,2,5 trisubstitués à partir de peroxydes d'alkyl-2 hexène-5 yle-2 et de *tert*-butyle; (*iv*) certains tétrahydropyrannes-2,2,3 trisubstitués à partir de peroxydes d'alkyl-5 alcène-4 yle et de *tert*-butyle.

Partie expérimentale

Techniques utilisées

Les analyses en cpg ont été effectuées sur un chromatographe Intersmat ICG 112 F (ionisation de flamme; gaz vecteur : azote), équipé de colonnes d'acier inox (longueur = 1,50 m ou 2 m; diamètre intérieur = 2 mm). Deux phases ont été utilisées : FFAP (10%) et OV 17 (10%).

Les identifications ont été réalisées par comparaison des temps de rétention avec ceux des échantillons préparés en référence. Les dosages ont été effectués par la méthode de l'étalon interne. En l'absence de produits de référence, après vérification de la pureté des produits par cpg, les techniques spectroscopiques ont permis de confirmer la structure des composés.

Les spectres de rmn ^{1}H ont été enregistrés sur des appareils Perkin Elmer R 12 B opérant à 60 MHz et Bruker WP 60 CW fonctionnant à 60 MHz; le solvant utilisé est CCl_4 contenant 10% de TMS (étalon interne).

Les spectres de rmn ^{13}C ont été effectués sur un appareil Bruker AC 200 fonctionnant à 50,3 MHz; le solvant utilisé est $CDCl_3$ contenant 5% de TMS (étalon interne).

Les séparations en chromatographie liquide à haute performance (hplc) ont été réalisées sur un appareil Prep LC/System 500 Waters, équipé d'une cartouche Prep Pak-500/Silica.

Les spectres de masse ont été enregistrés sur des appareils Micromass 16 F et 70-70, en ionisation électronique (70 eV) ou ionisation chimique, couplés avec un chromatographe en phase gazeuse de type Pye–Unicam, série 204.

Matières premières

Tous les solvants utilisés sont des produits commerciaux, distillés avant emploi.

Le peracétate de *tert*-butyle est préparé par action de l'hydroperoxyde de *tert*-butyle sur le chlorure d'acétyle en présence de pyridine (4).

Peroxyde de pentène-4 yle et de tert*-butyle,* ***P1*** : il a été préparé selon la réf. 1, par action de *t*BuOOH sur le bromo-1 pentène-4 (Rdt 39%), et possède des constantes physiques en accord avec la littérature.

Peroxyde de tert*-butyle et de méthyl-4 pentène-4 yle,* ***P2*** : il a été préparé selon la réf. 5, par action de *t*BuOOH sur le mésylate du méthyl-4 pentène-4 ol-1 (6), Eb_{25} 75°C (litt. (6) Eb_{19} 67,5–69°C); rmn ^{1}H δ(ppm) : 4,7 (s, 2H, CH_2=), 4–3,4 (m, 3H, CH_2OH), 2,3–1,5 (m, 7H, autres protons). **P2** est purifié par chromatographie sur gel de silice; Rdt = 39%; n_D^{20} = 1,4225; rmn ^{1}H δ(ppm) : 4,8 (s, 2H, CH_2=), 3,9 (t, J = 8 Hz, 2H, CH_2O), 2,2–1,3 (m, 7H, autres H), 1,2 (s, 9H, $(CH_3)_3C$).

Peroxyde de tert*-butyle et de méthyl-2 hexène-5 yle-2,* ***P3*** : il a été préparé selon la réf. 7, par action de *t*BuOOH sur le bromo-2 méthyl-2 hexène-5 (8), Eb_{90} 82°C (litt. (8) Eb_{95} 87–89°C); rmn ^{1}H δ(ppm) : 6–4,8 (m, 3H, CH_2=CH), 2,8–1,8 (m, 4H, autres CH_2), 1,2 (s, 6H, $(CH_3)_2C$). **P3** est isolé par distillation; Rdt = 28%; Eb_1 43°C; n_D^{20} = 1,4198; rmn ^{1}H δ(ppm) : 6–4,9 (m, 3H, CH_2=CH), 2,3–1,3 (m, 4H, autres CH_2), 1,2 et 1,15 (2s, 15H, $(CH_3)_3C$ et $(CH_3)_2C$).

Peroxyde de tert*-butyle et de méthyl-5 hexène-4 yle,* ***P4*** : il a été obtenu selon la réf. 5, par action de *t*BuOOH sur le mésylate du méthyl-5 hexène-4 ol-1 (9), Eb_{30} 86°C (litt. (9) Eb_{15} 79°C); rmn ^{1}H δ(ppm) : 5,1 (t, J = 8 Hz, 1H, =CH), 3,6–3,2 (m, 3H, CH_2OH), 2,2–1,8 (m, 4H, autres CH_2), 1,65 et 1,6 (2s, 6H, $CH_3)_2C$). **P4** est purifié par chromatographie sur gel de silice; Rdt = 40%; n_D^{20} = 1,4329; rmn ^{1}H δ(ppm) : 5,3–5 (m, 1H, =H), 3,9 (t, J = 8 Hz, 2H, CH_2O), 2,5–1,3 (m, 10H, $(CH_3)_2C$ et autres CH_2), 1,2 (s, 9H, $(CH_3)_3C$).

Additions radicalaires

Les études analytiques ont été réalisées en introduisant 2 cm^3 de solution dans des ampoules en Pyrex scellées, placées 12 h dans un bain thermostaté à 110°C (rapport molaire 100/1).

Les études préparatives ont été effectuées sur des volumes de 90 ou 180 cm^3 dans des autoclaves de 125 ou 250 cm^3 placés pendant 12 h dans une étuve préalablement portée à 110°C. Les rapports molaires substrat/composé insaturé/amorceur sont de 100/1/0,5.

Après élimination du solvant en excès, les produits de réaction sont isolés par les méthodes habituelles (distillation, chromatographie sur gel de silice ou hplc).

Produits de reactions[2]

1. Additions radicalaires à ***P1***

(Dichloro-2,2 éthyl)-2 tétrahydrofuranne, ***1***a : $Eb_{0,5}$ 45°C; n_D^{20} = 1,4842; rmn ^{1}H δ(ppm) : 6 (t, J = 8 Hz, 1H, $CHCl_2$), 4,25–3,5 (m, 3H, CH_2—O—CH), 2,5–1,5 (m, 6H, autres protons); principaux pics du spectre de masse, m/z (abondance) : 27 (32), 39 (24), 41 (41), 42 (21), 43 (35), 71 (100), 85 (19).

Cyclohexylméthyl-2 tétrahydrofuranne, ***1***b : $Eb_{0,35}$ 77°C; n_D^{20} = 1,4721 (litt. (10) $Eb_{0,1}$ 45°C; n_D^{20} = 1,471); rmn ^{1}H δ(ppm) : 4,25–3,5 (m, 3H, CH_2—O—CH), 2,25–1 (m, 17H, autres protons); principaux pics du spectre de masse, m/z (abondance) : 41 (35), 43 (30), 55 (21), 71 (100).

Méthyl-2 (tétrahydrofuryl-2)-3 propionate de méthyle, ***1***c : $Eb_{0,45}$ 55°C; n_D^{20} = 1,4422; rmn ^{1}H δ(ppm) : 4,1–3,6 (m, 3H, CH_2—O—CH), 3,5 (s, 3H, OCH_3), 2,75–1,3 (m, 7H, autres CH_2 et CH), 1,1 (d, J = 8 Hz, 3H, CH_3—CH); principaux pics du spectre de masse, m/z (abondance) : 45 (36), 71 (100), 85 (32).

(Tétrahydrofuryl-2)-3 propanenitrile, ***1***d : Eb_4 74°C; n_D^{20} = 1,4499 (litt. (11) Eb_8 92–94°C; n_D^{20} = 1,4468); rmn ^{1}H δ(ppm) : 4–3,5 (m, 3H, CH_2—O—CH), 2,5–1,3 (m, 8H, autres protons); principaux pics du spectre de masse, m/z (abondance) : 39 (28), 41 (53), 42 (24), 43 (74), 55 (22), 71 (100).

(Tétrahydrofuryl-2) méthyl dioxanne-1,4, ***1***e : $Eb_{0,5}$ 74°C; n_D^{20} = 1,4661; rmn ^{1}H δ(ppm) : 4,3–4 (m, 10H, CH_2—O et CH—O), 2–1,2 (m, 6H, autres protons); principaux pics du spectre de masse, m/z (abondance) : 31 (17), 41 (29), 43 (75), 71 (100), 87 (16).

Acide méthyl-2 (tétrahydrofuryl-2)-3 propionique, ***1***f : $Eb_{0,35}$ 92°C; n_D^{20} = 1,4590 (litt. (12) Eb_{13} 154°C; n_D^{20} = 1,4561); rmn ^{1}H δ(ppm) : 11,2 (s, 1H, $COOH$), 4–3,5 (m, 3H, CH_2—O—CH), 2,8–2,2 (m, 1H, CH—COO), 2,1–1,3 (m, 6H, autres CH_2), 1,2 (d, J = 8 Hz, 3H, CH_3); principaux pics du spectre de masse, m/z (abondance) : 41 (36), 42 (19), 43 (55), 71 (100), 85 (21).

2. La pureté des produits nouveaux isolés ayant été vérifiée par cpg sur deux colonnes de polarités différentes et l'étude spectroscopique (rmn, masse) accréditant leurs structures, il ne nous a pas paru nécessaire d'effectuer leur analyse centésimale.

(Tétrahydrofuryl-2)-4 butanone, ***1***g : $Eb_{0,8}$ 61°C; n_D^{20} = 1,4464 (litt. (13) Eb_2 81°C; n_D^{19} = 1,4459); rmn ^1H δ(ppm) : 4–3,5 (m, 3H, CH_2—O—CH), 2,6 (t, J = 8 Hz, 2H, CH_2—CO), 2 (s, 3H, CH_3), 2–1,3 (m, 6H, autres protons); principaux pics du spectre de masse, m/z (abondance) : 41 (28), 43 (100), 71 (69), 84 (40).

2. Additions radicalaires à ***P2***

(Dichloro-2,2 éthyl)-2 méthyl-2 tétrahydrofuranne, ***2***a : $Eb_{0,3}$ 76°C; n_D^{20} = 1,4767; rmn ^1H δ(ppm) : 5,9 (t, J = 8 Hz, 1H, $CHCl_2$), 3,9–3,6 (m, 2H, CH_2—O), 2,5–1,3 (m, 6H, autres CH_2), 1,2 (s, 3H, CH_3); principaux pics du spectre de masse, m/z (abondance) : 42 (29), 43 (100), 85 (70).

Cyclohexylméthyl-2 méthyl-2 tétrahydrofuranne, ***2***b : $Eb_{0,8}$ 86°C; n_D^{20} = 1,4696; rmn ^1H δ(ppm) : 3,8–3,5 (m, 2H, CH_2—O), 2–1,2 (m, 17H, autres CH_2 et CH), 1,1 (s, 3H, CH_3); principaux pics du spectre de masse, m/z (abondance) : 43 (34), 85 (100).

Méthyl-2 (méthyl-2 tétrahydrofuryl-2)-3 propionate de méthyle, ***2***c : $Eb_{0,5}$ 74°C; n_D^{20} = 1,4402; rmn ^1H δ(ppm) : 3,9–3,6 (m, 2H, CH_2—O), 3,5 (s, 3H, OCH_3), 2,6–1,25 (m, 7H, autres CH_2 et CH), 1,2 (d, J = 8 Hz, 3H, CH_3—CH), 1,1 (s, 3H, CH_3—C—O); principaux pics du spectre de masse, m/z (abondance) : 43 (48), 85 (100).

(Méthyl-2 tétrahydrofuryl-2)-3 propanenitrile, ***2***d : Eb_3 80°C; n_D^{20} = 1,4507; rmn ^1H δ(ppm) : 3,9–3,6 (m, 2H, CH_2—O), 2,5–1,5 (m, 8H, autres CH_2), 1,2 (s, 3H, CH_3); principaux pics du spectre de masse, m/z (abondance) : 41 (29), 42 (22) 43 (100), 82 (46), 85 (55), 124 (17).

(Méthyl-2 tétrahydrofuryl-2) méthyl dioxanne-1,4, ***2***e : $Eb_{0,6}$ 56°C; n_D^{20} = 1,4603; rmn ^1H δ(ppm) : 4–3,4 (m, 9H, CH_2—O et CH—O), 2,1–1,2 (m, 6H, autres CH_2), 1,1 (s, 3H, CH_3); principaux pics du spectre de masse, m/z (abondance) : 32 (24), 43 (83), 85 (100), 87 (17).

Acide méthyl-2 (méthyl-2 tétrahydrofuryl-2)-3 propionique, ***2***f : $Eb_{0,25}$ 95°C; n_D^{20} = 1,4801; rmn ^1H δ(ppm) : 11,2 (s, 1H, $COOH$), 4–3,5 (m, 2H, CH_2—O), 2,6–1,3 (m, 7H, autres CH_2 et CH), 1,25 (d, J = 8 Hz, 3H, CH_3—CH), 1,1 (s, 3H, CH_3—C—O); principaux pics du spectre de masse, m/z (abondance) : 28 (20), 43 (41), 85 (100).

(Méthyl-2 tétrahydrofuryl-2)-4 butanone, ***2***g : $Eb_{0,4}$ 76°C; n_D^{20} = 1,4547 (litt. (14) $Eb_{0,5}$ 80–81°C); rmn ^1H δ(ppm) : 3,8–3,5 (m, 2H, CH_2—O), 2,5–1,25 (m, 8H, autres CH_2), 2 (s, 3H, CH_3—C), 1,1 (s, 3H, CH_3—C—O); principaux pics du spectre de masse, m/z (abondance) : 43 (100), 85 (64).

3. Additions radicalaires à ***P3***

(Dichloro-2,2 éthyl)-2 diméthyl-5,5 tétrahydrofuranne, ***3***a : Eb_{10} 98°C; n_D^{20} = 1,4592; rmn ^1H δ(ppm) : 5,9 (t, J = 8 Hz, 1H, $CHCl_2$), 4,25–4 (m, 1H, CH—O), 2,5–1,5 (m, 6H, CH_2), 1,2 (s, 6H, CH_3); principaux pics du spectre de masse, m/z (abondance) : 43 (100), 55 (28), 59 (39), 70 (33), 81 (39), 99 (51), 181 (68), 183 (42).

Cyclohexylméthyl-2 diméthyl-5,5 tétrahydrofuranne, ***3***b : $Eb_{0,3}$ 63°C; n_D^{20} = 1,4597; rmn ^1H δ(ppm) : 3,8–3,5 (m, 1H, CH—O), 1,8–1,3 (m, 17H, autres CH et CH_2), 1,1 (s, 6H, CH_3); principaux pics du spectre de masse, m/z (abondance) : 43 (21), 55 (20), 81 (56), 99 (100).

(Diméthyl-5,5 tétrahydrofuryl-2)-3 méthyl-2 propionate de méthyle, ***3***c : Eb_8 110°C; n_D^{20} = 1,4364; rmn ^1H δ(ppm) : 4–3,5 (m, 1H, CH—O), 3,5 (s, 3H, OCH_3), 2,8–1,8 (m, 7H, autres CH et CH_2), 1,6 (d, J = 8 Hz, 3H, CH_3—CH), 1,1 (s, 6H, autres CH_3); principaux pics du spectre de masse, m/z (abondance) : 41 (30), 43 (100), 55 (39), 70 (25), 81 (79), 88 (43), 99 (83) 112 (36), 144 (43).

(Diméthyl-5,5 tétrahydrofuryl-2)-3 propanenitrile, ***3***d : $Eb_{0,5}$ 49°C; n_D^{20} = 1,4330; rmn ^1H δ(ppm) : 4–3,7 (m, 1H, CH—O), 2,5–1,3 (m, 8H, CH_2), 1,1 (s, 6H, CH_3); principaux pics du spectre de masse, m/z (abondance) : 41 (22), 43 (100), 55 (33), 59 (23), 138 (29).

(Diméthyl-5,5 tétrahydrofuryl-2) méthyl dioxanne-1,4, ***3***e : $Eb_{0,1}$ 55°C; n_D^{20} = 1,4557; rmn ^1H δ(ppm) : 3,8–3,4 (m, 8H, CH_2—O et CH—O), 1,8–1,3 (m, 6H, autres CH_2), 1,1 (s, 6H, CH_3); principaux pics du spectre de masse, m/z (abondance) : 29 (15), 31 (17), 32 (42), 41 (26), 43 (79), 55 (26), 81 (100), 86 (30), 87 (65), 89 (99), 144 (21).

Acide (diméthyl-5,5 tétrahydrofuryl-2)-3 méthyl-2 propionique, ***3***f : Eb_2 113°C; n_D^{20} = 1,4506; rmn ^1H δ(ppm) : 9,8 (s, 1H, $COOH$), 4–3,7 (m, 1H, CH—O), 2,8–1,7 (m, 7H, autres CH et CH_2), 1,6 (d, J = 8 Hz, 3H, CH_3—CH), 1,1 (s, 6H, autres CH_3); principaux pics du spectre de masse, m/z (abondance) : 39 (24), 41 (43), 43 (100), 55 (34), 81 (33), 99 (26).

(Diméthyl-5,5 tétrahydrofuryl-2)-4 butanone, ***3***g : $Eb_{0,5}$ 78°C; n_D^{20} = 1,4396; rmn ^1H δ(ppm) : 4–3,7 (m, 1H, CH—O), 2,5–1,3 (m, 8H, CH_2), 2 (s, 3H, CH_3—C=O), 1,2 (s, 6H, autres CH_3); principaux pics du spectre de masse, m/z (abondance) : 43 (100), 55 (17), 81 (23), 99 (16), 112 (15).

4. Additions radicalaires à ***P4***

Dichlorométhyl-3 diméthyl-2,2 tétrahydropyranne, ***4***a : $Eb_{0,5}$ 46°C; n_D^{20} = 1,4870; rmn ^1H δ(ppm) : 6 (d, J = 8 Hz, 1H, $CHCl_2$), 3,7–3,4 (m, 2H, CH_2—O), 2,4–1,5 (m, 5H, autres CH et CH_2), 1,25 et 1,2 (2s, 6H, CH_3); rmn ^{13}C δ(ppm) : 74,9 ($CHCl_2$), 73,7 ($C(CH_3)_2$), 61,2 (CH_2O), 56,1 (CH—$CHCl_2$), 29,5 et 19,5 (CH_3), 25,8 et 19,1 (autres CH_2); principaux pics du spectre de masse, m/z (abondance) : 41 (33), 43 (100), 55 (16), 68 (18), 85 (67).

(Diméthyl-2,2 tétrahydropyrannyl-3)-2 propionate de méthyle, ***4***c : $Eb_{0,8}$ 66°C; n_D^{20} = 1,4566; rmn ^1H δ(ppm) : 4–3,3 (m, 2H, CH_2—O), 3,6 (s, 3H, OCH_3), 2,8–1,3 (m, 6H, autres CH_2 et CH), 1,5 (d, J = 8 Hz, 3H, CH_3—CH), 1,2 et 1,1 (2s, 6H, autres CH_3); principaux pics du spectre de masse, m/z (abondance) : 39 (24), 41 (59), 43 (93), 55 (100), 59 (33), 85 (22), 88 (52), 99 (57), 113 (31), 114 (20), 125 (23), 127 (28), 142 (59).

(Diméthyl-2,2 tétrahydropyrannyl-3) éthanenitrile, ***4***d : $Eb_{0,2}$ 59°C; n_D^{20} = 1,4670; rmn ^1H δ(ppm) : 3,7–3,4 (m, 2H, CH_2—O), 2,4–1,3 (m, 7H, autres CH_2 et CH), 1,1 et 1,2 (2s, 6H, CH_3); rmn ^{13}C δ(ppm) : 118,8 (CN), 73,2 ($C(CH_3)_2$), 61,1 (CH_2O), 41,3 (CH—CH_2CN), 28,1 et 18,9 (CH_3), 24,9 et 19,8 (autres CH_2); principaux pics du spectre de masse, m/z (abondance) : 41 (33), 43 (100), 55 (16), 66 (18), 85 (67).

(Diméthyl-2,2 tétrahydropyrannyl-3) dioxanne-1,4, ***4***e : ***4e*** n'a pu être obtenu parfaitement pur après distillation (cpg); $Eb_{0,4}$ 52°C; n_D^{20} = 1,4339; rmn ^1H δ(ppm) : 3,8–3,3 (9H, CH_2—O et CH—O), 2,8–1,3 (m, 5H, autres CH et CH_2), 1,2 et 1,1 (2s, 6H, CH_3); principaux pics du spectre de masse, m/z (abondance) : 27 (15), 29 (17), 31 (25), 41 (52), 43 (31), 45 (15), 55 (100), 69 (71), 73 (18), 81 (37), 86 (48), 87 (84), 96 (40), 97 (20), 125 (24).

Acide (diméthyl-2,2 tétrahydropyrannyl-3)-2 propionique, ***4***f : $Eb_{0,2}$ 92°C; n_D^{20} = 1,4691; rmn ^1H δ(ppm) : 10,5 (s, 1H, $COOH$), 3,75–3,25 (m, 2H, CH_2—O), 2,75–1,3 (m, 6H, autres CH_2 et CH), 1,5 (d, J = 8 Hz, 3H, CH_3—CH), 1,2 et 1,1 (2s, 6H autres CH_3); principaux pics du spectre de masse, m/z (abondance) : 32 (15), 39 (23), 41 (49), 43 (91), 55 (97), 56 (19), 58 (29), 59 (100), 74 (46), 83 (28), 85 (31), 87 (26), 113 (24), 128 (74).

(Diméthyl-2,2 tétrahydropyrannyl-3) acétone, ***4***g : $Eb_{0,5}$ 55°C; n_D^{20} = 1,4639; rmn ^1H δ(ppm) : 3,75–3,25 (m, 2H, CH_2—O), 2,5–1,4 (m, 7H, autres CH_2 et CH), 2,1 (s, 3H, CH_3—C=O), 1,2 et 1,1 (2s, 6H, autres CH_3); principaux pics du spectre de masse, m/z (abondance) : 41 (19), 43 (100), 59 (21), 112 (25).

Remerciements

Dans ce travail, on décrit la préparation chimique des dihydroxy-10,11 dihydroquinidines, des métabolites de la quinidine. La séparation des isomères 10(*R*) et 10(*S*) a été réalisée à l'aide des dérivés isopropylidènes. On a déterminé les caractéristiques physiques de chacun des isomères et on a déterminé leur structure respective par résonance magnétique nucléaire du ^{1}H à 400 MHz. Grâce à la diffraction des rayons X, il a été établi que le composé majoritaire, de point de fusion 239°C, possède la configuration 10(*R*). Ce composé cristallise avec une molécule d'eau, dans une maille orthorhombique de dimensions a = 8,756(2), b = 11,499(7) et c = 19,123(5) Å et le groupe spatial est $P2_12_12_1$. La structure a été affinée jusqu'à une valeur finale de R = 0,040 pour 2039 réflexions observées.

FRANÇOIS-XAVIER JARREAU, J. J. KOENIG, MICHEL PAYS, ROBERT LEROYER, FRANÇOIS BRISSE, and JEAN-CLAUDE RICHER. Can. J. Chem. **65**, 2701 (1987).

This paper describes the chemical preparation of the 10,11-dihydroxyquinidines, some of the metabolites of quinidine. The 10(*R*) and 10(*S*) isomers have been separated using the isopropylidene derivatives. The physical characteristics of each of these isomers have been determined and their respective structures have also been determined using ^{1}H nuclear magnetic resonance at 400 MHz. On the basis of an X-ray diffraction structure determination, it has been shown that the main product, melting point 239°C, is the 10(*R*) isomer. This product crystallizes with one molecule of water in the orthorhombic system with a = 8.756(2), b = 11.499(7), and c = 19.123(5) Å and space group $P2_12_12_1$. The structure has been refined to a final value of R = 0.040 for 2039 observed reflections.

Introduction

La dégradation oxydative de la quinidine, aussi bien chez l'animal que chez l'homme, conduit aux principaux produits suivants (pour revues, voir la réf. 1) : l'hydroxy-3(*S*) quinidine (2, 3); la desméthylquinidine (cupréidine) (4); la *N*-oxyde de quinidine (5); l'hydroxy-2′ quinidine (2, 3) et la dihydroxy-10,11 dihydroquinidine (6) qui n'a été observée jusqu'à maintenant que chez l'animal.

La préparation par synthèse des trois premiers de ces composés a déjà été réalisée (5, 7, 8). Celle du quatrième présente des difficultés liées au caractère polyfonctionnel de la molécule (9). Enfin, les tentatives de préparation du «dihydrodiol» (5, 10) n'ont pas permis jusqu'à récemment de l'isoler à l'état pur (5, 11). Par ailleurs, une combinaison des deux techniques décrites antérieurement nous a récemment permis d'isoler une faible quantité de l'isomère le plus polaire.[1]

Résultats et discussion

Dans le but d'élucider définitivement la structure du métabolite naturel de la quinidine dihydroxylée en 10 et 11 et de déterminer sa configuration absolue, une synthèse efficace en a été réalisée selon le schéma 1.

Par oxydation au moyen de OsO_4 (12), l'acétyl quinidine (**1**) est transformée en deux produits qui ont été séparés par chromatographie après transformation en dérivés isopropylidènes **2** et **3**. La déprotection de chacun de ces dérivés livre un composé pur cristallisé.

Les structures de ces deux molécules ont été établies sur la base de leurs caractéristiques spectrales. Alors que les spectres de masse à haute résolution confirment les compositions attendues, les spectres ir et uv des produits **4** et **5**, marqués par le noyau méthoxyquinoléine, sont identiques entre eux et avec ceux de la quinidine et de la dihydroquinidine. De plus, les deux $[\alpha]_D$ ont des valeurs peu différentes et très positives comme celles des dérivés quinidiniques, quoique sensiblement plus faibles.

Ce n'est que par rmn du ^{1}H à 400 MHz que l'on a pu mettre en évidence des différences entre **4** et **5**; dans ces conditions, tous les protons sont distincts (tableaux 1 et 2). Il apparaît clairement que la transformation chimique a affecté la chaîne vinyle, devenue éthyle disubstituée, sans altérer le reste de la molécule. Les différences entre les deux spectres sont le reflet d'une stéréoisomérie au niveau de l'hydroxyle en 10. L'attribution des massifs a été établie par analogie avec les spectres de la quinidine **1** et confirmée par découplage dans la partie modifiée de la molécule, c'est-à-dire sur les protons en 3 et en 10 (sur l'isopropylidène du majoritaire, **2**) et par rapprochement avec les spectres à haute résolution des dérivés hydroxy-3 de la quinidine et de la dihydroquinidine.[2]

Donc, compte tenu du réactif employé pour l'oxydation de la quinidine, des transformations chimiques appliquées ensuite et

SCHÉMA 1

des caractéristiques spectrales des deux produits formés, il est possible d'affirmer qu'il s'agit bien des deux dihydroxy-10,11 dihydroquinidines stéréoisomères par rapport au carbone secondaire 10. Toutefois, l'attribution de la stéréochimie à chacun de ces deux isomères n'est pas possible avec ces seuls éléments. Aussi la détermination de la structure et de la configuration absolue de l'isomère majoritaire a été réalisée par diffraction des rayons X.

Les coordonnées atomiques finales, leurs écarts-types et les facteurs thermiques équivalents U_{eq} sont présentés dans le tableau 3.[3] Ces coordonnées correspondent à la configuration absolue, telle que déterminée en tenant compte de la dispersion anormale des atomes d'oxygène et d'azote (17). La configuration absolue ainsi trouvée est en accord avec celle du parent quinidine, elle aussi établie par diffraction des rayons X par Carter, McPhail et Sim (18). La numérotation des atomes est indiquée sur la figure 1 alors que la conformation moléculaire adoptée par l'isomère 10(*R*) est représentée par la paire stéréo

3. Les tables des coordonnées des atomes d'hydrogène, des facteurs thermiques anisotropes, des plans moyens et la liste des facteurs de structure observés et calculés sont disponibles. On peut les acheter en s'adressant au Dépôt de données non publiées, ICIST, Conseil National de Recherches du Canada, Ottawa (Ontario), Canada K1A 0S2.

conformation parallèle à l'axe N—C(4) du noyau quinuclidine et orientée en direction opposée de l'azote. Cette conformation, qui semble la préférée pour les fins de l'oxydation, est vraisemblablement aussi favorisée dans l'état fondamental. Ces connaissances sont d'une importance capitale dans la compréhension des réactions qui se produisent en milieux biologiques, qui ont été examinées et dont les résultats feront l'objet d'une communication ultérieure.

Distances et angles

Les distances interatomiques C(sp^3)—C(sp^3) observées dans l'intervalle 1,520(3)–1,552(3) Å ont une moyenne de 1,539 Å. Les trois distances C(sp^3)—N sont très voisines et ont une moyenne de 1,482 Å. Les trois distances C(sp^3)—OH sont aussi très voisines et leur moyenne est de 1,426 Å. Les angles de valence du cycle quinuclidique impliquant les atomes de C ont une moyenne de 109,2° qui ne diffère pas significativement des angles de valence à l'azote dont la moyenne est 109,1°. Il faut toutefois noter que ce sont les trois atomes de carbone liés à l'azote qui ont les angles de valence les plus ouverts. Dans le noyau méthoxyquinoléique on retrouve une alternance de liaisons courtes et longues telle que rapportée pour le naphtalène, et ses dérivés (16). Les longueurs observées ici, qui varient de 1,321(3) à 1,429(3) Å, sont quelque peu perturbées au voisinage de N(1′). En ce qui concerne les angles de valence, ils ont une moyenne de 120,0° et ce sont les angles à N(1′), C(2′) et C(10′) qui s'écartent le plus de la moyenne. Le noyau méthoxyquinoléique est pratiquement plan, les déviations des atomes du plan moyen n'excédant pas 5σ. L'atome O(6′) fait aussi partie du plan moyen tandis que C(Me) s'en écarte de 0,153(4) Å.

Le système de ponts-hydrogène

La présence d'une molécule d'eau de cristallisation a été révélée au cours de la détermination structurale. Elle est associée par ponts-hydrogène à O(11), O(10) et N(1). Les caractéristiques géométriques de ces liaisons sont données dans le tableau 6. On y remarque des liaisons hydrogène de forces moyennes puisque les distances O...O* varient de 2,693(3) à 2,788(3) Å. Les deux atomes d'azote N(1) et N(1′) sont impliqués dans ces interactions avec la molécule d'eau et l'oxygène alcoolique O(10) respectivement. Les distances O...N* ont les valeurs de 2,750(2) et 2,795(3) Å.

Partie expérimentale

Les points de fusion ont été mesurées sur un banc Kofler et ne sont pas corrigés. Les spectres infrarouges ont été déterminés sur un appareil Perkin Elmer, modèle 157-G. Les spectres ultraviolets ont été déterminés sur un appareil Perkin Elmer modèle 402. Les indices de rotation ont été mesurés à l'aide d'un polarimètre Perkin Elmer modèle 141MC. Les spectres rmn du ^{1}H ont été déterminés à l'aide d'appareils Varian, modèle EM-360, et Bruker, modèle WM 400; ces mesures ont été faites dans le méthanol-d_4 et les déplacements chimiques, exprimés en ppm, sont déterminés par rapport au TMS. Les spectres de masse ont été déterminés à l'aide d'un appareil AEI, modèle MS-901. Les chromatographies analytiques ont été réalisées sur des plaques de 0,25 mm, type 60F-254, de silice (Merck 5719) ou d'alumine (Merck 5731) alors que les chromatographies préparatives ont été réalisées sur une colonne de gel de silice 60H (Merck 7736), sous une pression de 300 mbar (1 bar = 100 kPa) («chromatographie flash»).

Diméthyl méthylène dioxy)-10,11 dihydro-10,11 quinidine 5 (2 et 3)

À une solution, refroidie à 10°C et agitée, de 5,00 g (13,6 mmol) d'acétylquinidine (**1**) dans 52 mL de pyridine, on ajoute 3,50 g (13,8 mmol) de OsO_4 et on laisse reposer 1 nuit à 20°C; après traitement (12), 4,58 g de bases sont obtenus. À 4,30 g de ces bases, on ajoute 65 mL de DMF, 75 mL de diméthoxypropane et 2,90 g d'acide tosylique; après 1 nuit à 20°C, on procède à l'extraction pour obtenir 4,99 g de bases. Enfin, si on traite 4,88 g de celles-ci par 0,2 mL de NaOH 10 M dans 100 mL de MeOH à 20°C pendant 2,5 h, on obtient 4,07 g d'un mélange d'alcaloïdes qui présente en ccm trois taches distinctes et qu'on a séparé par chromatographie sur colonne (support, 140 g de silice 60H Merck 7736; éluant CH_2Cl_2 : EtOH : NH_4OH, 91 : 8,0 : 0,8; pression de 300 mbar). On obtient ainsi par ordre de polarité croissant : 1,91 g (4,8 mmol) de l'isomère majoritaire 10(*R*), la dihydroxy-10,11 dihydro-10,11 quinidine sous la forme de dérivé di-*O*-isopropylidène-10,11 (**2**); 1,00 g (2,5 mmol) de l'isomère minoritaire 10(*S*) (**3**); 463 mg (1,4 mmol) de dihydroquinidine et 360 mg de mélange de fractions intermédiaires.

Le rendement est d'environ 60% en dihydrodiols purs et séparés en ses deux stéréoisomères (en proportion 1,9/1); le rendement est calculé à partir de la *O*-acétylquinidine et tient compte du fait que le produit initial contient environ 10–15% de dérivé dihydro.

L'isomère majoritaire 10(*R*) (**2**) présente les caractéristiques suivantes : *F* 196°C (AcOEt); rmn ^{1}H ($CDCl_3$) δ : 1,34 et 1,37 (2s, 2Me), 3,50 et 4,0 (t, 2H-11), 3,26 (s, OMe), 4,45 (q, H-10), 5,69 (s, H-9), 7,23, 7,47, 7,87 et 8,40 (5H, aromatiques) ppm. L'isomère minoritaire 10(*S*) (**3**) présente les caractéristiques suivantes : *F* 188°C (AcOEt); rmn ^{1}H ($CDCl_3$) δ : 1,37 (2Me), 3,47 et 3,97 (2t, 2H-11), 3,73 (s, OMe), 4,37 (m, H-10), 7,10, 7,53, 7,78 et 8,40 (5H, aromatiques) ppm.

Dihydroxy-10,11 dihydro-10,11 quinidines (4 et 5)

*Isomère majoritaire 10(*R*) (4)*

On dissout 500 mg de diméthyl méthylènedioxy-10,11 dihydroquinidine-10(*R*) dans 2,3 mL de MeOH et on ajoute 2,5 mL (4,8 milliéquivalents) de résine IR 120-H^+ en suspension dans l'eau et on agite la suspension à température ambiante pendant 1 nuit.

TABLEAU 7. Données cristallographiques

$C_{20}H_{26}N_2O_4 \cdot H_2O$	P.M. = 376,46	$F(000)$ = 808 e	orthorhombique
a = 8,756(2) Å	b = 11,499(7) Å	c = 19,123(5) Å	V = 1925,4 Å^3
$P2_12_12_1$	Z = 4	d_0 = 1,28	d_c = 1,298 g cm^{-3}
μ(CuKα) = 7,27 cm^{-1}		λ(CuK$\bar{\alpha}$) = 1,54178 Å	T = 190 K

Par la suite, on filtre, rince et élue les bases par un mélange de $MeOH/NH_4OH$ et on concentre à sec avant de cristalliser le résidu (405 mg) dans du EtOH aqueux pour obtenir 343 mg de cristaux de dihydroxy-10,11 dihydro-10,11-quinidine 10(*R*) (**4**) qui présente les caractéristiques suivantes : *F* 239°C (*i*-PrOH); $[\alpha]_D$ +188° (*c* 1,09, EtOH 95); uv (EtOH) λ_{max} : 233 (30 200), 280 (3600), 290 (3100), 322 (4100), 333 (4600) nm; masse calculée pour $C_{20}H_{26}N_2O_4$: 358.4; trouvée (par sm) : 358 (ions principaux à *m/e* 340 (10), 283 (10) et 227 (100)).

*Isomère minoritaire 10(*S*) (**5**)*

De la même manière, à partir de 250 mg du produit **3**, on obtient 174 mg de cristaux (acétonitrile) de dihydroxy-10,11 dihydro-10,11-quinidine 10(*S*) (**5**) qui présentent les caractéristiques suivantes : *F* 228°C (*i*-PrOH–AcOEt); $[\alpha]_D$ +182° (*c* 1,03, EtOH 95); masse calculée pour $C_{20}H_{26}N_2O_4$: 358,4; trouvée (par SM) : 358 (ions principaux à *m/e* 340 (100), 221 (60) et 181 (100)).

*Étude structurale de l'isomère majoritaire 10(*R*) (**4**)*

Le composé 10(*R*), recristallisé à partir de sa solution dans l'isopropanol, se présente sous forme de cristaux prismatiques, incolores et de dimensions 0,16 × 0,25 × 0,35 mm. La détermination précise de la maille cristalline a été faite à partir de 25 réflexions bien centrées mesurées dans l'intervalle $25 \leqslant 2\theta \leqslant 70°$. Les seules absences systématiques rencontrées, du type $h00$, $h \neq 2n$; $0k0$, $k \neq 2n$ et $00l$, $l \neq 2n$, sont caractéristiques du groupe spatial $P2_12_12_1$. Les données cristallographiques d'intérêt sont rapportées dans le tableau 7. La collection des intensités diffractées sur un diffractomètre automatique Nonius CAD4 a été effectuée par la méthode de balayage ω–2θ avec une largeur de balayage $\Delta\omega = (1{,}00 + 0{,}14 \text{ tg } \theta)°$ en utilisant la radiation du cuivre et un monochromateur de graphite à 190 K. L'orientation et la stabilité du cristal ont été suivies grâce à 7 réflexions de référence dont les intensités étaient mesurées toutes les heures et l'orientation vérifiée à toutes les 100 mesures. Les intensités de 2188 réflexions ont été enregistrées dans la sphère de réflexion limitée par $2\theta_{max} = 150°$, $0 \leqslant h \leqslant 10$, $0 \leqslant k \leqslant 14$ et $0 \leqslant l \leqslant 23$. La fluctuation maximum des intensités de référence n'a pas dépassé 3,2%. Au total, les 2039 réflexions pour lesquelles $I \geqslant 3{,}0\sigma(I)$ sont considérées observées et servent à la détermination et à l'affinement de la structure. Les coordonnées de la majorité des atomes de la molécule ont été établies grâce au programme MULTAN.[4] Tous les atomes, y compris une molécule d'eau de cristallisation, ont été trouvés à la suite d'une série d'affinement et de synthèses de différence Fourier. Les atomes semi-lourds ont été affinés anisotropiquement alors que les atomes d'hydrogène, trouvés sur les cartes de différence Fourier, étaient isotropes. La quantité minimisée est $\Sigma w(|F_o| - |F_c|)^2$ où les poids w sont dérivés des statistiques de comptage. L'affinement a convergé quand $\Delta/\sigma_{max} = 0{,}37$ et $\Delta/\sigma_{moyen} = 0{,}06$, alors $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0{,}0399$, $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0{,}0496$ et $S = [\Sigma w(|F_o| - |F_c|)^2/(m - n)]^{1/2} = 2{,}026$. La configuration absolue correspond à celle établie pour la quinidine (18). Les valeurs extrêmes de la densité électronique résiduelle de la dernière synthèse de différence Fourier sont −0,22 et +0,20 e Å^{-3}. Les courbes de diffusion de C, N, O sont tirées de Cromer et Mann (14) et celles de l'hydrogène viennent de Stewart, Davidson et Simpson (15). Pour l'autre configuration, S prend la valeur de 2,043 alors que R et R_w prennent les valeurs de 0,0402 et 0,050 respectivement.

The influence of charge on nuclear magnetic resonance isotope effects

RODERICK E. WASYLISHEN[1] AND NEIL BURFORD
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received May 22, 1987

RODERICK E. WASYLISHEN and NEIL BURFORD. Can. J. Chem. **65**, 2707 (1987).

Deuterium isotope effects on the ^{31}P shielding constants and spin–spin coupling constants in the isoelectronic series, PH_2^-, PH_3, PH_4^+, are examined. Also, deuterium isotope effects on the nuclear magnetic resonance parameters of SnH_3^- are examined and compared with our earlier results on SnH_4 and SnH_3^+. The experimental results are analyzed using the models of Jameson and Osten. In each isoelectronic series it is found that the isotope effects on the heavy atom chemical shifts are largest for the negatively charged ions and essentially zero for the positively charged ions, as predicted by recent molecular orbital calculations. The primary isotope effects on J(A,H) are positive for all species containing lone-pair electrons, otherwise $\Delta_p\,{}^1J$(A,H) is negative. The primary and secondary isotope effects on J(Sn,H) in the SnH_3^- ion are the largest reported to date.

RODERICK E. WASYLISHEN et NEIL BURFORD. Can. J. Chem. **65**, 2707 (1987).

On a étudié les effets isotopiques du deutérium sur les constantes d'écran du ^{31}P et sur les constantes de couplage spin–spin de la série isoélectronique PH_2^-, PH_3 et Ph_4^+ : On a aussi étudié les effets isotopiques du deutérium sur les paramètres en résonance magnétique nucléaire du SnH_3^- et on les a comparés avec nos résultats antérieurs sur le SnH_4 et le SnH_3^+. On a analysé les résultats expérimentaux en utilisant les modèles de Jameson et Osten. Dans chacune des séries isoélectroniques, on a trouvé que les effets isotopiques sur les déplacements chimiques de l'atome lourd sont les plus importants pour les ions chargés négativement et essentiellement zéro pour les ions chargés positivement; ces résultats sont en accord avec les prédictions dérivées de calculs récents d'orbitales moléculaires. Les effets isotopiques primaires sur J(A,H) sont positifs pour toutes les espèces contenant des paires libres d'électrons; autrement, la valeur de $\Delta_p\,{}^1J$(A,H) est négative. Les valeurs des effets électroniques primaire et secondaire sur J(Sn,H) dans l'ion SnH_3^- sont les valeurs les plus élevées à être rapportées à date.

Introduction

It has been known for several years that in simple hydrides, AH_x, replacement of a hydrogen atom by deuterium leads to increased shielding of nucleus A (1–3). Recently, Jameson and Osten (4) have developed a simple model that allows qualitative estimate of $^{2/1}H$-induced one-bond isotope effects on the shielding constant of A in any simple hydride. The model predicts isotope effects on the shielding constant to increase as one moves across any row or down any group of the periodic table due to the periodicity of $\langle r^{-3}\rangle_A$ for the valence p or d orbitals of atom A. This general periodic variation of $^{2/1}H$ isotope effects in simple hydrides is supported by recent theoretical calculations of Chesnut and Foley (5, 6), which show that the shielding derivative with respect to bond extension, $(\partial\sigma^A/\partial\Delta r)_e$, also exhibits a systematic variation as one moves across either the first or second row of the periodic table. The shielding derivative is intimately related to the isotope effect on σ^A because the main influence of deuterium substitution is to decrease the average mean bond displacement, $\Delta r_{A-^{2/1}H}$ (3, 7–9).

For any particular isotope, A, it has also been recognized that the extent of the $^{2/1}H$ isotope effect on σ^A will show some variation depending upon the detailed electronic structure of the molecule (2, 3). For example, the $^{2/1}H$ isotope effect on the ^{15}N chemical shift of ammonia is -0.62 ppm/^2H, about twice the shift observed in the isoelectronic ammonium ion, -0.29 ppm/^2H (10–12). The detailed explanation for this observation is not entirely clear; however, it does appear that the gross atomic charge on the central atom is important (5). To examine further the influence of charge we have measured very accurate $^{2/1}H$ induced isotope effects on ^{31}P and ^{119}Sn chemical shifts in PH_2^-, PH_4^+, and SnH_3^-, respectively. This allows us to compare our results with earlier experimental data on PH_3 (13) and on SnH_4 and SnH_3^+ (14). Investigation of these two series of isoelectronic molecules also permits us to make a systematic experimental study of isotope effects on spin–spin coupling constants (15).

[1]Author to whom correspondence may be addressed.

Theory

The one-bond isotope shift is defined by eq. [1],

$$[1]\quad {}^1\Delta A(^{2/1}H) = \sigma^A(A—{}^1H) - \sigma^A(A—{}^2H)$$

and for end atom isotopic substitution in a simple hydride, eq. [2] is a good approximation (3, 4, 8),

$$[2]\quad {}^1\Delta A(^{2/1}H) \cong (\partial\sigma^A/\partial\Delta r_{AH})_e[\langle\Delta r_{A—H}\rangle - \langle\Delta r_{A—D}\rangle] \cong (\partial\sigma^A/\partial\Delta r_{AH})_e(1/4)\langle\Delta r_{AH}\rangle$$

where $\langle\Delta r_{AH}\rangle$ is the mean bond displacement, 15–20 $\times$ 10^{-3} Å (9). As mentioned in the introduction, $\sigma^A(A—{}^2H) > \sigma^A(A—{}^1H)$; hence ${}^1\Delta A(^{2/1}H)$ and $(\partial\sigma^A/\partial\Delta r_{AH})$ are invariably negative. A more complete analysis of isotope effects on σ^A involves contributions from mean square bond displacements and mean bond angle displacements. Thus terms such as $(\partial^2\sigma^A/\partial\Delta r_{AH}{}^2)_e\langle(\Delta r_{AH})^2\rangle$ and $(\partial\sigma^A/\partial\Delta\alpha)_e[\langle\Delta\alpha\rangle_{light} - \langle\Delta\alpha\rangle_{heavy}]$ must be considered; however, it is generally thought that these contributions to ${}^1\Delta A(^{2/1}H)$ are relatively small (3, 4, 8, 9, 16).

Recently, Jameson and Osten (15) have summarized isotope effects on spin–spin coupling constants. They define the primary and secondary isotope effect on spin–spin coupling constants using eqs. [3] and [4], respectively.

$$[3]\quad \Delta_p{}^1J(A,^{2/1}H) = |{}^1J(A,D)|(\gamma_H/\gamma_D) - |{}^1J(A,H)|$$

$$[4]\quad \Delta_s{}^1J(A,B)[^{2/1}H] = |{}^1J(A,B)_D| - |{}^1J(A,B)_H|$$

where B is either ^1H or ^2H. The interpretation of isotope effects on spin–spin coupling constants is similar to that of isotope effects on shielding constants (13, 15, 17, 18). Primary isotope effects on J can be estimated by eq. [5] (15),

$$[5]\quad \Delta_p{}^1J(A,^{2/1}H) = (\partial J/\partial\Delta r_{AH})_e[\langle\Delta r_{A—D}\rangle - \langle\Delta r_{A—H}\rangle]$$

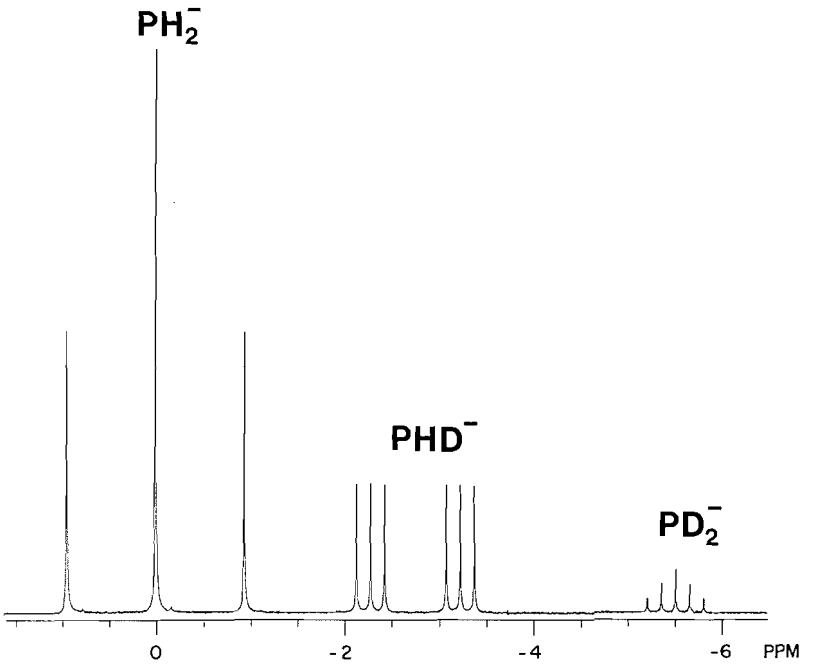

FIG. 1. Phosphorus-31 nmr spectrum of $PH_{2-n}D_n^-$ ($n \leq 2$) at 20°C in liquid ammonia.

Experimentally, primary isotope effects on $^1J(A,^{2/1}H)$ are generally negative unless atom A has one or more electron lone pairs (e.g., PH_3, H_2Se), in which case they are positive (15). Secondary isotope effects on spin–spin coupling constants are usually much smaller than primary isotope effects, and they are more difficult to interpret. The interested reader should consult ref. 15.

Experimental

A sample of $PH_{4-n}D_n^+$ ($n \leq 4$) (~0.7 *M*) was prepared by condensing phosphine (2.7 mmol) into a mixture of boron trifluoride (2.5 mL), CH_3OH (0.5 mL), and CH_3OD (1.5 mL) (19*a*). Potassium phosphide was prepared from potassium metal (0.12 g, 3 mmol) and phosphine (excess) in ammonia (5 mL) (19*b*). The ammonia and excess phosphine were removed under vacuum and the remaining white solid was dissolved in a 1:2 mixture of ammonia and ammonia-d_3. A sample of $NaSnH_{3-n}D_n$ ($n \leq 3$) was prepared by condensing stannane into a solution of sodium (0.07 g, 3 mmol) in a 1:2 mixture of NH_3 and ND_3 (20). Ammonia was dried over sodium before use in all cases. The solutions were all sealed in thick-walled 10 mm o.d. nmr tubes. We would like to point out that $NaSnH_3$ in liquid ammonia undergoes slow decomposition with the evolution of hydrogen gas at 20°C. We stored our sample at liquid nitrogen temperatures; however, after remaining at 20°C for 3 to 5 h the sealed nmr tube exploded violently.

The nmr spectra were obtained using a high-frequency broadband multinuclear nmr probe in a Nicolet-360 spectrometer operating at B_0 = 8.48 T. Phosphorus-31 and ^{119}Sn chemical shifts were referenced with respect to external 85% H_3PO_4 and neat $SnCl_4$, respectively, at 20°C.

Results and discussion

1. $^{2/1}H$ induced isotope effects on shielding constants

(a) PH_2^-, PH_3, and PH_4^+

Phosphorus-31 nmr spectra of $PH_{2-n}D_n^-$ and $PH_{4-n}D_n^+$ at 20°C are shown in Figs. 1 and 2 and the measured isotope shifts are summarized in Tables 1 and 2. The corresponding $^{2/1}H$ isotope effects on the ^{31}P chemical shifts in phosphine are summarized in Table 3; the data are from Jameson and Jameson (13). The first point to note is the decrease in $|^1\Delta^{31}P(^{2/1}H)|$: −2.76, −0.85, and 0.00 ppm/D on going from PH_2^- to PH_3 to PH_4^+. Assuming eq. [2] applies we calculate $(\partial\sigma^P/\partial\Delta r)_e$ values of −585 ± 65, −180 ± 20, and 0 ± 10 ppm/Å, respectively, for PH_2^-, PH_3, and PH_4^+. The observed trend is in agreement with the proposal of Chesnut (5) that the gross charge is related to $(\partial\sigma^P/\partial\Delta r)_e$ and hence the isotope shift. The derivative calculated for phosphine is in excellent agreement with the theoretical value of −150.8 ppm/Å (6). The good agreement suggests that bond angle deformation must make minor contributions to the isotope shift in phosphine. This conclusion is supported by the theoretical calculations of Chesnut and Foley (6) and the arguments of Jameson and Osten (16).

In the case of PH_2^- we also believe that the isotope shift is dominated by $(\partial\sigma^P/\partial\Delta r)_e$; the large derivative is due to both the increased electron density at the phosphorus and to the larger paramagnetic shielding that results from the two groups of lone pairs of electrons on the phosphorus atom. Unfortunately, high-level molecular orbital calculations of the various shielding derivatives are not available for PH_2^-.

To our knowledge the phosphonium ion is the first example where a one-bond $^{2/1}H$ isotope shift is observed to be positive, i.e., $\sigma(PH_4^+) - \sigma(PD_4^+)$ is positive. The calculations of Chesnut (5) predict $(\partial\sigma^P/\partial\Delta r)_e = -52.9$ ppm/Å; this would correspond to a $^1\Delta^{31}P(^{2/1}H)$ of approximately −0.25 ppm. Considering the range of observed $\partial\sigma^P/\partial\Delta r_{PH}$ values, the possible influence of solvent effects, and anion–cation interactions (2, 3, 21), the agreement between theory and experiment is good. It is of interest to point out that the molecular orbital calculations (5) predict a small positive value for $(\partial\sigma^{Al}/\partial\Delta r)_e$ in AlH_4^-, +11.6 ppm/Å; however, experiments imply a small negative value. The isotope shifts, $^1\Delta Al(^{2/1}H)$, reported in three independent studies are very small, 0 ppm/^2H (22), −0.04 ± 0.02 ppm/^2H (23), and −0.1 ppm/^2H (24); again considering the possible influence of intermolecular interactions, the agreement between theory and experiment is good.

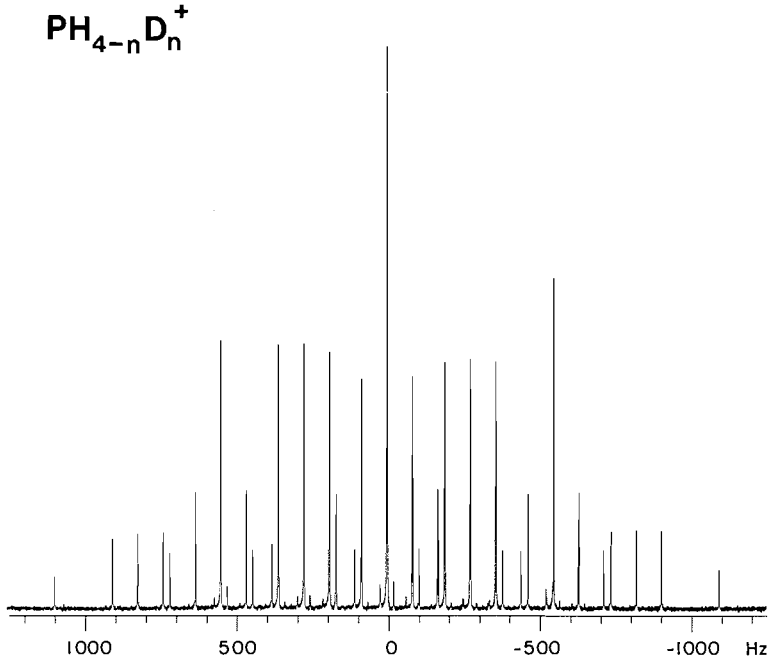

FIG. 2. Phosphorus-31 nmr spectrum of $PH_{4-n}D_n^+$ ($n \leq 4$) in BF_3 and methanol at 20°C.

TABLE 1. Phosphorus-31 chemical shifts for $PH_{2-n}D_n^-$ ($n \leq 2$) in liquid ammonia at 20°C

Molecule	$^1\Delta^{31}P(^{2/1}H)_{obs}$[a]	$^1\Delta^{31}P(^{2/1}H)_{add}$	Δ
PH_2^-	0.0000 ppm	0.0000 ppm	0
PHD^-	−2.7613	−2.7599	0.0014
PD_2^-	−5.5197	−5.5197	0

[a]Error ±0.0002 ppm; the chemical shift of PH_2^- w.r.t. 85% H_3PO_4 is −279.4 ppm.

TABLE 2. Phosphorus-31 chemical shifts and spin–spin coupling constants for the $PH_{4-n}D_n^+$ ($n \leq 4$) ion in methanol and boron trifluoride at 20°C

Molecule	$^1\Delta^{31}P(^{2/1}H)_{obs}$[a]	$^1J(^{31}P,H)$[b]	$^1J(^{31}P,D)$[c]
PH_4^+	0.000 ppm	547.98 Hz	—
PH_3D^+	−0.004	547.78	83.32 Hz
$PH_2D_2^+$	−0.002	547.56	83.81
PHD_3^+	+0.006	547.37	83.76
PD_4^+	+0.018	—	83.66[d]

[a]Error ±0.001 ppm; the chemical shift is −105.3 ppm w.r.t. 85% H_3PO_4.
[b]Error ±0.05 Hz; $\Delta_s\ ^1J(^{31}P,H)\ [^{2/1}H] = -0.20 \pm 0.05$ Hz.
[c]Error ±0.10 Hz; $\Delta_p\ ^1J(^{31}P,H) = -1.68 \pm 0.35$ Hz.
[d]Error ±0.10 Hz.

(b) SnH_3^-, SnH_4, and SnH_3^+

The ^{119}Sn nmr spectrum of $NaSnH_{3-n}D_n$ at −50°C is shown in Fig. 3 and the results are summarized in Table 4. The isotope shifts, $^1\Delta Sn(^{2/1}H)$, in the series SnH_3^-, SnH_4, and SnH_3^+ are −3.09, −0.40, and −0.05 ppm/D, respectively. The trend observed in this isoelectronic series of hydrides is the same as that observed for the phosphorus hydrides, and similar qualitative arguments can be used to rationalize the variation in isotope shifts. One point to note is that on going from PH_3 to PH_2^- there is not a significant change in the HPH bond angle (93.5 ± 2° in both compounds (25, 26)); however, on going from SnH_4 to SnH_3^- there will be a substantial change in the HSnH bond angle from 109.47° to 92.5 ± 4° (27, 28). This change in geometry, concomitant with the lone-pair contribution, in part accounts for the large change in $^1\Delta^{119}Sn(^{2/1}H)$ between SnH_3^- and SnH_4. Assuming that only differences in the mean bond displacement are responsible for the isotope shift, we calculate $(\partial\sigma^{Sn}/\partial\Delta r_{SnH})_e = -700 \pm 100$ ppm/Å. If other terms contribute to the isotope shift the value of −700 ppm/Å is probably an upper limit to the bond displacement derivative (3).

TABLE 3. Phosphorus-31 chemical shifts for $PH_{3-n}D_n$ ($n \leq 3$)[a]

Molecule	$^1\Delta^{31}P(^{2/1}H)_{obs}$	$^1\Delta^{31}P(^{2/1}H)_{add}$	Δ
PH_3	0.0000 ppm	0.0000 ppm	0
PH_2D	−0.8045	−0.8458	−0.0413
PHD_2	−1.6491	−1.6916	−0.0425
PD_3	−2.5373	−2.5373	0

The $^{2/1}H$ isotope effects on the ^{119}Sn chemical shifts of SnH_2D^+ and $SnHD_2^+$ deviate from additivity by the same amount, −0.015 ppm. Interestingly, the deviations from additivity are negative, i.e., each replacement of a hydrogen in SnH_3^- by deuterium results in a larger change in $^1\Delta^{119}Sn$ (−3.093, −3.109, and −3.123 ppm, respectively). Negative deviations are also observed for phosphine (13); however, for all other molecules that we have studied (NH_4^+, NH_3, PH_2^-, and SnH_4) deviations are positive.

2. Isotope effects on spin–spin coupling constants

Spin–spin coupling constants involving ^{31}P in the series $PH_{2-n}D_n^-$, $PH_{3-n}D_n$, and $PH_{4-n}D_n^+$ are given in Tables 5, 6, and 2, respectively. The coupling constants involving ^{119}Sn in $SnH_{3-n}D_n^-$ are given in Table 7. A single table summarizes all spin–spin coupling constants in the phosphorus and tin hydrides (Table 8).

Primary isotope effects on J are positive for all species with one or more lone pairs (PH_2^-, PH_3, and SnH_3^-); otherwise they are negative (PH_4^+, SnH_4, and SnH_3^+). This observation is attributed to a negative derivative, $(\partial K/\partial \Delta r)_e$, for those molecules with one or more lone pairs; otherwise $(\partial K/\partial \Delta r)_e$ is positive. For example, in the case of PH_2^-, theoretical molecular orbital calculations by Lazzeretti *et al.* (26) predict $\delta\partial J/\partial \Delta r \cong -700$ Hz/Å; also these same calculations predict bond angle deformations to have a relatively small influence on

J compared to bond length deformations. Assuming eq. [5] is valid (i.e., ignoring terms involving $(\partial J/\partial\Delta\alpha)_e$), we calculate $(\partial J/\partial\Delta r)_e = -570$ Hz/Å, in good agreement with the molecular orbital calculations. Jameson and Osten (15) have proposed that in the case of H_2Se and PH_3 the negative derivative, $(\partial J(A,H)/\partial\Delta r_{AH})_e$, arises from the molecular orbital which has nonbonding character (i.e., the heavy atom lone pair).

In discussing the isotope effects where one of the nuclei has a negative magnetogyric ratio (e.g., ^{119}Sn) it is important to work with reduced coupling constants, $K(A,B) = 4\pi^2 J(A,B)/h\gamma_A\gamma_B$. Using the definitions outlined in ref. 15, $\Delta_p {}^1K(A,^{2/1}H)$ will always have the same sign as $\Delta_p {}^1J(A,^{2/1}H)$; however, the sign of any given derivative involving J will be opposite to the corresponding derivative involving K if A has a negative magnetogyric ratio. Thus, for SnH_3^-, $\partial J(Sn,H)/\partial\Delta r$ is positive (+2400 Hz/Å); however, $\partial K(Sn,H)/\partial\Delta r$ is negative as found in all other hydrides where "A" has one or more lone pairs. We have also carried out measurements on the same sample of $SnH_{3-n}D_n^-$ ($n \leq 3$) at 20°C; as expected, $^1J(^{119}Sn,H)$ decreased with increasing temperature; however, within experimental error $\Delta_p {}^1J(^{119}Sn,H)$ was independent of temperature. At 20°C, $^1J(^{119}Sn,H) = 101.00 \pm 0.05$ Hz in SnH_3^-. The primary isotope effect on J observed for SnH_2D^- at 20°C is the largest isotope effect on J, 10.7 ± 1%, of which we are aware (29).

The secondary isotope effects on $J(A,H)$ [$^{2/1}$H] observed for the tin and phosphorus hydrides show no obvious trends. The value of $\Delta_s J(^{119}Sn,H)$ [$^{2/1}$H] in SnH_3^- is 3% of $J(^{119}Sn,H)$ and is the largest secondary isotope effect on J reported to date.

Acknowledgements

We wish to thank Professor C. J. Jameson for her interest in this study, Mr. Brian Millier for rebuilding one of our nmr probes, and Mr. Jürgen Mueller for the construction of thick-walled nmr tubes and some specialized glassware. We are grateful to NSERC for financial support. All nmr spectra were recorded at the Atlantic Magnetic Resonance Centre.

A 2-methylthio-3,5-diaryl-1,3,4-thiadiazolium cation; its reactions, and further exploration of the chemistry of 2-alkyl-3,5-diaryl-1,3,4-thiadiazolium cations

HAROLD MASTALERZ, TAJ MOHAMMAD, AND MARTIN S. GIBSON[1]

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received March 13, 1987

HAROLD MASTALERZ, TAJ MOHAMMAD, and MARTIN S. GIBSON. Can. J. Chem. **65**, 2713 (1987).

Activation of a representative 3,5-diaryl-1,3,4-thiadiazole-2-thione by thione S-methylation gives a cation that is readily susceptible to nucleophilic substitution. Reactions with diethyl malonate, ethyl acetoacetate, acetylacetone, cyclopentan-1,3-dione, or 3-ethylrhodanine under basic conditions lead to β,β-disubstituted methine bases and (or) β-substituted methine bases in cases where deacetylation occurs under the reaction conditions. This cation and the 2-alkyl-3,5-diaryl-1,3,4-thiadiazolium cation are convenient sources of a series of neutral and cationic dyes containing the 1,3,4-thiadiazole ring system.

HAROLD MASTALERZ, TAJ MOHAMMAD et MARTIN S. GIBSON. Can. J. Chem. **65**, 2713 (1987).

L'activation d'une diaryl-3,5 thiadiazole-1,3,4 thione-2 caractéristique par une S-méthylation de la thione conduit à un cation qui peut facilement subir une réaction de substitution nucléophile. Les réactions avec le malonate de diéthyle, l'acétoacétate d'éthyle, l'acétylacétone, la cyclopentanedione-1,3 ou l'éthyl-3 rhodanine, dans des conditions basiques, conduisent à des bases méthines β,β-disubstituées et (ou) à des bases méthines β-substituées, dans les cas où une déacétylation se produit dans les conditions de la réaction. Ce cation ainsi que le cation alkyl-2 diaryl-3,5 thiadiazole-1,3,4 ium sont des sources intéressantes d'une série de colorants neutres ou cationiques contenant le système cyclique thiadiazole-1,3,4.

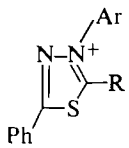
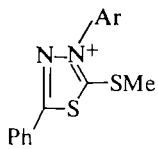
We have previously described syntheses of a number of 1,3,4-thiadiazolium perchlorates **1**, together with a study of their reactions (1). The 2-alkyl substituted salts **1** are synthetically useful for elaboration at the 2-position since they react with electrophiles in the presence of a base, reactions which are considered to proceed by electrophilic substitution of an intermediate methine base. The related 2-alkyl-2-alkoxy-2,3-dihydrothiadiazoles react similarly with electrophiles when thermolysed; again, an intermediate methine base is assumed to be involved. We now report a complementary approach to 2-functionalization in which a representative 2-methylthio-1,3,4-thiadiazolium salt **2** (Ar = $C_6H_3Br_2$-2,4) is used, together with additional reactions of **1** (Ar = $C_6H_3Br_2$-2,4).



1 ClO_4^-



2*a* $MeSO_4^-$ **2***b* ClO_4^-

The methosulfate **2***a* was prepared by methylating the corresponding 3-aryl-5-phenyl-1,3,4-thiadiazole-2-thione (2) with dimethyl sulfate; subsequent treatment with sodium perchlorate gave **2***b*. The site of methylation (thione sulfur) and the susceptibility of the 2-substituent in **2** to nucleophilic displacement were confirmed by hydrolysis of **2***a* to the corresponding 3-aryl-5-phenyl-1,3-4-thiadiazol-2-one (2, 3) and methanethiol. Further, treatment of **2***a* with aqueous sodium hydrosulfide regenerated the original thione.

Compound **2***a* was found to condense readily with diethyl malonate in acetonitrile solution in the presence of triethylamine as added base to give **3***a* (eq. [1]). Deprotonation of diethyl malonate generates the carbanion that displaces methylthiolate ion, and a further deprotonation then gives **3***a*. A similar reaction of **2***a* with ethyl acetoacetate gave **3***b* as the major product. The two compounds **3***a*, **3***b* are of interest in that the methylene proton signals in their ^1H nmr spectra appear as multiplets rather than quartets at ambient temperature, perhaps indicative of restricted rotation. Their mass spectra show molecular ions and expected fragmentation patterns. The reaction of **2***a* with ethyl acetoacetate also gave a second product, **3***c*, resulting from deacetylation of the primary product **3***b*. Methylthiolate ion is assumed to be the deacetylating agent, although methyl thiolacetate was not detected among the products. In a similar way, condensation of **2***a* with acetylacetone gave the known 2-acetonylidene-2,3-dihydro-1,3,4-thiadiazole **3***d* (4); none of the diacetyl derivative (**3**; X,Y = COMe) was isolated. We have since noted a related deacetylation phenomenon in some reactions of 1,1-dimorpholinoethene and 1,1-dipiperidinoethene (5), an example being provided by the formation of ethyl (*E*)-3-(1-piperidino)crotonate from 1,1-dipiperidinoethene and ethyl acetoacetate. However, deacylation in the present series of reactions seems unusual and is probably not general. For instance, substitution of cyclopentan-1,3-dione for acetylacetone in the foregoing reaction with **2***a* led to **3***e*, with little or no sign of acyl cleavage. In a final example, 3-ethylrhodanine condensed readily with **2***a* to give **3***f*. The formulation **3***f* is consistent with the ^1H nmr and mass spectra of the compound, the mass spectrum exhibiting features resulting from fragmentation of the rhodanine-derived ring; the base peak (*m/z* 359) arises from the molecular ion through loss of EtNCS, CO, and Br.

[1] 
2 **3** (*a–f*)

a X, Y = COOEt
b X, Y = COMe, COOEt
c X, Y = H, COOEt
d X, Y = H, COMe
e X, Y = —$COCH_2CH_2CO$—
f X, Y = —SCSNEtCO—

(Ar = $C_6H_3Br_2$-2,4)

Compounds **3***b*, *c*, *d*, and *f* may formally exist as two geometrical isomers. The reactions leading to their formation appear stereospecific, only one compound being obtained in each case. We now have the results of an X-ray crystallographic

study[2] of compound **3** (Ar = $C_6H_3Br_2$-2,4; X,Y = H, COPh) (4), which is closely related to **3***d*. These establish (*Z*) geometry for this compound, with a close oxygen–sulfur contact (the oxygen–sulfur interatomic distance is 2.629(5) Å), indicating an oxygen–sulfur interaction as foreshadowed in our earlier work (6). Of additional interest is the revelation that the 3-aryl substituent is skewed out of the plane of the thiadiazolene ring. Since this substituent is unsymmetrically substituted (2,4-dibromophenyl), the molecule is chiral, and an energy barrier to rotation may be assumed for this and related compounds. From these and spectroscopic correlations, we therefore assign (*Z*) geometry to **3***d* (i.e., X = H, Y = COMe), with similar geometry probably also applying to **3***c*. The geometries of **3***b* and *f* are not known at this point.

This method can evidently be extended to allow for interpolation of a double bond. For example, the thione sulfur in the known 2-thioacetonylidene-2,3-dihydro-1,3,4-thiadiazole **4** (6) was activated to nucleophilic displacement by methylation (methyl iodide); treatment of the resulting salt with 3-ethylrhodanine, as in the preparation of **3***f*, resulted in the formation of **5** (eq. [2]; Ar = $C_6H_3Br_2$-2,4).

[2] 
4 **5**

Dyes (for pertinent review and references, see ref. 7) of type **5** should also be accessible from salts of type **1** (R = Me, Et). We first attempted to extend the chain from the 2-position of **1** (R = Me) by condensation with *N*,*N*′-diphenylformamidine and acetylation, to be followed by condensation with 3-ethylrhodanine (8). This was unsuccessful, only tars being obtained. Success was achieved by reversing the order of assembly. 3-Ethylrhodanine was condensed with ethyl *N*-phenylisoformamidate, this being preferable to the earlier procedure (8) using *N*,*N*′-diphenylformamidine, and the product was then acetylated. Condensation of this acetyl derivative with **1** (R = Me) gave **6***a* (R′ = H), while similar treatment of **1** (R = Et) gave **6***b* (R′ = Me) (eq. [3]).

[3] 
6*a* (R′ = H) **6***b* (R′ = Me)

Visible spectral data (λ_{max}) are reported in the experimental section for **3***f*, **5**, **6***a*, and **6***b*, from which we note that interpolation of a double bond in the system of **3***f* produces a bathochromic shift of some 90–100 nm, similar to that noted in other systems of this type.

We have also explored the preparation of some simple cationic dyes (7) based on these thiadiazolium salts. In the first of these, the perchlorate **1** (R = Me) was deprotonated to the methine base in the presence of the perchlorate **2***b*. In this reaction, the nucleophilic methine base displaces methylthiolate ion from **2***b*, and subsequent deprotonation then gives the dye **7** (eq. [4]). Compound **7** was also prepared by extension of our earlier nuclear synthesis (1), providing independent evidence of structure. The benzothiohydrazide **8** (2 mol) was condensed with malononitrile (1 mol) in acetic acid containing perchloric acid to give **7**; the overall reaction course is shown in eq. [5]. The related dye **9** containing an interpolated double bond was prepared directly from **1** (R = Me) and triethyl orthoformate (8) (eq. [6]). Finally, **10** was prepared by condensing **1** with *p*-dimethylaminobenzaldehyde in acetic anhydride as solvent (9) (eq. [7]).

10

A wide variety of 1,3,4-thiadiazole derivatives is thus readily available from cations such as **1** and **2** and similar approaches are likely to find continued use with related systems.

Experimental

Visible spectra were recorded on a Hitachi Perkin Elmer (Coleman 124 model) double beam grating spectrophotometer; absorption maxima are quoted in nm (log ε in parentheses). The ir spectra were recorded for KBr discs on a Perkin Elmer model 237B instrument. The ^{1}H nmr spectra were recorded on a Bruker WP 60 spectrometer (tetramethylsilane as internal reference). Mass spectra were determined with an AEI MS-30 double beam spectrometer; *m*/*z* values are

For personal use only.

reported for the lowest isotopic species unless noted otherwise (relative intensities in parentheses). Melting point data are uncorrected.

3-(2,4-Dibromophenyl)-2-methylthio-5-phenyl-1,3,4-thiadiazolium methosulfate **2**a *and perchlorate* **2**b*; hydrolysis and thiohydrolysis thereof*

A solution of 3-(2,4-dibromophenyl)-5-phenyl-1,3,4-thiadiazole-2-thione (2) (20.0 g, 0.047 mol) and dimethyl sulfate (13.6 g, 0.108 mol) in dry benzene (50 mL) was boiled under reflux for 12 h, cooled, and refrigerated for 24 h. The methosulfate **2***a* (24.8 g, 96%) separated as colourless prisms, mp 200–205°C, raised to mp 208–210°C by crystallization from acetic acid – benzene. Though not analytically pure, this was sufficiently pure for further preparative work. *Anal.* calcd. for $C_{16}H_{14}Br_2N_2O_4S_3$: C 34.67, H 2.55, N 5.05; found: C 33.88, H 2.35, N 4.86.

A solution of sodium perchlorate (75.0 g) in water (150 mL) was added to a stirred solution of **2***a* (24.0 g) in acetic acid (500 mL). After 10 min, water (500 mL) was added and the precipitated solid (20.3 g, 86%) was collected and dried. Crystallization from acetic acid gave the perchlorate **2***b* as colourless prisms, mp 210–212°C. *Anal.* calcd. for $C_{15}H_{11}Br_2ClN_2O_4S_2$: C 33.20, H 2.04, N 5.16; found: C 33.24, H 2.09, N 5.26.

(*i*) A suspension of **2***a* (500 mg) in water (25 mL) was stirred overnight. The strong stench of methyl mercaptan was noticed. The solid was collected, washed with water, and crystallized from ethanol. This gave 3-(2,4-dibromophenyl)-5-phenyl-1,3,4-thiadiazol-2-one (200 mg, 53%), mp 150–152°C (lit. (2) mp 148–150°C), identical (mixture mp; tlc) with an authentic sample (3).

(*ii*) A suspension of **2***a* (470 mg) in a solution of sodium hydrosulfide (3.0 g) in water (25 mL) was stirred for 6 h. The solid was collected, washed with water, and crystallized from ethanol. This gave 3-(2,4-dibromophenyl)-5-phenyl-1,3,4-thiadiazole-2-thione (290 mg, 80%), mp and mixture mp 128–129°C (lit. (2) mp 129°C).

Reaction of 3-(2,4-dibromophenyl)-2-methylthio-5-phenyl-1,3,4-thiadiazolium methosulfate **2**a *with carbon acids: General procedure*

A mixture of **2***a* (5 mmol), the carbon acid (5.5 mmol), and triethylamine (8 mmol) in dry acetonitrile (18 mL) was refluxed under nitrogen for 30 min. In cases (*a*)–(*c*), the reaction mixture was concentrated to ca. half volume and then chilled. In the remaining two cases, the reaction mixture was simply cooled. In all cases, the solid products were collected, washed with acetonitrile, and purified as noted below.

(a) From diethyl malonate

Compound **3***a* (48%) crystallized from ethanol as cream prisms, mp 175–177°C; ir: 1725 and 1650 (C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.20 (t, 6H, $-CH_2CH_3$), 3.93 (m, sharpening to q at 50°C, 4H, $-CH_2CH_3$), and 7.2–8.0 (m, 8H, arom.) ppm; mass spectrum *m/z*: 552 (M^+, 18), 507 ($M^+ - OC_2H_5$, 7), 480 ($M^+ - CO_2C_2H_4$, 8), 473 ($M^+ - Br$, 22), 435 ($480 - OC_2H_5$, 5), 408 ($480 - CO_2C_2H_4$, 9), and 103 (C_6H_5CN, 100). *Anal.* calcd. for $C_{21}H_{18}Br_2N_2O_4S$: C 45.51, H 3.27, N 5.05; found: C 45.58, H 3.24, N 5.08.

(b) From ethyl acetoacetate

The crude product consisted of two components (tlc), which were separated chromatographically (silica; benzene as eluant).

First eluted, compound **3***c* (22%) crystallized from ethanol as fluffy cream needles, mp 147–148°C; ir: 1655 (C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.25 (t, 3H, $-CH_2CH_3$), 4.20 (q, 2H, $-CH_2CH_3$), 4.83 (s, 1H, HC=C), and 7.2–8.0 (m, 8H, arom.) ppm; mass spectrum *m/z*: 480 (M^+, 57; base peak at *m/z* 482), 435 ($M^+ - OC_2H_5$, 9), 408 ($M^+ - CO_2C_2H_4$, 23), 401 ($M^+ - Br$, 71), 373 ($401 - C_2H_4$, 11), 356 ($401 - OC_2H_5$, 39), and 322 ($401 - Br$, 24). *Anal.* calcd. for $C_{18}H_{14}Br_2N_2O_2S$: C 44.84, H 2.93, N 5.81; found: C 44.77, H 2.96, N 5.70.

Second eluted, compound **3***b* (30%) crystallized as cream prisms, mp 180–183°C; ir: 1710 and 1605 (C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.26 (t, 3H, $-CH_2CH_3$), 2.46 (s, 3H, CH_3CO), 3.67 (m, 2H, $-CH_2CH_3$), and 7.26–8.03 (m, 8H, arom.) ppm; mass spectrum *m/z*: 522 (M^+, 18), 507 ($M^+ - CH_3$, 5), 477 ($M^+ - OC_2H_5$, 7), 443 ($M^+ - Br$, 46), 435 ($477 - CH_2CO$, 16), 415 ($443 - C_2H_4$, 10), 401 ($443 - CH_2CO$, 96; base peak at *m/z* 403), and 356 ($401 - OC_2H_5$, 68). *Anal.* calcd. for $C_{20}H_{16}Br_2N_2O_3S$: C 45.82, H 3.08, N 5.34; found: C 46.09, H 3.13, N 5.22.

(c) From acetylacetone

Compound **3***d* (47%) crystallized from acetonitrile as tan prisms, mp 153–156°C, raised by recrystallization to mp 155–157°C; mixture mp 155–157°C (lit. (4) mp 154–155°C).

(d) From cyclopentan-1,3-dione

Compound **3***e* was obtained as a cream solid (82%), mp 209–211°C (mp 207–208°C after crystallization from ethanol); ir: 1690 and 1620 (C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.53 (s, 4H, $-CH_2-$), and 7.23–7.98 (m, 8H, arom.) ppm; mass spectrum *m/z*: 411 ($M^+ - Br$, 98; base peak at *m/z* 413) (no molecular ion observed). *Anal.* calcd. for $C_{19}H_{12}Br_2N_2O_2S$: C 46.37, H 2.46, N 5.69; found: C 45.89, H 2.22, N 5.99.

(e) From 3-ethylrhodanine

Compound **3***f* (76%) crystallized from acetone–benzene as bright yellow prisms, mp 240–242°C; vis (EtOH): 424 nm (4.70); ir: 1650 (C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.26 (t, 3H, $-CH_2CH_3$), 4.14 (q, 2H, $-CH_2CH_3$), and 7.2–8.0 (m, 8H, arom.) ppm; mass spectrum *m/z*: 553 (M^+, 40), and 359 ($C_{15}H_8BrN_2S_2$, 91; base peak at *m/z* 361). *Anal.* calcd. for $C_{19}H_{13}Br_2N_3OS_3$: C 41.10, H 2.36, N 7.57; found: C 41.11, H 2.19, N 7.58.

Conversion of **4** *into* **5**

Compound **4** (ref. 6) (1.28 g, 2.34 mmol) was heated under reflux with methyl iodide (3.65 g, 25.7 mmol) in dry benzene (40 mL) for 1 h. The salt (1.6 g, 99%) separated as an orange solid, mp 185–190°C (dec.). This was used without further purification as partial decomposition occurred on attempted crystallization.

A mixture of the foregoing salt (1.0 g, 1.45 mmol), 3-ethylrhodanine (320 mg, 1.99 mmol), triethylamine (330 mg, 3.27 mmol), and dry ethanol (20 mL) was heated under reflux for 1 h. When cool, the precipitate was collected and washed with ethanol. Crystallization from methanol–pyridine gave **5** (810 mg, 93%) as red prisms, mp 247–249°C; vis (EtOH): 510 nm (4.65); ir: 1650 (C=O) cm^{-1}; mass spectrum *m/z*: 593 (M^+, 20) and 103 (C_6H_5CN, 100). *Anal.* calcd. for $C_{22}H_{17}Br_2N_3OS_3$: C 44.38, H 2.88, N 7.06; found: C 44.82, H 2.89, N 6.82.

5-Anilinomethylene-3-ethylrhodanine and its acetyl derivative

A mixture of 3-ethylrhodanine (4.0 g, 24.8 mmol), ethyl *N*-phenylisoformamidate (4.5 g, 32.4 mmol), and ethanol (5 mL) was heated under reflux for 25 min. When cool, the red solid (6.0 g, 95%), mp 181–184°C (lit. (8) mp 184–186°C), was collected, washed with methanol, and dried.

The red solid (6.0 g) was heated under reflux with a mixture of acetic anhydride (25 mL) and triethylamine (3.2 mL) for 10 min. When cool, the solid was collected and washed with methanol. Crystallization from methanol gave the acetyl derivative as yellow needles (4.9 g, 70%), mp 90–94°C, resolidifying, and then mp 123–125°C (lit. (8) mp 85–87°C and 128–130°C, respectively).

Condensation of the foregoing acetyl derivative with 2-alkylthiadiazolium perchlorates **1** *(Ar =* $C_6H_3Br_2$*-2,4)*

(*a*) A mixture of **1** (R = Me) (1) (1.0 g, 1.96 mmol), the foregoing acetyl derivative (780 mg, 2.64 mmol), triethylamine (400 mg, 3.95 mmol), and ethanol (20 mL) was heated under reflux for 30 min. When cool, the precipitate (940 mg, 82%; mp 240–244°C) was collected, washed with ethanol, and dried. Crystallization from methanol–pyridine gave **6***a* as red prisms, mp 242–244°C; vis (EtOH): 517 nm (4.79); ir: 1695 (C=O) cm^{-1}; mass spectrum *m/z*: 579 (M^+, 26) and 103 (C_6H_5CN, 100). *Anal.* calcd. for $C_{21}H_{15}Br_2N_3OS_3$: C 43.39, H 2.60, N 7.23; found: C 43.39, H 2.47, N 7.14.

(*b*) The perchlorate **1** (R = Et) (1) (1.0 g, 1.91 mmol), similarly treated (2 h reflux), gave **6***b* as red prisms (630 mg, 55%), mp 213–215°C; vis (EtOH): 519 nm (4.74); ir: 1690 (C=O) cm^{-1}; mass spectrum *m/z*: 593 (M^+, 22) and 103 (C_6H_5CN, 100). *Anal.* calcd. for

$C_{22}H_{17}Br_2N_3OS_3$: C 44.38, H 2.88, N 7.06; found: C 44.89, H 2.93, N 6.91.

Alternative syntheses of **7**

(a) From **1** *(R = Me; Ar = $C_6H_3Br_2$-2,4) and* **2**b *(Ar = $C_6H_3Br_2$-2,4)*

A suspension of perchlorate **1** (1.9 g, 3.72 mmol) and perchlorate **2***b* (2.0 g, 3.69 mmol) in ethanol (40 mL) and triethylamine (0.41 g, 4.03 mmol) was heated under reflux for 30 min. When cool, the precipitated solid was collected and washed with ethanol. Crystallization from methanol–pyridine gave the carbocyanine perchlorate **7** (2.63 g, 79%) as yellow prisms, mp >325°C; vis (EtOH): 427 nm (4.70); ir: 1515, 1490, 1470, 1450, 1280, 1100, and 770 cm^{-1}. *Anal.* calcd. for $C_{29}H_{17}Br_4ClN_4O_4S_2$: C 38.50, H 1.89, N 6.19; found: C 38.44, H 1.93, N 6.10.

(b) From N′*-(2,4-dibromophenyl)benzothiohydrazide and malononitrile*

A mixture of *N′*-(2,4-dibromophenyl)benzothiohydrazide **8** (10) (2.0 g, 5.18 mmol), malononitrile (170 mg, 2.58 mmol), acetic acid (4 mL), and 70% perchloric acid (2 mL) was heated under reflux for 5 min, and then allowed to cool. Water (40 mL) was added slowly, whereupon the colorless precipitate dissolved and a yellow gum (which solidified on trituration with water) separated. Crystallization from methanol–pyridine gave **7** (1.8 g, 77%) as yellow prisms, mp >325°C, with an ir spectrum identical to that of the foregoing sample.

Condensation of **1** *(R = Me; Ar = $C_6H_3Br_2$-2,4) with triethyl orthoformate*

A mixture of the perchlorate **1** (1.0 g, 1.96 mmol), triethyl orthoformate (0.89 g, 6.02 mmol), and pyridine (10 mL) was heated under reflux for 45 min. Crystallization of the precipitated solid from methanol–pyridine gave the tricarbocyanine perchlorate **9** (740 mg, 81%) as lustrous golden-green prisms, mp 290–295°C. These crystals retained pyridine, and an analytical sample, mp 298–303°C, was obtained by recrystallization from aqueous dimethyl sulfoxide; vis (EtOH): 560 nm (5.01); ir: 1560, 1475, 1360, 1300, 1200, 1180, 1090, and 880 cm^{-1}. *Anal.* calcd. for $C_{31}H_{19}Br_4ClN_4O_4S_2$: C 40.01, H 2.06, N 6.02, S 6.89; found: C 40.00, H 2.32, N 5.89, S 6.60.

Condensation of **1** *(R = Me; Ar = $C_6H_3Br_2$-2,4) with* p*-dimethylaminobenzaldehyde*

A mixture of the perchlorate **1** (500 mg, 0.98 mmol), *p*-dimethylaminobenzaldehyde (180 mg, 1.21 mmol), and acetic anhydride (5 mL) was heated under reflux for 20 min. The precipitated solid was collected and crystallized from methanol–pyridine to give the styryl dye **10** (510 mg, 81%) as green prisms, mp 263–265°C; vis (EtOH): 555 nm (4.91); ir: 1580, 1530, 1470, 1440, 1380, 1275, 1175, and 1100 cm^{-1}. *Anal.* calcd. for $C_{24}H_{20}Br_2ClN_3O_4S$: C 44.92, H 3.14, N 6.55; found: C 45.09, H 3.03, N 6.38.

Condensation reactions of 1,1-dimorpholinoethene and of 1,1-dipiperidinoethene with carbon acids

SHAM S. GANDHI AND MARTIN S. GIBSON[1]

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received March 13, 1987

SHAM S. GANDHI and MARTIN S. GIBSON. Can. J. Chem. **65**, 2717 (1987).

1,1-Dimorpholinoethene and 1,1-dipiperidinoethene condense with such compounds as malononitrile, ethyl cyanoacetate, cyanoacetamide, and diethyl malonate to give the corresponding β,β-disubstituted enamine, a molecule of morpholine or piperidine being eliminated in the process. Similar reactions with acetylacetone and ethyl acetoacetate proceed with loss of the acetyl group to give the β-substituted enamine. 1,1-Dipiperidinoethene and nitromethane give the β-nitroenamine. Secondary processes of either hydrolysis or further Michael addition and elimination are noted in condensations of 1,1-dimorpholinoethene or 1,1-dipiperidinoethene with cyanoacetamide under more basic conditions. 1,1-Dipiperidinoethene is arylated at the 2-position by 2,4-dinitrochlorobenzene.

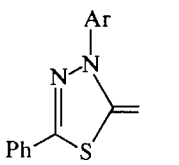
SHAM S. GANDHI et MARTIN S. GIBSON. Can. J. Chem. **65**, 2717 (1987).

Le dimorpholino-1,1 éthène et le dipipéridino-1,1 éthène se condensent avec des composés comme le malononitrile, le cyanoacétate d'éthyle, le cyanoacétamide et le malonate de diéthyle pour conduire à la formation des ènamines β,β-disubstituées correspondantes alors qu'une molécule de morpholine ou de pipéridine est éliminée au cours de la réaction. Des réactions semblables avec l'acétylacétone ou l'acétoacétate d'éthyle se produisent avec la perte d'un groupement acétyle et elles conduisent à la formation d'ènamines β-substituées. Lorsqu'on effectue des condensations entre le dimorpholino-1,1 éthène ou le dipipéridino-1,1 éthène, en utilisant des conditions expérimentales beaucoup plus basiques, on note aussi des réactions secondaires impliquant soit des hydrolyses ou des additions de Michael accompagnées d'éliminations. Par réaction avec le dinitro-2,4 chlorobenzène, le dipipéridino-1,1 éthène subit une réaction d'arylation en position 2.

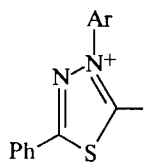
[Traduit par la revue]

Methine bases ("anhydro-bases") (**1**) have been implicated as intermediates in various reactions of 1,3,4-thiadiazolium salts (**2**) (1) and of analogous salts in many other aromatic heterocyclic systems (2). Often, however, evidence for the involvement of such methine bases has been indirect, stemming from trapping experiments using electrophilic reagents or, in the absence of such reagents, from isolation of methine base dimers or other artifacts (1). We have latterly been interested in the 1,1-enediamines **3** and **4** (3) as usable models for methine base studies, and we now report details of their reactions with a variety of carbon acids.

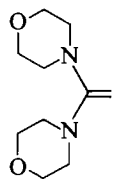
1,1-Dimorpholinoethene (**3**) and 1,1-dipiperidinoethene (**4**) are basic, electron-rich alkenes, giving amidinium salts when treated with acids, and are prone to hydrolysis, giving the corresponding amide and amine (**5** and morpholine, **6** and



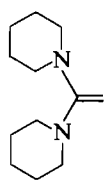
1



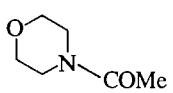
2



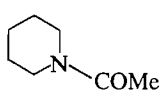
3



4



5



6

piperidine, respectively) (3); **4** has been shown to form 1:1 adducts with boron halides via the 2-carbon atom (4). As nucleophiles, **3** and **4** undergo a variety of substitution reactions at the 2-carbon atom when treated with electrophiles. Generally these reactions yield mono- or di-substitution products, but cases involving subsequent cyclization or hydrolysis have been noted. Examples include their reactions (*a*) with alkyl halides (*N*-alkylation is a possible side reaction in related cases) (5), (*b*) with ketene and with acyl chlorides (6), (*c*) with sulfonyl halides (7), (*d*) with phenyl isocyanate and with phenyl isothiocyanate (5), (*e*) with aromatic aldehydes (8), and (*f*) with α,β-unsaturated carbonyl compounds and with Mannich bases (9). Monosubstitution occurs in the reaction of **4** with 1-(2,2-dicyanovinyl)-4-methyl-1,2,3-triazole (10). The electron-rich double bonds of **3** and **4** can participate in cycloaddition reactions of the 1,3-dipolar and Diels–Alder types (11, 12) and of the 2 + 2 type (7, 13), some of which are succeeded by fragmentation reactions. A case of electron transfer from **3** to an electron-deficient substrate, ethyl benzoylazocarboxylate, has also been recorded (14). Not surprisingly, the reactivity of these 1,1-enediamines has at times led to complex reaction mixtures, with attendant difficulties in complete characterization of the reaction products and delineation of reaction pathways.

With basicity and nucleophilicity of these 1,1-enediamines manifested at the 2-carbon atom, it seemed likely that a general synthesis of enamines substituted with electron-attracting group(s) at the β-position could be developed by reacting **3** and **4** respectively with various carbon acids. Proton transfer between the two reactants would provide the corresponding amidinium ion and carbanion; combination of the ions, followed by elimination of morpholine or piperidine as appropriate, should then lead to the substituted enamine. These transformations are summarized in Scheme 1 for **3** → **7** and **4** → **8**.

We prepared **3** and **4** by known methods (3) and fractionated the compounds before use to limit the extent of contamination by their hydrolysis products, as the presence of these might complicate the isolation of the desired reaction products, **7** and **8**, respectively. We found that **3** and **4** each reacted readily with a variety of well-known carbon acids when refluxed in dry ether

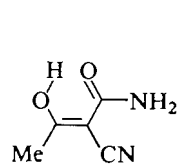
SCHEME 1

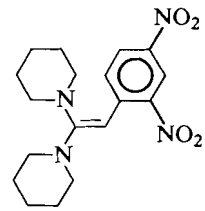
or tetrahydrofuran. Thus **3** reacted with malononitrile, with ethyl cyanoacetate, and with cyanoacetamide to give **7***a*, *b*, and *c*, respectively, as crystalline solids. In each case these products were accompanied by morpholine, as expected, and also by **5**, indicating that some hydrolysis of **3** had occurred as a side reaction. This hydrolysis proved to be an ubiquitous feature of these reactions. From **3** and diethyl malonate, **7***d* was isolated in poor yield as an oil, contaminated with **5**. The reactions of **3** with acetylacetone and with ethyl acetoacetate gave **7***e* and *f*, respectively, loss of an acetyl group accompanying the reaction (the crude materials from these reactions apparently contained traces of the expected products (^{1}H nmr) in each case). Our assumption here is that morpholine generated during the reaction (as well as by hydrolysis of **3**) was the deacetylating agent, being transformed in the process to **5**. A similar deacetylation process has been noted in condensations of a 2-methylthio-1,3,4-thiadiazolium salt with acetylacetone and with ethyl acetoacetate in the presence of triethylamine, the displaced methylthiolate ion being the presumed nucleophile in these cases (1).

Reaction also clearly occurred between **3** and ethyl nitroacetate, but the only characterizable products were the morpholinium salt of ethyl nitroacetate, recovered in low yield, and **5**. Our interpretation is that hydrolysis of the amidinium ion salt supervenes, and little or no condensation occurs. Interestingly, the less basic 1,1-diethoxyethene has been found to condense with ethyl nitroacetate to yield the corresponding β,β-disubstituted vinyl ether (15). The last carbon acids examined were the weakly acidic fluorene and xanthene. These were recovered from attempted reactions (at the bp of diethyl ether) with **3** and with **4**.

We also attempted the condensation of **3** with cyanoacetamide in isopropanol containing sodium isopropoxide, primarily to determine whether further reaction of the condensation product **7***c* would occur under these conditions. The normal isolation procedure was modified to include an acid treatment. From this experiment, we isolated a small yield of (*Z*)-2-cyano-3-hydroxycrotonamide (**9**), with properties corresponding to those reported for the compound produced by hydrolysis of 5-amino-4-cyano-3-methylisothiazole (16). This amide is formally a product of hydrolysis of **7***c*, i.e., of enamine to ketone (enol) function (cf. ref. 15). The relative solubility of **9** or hydrolysis to simpler products may account for low recovery in this experiment.



