[1] Scleroderolide is produced by the fungus in smaller amounts and is difficult to purify.

[2] Scleroderolide isolated as its monoacetate from other later cultures showed the same optical rotation.

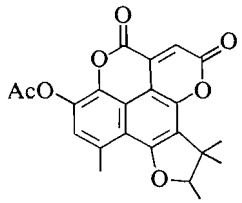
8

P. herquei, it is possible that both enantiomers of atrovenetin are produced (10). In our case, the low optical purity (ca. 20% e.e. enantiomeric excess) of the initially isolated scleroderolide might be due to the use of a mutant strain on that occasion, although we cannot completely exclude the possibility that the strain used initially was incorrectly labelled.

Scleroderolide (**1**) is readily converted to the monoacetate **1***a* by treatment with acetic anhydride in the presence of pyridine or 4-*N*,*N*-dimethylaminopyridine. Utilizing longer reaction times, we attempted to prepare the diacetate **1***b*. A major product was obtained, the ^{1}H nmr spectrum of which was very similar to that of **1***a* except that the phenolic OH resonance at δ 13.75 was replaced by a signal at δ 6.94 (not D_2O exchangeable). The hrms of this product displayed a molecular ion at *m/z* 394 ($C_{22}H_{18}O_7$). The ir spectrum shows carbonyl absorption at 1774 and 1738 cm^{-1}. These data are consistent with structure **9**. Compound **9** presumably is formed by base catalyzed cyclization of the initially formed diacetate **1***b*.



9

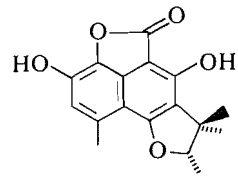
The diacetate **1***b* is readily formed under acidic conditions (e.g., acetic anhydride – trifluoroacetic acid). Remarkably, its ^{1}H and ^{13}C nmr spectra are temperature dependent. For example, the ^{1}H nmr spectrum of **1***b* (in toluene-d_8) exhibits broad signals for the C-2′, C-4′, and C-5′ hydrogens at room temperature. At 60°C these signals are sharp, whereas at 0°C they appear as resolved pairs. Further cooling to −60°C induces broadening in the signals for the C-1′, C-8, and $ArCH_3$ hydrogens as well as the acetate methyl group at C-9. Interestingly, the acetate methyl at C-4 remains relatively unchanged with temperature. Similarly, the ^{13}C nmr spectrum ($CDCl_3$) shows several broad signals at room temperature, which are sharp at 55°C and are resolved into pairs at −60°C. Since the ^{1}H and ^{13}C nmr spectra of **1***a* do not show this temperature dependence, it appears that the acetate group at C-4 in **1***b* is the structural feature responsible for these unusual results. The effect could, in principle, be due to acetyl migration from the C-4 to the C-3 oxygen (Scheme 1) or to restricted rotation of the acetate group (Scheme 2). To examine this further, we investigated the nmr spectra of several derivatives of sclerodin (**3**).

Sclerodin diacetate (**3***c*) and sclerodin dimethyl ether (**3***d*) have previously (1) been prepared. The monoacetate **3***a* was obtained from **3** by treatment with acetic anhydride – pyridine, while monoacetate **3***b* may be obtained either from **3** by treatment with acetic anhydride – trifluoroacetic acid (along with the diacetate **3***c*) or from **3***c* by hydrolysis ($NaHCO_3$).

The ^{1}H nmr spectra of **3***d* (1) and **3***a* do not show temperature dependence, but the spectra of **3***b* and **3***c* exhibit temperature dependent features very similar to those of **1***b*. Since the propensity for acetyl migration is expected to be similar for **3***a* and **3***b*, we concluded that it is restricted rotation of the acetate group at C-4 which is responsible for the temperature dependent nmr spectra in these compounds.

Sclerodione (**5**), a metabolite of *G. abietina* (1), on standing in solution is oxidized to sclerodin (**3**). Treatment of **5** with hydrogen peroxide gives **3**, along with lactone **10** (1).

Reasoning that the lactone **10** may be derived from scleroderolide (**1**) by peroxide oxidation of the corresponding α-keto



10

acid, we decided to investigate the reaction of sclerodione (**5**) with *m*-chloroperbenzoic acid. To our satisfaction, we found that this reaction led to the formation of both sclerodin (**3**) and scleroderolide (**1**), isolated as its monoacetate **1***a*.