9



10

Turning to the chemistry of **4**, we noted that, although its reactions with simple alkyl halides were known (5), apparently no case of nucleophilic aromatic substitution had been examined. We found that **4** reacted with 2,4-dinitrochlorobenzene to give **10**, together with piperidinium chloride and **6**, the latter compounds presumably arising from proton transfer to **4** and subsequent hydrolysis. Compound **4** could be utilized somewhat more efficiently by incorporating triethylamine as base in this reaction, but purification of **10** was still rather tedious.

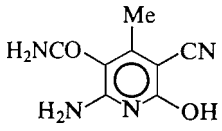
Mutatis mutandis, reactions of **4** with carbon acids were conducted as for **3** with carbon acids. Pure crystalline products, **8***b* and *e*, were obtained using ethyl cyanoacetate and acetylacetone (again one acetyl group was displaced). Further, condensation of **4** with nitromethane provided a simple alternative route to **8***g* (17). Reaction of **4** was also effected with malononitrile and with ethyl acetoacetate (acetyl loss observed) to give **8***a* and *f*, respectively, as oils.

With the exception of **7***a*, **7***d*, and **8***a*, all compounds **7** and **8** prepared in this series may exist as geometrical isomers. The indications are that we obtained only one isomer from each reaction, with the possible exception of **8***f*, which may contain a small amount of the second isomer. Thus, the ^{1}H nmr spectrum of **8***f* exhibits, for the major component, signals at δ 2.42 (CH_3 C=C) and 4.75 (HC=C) ppm, confirming (*E*) geometry (18), and similarly for **7***f* (19). The downfield shift for this methyl proton signal arises from deshielding of the methyl protons by the *cis*-carbonyl function and, applied to the cases of **7***e* and **8***e*, allows the assignment of (*E*) geometry to these compounds also (19); by extension, (*E*) geometry can similarly be assigned to **8***g* (17). The ^{1}H nmr spectra of **7***a* and **8***a* reveal signals (for CH_3 C=C) at δ 2.32 and 2.29 ppm respectively. For compounds **7***b*, **7***c*, and **8***b*, the corresponding signals appear at δ 2.47, 2.43, and 2.47 ppm, respectively, suggesting that this methyl group lies *cis* to a carbonyl rather than a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

nitrile group and again implying (*E*) geometry. The foregoing assignments would conform to the view that the thermodynamically more stable isomer (17, 18) is obtained from these reactions. We make a further comment about **8***f*; like the other compounds which we obtained as oils, this was not 100% pure and its ^{1}H nmr spectrum contained a low intensity peak at δ 2.07 ppm that may suggest the presence (<10%) of the (*Z*) isomer (18).

A variety of "push–pull" olefins, **7** and **8**, is thus available from these reactions of **3** and of **4** with carbon acids. The resulting β-substituted enamines are of interest to us as polyfunctional synthetic intermediates and in this context we have briefly examined the reaction of **4** with cyanoacetamide in ethanol containing sodium ethoxide. This reaction gave 2-amino-5-cyano-6-hydroxy-4-methylnicotinamide (**11**). We envisage this process as involving Michael addition of cyanoacetamide (anion) to the intermediate **8***c*, followed by loss of piperidine and ring closure by dehydration. The factors that favour production of a polyfunctional pyridine over hydrolysis, as in **7***c* → **9**, remain to be examined and we hope to develop a more general pyridine synthesis using this approach.



11

Our syntheses of **7** and **8** have a bearing on the production of pyrazole derivatives from a variety of 2-substituted 1,3,4-oxadiazolium salts (the correspondence is with our amidinium ion intermediates) and carbon acids in the presence of triethylamine (20). The latter reactions were interpreted as proceeding with ring opening of the heterocyclic ring to yield a labile β,β-disubstituted enehydrazide (corresponding to our **7**, **8**), which then underwent cyclization to the pyrazole; one such intermediate was isolated and shown to cyclize in this way. This interpretation is reinforced by our current study, although no such secondary cyclization is possible with our series of compounds.

Experimental

Instrumental techniques were as noted in the preceding publication (1*a*).

1,1-Dimorpholinoethene (3)

This was prepared by the literature method (3) and was characterized by reaction with *p*-methoxybenzaldehyde to give (*E*)-*p*-methoxycinnamomorpholide, mp 100–101°C (from ether – light petroleum (bp 60–80°C)) (lit. (8) mp 100–101°C). Compound **3** was freshly prepared and fractionated prior to use in the following reactions.

Reaction of 3 with carbon acids: General procedure

A mixture of **3** (0.01 mol) and the carbon acid (0.01 mol) in dry ether or tetrahydrofuran (15–40 mL) was refluxed under nitrogen. Reactions were monitored chromatographically for consumption of **3** and in most cases were complete within 8 h. The solvent was then removed by evaporation *in vacuo* and the residue was submitted to analysis by glc or glc/ms. The desired product was normally accompanied by morpholine and **5**.

The crude reaction product was triturated with light petroleum (bp 40–60°C). In cases where this procedure induced crystallization, the solid material was collected and purified by recrystallization from aqueous ethanol or occasionally from water. In the remaining cases, the light petroleum layer was decanted and the residual oil was chromatographed and (or) distilled *in vacuo*; working on this scale, we were not able to obtain pure compounds in this way and identification is based on spectroscopic correlations, where possible with published data (18, 19).

The following compounds were obtained as solids (from the carbon acids noted in parentheses):

(*a*) 2-Cyano-3-(1-morpholino)crotononitrile (**7***a*) (74%), mp 105–106°C (prepared from malononitrile); ir: 2200 and 2180 (C≡N) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.32 (s, 3H, CH_3) and 3.79 (s, 8H, CH_2 of morpholino ring); mass spectrum, *m/z*: 117 (M^+). *Anal.* calcd. for $C_9H_{11}N_3O$: C 61.00, H 6.26, N 23.71; found: C 60.99, H 6.26, N 23.54.

(*b*) Ethyl (*E*)-2-cyano-3-(1-morpholino)crotonate (**7***b*) (50%), mp 95–96°C (prepared from ethyl cyanoacetate); ir: 2200 (C≡N) and 1675 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.23 (t, 3H, CH_2CH_3), 2.47 (br s, 3H, CH_3), 3.76 (br s, 8H), and 4.18 (q, 2H, CH_2CH_3); mass spectrum, *m/z*: 224 (M^+, 21), 152 (80), and 151 (100). *Anal.* calcd. for $C_{11}H_{16}N_2O_3$: C 58.91, H 7.19, N 12.49; found: C 58.80, H 7.14, N 12.50.

(*c*) (*E*)-2-Cyano-3-(1-morpholino)crotonamide (**7***c*) (36%), mp 160–162°C (prepared from cyanoacetamide); ir: 3365 and 3175 (N—H), 2180 (C≡N) and 1640 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.43 (br s, 3H, CH_3), 3.45–4.0 (m, 8H), and 5.75 (br s, 2H, NH_2); mass spectrum, *m/z*: 195 (M^+, 29), 178 (100), and 151 (43). *Anal.* calcd. for $C_9H_{13}N_3O_2$: C 55.37, H 6.71, N 21.52; found: C 55.54, H 6.67, N 21.15.

The following compounds were obtained as oils; yields (in parentheses) are for distilled compounds containing small amounts of retained acetomorpholide (**5**) and other minor products:

(*d*) Ethyl 2-ethoxycarbonyl-3-(1-morpholino)crotonate (**7***d*) (10%), bp 180–185°C/20 Torr (1 Torr = 133.3 Pa) (prepared from diethyl malonate); ir: 1755 sh, 1740, and 1655 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.28 (t, 6H, CH_2CH_3), 2.27 (s, 3H, CH_3), 3.36–3.75 (m, 8H), and 4.20 (q, 4H, CH_2CH_3); mass spectrum, *m/z*: 271 (M^+, 11), 198 (43), 152 (64), 150 (57), and 127 (100).

(*e*) (*E*)-4-(1-Morpholino)-3-pentenone (**7***e*) (33%), bp 135–136°C/20 Torr (lit. (19) mp 46–47°C) (prepared from acetylacetone); ir: 1640 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.09 (s, 3H, CH_3CO), 2.47 (s, 3H, CH_3), 3.30–3.81 (m, 8H), and 5.25 (s, 1H, HC=C); mass spectrum, *m/z*: 169 (M^+, 47), 154 (50), 152 (100), and 126 (75).

(*f*) Ethyl (*E*)-3-(1-morpholino)crotonate (**7***f*) (31%), bp 154–156°C/20 Torr (lit. (19) bp 124–128°C/1 Torr (prepared from ethyl acetoacetate); ir: 1690 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.22 (t, 3H, CH_2CH_3), 2.44 (s, 3H, CH_3), 3.57—3.75 (m, 8H), 4.06 (q, 2H, CH_2CH_3), and 4.75 (s, 1H, HC=C); mass spectrum, *m/z*: 199 (M^+, 33) and 126 (100).

Reaction of 3 with ethyl nitroacetate

Compound **3** and ethyl nitroacetate reacted exothermically in dry ether under the conditions of the foregoing general procedure (5 h reflux). Crystallization from light petroleum (bp 80–100°C) of the yellowish gummy solid resulting from trituration gave yellowish needles (420 mg, 20%) of the morpholine salt of ethyl nitroacetate, mp 125–127°C, identical with a sample prepared by mixing equivalent quantities of morpholine and ethyl nitroacetate in dry ether (colourless needles, mp 123–125°C); ir: 1675 (C=O), 1460 and 1280 (NO_2) cm^{-1}.

Reaction of 3 with cyanoacetamide in 2-propanol containing sodium 2-propoxide

Cyanoacetamide (769 mg, 9.15 mmol), dissolved in dry 2-propanol (15 mL), was added to a warm stirred solution of sodium 2-propoxide (from 421 mg sodium, 18.3 mmol) in 2-propanol (70 mL). After 15 min, a solution of **3** (1.814 g, 9.24 mmol) in 2-propanol (25 mL) was added and the stirred mixture was refluxed for 4 h. The solvent was then removed by evaporation *in vacuo* and the residue was triturated with dry light petroleum (bp 60–80°C). The resulting hygroscopic yellow solid (350 mg) was dissolved in water (7 mL) and the solution was acidified to pH 3 using concentrated hydrochloric acid. On standing overnight, the solution deposited colourless plates of (*Z*)-2-cyano-3-hydroxycrotonamide (**9**) (30 mg, 2.6%), mp 174–176°C (lit. (16) mp 171–173°C). Identity was established by correlation of ir and mass

spectra with published data and from the ^{1}H nmr spectrum; δ (DMSO-d_6): 2.20 (s, 3H, CH_3) and 3.43–3.56 (br, ca. 3H, exchangeable with D_2O) (lit. (16) δ (perdeuterioacetic acid): 1.85 (s, CH_3)).

*1,1-Dipiperidinoethene (**4**)*

This was prepared by the literature method (3) and was characterized both by reaction with methyl iodide to give *N,N'*-bispentamethylenepropionamidinium iodide, mp 158–160°C (from acetone – ethyl acetate) (lit. (5) mp 158–159°C), and by reaction with ethyl iodide to give *N,N'*-bispentamethylenebutyramidinium iodide, mp 213–215°C (from acetone – ethyl acetate) (lit. (5) mp 212–212.5°C). (**Note**: exclusion of moisture is necessary to prevent contamination of these derivatives by products from hydrolysis reactions.) Compound **4** was freshly prepared and fractionated prior to use in the following reactions.

*2,4-Dinitrophenylation of **4***

A freshly prepared solution of **4** (2.26 g, 11.8 mmol) in dry dichloromethane (30 mL) was added under nitrogen to a stirred, freshly prepared solution of 1-chloro-2,4-dinitrobenzene (2.35 g, 11.6 mmol) and triethylamine (1.35 g, 13.3 mmol) in dichloromethane (40 mL). The solution immediately became dark red-brown in colour. After 24 h, the solvent was evaporated *in vacuo* and the residue was then stirred with 5% hydrochloric acid for 3 h. Extraction with dichloromethane, followed by washing, drying, and evaporation of the organic extract gave a dark brown gum. Several crystallizations from benzene gave an analytically pure sample (190 mg, 4.6%) of 1-(2,4-dinitrophenyl)-2,2-di(1-piperidino)ethene (**10**) as dark brown crystals, mp 192–194°C; ir: 1515 and 1320 (NO_2) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.66 (br s, 12H), 3.21 (br s, 8H), 5.52 (s, 1H, HC=C), 6.65 (d, 1H, arom H-6; J = 9.5 Hz), 7.99 (dd, 1H, arom H-5; J = 9.5 and 2.0 Hz), and 8.84 (d, 1H, arom H-3; J = 2.0 Hz); mass spectrum, *m/z*: 360 (M^+). *Anal.* calcd. for $C_{18}H_{24}N_4O_4$: C 59.99, H 6.71, N 15.55; found: C 60.20, H 6.76, N 15.56.

*Reaction of **4** with carbon acids: General procedure*

The procedure followed was the same as that described for corresponding reactions of **3**; the desired product was normally accompanied by piperidine and **6**.

The following compounds were obtained as solids (from the carbon acids noted in parentheses):

(*a*) Ethyl (*E*)-2-cyano-3-(1-piperidino)crotonate (**8***b*) (22%), mp 75–76°C (prepared from ethyl cyanoacetate); ir: 2195 (C≡N) and 1680 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.30 (t, 3H, CH_2CH_3), 1.72 (br s, 6H, 3 × CH_2 of piperidino ring), 2.47 (s, 3H, CH_3), 3.55 (br s, 4H, 2 × CH_2 of piperidino ring), and 4.17 (q, 2H, CH_2CH_3); mass spectrum, *m/z*: 222 (M^+, 10) and 149 (100). *Anal.* calcd. for $C_{12}H_{18}N_2O_2$: C 64.84, H 8.16, N 12.60; found: C 64.62, H 8.10, N 12.66.

(*b*) (*E*)-4-(1-Piperidino)-3-pentenone (**8***e*) (28%), mp 45–47°C (lit. (19) mp 47–48°C) (prepared from acetylacetone); ir: 1650 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.62 (m, 6H), 2.07 (s, 3H, CH_3CO), 2.51 (s, 3H, CH_3), 3.36 (m, 4H), and 5.22 (s, 1H, HC=C); mass spectrum, *m/z*: 167 (M^+, 36), 152 (60), 150 (100), and 124 (89). *Anal.* calcd. for $C_{10}H_{17}NO$: C 71.81, H 10.24, N 8.37; found: C 71.45, H 10.17, N 8.21.

(*c*) (*E*)-1-Nitro-2-(1-piperidino)propene (**8***g*) (43%), mp 86–87°C (lit. (17) mp 84°C) (prepared from nitromethane); ^{1}H nmr ($CDCl_3$) δ: 1.69 (m, 6H), 2.60 (s, 3H, CH_3), 3.43 (m, 4H), and 6.91 (s, 1H, HC=C); mass spectrum, *m/z*: 170 (M^+, 37) and 124 (100). *Anal.* calcd. for $C_8H_{14}N_2O_2$: C 56.45, H 8.29, N 16.46; found: C 56.09, H 8.40, N 16.03.

The following compounds were obtained as oils; yields (in parentheses) are for chromatographed or distilled compounds containing small amounts of acetopiperidide (**6**) and other minor products:

(*d*) 2-Cyano-3-(1-piperidino)crotononitrile (**8***a*) (36%) (prepared from malononitrile); ir: 2210 and 2190 (C≡N) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.75 (m, 6H), 2.29 (s, 3H, CH_3), and 3.72 (m, 4H); mass spectrum, *m/z*: 175 (M^+).

(*e*) Ethyl (*E*)-3-(1-piperidino)crotonate (**8***f*) (25%), bp 112–114°C/1 Torr (lit. (19) bp 122°C/0.6 Torr) (prepared from ethyl acetoacetate); ir: 1690 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.23 (t, 3H, CH_2CH_3), 1.59 (m, 6H), 2.42 (s, 3H, CH_3), 3.27 (m, 4H), 4.06 (q, 2H, CH_2CH_3), and 4.75 (s, 1H, HC=C); mass spectrum, *m/z*: 197 (M^+, 17) and 124 (100).

*Reaction of **4** with cyanoacetamide in ethanol containing sodium ethoxide*

Cyanoacetamide (635 mg, 7.55 mmol) was dissolved in a warm stirred solution of sodium ethoxide (from 450 mg sodium, 19.6 mmol) in absolute ethanol (75 mL). A solution of **4** (1.468 g, 7.63 mol) in ethanol (15 mL) was then added and the mixture was refluxed for 3 h. When cool, the mixture was filtered to remove a small amount of yellow solid and the filtrate was then evaporated *in vacuo*. The residue was dissolved in water (10 mL) and the solution was acidified to pH 3 using concentrated hydrochloric acid. On standing overnight the solution deposited a light brown solid (350 mg, 48% based on **4**). Crystallization from aqueous ethanol gave 2-amino-5-cyano-6-hydroxy-4-methylnicotinamide (**11**), mp 309–310°C (dec.); ir: 2220 (C≡N), 1660 and 1640 (C=O) cm^{-1}; ^{1}H nmr (D_2O/DMSO-d_6) δ: 2.32 (s, CH_3); mass spectrum, *m/z*: 192 (M^+, 20), 175 (55), 174 (50), 149 (45), 147 (20), 131 (15), 119 (20), 106 (40), 105 (50), 93 (23), and 69 (100). *Anal.* calcd. for $C_8H_8N_4O_2$: C 50.00, H 4.20, N 29.15; found: C 49.64, H 4.17, N 28.53. *Mol. Wt.* calcd. for $C_8H_8N_4O_2$: 192.0647; found (ms): 192.0586.

Enzymes in organic synthesis. 40.[1] Evaluation of the enantioselectivity of the pig liver esterase catalyzed hydrolyses of racemic piperidine carboxylic acid esters

ERIC J. TOONE AND J. BRYAN JONES
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received April 29, 1987

ERIC J. TOONE and J. BRYAN JONES. Can. J. Chem. **65**, 2722 (1987).

Pig liver esterase (PLE) catalyzed hydrolysis of racemic piperidine esters proceeds enantioselectively to give product acids and recovered esters in 0–47% enantiomeric excess.

ERIC J. TOONE et J. BRYAN JONES. Can. J. Chem. **65**, 2722 (1987).

L'hydrolyse, catalysée par l'EFC (estérase du foie de cochon), d'esters racémiques de la pipéridine se produit d'une façon énantiosélective pour conduire à des produits acides et à des esters récupérés dont l'excès énantiomérique varie de 0 à 47%.

Introduction

Enzymes are now established as important tools in the field of asymmetric synthesis (2), with the resolution of racemates being one area in particular where the utility of enzymes has been traditionally recognized (3). While the resolution approach to the preparation of pure stereoisomers suffers from the disadvantage that only half of the starting material is transformed into the desired product, it is often possible to recycle the unwanted enantiomer by epimerization to the racemic form. Furthermore, in many cases a racemic starting material can be very cheap. Resolution can then offer the most cost efficient route to enantiomerically pure chiral synthons (4).

Esterases are a very attractive class of enzymes for use in resolution and other aspects of organic synthesis since they do not require expensive cofactors. One of the most promising of the esterases is pig liver esterase (PLE, E.C. 3.1.1.1). PLE is a commercially available enzyme that catalyses the hydrolysis of a broad range of ester substrates. While several reports of the use of PLE in the asymmetric hydrolysis of symmetrical diesters have appeared (5), there have been relatively few examples of resolution of racemates using PLE (6).

The enzymatic production of enantiomerically pure amino acids for use as chirons in organic synthesis is of considerable interest (7). Enzyme-catalyzed methods for the production of pure enantiomers of natural amino acids are well documented (8), but so far the use of enzymes for the resolution of racemates of unnatural amino acids of chiron value has not been widely explored. We have now begun to investigate the utility of enzymes in the resolution of unnatural amino acids. In this paper, we report on the potential of PLE for the resolution of some unnatural amino acid derivatives of the N-protected monosubstituted piperidine types represented by structures (+/−) **1–6**.

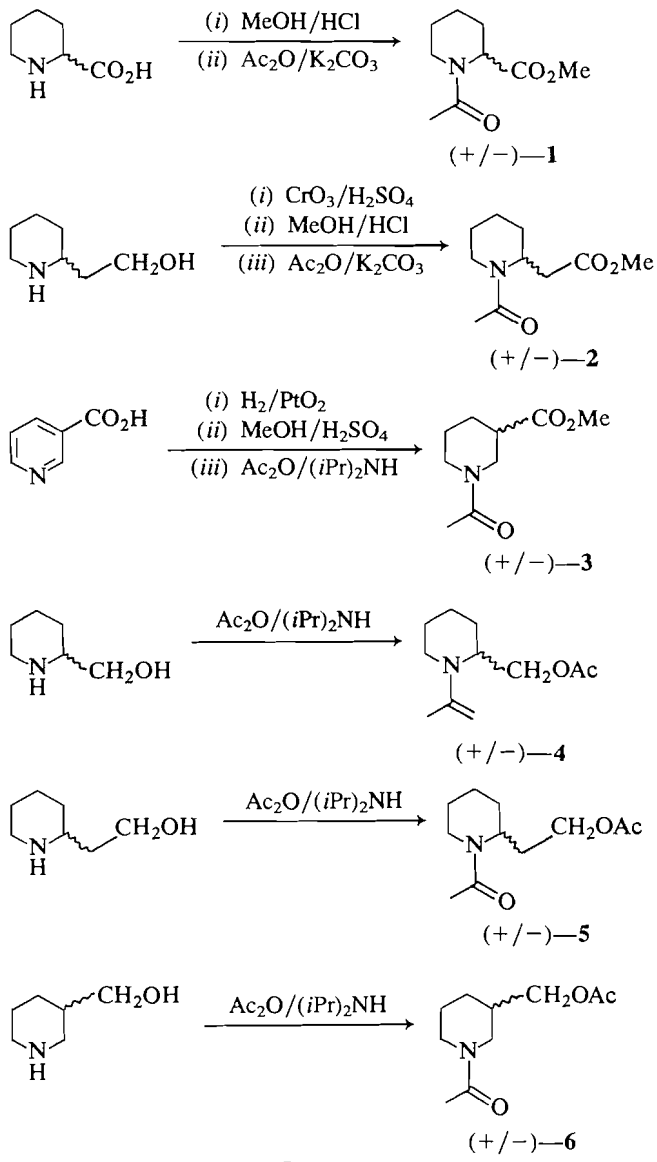
Results

The N-acylated piperidine substrates **1–6** were prepared as outlined in Scheme 1.

Each of compounds **1–6** was a substrate for PLE. Despite the fact that (+/−)-**1** and (+/−)-**2** were hydrolyzed much more slowly than the reference substrate ethyl butyrate (Table 1), all were sufficiently active to be considered good candidates for preparative scale resolution.

The resolutions were evaluated for each of compounds **1–6** on a 1–1.5 g scale at pH 7. The results are summarized in Scheme 2.

[1]For Part 39 see ref. 1.



SCHEME 1

For the product acids (−)-**7**, (−)-**8**, and (+/−)-**9**, the enantiomeric excess (ee) values were determined by 200-MHz ^{1}H nmr examination of the diastereomeric salts formed between product acids and (−)-*S*-phenethylamine (9). For substrates (+/−) **4–6** the product alcohols **10–12** were converted by Jones oxidation to the corresponding carboxylic acids, **7–9**,

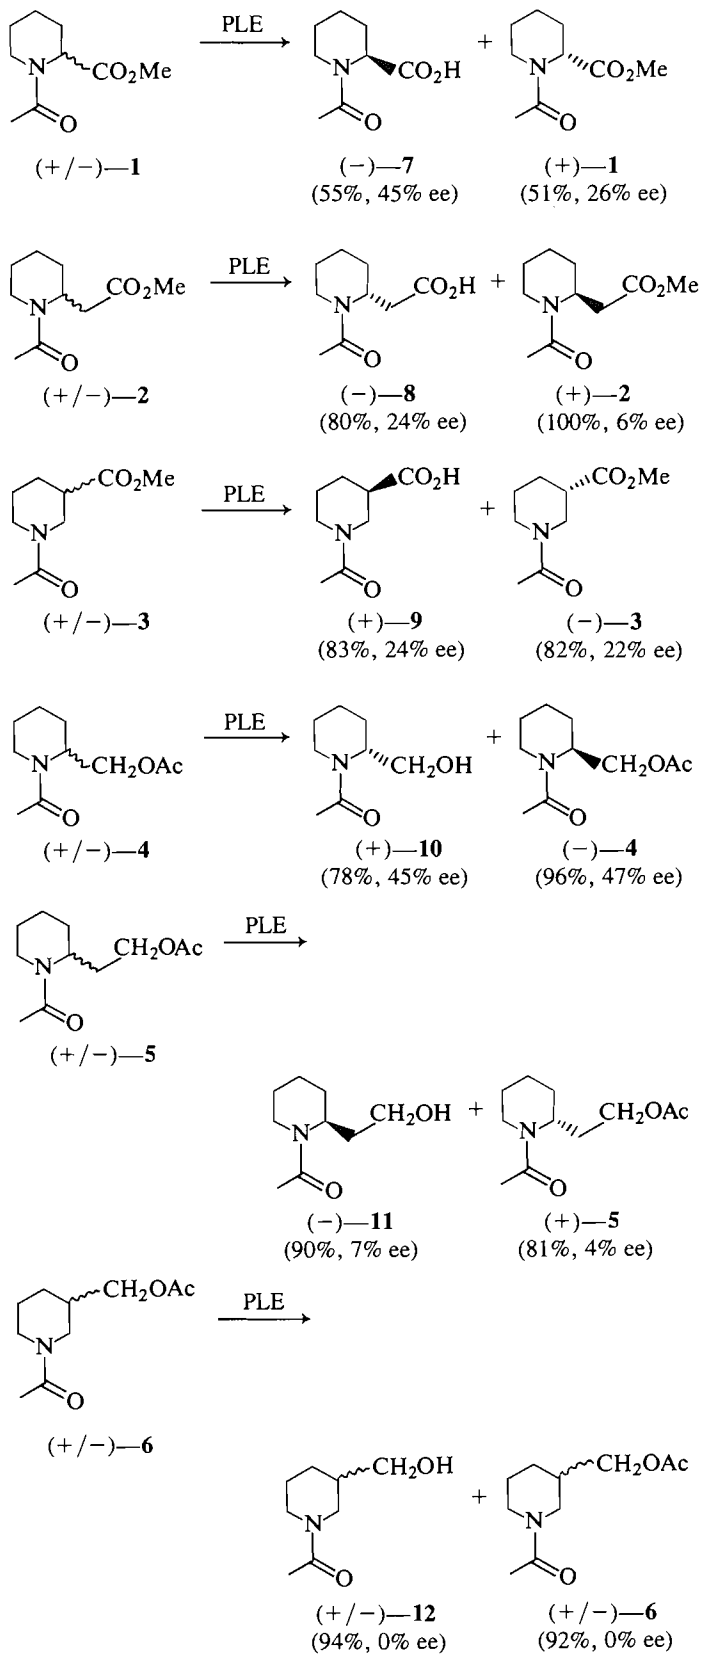

SCHEME 2

and their (−)-*S*-phenethyl amine salts again examined. The enantiomeric excesses of the unhydrolyzed acetates (−)-**4** and (+)-**5** were determined similarly, following their conversion to their alcohols (−)-**10** and (+)-**11** by base hydrolysis, and then oxidation to the corresponding acids **7** and **8**. The enantiomeric excesses of unhydrolyzed esters **1**–**3** were determined by esterification of the optically active acids **7**–**9** of known absolute configuration with diazomethane, and comparison of optical rotations.

TABLE 1. Relative rates of PLE hydrolysis[a]

Substrate	Relative rate
Ethyl butyrate	100
(+/−)-**1**	<0.01
(+/−)-**2**	<0.01
(+/−)-**3**	14
(+/−)-**4**	1
(+/−)-**5**	3
(+/−)-**6**	1

[a]Determined at pH 7.0, 25°C, in distilled water.

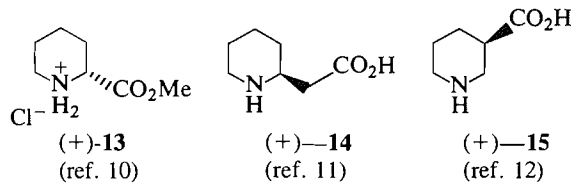

FIG. 1

The absolute configurations were all assigned by optical rotation correlations with known compounds as follows: (−)-**7**, (+)-**1**, (+)-**10**, and (−)-**4** with (+)-**13** (10); (−)-**8**, (+)-**2**, (−)-**11**, and (+)-**5** with (+)-**14** (11); and (+)-**9** and (−)-**3** with (+)-**15** (12).

Discussion

The preparations of substrates were routine, as were their preparative-scale PLE-catalyzed hydrolyses. Hydrolyses were stopped after 50% conversion. The hydrolyses were carried out at pH 7.0 to avoid the possibility of competing chemical hydrolysis or epimerization under the higher pH conditions that have been used in other applications (13). This would have been a significant problem for substrates (+/−)-**1** and (+/−)-**2**, due to the long reaction time. In fact, even at pH 7.0, it appears that some epimerization of optically active ester took place during the relatively long reaction times, as indicated by the fact that for (+/−)-**1** and (+/−)-**2** the enantiomeric excesses of the recovered esters are substantially lower than those of the product acids. In these cases, epimerization of the product acids would be virtually nonexistent since they are present in solution as their carboxylate salts.

The piperidine esters **1**–**6** represent a new class of PLE substrates whose structures are of clear synthetic value, for example as chirons for alkaloids such as coniine and sedrine. While the enantiomeric excess levels observed in the initial study are below the levels required for asymmetric synthesis, they demonstrate that PLE does possess significant enantiomeric stereoselectivity towards each of **1**–**6**. It is possible to increase the enantiomeric excess values of PLE-catalyzed reactions to acceptable asymmetric synthetic levels by manipulation of reaction conditions, particularly by varying organic solvent composition and temperature (14), and we are now exploring this aspect. In addition, in resolutions of this nature, it is always possible to reesterify the product acids and subject optically enriched material to a second enzymic hydrolysis (15). This approach will also be followed if the reaction conditions' improvement of ee is not satisfactory.

Experimental

All melting points were taken on a Electrothermal capillary melting point apparatus, and are uncorrected. The ir spectra were recorded as films for liquids and KBr discs for solids on a Nicolet 5DX FTIR spectrophotometer. All routine ^{1}H nmr spectra were recorded in $CDCl_3$ on a Varian T60 instrument. High field ^{1}H nmr spectra were recorded on a Varian XL200 instrument. Optical rotations were measured in a Perkin–Elmer 141 polarimeter in a thermostated cell. Elemental analyses were carried out by Galbraith Laboratories. Analytical glc work was carried out on a Varian Series 2700 gas chromatograph. The pH stat used was a Radiometer REA 270 pH stat, equipped with a TTT80 titrator and an ABU 80 autoburette. Pig liver esterase (EC 3.1.1.1) was obtained from Sigma Chemical Company.

Synthesis of substrates

N-*Acetyl-2-carbomethoxypiperidine (**1**)*

2-Piperidinecarboxylic acid (Aldrich, 1.5 g, 11.5 mmol) in HCl-saturated methanol (100 mL) was stirred at 21°C for 24 h. The methanol was removed by rotary evaporation and the yellow solid recrystallized once from methanol – ethyl acetate (1:1) to yield (+/−)-2-carbomethoxypiperidine hydrochloride (1.62 g, 78% yield), mp 212°C (lit. (16) mp 213–214°C); ir ν: 1748 cm^{-1}; ^{1}H nmr δ: 1.9–2.1 (m, 6H), 3.1–3.3 (m, 3H), 3.95 (s, 3H), 5.1 (br s, 1H) ppm. To this ester (0.75 g, 4.2 mmol) in ethyl acetate (15 mL) was added K_2CO_3 (2.1 g, 21 mmol) in water (5 mL), and acetic anhydride (1.1 g, 10 mmol), and the mixture was stirred for 24 h at 21°C. The layers were separated and the aqueous phase extracted with ethyl acetate (2 × 25 mL). The combined organic phases were washed with 1 M hydrochloric acid (15 mL), 5% aqueous Na_2CO_3 (15 mL), and saturated aqueous NaCl (15 mL), dried ($MgSO_4$), and concentrated *in vacuo* on a rotary evaporator. The residual oil was Kugelrohr distilled (bp 80°C/0.1 Torr; 1 Torr = 133.3 Pa) to yield *N*-acetyl-2-carbomethoxypiperidine **1** (0.44 g, 56% yield); ir ν: 1748, 1649 cm^{-1}; ^{1}H nmr δ: 1.5–1.9 (m, 6H), 2.2 (s, 3H), 3.2–3.5 (m, 2H), 3.8 (s, 3H), 5.4 (br, 1H) ppm. *Anal.* calcd. for $C_9H_{15}NO_3$: C 58.37, H 8.11, N 7.46; found: C 58.16, H 8.18, N 7.46%.

N-*Acetyl-2-carbomethoxymethylpiperidine (**2**)*

2-Carboxymethylpiperidine was prepared by the method of Marshall *et al.* (17), and esterified as above to give 2-carbomethoxymethylpiperidine hydrochloride, in 83% yield, mp 218–221°C (lit. (17) mp 218–220°C); ir ν: 1741 cm^{-1}; ^{1}H nmr δ: 1.7–2.1 (m, 6H), 2.9–3.1 (m, 5H), 3.7 (s, 3H) ppm. This ester (0.42 g, 2.2 mmol) was acetylated with acetic anhydride (0.45 g, 4.4 mmol) and K_2CO_3 (1.2 g, 8.8 mmol) as above to yield *N*-acetyl-2-carbomethoxymethylpiperidine **2** (0.3 g, 72% yield), bp 85°C/0.1 Torr; ir ν: 1737, 1644 cm^{-1}; ^{1}H nmr δ: 1.6–2.0 (m, 6H), 2.1 (s, 3H), 2.7–2.9 (m, 3H), 4.8–5.1 (m, 2H) ppm. *Anal.* calcd. for $C_{10}H_{17}NO_3$: C 60.28, H 8.60, N 7.03; found: C 60.31, H 8.66, N 6.99%.

N-*Acetyl-3-carboxymethylpiperidine (**3**)*

To nicotinic acid (10 g, 80 mmol) in water (100 mL) was added 6 M hydrochloric acid (13.5 mL, 6 M, 1 equiv.). PtO_2 (200 mg) was added and the mixture was stirred under hydrogen (50 psi; 1 psi = 6.9 kPa). After 24 h (3 equiv. H_2 uptake), the water was removed by rotary evaporation, and the residual solid recrystallized from absolute EtOH to give 3-carboxypiperidine hydrochloride (12.7 g, 95% yield), mp 239–240°C (dec.) (lit. (18) mp 240–242°C); ir ν: 1625 cm^{-1}; ^{1}H nmr δ: 1.8–2.1 (m, 6H), 3.2–3.4 (m, 5H), 9.2 (s, 1H) ppm. This ester (1.0 g, 6 mmol) was dissolved in dry MeOH (50 mL) containing 2 drops concentrated sulfuric acid and the mixture was stirred for 24 h at 20°C. The methanol was removed by rotary evaporation and the residual oil taken up in THF (50 mL) and cooled to 0°C. Acetic anhydride (6.2 g, 60 mmol), diisopropyl amine (4.0 g, 40 mmol), and catalytic dimethylaminopyridine (DMAP) were then added and the solution warmed to 20°C. After stirring for 24 h the solvent was removed and the desired product was obtained in pure form by Kugelrohr distillation (bp 85°C/0.25 Torr) (0.67 g, 58% yield); ir ν: 1733, 1648 cm^{-1}; ^{1}H nmr δ: 1.8–2.1 (m, 4H), 2.2 (s, 3H), 2.8–3.6 (m, 4H), 3.8 (s, 3H) ppm. *Anal.* calcd. for $C_9H_{15}NO_3$: C 58.37, H 8.11, N 7.46; found: C 58.37, H 8.08, N 7.50%.

N-*Acetyl-2-acetoxymethylpiperidine (**4**)*

2-Hydroxymethylpiperidine (1.5 g, 13 mmol) was dissolved in dry diethyl ether (50 mL). To this was added dropwise at 0°C acetic anhydride (16.2 g, 130 mmol), diisopropyl amine (3.95 g, 39 mmol), and catalytic DMAP, and the resulting solution was stirred at 20°C for 2 days. The solvent was removed by rotary evaporation, and the excess acetic anhydride and diisopropyl amine by Kugelrohr distillation (40°C/0.25 Torr). The residual oil was taken up in ethyl acetate (50 mL) and washed with 1 M hydrochloric acid (2 × 20 mL), followed by saturated aqueous $NaHCO_3$ (2 × 20 mL) and saturated aqueous NaCl (2 × 20 mL). The organic phase was dried ($MgSO_4$) and concentrated *in vacuo* on a rotary evaporator. The residual oil was purified by flash chromatography on silica (ether–methanol (5:1) elution) to give *N*-acetyl-2-acetoxymethylpiperidine (**4**, 1.05 g, 38% yield); ir ν: 1742, 1644 cm^{-1}; ^{1}H nmr δ: 1.7 (m, 6H), 2.15 (s, 3H), 2.2 (s, 3H), 2.45 (m, 2H), 4.1–4.4 (m, 3H) ppm. *Anal.* calcd. for $C_{10}H_{17}NO_3$: C 60.35, H 8.54, N 7.01; found: C 60.29, H 8.60, N 7.11%.

N-*Acetyl-2-acetoxyethylpiperidine (**5**)*

This was prepared, as was **4** above, from 2-hydroxyethylpiperidine (2 g, 17 mmol), acetic anhydride (15.8 g, 155 mmol), and diisopropyl amine (4.56 g, 45 mmol) with ether–methanol (4:1) elution from silica, giving pure *N*-acetyl-2-acetoxyethylpiperidine (**5**, 1.4 g, 40% yield); ir ν: 1736, 1618 cm^{-1}; ^{1}H nmr δ: 1.7 (br s, 6H), 2.15 (s, 3H), 2.20 (s, 3H) 2.3–2.6 (m, 2H), 3.6 (br s, 2H), 3.8–4.2 (m, 3H) ppm. *Anal.* calcd. for $C_{11}H_{19}NO_3$: C 61.95, H 8.98, N 6.57; found: C 62.01, H 8.88, N 6.49%.

N-*Acetyl-3-acetoxymethylpiperidine (**6**)*

This was prepared, as was **4** above, from 3-hydroxymethylpiperidine (2 g, 17 mmol), acetic anhydride (21.6 g, 170 mmol), and diisopropyl amine (5.3 g, 52 mmol), to give *N*-acetyl-3-acetoxymethylpiperidine (**6**, 1.5 g, 38% yield); ir ν: 1742, 1618 cm^{-1}; ^{1}H nmr δ: 1.2–1.8 (m, 5H), 2.05 (s, 6H), 2.2–2.5 (m, 2H), 3.6 (m 1H), 3.9 (m, 2H), 4.2–4.4 (m, 1H) ppm. *Anal.* calcd. for $C_{10}H_{17}NO_3$: C 60.35, H 8.54, N 7.01; found: C 59.96, H 8.44, N 6.92.

*Preparative-scale PLE-catalysed hydrolyses of racemic esters **1**–**6***

(a) Of N-*acetyl-2-carbomethoxypiperidine ((+/−)-**1**)*

The ester (+/−)-**1** (1 g, 5.4 mmol) was dissolved in distilled water (75 mL), pH was adjusted to 7.0 with 0.25 M NaOH, and PLE (3600 units) was added. The pH was held constant at 7.0 by addition of 0.25 M aqueous NaOH from a pH stat. When one-half equivalent of base had been added (10 days) there was no further uptake of base, and the reaction was stopped by saturating the solution with NaCl. The pH was readjusted to 7.0 and the solution extracted with ethyl acetate (3 × 50 mL). The combined organic phase was dried ($MgSO_4$) and concentrated *in vacuo* on a rotary evaporator to give (2*R*)-*N*-acetyl-2-carbomethoxypiperidine ((+)-**1**, 260 mg, 51% yield, 26% ee), $[\alpha]_D^{25}$ +19.4° (*c* 5.44, $CHCl_3$); spectral characteristics were identical to those of racemic **1** above. The aqueous solution was then acidified to pH 2.0 with 6 M hydrochloric acid and reextracted with ethyl acetate (3 × 50 mL). The combined organic phase was dried ($MgSO_4$) and concentrated *in vacuo* on a rotary evaporator to give (2*S*)-*N*-acetyl-2-piperidinecarboxylic acid ((−)-**7**, 259 mg, 55% yield, 45% ee) as a slowly crystallizing oil, mp 140–141°C; $[\alpha]_D^{25}$ −7.4° (*c* 10, $CHCl_3$); ir ν: 1728, 1608 cm^{-1}; ^{1}H nmr δ: 1.6–2.0 (m, 6H), 2.25 (s, 3H), 3.4–3.8 (m, 2H), 5.5 (m, 1H), 8.8 (s, 1H) ppm.

(b) Of N-*acetyl-2-carbomethoxymethylpiperidine ((+/−)-**2**)*

The above procedure was followed using (+/−)-**2** (1 g, 5 mmol) in water (25 mL) and PLE (1774 units) for 2.5 days, yielding (2*S*)-*N*-acetyl-2-carbomethoxymethylpiperidine ((+)-**2**, 502 mg, 100% yield, 6% ee); $[\alpha]_D^{25}$ +1.0 (*c* 11.6, $CHCl_3$) (spectra identical to racemic **2** above) and (2*R*)-*N*-acetyl-2-carboxymethylpiperidine ((−)-**8**, 372 mg, 80% yield, 24% ee), mp 91–93°C; $[\alpha]_D^{25}$ −1.7° (*c* 7.2, $CHCl_3$); ir ν: 1722, 1588 cm^{-1}; ^{1}H nmr δ: 1.5–1.7 (m, 6H), 2.1 (br s, 2H), 2.2 (s, 3H), 2.4–2.8 (m, 2H), 4.6 (br, 1H), 10.5 (s, 1H) ppm.

(c) Of N-acetyl-3-carboxymethylpiperidine ((+/−)-**3**)

The above procedure was followed using (+/−)-**3** (1.0 g, 5.3 mmol) in water (25 mL) and PLE (260 units) for 2.6 h, yielding (3*R*)-*N*-acetyl-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

3-carbomethyoxypiperidine ((−)-**3**, 411 mg, 82% yield, 22% ee); $[\alpha]_D^{25}$ −14.6° (*c* 8.2, $CHCl_3$) (spectra identical to racemic ester **3** above), and (3*S*)-*N*-acetyl-3-piperidinecarboxylic acid ((+)-**9**, 385 mg, 83% yield, 24% ee), mp 114–116; $[\alpha]_D^{25}$ +11.6° (*c* 4.1, $CHCl_3$); ir *ν*: 1604, 1703 cm^{-1}; ^1H nmr δ: 1.6–1.8 (m, 4H), 2.1 (s, 3H), 2.4–2.8 (m, 2H), 3.6–3.8 (m, 2H), 10.7 (s, 1H) ppm.

(d) Of N-acetyl-2-acetoxymethylpiperidine ((+/−)-*4*)

(+/−)-**4** (1.0 g, 5 mmol) was dissolved in distilled water (20 mL). The pH was adjusted to 7.0 with 0.25 M NaOH, and PLE (523 units) was added. The pH was kept constant at 7.0 with 0.25 M NaOH, using a pH stat. After addition of one-half equivalent of base (10.5 h), the reaction was stopped by freezing, followed by lyophilization. The residual product was taken up in ethyl acetate (2 × 50 mL), filtered through Celite, dried ($MgSO_4$), and concentrated *in vacuo* on a rotary evaporator. The remaining oil was separated using a Chromatatron (silica, ether–acetone (3:2) development). The high R_f fraction was identified as (2*R*)-*N*-acetyl-2-acetoxymethylpiperidine ((−)-**4**, 494 mg, 96% yield, 47% ee); $[\alpha]_D^{25}$ −18.3 (*c* 9.6, $CHCl_3$) (spectra identical to racemic acetate **4** above), The low R_f fraction was identified as (2*S*)-*N*-acetyl-2-hydroxymethylpiperidine ((+)-**10**, 326 mg, 78% yield, 45% ee); $[\alpha]_D^{25}$ +20.5 (*c* 4.0, $CHCl_3$); ir *ν*: 3400 (br), 1618 cm^{-1}; ^1H nmr δ: 1.4–1.8 (m, 6H), 2.2 (s, 3H), 3.6–3.8 (m, 3H), 4.0–4.3 (m, 2H), 4.8 (br, 1H) ppm.

(e) Of N-acetyl-2-acetoxyethylpiperidine ((+/−)-*5*)

The above procedure was followed using (+/−)-**5** (1.0 g, 4.7 mmol) in water (20 mL) with PLE (300 units) for 4 h, followed by chromatography on silica (ether–THF (4:1)), yielding (2*R*)-*N*-acetyl-2-acetoxyethylpiperidine ((+)-**5**, 507 mg, 100% yield, 4% ee); $[\alpha]_D^{25}$ +2.6° (*c* 14, $CHCl_3$) (spectra identical to racemic acetate **5** above), and (2*S*)-*N*-acetyl-2-hydroxyethylpiperidine ((−)-**11**, 383 mg, 90% yield, 7% ee); $[\alpha]_D^{25}$ −1.7° (*c* 16, $CHCl_3$); ir *ν*: 3400 (br), 1625 cm^{-1}; ^1H nmr δ: 1.4–1.6 (m, 6H), 2.1 (s, 3H), 2.8–3.0 (m, 2H), 3.4–3.6 (m, 2H), 3.8–4.2 (m, 2H), 4.5–5.0 (m, 2H) ppm.

(f) Of N-acetyl-3-acetoxymethylpiperidine ((+/−)-*6*)

The above procedure was followed using (+/−)-**6** (1.0 g, 5 mmol) in water (30 mL) with PLE (110 units) for 12 h, followed by chromatography on silica (ethyl acetate – methanol (98:2) elution) yielding racemic *N*-acetyl-3-acetoxymethylpiperidine ((+/−)-**6**, 496 mg, 94% yield); $[\alpha]_D^{25}$ 0.0 (*c* 9.4, $CHCl_3$) (spectra identical to racemic acetate **6** above), and racemic *N*-acetyl-3-hydroxymethylpiperidine ((+/−)-**12**, 384 mg, 92% yield); $[\alpha]_D^{25}$ 0.0° (*c* 12.0, $CHCl_3$); ir *ν*: 3370 (br), 1622 cm^{-1}; ^1H nmr δ: 1.2–1.8 (m, 5H), 2.1 (s, 3H), 2.6–3.0 (m, 1H), 3.3–3.6 (m, 3H), 3.8–4.5 (m, 3H) ppm.

Enantiomeric excess determinations

(A) By nuclear magnetic resonance

The method of Schneider *et al.* (9) was employed. The general method was as follows: to approximately 20 mg optically active acid was added 1.5 equivalents of (−)-(*S*)-phenethylamine. The resulting oil was dissolved in $CDCl_3$ and the proton spectrum examined at 200 MHz. In all cases, the separation of the diastereotopic *N*-acetate methyl peaks was sufficient to permit the ee values to be determined. The racemic acids (+/−) **1**–**3**, were used as standards.

This technique was applied to the product acids (−)-**7**, (−)-**8**, and (+)-**9** directly, and to alcohol products (+)-**10** and (−)-**11** following oxidation.

*Oxidation of optically active alcohols **10** and **11***

1. Of N-*acetyl-2-hydroxymethylpiperidine ((+)-**10**)*

N-Acetyl-2-hydroxymethylpiperidine ((+)-**10**, 100 mg, 0.6 mmol) from PLE hydrolysis was dissolved in 1 M aqueous phosphate buffer (20 mL, pH 6.5). To this was added $KMnO_4$ (0.7 g, 3 mmol), and the mixture stirred at 70°C for 8 h. The mixture was cooled to 20°C and $Na_2S_2O_5$ added until the purple colour was destroyed. The resulting mixture was filtered through Celite, and the filtrate saturated with NaCl. The pH was readjusted to 6.5 and the solution extracted with dichloromethane (2 × 25 mL). The aqueous phase was acidified to pH 2.0 with 6 M hydrochloric acid and reextracted with dichloromethane (3 × 25 mL). The pH 2.0 extract was dried ($MgSO_4$) and concentrated *in vacuo* on a rotary evaporator to give (2*S*)-*N*-acetyl-2-piperidinecarboxylic acid ((−)-**7**, 22 mg, 21% yield); $[\alpha]_D^{25}$ −7.5° (*c* 2.0, $CHCl_3$). Spectra were identical to **7** above.

2. Of N-*acetyl-2-hydroxyethylpiperidine ((+)-**11**)*

The above procedure was followed with *N*-acetyl-2-hydroxyethylpiperidine ((+)-**11**, 100 mg, 0.5 mmol) and $KMnO_4$ (0.7 g, 3 mmol) for 7 h to yield (2*S*)-*N*-acetyl-2-carboxymethylpiperidine ((+)-**8**, 15 mg, 16% yield); $[\alpha]_D^{25}$ +0.65° (*c* 1.4, $CHCl_3$). Spectra were identical to **8** above.

(B) By optical rotation

The enantiomeric excesses of the remaining products were determined by comparison of optical rotations with compounds of known enantiomeric excess. Thus, optically active acids **7**–**9** were esterified, giving the enantiomeric excesses of product esters **1**–**3** by rotation. Optically active acetates **4** and **5** were deacylated and enantiomeric excesses obtained by comparison of rotations with product alcohols **10** and **11**.

1. Esterification of optically active acids 7–9

(a) Of (2S)-N-*acetyl-2-piperidinecarboxylic acid ((−)-7).* Optically active *N*-acetyl-2-piperidinecarboxylic acid ((−)-**7**, 290 mg, 1.7 mmol) from PLE catalysed hydrolysis was dissolved in methanol (5 mL). Ethereal diazomethane was added until persistence of colour. Colour was removed by dropwise addition of acetic acid. The resulting solution was dried ($MgSO_4$) and concentrated *in vacuo* on a rotary evaporator to give (2*S*)-*N*-acetyl-2-carbomethoxypiperidine ((−)-**1**, 305 mg, 95% yield); $[\alpha]_D^{25}$ −33.1° (*c* 6.0, $CHCl_3$). Spectra were identical to racemic **1** above.

(b) Of (2R)-N-*acetyl-2-carboxymethylpiperidine ((−)-8).* The above procedure was followed with *N*-acetyl-2-carboxymethylpiperidine ((−)-**8**, 210 mg, 1.7 mmol) to give (2*R*)-*N*-acetyl-2-carbomethoxypiperidine ((−)-**2**, 241 mg, 93% yield); $[\alpha]_D^{25}$ −4.3° (*c* 2.1, $CHCl_3$). Spectra were identical to racemic **2** above.

(c) Of (3S)-N-*acetyl-3-piperidinecarboxylic acid ((+)-9).* The above procedure was followed with *N*-acetyl-3-piperidinecarboxylic acid ((+)-**9**, 50 mg, 0.2 mmol), to give (3*S*)-*N*-acetyl-3-carbomethoxypiperidine ((+)-**3**, 36 mg, 96% yield); $[\alpha]_D^{25}$ +13.3 (*c* 4.0, $CHCl_3$). Spectra were identical to racemic **3** above.

2. Deacetylation of optically active acetates 4 and 5

(a) Of (2S)-N-*acetyl-2-acetoxymethylpiperidine ((−)-4).* (2*S*)-*N*-Acetyl-2-acetoxymethylpiperidine ((−)-**4**, 352 mg, 1.8 mmol) from PLE hydrolysis, was dissolved in distilled water (25 mL). To this was added NaOH (72 mg, 1.8 mmol) and the solution stirred for 10 h. The mixture was saturated with NaCl, and extracted with dichloromethane (3 × 50 mL). The combined organic phase was dried ($MgSO_4$), and concentrated *in vacuo* on a rotary evaporator to give (2*S*)-*N*-acetyl-2-hydroxymethylpiperidine ((−)-**10**, 265 mg, 79% yield); $[\alpha]_D^{25}$ −22.9° (*c* 3.95, $CHCl_3$). Spectra were identical to **10** above.

(b) Of (2R)-N-*acetyl-2-acetoxymethylpiperidine ((+)-5).* The above procedure with (2*R*)-*N*-acetyl-2-acetoxymethylpiperidine ((+)-**5**, 200 mg, 1 mmol) in water (25 mL) and NaOH (40 mg, 1 mmol) for 10 h gave (2*R*)-*N*-acetyl-2-hydroxymethylpiperidine ((+)-**11**, 143 mg, 79% yield); $[\alpha]_D^{25}$ +0.48° (*c* 12 in $CHCl_3$). Spectra were identical to **11** above.

Absolute configuration determinations

(a) N-*Acetyl-2-carbomethoxypiperidine (1)*

2-Piperidinecarboxylic acid was resolved as its (+)-tartrate salt according to the method of Portoghese *et al.* (10), to yield (2*R*)-(+)-2-carbomethoxypiperidine hydrochloride, mp 175–176°C (lit. (10) mp 177–180°C); $[\alpha]_D^{25}$ +9.3° (*c* 9, H_2O) (lit. (9) $[\alpha]_D^{25}$ +9.8 (*c* 1, 6 M HCl)). Optically active ester (200 mg, 1.4 mmol) was dissolved in dry THF (25 mL). To this was added acetic anhydride (1.43 g, 14 mmol) and diisopropyl amine (0.7 g, 7 mmol). This was stirred at 20°C for 48 h. THF was removed by rotary evaporation and excess acetic anhydride and diisopropyl amine removed by Kugelrohr distillation (40°C/0.25 Torr). The residual oil was purified by flash chromatography (silica, diethyl ether elution) to yield (2*R*)-(+)-*N*-acetyl-2-carbomethoxypiperidine (2*R*-(+)-**1**, 140 mg, 53% yield); $[\alpha]_D^{25}$ +65.2° (*c* 9.53, $CHCl_3$). Spectra were identical to racemic **1** above.

(b) N-*Acetyl-2-carboxymethylpiperidine (8)*

(2*R*)-*N*-Acetyl-2-carboxymethylpiperidine (−)-**8**, 180 mg, 1 mmol) from the PLE catalysed hydrolysis was dissolved in water (25 mL). To this was added NaOH (100 mg, 2.5 mmol) and the solution stirred at 70°C for 12 h. The solution was cooled to 20°C and extracted with methylene chloride (4 × 50 mL). The combined organic phase was dried ($MgSO_4$) and concentrated *in vacuo* on a rotary evaporator to yield (2*R*)-(−)-2-carboxymethylpiperidine, the enantiomer of which is of known absolute configuration (11) (128 mg, 78% yield), mp 216–220°C (lit. (11) mp 218–221°C); $[\alpha]_D^{25}$ −8.2° (*c* 9, H_2O) (lit. (11) $[\alpha]_D^{25}$ +22.1° (*c* 0.6, H_2O), 64% ee reported); ir *ν*: 3400, 1591 cm^{-1}; ^1H nmr (D_2O/ppts) δ: 1.5–1.7 (m, 6H), 2.1 (br s, 2H), 2.4–2.8 (m, 2H), 4.6–5.5 (m, 3H), 11.2 (s, 1H) ppm.

(c) N-*Acetyl-3-piperidinecarboxylic acid (9)*

The above procedure was followed using (3*S*)-*N*-acetyl-3-piperidinecarboxylic acid ((+)-**9**, 210 mg, 1.2 mmol) in water (25 mL) with NaOH (121 mg, 3 mmol) for 10 h, yielding (3*S*)-(+)-3-piperidinecarboxylic acid of known absolute configuration (12) (125 mg, 69% yield), mp 255–258°C (dec.) (lit. (12) mp 259–260°C); $[\alpha]_D^{25}$ +0.9° (*c* 11.5, H_2O) (lit. (12) $[\alpha]_D^{25}$ +3.6° (*c* 5, H_2O)). Spectra were identical to racemic acid above.

Reactions of dimethylsilylene with pinenes

DONG WANG AND T. H. CHAN[1]
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received May 26, 1987

DONG WANG and T. H. CHAN. Can. J. Chem. **65**, 2727 (1987).

Photolysis of β-pinene and dodecamethylhexasilane (**2**) followed by methanol quenching gave the allylsilane **5** and the methoxysilane **6**. The intermediacy of the silirane **7** was proposed. Photolysis of α-pinene and **2** gave **6** only. The formation of another silirane **15** as intermediate was verified by deuterium labelling experiment. The potential of silylene chemistry in organic synthesis was examined.

DONG WANG et T. H. CHAN. Can. J. Chem. **65**, 2727 (1987).

La photolyse du β-pinène en présence de dodécaméthylhexasilane **2**, suivie d'un piégeage au méthanol, conduit à l'allylsilane **5** et au méthoxysilane **6**. On suggère que le silirane **7** est un intermédiaire dans la réaction. La photolyse de l'α-pinène en présence du composé **2** ne fournit que le composé **6**. Faisant appel à une expérience de marquage au deutérium, on a démontré que le silirane **15** est un intermédiaire dans cette réaction. On a examiné le potentiel de la chimie du silylène en synthèse organique.

Introduction

Silylene, the silicon analog of carbene, has been a subject of intensive investigation in the last decade (1–4). In the presence of alkenes or alkynes, dimethylsilylene is known to add to the double bond to form the corresponding siliranes (5) or silirenes (6). Thus, photolysis of decamethyltetrasilane (**3**) with cyclohexene gave the bicyclic compound **4** (Scheme 1) (7). Siliranes such as **4** are quite unstable. They can rearrange to an allylsilane. In addition, the endocyclic silicon–carbon bond can be cleaved under very mild conditions with polar reagents (e.g., CH_3OH) to give ring-opened adducts (for a review of silylene chemistry, see ref. 1).

In this paper we report the reactions of dimethylsilylene with pinenes in the hope of exploring the factors that may be significant in defining the use of silylene chemistry in organic synthesis (for examples of the use of dimethylsilylene in organic synthesis, see refs. 8 and 9).

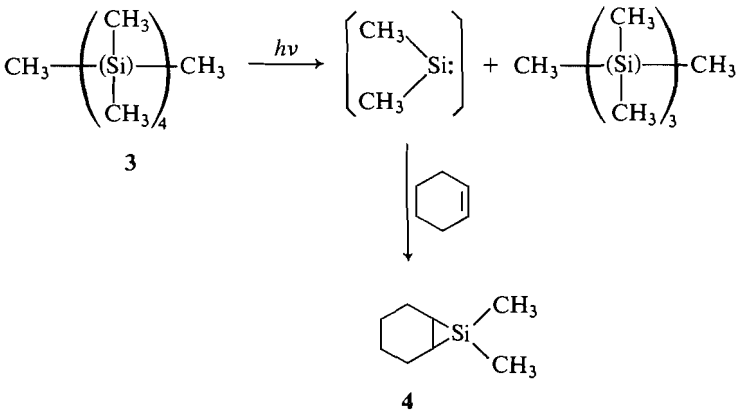
Results and discussion

1. Reaction of dimethylsilylene with β-pinene

Dimethylsilylene (**1**) was generated by the photolysis of dodecamethylcyclohexasilane (**2**) (10). Thus, a mixture of β-pinene and **2** in cyclohexane was photolysed in a Rayonet photochemical reactor. At the end of reaction, the mixture was quenched with methanol and the products purified by distillation and then flash chromatography. Two main products, **5** and **6**, in a combined yield of about 60–69% (based on **2**) were identified (Scheme 2).

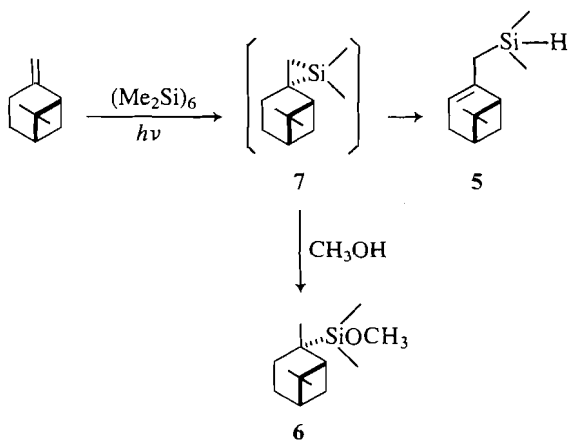
The structure of **5** was quite evident from its spectroscopic data. Its identity was further confirmed by synthesis from an independent route according to Scheme 3, using conventional chemistry.

By analogy with the known rearrangement of **4** to allylsilane, it was likely that the silirane **7** was formed in the photolysis of **2** with β-pinene. Compound **5** was then derived from **7** by a similar process. Efforts to isolate **7** were not successful. Its presence was inferred as well from the other product of the reaction, compound **6**, formed by the methanolysis of the silirane **7**. Heterolysis of siliranes has been reported previously (6). The present methanolysis of **7** to give **6** is noteworthy in two respects. The first is that the reaction is regiospecific. In the opening of the unsymmetrical silirane **7**, we observed cleavage of the silicon–carbon bond where the carbon is less substituted. The other expected regioisomer, compound **8** (9), was not detected in the reaction mixture. Regiospecificity in the heterolysis of unsymmetrical siliranes has been noted in the literature before (6). The present example indicates that a silicon – primary carbon bond is cleaved preferentially over a silicon – tertiary carbon bond (*vide infra*). The second interesting feature is the stereochemistry of **6**. Because the two faces of the

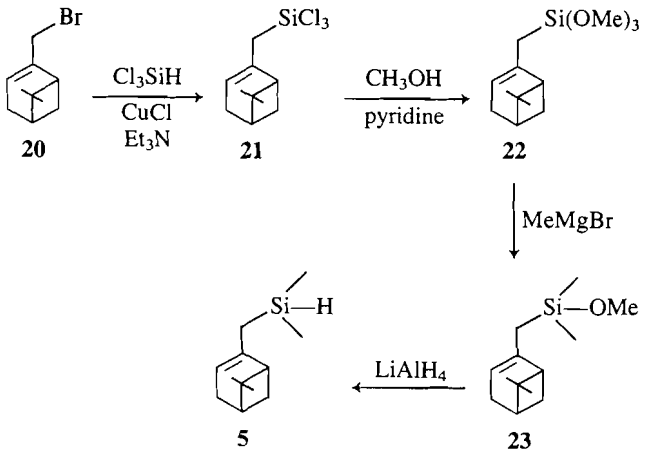


SCHEME 1

[1]Author to whom correspondence may be addressed.

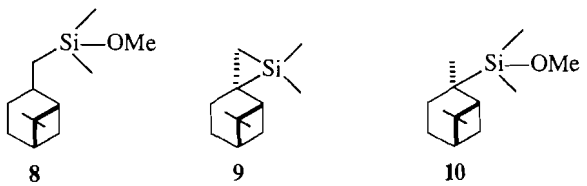


SCHEME 2

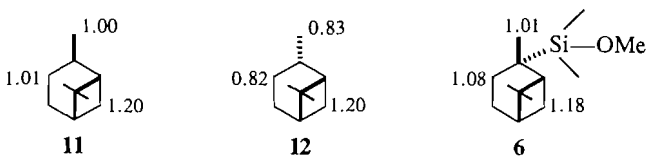


SCHEME 3

β-pinene double bond are not equivalent, dimethylsilylene can add *syn* or *anti* to the *gem*-dimethyl carbon bridge to give **7** or **9**. On methanolysis, two stereoisomers, **6** or **10**, can result. In the



reaction mixture, only one stereoisomer was found. On steric grounds, one assumes that the dimethylsilylene would add to the double bond from the less hindered side to give **7**. We thus assigned structure **6** rather than **10** to the product isolated. This structural assignment was supported by ^{1}H nmr data. The



C10-methyl and the *syn*-methyl of *cis*-pinane (**11**) both resonate at about 1.01 ppm. By contrast, the C10-methyl and the *syn*-methyl of *trans*-pinane (**12**) both resonate at about 0.82 ppm. In the case of **6**, the C10-methyl resonates at 1.01 ppm, more in line with **11**.

Normally, in the trapping of silylene with simple alkenes, the alkene was used in large excess. We found that the combined yield of **5** and **6** diminished only slightly from 69% to 60% even if the ratio of β-pinene to **2** was reduced from 40:1 to 4:1. Furthermore, the relative amount of **5** to **6** could be modified by a change in the length of photolysis time.

2. Reaction of dimethylsilylene with α-pinene

When a mixture of α-pinene and **2** in cyclohexane was photolysed under similar conditions, compound **6** was obtained on quenching the reaction mixture with methanol. The yield of **6** was about 27%. Various attempts to change the reaction conditions by using different ratios of α-pinene to **2** or different lengths of photolysis time, etc., did not lead to significant improvement in the yield of **6**. Nor was it possible to detect or isolate the allylsilanes **13** or **14** from the reaction mixture (Scheme 4).

The formation of **6** can be explained on the basis of methanolysis of the silirane **15**. Again, efforts to isolate **15** were not successful. The formation of the same product **6** from the reactions of the two pinenes raised the question whether two different siliranes, **7** and **15**, were involved as the intermediates. We were able to resolve this question by quenching the photolysis mixture with CH_3OD. When the reaction from the photolysis of β-pinene and **2** was treated with CH_3OD at the end, compound **6***a* was obtained, with deuterium incorporation at the C10-methyl. On the other hand, compound **6***b* obtained from α-pinene contained deuterium at the ring methylene (Scheme 5). This experiment established clearly that two distinct siliranes were involved. Furthermore, it also suggests that in the methanolysis of unsymmetrical siliranes, cleavage of a silicon – secondary carbon bond is preferred over a silicon – tertiary carbon bond.

3. Potential of silylene chemistry in organic synthesis

Activation of the allylic position of an alkene is an important operation in synthetic organic chemistry. The use of palladium or other metals to activate an allylic compound for nucleophilic substitution reactions has proved useful in synthesis. The ability of silylene to react with alkenes to yield the corresponding allylsilanes provides activation in a complementary fashion since allylsilanes are known to react with electrophiles to give substitution products (Scheme 6). The formation of the allylsilane **5** in the reaction of β-pinene with dimethylsilylene is therefore an activation of β-pinene, permitting the synthesis of substituted β-pinenes. We demonstrated this by the reaction of the allylsilane **5** with a number of electrophiles (Scheme 7). Reaction of **5** with 10% HCl in $CHCl_3$ gave β-pinene in 90% yield. With bromine as the electrophile in the presence of pyridine, the bromo compound **16** was obtained presumably by addition and elimination, followed by rearrangement. The isomeric bromo compound was known to rearrange to **16** on column chromatography. Epoxidation of **5** with *m*-chloroperbenzoic acid (MCPBA) followed by acid opening of the epoxide gave the hydroxy compound **17**, again with the hydroxy group *trans* to the *gem*-dimethyl bridge. Finally, the reaction of **5** with acetyl chloride/aluminum chloride gave the acetyl compound **18**, which upon column chromatography rearranged to the more stable α,β-unsaturated ketone **19**. The last reaction is particularly instructive in demonstrating the use of silylene chemistry for the formation of new carbon–carbon bonds.

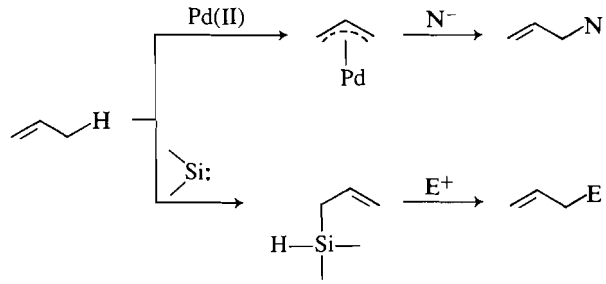

SCHEME 6

Conclusion

The present study demonstrates that the addition of dimethylsilylene to the double bond of pinenes occurs on the less hindered face. The methanolysis of unsymmetrical siliranes is regiospecific, with cleavage of a silicon – primary carbon bond or a silicon – secondary carbon bond preferred over a silicon – tertiary carbon bond. Dimethylsilylene reaction with β-pinene can be used as a way to introduce electrophiles into the allylic position. In spite of many obvious problems, silylene chemistry appears to be potentially useful in organic synthesis (8).

Experimental

Boiling points and melting points are reported uncorrected. Nuclear magnetic resonance spectra were recorded on Varian XL-200 and T-60A spectrometers. Low and high resolution EI mass spectra were determined on a Dupont 21-492B instrument and gc/ms were done on a Hewlett–Packard 5980A instrument. Infrared spectra were recorded on Perkin–Elmer-297 or Nicolet 7002 MC spectrophotometers. Analytical gas chromatography was performed on a Hewlett–Packard 5730A

instrument equipped with a flame ionization detector using helium carrier gas flow. The column used was a 10 ft × 0.125 in. 6% OV-101 on Chromosorb W. HP. 80/100. Elemental analyses were performed using a Carlo Erba Elemental Analyses MOD-1102.

Photolysis of β-pinene with 2

A mixture of 1.95 g (14 mmol) of β-pinene and 1.25 g (3.6 mmol) of **2** in 85 mL of cyclohexane in a quartz flask was photolysed under nitrogen with low pressure mercury lamps (254 nm) in a Rayonet photochemical reactor. At the end of the reaction (20–40 h), 3 mL of dry methanol was added to the mixture. The reaction mixture was concentrated and distilled under reduced pressure. The first fraction (bp 45°C/10 Torr; 1 Torr = 133.3 Pa) was mainly unreacted β-pinene. The second fraction (bp 95–105°C/10 Torr) was a mixture of 10-dimethylsilyl-α-pinene (**5**) and 2-dimethylmethoxysilyl-pinane (**6**) in a combined yield of 60%. The mixture was purified by silica gel flash chromatography eluting with pentane – ethyl acetate (100:1) to give compounds **5** and **6**.

Compound 5: ir: 2080 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.00 (d, 6H), 0.82 (s, 3H), 1.22 (s, 3H), 1.47 (m, 2H), 1.62–2.47 (m, 6H), 3.83 (m, 1H), 5.04 (m, 1H); gc/ms, *m/z*: 194 (M^+, 8%), 179 (2), 149 (24), 59 (100). The spectroscopic data were identical to those for the same compound synthesized by an independent route (see below).

Compound 6: ir: 1090 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.04 (s, 6H), 1.01 (s, 3H), 1.08 (s, 3H), 1.18 (s, 3H), 1.50–2.30 (m, 8H), 3.42 (s, 3H); gc/ms: 226 (0.1%), 136 (2), 121 (3), 89 (100).

The total yield of **5** and **6** was slightly greater (69%) if a larger excess of β-pinene was used (ratio of β-pinene to **2**, 40-fold excess). The work-up was somewhat more difficult in removing the excess β-pinene. The use of β-pinene to **2** in a ratio of about 4:1 was to be preferred.

The proportion of **5** to **6** in the reaction mixture was dependent on the length of photolysis time. For a photolysis of 20 h before methanol quenching, the ratio of **5** to **6** was 1:4. If photolysis was extended to 40 h, the ratio of **5** to **6** was 2.

2-Dimethylmethoxysilyl-10-deutero-pinane-(6a)

Photolysis of β-pinene with **2** was carried out as described above for 20 h. The mixture was quenched with methanol-O-*d*. Compound ***6a*** was obtained after column chromatography. Its ^1H nmr spectrum was the same as that of compound **6** with the exception of the peak at 1.01, which was changed into a 1:1:1 triplet with J_{HD} = 2 Hz and a relative intensity of ~2H. It had gs/ms: 227 (0.1%), 137 (2), 122 (3), 89 (100).

Photolysis of α-pinene with 2

A mixture of α-pinene and **2** in cyclohexane was photolysed under nitrogen in the same manner as described for β-pinene. After quenching the reaction mixture with methanol, and work-up, compound **6** was obtained in 27% yield after column chromatography. It had identical properties to those of the compound obtained from the photolysis of β-pinene. Varying the amount of α-pinene or photolysis time did not lead to significant change in the outcome of the reaction.

2-Dimethylmethoxysilyl-3-deutero-pinane (6b)

Photolysis of α-pinene (2.0 mL) with **2** (1.02 g) in 85 mL cyclohexane was carried out as described above for 30 h. The mixture was quenched with methanol-O-*d* and worked up as above. Compound ***6b*** was obtained after column chromatography. Its ^1H nmr spectrum was identical to that of compound **6** with the exception that the multiplet at ~1.9–2.2 ppm was reduced in intensity. It has gc/ms: 227 (0.1%), 137 (2), 122 (3), 89 (100).

10-Trimethoxysilyl-α-pinene (22)

10-Bromo-α-pinene (**20**) was prepared from myrtenol according to literature procedure (11). To a mixture of trichlorosilane (1.7 g, 11 mmol) and compound **20** (2.5 g, 11 mmol) was added dropwise under nitrogen a mixture of triethylamine (1.2 g, 12 mmol), cuprous chloride (0.06 g, 6 mmol), and 25 mL of ether. After the mixture was stirred for 4 h at room temperature, the solid was removed by filtration. To the ether solution, a solution of 2.6 mL pyridine and 1.3 mL methanol was added. The mixture was stirred overnight at room temperature. The mixture was filtered and the filtrate was evaporated *in vacuo* to yield crude 10-trimethoxysilyl-α-pinene (**22**); ^1H nmr ($CDCl_3$) δ: 0.85 (s, 3H), 1.25 (s, 3H), 1.52 (m, 2H), 1.80–2.50 (m, 6H), 3.52 (s, 9H), 5.15 (m, 1H); ms, *m/e*: 256 (M^+, 14%), 241 (20), 181 (55), 121 (100). *Anal.* calcd. for $C_{13}H_{24}O_3Si$: C 60.89, H 9.43; found: C 60.44, H 9.36.

10-Dimethylmethoxysilyl-α-pinene (23)

To the solution of crude **22** in 30 mL of ether, methylmagnesium bromide solution (~2.0 M, 20 mL) was added. The mixture was stirred for 15 h at room temperature. The excess Grignard reagent was destroyed by aqueous ammonium chloride solution. The organic solvent was dried and distilled under reduced pressure to give 1.5 g of 10-dimethylmethoxysilyl-α-pinene (**23**) (63% yield), bp 80–83°C/0.5 Torr. *Anal.* calcd. for $C_{13}H_{24}OSi$: C 69.58, H 10.78; found: C 69.76, H 10.76.

10-Dimethylsilyl-α-pinene (5)

To a suspension of lithium aluminum hydride (1.2 g) in ether (25 mL), compound **23** (2.0 g, 8.8 mmol) was added. The mixture was stirred overnight at room temperature. The excess hydride was destroyed by aqueous ammonium chloride. The organic layer was washed with water, dried ($MgSO_4$), and filtered. The filtrate was distilled under reduced pressure to give 1.4 g of compound **5** (82% yield), bp 62–64°C/1 Torr. The spectroscopic data of this compound were identical to those of the compound prepared via the photolysis of β-pinene with **2**. *Anal.* calcd. for $C_{12}H_{22}Si$: C 74.15, H 11.41; found: C 74.50, H 11.75.

Protodesilylation of 5

A mixture of **5** (0.1 g) and 0.5 mL of 10% HCl in 3 mL of chloroform was stirred at room temperature for 24 h. The main product (90%) was identified to be β-pinene by ^1H nmr and gc.

Bromodesilylation of 5

To a solution of **5** (0.15 g) and pyridine (0.06 mL) in hexane (5 mL) at −78°C, bromine (0.22 g) was added dropwise. After stirring for 0.5 h, the mixture was warmed to room temperature and stirred for another 0.5 h. The mixture was concentrated *in vacuo* and the product passed through a silica gel column, eluting with pentane – ethyl acetate (75:1). 10-Bromo-α-pinene was isolated in 65% yield, and identified by ^1H nmr and gc comparison with an authentic sample.

3-Hydroxy-β-Pinene (17)

1. From β-pinene

An authentic sample of compound **17** was prepared by lead tetraacetate oxidation of β-pinene followed by base hydrolysis according to literature procedure (12). It had bp 83–85°C/10 Torr.

2. From oxidation of 5

A mixture of compound **5** (0.2 g, 1 mmol), MCPBA (0.4 g), and sodium bicarbonate (4 g) in dichloromethane (15 mL) was stirred at room temperature for 3 days. The solid was filtered and the filtrate was evaporated to dryness. The residue was stirred with dilute sulfuric acid at room temperature for 1 h. The mixture was extracted with ethyl acetate. The organic solution was washed with water, dried ($MgSO_4$), and filtered. The filtrate was evaporated and the residue purified by flash chromatography (pentane – ethyl acetate 15:1) to give compound **17** in 72% yield.

3-Acetyl-α-pinene (18)

To a solution of compound **5** (0.40 g, 2 mmol) and acetyl chloride (0.19 g, 2.4 mmol) in 10 mL of dichloromethane at −78°C, a solution of $TiCl_4$ (0.41 g, 2.2 mmol) in 2 mL of CH_2Cl_2 was added. The mixture was stirred for 1 h, poured into an aqueous solution of sodium bicarbonate, and then extracted with ethyl acetate. The organic layer was washed with water, dried ($MgSO_4$), and filtered. The filtrate was evaporated to dryness. The residue was purified by column chromatography (pentane – ethyl acetate 75:3) to give compound **18** in 57% yield. It had spectral data in agreement with the structure and similar to those reported in the literature (13).

Synthesis of optically active forms of the δ-lactone of 3,5-dihydroxydecanoic acid

TSUGUO SATŌ
Tōhoku College of Pharmacy, Komatsushima, Sendai, Miyagi, Japan

Received April 14, 1987

TSUGUO SATŌ. Can. J. Chem. **65**, 2732 (1987).

The δ-lactone of 3,5-dihydroxydecanoic acid was synthesized from methyl-3-oxooctanoate by utilizing its baker's yeast reduction.

TSUGUO SATŌ. Can. J. Chem. **65**, 2732 (1987).

Utilisant l'oxo-3 octanoate de méthyle comme produit de départ qui est réduit par de la levure de pain, on a réalisé la synthèse de la δ-lactone de l'acide dihydroxy-3,5 décanoïque.

[Traduit par la revue]

Introduction

In 1972 R. F. Vesonder *et al.* isolated the δ-lactone of 3,5-dihydroxydecanoic acid from culture liquor of the fungus (1). However, the absolute configuration of this compound has yet to be defined. Recently, utilization of the biochemical system has been reported as an effective method in asymmetric synthesis (2). This has prompted me to present the enantiomerically pure forms of the δ-lactone.

Results and discussion

I describe a simple synthesis of the optically active forms of the δ-lactone of 3,5-dihydroxydecanoic acid starting from methyl (*R*)-3-hydroxydecanoate **2**, which was readily obtainable in 99% optical purity by reduction of ethyl-3-oxooctanoate **1** with baker's yeast (3). The optical purity was estimated by hplc analysis. The synthetic route is shown in Scheme 1.

Protection of the OH group of (*R*)-**2** as a tetrahydropyranyl (THP) ether gave (*R*)-**3**. This was reduced with DIBAL-H and condensed with ethyl acetate, treating with LDA to give **5**. Removal of the THP protective group of **5** with pyridinium-*p*-toluenesulfonate (PPTS) yielded **6**. Then **6** was treated with *p*-toluenesulfonic acid (PTS) to give the desired lactone **7**. This diastereomeric mixture **7** could be separated by tlc to give **8** as a colourless oil. The nmr spectrum of **8** coincided with the spectrum of the lactone that was reported by R. F. Vesonder (1). On the other hand, A. Numata *et al.* (5) isolated (3*S*,5*S*)-3-hydroxyhexan-5-olide (4) from *Osmunda japonica* Thunb. In the nmr data of this compound, the signal due to CHOH was reported at δ 4.36 (q, J = 4 Hz). According to the above nmr spectral properties, the absolute configuration of the CHOH of lactone **8** was assigned to be (3*R*). In conclusion, I propose (3*R*,5*R*)-(+)-3-hydroxydecan-5-olide.

Experimental

The ir spectra were determined as film on a Shimadzu IR-430 spectrometer. The nmr spectra were recorded at 60 or 90 MHz with TMS as an internal standard and $CDCl_3$ as a solvent on a JEOL PMX-60 and FX90Q spectrometer. Optical rotations were measured on a Jasco DIP-360 polarimeter. High resolution mass spectra (hrms) were obtained with a Hitachi M-80A spectrometer and Data Processing System M-003. Microelemental analyses were performed at Kobe Women's College of Pharmacy.

Ethyl 3-oxooctanoate ***1***

This was prepared from *n*-butylbromide and ethyl acetoacetate in 70% yield (6); ir ν: 1740, 1715, 1630, 1235, 1150 cm^{-1}; ^1H nmr δ: 1.13 (3H, t, J = 4 Hz), 1.50 (3H, t, J = 7 Hz), 2.76 (2H, t, J = 7 Hz), 3.63 (2H, s), 4.43 (2H, q, J = 7 Hz); ms, m/z: 186 (M^+, 3.8), 99 (100). *Mol. Wt.* calcd. for $C_{10}H_{18}O_3$: 186.1277; found (hrms) m/z: 186.1266. *Anal.* calcd. for $C_{10}H_{18}O_3$: C 64.49, H 9.74; found: C 64.71, H 10.14.

*Methyl (*R*)-(−)-3-hydroxydecanoate* ***2***

A solution of **1** (3.945 g) was reduced according to the reported procedure (3). The acidified filtrate was concentrated and treated with CH_2N_2 in ether to give crude **2**, which was chromatographed on an SiO_3 column to afford oily **2** (1.20 g, 32%); $[\alpha]_D^{18}$ −11.65 (*c* 2.3, $CHCl_3$); ir ν: 3400, 1720, 1188, 1160, 1120 cm^{-1}; ^1H nmr δ: 2.4 (2H, d, J = 2 Hz), 4.06 (1H, m), 3.7 (3H, s); ms m/z: 175 (M^+ + 1,

1.5), 103 (100). *Mol. Wt.* calcd. for $C_9H_{19}O_3$: 175.1322; found (hrms) *m/z*: 175.1366. *Anal.* calcd. for $C_9H_{18}O_3$: C 62.04, H 10.41; found: C 61.98, H 10.25.

Determination of the optical purity of **2**

To a solution of **2** (4 mg, toluene 0.3 mL) was added 3,5-dinitrophenylisocyanate (10 mg) and pyridine (0.5 mL) at room temperature. After being kept 1 h, the reaction mixture was evaporated, followed by hplc analysis (column: Sumipax OA-4000 25 × 4 mm; solvent:hexane–1,2-dichloroethane–ethanol (100:20:1), 1 mL/min; pressure: 35 kg/cm^2; detector: 254 nm). The two diastereomers showed retention times of 12 min 3 s and 14 min, respectively. (*R*)-**2** was shown to be 99.9% pure.

*Methyl (*R*)-(−)-3-tetrahydropyranyloxyoctanoate* **3**

To a stirred solution of **2** (1.20 g, 6.9 mmol) and *p*-toluenesulfonate (7.2 mg, 0.042 mmol) in dry CH_2Cl_2 was added dropwise 2,3-dihydropyran (0.50 g, 6.0 mmol). The mixture was stirred for 1 h at room temperature. It was then washed with saturated $NaHCO_3$ solution and brine, dried ($MgSO_4$), and concentrated *in vacuo* to give **3**, which was chromatographed on an SiO_2 column to afford oily **3** (1 g, 56%); $[\alpha]_D^{28}$ −5.90 (*c* 1.033, $CHCl_3$); ir *ν*: 1725, 1190, 1160, 1120, 1070, 1020 cm^{-1}; ^{1}H nmr δ: 0.79–1.0 (3H, m), 2.46–2.63 (2H, br s), 3.66 (3H, s); ms *m/z*: 258 (M^+, 6.1), 85 (100). *Mol. Wt.* calcd. for $C_{14}H_{25}O_4$: 257.1687; found (hrms) *m/z*: 257.1719. *Anal.* calcd. for $C_{14}H_{26}O_4$: C 65.08, H 10.14; found: C 64.74, H 9.50.

*(*R*)-3-Tetrahydropyranyloxyoctanal* **4**

A solution of **3** (1.0 g, 3.9 mmol) in dry toluene (12 mL) was added dropwise at −78°C to a stirred and cooled solution of *i*-Bu_2AlH in toluene (16%, 4 mL) under Ar. After the addition, the mixture was kept at −78°C for 10 min. The saturated NH_4Cl solution was added dropwise to the stirred mixture, then the reaction temperature was gradually raised to room temperature. The reaction mixture was continuously extracted with ether for 1 h. The organic extract was washed with $NaHCO_3$ solution, dried ($MgSO_4$), and concentrated *in vacuo*. The residue was chromatographed on an SiO_2 column to afford oily **4** (0.82 g, 92%); $[\alpha]_D^{28}$ −4.20 (*c* 2.0, $CHCl_3$); ir *ν*: 2540, 1740, 1195, 1140, 1080, 1030, 1020 cm^{-1}; ^{1}H nmr δ: 2.5–2.81 (2H, m), 4.81 (1H, br s), 9.83 (1H, br s); ms, *m/z*: 228 (M^+, 1.5), 85 (100). *Mol. Wt.* calcd. for $C_{13}H_{24}O_3$: 228.1740; found (hrms) *m/z*: 228.1737. *Anal.* calcd. for $C_{13}H_{24}O_3$: C 68.38, H 10.59; found: C 67.91, H 10.12.

*Ethyl (3*RS,5R*)-3-hydroxy-5-tetrahydropyranyloxydecanoate* **5**

A solution of LDA was prepared by the addition of *n*-BuLi in *n*-hexane (1.5 M, 3.6 mL) to a stirred and cooled solution of $(i\text{-Pr})_2NH$ (0.6 mL, 4.6 mmol) in dry THF (15 mL) at −78°C under Ar. After stirring for 10 min at −78°C, the mixture was warmed to room temperature and stirred for 10 min. It was then cooled to −78°C. Ethyl acetate (0.45 mL, 4.6 mmol) was added dropwise to the resulting slurry, which was then stirred for 15 min; next a solution of **4** (0.820 g, 3.6 mmol) in dry THF (4 mL) was added slowly to the stirred solution during 10 min. Saturated NH_4Cl solution was then added to the mixture. After the addition the reaction temperature was gradually raised to room temperature. The mixture was diluted with ether. The ether solution was washed with saturated $NaHCO_3$ solution, dried ($MgSO_4$), and concentrated *in vacuo*. The residue was chromatographed on an SiO_2 column; 0.45 g of **5** (oil, 40%); $[\alpha]_D^{28}$ −13.22 (*c* 0.930, $CHCl_3$); ir *ν*: 3450, 1730, 1130, 1075, 1022 cm^{-1}; ^{1}H nmr δ: 2.50 (2H, dd, *J* = 6 Hz, *J* = 2 Hz), 4.25 (2H, q, *J* = 7 Hz); ms, *m/z*: 299 (20). *Anal.* calcd. for $C_{17}H_{32}O_5$: C 64.52, H 10.19; found: C 64.20, H 9.87.

*Ethyl (3*RS,5R*)-3,5-dihydroxydecanoate* **6**

PPTS (13.15 mg, 0.052 mmol) was added to a solution of **5** in EtOH (0.100 g, 0.349 mmol). The mixture was stirred for 2 h. It was then washed with saturated $NaHCO_3$ solution, saturated NH_4Cl solution, dried ($MgSO_4$), and concentrated *in vacuo*. The residue was chromatographed on an SiO_2 column to afford oily **6** (0.086 g, 97%); ir *ν*: 3350, 1720, 1150, 1020 cm^{-1}; ^{1}H nmr δ: 2.58 (2H, br s, *J* = 4 Hz), 4.26 (2H, q, *J* = 6 Hz). *Anal.* calcd. for $C_{12}H_{24}O_4$: C 62.04, H 10.41; found: C 61.66, H 10.39.

*(3*R,5R*)-(+)-3-Hydroxydecan-5-olide* **8**

PTS (48.91 mg, 0.25 mmol) in benzene (12 mL) was added dropwise to a solution of **6** (86 mg, 0.427 mmol) in benzene (2 mL). The mixture was stirred and heated for 30 min. It was then washed with saturated $NaHCO_3$ solution, saturated NH_4Cl solution, dried ($MgSO_4$), and concentrated *in vacuo* to give 67 mg (84%) of **7**. This residue was purified by preparative tlc on a silica gel plate (Merck, Kieselgel 60 F_{254}, 0.5 mm) using a mixture of ether and *n*-hexane (1:1 v/v) to give 33 mg (42%) of **8**; $[\alpha]_D^{24}$ +24.9 (*c* 0.825, $CHCl_3$); ir *ν*: 3425, 1715, 1255, 1165, 1065, 1040 cm^{-1}; ^{1}H nmr δ: 0.88 (3H, t, *J* = 4 Hz), 2.68 (2H, d, *J* = 4 Hz), 4.36 (1H, q, *J* = 4 Hz), 4.50–4.80 (1H, m); ms, *m/z*: 187 (M^+ + 1, 58), 169 (100). *Mol. Wt.* calcd. for $C_{10}H_{19}O_3$: 187.1335; found (hrms) *m/z*: 187.1334. *Anal.* calcd. for $C_{10}H_{18}O_3$: C 64.49, H 9.74; found: C 64.14, H 9.72.

1,*n*-Radical ions. The photosensitized (electron transfer) formation of 1,5-radical cations[1]

DONALD R. ARNOLD,[2] BRIAN J. FAHIE, LAURIE J. LAMONT, JACEK WIERZCHOWSKI, AND KENT M. YOUNG
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received May 6, 1987

DONALD R. ARNOLD, BRIAN J. FAHIE, LAURIE J. LAMONT, JACEK WIERZCHOWSKI, and KENT M. YOUNG. Can. J. Chem. **65**, 2734 (1987).

The photosensitized (electron transfer) reactions of 3-phenyl-2,3-dihydrobenzofuran (**8***a*), 5-methyl-3-phenyl-2,3-dihydrobenzofuran (**8***b*), *cis* and *trans*-2-methoxy-1-phenylindane (**9**, *cis* and *trans*), 3,3-diphenyltetrahydrofuran (**10**), and 2,2-diphenyl-1-methoxycyclopentane (**11**) have been studied using 1,4-dicyanobenzene as an electron-accepting photosensitizer and acetonitrile–methanol (3:1) as solvent. These reaction conditions cause carbon–carbon bond cleavage of analogous acyclic β,β-diphenylethyl ethers to give products derived from the diphenylmethyl radical and the α-oxycarbocation intermediates. The purpose of this study was to determine if this reaction could be applied to five-membered cyclic derivatives to give 1,5-radical cations.

The primary products from **8***a* and **8***b* were the dehydrogenated, aromatized 3-phenylbenzofurans **14***a* and **14***b*. These products react further; continued irradiation gave the methanol adducts, *cis* and *trans*-2-methoxy-3-phenyl-2,3-dihydrobenzofuran (**15***a* and **15***b*, *cis* and *trans*). The only observed reaction of the indanes (**9**, *cis* and *trans*) was *cis–trans* isomerization. Deuterium was incorporated at the bis-benzylic position of **8** and **9** when the irradiation was carried out in acetonitrile–methanol-O-*d*. These results are consistent with reversible deprotonation from the radical cations. There was no evidence for carbon–carbon bond cleavage with either **8** or **9**. The relative rate, deprotonation faster than carbon–carbon bond cleavage, is explained in terms of the conformation of the bond that cleaves in relation to the singly occupied molecular orbital (SOMO) of the radical cation. Oxidation potential measurements support the conclusion that the SOMO of **8** and **9** is largely associated with the fused phenyl ring and is therefore orthogonal to the benzylic carbon–carbon bond. Irradiation of *cis* or *trans*-2-methoxy-3-phenyl-2,3-dihydrobenzofuran (**15***a*, *cis* or *trans*), under these conditions, leads to *cis–trans* isomerization. The mechanism in this case involves the reversible loss of methanol. There is evidence that the addition of methanol to **14** involves the sensitizer radical anion – **14** radical cation pair.

In contrast with the fused bicyclic systems, the monocyclic tetrahydrofuran **10** and the methoxycyclopentane **11** both cleave under these conditions; the products are the expected acetals **22** and **29** formed from the intermediate 1,5-radical cations. In **10** and **11** the SOMO, which is largely associated with the diphenylmethyl moiety, can overlap with the adjacent carbon–carbon bond and cleavage occurs as in analogous acyclic systems. Both **10** and **11** are relatively stable to irradiation under conditions that are identical except with acetonitrile as solvent (without methanol). We found no evidence for cyclization of the intermediates (1,5-radical cation or 1,5-diradical) into the terminal phenyl ring.

DONALD R. ARNOLD, BRIAN J. FAHIE, LAURIE J. LAMONT, JACEK WIERZCHOWSKI et KENT M. YOUNG. Can. J. Chem. **65**, 2734 (1987).

Utilisant le dicyano-1,4 benzène comme photosensibilisateur accepteur d'électrons et un mélange d'acétonitrile–méthanol (3:1) comme solvant, on a étudié les réactions photosensibilisées (transferts d'électrons) du phényl-3 dihydro-2,3 furanne (**8***a*), du méthyl-5 phényl-3 dihydro-2,3 benzofuranne (**8***b*), des méthoxy-2 phényl-1 indanes *cis* et *trans* (**9**-*cis* et -*trans*), du diphényl-3,3 tétrahydrofuranne (**10**) et du diphényl-2,2 méthoxy-1 cyclopentane (**11**). Lorsqu'on soumet les éthers acycliques β,β-diphényléthyliques analogues aux mêmes conditions, il se produit une rupture de la liaison carbone–carbone qui conduit à des produits provenant du radical diphénylméthyle et des intermédiaires α-oxycarbocationiques. Le but du présent travail était de déterminer si cette réaction pouvait être appliquée à des dérivés cycliques à cinq chaînons pouvant conduire à des cations radicaux-1,5.

Les produits primaires des réactions des produits **8***a* et **8***b* sont les phényl-3 benzofurannes déshydrogénés et aromatisés **14***a* et **14***b*. Ces produits donnent lieu à des réactions subséquentes; si l'on continue l'irradiation, il y a formation des adduits avec le méthanol, les méthoxy-2 phényl-3 dihydro-2,3 benzofuranne *cis* et *trans* (**15***a* et **15***b*, *cis* et *trans*). Dans le cas des indanes (**9**, *cis* et *trans*), la seule réaction observée est l'isomérisation *cis–trans*. Lorsqu'on effectue l'irradiation dans un mélange d'acétonitrile–méthanol-O-*d*, il y a incorporation de deutérium à la position bis-benzylique des produits **8** et **9**. Ces résultats sont en accord avec une déprotonation réversible des cations radicaux. Aucun résultat ne nous permettrait de croire que les produits **8** ou **9** donnent lieu à une rupture de la liaison carbone–carbone. Le fait que la réaction de déprotonation est plus rapide que la réaction de rupture de la liaison carbone–carbone est expliqué en fonction de la conformation de la liaison qui se brise par rapport à l'orbitale moléculaire occupée seule (OMOS) du cation radical. Des mesures de potentiels d'oxydation sont en accord avec la conclusion que les OMOS des composés **8** et **9** sont largement associées avec le cycle phényle condensé et qu'elles sont donc orthogonales à la liaison carbone–carbone benzylique. Dans ces conditions, l'irradiation des composés méthoxy-2 phényl-3 dihydro-2,3 benzofurannes *cis* et *trans* (**15***a*, *cis* et *trans*) conduit à une isomérisation *cis–trans*. Dans ce cas, le mécanisme implique la perte réversible de méthanol. On a des indications à l'effet que l'addition de méthanol au composé **14** implique la paire anion radical sensibilisateur – cation radical **14**.