The *S* configuration at C-2′ has been established (1) for some metabolites of *G. abietina*. The (+)-form ($[\alpha]_D$ +75°) of sclerodin (**3**) has been shown to have the *R* configuration at C-2′ by X-ray crystallography (11). Consequently sclerodin (**3**, $[\alpha]_D$ −72.6°) from *G. abietina* is assigned the *S* configuration. *Ent*-atrovenetinone (**4**) and sclerodione (**5**) from *G. abietina*, on oxidation gave sclerodin (**3**, $[\alpha]_D$ −72.6°), establishing the *S* configuration for **4** and **5**. Similarly, scleroderolide (**1**, $[\alpha]_D$ −116°) can be prepared, as mentioned above, from sclerodione (**5**), thus allowing the assignment of the *S* configuration at C-2′ for **1**.

To the best of our knowledge, scleroderolide (**1**) is the first natural product possessing the interesting phenylglyoxylate lactone structure. Its biosynthesis is discussed in Part 4 of this series.

Experimental

All solvents except diethyl ether were distilled prior to use. ACS quality anhydrous diethyl ether was used without purification. Petroleum ether refers to Skelly Oil Company light petroleum (Skellysolve B), bp 62–70°C. Pyridine was distilled from CaH_2 and stored over molecular sieves; acetic anhydride was dried over P_2O_5 and distilled from sodium acetate.

Analytical thin-layer chromatography (tlc) was carried out on aluminum sheets (75 × 25 or 75 × 50 mm) precoated (0.2 mm) with silica gel $60F_{254}$ (E. Merck, Darmstadt). Preparative thin-layer chromatography (ptlc) was carried out on glass plates (20 × 20 cm) precoated (0.25 mm) with the same adsorbent. Materials were detected by visualization under an ultraviolet (uv) lamp (254 or 350 nm), or by spraying with a solution of phosphomolybdic acid (5%) containing a trace of ceric sulfate in aqueous sulfuric acid (5%, v/v), followed by charring on a hot plate. Flash column chromatography (12) was performed with Merck Silica Gel 60 (40–63 μm).

High resolution mass spectra (hrms) were recorded on an A.E.I. MS-50 mass spectrometer coupled to a DS 50 computer. Chemical ionization mass spectra (cims) were recorded on an A.E.I. MS-9 mass spectrometer. Ammonia was used as reagent gas. Data are reported as *m/z* (relative intensity). Unless diagnostically significant, peaks with intensities less than 20% of the base peak are omitted. Infrared (ir) spectra were recorded on a Nicolet 7199 FT interferometer. Optical rotations were measured on a Perkin Elmer Model 141 polarimeter.

SCHEME 2

^{1}H nuclear magnetic resonance (^{1}H nmr) spectra were measured on a Bruker WH-200 spectrometer on a Bruker WH-400 spectrometer. ^{13}C nuclear magnetic resonance (^{13}C nmr) spectra were measured on a Bruker WH-400 spectrometer. For ^{1}H nmr, residual $CHCl_3$ in $CDCl_3$ was employed as the internal standard (assigned as 7.26 ppm downfield from tetramethylsilane (TMS)) and measurements are reported in ppm downfield from TMS (δ). For ^{13}C nmr, $CDCl_3$ was employed as the internal standard (assigned as 77.0 ppm downfield from TMS) and measurements are reported in ppm downfield from TMS (δ). Melting points were recorded on a Fisher–Johns melting point apparatus and are uncorrected.

Growth of Gremmeniella abietina *and extraction of metabolites*

Stock cultures of *Gremmeniella abietina* (strain C-699, Northern Forest Research Centre, Canadian Forestry Service, Edmonton) were maintained in slant tubes on potato dextrose agar at 4°C. To initiate large scale cultures, small fragments of agar containing the mycelium were aseptically transferred to Erlenmeyer flasks (5 × 300 mL) containing a sterile culture medium (200 mL) composed of 10% (v/v) clarified V-8[3] juice and 1% (w/v) glucose. The cultures were shaken for 10 days at 15–17°C. The content of each inoculation flask was transferred to two 2.8-L Fernbach flasks containing the same liquid medium (900 mL) and the flasks (ten) were kept at 15–17°C. After 4 weeks the mycelium was separated from the broth by filtration through cheesecloth. The wet mycelium was extracted with diethyl ether or dichloromethane (24 h), and twice with methanol (24 h), in a Soxhlet extractor. The ether (or dichloromethane) and methanol extracts were dried over sodium sulfate and the solvents evaporated *in vacuo* at 30°C.