Par opposition avec les résultats obtenus avec les systèmes bicycliques condensés, les composés monocyliques comme le tétrahydrofuranne **10** et le méthoxycyclopentane **11** se clivent tous les deux dans ces conditions; les produits obtenus sont les acétals attendus **22** et **29** qui se forment à partir des cations radicaux-1,5 intermédiaires. Dans les cas des produits **10** et **11**, les OMSO, qui sont largement associées avec la portion diphénylméthyle, et la liaison carbone–carbone voisine peuvent se recouvrir et un clivage se produit alors comme dans les systèmes acycliques. Si les conditions des réactions ne sont modifiées que par l'élimination du méthanol dans le solvant, les composés **10** ainsi que **11** sont relativement stables. Les résultats obtenus ne suggèrent pas que les intermédiaires cation radical-1,5 ou diradical-1,5 se cyclisent dans le noyau phényle terminal.

Introduction

Radical ions have received the least attention of all the common intermediates in organic chemistry. Most research in this area has focused on those special examples which are stable and are consequently the least interesting from the point of view of reactivity (3). Of the reactive species, 1,2-radical ions are the most studied. This class includes the alkene radical cations (4) and the ketyls generated by the one-electron reduction of carbonyl compounds (5). Reactions involving 1,3-radical ions are much less common although both theoretical and experimental interest in these species has increased markedly in recent years (2, 6). These intermediates have been formed by the cleavage of three-membered ring compounds. Addition of a 1,2-radical ion to a double bond or cleavage of a four-membered ring compound can lead to a 1,4-radical ion. A few examples of this class have been studied (4, 7). 1,*n*-Radical ions with $n > 4$ are virtually unknown (8),[3] this is in spite of the fact that these intermediates should also be readily available by cleavage of the molecular ions or larger membered ring compounds. In fact, the relationship between the ring-closed (the one-electron two-center bond) and ring-opened species is one of the interesting aspects of this area.

We have earlier shown (1*a*, 1*b*, and 10) that the radical cations of methyl 2,2-diphenylethyl ether (**1**) and 2-methoxy-2-diphenylmethylnorbornane (**2**, *endo* and *exo*) are readily formed by photosensitization (electron transfer) and that they cleave, giving the radical and the carbocation intermediates (reactions [1] and [2]). The mechanism of these reactions is

[1] $Ph_2CHCH_2OCH_3$ (**1**) $\xrightarrow[CH_3CN,\ CH_3OH]{h\nu,\ \text{Sens.}}$ Ph_2CH_2 (**5**) + $CH_3OCH_2OCH_3$ (**6**)

[2] **2**, *exo, endo* $\xrightarrow[CH_3CN,\ CH_3OH]{h\nu,\ \text{Sens.}}$ + 5 (**7**, $(OCH_3)_2$)

Sens.: 1,4-dicyanobenzene (**3**) or
1,4-dicyanonaphthalene (**4**)

summarized in abbreviated form in Scheme 1. 1,4-Dicyanobenzene (**3**) and 1,4-dicyanonaphthalene (**4**) have been used as electron-accepting photosensitizers for these reactions in the solvent acetonitrile–methanol (3:1).

The stability of the diphenylmethyl radical and α-oxycarbocation help to lower the bond dissociation energy of the central bond of the radical cations of **1** and **2**. Thus, the radical cation cleavage (Scheme 1, step 4) occurs rapidly enough to compete

[3]The nomenclature in this area has not been fully defined. We recognize a difference between 1,*n*-radical ions and distonic radical ions (9). Distonic radical ions are coordinatively saturated at the ionic site and are not available by one-electron transfer involving a stable precursor without extensive rearrangement. They are common products of gas phase ionization reactions, and are occasionally encountered as intermediates in solution. The 1,5-ammonium salt – alkyl radical intermediate in the Hofmann–Loffler–Freytag reaction is a distonic radical cation.

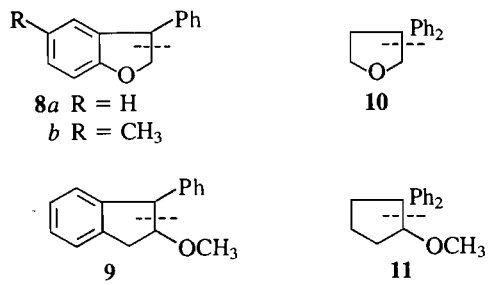
effectively with other fast reactions, particularly deactivation by back electron transfer (Scheme 1, step 3) and deprotonation from the bis-benzylic position (Scheme 1, step 8).

We have studied the photosensitized (electron transfer) reactions of **8**–**11** (Chart 1) (and **15**) under conditions identical



8*a* R = H
b R = CH_3

10

9 **11**

CHART 1

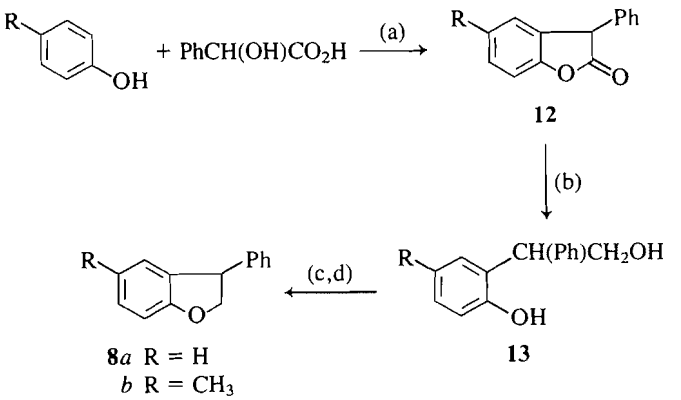
with those used previously in reactions [1] and [2]. Compounds **8**–**11** are cyclic analogs of **1** and **2**. They incorporate the β,β-diphenylethyl ether moiety so the radical cation might be expected to undergo the cleavage process, at the bond indicated (Chart 1), to give 1,5-radical cations. However, the carbon–carbon bond that would be expected to cleave in **8** and **9** is conformationally constrained by virtue of the fused bicyclic structure. Also, **8** is a dihydroaromatic compound. These features may be important in influencing the ultimate reactivity of **8** and **9**.

Results and discussion

The fused phenyl bicyclic systems 8, 9, and 15

3-Phenyl-2,3-dihydrobenzofuran (**8***a*) is a known compound (11*d*). It and 5-methyl-3-phenyl-2,3-dihydrobenzofuran (**8***b*) were prepared by the reported procedure (Scheme 2) (11). The 5-methyl derivative was used in our preliminary study because it can be prepared in higher yield than the unsubstituted compound and because the distinctive proton nuclear magnetic resonance (^{1}H nmr) signal due to the 5-methyl protons provides a useful probe for following the progress of reactions of **8***b*.

Irradiation of **8***a* in acetonitrile–methanol (3:1), with 1,4-dicyanobenzene (**3**) as the electron-accepting photosensitizer (conditions identical to those used for reactions [1] and [2]) led to a relatively inefficient consumption of **8***a*. Analysis of the photolysate by capillary column vapour phase chromatography with a mass selective detector (gc/ms) indicated two major volatile products were formed. These products constituted more than half of the reacted starting material; no other product of similar retention time was detected. The crude photolysis mixture was separated by column chromatography and the products were identified by spectroscopic techniques (infrared

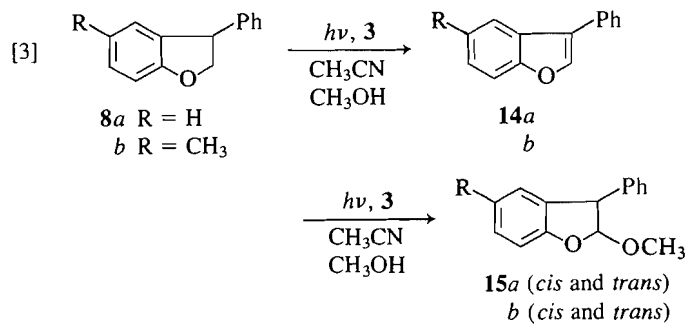


SCHEME 2. The synthesis of 3-phenyl-2,3-dihydrobenzofurans (**8***a* and **8***b*) (11). (a) 75% H_2SO_4, 130°C, 45 min; (b) $LiAlH_4$; (c) phthalic anhydride, pyridine, 48 h; (d) 2% NaOH, reflux 1 h.

(ir), ^{1}H nmr, and mass spectrometry (ms)). They are the isomeric *cis* and *trans*-2-methoxy-3-phenyl-2,3-dihydrobenzofurans (**15***a*, *cis* and *trans*) (reaction [3]).

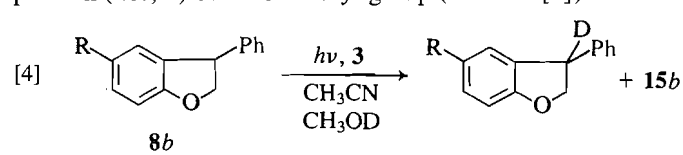
It seemed probable that these products resulted from a photosensitized (electron transfer) addition of methanol to the 3-phenylbenzofuran formed as a primary product. Control experiments supported this conclusion. Irradiation of 3-phenylbenzofuran (**14***a*) (12) under these conditions led to the same methanol adducts in good yield, and **14***a* was formed by irradiation of **8***a* under identical conditions but in acetonitrile without added methanol.

Similar results were obtained starting with **8***b* (reaction [3]).



A possible first step in the formation of **14** from the radical cation of **8** is deprotonation from the bis-benzylic (i.e., 3) position. Subsequent loss of the hydrogen from the 2-position, either by disproportionation or by hydrogen transfer to the sensitizer radical anion, has aromatization as a driving force and therefore should be favoured. Reversible deprotonation of radical cations similar to those of **8***a* and **8***b* has been observed under these conditions (Scheme 1, step 8) (1*a*); this possibility was tested.

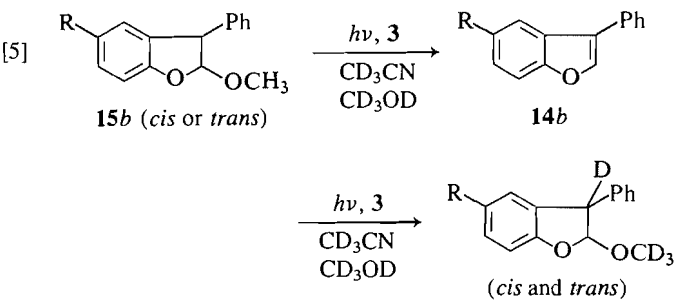
The photosensitization (electron transfer) of **8***b* was carried out in acetonitrile–methanol-O-*d* until reaction [3] was 20% complete. The unreacted starting material was isolated from the reaction mixture and the deuterium content was determined by ^{1}H and ^{2}H nmr. The proton at the bis-benzylic position was more than 90% exchanged for deuterium. There was no evidence for deuterium incorporation at either the methylene position (i.e., 2) or the 5-methyl group (reaction [4]).



Our study was next extended to the isomeric methanol adducts **15**, *cis* and *trans*. The radical cation of **15** should be even more prone to carbon–carbon bond cleavage than **8** since cleavage would result in a carbocation stabilized by two electron-donating oxygen atoms.[4] Furthermore, with **15**, *cis–trans* isomerization that would accompany reversible cleavage could be observed.

The photosensitized (electron transfer) reactions of **15** *cis* and *trans* were carried out in the usual way. The *cis–trans* isomerization was observed but none of the products expected from carbon–carbon bond cleavage were formed, even after prolonged irradiation.

An alternative mechanism for configurational isomerization would involve the reversible deprotonation at the bis-benzylic position analogous to that observed with **8**. To test this possibility **15***b* *cis* and **15***b* *trans* were irradiated as before except that the solvent was acetonitrile-d_3–methanol-d_4 (3:1). Analysis (^{1}H nmr) of the isomerized product and the recovered starting material, as a function of irradiation time, indicated that *exchange of both the bis-benzylic proton and the methoxy group had occurred in both isomers, and that the rate of exchange was essentially the same at both positions* (reaction [5]).



In the case of **15***b* *cis* yielding **15***b* *trans*, there was some evidence that the exchange of the bis-benzylic proton may have been somewhat more rapid than the exchange of the methoxy group; but, the difference in rate was small so that a mechanism that exchanges protons at both positions must dominate.

To explain these results we propose that following deprotonation from the bis-benzylic position (i.e., 3), the resulting radical aromatizes to **14** by loss of the methoxy radical. Then perdeutero methanol adds to the radical cation of **14** (reaction [3]).

This mechanism requires loss of the methoxy radical from the same radical that was invoked as an intermediate during the addition of methanol to the radical cation of **14**. The difference may be that the addition of methanol occurs while the radical cation of **14** is still in the solvent cage with the sensitizer radical anion. Under these conditions the radical would be reduced rapidly by back electron transfer from the sensitizer radical anion and the anion would be protonated. This would effectively prevent reversal by loss of methoxy radical in this case. The deprotonation of the radical cation of **15** and subsequent loss of methoxy radical would then occur outside the radical ion cage. A similar proposal of addition of methanol to the radical cation of an alkene held within a solvent cage of a radical ion pair has recently been reported (13).

The 2-methoxy-1-phenylindanes (**9**, *cis* and *trans*) were

[4]Cleavage of the radical cation of acyclic β,β-diphenylethyl acetals is a facile reaction. For example, 2-(2,2-diphenylethyl)-1,3-dioxalane gives a good yield of diphenylmethane and 2-methoxy-1,3-dioxalane under these conditions (D. R. Arnold, L. J. Lamont, and J. Trottier, unpublished results).

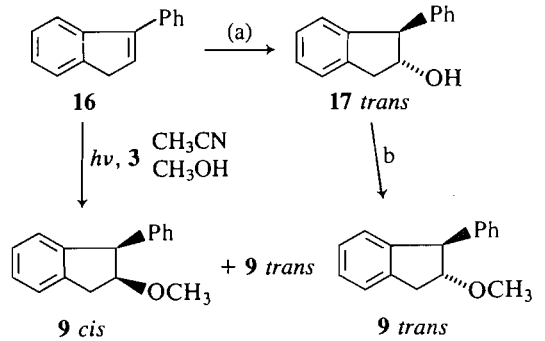

SCHEME 3. The synthesis of 2-methoxy-1-phenylindane (**9**). (a) 9-BBN, THF, reflux; NaOH, H_2O_2, aq.; (b) NaH, dimethyl sulfate, reflux, 24 h (14).

prepared by two methods starting with 1-phenylindene (**16**) (Scheme 3). The hydroboration sequence (14) gave exclusively **17** *trans*, while the photosensitized (electron transfer) addition of methanol to the indene (4, 15) gave predominantly **17** *cis* (*cis*:*trans*, 6:1). These are new compounds; the structural assignments were firmly established by spectral methods (^{1}H nmr).

The photosensitization (electron transfer) of either **9** *cis* or **9** *trans* led to inefficient configurational isomerization (reaction [6]). Isomerization was accompanied by incorporation of

[6] 
9 *cis* 9 *trans*

deuterium in the bis-benzylic position when acetonitrile-d_3–methanol-d_4 (3:1) was used as the solvent. Analysis of the isomers recovered after prolonged irradiation in this perdeutero solvent mixture indicated that exchange also occurred, albeit much less efficiently, at the mono-benzylic position (i.e., 3) and at the methoxy.

Apparently reversible deprotonation of the radical cation is again the dominant process. Deprotonation from the bis-benzylic position is favoured. Deprotonation from the mono-benzylic position and loss of methoxy radical followed by readdition of methanol to **16** both occur but are relatively inefficient processes. The loss of the methoxy radical does not have the driving force of aromatization in this case.

This efficiency of exchange at the bis-benzylic position relative to that at the mono-benzylic position was also observed upon irradiation of 1-phenylindane (**18**). Irradiation of **18** under the usual conditions, with acetonitrile–methanol-O-*d* (3:1) as the solvent, led to incorporation of deuterium at the bis-benzylic position (reaction [7]). Prolonged irradiation in this medium

[7] 
18

led to further incorporation of deuterium in the mono-benzylic position; however, the relative rate of exchange at these two positions is in the order of 100:1. The kinetic acidity of the radical cation of **18** therefore follows the thermodynamic acidity. The pK_a of the proton at the bis-benzylic position must be considerably more negative by virtue of the additional resonance stabilization of the radical, which weakens the carbon–hydrogen bond (1*a*, 16).

TABLE 1. The oxidation potential of some diphenylmethyl compounds[a]

Diphenylmethyl compound	E_p (V)[b]	$E_p - E_p/2$ (mV)

[d]Reference 10.

All of these reactions (reactions [3]–[7]) can be accounted for by a first step involving the deprotonation of the radical cation (Scheme 1, step 8). We found no evidence for carbon–carbon bond cleavage of the radical cations of these fused phenyl bicyclic systems. In contrast, in reactions [1] and [2] carbon–carbon bond cleavage is much more favourable than deprotonation. This dichotomy may appear surprising at first, but it can be explained in terms of the conformation of the singly occupied molecular orbital (SOMO) of the radical cation relative to the bond (carbon–carbon versus carbon–hydrogen) that cleaves.

Table 1 lists the oxidation potentials of **1**, **2**, **8***b*, **9**, **17**, and some other compounds of interest. The SOMO of **1** and **2** is largely associated with the diphenylmethyl moiety (1*a*, 10). The oxidation potential of **8** is considerably lower than that of **1**, **2**, and other diphenylmethyl derivatives listed in Table 1. This is consistent with the SOMO of **8** being largely associated with the fused phenyl ring. This is expected since this ring is substituted with an electron-donating group (that is, the oxygen atom) that lowers the oxidation potential.

In the case of **1** and **2** there are favourable conformations of the radical cation that allow the SOMO to be parallel to the σ-orbital involved in the carbon–carbon bond that cleaves. This conformation is not possible for the bicyclic structure of **8** and **15**. Instead, the carbon–hydrogen bond is held more closely parallel with the SOMO.

The loss of methanol from the radical cations of **15***b*, *cis* and *trans*, is also a dominant process in the gas phase. The question that arises is whether the mechanism of this reaction involves a concerted loss of the methanol molecule, which might be favoured in the case of the *trans* isomer (where the methoxy group and the proton are *cis*), or whether a stepwise loss of a proton and a methoxy radical is involved. The base peak in the mass spectrum of both isomers is the molecular ion (m/z = 240). The relative abundance of the 208 m/z peak (that is, the molecular ion minus methanol) versus the ionizing voltage is shown for the two isomers in Fig. 1. Loss of methanol from the radical cation of the *trans* isomer is only about twice as efficient as from the *cis* isomer. Furthermore, a significant metastable peak at 180.3 m/z in the spectrum of both isomers provides additional evidence that methanol is lost from the molecular ion of both. We found no evidence that loss of methanol occurs by different mechanisms in these two isomers.

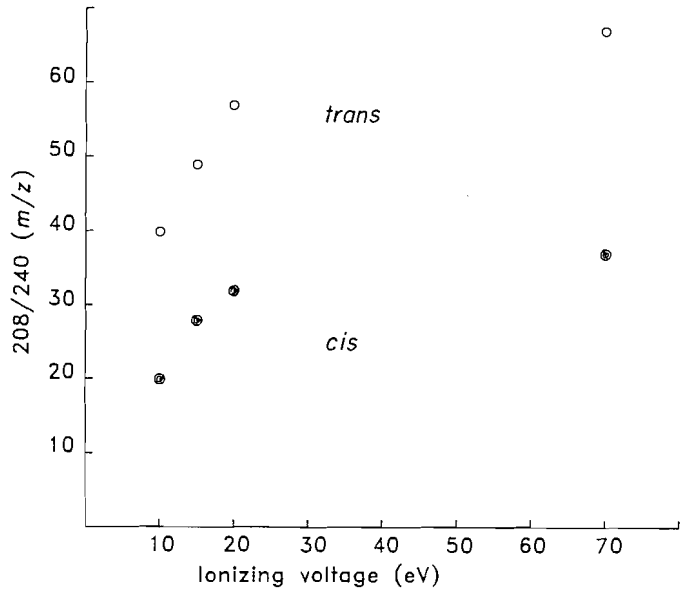

FIG. 1. The relative abundance of the 208 m/z fragment (molecular ion minus methanol) as a function of ionizing voltage for **15***b* *cis* and *trans*.

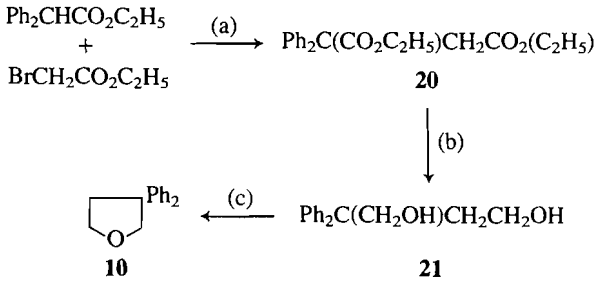
It would seem likely that for **9** *cis* and *trans* the SOMO would at least partially reside on the unfused phenyl ring and that carbon–carbon bond cleavage could then occur. However, the oxidation potential of **9** *trans* is also somewhat lower than that of **1**, **2**, and other diphenylmethyl compounds listed in Table 1. We suggest that in these radical cations also the SOMO is associated largely with the fused phenyl ring and is therefore orthogonal to the benzylic carbon–carbon bond.[5]

*The monocyclic systems **10** and **11***

The radical cations of 3,3-diphenyltetrahydrofuran (**10**) and 2,2-diphenyl-1-methoxycyclopentane (**11**) should be able to attain a conformation that would allow sufficient overlap of the SOMO associated with the diphenylmethyl moiety with the σ-orbital of the benzylic carbon–carbon bond so that cleavage will occur. The preferred conformation of **10**, in the crystal, has been determined by X-ray analysis.[6] The bis-benzylic carbon–carbon bond of **10** forms an angle of 62° with the plane of one of the phenyl rings.

The preparation of the tetrahydrofuran (**10**) has been reported (17*a*). The synthetic procedure used is shown in Scheme 4.

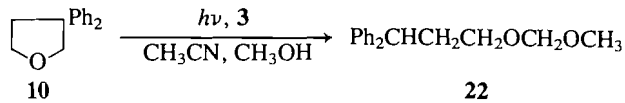


SCHEME 4. The synthesis of 3,3-diphenyltetrahydrofuran (**10**) (17). (a) NaH, ether; (b) $LiAlH_4$, ether; (c) HBr 49% aq., reflux.

[5]The site of the SOMO can be changed to the unfused phenyl ring of **9** by appropriate substitution. For example, carbon–carbon bond cleavage occurs when 2-methoxy-1-(4-methoxyphenyl)indane is subjected to these conditions (D. R. Arnold and K. Henseleit, unpublished results).

[6]T. S. Cameron and B. Vincent, unpublished results.

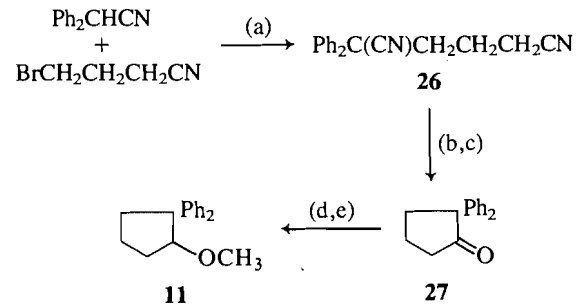
Irradiation of an acetonitrile–methanol (3:1) solution of 1,4-dicyanobenzene **3** and **10** under the usual conditions gave a good yield of methyl (3,3-diphenylpropyl) formaldehyde acetal **22** (reaction [8]).



The proof of structure for **22** rests upon an analysis of the ^1H and ^{13}C nmr spectra and upon the isolation and characterization of 3,3-diphenyl-1-propanol (**23**), a known compound (18), following hydrolysis of the crude photolysate.

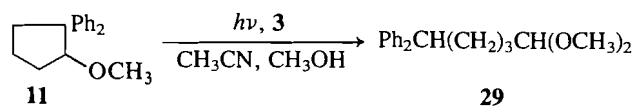
Carbon–carbon bond cleavage of the radical cation (step 4, Scheme 1) gives the 1,5-radical cation, which is trapped by the nucleophile methanol. Similar irradiation of **10** in acetonitrile without added methanol causes relatively little reaction. There was no evidence (gc/ms) for formation of any rearranged or isomerized product. This indicates that in the absence of an effective nucleophilic trapping reagent, the intermediate 1,5-radical cation returns to the starting tetrahydrofuran.[7] It is not clear whether back electron transfer precedes (in which case the intermediate 1,5-diradical would be involved) or is subsequent to ring closure.

The cyclopentane **11** was prepared from the known alcohol **28** (20*a*) by treatment with sodium hydride followed by dimethylsulphate (Scheme 5).



SCHEME 5. The synthesis of 2,2-diphenyl-1-methoxycyclopentane (**11**) (20). (a) $NaNH_2$, NH_3, benzene; (b) KOH aq., ethylene glycol; (c) acetic anhydride; (d) $LiAlH_4$; (e) NaH, dimethyl sulfate.

Irradiation of an acetonitrile–methanol (3:1) solution of 1,4-dicyanobenzene (**3**) and **11** under the usual conditions led to the efficient formation of 5,5-diphenylpentanal dimethylacetal **29** (reaction [9]). The structure assigned to **29** is consistent with



the spectral (^1H nmr and ms) data. The aldehyde **30**, obtained upon hydrolysis of the crude photolysate, was also fully characterized.

Again in this case **11** was relatively stable to irradiation under conditions identical to earlier experiments except that no methanol was used. The 1,5-radical cation is efficiently trapped with added nucleophile, but no evidence was found for rearrangement or isomerization of **11** in the absence of the trapping agent.

[7]A pattern of reactivity of 1-phenyl-1,*n*-radical cations seems to be emerging. The 1,3- and 1,5-radical cations apparently do not cyclize into the terminal phenyl while the 1,4-homologues do (2*a*, 4, 19). The transition state is 6-*endo*–*trig* in the reactive case.

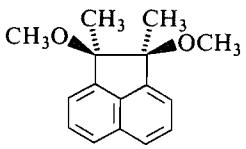
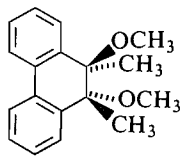
The oxidation potentials of **10** and **11** are listed in Table 1. Incorporation of the diphenylmethyl moiety in a five-membered ring has little effect on the oxidation potential. The SOMO of both **10** and **11** can overlap sufficiently with the σ-orbital of the benzylic carbon–carbon bond so that cleavage can occur.

The marked difference in reactivity of the bicyclic fused radical cations and the monocyclic analogues illustrates the importance of overlap of the SOMO with the bond that cleaves. This concept has been recognized as an important factor directing the deprotonation from the carbon α to the nitrogen of the radical cation of tertiary amines (21), and from the benzylic position of alkyl aromatic radical cations (22). There are exceptions, however. We know of two examples where cleavage of a carbon–carbon bond that is orthogonal to the SOMO does occur. The photosensitized (electron transfer) irradiation of *meso*-1,2-dimethyl-1,2-dimethoxyacenaphthene (**31**) and *rac*-9,10-dimethoxy-9,10-dimethyl-9,10-dihydro-



31



32

phenanthrene (**32**) in acetonitrile with **4** as the electron acceptor leads to formation of the diastereomers (**8***a*, **8***b*). As both the radical and the cationic centers are conjugatively coupled through the π-system in both of these cases, factors other than conformation (e.g., orbital symmetry) may be involved.

In summary, 1,5-radical cations are formed as intermediates upon cleavage of the radical cation of five-membered cyclic compounds. In the presence of nucleophiles, reaction proceeds as with acyclic analogues. For example, the acetals **22** and **29** are formed in high yield in reactions [8] and [9]. The bond cleavage process requires orbital overlap with the SOMO. When the SOMO is held orthogonal to the adjacent bond, as in the bicyclic systems **8**, **9**, and **15**, deprotonation of the radical cation occurs instead. Product formation is then dependent upon the subsequent reactivity of the radical.

Experimental

General information

The ^{1}H nmr spectra were recorded on a Varian Associates EM360L, CFT-20, T-60 or a Nicolet Industries narrow bore 360-MHz spectrometer and are reported in parts per million downfield from TMS. The ^{2}H nmr spectra were obtained on the Nicolet instrument operating at 55.4 MHz. The ^{13}C nmr spectra were recorded on the CFT-20 or on the Nicolet spectrometer operating at 90 MHz. Infrared spectra were recorded on an air-purged Perkin Elmer 180 grating spectrometer, a Perkin Elmer 233B, or a Perkin Elmer 1320 spectrometer and are reported in wavenumbers (relative to the 1601.8 cm^{-1} absorption of polystyrene). Mass spectra were recorded on a modified Du Pont CEC Model 21-104 mass spectrometer, except where noted.

The gc/ms analyses were done on an Hewlett Packard 5890A GC/5970 mass selective detector interfaced with an H.P. 9816 microcomputer. The columns used for analyses were 25 m × 0.2 mm methyl silicone or 5% phenyl methyl silicone on fused silica, with a film thickness of 0.25 μm, or a 25 m × 0.2 mm Carbowax 20M, with a film thickness of 0.25 μm where noted. Product analyses were determined by vapor phase chromatography (gc) using a Varian Aerograph 1200 chromatograph with flame ionization detection. The column used was 1/8 in. × 6 ft copper packed with 8% SE-30 on Chromosorb G 60/80. An Aerograph Autoprep A-700 (3.8 in. × 6 ft aluminum columns packed with 5 or 10% SE-30 on Chromosorb 60/80 NAW) was used for prep-gc. Preparative medium pressure liquid chromatography (mplc) was carried out using a 25 × 1000 mm column packed with tlc grade silica gel (without binder) (Merck) at 15 psi (helium) (1 psi = 6.9 kPa) with hexanes. The columns were eluted with a hexanes/methylene chloride gradient and the eluate was monitored/collected by a uv spectrometer/fraction collector. Ultraviolet–visible absorption spectra were recorded on a Cary–Varian 219 absorption spectrophotometer and are reported in nanometers. Melting points were taken on a Thermolyne melting point apparatus, and are uncorrected. Combustion analyses were performed by Canadian Microanal. Service Ltd., Vancouver, B.C.

Proton nmr spectra for **9** and **17** were simulated using the Lame (Laocoon with magnetic equivalence) simulation program on a CDC Cyber 170-730 mainframe computer. Irradiations were done in Pyrex tubes using a General Electric Co. 1-kW medium pressure mercury vapor lamp (CGE HR 1000 DX 36-15) with a quartz cooling jacket immersed in a constant temperature bath at 10°C.

Oxidation potentials were obtained by cyclic voltammetry using a three-electrode cell that has been previously described (2*a*). The working electrode was a platinum sphere (1 mm diameter) and the counter electrode was a Pt wire. The reference electrode was a saturated calomel electrode (SCE). The electrolyte used was 0.1 M tetraethylammonium perchlorate in acetonitrile. Substrate concentrations were typically 1 mM.

Materials

All solvents used were distilled prior to use. Acetonitrile, 1,4-dicyanobenzene (**3**), and 1,4-dicyanonaphthalene (**4**) for photochemical use were purified as previously described (1*a*). Deuterated acetonitrile and methanol-d_4 were obtained from Stohler Isotopes. Methanol-O-*d* was obtained from Aldrich Chemical Co.

*3-Phenyl-2,3-dihydrobenzofuran (8*a*)*

This compound was prepared starting with mandelic acid and phenol using reported procedures (11). The colourless needles of **8***a* obtained upon recrystallization from 95% ethanol had mp 37.5°C (lit. (11*e*) mp 38–39°C); ^{1}H nmr (360 MHz) in $CDCl_3$: 6.83–7.30 (m, 9H), 4.87 (dd, 1H, J = −8.85 Hz, J = 9.7 Hz), 4.64 (dd, 1H, J = 9.7 Hz, J = 7.3 Hz), 4.39 (dd, 1H, J = −8.85 Hz, J = 7.3 Hz).

*5-Methyl-3-phenyl-2,3-dihydrobenzofuran (8*b*)*

The methyl derivative was prepared by a procedure similar to that used for **8***a* except *para*-cresol was used instead of phenol. The intermediate 5-methyl-3-phenyl-2-coumaranone (**12***b*) is a known compound (11*c*). Recrystallization (95% ethanol) gave **12***b* as colourless crystals. From **12***b* (4 g, 0.02 mol), **8***b* (1.7 g, 8.1 × 10^{-3} mol, 45% yield) was obtained as colourless crystals, mp 60.5°C; ^{1}H nmr (360 MHz) in $CDCl_3$: 6.74–7.30 (m, 8H), 4.83 (dd, 1H, J = −8.85 Hz, J = 9.5 Hz), 4.57 (dd, 1H, J = 9.5 Hz, J = 7.3 Hz), 4.36 (dd, 1H, J = −8.85 Hz, J = 7.3 Hz), 2.2 (s, 3H); ^{13}C nmr (90 MHz) in $CDCl_3$: 158.0, 142.9, 130.5, 130.1, 128.9, 128.7, 127.9, 126.9, 125.7, 109.1, 79.2, 48.6, 20.8. *Anal.* calcd. for $C_{15}H_{14}O$: C 85.68, H 6.71; found: C 85.66, H 6.77.

*3-Phenylbenzofuran and 5-methyl-3-phenylbenzofuran (**14**a and b)*

These known compounds were prepared by the reported procedure (23). The intermediate aryloxyacetophenones were cyclodehydrated using polyphosphoric acid, keeping the temperature below 45°C to avoid rearrangement of the initial products. 3-Phenylbenzofuran (**14***a*) was purified by recrystallization from methanol (Dry Ice – acetone) to colourless crystals, mp 41–43°C (lit. (23*a*) mp 41–42°C); ^{1}H nmr (T-60) in $CDCl_3$: 7.0–7.7 (m). The methyl derivative (**14***b*) was also purified by recrystallization from methanol at low temperature; the crystals melt upon warming to room temperature; ^{1}H nmr (T-60) in $CDCl_3$: 7.65–6.9 (m, 9H), 2.4 (s, 3H) (in agreement with the reported spectrum (23*b*)).

*Irradiation of 5-methyl-3-phenyl-2,3-dihydrobenzofuran (8*b*)*

A solution of 5-methyl-3-phenyl-2,3-dihydrobenzofuran (**8***b*) (0.50 g, 2.38 × 10^{-3} mol) and 1,4-dicyanobenzene (**3**) (0.30 g, 2.34 ×

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

10^{-3} mol) in acetonitrile–methanol (3:1) (30 mL) was placed in a Pyrex tube, purged with nitrogen, and irradiated for 20 h with a 1-kW medium pressure mercury vapor lamp. Analysis of the reaction mixture by gc/ms indicated that two products were formed with the composition of methanol adducts. There was no evidence for formation of the dehydrogenation product **14***b*. After prolonged irradiation the solvent was evaporated and the crude photolysate was chromatographed on silica gel using hexanes – diethyl ether (3:1). Unreacted starting material (0.17 g) was recovered, followed by a mixture (0.18 g) of the isomeric methanol adducts **15***b*, *cis* and *trans* (45% yield). Analysis of the mixture by ^{1}H nmr indicated that the *cis*:*trans* ratio was 1:0.85. This mixture was rechromatographed on silica gel using mplc, eluting with ethyl ether (4%) in hexanes. The *trans* isomer eluted first.

The *trans* isomer (**15***b trans*) was recrystallized from ethanol giving colourless prisms (mp 48°C); ^{1}H nmr (EM360L) in $CDCl_3$: 6.9–7.3 (m, 8H), 5.4 (d, 1H, J = 1.9 Hz), 4.4 (d, 1H, J = 1.9 Hz), 3.6 (s, 3H), 2.2 (s, 3H). *Anal.* calcd. for $C_{16}H_{16}O_2$: C 79.97, H 6.71; found: C 79.79, H 6.66.

The *cis* isomer (**15***b cis*) was an oil; ir (PE 180), neat: 3020 (w), 2920 (m), 2835 (w), 1600 (w), 1480 (s), 1650 (w), 1225 (w), 1180 (w), 1110 (m), 1090 (s), 930 (m), 910 (s), 800 (m), 720 (w), 685 (s); ^{1}H nmr (EM360L) in $CDCl_3$: 6.8–7.3 (m, 8H), 5.6 (d, 1H, J = 6.5 Hz), 4.6 (d, 1H, J = 6.5 Hz), 3.4 (s, 3H), 2.2 (s, 3H). *Anal.* calcd. for $C_{16}H_{16}O_2$: C 79.97, H 6.71; found: C 79.99, H 6.71.

*Irradiation of 3-phenyl-2,3-dihydrobenzofuran (**8**a)*

The irradiation procedure used for this unsubstituted compound was essentially the same as that used for the methyl derivative. The isomers were separated by chromatography (mplc). The *trans* isomer (**15***a trans*) was eluted first. Recrystallization from ethanol gave colourless needles, mp 95°C; ir (PE 180), KBr: 3060 (m), 3020 (m), 2985 (m), 2960 (m), 2940 (s), 2840 (m), 1600 (s), 1500 (s), 1470 (s), 1450 (m), 1370 (s), 1220 (s), 1100 (s), 920 (s), 860 (s), 740 (s), 690 (s); ^{1}H nmr (EM360L) in $CDCl_3$: 6.8–7.4 (m, 9H), 5.4 (d, 1H, J = 2.4 Hz), 4.4 (d, 1H, J = 2.4 Hz), 3.5 (s, 3H). *Anal.* calcd. for $C_{15}H_{14}O_2$: C 79.62, H 6.24; found: C 79.39, H 6.20.

The *cis* isomer (**15***a cis*) is an oil; ir (PE 180), neat: 3060 (sh), 3020 (m), 2935 (b), 2840 (m), 1600 (m), 1500 (m), 1470 (s), 1450 (s), 1210 (m), 1180 (s), 1100 (s), 920 (s), 870 (s), 740 (s), 690 (s); ^{1}H nmr (EM360L) in $CDCl_3$: 6.8–7.3 (m, 9H), 5.6 (d, 1H, J = 6.5 Hz), 4.7 (d, 1H, J = 6.5 Hz), 3.4 (s, 3H). *Anal.* calcd. for $C_{15}H_{14}O_2$: C 79.62, H 6.24; found: C 79.69, H 6.28.

*Irradiation of 3-phenyl-2,3-benzofuran (**14**a) and 5-methyl-3-phenyl-2,3-benzofuran (**14**b)*

The methanol adducts **15***a* and **15***b cis* and *trans* were formed in good yield (90%) when **14***a* and **14***b* were irradiated under the conditions described above.

*Deuterium exchange experiment with 5-methyl-3-phenyl-2,3-dihydrobenzofuran (**8**b)*

A solution of 5-methyl-3-phenyl-2,3-dihydrobenzofuran (**8***b*) (0.15 g) and 1,4-dicyanobenzene (**3**) (0.10 g, 4.8×10^{-4} mol) in acetonitrile–methanol-O-*d* (1:1) (10 mL) was purged with nitrogen and irradiated for 6 days. Analysis of the photolysate by gc (8% SE-30) indicated the reaction was 20% complete, giving the methanol adducts (**15***b cis* and *trans*). The solvent was evaporated and a sample of unreacted starting material was recovered by prep-gc (5% SE-30). Integration of the ^{1}H nmr spectrum showed that 90% of the proton resonance at 4.57 ppm had exchanged; the other two protons at 4.36 and 4.83 ppm appeared as doublets with a coupling constant J = −8.8 Hz; ^{2}H nmr showed a single peak at 4.5 ppm. There was no evidence for deuterium at any other position; as much as 5% incorporation would have been detected.

*Deuterium exchange experiment with 2-methoxy-5-methyl-3-phenyl-2,3-dihydrobenzofuran (**15**b, cis and trans)*

1. The photolysis mixture consisted of 2-methoxy-5-methyl-3-phenyl-2,3-dihydrobenzofuran **15***b cis* and *trans* (1:1) (0.05 g, 2.1×10^{-4} mol) and 1,4-dicyanobenzene (**3**) (0.01 g, 7.8×10^{-5} mol) in acetonitrile (0.5 mL) – methanol-d_4 (0.2 mL) placed in a Pyrex nmr tube. The solution was purged with nitrogen and irradiated. Progress of the reaction was followed by ^{1}H nmr, integrating the region for the 2-H and 3-H protons of the two isomers. After 4 days of irradiation the ratio of isomers was *cis*:*trans* 20:80. The solvent was evaporated and the isomers were separated by preparative gas chromatography. Analysis of the ^{1}H nmr of the *cis* isomer showed that the 3-H proton (4.65 ppm) was 40% exchanged while the methoxy protons (3.38 ppm) were 23% exchanged for deuterium. The results for the *trans* isomer were 14% exchange of the 3-H proton (4.27 ppm) and 12% exchange of the methoxy protons (3.52 ppm). Integration of the ^{2}H nmr spectra gave similar results; there was no evidence for deuterium incorporation at the 2-H or 5-methyl positions (<5%).

2. The experiment described above was repeated starting with the pure isomers in acetonitrile-d_3 and methanol-d_4 solution. The progress of the reaction was followed by ^{1}H nmr. The degree of isomerization was calculated from the integration of the signals due to the 2-H protons. The extent of deuterium incorporation was assessed by integration of the signals due to the 3-H and methoxy protons in comparison to the signal due to the proton at 2-H, which does not exchange. Integration of the methoxy proton signal was complicated by the overlapping signal due to the residual protons in the methanol. Experimental accuracy was ±5%.

The isomerization of the *cis* isomer was significantly more efficient than that of the *trans* isomer. After irradiating the *cis* isomer for 36 h the ratio of *cis*:*trans* was 80:20, the *trans* product had incorporated 60% deuterium at the 3-H position and 43% deuterium at the methoxy position, while the *cis* isomer had incorporated 20% deuterium at the 3-H position and 11% at the methoxy position. Starting with the *trans* isomer, after 36 h *trans*:*cis* = 95:5; after 80 h *trans*:*cis* = 90:10. The *cis* product incorporated >90% deuterium at the 3-H position and 65% deuterium at the methoxy position, while the *trans* isomer incorporated 16% deuterium at the 3-H and 16% at the methoxy position.

*2-Methoxy-1-phenylindane (**9**, cis and trans)*

Two methods were used for the preparation of these compounds starting with 1-phenylindene (**16**) (23).

Method 1 (4*a*, 15)

A solution of 1-phenylindene (0.50 g, 2.78×10^{-3} mol) and 1,4-dicyanobenzene (0.237 g, 1.85×10^{-3} mol) in acetonitrile (30 mL) – methanol (10 mL) was irradiated in a Pyrex tube at 10°C. After 20 h irradiation, gc analysis showed that reaction was complete. The solvent was evaporated and the product purified by mplc. Both the *cis* and *trans* isomers of **9** were obtained.

cis **9**: ir (PE 180), neat: 3060 (w), 3020 (m), 2920 (m), 2900 (m), 2820 (m), 1600 (w), 1500 (m), 1450 (s), 1105 (s), 1090 (s), 720 (s), 700 (s), 680 (s); ^{1}H nmr (360 MHz) in C_6D_6: 7.15 (m, 9H), 4.18 (d, 1H, J = 6.2 Hz), 3.89 (dd, 1H, J = 6.2 Hz, J = 4.0 Hz, J = 6.0 Hz), 2.87 (dd, 1H, J = 15.7 Hz, J = 4.0 Hz), 3.00 (dd, 1H, J = 15.4 Hz, J = 6.0 Hz), 2.82 (s, 3H).

trans **9**: ir (PE 180), neat: 3060 (w), 3020 (m), 2920 (m), 2900, 2820 (w), 1600 (w), 1500 (m), 1450 (m), 1105 (s), 1090 (s), 730 (s), 680 (s); ^{1}H nmr (360 MHz) in C_6D_6: 6.8 (m, 9H), 4.05 (d, 1H, J = 6.3 Hz), 3.72 (ddd, 1H, J = 6.3 Hz, J = 6.57 Hz, J = 6.60 Hz), 2.77 (dd, 1H, J = 15.7 Hz, J = 6.57 Hz), 2.74 (s, 3H), 2.56 (dd, 1H, J = 15.7 Hz, J = 6.60 Hz).

Method 2 (14)

To a stirred solution of 0.50 M 9-borabicyclo[3.3.1]nonane (9-BBN) (60 mL, 0.03 mol) in tetrahydrofuran under nitrogen purge was added dropwise 1-phenylindene (5.4 g, 0.03 mol). The reaction was then refluxed for 7 h, cooled, and then 20 mL of water was added. To this mixture was added dropwise a solution of sodium hydroxide (4.0 g, 0.10 mol) in water (35 mL), and hydrogen peroxide (15 mL, 30% aq.). This mixture was stirred for 2 h at room temperature and was extracted with diethyl ether. The combined organic layers were washed with water, saturated aqueous sodium chloride, saturated aqueous ammonium chloride, dried over magnesium sulfate, and the solvent evaporated to give a pale yellow liquid (6.7 g). This product was then purified by liquid column chromatography over silica gel, eluting with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

a hexane – diethyl ether gradient to give 3.20 g (0.016 mol, 80%) of *trans*-1-phenyl-2-indanol (**17**); ir (PE 1320), neat: 3340 (b), 3060 (m), 3040 (m), 2940 (s), 2900 (s), 2840 (m), 1600 (w), 1500 (s), 1450 (s), 1055 (s), 725 (s), 680 (s); ^{1}H nmr (EM360L) in $CDCl_3$: 7.2 (m, 9H), 4.4 (m, 2H), 3.1 (m, 3H).

An ethereal solution of the indanol (**17** *trans*) (3.0 g, 0.014 mol) was added dropwise to a stirred suspension of sodium hydride (3.48 g, 0.14 mol) and diethyl ether. Then dimethyl sulfate (3.60 g, 0.03 mol) was added, and the reaction mixture was refluxed for 24 h. The reaction was then poured into iced aqueous hydrochloric acid, and the layers separated. The organic layer was washed with aqueous ammonia (to remove excess dimethyl sulfate), water, and saturated aqueous sodium chloride, dried over magnesium sulfate (anhydrous), and the solvent evaporated. The product was purified by liquid column chromatography using silica gel, eluting with 10% diethyl ether in hexane to give 2.80 g (0.013 mol, 87%) of the methyl ether. The ir (PE 180), neat, was superimposable upon that of *trans* **9** as prepared above. The ^{1}H nmr (60 MHz) in $CDCl_3$ was also identical. *Anal.* calcd. for $C_{16}H_{16}O$: C 85.68, H 7.19; found: C 85.83, H 7.20.

*1-Phenylindane (**18**)*

A solution of 1-phenylindene (2.0 g, 0.01 mol) was stirred under an atmosphere of nitrogen with 0.5 M 9-BBN (25 mL, 0.013 mol) in tetrahydrofuran for 16 h and then refluxed for 6 h. The solvent was removed by rotary evaporation and the residue was dissolved in diglyme (50 mL) and propionic acid (1.2 g, 0.016 mol). This mixture was stirred at room temperature for 4 h and then refluxed for 2 h. The reaction was then quenched by the addition of 1 M sodium hydroxide (100 mL) and pentane (75 mL). The layers were separated and the aqueous layer extracted twice with pentane; the combined organic layers were washed with 50 mL water (5×), dried over anhydrous magnesium sulfate, and the solvent evaporated to give a pale yellow oil. The gc/ms analysis showed a trace amount of starting material present. The olefin in the mixture was oxidized using *meta*-chloroperbenzoic acid in methylene chloride. Subsequent purification by column chromatography over silica gel yielded 1.0 g (0.005 mol, 49.5%) of 1-phenylindane (**18**) as a colourless oil (23); ^{1}H nmr (360 MHz) in $CDCl_3$: 7.2 (m, 9H), 4.31 (dd, 1H, J = 8.215 Hz, J = 8.218 Hz), 3.03 (ddd, 1H, J = −15.73 Hz, J = 3.50 Hz, J = 8.89 Hz), 2.93 (ddd, 1H, J = −15.73 Hz, J = 8.40 Hz, J = 8.14 Hz), 2.56 (dddd, 1H, J = 8.218 Hz, J = 3.50 Hz, J = 8.40 Hz, J = −12.85 Hz), 2.04 (dddd, 1H, J = 8.215 Hz, J = 8.89 Hz, J = 8.14 Hz, J = −12.85 Hz); ms (155°C, 70 eV) m/z: 194 (M^+, 100), 115 (29.6), 91 (9.2).

Irradiation of trans *1-phenyl-2-methoxyindane (**9**)*

1. A solution of *trans* **9** (0.064 g, 2.86×10^{-4} mol) and 1,4-dicyanobenzene (0.018 g, 1.43×10^{-4} mol) in acetonitrile (30 mL) was irradiated through Pyrex at 10°C for 170 h. The reaction progress was monitored by gc/ms. After 170 h no significant reaction was observed, the starting material remaining unconsumed.

2. A solution of *trans* **9** (0.040 g, 1.79×10^{-4} mol) and 1,4-dicyanobenzene (0.015 g, 1.17×10^{-4} mol) in acetonitrile–methanol (1.0 mL, 3:1 ratio) was irradiated at 10°C through Pyrex, and the reaction progress monitored by gc/ms using a Carbowax 20M capillary column. The solution became an amber colour after approximately 20 h irradiation. After 92 h approximately 1.3% conversion to the *cis* isomer of **9** was detected. Irradiation for an additional 100 h did not change the *cis* to *trans* ratio. No other efficient processes were detected.

3. A solution of *trans* **9** (0.040 g, 1.79×10^{-4} mol) and 1,4-dicyanobenzene (0.015 g, 1.17×10^{-4} mol) in acetonitrile-d_3–methanol-O-*d* (1.0 mL, 3:1 ratio) was irradiated at 10°C through Pyrex. After 55 h irradiation deuterium was detected at the methoxy position. Also observed at this time, by ^{2}H nmr, was a deuterium resonance for the methoxy group of the *cis* isomer of **9**. The ratio of the *cis* to *trans* isomers at this time was approximately 1:3; ^{2}H nmr (55.4 MHz) in $CHCl_3$: 3.25 (s), 3.10 (s). After an additional 70 h irradiation the ^{2}H nmr showed a new resonance due to deuterium at the bis-benzylic (C-1) position. The ratio of the *cis* to *trans* isomer at this time was approximately 1:1.85; ^{2}H nmr (55.4 MHz) in $CHCl_3$: 4.12 (s), 3.27 (s), 3.11 (s).

*Irradiation of 1-phenylindane (**18**)*

1-Phenylindane (45 mg, 2.32×10^{-4} mol) and 1,4-dicyanobenzene (15 mg, 1.17×10^{-4} mol) in acetonitrile–methanol-O-*d* (1 mL, 3:1) was placed in a Pyrex tube and was irradiated in a constant temperature bath (10°C). Reaction progress was monitored by ^{1}H nmr, ^{2}H nmr, and gc/ms. After 12 h irradiation the ^{1}H nmr spectrum showed a significant (>90%) reduction in the intensity of the bis-benzylic proton at 4.33 ppm. The ^{2}H nmr spectra, at this time, also showed significant incorporation of deuterium at this position, but little or no (<5%) incorporation of deuterium at the mono-benzylic position (3 ppm).

*3,3-Diphenyltetrahydrofuran (**10**)*

The diester, diethyl-2,2-diphenylsuccinate, was prepared according to the reported synthesis (17*b*) with the exception that anhydrous ether was used instead of DMF. The reduction to form the diol (**21**) was done according to the reported procedure (17*a*). The diol (1.0 g) was then cyclized by refluxing for 1 h with an excess (2–3 mL) of hydrobromic acid (49%). The cooled reaction mixture was diluted with water and the organic layer was extracted with ether, washed with saturated sodium bicarbonate solution, dried over magnesium sulfate, and the solvent was evaporated to yield 80% of the ether (**10**). The product (**10**) was purified by chromatography on silica gel using hexanes and methylene chloride as eluants. The product was recrystallized from 95% ethanol, mp 57–59°C; ir (PE 180), KBr: 3050 (m), 3020 (m), 2980 (m), 2940 (m), 2880 (s), 2840 (s), 1600 (w), 1485 (s), 1440 (s), 1100 (s), 755 (s), 690 (s); ^{1}H nmr (360 MHz) in $CDCl_3$: 7.13–7.27 (m, 10H), 4.28 (s, 2H), 3.91–3.95 (t, 2H, J = 7.0 Hz), 2.51–2.55 (t, 2H, J = 7.0 Hz); ^{13}C nmr (90 MHz) in $CDCl_3$: 145.8, 128.3, 127.4, 126.3, 77.2, 67.1, 55.4, 38.6.

*1-Methoxy-2,2-diphenylcylopentane (**11**)*

The preparation of 2,2-diphenylcyclopentanone (**27**) was previously described (20*b*). The reduction of ketone **27** to the corresponding alcohol was carried out by the reported procedure (20*a*). 2,2-Diphenylcyclopentanol (**28**) (2 g, 0.0084 mol) dissolved in anhydrous ether was added dropwise to a stirred suspension of NaH (2 g, 0.084 mol) in anhydrous ether. After the addition was complete, dimethyl sulfate (3.18 g, 0.025 mol) was added slowly. The mixture was stirred for 1 h and then refluxed overnight. The reaction mixture was poured into water and extracted with ether. The combined organic layers were washed three times with aqueous ammonia, twice with brine, dried (magnesium sulfate), and the solvent was evaporated. The product was purified by vacuum distillation (bp 125°C/0.25 Torr; 1 Torr = 133.3 Pa) and by chromatography using silica gel (Kieselgel 60) with hexanes and methylene chloride as eluants; ir (PE 180), neat: 3080 (m), 3060 (m), 3020 (m), 2980 (b), 2880 (m), 2820 (m), 1600 (s), 1500 (s), 1450 (s), 1100 (s), 750 (s), 685 (s); ^{1}H nmr (360 MHz) in $CDCl_3$: 7.2 (m, 10H), 4.30 (t, 1H, J = 4.5 Hz), 3.29 (s, 3H), 2.5 (m, 2H), 1.8 (m, 4H); ^{13}C nmr (90 MHz) in $CDCl_3$: 147, 146, 128.5, 128, 127.6, 126.8, 125.7, 125.5, 87.1, 57, 56, 35, 28, 20. $E^{ox}_{1/2}$ = 2.13 ± 0.02 V (taken as 0.03 V before anodic peak potential).

*Irradiation of 3,3-diphenyltetrahydrofuran (**10**)*

A solution of **10** (40 mg, 1.8×10^{-4} mol) and 1,4-dicyanobenzene (**3**) (15 mg, 1.1×10^{-4} mol) in acetonitrile was irradiated for 170 h through Pyrex. The reaction was monitored by gc/ms using a methyl silicone column. No major volatile product was observed but the mixture became dark yellow.

A solution of **10** (0.443 g, 1.98×10^{-3} mol) and 1,4-dicyanobenzene (**3**) (0.150 g, 1.17×10^{-3} mol) in acetonitrile–methanol (30 mL; 3:1 ratio) was irradiated for 170 h through Pyrex. The reaction progress was monitored by gc/ms using the 5% phenyl capillary column. In this reaction, **3** was partially consumed. Three minor products were detected but were not isolated. Comparison of their mass spectra with those in the N.B.S. library indicated that they may be benzonitrile, *para*-cyanotoluene, and *para*-cyanobenzyl alcohol.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

The major product of this irradiation was methyl 3,3-diphenylpropyl formaldehyde acetal (**22**). The starting material and product were not separated. The ^{1}H nmr (360 MHz) and ^{13}C nmr (90 MHz) spectra were recorded using the mixture of **10** and the photochemical product. Peaks attributed to **29** were determined by subtraction; ^{1}H nmr (360 MHz) in $CDCl_3$: 7.1–7.2 (m, 10H), 4.54 (s, 2H), 4.13 (t, 1H, J = 7.9 Hz), 3.45 (t, 2H, J = 6.8 Hz), 3.38 (s, 3H), 2.34 (m, 2H); ^{13}C nmr (90 MHz) in $CDCl_3$: 144.4, 128.4, 127.8, 126.1, 96.4, 65.8, 55.1, 47.4, 35.5. The acetal was acid hydrolyzed by heating the mixture dissolved in ethylene glycol with a catalytic amount of *para*-toluenesulfonic acid for 1.5 h. The reaction mixture was poured into saturated sodium bicarbonate solution, extracted with methylene chloride, washed with water, dried (magnesium sulfate), and the solvent was evaporated. The gc/ms (5% phenyl) determined that a small amount of the acetal had been converted to the alcohol, 3,3-diphenylpropanol (**23**). The identity of this product was confirmed by direct comparison with an authentic sample of **23** prepared by the reported procedure (18).

A solution of **10** (0.225 g, 1.0×10^{-3} mol) and **3** (0.124 g, 9.7×10^{-4} mol) in acetonitrile–water (30 mL, 3:1 ratio) was irradiated for 170 h through Pyrex. The reaction progress was monitored by gc/ms (5% phenyl) capillary column. The alcohol, 3,3-diphenylpropanol (**23**), was formed in essentially quantitative yield at 10% conversion. The reaction mixture was separated by column chromatography using silica gel. Comparison of the product with an authentic sample of 3,3-diphenylpropanol (18) established the structure (**23**); ^{1}H nmr (360 MHz) in $CDCl_3$: 7.1–7.3 (m, 10H), 4.11 (t, 1H, J = 7.9 Hz), 3.57 (t, 2H, J = 6.5 Hz), 2.29 (dt, 2H, J = 7.9 Hz, J = 6.5 Hz), 1.63 (br s, 1H); ^{13}C nmr (90 MHz) in $CDCl_3$: 144.5, 128.5, 127.8, 126.2, 61.1, 47.4, 38.3.

*Irradiation of 1-methoxy-2,2-diphenylcyclopentane (**11**)*

A solution of **11** (0.502 g, 1.99×10^{-3} mol) and **3** (0.20 g, 1.6×10^{-3} mol) in acetonitrile–methanol (30 mL, 3:1 ratio) was irradiated at 10°C through Pyrex. The reaction was monitored by gc/ms (5% phenyl) capillary column. After 170 h of irradiation the starting material had been converted to 1,1-dimethoxy-5,5-diphenylpentane (**29**); ^{1}H nmr (360 MHz) in $CDCl_3$: 7.1–7.3 (m, 10H), 4.35 (t, 1H, J = 5.8 Hz), 3.94 (t, 1H, J = 7.7 Hz), 3.31 (s, 6H), 2.12 (dt, 2H, J = 7.7 Hz, J = 10.1 Hz), 1.6 (m, 2H), 1.3 (m, 2H); ^{13}C nmr (90 MHz) in $CDCl_3$: 144.7, 128.1, 127.5, 125.8, 104.2, 52.4, 51.1, 35.3, 32.2, 22.8.

The reaction mixture was dissolved in 75 mL of 3–5% aqueous HCl. Dioxane was added to increase the solubility of the acetal. The mixture was refluxed for 45 min. The aqueous layer was extracted with ether, washed with saturated sodium bicarbonate solution, dried (magnesium sulfate), and the solvent was evaporated to yield 60% (overall from **11**) of the aldehyde, 5,5-diphenylpentanal (**30**). The aldehyde was purified by column chromatography (silica gel); ir (PE233B) in CCl_4: 3080 (m), 3040 (m), 3100 (s), 2960 (b), 2720 (s), 1720 (s), 1600 (m), 1500 (s), 1450 (s), 1030 (m); ^{1}H nmr (360 MHz) in $CDCl_3$: 9.68 (t, 1H, J = 1.4 Hz), 7.1–7.3 (m, 10H), 3.88 (t, 1H, J = 7.0 Hz), 2.4 (dt, 2H, J = 7.4 Hz, J = 7.2 Hz), 2.0 (m, 2H), 1.6 (m, 2H); ^{13}C nmr (90 MHz) in $CDCl_3$: 202.2, 144.5, 128.5, 127.7, 126.2, 51.2, 43.8, 35.1, 20.7.

Received March 24, 1987

JAMES P. JOHNSON, MICHAEL MURCHIE, JACK PASSMORE, MAHMOUD TAJIK, PETER S. WHITE, and CHI-MING WONG. Can. J. Chem. **65**, 2744 (1987).

The crystal structures of the compounds SBr_3AsF_6 (**1**), SeI_3AsF_6 (**2**), SeI_3SbF_6 (**3**), and TeI_3SbF_6 (**4**) are reported and the quantitative preparation of the hitherto unknown **3** and **4** from SbF_5 and the respective elements in SO_2 are given. Crystal data are as follows: **1**, monoclinic, space group $P2_1/c$, with $a = 8.015(1)$ Å, $b = 9.342(1)$ Å, $c = 12.126(2)$, $\beta = 97.81(1)°$, and $Z = 4$; **2**, monoclinic, space group $P2_1/c$, with $a = 8.380(2)$ Å, $b = 10.237(1)$ Å, $c = 12.524(1)$ Å, $\beta = 99.36(1)°$, and $Z = 4$; **3**, monoclinic, space group $P2_1/c$, with $a = 8.548(2)$ Å, $b = 10.297(6)$ Å, $c = 12.877(8)$ Å, $\beta = 98.70(3)°$, and $Z = 4$; **4**, monoclinic, space group $P2_1/c$, with $a = 8.463(1)$ Å, $b = 10.676(2)$ Å, $c = 13.121(4)$ Å, $\beta = 100.05(1)$, and $Z = 4$. Compounds **1**, **2**, **3**, and **4** are isostructural and were refined to a final R values of 0.040, 0.051, 0.047, and 0.037, respectively. The structures of these salts consist of essentially discrete MX_3^+ cations and $M'F_6^-$ anions (M = S, Se, Te; X = Br, I; M′ = As, Sb) with some cation–anion interactions. The SeI_3^+ bond distances and angles were essentially identical in both AsF_6^- and SbF_6^- salts (average Se—I distance and I—Se—I angle for AsF_6^- salt; 2.508(2) Å, 102.4(1)° and for SbF_6^- salt; 2.512(1) Å, 102.3(1)°). Similarly the average Te—I bond distance and I—Te—I angle for TeI_3SbF_6 were 2.666(1) Å and 99.8(1)° which are essentially identical to those in the previously reported TeI_3AsF_6. The average S—Br distance and Br—S—Br angle were 2.142(6) Å and 103.4(2)° in SBr_3AsF_6. Estimates of the S—I bond distance and I—S—I bond angle in the as yet unknown $SI_3M'F_6$ are made from the extrapolation of MX_3^+ data. The bond distances observed in the simple MX_3^+ cations (M = S, Se, Te; X = Cl, Br, I) with anions of very low basicity are within 0.02 Å of the corresponding distances calculated by the Schomaker–Stevenson equation. The observed and estimated bond distances in SBr_3^+, SI_3^+, and SeI_3^+ are significantly longer than the corresponding S—Br, S—I, and Se—I distances in S_7I^+, S_7Br^+, and $Se_6I_2^{2+}$. This observation is used to support the thesis that the long intra-cationic halogen–chalcogen contacts in polychalcogen–halogen cations are weakly bonding, and responsible for the cluster-like nature of these cations. The heats of formation of **1** and **2** from their respective elements and AsF_5 were estimated.

JAMES P. JOHNSON, MICHAEL MURCHIE, JACK PASSMORE, MAHMOUD TAJIK, PETER S. WHITE et CHI-MING WONG. Can. J. Chem. **65**, 2744 (1987).

On a déterminé les structures cristallines des composés SBr_3AsF_6 (**1**), SeI_3AsF_6 (**2**), SeI_3SbF_6 (**3**) et TeI_3SbF_6 (**4**) et on a aussi réalisé la préparation quantitative des composés **3** et **4** (inconnus jusqu'à maintenant) à partir du SbF_5 et de leurs éléments respectifs mis en solution dans du SO_2. Les données cristallographiques sont les suivantes : **1**, monoclinique, groupe d'espace $P2_1/c$ avec $a = 8{,}015(1)$, $b = 9{,}342(1)$ et $c = 12{,}126(2)$ Å, $\beta = 97{,}81(1)°$ et $Z = 4$; **2**, monoclinique, groupe d'espace $P2_1/c$ avec $a = 8{,}380(2)$, $b = 10{,}237(1)$ et $c = 12{,}524(1)$ Å, $\beta = 99{,}36(1)$ Å et $Z = 4$; **3**, monoclinique, groupe d'espace $P2_1/c$ avec $a = 8{,}548(2)$, $b = 10{,}297(6)$ et $c = 12{,}877(8)$ Å, $\beta = 98{,}70(3)°$ et $Z = 4$; **4**, groupe d'espace $P2_1/c$ avec $a = 8{,}463(1)$, $b = 10{,}676(2)$ et $c = 13{,}121(4)$ Å, $\beta = 100{,}05(1)$ et $Z = 4$. Les composés **1**, **2**, **3** et **4** sont isostructuraux et on les a affinés jusqu'à des valeurs finales respectives de R de 0,040, 0,051, 0,047 et 0,037. Les structures de ces sels sont formées essentiellement de cations MX_3^+ et d'anions $M'F_6^-$ discrets (M = S, Se, Te; X = Br, I; M′ = As, Sb) et d'un peu d'interactions cations–anions. Les longueurs des distances et des angles du SeI_3^+ sont essentiellement identiques aux valeurs observées dans les sels de AsF_6^- et de SbF_6^- (distances Se—I et angles I—Se—I moyens : pour le sel de AsF_6^-, 2,508(2) Å et 102,4(1)°, et pour le sel de SbF_6^-, 2,512(1) Å et 102,3(1)°). De la même manière, les moyennes des longueurs des liaisons Te—I et des angles I—Te—I du TeI_3SbF_6 sont respectivement 2,666(1) Å et 99,8(1)°, pratiquement identiques à celles rapportées antérieurement pour le TeI_3AsF_6. Dans le SBr_3AsF_6, les moyennes des distances S—Br et des angles Br—S—Br sont respectivement 2,142(6) Å et 103,4(2)°. En faisant une extrapolation à partir des données relatives aux MX_3^+, on propose des évaluations pour les distances S—I et les angles I—S—I des $SI_3M'F_6$ qui sont inconnus jusqu'à maintenant. Les longueurs des liaisons que l'on a observé dans les cations MX_3^+ simples (M = S, Se, Te; X = Cl, Br, I) associés à des anions de basicité faible sont identiques, à 0,02 Å près, aux distances correspondantes calculées en utilisant l'équation de Schomaker–Stevenson. Les longueurs des liaisons, tant évaluées qu'observées, dans les ions SBr_3^+, SI_3^+ et SeI_3^+ sont beaucoup plus longues que les distances S—Br, S—I et Se—I correspondantes des ions S_7I^+, S_7Br^+ et $Se_6I_2^{2+}$. On utilise cette observation pour supporter la thèse selon laquelle les contacts intra-ioniques halogènes–chalcogènes, qui sont longs dans les cations polychalcogènes–halogènes, provoquent une liaisons faible qui est responsable du fait que ces cations sont pratiquement des agrégats. On a évalué les chaleurs de formation des composés **1** et **2** à partir du AsF_5 et de leurs éléments respectifs.

[Traduit par la revue]

Introduction

The structures of the Group V trihalides both in the gas phase and in the solid state are well established (1). The structures are of interest in terms of the bonding and stereochemistry in these simple molecules, and also of interest in terms of the secondary interactions which are observed in the solid state (1–7). Before the present work was carried out the crystal structures of salts containing most of the isoelectronic Group VI trihalide cations, MX_3^+ (M = S, Se, Te; and X = F, Cl, Br, I) were known, with the exceptions of the SBr_3^+, SI_3^+, and SeI_3^+ salts. The preparation (8, 9), Raman spectra (10), and cell parameters (11) of $SBr_3M'F_6$ (M′ = As, Sb) obtained from X-ray powder data

have been reported. Cell parameters for SeI_3AsF_6 obtained from single crystal data have been obtained, and the volume per formula unit of 257.1 Å^3 was shown to be consistent with the presence of SeI_3^+ and AsF_6^- ions, which were estimated to be 161 Å^3 and 100 Å^3, respectively (12). However, vibrational spectroscopic data for $SeI_3M'F_6$ (M' = As, Sb) are not available. Our attempts to prepare SI_3^+ salts have so far been unsuccessful, although bond distances and angles in the hypothetical SI_3^+, and in SeI_3^+ and SBr_3^+, have been predicted by extrapolation from the structural data for related Group V trihalides and Group VI trihalide cations (11).

Well-determined X-ray crystal structures of SBr_3AsF_6, SeI_3AsF_6, SeI_3SbF_6, and TeI_3SbF_6 are reported below. These are the first structural determinations of salts of the SBr_3^+ and SeI_3^+ cations by X-ray diffraction, and the first structural determination of the SeI_3^+ cation by any method. The X-ray structure of the TeI_3^+ cation, as the AsF_6^- salt, has previously been reported (13). This structural information can be used to obtain a better estimate of the S—I bond distance in the hypothetical SI_3^+ and therefore an estimate of the corresponding sulphur–iodine bond strength. The structures of the SX_3^+ and SeX_3^+ cations (X = Br, I) are of interest, as these are the simplest binary cations which contain the M(IV)$^+$—X (M = S, Se) bond. Therefore they can be used as benchmarks for comparison with corresponding bond distances in more complicated sulphur—bromine, sulphur—iodine, and selenium—iodine cations. These include S_7Br^+ (14), S_7I^+ (15, 16), $(S_7I)_2I^{3+}$ (16), $Se_2I_4^{2+}$ (17), and $Se_6I_2^{2+}$ (18) containing S(IV)$^+$—Br, S(IV)$^+$—I, and Se(IV)$^+$—I covalent bonds. A preliminary report of the selenium—iodine bond distance in SeI_3AsF_6 has been published (17).

Experimental

The apparatus and techniques used in this work are as previously described (9), except where stated. Elemental sulphur (Fisher Scientific), selenium (B.D.H.), tellurium (B.D.H.), iodine (B.D.H.) and AsF_5 (Ozark-Mahoning) were used without further purification. Bromine (Fisher Scientific) was stored over PO_{10} and SbF_5 (Ozark-Mahoning) was triply distilled in a glass vessel prior to use. $Se_4(AsF_6)_2$ and $I_2Sb_2F_{11}$ were prepared by their published procedures described in refs. 19 and 20. SO_2 (Matheson) and AsF_3 (Ozark-Mahoning) were distilled onto, and stored over, CaH_2 and NaF, respectively.

A glass extracting vessel (21), designed to allow continuous extraction of sparingly soluble material from insoluble products by liquid SO_2, was used to separate SeI_3SbF_6 and TeI_3SbF_6 from their reduced products. Single crystals of SeI_3SbF_6, SeI_3AsF_6, TeI_3SbF_6, and SBr_3AsF_6 were mounted and flame sealed in rigorously dried Pyrex capillaries as described in ref. 22.

Infrared spectra were obtained with a Perkin-Elmer 687 spectrometer using AgCl and KBr plates. Nuclear magnetic resonance spectra were recorded unlocked at −80°C with a Varian XL-200 spectrometer using a 10 mm probe (broad-band over the frequency range 20–125 MHz) tuned to 38.164 MHz, to obtain ^{77}Se nmr spectra. ^{19}F nmr spectra were obtained with the same probe using the ^{1}H decoupler coil, retuned to 188.220 MHz, as the observe coil. Typically, ^{77}Se and ^{19}F nmr spectra were accumulated in 32 kwords of memory over a spectral width of 100 kHz (6.1 Hz/data point, line broadening of 5 Hz, acquisition time of 0.16 s) with pulse widths of 20 and 6 μs, in 2000–7000 and 1000–3000 scans, respectively. Samples were prepared in a 10 mm o.d. thick walled nmr tubes fitted with J. Young (O-ringette PTFE stopcock; model BST/2) valves and were referenced externally to $(CH_3)_2Se$ and CCl_3F. Powder X-ray diffraction photographs were obtained from a Philips Debye-Scherrer camera with Straumanis mounting using nickel filtered Cu-Kα radiation. Samples were mounted and flame sealed in 0.5 mm o.d. glass capillary tubes.

Preparation of SeI_3SbF_6

A preweighed quantity of SbF_5 (0.97 g, 4.48 mmol) was condensed onto a mixture of Se (0.20 g, 2.57 mmol), I_2 (1.01 g, 3.98 mmol), and SO_2 (14.34 g) in a glass extracting vessel (21), forming a dark brown solution over a gray–black solid, on warming to room temperature. The mixture was stirred for 1 day, producing a brown–black solution over a dark brown precipitate. The solution and precipitate were poured through the pressure equalizing bridge and placed above the sintered glass frit in the extractor. A brown–black soluble product was separated from a white insoluble solid after 10 min of continuous extraction with SO_2. The volatile material was removed by pumping under dynamic vacuum leaving 1.85 g and 0.34 g of crystalline brown–black soluble and white insoluble solids (calculated weights of SeI_3SbF_6 and $(SbF_3)_3SbF_5$, based on Se, are 1.79 and 0.32 g, according to eq. [1]). The Raman spectrum and X-ray powder diffraction photograph of the insoluble white solid confirmed the presence of $(SbF_3)_3SbF_5$ (23). The infrared spectrum of the brown–black soluble solid gave peaks at 677 w, 640 sh, 620 vs, 608 sh, 526 sh, and 362 m, cm^{-1} consistent with the presence of the SbF_6^- anion (24). A sample of the soluble solid (0.36 g), redissolved in SO_2 (4.35 g), was identified as SeI_3SbF_6 by ^{77}Se and ^{19}F nmr spectroscopy. The chemical shifts were $\delta_{(CH_3)_2Se}$ = 832 ppm (cf. $\delta_{(CH_3)_2Se}(SeI_3^+)$ in SeI_3AsF_6 dissolved in SO_2 = 842 ppm (25)) and δ_{CCl_3F} = −114.6 ppm (cf. $\delta_{CCl_3F}(SbF_6^-)$ in $(CH_3)_3CSbF_6$ dissolved in SO_2ClF = −117.9 ppm (26)).

Brown–black single crystals of SeI_3SbF_6 were obtained in the following reaction. A mixture of SbF_5 (3.47 g, 16.05 mmol) and SO_2 (7.4 g) were poured onto a mixture of Se (0.63 g, 8.03 mmol) and I_2 (3.03 g, 11.95 mmol), in a two-bulbed vessel equipped with a coarse sintered glass frit. A red–brown solution over a dark precipitate was formed after less than 5 min. After 4 days, the red supernatant was filtered into the second bulb of the vessel, leaving behind a brown crystalline material. The solvent was slowly condensed back onto this solid material by cooling the bulb containing the solid material with running tap water (ca. 10°C). After 10 h, a highly crystalline brown product was obtained in the second bulb. The volatile materials were removed by pumping under dynamic vacuum overnight. Several crystals from the second bulb were mounted in capillaries and subsequently identified as SeI_3SbF_6 by X-ray diffraction analysis.

Preparation of TeI_3SbF_6

Tellurium (0.21 g, 1.64 mmol), I_2 (0.66 g, 2.61 mmol), and SbF_5 (0.58 g, 2.66 mmol) in SO_2 (11.50 g) were reacted in an extracting vessel (21) in a manner identical to that described for the quantitative preparation of SeI_3SbF_6. The mixture was stirred for 1 day, producing a dark brown solution over a brown–beige precipitate. A highly brown–yellow soluble solid was separated from a light gray–white insoluble solid, after less than 1 day of continuous extraction with SO_2. The volatile material was removed, leaving a total of 1.42 g of soluble and insoluble solids (total calculated for a 6:1 mixture of TeI_3SbF_6 and $(SbF_3)_3SbF_5$ is 1.39 g according to eq. [1]). Attempts to obtain a Raman spectrum of the gray–white insoluble solid were unsuccessful. However, X-ray powder diffraction photography confirmed the presence of the $(SbF_3)_3SbF_5$ in the reduced product (23). The infrared spectrum of the brown–yellow soluble solid showed peaks at 642 s, sh, 630 vs, and 560 sh, cm^{-1} confirming the presence of the SbF_6^- anion (24).

Single crystals of TeI_3SbF_6 were obtained by the following reaction. A solution of $I_2Sb_2F_{11}$ (0.54 g, 0.77 mmol) in liquid SO_2, (5.20 g) was poured onto elemental Te (0.20 g, 1.57 mmol) in a two-bulbed vessel equipped with a coarse sintered glass frit. A brown solution over a dark solid was observed after less than 5 min. After 3 days, a brown transparent solution was filtered into the second bulb, leaving behind a dark brown solid. Red–black crystalline plates were formed under the transparent brown solution after standing at room temperature for 1 week. The solvent was decanted into the first bulb, and the volatile materials were removed by pumping under dynamic vacuum. Several of the red–black crystals were mounted in capillaries, and were subsequently identified as TeI_3SbF_6 by X-ray diffraction analysis.

Preparation of SeI_3AsF_6

A detailed account of the quantitative preparation of SeI_3AsF_6 has been reported in ref. 12.

Single crystals of SeI_3AsF_6, used in the X-ray crystal structure determination, were obtained in the following reaction. $Se_4(AsF_6)_2$ (0.68 g, 0.97 mmol) and I_2 (0.50 g, 1.96 mmol) were reacted in AsF_3 (6.36 g) in a two-bulbed vessel equipped with a coarse sintered glass frit. A red–brown solution over unreacted I_2 was noted after 10 min. After 1 day, the I_2 appeared to have completely reacted. The solution was very slowly concentrated (approximately 2 weeks) by condensing the solvent into the second bulb which was held at ~10°C, producing a black crystalline solid under a viscous red–brown solution. On removal of the volatile material, the red–brown solution became a tarry froth. Examination of the product in the dry box revealed that it was a mixture of small black crystals and a red–brown paste. Several of the black crystals were mounted in glass capillaries and shown to be SeI_3AsF_6 by X-ray diffraction analysis. The paste was not identified.

Preparation of SBr_3AsF_6

The quantitative preparation of SBr_3AsF_6 has been previously described (8, 9). Single crystals of SBr_3AsF_6 were obtained in the following reaction. AsF_5 (2.35 g, 13.8 mmol) was condensed onto a mixture of S_8 (0.296 g, 1.15 mmol), Br_2 (2.21 g, 13.8 mmol), and SO_2 (7.52 g) in a two-bulb vessel equipped with a course sintered glass frit. A reddish-orange solution was formed with no precipitate, on warming to room temperature. The solution was cooled to 10°C for 5 min, which resulted in the formation of a yellow microcrystalline precipitate. The reddish-orange solution above the precipitate was filtered into the second bulb. The solvent was slowly (2 days) condensed back into the first bulb, producing a large quantity of yellow–orange crystals in the other bulb which was at room temperature. The crystals were then held at 0°C while the volatile materials were removed. The total yield of the solid material in both bulbs was 4.20 g (calculated for SBr_3AsF_6 based on sulphur is 4.25 g). Several crystals from the second bulb were quickly mounted in the dry box. The crystals were stored at −20°C prior to X-ray analysis. One of the crystals was identified as SBr_3AsF_6 by single crystal X-ray diffraction analysis. The X-ray powder photograph of the crystals corresponded to that reported previously (11).

In contrast to solid SeI_3AsF_6, SeI_3SbF_6, and TeI_3SbF_6, which appear to be stable at room temperature when stored under dry nitrogen, solid SBr_3AsF_6 slowly gives off bromine (8) under these conditions. It does appear to be stable at −20°C and in sulphur dioxide solution. Previous attempts to obtain single crystals of SBr_3AsF_6 were unsuccessful. The difference between this and earlier work appear to be that in this work a more dilute solution was used, the crystals were held at 0°C while the volatiles were removed, and the crystals were mounted quickly and stored at −20°C.

Single crystal X-ray diffraction studies

Crystals were examined in a dry box filled with dry nitrogen using a Wild M3 microscope of long focal length mounted outside the box. A number of crystals were flame sealed in rigorously dried capillary tubes and specimens for further study were selected on the basis

of X-ray diffraction photographs. Initial cell dimensions and crystal symmetry were established by precession photography after which the crystals were mounted on either a Picker FACS-I or an Enraf-Nonius CAD-4 diffractometer, both of which were equipped with graphite monochromated MoKα radiation. After alignment, intensity data were collected using ω–2θ scans, full details of the data collection parameters and other crystallographic information for each crystal are given in Table 1. The intensity data were averaged and reduced to structure factors using the routine DATRD2 (27).

Although the compounds are isostructural with TeI_3AsF_6 and $TeBr_3AsF_6$ it was found necessary to redetermine each structure using the MULTAN-80 suite of programs (28). The program SHELX-76 (29) was used for least-squares refinement. None of the four crystals had a well-defined shape, making an analytical absorption correction difficult, so after refinement of the structures with isotropic thermal parameters, the empirical absorption correction, DIFABS, of Walker and Stuart (30) was applied to the unaveraged data. Final cycles of least squares were performed with all atoms assigned anisotropic thermal parameters. Final atomic coordinates are given in Table 2.[1] All computations were performed on a Wicat Systems microcomputer using local implementations of the software.

Discussion

Preparation of SBr_3AsF_6, SeI_3AsF_6, SeI_3SbF_6, TeI_3SbF_6

This is the first report of the preparations of SeI_3SbF_6 and TeI_3SbF_6. The preparations of SBr_3^+, SeI_3^+, and TeI_3^+ cations as salts of the AsF_6^- anion have been reported earlier (8, 9, 12, 13). SeI_3SbF_6 and TeI_3SbF_6 were prepared essentially quantitatively from the respective chalcogen, iodine, and antimony pentafluoride in liquid sulphur dioxide solution according to reaction [1].

$$[1]\quad 6M + 9X_2 + 10SbF_5 \xrightarrow{SO_2} 6MX_3SbF_6 + (SbF_3)_3SbF_5$$
(M = Se, Te, X = I; and M = S, X = Br)

SBr_3SbF_6 has also been prepared quantitatively in a similar manner, although the reduced product was not known to be $(SbF_3)_3SbF_5$ at that time (8). Reaction [1] likely represents a general route to the preparations of the hexafluoroantimonate salts of the Group VI trihalide cations with the exception of SI_3^+.

SBr_3AsF_6 and SeI_3AsF_6 may be readily prepared quantitatively from the respective chalcogen, halogen, and arsenic pentafluoride in liquid sulphur dioxide according to reaction [2], or with an excess of arsenic pentafluoride.

$$[2]\quad 2M + 3X_2 + 3AsF_5 \xrightarrow{SO_2} 2MX_3AsF_6 + AsF_3$$
(M = S, Se, Te; X = Br, I (except for SI_3^+), and likely Cl)

$SBr_3M'F_6$ (M′ = As, Sb) have been identified in solution and in the solid state by Raman spectroscopy (8, 10). The cell parameters of SBr_3AsF_6 obtained from X-ray powder photographs (11) are similar to those obtained from single crystals and the composition of the bulk material is therefore SBr_3AsF_6. Vibrational spectroscopic data for the SeI_3^+ and TeI_3^+ cations in $SeI_3M'F_6$ and $TeI_3M'F_6$ have not been reported. However, SeI_3AsF_6 and SeI_3SbF_6 have been identified in solution by ^{77}Se nmr spectroscopy (ref. 25 and this work). $TeI_3M'F_6$ are sparingly soluble in sulphur dioxide and therefore is not readily identified in solution by ^{125}Te nmr. The Group VI trihalide cations are of interest in their own right, and in addition are potentially useful reagents (31) in the synthesis of novel chalcogen–halide cations, e.g. in the synthesis of $Se_6I_2^{2+}$ and $Se_4I_4^{2+}$ according to reactions [3] and [4].

$$[3]\quad 2SeI_3^+ + 2Se_8^{2+} \xrightarrow{SO_2} 3Se_6I_2^{2+}$$

$$[4]\quad 4SeI_3^+ + Se_8^{2+} \xrightarrow{SO_2} 3Se_4I_4^{2+}$$

[a]All interactions less than the sum of van der Waals' radii are included (r_S = 1.85, r_{Se} = 2.00, r_{Te} = 2.20, r_{Br} = 1.95, r_I = 2.15, and r_F = 1.35 Å, ref. 48).
[b]Reference 13.
[c]M = S, Se, and Te; M′ = As and Sb; and X = Br and I.
[d]Sum of bond valences of the M---F contacts (valence unit, v.u.). Bond valence in valence unit (v.u.), $S = (R/R_0)^{-N}$, ref. 6, where R is the observed bond distance (Å), R_0 = 1.550, N = 3.8 for S(IV)—F, R_0 = 1.71, N = 4.0 for Se(IV)—F, and R_0 = 1.779, N = 3.5 for Te(IV)—F.
[e]In these cases the bond distances are longer than the sum of the corresponding van der Waals' radii.

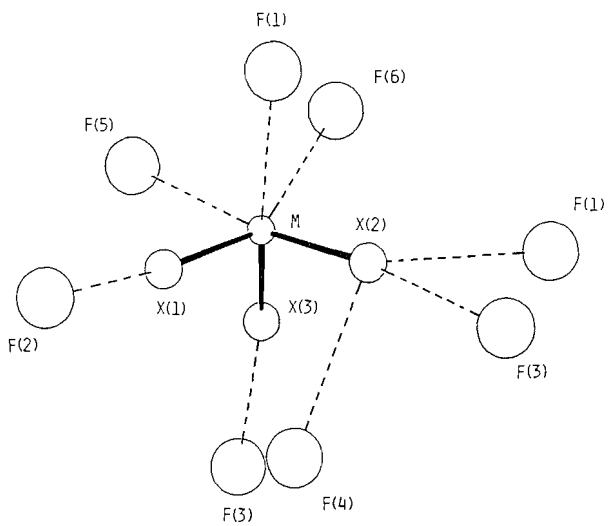

FIG. 1. MX_3^+ cation (M = S, Se, Te; and X = Br, I) with anion contacts. Corresponding bond distances and angles are listed in Tables 3 and 4. S—F(1) in SBr_3AsF_6, Se—F(1) and I(2)—F(4) in SeI_3AsF_6, I(2)—F(4) in SeI_3SbF_6, and I(2)—F(3) in TeI_3SbF_6 are longer than their corresponding sum of Van der Waals' radii.

TeI_3SbF_6 salts consist of discrete MX_3^+ cations (M = S, Se, Te; and X = Br, I), and $M'F_6^-$ anions (M′ = As, Sb) with definite cation–anion interactions. Figure 1 shows the MX_3^+ cation with anion contacts; corresponding bond distances and angles are presented in Tables 3 and 4. The SBr_3AsF_6, SeI_3AsF_6, SeI_3SbF_6, and TeI_3SbF_6 salts are isostructural with $TeBr_3AsF_6$ and TeI_3AsF_6. The packing in all these compounds are similar to that in $TeBr_3AsF_6$ which has been illustrated in ref. 11.

The geometry of the SBr_3^+, SeI_3^+, and TeI_3^+ cations

The SBr_3^+, SeI_3^+, and TeI_3^+ cations are of approximately C_{3v} symmetry. The average bond distances and angles in the SBr_3^+ cation are 2.142(6) Å and 103.4(2)°, those of the SeI_3^+ cation in both AsF_6^- and SbF_6^- salts (2.508(2) Å, 102.4(1)° and 2.512(1) Å, 102.3(1)°, respectively) are essentially identical. The average bond distance and angle of TeI_3^+ cation in SbF_6^- salt (2.666(1) Å, 99.8(1)°) are also identical to those in the AsF_6^- salt (2.667(1) Å, 99.9(3)°) (13). For Group VI trihalide cations with counterions of very different basicity, the more basic the counterion, the longer the chalcogen halide bond, e.g. the average $SeCl_3^+$ distance in $SeCl_3MoOCl_4$ is 2.148(2) Å (32), longer than those in the less basic $AlCl_4^-$ and $SbCl_6^-$ salts, $SeCl_3AlCl_4$ (2.11(1) Å) (33) and $SeCl_3SbCl_6$ (2.10(1) Å) (34). Presumably the more basic anion donates electron density into the antibonding σ* orbitals of the cation more effectively, leading to chalcogen–halide bond lengthening (2, 34). Clearly, the difference in basicity of the AsF_6^- and SbF_6^- anions is not sufficiently large to affect the geometry of the SeI_3^+, TeI_3^+, or $TeCl_3^+$ cations (Table 5), or alternatively the differences in geometry are too small to be detected by our experiments. Consistently, the vibrational data of the SBr_3^+ cation for both the AsF_6^- and the SbF_6^- salts are also very similar (8, 10).

All the chalcogen–halogen bond distances in the MX_3^+ salts of very weakly basic anions, including those in SBr_3^+, SeI_3^+, and TeI_3^+, are within 0.02 Å of the corresponding distances calculated by the Schomaker–Stevenson equation (35). The exceptions are the M—F bonds in MF_3^+ (M = S, Se, Te) which are ~0.10 Å shorter than the values calculated by the Schomaker–Stevenson equation (Table 6). However, it is well-known that bond distances of related perfluoro compounds

For personal use only.

are also shorter than the corresponding distances calculated by the Schomaker–Stevenson equation, e.g. PF_3 (36), CF_4 (37), and SiF_4 (38) (observed bond distances 1.570(1), 1.32, and 1.56(1) Å; calculated bond distances, 1.66, 1.36, and 1.70 Å, respectively; see Table 6). The agreement of the observed bond distances in the known MCl_3^+, MBr_3^+, and MI_3^+ (M = S, Se, Te) cations with the corresponding values calculated by the Schomaker–Stevenson equation is within 0.02 Å. This is remarkable in view of the fact that the Schomaker–Stevenson equation utilizes covalent radii and electronegativity values for neutral dico-ordinate chalcogens (i.e. (M(II)), whereas the central atoms in the MX_3^+ salts are all positively charged with a formal valence of IV. However, the M—X bond distance in the MX_3^+ cation are slightly shorter than those in the related M[II] compounds (e.g. SCl_3^+, 1.970; SCl_2 (39), 2.014(5); CF_3SCl (40), 2.015(3); SBr_3^+, 2.142(8); CF_3SBr (41), 2.162(6); $SeCl_3^+$, 2.10(1); $SeCl_2$ (42), 2.157(3) Å).

The small variations of the bond angles (X—M—X) within the SBr_3^+, SeI_3^+, and TeI_3^+ are consistent with VSEPR theory (5), i.e. the longer the adjacent bonds, the smaller the corresponding angles (Tables 3 and 4).

The SBr_3^+, SeI_3^+, and TeI_3^+ cations all can be regarded as having AX_3E tetrahedral geometry in VSEPR terms (5) with the lone pair of electrons, E, occupying one of the vertices. The structures of SBr_3^+, SeI_3^+, and TeI_3^+ cations are very similar to those of their isoelectronic counterparts, PBr_3 (43), AsI_3 (44), and SbI_3 (45) in the solid state. The shorter bond distances and slightly larger angles in Group VI trihalide cations (SBr_3^+, 2.142(8) Å, 103.4(2)°; SeI_3^+, 2.510(2) Å, 102.4(1)°; and TeI_3^+, 2.667(1) Å, 99.9(3)°) than those in Group V trihalides (PBr_3(s), 2.213(4) Å, 100.5(2)° (43); AsI_3(s), 2.591(1) Å, 99.67(5)° (44); and SbI_3(s), 2.87(1) Å, 95.8(3)° (45)) are consistent with the greater charge and smaller size of the formerly positively charged sulphur, selenium, and tellurium atoms.

The variation of bond angles in group VI trihalide cations

The average bond angles (X—M—X) in the Group VI trihalide cations, MX_3^+, decreases as the electronegativity of M decreases (S → Te) and as the electronegativity of the ligand X increases (I → F) as shown in Table 5 and consistent with VSEPR theory (5). Alternatively, the bond angle variations can be understood in terms of relative size, e.g. the larger the halogen, X, the larger the X—M—X angle (46, 47). The observed angles are consistent with both models except for the angle in $SeCl_3^+$ in $SeCl_3SbCl_6$ (see Table 5), which appears to be too large.

Cation–anion interactions

Table 4 includes all cation–anion contacts that are less than the sum of the appropriate van der Waals radii (48). There are two to three fluorine cation–anion contacts, M---F (M = S, Se, Te), to the central atoms of the MX_3^+ cations. In terms of

VSEPR model, these contacts are grouped around the lone pair electrons of the MX_3^+ cation. With inclusion of the M---F contacts, the overall geometry around the sulphur and selenium atoms can be described as AX_3Y_2E in SBr_3AsF_6 and SeI_3AsF_6 and AX_3Y_3E around the selenium and tellurium atoms in SeI_3SbF_6 and TeI_3SbF_6. Various overall geometries including the more complicated $AX_3Y_3Y'E$, $AX_3Y_3Y'_2E$, $AX_3Y_3Y'_3E$, and AX_5Y_4E of the central atoms in other Group VI trihalide cations have been observed and discussed (34). The strength of the M---F contacts can be assessed by the relative magnitude of the bond valences, as defined by Brown (6). The sum of the bond valences of the M---F contacts, listed in Tables 3 and 5, increases as the electronegativity of the ligand, X, increases or the electronegativity of the central atom, M, decreases. This is consistent with the charge being more localized on the trico-cordinate atom, as the differences in electronegativity between M and X increase.

Contacts between X and the anionic fluoride (or chloride) are not common in Group VI trifluoride and trichloride cations. However, significant X---F contacts have been observed in $SeBr_3SbF_6$, $TeBr_3AsF_6$, and TeI_3SbF_6. These contacts are also observed in SBr_3AsF_6, SeI_3AsF_6, SeI_3SbF_6, and TeI_3AsF_6, and are consistent with the higher polarizability and more electropositive nature of Br and I. Consistently, the weaker M---F contacts in the tribromide and triiodide cations lead to more and/or stronger X---F contacts (see Table 3). The weak M---F contacts and the relatively strong X---F contacts in SBr_3^+ and SeI_3^+ can be attributed to the similarity in electronegativity of M and X ($\chi_S = 2.58$, $\chi_{Se} = 2.55$, $\chi_{Br} = 2.96$, $\chi_I = 2.66$ (49)). Thus the positive charge is more delocalized in SBr_3^+ and SeI_3^+ than in the other MX_3^+ cations.

A prediction of the geometry of SI_3^+ in the non-existent $SI_3M'F_6$ ($M' = As, Sb$)[2]

An estimate of bond distances and angles in MX_3^+ cations, for which structures were unknown, were determined by extrapolation of known data from Group V trihalides and Group VI trihalide cations (11). The estimated bond distances and angles for SBr_3^+, SeI_3^+, and TeI_3^+ deviated (~0.02 Å and 1°) from the values obtained in the present work and for TeI_3^+ in TeI_3AsF_6 (13).[3] A more accurate fit is desirable, and in addition the method cannot give an accurate estimate of the S—I distance in $SI_3M'F_6$, as the method relies on the structural determination of the isoelectronic Group V trihalide (PI_3) in the gas phase, for which an accurate structure is not available

[2]Various attempts to prepare solid $SI_3M'F_6$ in our laboratory led in all cases to $S_2I_4(MF_6)_2 + I_2$ solids (19, 51).

[3]SBr_3^+, estimated 2.164(5) Å, 101.1(9)°, observed 2.142(6) Å, 103.4(2)°; SeI_3^+, estimated 2.492(5) Å, 101.0°, observed 2.510(2) Å, 102.4(1)°; TeI_3^+, estimated 2.650 Å, 99.2°, observed 2.667(2) Å, 99.9(2)°.

[a]Data from the available salts containing the anions of lowest basicity are used.
[b]From Schomaker–Stevenson equation (35): Schomaker–Stevenson distance for M—X = $r_m + r_x - 0.09|\chi_m - \chi_x|$(Å) where r_m and r_x are the covalent radii (35) and χ_m and χ_x are Pauling's electronegativities (49).
[c]Average values of the two salts are used.

(P—I distance in PI_3(g) = 2.43(3) Å (50)). We have therefore developed another approach using only the data for the known Group VI trihalide cations of low basicity. The differences in bond distance, i.e. d(M—I) − d(M—Br), d(M—Br) − d(M—Cl), d(M—Cl) − d(M—F), in the appropriate cations are essentially constant as shown in Table 6. The S—I bond distance in $SI_3M'F_6$ can therefore be estimated as equal to the S—Br distance in SBr_3^+ plus the average of (d(M—I) − d(M—Br)) and equals to 2.38(1) Å. The accuracy of all the structures is high, which lends confidence to the estimation. The chalcogen–iodine distances calculated by the Schomaker–Stevenson equation are 0.02 Å shorter than the observed or estimated distances in SI_3^+, SeI_3^+, and TeI_3^+. This consistency supports the estimation of the S—I distance in SI_3^+ as 2.38(1) Å.

The ratio of d(Br—Br)/d(I—I), d(Cl—Cl)/d(Br—Br), and d(F—F)/d(Cl—Cl) in corresponding pairs of MX_3^+ cations are essentially constant (Table 6). Therefore the I—I separation in the hypothetical SI_3^+ cation is estimated as (Br—Br separation in SBr_3^+)/0.896 = 3.752 Å, leading to a predicted angle of 104(2)°.

A comparison of the chalcogen–halide bond distances in SBr_3^+ and that estimated for SI_3^+ with the chalcogen–halide distances in the binary polychalcogen–halogen cations

Recently, a number of novel binary sulphur and selenium–iodine cations, including S_7I^+ (15, 16), $(S_7I)_2I^{3+}$ (16), $S_2I_4^{2+}$ (51), $Se_2I_4^{2+}$ (17), $[Se_6I]_n^{n+}$ (52), and $Se_6I_2^{2+}$ (18), and the sulphur—bromine cation, S_7Br^+ (14), have been prepared and structurally characterized. The iodine and bromine atoms form formally single covalent bonds with the positively charged trico-ordinate sulphur and selenium atoms in these cations except in $S_2I_4^{2+}$ and the polymeric $[Se_6I]_n^{n+}$ cations. A major motivation for this work was to accurately determine the structures of SBr_3^+, SeI_3^+, and estimate that of SI_3^+, in order to compare the "bench mark" chalcogen—halogen bond distances in these simple cations, with those in the more complex cations. In this way it was hoped to aid in a better understanding of the geometry and bonding in these novel polychalcogen–halogen cations. Such a comparison is given in Table 7.

The M—X (M = S, Se; X = Br, I) bond distances in S_7Br^+, S_7I^+, $(S_7I)_2I^{3+}$, $Se_2I_4^{2+}$, and $Se_6I_2^{2+}$ cations are all significantly shorter (Table 7) than the corresponding bond distances

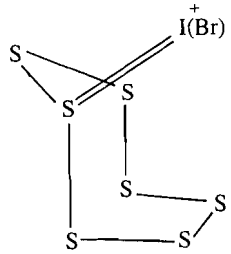
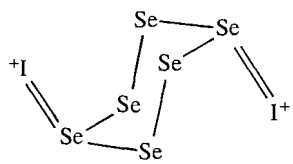
[d]The S—I interaction is via a π^*—π^* bond. An average value is quoted.

in the Group VI trihalide cations. The shorter Se—I bond in $Se_2I_4^{2+}$ relative to that in SeI_3^+ has been attributed to the presence of π-bonding which results in a formal bond order of 1.25 per Se—I bond (17). The exocyclic chalcogen—halogen bonds in the other binary polychalcogen—halogen cation are also shorter than those in the corresponding simple chalcogen trihalide cations, MX_3^+ (Table 7). This suggests that they may also have some π-bonding character. It is conceivable that there is some π-bonding in MX_3^+ themselves, but this will be spread over three bonds, and will be less than that in the one chalcogen—halogen bond in the polychalcogen—halogen cations. Thus the shorter exocyclic M—X bonds in the binary polychalcogen—halogen cations may arise from some localisation of the positive charge onto the exocyclic halogen atoms and therefore some contribution to the overall structure by valence bond structures **I** and **II** for $S_7I(Br)^+$ and $Se_6I_2^{2+}$ respectively.



I



II

Although the contribution from valence bond structures **I** and **II** may be small, the I(Br)---F interionic contacts in these cations are significant (d(I---F) for S_7ISbF_6, 2.926(9) Å (15); for $Se_6I_2(AsF_6)_2.2SO_2$, 3.16(1) and 3.17(1) Å (18); the sum of van der Waal's radii is 3.50 Å) and consistent with some positive charge localisation on the exocyclic halogen atoms. The trico-ordinate chalcogen atom presumably carries the greatest positive charge, and in addition there will be charge delocalisation into the ring giving rise, in part, to the observed chalcogen–chalcogen bond distance alternation in the ring.

The exocyclic halogen atoms in the $S_7I(Br)^+$ and $Se_6I_2^{2+}$ cations adopt the *endo*-configuration (**III***a* and **VI***a*) and form the weak, but definite, intra-cationic contacts (e.g. d(I---S(6)) for S_7ISbF_6(15), 3.394(3) Å; d(I—Se(1′)) and d(I—Se(3′)) for $Se_6I_2(AsF_6)_2.2SO_2$(18), 3.719(2) and 3.709(2) Å; where the sum of van der Waals' radius is 4.00 Å for S—I and 4.15 Å for Se—I). Presumably the intra-ionic contacts reflect attraction (weakly bonding or electrostatic), or the sterically less hindered isomer **III***b* and **IV***b* would be preferred. In $S_7I(Br)^+$ (**III***a*), the I(Br)S(1)S(7)S(6) atoms lie in a plane, which is at 90.2° to the S(4)S(5)S(6)S(7) plane and is reminiscent of the planar I_4^{2+} cation (53) and the S_2I_2 units in $S_2I_4^{2+}$ cations (51), both of which contain dimers joined by π^*—π^* bonds. The electron density in the π^* antibonding orbital of the exocyclic chalcogen—halogen bond may be delocalised into the ring through I(Br)---S(6) interactions. This then would lead to a reduction of π^* electron density in the I(Br)—S(6) bond, and therefore an increase in π bonding and corresponding decrease in bond length. A similar situation can hold in $Se_6I_2^{2+}$. Thus the relatively short exocyclic chalcogen—halogen bonds in the

SeI_3^+(g) + AsF_6^-(g) → SeI_3AsF_6(s)	−123 ± 5	*e*
SBr_3^+(g) + AsF_6^-(g) → SBr_3AsF_6(s)	−128 ± 5	*e*

[a]The S—I bond energy in SI_2 was calculated to be 47.5 kcal mol^{-1} by Sanderson (66), assuming d(S—I) = 2.37 Å (sum of nonpolar covalent radii). This is similar to the experimental S—I bond energy of 49.4 ± 2 kcal mol^{-1} in H(S—I) (67). The Se—I bond energy in SeI_2 was calculated to be 41.2 kcal mol^{-1} by using Sanderson's approach (assuming d(Se—I) = 2.50 Å, sum of nonpolar covalent radii). Johnson (68) estimated the Se—I bond energy in SeI_2 to be 42 kcal mol^{-1}. No experimentally determined Se—I bond energy is available. In order to keep the estimations of the heat of formations consistent, the calculated bond energies in SI_2 and SeI_2 by Sanderson are used (i.e. D(S—I) = 47.5 and D(Se—I) = 41.2 kcal mol^{-1}).

[b]The sublimation energies are expected to be similar to those of SiI_4 (69), PI_3 (65, 69), and CII (70) (18, 15, and 13 kcal mol^{-1}, respectively) for SI_2, and to those of GeI_4 (65), AsI_3 (70), and BrI (65) (20, 23, and 12 kcal mol^{-1}) for SeI_2. Thus, the sublimation energies of SI_2 and SeI_2 are estimated to be 15 and 20 kcal mol^{-1}, respectively.

[c]The heat of reaction for the formation of $2AsF_6^-$(g) and AsF_3(g) may be estimated as follows:

Reaction	ΔH
As(s) + (3/2)F(g) → AsF_3(g)	−187.8 (ref. 65)
AsF_5(g) → As(s) + (5/2)F_2(g)	295.6 (ref. 71)
F_2(g) + $2e^-$ → $2F^-$(g)	−119 (ref. 71)
$2AsF_5$(g) + $2F^-$(g) → $2AsF_6^-$(g)	−222 (refs. 72, 73)
$3AsF_5$(g) + $2e^-$ → $2AsF_6^-$(g) + AsF_3(g)	−233 kcal mol^{-1}

[d]The atomization energies of SeI_3^+(g) and SBr_3^+(g) were estimated from the sums of the respective bond dissociation energies. It is reasonable to assume that the Se(IV)$^+$—I and S(IV)$^+$—Br bond energies are similar to the energies of iodine bonded to neutral Se(II) and bromine bonded to neutral S(II), respectively, because the M(IV)$^+$—X bond lengths are similar to those in M(II)—X (Schomaker–Stevenson distances, Table 6). The Se(IV)$^+$—I and S(IV)$^+$—Br bond strengths can therefore be considered to be similar to the Se(II)—I bond in SeI_2 (41.2 kcal mol^{-1}, footnote *a*) and S(II)—Br bond in S_2Br_2 (56 kcal mol^{-1}, calculated by Sanderson (66)). Thus, the atomization energies for SeI_3^+(g) and SBr_3^+(g) are as follows:

$$SeI_3^+(g) \rightarrow Se^+(g) + 3I(g) \qquad \Delta H = 3(41.2) = 124 \text{ kcal mol}^{-1}$$

$$SBr_3^+(g) \rightarrow S^+(g) + 3Br(g) \qquad \Delta H = 3(56) = 168 \text{ kcal mol}^{-1}$$

On the other hand, it can be argued that the bond dissociation energies are higher than this because bond cleavage is accompanied by charge delocalisation on the chalcogen. Thus the estimated bond dissociation energies are in fact lower limits of the actual values.

[e]Bartlett and co-workers (72, 73) have shown that there is an essentially linear relationship, for simple A^+B^- salts (e.g. NaCl, KBr, KI) between the lattice energies and (molecular volume)$^{1/3}$, where the equation of the line may be represented by ΔU = (556.3(molecular volume)$^{-1/3}$ + 26.3) kcal mol^{-1}. Therefore the crystal lattice energies of SeI_3AsF_6 and SBr_3AsF_6 (molecular volumes are 265 and 225 Å^3, respectively) are estimated as 113 ± 5 kcal mol^{-1} and 118 ± 5 kcal mol^{-1}. However, Bartlett and co-workers noted that for species such as ClO_2BF_4 and SF_3BF_4, there was a positive deviation (~6–8 kcal mol^{-1}) from the line, which was attributed to the dispersion energies of these salts being greater than those of the simple salts (e.g. NaCl, KBr). A conservative estimate of 10 kcal mol^{-1} has been used for the positive deviation of SeI_3AsF_6 and SBr_3AsF_6, and, therefore, ΔU (corrected) for SeI_3AsF_6 and SBr_3AsF_6 are estimated as 123 ± 5 kcal mol^{-1} and 128 ± 5 kcal mol^{-1}, respectively. A more sophisticated treatment would give improved estimates of the dispersion energies of SBr_3^+ and SeI_3^+, which are undoubtedly greater than those of ClO_2^+ or SF_3^+.

polychalcogen—halogen cations support the thesis that the long intracationic contacts are bonding in nature and responsible for the cluster-like geometries of this and related cations and molecules. It is likely that both the localisation of the positive charge onto the halogen atom (resonance structures **I** and **II**) and the delocalisation of the π^* electron density in the M—X bond onto the chalcogen ring both contribute to the shortening of the exocyclic M—X bond.

The AsF_6^- and SbF_6^- anions

The average M′—F distances and F—M′—F angles (M′ = As, Sb) in $SBrAsF_6$ (1.70(1) Å, 90.0(8)°), SeI_3AsF_6 (1.71(1) Å, 90.0(8)°), SeI_3SbF_6 (1.87(1) Å, 89.9(5)°), and TeI_3SbF_6 (1.87(1) Å, 90.0(5)°) are similar to those in $TeBr_3AsF_6$ (1.86(4) Å and 90(2)°) and $SeBr_3SbF_6$ (1.71(1) Å, 90.0(7)°). The AsF_6^- and SbF_6^- anions have distorted octahedral geometry as a result of the cation—anion contacts. A correlation between the M′—F bond distances and cation—anion contact distances is not observed.

The thermodynamic stability of SBr_3AsF_6 and SeI_3AsF_6

The neutral binary sulphur and selenium iodides are unstable and were once considered to be non-existent (54). Since then S_2I_2 has been prepared and characterized at −90°C (55, 56), and SI_2 has been detected at −246°C (57). Neutral binary selenium iodides remain uncharacterized (58). The heat of formation of $SI_2(s)$ and $SeI_2(s)$ according to reactions [5] and [6] are estimated to be positive, i.e. $SI_2(s)$ and $SeI_2(s)$ are unstable with respect to the elements. Entropy considerations further favour the elements rather than the binary iodides.

[5] $(1/8)S_8(s) + I_2(s) \rightarrow SI_2(s)$

$$\Delta H(\text{eq. [5]}) = \Delta H(\text{Atom.E., S(g)}) + 2\Delta H(\text{Atom.E., I(g)}) - 2D(\text{S—I}) - \Delta H(\text{Subl.E., } SI_2(g))^4$$
$$= 66.6 + 51 - 95 - 15$$
$$= 8 \text{ kcal mol}^{-1}$$

[6] $Se(\text{hexagonal}) + I_2(s) \rightarrow SeI_2(s)$

$$\Delta H(\text{eq. [6]}) = \Delta H(\text{Atom.E., Se(g)}) + 2\Delta H(\text{Atom.E., } I_2(g)) - 2D(\text{Se—I}) - \Delta H(\text{Subl.E., } SeI_2(g))$$
$$= 54 + 51 - 82 - 20$$
$$= 3 \text{ kcal mol}^{-1}$$

The heat of reaction [7] accompanying the formation of $SeI_3AsF_6(s)$ is estimated to be about -24 kcal mol^{-1}.

[7] $2Se(\text{hexagonal}) + 3I_2(s) + 3AsF_5(g) \rightarrow 2SeI_3AsF_6(s) + AsF_3(l)$

$$\Delta H(\text{eq. [7]}) = 2\Delta H(\text{Atom.E., Se(g)}) + 2\text{IP}(Se^+(g)) + 6\Delta H(\text{Atom.E., I(g)}) - 6D(Se^+—I) - \Delta H(3AsF_5(g) + 2e \rightarrow 2AsF_6^-(g) + AsF_3(g)) - 2U(SeI_3AsF_6) - \Delta H(\text{Vap.E., } AsF_3(g))$$
$$= 108 + 452 + 153 - 248 - 233 - 246 - 9$$
$$= -24 \text{ kcal mol}^{-1}$$

The major energy terms favouring the formation of SeI_3AsF_6 are its crystal lattice energy (2×123 kcal mol^{-1}), and the energy associated with the reduction of AsF_5 ($3AsF_5(g) + 2e \rightarrow 2AsF_6^-(g) + AsF_3(l)$, $\Delta H = -242$ kcal mol^{-1}) which more than offset (by -36 kcal mol^{-1}) the energy needed to ionise $2Se(g)$ to $2Se^+(g)$ (2×226 kcal mol^{-1}). The atomisation energy of selenium and iodine is almost compensated ($+13$ kcal mol^{-1}) by the formation of $2SeI_3^+$ from $2Se^+(g) + 6I(g)$. Thus the overall reaction is exothermic. The actual value of the heat of reaction [7] (and [8]) is likely more negative than shown, as the value of the bond dissociation energy of SeI_3^+ (and SBr_3^+) used in the estimation is a lower limit (see Table 8, footnote *c*). Entropy strongly favours the reactants, and therefore this must be offset by a significant negative reaction enthalpy as the reaction is observed to readily proceed at room temperature. Thus SeI_3AsF_6 is stable, formally a salt of the non-existent SeI_4. This is reminiscent of the existence, in the solid state, of various salts of $S_2I_4^{2+}$ (51), NF_4^+ (59), and ClF_6^+ (60) cations, which are formally salts of the non-existent I_3SSI_3, NF_5, and ClF_7.

The heat of reaction [8] leading to SBr_3AsF_6 is estimated in a similar manner to be exothermic (data given in Table 8).

[8] $(1/4)S_8(s) + 3Br_2(l) + 3AsF_5(g) \rightarrow 2SBr_3AsF_6(s) + AsF_3(l)$

$\Delta H(\text{eq. [8]}) = -62$ kcal mol^{-1}

The higher enthalpy of reaction [8] leading to SBr_3AsF_6 relative to reaction [7] giving SeI_3AsF_6 is largely due to the greater strength of the S^+—Br bond (56 kcal mol^{-1}) relative to the Se^+—I bond (41 kcal mol^{-1}). Nevertheless, SBr_3AsF_6 slowly dissociates, or disproportionates at room temperature, although it is stable at −20°C. Thus the decomposition is likely entropy controlled.

Structure and absolute configuration of [1-(*N*,*N*-dimethylammonium)ethyl]ferrocene tartrate dihydrate

YAO GUANG LUO, RICHARD J. BARTON, AND BEVERLY E. ROBERTSON
Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received May 12, 1987

YAO GUANG LUO, RICHARD J. BARTON, and BEVERLY E. ROBERTSON. Can. J. Chem. **65**, 2756 (1987).

Crystals of [1-(*N*,*N*-dimethylammonium)ethyl]ferrocene tartrate dihydrate are triclinic, space group $P\bar{1}$, $a = 7.235(1)$, $b = 11.372(2)$, $c = 12.724(3)$ Å, $\alpha = 90.78(1)$, $\beta = 102.75(1)$, $\gamma = 91.76(2)°$, $V = 1020.3$ Å^3 at 20 ± 2°C with $Z = 2$. The structure was solved by direct methods. The correct enantiomer was chosen based on full-matrix least-square refinements of each enantiomer. For the correct enantiomer, $R = 0.031$, $R_w = 0.035$ for 11052 reflections with $I \geq 2\sigma(I)$. Although the two crystallographically independent units of the complex in the structure are chemically equivalent, they are structurally different. The absolute configuration of the amino-substituted carbon atom is (*S*), and that of the tartrate anion is (*R*,*R*). The mean ferrocenyl Fe—C bond lengths are 2.037(2) Å and 2.027(3) Å for each molecule, respectively. The NMe_2 group is located outside the planes of the cyclopentadienyl rings. The tartrate ions are connected through water molecules by hydrogen bonds.

YAO GUANG LUO, RICHARD J. BARTON et BEVERLY E. ROBERTSON. Can. J. Chem. **65**, 2756 (1987).

Les cristaux du tartrate de [(*N*,*N*-diméthylammonium)-1 éthyl]ferrocène dihydraté sont tricliniques, groupe d'espace $P\bar{1}$ avec $a = 7,235(1)$, $b = 11,372(2)$ et $c = 12,724(3)$ Å, $\alpha = 90,78(1)$, $\beta = 102,75(1)$ et $\gamma = 91,76(2)°$, $V = 1020,3$ Å^3 à 20 ± 2°C et $Z = 2$. On a résolu la structure par des méthodes directes. On a choisi l'énantiomère correct en se basant sur un affinement par la méthode des moindres carrés (matrice entière) de chacun des énantiomères. Dans le cas du bon énantiomère, on a obtenu des valeurs de $R = 0,031$ et $R_w = 0,035$ pour 11052 réflexions avec $I \geq 2\sigma(I)$. Les deux unités qui forment la structure complexe sont indépendantes d'un point de vue cristallographique alors qu'elles sont équivalentes d'un point de vue chimique; toutefois, elles sont différentes du point de vue de la structure. La configuration absolue de l'atome de carbone portant le groupement aminé est (*S*) alors que celle de l'anion tartrate est (*R*,*R*). Les longueurs moyennes des liaisons Fe—C sont respectivement 2,037(2) et 2,027(3) Å pour chacune des molécules. Le groupement NMe_2 est situé à l'extérieur des plans des noyaux cyclopentadiènyles. Les ions tartrates sont reliés par des liaisons hydrogènes de molécules d'eau.

[Traduit par la revue]

Introduction

Resolved optically active *N*,*N*-dimethyl-α-ferrocenylethylamine (DMFEA) has been widely employed as a starting material in the preparation of optically active ferrocenyl derivatives, with planar chirality or both planar and central chirality, which are useful in asymmetrically induced syntheses (1, 2). Optically active ferrocenyl derivatives are also used as a precursor for the chiral ferrocenylphosphine used in the preparation of several transition metal complexes which have been found to have catalytic activity in: (*i*) the asymmetric hydrogenation of olefins and ketones (3–6); (*ii*) the asymmetric hydrosilation of olefins and ketones (7, 8); (*iii*) the asymmetric isomerization of allylamines to enamines (9); (*iv*) Grignard cross-coupling reactions (10). Several structures and absolute configurations of these derivatives and related complexes have been well characterized (2, 4, 11, 12). The absolute configuration of the compound itself, however, was only determined by optical methods (13). This paper reports the results of an X-ray crystallographic determination of the crystal structure and absolute configuration of the title compound.

Experimental

$C_{18}H_{29}FeNO_8$ fw = 443.27

Triclinic. Space group $P\bar{1}$, from structure analysis. $a = 7.235(1)$, $b = 11.372(2)$, $c = 12.724(3)$ Å, $\alpha = 90.78(1)$, $\beta = 102.75(1)$, $\gamma = 91.76(2)°$, $V = 1020.3$ Å^3. $T = 20 \pm 2$°C. $Z = 2$, $D_x = 1.445$ g/cm^3, $D_m = 1.44$ g/cm^3. $F(000) = 468$, $\mu(\text{MoK}\alpha) = 7.78$ cm^{-1}.

The compound was synthesized and provided by W. R. Cullen of the University of British Columbia. The compound was synthesized by the reaction between α-ferrocenylethyl acetate and dimethylamine in methanol solution overnight at room temperature. After the evaporation of the solvent, the oily residue was swirled with aqueous phosphoric acid and benzene. The acid solution was then separated and treated with sodium carbonate until the pH reached about 10. The product was then extracted with dichloromethane, and the enantiomer was resolved by crystallization with (*R*)-tartaric acid from methanol (14). A recrystallization at room temperature from a methanol/water solution yielded yellow–orange crystals.

Unit-cell parameters were measured by least-squares refinement on the positions of 50 reflections. The density of the crystal was determined by the flotation method. Intensities were measured with graphite-monochromated MoKα radiation ($\lambda = 0.71069$ Å) on a modified Picker FACS-1 diffractometer, using the NRCC diffractometer control system (15) employing the θ–2θ scan technique. Data were measured in the range of $3° \leq 2\theta \leq 60°$, using a scan speed of 2°/min. The intensities of three reference reflections, measured after every 47 reflections throughout the data collection, showed less than 7% drift. A total of 11862 Freidel related reflections were collected of which 11052 were considered as observed with $I/\sigma(I) \geq 2.0$ and were used in the structure determination.

The data were corrected for the Lorentz effect and polarization. All calculations were carried out with the XTAL system of crystallographic programs (16). The Gaussian integration method was used for absorption corrections giving minimum and maximum transmission factors of 0.679 and 0.841. Scattering factors were taken from the XTAL system. A dispersion correction, taken from International tables for X-ray crystallography, Vol. 4 (17), was applied to the scattering factor of the iron atom.

The structure was solved by direct methods; the Fe positions were obtained from the *E*-map. Several subsequent electron density and difference Fourier syntheses revealed all non-hydrogen atoms. The structure was refined on *F* with anisotropic temperature factors using each enantiomer. Convergence was reached at $R = 0.044$, $R_w = 0.057$ (where $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, and $w = 1/\sigma^2(F)$), for one enantiomer, compared to $R = 0.059$, $R_w = 0.075$ for the other. Hydrogen atoms were then obtained either from difference Fourier syntheses or from calculated positions. Hydrogen atoms assigned to calculated positions were constrained to have their C—H bond lengths fixed at 1.0 Å. All other hydrogen atoms were constrained to maintain their original bond lengths as found from the difference map. The temperature factors for all hydrogen atoms were refined isotropically during subsequent

refinement. The structure was refined further using the enantiomer with lower R value by minimizing $\Sigma w(|F_o| - |F_c|)^2$. The final value of R and R_w were 0.032 and 0.036 for 11052 reflections with $I \geq 2\sigma(I)$. For all 11862 reflections $R = 0.034$. A final difference map showed a maximum fluctuation of 0.56 e $Å^{-3}$ at a position located 0.87 Å from the Fe atom. The average shift/error and maximum shift/error were 2.2×10^{-4} and 5.7×10^{-3}, respectively, at the termination of refinement. The atomic coordinates and their equivalent isotropic temperature factors are given in Table 1.[1] The important bond lengths and angles are given in Tables 2 and 3, respectively. Figure 1 shows the stereo view of one of the ferrocenyl cation and Fig. 2 shows the packing diagram.

Results and discussion

The choice of correct absolute configuration of the compound is verified by using Hamilton's significance test (18), which shows that the choice of enantiomer is correct with a significance level better than 99.5%. A Bijvoet ratio test (19) of 10 reflections also supports this assignment.

The unit cell contains two ferrocene cations, two tartrate anions, and four waters of crystallization. The result shows the anticipated (*R*,*R*)-configuration for the two tartrate ions and shows that the two crystallographically independent ferrocene moieties have an (*S*)-configuration in a right handed coordinate system.

The iron atom is π-bonded to two cyclopentadienyl rings. The two cyclopentadienyl rings are planar and deviate slightly from a parallel arrangement; the angles between two cyclopentadienyl planes are 1.8° in cation(I) and 4.0° in cation(II). The structure of ferrocene in the solid state shows the two cyclopentadienyl rings nearly eclipsed (20). They are also

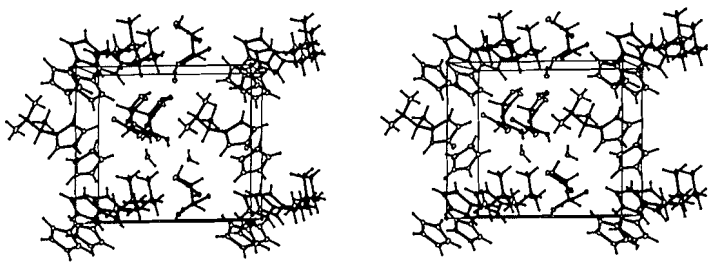

FIG. 2. Packing diagram of a ferrocenyl cation.

nearly eclipsed in a series of ferrocene derivatives which are related to DMFEA such as *N*-formylaminomethylferrocene (21), (*p*-methoxyphenyl)hydroxymethyl-3*N*,*N*-dimethyl-1-ferrocenylamine (2), [1-(2-diphenylphosphinoferrocenyl)ethyl]dimethylamine (12) and $Fe(\eta^5\text{-}C_5H_3\text{-}(PMe_3)_2\text{-}1,3)(\eta^5\text{-}C_5H_3\text{-}(CHMeNMe_2)P(CMe_3)_2\text{-}1,2)$ (4). However, in 2-(α-(dimethylamino)ethyl)-1,1′,3-tris(trimethylsilyl)ferrocene (11), which was prepared from DMFEA, the cyclopentadienyl rings are staggered. In the title compound, the situation is quite unusual. In cation(I), the two cyclopentadienyl rings are close to the eclipsed conformation with rotation angles from 4.5 to 6.6° (average 5.4°). (The rotation angle is defined in terms of vectors from each cyclopentadienyl ring atom to the mean ring center.) However, in cation(II), the two cyclopentadienyl rings are closer to the ideal staggered conformation with the rotation angles from 24.2 to 25.1° (average 24.7°). This difference is presumably caused by packing effects.

The averages of the ferrocenyl Fe—C distances are 2.037(2) and 2.027(3) Å in cation(I) and (II), respectively. These distances are similar to the equivalent distances in other derivatives (2, 4, 11, 12). The distances from the Fe atom to the cyclopentadienyl ring planes are 1.643(1) and 1.656(2) Å in cation(I); and 1.633(1) and 1.649(2) Å in cation(II).

The carbon atoms in the unsubstituted cyclopentadienyl rings show slightly greater thermal motion than those in the substituted rings. The average C—C bond lengths in cation(I) are 1.421(5) Å for the substituted ring and 1.384(5) Å for the unsubstituted ring. The equivalent values for cation(II) are 1.419(8) and 1.379(18) Å, respectively. These values and their differences are similar to those reported for other derivatives of DMFEA (2, 4, 11, 12). However, greater variations are observed for the individual bond lengths. Within the cyclopentadienyl rings, the C—C bond lengths vary from 1.334(6) to 1.440(8) Å. We have carried out an analysis of these differences in order to determine the significance of environmental (i.e. packing) effects according to the method of Taylor and Kennard (22). The result shows that the variation is greater than 9 times the semi-weighted average standard deviation of the C—C bond lengths. Consistent with the variation among the C—C bond lengths, the maximum variation from 105.3(4) to 110.7(4)° among the C—C—C angles is more than 10 times the semi-weighted average standard deviation of the ring C—C—C bond angles. Based on the assumption made by Taylor and Kennard, we must conclude that parts of these differences are real.

The difference map shows peaks at positions approximately 0.90 Å from the N atoms of the amino-substituted ethyl groups. We interpret these peaks as representing hydrogen atoms and, therefore, the amino group must be positively charged. This conclusion is supported by the fact that the C—N—C bond angles around the N atoms range from 110.6(2) to 114.7(2)°. If there is only lone pair electron density on the N atom one would expect that the C—N—C bond angles would be less than 109°.

TABLE 4. Hydrogen bond lengths (Å) and angles (deg) with esd's in parentheses

Atoms	Distance O(N)···O	Distance H···O	Angles O(N)—H···O
O(3′)—H(03′)···O(7)	2.654(2)	1.660(2)	149.3(2)
O(8)—H(082)···O(6)	2.651(3)	1.833(3)	163.1(2)
O(3)—H(03)···O(10)	2.697(2)	1.843(2)	167.1(2)
N(1)—H(01)···O(6′)	2.787(2)	1.876(2)	173.1(2)
O(8)—H(081)···O(4)	2.792(2)	1.927(2)	175.8(2)
N(1′)—H(01′)···O(8)	2.781(3)	1.931(3)	155.1(2)
O(9)—H(092)···O(6′)	2.786(2)	1.965(2)	156.2(2)
O(9)—H(091)···O(4′)	2.867(3)	2.018(3)	166.3(2)
O(4)—H(04)···O(9)	2.786(3)	2.066(3)	153.4(2)
O(4′)—H(04′)···O(8)	2.855(2)	2.078(2)	155.5(2)
O(10)—H(0102)···O(2)	2.881(3)	2.131(3)	145.9(2)
O(10)—H(0101)···O(3′)	2.905(3)	2.189(3)	139.4(4)
O(10)—H(0101)···O(2′)	2.905(2)	2.203(2)	137.6(3)

This conclusion is consistent with evidence that the tartrate ions carry negative charges. The H—N—C bond angles range from 104 to 110°.

The three N—C bond lengths are of the order of 1.482(5) to 1.540(3) Å which is longer than average N—C single bond lengths. In both cations, atom C(11) lies in the same plane as the C(1)—C(5) cyclopentadienyl ring, the C(12) methyl group lies between two cyclopentadienyl ring planes and the NMe_2 group is outside the ring planes. The distance from C(12) to the C(1)—C(5) ring plane is 0.737(6) and 0.515(6) Å in cation(I) and (II), respectively. The C(12)—C(11)—C(1)—C(5) torsional angles are 33.7(3) and 29.5(3)°, respectively. The N(1)—C(11) bond is nearly perpendicular to the cyclopentadienyl ring plane; the torsional angles C(2)—C(1)—C(11)—N(1) are 88.8(2) and 81.4(3)°, respectively. The distances from N(1), C(13), and C(14) to the ring (C(1)—C(5)) plane are 1.462(4), 2.202(5), and 2.240(5) Å in cation(I), and 1.531(5), 2.012(7), and 2.449(6) Å in cation(II). Viewed down the N(1)—C(11) bond, the $CHMeNMe_2$ group adopts a staggered conformation in both cations. The torsional angle defined by C(13)—N(1)—C(11)—C(12) is 173.0(2)° in cation(I) and 154.5(2)° in cation(II). It was thought that the initial site of lithiation of DMFEA would be the position next to the ethyl-substituted carbon atom (11). Therefore the NMe_2 group would be expected to be oriented in such a way that the lone pair on the nitrogen atom is directed toward this position. However, the result shows that the lone pair on the nitrogen atom is directed away from the ring in both cations. This result supports the suggestion that "only small barriers exist for the rotation of all or part of the $CHMeNMe_2$ group attached to a substituted ferrocene ring" (11).

Bond lengths and angles in the tartrate anion are normal. One noteworthy feature is the C—O distances for the carboxyl groups in both ions. On one end they are similar (average 1.234(2) Å for C=O bond and 1.257(2) Å for C—O bond) but on the other end they are significantly different (average 1.212(3) Å for C=O bond and 1.292(3) Å for C—O bond). This similarity of the bond lengths at one end implies delocalization of electron density among the O—C—O atoms, and suggests that the negative charge is associated with this end of the ion.

The shortest intermolecular distance between cation and anion is 1.876(2) Å (O(6′)···H(01)) and the shortest contact between adjacent cations is 2.818(4) Å (C(8′)···H(2)). The tartrate anions are connected by water molecules through hydrogen bonds with bond lengths and angles listed in Table 4.

The apparent molecular polarization at infinite dilution of acetoacetanilide, and benzoylacetanilide in five constant-ratio mixtures of triethylamine in benzene leads to the inference that the equilibrium constants of the association process between the anilide and the amine in benzene are 357 and 600, and that the dipole moments of the complexes formed are 4.43 and 5.25 D, respectively.

On a mesuré les polarisations moléculaires apparentes, à dilution infinie, des acétyl- et benzoyl-acétanilides, dans cinq mélanges à rapports constants de triéthylamine dans le benzène; les résultats obtenus suggèrent que les constantes d'équilibre des processus d'association entre les anilides et l'amine, en présence de benzène, sont respectivement 357 et 600 alors que les moments dipôlaires des complexes qui se forment sont respectivement 4,43 et 5,25 D.

Several papers (1–3) have described the application of dielectric polarization measurements to the problem of molecular interaction in solution but only one (3) article by Few and Smith reports extensive data for a range of compounds. Their method (3) involved the determination of apparent molecular polarization at infinite dilution of a compound A in an active solvent B, in an inert solvent S, and in mixtures of B and S in constant proportion. By so doing, they were able to deduce the equilibrium constant, K, of the association process as well as the dipole moment, μ_{AB}, of the complex formed.

We are currently studying molecular interactions between amines and amides in solution by static dielectric measurements. This paper is concerned with interactions between triethylamine and acetoacetanilide and benzoylacetanilide, respectively, in benzene solution. For this purpose, the method developed by Few and Smith (3) has been utilized.

Experimental and results

Acetoacetanilide and benzoylacetanilide were prepared as described before (4). Benzene and triethylamine were purified according to recommended procedures (5). The purity of compounds was checked by comparing their physical constants with those cited in the literature (4, 5).

Five mixtures of different concentrations of triethylamine, B, in inert solvent benzene, S, were made up having weight fractions, w_B, varying between 0.01 and 0.1. Then a group of dilute solutions of the anilide, A, in each of these constant-ratio solvent mixtures, BS, were made by weight, and all solutions were left to stand at 30°C for 24 h to equilibrate before measurements.

The static dielectric constant, ϵ, density, d, and refractive index for the sodium-D line, n_D, were measured at 30°C for these solutions as described earlier (6).

For the calculation of the equilibrium constant, K, of the association process and the dipole moment, μ_{AB}, of the complex, the following equation derived by Few and Smith (3) was used.

$$[1] \quad \frac{\Delta P}{P_A^* - P_A} = 1 + \frac{M_B}{K w_B d}$$

[1]Author to whom correspondence should be addressed.

Herein, we have P_A^* = molecular polarization at infinite dilution of the anilide, A, in a constant-ratio mixture of the active polar solvent, triethylamine, B, and the inert, non-polar solvent benzene, S; P_A = molecular polarization at infinite dilution of the anilide, A, in the inert solvent benzene, S; ΔP = increase in molecular polarization at infinite dilution attending the formation of 1 mol of the association complex AB from the anilide, A, and the amine, B, i.e., equals $P_{AB} - P_A - P_B$; w_B = weight fraction of the amine, B, in a given solvent mixture, BS, which, at the same time, was considered to be approximately equal to that of the amine in very dilute solution of the anilide, A, in the same solvent mixture; M_B = molecular weight of the amine, B; d = density of the solvent mixture, BS, which was also taken to be approximately equal to the density of very dilute solutions of the anilide, A, in the same solvent mixture; and K = equilibrium constant of the association process A + B = AB, where the active masses of the reactants and resultants were expressed in terms of their concentrations in mol per cm^3.

Obviously, this equation would first permit the values of K and P_{AB} to be deduced from a plot of $1/(P_A^* - P_A)$ against $1/w_B d$, provided, of course, that the plot is linear. In this case, the slope of the line would be equal to $M_B/K\Delta P$, and the intercept on the y-axis, $1/\Delta P$. Subsequently, for the determination of the apparent solution moment, μ_{AB}, of the complex, the molecular refraction, R_{AB}, was deduced the same way as that of the molecular polarization. That is, the equation

$$[2] \quad \frac{\Delta R}{R_A^* - R_A} = 1 + \frac{M_B}{K w_B d}$$

which is analogous to eq. [1], was used to deduce from the slope of the linear plot of $1/(R_A^* - R_A)$ against $1/w_B d$, which is equal to $1/\Delta R$, the value of R_{AB}. Consequently, from a knowledge of P_{AB} and R_{AB} the dipole moment, μ_{AB}, of the complex was calculated in the usual way by refractivity method.

The results obtained are summarized in Tables 1 and 2 for acetoacetanilide-, and benzoylacetanilide–triethylamine–benzene systems, respectively.[2]

[2]Tables 3 to 9 of original data have been deposited with the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Since triethylamine has an appreciable dipole moment (~0.7 D), it follows that the constant-ratio solvent mixtures of the amine and benzene definitely increase in polar character with increasing amine content. This suggests the use of the following equation, which was previously (9) derived from Onsager's equation (8), rather than from the usual Debye equation (7), for the determination of the apparent solution moment, μ_2, of the anilide in these mixtures.

$$[3]\quad \mu_2^2 = F\left(\frac{d\epsilon_{12}}{dC_2}\right)_{C_2\to 0}\frac{1}{A_2} + \frac{A_1\mu_1^2C_1^0V_2 + B_1C_1^0V_2 - B_2}{A_2}$$

Here C_2 = the number of gram-molecules of solute per L of solution; C_1^0 = the molar concentration of pure solvent; V_2 = the molar volume (in L) of pure solute;

$$A_1 = \frac{4\pi N}{9000kT}\frac{(n_1^2+2)^2\epsilon_{12}(2\epsilon_{12}+1)}{(2\epsilon_{12}+n_1^2)^2}$$

$$A_2 = \frac{4\pi N}{9000kT}\frac{(n_2^2+2)^2\epsilon_{12}(2\epsilon_{12}+1)}{(2\epsilon_{12}+n_2^2)^2}$$

$$B_1 = 3V_1\frac{\epsilon_{12}(n_1^2-1)}{(2\epsilon_{12}+n_1^2)}$$

$$B_2 = 3V_2\frac{\epsilon_{12}(n_2^2-1)}{(2\epsilon_{12}+n_2^2)}$$

and

$$F = 1 - C_2\mu_2^2A_2\frac{(n_2^2+4\epsilon_{12}n_2^2-2\epsilon_{12})}{\epsilon_{12}(2\epsilon_{12}+1)(2\epsilon_{12}+n_2^2)} - C_1\mu_1^2A_1\frac{(n_1^2+4\epsilon_{12}n_1^2-2\epsilon_{12})}{\epsilon_{12}(2\epsilon_{12}+1)(2\epsilon_{12}+n_1^2)} - C_2B_2\frac{n_2^2}{\epsilon_{12}(2\epsilon_{12}+n_2^2)} - C_1B_1\frac{n_1^2}{\epsilon_{12}(2\epsilon_{12}+n_1^2)}$$

The slope $d\epsilon_{12}/dC_2$ in the limit as C_2 approaches zero was determined and the terms A_1, A_2, B_1, and B_2 were calculated using the dielectric constant of the solvent, ϵ_1, instead of that of the solution, ϵ_{12}. Similarly, in deriving the numerical value of the factor F for the condition of infinite dilution, the second and fourth terms of F involving C_2 disappear; C_1 becomes C_1^0, and ϵ_{12} becomes equal to ϵ_1. The dipole moment of the solvent mixture, μ_1, was approximated by $(N_B\mu_B^2)^{1/2}$, where N_B is the mole fraction of triethylamine in this mixture, and μ_B (= 0.74 D) its dipole moment in benzene. The results obtained are summarized in Tables 10 and 11.

Based on precisions of ±0.0005 in static dielectric constant, ±0.0001 in density and refractive index, and ±0.05% in solution concentration, the uncertainty of molecular polarization is of the order of 2%. Accordingly, the dipole moments obtained are accurate to ±0.03 D, and the equilibrium constants are in error by ±3%.

Discussion

It will be seen from Tables 2 and 11 that the apparent solution moments of the anilides in the various constant-ratio mixtures obtained by the usual Debye equation are in close agreement with those obtained using the modified Onsager equation, so that it might first be inferred that under such conditions when the polarity of the solvent is sufficiently low, both equations would practically lead to identical dipole moments.

On the other hand, if one accepts *a priori* that complex formation between the anilide and the amine takes place through one or another type of reaction, then the applicability of the Onsager equation, in which no account was taken of such interactions (10) would be as inappropriate as use of the usual Debye equation. Accordingly, the observed agreement between the dipole moments obtained by using these two equations can be considered only coincidental.

Although "incorrect" dipole moments are obtained this way, the apparent increase of the moment with increasing concentration of the amine can be taken as evidence of an increase in complex formation. This, in turn, suggests an estimate can be made of the fraction of anilide introduced in the constant-ratio mixture of triethylamine and benzene, which is complexed with the amine at infinite dilution. For this purpose, the following equation also suggested by Few and Smith (3) in their derivation of eq. [1] has been used.

$$[4]\quad P_A^* - P_A = \Delta P(\Delta w_A/w_A)$$

The values of this fraction expressed as $\Delta w_A/w_A$ are listed in Table 12. It is obvious from this table that an increase in the proportion of triethylamine in the solvent mixture favours complex formation, as is to be expected. Also, for a given solvent mixture, benzoylacetanilide has a greater tendency to form complex with triethylamine than does acetoacetanilide. This agrees with the fact that the equilibrium constant, K, is higher in the former case than in the latter. Both observations are also consistent with the fact that acetoacetanilide is less acidic than benzoylacetanilide, pK_a values being 10.7 and 9.8, respectively (11).

9.241	0.141	6.560	0.120
11.474	0.295	7.966	0.175

However, owing to their insolubility, an estimate could not be made of the fraction of both anilides which complexes at infinite dilution in pure triethylamine.

Finally, from the values of the apparent solution moments, μ_{AB}, μ_A, and μ_B in benzene, an estimate can be made of the dipole moment change, $\Delta\mu$ ($= \mu_{AB} - \mu_A - \mu_B$), accompanying the formation of the complex AB. Thus the fact that $\Delta\mu$ is 0.46 D for acetoacetanilide–triethylamine complex, and 1.01 D for benzoylacetanilide–triethylamine complex, might be taken as a confirmation of the above conclusion that the extent to which such complexes are formed is lower in the former case than in the latter.

Many theories (12–15) have been advanced concerning the nature of interaction involved in complex formation. One theory, known as charge-transfer interaction, was first recognized by Mülliken (16) as a result of the discovery of a new absorption band in some systems (17). The other type of interaction is hydrogen bonding in which the hydrogen bridge is regarded (15, 18) as a path for the flow of charge between the atoms it connects, so that both types are now considered (19, 20) as electron donor–acceptor interactions.

In our present study the anilide in dilute solutions of the triethylamine–benzene solvent mixtures mainly exists (21) in the enolic form and hence, complex formation expectedly takes place through hydrogen-bonding action between the enolic proton and the amine nitrogen, this proton being more acidic in benzoylacetanilide than that in acetoacetanilide.

An investigation of the influence of changes in the dielectric constants of the inert non-polar solvent on the equilibrium

Synthetic oligosaccharides related to Group B streptococcal polysaccharides. The rhamnotriose moiety of the common antigen[1]

VINCE POZSGAY, JEAN-ROBERT BRISSON, AND HAROLD J. JENNINGS
Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received May 15, 1987

VINCE POZSGAY, JEAN-ROBERT BRISSON, and HAROLD J. JENNINGS. Can. J. Chem. **65**, 2764 (1987).

The methyl glycoside (**1**) of the α-L-Rha*p*-(1→2)-α-L-Rha*p*-(1→2)-α-L-Rha*p*-(1→ portion of the group-specific, common antigen polysaccharide of Group B Streptococci has been synthesized. The key compound of the synthesis was methyl 3,4-di-*O*-benzyl-α-L-rhamnopyranoside (**4**). Controlled acetolysis of **4** gave 1,2-di-*O*-acetyl-3,4-di-*O*-benzyl-α-L-rhamnopyranose (**10**), which upon reaction with **4** under catalysis by trimethylsilyl trifluoromethanesulfonate (TMS-Tf) yielded the α-(1→2)-linked dirhamnoside. Subsequent rhamnosylation followed by deprotection gave **1**. TMS-Tf was also used in rhamnosylation reactions with tetra-*O*-acetyl-α-L-rhamnopyranose. Acetylation of acceptor alcohols was found to be a major side reaction in the TMS-Tf assisted glycosylations. One-dimensional nuclear Overhauser enhancement differential spectroscopy indicated that, in solution, **1** takes up a bent instead of an extended conformation.

VINCE POZSGAY, JEAN-ROBERT BRISSON et HAROLD J. JENNINGS. Can. J. Chem. **65**, 2764 (1987).

On a synthétisé le glycoside de méthyle (**1**) de la portion α-L-Rha*p*-(1→2)-α-L-Rha*p*-(1→2)-α-L-Rha*p*-(1→ du polysaccharide antigénique commun et spécifique du streptocoque du groupe B. Le composé clé de la synthèse est le di-*O*-benzyl-3,4 α-L-rhamnopyrannoside de méthyle (**4**). Une acétolyse contrôlée du produit **4** conduit au di-*O*-acétyl-1,2 di-*O*-benzyl-3,4 α-L-rhamnopyrannose (**10**) qui, par une réaction avec le composé **4** catalysée par le trifluorométhanesulfonate de triméthylsilyle (Tf-TMS), conduit au dirhamnoside qui comporte la liaison α-(1→2). Une rhamnosylation subséquente, suivie d'une déprotection, conduit au composé **1**. On a aussi utilisé le Tf-TMS dans des réactions de rhamnosylation impliquant le tétra-*O*-acétyl α-L-rhamnopyrannose. On a trouvé que l'acétylation des alcools accepteurs est une réaction secondaire importante dans les réactions de glycosylation assistées par le Tf-TMS. La spectroscopie différentielle, unidimensionnelle de l'effet Overhauser nucléaire indique que, en solution, la conformation du composé **1** est plutôt repliée qu'étendue.

[Traduit par la revue]

Introduction

Group B Streptococci are the major causative organisms of bacterial meningitis in newborn infants (1) and are responsible for a number of serious infections in adults (2). These organisms have been classified into four distinct serotypes (1), each type being characterized by a unique, immunodeterminant capsular polysaccharide (3–5). At the same time, each type of the group possesses a complex, group-specific common antigen polysaccharide ("C-substance"), which has been shown by studies in our laboratories to contain a backbone polymer of the pentasaccharide repeating unit (6):

α-L-Rha*p*-(1→2)-α-L-Rha*p*-(1→2)-α-L-Rha*p*-(1→1)-D-Glcol-(3←1)-α-L-Rha*p*

Also, the isolation (6) from the common antigen polysaccharide of the octasaccharide

α-L-Rha*p*-(1→3)-α-D-Gal*p*-(1→3)-β-D-GlcNAc*p*-(1→4)-[α-L-Rha*p*-(1→2)]-α-L-Rha*p*-(1→2)-α-L-Rha*p*-(1→1)-D-Glcol-(3←1)-α-L-Rha*p*

showed that some of the pentasaccharide repeating units are substituted by the trisaccharide α-L-Rha*p*-(1→3)-α-D-Gal*p*-(1→3)-β-D-GlcNAc*p*. Although the exact nature of this heterogeneity associated with the Group B streptococcal common antigen remains to be established (6), the recognition of its structural units is expected to make possible the identification of its major, immunodominant region(s). As a tool for mapping these regions, and those of other Group B streptococcal polysaccharides, we have currently been using synthetic approaches to obtain oligosaccharides related to these polymers. The tailored oligosaccharides together with those obtained in limited quantities by degradation from polysaccharides will then be used in serological experiments. In addition, conformational data obtained on the synthetic oligosaccharides are expected to help understanding the properties of the native, Group B streptococcal polysaccharides. In this paper we report the synthesis of the methyl glycoside (1) of the rhamnotriose fragment of the common antigen polysaccharide.

Results and discussion

Our synthetic strategy was based on chain elongation starting at the reducing end. This strategy avoids the formation of anomeric mixtures that might be formed due to the nonparticipating (7) nature of a glycosyl group (8).

The synthetic route described here required a methyl α-L-rhamnopyranoside (**2**) derivative as the reducing terminal moiety, selectively protected at HO-3 and -4. Dibenzyl derivative **4** was selected; it was first prepared by Lipták *et al.* (9) by $LiAlH_4$–$AlCl_3$ reduction of methyl 4-*O*-benzyl-2,3-*O*-*exo*-benzylidene-α-L-rhamnopyranoside in ca. 21% overall yield from **2**. Subsequently, **4** was obtained (10) in 9% yield as the minor product in phase-transfer catalyzed benzylation of methyl 4-*O*-benzyl-α-L-rhamnopyranoside (**3**). Also, **4** was obtained from **3** using tributyltin oxide-mediated regioselective benzylation, in 65% yield (11). David *et al.* (12) reported that alkylation of stannylene derivatives of polyhydroxy compounds is greatly accelerated in the presence of quaternary ammonium halides. Using this observation, we were now able to convert **3** to **4** in 91% yield, with an equimolar amount of Bu_2SnO, Bu_4NBr, and a slight excess of benzyl bromide. Although not part of the present synthetic work, we tested the scope of this technique and found that it is equally successful for the preparation of the 3-*O*-allyl (**8**, ref. 10) and 3-*O*-(4-methoxybenzyl) derivative (**9**) using allyl bromide and 4-methoxybenzyl chloride, respectively, as alkyl donors. The corresponding derivatives of methyl α-L-thiorhamnopyranoside are also accessible, in similar

yields.[2] As **3** can be obtained from **2** in three steps (isopropylidenation, benzylation, acid hydrolysis) in a combined yield of >90%, the methodology suggested here is clearly the method of choice for the synthesis of 3-*O*-ether derivatives of **3**.

As the rhamnosyl donor for the "middle" unit, 1,2-di-*O*-acetyl-3,4-di-*O*-benzyl-α-L-rhamnopyranose (**10**) (13) was envisaged. In **10** the acetoxy group at C-1 would function as the leaving group in the glycosylation reaction whilst the acetyl group at HO-2 would fulfill a dual functional role; as a participating group (7) it should assist the formation of the new, 1,2-*trans* interglycosidic linkage and as a "temporary" protecting group it is selectively removable after glycosylation, making thus available the site of subsequent chain elongation. Compound **10** was prepared earlier by one of us (13) by acetylation of 2-*O*-acetyl-3,4-di-*O*-benzyl-L-rhamnopyranose. We have obtained crystalline **10** now simply by acetolysis of the key compound of this study, namely **4**, in 76.5% yield.

Reaction of **4** with **10** under catalysis by trimethylsilyl trifluoromethanesulfonate (TMS-Tf), as suggested by Paulsen and Paal (14) in the presence of powdered 4 Å molecular sieves followed by deacetylation (Zemplén), gave the partially blocked disaccharide **12** in 64.9% yield. In this reaction the formation of 1,2-*cis* linked disaccharide was not observed and the benzyl protecting groups were sufficiently stable in both the glycosyl donor and glycosyl acceptor to survive the acidic conditions (14) of the reaction. In addition to the efficiency of its preparation and its high reactivity under catalysis by TMS-Tf, the new rhamnosyl donor **10** has the advantage of stability during storage. A noteworthy side reaction in this glycosylation was the formation of trisaccharide **15** in 4.9% yield, the structure of which was proven by its nmr spectra and by the fact that its hydrogenolytic debenzylation gave **1**. Rhamnosylation of **12** with crystalline 2,3,4-tri-*O*-acetyl-α-L-rhamnopyranosyl bromide (15) under $Hg(CN)_2$ catalysis (16) followed by deacetylation (Zemplén) gave the partially protected trirhamnoside **16**, hydrogenolysis of which afforded **1**.

TMS-Tf catalysis was used also to synthesize disaccharides **14** (9) and **18** (9). Reaction of 1,2,3,4-tetra-*O*-acetyl-α-L-rhamno-

pyranose (**11**, refs. 13, 17) with glycosyl acceptors **4** and **6** (9, 10) gave the desired disaccharides **13** (9) and **17** (9) in 36.7 and 70.8% yields, respectively. These glycosylations were accompanied by extensive acetylation of the acceptors **4** and **6**, giving acetates **5** and **7** in 22.3 and 14.8% yields, respectively.

This type of side reaction has been reported recently by Kováč (18), who observed that TSM-Tf catalysed reaction between 1,2,3,4,6-penta-*O*-acetyl-β-D-galactopyranose and methyl 2,3,4-tri-*O*-benzoyl-β-D-galactopyranoside gave, in addition to the desired disaccharide, the 6-*O*-acetate of the glycosyl acceptor in 28% yield. The observations reported (18) and observed by us show that acetylation of acceptor alcohols is a major side reaction in TMS-Tf assisted glycosylation, the occurrence of which is not related to molecular sieves. Removal of the blocking groups from **13** and **17** as above gave **14** and **18**. The yields of the glycosylation reactions between **10** and **4** (64.9%) and between **11** and **4** (36.7%) reflect the increased reactivity of glycosyl donor **10** versus **11**, in agreement with the observations by Paulsen and Paal (14) for a partially benzylated galactopyranosyl donor. It is also apparent that HO-2 of L-rhamnose is less nucleophilic than HO-3 towards the cyclic 1,2-*O*-dioxocarbenium cation, which is the probable reactive intermediate generated (14) by TMS-Tf.

Structures of the compounds described in this study were verified by combined application of high-resolution, Fourier-transform ^1H and ^{13}C nmr spectroscopic measurements performed at 500 and 200 MHz for protons and at 125 and 50 MHz for carbons, respectively.

Published ^{13}C nmr assignments for key compounds **4** (9), **6** (9), and **10** (13) could now be confirmed by the use of two-dimensional C–H heteronuclear correlated spectroscopy with a composite pulse sequence (19). For **4**, the line reported (9) at 80.2 ppm is resolved at the higher field used by us into two separate resonances, which were individually assigned (Experimental).

The ^{13}C chemical shifts of the free disaccharides **14** and **18** and trisaccharide **1** (Table 1) were assigned by using the CHORTLE technique (20). Our assignments for **14** and **18** are in agreement with those published by Lipták *et al.* (9) except for the relative assignments of C-2_A and C-3_B in **18**. We want to note that the difference between these shifts is small and that their reassignment was made possible by using techniques and high field strength not available at the time of the original assignment. Carbon T_1 values of **1** were also determined, using the inversion–recovery technique to obtain insight into the relative segmental motion of the individual sugar units. Segmental motion of the individual units within an oligosaccharide was originally demonstrated by Allerhand and Doddrell (21), who found that in stachyose the carbon T_1 values of the α-(1→6)-linked terminal D-galactopyranosyl group were larger than those of the identically linked, internal D-galactopyranosyl unit. Carbon T_1 data for **1** (Table 2) are in agreement with the expected trend and further confirm the ^{13}C assignments for **1**. In the absence of any bulky terminal anchor (22, 23), the middle unit has the shortest T_1 values, indicating the slowest segmental motion among the individual units.

The ^1H nmr spectra of **1**, **14**, and **18** were unambiguously assigned (Table 3) by the use of 500 MHz one-dimensional and two-dimensional (2-D) homonuclear correlation spectroscopy (COSY) (24) and for **1** also homonuclear, relayed-correlation spectroscopy (RELAYED-COSY) (25). The assignments were aided by heteronuclear, proton–carbon chemical-shift correlation experiments (CHORTLE) (*vide supra*). For example, in **14** the heteronuclear shift-correlation experiment established that the proton (H-2_A) attached to the linkage carbon (C-2_A, 79.36 ppm) resonates at 3.922 ppm. Sequential connectivities in the 2-D COSY spectrum of **14** unambiguously identified the remaining protons. The proton spectrum of **18** was assigned in a similar way. The assignment of the proton spectrum of **1** was assisted by nOe measurements. Saturation of the anomeric proton resonating at 4.754 ppm resulted in a significant nOe for the aglycon methyl group whilst no such enhancement was observed upon saturation of the other two anomeric resonances. Assignment of the resonance at 4.754 ppm to H-1_A was then straightforward, and connectivities in the 2-D COSY spectrum of **1** established the identities of the other resonances belonging to the reducing end unit. Starting point for identification of

Saturated proton[a]	Observed nOe[b]		
H-1_A	H-2_A 3.1%	H-5_B 3.4%	OCH_3 4.3%
H-1_B	H-2_A 6.9%	H-2_B 3.6%	H-5_C 4.6%
H-1_C	H-2_B + H-2_C 10.9%		

[a]For designations A–C see formula **1**.
[b]Intensity of the irradiated resonance is taken as 100%. Estimated error of measurement is ca. 10%.

the protons of the middle ring was the recognition that the linkage carbon (C-2_B) of this unit resonates at 78.95 ppm. The proton–carbon heteronuclear correlation experiment then identified the position of H-2_B as 4.075 ppm and the 2D-COSY spectrum led to the assignment of the remaining resonances. The nOe measurements (Table 4) confirmed the ^{1}H nmr assignments and also revealed the proximity of H-1_A and H-5_B and H-1_B and H-5_C. Analogous nOes were reported by Bock *et al.* (26) between the corresponding protons of α-(1→2)-linked L-rhamnopyranosyl units in oligosaccharides related to the *Shigella flexneri* O-antigen. This geometry is, however, not general for α-L-Rhap-(1→2)-α-L-Rhap disaccharide units, as Christian *et al.* (27) found no nOe between the corresponding protons of α-(1→2)-linked L-rhamnopyranosyl units within a glycan composed of the →2)-α-L-Rhap-(1→2)-α-L-Rhap(1→3)-β-L-Rhap-(1→ repeating unit. The nOe data for **1** show that the inter-residue geometry for rings A and B corresponds to that of B and C and is in agreement with the geometry proposed (26) for α-L-Rhap(1→2)-α-L-Rhap with φ and ψ values around both interglycosidic linkages of about 45° and 15° (26), respectively. The three-bond, heteronuclear $^{13}C-O-C-^1H$ coupling constants (Table 1) across the glycosidic linkage are also in support of this (26).

Compound **1** proved to be an excellent inhibitor in serological inhibition experiments[3] between the common antigen polysaccharide and antibodies raised against it. This observation strongly indicates that the conformational determinant represented by **1** is crucial to the serological specificity of the common antigen polysaccharide. Further work along these lines is in progress in our laboratories.

Experimental

Anhydrous dichloromethane used in glycosylation reactions was purchased from Aldrich (Gold label) and was transferred using the syringe technique. Other solvents were of hplc quality. Syrupy and solid compounds and reagents were dried in high vacuum using a liquid nitrogen trap. All glycosylation reactions were performed under nitrogen. Column chromatography was made on silica gel 60 (0.063–0.2 mm, E. Merck, Cat. No. 7734).

Melting point was determined on a Fisher–Johns apparatus and is uncorrected. Optical rotations were measured with a Perkin–Elmer 243 automatic polarimeter at 20°C. The nmr spectra were measured with a Bruker AM-500 or an AM-200 spectrometer at 500 and 200 MHz for protons and 125 or 50 MHz for carbons, using standard Bruker software DISNMR, at 300 K if not stated otherwise. Referencing was made to internal acetone (2.225 ppm for protons or 31.07 ppm for carbons) or to internal $CDCl_3$ (77.0 ppm for the central line of its triplet for carbons). Assignments given in Tables 1 and 3 and those for **4** and **9** are definitive; others are tentative. Proton-coupled ^{13}C nmr spectra were measured using the WALTZ decoupling (28).

*Methyl 3,4-di-O-benzyl-α-L-rhamnopyranoside (**4**)*

A solution of methyl 4-*O*-benzyl-α-L-rhamnopyranoside (**3**) (20.0 g, 74.6 mmol) and dibutyltin oxide (19 g, 76.3 mmol) in dry benzene (300 mL) was refluxed for 14 h under stirring under a Dean–Stark trap, followed by concentration to ca. 150 mL. After cooling to ca. 65°C, tetrabutylammonium bromide (24 g, 74.5 mmol) and benzyl bromide (10 mL, 84.1 mmol) were added and the mixture was further stirred at 65°C for 2 h. Concentration followed by chromatography (ethyl acetate–hexane, 1:1) gave syrupy **4** (24.3 g, 91.0%); $[\alpha]_D$ −45 (*c* 0.8, CH_2Cl_2) (lit. (10) $[\alpha]_D$ −44 ($CHCl_3$)); ^{13}C nmr (50 MHz, $CDCl_3$): 138.35, 137.86 (2 aromatic quat. carbons), 128.47–127.63 (aromatic carbons), 99.00 (C-1), 79.97 (C-3), 79.84 (C-4), 75.27, 71.91 ($2CH_2$ (Bn)), 68.37 (C-2), 67.07 (C-5), 54.67 (OCH_3), 17.83 (C-6).

*Methyl 3-O-allyl-4-O-benzyl-α-L-rhamnopyranoside (**8**)*

Compound **8** was prepared and isolated similarly to **4**, using allyl bromide as the alkyl donor. Yield: 92%, syrup; $[\alpha]_D$ −70 (*c* 0.9, CH_2Cl_2) (lit. (10) $[\alpha]_D$ −71 ($CHCl_3$).

*Methyl 4-O-benzyl-3-O-(4-methoxybenzyl)-α-L-*rhamnopyranoside (*9*)

Compound **9** was prepared and isolated similarly to **4**, using 4-methoxybenzyl chloride as the alkyl donor. Yield: 91%, syrup; $[\alpha]_D$ −42.1 (*c* 1.6, CH_2Cl_2); ^{13}C nmr (50 MHz, $CDCl_3$): 159.19 (C-4 (MBn)), 138.34 (aromatic quat. carbon), 129.90, 129.36, 128.18, 127.70, 127.48 (aromatic carbons), 113.72 (C-3 + C-5 (MBn)), 99.94 (C-1), 79.72 (C-4), 79.53 (C-3), 76.36 (CH_2 (Bn)), 71.46 (CH_2 (MBn)), 68.23 (C-2), 66.99 (C-5), 55.02, 54.51 ($2OCH_3$), 17.75 (C-6). *Anal.* calcd. for $C_{22}H_{28}O_6$: C 68.02, H 7.26; found: C 68.10, H 7.36.

*1,2-Di-O-acetyl-3,4-di-O-benzyl-α-L-rhamnopyranose (**10**)*

To an ice-cold stirred solution of **4** (3.5 g, 9.78 mmol) in acetic anhydride (20 mL) was added concentrated sulfuric acid (0.3 mL). After 30 min the mixture was poured into a stirred, ice-cold solution of

[3]F. Michon, A. Gamian, V. Pozsgay, and H. J. Jennings. In preparation.

For personal use only.

sodium hydrogen carbonate (5 g) in water (200 mL). After 30 min the crystalline solid was filtered and washed with water. Yield: 3.2 g (76.5%); mp 107–109°C (MeOH) (lit. (13) mp 106–107°C); $[\alpha]_D$ −20 (*c* 1.1, CH_2Cl_2) (lit. (13) $[\alpha]_D$ −20 ($CHCl_3$)). The ^1H and ^{13}C nmr data are identical with those reported (13).

*Methyl 3,4-di-*O*-benzyl-2-*O*-(3,4-di-*O*-benzyl-α-L-rhamnopyranosyl)-α-L-rhamnopyranoside (12)*

A solution of **4** (2.52 g, 7.04 mmol) and **10** (3.66 g, 8.55 mmol) in anhydrous dichloromethane (20 mL) was stirred with powdered, 4 Å molecular sieves (~2 g) for 30 min at room temperature. Trimethylsilyl trifluoromethanesulfonate (0.4 mL, 2.07 mmol) was added and stirring was continued for 2 h. The mixture was filtered, and the filtrate extracted with ice-cold, 5% aqueous sodium hydrogen carbonate solution. The organic layer was dried ($CaSO_4$) and concentrated under reduced pressure. The residual syrup was dissolved in anhydrous methanol (100 mL) containing a catalytic amount of sodium methoxide. After 4 h the solution was neutralized with acetic acid, followed by concentration. Chromatography on silica gel with hexane – ethyl acetate (3:1) first gave syrupy **15** (350 mg, 4.9%); ^{13}C nmr (50 MHz, $CDCl_3$): 138.20, 137.95, 137.77 (quat. aromatic carbons), 128.05, 127.57, 127.33 (aromatic carbons), 100.24, 100.11, 99.63 (C-1_A, C-1_B, C-1_C), 80.09, 79.79 (2×), 79.26, 79.20, 78.82 (C-3_A, C-3_B, C-3_C, C-4_A, C-4_B, C-4_C), 74.98, 74.85 (2×) (3 CH_2 (Bn)), 73.97, 73.78 (C-2_A, C-2_B), 71.95, 71.73, 71.60 (3 CH_2 (Bn)), 68.39, 68.15, 67.73, 67.47 (C-2_C, C-5_A, C-5_B, C-5_C), 54.18 (OCH_3), 17.74, 17.66, 17.49 (C-6_A, C-6_B, C-6_C).

Further elution gave syrupy **12** (3.12 g, 64.9%); $[\alpha]_D$ −16.2 (*c* 0.37, CH_2Cl_2); ^{13}C nmr (50 MHz, $CDCl_3$): 138.4, 138.2, 138.1, 137.7 (aromatic quat. carbons), 128.2, 127.7, 127.5 (aromatic carbons), 100.6 (C-1_A), 99.8 (C-1_B), 80.1, 79.9, 79.7, 79.3 (C-3_A, C-4_A, C-3_B, C-4_B), 75.1, 75.0 (2 CH_2 (Bn)), 74.2 (C-2_A), 71.2 (2×) (2 CH_2 (Bn)), 68.5 (C-2_B), 67.8 (C-5_B), 67.5 (C-5_A), 54.4 (OCH_3), 17.9, 17.8 (C-6_A, C-6_B). *Anal.* calcd. for $C_{41}H_{48}O_9$: C 71.90, H 7.06; found: C 71.75, H 7.20.

*Methyl 2-*O*-(2,3,4-tri-*O*-acetyl-α-L-rhamnopyranosyl)-3,4-di-*O*-benzyl-α-L-rhamnopyranoside (13)*

To a stirred mixture of **4** (480 mg, 1.34 mmol), **11** (560 mg, 1.68 mmol), and powdered 4 Å molecular sieves (0.5 g) in anhydrous dichloromethane (10 mL), trimethylsilyl trifluoromethanesulfonate (60 μL, 0.31 mmol) was added at room temperature and the mixture was further stirred for 3 h. Triethylamine (1 mL) was added, the mixture was filtered, and the solution concentrated. Silica gel chromatography of the residual syrup (hexane – ethyl acetate, 3:1) gave first syrupy **5** (120 mg, 22.3%); ^{13}C nmr (50 MHz, $CDCl_3$): 170.09 (*C*=O), 138.38, 137.9 (2 aromatic quat. carbons), 128.2, 127.9, 127.7, 127.5 (aromatic carbons), 98.53 (C-1), 79.85 (C-4), 77.85 (C-3), 75.2, 71.5 (2 CH_2 (Bn)), 68.72 (C-2), 67.36 (C-5), 54.60 (OCH_3), 20.90 (CH_3CO), 17.85 (C-6). Further elution gave syrupy **13** (310 mg, 36.7%); $[\alpha]_D$ −44.5 (*c* 0.33, CH_2Cl_2) (lit. (9) mp 124–126°C; $[\alpha]_D$ −38.4 (*c* 0.53, $CHCl_3$). For ^{13}C nmr see ref. 9.

*Methyl 2-*O*-(α-L-rhamnopyranosyl)-α-L-rhamnopyranoside (14)*

Compound **14** was obtained from **13** by Zemplén deacetylation followed by hydrogenolysis (10% Pd–C), gel filtration through Sephadex G-10 (water), and freeze-drying; $[\alpha]_D$ −48 (*c* 0.9, H_2O) (lit. (9) $[\alpha]_D$ −92 (*c* 1.28, H_2O); lit (29) $[\alpha]_D$ −46 (*c* 1, H_2O)). For ^1H nmr and ^{13}C nmr see Tables 3 and 1, respectively.

*Methyl 3,4-di-*O*-benzyl-2-*O*-[3,4-di-*O*-benzyl-2-*O*-(α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-α-L-rhamnopyranoside (16)*

A mixture of **12** (670 mg, 0.978 mmol), mercuric cyanide (1.1 g, 4.35 mmol), powdered 4 Å molecular sieves (~1.5 g), and anhydrous acetonitrile (10 mL) was stirred for 1 h, then crystalline 2,3,4-tri-*O*-acetyl-α-L-rhamnopyranosyl bromide (15) (1.1 g, 3.11 mmol) was added and stirring was continued for 12 h. The mixture was filtered and concentrated; the residue was dissolved in chloroform (20 mL) and extracted with 5% aqueous potassium iodide, then with water. Drying ($CaSO_4$) and concentration left a syrup, which was dissolved in anhydrous methanol (20 mL) to which a catalytic amount of sodium methoxide was added. The solution was kept at room temperature for 4 h, neutralized with acetic acid, and concentrated. Chromatography of the residue (ethyl acetate – hexane, 2:1) gave syrupy **16** (597 mg, 73.4%); $[\alpha]_D$ −35.8 (*c* 0.43, CH_2Cl_2); ^{13}C nmr (50 MHz, $CDCl_3$): 138.32, 138.17 (aromatic quat. carbons), 128.42–127.65 (aromatic carbons), 100.84, 100.42, 99.82 (C-1_A, C-1_B, C-1_C), 80.45, 80.22, 79.44, 79.05 (C-3_A, C-3_B, C-4_A, C-4_B), 75.19 (2 CH_2 (Bn)), 74.33, 74.19 (C-2_A, C-2_B), 73.13 (C-4_C), 72.39 (CH_2 (Bn)), 72.01 (CH_2 (Bn)), 71.54 (C-3_C), 70.88 (C-2_C), 68.55, 68.41 (C-5_A, C-5_B), 67.68 (C-5_C), 54.54 (OCH_3), 17.98 (2×), 17.45 (C-6_A, C-6_B, C-6_C). *Anal.* calcd. for $C_{47}H_{58}O_{13}$: C 67.93, H 7.03; found: C 66.67, H 6.99.

*Methyl 3-*O*-(2,3,4-tri-*O*-acetyl-α-L-rhamnopyranosyl)-2,4-di-*O*-benzyl-α-L-rhamnopyranoside (17)*

A mixture of **6** (350 mg, 0.976 mmol), **11** (1.5 g, 4.5 mmol), powdered 4 Å molecular sieves (2 h), and anhydrous dichloromethane (10 mL) was stirred at room temperature for 1 h. Trimethylsilyl trifluoromethanesulfonate (100 μL, 0.517 mmol) was added and stirring was continued for 3 h. Work-up, similar to that for **13**, gave syrupy **7** (58 mg, 14.8%); ^{13}C nmr (50 MHz, $CDCl_3$): 170.14 (*C*=O), 138.25 (aromatic quat. carbons), 129.7–126.8 (aromatic carbons), 98.67 (C-1), 79.00 (C-4), 76.08 (C-2), 74.82, 73.01 (2CH_2 (Bn)), 73.72 (C-3), 67.54 (C-5), 54.68 (OCH_3), 20.98 (CH_3CO), 17.94 (C-6); and **17** (432 mg, 70.1%); $[\alpha]_D$ −46.2 (*c* 1.64, CH_2Cl_2) (lit. (9) $[\alpha]_D$ −46.1 (*c* 0.56, $CHCl_3$). For ^{13}C nmr of **17** see ref. 9.

*Methyl 3-*O*-(α-L-rhamnopyranosyl)-α-L-rhamnopyranoside (18)*

Compound **18** was obtained from **17** as described for **14**; $[\alpha]_D$ −81 (*c* 0.4, H_2O) (lit. (9) $[\alpha]_D$ −78 (*c* 1.52, H_2O). For ^1H nmr and ^{13}C nmr see Tables 3 and 1, respectively.

*Methyl-2-*O*-[2-O-(α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-α-L-rhamnopyranoside (1)*

1. A mixture of 10% palladium on carbon (0.5 g) in 95% ethanol (5 mL) and acetic acid (5 mL) was stirred under hydrogen under atmospheric pressure for 2 h. A solution of **16** (530 mg) in 95% ethanol (10 mL) was then added and stirring was continued for 14 h. Removal of catalyst followed by concentration left a syrup, which was purified on a column of Sephadex G-15 (water). The major fraction was freeze-dried to give **1** as a white amorphous powder (252 mg, 84.0%); $[\alpha]_D$ −57.7 (*c* 1, H_2O). For ^1H nmr and ^{13}C nmr see Tables 3 and 1, respectively. *Anal.* calcd. for $C_{19}H_{34}O_{13}$: C 48.50, H 7.28; found: C 48.29, H 7.39.

2. Hydrogenolysis of **15** as described for **16** gave **1** (86%) having identical $[\alpha]_D$ and ^1H nmr and ^{13}C nmr spectra to the compound obtained from **16** by hydrogenolysis.

Bicyclization of aza-compounds by positive halide ions. II. Lactams and some related cyclizations[1,2]

RICHARD M. ELOFSON, FAHMI F. GADALLAH, AND JAMES K. LAIDLER
Alberta Research Council, 250 Karl Clark Road, Edmonton, Alta., Canada T6H 5X2

Received April 22, 1986[3]

This paper is dedicated to Dr. O. E. (Ted) Edwards

RICHARD M. ELOFSON, FAHMI F. GADALLAH, and JAMES K. LAIDLER. Can. J. Chem. **65**, 2770 (1987).

Anodic oxidation of lactams in the presence of halide ions produced excellent yields of bicyclic compounds with reactants having rings in the range of eight to ten atoms (C_7 to C_9). Smaller rings did not react to form bicyclic products and larger rings gave reduced yields. Attempts were made to cyclize non-cyclic amides and to bicyclize cycloheptyl and cyclooctyl acetamide with limited success.

RICHARD M. ELOFSON, FAHMI F. GADALLAH et JAMES K. LAIDLER. Can. J. Chem. **65**, 2770 (1987).

Lorsqu'on soumet des lactames cycliques comportant de huit à dix atomes (C_7 à C_9) à une oxydation anodique en présence d'ions halogénures, on obtient des composés bicycliques avec d'excellents rendements. Lorsqu'on soumet des composés cycliques plus petits à cette réaction, ils ne donnent pas de produits bicycliques alors que les composés dont le cycle est plus grand donnent de moins bons rendements. Lorsqu'on a essayé de cycliser des amides non-cycliques ou de provoquer une bicyclisation des cycloheptyl- et cyclooctyl-acétamides, les résultats ont été mitigés.

[Traduit par la revue]

Introduction

We have previously reported (1) the bicyclization of cyclic amines in moderate yields by anodic oxidation in the presence of halide ions, particularly bromide ion. Following the example of Edwards and co-workers (2–4) it was decided to attempt the bicyclization of a number of lactams by electrochemical means. Since amides are not readily attacked at anodes (5) and are much more resistant to chemical reagents, it was anticipated that more severe conditions in the form of higher anode potentials and/or higher temperatures might be required. On the other hand, since amides are resistant to direct anodic attack, any bicyclic products produced by indirect processes as described in the previous paper (1) should be safe from further degradation at the electrode. These postulates have been confirmed in the experiments described below.

Because of the success with lactams it was decided to attempt to bicyclize cycloheptylacetamide and cyclooctylacetamide and to cyclize non-cyclic amides. These results, to date much less successful and preliminary in nature, are included only because no further work in this area is likely from this laboratory.

Results

The first attempt to bicyclize lactams was to duplicate the conditions for bicyclization of amines with the addition of $Ca(OH)_2$ to maintain alkaline conditions. Under these conditions very little bicyclization occurred. The temperature was then raised to 60°C but this resulted in attack of the acetonitrile to produce succinonitrile and bromoform. Acetonitrile was finally replaced with dioxane and the electrolyses were conducted at the elevated temperature of 85°C. The results for bicyclization of a number of lactams are shown in Table 1.

As shown in Table 1 the yields of bicyclic products from C_7 to C_9 lactams were near quantitative. No bicyclization of C_6 lactam occurred and the C_{10} and C_{12} lactams were bicyclized in reduced but significant yields. As expected the C_7 lactam produced only one isomer **a** with two five-membered rings

TABLE 1. Bicyclization of lactams at 100 mA, 85°C, C anode, $Ca(OH)_2$, LiBr (0.1 *M*), 20% H_2O in dioxane

Lactam	Time (h)	Starting material (%)	Bicyclic products (%)
$C_6H_{11}NO$	5	100	0
$C_7H_{13}NO$	3.5	12	85
$C_8H_{15}NO$	3	Trace	89[a]
$C_9H_{17}NO$	12	16	83
$C_{10}H_{19}NO$	6	49	46[b]
$C_{12}H_{23}NO$	6	61	10

[a]In CH_3OH bicyclic yield 82%.
[b]No change after 8 h.

[1] 
(reaction [1], Fig. 1). The C_8 amide produced two isomers, **b** and **c** each with one five-membered ring and one six-membered ring but with the carbonyl function reversed. The ratio of the respective isomers varied somewhat but was in approximate agreement with Edwards (4), viz. about 1:3 to 1:5. From the C_9 lactam three bicyclic products **d**, **e**, and **f** were obtained, viz. 1-azabicyclo[4,4,0]decan-2-one, 1-azabicyclo[5,3,0]decan-10-one, and 1-azabicyclo[5,3,0]decan-2-one. Again the ratios varied, but for the run reported in Table 1 the ratio was 11:1:3 for the respective isomers. Bicyclization of the C_{10} lactam produced three isomers **g**, **h**, and **i**, viz. 1-azabicyclo[6,3,0]-undecan-2-one, 1-azabicyclo[6,3,0]undecan-11-one, and 1-azabicyclo[5,4,0]undecan-2-one in a ratio 23:8:16, respectively. For the C_{12} lactam, yields were very much reduced and no attempt was made to sort out the isomers that were produced. In the case of the C_{10} lactam, the yield did not increase when the reaction time was increased to 8 h but the amount of starting material declined.

Table 2 depicts the results of attempts to cyclize primary amides under the conditions used in Table 1. When aqueous methanol was used as the solvent together with higher current more complex products were obtained. Methoxylation was

TABLE 2. Anodic oxidation of amides at C anode, $Ca(OH)_2$, LiBr (0.1 *M*), 20% H_2O in dioxane

Compound	*I* (mA)	*I* (°C)	Time (h)	Starting material (%)	Cyclization products (%)
Pentylacetamide	100	85	4.5	78	6.5
Isohexylacetamide	100	85	3	92	Nil
Cycloheptylacetamide	200	85	3	77	13.4
Cyclooctylacetamide	200	85	3	53	17

involved but otherwise the products were not established. *N*-Pentyl acetamide produced a 6.5% yield of 2-methyl-*N*-acetylpyrolidine after 4.5 h, in dioxane, according to reaction [2]. No *N*-acetylpiperidine was detected. This would seem to agree with the well-known propensity of free radicals to extract secondary hydrogen atoms instead of primary hydrogen atoms.

[2] 
Isohexylacetamide in methanol yielded two products, not including the expected 2,2-dimethyl-*N*-acetylpyrolidine in methanol. The retention times and molecular ions corresponded to methoxylated and brominated cyclized products but were not otherwise characterized. No identifiable products were obtained in dioxane. Large amounts of starting material were recovered from each of the last two reactions.

Cycloheptylacetamide was subjected to electrolysis under the conditions listed in Table 2. After 3 h at 200 mA the reaction mixture was worked up and yielded 13.4% of a product that came 0.9 min before the starting material, by glc, with the correct molecular ion for the bicyclized material of 153 mass units, but which was not identified further. The reaction presumably is depicted in [3].

LiI	3	95	Trace

Cyclooctylacetamide produced a mixture of bicyclized products which after reduction with lithium aluminum hydride yielded 17% bicyclic material with a retention time shorter than that of the starting material according to reaction [4]. The primary products of the reaction could not be separated by glc so the bicyclic amides were reduced with $LiAlH_4$ and produced three products, with the correct molecular ions by mass spectrometry.

[4] 
Discussion

Table 3 illustrates the point that lactams are indeed very resistant to anodic attack (5). In fact in these experiments there was little evidence in the absence of halide ion of direct attack on the lactams, Table 4, reaction [1]. In order to obtain significant yields of bicyclized material, halide ions must be present as shown in Table 4.

As in the case of the bicyclization of the amines, bromide ions gave the best results (Table 4). Possibly the advantage of bromide over chloride was not as great for bicyclization of the lactams as for the cyclic amines. Not surprisingly iodine was not effective since iodine in any form would not be expected to react with lactams. These results are consistent with the mechanistic proposals made in [1], namely oxidation of the halide ion at the electrode followed by reaction of the halide cation species produced with the amide. The work of Anson (6), as discussed previously (1), accounts nicely for this sequence of adsorption and oxidation. The high anodic potentials of amides make the hypothesis for removal of two electrons from the halide moiety before reaction with the organic species even more plausible than in the case of bicyclization of cyclic amines.

The results shown in Table 5 indicate that the mechanism for the next step probably does not simply involve formation of

N-haloamides and their subsequent thermal decomposition. Not enough additional work has been done to support the proposal that the X^+ species first produced at the anode in the triplet state (Hund's Rule) reacts directly with the amide. It could be argued that the higher temperatures required for the amide reactions support a conventional electrophilic mechanism with a significant energy of activation. Clearly, the environment of the X^+ species produced at the electrode must be important in order to account for the results shown in Table 5. Steric or entropy factors are responsible for the high yields upon bicyclization of lactams of moderate ring size and the low yields for cyclization of amides studied here.

Experimental

The reaction conditions were similar to those already described (1). For the results described in this paper a three-necked round bottom flask, 200 mL, was fitted with a condenser to minimize solvent loss and flushed with a slow stream of nitrogen. A stainless steel rod (SS-304), 0.3 cm in diameter was used as the cathode. The anode was a rod 1.5 cm by 5 cm of carbon (Union Carbide S2408-60). Two millimoles of amide were dissolved in 100 mL of solvent, usually 20% water in dioxane with the electrolyte as specified. The current was maintained at 100 mA unless specified otherwise. Under these conditions the initial anode potential was found to be about 2.3 V at a current of 100 mA. All electrochemical operations were accomplished with a Princeton Applied Research Electrochemical System, Model 170.

Quantitative analyses were done by glc (Hewlett-Packard F&M 810) with the columns and packing as specified in Table 6. The temperature was programmed as specified in Table 6. Helium flow was 60 mL/min. Retention times and molecular ions are presented in Table 6.

Qualitative analyses were done by glc and mass spectrometry using known compounds as standards or simply by glc – mass spectrometry as indicated. Mass spectra were obtained with a Perkin Elmer GLC Mass Spectrometer Model 270.

The work up procedure for electrolysis with 20% dioxane as solvent consisted of filtration to remove $Ca(OH)_2$, solid washed with dioxane, water added, extracted 5 times with benzene, benzene washed 4 times with water, benzene solution dried, and concentrated as required.

The C_6, C_7, C_8, and C_{12} lactams were obtained from Aldrich Chemical Co., Milwaukee, WI. The C_9 and C_{10} lactams were prepared from the respective cyclic ketones (Aldrich) using the Beckmann rearrangement. N—Cl—C_7 lactam was prepared according to the procedure of Edwards (2).

The C_7 bicyclic lactam was isolated from the electrolysis reaction and identified by nmr and mass spectrometry (2). The C_8 and C_9 bicyclic lactams were identified by comparison with authentic samples supplied through the courtesy of Dr. M. H. Benn, University of Calgary. The C_{10} bicyclic lactams were identified with the aid of data from the thesis of K. N. Vohra, University of Calgary, 1973.

No attempt was made to identify the individual C_{12} bicyclic lactams except to note that their unseparated retention time was shorter than that of the parent lactam and their molecular ions by mass spectra corresponded to the required formulae. In all cases reported in this paper the bicyclized material had retention times shorter than the parent compounds.

[a]Compounds **b**, **c**, **d**, **e**, and **f** are identical to compounds provided by M. Benn; compounds **g**, **h**, and **i** are identified from Vohra's Thesis.

n-Pentylacetamide was prepared by acetylation of *n*-pentylamine; purity was checked by glc on SE30 and Versamid 900 columns.

Isohexylacetamide was prepared by acetylation of the amine; purity checked by glc on SE30, and mass spectra. The amine was prepared by reduction of the amide of 4-methyl pentanoic acid with lithium aluminum hydride in ether.

Cycloheptylacetamide was prepared by acetylation of the amine (Aldrich). Purity was checked by glc and mass spectra.

Cyclooctylacetamide was prepared by acetylation of cyclooctylamine (Aldrich) with acetic anhydride and recrystalized from *n*-pentane. The electrolysis of this amide produced a mixture of bicyclic amides and starting material which resisted separation by glc. Reduction of the mixed amides with $LiAlH_4$ in ether was followed by destruction of excess reagent with HCl. Extraction of this solution with ether, after basification with NaOH, produced a solution which after drying yielded the ethyl amines with retention times as shown in Table 7.

Mass spectra and retention times indicated that bicyclization had taken place as indicated in Table 2.

2-Methylpyrrolidine was prepared by photolysis of *N*-chloro-*n*-pentylamine (8, 9). Gas–liquid chromatography on Versamid 900 and mass spectra showed that the product of acetylation of this reaction corresponded to the product of the electrolysis of *n*-pentylacetamide.

The effect of electron-pair donor solvents on methylene reactivity

MIQUEL MORENO, JOSÉ M. LLUCH, ANTONIO OLIVA, AND JUAN BERTRÁN
Departament de Química, Universitat Autònoma de Barcelona, Bellaterra, Barcelona, Spain

Received March 5, 1987

MIQUEL MORENO, JOSÉ M. LLUCH, ANTONIO OLIVA, and JUAN BERTRÁN. Can. J. Chem. **65**, 2774 (1987).

The effect of electron pair donor solvents on methylene reactivity has been theoretically studied by means of *ab initio* methods, using the split valence 3-21G basis set. The calculations have been done on the well-known methylene addition to ethylene, taking one water molecule in order to represent the donor solvent. We have shown that the process takes place via the formation of a reversible complex between water and methylene, the formation of this complex permitting to explain the experimentally observed decrease of methylene's electrophilicity. The analysis of the variation of the electronic charge density and of the solvation parameters along the reaction coordinate have also allowed to interpret the reaction in terms of the transfer of an electrophile (methylene) from a nucleophile (water) to another nucleophile (ethylene).

MIQUEL MORENO, JOSÉ M. LLUCH, ANTONIO OLIVA et JUAN BERTRÁN. Can. J. Chem. **65**, 2774 (1987).

Faisant appel à des méthodes *ab initio* et utilisant un ensemble de base 3-21G, on a réalisé une étude théorique de l'effet des solvants donneurs de paires d'électrons sur la réactivité du méthylène. On a réalisé les calculs en prenant comme exemple l'addition bien connue de méthylène sur l'éthylène et en utilisant une molécule d'eau pour représenter le solvant donneur de paires d'électrons. On a démontré que le processus se produit par le biais de la formation d'un complexe réversible entre l'eau et le méthylène; la formation de ce complexe permet d'expliquer le fait observé expérimentalement selon lequel le caractère électrophile du méthylène diminue. Une analyse de la variation de la densité de la charge électronique et des paramètres de solvatation en fonction des coordonnées de la réaction a aussi permis d'interpréter la réaction en fonction du transfert d'un électrophile (méthylène) d'un nucléophile (l'eau) vers un autre nucléophile (éthylène).

[Traduit par la revue]

Introduction

It is well known that solvent greatly influences reactions in which ionic species intervene (1). It is equally well recognized that the reactivity of neutral species such as free radicals and carbenes is generally insensitive to the nature of the solvent. However, recent experimental works (2–4) have shown that some electron-pair donor solvents modify the reactivity of carbenes. For instance, competition between pairs of alcohols in their reactions with arylcarbenes indicate that the O—H insertion selectivity is drastically increased in the presence of 1,4-dioxane with respect to that encountered in the same reactions without solvent. Similar competition between alcohol and olefin again shows that the O—H insertion/addition selectivities of arylcarbenes are also considerably enhanced by 1,4-dioxane.

This experimental behaviour has been interpreted by the reversible formation of a complex between the carbene and the solvent. Given that most singlet carbenes are known to react as electrophiles, it seems quite reasonable to assume that they can form complexes with electron-pair donor solvents through the interaction between the vacant *p* orbital of the carbene and the lone pair electrons of the solvent. This complexation is expected to reduce the electrophilicity of the carbene, its selectivity being consequently increased according to the Reactivity–Selectivity Principle. If the interaction between the carbene and the solvent is too strong the formation of the complex would not be reversible and the reaction would give rise to solvent-incorporated products. As a matter of fact, this is presumably what occurs in the case of ethers more basic than 1,4-dioxane, e.g. THF.

A related case to this change of reactivity is presented by chlorophenylcarbene. This is a typically electrophilic carbene that should exhibit preferential reactivity versus nucleophilic olefins (5–7). However, chlorophenylcarbene reacts with electrophilic olefins, such as vinyl ethers and α,β-unsaturated carbonyl compounds, to form cyclopropane products in high yields (8). Here the interpretation again involves the formation of a complex between the carbene and the corresponding olefin, in such a way that the carbene is displaced to a more nucleophilic zone of the spectrum of carbene philicity.

To our knowledge, until now no theoretical works have been devoted to the study of the modification of singlet carbene reactivities by electron-pair donor solvents. The object of this study is to reach a more thorough understanding of the experimental facts. To this aim, we have studied the well known methylene addition reaction to ethylene, taking one water molecule to represent the donor solvent. It is true that methylene and water actually react to give methanol (9–11) but it has recently been found (12) that the complex methylene–water exists as a local energy minimum. In any case water is a good theoretical model to simulate an ether which is not excessively basic.

Methodology

Ab initio SCF calculations were done with the GAUSSIAN 80 and 82 series of programs (13) using the double ζ quality 3-21G basis set (14). Some points have been recalculated with the 6-31G** basis set (15) where the electron correlation has been introduced using the Møller–Plesset perturbation theory up to third order, MP3 (16). Geometry optimization and location of stationary points were carried out with the Schlegel gradient minimization algorithm (17). Analytical second derivatives of energy with respect to the cartesian coordinates (18) were used to characterize the nature of the stationary points, since, as it is well known, the force constant matrix presents no negative eigenvalues for an equilibrium structure and only one negative eigenvalue for a transition state.

Results and discussion

First, we have studied the structure of the complex between singlet methylene and water. In fact, the interaction between these two molecules can lead to two different complexes, depending on whether water acts as an electrophile (one hydrogen atom interacts with the HOMO of methylene) or as

a nucleophile (the oxygen atom interacts with the LUMO of methylene). We have only considered the second case, in which the interaction is more favourable (9, 10) and might be responsible for the experimental results mentioned in the introduction.

Figure 1 presents the equilibrium structure of the complex obtained by complete geometry optimization. It belongs to the C_s point group, with its plane of symmetry bisecting ∠HOH and ∠HCH. This structure is similar to that found by Pople *et al.* (9, 10) using another basis set. It is worthy to note the existence of an important charge transfer (0.188 au) from water to methylene, in spite of the great value of the C—O distance between both molecules. This important charge transfer indicates the great electrophilicity of singlet methylene, which has a vacant *p* orbital and is therefore an electron-deficient molecule. As a direct consequence, the interaction between water and methylene is rather strong and the complex formed is well stabilized (20.3 kcal mol^{-1}) with respect to the isolated constituents.

It is interesting to discuss how this interaction energy changes when larger basis sets and correlation corrections are included. To this aim we have recalculated the stabilization energy of the methylene–water complex at several levels of calculation. The results are shown in the first row of Table 1. One can observe that the depth of the well decreases with increasing size in the basis set. This was to be expected since the basis set superposition error exaggerates the stabilization of the complex when small basis sets are used. On the other hand, the introduction of electron correlation increases the depth of the well. So, both effects tend to compensate each other as already found by Pople *et al.* (9). These authors obtained a binding energy of 14.7 kcal mol^{-1} with the MP4/6-31G**//MP2/6-31G* level of calculation, their highest.

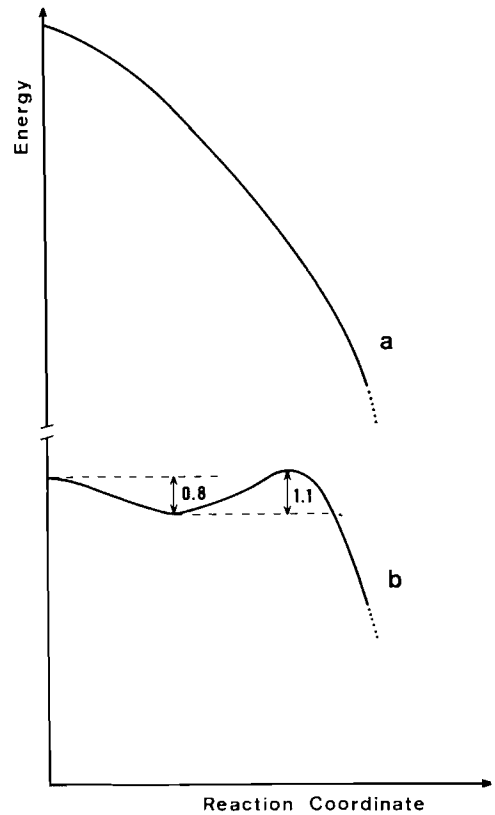

FIG. 2. Schematic representation of the energy profiles in kcal mol^{-1} for the non-solvated (*a*) and solvated (*b*) methylene addition to ethylene.

To study the solvent effect on the reactivity of singlet methylene, we have studied its addition and the addition of the CH_2–H_2O complex to ethylene. For the reaction with non-solvated methylene we have obtained the reaction path using the reaction coordinate method; as independent variable we have chosen the distance between the midpoint of the C—C bond of ethylene and the C atom of methylene, all the remaining geometrical parameters being optimized for each value of the independent variable. In the case of reaction with the complex methylene–water, the stationary points of the potential energy hypersurface have been directly located. Figure 2 schematically presents the energy profiles so obtained.

One can observe that the reaction of ethylene with isolated singlet methylene takes place with no energy barrier, in good agreement with *ab initio* calculations previously done by other authors (19, 20). Thus, the energy monotonically decreases until cyclopropane is reached, the reaction being highly exothermic (93.1 kcal mol^{-1}). On the other hand, the introduction

[a]In atomic units.

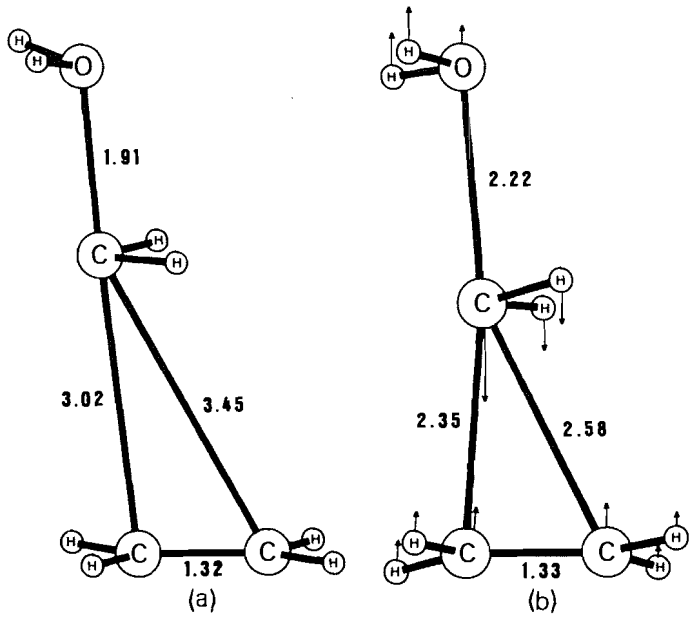

FIG. 3. Geometrical structure of the intermediate (*a*) and of the transition state (*b*) for the addition of the water–methylene complex to ethylene (distances in Å).

of one water molecule solvating methylene leads to a drastically different energy profile, since now there exists an intermediate situated in a well of very shallow depth (0.8 kcal mol^{-1}), followed by a small energy barrier of 1.1 kcal mol^{-1} with respect to the intermediate. Furthermore, the presence of one water molecule notably reduces the exothermicity of the process, the energy of the reaction now being −72.8 kcal mol^{-1}.

As we have already done with the binding energy of the methylene–water complex, let us now discuss the effect of the size of the basis set and of the correlation energy in the energy profiles in Fig. 2. The results obtained are in the three last rows in Table 1. The shape of the non-solvated energy profile (Fig. 2*a*) is independent of the level of calculation, but, as can be observed in the last row in Table 1, its exothermicity decreases with larger basis sets and increases when electron correlation is introduced. The effect on the solvated energy profile (Fig. 2*b*) is more complicated, since the second and third rows of data in Table 1 show that the intermediate and the subsequent energy barrier disappear at the 6-31G**//3-21G and MP3/3-21G//3-21G levels of calculation. However, these calculations are subjected to some important limitations. First, there is the assumption of unchanged 3-21G geometries. Secondly, this basis set does not give significant correlation corrections. These limitations prevent us from knowing if an intermediate does exist. However, in all cases the slope of the solvated energy profile is drastically reduced. Thus it is important for us to note that the solvent does noticeably change the energy profile of the addition in the sense of reducing the reactivity of singlet methylene.

To understand this change of energy profile it is interesting to analyze the variation of the most important geometrical parameters along the reaction path. Figure 3 presents the structures corresponding to the intermediate (*a*) and to the transition state (*b*) of the reaction with solvated methylene. In the transition state, the components over each atom of the transition vector are also drawn. The final product structure is not presented, since it corresponds to cyclopropane and water situated very far apart as expected, given that cyclopropane has no vacant *p* orbitals and has, therefore, a hydrophobic behaviour. One can observe that solvated methylene and ethylene approach each other in parallel planes, in such a way that the predominant frontier orbital interaction will be between the HOMO of ethylene and the LUMO of the complex methylene–water. In other words, this complex, as isolated methylene, is acting as an electrophile.

One can also observe that the approach between the two reactants is accompanied by a progressive desolvation of methylene, as indicated by the evolution of bond distance C—O. In the intermediate, the interaction between methylene and ethylene is still quite weak and the desolvation has scarcely begun. On the contrary, it is already noticeable in the transition state. Desolvation is clearly in progress at this point of the energy profile as indicated by components of the transition vector. Methylene is moving away from water as it approaches ethylene. Furthermore, the greater component of the transition vector over the carbon atom of methylene with respect to those on the hydrogen atoms shows that methylene has already begun to rotate in order to adopt the position it has in cyclopropane.

Let us now analyze the progress of charge transfer along the reaction path. Table 2 presents the net charges over the three groups (water, methylene, and ethylene). One can observe that charge transfer from water to methylene decreases monotonically from reactants to products, the decrease is intimately related to the increase in desolvation. On the other hand, the charge transfer from ethylene to methylene increases initially, and then decreases to zero in cyclopropane where the three CH_2 groups are equivalent. It is interesting to mention that the corresponding values of the charge transfer from ethylene to methylene in the absence of water are notably greater than those presented in Table 2 for the same value of the reaction coordinate. For instance, charge transfers of 0.041 and 0.095 au have been obtained in the absence of water for the values of the reaction coordinate corresponding to the intermediate and the transition state of the hydrated reaction. This decrease in charge transfer in the presence of solvent clearly shows that the electrophilicity of the complex methylene–water is much smaller than that of free methylene.

A deeper insight into the mechanism of the process can be achieved by inspecting the topology of the electronic charge density at the complex, intermediate, and transition state. Figure 4 presents the isodensity contour plots of these three

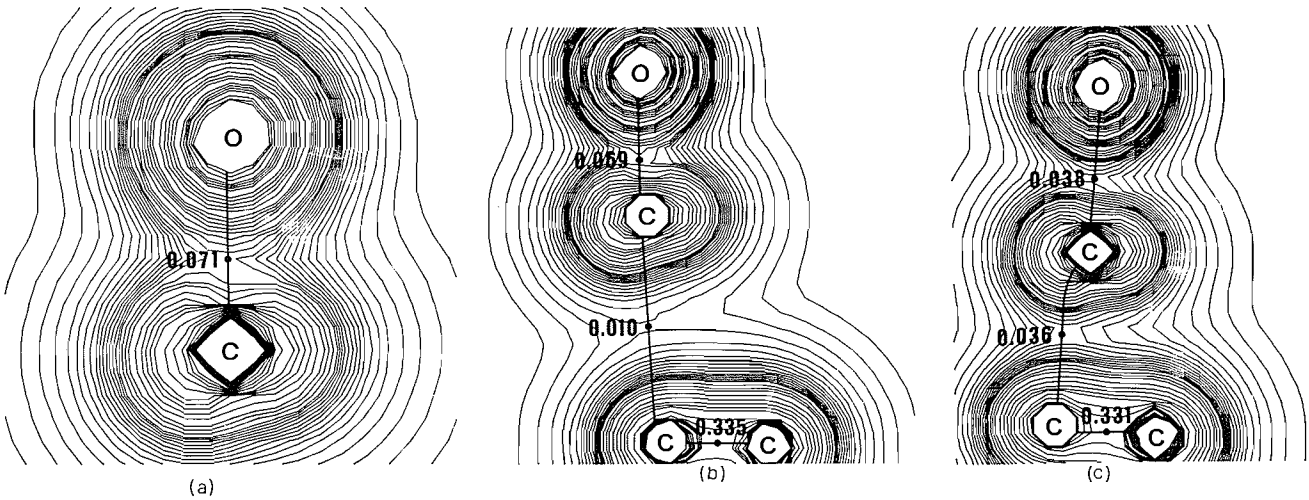

FIG. 4. Isodensity contour plots in the plane formed by the heavy atoms in the water–methylene complex (*a*), the intermediate (*b*), and the transition state (*c*). Numbers indicate electron density in the bond critical points (.).

structures in the plane which contains the heavy atoms of the system. Bond critical points and bond paths linking the atoms on the planes of the figure are also shown. According to the Bader terminology (21), bond paths are a unique pair of gradient paths which originate at each bond critical point, i.e. at the saddle point situated between two linked atoms. Two interesting facts can be observed in Fig. 4. First, the charge density at the critical point linking the carbon atom in methylene to the oxygen atom in water decreases from the complex to the transition state, again showing the desolvation of methylene. Thus, desolvation is small in the intermediate, but already rather important in the transition state. Secondly, the carbon atom in methylene is initially bonded to only one of the carbon atoms in ethylene. A similar asynchronous approach had previously been found (19, 20) for the addition to ethylene in free methylene.

The change in the energy profile when methylene is solvated by one water molecule can be now easily understood. As one can observe in Fig. 2, the addition of free methylene to ethylene is accompanied by a strong energy decrease from the beginning of the process. On the other hand, the introduction of one water molecule stabilizes all points in the energy profile, and this stabilization decreases as desolvation increases according to the sequence reactant > intermediate > transition state > product. As a direct consequence, the initial part of the energy profile is rather flat and the exothermicity of the process clearly decreases. The presence or absence of an intermediate depends on a subtle balance between the slope of the energy profile in the absence of water and the decrease in stabilization on desolvation.

The energy profile of the addition of $CH_2.H_2O$ to ethylene can be related to those found in several electron, proton, or group transfer processes. In these cases, the energy profile frequently presents a double-well shape, and the process occurs via a three-step mechanism: formation of a first intermediate without energy barrier, subsequent isomerization through a transition state to a second intermediate where the transfer has already been produced, and final dissociation to the reaction product. In our case the second intermediate does not appear, since it would correspond to the hydrophobic interaction between cyclopropane and water. The first intermediate only appears at the 3-21G//3-21G level of calculation, although we observe a drastic reduction in slope of the energy profile in this zone at all the levels of calculation. In any case, the reaction we studied can be interpreted as the transfer of an electrophile (methylene) from a nucleophile (water) to another nucleophile (ethylene).

Conclusions

Using water as a model of lone-pair donor solvent, we have shown that the addition of methylene takes place via the formation of a reversible complex between water and methylene. The electrophilicity of methylene is thus noticeably reduced, leading to an important decrease in the exothermicity of the process, resulting in an energy profile very similar to those in group transfer reactions. In conclusion, this work enables one to reach a theoretical interpretation of the experimental behavior of electrophilic carbenes in the presence of electron-pair donor solvents.

Surface tension and density of the molten $LaCl_3$–NaCl binary system

G. Liu, J. M. Toguri, and N. M. Stubina

Department of Metallurgy and Materials Science, University of Toronto, 184 College Street, Toronto, Ont., Canada M5S 1A4

Received February 19, 1987[1]

G. Liu, J. M. Toguri, and N. M. Stubina. Can. J. Chem. **65**, 2779 (1987).

The surface tension and density of the $LaCl_3$–NaCl system were determined as a function of temperature by the maximum bubble pressure technique. The surface tension and density were found to vary linearly with temperature ($1123 < T < 1248$ K). At constant temperature, the surface tensions of $LaCl_3$–NaCl melts showed a small negative deviation from Guggenheim's Equation.

G. Liu, J. M. Toguri et N. M. Stubina. Can. J. Chem. **65**, 2779 (1987).

Faisant appel à la technique de la pression maximale de la bulle, on a déterminé la tension superficielle et la densité du système LaCl–NaCl en fonction de la température. On a trouvé que la tension superficielle et la densité varient d'une façon linéaire avec la température ($1123 < T < 1248$ K). A température constante, les tensions superficielles de mélanges fondus de $LaCl_3$–NaCl présentent une légère déviation par rapport à l'équation de Guggenheim.

Introduction

One method of producing lanthanum metal is by fused-salt electrolysis of a chloride melt containing lanthanum. A possible electrolyte for this process would be a $LaCl_3$–NaCl mixture. Kim and Ejima (1) and Cho and Kuroda (2) have measured the density of $LaCl_3$–NaCl binary melts. Foerthmann *et al.* (3) measured the electrical conductivity of this system. However, surface tension data for $LaCl_3$–NaCl melts are not available in the literature.

In the present study, surface tensions and densities of binary $LaCl_3$–NaCl melts were measured.

Experimental

The experimental apparatus and procedure for the present study have been described in detail previously (4) and thus only a brief description is given here. The well established maximum bubble pressure technique was selected for the determination of surface tension and density of the $LaCl_3$–NaCl system. With this technique, surface tension and density of the salt can be measured simultaneously. Briefly, it involves the slow formation of a gas bubble at the tip of a capillary immersed in the molten salt. Schrödinger (5) developed the following equation which relates the surface tension to the maximum bubble pressure:

$$[1] \quad \gamma = \frac{rP_\gamma}{2}\left[1 - (2/3)\left(\frac{r\rho g}{P_\gamma}\right) - (1/6)\left(\frac{r\rho g}{P_\gamma}\right)^2\right]$$

where γ is the surface tension, r is the radius of the capillary, P_γ is the maximum pressure difference inside and outside the bubble at the level of the end of the tip, ρ is the density difference between the liquid salt and the gas, and g is the acceleration due to gravity.

Apparatus

A schematic diagram of the experimental apparatus is shown in Fig. 1. The furnace had a uniform temperature (±2.5 K) region of 5.0 cm. The salt mixture was contained in a quartz crucible under an argon atmosphere. The crucible had an inner diameter of 20 mm and a height of 60 mm. The quartz capillary was 50 mm long, with an outer diameter of ~2.2 mm, and an inner diameter of ~1.08 mm.

Procedure

The sodium chloride used in this work was obtained from Baker Chemical Co. ("Baker Analysed" reagent grade). Lanthanum chloride was obtained from Aldrich Chemical Co. Inc. These materials were predried in a vacuum oven at 400 K for 3 days and then analyzed by DTA. The argon (99.999%) used to form the bubble was passed through a copper getter furnace and through two drying columns (drierite and phosphoric anhydride) in order to remove any traces of oxygen or water.

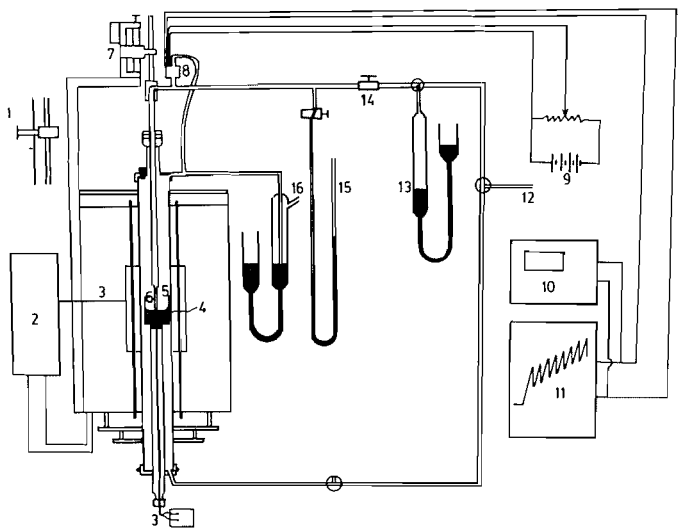

FIG. 1. Experimental apparatus: (*1*) cathetometer; (*2*) temperature controller; (*3*) thermocouple; (*4*) sample; (*5*) graphite crucible; (*6*) capillary; (*7*) capillary drive; (*8*) pressure transducer; (*9*) dry cell; (*10*) digital multimeter; (*11*) recorder; (*12*) purified argon inlet; (*13*) gas reservoir; (*14*) needle valve; (*15*) manometer; (*16*) gas outlet.

The quartz crucible containing the required salt mixture was positioned in the furnace and heated to the desired temperature under a flowing argon atmosphere. Excess pressure was applied to the capillary while it was lowered towards the melt surface. The capillary was then lowered very slowly until a sudden pressure jump was registered by the pressure transducer, indicating that the capillary had touched the melt surface and the surface position was recorded.

The bubbling rate was adjusted to about 1 bubble/min which was in the region where the transducer output was independent of the gas flowrate. The pressure was increased linearly with immersion depth until a bubble was released at the capillary tip followed by a sudden decrease in pressure. The capillary immersion depth was changed several times while the maximum pressure was recorded.

The density of the molten salt mixture was calculated from the slope of the maximum pressure versus immersion depth data, while the surface tension was evaluated from the obtained maximum pressure for zero immersion using Schrödinger's equation.

The temperature effect on surface tension and density was deter-

mined during both heating and cooling cycles. Since the salts wetted the capillary tip, the inner radius of the capillary tip was used for surface tension calculation. All measurements were corrected for thermal expansion of the capillary orifice.

Results and discussion

Surface tension and density data determined in the present study for NaCl, $LaCl_3$, and $LaCl_3$–NaCl mixtures are listed in Tables 1 and 2, respectively.

The dependence of surface tension on temperature, over a range from 1120 to 1250 K, for pure $LaCl_3$ and pure NaCl is shown in Fig. 2. In both cases, a linear relationship was observed. Results obtained by Smirnov and Stepanov (6) for pure $LaCl_3$ and by Sokolova and Voskresenskaya (7) for NaCl are included in the diagram. The results from this study are in excellent agreement with those from other investigators.

Density curves for the two pure salts are shown in Fig. 3. For pure NaCl, the data obtained by Van Artsdalen and Yaffe (8) are included as a comparison. For $LaCl_3$, data recommended by Janz *et al.* (9) are systematically higher than the results obtained in this study, as shown in Fig. 3. While the reasons for the consistently lower values for $LaCl_3$ are not clear, the results are in accord if an overall accuracy limit of $\sim \pm 1\%$ is assumed.

In Fig. 4, the surface tension measurements for various $LaCl_3$–NaCl mixtures are presented. The surface tension of each melt decreases with increasing temperature in the range investigated. The curves for 12.5 and 25.0 mol% $LaCl_3$ are almost superimposed.

The corresponding density values for these melts are shown in Fig. 5. Included in Fig. 5 are density results obtained by Cho and Kuroda (2). The results from this study are in excellent agreement with their findings. A decrease in density with an increase in temperature was observed. Linear relationships of the form:

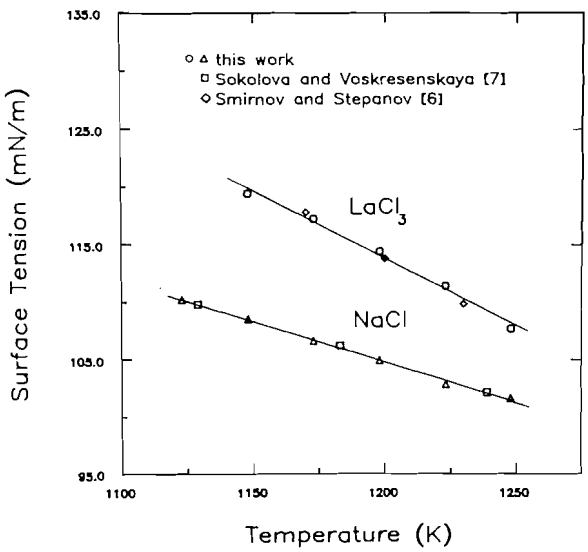

FIG. 2. Surface tensions of pure $LaCl_3$ and NaCl.

[2] $\gamma = A + BT(\mathrm{K})$ (mN/m)

and

[3] $\rho = C + DT(\mathrm{K})$ (g/mL)

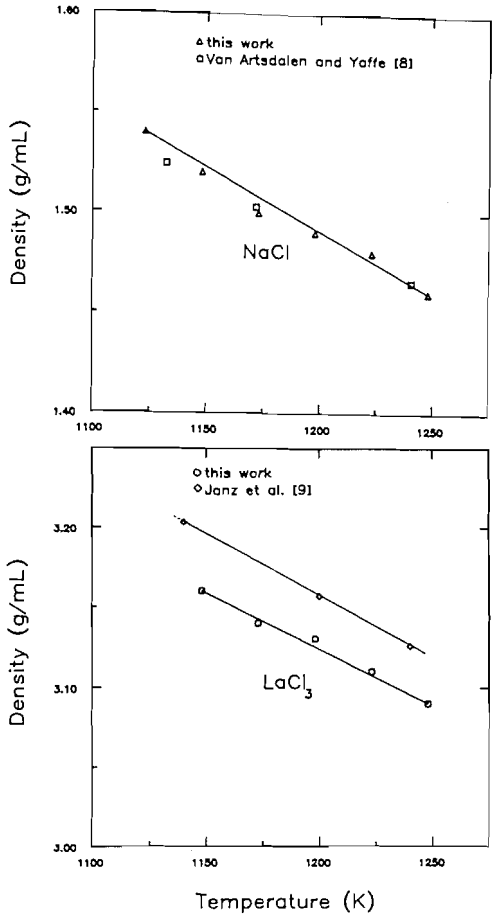

FIG. 3. Densities of pure $LaCl_3$ and NaCl.

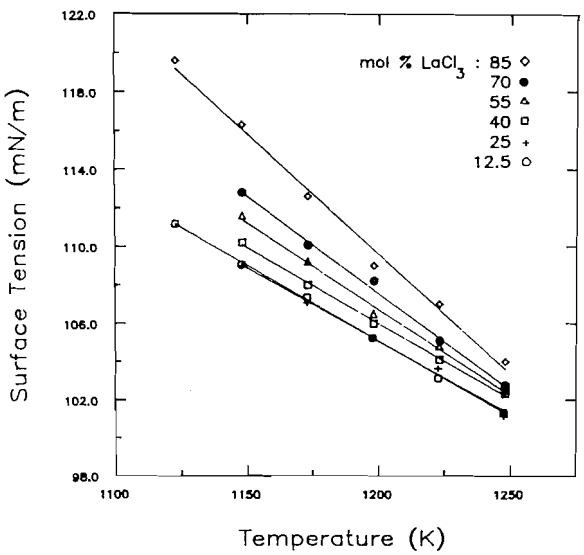

FIG. 4. Effect of temperature on the surface tension of $LaCl_3$–NaCl melts.

were obtained. The linear regression coefficients (A, B, C, and D) are summarized in Tables 1 and 2. The standard error of estimation is also included.

A surface tension isotherm for the $LaCl_3$–NaCl system at 1148 K is shown in Fig. 6. There is only a small negative departure from Guggenheim's equation for ideal solutions (10). The maximum deviation between the measured results and Guggenheim's equation was less than 2%. This indicates that

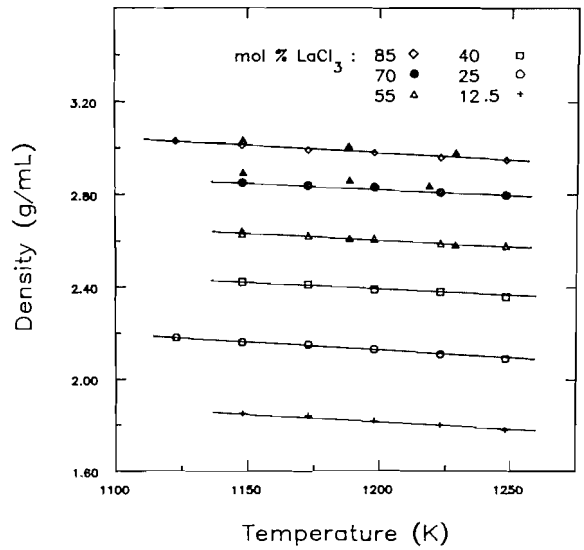

FIG. 5. Effect of temperature on the density of $LaCl_3$–NaCl melts. Data by Cho and Kuroda (2) are designated by ▲.

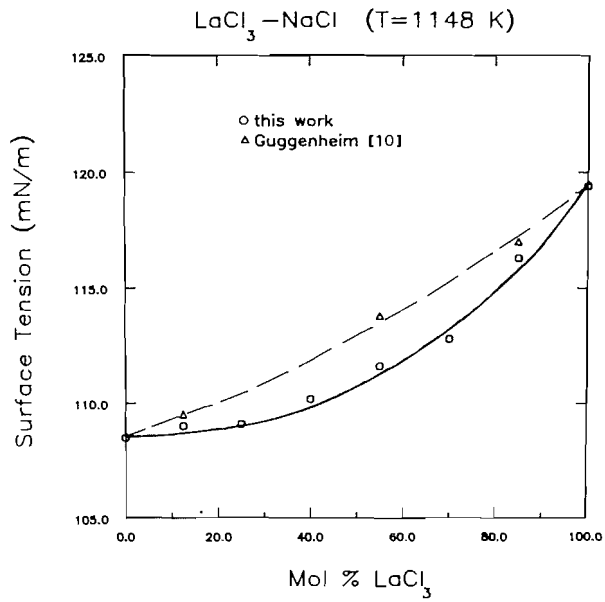

FIG. 6. Surface tension isotherm for the $LaCl_3$–NaCl system at 1148 K.

this molten binary system can be regarded as a simple mixture of components that do not form complexes. This result could also be explained by examining the nature of Na and La ions. The radii of Na and La are similar, 0.97 and 1.016 Å, respectively (11). Moreover, the difference in electronegativity between Na and La is not very large.

Molar volumes (V) for the molten $LaCl_3$–NaCl system were calculated from the density data using the following equation:

$$[4] \quad V = \frac{\sum^{i} X_i M_i}{\rho}$$

where M_i is the molecular weight of component i and X_i is the mole fraction of component i. The molar volumes obtained in this study, as well as the values obtained from a simple additive relationship, are listed in Table 3 for a temperature of 1248 K. The deviations from ideality are small. This confirms the result that the binary $LaCl_3$–NaCl system can be regarded as a simple mixture that does not form complexes.

TABLE 3. Molar volume and deviation from additivity at 1248 K

Parameter	Value when mol% $LaCl_3$ =					
	85	70	55	40	25	12.5
Molar volume (g/mL)	73.6	67.6	62.5	56.4	50.3	45.9
Values of additivity (g/mL)	73.5	67.6	61.7	55.8	49.9	44.9
Deviation (g/mL)	0.1	0.0	0.8	0.6	0.4	1.0

Reçu le 26 mai 1987

MOHIEDDINE FOURATI, MONCEF CHAABOUNI, JEAN-LOUIS PASCAL et JACQUELINE POTIER. Can. J. Chem. **65**, 2783 (1987).

Afin d'optimiser la préparation de complexes perchlorato de Cd(II) et Hg(II), on a testé successivement les réactions de Cl_2O_6 avec $CdCl_2$, $CdCO_3$, $Cd(NO_3)_2 \cdot nH_2O$, $HgCl_2$, $Hg(ClO_4)_2 \cdot 6H_2O$ et $Hg(NO_3)_2 \cdot H_2O$. Les complexes $Cd(ClO_4)_2$, $ClO_2Cd(ClO_4)_3$, $NO_2Cd(ClO_4)_3$, $HgClClO_4$, $Hg(ClO_4)_2$ et $(NO_2)_2Hg(ClO_4)_4$ ont été caractérisés. Parmi ces complexes seul $HgClClO_4$ est ionique avec $HgCl^+$ polymère en chaîne; les autres sont des complexes perchlorato. $Cd(ClO_4)_2$ s'apparente aux complexes à structure en couches $M(ClO_4)_2$ (M = Co, Ni, Zn), dans lesquels le groupe ClO_4 est tridenté en pont. $Hg(ClO_4)_2$ se rapproche de $HgCl_2$ ou de $Hg(SR)_2$ (SR : thiocarbamate) avec des groupes ClO_4 monodentés en interaction avec les molécules voisines. Dans les sels $ClO_2Cd(ClO_4)_3$, $NO_2Cd(ClO_4)_3$ et $(NO_2)_2Hg(ClO_4)_4$, les anions sont des polymères; leurs structures sont analogues respectivement à celles de $ACuCl_3$, $NO_2Co(ClO_4)_3$ et $(NO_2)_2Cu(ClO_4)_4$.

MOHIEDDINE FOURATI, MONCEF CHAABOUNI, JEAN-LOUIS PASCAL, and JACQUELINE POTIER. Can. J. Chem. **65**, 2783 (1987).

To improve the synthesis of perchlorato complexes of Cd(II) and Hg(II), reactions of Cl_2O_6 with $CdCl_2$, $CdCO_3$, $Cd(NO_3)_2 \cdot nH_2O$, $HgCl_2$, $Hg(ClO_4)_2 \cdot 6H_2O$, and $Hg(NO_3)_2 \cdot H_2O$ were tried. The complexes $Cd(ClO_4)_2$, $ClO_2Cd(ClO_4)_3$, $NO_2Cd(ClO_4)_3$, $HgClClO_4$, $Hg(ClO_4)_2$, and $(NO_2)_2Hg(ClO_4)_4$ were characterized. Among these complexes only $HgClClO_4$ is ionic ($HgCl^+$ is a polymeric chain); the others are perchlorato complexes. $Cd(ClO_4)_2$ is related to the layered complexes $M(ClO_4)_2$ (M = Co, Ni, Zn) in which ClO_4 is a bridging tridentate. $Hg(ClO_4)_2$ is close to $HgCl_2$ or $Hg(SR)_2$ (SR: thiocarbamate); ClO_4 is a monodentate and it interacts with neighbouring molecules. In the salts $ClO_2Cd(ClO_4)_3$, $NO_2Cd(ClO_4)_3$, and $(NO_2)_2Hg(ClO_4)_4$ the anions have polymeric arrangements; their structures are analogous to those of $ACuCl_3$, $NO_2Co(ClO_4)_3$, and $(NO_2)_2Cu(ClO_4)_4$, respectively.

Introduction

La synthèse et l'analyse structurale de complexes perchlorato non solvatés par des molécules d'eau ou des bases organiques dans lesquels les groupements ClO_4 sont fortement liés à l'élément central ont connu un essor important ces dernières années (1). Ceci a été rendu possible par l'utilisation d'agents perchloratants performants : Cl_2O_6 (1*b*), $ClOClO_3$ (2), $HClO_4$–Cl_2O_7 (3), NO_2ClO_4 (4) et la mise en oeuvre de nombreuses méthodes d'analyses structurales : spectroscopie de vibration (1*b*, 5), diffraction des rayons X sur poudre et monocristaux (1*c*, 6), EXAFS (7), etc. Une mise au point récente résume ces travaux (1*a*).

En 1982, certains d'entre nous avaient présenté une préparation originale de $Zn(ClO_4)_2$ et de $ClO_2Zn(ClO_4)_3$ par action de Cl_2O_6 sur un métal (8), puis complété cette étude par la synthèse de sels de nitryle (9) et l'analyse par EXAFS de $Zn(ClO_4)_2$ (7*c*). Récemment, Rosolovskii et coll. (10) ont proposé de nouvelles synthèses : action de NO_2ClO_4 sur $ZnCl_2$, déshydratation par voie thermique de $Zn(ClO_4)_2 \cdot 6H_2O$. Leurs résultats sont analogues aux nôtres.

Il a paru logique d'étudier les complexes perchlorato des autres éléments de la colonne IIB (colonne 12 selon la nouvelle nomenclature de l'IUPAC et de l'ACS (11)) afin de pouvoir comparer les complexes de Cd et Hg à ceux de Zn et suivre leur condition de formation en fonction de l'acidité décroissante selon Pearson (12*a*) lorsqu'on passe de Zn à Hg.

Lorsqu'a débuté ce travail (15) seule l'enthalpie de formation de $Cd(ClO_4)_2$ avait été calculée (13) et sa densité mesurée (14). Récemment Nikitina et Rosolovskii (16) ont publié une étude portant notamment sur la synthèse de $Cd(ClO_4)_2$ par déshydratation thermique de $Cd(ClO_4)_2 \cdot 6H_2O$. Cette voie de synthèse est toutefois aléatoire puisqu'elle peut conduire soit à des composés légèrement hydratés soit à des oxohydroxo-perchlorates. Jusqu'à maintenant, l'étude des complexes perchlorato de Hg(II) non solvatés était plus réduite (17). Il était fait état de la formation possible de $Hg(ClO_4)_2$ par chauffage de $Hg(ClO_4)_2 nL$ (L : pyridine, dioxane, quinoline), avec les très graves dangers d'une telle voie de préparation (18).

Dans les lignes suivantes, nous présentons les synthèses et l'étude structurale par spectroscopie de vibration et diffraction des rayons X sur poudre de divers complexes perchlorato de Cd(II) et Hg(II).

Partie expérimentale

Attention : Le trioxyde de chlore et les perchlorates anhydres sont des composés très réactifs, particulièrement au contact des matières organiques et sous les chocs (19). Les réactions doivent être surveillées attentivement, les complexes sont extrêmement hygroscopiques et sont manipulés sur une ligne vide (1*b*) ou dans une boîte à gants contenant de l'azote ou de l'argon très pur et sec (<5 ppm en H_2O ou O_2). D'une façon générale, les expériences sont conduites dans une pièce faiblement éclairée et en l'absence de lumière fluorescente. Au cours de ce travail, un complexe résultant de la décomposition thermique de $(NO_2)_x Hg(ClO_4)_{2+x}$ a explosé spontanément et violemment dès qu'il a été exposé à la lumière du jour.

[a]Quantité en gramme (expérience type).
[b]Température de la réaction ou de la transformation (°C).
[c]Temps (heure).
[d]Nature et couleur à température ambiante; s : solide; b : blanc; o : orange; bj : blanc jaune; jo : jaune orange.
[e]Les valeurs théoriques sont données entre parenthèse; les méthodes de dosage sont spécifiées dans le texte et dans les références 22, 23, 24.
[f]Masse en grammes obtenue après réaction ou transformation; la masse attendue est donnée entre parenthèses.
[g]Prolabo Rectapur (sauf indication les produits sont utilisés sans purification préalable).
[h]Identifié par spectroscopie Raman.
[i]Merck très pur.
[j]Pompage dynamique de l'excès de Cl_2O_6.
[k]Merck pour analyse vendu comme contenant $4H_2O$ (!).
[l]Préparé à partir du produit (*k*) placé sous vide dynamique (10^{-2} Torr) durant 60 h à T ambiante.
[m]$(NO_2)_2Cd(ClO_4)_4$: $NO_2Cd(ClO_4)_3 + NO_2ClO_4$.
[n]Merck pour analyse.
[o]Sur la base de $HgClClO_4$.
[p]Ce produit est préparé par dissolution de HgO dans un minimum d'acide perchlorique commercial à 72%; la solution est ensuite concentrée à chaud puis évaporée lentement sous vide.
[q]Prolabo pur en plaque.
$\varepsilon < 0{,}05$.

Produits de base

L'agent perchloratant, le trioxyde de chlore est préparé et purifié selon les méthodes déjà décrites (20). La provenance, la pureté et l'utilisation des sels de base qui sont transformés en perchlorates sont reportées dans le tableau 1.

Méthodes d'analyses

Les appareils d'analyse infra-rouge (ir), Raman, rayons X (RX) sur poudre ainsi que les méthodes d'échantillonnage ont été présentés par ailleurs (1*b*, 21) de même que les protocoles de dosage des cations métalliques (22), de l'ion perchlorate (23) et du cation ClO_2^+ (ClO_3^- dans l'eau) (24). L'ion NO_2^+ (NO_3^- en solution) n'est pas dosé, sa quantité est déterminée par différence ou sa présence est décelée par spectroscopie de vibration.

D'une façon générale, moyennant le respect de précautions élémentaires (1*b*), ces analyses sont effectuées sans difficultés majeures. Notons cependant la nécessité de complexer au préalable Hg(II) par l'EDTA 0,1 ou 0,01 M avant d'analyser ClO_4^- par potentiométrie. Les résultats analytiques sont reportés dans le tableau 1.

Résultats et discussion

Synthèse des complexes perchlorato de cadmium (II) et de mercure (II)

Quel que soit le complexe perchlorato le principe de la synthèse est le même; nous n'y reviendrons pas (1*b*).

Notons cependant que devant les difficultés rencontrées, les synthèses sont recommencées plusieurs fois. Seuls les résultats d'expériences types sont donnés dans le tableau 1.

(a) Synthèse à partir de chlorures

La séquence habituellement rencontrée (1*b*, 5) :

[1] $$MCl_2 \xrightarrow[(3+n)Cl_2O_6]{} ClO_2M(ClO_4)_3 nCl_2O_6 \xrightarrow[T]{} M(ClO_4)_2$$

s'observe difficilement avec $CdCl_2$ et jamais avec $HgCl_2$. Dans ces deux cas le remplacement de Cl par ClO_4 est délicat et il reste toujours des traces de $CdCl_2$ ou $HgCl_2$ n'ayant pas réagi.

Le sel de chloryle de Cd est peu stable et perd facilement Cl_2O_6 à température ambiante sous vide dynamique. En outre, si n est trop grand (cf. réaction [1]), on obtient une phase unique, liquide rouge sang instable qui se décompose à température ambiante pour donner directement $Cd(ClO_4)_2$ sans permettre d'isoler le sel de chloryle.

Avec le mercure, il y a une étape intermédiaire avant d'obtenir $Hg(ClO_4)_2$:

[2] $$HgCl_2 + Cl_2O_6 \rightarrow HgClClO_4 + \tfrac{1}{2}Cl_2 + ClO_2$$

$HgClClO_4$ est un complexe ionique défini. Ce sel peut être souillé soit par $HgCl_2$ si le temps de contact des réactifs n'est pas suffisant, soit par $Hg(ClO_4)_2$ si l'excès de Cl_2O_6 et le temps de contact des réactifs sont trop importants. Dans le premier cas, on peut purifier $HgClClO_4$ par sublimation de $HgCl_2$ à 110°C sous 1,33 Pa.

Soulignons que :

(*i*) le remplacement partiel des chlorures a déjà été observé avec le gallium (25), le bore (21), le germanium (26), le titane (27) et l'étain (6*a*); avec les deux derniers éléments il y a oxydation partielle.

(*ii*) il est possible d'obtenir $Hg(ClO_4)_2$ à partir de $HgClClO_4$, mais cette opération est fastidieuse car elle demande plusieurs additions successives de Cl_2O_6 et des temps de contact importants.

Afin de pallier les difficultés précédentes, deux réactions originales ont été effectuées pour préparer les perchlorates de Cd et Hg.

(b) Synthèse des perchlorates de cadmium à partir de $CdCO_3$

Cette réaction s'inspire des synthèses classiques des perchlorates hydratés par action de l'acide perchlorique commercial sur les carbonates (28).

$CdCO_3$ réagit très facilement et très rapidement dans le milieu très acide que constitue Cl_2O_6 pour donner $ClO_2Cd(ClO_4)_3$ selon les réactions :

[3] $$CdCO_3 + 2Cl_2O_6 \rightarrow Cd(ClO_4)_2 + CO_2 + 2ClO_2 + \tfrac{1}{2}O_2$$

[4] $$Cd(ClO_4)_2 + Cl_2O_6 \rightarrow ClO_2Cd(ClO_4)_3$$

La formation de ClO_2 et CO_2 au cours de la réaction [3] a été vérifiée en ir selon un procédé déjà décrit (20*b*).

Les observations faites plus haut sur la formation et la stabilité de $ClO_2Cd(ClO_4)_3$ sont valables dans le cadre de la réaction [4].

(c) Synthèse de $Hg(ClO_4)_2$ à partir de $Hg(ClO_4)_2 \cdot 6H_2O$

Les propriétés déshydratantes de Cl_2O_6 (1*b*, 9) permettent de synthétiser $Hg(ClO_4)_2$ à partir de $Hg(ClO_4)_2 \cdot 6H_2O$. Cette méthode dérive de la préparation des perchlorates à partir des chlorures hydratés (1*b*, 5, 9). Rappelons que la préparation se fait en deux étapes : Cl_2O_6 réagit d'abord sur le chlorure hydraté pour donner un perchlorate hydraté puis il y a déshydratation.

Notons que quel que soit l'excès de Cl_2O_6, il est impossible d'isoler à température ambiante un perchlorato mercurate de chloryle stable.

(d) Synthèse de perchlorato cadmiates et mercurates à partir de nitrates hydratés

La réaction de Cl_2O_6 avec des nitrates hydratés a déjà été éprouvée (1*b*, 9, 15, 29). On a pu préparer des perchlorato métallates de Mn, Fe, Co, Ni, Cu, Zn, Th et Al, et proposer une méthode simple de préparation de NO_2ClO_4 à partir de HNO_3 (29*b*).

Cette réaction obéit généralement aux équations :

[5] $$M(NO_3)_n \cdot mH_2O + (2n+m)Cl_2O_6 \rightarrow (NO_2)_nM(ClO_4)_{2n} + 2nClO_2 + n/2O_2 + mHClO_4 + mHClO_3$$

[6] $$(NO_2)_nM(ClO_4)_{2n} \rightarrow (NO_2)_{n-1}M(ClO_4)_{2n-1} + NO_2ClO_4$$

(n, degré d'oxydation du métal)

Les étapes intermédiaires conduisant à [5] ont été explicitées par ailleurs (1*b*, 9). On a pu montrer que la réaction [5] était tributaire de l'engagement du nitrate vis à vis du métal dans le sel de base, et du degré d'hydratation (m) du sel : si $m < 2$ la réaction est difficile, si $m > 5$ il y a compétition entre la réaction [5] et la réaction parasite :

[7] $$ClO_2^+ + NO_3^- \rightarrow NO_2 + \tfrac{1}{2}O_2 + ClO_2$$

Le nitrate est détruit totalement ou partiellement et une réaction analogue à [1] a lieu. Ceci conduit à la formation du mélange : $(ClO_2)_xM(ClO_4)_{(n+x)}$, $(NO_2)_mM(ClO_4)_{(n+m)}$ (cas des complexes perchlorato de Co (1*b*, 9), d'Al (15)). Lorsque Cl_2O_6 réagit avec $Cd(NO_3)_2 \cdot 6{,}5H_2O$ (tableau 1) on obtient un mélange de $Cd(ClO_4)_2$ et $NO_2Cd(ClO_4)_3$. Le faible stabilité de $ClO_2Cd(ClO_4)_3$ ne permet pas d'observer sa formation.

Avec $Cd(NO_3)_2 \cdot 1{,}8H_2O$ et $Hg(NO_3)_2 \cdot 1H_2O$, les réactions obéissent à l'équation [5] mais sont lentes et nécessitent un large excès de Cl_2O_6 pour être complètes. Pour le complexe de cadmium, l'analyse chimique révèle des traces ($\varepsilon < 0{,}05$) de nitrate de base mais la spectroscopie de vibration et les diagrammes de poudre ne permettent pas de le détecter. La phase $NO_2Cd(ClO_4)_3$ a pu être caractérisée sans ambiguïté.

Le complexe de mercure attendu dans la première étape, $(NO_2)_2Hg(ClO_4)_4$, a été préparé, par contre son chauffage sous vide selon la méthode décrite (15) n'a pas permis d'isoler $NO_2Hg(ClO_4)_3$ mais un complexe de stoechiométrie voisine :

For personal use only.

$(NO_2)_{0,8}Hg(ClO_4)_{2,8}$. Ce dernier composé est un mélange. Une tentative pour le purifier à 126°C durant 14 h a conduit à un produit qui a explosé à température ambiante dès qu'il a été exposé à la lumière du jour.

(e) Remarques sur la synthèse des complexes perchlorato de Cd et Hg

Au cours de ce travail, nous avons montré que la faisabilité des synthèses des complexes perchlorato était liée à l'environnement du centre métallique. Nous avons déjà exploité et expliqué ces faits (1*b*, 5, 9, 15). Cependant, la colonne IIB présente une particularité évidente : la réactivité des chlorures anhydres de ces éléments vis à vis de Cl_2O_6 décroît nettement quant le numéro atomique croît.

Par exemple, il y a substitution partielle des atomes de chlore de $HgCl_2$ avec formation de $HgClClO_4$, et l'obtention de $Hg(ClO_4)_2$ est difficile.

Par ailleurs, $ClO_2Zn(ClO_4)_3$ est stable (1*b*), $ClO_2Cd(ClO_4)_3$ est instable, alors que $ClO_2Hg(ClO_4)_3$ n'a pas pu être isolé à température ambiante.

Cette réactivité décroissante des éléments du groupe IIB liée à la stabilité des composés formés, peut s'expliquer aisément en faisant appel au concept H.S.A.B. (Hard and Soft Acid and Bases) de Pearson (12*a*) :

(*i*) quand on passe de Zn à Hg, la mollesse des centres acides M^{2+} augmente (Zn^{2+} est considéré comme un acide frontière (ou limite), Cd^{2+} comme un acide mou et Hg^{2+} comme un acide très mou), ceci défavorise la coordination de ClO_4^- : base parmi les moins dures.

(*ii*) il est difficile pour ClO_4^- de remplacer des bases plus dures que lui, tel que Cl^-, déjà liées à des acides mous. Remarquons ici que la substitution relativement facile de CO_3^{2-} par ClO_4^-, rencontrée lors de l'utilisation de $CdCO_3$, s'explique par la dureté sensiblement comparable de ces deux ligands.

Remarquons également que l'accroissement des rayons des cations M^{2+} (Zn < Cd < Hg) peut rendre compte des difficultés de perchloratation lorsqu'on passe de Zn à Hg.

Analyse structurale

Si l'on exclut $HgClClO_4$ qui est un composé ionique, tous les composés isolés au cours de ce travail sont, d'après leurs spectres de vibration (figures 1, 2, 5, 6, 7, 9), des complexes perchlorato dans lesquels le groupement ClO_4 est lié au métal.

Seule l'étude du diagramme X de poudre de $Cd(ClO_4)_2$ a pu être menée à bien (tableau 2); les autres produits présentent les diagrammes complexes (tableau 4) et les composés auxquels on pourrait éventuellement les comparer ont des symétries cristallines trop faibles pour que l'on puisse établir surement un isomorphisme.

La comparaison des spectres de vibration montre que les complexes sont différents dans leur arrangement moléculaire.

(a) Le perchlorate de chloro-mercure : $HgClClO_4$

Seul le spectre Raman de ce composé a pu être enregistré avec précision (fig. 1). Le spectre infra-rouge est largement perturbé par un effet Christiansen (30) et sa qualité n'a pu être améliorée en utilisant une suspension dans du Nujol, car le produit est très réactif.

On relève sur le spectre Raman les raies caractéristiques d'un groupement ClO_4 ionique : 460 cm^{-1} $\delta_s(E)$; 622 $\delta_{as}(F_2)$; 924–935 $\nu_s(A_1)$ (dédoublée par effet de cristal); 1025–1101 cm^{-1} $\nu_{as}(F_2)$. Le cation associé est donc $HgCl^+$. Les vibrations de valence de $HgCl_2$ interviennent à 313 et 375 cm^{-1} (31). Si $HgCl^+$ était monomère, HgCl serait détecté à une fréquence supérieure ou égale à la moyenne des fréquences ν HgCl dans $HgCl_2$ (344 cm^{-1}). Sur le spectre Raman on relève deux raies à 247 et 272 cm^{-1} et un épaulement à 286 cm^{-1}. Leur nombre et les fréquences observées sont l'indication de la formation de $(HgCl^+)_n$ et de ponts Hg–Cl–Hg. Ce fait n'est pas surprenant puisque de nombreux complexes HgXL (X = I, L = NO_3^- (32); X = OH, L = ClO_4^- (33); X = OH, L = ClO_3^- ou BrO_3^- (34); X = NH_2, L = Cl^- (34) etc.) présentent des cations HgX^+ polymères en chaîne analogues à HgO (34).

[a]Rosolovskii et coll. (réf. 10).
[b]Ce travail : groupe d'espace $R\bar{3}$; a = 10,18; c = 14,78 Å.

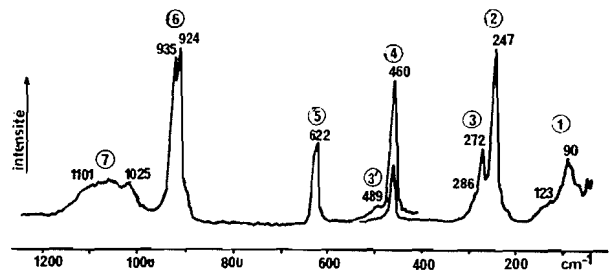

FIG. 1. Spectre Raman de $HgClClO_4$ (1) : vibrations de réseau + $\delta(HgCl)_n$; (2) ν_s HgCl; (3) (et 3' ?); ν_{as} HgCl; (4) δ_s ClO_4; (5) δ_{as} ClO_4; (6) ν_s ClO_4; (7) ν_{as} ClO_4.

Compte tenu de ces remarques, nous avons porté sur le spectre Raman (fig. 1) les principales attributions des fréquences observées.

(b) Le bis(perchlorato cadmium) : $Cd(ClO_4)_2$

Les spectres infra-rouge et Raman de ce complexe sont reproduits sur la figure 2 et sont comparés à ceux de $Ni(ClO_4)_2$. L'allure de ces spectres montre qu'il existe une grande analogie entre les structures moléculaires des deux complexes.

Il a été possible d'indexer le diagramme de poudre de $Cd(ClO_4)_2$ dans le même groupe d'espace $R\bar{3}$ (système trigonal) que $Ni(ClO_4)_2$ (tableau 2), bien que Nikitina et Rosolovskii (16) aient considéré une maille cubique. Les paramètres de la maille de $Cd(ClO_4)_2$ se rapprochent de celle de $Zn(ClO_4)_2$ (tableau 3), qui comme $Ni(ClO_4)_2$ possède une structure lamellaire (7*c*) et des groupements ClO_4 tridentés en pont.

On considère que $Cd(ClO_4)_2$ a le même arrangement (fig. 3). L'environnement du métal est octaédrique comme cela a été trouvé pour de nombreux complexes de Cd (39).

Les principales attributions des bandes ou raies sont notées

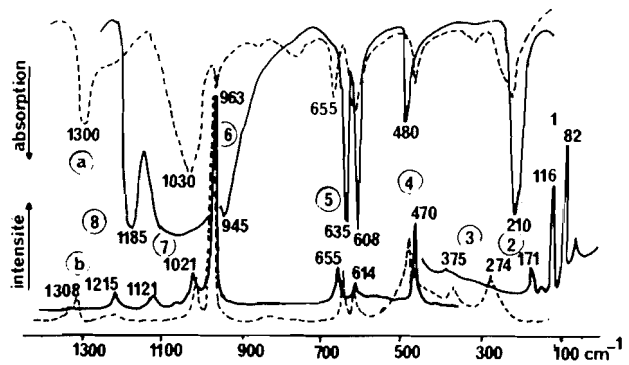

FIG. 2. Spectres (a) infra-rouge et (b) Raman de $Cd(ClO_4)_2$ (—) comparés à ceux de $Ni(ClO_4)_2$ (-----) : (1) réseau + déf. MO_6; (2) ν_{as} MO_6; (3) ν_s MO_6; (4) ρ_r ClO_4; (5) δ_s et δ_{as} ClO_{3p}; (6) ν_s ClO_p; (7) ν_{as} ClO_p; (8) ν ClO_t; O_p : oxygène lié à M; O_t : oxygène non lié.

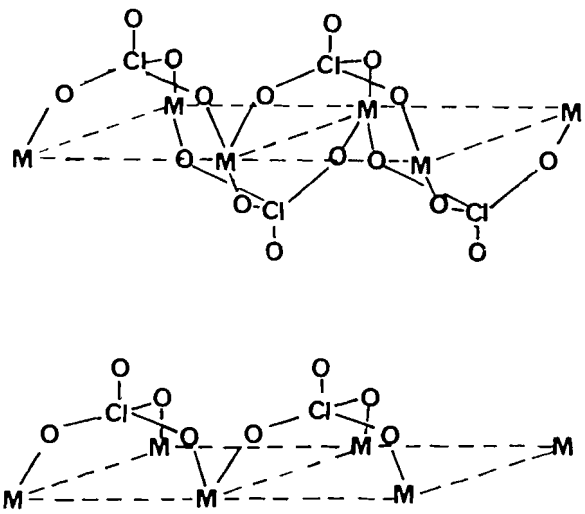

FIG. 3. Modèle possible pour $Cd(ClO_4)_2$: structure en couche analogue à celle de $Zn(ClO_4)_2$ (7*c*) et $Ni(ClO_4)_2$ (7*c*).

sur la figure 2. Les fréquences observées indiquent que l'interaction élément central (Cd) ↔ ClO_4 est plus faible que dans $M(ClO_4)_2$ (M = Ni, Co, Zn). Ceci est particulièrement vérifié avec la fréquence peu élevée (1185 cm^{-1}) relative à la vibration ν_{as} ClO_t (O_t : oxygène terminal non lié). Dans le cas d'un groupement ClO_4 fortement lié à un métal, la liaison ClO_t prend le caractère d'une double liaison et la vibration correspondante apparaît vers 1300 cm^{-1} (cf. $Ni(ClO_4)_2$). D'après la courbe ν ClO = $f(d\text{ClO})$ (1*c*) on en déduit, pour $Cd(ClO_4)_2$, que $d\text{ClO}_t$ = 1,40 Å et $d\text{ClO}_p$ = 1,43 Å (O_p : oxygène lié au métal). $[ClO_4]$ est peu perturbé; ceci est en accord avec la remarque précédente.

Les vibrations de valence symétriques du squelette CdO_6 apparaissent sous forme d'une bande intense en ir à 210 cm^{-1} et d'une raie de faible intensité vers 375 cm^{-1} en Raman.

Si l'on se réfère aux données relatives à divers complexes de cadmium dans lequels le centre Cd^{2+} est lié à des bases organiques : 2,22 < d(Cd—O) < 2,33 Å (39); la distance Cd—O dans $Cd(ClO_4)_2$ doit être supérieure à 2,22 Å. Cette hypothèse est en accord avec une valeur d(Cd—O) ≃ 2,40 Å, déduite de la relation dMO = f(R) (35) (R : rayons ionique effectif selon Brown et Shannon (36)). Cette distance M—O est nettement plus grande que celles habituellement observées dans des complexes perchlorato (Ni—O : 2,04 (7*b*); Co—O : 2,09

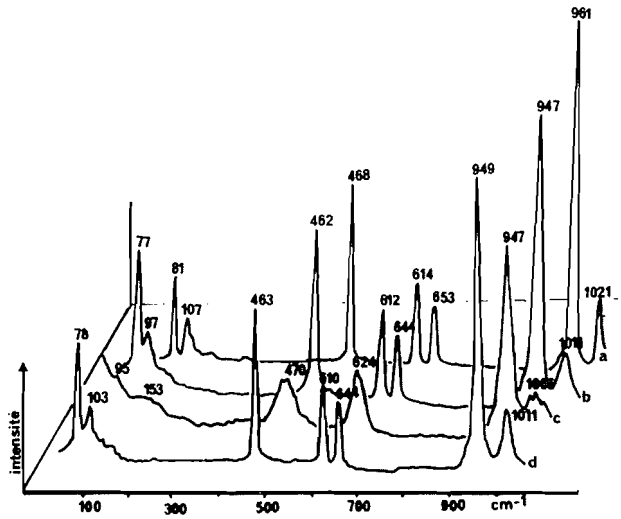

FIG. 4. Transformation de phase dans $Cd(ClO_4)_2$ suivie par spectroscopie Raman : (a) température ambiante; (b) 248°C; (c) 273°C; (d) 170°C (au refroidissement).

(7*b*); Cu—O : 1,95 (7*a*); Ti—O : 2,06 (1*c*)). Elle pourrait expliquer la variation des paramètres cristallins de $Cd(ClO_4)_2$ par rapport à ceux des complexes voisins.

Remarque : $Cd(ClO_4)_2$ présente une transformation de phase autour de 273°C et elle est réversible. Ce phénomène a pu être suivi par spectroscopie Raman (fig. 4). À cette température élevée, $Cd(ClO_4)_2$ est quasiment ionique.

(c) Le bis(perchlorato) mercure (II) : $Hg(ClO_4)_2$

Les spectres infra-rouge et Raman de ce complexe sont reproduits sur la figure 5. Ils sont différents de ceux de $Zn(ClO_4)_2$ ou $Cd(ClO_4)_2$. Alors que les spectres de ces derniers sont caractéristiques de groupements ClO_4 tridentés, ceux de $Hg(ClO_4)_2$ présentent des bandes ou raies de groupements ClO_4 monodentés. Elles sont localisées pour les vibrations de valence, autour de 800 (ν ClO_p), 1000 (ν_s ClO_t) et 1150 cm^{-1} (ν_{as} ClO_t). La raie relative à ν_s ClO_t apparaît à une fréquence anormalement basse. Rappelons qu'elle est habituellement située autour de 1050 cm^{-1} (21). On peut lier ce phénomène à une interaction secondaire similaire à celle notée pour $HgCl_2$ (37) et $Hg(SCNEt_2)_2$ (38), ou le ligand interéagit avec les atomes de mercure des molécules voisines. Le mercure est alors dans un environnement octaédrique déformé comme cela est habituellement rencontré (34).

La symétrie locale élevée autour de Hg se traduit par l'activité sélective infra-rouge–Raman et par le dédoublement des bandes et raies. Une attribution est proposée sur la figure 5. Les fréquences des vibrations de valence de ClO_4 montrent que la variation des distances ClO est importante : $d(ClO_p)$ ≈ 1,55 Å, $d(ClO_t)$ ≈ 1,40 Å. Elles classent $Hg(ClO_4)_2$ parmi les complexes où les groupements ClO_4 sont très fortement engagés.

(d) Le perchlorato cadmiate de chloryle : $ClO_2Cd(ClO_4)_3$

Les spectres ir et Raman de $ClO_2Cd(ClO_4)_3$ sont représentés sur la figure 6. Il existe une similitude du spectre Raman de ce complexe avec celui de $ClO_2Cu(ClO_4)_3$ (1*b*).

On note en tout premier lieu les raies et bandes relatives au cation ClO_2^+ : ν_{as} : 1295 et 1280 (ir) et 1307 et 1293 (R); ν_s : 1064 et 1056 (R); δ : 510 (ir) et 519 (R) cm^{-1}. Sur le spectre Raman mieux résolu que le spectre ir les autres raies sont attribuées à $Cd(ClO_4)_3^-$. Dans cet anion coexistent des groupements ClO_4

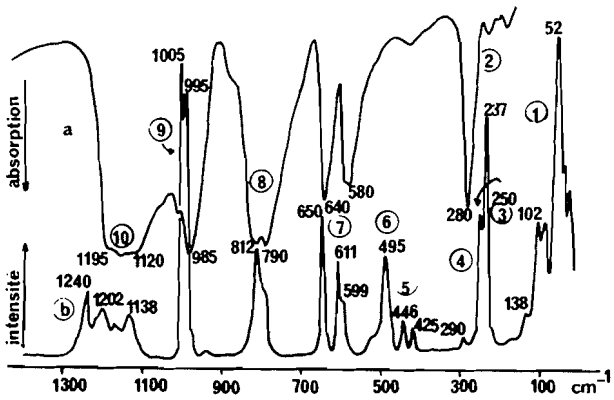

FIG. 5. Spectres (a) infra-rouge et (b) Raman de $Hg(ClO_4)_2$: (1) réseau + déf. HgO_2O_4 (cf. texte); (2) ν_s HgO; (3) ρ_r ClO_4; (4) ν_{as} HgO; (5) ν_{as} HgO + δ_s ClO_3; (6) δ_s ClO_3; (7) δ_{as} ClO_3; (8) ν ClO_p; (9) ν_s ClO_t; (10) ν_{as} ClO_t.

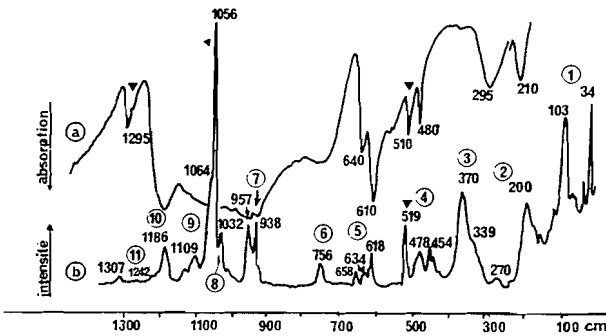

FIG. 6. Spectres (a) infra-rouge et (b) Raman de $ClO_2Cd(ClO_4)_3$: ▼ ClO_2^+; sur le spectre Raman les autres raies ou bandes sont attribuées à $Cd(ClO_4)_3^-$: (1) réseau; (2) ν MO; (3) ρ_r (m); (4) δ_s ClO_2 (m, b); (5) δ_{as} ClO_2 (m, b), ρ_w, ρ_r (b); (6) ν ClO_p (m); (7) ν_s, ν_{as} ClO_p (b); (8) ν_s ClO_t (m); (9) ν_s ClO_t (b); (10) ν_{as} ClO_t (b); (11) ν_{as} ClO_t (m) (m : monodenté, b : bidenté).

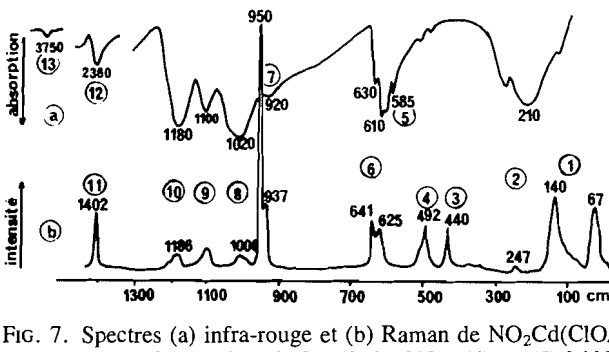

FIG. 7. Spectres (a) infra-rouge et (b) Raman de $NO_2Cd(ClO_4)_3$: (1) réseau + déf. CdO_6; (2) ν CdO_6; (3) δ_s ClO_2; (4) ρ_t; (5) δ NO_2^+; (6) δ_{as} ClO_2 + ρ_r + ρ_w; (7) ν_s ClO_p; (8) ν_{as} ClO_p; (9) ν_s ClO_t; (10) ν_{as} ClO_t; (11) ν_s NO_2^+; (12) ν_{as} NO_2^+; (13) (ν_s + ν_{as}) NO_2^+.

monodentés et bidentés; les principales attributions sont notées sur le spectre. On a déjà montré que les structures des perchlorato complexes dérivaient de celles de chlorures correspondants (7); $ClO_2Cd(ClO_4)_3$ doit se rapprocher de $ACdCl_3$ ou des composés $ACuCl_3$ (40), polymères avec des ligands pontants et terminaux.

(e) Le tris(perchlorato) cadmiate de nitryle : $NO_2Cd(ClO_4)_3$

Les spectres infra-rouge et Raman de $NO_2Cd(ClO_4)_3$ sont reproduits sur la figure 7. Ils sont semblables à ceux de $NO_2Ni(ClO_4)_3$ (1*b*) et sont comparables aux spectres infra-

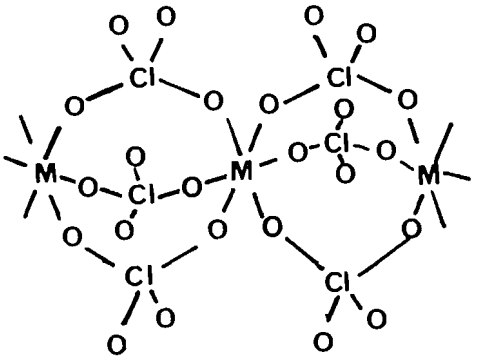

FIG. 8. Structure de l'anion $M(ClO_4)_3^-$ d'après des données EXAFS (41).

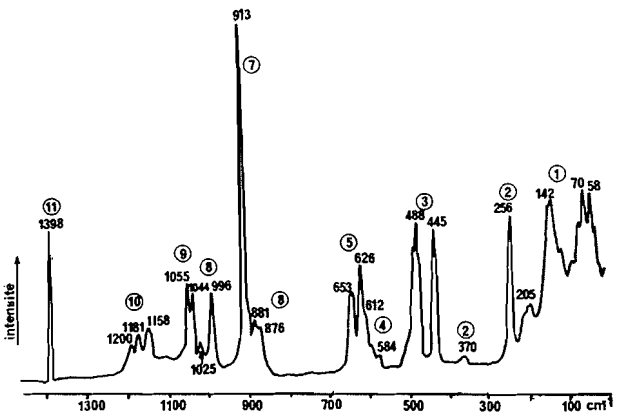

FIG. 9. Spectre Raman de $(NO_2)_2Hg(ClO_4)_4$: (1) δ HgO_6 + réseau; (2) ν HgO_6; (3) δ_s ClO_2 (m, b); (4) δ NO_2^+; (5) δ_{as} ClO_2 (m, b), ρ_r + ρ_w (b); (6) ν_{as} ClO_p (b) + ν ClO_p (m); (7) ν_s ClO_p (b); (8) ν_s ClO_t (m, en interaction); (9) ν_s ClO_t (m, libre); (10) ν_s, ν_{as} ClO_t (b), ν_{as} ClO_t (m); (11) ν_s NO_2^+.

rouge de divers complexes $ACd(ClO_4)_3$ (A = Li, Na, K, Rb, Cs, Bu_4N) isolés récemment par Rosolovskii et coll. (10).

Le diagramme de poudre de $NO_2Cd(ClO_4)_3$ est très proche de celui du sel de césium préparé par Rosolovskii et coll., mais diffère de ceux de la série isomorphe $NO_2M(ClO_4)_3$ (M = Mn, Co, Ni, Zn) et $ClO_2M'(ClO_4)_3$ (M' = Co, Ni) (1*b*, 9).

Les résultats de la spectroscopie de vibration indiquent que l'arrangement moléculaire de $NO_2Cd(ClO_4)_3$ est identique à celui de $NO_2Ni(ClO_4)_3$. Une étude EXAFS récente (41) a montré que le sel de nickel (ou de cobalt) était analogue aux chlorures $ANiCl_3$ (A = R_4N) à structure polymère en chaîne

(42) (fig. 8). Les groupements ClO_4 sont bidentés en pont et l'environnement du métal est octaédrique. Les principales attributions sont notées dans la légende de la figure 7. Les fréquences observées indiquent que le groupement ClO_4 dans $NO_2Cd(ClO_4)_3$ est peu perturbé; il a un caractère ionique important.

(f) Le tétrakis(perchlorato) mercurate de nitryle : $(NO_2)_2$-$Hg(ClO_4)_2$

Le spectre Raman de ce complexe est reproduit sur la figure 9. Il ne présente aucune raie caractéristique de NO_2ClO_4 (29*b*). C'est un complexe défini. La comparaison du diagramme de poudre et du spectre Raman de ce produit avec ceux de $(NO_2)_2Cu(ClO_4)_4$ (1*b*, 9) montre que ces complexes sont isomorphes et ont le même arrangement moléculaire. Sur le spectre (fig. 9) pour $Hg(ClO_4)_4^{2-}$, dans le domaine des vibrations de valence symétrique, on relève des raies caractéristiques de groupements ClO_4 monodentés libres ou perturbés par des interactions (respectivement à 1055, 1044 et 996 cm^{-1}). La raie intense à 913 cm^{-1} dénote la présence de groupements ClO_4 bidentés.

L'anion pourraît adopter un arrangement analogue à celui trouvé pour des motifs polymères HgX_4^{2-} (43), différent des anions monomères HgI_4^{2-} (43) et $Hg(NO_2)_4^{2-}$ (44). Les principales attributions sont notées dans la légende de la figure 9.

Conclusion

Avec ce travail, la connaissance des complexes perchlorato de la colonne IIB (ou 12) a progressé. Si les complexes de cadmium se rapprochent de ceux du zinc, du cobalt ou du nickel (avec modifications des paramètres cristallins dues, certainement, aux rayons ioniques effectifs différents des cations métalliques), les complexes du mercure en diffèrent totalement contrairement aux complexes fluorosulfato de la même série (46). Le comportement des complexes perchlorato semble être dû à l'acidité différente, selon Pearson, des cations M^{2+} (M = Zn, Cd, Hg). Ces différences d'acidité influent aussi bien sur les préparations que sur l'arrangement structural. Cependant, d'une façon générale, les complexes perchlorato isolés ont des structures qui dérivent de celles des halogénures correspondants.

Remerciements

Les auteurs remercient le C.N.R.S. (France) et la D.R.S.T. (Tunisie) pour l'aide financière qu'ils leur ont apportée.

NOTE : Alors que la rédaction de cet article était achevée, nous avons eu connaissance du travail de Rosolovskii et coll. (47) sur $Hg_2(ClO_4)_2$ et $Hg(ClO_4)_2$. Leurs méthodes de synthèses diffèrent des nôtres (déshydratation par voie thermique des complexes hydratés) pour $Hg(ClO_4)_2$. Leurs résultats spectroscopiques sont analogues aux nôtres. On note cependant de légères différences dans les données des diagrammes de poudre X.

Use of Pd/sepiolite systems as hydrogenation catalysts. II. Hydrogenolysis of *N*-blocked amino acids and dipeptides by hydrogen transfer

A. ARAMENDIA, V. BORAU, C. JIMENEZ, J. M. MARINAS, AND M. E. SEMPERE
Department of Organic Chemistry, Faculty of Sciences, Córdoba University, 14004 Córdoba, Spain

Received January 16, 1986[1]

A. ARAMENDIA, V. BORAU, C. JIMENEZ, J. M. MARINAS, and M. E. SEMPERE. Can. J. Chem. **65**, 2791 (1987).

We have carried out the deprotecting of various *N*-protected amino acids and dipeptides by subjecting them to hydrogen transfer with several palladium catalysts supported on different solids. The hydrogen donor itself has been used "*in situ*" to reduce the corresponding Pd salt on the support. We have also analyzed the effect of various factors on the deprotecting rate for Z-glycine. Such factors include the procedure used in synthesizing the catalysts ("*in situ*" or by conventional reduction), the type of support, hydrogen donor, promoting effect of alkaline hydroxides, type of reactor (closed or open), and magnetic or ultrasonic agitation. We have found that the ease of adsorption of the protected amino groups (*Z*—NH—) is fundamental in accounting for the order of deprotecting rates found. We have compared the activity of new catalysts in the deprotecting process with that of a commercial one containing 10% Pd over carbon, supplied by Fluka (ref. 75990).

A. ARAMENDIA, V. BORAU, C. JIMENEZ, J. M. MARINAS et M. E. SEMPERE. Can. J. Chem. **65**, 2791 (1987).

On a effectué la déprotection de divers acides aminés et de divers dipeptides portant un groupement protecteur sur le N; pour ce faire, on les a soumis à un transfert d'hydrogène avec plusieurs catalyseurs de palladium supportés sur divers solides. Le donneur d'hydrogène lui-même a été utilisé *in situ* afin de réduire le sel de palladium correspondant sur le support. En plus de ce travail, on a analysé l'influence de divers facteurs sur le taux de déprotection de la Z-glycine. Parmi ces facteurs, on note la procédure utilisée pour synthétiser les catalyseurs (*in situ* ou réduction conventionnelle), le type de support, le donneur d'hydrogène, l'effet activant des hydroxydes alcalins, le type de réacteur (ouvert ou fermé) et la méthode d'agitation (magnétique ou ultrasonique). On a trouvé que la facilité d'adsorption des groupements aminés protégés (*Z*—NH—) est fondamentale pour expliquer l'ordre que l'on a trouvé pour les taux de déprotection. On a comparé l'activité des nouveaux catalyseurs dans le processus de déprotection avec celle d'un catalyseur commercial contenant 10% de Pd sur du charbon et qui avait été fourni par Fluka (ref. 75990).

[Traduit par la revue]

Introduction

The reduction of different organic functions by hydrogen transfer (1) plays a major role in the field of organic synthesis nowadays. In the last few years, transfer reduction processes have been applied as a convenient method for removal of some protecting groups commonly used in peptide synthesis (2–8) such as *N*-benzyloxycarbonyl groups, C-terminal benzyl ester, the nitro function of nitroarginine or the *N*-benzyl grouping of N^2-benzylhistidine. In some instances, the reduction has been carried out in solid phase (Bradykinin synthesis) (4). The following are used as hydrogen donors: cyclohexene (2, 4, 7), cyclohexadiene (3), formic acid (5, 6), and ammonium formate (9). On the other hand, the process of deprotecting, by hydrogen transfer, showed negligible racemization (8).

In this paper we report the deprotecting of various *N*-blocked amino acids and dipeptides blocked in their amino function by the action of the benzyloxycarbonyl group (Z), using various hydrogen donors such as cyclohexene, formic acid, α-Phellandrene (5,6-dihydro-*p*-methylisopropylbenzene) and the formic acid – triethylamine at room temperature.

The following have been used as catalysts: Pd deposited at low concentration (3% by weight) on aluminium ortophosphate, aluminium ortophosphate – silica, aluminium ortophosphate – alumina, and a sepiolite from Vallecas (Madrid, Spain) supplied by TOLSA S.A.

Catalytic systems of $Pd/AlPO_4$, $Pd/AlPO_4–SiO_2$, and $Pd/AlPO_4–Al_2O_3$ had been employed earlier in transfer reductions of nitro groups (10) and α,β-unsaturated carbonyl compounds (11–14), as well as in the decarbonilation of aromatic aldehydes (15). Likewise, Pd–sepiolite catalysts are now being used as reduction catalysts for aromatic nitro-compounds and imines (16, 17).

[1]Revision received July 10, 1987.

Experimental

Supports

We have used eight different supports, as shown in Table 1. Support S is made of commercial silica from Merck (Kieselgel, 200–250 mesh). The sepiolite (Sep) was supplied by TOLSA S.A. (Madrid, Spain) and was extracted from their deposite in Vallecas (Madrid). The thus-labelled Sep_{300} was calcined at 300°C for 4 h. Whereas sepiolite Sep_{400} was calcined over the same period at 400°C. Support B consists of aluminium ortophosphate synthesized in our laboratory (18), whereas supports E, P2, and F72 contain $SiO_2–AlPO_4$ (80:20 by weight) and were obtained by different procedures reported elsewhere (19, 20). Support CB consists of $Al_2O_3–AlPO_4$ (25:75 by weight), the synthesis of which was described in an earlier paper (21). Table 1 gives a summary of the texture properties of the different supports used.

Table 2 lists the titration results of the acidic, basic, oxidizing, and reducing sites of the supports with cyclohexylamine (CHA), *m*-nitrobenzoic acid (MNBA), phenothiazine (PT), and tetracyanoethylene (TCNE), respectively, using a procedure developed by our team (22, 23) described below.

All supports were sifted through 200–250 mesh.

Surface chemical properties

Surface acidity and basicity of the catalysts were determined by the titration method with cyclohexylamine (CHA pK_a = 10.6), and *m*-nitrobenzoic acid (*m*-NB pK_a = 3.47), respectively. One-electron donor and one-electron acceptor properties were determined on the basis of adsorption on the catalyst surface of tetracyanoethylene (TCNE, electron affinity 2.88 eV) or phenothiazine (Ft, ionization energy 7.13 eV) using the same spectrophotometric method already cited.

In each experiment a freshly prepared titrant agent solution (10 mL) is pippeted into a cylindrical glass tube previously was loaded with the solid (about 0.1 g). The tube is fitted with a ground glass stopper, shaken for 1 h at constant temperature (298 K), and the concentration of substrate in solution, in equilibrium with the adsorbed substrate, is determined spectrophotometrically.

Sorption experiments are developed at the maximum absorption

[a]X_m = moles of titrant/g support, CHA = cyclohexylamine, *m*-NB = *m*-nitrobenzoic acid, Ft = phenothiazine, TCNE = tetracyanoethylene.

wavelength (λ_{max}, nm) and between the titrant concentrations where the Lambert–Beer law is fitted. The time required for the system to reach equilibrium at constant temperature was checked for each solid and titrant, and it was never more than 45 min.

The chemical interaction between the adsorbate and the surface is consistent with the Langmuir adsorption isotherm equation:

$$c/X = (1/bX_m) + c/X_m$$

where c is the concentration of substrate in solution, in equilibrium with the adsorbed substrate; b is a constant; X is the amount of adsorbed substrate per g of solid, and X_m is the monolayer coverage, which corresponds to the theoretical amount of solute by 1.0 g of solid system if all sites are covered.

The method is capable of providing useful data not only on the total concentration of sites but also on their strength as well as the relative number of sites accessible to adsorbed molecules, by the use of compounds with different pK_a (or ionization energy, or election affinity) and steric hindrance.

The determination of surface chemical properties by the spectrophotometric method was carried out in cyclohexane solutions (spectroscopic grade, Merck) at 298 K.

Catalysts

The catalysts obtained "*in situ*" were prepared by adding over the corresponding support the amount of salt required for each reaction and, over both and in this order, the donor and the protected amino acid or dipeptide, previously dissolved in methanol or a methanol – acetic acid mixture.

The catalyst not obtained "*in situ*" was prepared by incipient impregnation with Na_2PdCl_4, drying in an oven at 110°C for 24 h, calcination (by increasing the temperature at a rate of 1°C min^{-1} up to 250°C) and subsequent reduction in a hydrogen stream at a flow-rate of 60 mL min^{-1}, following the same thermal treatment as for its calcination. It is labelled Pd_3F-72, the postscript indicating the Pd content (%).

Catalysts promoted by alkaline hydroxides

In this case, the amount of alkaline hydroxide needed was added over the support – metal salt mixture, and the remainder of reagents were then added as for the catalysts not promoted by alkaline hydroxides. The metal precursor used in this case was always $PdCl_2$ from Riedel (ref. 14757).

The commercial catalyst used as reference consists of 10% Pd over carbon (Fluka, ref. 75990).

Chemicals

Both Pd salts, hydrogen donors, and protected amino acids and dipeptides used were commercial reagents supplied by Merck, Fluka and Sigma. All were distilled or recrystallized prior to use.

Product analysis

The reaction products, once homogenized with excess methanol, were analyzed by hplc, using a Perkin-Elmer series 2 liquid chromatograph furnished with a variable-wave LC-75 ultraviolet detector. The working wavelength was 254 nm. An LKB column (LiChrosorb RP-18, 5 μm 4 × 250 mm) was used. A methanol–water mixture (75:25 by volume) with a flow of 0.8 mL min^{-1} were used as carrier. The internal standard employed was naphthalene.

In addition to the deprotecting product, the deprotecting of the benzyloxycarbonyl group (Z) yields CO_2 and toluene. Cyclohexene used as a donor is transformed into benzene. The occurrence of both toluene and benzene has been checked by gc–ms, using the Hewlett-Packard 5990B system and a column (2 m long, 1/8 in. wide) containing 5% polyphenyl ether over chromosorb GAW-DMCS. Free amino acids and peptides were recovered by distillation of the solvent and subsequent recrystallization. Their melting points were checked

on an oil-bath apparatus and were consistent with those given in the literature for the pure products.

Thermogravimetric analysis

The catalyst was placed in the thermogravimetric analyser (Cahn 2000) and allowed to dry under flowing N_2 overnight. The TGA was conducted in an air atmosphere at a heating rate of 10 K/min.

X-Ray diffraction analysis

X-Ray diffractograms were recorded on a Siemens D 500-1 apparatus, by using the Cu K_α radiation, with $\lambda = 1.5418$ Å.

Determination on the Pd content

The chemical analysis of the metal content was made by atomic absorption spectrometry using a Perkin-Elmer 370 instrument with a hollow cathode lamp, at $\lambda = 247.8$ nm.

Experimental setup and conditions

The reactions were carried out in a two-necked flask fitted with a reflux condenser and septum for all the samples, using 1.44×10^{-3} mol of protected amino acid or dipeptide, 0.5 g of 3% palladium supported catalyst and 3.97×10^{-2} mol of hydrogen donor and 5 mL of methanol as solvent. Some acetic acid had to be added in order to facilitate the dissolution of the starting product in the case of the dipeptides. The reaction mixture was placed on a silicone bath at 30°C and stirred magnetically at 700 rpm. Under these conditions we have verified that the process is not diffusion-controlled. Moreover, blank runs indicated a lack of activity in the absence of metallic phase, even in the presence of pure supports.

Results and discussion

Table 3 lists the results obtained on the effect of temperature on the deprotecting rate of Z-glycine. As can be seen, the effect is significant. When using cyclohexene as a donor, the time needed to achieve 100% conversion is three times shorter at 80°C than at 30°C. Nevertheless, for subsequent experiments, we chose a temperature of 30°C because the thermal lability of some groups occurring in natural products.

As can be seen in Table 4, the catalyst reduced "*in situ*" is much more active than that prepared by a conventional incipient impregnation procedure when using the commonest hydrogen donors cyclohexene and formic acid. For this reason, we only employed catalysts reduced "*in situ*" in all subsequent experiments.

[a]Support, F-72; salt, Cl_4PdNa_2; donor, 3.94×10^{-2} mol cyclohexene; acceptor, 1.44×10^{-3} mol Z-Gly. Solvent, 5 mL methanol; reaction temperature, 30°C. We have used only formic acid both as the solvent and the donor, the resulting yield is the same.

[b]Catalyst prepared by incipient impregnation as described under "Experimental".

[c]*X* (%) = 100 at $t_{reaction} = 6$ h.

Table 5 lists the results obtained in analyzing the influence of the precursor salt. The reaction rate decreases in the order $(CH_3COO)_2Pd > Na_2PdCl_4 > Pd(NO_3)_2$ for salts dissolved in dimethylformamide. For a given salt (e.g. Na_2PdCl_4 dissolved in H_2O or DMF), the activity of the catalyst obtained is higher for aqueous solutions than for organic solvent.

The results of the XPS experiments, carried out with an Mg excitation source and an MgK_α anode at a potential of 12 kV, an intensity of 20 mA, a multiplier potential of 2.8 kV, and a vacuum of 10^{-8} mbar by recording at a constant *E*, are shown in Figs. 1–4 for the systems obtained using Na_2PdCl_4, $Pd(NO_3)_2$, $Pd(CH_3COO)_2$, and $(NH_3)_4PdCl_2$, respectively, as precursors. As can be seen, the results show that the systems formed from the precursors Na_2PdCl_4, $Pd(NO_3)_2$, and $(CH_3COO)_2Pd$ contain no unreduced Pd. On the other hand, some Pd^{2+} was found in the $Cl_2(NH_3)_4Pd$ sample. The high stability of the Pd—NH_2 bond obviously hinders the precursor reduction.

By using molecular hydrogen we have checked that Na_2PdCl_4, $Pd(CH_3COO)_2$, and $Pd(NO_3)_2$ also reduced much more readily than $(NH_3)_4PdCl_2$. Since the dispersion of Pd in these systems generated "*in situ*" is similar, their differences in activity must be related (at least in part) to the ease of reduction of the different precursors. This points to Pd^0 rather than to any Pd^{2+} salt or complex as the actual catalytic species.

To demonstrate that the catalytic activity is related to the Pd^0 content, we carried out the following experiments: (*a*) determination of Pd^{2+} in the liquid phase and on the support after 5 min reaction for all Pd precursors used. (*b*) Determination of Pd^{2+} from precursor Na_2PdCl_4 after reacting for 5 min in the absence of support. No Pd^{2+} from the Na_2PdCl_4 remains in solution after reacting for 5 min while both Pd^0 and Pd^{2+} from $Pd(NO_3)_2$ and $(CH_3COO)_2Pd$ are found. On the other hand, only Pd^{2+} (2.5% in solution and the remainder adsorbed on the support) is found from $Cl_2(NH_3)_4Pd$. (*c*) TGA studies of the catalyst samples from Na_2PdCl_4 as precursor, both in the absence and presence of the support. A weight increase equivalent to 95% of that theoretically corresponding to the full conversion of Pd^0 present to PdO was found. (*d*) X-Ray diffraction studies of the catalyst samples prior to and following the TGA: The results obtained allow us to state that the samples are Pd^0 ($2\theta = 40.4$; $2\theta = 47.2$), see Fig. 5*a*, and PdO ($2\theta = 34$; $2\theta = 55$), see Fig. 5*b*, before and after the TGA, respectively.

We therefore believe the Pd^0 content is the determining factor of the rates found.

As for hydrogen donors (Table 6), cyclohexene yields much

better results than the others. Moreover, neither limonene nor tetralin used at 30°C for 2 h allows the desired deprotecting. In both cases Na_2PdCl_4 remains unchanged.

Silica has proved to be the most efficient support (Table 7), followed by the SiO_2–$AlPO_4$ systems. Thus, the order of activity found according to the support used was F-72 > P2 > E > CB > Sep. This order can be accounted for by the acidic sites of these supports (see Table 2). The higher the density of acidic sites, the more favourable the hydrogenolysis of the protecting group. The order varies inversely with the number of basic sites: the higher their density, the lower the hydrogenolysis rate. In fact, it is the silica support which contains a large number of acidic sites and a high density of reducing sites, but virtually no basic centres, which yields the best results.

[a]Salt, Cl_4PdNa_2; donor, 3.94×10^{-2} mol cyclohexene; acceptor, 1.44×10^{-3} mol; solvent, 5 mL MeOH; reaction temperature, 30°C.

On the other hand, the yields obtained in the absence of support (Table 7) are substantially lower than those achieved with any of the supports assayed.

Table 8 shows the results found in the possible promoting effect of NaOH. We found an optimum molar ratio of NaOH-to-Pd of 4. The influence of alkaline hydroxides on the promotion of Pd catalysts has been widely discussed by several authors (24), and our team encountered this effect in earlier works (e.g. in the reduction of benzylidene derivatives (25) and other organic functions (26)). Table 9 also shows the effect of the type of alkaline hydroxide on the optimum ratio found. The order found was $Na^+ > K^+ > Li^+$. The greater similarity between the ionic radii of Na and Pd ($r_{Pd^{2+}} = 0.86$, $r_{Na^+} = 0.95$, $r_{Li^+} = 0.60$, $r_{K^+} = 1.33$ Å) could account for this order. Other authors (27) have found that LiOH exerts a more marked effect on the promotion of Ni catalysts, which is logical taking into account the greater similarity between the ionic radii of Ni^{2+} and Li^+ ($r_{Ni^{2+}} = 0.63$ Å).

The strong promoting effect of alkaline hydroxides is attributed in this particular case to the formation of a Pd^{2+} hydroxide reported as an active catalyst (7), or its precursor (28) in hydrogenolytic processes. On the other hand, we have verified that the NaOH-to-Pd ratio influences the Pd dispersion (25, 26) as stated by other authors who have used Pd/C (28) and $Co/\gamma\text{-}Al_2O_3$ catalysts (29).

Table 10 compares the conversions obtained with different amino acids protected in their amino group by a benzyloxycarbonyl function (Z). The presence of sulphur (e.g. in methionine) inhibits the deprotecting as the Pd salt remains dissolved and does not allow the formation of the catalytic species. The rate order found for the different amino acids glycine > alaline > valine coincides with an increasing order of steric hindrance of the adsorption of the protected amino group on the catalyst. In comparing serine and alanine, the higher rate of the former could be attributed to the negative interaction of the OH group, since its binding to the catalyst via this position would hinder the hydrogenolysis of the Z—N— group. The adsorption mechanism also seems to be a decisive factor for the dipeptides analyzed (see Table 11). These compounds bear two —NH— groups which can bind to the catalyst. The introduction of CH_3— groups next to the peptide —NH— groups will indirectly favour the adsorption via blocked —NH— and hence the hydrogenolysis Z—Gly—Gly > Z—Gly—Ala. As can be seen, the introduction of an aromatic ring in the vicinity of a peptide —NH— group which is strongly absorbed on the catalyst (Z—Gly—Gly—nitrophenylester) hinders the deblocking. Again, in Z—Valyl—Ala methyl ester, the presence of the isopropyl group of valine slows down the reaction through the steric hindrance of the adsorption via Z—NH— group.

In summary, the ease of adsorption on the catalyst is a decisive factor in accounting for the order of deblocking rates found. The deblocking rates obtained with our catalysts are much higher than that of the Pd(10%)/C catalyst supplied by Fluka (ref. 75990): in fact, this commercial catalyst achieves a deblocking less than 1% for Z—glycine after 2 h, whereas support F-72 and the use of the optimum NaOH-to-Pd ratio for 1 h allows 100% conversion. Further experiments made by our team have shown that our catalysts are highly active in the hydrogenolysis of benzyl ethers and esters. On the other hand, we have started to perform the deblocking in a closed reactor (Berghol Heiz) by hydrogen transfer at 40°C, achieving 100% conversion in 5 min by using the optimum catalyst reported in this paper and the amounts of hydrogen donor and substrate described under "Experimental". Ultrasonic agitation (see Table 10) yielded better results than magnetic stirring (48% and 10% respectively, at 20°C for 5 min).

TABLE 8. Optimization of the NaOH-to-Pd ratio for hydrogenolysis (transfer) of Z—glycine[a]

We also performed tests to determine the possible racemization caused by the support or the reaction medium. As far as Z—L-alanine is concerned, the specific optical activity of the reaction product allows one to state that racemization is negligible. We have applied Izumiya's test to Z—L-alanyl—L-phenylalanine, finding no diastereoisomers when using the optimum catalyst.

Analytical potentiometry is a powerful technique to investigate multiple species in solution and their formation constants. However, there have been some difficulties in this method resulting primarily from the theoretical approach. In this paper we critically examined them and improvements have been implemented successfully. Suitable experimental designs are adapted and preliminary computation of potentiometric data are performed to minimize potential sources of errors. Criteria are proposed to choose the best set of titration curves. A correction is introduced to partially minimize the errors originating from the volume variation. A linear-scaled minimization algorithm has been implemented to extract the value of the complex stability constants from the experimental free ion concentrations. This has two advantages over the earlier non-linear minimization process. The execution time is faster and it facilitates the selection of the best fit of species. A series of 14 programs are introduced to run on a low memory microcomputer.

PATRICK DECOCK et BIBUDHENDRA SARKAR. Can. J. Chem. **65**, 2798 (1987).

Il est reconnu que la méthode de potentiométrie analytique présente un grand intérêt dans l'étude de la répartition des espèces en solution. Elle permet d'accéder à la valeur de leur constante de formation. L'approche théorique de cette technique repose sur des approximations conceptuelles qui n'ont pas pu être totalement contournées dans les versions antérieures. Nous avons examiné les points les plus critiques afin d'y pallier. (Aucun programme, aussi sophistiqué soit il, ne peut aboutir à des résultats valables qu'avec des données qui le sont également.) Aussi une méthodologie expérimentale, liée à des calculs préliminaires sur les données potentiométriques, est proposée. Elle contribue à minimiser les sources d'erreurs expérimentales potentielles. Des critères ayant pour but de sélectionner les meilleurs jeux de courbe de titration sont décrits. Des corrections, réduisant les effects des variations des volumes, sont exposées. Un processus de minimisation linéaire, permettant d'extraire les valeurs des constantes de formation des complexes de celles des concentrations en ions libres expérimentales a été introduite avec succès. Ce type de minimisation présente deux avantages essentiels sur les techniques non linéaires utilisées antérieurement. Elle est rapide en temps d'exécution machine et elle est en soit un critère de selection du choix des espèces présentes en solution. Une série de 14 programmes, concus spécialement dans le contexte de la microinformatique est introduite.

Introduction

Based on a procedure by Lefebvre (1), Österberg (2) and Sarkar and co-workers (3–5) had developed a method for determining the concentration of free ligand(s) and metal as a function of pH in a multicomponent system at equilibrium. Subsequently, this laboratory has used this technique extensively to study a variety of metal–ligand equilibria of biological interest (6–14). There are variations of this procedure which are alternatively called as FICS (free ion concentrations in solution) or analytical potentiometry (15–17). There are also other techniques (18–25) available to study species distribution and formation constants which employ different approaches to calculate free concentrations of ions. They all need high speed and large memory computers.

Successful application of analytical potentiometry requires a large quantity of data and high degree of experimental accuracy. The last difficulty can be partially solved by using high concentration of ligands and metal if there is no problem of solubility. Attempts have been made to minimize potential sources of errors by adapting newer experimental designs (15). In this paper we propose a general method which reduces the number of experimental data and at the same time increases the overall accuracy. A correction is included which takes into account the volume variation during the titration. A linear-scaled least-squares algorithm is proposed to expedite the microcomputer solution of metal complex stability constants from potentiometric data. Contrary to the non-linear procedures, this method of minimization allows one to choose the correct set of species easily.

Theory

In analytical potentiometry, the basic relationship for determining the average free concentrations $\bar{C}_i^{\nu}$ at pH = ν in complex equilibria is

$$[1] \quad p\bar{C}_i^{\nu} = p\bar{C}_i^{0} - \int_{pH^0}^{pH} \left(\frac{\partial T_{i,j}^{*\nu}}{\partial T_{i,j}^{\nu}} \right)_{T_{s,j}^{\nu}(s \neq i),\, pH,\, \theta,\, v} dpH$$

where C_i^0 is the average free concentration of ion i (for metal $i = 1$, for ligand 1 and 2, $i = 2$ and 3) at initial pH (pH^0). $T_{i,j}^{\nu}$ and $T_{i,j}^{*\nu}$ are the analytical concentration of ion i and the concentration of protons liberated, respectively, at pH = ν.

To evaluate the derivative part of eq. [1], we assume that the hypersurface which is determined by the ratio of pH and the concentrations $T_{i,j}^{\nu}$ ($i = 1$ to 3) is flat (1). This condition must be examined carefully for all titration sets. With the above assumption as well as taking into consideration of all the constants of eq. [1], a linear correlation between $T_{i,j}^{*\nu}$ and $T_{i,j}^{\nu}$ can be expected. Consequently the derivative term of eq. [1] is the slope (S_i^{ν}) of this straight line. However, establishing such ideal conditions is not feasible, hence we decided to make an

approximation relating $T_{i,j}{}^{*\nu}$ and $T_{i,j}{}^{\nu}$ by a linear least-squares line passing through three different values of j. Our objective is to increase the probability of keeping the line in a flat region of the hypersurface. This is closely approximated by limiting the titration set to three curves and using the differences between $T_{i,j}{}^{\nu=\mathrm{pH}_0}$. Satisfactory results have been obtained with several systems following such an approach (26).

All our titrations are carried out in the presence of an excess of strong acid. This serves three important functions: it enables one to verify the electrode response; low pH causes complete protonation of ligand(s); and it facilitates the measurement of the accurate amount of ligand(s) in the complex solution. We take into account the excess of strong acid (NH_j) in the following eq. [2]

$$[2]\quad T_{i,j}{}^{*\nu} = \frac{V_j{}^{\nu} \times \mathrm{CB}_j + \mathrm{NH}_j}{V_j{}^{0} + V_j{}^{\nu}}$$

where $V_j{}^0$ is the initial volume of the solution, CB_j is the base concentration of the titration j, $V_j{}^{\nu}$ is the added volume of base at pH = ν for the titration j.

The analytical concentration of metal and ligand(s) are given in eq. [3]

$$[3]\quad T_{i,j}{}^{\nu} = \frac{N_{i,j}}{V_j{}^{0} + V_j{}^{\nu}}$$

where $N_{i,j}$ is the analytical mole number of ion i.

Calculations of the slopes $S_j{}^{\nu}$ are performed for all the combinations of ligand(s) or metal variations by sets of three titrations. The best set of curves is chosen using the following criteria:

1. Lowest sum of standard deviations of the least squares lines calculated at each pH.
2. Minimum value at each pH of the quantities appearing in

$$\frac{T_{i,2}{}^{*\nu} - T_{i,1}{}^{\nu}}{T_{i,2}{}^{\nu} - T_{i,1}{}^{\nu}} - S_i{}^{\nu} \quad \text{and} \quad S_i{}^{\nu} - \frac{T_{i,3}{}^{*\nu} - T_{i,2}{}^{\nu}}{T_{i,3}{}^{\nu} - T_{i,2}{}^{\nu}}$$

3. Lowest degree of curvature (DC_i) of the function $T_{i,j}{}^{*\nu}$ against $T_{i,j}{}^{\nu}$ at each pH as it is defined in eq. [4]

$$[4]\quad \mathrm{DC}_i = \sum_{\nu=\mathrm{pH}^0}^{\mathrm{pH}} T_{i,2}{}^{*\nu} - (T_{i,3}{}^{*\nu} - T_{i,1}{}^{*\nu}) \times (T_{i,2}{}^{\nu} - T_{i,1}{}^{\nu})/(T_{i,3}{}^{\nu} - T_{i,1}{}^{\nu}) - T_{i,1}{}^{*\nu}$$

The coefficients j (1 to 3) are such that

$$[5]\quad T_{i,j=1}^{\nu} < T_{i,j=2}^{\nu} < T_{i,j=3}^{\nu}$$

4. In the case of metal variation (i = 1), an additional criterion is adopted: Minimum deviation between the volume of added base extracted from the set of three titrations at the extrapolated (β^{ν}) zero metal concentration and the same volume calculated from $\mathrm{p}K_a$ values. It is performed utilizing the following equations:

$$[6]\quad H^* = [\mathrm{H_3O^+}] - K_w/[\mathrm{H_3O^+}]$$

$$[7]\quad \mathrm{NU}_t{}^{\nu} = \mathrm{NP}_t + \sum_{r=1}^{\mathrm{NP}_t} (\mathrm{NP}_t - r) \frac{[\mathrm{H_3O^+}]}{\prod_{k=1}^{r} K_{\mathrm{a}_{t,k}}}$$

where NP_t is the number of titratable protons of ligand(s) ($t = i - 1$) and $K_{\mathrm{a}_{t,k}}$ the kth acidity constant of ligand t.

$$[8]\quad \mathrm{DE}_t{}^{\nu} = 1 + \sum_{r=1}^{\mathrm{NP}_t} \frac{[\mathrm{H_3O^+}]}{\prod_{k=1}^{r} K_{\mathrm{a}_{t,k}}}$$

$$[9]\quad \mathrm{DB}^{\nu} = \frac{B^{\nu}}{C_m} + \mathrm{NH_m} - \left(\sum_{t=1}^{\substack{nb\ of \\ ligands}} \left(N_{t+1,\mathrm{m}} \frac{\mathrm{NU}_t{}^{\nu}}{\mathrm{DE}_t{}^{\nu}} \right) + \mathrm{NH_m} - H^* V_m{}^{0} \right) \div \left(\mathrm{CB_m} + H^* \right)$$

In the above eq. [9] the subscript m indicates values corresponding to the middle point titration curve. The results are computations of all combinations of sets of three titration curves. The above-mentioned criteria allow one to choose the best set of titration curves.

The integral of eq. [1] is evaluated by Simpson's numerical integration taking into account the volume variation as follows:

$$[10]\quad I_i{}^{\nu} = I_i{}^{\nu-1} - \log (V_m{}^{0} + V_m{}^{\nu-1}) + \log (V_m{}^{0} + V_m{}^{\nu}) + f(\mathrm{pH}, S_i{}^{\nu})$$

where $f(\mathrm{pH}, S_i{}^{\nu})$ is the classical Simpson's function. The initial value of $I_i{}^{\nu}$ corresponding to pH^0 ($I_i{}^{\mathrm{pH}^0}$) is given for metal ion by eq. [11] and for the fully protonated ligand(s) by eq. [12]

$$[11]\quad I_1{}^{\mathrm{pH}^0} = -\log N_{1,m} + \log (V_m{}^{0} + V_m{}^{\mathrm{pH}^0})$$

$$[12]\quad I_i{}^{\mathrm{pH}^0}(i = 2 \text{ or } 3) = -\log N_{1,\mathrm{m}} + \log (V_m{}^{0} + V_m{}^{\mathrm{pH}^0}) + \log \left(1 + \sum_{r=\mathrm{NP}_t}^{1} \frac{\prod_{k=\mathrm{NP}_t}^{r} K_{\mathrm{a}_{t,k}}}{[\mathrm{H}^0]^r} \right)$$

For metal ion

$$[13]\quad \mathrm{p}\bar{C}_1{}^{\nu} = I_1{}^{\nu}$$

For ligand(s), the concentration of completely deprotonated form is determined at each pH as follows

$$[14]\quad \mathrm{p}\bar{C}_i{}^{\nu}(i = 2 \text{ or } 3) = I_i{}^{\nu} + \sum_{k=1}^{\mathrm{NP}_t} \mathrm{p}K_{\mathrm{a}_{t,k}} - \mathrm{NP}_t \times \mathrm{pH}$$

At each pH, there are N species $\mathrm{M}_x\mathrm{H}_y\mathrm{L}_z(\mathrm{Kt})$ in equilibria. The concentration of each species l ($\mathrm{CS}_l{}^{\nu}$) is given by eq. [15]

$$[15]\quad \mathrm{CS}_l{}^{\nu} = \beta_l \prod_i (C_{i,l}{}^{\nu\, q_{l,i}})$$

where β_l is the formation constant and $q_{l,i}$ are the stoichiometric coefficients of species l.

In analytical potentiometry an excess of ligand is used so that only the metal mass balance equation is considered in solving β_l values.

$$[16]\quad T_{1,\mathrm{m}}{}^{\nu} = \bar{C}_1{}^{\nu} + \sum_{l=1}^{N} \beta_l q_{l,1} \prod_i (\bar{C}_i{}^{\nu})^{q_{l,i}}$$

In this equation the values of $\bar{C}_1{}^{\nu}$ can closely approach to $\bar{C}_{i,m}{}^{\nu}$. Each element of Jacobian matrix in relation to metal ion is

$$[17]\quad J_{l,1}{}^{\nu} = \frac{\partial T_{1,\mathrm{m}}}{\partial \beta_l}$$

From eq. [16] and eq. [17] we obtain:

$$[18]\quad J_{l,1}{}^{\nu} = q_{l,1} \prod_i (\bar{C}_i{}^{\nu})^{q_{l,i}}$$

Equation [16] can be written as a matrix equation as following

[19] $\mathbf{JB} = \mathbf{\Delta}$

where $\mathbf{J}$ is the Jacobian matrix and each β_l forms the $\mathbf{B}$ matrix. The elements of matrix $\mathbf{\Delta}$ are given by the following equation for each pH.

[20] $\delta^\nu = T_{l,m}{}^\nu - \bar{C}_l{}^\nu$

Equation [19] is in fact a set of overdetermined equations of N unknowns. Theoretically, it can be solved by a fast and direct minimization process.

[21] $\mathbf{J}^T\mathbf{JB} = \mathbf{J}^T\mathbf{\Delta}$

[22] $\mathbf{B} = (\mathbf{J}^T\mathbf{J})^{-1}\mathbf{J}^T\mathbf{\Delta}$

For the purpose of inverting the wide range of values in matrix $\mathbf{J}^T\mathbf{J}$, an effective scaling is necessary for the overall goal of refinement and reducing the rounding errors (27). It should be pointed out that the use of β_l values greater than 10^{37} also poses a problem.

To circumvent these difficulties we propose the following way to decompose matrix $\mathbf{B}$ to two matrices.

[23] $\mathbf{B} = \xi\mathbf{M}$

$\mathbf{M}$ has the mantissa elements of β_l and the diagonal ξ matrix has the exponents of β_l.

A scale factor is calculated by eq. [24]

[24] $$S = 1 \Big/ \sum_{\nu=1}^{NN} \delta^\nu$$

where NN is the number of pH values considered in the minimization step. Combining eqs. [21], [23], and [24] we obtain

[25] $(\mathbf{SJ}\xi)^T(\mathbf{SJ}\xi)\mathbf{M} = \mathbf{S}(\mathbf{SJ}\xi)^T$

It is now easy to obtain a triangular inferior matrix $\mathbf{L}$ with units on the principal diagonal and a triangular superior matrix $\mathbf{R}$ solving eq. [26]

[26] $(\mathbf{SJ}\xi)^T(\mathbf{SJ}\xi) = \mathbf{LR}$

Matrix $\mathbf{M}$ is obtained by solving the following matrix equations

[27] $\mathbf{LRM} = \mathbf{S}(\mathbf{SJ}\xi)^T\mathbf{\Delta}$

[28] $\mathbf{RM} = \mathbf{L}^{-1}\mathbf{S}(\mathbf{SJ}\xi)^T\mathbf{\Delta}$

[29] $\mathbf{M} = \mathbf{R}^{-1}\mathbf{L}^{-1}\mathbf{S}(\mathbf{SJ})^T\mathbf{\Delta}$

And finally β_l values are given in log form by eq. [30].

[30] $\log \beta_l = \log m_l + e_l$

The strategy adopted in the calculations consist of determining the scaler followed by the matrix $\mathbf{J}\xi$. Each element of $\mathbf{J}$ or ξ can be larger than $10^{\pm 37}$, but the product of each element performed in log units is in the scale of δ^{-1}. Matrix $\mathbf{SJ}\xi$ is obtained and multiplied by $(\mathbf{SJ}\xi)^T$. Matrix $\mathbf{S}(\mathbf{SJ}\xi)^T\mathbf{\Delta}$ is also calculated. Subsequently $\mathbf{R}$ and $\mathbf{L}$ are determined, inverted, and multiplied by $\mathbf{S}(\mathbf{SJ}\xi)^T\mathbf{\Delta}$ in sequential order.

It could happen that some elements m_l of $\mathbf{M}$ are negative. In this case the species with the more negative value is rejected and a new minimization is performed with $N - 1$ species.

Data analysis

Calculations are performed by a series of programs written in BASIC APPLESOFT or in compiled language for a 48 Kb computer. These are designed to be used quite easily. The few questions asked to the users are clearly explained and any unscaled or wrong inputs are critically monitored. The following programs are utilized by data analysis (Fig. 1).

Program 1: DATA ENTRY

Two programs are involved at this stage. With one, the data (pH, volume of base) are entered in the keyboard, titration curves are displayed or printed, and data files are created. The second one is an on-line data acquisition system monitoring titration experiments.

Program 2: CONVERSION

The main objective of this program is to move the P-1 data files in random access files. In this way 20 titrations of 300 experimental values each can be computed in the subsequent programs.

Program 3: VARIATIONS

With this program the best set of titration curves is determined and eqs. [1] and [11] solved.

Program 4: PROPOSITIONS

An estimation of β values, a probability of the existence of the proposed species, and the pH where their concentrations are maximum, are obtained with this program.

Program 5: MINIMIZATION COMBINATION

Equations [16] to [30] are computed in this program whereby the final concentration of species as a function of pH are obtained.

Program 6: GRAPHICS

It is an utility program to display a graph of the data saved in files created by P-3 and P-5. The same program saves the screen display in binary files which are adapted to a commercial software PHOTO (Program 7) (28). With this program it is possible to display quickly on the screen a "photo" saved on the disc and transmit it on to any type of printer.

Other programs listed in Fig. 1 do not directly concern the theoretical part of the method of analytical potentiometry as has been described. However, these programs are used in conjunction with the above programs in order to obtain the necessary essential parameters for the purpose of data analysis. Following is a brief description of the other programs.

Program 8: DERIVATION

It performs the calculation of dV/dpH as a function of volume of base added through a least-squares polynomial filter of 3, 5, 7, 9, or 11 points moving along the titration curve. Equivalent volumes are calculated from the intercept of two least-squares lines. We included the possibility of obtaining the second derivative.

Program 9: IONIZATION

This program uses the data of base titration against phthalate or strong acid. Its output is pK_w.

Program 10: ACTIVITY

This program is used to calculate the relation between activity of H_3O^+ and its concentration. It is performed by calculating the deviation between the theoretical slope and the least squares line of pH read against $-$ log [HCl] in the acidic and basic range where electrode response is more linear.

Program 11: ELECTRODE

This program calculates the theoretical initial pH's from the real concentrations of ions i and strong acid in a titration mixture (P-8). A comparison of the experimental pH values with those of the theoretical enables one to decide whether to reject the

For personal use only.

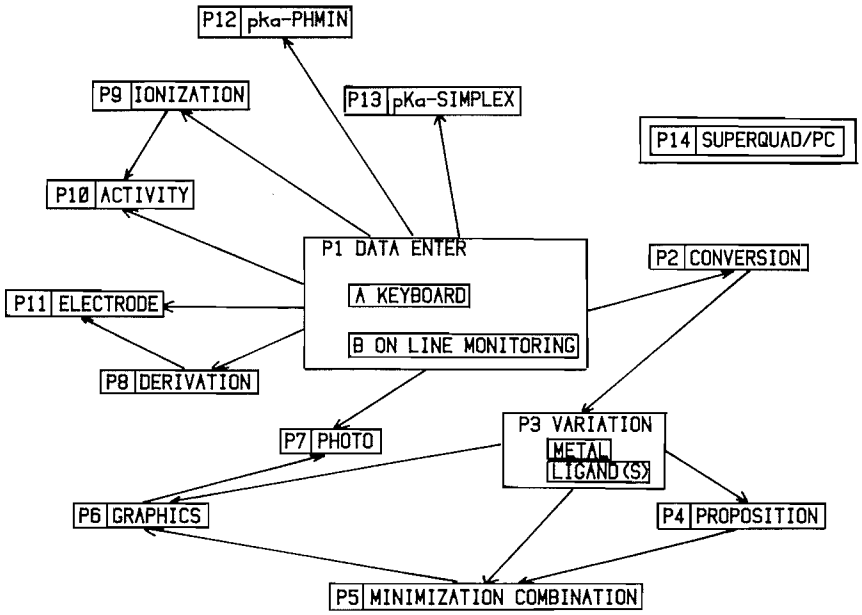

FIG. 1. Programs utilized for data analysis.

titration data or to make suitable pH adjustments necessitated by improving electrode response.

Program 12: PKA-PHMIN

This program calculates the values of pK_a's of ligand(s) through the process of minimization at each pH values.

Program 13: PKA-SIMPLEX

It is a program which refines all the wanted titration parameters simultaneously using a simplex algorithm. The minimization is done with respect to the volumes of base added (29).

Program 14: SUPERQUAD/PC

This program (25) has been used to determine the species and their stability constants in an equilibrium mixture containing metal and ligand(s) in solution. The program has recently been modified by one of us (P.D.) to run in Fortran 77 on an IBM-PC microcomputer with 8087 coprocessor. The compiled program occupies about 140 Kbytes of space.

Methods and discussion

In potentiometry, equations and algorithms used to obtain free ion concentrations are essential. Equally important is the process of minimization to obtain the best ion mass balance. However, the corrections of experimental data introduced in the programs of analytical potentiometry is most crucial. In this connection, two major difficulties are encountered: (1) the exact nature and the analytical amounts of chemicals introduced in the titration solutions and (2) the quality of electrode response during the titration. From our experience, we have noticed that these difficulties are the major sources of erroneous results. In order to circumvent these problems, we propose the following steps.

Solutions

A probable source of error may be caused by the limited amount of materials available for titration. This can be partially overcome by preparing the solutions in certain ways. One can prepare four solutions in all. First a stock solution S in 0.15 *M* background electrolyte in strong acid. Second, a solution SL_1 is obtained by dilution of weighted amount of ligand in solution S. This solution must have an excess of strong acid in order to fully protonate the ligand. The third and fourth SL_2 and SL_3 are also prepared by dilution of SL_1, with S. Solution SL_2, for instance, could be adjusted to the ligand concentration at the middle point.

Titrations

Electrodes are calibrated with buffers in terms of activity. At least three titrations of solution S are performed. The exact amount of strong acid in the titration solution is obtained with P-8. Thereafter, the relation between pH and $-\log [H_3O^+] (\gamma L)$ is obtained with P-10 using the pK_w value calculated by P-9.

Purity and pK_a's of ligand

Titrations of solutions SL_1, SL_2, and SL_3 are carried out and the purity and the amount of ligand are determined using the program P-8. More often, the results of P-8 on the three different titrations show a difference with the expected value. This may be due to the method of manipulation rather than the presence of an impurity. This can be discerned from the output of P-8. If the presence of protonated impurity is not detected, the concentration of ligand is corrected and the study is allowed to continue. If the impurity has ionizable protons, the studies are undertaken as though it is a two ligand system.

Titration data corrected from γL by following equation:

$$-\log [H_3O^+] = pH + \gamma L$$

are introduced sequentially in P-12, P-13, and P-14. In this manner, pK_a's are calculated and the values of ligand concentrations are adjusted.

Metal variation

At least three titrations of solution SL_2 added with different amounts of metal are performed. Ligand(s) and strong acid concentrations are estimated by P-8 and eventually corrected. Alongside, electrode response is tested by P-11. If necessary, a correction of pH is applied. Actually, the amount of metal introduced in the titration is most critical. It would be important to have an independent verification of this amount. Attempts are under way using cyclic voltamperometry for such a verification.

Program 3 is run with at least three data files created by P-2.

At this stage the correction of volume variation is initiated. It should be pointed out that this correction can influence the species distribution particularly at high pH.

Ligand variation

Solutions SL_1 and SL_3 with added amounts of metal corresponding to the middle point concentration are titrated and corrected by P-8 and P-11. These two titrations are analyzed along with the one containing solution SL_2 having the same amount of metal (obtained from the metal variation experiment) by P-3. This step does not present any difficulty as there is very little correction to be made for the ligand and strong acid. Experimentally it can be shown that the standard deviations in metal variation are on the average of 10 to 20 times higher than in ligand variation. At this step $p\bar{C}_i^{\nu}$ values have been determined in the best case, with only five titrations.

Propositions

The proposition program P-4 is run with the data file created by P-3. One can propose an extensive set of stoichiometric coefficients of species (<31). An approximate β value and the pH of its maximum concentration are calculated for each species. In general, when the criterion of curvature DC_i is too high, it is often preferable to introduce multimetal and multiligand species. The program P-4 calculates the Jacobian elements $\mathbf{J}_{l,1}^{\nu}$ of each species as a function of pH. If the variation of $\mathbf{J}_{l,1}^{\nu}$ on the pH range does not pass by a maximum, the probability of the existence of the species l is negligible. Finally, the knowledge of the pH region, where these species are likely to be present, is very helpful in the subsequent minimization steps.

Minimization

The minimization based on a linear least squares method is performed by P-5 with data files created by P-3 and P-4. When a right set of proposed species is introduced in the minimization process, the β_l values are obtained quickly without giving rise to false minima. It is possible that some calculated elements m_l of matrix **M** are negative which indicates that the proposed set of species has no chemical meaning. In this instance P-5 rejects the species with the more negative value and performs a new minimization with the remaining $N - 1$ species. One should be cautioned here, that this procedure may result in the rejection of a real species if a false species is introduced at the initial stage. In order to overcome this problem we have introduced a procedure to propose a higher than real number of species, chosen on the basis of "chemical intuition". The minimization process is carried out for each possible set of proposed species and standard deviations are calculated. The knowledge of the frequency of rejection of each species facilitates the choice of best set of species. However, the above method of analysis does not detract from the fact that some mathematical set of species without any chemical meaning may provide a better standard deviation than that given by the real set of species.

Two other difficulties should be pointed out regarding the minimization procedure. Firstly, the postulation that the values of $\bar{C}_i^{\nu}$ can closely approach $C_{i,m}^{\nu}$ is an approximation. Secondly, β_l values are calculated on the basis of the lowest sum of δ_1^{ν} terms as it has been shown in eq. [20]. This equation shows that δ_1^{ν} is the difference between $T_{1,m}^{\nu}$ and $\bar{C}_1^{\nu}$. The volume correction is certainly helpful in the reduction of errors. However, it has been shown that for the purpose of volume correction, $T_{1,m}^{\nu}$ is calculated from $N_{1,m}$ which could have large errors. The resultant effect of such errors can be amplified at the level of δ_1^{ν} values. In analytical potentiometry one uses excess ligand(s) which justifies the use of metal mass balance in the calculation. Unfortunately, the minimization provides the lowest least-squares sum of δ_1^{ν} which is related to metal mass balance equation. Thus one should be aware of the possible errors in δ_1^{ν} values arising from the methodology. We have incorporated the possibility of minimization at a restricted part of pH range. In the end of minimization the species distribution is calculated and displayed on screen by P-6 along with standard deviations at each pH.

Conclusion

1. A general procedure is proposed for analytical potentiometry which includes minimization of potential sources of errors and a fast linear-scaled least-squares algorithm to expedite the microcomputer solution of metal complex stability from potentiometric data.

2. Programs have been written in BASIC APPLESOFT on a microcomputer Apple II. They allow the computation of at least 40 titration curves of 300 data each and in theory 20 species.

3. Besides dealing with the theoretical part of analytical potentiometry, programs are also written to obtain the necessary essential parameters for the purpose of data analysis.

4. An additional amount of acid in titration solutions and variation of volumes, previously neglected, have now been incorporated in this procedure. Attempts have been made to control the exact amount of metal introduced in the titration vessel.

5. The method reduces the number of experimental data and at the same time increases the overall accuracy.

PATRICK DECOCK and BIBUDHENDRA SARKAR. Can. J. Chem. **65**, 2804 (1987).

An advanced methodology for the data analysis by analytical potentiometry (Decock and Sarkar. Can. J. Chem. **65**, 0000 (1987)) has been utilized to analyze three different metal–ligand systems. The results are compared with those obtained by SUPERQUAD adapted for microcomputer. An excellent agreement has been attained with the stability constant data of Ni(II)–glycine complexes of an earlier multi-laboratory study. The technique has been utilized to investigate the effect of ligand concentration in the equilibria of Cu(II) complexes of glycylglycyl-L-tyrosine-*N*-methyl amide. The third system studied by this technique was Zn(II) complexes of 3,6-diazaoctane-1,8-diamine, a ligand of potential therapeutic efficacy against metal toxicity.

PATRICK DECOCK et BIBUDHENDRA SARKAR. Can. J. Chem. **65**, 2804 (1987).

Des modifications apportées à la méthode de potentiométrie analytique, décrites dans la première partie de cette publication, sont utilisées pour analyser les équilibres de complexes dans trois systèmes métal–ligand différents. Les résultats obtenus sont comparées à ceux issus du programme SUPERQUAD, que nous avons adapté pour être utiliser sur un microordinateur. Les résultats acquis, pour les complexes du Ni(II) et de la glycine sont très proches de ceux publiés dans un travail antérieur par une série de laboratoires différents. La technique préconisée est également appliquée à l'analyse de système Cu(II) – glycylglycyl-L-tyrosine-*N*-méthyl amide et les effets de l'influence de la concentration du ligand sont considérés. Le troisième système étudié est relatif au Zn(II) associé au diaza-3,6 octanediamine-1,8 qui est un ligand présentant une efficacité térapeutique potentielle à l'encontre de la toxicité des métaux.

Introduction

We have proposed an advanced methodology for the data analysis of metal–ligand equilibria by analytical potentiometry (AP) (1). In this article we report the application of this method in the studies of equilibria involving three different metals Ni(II), Cu(II), and Zn(II) with different ligands. We have examined the procedure by studying the Ni(II)–glycine system since it was chosen as a test system for a previous inter-laboratory procedure evaluation (2). We also report an analysis of Cu(II) complexation of a peptide, glycylglycyl-L-tyrosine-*N*-methyl amide (GGTNMA). The third system we examined is Zn(II) complexation of 3,6-diazaoctane-1,8-diamine (Trien), a ligand of potential therapeutic efficacy against metal toxicity. The results obtained by AP were further compared with those from SUPERQUAD (3) adapted for microcomputer (SPC).

Experimental

Potentiometric studies were performed using both AP and SPC procedures. The solutions were prepared in deionized and twice redistilled water under argon atmosphere ($R > 1$ MΩ). Carbonate-free sodium hydroxide solutions were prepared and stored under argon and standardized against N.B.S. grade potassium hydrogen phthalate. HCl solutions were standardized with 0.1013 *M* NaOH and checked by the program DERIVATION (1). Puratronic metal chloride was used to prepare a 0.2 *M* (in HCl) solution which was checked by titration with EDTA.

Glycine (Fluka) was recrystallized from water–ethanol mixtures prior to use. For the Ni(II)–glycine system, ligand concentrations varied between 0.6×10^{-2} and 1.5×10^{-2} *M* and metal between 10^{-3} and 3×10^{-3} *M*. The peptide, glycylglycyl-L-tyrosine-*N*-methyl amide, was synthesized as reported earlier (4). For Cu(II)–GGTNMA, five different order of concentrations were studied with respect to the same average ligand-to-metal ratio of 5:1 as indicated in Table 1. 3,6-Diazaoctane-1,8-diamine tetrahydrochloride has been purified as previously reported (5). Purity was checked by high voltage paper electrophoresis at pH 6.9 (phosphate buffer). A total of 41 different titrations were performed to study the Zn(II)–Trien system (Table 2). All solutions were prepared in 0.15 *M* NaCl.

The potentiometric titrations were carried out on a Tacussel ISIS 20000 pH meter at 25 ± 0.03°C with a TB 10/HA glass electrode and a KCl-saturated reference electrode. All calculations were performed on APPLE II or IBM PC computers for AP and SPC programs, respectively.

Results and discussion

Nickel(II)–glycine

Studies were carried out in the pH range 3 to 9 using a high ligand and metal concentration to minimize the errors. Best mathematical fit of the data resulted in the identification of three species: NiL, NiL_2, and NiL_3. We were not able to detect any species such as $NiH_{-1}L$. Stability constants calculated by AP are compared with those obtained by SPC as well as with those of earlier studies (Table 3). All results are quite consistent. When volume corrections are incorporated in AP there is a better agreement between AP and SPC. Results also indicate the SPC programs designed for a microcomputer is operating successfully.[4]

*Copper(II) – glycylglycyl-L-tyrosine-*N*-methylamide*

This system was chosen to investigate the capability of the method (1) to analyze the chelation of Cu(II) by a peptide. The

two pK_a values of the peptide calculated by programs PKA-PHMIN, PKA-SIMPLEX, and SPC (1) are presented in Table 4 where they are compared with the previous results. The metal peptide titrations were carried out using the condition I as described in Table 1. Titration data are shown in Fig. 1. Complexation begins with the species CuHL and following deprotonation the last species $CuH_{-3}L$ is formed at high pH. The result of log β values (Table 5) and the pH of the maximum concentration of species (Fig. 2) are consistent with both AP and SPC, although some minor differences are observed in the concentration of species as a function of pH. The new version of AP eliminates the species $CuH_{-2}L_2$ which was previously described at high pH (6). It is also rejected by SPC. An increasing shift in the species distribution is observed at high pH using the two AP methods.

We have examined the influence of concentration in this study. Five different concentrations of Cu(II)–peptide have been investigated. The average ratio of metal-to-ligand was kept constant. The total amount of peptide used to perform a complete set of data analysis, as described previously (1), is in the scale of 10 to 86.5 mg (Table 1). The results are summarized in Table 6 where these are compared to SPC. In systems II and V species $CuH_{-2}L_2$ is rejected by both programs. $CuH_{-3}L$ is also eliminated in the refinement of system V. In all cases, the formation constants of the highest concentration species are

consistent with SPC results. No particular effect of ligand concentration was observed.

From a theoretical standpoint it could be assumed that the β values obtained from low ligand concentration systems are

For personal use only.

better. In this case the approximations of the method supporting AP programs are minimized. This point has been verified by the results of the partial volume correction. On the other hand, the errors expected on the initial concentrations of ligands and protons, recalculated by program DERIVATION, are higher.

Both AP and SPC, although based on two different mathematical approaches, lead to the same type of complexes. The difference in the β-values are small but somewhat larger than those in the Ni(II)–glycine system. This difference could result from the approximation $C_l^{\nu} \simeq \bar{C}_{l,m}^{\nu}$ (1). The other possibility would be an error in the metal concentration which is not treated in the same manner by the two programs. The satisfactory convergence of results obtained by both methods could be attributed to the system which has only a series of mononuclear species in different protonation states. However, the deviation may be more pronounced in complicated systems such as the one described below.

Zinc(II) – 3,6-diazooctane-1,8-diamine (Trien)

The results of the four pK_a's of Trien and the stability constants of the complexed species are given in Table 7, and they are compared with the literature values. The titration data are presented in Fig. 3. It is shown in Fig. 4 that the complexation begins above pH 5 with the formation of the species ZnH_2L. Subsequently, the species ZnH_2L_2 is formed which predominates over the pH range 6.5 to 8. This is the major species around pH 7.8 containing approximately 90% of Zn(II). At pH 8 the species $ZnHL_2$ starts to form, reaching a maximum at pH 8.4. Finally the completely deprotonated species ZnL_2 is formed which starts to predominate at pH 9 and above.

No precise structural assignments of the Zn(II)–Trien species are possible from the presently available data. However, some of the possibilities can be discussed. The low pH species ZnH_2L is most likely from two of the closest proton bearing sites enabling the formation of a stable five-membered chelate ring. The next species ZnH_2L_2 is most likely an octahedral species where both the ligands in this species could form two five-membered rings each. The high pH species $ZnHL_2$ and ZnL_2 are formed from ZnH_2L_2 by the subsequent ionization of protons. This contention is substantiated by the similar log K values calculated for the formation of $ZnHL_2$ and ZnL_2 species (Table 8).

AP and SPC programs lead to the same kind of species. However, the differences on calculated values of formation constants are higher than those observed for Ni(II)—glycine and Cu(II)—peptide. This difference increases with the higher pH species. This may be due to the uncertainties of the exact concentration of Zn(II) introduced in each titration solutions. It could also be assumed that if some error occurs in the values of S_i^{ν} (1) at a pH range, the same error will greatly increase past the pH of complexation of all Zn(II). Subsequently an error propagation could result at higher pH on $\bar{C}_i^{\nu}$. The real problem of the approximation of $C_{i,m}^{\nu}$ by $\bar{C}_i^{\nu}$ (1) will be crucial in such a system. Th minimization procedure on $\bar{C}_i^{\nu}$ values could also contribute to propagation of errors. In SPC errors are also expected, but the different mathematical approach does not lead to the same kind of error values and so of formation constants.

Conclusions

1. An advanced method of data analysis by analytical potentiometry utilizing a series of programs running on microcomputer (1) has been used successfully to obtain accurate data

for the determination of stability constants and the distribution of simultaneously existing multiple species of three different metal–ligand systems.

2. Potential sources of errors have been minimized by introducing preliminary computations of titration curves.

3. Consideration of the volume variations, selection criteria of the best set of titration curves, and the implementation of a different algorithm of a linear minimization technique — all contributed to the power of the technique.

4. The data analysis technique has been utilized to study the Ni(II)–glycine system the results of which are in good agreement with those obtained earlier by an inter-laboratory study.

5. The stability constants of Cu(II) – glycylglycyl-L-tyrosine-*N*-methyl amide and Zn(II) – 3,6-diazaoctane-1,8-diamine complex species have been derived by the above method.

Heat capacities and volumes of some non-electrolytes in *N*,*N*-dimethylformamide at 298.15 K

HENRYK PIEKARSKI[1]

Department of Physical Chemistry, Free University, De Boelelaan 1083, 1081 HV Amsterdam, The Netherlands

Received March 5, 1987

HENRYK PIEKARSKI. Can. J. Chem. **65**, 2810 (1987).

Heat capacities and densities of dilute solutions of formamide, acetone, tetrahydrofuran, ethylene glycol, 2-methoxyethanol, and 2-ethoxyethanol in *N*,*N*-dimethylformamide were determined at 298.15 K. Apparent molal heat capacities and volumes for these solutes in DMF were calculated and compared with the analogous data for other substances in DMF solution as well as with the data concerning solutions in methanol and water. Heat capacities of cavity formation (ΔC_{cav}) in DMF were calculated on the basis of the Scaled Particle Theory. ΔC_{cav} appeared to be linearly correlated with the standard partial molal volume of corresponding solutes in DMF. Similar dependences were also found for aqueous and methanolic solutions of the non-electrolytes.

HENRYK PIEKARSKI. Can. J. Chem. **65**, 2810 (1987).

Opérant à 298,15 K, on a déterminé les capacités calorifiques et les densités de solutions diluées de formamide, d'acétone, de tétrahydrofuranne, d'éthylèneglycol, de méthoxy-2 éthanol et d'éthoxy-2 éthanol dans le *N*,*N*-diméthylformamide. On a calculé les volumes et les capacités calorifiques molals apparents de ces solutés dans le DMF et on a comparé ces valeurs avec des données semblables d'autres substances en solution dans le DMF ainsi qu'avec des données concernant des solutions dans le méthanol ainsi que dans l'eau. En se basant sur la théorie de la particule scalaire, on a calculé les capacités calorifiques de la formation de la cavité (ΔC_{cav}) dans le DMF. Il semble exister une corrélation linéaire entre les valeurs de ΔC_{cav} et le volume molal partiel standard des solutés correspondants dans le DMF. On a trouvé des corrélations semblables pour les solutions aqueuses et méthanoliques de non-électrolytes.

Introduction

Physicochemical properties of the mixtures of *N*,*N*-dimethylformamide with different compounds are a subject of numerous investigations today. The present of "peptide-like" and methyl groups in molecules makes DMF an "attractive solvent" in view of the model function for the interior of a protein. Moreover, its molecules are highly polar, but practically non-associated, which makes DMF a good solvent for different groups of compounds.

Molar heat capacities and volumes are among the most frequently examined properties of binary mixtures. Many of the above mentioned investigations have been devoted to systems containing DMF (1–7). The present study is aimed at determining molar heat capacities and molar volumes of the solutions of several substances not investigated till now (namely: formamide, acetone, tetrahydrofuran, ethylene glycol, 2-methoxyethanol, and 2-ethoxyethanol) in DMF solvent. The results were to be compared with the analogous data concerning the other DMF–non-electrolyte mixtures investigated earlier. Moreover, it is of interest to see whether some close correlations exist between the volumetric functions and C_p for the different solutes in a solvent as relatively unstructured as DMF.

Experimental

Materials

The origin, and purification of the chemicals are as follows: *N*,*N*-dimethylformamide, formamide, 2-methoxyethanol, and 2-ethoxyethanol (all Baker Analyzed Reagents) were stored over molecular sieves 4 Å for at least one week and used without further purification. Acetone and tetrahydrofuran (Baker Analyzed Reagents) were purified by distillation and dried with molecular sieves. Ethylene glycol (also Baker A.R.) was distilled under reduced pressure. Their water content determined by the modified Karl Fischer procedure (8) was less than 1×10^{-4} volume fraction. Gas–liquid chromatography showed a mole-fraction purity higher than 0.995 for each compound.

Procedure

Liquid mixtures of DMF with the solutes were prepared by mass, avoiding contact with air. Further uptake of water was reduced as much as possible by storing the polyethylene vials with pure solvent and the mixtures in dessicators under nitrogen and above granulated P_2O_5. After these manipulations the water content did not increase by a detectable amount.

Densities of mixtures, ρ, relative to the density of reference liquid were measured using a digital flow densimeter (Sodev, Model 03, Sherbrooke, Quebec). Heat capacities per unit volume (C_p/V) were measured with a Picker flow microcalorimeter (Setaram, Model "chaleur specifique", Lyon, France). The procedure was as reported previously (5, 7).

Results

Densities, ρ, of the investigated solutions in *N*,*N*-dimethylformamide at 298.15 K relative to that of pure DMF ρ_1^* are presented in Table 1 as a function of the molality m of the solute.[2] The density of pure DMF as measured with respect to pure water was $\rho_1^* = 0.943286\ \mathrm{g\ cm^{-3}}$ (7), corresponding to to a molar volume $V_1^* = 77.49\ \mathrm{cm^3\ mol^{-1}}$.

Changes in the heat capacities per unit volume with respect to that of DMF

$$\Delta(C_p/V) = [(C_p/V) - (C_{p,1}^*/V_1^*)]$$

are also reported in Table 1. The results refer to a mean temperature 298.15 K. For heat capacity calculations $(C_{p,1}^*/V_1^*) = 1.9146\ \mathrm{J\ K^{-1}\ cm^{-3}}$ was adopted (3).

The apparent molal volume $V_{\Phi,2}$ and heat capacity $C_{\Phi,2}$ of the solute in the mixtures were calculated from the data using the following equations:

$$[1] \quad V_{\Phi,2} = M_2/\rho - 1000(\rho - \rho_1^*)/m\rho\rho_1^*$$

[1]On leave from the University of Łódź, Department of Physical Chemistry, ul. Nowotki 18, 91-416 Łódź, Poland.

[2]Throughout this paper, subscript 1 refers to the pure solvent (DMF) and 2 to the solute while asterisks refer to the pure liquid.

and

[2] $$C_{\Phi,2} = M_2 c_p + 1000(c_p - c_{p,1})/m$$

where M_2 is the solute molecular weight, m is the molality, and $c_p = C_p/V\rho$ the gravimetric (specific) heat capacity. Calculated values of $V_{\Phi,2}$ and $C_{\Phi,2}$ are also given in Table 1.

The apparent molal volumes and heat capacities were next fitted by least-squares methods to equations of the form:

[3] $$V_{\Phi,2} = V^\infty_{\Phi,2} + b_v m$$

or

[4] $$C_{\Phi,2} = C^\infty_{\Phi,2} + b_c m$$

The limiting partial molal quantities ($V^\infty_{\Phi,2} = V^\infty$ and $C^\infty_{\Phi,2} = C^\infty_{p,2}$) and the empirical constants b_v and b_c, as well as the molar values V^*_1 and $C^*_{p,2}$ for pure solutes are summarized in Table 2.

It is known that $C^\infty_{p,2}$, the partial molal heat capacity of the solute at infinite dilution, contains the heat capacity of the solute along with the solute–solvent interaction term. $C^*_{p,2}$ is usually chosen to represent the heat capacity of the liquid solute when solute–solvent interactions are absent (20). As can be seen from the data in Table 2, as well as from the literature (1–7), the limiting partial molal heat capacities for most of the solutes in DMF solution are not too different from the molar quantities ($C^\infty_{p,2} - C^*_{p,2} = \Delta C_{p,2} \approx 0$). Relatively small $\Delta C_{p,2}$ values in DMF are probably connected with the fact that DMF is unstructured and for this reason it is not too sensitive to the presence of the solute. Moreover, this suggests that any specific interactions with DMF in these systems if present at all are very small. Figure 1 presents the heat capacity of solvation of non-electrolytes in DMF, $\delta C^\infty_{p,2} = C^\infty_{p,2} - C^g_{p,m}$ (where $C^g_{p,m}$ is the molal heat capacity of the non-electrolyte in gas phase) as a function of the molecular polarizability (α) of the non-electrolyte. Observed linear correlation of $\delta C^\infty_{p,2}$ and α suggests that electrostatic interactions are dominating forces in most of the analyzed systems.

Partial molal volumes for most of the investigated thus for non-electrolytes are a bit lower in DMF solution than are the corresponding molar volumes ($V^\infty_2 - V^*_2 = \Delta V_2 < 0$). Alkanols higher than C_4, for which $\Delta V_2 > 0$, are the exception in this case.

Much attention has been devoted to finding whether any direct relations exist between the heat capacities and volumetric properties of the solutions in a given solvent. Among others Arnett and co-workers analyzed different dependences between molar volumes of alcohols in aqueous solution and some functions derived from the heat capacities of these solutions (20). It appeared that some simple dependences existed only for solutions of closely related compounds like normal alkanols.

No simple correlations between V^∞_2 and $C^\infty_{p,2}$ could be found for solutions in DMF. Since the partial molal volume of a solute in a given solvent is related to the dimension of a cavity created in the solvent structure, it can be supposed that a correlation exists between V^∞_2 and heat capacity of the cavity creation (ΔC_{cav}). The cavity term can be calculated from the Scaled Particle Theory (21):

[5] $$\Delta C_{cav} = A\sigma_2^2 + B\sigma_2 + C$$

where

[6] $$A = [3J/((1-y)^2\sigma_1^2)] \times [Z(1+2y)(1-y) - y\alpha_p(4y+5)]$$

[7] $$B = [3J/((1-y)\sigma_1)][Z(1-y) - 2y\alpha_p]$$

[8] $$C = J[Z(1-y) - y\alpha_p]$$

and

[9] $$J = RT^2 y\alpha_p/(1-y)^2$$

[10] $$Z = 2/T - \alpha_p + (1/\alpha_p)(\partial\alpha_p/\partial T_p)$$

where

σ_1 = hard sphere diameter of solvent molecule

and

σ_2 = hard sphere diameter of solute molecule

[11] $y = \pi N_A \sigma_1^3 / 6 V_1^*$

The parameters, necessary for these calculations, are given in Table 3. The hard sphere diameters of the solute, σ_2, were taken from Kim's compilation (10), or were calculated using the method proposed in his paper. Table 4 presents the cavity term ΔC_{cav} for several solutes in *N*,*N*-dimethylformamide. The same data are plotted as a function of the standard partial molal volumes of the corresponding solutes in DMF solution in Fig. 2. For the sake of comparison the analogous dependences for aqueous and methanolic solutions are also presented in the figure. The ΔC_{cav} and V_2^∞ values in the latter solvents are taken from the papers of French and Criss (21, 24) and of Cabani and co-workers (25), or calculated (some for ΔC_{cav} in water) using the hard sphere diameters σ_2 given in Kim's paper (10). To make possible a comparison of these data the same values of σ_2 were used for ΔC_{cav} calculations in each solvent.

As can be seen in Fig. 2 there are good linear correlations in all systems studied. The equations correlating ΔC_{cav} and V_2^∞ have a form:

$$\Delta C_{cav} = (1.676 \pm 0.065) V_2^\infty + (49.680 \pm 4.475) \quad \text{in DMF solution}$$

$$\Delta C_{cav} = (2.632 \pm 0.068) V_2^\infty + (51.963 \pm 4.619) \quad \text{in water}$$

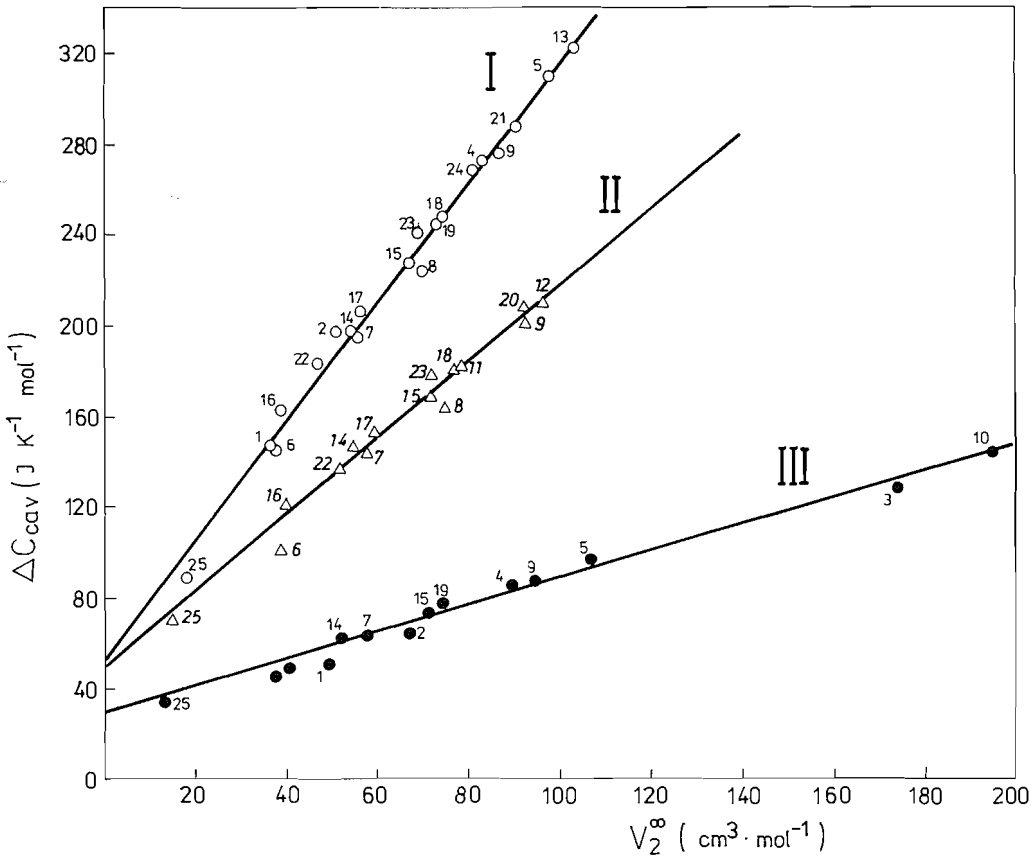

FIG. 2. Correlation between heat capacity of formation of cavity, ΔC_{cav}, and standard partial molal volume of the solutes in water (I), DMF (II), and methanol (III) at 298.15 K. *1*, Methane; *2*, ethane; *3*, octane; *4*, benzene; *5*, toluene; *6*, methanol; *7*, ethanol; *8*, propanol; *9*, *i*-butanol; *10*, *n*-decanol; *11*, 2-methoxyethanol; *12*, 2-ethoxyethanol; *13*, cyclohexanol; *14*, ethylene glycol; *15*, acetone; *16*, formamide; *17*, *N*-methylformamide; *18*, *N*,*N*-dimethylformamide; *19*, *N*-methylacetamide; *20*, *N*,*N*-dimethylacetamide; *21*, *N*-butylacetamide; *22*, acetonitrile; *23*, dimethylsulfoxide; *24*, dioxane; *25*, water.

and

$$\Delta C_{cav} = (0.608 \pm 0.028)V_2^{\infty} + (27.190 \pm 2.894) \quad \text{in methanol}$$

The observed dependence appears to be especially surprising in aqueous solutions since it encompasses both solutes which are able to interact with water through H-bond formation and the compounds that are hydrophobically hydrated such as hydrocarbons and higher alkanols. This observation seems to confirm Stillinger's opinion that in aqueous solution, the formation of a cage around the hydrophobic solute contributes to $C_{p,2}^{\infty}$ through an interaction term ΔC_{int} but not through the cavity term ΔC_{cav} (26). Comparison of the slopes of these functions indicates that the expansion of the cavity dimension in DMF is less related to the solvent structure disturbance than it is in water. The opposite appears to be true when comparing

For personal use only.

DMF with methanol. The values of isothermal compressibility coefficient β_T of these solvents (DMF, 6.3×10^{-5} atm^{-1} (27); water, 4.63×10^{-5} atm^{-1} (21); methanol, 12.64×10^{-5} atm^{-1} (21)) confirm this opinion.

The correlations makes it possible to find the cavity term for a solute for which V_2^∞ is given.

The knowledge of the cavity term and limiting partial molal heat capacity allows us to calculate the solute–solvent "interaction term", ΔC_{int}, according to a formula given by SPT (21):

$$[12] \quad \Delta C_{int} = \delta C_{p,2}^\infty - \Delta C_{cav} - R[2\alpha_p T + (\partial\alpha_p/\partial T)_p T^2 - 1]$$

where, as defined earlier, $\delta C_{p,2}^\infty = C_{p,2}^\infty - C_{p,m}^g$. The values of ΔC_{int} and $\delta C_{p,2}^\infty$ for several solutes in DMF are also presented in Table 4. These values show that ΔC_{int} in DMF solution is negative for all non-electrolytes investigated, just as it was found for methanolic solutions (water was an exception), and for aqueous solutions of substances that were capable of interacting strongly with water (methanol, NMA, acetone, DMSO, water) (24). The positive ΔC_{int} values, characteristic of aqueous solutions of hydrophobic substances were not found in DMF solution. This observation seems to confirm the conclusion reached earlier (21) that positive ΔC_{int} in water were related to the formation of cages around the hydrophobic solutes.

The change in heat capacities of the solute transfer from DMF to water ΔC_p^∞(DMF→ W) Table 4 for most of the examined systems are large and positive. This is caused by large, negative ΔC_{int} for these solutes in DMF and ΔC_{cav} values generally lower than that in aqueous solutions. Negative values of ΔC_p^∞(DMF→ W) observed in the case of water and formamide as solutes are probably joined with relatively high negative interaction term of these solutes in water owing to their molecular structure, possibility of strong H-bond formation, and lack of hydrocarbon groups that bring in positive interaction contributions.

The saturated ligand H_2L1, derived by template condensation of 4-methyl-2,6-diformylphenol and 1,3-diaminopropane, followed by borohydride reduction, generates binuclear, antiferromagnetically coupled, copper(II) complexes which exhibit cyclic voltammetry involving two one-electron oxidation steps ($E_{1/2}$ = 1.1 to 1.2 V, 1.3 to 1.4 V; $Pt/CH_3CN/SCE$) and two one-electron reduction steps ($E_{1/2}$ = −0.75 to −0.76 V, −0.89 to −0.90 V (GC/DMSO/SCE) with the formation of Cu(III)–Cu(III) and Cu(I)–Cu(I) and mixed oxidation state species. A trinuclear derivative, $[Cu_2(L1)(CuCl_4)]$, appears to contain a spin-coupled binuclear species bound to a magnetically isolated tetrachlorocuprate(II) entity. The complex $[Cu_2(L1)(CH_3OH)_2](ClO_4)_2$ forms brown crystals with a = 8.6516(7), b = 11.6832(9), c = 16.7205(6) Å, β = 92.596(5)°, $P2_1/n$, Z = 2, R_f = 0.037 and has a copper–copper separation of 3.088(1) Å and two weakly bound *trans*-axial methanol molecules (Cu—O, 2.413(4) Å). Variable temperature magnetic studies on $[Cu_2(L1)(ClO_4)_2]$ and $[Cu_2(L1)](ClO_4)_2$ indicate strong antiferromagnetic exchange ($-2J$ = 824 ± 5 cm^{-1}, 827 ± 7 cm^{-1}, respectively) in both cases.

SANAT K. MANDAL, LAURENCE K. THOMPSON, KAMALAKSHA NAG, JEAN-PIERRE CHARLAND et ERIC J. GABE. Can. J. Chem. **65**, 2815 (1987).

On peut obtenir le ligand saturé H_2L1 par une condensation du méthyl-4 diformyl-2,6 phénol avec du diamino-1,3 propane, suivie d'une réduction par le borohydrure; il génère des complexes binucléaires du cuivre(II) qui sont couplés d'une façon antiferromagnétique et qui présentent un voltamétrie cyclique impliquant deux étapes d'oxydation par un électron ($E_{1/2}$ = 1,1 à 1,2 V et 1,3 à 1,4 V; $Pt/CH_3CN/SCE$) et deux étapes de réduction par un électron ($E_{1/2}$ = −0,75 à −0,76 V et −0,89 à −0,90 V; GC/DMSO/SCE) avec la formation d'espèces Cu(III)–Cu(III), Cu(I)–Cu(I) et d'espèces de niveaux d'oxydation mixtes. Un dérivé trinucléaire, $[Cu_2(L1)(CuCl_4)]$, semble contenir une espèce binucléaire couplés par les spin à une entité tétrachlorocuprate(II) isolée d'un point de vue magnétique. Le complexe $[Cu_2(L1)(CH_3OH)_2](ClO_4)_2$ forme des cristaux bruns avec a = 8,6516(7), b = 11,6832(9) et c = 16,7205(6) Å, β = 92,596(5)°, $P2_1/n$, Z = 2, R_f = 0,037; ils comportent une séparation cuivre–cuivre de 3,088(1) Å et deux molécules de méthanol faiblement liées en positions trans et axiales (Cu—O, 2,413(4) Å). Des études magnétiques à température variable sur le $[Cu_2(L1)(ClO_4)_2]$ et sur le $[Cu_2(L1)](ClO_4)_2$ indiquent que, dans chaque cas, il se produit un fort échange antiferromagnétique ($-2J$ = respectivement 824 ± 5 cm^{-1} et 827 ± 7 cm^{-1}).
[Traduit par la revue]

Introduction

Binuclear copper(II) complexes of the unsaturated macrocyclic ligand H_2L3 and its derivatives have been the focus of extensive studies (1–13) but the half saturated macrocycle, H_2L2 (14, 15), and the fully saturated macrocycle, H_2L1 (16), have received much less attention (Fig. 1). Structural studies on $[Cu_2(L3)Cl_2].6H_2O$ (4, 5) and the mixed valence state species $[Cu(II)Cu(I)(L3)]ClO_4.0.5CH_3OH$ (13), involving the unsaturated macrocycle, have been reported and indicate square-pyramidal copper(II) centres and essentially square planar copper centres, respectively. In both cases the two copper centres are bound by four in-plane donors: two azomethine nitrogen centres and two oxygen atoms from the phenoxide bridges. In a recent report (16) the structure of the complex $[Cu_2(L1)(ClO_4)_2]$, involving the fully saturated macrocycle, has been shown to consist of two copper(II) centres bridged by the two phenoxide oxygen atoms with two secondary amine nitrogen donors completing the in-plane donor sets, and two axially bound, bidentate perchlorates forming distorted, axially elongated, octahedra. This complex exhibits remarkable electrochemistry involving two one-electron oxidation steps (cyclic voltammetry, $E_{1/2}$ = 1.21 V, 1.41 V; $Pt/CH_3CN/SCE$) and two one-electron reduction steps ($E_{1/2}$ = −0.76 V, −0.90 V; GC/DMSO/SCE) with the formation of Cu(III)–Cu(III), Cu(I)–Cu(I), and mixed oxidation state species. Electron spin resonance data indicate that the odd electron is localised on one copper centre only in both the half-oxidized and half-reduced species (16).

In the present study we report the crystal structure of the complex $[Cu_2(L1)(CH_3OH)_2](ClO_4)_2$, an unusual binuclear, five-coordinate, copper(II) species involving in-plane N_2O_2 coordination and *trans*-coordination of two methanol molecules with relatively long Cu—O (MeOH) separations (2.413 Å). Variable temperature magnetic studies indicate very strong antiferromagnetic exchange between the copper(II) centres in $[Cu_2(L1)](ClO_4)_2$ and $[Cu_2(L1)(ClO_4)_2]$ ($-2J$ = 827 ± 7 cm^{-1}, 824 ± 5 cm^{-1}, respectively). Other copper(II) derivatives of this ligand are also described, including the trinuclear species $[Cu_2(L1)(CuCl_4)]$, which appears to consist of a

strongly coupled binuclear entity bound to an essentially magnetically isolated tetrachlorocuprate(II) anion.

Experimental

Synthesis of the ligand and complexes

The ligand, H_2L1, was synthesized according to the published procedure (16).

*$[Cu_2(L1)(CH_3OH)_2](ClO_4)_2$ (**I**), $[Cu_2(L1)(H_2O)_2](ClO_4)_2$ (**II**), $[Cu_2(L1)](ClO_4)_2$ (**III**)*

H_2L1 (0.41 g, 0.001 mol) was dissolved in a mixture of dry methanol (5 mL) and 2,2-dimethoxypropane (10 mL) and $Cu(ClO_4)_2.6H_2O$ (0.75 g, 0.002 mol) was dissolved separately in a similar solvent mixture. The solutions were refluxed separately for 30 min, cooled to room temperature, and mixed. After 30 min green needles formed (**II**), which were removed by decanting. On further standing a mixture of brown and green crystals was obtained (yield 0.23 g) and was decanted. Finally a third crop of brown crystals (**I**) was obtained (yield 0.06 g). This original complex was studied by X-ray crystallography (see Discussion), but in all subsequent preparations only mixtures of **II** and **III** were obtained. If the ligand and copper perchlorate are refluxed separately with excess 2,2-dimethoxypropane in methanol for 5–6 h, cooled, and then mixed, the brown product **III** is obtained as the exclusive product.

*$[Cu_2(L1)(CuCl_4)]$ (**IV**)*

H_2L1 (0.41 g, 0.001 mol) was dissolved in methanol (5 mL) and a solution of $CuCl_2.2H_2O$ (0.35 g, 0.002 mol) in methanol (10 mL) was added and the mixture left for several hours. Green–brown crystals formed and were filtered off, washed with methanol, and air dried (yield 0.25 g).

*$[Cu_2(L1)(NCS)_2].H_2O$ (**V**)*

H_2L1 (0.41 g, 0.001 mol) was dissolved in butanol (30 mL) and a solution of $Cu(ClO_4)_2.6H_2O$ (0.75 g, 0.002 mol) in butanol (20 mL) added. After 5 to 6 h green crystals formed and were filtered off, washed with butanol, and air dried. The green crystalline compound (0.2 g) was dissolved in hot acetonitrile (30 mL) and a saturated aqueous solution of NH_4SCN (10 mL) added with stirring. On reducing the volume of the solution a green compound (**V**) formed and was separated by filtration, washed with water and ethanol, and air dried (yield 0.12 g).

Analytical data for compounds **II**–**V** are given in Table 1.

Electrochemical measurements

The electrochemical experiments were performed at room temperature in dimethylsulfoxide (spectroscopic grade, dried over molecular sieves) and acetonitrile (spectroscopic grade, dried over molecular sieves) under O_2-free conditions using a BAS CV27 Voltammograph and a Houston Omnigraph 2000XY recorder. A three-electrode system was used (cyclic voltammetry) in which the working electrode was either glassy carbon (reduction in DMSO) or platinum (oxidation in acetonitrile), the counter electrode platinum, with a standard calomel (SCE) electrode as reference. For coulometry measurements a three-electrode system was employed consisting of a platinum mesh flag working electrode, a platinum mesh counter electrode, and a silver rod as reference electrode. The supporting electrolyte was tetraethylammonium perchlorate (TEAP) (0.1 *M*) and all solutions were 10^{-3}–10^{-4} in complex. The best combination of experimental conditions (working electrode, scan rates, solvent etc.) was determined by preliminary experiment.

Magnetic measurements

Room-temperature magnetic moments were measured by the Faraday method using a Cahn 7600 Faraday magnetic susceptibility system. Variable-temperature magnetic susceptibility data were obtained in the range 5–300 K (compounds **III**, **VI**) using an Oxford Instruments superconducting Faraday magnetic susceptibility system with a Sartorius 4432 microbalance. A main solenoid field of 1.5 Tesla and a gradient field of 10 T m^{-1} were employed.

Data for X-ray crystallographic analysis for $[Cu_2(L1)(CH_3OH)_2](ClO_4)_2$ (**I**) are as follows:

$C_{26}H_{42}N_4O_{12}Cl_2Cu_2$ fw = 796.29
Monoclinic, $P2_1/n$, a = 8.6516(7), b = 11.6832(9), c = 16.7205(6) Å, β = 92.596(5)°, V = 1679.6 Å^3, Z = 2(MoKα, $\lambda\alpha$ = 0.70930 Å); μ = 1.49 mm^{-1}, D_{calcd} = 1.575 g cm^{-3}.

Crystals of **I** are brown in colour. The diffraction intensities of an approximately 0.30 × 0.30 × 0.20 mm crystal were collected with graphite monochromatized MoKα radiation using the ω scan mode to $2\theta_{max}$ = 44° using a Nonius diffractometer. A total of 2284 reflections were measured, of which 2172 were considered unique, and 1769 reflections were considered to be significant with $I_{net} > 2.5\sigma(I_{net})$. Lorentz and polarization factors were applied and no correction was made for absorption. The cell parameters were obtained by the least-squares refinement of the setting angles of 44 reflections with 2θ in the range 40–45° (λMoKα = 0.70930 Å). The structure was solved by direct methods using MULTAN (17) and refined by full-matrix least-squares methods to final residuals of R_f = 0.037 and R_w = 0.022 for the significant data (0.049 and 0.022 for all data) with weights based on counting statistics. All hydrogen atoms were located from a difference map and refined. All calculations were performed with the NRCVAX system of programs (18). Scattering factors were taken from ref. 19. The final atomic positional parameters and equivalent isotropic temperature factors are listed in Table 2, thermal parameters in Table 3, and observed and calculated structure factors in Table 4.[3]

Results and discussion

Description of the structure of $[Cu_2(L1)(CH_3OH)_2](ClO_4)_2$ (I)

The crystal structure of **I** is shown in Fig. 2 and consists of two square-pyramidal copper(II) centres bridged by two phenoxide oxygen atoms with two secondary amine nitrogen donors completing the distorted CuN_2O_2 plane. Interatomic distances and angles relevant to the copper coordination spheres

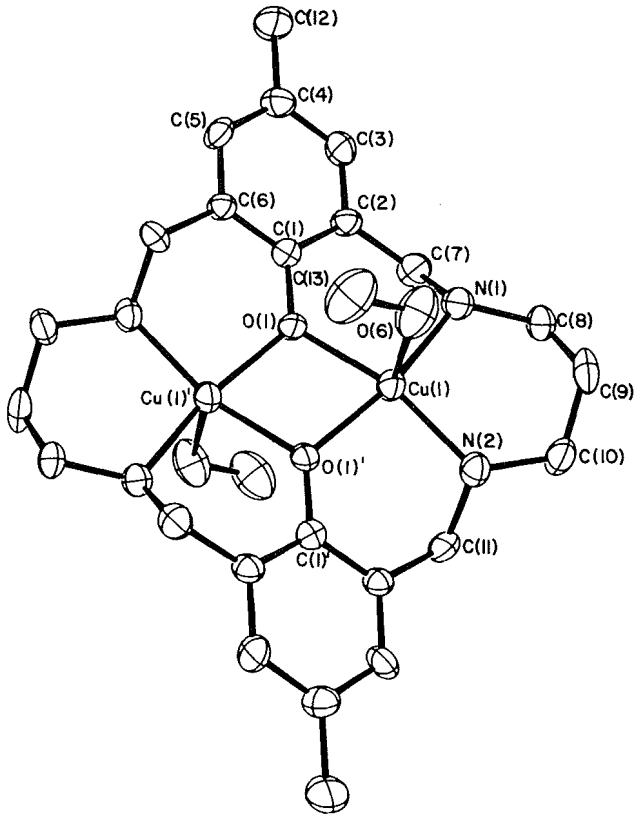

FIG. 2. Structural representation of $[Cu_2(L1)(CH_3OH)_2]^{2+}$ (**I**) with hydrogen atoms omitted (40% probability thermal ellipsoids).

are listed in Table 5. The distortion in the CuN_2O_2 plane involves an acute angle O(1)—Cu(1)—O(1)′ of 76.1° and the copper centre is displaced from the mean plane of the atoms O(1), N(1), N(2), O(1)′, toward the coordinated methanol by 0.11 Å. The oxygen bridge angles, Cu—O(1)—Cu, are 103.9° and the two copper centres are separated by 3.088 Å. The methanol molecules are bound in a *trans* fashion, above and below the binuclear centre, with Cu—O separations of 2.413 Å. Coordinated methanol molecules have been observed for a number of other mononuclear and binuclear copper(II) complexes and copper–oxygen separations are found in the range 2.16–2.48 Å in a literature sampling (20–28). The methanol–copper interaction in **I** is relatively weak and the overall *trans* arrangement of the two methanol molecules about the diphenoxide bridged binuclear centre is similar to that observed for the bistriketonate system $[Cu_2(HXFDAA)_2(CH_3OH)_2]$ (HXFDAA = 1,1,1,7,7,7-hexafluoro-2,4,6-heptanetrionate) (27), which involves two *trans* square-pyramidal CuO_5 chromophores with two ketonic oxygen bridges and relatively short copper–methanol separations (2.223 Å).

The structure of **I** is very similar to that of the complex $[Cu_2(L3)Cl_2].6H_2O$ (5), which involves a *trans* arrangement of two axially bound chlorine atoms (Cu—Cl 2.582 Å) about the binuclear centre. Similar distortions were observed in the CuN_2O_2 planes with slightly shorter Cu—N and slightly longer Cu—O distances than those observed for **I**. The copper–copper separation (3.133 Å) and the Cu—O—Cu angle (104.5°) are larger for this compound also. The binuclear centre in **I** also compares closely with that of the complex $[Cu_2(L1)(ClO_4)_2]$ (**VI**) (16), which has the same basic structure but with two weakly bound bidentate axial perchlorate groups forming what is best described as a severely distorted, elongated octahedron at each copper centre.

Synthesis, spectral, magnetic, and electrochemical properties of the complexes

The copper coordination chemistry of H_2L1 is quite complicated and even relatively subtle differences in reaction conditions can lead to different compounds using the same copper salt. In the case of the perchlorate derivatives three different compounds have been obtained from methanol/2,2-dimethoxypropane mixtures. The green diaquoderivative (**II**) clearly results from incomplete drying of the solvent while the anhydrous brown compound $[Cu_2(L1)](ClO_4)_2$ is formed when all the water in the solvent mixture has been consumed by reaction with 2,2-dimethoxypropane. The dimethanol complex (**I**), which was characterized by X-ray crystallography, was obtained from the original synthesis (Experimental), but in all subsequent preparations only the brown compound $[Cu_2(L1)](ClO_4)_2$ was obtained in addition to compound **II**. Consequently, although compound **I** has been characterized structurally, no other physical characterization has been carried out on this complex. Structurally, however, the binuclear macrocyclic entity $[Cu_2(L1)]^{2+}$ will likely be the same in all three systems.

The infrared spectra of **II** and **III** are very similar with strong ν_3 perchlorate vibrations at 1100 cm^{-1} indicative of ionic perchlorate and NH stretching absorptions at 3230 and 3250 cm^{-1}, respectively. Two strong absorptions at 3490 and 3560 cm^{-1} suggest that in **II** both water molecules are coordinated. Compound **II** has a visible absorption at 17 400 cm^{-1} while compound **III** absorbs at 16 600 cm^{-1} (Table 6). The blue complex $[Cu_2(L1)(ClO_4)_2]$(VI), which involves very long axial Cu—O (perchlorate) interactions (2.821 Å), has a visible absorption at 17 700 cm^{-1} and exhibits three ν_3 perchlorate absorptions (1120, 1085, 1025 cm^{-1}) (16) in the infrared indicative of low symmetry, coordinated perchlorate. Structurally all three complexes are clearly closely related and it seems reasonable to assume that for **II** the water molecules are bound in a *trans*-axial square-pyramidal arrangement while for compound **III** a binuclear square-planar structure exists.

Room temperature magnetic moments for compounds **II**, **III**, and **VI** are around 0.5 BM (Table 6) indicating strong spin exchange between the copper(II) centres. Variable temperature magnetic susceptibility measurements were performed on powdered samples of **III** and **VI** in the temperature range 5–300 K. The results are summarised in Figs. 3 and 4, respectively. The best-fit lines were calculated from the Van Vleck equation (29) for exchange-coupled pairs of copper(II) ions (eq. [1]):

$$[1]\quad \chi_M = \frac{N\beta^2 g^2}{3kT}\left[1 + \frac{1}{3}\exp(-2J/kT)\right]^{-1}(1-\rho) + \left[\frac{N\beta^2 g^2}{4kT}\right]\rho + N\alpha$$

In this expression $2J$ (in the spin Hamiltonian $H = 2J\hat{s}_1.\hat{s}_2$) is the singlet–triplet splitting or exchange integral and other symbols have their usual meaning. ρ represents the fraction of a possible magnetically dilute copper(II) impurity. The temperature-independent paramagnetism for a binuclear copper(II) complex, $N\alpha$, was taken as 120×10^{-6} cgs units/mol. The parameters giving the best fit were obtained by using a non-linear regression analysis with ρ as a floating parameter. The exchange integral ($-2J$) for **III** was found to be 827 ± 7 cm^{-1} ($g = 2.14 \pm 0.03$, $\rho = 0.00055$) and for **VI** was found to be 824 ± 5 cm^{-1} ($g = 2.17 \pm 0.02$, $\rho = 0.00075$) indicating very strong exchange between the copper(II) centres in both cases.

It is of interest to compare the magnetism of **III** and **VI**

with that of $[Cu_2(L3)Cl_2].6H_2O$ ($-2J$ = 588 cm^{-1}) (11). Structurally all the compounds are similar with weakly bound axial ligands in two cases. The dominant structural feature, which is likely to influence the antiferromagnetic exchange between the copper centres the most, is the planar arrangement of oxygen bridges and the phenoxide bridge angle. It is well established that magnetic exchange in a series of dihydroxo-bridged binuclear copper(II) complexes, $[Cu_2B_2(OH)_2]^{2+}$ (B = bidentate nitrogen donor) varies as a function of hydroxide bridge angle (30), and for a hydroxide bridge angle of 104.1° $-2J$ was found to be 508 cm^{-1}. This value compares with that for $[Cu_2(L3)Cl_2].6H_2O$, which has a slightly larger bridge angle (104.5°). However, the value associated with **VI** is much larger for what is a smaller oxygen bridge angle (102.8° (16)). A comparable angle is found for compound **I** (103.9°). The dominant exchange pathway, through the two oxygen bridge atoms, involves interaction of the two copper $d_{x^2-y^2}$ orbitals and s and p orbitals on the oxygen with a predominantly σ overlap. Out-of-plane distortions at the copper centres will, no doubt, lead to some reduction in σ overlap and hence exchange, but the effect on exchange is likely to be small (31). The copper centres are displaced from the mean planes of the N_2O_2 donor sets in **I** and $[Cu_2(L3)Cl_2].6H_2O$(5) by 0.11 and 0.21 Å, respectively. For **VI**, although the copper centres lie in the mean plane of the N_2O_2 donor set, the magnetic orbital is not planar (O ± 0.097(5) Å, N ± 0.209(8) Å versus mean N_2O_2 plane) (16). In addition, the spin exchange between copper(II) centres bridged by oxygen donors (e.g. alkoxide, phenoxide) has been shown to be dependent on the degree of pyramidal distortion at the oxygen bridge (32, 33) and that in severe cases the overall exchange situation can be dominated by a ferromagnetic component. The complex $[Cu_2(L3)Cl_2].6H_2O$ has a solid angle at the phenoxide bridge of 357.4° (5), whereas

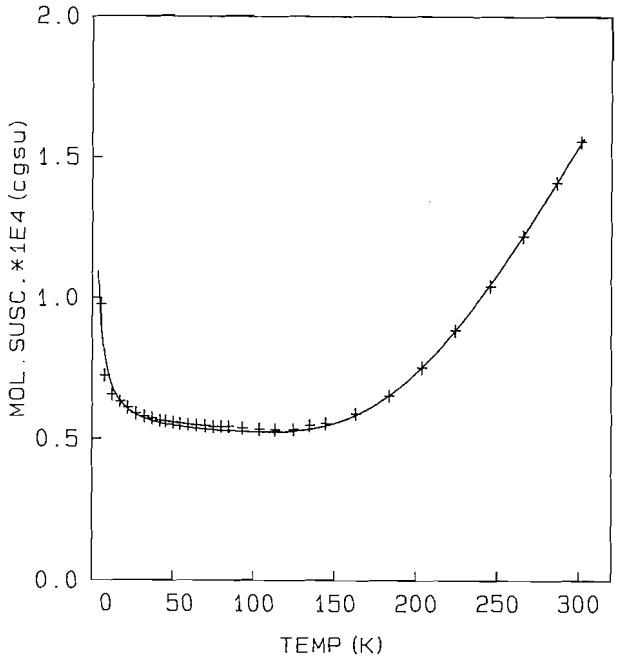

FIG. 3. Magnetic susceptibility data for $[Cu_2(L1)](ClO_4)_2$ (**III**). The solid line was calculated from eq. [1] with $g = 2.14 \pm 0.03$, $-2J = 827 \pm 7\ cm^{-1}$, and $N\alpha = 60 \times 10^{-6}$ cgs units ($cm^3\ mol^{-1}$)/Cu and assuming 0.055% paramagnetic impurity ($\rho = 0.00055$).

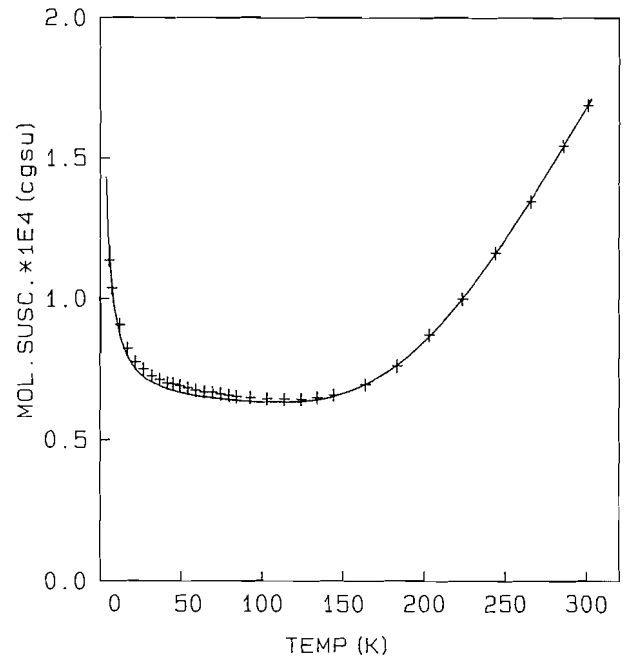

FIG. 4. Magnetic susceptibility data for $[Cu_2(L1)(ClO_4)_2]$ (**VI**). The solid line was calculated from eq. [1] with $g = 2.17 \pm 0.02$, $-2J = 824 \pm 5\ cm^{-1}$, and $N\alpha = 60 \times 10^{-6}$ cgs units ($cm^3\ mol^{-1}$)/Cu and assuming 0.075% paramagnetic impurity ($\rho = 0.00075$).

for **I** and **VI** solid oxygen angles of 359.6° and 360.0° are found, respectively. However, such a small pyramidal distortion for $[Cu(L3)Cl_2].6H_2O$ is not considered significant in terms of reducing the net antiferromagnetic exchange by in excess of $200\ cm^{-1}$.

Another factor, which appears to contribute to the exchange situation, is the degree of saturation at the nitrogen donor centres. It has been established that as the extent of saturation

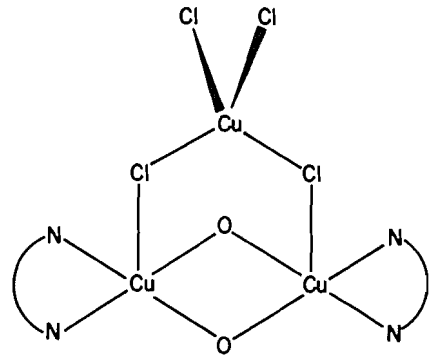

FIG. 5. Proposed structural representation for $[Cu_2(L1)(CuCl_4)]$ (**IV**).

at these centres increases ($H_2L3 \rightarrow H_2L2 \rightarrow H_2L1$) the first one-electron reduction potential exhibits a dramatic negative shift in DMSO for the complexes $[Cu_2(L3)](ClO_4)_2.2H_2O$, $[Cu_2(L2)](ClO_4)_2.2H_2O$, and $[Cu_2(L1)(ClO_4)_2]$ (**VI**) ($E_{1/2} = -0.43$ V, -0.58 V, -0.76 V, respectively) (16). This trend can be interpreted in terms of a stabilising effect of the copper(I) state with increasing unsaturation and has been observed before for macrocyclic (N_4), mononuclear copper(II) (34), and nickel(II) (35) complexes. The copper–nitrogen bonds can be considered to be more strongly polarized when the nitrogen centres are unsaturated, which would lead to a situation where the copper(II) ions would become reduced more readily. This charge delocalization effect will, no doubt, polarize the electron density in the copper magnetic orbital, with the result that exchange will diminish as unsaturation increases. This is reflected in the room temperature magnetic moments for the copper perchlorate complexes of H_2L3, H_2L2, and H_2L1 ($\mu_{eff} = 0.72$ BM (12), 0.71 BM (14), and 0.51 BM ($-2J = 824 \pm 5\ cm^{-1}$ for **VI**), respectively), which indicate that any nitrogen unsaturation causes reduced antiferromagnetic exchange. The presence of *trans*-axial chlorines in $[Cu_2(L3)Cl_2].6H_2O$ appears to exert an additional electron delocalization effect, despite the fact that they are bound orthogonally to the copper magnetic orbital (μ_{eff}(rt) = 0.80 BM) (11).

The trinuclear complex, $[Cu_2(L1)(CuCl_4)]$ (**IV**), is most unusual, and exhibits far-infrared bands which can be associated with both terminal and bridging Cu—Cl bonds (280, $260\ cm^{-1}$). A relatively low energy charge transfer absorption at $23\,800\ cm^{-1}$ can be associated with halogen-to-metal charge transfer. The room temperature magnetic moment (μ_{eff} = 1.30 BM) would be the average of the contributions of the three copper centres. On the assumption that the binuclear fragment $[Cu_2(L1)]^{2+}$ in **IV** is similar to that in **VI** an estimate of its room temperature contribution to the magnetic moment would be based on a value of μ_{eff} of about 0.5 BM. If the mononuclear fragment was considered to be $CuCl_4^{2-}$ then a contribution from this species based on a room temperature magnetic moment (μ_{eff}) of 1.9 BM would not be unreasonable. Assuming these values the average magnetic moment (μ_{eff}) for **IV** becomes 1.3 BM, in good agreement with the observed value. In the absence of structural data a reasonable suggestion for the structure of **IV** would involve a binuclear, cationic fragment similar to that in **I** and **VI** with a distorted $CuCl_4^{2-}$ moiety associated with the cation via a *cis*-axial interaction (Fig. 5). A similar situation was found to exist for the complex $[Cu_2(PPDMe)(OH)Cl_2][CuCl_3(H_2O)].H_2O$ (PPDMe = 3,6-bis(3,5-dimethyl-1-pyrazolyl)pyridazine (μ_{eff} = 1.03 BM)) (36) which has a long copper–chlorine axial interaction (2.955 Å)

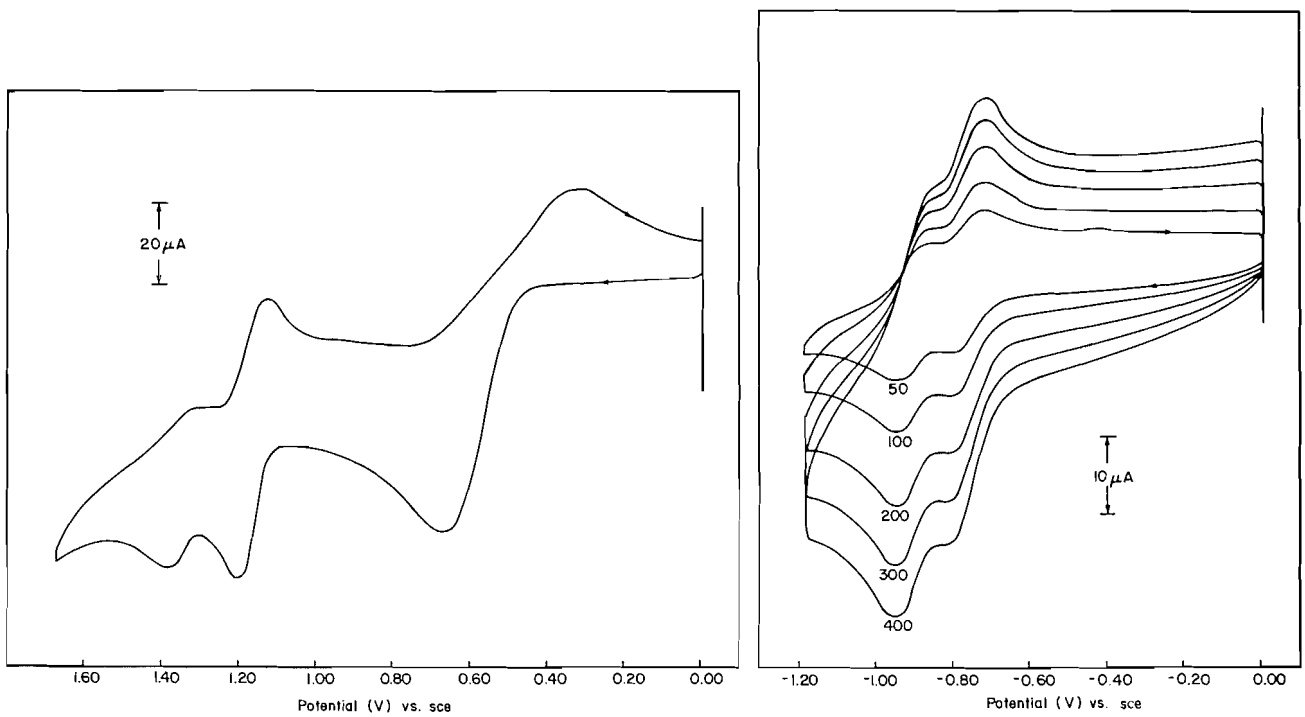

FIG. 6. Cyclic voltammograms for $[Cu_2(L1)(SCN)_2].H_2O$ (**V**) at positive (200 mV s^{-1}) (GC/CH_3CN/TEAP/SCE) and negative (50, 100, 200, 300, 400 mV s^{-1}) potentials (GC/DMSO/TEAP/SCE).

and a very strongly coupled binuclear cation. The proposed axial copper–chlorine interaction in **IV** would represent an orthogonal, magnetically isolated situation and so a chlorine bridge would not be involved in mediating spin exchange between the binuclear entity and the $CuCl_4{}^{2-}$ group.

The thiocyanate derivative **V** exhibits two infrared bands associated with thiocyanate, νCN, stretch at 2058 and 2035 cm^{-1}, which can be associated with two *cis*-isothiocyanate groups bound to the binuclear, macrocyclic entity. Two visible bands are observed for this compound (Table 5), clearly distinguishing it from the other derivatives, and indicating the involvement of thiocyanate as a ligand. The low room temperature magnetic moment indicates the presence of very strong exchange between the two copper(II) centres, with an exchange integral that is likely to be comparable with that found for **III** and **VI**.

The electrochemical properties of **II** and **III** are essentially identical and compare very closely with those of **V** on reduction. Two clearly defined cyclic voltammetry waves are observed at

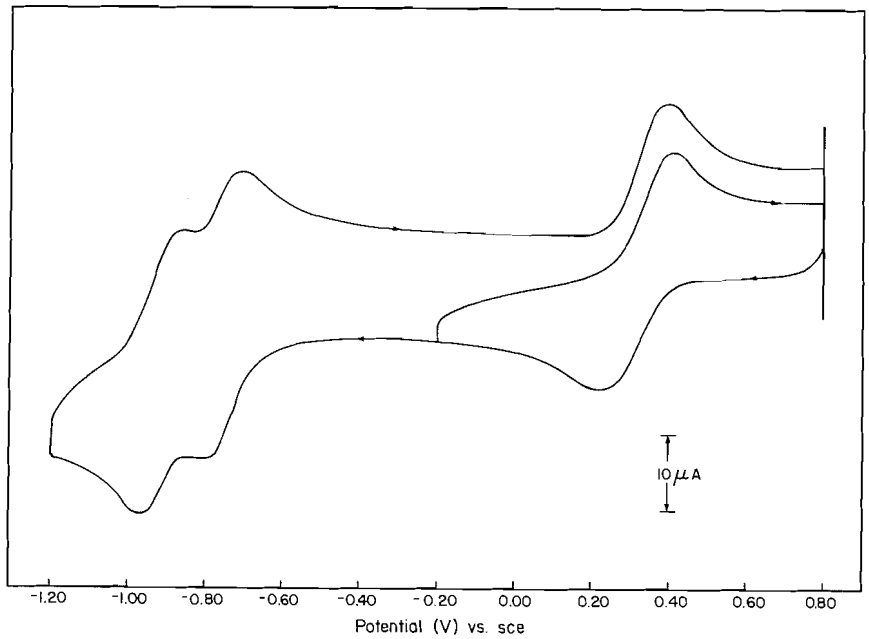

FIG. 7. Cyclic voltammograms for $[Cu_2(L1)(CuCl_4)]$ (**IV**) (200 mV s^{-1}) (GC/DMSO/TEAP/SCE).

negative potentials in DMSO in all cases, associated with two single electron reduction steps, while two waves are observed in CH_3CN at positive potentials for **II** and **V** only associated with two single electron oxidation steps (Table 7). All three complexes exhibit cyclic voltammetry which compares very closely with that of $[Cu_2(L1)(ClO_4)_2]$ (16), which exhibits two one-electron reduction steps and two one-electron oxidation steps under similar conditions. Figure 6 illustrates cyclic voltammograms for **V** at both positive and negative potentials. The peak-to-peak separations (ΔE_p) vary slightly as a function of scan rate at negative potentials indicating quasi-reversible redox processes. The broad, irreversible wave at $E_{1/2} = 0.51$ V (GC/CH_3CN/SCE/TEAP) is associated with thiocyanate and a similar wave is observed for sodium thiocyanate under similar conditions. The potentials associated with these redox processes and the conproportionation constants representing the stability of the mixed oxidation state intermediates compare closely with the complex $[Cu_2(L1)(ClO_4)_2]$ and it is assumed that in solution the active species in all cases is the solvated cation $[Cu_2(L1)]^{2+}$. This is supported by conductance data which indicate all species to be 1:2 electrolytes in these solvents.

The trinuclear complex, **III**, exhibits reduction waves similar to the other complexes, but at positive potentials the electrochemistry is dominated by a redox wave at 0.30 V (GC/DMSO/SCE/TEAP) (Fig. 7) and 0.45 V (Pt/CH_3CN/SCE/TEAP) associated with a mononuclear copper entity. Controlled potential electrolysis of **III** in DMSO at −0.09 V involved passage of 0.97 equivalents of charge indicating one electron reduction of the mononuclear copper species. Other waves, which can be attributed to chloride, prevent observation of any oxidation waves due to the binuclear copper species. The difference in potential for this species as a function of solvent indicates some solvation at this site. Conductance measurements in DMSO indicate that compound **III** is a 1:1 electrolyte. The dissociation of this complex is perhaps most likely to occur with the formation of the cation $[Cu_2(L1)]^{2+}$ and a solvated chlorocuprate anion.

Some phase relationships between basic bismuth chlorides in aqueous solutions at 25°C[1]

PETER TAYLOR AND VINCENT J. LOPATA

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

FOR ERRATA SEE 66(6)19 88 P. 1540

Received June 23, 1987

PETER TAYLOR and VINCENT J. LOPATA. Can. J. Chem. **65**, 2824 (1987).

Observations are reported on the interconversion of solid α-Bi_2O_3, $Bi_{12}O_{17}Cl_2$, BiOCl, and a daubréeite-like phase tentatively identified as $Bi_2O_2(OH)Cl$, in aqueous chloride solutions at 25°C. Equilibrium constants, K, for these interconversions are expressed as anion activity ratios, $\{Cl^-\}/\{OH^-\}$. Experimental values of K for equilibrium between Bi_2O_3 and each of the chlorides are $10^{0.56 \pm 0.20}$ for $Bi_{12}O_{17}Cl_2$, $10^{1.5 \pm 0.4}$ for $Bi_2O_2(OH)Cl$, and $10^{3.13 \pm 0.04}$ for BiOCl; the latter two represent metastable equilibria. These equilibrium constants yielded the following estimates of Gibbs energies of formation: $Bi_{12}O_{17}Cl_2$, -3141 ± 6 kJ mol^{-1}; "$Bi_2O_2(OH)Cl$", -696 ± 4 kJ mol^{-1}; BiOCl, -321.5 ± 1.3 kJ mol^{-1}. Phase relationships among these solids are discussed, with reference to natural occurrence, other bismuth oxychlorides, and the stability of other basic salts of bismuth.

PETER TAYLOR et VINCENT J. LOPATA. Can. J. Chem. **65**, 2824 (1987).

On rapporte des observations relatives à l'interconversion, dans des solutions aqueuses de chlorure, à 25°C, d'α-Bi_2O_3, de $Bi_{12}O_{17}Cl_2$, de BiOCl et d'une phase qui ressemble à de la daubréeite que l'on a identifiée provisoirement comme du $Bi_2O_2(OH)Cl$. On exprime les constantes d'équilibre, K, pour ces interconversions sous la forme de rapports d'activités d'anions, $\{Cl^-\}/\{OH^-\}$. Les valeurs expérimentales de K pour l'équilibre entre Bi_2O_3 et chacun des chlorures sont $10^{0.56 \pm 0.20}$ pour le $Bi_{12}O_{17}Cl_2$, $10^{1.5 \pm 0.4}$ pour le $Bi_2O_2(OH)Cl$ et $10^{3.13 \pm 0.04}$ pour le BiOCl; dans les deux derniers cas, il s'agit d'équilibres métastables. Ces constantes d'équilibre ont permis d'évaluer que les énergies de Gibbs de formation sont respectivement de -3141 ± 6 kJ mol^{-1} pour le $Bi_{12}O_{17}Cl_2$, de -696 ± 4 kJ mol^{-1} pour le "$Bi_2O_2(OH)Cl$" et de $-321{,}5 \pm 1{,}3$ kJ mol^{-1} pour le BiOCl. On discute des relations de phase entre ces solides en fonction de leur état naturel, d'autres oxychlorures de bismuth et de la stabilité d'autres sels basiques du bismuth.

[Traduit par la revue]

Introduction

Bismuth(III) oxychloride chemistry is complex, with four intermediate compounds between BiOCl and Bi_2O_3. One such compound, $Bi_7O_9Cl_3$, was reported as long ago as 1844 (1). This report was viewed with skepticism, but was finally vindicated almost a century later by Sillen and Edstrand (2), who showed, however, that the correct stoichiometry is $Bi_{24}O_{31}Cl_{10}$. Another oxychloride, $Bi_{12}O_{15}Cl_6$, was identified by Hopfgarten (3). Two further compounds, Bi_3O_4Cl and $Bi_{12}O_{17}Cl_2$, have been reported by Nurgaliev *et al.* (4–6) as products of both dry and hydrothermal syntheses, and Aurivillius (7) has reported some additional crystallographic information on these phases. As well as these anhydrous compounds, the hydroxychloride $BiO(OH)_xCl_{1-x}$ ($x \simeq 0.5$) has been reported both as a mineral, daubréeite (8), and as a synthetic material (9). The only other bismuth oxychloride mineral is bismoclite, BiOCl (8).

We have recently measured the stability limits of basic bismuth carbonates and iodides in aqueous solutions at or near 25°C (10, 11). Some of these compounds show promise as waste forms for immobilization and disposal of ^{14}C and ^{129}I, which are long-lived radioactive waste products from nuclear power generation. We need information on the stability of bismuth chlorides, to help predict the behavior of the carbonates and iodides in saline groundwaters. Here we report observations on the preparation and interconversion of basic bismuth chlorides in aqueous solutions.

Our experimental strategy was to examine the conditions under which various basic bismuth chlorides are formed, in aqueous solutions at or near 25°C, and hence to determine whatever equilibrium relationships we could. We have examined the sequential hydrolysis of BiOCl and the reaction of Bi_2O_3 with dissolved chloride, and analysed solutions in contact with combinations of Bi_2O_3 and three basic chlorides: $Bi_{12}O_{17}Cl_2$, BiOCl, and a daubréeite-like compound with approximate composition $Bi_2O_2(OH)Cl$.

[1]AECL No. 9448.

Background on phase relationships

The $BiCl_3$–Bi_2O_3 phase diagram, determined by Nurgaliev *et al.* (4), indicates that all five bismuth oxychlorides (BiOCl, $Bi_{12}O_{15}Cl_6$, $Bi_{24}O_{31}Cl_{10}$, Bi_3O_4Cl, and $Bi_{12}O_{17}Cl_2$) are stable with respect to disproportionation at room temperature. In the aqueous system, $BiCl_3$–Bi_2O_3–H_2O–[pH],[2] interconversion of these solids can be represented by a series of equilibria similar to those we have previously described (11) for the sequential hydrolysis of BiI_3:

$$[1] \quad (1/2)BiCl_3(s) + OH^-(aq) \rightleftharpoons (1/2)BiOCl(s) + (1/2)H_2O(l) + Cl^-(aq)$$

$$[2] \quad 2BiOCl(s) + OH^-(aq) \rightleftharpoons (1/6)Bi_{12}O_{15}Cl_6(s) + (1/2)H_2O(l) + Cl^-(aq)$$

$$[3] \quad Bi_{12}O_{15}Cl_6(s) + OH^-(aq) \rightleftharpoons (1/2)Bi_{24}O_{31}Cl_{10}(s) + (1/2)H_2O(l) + Cl^-(aq)$$

$$[4] \quad (1/2)Bi_{24}O_{31}Cl_{10}(s) + OH^-(aq) \rightleftharpoons 4Bi_3O_4Cl(s) + (1/2)H_2O(l) + Cl^-(aq)$$

$$[5] \quad 2Bi_3O_4Cl(s) + OH^-(aq) \rightleftharpoons (1/2)Bi_{12}O_{17}Cl_2(s) + (1/2)H_2O(l) + Cl^-(aq)$$

$$[6] \quad (1/2)Bi_{12}O_{17}Cl_2(s) + OH^-(aq) \rightleftharpoons 3Bi_2O_3(s) + (1/2)H_2O(l) + Cl^-(aq)$$

[2]Here, [pH] denotes a non-interacting acid or base, i.e. one that is not incorporated in any of the solids.

TABLE 1. Gibbs energies of formation, $\Delta_f G^0$ (298.15 K) of species discussed[a]

Species	$\Delta_f G^0$, kJ mol^{-1}		
	Ref. 12	Ref. 13	This work
$BiCl_3$(s)	−315.0	—	—
BiOCl(s)	−322.1	—	−321.5 ± 1.3
$Bi_2O_2(OH)Cl$(s)	—	—	−696 ±4[b]
$Bi_{12}O_{17}Cl_2$(s)	—	—	−3141 ±6[b]
α-Bi_2O_3(s)	−493.7	−493.5 ±1.5	—
H_2O(l)	−237.13	−237.14 ± 0.08	—
OH^-(aq)	−157.24	−157.33 ± 0.09	—
Cl^-(aq)	−131.23	−131.27 ± 0.11	—

[a]For Gibbs energy calculations, we used $\Delta_f G^0$ values from ref. 12, and uncertainties from ref. 13. The major sources of uncertainties in our Gibbs energy data are $\Delta_f G^0$ for α-Bi_2O_3, and our own experimental errors.
[b]From experiments on poorly crystalline material.

When the reactions are expressed in this way, all the equilibrium constants (K_1, K_2, ... K_6) take the form $\{Cl^-\}/\{OH^-\}$, and are expected to decrease in this order. The stability field of each solid can then be expressed in terms of this activity ratio, for example $Bi_{12}O_{15}Cl_6$ will be stable in contact with a solution having $\{Cl^-\}/\{OH^-\}$ between K_2 and K_3. It is possible, however, that the stability fields of hydrous chlorides, such as daubréeite, might encroach on, or eliminate, those of some of the anhydrous solids.

We make a distinction here between the activity {X} and concentration [X] of a given species. Since all of the experimental equilibrium constants discussed below are ratios of activities of singly charged anions, $\{Cl^-\}/\{OH^-\}$, activity coefficients virtually cancel out and this term is interchangeable with $[Cl^-]/[OH^-]$. The distinction is maintained, however, to indicate whether a measured quantity is a concentration or an activity, and to assure that activities and concentrations are not mixed in the same expression. Similarly, the distinction between molarity and molality virtually cancels out in the term $\{Cl^-\}/\{OH^-\}$, and is inconsequential at the level of accuracy of these experiments.

Gibbs energies of formation, $\Delta_f G^0$, are available for solid $BiCl_3$, BiOCl, and Bi_2O_3, but not for any of the other oxychlorides (12, 13). These and other relevant Gibbs energies are listed in Table 1. The value of −322.1 kJ mol^{-1} recommended for BiOCl dates back to a 1918 electrochemical study of reaction [7] by Noyes and Chow (14):

[7] $BiOCl(s) + (3/2)H_2(g) \rightleftharpoons Bi(s) + H_2O(l) + H^+(aq) + Cl^-(aq)$

Vasil'ev and Grechina (15, 16) have recommended slightly less negative values, based on reinterpretation of the data of Noyes and Chow (−321.0 ± 0.3 kJ mol^{-1}), and on their own electrochemical measurements (−319.4 ± 0.2 kJ mol^{-1}). Other work on the solubility of BiOCl has been concerned principally with the speciation of bismuth in solution, and has not explicitly addressed the thermodynamics of BiOCl (17, 18). Sammour and Moussa, however, do mention that some of their emf measurements were consistent with those of Noyes and Chow (14, 19). Thus, although there may be some cause for revising the recommended value of $\Delta_f G^0$ for BiOCl, any change is likely to be small, probably <3 kJ mol^{-1}.

Using the Gibbs energies in Table 1, and the standard relationship between Gibbs energy of reaction, $\Delta_r G^0$, and equilibrium constant, K [8]:

[8] $\Delta_r G^0 = -RT \ln K$

we obtain $\log_{10} K_1 = 16.8$. This indicates that $BiCl_3$ is unstable with respect to hydrolysis to BiOCl, even in concentrated HCl. This is consistent with various studies on BiOCl in acidic media (14–19). We can also calculate a metastable equilibrium constant for coexisting BiOCl and Bi_2O_3:

[9] $BiOCl(s) + OH^-(aq) \rightleftharpoons (1/2)Bi_2O_3(s) + (1/2)H_2O(l) + Cl^-(aq)$

$\Delta_r G^0 = -17.3$ kJ mol^{-1}

$K_9 = \{Cl^-\}/\{OH^-\} = 10^{3.03}$

Experimental

Starting materials were reagent-grade $Bi(NO_3)_3 \cdot 5H_2O$, α-Bi_2O_3, NaCl, KCl, and carbonate-free aqueous solutions of NaOH and KOH. It was sometimes necessary to remove traces of bismuth carbonates (10) from Bi_2O_3 by heating at 550°C for 2 h, or by washing overnight with concentrated NaOH, then filtering and washing with freshly deionized water immediately before use.

Bismuth oxychloride, BiOCl, was prepared in 10 to 50 g quantities by adding $Bi(NO_3)_3 \cdot 5H_2O$ to water, and mixing the resulting milky suspension of basic bismuth nitrate(s) with a slight excess of NaCl solution. The net hydrolysis of Bi^{3+} to $(BiO)_n^{n+}$ was accompanied by production of acid, in accordance with the overall reaction:

[10] $Bi(NO_3)_3 + H_2O + NaCl \rightleftharpoons BiOCl + NaNO_3 + 2HNO_3$

The pH was adjusted to neutral, and the white precipitate was filtered and washed. The product gave a well-resolved X-ray diffraction pattern, in excellent agreement with the published pattern of BiOCl (20).

Solutions of desired chloride and hydroxide concentration were prepared using deionized water. Adjustments and measurements of pH were made with automatic titration equipment (Metrohm E526 titrator and E535 dosimat, or Mettler DV/DK modular system), calibrated with standard buffer solutions at pH = 6.86 and 9.18. Chloride activities were determined using Orion chloride-ion specific and double-junction reference electrodes, calibrated with solutions of known activity (10^{-2} to 10^{-5} mol dm^{-3}).

Preparative experiments were performed in screw-top Teflon bottles or flame-sealed Pyrex vials, at ambient temperature (22 ± 2°C) unless otherwise stated. Titrations were run in a nitrogen-purged vessel, thermostatted at 25.0°C. Solids were identified by X-ray powder diffraction (XRD), using a Rigaku Rotaflex diffractometer system with a 12 kW rotating-anode CuKα X-ray source; some measurements were also made with a Philips PW-1150 diffractometer.

Results and discussion

(a) Preparative experiments

(i) Hydrolysis of BiOCl

Samples of BiOCl (0.5 g) were allowed to react for 8 days with 100 cm^3 of solutions containing NaCl + NaOH, or KCl + KOH, in different proportions, with a total concentration of 1 mol dm^{-3}. No change was detected by XRD in the BiOCl recovered from solutions with $[Cl^-]/[OH^-] = 4$ or 9. In the solution with $[Cl^-]/[OH^-] = 1$, the BiOCl was partly converted to a near-amorphous material with very broad XRD features at $d \approx 3.4$ Å and 3.0 Å. This may have been $Bi_{24}O_{31}Cl_{10}$, which has several XRD features grouped near these positions (2).

In solutions with $[Cl^-]/[OH^-] = 0.25$ and 0.11, the BiOCl was converted to a bright yellow solid. Peaks in the diffraction pattern of this material were broad, but their positions are in good agreement with the $Bi_{12}O_{17}Cl_2$ pattern reported by Nurgaliev *et al.* (5) and corroborated by Aurivillius (7), as shown in Table 2. We generally observed somewhat higher

intensities than Nurgaliev *et al.* for the weaker peaks. Chloride analyses were also consistent with $Bi_{12}O_{17}Cl_2$ (experimental, 2.66 to 2.95%; calculated, 2.49%).

The hydrolysis of BiOCl provided a convenient method for preparing up to 10 g of $Bi_{12}O_{17}Cl_2$, although the product often contained traces of α-Bi_2O_3. Prolonged exposure of the wet solid to air also resulted in contamination with basic bismuth carbonates. The traces of oxide persisted when the $Bi_{12}O_{17}Cl_2$ was contacted for up to 12 days with solutions having $[Cl^-]/[OH^-]$ between 0.1 and 1.0. At still lower ratios, further conversion to α-Bi_2O_3 was observed. Both BiOCl and $Bi_{12}O_{17}Cl_2$ were converted quantitatively to α-Bi_2O_3 in a few hours in initially chloride-free 1.0 mol dm^{-3} NaOH solution. Traces of Bi_2O_3 were removed from 0.3 g samples of $Bi_{12}O_{17}Cl_2$ by exposure to solutions with $[Cl^-]/[OH^-]$ between 2.3 and 9 for about 10 days.

These observations of the interconversion of Bi_2O_3 and $Bi_{12}O_{17}Cl_2$ indicate that K_6 lies between 0.1 and 2.3. However, the apparent kinetic stability of BiOCl at $[Cl^-]/[OH^-]$ ratios down to 4 (cf. $\log K_9 = 3.03$, above), and the ill-defined hydrolysis product at $[Cl^-]/[OH^-] = 1$, prevented the acquisition of other equilibrium information from hydrolysis reactions.

(ii) Reaction of α-Bi_2O_3 with chloride solutions

Samples of α-Bi_2O_3 (0.5 g) were allowed to react for 8 days with solutions identical to those used in the BiOCl hydrolysis experiments, as well as 1 mol dm^{-3} NaCl and KCl solutions. The Bi_2O_3 was unchanged by solutions with $[Cl^-]/[OH^-] \leq 1$, except for traces of basic bismuth carbonates (10). In solutions with $[Cl^-]/[OH^-] \geq 9$, Bi_2O_3 was converted (>80%, estimated from XRD intensities) to a solid with a rather diffuse diffraction pattern, similar but not identical to that of BiOCl, as shown in Table 3. The unit cell of BiOCl is tetragonal (9), with $a = 3.891$ Å, $c = 7.369$ Å, $c/a = 1.894$.

The XRD peak positions varied slightly between preparations, corresponding to variations in cell dimensions within the limits $a = 3.80$–3.82, $c = 7.50$–7.58 Å, $c/a = 1.97$–1.99. Although the diffraction peaks were broad, the variation in c, at least, exceeded the experimental uncertainty. The cell dimensions were significantly different from both BiOCl and natural daubréeite, BiO(OH,Cl) ($a = 3.85$ Å, $c = 7.40$ Å, $c/a = 1.922$, ref. 20).

The pattern was too poor for the usual unit-cell refinement methods. The 002 and 200 peaks, however, were reasonably sharp, yielding the estimated cell dimensions $a = 3.80_8$ Å, $c = 7.57_8$ Å, $c/a = 1.990$, from which the calculated pattern in Table 3 was derived. The data in Table 3 are from the purest sample prepared from Bi_2O_3; it contained about 6 wt.% chlorine (calc. for $Bi_2O_2(OH)Cl$, 7.1%; BiOCl, 13.6%).

Bannister and Hey reported identical diffraction patterns for natural daubréeite and a synthetic material containing 7.5% and 10.25% chlorine, respectively. Our data indicate some variation in composition of our products, with a stoichiometry near

$Bi_2O_2(OH)Cl$. We have assumed this stoichiometry for estimation of Gibbs energies and phase relationships, below. We did not observe any other solid products in reactions between Bi_2O_3 and neutral or alkaline chloride solutions at room temperature.

(iii) Other preparative experiments

We tried two other approaches to clarify the sequence of interconversion of basic bismuth chlorides, namely, reaction of Bi_2O_3 with chloride/hydroxide solutions at 70 and 100°C, and reaction of bismuth nitrate with chloride/hydroxide solutions at 22°C. After 2 days at 70 and 100°C, partial conversion of Bi_2O_3 to Bi_3O_4Cl was observed at $[Cl^-]/[OH^-] \geq 10$. Daubréeite was formed together with Bi_3O_4Cl at $[Cl^-]/[OH^-] \geq 16$ at 70°C. No reaction was observed at $[Cl^-]/[OH^-] \leq 5$.

About 2 mmol of bismuth nitrate was contacted at 22°C with solutions (100 cm^3) containing a total of 39 mmol of sodium chloride and hydroxide, with the $[Cl^-]/[OH^-]$ ratio ranging from 0.016 to 3.3. Daubréeite was formed at $[Cl^-]/[OH^-] = 3.3$, and Bi_3O_4Cl at $[Cl^-]/[OH^-] = 1.6$. An unidentified phase, with a diffraction pattern resembling that of $Bi_{12}O_{17}Cl_2$, was obtained at $[Cl^-]/[OH^-]$ ratios between 0.065 and 0.85. Bismuth oxide was precipitated at $[Cl^-]/[OH^-] \leq 0.1$, and was the sole product at $[Cl^-]/[OH^-] \leq 0.03$.

Although both these series of experiments revealed conditions under which Bi_3O_4Cl can occur, they offered little prospect of further clarification of phase relationships.

(b) Heterogeneous titrations

We have attempted to measure equilibrium chloride activities, as a function of pH, by adding successive aliquots of NaOH to stirred, thermostatted suspensions of the following three solid mixtures, at 25°C: (*i*) Bi_2O_3 + BiOCl, (*ii*) Bi_2O_3 + "$Bi_2O_2(OH)Cl$", (*iii*) Bi_2O_3 + $Bi_{12}O_{17}Cl_2$.

No more than one of these mixtures can be a stable phase assemblage at a given temperature. However, the sluggish interconversion of many of the solids gave some hope of measuring metastable equilibria, and hence deducing the true equilibrium phase relationships. We did not attempt to measure any equilibria involving the other three oxychlorides ($Bi_{12}O_{15}Cl_6$, $Bi_{24}O_{31}Cl_{10}$, Bi_3O_4Cl), since they occurred rarely (or not at all) in preparative experiments.

In these titrations we used 5 g of solid, initially suspended in 40 cm^3 of water. The chloride activity and pH usually stabilized within about an hour of addition of aliquots of NaOH. Solids were filtered and washed between titrations.

(i) Bi_2O_3 + BiOCl

The results of two titrations of a mixture of Bi_2O_3 and BiOCl with NaOH solution are shown in Fig. 1. The data are consistent with the metastable equilibrium [9], with $\log K_9 = 3.13 \pm 0.04$. This is in good agreement with the value of 3.03 derived above from literature values for Gibbs energies (Table 1). The difference corresponds to a discrepancy in Gibbs energies of only 0.6 kJ mol^{-1}; we obtain $\Delta_f G^0$ (BiOCl, s, 298 K) = -321.5 ± 1.3 kJ mol^{-1}.

(ii) Bi_2O_3 + "$(BiO)_2(OH)Cl$"

Bismuth oxide (5 g, 10.7 mmol) was pretreated with either NaCl or HCl (1 mmol) to convert it partly to the hydroxychloride (confirmed by XRD), then filtered, washed, and titrated with NaOH in the manner described above. Data are presented in Fig. 2. There was more variation between runs than in the titrations with Bi_2O_3 + BiOCl, but the behaviour was otherwise similar, with $\{Cl^-\}/\{OH^-\} \sim 30$. Assuming the formula $Bi_2O_2(OH)Cl$, we can write the following relationship:

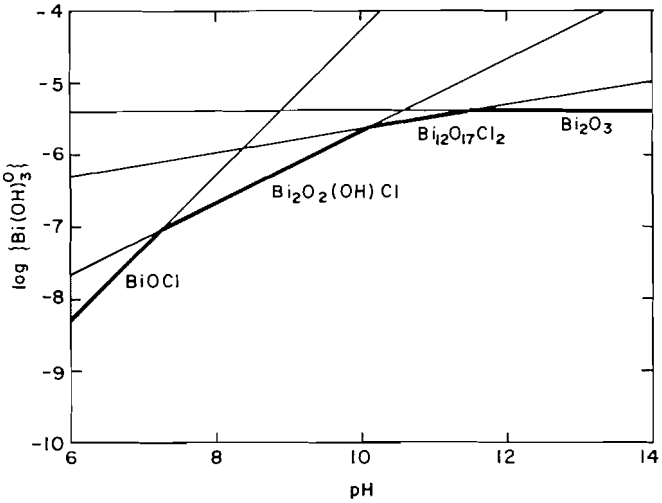

FIG. 1. Measured pH and chloride activity of solutions in contact with α-Bi_2O_3 + BiOCl. First titration, ○; second titration, ●; increasing pH and $\{Cl^-\}$ corresponds to successive additions of NaOH.

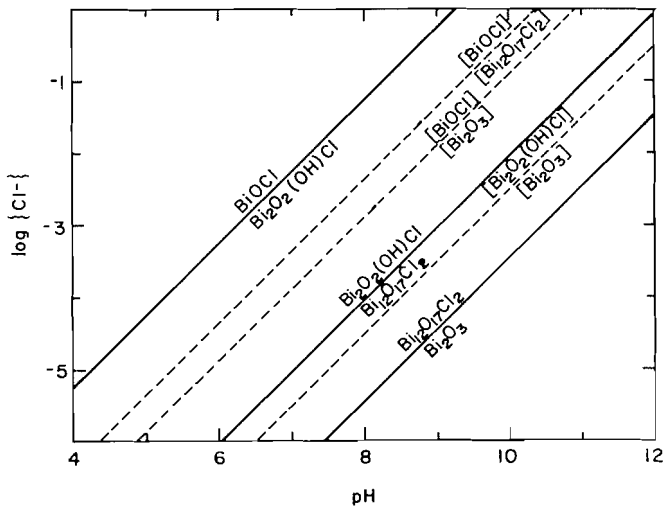

FIG. 2. Measured pH and chloride activity of solutions in contact with α-Bi_2O_3 + "$Bi_2O_2(OH)Cl$". Oxide pretreated with HCl (○) or NaCl (◒, ●).

[11] $Bi_2O_2(OH)Cl(s) + OH^-(aq) \rightleftharpoons Bi_2O_3(s) + H_2O(l) + Cl^-(aq)$

$K_{11} = \{Cl^-\}/\{OH^-\} = 10^{1.5 \pm 0.4}$

$\Delta_f G^0(Bi_2O_2(OH)Cl, s, 298\ K) = -696 \pm 4$ kJ mol^{-1}

Since the hydroxychloride was rather poorly crystalline, as indicated by XRD, there is probably a positive bias of a few kilojoules per mole, in addition to the stated uncertainty.

(iii) Bi_2O_3 + $Bi_{12}O_{17}Cl_2$

A sample of $Bi_{12}O_{17}Cl_2$ (5 g), containing traces of α-Bi_2O_3 (see "Hydrolysis of BiOCl" above), was suspended in deionized water under a nitrogen purge, and titrated with NaOH. Data for three successive titrations are presented in Fig. 3.

In the first titration, the chloride activities showed a persistent downward drift, resulting in a slope of about 0.6 in the plot of $\log\{Cl^-\}$ vs. pH. The second and third titrations, however, showed reproducible equilibrium behaviour of the type expected from eq. [6]. We conclude that there was insufficient Bi_2O_3 in the initial sample to sustain equilibrium, or there was some aging of the $Bi_{12}O_{17}Cl_2$, in the early stages of the first titration.

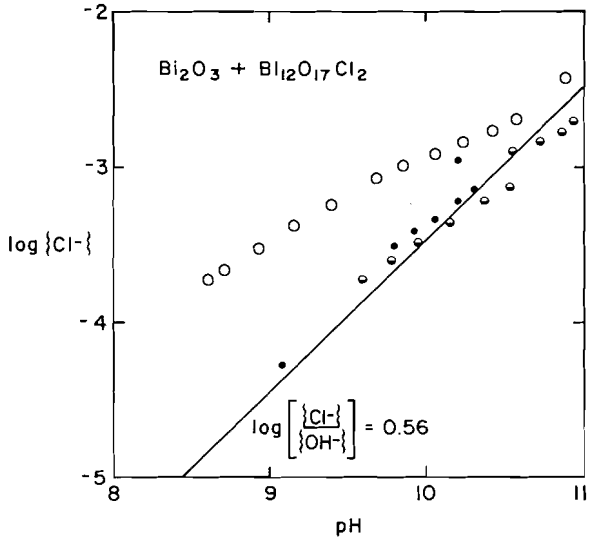

FIG. 3. Measured pH and chloride activity of solutions in contact with α-Bi_2O_3 + $Bi_{12}O_{17}Cl_2$. Three successive titrations (○, ◒, ●).

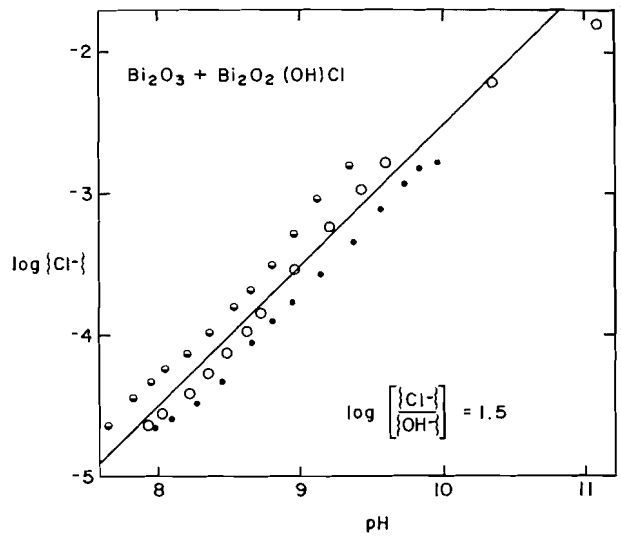

FIG. 4. Phase relationships between α-Bi_2O_3, $Bi_{12}O_{17}Cl_2$, "$Bi_2O_2(OH)Cl$", and BiOCl, calculated from equilibrium data in Figs. 1 to 3.

Based on the two subsequent titrations, we estimate that $\log K_6 = 0.56 \pm 0.20$, whence $\Delta_f G^0(Bi_{12}O_{17}Cl_2, s, 298\,K) = -3141 \pm 6\,kJ\,mol^{-1}$. Again, there is probably a small positive bias in this value, because of the poor crystallinity of the $Bi_{12}O_{17}Cl_2$.

(c) Deduction of phase relationships

The descending order of the observed equilibrium constants, $K_9 > K_{11} > K_6$, follows the descending order of Cl:Bi ratios in the solids, 1:1 (BiOCl) > 1:2 ($Bi_2O_2(OH)Cl$) > 1:6 ($Bi_{12}O_{17}Cl_2$). This indicates that all three solids have stability fields within the system $BiCl_3$–Bi_2O_3–H_2O–[pH] at 25°C; these fields are bounded by equilibria [12], [13], and [6].

[12] $2BiOCl(s) + OH^-(aq) \rightleftharpoons Bi_2O_2(OH)Cl(s) + Cl^-(aq)$

$$\log K_{12} = 2 \log K_9 - \log K_{11} = 4.76 \pm 0.48$$

(using our value of K_9)

[13] $(3/2)Bi_2O_2(OH)Cl(s) + OH^-(aq) \rightleftharpoons (1/4)Bi_{12}O_{17}Cl_2(s) + (5/4)H_2O(l) + Cl^-(aq)$

$$\log K_{13} = 1.5 \log K_{11} - 0.5 \log K_6 = 1.97 \pm 0.70$$

In addition, we can calculate the metastable equilibrium relationship, [14]:

[14] $(6/5)BiOCl(s) + OH^-(aq) \rightleftharpoons (1/10)Bi_{12}O_{17}Cl_2(s) + (1/2)H_2O(l) + Cl^-(aq)$

$$\log K_{14} = 1.2 \log K_9 - 0.2 \log K_6 = 3.65 \pm 0.09$$

These relationships are all depicted in Fig. 4. Stated uncertainties do not include the bias arising from poor crystallinity of $Bi_2O_2(OH)Cl$ and $Bi_{12}O_{17}Cl_2$.

The relatively broad stability field of $Bi_2O_2(OH)Cl$ implies that it may have supplanted some of the other anhydrous phases ($Bi_{12}O_{15}Cl_6$, $Bi_{24}O_{31}Cl_{10}$, Bi_3O_4Cl) in the low-temperature aqueous system. The relative stability of the hydrous phase is expected to decrease with increasing temperature; there is some evidence that $Bi_2O_2(OH)Cl$ is itself supplanted by Bi_3O_4Cl above about 70°C.

Figure 4 indicates that BiOCl is stable in acidic, or concentrated neutral, chloride solutions, whereas $Bi_2O_2(OH)Cl$ is stable in more dilute neutral, or concentrated and slightly alkaline solutions. This probably has some bearing on the occurrence of the minerals bismoclite and daubréeite. The narrow stability field of $Bi_{12}O_{17}Cl_2$ is consistent with its apparent absence in nature; similar observations have been made (10, 21) on the absence or scarcity of $(BiO)_4(OH)_2CO_3$ (basobismutite?) and $Pb_{10}O(OH)_6(CO_3)_6$ (plumbonacrite).

(d) Solubility relationships

The stability data also allow us to estimate the relative solubilities of the basic bismuth chlorides. The predominant hydrolysed bismuth species at pH 7–13 is neutral $Bi(OH)_3$, with a Gibbs energy of formation of about -571.6 kJ mol^{-1} (22–24). Bismuth chloride complexes appear to be stable only in acidic solutions (17). The solubilities of α-Bi_2O_3 and the bismuth oxychlorides in neutral to basic solutions can thus be approximated by equilibria [15] to [18]:

[15] $(1/2)Bi_2O_3(s) + (3/2)H_2O(l) \rightleftharpoons Bi(OH)_3(aq)$

$$K_{17} = \{Bi(OH)_3\} = 10^{-5.4}$$

[16] $(1/12)Bi_{12}O_{17}Cl_2(s) + (1/6)OH^-(aq) + (17/12)H_2O(l) \rightleftharpoons Bi(OH)_3(aq) + (1/6)Cl^-(aq)$

$$K_{18} = \{Bi(OH)_3\}\{Cl^-\}^{1/6}/\{OH^-\}^{1/6} = 10^{-5.3}$$

[17] $(1/2)Bi_2O_2(OH)Cl(s) + (1/2)OH^-(aq) + H_2O(l) \rightleftharpoons Bi(OH)_3(aq) + (1/2)Cl^-(aq)$

$$K_{19} = \{Bi(OH)_3\}\{Cl^-\}^{1/2}/\{OH^-\}^{1/2} = 10^{-4.7}$$

[18] $BiOCl(s) + OH^-(aq) + H_2O(l) \rightleftharpoons Bi(OH)_3(aq) + Cl^-(aq)$

$$K_{20} = \{Bi(OH)_3\}\{Cl^-\}/\{OH^-\} = 10^{-2.4}$$

(using BiOCl data from ref. 12)

Equilibrium $Bi(OH)_3$ activities as a function of pH, at a chloride-ion activity of 10^{-2} mol dm^{-3}, are shown in Fig. 5. This figure helps to rationalize some of our experimental observations. Within its stability range, $Bi_{12}O_{17}Cl_2$ is only marginally less soluble than Bi_2O_3, but about two orders of magnitude less soluble than BiOCl. Thus, BiOCl can provide a much higher supersaturation than Bi_2O_3, which may explain why we were able to form $Bi_{12}O_{17}Cl_2$ easily from BiOCl, but not from Bi_2O_3. Bismuth oxide, however, can provide over an order of magnitude of bismuth supersaturation with respect to $Bi_2O_2(OH)Cl$, which we did obtain from the oxide. The low solubility of BiOCl within most of the stability field of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12

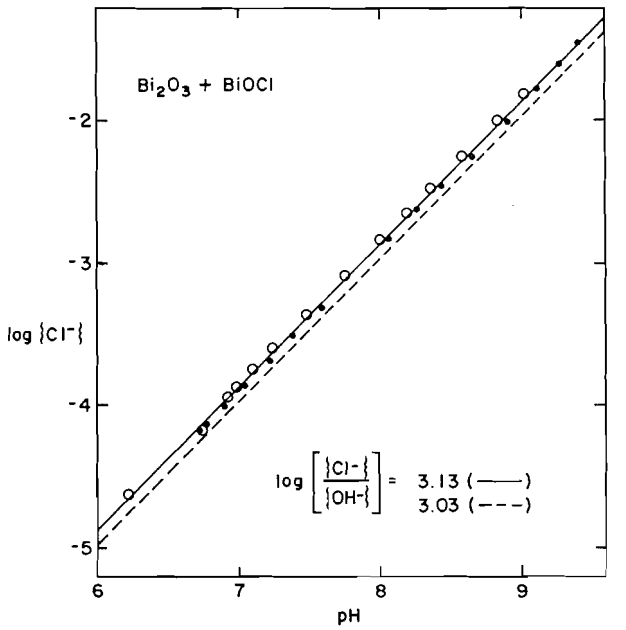

FIG. 5. Calculated $Bi(OH)_3^0$ activities in contact with bismuth oxide and oxychlorides at a Cl^- activity of 10^{-2} mol dm^{-3}, as a function of pH. For any change in log {Cl^-}, change the pH scale by an equal and opposite quantity. The $Bi(OH)_3^0$ activity approximates total bismuth within the pH limits 7–13. Bold portions of lines represent the range over which each solid is stable.

$Bi_2O_2(OH)Cl$ (and vice versa) may also explain why these solids do not easily interconvert. Interconversion of these two phases by direct anion exchange would not depend on solubilities, but on solid-state interdiffusion of OH^- and Cl^-. This is also expected to be slow, however, since the anion sites between the $(BiO)_n^{n+}$ layers are fully occupied, and efficiently packed (9, 25).

(e) Comparison with other basic bismuth salts

The two chloride-deficient phases, $Bi_2O_2(OH)Cl$ and $Bi_{12}O_{17}Cl_2$, are stable within a narrow band of solution conditions, between K_6 and K_{12}, which brackets about four pH units at a given chloride activity. This contrasts with the basic iodide, Bi_5O_7I, whose stability field spans seven pH units at a given iodide activity (11). Also, Bi_5O_7I is more resistant to hydrolysis than $Bi_{12}O_{17}Cl_2$:

[19] $Bi_5O_7I(s) + OH^-(aq) \rightleftharpoons (5/2)Bi_2O_3(s) + (1/2)H_2O(l) + I^-(aq)$
$K_{19} = \{I^-\}/\{OH^-\}$; $\log K_{19} = -3.4$ (ref. 11) cf. $\log K_6 = 0.6$.

The relative stability of Bi_5O_7I may arise from better steric accommodation of iodide in the $[Bi_5O_7]_n^{n+}$ cation network, compared with chloride and $[Bi_{12}O_{17}]_n^{2n+}$ (neither structure is known, but both are presumed to contain extensive polymeric bismuth–oxygen networks; this is the case with $Bi_{24}O_{31}Cl_{10}$ (2), $Bi_{12}O_{15}Cl_6$ (3), and β-Bi_5O_7I (26)). It is also possible that some weak Bi...I covalent interaction contributes to the iodide's stability.

Even though Bi_5O_7I is much more stable than the basic bismuth chlorides towards hydrolysis, it is susceptible to "anion exchange" reaction with concentrated chloride solutions:

[20] $2Bi_5O_7I + 5Cl^- + 4H_2O \rightleftharpoons 5Bi_2O_2(OH)Cl + 2I^- + 3OH^-$
$K_{20} = \{OH^-\}^3\{I^-\}^2/\{Cl^-\}^5 = 10^{-14.3 \pm 2.4}$
(based on K_{11} and data for Bi_5O_7I from ref. 11)

We have found that Bi_5O_7I is converted to $Bi_2O_2(OH)Cl$ by concentrated chloride solutions ($>10^{-2}$ mol dm^{-3}). A sample prepared by contacting 0.5 g Bi_5O_7I with 1.0 mol dm^{-3} NaCl at 90°C for 48 h contained 7.2 wt.% chlorine (calculated for $Bi_2O_2(OH)Cl$, 7.1%). This reaction is a major limiting factor on the performance of the suggested bismuth oxyiodide waste form for iodine-129 (11, 27). Bismutite ($(BiO)_2CO_3$), however, is sufficiently stable that exchange reactions with chloride are unlikely to limit its performance as a waste form for carbon-14 (10, 22).

DAVID M. MCKINNON, PETER D. CLARK, ROBERT O. MARTIN, LOUIS T. J. DELBAERE, and J. WILSON QUAIL. Can. J. Chem. **65**, 2830 (1987).

3,5-Diphenyl-1,2-dithiolium-4-olate (**1**) reacts with aniline to form 1-phenylimino-2-phenylamino-3-phenylindene (**3***a*). Under suitable conditions, 6-phenylbenzo[*b*]indeno[1,2-*e*]-1,2-thiazine is also formed. These structures are confirmed by alternative syntheses. The molecular structure of **3***a* has been determined by single crystal X-ray diffraction. Compound **3***a* crystallizes in the monoclinic space group $C2/c$ with unit cell dimensions $a = 20.777(3)$ Å, $b = 6.130(3)$ Å, $c = 31.327(3)$ Å, $\beta = 99.59(1)°$, and $Z = 8$. The structure was solved by direct methods and refined by least squares to a final $R = 0.055$. The molecular structure of **3***a* shows the three phenyl containing substituents to have the planes of their ring systems tilted between 40° and 60° from the plane of the indene system due to steric repulsions.

DAVID M. MCKINNON, PETER D. CLARK, ROBERT O. MARTIN, LOUIS T. J. DELBAERE et J. WILSON QUAIL. Can. J. Chem. **65**, 2830 (1987).

Le diphényl-3,5 dithiolium-1,2 olate-4 (**1**) réagit avec l'aniline pour former le phénylimino-1 phénylamino-2 phényl-3 indène (**3***a*). Dans certaines conditions appropriées, il se forme aussi du phényl-6 benzo[*b*]indéno[1,2-*e*]thiazine-1,2. On a confirmé ces structures en se basant sur d'autres synthèses. On a déterminé la structure moléculaire du composé **3***a* à l'aide de la diffraction de rayons-X. Le composé **3***a* cristallise dans le groupe d'espace monoclinique $C2/c$, avec $a = 20,777(3)$, $b = 6,130(3)$ et $c = 31,327(3)$ Å, $\beta = 99,59(1)°$ et $Z = 8$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à une valeur finale de $R = 0,055$. La structure moléculaire du composé **3***a* démontre que, pour des raisons stériques, les plans des systèmes cycliques des trois substituants portant des noyaux phényles sont décalés de 40° à 60° du plan du système indénique.

[Traduit par la revue]

Introduction

The reaction of 3,5-diphenyl-1,2-dithiolium-4-olate (**1**) with aniline has been reported by Chinone *et al.* (1) to give a blue material, assigned the structure of 3,4,5-triphenylisothiazole (**2**). Since such a reaction would involve some unusual chemistry it has been reinvestigated. The results are reported below.

Results and discussion

When the reaction was performed as described, using redistilled aniline, a dark red mixture was obtained from which the only material isolated in any quantity was a dark red solid, mp 184–195°C. However, when the dithiole was treated with unpurified aniline, the red material was accompanied by greater or lesser amounts of a violet crystalline material whose mp (169°C) corresponds to that of the material reported (1). Its mass spectrum indicates a molecular weight of 311.007, which corresponds to a formula of $C_{21}H_{13}NS$, confirmed by analysis; Chinone *et al.* (1) have suggested a formula of $C_{21}H_{15}NS$. The analysis and mass spectrum of the red material were consistent with a formula of $C_{21}H_{20}N_2$.

While the ^1H nmr spectrum of the violet material only showed a complex series of absorptions in the aromatic region, the decoupled ^{13}C spectrum was more informative. Nine tertiary carbons were evident, of which two were at double intensity, consistent with the presence of a monosubstituted aromatic ring. There were eight quaternary carbon atoms of which three were of lesser intensity, consistent with their not being adjacent to tertiary carbon atoms. The presence of a thiocarbonyl function could be eliminated since the spectrum lacked a signal in that range (2, 3). Also the compound was unaffected by cold potassium permanganate in acetone. It thus appears that the sulfur atom present in the material is part of a heterocyclic ring.

Since blue colours are characteristic of pseudoazulenes and if the carbon skeleton of the starting dithiole were intact, a number of possible structures consistent with the above data may be advanced. Of these, fused benzothiopyrano[4,3-*b*] indoles may be eliminated on the basis of earlier studies (4). The red material, unlike the violet material, was amenable to X-ray structural determination (*vide infra*), which identified it as 1-phenylimino-2-phenylamino-3-phenylindene (**3***a*). On this basis the fused indene structures **4***a* and **5***a* were considered for the violet material.

It is reported that the system **5***a* may be made from indanedione by condensation with 2-aminobenzenethiol (5). While the isomeric system **4***b* could possibly have been formed by an alternative condensation mode (4), another synthesis of benzo[*b*]indeno[1,2-*e*]-1,4-thiazine (6) confirmed the structure as type **5**. Accordingly, 3-phenylindane-1,2-dione was treated with 2-aminobenzenethiol. A violet material was obtained, which was identical to that obtained above, establishing its formula as **5***a*.

Treatment of 3-phenylindane-1,2-dione with aniline afforded a dark red material that was identical with the red material **3***a* isolated above.

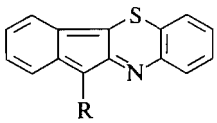
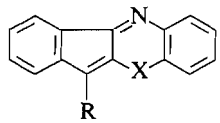
3
a Y = NHPh
b Y = OH
c Y = SH

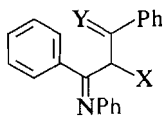


4
a R = Ph
b R = H

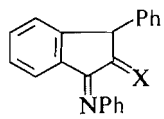


5
a R = Ph, X = S
b R = H, X = S
c R = Ph, X = NMe
d R = Ph, X = O

Compound **4***a*, compared to **5***a*, would also require bond fixation in one of the aromatic rings, and be less stable (compare data for related benzoindenothiopyrans (7)). In addition, the violet material failed to react with dimethyl acetylenedicarboxylate. A compound such as **4***a* with an *o*-quinonoid structure would be expected to react readily.



6
a X = OH, Y = S
b X = NHPh, Y = S
c X = NHPh, Y = NPh



7
a X = O
b X = S

Since the compound **1** reacts with hydrazine according to observed patterns for 1,2-dithiolium salts (8, 9), its reaction with aniline, as for 1,2-dithiolium salts (10), could form the compound **6***a*. Cyclization of **6***a* by known modes forms the indan-2-one **7***a* or its tautomer **3***b*, which react further with aniline to provide the indene **3***a*. Alternatively the compound **6***a* could react with aniline to give **6***b* or **6***c*, which cyclize to form **3***a* directly. The reactions forming **5***a* are not so clear, since they involve forming a sulfur bond to the central carbon atom that did not initially bear one, but a plausible reaction process would involve an intermediate compound of type **7***b*, which could have been formed from compounds such as **3***a* or **3***b* by reaction with hydrogen sulfide. The role of the impure aniline may be to provide some material that can reversibly associate with hydrogen sulfide eliminated in the initial reactions forming compounds of type **6**. A pericyclic or possibly radical reaction of compound **7***b* followed by dehydrogenation would form compound **5***a*. In support of this, the reaction of the 1,2-dithiole with redistilled aniline gave **5***a* when the reaction mixture was treated with hydrogen sulfide.

Two related pseudoazulenes, the pyrazine (**5***c*) and the 1,4-oxazine (**5***d*), were made by related methods, the condensation of 3-phenylindane-1,2-dione with 2-methylaminoaniline and 2-aminophenol, respectively.

The molecular structure of 1-phenylimino-2-phenylamino-3-phenylindene (**3***a*) has been determined by single crystal X-ray diffraction. Selected bond distances and angles of **3***a* are given in Tables 2 and 3, respectively. A view of the molecule is given in Fig. 1. The bond distances and angles in the phenyl rings of **3***a* are similar to those found for these groups in other structure determinations. The six-membered ring in the indene group has carbon–carbon bonds similar to other aromatic groups, whereas the bonds involving C(1), C(2), and C(3) are similar to either single or double bonds. For example, C(1)—N(1) is 1.274 Å, compared to values between 1.38 and 1.42 Å for all of the other C—N bonds in the molecule. The distance between C(2) and C(3) is 1.358 Å, compared to values between 1.47 and 1.49 Å for the other C—C distances involving these atoms. Thus, in the indene group there is an aromatic benzene ring and an α,β unsaturated imine.

The indene group (plane A), C(1)–C(9), is planar within 0.032 Å. The phenylimino group (plane B), C(10)–C(15), is planar within 0.007 Å, with N(1) out of the plane by 0.10 Å. The phenylamino group (plane C), C(16)–C(21) is planar within 0.016 Å, with N(2) and H(N2) out of the plane by 0.011 and 0.55 Å, respectively. The phenyl ring (plane D), C(22)–C(27), is planar within 0.0034 Å. The angles between the above planes are:

Plane 1	Plane 2	Angle (degrees)
A	B	60.2
A	C	39.9
A	D	51.6

The steric repulsions of groups B, C, and D with each other and with group A prevent the molecule from attaining a structure with delocalization of electrons between the separate π systems.

Experimental

The ^{1}H nmr and ^{13}C spectra were obtained in deuterochloroform solution using tetramethylsilane as an internal standard on Varian model 56/60 and Bruker WH90 spectrometers respectively. Mass spectra were obtained on a Finnigan Model 1015 mass spectrometer or, for accurate mass, on a VG7070-EHF mass spectrometer. Chromatography was performed on Merck silica gel Kieselgel PF-254, or on Camag alumina type 507C-1.

*Preparation of 6-phenylbenzo[*b*]indeno[1,2-*e*]-1,4-thiazone (**5**a)*

3-Phenylindane-1,2-dione (1.11 g, 5.0 mmol) and 2-aminobenzenethiol (0.62 g, 5 mmol) in acetic acid (10 mL) containing concentrated sulfuric acid (2 drops) was heated under reflux 10 min. The bluish solution was poured into water, neutralized with dilute sodium hydroxide solution, and extracted with chloroform. The dried extract was evaporated, and chromatographed in benzene on alumina. A fast running dark blue band was collected. Evaporation gave a violet oil, which crystallized under ethanol. It was recrystallized from an ethanol–dimethylformamide 1:1 mixture as fine dark violet needles, mp 168°C (yield 63%). The ^{1}H nmr spectrum has δ: 8.4–7.2 (complex bands) ppm. The ^{13}C nmr spectrum δ: 156.80(4°)*, 142.77(4°), 138.94(4°), 133.78(4°), 133.05(4°), 132.71(3°), 132.52(4°)*, 131.07(3°), 128.91(3°, on phenyl substituent), 128.47(3°), 128.19(3°), 127.58(3°, on phenyl substituent), 126.59(3°), 125.97(3°), 124.37(3°), 122.48(3°), 120.85(4°), 118.53(3°), 116.03(4°)*. *Anal.* calcd. for $C_{21}H_{13}NS$: C 81.03, H 4.18, N 4.50, S 10.29; found: C 81.11, H 4.06, N 4.39, S 10.44. The mass spectrum M^+: 311.0775; M^+ calcd. for $C_{21}H_{13}NS$: 311.0781.

*These correspond to 4° carbon atoms *not* attached to 3° carbon atoms.

*Preparation of 1-phenylimino-2-phenylamino-3-phenylindene (**3**a)*

3-Phenylindan-1,2-dione (1.11 g, 5.0 mmol) and excess aniline (3 mL) were heated together under reflux for 5 min. The initially violet colored solution became dark red. The mixture was poured into 20%

concentrated hydrochloric acid in water, and the crude dark material collected. Chromatography on alumina in benzene indicated a dark red band, which was collected and evaporated. The dark red oil crystallized under ethanol and was recrystallized from hexane as dark red prisms, mp 184–185°C (yield 81%). The ^{1}H nmr spectrum δ: 8.5–7.2 (complex bands) ppm. *Anal.* calcd. for $C_{27}H_{20}N_2$: C 87.1, H 5.38, N 7.53; found: C 87.18, H 6.04, N 7.61. The mass spectrum M^+: 372; M^+ calcd.: 372.

Reaction of 3,5-diphenyl-1,2-dithiolium-3-olate with aniline

(a) With impure aniline

The reaction was performed as described (1), but the residue from evaporation of excess aniline was examined by tlc. Two bands were evident, a dark red and a dark blue one; these were isolated. Work-up gave the products **3***a* (yield 43%) and **5***a* (yield 24%), which were identical (ms, mixture mp) to the compounds prepared above.

(b) With redistilled aniline

Performed as above (1), the major product of the reaction was the indene **3***a*. None of the **5***a* was evident, but traces of yellow material were present.

(c) With redistilled aniline and hydrogen sulfide

This was performed as in (*b*) but a slow stream of hydrogen sulfide was passed through for the first 30 min; then the solution was refluxed a further 1 h. Work-up afforded the indene **3***a* and the thiazine **5***a* (yields 40 and 15%, respectively).

*Preparation of 6-phenylbenzo[*b*]indeno[1,2-*e*]pyrazine (***5***c)*

3-Phenylindane-1,2-dione (222 mg, 1.0 mmol) and 2-methylaminoaniline (108 mg, 1.0 mmol) in ethanol (5 mL) were refluxed 10 min. The dark blue solution was evaporated, then purified by chromatography on silica gel in benzene. Collection and evaporation of a dark blue band gave an oil, which crystallized under methanol. It recrystallized from toluene as dark blue needles, mp 172°C (yield 55%). The ^{1}H nmr spectrum, δ: 3.48 (3H, s, the methyl protons), 7.47–8.28 (13H, bands, the aromatic protons) ppm. *Anal.* calcd. for $C_{22}H_{16}N_2$: C 85.71, H 5.19, N 9.09; found: C 85.83, H 5.06; N 9.20. The mass spectrum M^+: 308; calcd. for $C_{22}H_{16}N_2$: 308.

*Preparation of 6-phenylbenzo[*b*]indeno[1,2-*e*]-1,4-oxazine (***5***d)*

3-Phenylindane-1,2-dione (222 mg, 1.0 mmol) and 2-aminophenol (109 mg, 1.0 mmol) in acetic acid (5 mL) and sulfuric acid (1 drop) were heated at 100°C for 1 h. Dilution with water afforded a crude product that was collected and purified by chromatography on silica gel, in a benzene–chloroform (5:1) mixture. Collection and evaporation of a purple band gave a dark oil that solidified under methanol. It recrystallized from toluene as dark purple needles, mp 185–186°C, subliming above 140°C (yield 40%). The ^{1}H nmr spectrum, δ: 7.25–8.09 (bands, the aromatic protons) ppm. *Anal.* calcd. for $C_{21}H_{13}NO$: C 85.42, H 4.41, N 4.75; found: C 85.27, H 4.56, N 4.51. The mass spectrum, M^+: 295; calcd. for $C_{21}H_{13}NO$: 295.

Crystallographic data collection and analysis

Crystals of **3***a* were grown from a supersaturated solution in methanol. The red crystals of **3***a* exhibited the forms {001}, {010}, and {100}. The crystal data were the following:

$C_{27}H_{20}N_2$ mw = 372.45

Monoclinic, $C2/c$, a = 20.777(3) Å, b = 6.130(3) Å, c = 31.327(3) Å, β = 99.59(1)°, Z = 8, V = 3934.1 Å^3, ρ_o = 1.243 g cm^{-3}, ρ_c = 1.258 g cm^{-3}, $F(000)$ = 1568 e, radiation Ni-filtered Cu K_α (λ = 1.5418 Å), $(\sin\theta/\lambda)_{max}$ = 0.6095, crystal dimensions (mm) 0.09 × 0.28 × 0.35, max. decay correction 1.02, T = 11°C. Quantitative data collection was carried out on a single crystal mounted about the c-axis on an Enraf–Nonius CAD4F diffractometer with an $\omega/2\theta$ scan. A total of 3739 reflections was collected, of which 2939 unique reflections had a net $I > 3\sigma(I)$. Lorentz and polarization corrections were applied. Intensities of three standard reflections were monitored throughout the data collection. No absorption correction was applied. Observed weights for the reflections were taken as $1/[\sigma(F)]^2$.

X-ray diffraction data collected on the **3***a* crystal were processed using the XTAL system (11) of crystallographic programs. The structure was solved using the structure solution part of the XTAL system. The figures of merit CFOM and AMOS were used to choose the best set of phases used in the structure determination. The values were 0.96 and 82%, respectively. The positions of 23 of the 29 non-hydrogen atoms were determined from a calculated E map. The remaining non-hydrogen atoms were found in difference Fourier maps. Least-squares isotropic refinement gave an R value of 0.126. Anisotropic refinement was then carried out and gave an R value of

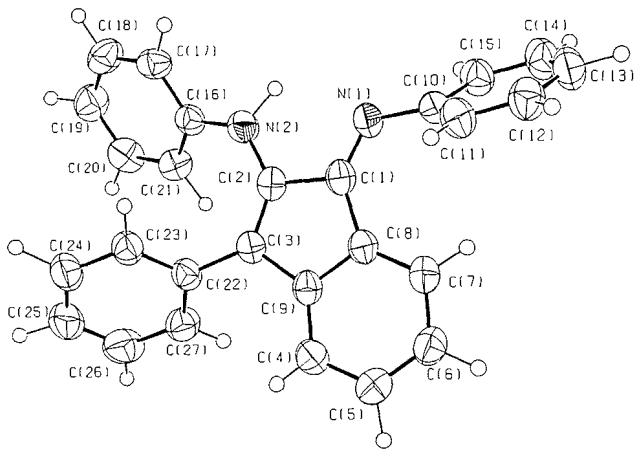

FIG. 1. ORTEP perspective drawing of **3***a*.

0.105. The positions of the hydrogen atoms were located by using difference Fourier maps. Finally, full matrix least-squares refinement of anisotropic temperature factors for the non-hydrogen atoms and isotropic refinement for the hydrogen atoms converged to an R index of 0.055, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. The R_w was 0.046, $R_w = (\Sigma w\Delta^2/\Sigma wF_o^2)^{1/2}$. The number of parameters refined was 342. The largest and average shift/error ratios were 0.034 and 0.0023, respectively, in the final cycle. The largest residual peaks on a ΔF map were 0.247 e Å^{-3}. The value of the Goodness of Fit was 1.574. An ORTEP (12) representation of the molecule is shown in Fig. 1 and all final atomic coordinates are given in Table 1. Crystallographic computations were carried out using the XTAL system (11) on a VAX 8600 computer at the University of Saskatchewan.[1]

[1]Tables of observed and calculated structure factors, atomic parameters of H-atoms, and anisotropic thermal parameters are included as supplementary material and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Received March 18, 1987

BRUCE FRANCIS MOLINO and BERT FRASER-REID. Can. J. Chem. **65**, 2834 (1987).

A procedure has been developed for pyranosidic homologation of methyl α-D-glucopyranoside via C4 and C6. Reaction of the aldehydo group of compound **2** with the Wittig–Bestmann reagent, $Ph_3P{=}CHCH(OEt)_2$, gave an *E*/*Z* mixture of acetals, **4**, which cyclizes under the specific catalysis of pyridinium *p*-toluenesulfonate and in the presence of alcohols to give anomerically pure olefinic bipyranosides, **6***a–d*. A general procedure for epoxidation of the latter involves osmium tetroxide hydroxylation, followed by reaction with phosgene iminium chloride (Viehe's salt) to give chlorocarbamates **12** and **13**, which are then subjected to the action of sodium methoxide. This allows for the formation of a single series of diastereomeric epoxides, **7**, and controlled cleavage of the latter with nucleophiles then follows well-established precedents. Selective access to the "ends" of the bipyranosides **7***c* and *d* can be obtained by oxidative removal of the activated benzyl glycosides with DDQ.

BRUCE FRANCIS MOLINO et BERT FRASER-REID. Can. J. Chem. **65**, 2834 (1987).

On a développé un méthode pour effectuer l'homologation de l'α-D-glucopyrannoside de méthyle via C4 et C6. La réaction du groupement aldéhydique du composé **2** avec le réactif de Wittig–Bestmann, $Ph_3P{=}CHCH(OEt)_2$, conduit à un mélange *E*/*Z* des acétals **4** qui, en utilisant des conditions de catalyse spécifique du *p*-toluènesulfonate de pyridinium et en présence d'alcools, se cyclise pour donner les bipyrannosides oléfiniques anomériquement purs **6***a–d*. Une méthode générale pour effectuer l'époxydation de ces derniers composés implique une hydroxylation par le tétroxyde d'osmium, suivie par une réaction avec le chlorure d'iminium phosgène (sel de Viehe), qui conduit aux chlorocarbamates **12** et **13** qui sont alors soumis à l'action du méthylate de sodium. Cette procédure permet de former une seule série d'époxydes diastéréomères (**7**); un clivage sélectif de ces derniers à l'aide de nucléophiles se produit en suivant les précédents bien établis. On peut accéder d'une façon sélective aux «bouts» des bipyrannosides **7***c* et **7***d* en procédant à un enlèvement oxydatif des glycosides de benzyle activés par du DDQ.

[Traduit par la revue]

In an effort to extend the range of simple sugar derivatives to accommodate increased numbers of contiguous chiral centers, we have developed a process termed pyranosidic homologation in which a "satellite" pyranose ring is appended to a "primary" ring (1). The assembly obtained thereby provides additional stereogenic centers, which can be manipulated according to well-precedented transformations from the carbohydrate literature. This principle is illustrated in Chart 1 for the bipyranose **I**, whose substituents, X and Y, can be introduced into **II** by taking advantage of the highly developed chemistry of unsaturated sugars (2, 3). The efficient formation of bipyranose **II** from a monopyranose precursor, **III**, is an obvious first step. In this manuscript, we give details of our studies related to the transformations **III** → **II** → **I**.[6]

Methyl 2,3-di-*O*-benzyl-α-D-glucopyranoside **1***a* (5) was a convenient starting material for model studies. By routine protecting group strategies, the primary alcohol in **1***d* was exposed in 87% overall yield from **1***a*. Oxidation to aldehyde **2** proceeded cleanly both with Collin's reagent (6) and pyridinium chlorochromate (7) in yields of approximately 60%. However, Swern oxidation using trifluoracetic anhydride, dimethylsulfoxide, and triethylamine (8) proved to be more adaptable to large-scale preparation, with the aldehyde **2** being isolated in yields of 72%.

The formation of **II** required a *Z* olefinic precursor. 2,2-Diethoxyethylidenetriphenylphosphorane, **3**, had been shown by Bestmann *et al.* (9) to react with aldehydes to give *Z*-α,β-unsaturated diethoxy acetals with typically 10:1 *Z*/*E* ratios. Indeed, reaction of phosphorane **3** with aldehyde **2** proceeded smoothly to give an unsaturated acetal, **4**, in excellent yields; however, the *Z*/*E* ratio could not be determined because the mixture was inseparable chromatographically, and the olefinic region in the ^1H nmr spectrum was too complex for assignment. However, subsequent transformations were to show that the olefinic geometry was of no importance to our future plans. Thus, when the crude unsaturated acetal **4** (undoubtedly a *Z*/*E* mixture) was treated with methanol and pyridinium *p*-toluenesulfonate (PPTS) (10) under reflux, cyclization occurred to give a single product whose structure, as the bicyclic olefin **6***a*, was suggested by the value $J_{6,7}$ = 10.1 Hz. Similarly, use of benzyl alcohol, as well as its 4-methoxy and 3,4-dimethoxy derivatives, in refluxing benzene gave the corresponding products, **6***b*, **6***c*, and **6***d*, respectively.

In the transformations of **4** into **6**, four acid-catalyzed processes were occurring *in situ*, which may be rationalized as shown in Chart 2. Probable steps are (*a*) cleavage of the α-ethoxyethyl group from O4; (*b*) cleavage of the allylic diethylacetal to give a stabilized carbocation, e.g., **IV** (*E*/*Z*); (*c*) cyclization with the C4-OH to give the ethyl enoside, **V**; (*d*) glycosidic exchange at the activated anomeric center with the alcohol ROH to give **6**. Formation of the axial glycoside was expected to be favored in view of the anomeric effect (11). However, the reactions here were more selective than with simple alkyl hex-2-enopyranosides (2), where anomeric mixtures are usually much richer. Thus, in the present case, regardless of the alcohol used, only the axial product was detected.

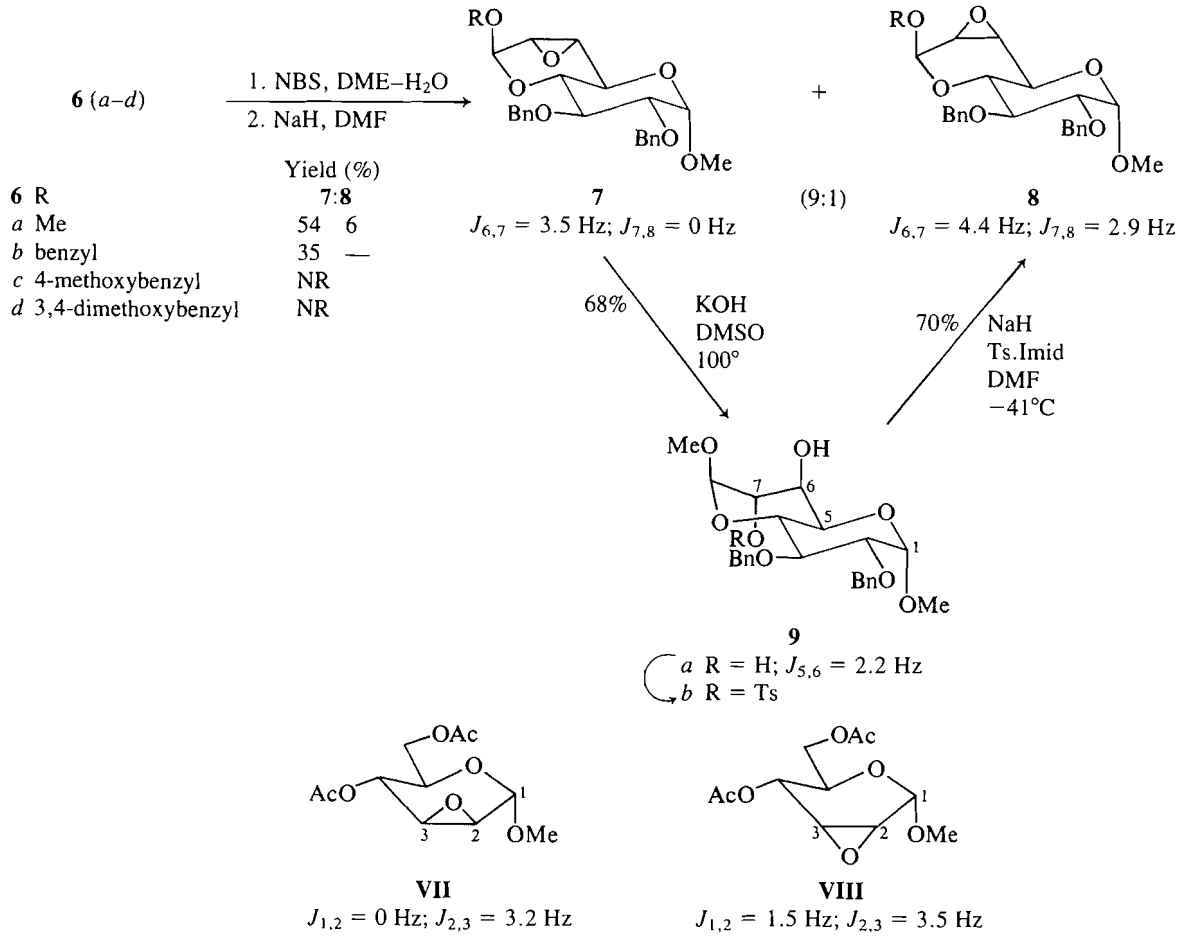

SCHEME 2

A second gratifying observation was that there was no trace of any *trans*-unsaturated acetal (i.e., **4***E*), or the aldehyde obtained therefrom (i.e., **5**) at the end of the reaction. *This implied that both* Z *and* E *forms of* **4** *had cyclized.* A control experiment was therefore carried out to determine the fate of the *E*-α,β-unsaturated aldehyde, **5**. The desired material was prepared by reaction of formylmethylene triphenylphosphorane (12) with aldehyde **2**. Acid-catalyzed methanolysis of the product, **5** ($J_{6,7}$ = 16.0 Hz), did give **6** in 52% yield.

During attempts to optimize the yields in this series of reactions, it became apparent that the cyclization of **4** or **5** would not proceed with acid catalysts other than pyridinium *p*-toluenesulfonate (10). For example, acetic acid, trifluoroacetic acid, *p*-toluenesulfonic acid, or α-pyridone led either to decomposition or simply removal of the protecting groups. *Thus, with these other acids, even the* Z *isomer did not cyclize!!* The specific action of pyridinium *p*-toluenesulfonate implies that the reagent is functioning as something other than a simple acid. This effect can be rationalized by postulating the intermediacy of the salt, **VI** (Chart 2), formed by conjugate addition of pyridine to **IV** *E*/*Z*. Cyclization of **VI** would then occur, regardless of the *Z* or *E* configuration of the precursor, with subsequent or concomitant β-elimination of pyridine to give **V**.

Epoxidation of the bicyclic olefin **6***a* was effected by treating the mixture of bromohydrins obtained from reaction with *N*-bromosuccinimide with sodium hydride. A 9:1 mixture of **7** and **8** was thereby obtained in 60% overall yield from olefin **6***a*.

The stereochemical assignments for the epoxides **7** and **8** were made on the basis of favorable comparisons of the coupling constants with those of related epoxides, **VII** and **VIII** (13), as shown in Scheme 2. Nevertheless, the stereochemistry was confirmed by interconversion of the epoxides. Thus, solvolysis of **7** with potassium hydroxide gave the expected *trans* diol **9***a* ($J_{5,6}$ = 2.2 Hz) and, following the precedent of Hicks and Fraser–Reid (14), the material was treated with sodium hydride and tosyl imidazole, whereupon selective sulfonation occurred at O7 to give **9***b*, followed by *in situ* ring closure to give epoxide **8** in 70% overall yield. The configurations of epoxides **7** and **8** were thereby confirmed.

While the bromohydrin route for epoxidation of the methyl glycoside **6***a* was satisfactory, it transpired that this would not be a general method for the benzylated analogues **6***b*–*d*. Thus, under these conditions, the yield of the epoxide **7***b* from the benzyl glycoside **6***b* was only 35%, and the methoxybenzyl analogue, **6***c*, did not form a bromohydrin at all. This meant that benzyl glycosides could not be used for the "top" ring if the bromohydrin route was to be relied upon, and would have imposed a serious limitation because differentiation of the two glycosidic centers was clearly a valuable asset of **6** (*b*, *c*, and *d*).

It therefore became necessary to develop an alternative method for epoxidation, and an indirect procedure eventually proved best (15). Hydroxylation of **6***a*–*d* proceeded cleanly under standard conditions to give, in each case, a single product, **10***a*–*d* ($J_{5,6} \cong 9.7$ Hz), in keeping with precedent (16).

In keeping with the work of Copeland and Stick (17) on methyl 4,6-*O*-benzylidene-α-D-mannopyranoside, the diol **10***a*

SCHEME 4

was treated with Viehe's salt (phosgene iminium chloride) (18) and triethylamine in refluxing 1,2-dichloroethane. Two isomers were formed in ~16:1 ratio, a result that is in keeping with the proposed cyclic iminium carbonate intermediate **11**, which would be expected to undergo nucleophilic attack at C6 and (less preferably) at C7, leading to **12** and **13**, respectively. Thus, when the mixture of chlorocarbamates **12***a* and **13***a* was treated with sodium methoxide in methanol under reflux, the epoxide **7***a* was obtained in good yield, along with small amounts of the unreacted chlorocarbamate **13***a*. Similarly, the benzyl glycosides **6***c* and *d* were converted into epoxides **7***c* and *d* via the relevant intermediates **10**, **12**, and **13**.

Although the method in Scheme 3 for making the epoxide **7** required one more step than going through the bromohydrin intermediates (Scheme 2), it had the advantage that none of the diastereomeric epoxide **8** was formed. Furthermore, the reaction worked well on all scales attempted (0.1–1.5 mmol) without any diminution of yield.

With respect to cleavage of the epoxides, Parker and Babine (19) had shown that dimethylmagnesium was a preferred reagent for opening 2,3-epoxides having the α-D-*manno* configuration. Accordingly, exposure of the bicyclic epoxide **7** to a large excess of this reagent gave **14** as the only product in excellent yields. The stereochemistry of the products was apparent from the values $J_{5,6}$ = 5.3 Hz, in all cases.

It was desirable to see whether the two "ends" of the bipyranosides **14** could be differentiated. Acid-catalyzed hydrolysis did not seem to be a promising procedure. However, the studies of Oikawa *et al.* (20) on selective oxidations of activated benzyl ethers proved to be timely. Thus, oxidation of the 4-methoxybenzyl glycosides **14***c* with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) gave the anomeric mixture **15** in 41% yield. We found that this low yield was due to some loss of the benzyl groups at C2 and C3. Hence the more readily oxidizable 3,4-dimethoxybenzyl group was examined, since it is known to be more readily cleaved by DDQ (20). This indeed proved

to be the case, with compound **14***d* affording the product **15** in 70% yield.

In summary, an efficient synthetic route has been developed for the preparation of bipyranose derivatives via pyranosidic homologation of methyl α-D-glucopyranoside. The net result is the extension of the carbon chain at C6 with stereoselective formation of two new chiral centers on a rigid bicyclic framework. Application of Viehe's salt to the formation of an epoxide from a *cis* diol (Scheme 3) is a valuable development, and selective access to the anomeric center of the top ring (**14***d*→ **15**) enhances the value of these intermediates for further transformations.

Experimental

General procedures

Melting points were determined in capillary tubes using a Buchi Model 510 melting point apparatus, and are uncorrected. Elemental analyses were performed by Dr. F. Kasler, University of Maryland, or by M-H-W Laboratories, PO Box 15149, Phoenix, AZ. The ir spectra were recorded on a Perkin–Elmer model 298 spectrometer using sodium chloride plates for thin films of liquids, syrups, or solids in Nujol mulls. Optical rotations were determined at the sodium D line using a Perkin–Elmer 241 polarimeter. The ^{1}H nmr spectra were determined on the following spectrometers: Varian XL-100, Varian XL 200, or Brucker WM-250. Unless otherwise stated, the solvent used was $CDCl_3$ with internal tetramethylsilane or $CHCl_3$ as the standard. The coupling constants were verified by homonuclear decoupling experiments. For the purpose of ^{1}H nmr interpretation, compound structures have been numbered in the schemes. High resolution mass spectra (hrms) were performed at the Research Triangle Park, North Carolina, with a VG707OF instrument. The progress of all reactions was monitored by thin-layer chromatography (tlc), which was performed on aluminum plates precoated with silica gel HF-254 (0.2-mm layers) containing a fluorescent indicator (Merck, 5539). The following solvent systems were used: EtOAc – petroleum ether mixtures, A = 1:9; B = 1:4; C = 3:7; D = 1:1; E = 7:3; F = 2% MeOH in CH_2Cl_2. Detection was first by uv (254 nm), then charring with sulfuric acid spray, or charring with a solution of ammonium molybdate(VI) tetrahydrate (12.5 g) and cerium(IV) sulfate tetrahydrate (5.0 g) in 10% aqueous sulfuric acid (500 mL). Flash chromatography was performed using Kieselgel 60 (230–400 mesh, E. Merck).

Selective silylation of primary alcohols

tert-Butyldimethylsilyl or *tert*-butyldiphenylsilyl chloride (1.5 mmol per mmol of alcohol) was added to a solution of triethylamine (1.7 mmol per mmol of alcohol), 4-dimethylaminopyridine (0.05 mmol per mmol of alcohol), and the alcohol in dry methylene chloride (10 mL per mmol of alcohol). The reaction was usually complete after 16 h at room temperature, at which time the solution was diluted with methylene chloride and washed successively with saturated solutions of sodium bicarbonate and sodium chloride. The organic phase was dried over anhydrous sodium sulfate, filtered, and evaporated *in vacuo*. The crude residue was purified by flash chromatography.

Swern oxidation

A solution of dimethylsulfoxide (2.0 equiv.) in dry methylene chloride (4 mL/mmol) was added dropwise to a cooled (−78°C) solution of oxalyl chloride in dry methylene chloride (4 mL/mmol) under an argon atmosphere. The solution was stirred for 15 min at −78°C and then a solution of the alcohol in methylene chloride (5 mL/mmol) was added dropwise. The reaction was stirred for 20–30 min and dry triethylamine (5 equiv.) was added dropwise. The reaction mixture was warmed to room temperature and quenched with an aqueous saturated sodium bicarbonate solution (10 mL). The methylene chloride layer was separated and the aqueous layer extracted with methylene chloride (3 × 10 mL). The combined methylene chloride layers were dried over anhydrous sodium sulfate and then concentrated *in vacuo*. The residue was purified by flash silica gel chromatography.

*Methyl 2,3-di-*O*-benzyl-4-*O*-(1-ethoxyethyl)-α-D-glucopyranose (**1***d*)*

A solution of methyl 2,3-di-*O*-benzyl-α-D-glucopyranoside (4) (**1***a*, 3.00 g, 8.01 mmol) in dry methylene chloride (30 mL) was selectively silylated by the general procedure. The resulting product, **1***b* (2.50 g, 5.10 mmol, R_f = 0.52 (D)), was dissolved in dry methylene chloride (25 mL) and treated at room temperature with pyridinium *p*-toluenesulfonate (0.0935 g, 0.765 mmol) and ethyl vinyl ether (5 mL). After 16 h, two products were observed by tlc and the reaction mixture was diluted with methylene chloride (50 mL), and washed with saturated sodium bicarbonate and sodium chloride solutions. The organic layer was separated, dried (Na_2SO_4), filtered, and concentrated *in vacuo* to give methyl 6-*O*-*tert*-butyldimethylsilyl-2,3-di-*O*-benzyl-4-*O*-(α-ethoxyethyl)-α-D-glucopyranoside (**1***c*) as a diastereomeric mixture (2.87 g, 94%); R_f = 0.44 and 0.38 (B). The crude oil **1***c* (2.70 g, 4.82 mmol) was dissolved in tetrahydrofuran (40 mL) and treated with tetra-*n*-butylammonium fluoride (5.3 mL of a 1 M tetrahydrofuran solution) at room temperature. After 3 h, the brown reaction mixture was concentrated *in vacuo* and the oily residue was purified by flash chromatography (D) to give a pale yellow oil **1***d* (2.04 g, 95%); tlc R_f = 0.50 and 0.43 (D); ^{1}H nmr (60 MHz, $CDCl_3$) δ: 1.00–1.52 (m, 6), 2.12 (br s, 1, OH, D_2Oex), 3.53 (s, 3, OCH_3), 3.53–4.22 (m, 8), 4.62–5.23 (m, 6), 7.50 (s, 10, $PhCH_2$). *Anal.* calcd. for $C_{25}H_{34}O_7$: C 67.24, H 7.67; found: C 67.50, H 7.68.

*Methyl 2,3-di-*O*-benzyl-4-*O*-(1-ethoxyethyl)-α-D-*gluco*-hexodialdo-1,5-pyranoside (**2**)*

Oxidation of **1***d* (1.76 g, 3.95 mmol) under Swern conditions (see General) gave a yellow oil, which was subjected to flash chromatography (C followed by D) to give the aldehyde **2** as a pale yellow oil (1.29 g, 74%); R_f = 0.55 (20:1 methylene chloride – methanol); ir (neat): 2930, 1742, 1050 cm^{-1}; ^{1}H nmr (60 MHz, $CDCl_3$) δ: 0.90–1.50 (m, 6), 3.37 (s, 3, OCH_3), 3.40–4.30 (m, 6), 4.50–5.11 (m, 6), 7.35 (s, 10, $PhCH_2$), 9.80 (d, 1, $J_{5,6}$ = 4.0 Hz, CHO); hrms *m*/*e* (M^+) calcd.: 444.2148; found: 444.2145.

*Methyl (E,Z)-2,3-di-*O*-benzyl-6,7-dideoxy-4-*O*-(1-ethoxyethyl)-α-D-*gluco*-octodiald-6-eno-1,5-pyranoside diethyl acetal (**4**)*

Formylmethylene triphenylphosphorane (12) (1.55 g, 4.73 mmol) was refluxed with freshly distilled bromoethane (80 mL) under an argon atmosphere overnight. Dry tetrahydrofuran (80 mL) was added and, after refluxing for another 3 h, the excess bromoethane was removed by standard fractional distillation. The resulting solution was cooled to room temperature and the oily product was treated with sodium ethoxide (3 equiv.) prepared fresh from the reaction of oil-free sodium hydride and ethanol. The mixture was stirred for 0.5 h under an argon atmosphere, during which time the oily residue and sodium ethoxide dissolved, resulting in an orange-red solution of **3**. The aldehyde **2** (0.700 g, 1.58 mmol) was added in tetrahydrofuran solution (5 mL) at room temperature. After 0.5 h, the reaction mixture was quenched with saturated ammonium chloride solution and extracted with ether. The combined organic layers were dried (K_2CO_3), filtered, and concentrated *in vacuo*. Purification of the residue by flash chromatography (C) gave **4** as a yellow oil (0.799 g, 82%); R_f = 0.58 (C); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 0.90–1.30 (m, 12), 3.35–3.95 (m, 10), 4.42–5.20 (m, 9), 5.25–5.80 (m, 3), 7.38 (s, 10); hrms *m*/*e* ($M^+ - CH_3CH_2OH$) calcd.: 498.2617; found: 498.2620.

*Methyl (E)-2,3-di-*O*-benzyl-6,7-dideoxy-4-*O*-(1-ethoxyethyl)-α-D-*gluco*-octodiald-6-eno-1,5-pyranoside (**5**)*

Aldehyde **2** (380 mg, 0.856 mmol) was refluxed with formylmethylene triphenylphosphorane (Ph_3P=CHCHO) (840 mg, 2.57 mmol) in dry benzene for 2 h. The reaction mixture was concentrated *in vacuo* and the residue was purified by flash column chromatography to give **5** (298 mg, 74%) as a pale yellow oil; R_f = 0.33 and 0.40 (1:2 ethyl acetate – hexane); ir (neat): 2940, 1692, 1452, 1372, 1100, 1045, 738, 690 cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$) δ: 1.01–1.32 (m, 6), 3.37 and 3.38 (two s, 3, OCH_3), 3.32–3.82 (m, 3), 3.97 (t, 1, $J_{2,3}$ = $J_{3,4}$ = 9.0 Hz, H3), 4.28–4.41 (m, 1, H5), 4.58–5.07 (m, 6),

6.28–6.44 (m, 1, H6), 6.96 (br dd, 1, $J_{6,7}$ = 16 Hz, $J_{7,8}$ = 4.2 Hz, H7), 7.28–7.45 (m, 10, *Ph*CH_2), 9.61 (dd, 1, $J_{6,8}$ = 1 Hz, H8); hrms *m/e* (M^+) calcd.: 470.2304; found: 470.2301.

*Dimethyl (8*R*)-2,3-di-*O*-benzyl-6,7-dideoxy-α-*D*-*gluco*-octodiald-6-eno-1,5:8,4-dipyranoside (**6**a)*

(*a*) A solution of the unsaturated acetal **4** (1.02 g, 1.87 mmol), pyridinium *p*-toluenesulfonate (0.1 equiv.), and absolute methanol (80 mL/mmol) was refluxed under argon in a round bottom flask fitted with a magnetic stirring bar and a condenser. After 24 h, the reaction mixture was concentrated *in vacuo* and the residue was purified by flash chromatography (C) to give **6***a* as a pale yellow oil (0.508 g, 74%); tlc R_f = 0.55 (1:2 ethyl acetate – hexane); $[\alpha]_D^{24}$ +0.67° (*c* 1.04, $CHCl_3$); ir (neat); 3025, 2900, 1368, 1092, 1043 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 3.38 (s, 3, OCH_3), 3.46 (s, 3, OCH_3), 3.53 (dd, 1, $J_{1,2}$ = 3.3 Hz, $J_{2,3}$ = 9.5 Hz, H2), 3.58 (t, 1, $J_{3,4}$ = $J_{4,5}$ = 9.4 Hz, H4), 3.90 (t, 1, H3), 4.13 (m, 1, H5), 4.58 (d, 1, H1), 4.76 (ABq, 2, *J* = 12 Hz, Δδ = 0.19 ppm, Ph*CH*$_2$), 4.91 (ABq, 2, *J* = 11 Hz, Δδ = 0.09 ppm, Ph*CH*$_2$), 4.91 (m, 1, H8), 5.70 (dt, 1, $J_{6,7}$ = 10.1 Hz, $J_{5,7}$ = $J_{7,8}$ = 2.4 Hz, H7), 5.95 (dt, 1, $J_{5,6}$ = $J_{6,8}$ = 1 Hz, H6), 7.30 (m, 10, *Ph*CH_2). *Anal.* calcd. for $C_{24}H_{28}O_6$: C 69.88, H 6.84; found: C 69.89, H 6.84.

(*b*) The *E*-α,β-unsaturated aldehyde **5** (145 mg, 0.308 mmol) was refluxed with pyridinium *p*-toluenesulfonate (20 mol%) in absolute methanol (10 mL) under argon. After 0.5 h, a more polar product was detected by tlc (R_f = 0.22 (C)) due to loss of the 4-(α-ethoxyethyl) protecting group. Refluxing was continued for 72–96 h, when further monitoring by tlc showed the formation of a less polar product (R_f = 0.55 (C)). The reaction mixture was concentrated *in vacuo* and the residue was purified by flash column chromatography (C) to give a pale yellow oil, **6***a* (66.1 mg, 52%). The physical properties of this material were identical with **6***a* described in part (*a*).

*Methyl-(1) benzyl-(8) (8*R*)-2,3-di-*O*-benzyl-6,7-dideoxy-α-*D*-*gluco*-octodiald-6-eno-1,5:8,4-dipyranoside (**6**b)*

The benzyl glycoside **6***b* was prepared, as described above, for the methyl analogue **6***a*, except that the benzyl alcohol (10 equiv.) in dry benzene (40 mL/mmol) was used. For **6***b* (~65% yield) R_f = 0.43 (C); $[\alpha]_D^{25}$ +4.2° (*c* 0.98, $CHCl_3$); ^1H nmr (200 MHz, $CDCl_3$) δ: 3.40 (s, 3, OCH_3), 3.57 (dd, 1, $J_{1,2}$ = 3.9 Hz, $J_{2,3}$ = 9.1 Hz, H2), 3.72 (t, 1, $J_{3,4}$ = $J_{4,5}$ = 9.4 Hz, H4), 3.96 (t, 1, H3), 4.17 (br d, 1, H5), 4.61 (d, 1, H1), 4.55–5.15 (m, 6, 3 Ph*CH*$_2$), 5.10 (br s, 1, H8), 5.74 (dt, 1, $J_{6,7}$ = 10.2 Hz, $J_{5,7}$ = $J_{7,8}$ = 2.5 Hz, H7), 5.98 (dt, $J_{5,6}$ = $J_{6,8}$ = 1 Hz), 7.35 (m, 15, 3, *Ph*CH_2). *Anal.* calcd. for $C_{30}H_{32}O_6$: C 73.75, H 6.60; found: C 73.79, H 6.72.

*Methyl-(1) 4-methoxybenzyl-(8) (8*R*)-2,3-di-*O*-benzyl-6,7-dideoxy-α-*D*-*gluco*-octodiald-6-eno-1,5:8,4-dipyranoside (**6**c)*

The title compound was prepared in 73% yield, as described in the preceding section, except that 4-methoxybenzyl alcohol was used; R_f = 0.31 (C); $[\alpha]_D^{25}$ +18.8° (*c* 1.35, $CHCl_3$); ^1H nmr (200 MHz, $CDCl_3$) δ: 3.40 (s, 3, OCH_3), 3.57 (dd, 1, $J_{1,2}$ = 3.7 Hz, $J_{2,3}$ = 9.2 Hz, H2), 3.70 (t, 1, $J_{3,4}$ = $J_{4,5}$ = 9.4 Hz, H4), 3.80 (s, 3, *p*-CH_3O*Ph*CH_2), 3.95 (t, 1, H3), 4.17 (br d, 1, H5), 4.61 (d, 1, H1), 4.64 (ABq, 2, *J* = 11.2 Hz, Δδ = 0.23 ppm, *p*-CH_3O*Ph*CH_2), 4.76 (ABq, 2, *J* = 11.0 Hz, Δδ = 0.18 ppm, Ph*CH*$_2$), 4.96 (ABq, 2, *J* = 11.3 Hz, Δδ = 0.09 ppm, Ph*CH*$_2$), 5.08 (br s, 1, H8), 5.71 (dt, 1, $J_{5,7}$ = $J_{7,8}$ = 2.5 Hz, $J_{6,7}$ = 10.3 Hz, H7), 5.97 (dt, 1, $J_{5,6}$ = $J_{6,8}$ = 1 Hz, H6), 6.8 (d of ABq, 2, *p*-CH_3O*Ph*CH_2), 7.20–7.52 (m, 12, *Ph*CH_2, *p*-CH_3O*Ph*CH_2). *Anal.* calcd. for $C_{31}H_{34}O_7$: C 71.80, H 6.61; found: C 71.75, H 6.73.

*Methyl-(1) 3,4-dimethoxybenzyl-(8) (8*R*)-2,3-di-*O*-benzyl-6,7-dideoxy-α-*D*-*gluco*-octodiald-6-eno-1,5:8,4-dipyranoside (**6**d)*

The title compound was prepared in 71% yield, as described in the preceding section, except that 3,4-dimethoxybenzyl alcohol was used; R_f = 0.20 (C); $[\alpha]_D^{19}$ +11.5° (*c* 1.08, $CHCl_3$); ^1H nmr (250 MHz, $CDCl_3$) δ: 3.39 (s, 3, CH_3), 3.53 (dd, 1, $J_{1,2}$ = 3.6 Hz, $J_{2,3}$ = 9.4 Hz, H2), 3.70 (t, 1, $J_{3,4}$ = $J_{4,5}$ = 9.5 Hz, H4), 3.76 and 3.85 (two s, 6, 3,4-di-CH_3O*Ph*CH_2), 3.94 (t, 1, H3), 4.16 (m, 1, H5), 4.60 (d, 1, H1), 4.63 (ABq, 2, *J* = 11.1 Hz, Δδ = 0.30 ppm, 3,4-di-CH_3O*Ph*CH_2), 4.74 (ABq, 2, *J* = 12.1 Hz, Δδ = 0.17 ppm, Ph*CH*$_2$), 4.94 (ABq, 2 = 11.2 Hz, Δδ = 0.08 ppm, Ph*CH*$_2$), 5.08 (br d, 1, $J_{7,8}$ = 2.9 Hz, H7), 5.71 (dt, 1, $J_{6,7}$ = 10.2 Hz, $J_{5,7}$ = 2.9 Hz, H7), 5.95 (dt, 1, $J_{5,6}$ = $J_{6,8}$ = 1 Hz, H6), 6.82 (m, 3, 3,4-di-CH_3O*Ph*CH_2), 7.24–7.47 (m, 10, 2*Ph*CH_2). *Anal.* calcd. for $C_{32}H_{36}HO_8$: C 70.05, H 6.61; found: C 69.94, H 6.72.

*Dimethyl (8*R*)-6,7-anhydro-2,3-di-*O*-benzyl-β-*L*-erythro-*D*-gluco-octodialdo-1,5:8,4-dipyranoside (**7**a)*

(*a*) A solution of the methyl enoside **6***a* (492 mg, 1.19 mmol) in dimethoxyethane–water (3:1 v/v, 10 mL) was treated with *N*-bromosuccinimide (2 equiv.). The reaction mixture was stirred in the dark at room temperature for 16 h, after which time a mixture of bromohydrins (R_f = 0.21 and 0.25 (C)) was observed. (If the reaction was allowed to continue for too long, decomposition was observed by tlc.) The reaction mixture was diluted with ether (3 volumes) and washed successively with 10% sodium thiosulfate and saturated sodium bicarbonate solutions. The organic layer was separated, dried ($MgSO_4$), filtered, and concentrated *in vacuo*. The resulting crude mixture of bromohydrins was dissolved in dry dimethylformamide (5 mL) and added to a vigorously stirred slurry of sodium hydride (2 equiv., oil-free) in dry dimethylformamide (10 mL) at 0°C under argon. The reaction mixture was warmed slowly to room temperature. After 2 h, methanol (1 mL) was carefully added to quench the excess sodium hydride. The reaction mixture was diluted with water and extracted with ether. The combined ether portions were washed with water and saturated sodium chloride solutions. The organic layer was separated, dried (Na_2SO_4), filtered, and concentrated *in vacuo*. The residue was purified by flash column chromatography (C) to afford **7***a* as a colorless syrup (275 mg, 54%); tlc R_f = 0.55 (C); $[\alpha]_D^{25}$ −1.36° (*c* 1.77, $CHCl_3$); ^1H nmr (600 MHz, $CDCl_3$) δ: 3.23 (br d, 1, $J_{6,7}$ = 3.5 Hz, H6), 3.38 (d, 1, H7), 3.42 (dd, 1, $J_{3,4}$ = 9.5 Hz, $J_{4,5}$ = 10.0 Hz, H4), 3.43 (s, 3, OCH_3), 3.45 (s, 3, OCH_3), 3.48 (dd, 1, $J_{1,2}$ = 3.7 Hz, $J_{2,3}$ = 9.3 Hz, H2), 3.67 (br d, 1, H5), 4.57 (d, 1, H1), 4.73 (ABq, 2, *J* = 11.8 Hz, Δδ = 0.18 ppm, Ph*CH*$_2$), 4.85 (ABq, 2, *J* = 10.8 Hz, Δδ = 0.06 ppm, Ph*CH*$_2$), 4.90 (s, 1, H8), 7.34 (m, 10, *Ph*CH_2). *Anal.* calcd. for $C_{24}H_{28}O_7$: C 67.27, H 6.59; found: C 66.94, H 6.59.

(*b*) A solution of the chlorocarbamate mixture **12***a* and **13***a* (40 mg, 0.075 mmol) in absolute methanol was added to a freshly prepared solution of sodium methoxide (5 equiv.) in absolute methanol (5 mL). The reaction mixture was refluxed for 6–8 h and monitored by tlc (D). Upon completion, the reaction mixture was concentrated *in vacuo*; the residue was dissolved in methylene chloride and washed with water and saturated sodium chloride solutions. The methylene chloride layer was dried (Na_2SO_4), filtered, and concentrated *in vacuo* and the residue purified by flash chromatography (D) to afford **7***a* as a colorless syrup (23 mg, 70%). The physical properties were identical with **7***a* described above in part (*a*).

Unreacted chlorocarbamate **13***a* was recovered (3.8 mg) as the only other product.

*Methyl-(1) benzyl-(8) (8*R*)-6,7-anhydro-2,3-di-*O*-benzyl-β-*L*-erythro-*D*-gluco-octodialdo-1,5:8,4-dipyranoside (**7**b)*

The epoxide **7***b* was prepared in 58% yield, as described above for **7***a*; tlc R_f = 0.53 (C); ^1H nmr (200 MHz, $CDCl_3$) δ: 3.18 (d, 1, $J_{6,7}$ = 3.6 Hz, H6), 3.38 (d, 1, H7), 3.48 (s, 3, OCH_3), 3.50–3.63 (m, 2, H2 + H4), 3.72 (d, 1, $J_{4,5}$ = 10.4 Hz, H5), 3.90 (t, 1, $J_{2,3}$ = $J_{3,4}$ = 10.0 Hz, H3), 4.48–5.00 (m, 5, H1, Ph*CH*$_2$), 5.09 (s, 1, H8), 7.30–7.45 (m, 10, *Ph*CH_2). *Anal.* calcd. for $C_{30}H_{32}O_7$: C 71.41, H 6.39; found: C 71.30, H 6.30.

*Methyl-(1) 4-methoxybenzyl-(8) (8*R*)-6,7-anhydro-2,3-di-*O*-benzyl-β-*L*-erythro-*D*-gluco-octodialdo-1,5:8,4-dipyranoside (**7**c)*

The epoxide **7***c* was prepared as described above for the conversion **12***a* → **7***a*, using the chlorocarbamate mixture **12***c* and **13***c* (545 mg, 0.849 mmol). Compound **7***c* was obtained as a white solid (329 mg, 73%), mp 60–61°C; tlc R_f = 0.50 (D); $[\alpha]_D^{19}$ −12.3° (*c* 1.67, $CHCl_3$); ^1H nmr δ (250 MHz, $CDCl_3$) δ: 3.13 (d, 1, $J_{6,7}$ = 3.6 Hz, H6), 3.33 (d, 1, H7), 3.43 (s, 3, OCH_3), 3.47–3.57 (m, 2, H2, H4), 3.68 (d, 1, $J_{4,5}$ = 10.2 Hz, H5), 3.81 (s, 3, CH_3OPhCH$_{22}$), 3.86 (t, 1, $J_{2,3}$ =

$J_{3,4}$ = 9.3 Hz, H3), 4.59 (d, 1, $J_{1,2}$ = 3.8 Hz, H1), 4.62 (ABq, 2, J = 11.1 Hz, $\Delta\delta$ = 0.28 ppm, p-CH_3OPhCH_2), 4.74 (ABq, 2, J = 12.0 Hz, $\Delta\delta$ = 0.28 ppm, PhCH_2), 4.91 (ABq, 2, J = 11.5 Hz, $\Delta\delta$ = 0.05 ppm, PhCH_2), 5.06 (s, 1, H8), 7.03 (ABq, 2, J = 8.6 Hz, $\Delta\delta$ = 0.35 ppm, p-CH_3OPhCH_2), 7.25–7.44 (m, 10, $Ph$$CH_2$). *Anal.* calcd. for $C_{32}H_{34}O_8$: C 69.65, H 6.41; found: C 69.41, H 6.70.

*Methyl-(1) 3,4-dimethoxybenzyl-(8) (8*R*)-6,7-anhydro-2,3-di-*O*-benzyl-β-*L*-*erythro*-*D*-gluco-octodialdo-1,5:8,4-dipyranoside (7*d*)*

The epoxide **7***d* was prepared as described above for the conversion **12***a* → **7***a*, using the chlorocarbamate mixture **12***d* and **13***d* (546 mg, 0.812 mmol). Compound **7***d* was obtained as a white solid (305 mg, 67%), mp 86.5–88.5°C; tlc R_f = 0.44 (D); $[\alpha]_D^{19}$ −1.9° (*c* 1.37, $CHCl_3$); ^{1}H nmr (250 MHz, $CDCl_3$) δ: 3.15 (d, 1, $J_{6,7}$ = 3.6 Hz, H6), 3.34 (d, 1, H7), 3.44 (s, 3, OCH_3), 3.46–3.59 (m, 2, H2, H4), 3.69 (d, 1, $J_{4,5}$ = 10.2 Hz, H5), 3.82–3.92 (m, 1, H3), 3.75 and 3.87 (two s, 6, 3,4-di-CH_3OPhCH_2), 4.60 (d, 1, $J_{1,2}$ = 3.8 Hz, H1), 4.63 (ABq, 2, J = 10.9 Hz, $\Delta\delta$ = 0.30 ppm, 3,4-CH_3OPhCH_2), 4.74 (ABq, 2, J = 12.1 Hz, $\Delta\delta$ = 0.17 ppm, PhCH_2), 4.91 (ABq, 2, J = 11.1 Hz, $\Delta\delta$ = 0.06 ppm, PhCH_2), 5.09 (s, 1, H8), 6.82 (m, 3, 3,4-di-CH_3OPhCH_2), 7.20–7.40 (m, 10, $Ph$$CH_2$). *Anal.* calcd. for $C_{32}H_{36}O_9$: C 68.07, H 6.43; found: C 68.21, H 6.24.

Unreacted chlorocarbamate **13***d* was recovered (70 mg) as the only other product.

*Dimethyl (8*R*)-6,7-anhydro-2,3-di-*O*-benzyl-α-*D*-gluco-octodialdo-1,5:8,4-dipyranoside (8)*

(*a*) The chromatography in the preceding experiment also provided the *D-erythro* diastereomer **8** as a colorless syrup (30.7 mg, 6%); tlc R_f = 0.31 (C); $[\alpha]_D^{25}$ −8.7° (*c* 1.59, $CHCl_3$); ^{1}H nmr (600 MHz, $CDCl_3$) δ: 3.39 (dd, 1, $J_{5,6}$ = 1.2 Hz, H6), 3.42 (s, 3, OCH_3), 3.46 (s, 3, OCH_3), 3.47 (dd, 1, $J_{7,8}$ = 2.9 Hz, H7), 3.47 (dd, 1, $J_{1,2}$ = 13.7 Hz, $J_{2,3}$ = 9.5 Hz, H2), 3.74 (t, 1, $J_{3,4}$ = $J_{4,5}$ = 9.5 Hz, H4), 3.84 (t, 1, H3), 3.92 (dd, 1, H5), 4.59 (d, 1, H1), 4.72 (ABq, 2, J = 12.1 Hz, $\Delta\delta$ = 0.18 ppm, PhCH_2), 4.83 (ABq, 2, J = 11.4 Hz, $\Delta\delta$ = 0.05 ppm, PhCH_2), 4.89 (d, 1, H8), 7.23–7.40 (m, 10, $Ph$$CH_2$). *Anal.* calcd. for $C_{24}H_{28}O_7$: C 67.27, H 6.59; found: C 66.95, H 6.68.

(*b*) A vigorously stirred solution of the diol **9***a* (68.3 mg, 0.153 mmol) in dry dimethylformamide (1 mL) was treated with oil-free sodium hydride (3.7 mg, 0.153 mmol) at −41°C under argon. After 0.5 h, tosyl imidazole (51.1 mg, 0.230 mmol) in dimethylformamide (0.5 mL) was slowly added and the resulting solution was stirred for 6 h at −41°C to give the sulfonate **9***b*. An additional equivalent of sodium hydride (3.7 mg) was then added and the reaction mixture was warmed to room temperature. After 2 h, several drops of methanol were added to the reaction mixture, followed by careful addition of water. The aqueous mixture was extracted with ether and the combined ether portions were washed with water, dried (Na_2SO_4), filtered, and concentrated *in vacuo*. The residue was purified by flash column chromatography (D) to give **8** (45.9 mg, 70%), identical to the material in part (*a*).

*Dimethyl (8*R*)-2,3-di-*O*-benzyl-β-*L*-threo-*D*-gluco-octodialdo-1,5:8,4-dipyranoside (9*a*)*

The epoxide **7***a* (120 mg, 0.281 mmol) was stirred with potassium hydroxide (236 mg, 4.2 mmol) in dimethyl sulfoxide and water (5 mL, 9:1 v/v) at 100°C for 20 h. The reaction mixture was cooled to room temperature, diluted with water, and extracted with ether. The combined ether portions were washed with saturated sodium chloride solution (3 × 25 mL), dried (Na_2SO_4), filtered, and concentrated *in vacuo*. The residue was purified by flash column chromatography to give the diol **9***a* (85 mg, 68%) as a colorless syrup; tlc R_f = 0.08 (E); $[\alpha]_D^{25}$ −26.0° (*c* 1.21, $CHCl_3$); ir (neat): 3485, 2940, 1052 cm^{-1}; ^{1}H nmr (600 MHz, $CDCl_3$) δ: 1.22 (br s, 1, OH), 2.98 (br s, 1, OH), 3.39 (s, 3, OCH_3), 3.44 (s, 3, OCH_3), 3.51 (dd, 1, $J_{1,2}$ = 3.7 Hz, $J_{2,3}$ = 9.2 Hz, H2), 3.85 (dd, 1, $J_{3,4}$ = 8.8 Hz, $J_{4,5}$ = 10.3 Hz, H4), 3.88 (dd, 1, $J_{5,6}$ = 2.2 Hz, H5), 3.98 (m, 2H, H6, H7), 4.00 (t, 1, H3), 4.64 (d, 1, H1), 4.72 (br s, 1, H8), 4.74 (ABq, 2, J = 12.5 Hz, $\Delta\delta$ = 0.18 ppm, PhCH_2), 4.89 (ABq, 2, J = 11.03 Hz, $\Delta\delta$ = 0.05 ppm, PhCH_2), 7.25–7.42 (m, 10, $Ph$$CH_2$). *Anal.* calcd. for $C_{24}H_{30}O_8$: C 64.56, H 6.77; found: C 64.18, H 6.82.

*Dimethyl (8*R*)-2,3-di-*O*-benzyl-β-*L*-erythro-*D*-gluco-octodialdo-1,5:8,4-dipyranoside (10*a*)*

N-methyl morpholine-*N*-oxide (1.1 equiv., 60 wt.% in water) and osmium tetroxide (1 mol%, 2.5 wt.% in *tert*-butanol) were added to a solution of the methyl enoside **6***a* (287 mg, 0.696 mmol) in acetone–water (5:1, 15 mL). The reaction mixture was stirred for 48 h at room temperature under argon and, upon completion (tlc, C), was quenched with sodium bisulfite (25 mg), diluted with water, and extracted with ethyl acetate. The combined ethyl acetate portions were dried (Na_2SO_4), filtered, and concentrated *in vacuo*. The residue was purified by filtration through a short silica gel column (E) to afford the diol **10***a* as a white amorphous solid (273 mg, 88%), mp 141–143.5°C; tlc R_f = 0.07 (D); $[\alpha]_D^{19}$ −5.4° (*c* 0.71, $CHCl_3$); ^{1}H nmr (250 MHz, $CDCl_3$) δ: 2.40 (d, 1, J = 1.5 Hz, OH, D_2Oex), 2.45 (d, 1, J = 1.5 Hz, OH, D_2Oex), 3.39 (s, 3, OCH_3), 3.40 (s, 3, OCH_3), 3.47 (dd, 1, $J_{1,2}$ = 3.7 Hz, $J_{2,3}$ = 9.4 Hz, H2), 3.51 (t, 1, $J_{3,4}$ = $J_{4,5}$ = 9.5 Hz, H4), 3.79 (t, 1, $J_{5,6}$ = 9.7 Hz, H5), 3.89 (dt, 1, $J_{OH,6}$ = $J_{6,7}$ = 1.5 Hz, H6), 3.95–4.03 (m, 2, H3, H7), 4.57 (d, 1, H1), 4.75 (ABq, 2, J = 12.2 Hz, $\Delta\delta$ = 0.19 ppm, PhCH_2), 4.88 (ABq, 2, J = 11.0 Hz, $\Delta\delta$ = 0.10 ppm, PhCH_2), 7.20–7.45 (m, 10, $Ph$$CH_2$). *Anal.* calcd. for $C_{24}H_{30}O_8$: C 64.56, H 6.77; found: C 64.52, H 6.80.

*Methyl-(1) 4-methoxybenzyl-(8) (8*R*)-2,3-di-*O*-benzyl-β-*L*-erythro-*D*-gluco-octodialdo-1,5:8,4-dipyranoside (10*c*)*

The diol **10***c*, prepared as described for **10***a* from the benzyl enoside **6***c* (4.33 mg, 0.834 mmol), was obtained as a white crystalline solid (388 mg, 84%), mp 136–137°C (recrystallized from ether); tlc R_f = 0.18 (E); $[\alpha]_D^{19}$ −27.7° (*c* 1.15, $CHCl_3$); ^{1}H nmr (250 MHz, $CDCl_3$) δ: 2.42 (d, 1, J = 4.0 Hz, OH, D_2Oex), 2.45 (d, 1, J = 3.0 Hz, OH, D_2Oex), 3.40 (s, 3, OCH_3), 3.81 (s, 3, CH_3OPh), 3.49 (dd, 1, $J_{1,2}$ = 3.7 Hz, $J_{2,3}$ = 9.3 Hz, H2), 3.62 (t, 1, $J_{3,4}$ = $J_{4,5}$ = 9.5 Hz, H4), 3.76–4.06 (m, 4, H3, H5, H6, H7), 4.55 (ABq, 2, J = 11.5 Hz, $\Delta\delta$ = 0.24 ppm, p-CH_3OPhCH_2), 4.58 (d, 1, H1), 4.76 (ABq, 2, J = 12.1 Hz, $\Delta\delta$ = 0.18 ppm, PhCH_2), 4.92 (br d, 1, $J_{7,8}$ = 1.2 Hz, H8), 4.94 (ABq, 2, J = 11.1 Hz, $\Delta\delta$ = 0.10 ppm, PhCH_2), 7.04 (ABq, 4, J = 8.2 Hz, $\Delta\delta$ = 0.35 ppm, p-CH_3OPhCH_2), 7.25–7.50 (m, 10, $Ph$$CH_2$). *Anal.* calcd. for $C_{31}H_{36}O_9$: C 67.38, H 6.57; found: C 67.26, H 6.49.

*Methyl-(1) 3,4-dimethoxybenzyl-(8) (8*R*)-2,3-di-*O*-benzyl-β-*L*-erythro-*D*-gluco-octodialdo-1,5:8,4-dipyranoside (10*d*)*

The diol **10***d*, prepared as described above for **10***a* from the corresponding benzyl enoside **6***d* (763 mg, 1.39 mmol), was obtained as a white crystalline solid (653 mg, 81%), mp 169–170°C (recrystallized from ether); tlc R_f = 0.02 (D); $[\alpha]_D^{19}$ −30.9° (*c* 1.44, $CHCl_3$); ^{1}H nmr (250 MHz, $CDCl_3$) δ: 2.50 (d, 1, J = 4.0 Hz, OH, D_2Oex), 2.54 (d, 1, J = 2.9 Hz, OH, D_2Oex), 3.40 (s, 3, OCH_3), 3.47 (dd, 1, $J_{1,2}$ = 3.6 Hz, $J_{2,3}$ = 9.3 Hz, H4), 3.76 and 3.87 (two s, 6, 3,4-di-CH_3OPhCH_2), 3.78–4.07 (m, 4, H3, H5, H6, H7), 4.58 (ABq, 2, J = 11.3 Hz, $\Delta\delta$ = 0.23 ppm, 3,4-di-CH_3OPhCH_2), 4.58 (d, 1, H1), 4.75 (ABq, 2, J = 12.1 Hz, $\Delta\delta$ = 0.18 ppm, PhCH_2), 4.95 (ABq, 2, J = 11.3 Hz, $\Delta\delta$ = 0.10 ppm, PhCH_2), 6.80 (m, 3, 3,4-di-CH_3OPhCH_2), 7.24–7.48 (m, 10, $Ph$$CH_2$). *Anal.* calcd. for $C_{32}H_{38}O_{10}$: C 65.97, H 6.57; found: C 65.82, H 6.65.

*Dimethyl (8*R*)-2,3-di-*O*-benzyl-6-chloro-6-deoxy-7-*O*-(N,N-dimethylcarbamoyl)-(8*R*)-β-*L*-threo-*D*-gluco-octodialdo-1,5:8,4-dipyranoside (12*a*) and dimethyl (8*R*)-2,3-di-*O*-benzyl-7-chloro-7-deoxy-6-*O*-(N,N-dimethylcarbamoyl)-α-*D*-threo-*D*-gluco-octodialdo-1,5:8,4-dipyranoside (13*a*)*

A solution of the *cis* diol **10***a* (58 mg, 0.13 mmol) in dry 1,2-dichloroethane (5 mL) and triethylamine (0.5 mL) was treated with phosgene iminium chloride (1.5 equiv.) and refluxed with vigorous stirring for 0.5–1 h under argon. The dark brown reaction mixture was cooled to room temperature, quenched with saturated sodium bicarbonate solution, and extracted with methylene chloride. The combined methylene chloride portions were washed with saturated sodium bicarbonate solution, dried (Na_2SO_4), filtered, and concentrated *in vacuo*. The residue was fractionated by flash column chromatography (D) to give **12***a* (57 mg, 82%) and **13***a* (3.8 mg, 5%). For **12***a*: tlc R_f = 0.25 (D); $[\alpha]_D^{19}$ −11.9° (*c* 0.77, $CHCl_3$); ir (neat):

The chlorocarbamate **12***c*, prepared as described for **12***a* from the diol **10***c* (722 mg, 1.31 mmol), was obtained as a colorless syrup (545 mg, 78%); tlc R_f = 0.38 (E); ir (neat): 2920, 1712, 1514, 1392, 1230, 1042 cm^{-1}; ^1H nmr (250 MHz, $CDCl_3$) δ: 2.91 and 2.92 (two s, 6, Me_2NCO_2), 3.41 (s, 3, OCH_3), 3.58 (dd, $J_{2,3}$ = 9.3 Hz, $J_{1,2}$ = 3.6 Hz), 3.80 (s, 3, *p*-CH_3OPhCH_2), 3.95–4.19 (m, 3, H5, H4, H3), 4.28 (br t, 1, H6), 4.61 (ABq, 2, J = 11.9 Hz, Δδ = 0.32 ppm, *p*-CH_3OPhCH_2), 4.71 (d, 1, H8), 4.75 (ABq, 2, J = 12.1 Hz, Δδ = 0.18 ppm, PhCH_2), 4.80 (br s, 1, H8), 4.93 (ABq, 2, J = 12.3 Hz, Δδ = 0.05 ppm, PhCH_2), 5.09 (d, 1, $J_{6,7}$ = 3.5 Hz, H7), 7.05 (ABq, 4, J = 9.03 Hz, Δδ = 0.37 ppm, *p*-CH_3OPhCH_2), 7.27–7.45 (m, 10, $Ph$$CH_2$); hrms m/e (M^+) calcd.: 641.2392; found: 641.2394.

*Dimethyl (8*R*)-2,3-di-*O*-benzyl-6-deoxy-6-*C*-methyl-β-*L*-threo-*D*-gluco-octodialdo-1,5:8,4-dipyranoside (**14**a)*

Dimethyl magnesium was generated *in situ* by adding methyllithium (9.9 equiv., stock ether solution, low lithium halide content) dropwise to methyl magnesium chloride (10.0 equiv., stock tetrahydrofuran solution) with stirring at 0°C under an argon atmosphere. A white precipitate (presumably lithium chloride) formed almost immediately upon complete addition of methyllithium. After 0.5 h, the epoxide **7***a* (150 mg, 0.281 mmol) dissolved in dry toluene (7 mL) was added to the dimethyl magnesium solution. The reaction mixture was refluxed for 3–5 h and monitored by tlc (D). Upon completion, it was cooled to 0°C, carefully quenched with saturated ammonium chloride solution, and extracted with ethyl acetate. The combined organic phases were dried over anhydrous sodium sulfate, filtered, and concentrated *in vacuo* and the residue was purified by filtration through a short silica gel column (D), followed by solvent evaporation to give **14***a* as the only product (133 mg, 86%); tlc R_f = 0.24 (D); $[\alpha]_D^{25}$ −27.1° (*c* 1.01, $CHCl_3$); ^1H nmr (200 MHz, $CDCl_3$) δ: 1.08 (d, 3, J_{6,CH_3} = 7.5 Hz, CH_3), 1.76 (d, 1, J = 6.5 Hz, OH, D_2Oex), 2.22 (m, 1, H6), 3.38 (s, 6, OCH_3), 3.42–3.51 (m, 1, H2), 3.65–3.78 (m, 2, H4, H7), 3.89–4.05 (overlapping dd and t, $J_{2,3}$ = $J_{3,4}$ = 9.2 Hz, $J_{5,6}$ = 4.7 Hz, H3, H5), 4.59–4.65 (m, 2, H1, H8), 4.75 (ABq, 2, J = 11.6 Hz, Δδ = 0.17 ppm, PhCH_2), 4.89 (ABq, 2, J = 11.2 Hz, Δδ = 0.08 ppm, PhCH_2), 7.30–7.44 (m, 10, $Ph$$CH_2$). *Anal.* calcd. for $C_{25}H_{32}O_7$: C 67.55, H 7.26; found: C 67.89, H 7.43.

*Methyl-(1) benzyl-(8) (8*R*)-2,3-di-*O*-benzyl-6-deoxy-6-*C*-methyl-β-*L*-threo-*D*-gluco-octodialdo-1,5:8,4-dipyranoside (**14**b)*

Compound **14***b*, prepared as described above for **14***a* from epoxide **7***b* (80.0 mg, 0.159 mmol), was obtained as a colorless syrup (67.8 mg, 82%); tlc R_f = 0.29 (D); $[\alpha]_D^{25}$ −52.1° (*c* 1.29, $CHCl_3$); ^1H nmr (200 MHz, $CDCl_3$) δ: 1.12 (d, 3, J_{6,CH_3} = 7.4 Hz, CH_3), 1.81 (br s, 1, OH, D_2Oex), 2.23 (m, 1, H6), 3.39 (s, 3, OCH_3), 3.48 (dd, 1, $J_{1,2}$ = 3.7, $J_{2,3}$ = 9.8 Hz, H2), 3.74–3.93 (m, 2, H4, H7), 3.92–4.09 (overlapping dd and t, 2, $J_{2,3}$ = $J_{3,4}$ = 9.8 Hz, $J_{5,6}$ = 5.3 Hz, H3, H5), 4.62 (d, 1, H1), 4.62 (ABq, 2, J = 12.2 Hz, Δδ = 0.33 ppm, PhCH_2), 4.75 (ABq, 2, J = 12.2 Hz, Δδ = 0.16 ppm, PhCH_2), 4.76 (br s, 1, H8), 4.93 (ABq, 2, J = 11.1 Hz Δδ = 0.08 ppm, PhCH_2), 7.30–7.47 (m, 15, $Ph$$CH_2$). *Anal.* calcd. for $C_{31}H_{36}O_7$: C 71.52, H 6.97; found: C 71.23, H 7.09.

Compound **14***c*, prepared as described above for **14***a* from epoxide **7***c* (329 mg, 0.615 mmol), was obtained as a colorless syrup (300 mg, 89%); tlc R_f = 0.20 (D); $[\alpha]_D^{19}$ −51.2° (*c* 1.25, $CHCl_3$); ^1H nmr (250 MHz, $CDCl_3$) δ: 1.10 (d, 3, J_{6,CH_3} = 7.5 Hz, CH_3), 1.85 (d, 1, $J_{7,OH}$ = 6.4 Hz, OH, D_2Oex), 2.22 (m, 1, H6), 3.39 (s, 3, OCH_3), 3.49 (dd, 1, $J_{1,2}$ = 3.7 Hz, $J_{2,3}$ = 9.1 Hz, H2), 3.70–3.87 (m, 2, H4, H7), 3.80 (s, 3, *p*-CH_3OPhCH_2), 3.98 (t, 1, $J_{3,4}$ = 9.1 Hz, H3), 4.02 (dd, 1, $J_{4,5}$ = 10.4 Hz, $J_{5,6}$ = 5.3 Hz, H5), 4.57 (ABq, 2, J = 11.7 Hz, Δδ = 0.31 ppm, *p*-CH_3OPhCH_2), 4.63 (d, 1, H1), 4.73 (br s, 1, H8), 4.76 (ABq, 2, J = 12.6 Hz, Δδ = 0.16 ppm, PhCH_2), 4.95 (ABq, 2, J = 11.2 Hz Δδ = 0.08 ppm, PhCH_2), 7.03 (ABq, 4, J = 8.6 Hz, 0.35 ppm, *p*-CH_3OPhCH_2), 7.17–7.47 (m, 10, $Ph$$CH_2$). *Anal.* calcd. for $C_{32}H_{38}O_8$: C 69.80, H 6.96; found: C 69.60, H 6.99.

*Methyl-(1) 3,4-dimethoxybenzyl-(8) (8*R*)-2,3-di-*O*-benzyl-6-deoxy-6-*C*-methyl-β-*L*-threo-*D*-gluco-octodialdo-1,5:8,4-dipyranoside (**14**d)*

Compound **14***d*, prepared as described above for **14***a* from epoxide **7***d* (284 mg, 0.503 mmol) was obtained as a colorless syrup (243 mg, 83%); tlc R_f = 0.14 (D); $[\alpha]_D^{19}$ −49.5° (*c* 3.13, $CHCl_3$); ^1H nmr (250 MHz, $CDCl_3$) δ: 1.10 (d, 3, J_{6,CH_3} = 7.4 Hz, CH_3), 1.87 (br d, 1, OH, D_2Oex), 2.24 (m, 1, H6), 3.40 (s, 3, OCH_3), 3.47 (dd, 1, $J_{1,2}$ = 3.6 Hz, $J_{2,3}$ = 9.3 Hz, H2), 3.72–3.85 (m, 2, H4, H7), 3.78 and 3.87 (two s, 6, 3,4-di-CH_3OPhCH_2), 3.95–4.06 (overlapping dd and t, 2, $J_{2,3}$ = $J_{3,4}$ = 9.3 Hz, 2, $J_{5,6}$ = 5.3 Hz, H3, H5), 4.43 (d of ABq, 1, J = 11.6 Hz, 3,4-di-CH_3OPhCH_2), 4.64 (d, 1, H1), 4.64–4.81 (m, 3, H8, PhCH, 3,4-di-CH_3OPhCH_2), 4.83 (d of ABq, J = 12.2 Hz, 1, PhCH), 4.95 (ABq, 2, J = 11.1 Hz Δδ = 0.08 ppm, PhCH_2), 6.82 (m, 3, 3,4-di-CH_3OPhCH_2), 7.22–7.47 (m, 10, $Ph$$CH_2$). *Anal.* calcd. for $C_{33}H_{40}O_9$: C 68.26, H 6.94; found: C 68.42, H 7.04.

*Methyl (8*R*,8*S*)-2,3-di-*O*-benzyl-6-deoxy-6-*C*-methyl-β-*L*-threo-*D*-gluco-octodialdo-8,4-pyranoso-1,5-pyranoside (**15**)*

(*a*) The *p*-methoxybenzyl methyl bipyranoside **14***c* (41.0 mg, 0.0745 mmol) was stirred with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (20) (DDQ, 25.4 mg, 0.112 mmol) in methylene chloride and water (18:1 v/v, 5 mL) under argon at room temperature. A dark green charge-transfer complex formed immediately and gradually faded to orange-yellow after 2 h. Thin-layer chromatography (E) showed significant starting material remained. An additional equivalent of

DDQ was added, and stirring continued for 2.5 h. The crude reaction mixture was filtered through a Celite pad and the solid residue was washed with methylene chloride (15 mL). The filtrate was concentrated *in vacuo* and the residue was dissolved in toluene (10 mL) and concentrated *in vacuo* to remove water as an azeotrope. The residue was purified by flash chromatography (D followed by E) to give the anomeric mixture **15** as a colorless syrup (13.3 mg, 41%); tlc R_f = 0.24 (E); ir (neat): 3430, 2900, 1452, 1358, 1030 cm^{-1}; ^1H nmr (250 MHz, $CDCl_3$) δ: 0.95 and 1.10 (two d, 2:1 respective ratio, CH_3), 1.18 and 0.36 (two m, 1:2 respective ratio, H6), 2.50 and 3.09 (two d, 2, OH, D_2Oex), 3.38 (s, 3, OCH_3), 3.40–3.58 (m, 2), 3.67–4.40 (m, 3), 4.58–6.04 (m, 6), 7.22–7.41 (m, 10). *Anal.* calcd. for $C_{24}H_{30}O_7$: C 66.96, H 7.02; found: C 66.81, H 7.13.

(*b*) Compound **15** was prepared in an improved yield when 3,4-dimethoxybenzyl methyl bipyranoside **14***d* (113 mg, 0.195 mmol) was stirred with DDQ (48.6 mg, 0.214 mmol) in methylene chloride – dioxane–water (10 mL, 18:2:1 v/v) under argon at room temperature. After 4 h, the dark green charge-transfer complex faded to an orange-yellow color. Thin-layer chromatography (E) showed some starting material still present so additional DDQ (10 mg) was added. After 2 h, only a trace of starting material was left. The reaction work-up was the same as previously described and **15** was obtained as a colorless syrup (58.8 mg, 70%). The physical properties were identical to the material in part (*a*).

Ion–ion–solvent interactions in aqueous ionic cosolvent systems. III. Thermodynamics of hydrogen bromide and hydrogen iodide from water to aqueous solutions of sodium nitrate from emf measurements at different temperatures and the structuredness of the solvents

SIBAPRASAD RUDRA, HIMANSU TALUKDAR, AND KIRON K. KUNDU[1]
Physical Chemistry Laboratory, Jadavpur University, Calcutta – 700 032, India

Received April 6, 1987

SIBAPRASAD RUDRA, HIMANSU TALUKDAR, and KIRON K. KUNDU. Can. J. Chem. **65**, 2843 (1987).

Standard free energies (ΔG_t^0) and entropies (ΔS_t^0) of transfer of hydrogen bromide and iodide from water to the aqueous 1, 2, and 4 *m* of sodium nitrate have been determined by measuring the emf's of the cell: Pt, H_2(g, 1 atm)/KOH(m_1), KX(m_2), solvent/AgX–Ag where X = Br or I at five equidistant temperatures ranging from 15–35°C. ΔG_t^0 values of HBr, HI as well as that of HCl obtained from earlier paper and particularly of the individual ions ΔG_t^0(i), obtained by use of modified TATB assumption reported earlier and also $\Delta G_{t,tr.int}^0$(i) obtained after correcting for "cavity" effect and Born-type electrostatic effect estimated tentatively by the scaled particle theory (SPT) and simple Born equation, respectively, reveal the relative order of stabilisation of Cl^-, Br^-, and I^- ions. Analysis of $T\Delta S_t^0$(HX)–composition profile (X = Cl, Br, and I) exhibits a characteristic "maxima" around 1.5 *m* $NaNO_3$ with the relative order HI > HBr > HCl in the region of maxima. Moreover, dissection of $T\Delta S_t^0$(HX) values into the individual ion contributions by use of the modified TATB assumption reported earlier, results in the characteristic "maxima" around 1.5 *m* $NaNO_3$ in $T\Delta S_t^0$(i) or $T\Delta S_{t,tr.int}^0$(i)–composition profiles for H^+ and "minima" for Cl^-, Br^-, and I^-. The results are discussed in terms of ion–ion–solvent interactions as well as the structural changes of the solvents.

SIBAPRASAD RUDRA, HIMANSU TALUKDAR et KIRON K. KUNDU. Can. J. Chem. **65**, 2843 (1987).

Opérant à des températures équidistantes entre 15 et 35°C et faisant appel à des mesures de fem de la cellule Pt, H_2(g, 1 atm)/KOH(m_1), KX(m_2), solvent/AgX–Ag, dans laquelle X = Br ou I, on a déterminé les énergies libres standard (ΔG_t^0) et les entropies (ΔS_t^0) pour le transfert du bromure et de l'iodure d'hydrogène de l'eau vers des solutions aqueuses 1, 2 et 4 *m* en nitrate de sodium. En se basant sur les valeurs des ΔG_t^0 du HBr et du HI, sur la valeur équivalente du HCl qui a été déterminée antérieurement, sur les valeurs des ΔG_t^0(i) des ions individuels qui ont été obtenues en utilisant l'hypothèse TATB proposée antérieurement ainsi que sur les valeurs de $\Delta G_{t,tr.int}^0$(i) obtenues après avoir effectué des corrections pour l'effet de «cavité» ainsi que pour l'effet électrostatique du type de Born évalués respectivement par la théorie des particules scalaires (TPS) et par une équation simple de Born, on peut en déduire l'ordre relatif de stabilisation des ions Cl^-, Br^- et I^-. Une analyse du profil $T\Delta S_t^0$(HX)/composition (X = Cl, Br, I) présente un "maximum" caractéristique autour de 1,5 *m* $NaNO_3$ et, dans cette région, l'ordre relatif est HI > HBr > HCl. De plus, une dissection des valeurs de $T\Delta S_t^0$(HX) en contributions ioniques individuelles, en utilisant l'hypothèse TATB modifiée proposée antérieurement, conduit à des "maxima" caractéristiques autour de 1,5 *m* en $NaNO_3$ dans les profils de $T\Delta S_t^0$(i) ou $T\Delta S_{t,tr.int}^0$(i)/composition pour H^+ et à des "minima" pour Cl^-, Br^- et I^-. On discute des résultats en fonction d'interactions ion–ion–solvent ainsi qu'en fonction de changements structuraux des solvants.

[Traduit par la revue]

Introduction

Systematic studies on different physico-chemical properties including thermodynamics of electrolytes and non-electrolytes, in aqueous ionic cosolvent systems parallel to that in aquo-organic cosolvent systems, constitute a new approach for understanding the thermodynamic and kinetic behaviour of electrolytes and non-electrolytes in salt solutions. In the previous papers (1, 2) we have reported for the first time the transfer energetics of HCl (1), free energies of transfer (ΔG_t^0), and entropies of transfer ($T\Delta S_t^0$) of some electrolytes and their constituent ions (2) from water to the aqueous mixtures of 1, 2, and 4 *m* $NaNO_3$ at 25°C, taking each composition as the individual solvent and the infinitely dilute solution of solute in each solvent as the standard state, exactly similar to what are usually done in aquo-organic solvent systems.

Recent studies (3–6) on the standard potentials (E^0) of the Ag–AgX (X = Cl, Br, and I) electrodes at different temperatures in different aquo-organic solvents and the related transfer energetics of HX are found to be amply useful in furnishing important reflections on the ion–solvent interactions as well as the structural features of the solvents relative to that of water. We have therefore extended the above idea to the aquo-ionic solvent system. As E^0 values of the Ag–AgCl electrode at different temperatures are already reported in the previous paper (1) we are now reporting the same for Ag–AgBr and Ag–AgI electrodes.

Since Pt/H_2 electrode is found to behave irratically in low pH solution of I^- in these solvents, a cell of the type

[A] Pt, H_2(g, 1 atm)/KOH(m_1), KX(m_2), solvent/AgX–Ag

has been used for both X = I and Br. The required autoionization constant (K_s) values of the solvents have of course been determined earlier and reported in another paper (7). In these aqueous ionic solvents the E^0 values have been determined at five equidistant temperatures ranging from 15–35°C for each composition.

Experimental

The method of preparation of solvent has been described earlier (1). Water used was triple distilled. Both KI and KBr (Merck, G.R.) were used after drying at 150°C and then in a vacuum desiccator for about 12 h. Ag–AgI and Ag–AgBr electrodes were of the thermal type and prepared by the method described earlier (8). Other experimental details including the preparation of solutions, platinized electrodes, and also the method of measurements were exactly the same as those described in the preceding papers (3*c*,*d*). The behaviour of electrodes, the time of attainment of equilibrium and criteria of equilibrium of the

cells were also essentially similar to that described in the said papers (3*c*,*d*).

Results

The emf (E) of cell [A] at any solvent composition is given by

$$[1]\quad E = E^0 - \frac{2.303\,RT}{F}\log(a_{H^+}\cdot a_{X^-})$$

where X = Br^- and I^- and the other terms have the usual significance. Replacing a_{H^+} in terms of K_s by $K_s a_{H_2O}/a_{OH^-}$, a_i of the ionic species by the product of molality (m_i) and the molal activity coefficient γ_i and 2.303 RT/F by k, we have an extrapolation function, $E^{0'}$ defined by [2]

$$[2]\quad E^{0'} = E + k\log\frac{m_{X^-}}{m_{OH^-}} + k\log K_s$$

$$= E^0 - k\log\frac{a_{H_2O}\gamma_{X^-}}{\gamma_{OH^-}} = E^0 + f(\mu)$$

As in previous cases (1, 3*c*,*d*), the standard states are so chosen that at infinite dilution in each solvent mixture the activity coefficient of ions concerned, as well as the activity of water (a_{H_2O}) are unity. Also, as the term $\log a_{H_2O}\gamma_{X^-}/\gamma_{OH^-}$ in dilute solution in each solvent mixture is as before (1, 3*c*,*d*) likely to be proportional to the "ionic strength" μ, extrapolation of the function $E^{0'}$ to $\mu = 0$ would yield E^0 values on the molal scale, henceforth denoted as E^0_m.

Notably, the values of K_s in eq. [2] are also based on this very assumption (see ref. 7) and not on the usual assumption of taking pure water as the standard state. Had the latter case been true the activity of water a_{H_2O} in each composition of the respective ionic and non-ionic cosolvent systems should have been accounted for. Eventually K_s values in the respective composition would have been altered by a constant factor $|-\log a_{H_2O}|$ depending upon the composition and the temperature. Evidently as in the cases of aquo-organic solvents (3*c*,*d*), E^0 values, though not K_s values, in this ionic cosolvent system would be independent of the assumed standard states.

Moreover, the "ionic strength" μ referred to above stands for that due to the "added" electrolytes viz. KX and KOH, in the respective compositions of $NaNO_3$ solutions. As indicated earlier (2) in our treatment the molalities of the added electrolytes are so small compared to the molalities of $NaNO_3$ in any composition that the "ionic strength" arising from the added electrolytes does not vary significantly and the effect of involved activity coefficient term is always small and disappears upon extrapolation to zero "ionic strength".

The E values of cell [A] at different temperatures after due correction to b_{H_2} = 1 atm, and the corresponding molalities of KOH, KI/KBr for each of the solvent mixtures are given elsewhere.[2] The required partial pressures of the mixed solvents for correcting b_{H_2} = 1 atm are taken from ref. 1.

Assuming as before (3*c*,*d*) that KOH and KI/KBr are completely dissociated in all these solvents m_{OH^-} and m_{I^-} or m_{Br^-} are taken as equal to m_1 and m_2, respectively, and $\mu = (m_1 + m_2)d_s$ where d_s is the density of the solvent. The values of d_s were obtained from the previous paper (1). The values of $E^{0'}$ computed by use of equation [2] at any temperature for any composition were then plotted against μ. And the resulting linear plots on extrapolation yielded the values of E^0_m which are given in Table 1. The uncertainties in the values of E^0_m so obtained lie within ±0.3 mV. Notably due to poisoning effect E^0_m values at 4 *m* $NaNO_3$ for Ag–AgBr electrode could not be determined.

As before (1), the E^0_m values at different temperatures for each solvent composition were then fitted into the E^0_m–temperature quadratic equation [3].

$$[3]\quad E^0_m = a + b(t - 25) + c(t - 25)^2$$

by the method of least squares where t is the temperature in degree Celcius. The coefficients a, b, and c for each of the solvent mixtures as well as for water are listed in Table 2. The E^0_m values in water for the Ag–AgBr and the Ag–AgI electrodes were taken from refs. 9 and 10, respectively.

The free energy changes ΔG^0_t accompanying the transfer of 1 mole of HX from the standard state in water (w) to that in each composition of $NaNO_3$ salt solution (s), i.e. of the process HX(w) → HX(s) were computed on the mole fraction scale at t = 25°C using the relation [4].

$$[4]\quad \Delta G^0_t(HX) = -F[(E^0_m)^{25}_s - (E^0_m)^{25}_s] - 2RT\ln\frac{M_s}{M_w}$$

where T = 298.15 and M_s and M_w are the average and pure molar mass of the mixed solvent and water, respectively. The corresponding entropy changes ΔS^0_t(HX) at 25°C were obtained by the use of eq. [5].

$$[5]\quad \Delta S^0_t(HX) = F(b_s - b_w) + 2F(t - 25)(c_s - c_w) + 2R\ln\frac{M_s}{M_w}$$

The values of ΔG^0_t and ΔS^0_t so obtained for HX for all the solvent compositions are presented in Table 2. The average estimated uncertainties (11) in ΔG^0_t and ΔS^0_t at 25°C for these mixed solvents are respectively ±0.03 kJ mol^{-1} and ±2 J K^{-1} mol^{-1}.

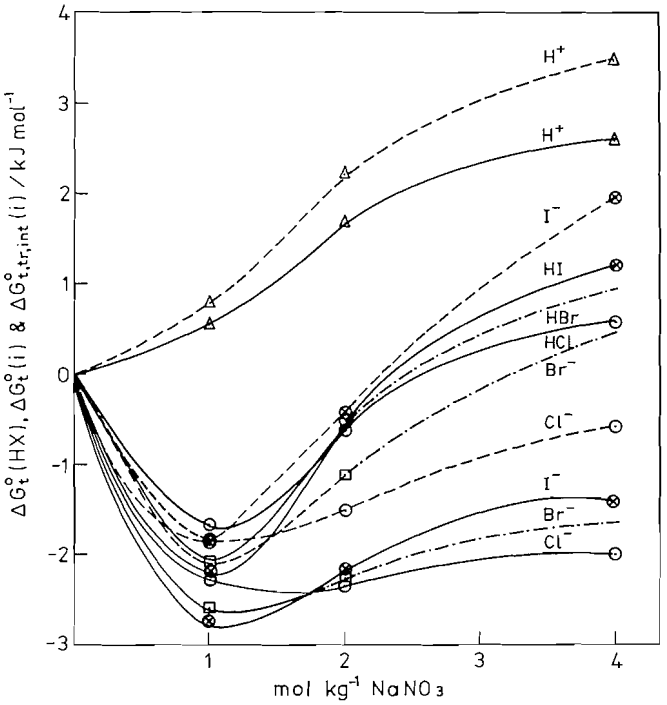

FIG. 1. Variation of ΔG_t^0(HX) of hydrogen halides, ΔG_t^0(i) (solid lines), and $\Delta G_{t,tr.int}^0$(i) (dotted lines) of different ions with molality of $NaNO_3$ in aqueous $NaNO_3$ solutions at 25°C.

Discussion

Free energy of transfer

ΔG_t^0(HX)–composition profiles are illustrated in Fig. 1. From Fig. 1 it is observed that ΔG_t^0–composition profiles of HX exhibit a slight roller-coaster type behaviour. A perusal of ΔG_t^0(HX) values (Table 2) including those for HCl (Table 3) as obtained from previous paper (*1*), reveals that up to 1.5 *m* $NaNO_3$ the downward trend of ΔG_t^0(HX) is in the order of HI > HBr > HCl but after 1.5 *m* $NaNO_3$ the upward trend of HI > HBr > HCl. So from Fig. 1 it can be said that the order of stabilisation of $I^- > Br^- > Cl^-$ in the initial compositions but the reverse is true at higher compositions. It is also evident from the ΔG_t^0(i)–composition profiles of H^+ and X^- as obtained by using the modified form of widely used tetraphenylarsonium tetraphenylborate reference electrolyte assumption (2) and are illustrated in Fig. 1.

In the previous paper (2) we have already accounted for the nature of ΔG_t^0(i)–composition profiles of H^+ and Cl^-. The behaviour of both Br^- and I^- being exactly similar to that of Cl^- we are now trying to account for the relative order of stabilization and destabilisation of the halide ions. Before doing so let us at first calculate tentatively the Born-type electrostatic effect $\Delta G_{t,Born}^0$ and cavity effect $\Delta G_{t,cav}^0$ by the simple Born equation (12) and the scaled particle theory (SPT) (13), respectively, as per formulation described and referred to in the previous papers (1, 2, 14). These and the required solvent and solute parameters are given in Table 3. Now the values of $\Delta G_{t,Born}^0$(i) and $\Delta G_{t,cav}^0$(i) when subtracted from the corresponding ΔG_t^0(i) values yielded $\Delta G_{t,tr.int}^0$(i) values, which are also illustrated in Fig. 1.

Significantly enough the composition profiles of $\Delta G_{t,tr.int}^0(X^-)$ are more or less similar to each other as well as to the respective profiles of $\Delta G_t^0(X^-)$. Their relative positions are of course

[a]The required diameters of the solvent constituents and the values of the scale effect $RT \ln V_w/V_s$ are taken from previous paper (1) and $\alpha = -\mathrm{d} \ln d_s/\mathrm{d}T$ also taken from that paper (1) and for solute species, $b_{Cl^-} = 0.362$ nm (9), $b_{Br^-} = 0.390$ nm (9), $b_{I^-} = 0.434$ nm (9).

[b]The required radii of the ionic species are obtained from the corresponding diameters of the species as indicated in *a* and that of H^+ as equal to 0.276 nm (1).

[c]The values within the parentheses are obtained by smooth extrapolation of the curve.

shifted upward as the magnitudes of $\Delta G^0_{t,tr.int}(X^-)$ are becoming increasingly less negative and in the case of I^- at higher composition of $NaNO_3$ these become even positive. However, it appears from the nature of $\Delta G^0_{t,tr.int}(X^-)$–composition profiles as well as their relative positions that X^- ions are stabilized at initial compositions. But beyond 1.5 *m* $NaNO_3$ composition X^- ions tend to become increasingly less stabilized and even destabilized, and the larger the size of X^- ion the greater is the tendency of destabilization.

As indicated in the previous papers (1, 2) and evidenced from various spectroscopic (15–17) and other evidences (18) in the solvent compositions up to 1.5 *m* $NaNO_3$ the prevalent ionic species are $(Na^+)_{aq}$ and NO_3^-. Now the observed stabilization of halide ions in the region therefore suggests that the attractive interaction of halide ions and $(Na^+)_{aq}$ over the repulsive interaction of halide ions and NO_3^- exceeds halide ion – H_2O interactions in pure water. This is probably due to the fact that the H_2O molecules in the hydration sphere round Na^+ have more protonic character (δ^+) than that in pure water and hence are likely to induce more "acid–base" type (19) short range attractive interaction with X^- than that in pure water. Now among Cl^-, Br^-, and I^- the charge density of $Cl^- > Br^- > I^-$, hence the repulsive interaction with unhydrated NO_3^- will be in the order of $Cl^- > Br^- > I^-$ but the attractive interaction with hydrated Na^+ is more for Cl^- than Br^- and I^- and hence the overall result is that the observed stabilization of Cl^-, Br^-, and I^- ions are more or less the same in the region.

But after 1–1.5 *m* $NaNO_3$ the reverse order, i.e., the order of less stabilization and even destabilization $I^- > Br^- > Cl^-$ is perhaps due to the change in solvating species. As various spectroscopic evidences (15–17) referred to earlier (1, 2) indicate, around 1.5–6.0 *m* $NaNO_3$ the constituent ions $(Na^+)_{aq}$ and NO_3^- are increasingly replaced by the solvent separated ion-pair (SSIP) viz. $(Na^+)_{aq}NO_3^-$. In SSIP the positive character round Na^+ is reduced to a greater extent by accompanying NO_3^- and consequently halide ions become increasingly destabilized with increasing concentration of $NaNO_3$. Now the relative order of destabilization $I^- > Br^- > Cl^-$ is probably due to the fact that owing to its smaller size and larger ionic force field the interaction of Cl^- with SSIP is greater than that of Br^- and I^- and also that of Br^- is greater than that of I^- ion.

Entropy of transfer

Figure 2 depicts the $T\Delta S^0_t$–composition profiles of HX at 25°C. The observed $T\Delta S^0_t$–composition profiles exhibit the characteristic maxima around 1.5 *m* $NaNO_3$ and after that show a downward trend followed by a slight upward trend at higher compositions. The maxima and also the downward trend follow the order HI > HBr > HCl. The nature of these profiles is of course contrary to the observed downward trend of non-electrolyte like *p*-nitroaniline (*p*NA) and benzoic acid (HBz) from the very beginning in aqueous $NaNO_3$ solutions (7) and as expected from the observed three-dimensional (3D) structure-breaking propensity of $NaNO_3$ (18). Of course, there is also a break around 1.5 *m* $NaNO_3$ in the case of *p*NA and HBz. Evidently complex structural contributions are involved in the transfer of hydrogen halides unlike that of *p*NA and HBz where the solvating species is only water.

Since the discussion of $T\Delta S^0_t(i)$–composition profile of H^+ and halide ions would be more informative about the involved ion–ion–solvent interactions and solvent structuredness, dissection of $T\Delta S^0_t(HX)$ into its ionic constituents are made by the modified form of the widely used tetraphenylarsonium tetraphenylborate RE assumption described in the previous paper (2) and are illustrated in Fig. 2. Figure 2 also depicts the $T\Delta S^0_{t,tr.int}(i)$–composition profiles of the halide ions and H^+, as obtained after subtracting $T\Delta S^0_{t,cav}(i)$ and $T\Delta S^0_{t,Born}(i)$ values from the corresponding $T\Delta S^0_t(i)$ values, the cavity and Born effects being computed by use of the formulations described in the previous paper (2). From Fig. 2 it is observed that as in the case of Cl^-, $\Delta S^0_t(i)/\Delta S^0_{t,tr.int}(i)$–composition profiles for Br^- and I^- also pass through a minimum around 1.5 *m* $NaNO_3$. But while the relative order of the downward trend of $\Delta S^0_t(X^-)$ values at initial compositions is $Cl^- > Br^- > I^-$, the upward trend at higher compositions is $Cl^- > Br^- > I^-$. On the other hand, while the $\Delta S^0_{t,tr.int}(X^-)$–composition profiles more or less overlap at the initial compositions the relative order of the upward trend at higher composition remains unaltered, i.e., $Cl^- > Br^- > I^-$.

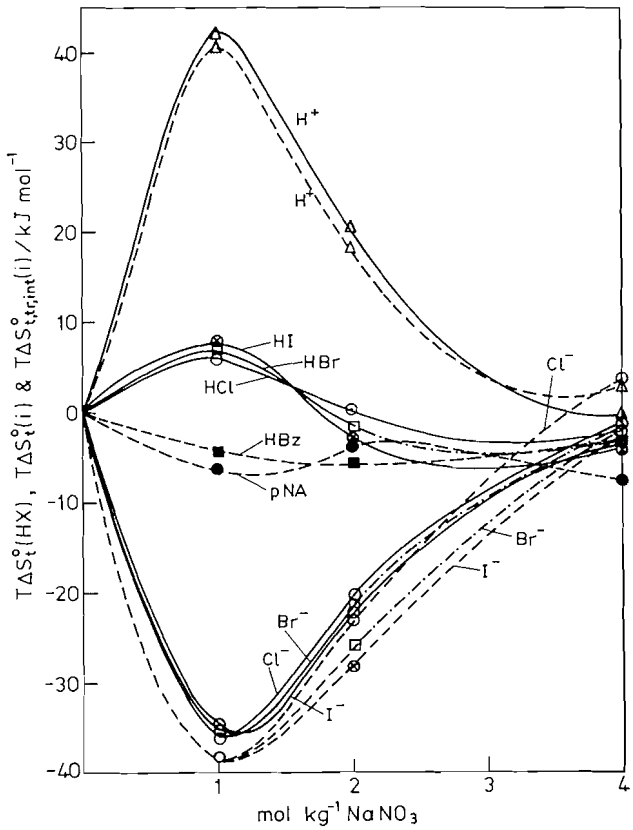

FIG. 2. Variation of $T\Delta S^0_t(HX)$ of hydrogen halides, $T\Delta S^0_t(i)$ (solid lines), and $T\Delta S^0_{t,tr.int}(i)$ (dotted lines) of different ions and also of pNA and HBz (dotted-lines) as obtained from ref. 7 with molality of $NaNO_3$ in aqueous $NaNO_3$ solutions at 25°C.

If we recall Kundu *et al.*'s four-step transfer process (1, 3*a*, 20) we have

$$\Delta S^0_{t,tr.int}(i) = (\Delta S^0_1 - \Delta S^0_2) + (\Delta S^0_3 - \Delta S^0_4)$$

where ΔS^0_1 is the positive entropy change accompanying the dehydration of the ion, if any, $|-\Delta S^0_2|$ is that accompanying the formation of 3D structure of water out of the molecules released from dehydration, ΔS^0_3 is the entropy change accompanying the break down of relevant structure of the solvents or of the solvating species in the solvent and $|-\Delta S^0_4|$ is that accompanying the interaction of the transferred ion with the solvating species in the solvent.

As indicated in course of explaining $\Delta S^0_{t,tr.int}(i)$–composition

profile for Cl^- (2) due to the large size, anions like Cl^-, Br^-, and I^- are nearly unhydrated and hence $\Delta S_1^0 \simeq 0$. But since the solvent molecules in the secondary solvation zone (SSZ) are in the disordered state, $|-\Delta S_2^0|$ and hence $|\Delta S_1^0 - \Delta S_2^0|$ will be a large negative quantity. And the SSZ around I^- being larger in size the magnitudes of $(\Delta S_1^0 - \Delta S_2^0)$ will be more negative for I^- than Br^- and Cl^-. But in the lower composition region, the halide ions are interacted upon by $(Na^+)_{aq}$ with $\Delta S_3^0 = 0$, and the order due to the interaction of Cl^- with $(Na^+)_{aq}$ will be greater than that of Br^- and I^- i.e. $(\Delta S_3^0 - \Delta S_4^0)$ will be more negative for Cl^- than Br^- and I^- and the overall magnitude $[(\Delta S_1^0 - \Delta S_2^0) + (\Delta S_3^0 - \Delta S_4^0)]$ might be more or less the same for the halide ions, as has been observed. But beyond 1.5 *m* $NaNO_3$ the "solvating" or interacting species are solvent-separated ion-pairs and hence the magnitude of ΔS_3^0 will be greater for Cl^- than that of Br^- and I^- and consequently the overall magnitude $[(\Delta S_1^0 - \Delta S_2^0) + (\Delta S_3^0 - \Delta S_4^0)]$ will be greater for Cl^- than Br^- and I^- and hence the observed order.

Notably, the mirror-image behaviour of $\Delta S_{t,tr.int}^0(i)$–composition profile of H^+ and also of other cations, which is true not only in this solvent system but also in other aquo-organic solvents (21–25), has been duly explained in our earlier paper (2).

Thus it appears that the order of $\Delta S_{t,tr.int}^0(i)$ rather than that of $\Delta S_t^0(i)$, conforms with what is expected from the four-step transfer process. And this substantiates our earlier contention (1, 2, 14) that $\Delta S_{t,tr.int}^0(i)$ should be a better indicator than $\Delta S_t^0(i)$ for inferring the relative structuredness of solvents.

The association equilibrium $(CH_3)_4Si + (CH_3)_3Si^+ \rightleftharpoons (CH_3)_7Si_2^+$ has been studied in a high pressure mass spectrometer ion source using tetramethylsilane/methane mixtures. Measurement of the equilibrium constant over a range of temperatures yields $\Delta H^0 = -22.3 \pm 0.4$ kcal mol^{-1} and $\Delta S^0 = -35.2 \pm 0.9$ cal mol^{-1} K^{-1}. Collision-assisted dissociation experiments suggest that the methyl groups retain their integrity in $(CH_3)_7Si_2^+$. Mixed ions such as $(CH_3)_7SiGe^+$ and $(CH_3)_7GeSn^+$ were not observed in mixtures of $(CH_3)_4X$ and $(CH_3)_4Y$ (X ≠ Y = Si, Ge, Sn). Instead CH_3^- transfer equilibrium reactions were observed viz. $(CH_3)_3Si^+ + (CH_3)_4Ge \rightleftharpoons (CH_3)_4Si + (CH_3)_3Ge^+$ ($\Delta H^0 = -10.2 \pm 1.2$ kcal mol^{-1}, $\Delta S^0 = -3.7 \pm 2.4$ cal K^{-1} mol^{-1}) and $(CH_3)_3Ge^+ + (CH_3)_4Sn \rightleftharpoons (CH_3)_4Ge + (CH_3)_3Sn^+$ ($\Delta H^0 = -8.1 \pm 0.9$ kcal mol^{-1}, $\Delta S^0 = -0.9 \pm 1.6$ cal K^{-1} mol^{-1}). These are in excellent agreement with some published differences in appearance potentials for $(CH_3)_3X^+$ from $(CH_3)_4X$ (X = Si, Ge, Sn).

ANASTASIA C. M. WOJTYNIAK, XIAOPING LI et JOHN A. STONE. Can. J. Chem. **65**, 2849 (1987).

Utilisant des mélanges de tétraméthylsilane/méthane, on a étudié l'équilibre d'association $(CH_3)_4Si + (CH_3)_3Si^+ \rightleftharpoons (CH_3)_7Si_2^+$ dans un spectromètre de masse à haute pression. En mesurant les constantes d'équilibre à diverses températures, on peut en déduire le $\Delta H^0 = -22{,}3 \pm 0{,}4$ kcal mol^{-1} et le $\Delta S^0 = -35{,}2 \pm 0{,}9$ cal mol^{-1} K^{-1}. Des expériences de dissociations assistées par des collisions suggèrent que les groupements méthyles conservent leur identité dans l'ion $(CH_3)_7Si_2^+$. On n'a pas observé la présence d'ions mixtes comme le $(CH_3)_7SiGe^+$ ou le $(CH_3)_7GeSn^+$ dans des mélanges de $(CH_3)_4X$ et $(CH_3)_4Y$ (X ≠ Y = Si, Ge, Sn). Toutefois, on a observé des réactions d'équilibre de transfert de CH_3^-; par exemple, $(CH_3)_3Si^+ + (CH_3)_4Ge \rightleftharpoons (CH_3)_4Si + (CH_3)_3Ge^+$ ($\Delta H^0 = -10{,}2 \pm 1{,}2$ kcal mol^{-1}, $\Delta S^0 = -3{,}7 \pm 2{,}4$ cal K^{-1} mol^{-1}) et $(CH_3)_3Ge^+ + (CH_3)_4Sn \rightleftharpoons (CH_3)_4Ge + (CH_3)_3Sn^+$ ($\Delta H^0 = -8{,}1 \pm 0{,}9$ kcal mol^{-1}, $\Delta S^0 = -0{,}9 \pm 1{,}6$ cal K^{-1} mol^{-1}). Ces valeurs sont en bon accord avec des valeurs publiées pour les différences dans les potentiels d'apparition des ions $(CH_3)_3X^+$ à partir des composés $(CH_3)_4X$ (X = Si, Ge, Sn).

[Traduit par la revue]

Introduction

The ion chemistry of $(CH_3)_4X$ (X = Si, Ge, Sn) is characterized by the formation of $(CH_3)_3X^+$. In the absence of other neutral molecules, $(CH_3)_3X^+$ associates with $(CH_3)_4X$ to yield ions which are described as $(CH_3)_7X_2^+$ although their structures have never been determined. $(CH_3)_7Si_2^+$ (m/z 161) was first reported in the mass spectrum of tetramethylsilane at a pressure of 5×10^{-3} Torr (1). Its formation was ascribed to the reaction

[1] $(CH_3)_4Si^+ + (CH_3)_4Si \rightarrow (CH_3)_7Si_2^+ + CH_3$

The formation of $(CH_3)_7Si_2^+$ was later observed in pure tetramethylsilane in a chemical ionization (CI) source at pressures up to 0.6 Torr (2). The suggested structure for $(CH_3)_7Si_2^+$ contained an Si—Si bond, one of the silicons being in the pentavalent state. This structure was proposed by analogy with pentavalent carbon containing ions such as CH_5^+. It is now known that CH_5^+ is better described in terms of CH_3^+ interacting with H_2, i.e., a structure with essentially a three centre, two electron bond (3). Klevan and Munson (4) studied the formation of $(CH_3)_7Si_2^+$ under similar CI conditions and showed that its relative intensity decreased with increasing ion source temperature. They confirmed, in agreement with ref. 2, that $(CH_3)_7Si_2^+$ is formed mainly by reaction of $(CH_3)_3Si^+$ with tetramethylsilane.

[2] $(CH_3)_3Si^+ + (CH_3)_4Si \rightarrow (CH_3)_7Si_2^+ * \xrightarrow{M} (CH_3)_7Si_2^+$

A kinetic analysis of the ion currents at low pressures and small extents of conversion as functions of temperature yielded an apparent activation energy for reaction [2] of −12 kcal mol^{-1}. Since ion–molecule association reactions have no activation energies the bond energy in the association complex was taken to be 12 kcal mol^{-1}. This is such a weak bond that at the temperatures employed, 343 to 443 K, only the presence of the high concentrations of $(CH_3)_4Si$ could allow observation of the association ion. Such a small binding energy is, however, not consistent with our observation of $(CH_3)_7Si_2^+$ in dilute mixtures (<3%) of tetramethylsilane in methane at 4 Torr and temperatures up to 500 K (5). Under these ion source conditions we never observe complexes with such small dissociation energies. We here report a more detailed study of reaction [2], in particular the determination of the reaction enthalpy and entropy.

We have previously reported the observation of $(CH_3)_7Sn_2^+$ in tetramethylstannane/methane mixtures (6) and of $(CH_3)_7Ge_2^+$ in tetramethylgermane/methane mixtures (7). No information was obtained on the binding energies in the complexes but the experimental conditions under which they were observed indicate binding energies considerably greater than 12 kcal mol^{-1}. Both tin and germanium have numerous stable isotopes and the isotopic patterns of $(CH_3)_7Sn_2^+$ and $(CH_3)_7Ge_2^+$ are complex and cover large m/z ranges. Mixed in with these $(CH_3)_7X_2^+$ ions is $(CH_3)_6X_2OH^+$ a protonated ether formed via the addition of adventitious water to $(CH_3)_3X^+$.

[3] $(CH_3)_3X^+ + H_2O \rightarrow (CH_3)_3XOH_2^+ \xrightarrow{(CH_3)_4X} (CH_3)_7XOH^+ + CH_4$

The spectrum is therefore very complex and we have not attempted to study it further. We have been unsuccessful in our attempts to observe mixed association ions of the form $(CH_3)_7XY^+$ (X ≠ Y = Si, Ge, Sn) but this study has led to

For personal use only.

observation of the CH_3^- transfer reactions described by reaction [4] for which we have been able to obtain both thermochemical and kinetic data.

[4] $(CH_3)_3X^+ + (CH_3)_4Y \rightleftharpoons (CH_3)_4X + (CH_3)_3Y^+$

Experimental

The high pressure ion source mass spectrometer equipped with pulsed electron beam has been described previously as has the method of preparing samples and collecting data (6, 7).

Collision assisted dissociation (CAD) spectra were obtained using a ZAB-2FQ reverse geometry instrument at the Ontario Regional Ion Chemistry Laboratory, Toronto, Canada. In this instrument $(CH_3)_7Si_2^+$ was prepared in 20/1 methane/tetramethylsilane mixtures at ~170°C and an ion source pressure of ~0.2 Torr. The collision gas was helium which was fed into the second field-free region after the magnetic analyzer at pressure sufficient to decrease the $(CH_3)_7Si_2^+$ beam intensity by ~5%.

Tetramethylsilane (MSD Isotopes, Montreal, Canada) and tetramethyltin (Strem Chemicals Inc., Newburyport, MA.) were dried over molecular sieve before use. Tetramethylgermanium (Alfa Inorganic) was purified by gas liquid chromatography to remove tetrahydrofuran and then dried over molecular sieve. Methane was from Matheson and was 99.99% pure.

Results

The normalized ion intensities for a $(CH_3)_4Si/CH_4$ (1/200) mixture after a short ionizing pulse of electrons at similar ion source pressures but two different temperatures are shown in Fig. 1. The reagent ions from methane (CH_5^+ and $C_2H_5^+$) react with $(CH_3)_4Si$ to give $(CH_3)_3Si^+$ and the subsequent reaction of this ion with $(CH_3)_4Si$ and adventitious water leads to the array of ions shown in the figure (5). It is immediately apparent that the reaction leading to $(CH_3)_7Si_2^+$ is much faster than any other reaction of $(CH_3)_3Si^+$ and indeed the build-up of the $(CH_3)_7Si_2^+$ ion intensity is not observed on the time scale shown. It occurs during the electron beam pulse. The parallellism between the yield curves for $(CH_3)_3Si^+$ and $(CH_3)_7Si_2^+$ strongly suggests that the following equilibrium occurs.

[5] $(CH_3)_3Si^+ + (CH_3)_4Si \rightleftharpoons (CH_3)_7Si_2^+$

Computed equilibrium constants for this reaction were found to be independent of total pressure and $(CH_3)_4Si$ concentration. Figure 2 shows the results for a temperature of 431 K when the equilibrium constant may be measured over particularly large ranges of composition and ion source pressure. The van't Hoff plot shown in Fig. 3 yields $\Delta H_5^0 = -22.3 \pm 0.4$ kcal mol^{-1} and $\Delta S_5^0 = -35.2 \pm 0.9$ cal mol^{-1} K^{-1}. This measured binding energy, $D((CH_3)_3Si^+ - (CH_3)_4Si)$ is almost double that suggested by Klevan and Munson (4) and the accompanying very large decrease in entropy shows that a covalent condensation product rather than a much looser cluster is probably being formed. Clustering is associated with standard entropy changes of ~20 cal K^{-1} mol^{-1} (8).

Information regarding the structure of $(CH_3)_7Si_2^+$ (m/z 161) was sought from its unimolecular dissociation and from ions formed by its collision assisted dissociation. The ion source conditions in the ZAB-2FQ instrument were not comparable to those in the high pressure, field-free ion source in which the thermochemical measurements were made. The much lower pressure in the more open source allowing some acceleration field penetration and the high ambient ion source temperature in the ZAB-2FQ almost certainly led to the ions under study being non-thermalized. For example, in the low pressure ZAB-2FQ source m/z 145 and 131 were equally as prominent as m/z 161

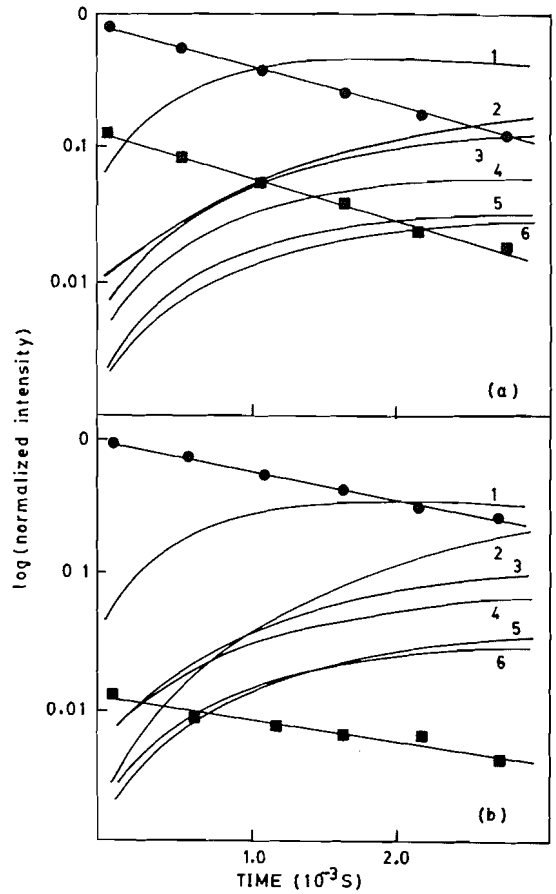

FIG. 1. Normalized ion intensities vs. time after a 30 μs ionizing pulse of electrons in a tetramethylsilane/methane (1/200) mixture at 4.5 Torr and (*a*) 429 K and (*b*) 468 K. ● $(CH_3)_3Si^+$, ■ $(CH_3)_7Si_2^+$. For clarity the experimental points are not shown for the other ions. The curves are for: *1*, $(CH_3)_3SiOH_2^+$; *2*, $(CH_3)_6Si_2OH^+$; *3*, $(CH_3)_3Si_2^+$; *4*, $(CH_3)_6Si_2H^+$; *5*, $C_4H_{13}SiO^+$; *6*, $C_4H_{11}SiO^+$.

whereas m/z 131 was small in the high pressure source and m/z 145 was never observed. m/z 145 and 131 have been reported in earlier CI studies (2, 4, 9) and in particular m/z 145 increased in yield with increasing pressure. Klevan and Munson (4) report that m/z 145 is kinetically one order higher than m/z 161 and that it arises from the reaction of m/z 161 with tetramethylsilane, although the nature of this reaction is not spelled out.

The unimolecular and the CAD spectra of $(CH_3)_7Si_2^+$ are shown in Table 1. There are only three significant ions in the unimolecular spectrum and it is to be noted that m/z 145 is not one of them and indeed it is absent from the spectrum. H_2 loss leads to m/z 159, an ion whose intensity is only ~1% of that of m/z 161 in the main beam. The major unimolecular decomposition leads to regeneration of $(CH_3)_3Si^+$. It could not be determined whether the two silicon atoms in the reactants which form $(CH_3)_7Si_2^+$ lose their identities or whether the reversal of reaction [5] preserves the initial identities. The only other significant unimolecular dissociation leads to m/z 87 which arises by loss of trimethylsilane.

[6] $(CH_3)_7Si_2^+ \rightarrow C_4H_{11}Si^+ + (CH_3)_3SiH$
(m/z 87)

The yields in the CAD spectrum relative to those in the unimolecular spectrum show slight reductions in relative abundances for all the common ions but the absolute intensites

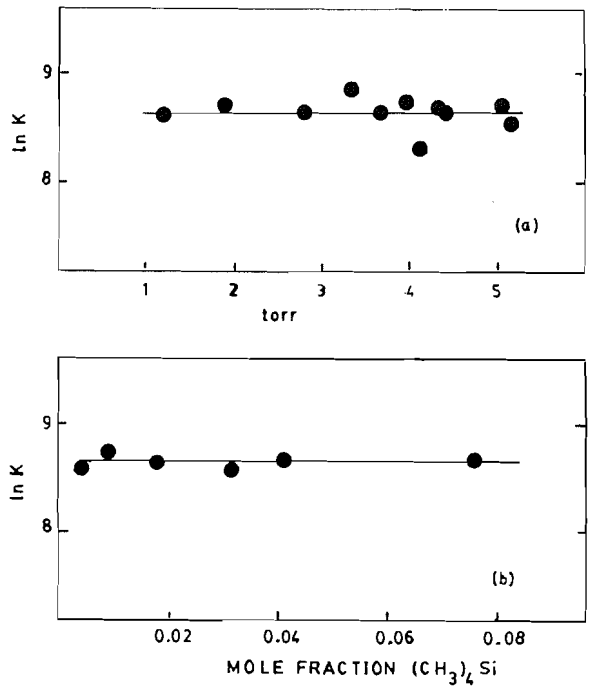

FIG. 2. The constancy with (*a*) total ion source pressure and (*b*) mole fraction of $(CH_3)_4Si$ of the equilibrium constant for the reaction $(CH_3)_4Si + (CH_3)_3Si^+ \rightleftharpoons (CH_3)_7Si_2^+$. Temperature 431 K. Mole fraction $(CH_3)_4Si$ in (*a*) is 0.018; ion source pressure in (*b*) is ~4 Torr.

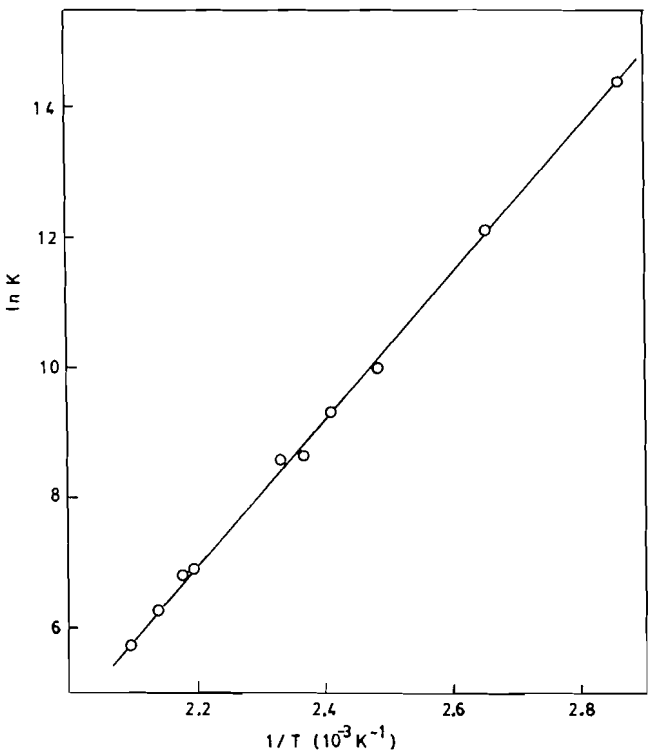

FIG. 3. van't Hoff plot for the equilibrium $(CH_3)_3Si^+ + (CH_3)_4Si \rightleftharpoons (CH_3)_7Si_2^+$.

are actually much greater, i.e., these ions are also produced as major ions by collsional excitation. The loss of $(CH_3)_4Si$ to give $(CH_3)_3Si^+$ accounts for 75% of total decomposition in both unimolecular and CAD spectra. In the CAD spectrum the groups of peaks around m/z values, 145, 131, 115 attest to the losses of 1, 2, and 3 methyl groups leaving ions still retaining both Si atoms. The most significant of these is m/z 145 resulting from the loss of CH_4.

TABLE 1. Relative abundances of fragment ions from m/z 161 in MIKE spectra

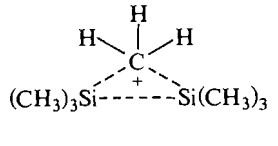
			Relative abundance	
m/z	Ion	Loss	Unimolecular	CAD[a]
160	$C_7H_{20}Si_2^+$	H	—	2
159	$C_7H_{19}Si_2^+$	H_2	10	5
146	$C_6H_{18}Si_2^+$	CH_3	—	2
145	$C_6H_{17}Si_2^+$	CH_4	—	4
133	$C_5H_{17}Si_2^+$	C_2H_4	2	1
131	$C_5H_{15}Si^{2+}$	C_2H_6	—	1
129	$C_5H_{13}Si^{2+}$		—	1
119	$C_4H_{15}Si_2^+$	C_3H_6	2	—
117	$C_4H_{13}Si_2^+$	C_3H_8	—	1
115	$C_4H_{11}Si_2^+$	$C_3H_8 + H_2$	—	1
101	$C_3H_9Si_2^+$	$C_4H_{10} + H_2$	1	2
87	$C_4H_{11}Si^+$	$(CH_3)_3SiH$	11	3
73	$(CH_3)_3Si^+$	$(CH_3)_4Si$	74	76

[a]He introduced as collision gas.

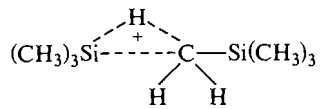
[7] $(CH_3)_7Si_2^+ \rightarrow C_6H_{17}Si_2^+ + CH_4$
(m/z 145)

The observation of this ion in earlier CI studies and in particular the kinetics of its formation observed by Klevan and Munson (4) show that it was most probably formed by the collisional dissociation of $(CH_3)_7Si_2^+$. m/z 145 was observed in the mass spectrum of tetramethylsilane/methane mixtures under CI conditions in the ZAB-2FQ but since no unimolecular dissociation corresponding to reaction [7] was observed it must be formed in a very fast reaction involving an excited $(CH_3)_7Si_2^+$.

$(CH_3)_7Si_2^+$ has been described as $(CH_3)_3Si—Si(CH_3)_4^+$ (2), $(CH_3)_3SiCH_2Si(CH_3)_3H^+$ (1), and as a product of the insertion of $(CH_3)_3Si^+$ into either an Si—C or C—H bond of $(CH_3)_4Si$ (4). The first structure involving a silicon–silicon bond can be ruled out since it involves the formation of pentavalent silicon. Neutral hypervalent silicon compounds have only been observed in structurally stabilized species with electron donor ligands such as oxygen atoms (10) or in anions (11). The electrophilic $(CH_3)_3)Si^+$ cation is not expected to induce hypervalency in the silicon of $(CH_3)_4Si$. SiH_5^+ (like CH_5^+) is best described as H_3Si^+ added across H—H (12). The second structure appears to be the equivalent of a protonated, substituted methane which would be unstable towards proton transfer. There is no evidence for m/z 161 being a Brønsted acid. The two possible structures resulting from insertion are:



I



II

Klevan and Munson (4) favoured **I** over **II** for several reasons. They surmised that hydride transfer to yield m/z 87 (reaction [6]) would be sufficiently endothermic for **II** to prevent its decomposition by this path. In addition they suggested that **I** can

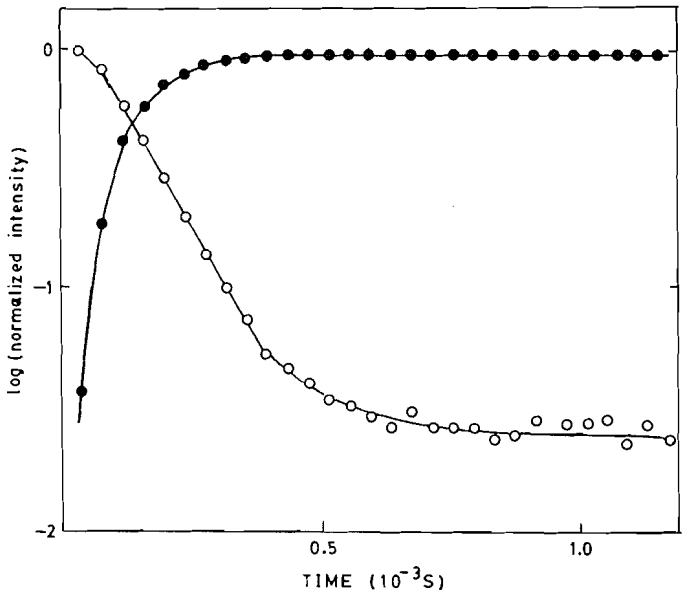


FIG. 4. The normalized intensities of $(CH_3)_3Sn^+$ ● and $(CH_3)_3Ge^+$ ○ in a $(CH_3)_4Sn/(CH_3)_4Ge/CH_4$ (0.0053/0.00026/1) mixture at 2.45 Torr and 565 K. The equilibrium constant for the CH_3^- transfer process $(CH_3)_3Ge^+ + (CH_3)_4Sn \rightleftharpoons (CH_3)_4Ge + (CH_3)_3Sn^+$ is obtained from the constant ratio of normalized ion intensities at long reaction times. The rate constant for the forward reaction is obtained from the slope of the initial linear portion of the $(CH_3)_3Ge^+$ curve.

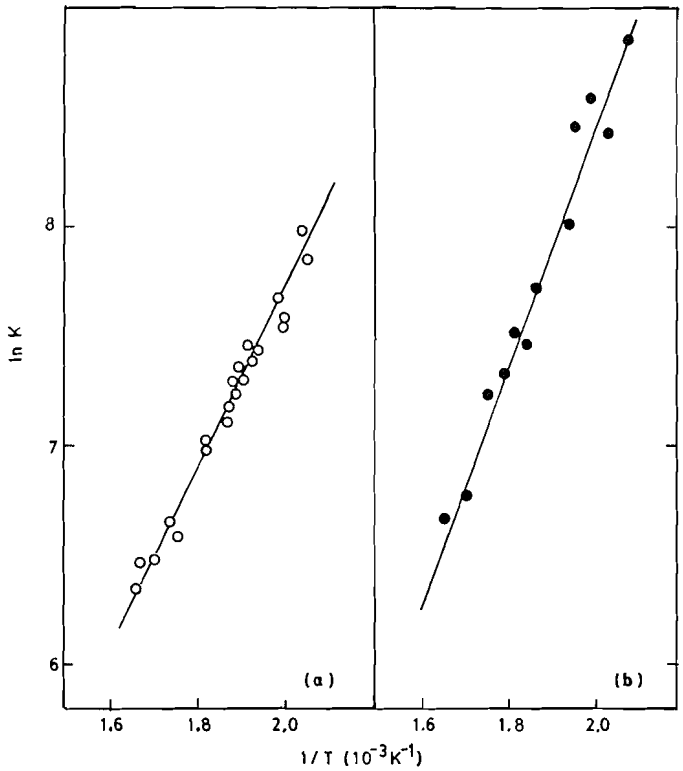

FIG. 5. van't Hoff plots for the equilibria (*a*) $(CH_3)_3Ge^+ + (CH_3)_4Sn \rightleftharpoons (CH_3)_4Ge + (CH_3)_3Sn^+$ and (*b*) $(CH_3)_3Si^+ + (CH_3)_4Ge \rightleftharpoons (CH_3)_4Si + (CH_3)_3Ge^+$.

react more readily than **II** by elimination of methane to give m/z 145 (reaction [7]). They also made analogies with carbon chemistry which are not supported by later experimental and theoretical results. For example, Hiraoka and Kebarle examined the reaction of $C_2H_5^+$ with ethane and provide thermodynamic data consistent with insertion into the alkane C—H bond followed by further rearrangement leading to loss of molecular hydrogen (13). We have shown above that reaction [7] involves an excited m/z 161 and therefore Klevan and Munson's arguments regarding ions in their ground states are not valid. Hydrogen loss is observed and m/z 145 is absent in the unimolecular decomposition spectrum m/z 161 and by analogy with Hiroaka and Kebarle's results a case may be made for structure **II**. Our experiments do not allow us to decide in favour of one structure or the other. We have found, however, that CH_3^- transfer occurs in mixtures of trimethylsilylalkyl compounds under CI conditions (14). Such reactions most probably proceed via a complex of the form $(CH_3)_6Si_2R^+$ which implies that a structure such as **I** is present on the reaction coordinate.

Methide transfer reactions

Since $(CH_3)_7X_2^+$ ions were found for X = Si, Ge, and Sn a search was made using the high pressure source for mixed ions, e.g., $(CH_3)_7SiGe^+$ in $(CH_3)_4Ge/(CH_3)_4Si/CH_4$ mixtures. None was ever observed. We also failed to observe the mixed ion $(CH_3)_7CSi^+$ in $(CH_3)_4C/(CH_3)_4Si/CH_4$ mixtures whose existence was speculated upon by Klevan and Munson (4). They could not draw any conclusion regarding its presence in their system since $(CH_3)_7CSi^+$ (m/z 145) is isobaric with $(CH_3)_5Si_2^+$. We had no such problem. In such "mixed" systems each of the different $(CH_3)_7X_2^+$ ions (X = Si, Ge, Sn) could be observed under suitable conditions, the relative yields, however, being regulated by the competing CH_3^- transfer reactions [8]–[10].

[8] $(CH_3)_3Si^+ + (CH_3)_4Ge \rightleftharpoons (CH_3)_4Si + (CH_3)_3Ge^+$

[9] $(CH_3)_3Si^+ + (CH_3)_4Sn \rightleftharpoons (CH_3)_4Si + (CH_3)_3Sn^+$

[10] $(CH_3)_3Ge^+ + (CH_3)_4Sn \rightleftharpoons (CH_3)_4Ge + (CH_3)_3Sn^+$

Equilibria [8] and [10] could be studied under suitable experimental conditions as illustrated in Fig. 4. The van't Hoff plots in Fig. 5 provide the thermodynamic data in Table 2. The error limits in Table 2 are one standard deviation from a least squares regression analysis of the data. These error limits are <6% of the absolute values of ΔH^0. The equilibrium constant for reaction [9] is very large and it was possible to attain equilibrium at long reaction times only at the highest attainable temperature (600 K). The measured equilibrium constant gave $\Delta G_9^0 = -15.9$ kcal mol^{-1} in excellent agreement with the sum $\Delta G_8^0 + \Delta G_{10}^0 = -15.7$ kcal mol^{-1} at the same temperature.

$(CH_3)_7XY^+$ ions are probably formed as unstable intermediates in reactions [8], [9], and [10] but fast exothermic, bimolecular dissociation precludes collisional stabilization. It might be possible to observe these weakly bonded complexes as stabilized ions by working at significantly higher pressure or at sub-ambient temperatures. Neither of these options is presently available in our laboratory.

Experimentally determined enthalpies of formation of silicon, germanium, and tin compounds are few and those that are available are not mutually consistent. Walsh (15, 16) has discussed the available data for some organosilicon compounds and cations and notes the high uncertainties prevalent in the literature for their enthalpies of formation. In particular and relevant to this study, $\Delta H_f^0((CH_3)_3Si^+)$ has a spread in literature values from 141 to 151 kcal mol^{-1}. There are similar uncertainties in the measured enthalpies of formation of neutral

TABLE 2. Thermodynamic data for the equilibria $(CH_3)_3X^+ + (CH_3)_4Y \rightleftharpoons (CH_3)_4X + (CH_3)_3Y^+$

X	Y	$-\Delta H^{0a}$ (kcal mol^{-1})	$-\Delta S^{0a}$ (cal K^{-1} mol^{-1})	$-\Delta H^0$(calc)^b (kcal mol^{-1})
Si	Ge	10.2 ± 0.6^c	3.7 ± 1.2	9.8
Ge	Sn	8.1 ± 0.5	0.9 ± 0.8	8.1
Si	Sn	18.4^d	4.6 ± 2.0^e	17.9

[a]Thermodynamic data from Fig. 5.
[b]Calculated from standard enthalpies of formation in ref. 21.
[c]Error limits are one standard deviation from a least-squares analysis.
[d]Calculated using the experimentally determined $\Delta G^0_{600} = -15.9$ kcal mol^{-1} and $\Delta S^0 = 4.6$ cal M^{-1} mol^{-1}.
[e]The sum of the two above values.

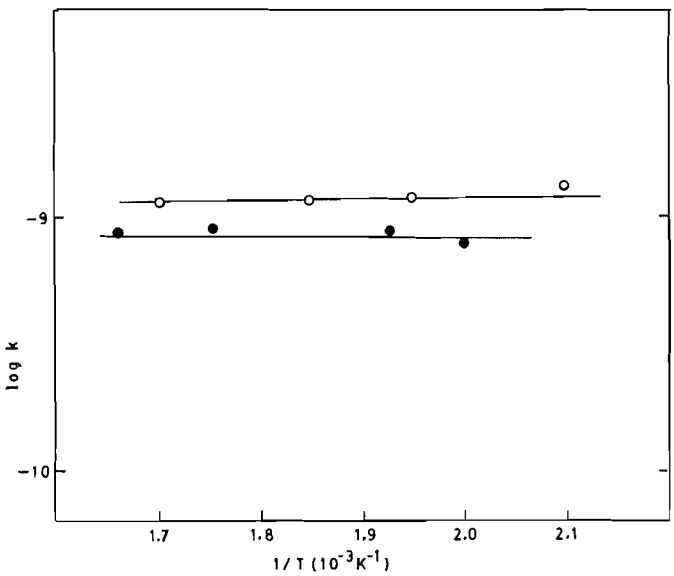

FIG. 6. Rate constants for CH_3^- transfer: ○, $(CH_3)_3Si^+ + (CH_3)_4Ge \rightarrow (CH_3)_4Si + (CH_3)_3Ge^+$; ●, $(CH_3)_3Ge^+ + (CH_3)_4Sn \rightarrow (CH_3)_4Ge + (CH_3)_3Sn^+$. The units of k are cm^3 molecule^{-1} s^{-1}.

organosilicon compounds. For example a tabulated value of -58.7 ± 2.4 kcal mol^{-1} (17) for $\Delta H_f^0((CH_3)_4Si)$ is close to a more recently determined value of -55.4 kcal mol^{-1} (18) but both are very different from the mass spectrometric value of -42.4 kcal mol^{-1} (19) favoured by Davidson (20) in his listing of self-consistent enthalpies of formation of the methylsilanes.

Relevant thermochemical data for silicon, germanium, and tin neutrals and ions are contained in a set of internally "self-consistent" values based on mass spectrometric ionization and appearance energies (21). The preferred value of $\Delta H_f^0((CH_3)_4Si) = -48.25$ kcal mol^{-1} is considerably different from the -55.4 kcal mol^{-1} preferred by Walsh (16) in his critical analysis of the thermochemistry of some silicon compounds. $\Delta H_f^0((CH_3)_4Ge) = -32.0 \pm 3.0$ kcal mol^{-1} is estimated in ref. 16 using unpublished results on $(C_2H_5)_4Ge$ and an assumed small correction for the change from ethyl to methyl. This value is lower than a recent bomb calorimetric determination of -24.5 ± 2.0 kcal mol^{-1} (22) and much lower than the value of -16.9 ± 2.3 kcal mol^{-1} given in a later compendium of thermochemical data (17). The latter collection does, however, retain essentially the same value of -3.35 kcal mol^{-1} for $\Delta H_f^0((CH_3)_4Sn)$.

Obviously there are no "accepted values" of thermochemical data with which to compare the present results. Surprisingly the results from these methide transfer experiments are in remarkably good agreement with the "self consistent" data of ref. 21 as shown in Table 2. This becomes understandable if the enthalpy change for CH_3^- transfer is written in terms of X—C bond dissociation energies, $D((CH_3)_3X—CH_3)$ and ionization energies of the trimethyl radicals, IE$((CH_3)_3X)$. For example, for reaction [8]:

$$\Delta H^0 = \mathrm{IE}((CH_3)_3Ge) + D((CH_3)_3Ge—CH_3) - \mathrm{IE}((CH_3)_3Si) - D((CH_3)_3Si—CH_3) = \mathrm{AP}((CH_3)_3Ge^+) - \mathrm{AP}((CH_3))_3Si^+)$$

$\mathrm{AP}((CH_3)_3X^+)$ is the appearance energy of $(CH_3)_3X^+$ from $(CH_3)_4X$. The concordance of our CH_3^- transfer results therefore validates the *relative* AP values for $(CH_3)_3Si^+$, $(CH_3)_3Ge^+$, and $(CH_3)_3Sn^+$ used in ref. 21 to derive ΔH_f^0 values. The absolute values are probably not too accurate, for example $\mathrm{AP}((CH_3)_3Si^+) = 242.4 \pm 4.6$ kcal mol^{-1} compared with a value of 235.95 ± 6.2 kcal mol^{-1} deducible from the data of Walsh (16) which is in agreement with the experimental 236.5 kcal mol^{-1} of Potzinger, Ritter, and Krause (19). The wide error limits for each value attest to the present state of knowledge.

Using the latest calorimetric value of $\Delta H_f^0((CH_3)_4Ge) = -24.5$ kcal mol^{-1} (22) together with $\Delta H_f^0((CH_3)_3Si^+) = 145.8$ kcal mol^{-1} (15), $\Delta H_f^0((CH_3)_4Si) = -55.7$ kcal mol^{-1} (18), and $\Delta H_8 = -10.2$ kcal mol^{-1} then $\Delta H_f^0((CH_3)_3Ge^+) = 166.8$ kcal mol^{-1}. This value, together with $\Delta H_f^0(\cdot CH_3) = 34.4$ kcal mol^{-1} (23) yields an appearance energy for $(CH_3)_3Ge^+$ from $(CH_3)_4Ge$ of 225.7 kcal mol^{-1} (9.79 eV). This is a significantly lower value than the 10.05 eV of ref. 21 but is tied to the more acceptable appearance potential for $(CH_3)_3Si^+$ from $(CH_3)_4Si$ of 10.23 eV calculable from the data of ref. 15.

Methide transfer equilibrium measurements such as the ones described in this paper provide precise information on appearance potential differences and might be used to more precisely define the thermochemistry of gas phase silicon ions and molecules if a link could be established by equilibrium methods to ions and neutrals with known thermochemical properties. We have been unsuccessful so far in establishing such a link to either hydrocarbons or halocarbons. We are pursuing such ideas.

The rate constants for methide ion transfer were measured for the forward directions of reactions [8] and [10]. Both reactions proceed with virtually unit efficiency; the calculated Langevin collision rate constants are 1.22×10^{-9} and 1.06×10^{-9} cm^3 molecule^{-1} s^{-1} for reactions [8] and [10], respectively. As seen in Fig. 6 the rate constants are independent of temperature as expected for fast exothermic reactions involving non-polar neutrals.

Platinum complexes with sterically demanding ligands: *trans*-bis(2,7-diazatetracyclo[6.3.0.0^{4,9}.0^{5,11}]undecane-*N*,*N*′)platinum(II) dichloride tetrahydrate

B. E. Brown, R. Faggiani, D. Hughes, and C. J. L. Lock[1]

The Laboratories for Inorganic Medicine, McMaster University, SSC-426, Hamilton, Ont., Canada L8S 4M1

Received May 7, 1987

B. E. Brown, R. Faggiani, D. Hughes, and C. J. L. Lock. Can. J. Chem. **65**, 2855 (1987).

The complex $[Pt(C_9H_{14}N_2)_2]Cl_2.4H_2O$ was isolated from a reaction mixture containing $K_2[PtCl_4]$ and a norbornane-based diamine, $C_9H_{14}N_2$. This product was analyzed with use of elemental analysis, nuclear magnetic resonance spectroscopy, and X-ray crystallography. $[Pt(C_9H_{14}N_2)_2]Cl_2.4H_2O$ crystallized in the triclinic system, space group $P\bar{1}$, a = 9.437(1) Å, b = 9.975(1) Å, c = 6.888(1) Å, α = 109.54(1)°, β = 109.71(1)°, γ = 93.63(1)°, Z = 1. The X-ray data were collected with use of a Syntex $P2_1$ diffractometer and MoKα radiation and the structure solved by the heavy atom method. Based on 1983 reflections, the structure was refined to R = 0.0310 and R_w = 0.0408. The platinum resides on an inversion center and is coordinated to the nitrogen atoms of the secondary amines. The chelating N—Pt—N angle is 79° but otherwise the bond lengths and angles agree well with values for similar structures.

B. E. Brown, R. Faggiani, D. Hughes et C. J. L. Lock. Can. J. Chem. **65**, 2855 (1987).

On a isolé le complexe $[Pt(C_9H_{14}N_2)_2]Cl_2.4H_2O$ d'un mélange réactionnel contenant du $K_2[PtCl_4]$ et une diamine, $C_9H_{14}N_2$, dérivée du norbornane. On a analysé ce produit en faisant appel à l'analyse centésimale, à la résonance magnétique nucléaire et à la diffraction des rayons-X. Le $[Pt(C_9H_{14}N_2)_2]Cl_2.4H_2O$ cristallise dans le système triclinique, groupe d'espace $P\bar{1}$, avec a = 9,437(1), b = 9,975(1) et c = 6,888(1) Å, α = 109,54(1), β = 109,71(1) et γ = 93,63(1)° et Z = 1. On a accumulé les données à l'aide d'un diffractométre Syntex $P2_1$ et de la radiation MoKα et on a résolu la structure par la méthode des atomes lourds. En se basant sur 1983 réflexions, on a affiné la structure jusqu'à des valeurs de R = 0,0310 et R_w = 0,0408. Le platine se trouve sur un centre d'inversion et il est coordonné aux atomes d'azote des amines secondaires. L'angle de chélation N—Pt—N est de 79°; par ailleurs, les longueurs des liaisons et les angles sont en bon accord avec les valeurs observées dans des structures semblables.

[Traduit par la revue]

Introduction

The anti-cancer drug *cis*-dichlorodiammineplatinum(II), cisplatin, represents a group of platinum(II) complexes that show anti-tumour activities (1). The major drawback to administering cisplatin is its renal toxicity (2). It has been shown, however, that replacement of the amine ligands by either cyclic amines or bulky amines reduces the toxicity (3, 4). We have attempted to prepare platinum complexes of the bulky polycyclic amine 2,7-diazatetracyclo[6.3.0.0^{4,9}.0^{5,11}]undecane, $C_9H_{14}N_2$. Two compounds were isolated from the reaction, the first a brown, insoluble powder, probably of a polymeric nature, and the second as colourless, plate-like crystals. This second compound was identified by single crystal X-ray diffraction and was shown to be *trans*-bis(2,7-diazatetracyclo[6.3.0.0^{4,9}.0^{5,11}]undecane-*N*,*N*′)platinum(II) dichloride tetrahydrate, **A**. The compounds were also examined by infrared and ^{1}H and ^{13}C nmr spectroscopy. The expected 1:1 platinum:diamine complex, *cis*-dichloro(2,7-diazatetracyclo[6.3.0.0^{4,9}.0^{5,11}]undecane-*N*,*N*′)-platinum(II), **B**, was not isolated.

Experimental procedures

The 2,7-diazatetracyclo[6.3.0.0^{4,9}.0^{5,11}]undecane was supplied by Dr. D. N. Butler at York University, Toronto, Ontario. The $K_2[PtCl_4]$ was prepared according to Kauffman and Cowan (5).

Preparation of $[Pt(C_9H_{14}N_2)_2]Cl_2.4H_2O$, A

A was prepared by dissolving 0.344 g $K_2[PtCl_4]$ (0.83 mmol) and 0.125 g of $C_9H_{14}N_2$ (0.83 mmol) in 50 mL of N_2-purged distilled water. The reaction was carried out under a nitrogen atmosphere, with the exclusion of light. The pH was maintained at 7.0–7.5 by reaction, as necessary, with dilute aqueous $NaHCO_3$ and HCl solutions. After 5 h a light brown powder had formed and was filtered off and the colourless filtrate evaporated to yield colourless plate-like crystals (yield ≤10%).

Infrared spectra were recorded on a Perkin-Elmer 283 grating spectrometer in the range 4000–200 cm^{-1}. The samples were prepared as KBr pellets. Spectra were calibrated against polystyrene and indene. Raman spectra from powder samples were excited by a Coherent Radiation Argon Laser Model 52 and measured in the range 3000–50 cm^{-1} on a Spex spectrometer Model 14018. Satisfactory spectra were obtained from the ligand, but the platinum complex, **A**, decomposed in the beam, even when the sample was cooled to 77 K. Spectral calibrations were made with use of $HgCl_2$.

Proton nmr spectra were recorded at 500.137 MHz on a Bruker AM-500 spectrometer. The single-pulse spectra were recorded over a 5.0 kHz sweep width in 32K data points (3.277 s acquisition time). Suppression of the HDO resonance was achieved by pre-saturation during the 1.0 s delay before acquisition. Sample temperature was maintained at 30 ± 1°C by a Bruker B-VT1000 variable temperature unit. The free induction decays were processed with use of Gaussian multiplication for resolution enhancement.

The ^{13}C nmr spectra were obtained at 125.759 MHz over a sweep width of 29.4 kHz in 32K data points (0.557 s acquisition time). A 2 Hz exponential line broadening was applied to the FID before Fourier transformation. The number of directly bonded protons was determined with use of the standard J-modulated spin echo pulse sequence with a 1.0 s relaxation delay and ^{13}C 90° pulse of 6.8 μs.

The ^{1}H COSY 2-D nmr spectra of the diamine were acquired with use of the pulse sequence 90°–z–90° sequence. The 90° ^{1}H pulse on the 5 mm dual frequency probe was 18.0 μs. The HDO resonance was suppressed by pre-saturation during the 2.0 s relaxation delay and evolution time before acquisition. Spectra were acquired over a sweep width of 1449.28 Hz in 1K data points in F2 with 64 scans for each of the 256 FID's. Zero-filling in the F1 dimension during 2-D Fourier transformation produced a 512 × 512 data matrix with a digital resolution of 2.831 Hz/point in both dimensions. All spectra were transformed with the application of the squared sine-bell function in both dimensions, followed by symmetrization of the transformed matrix.

Secondary extinction correction (x)[b]	0.0066(13)
$F(000)$	314.0
Number of variables	190
Error in obs. of unit wt.	1.1914

[a] $R = [\Sigma||F_o| - |F_c||]/\Sigma|F_o|$; $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)^{1/2}$.

[b] x is the secondary extinction factor given by the equation $F_c^* = F_c(1 - 0.0001(x)F_c^2/\sin\theta)$, where F_c^* and F_c are the values of the calculated structure factor corrected and not corrected for secondary extinction.

Samples were dissolved in 99.8% D_2O (MSD Isotopes) to concentrations of 3×10^{-4} M for the diamine and 1×10^{-4} M for the Pt-complex. Proton chemical shifts are reported in ppm relative to external sodium 4,4-dimethy-4-silapentan-1-sulfonate while ^{13}C chemical shifts are in ppm relative to external tetramethylsilane.

Collection of diffraction data and structure solution

A colourless, plate-like crystal was cut and ground to an acicular crystal of suitable size and sealed in a Lindemann capillary. Space groups $P1$ or $P\bar{1}$ were consistent with precession photographs. The latter was chosen and justified by the successful solution of the structure. A Delaunay reduction revealed no hidden symmetry. The cell parameters were determined by a least-squares refinement based on 15 automatically centered independent reflections in the range $21° \leq 2\theta \leq 29°$. Intensities were measured at 22°C on a Syntex $P2_1$ diffractometer with the use of graphite monochromatized MoKα radiation ($\lambda = 0.71069$ Å). Crystal data and other numbers related to data collection are summarized in Table 1. Corrections were made for Lorentz-polarization and absorption.[2]

The platinum atom was located on the inversion center, 0,0,0. The positions of the remaining atoms were obtained from subsequent full-matrix least-squares refinement and electron density difference calculations. Further refinement with use of anisotropic temperature factors for all non-hydrogen atoms, minimized $\Sigma w(|F_o| - |F_c|)^2$ until the final maximum shift/error was $\simeq 0.3$. Corrections were made for secondary extinction by the SHELX method (6). Scattering curves were taken from Cromer and Waber (7). Anomalous dispersion corrections were applied to the scattering curves for Pt and Cl (8). The atom parameters are listed in Table 2.[3]

[a] Pt lies on an inversion center and thus x, y, and z were not refined.

[b] $U_{eq} = (1/3)(U_{11} + U_{22} + U_{33} + 2U_{23}\cos\alpha + 2U_{13}\cos\beta + 2U_{12}\cos\gamma)$.

[2]The programs DATCO5, ABSORB, and DATRDN from the XRAY76 program (9) were used for preliminary data treatment. The structure was solved with use of SHELX (6). The above calculations were carried out on a Cyber 170/815 computer. The following calculations were carried out on a VAX 8600 computer. Plane calculations were made using LSQPL (10) and torsional angles obtained from CHEMX (11). Molecule and cell packing diagrams were obtained from SNOOPI (12).

[3]Tables of anisotropic temperature factors, hydrogen atom positional parameters and temperature factors, interatomic distances and angles involving hydrogen atoms, torsional angles, and the moduli of F_o and F_c have been deposited. They may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a]Atom related to O(2) by the transformation, $1 - x, -y, 1 - z$.

Discussion

The identity of the minor product, bis(2,7-diazatetracyclo-[6.3.0.0^{4,9}.0^{5,11}]undecane-*N*,*N*′)platinum(II) dichloride tetrahydrate, **A**, was established by X-ray crystallography. The structure of the cation of **A** is shown in Fig. 1 and bond lengths and angles are given in Table 2. The platinum atom lies on an inversion center and the usual square planar arrangement of ligands in a platinum(II) complex is attained by coordination of the amine nitrogen atoms. The Pt—N distances found here (2.048(4), 2.046(5) Å), are similar to those reported for other Pt–amine complexes (13, 14). The rigidity of the tetracyclic ligand has produced a N1—Pt—N3 chelating angle of 79°, which is less than the 83–90° usually observed for square-planar platinum(II) complexes (13–18). The remaining bond lengths and angles of the organic framework agree well with values reported for similar structures (19–21).

The packing of **A** in the unit cell is shown in Fig. 2. The packing arrangement can be described as comprising alternating cation layers and chloride and water layers. Within these latter layers there are chains consisting of six-membered hydrogen bonded rings O1..O2..Cl..O1′..O2′..Cl′ alternating with four-membered hydrogen bonded rings Cl..O2..Cl′..O2′. The cations are bound to the six-membered rings by N7..Cl and N2..O1 hydrogen bonds. Interatomic distances indicating hydrogen-bonding interactions have been included in Table 3.

The results of ^{1}H nmr studies of **A** and the ligand, 2,7-diazatetracyclo[6.3.0.0^{4,9}.0^{5,11}]undecane are reported in Table 4. The amine proton signals were unresolved because of rapid exchange with the solvent, D_2O. The two doublets for H_{10a} and H_{10s}, centered at 1.443 and 1.523 ppm, respectively,

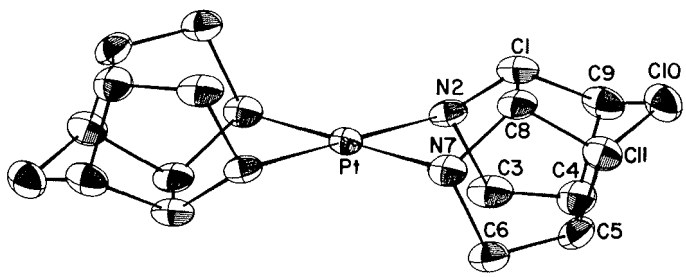

FIG. 1. The cation *trans*-bis(2,7-diazatetracyclo[6.3.0.0^{4,9}.0^{5,11}]-undecane-*N*,*N*′)platinum(II), showing the atom numbering.

represent an AB type system with a geminal coupling of −11.2 Hz. The H_{10s} proton also couples with the two bridgehead protons, H_9 and H_{11}, ($^3J_{10s,9(11)}$ = 1.7 Hz). A singlet at 2.209 ppm represents the H_4 and H_5 protons. The bridgehead protons, H_9 and H_{11}, appear as a singlet at 2.306 ppm. Another AB system caused by $H_{3e}(H_{6e})$ and $H_{3i}(H_{6i})$ is represented by the doublets centered at 2.706 and 2.894 ppm, respectively, with a geminal coupling of −11.6 Hz. The doublet arising from H_{3e} and H_{6e} is further split by coupling to H_4 and H_5, respectively, ($^3J_{3e(6e),4(5)}$ = 2.3 Hz). The H_1 and H_8 protons produced a singlet at 3.058 ppm.

Platination of the ligand results in a withdrawal of electron density from the hydrogen atoms. The extent of this withdrawal is reflected in the relative proton shifts to lower field. The reduction in the geminal coupling constants indicates that the platinum is siphoning electron density away from nitrogen atoms, making them more electronegative or/and the H—C—H bond angle is reduced upon platination of the ligand. The errors

C-3,6	47.2	55.7
C-1,8	60.7	72.5

[a]Chemical shifts are relative to external tetramethylsilane.

in the respective geminal H—C—H bond angles, however, do not allow us to confirm or refute any such reduction in these angles. Assignments of the signals were confirmed with use of COSY nmr experiments.

The ^{13}C nmr results are listed in Table 5. Assignments for $C_{4,5}$ and $C_{9,11}$ are not definitive from these experiments alone and may be interchanged. Comparison with similar compounds, however, supports our assignments (22). As expected, the relative shifts of ^{13}C nmr peaks upon platination are much smaller than those observed in the ^{1}H spectra.

The major product, the brown powder, was not satisfactorily identified. It was insoluble in common solvents and this precluded the use of many physical techniques in its identification. The material may have been a mixture containing the desired product, (L—L)$PtCl_2$, and the insolubility suggests a polymeric nature. The vibrational spectra were ambiguous. A poorly resolved band at 316 cm^{-1} might have been $\upsilon_{Pt—Cl}$, but we cannot be certain because it was part of a broad ligand vibrational manifold centered at 330 cm^{-1}. Analytical measurements showed that chlorine was present in the brown solid, but at nowhere near the level needed for (L—L)$PtCl_2$ (*Anal.* calcd. for (L—L)$PtCl_2$: C 26.0, H 3.4, N 6.7, Cl 17.0; found: C 21.4, H 3.2, N 5.8, Cl 10.2).

The question arises as to why it was difficult to obtain (L—L)$PtCl_2$ rather than the (L—L)$_2Pt^{2+}$ compound. This is the second time we have run into this problem recently (18). The problem is more general, however. Magnus' green salt, $[Pt(NH_3)_4][PtCl_4]$, is always formed in small amounts in the normal preparation of *cis*-$Pt(NH_3)_2Cl_2$ (23). It seems that the reaction

$$(L—L)PtCl_2 + L—L \rightarrow (L—L)_2Pt^{2+} + 2Cl^-$$

must be faster than, or at least competitive with, the reaction

$$PtCl_4^{2-} + L—L \rightarrow (L—L)PtCl_2 + 2Cl^-$$

and so (L—L)$PtCl_2$ is converted to (L—L)$_2Pt^{2+}$ as it is formed. To obtain the pure desired product, (L—L)$PtCl_2$, one clearly needs alternative methods of preparation.