Isolation of scleroderolide (1)

Pure scleroderolide (**1**) was obtained from crude mycelium extracts from *G. abietina* strain C-699. The dichloromethane extract (700 mg) was fractionated by flash column chromatography (dichloromethane–methanol – acetic acid, 47:2:1, 2 L) and the fractions (100 mL) were coevaporated with toluene. Fractions 5–7 were refractionated using the same process. After evaporation of the solvent the residue was dissolved in dichloromethane and petroleum ether was added to the solution (brownish) until precipitation occurred. The precipitate was filtered and crystallized from ethanol – petroleum ether to give scleroderolide (**1**, mp 232–233°C); tlc: R_f 0.26 (dichloromethane – petroleum ether – acetic acid, 10:10:1, double elution), yellow spot; $[\alpha]_D$ −116.0° (*c* 0.30, $CHCl_3$); ir ($CHCl_3$, solution): 3500 (br), 2920, 1750, 1610, 1470, 1380, 1365, 1205, 1030 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.34 (3H, s, C-3′ CH_3), 1.51 (3H, d, 6.5 Hz, C-2′ CH_3), 1.56 (3H, s, C-3′ CH_3), 2.75 (3H, s, ArCH_3), 4.77 (1H, q, 6.5 Hz, C-2′ H), 6.65 (1H, br s, OH), 6.92 (1H, s, C-8 H), 13.73 (1H, s, OH); ^{13}C nmr ($CDCl_3$)[4] δ: 14.6 (C-1′), 20.6 (C-5′), 22.3 (ArCH_3), 25.6 (C-4′), 43.1 (C-3′), 92.8 (C-2′), 107.2 (C-3a), 109.1 (C-6a), 117.1 (C-8), 119.4 (C-5), 122.2 (C-3b), 129.9 (C-9a), 137.1 (C-7), 144.5 (C-9), 155.7 (C-2), 167.4 (C-4), 169.6 (C-6), 170.1 (C-3); hrms, *m/z* calcd. for $C_{18}H_{16}O_6$ (M^+): 328.0947; found: 328.0950 (50), 300 (61), 285 (100), 270 (9), 267 (11), 257 (14); cims, *m/z*: 346 (*M* + 18, 46), 329 (*M* + 1, 100).

Scleroderolide monoacetate (1a)

Pure scleroderolide (**1**, 10 mg) was dissolved in dichloromethane (5 mL), and acetic anhydride (excess) and 4-*N*,*N*-dimethylaminopyridine were added at room temperature. After 30 min the reaction mixture was diluted with dichloromethane (20 mL) and washed successively with 5% aqueous hydrochloric acid (10 mL) and then water (10 mL). The dichloromethane layer was dried (Na_2SO_4), filtered, and concentrated to give the crude product (13 mg). Crystallization from dichloromethane – petroleum ether gave scleroderolide monoacetate (**1***a*, mp 183–186°C, 85% yield); tlc: R_f 0.32 (benzene–acetone – acetic acid, 90:10:0.1), yellow spot; $[\alpha]_D$ −69.3° (*c* 0.28, $CHCl_3$); ir ($CHCl_3$, solution): 3500 (br), 3000, 1760, 1620, 1590, 1470, 1420, 1370, 1300, 1225, 1195, 1030 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.35 (3H, s, C-3′ CH_3), 1.52 (3H, d, 6.5 Hz, C-2′ CH_3), 1.57 (3H, s, C-3′ CH_3), 2.43 (3H, s, OOCCH_3), 2.79 (3H, s, ArCH_3), 4.80 (1H, q, 6.5 Hz, C-2′ H), 7.01 (1H, s, C-8 H), 13.77 (1H, s, OH); ^{13}C nmr ($CDCl_3$) δ: 14.6 (C-1′), 20.5 (C-5′), 20.6 (OOC*C*H_3), 22.3 (ArCH_3), 25.6 (C-4′), 43.4 (C-3′), 93.0 (C-2′), 107.6 (C-3a), 113.5 (C-6a), 121.1 (C-5), 122.2 (C-3b), 122.3 (C-8), 135.0 (C-9a), 135.8 (C-7), 137.9 (C-9), 155.1 (C-2), 167.8 (C-4), 168.2 (OO*C*CH_3), 169.0 (C-6), 170.7 (C-3); hrms, *m/z* calcd. for $C_{20}H_{18}O_7$ (M^+): 370.1052; found: 370.1050 (26), 328 (64), 300 (100), 285 (96).

Scleroderolide diacetate (1b)

Pure scleroderolide (**1**, 10 mg) was dissolved in dichloromethane (5 mL), and acetic anhydride (excess) and trifluoroacetic acid (0.5 mL) were added at room temperature. After 24 h the reaction mixture was diluted with toluene and concentrated to give the crude product (14 mg). Crystallization from dichloromethane – petroleum ether gave pure scleroderolide diacetate (**1***b*, mp 200–202°C, 80% yield); tlc: R_f 0.22 (benzene–acetone – acetic acid, 90:10:0.1), yield spot; $[\alpha]_D$ −44.6° (*c* 0.28, $CHCl_3$); ir ($CHCl_3$, cast): 2970, 1760, 1670, 1625, 1580, 1530, 1460, 1410, 1360, 1180, 1040 cm^{-1}; ^{1}H nmr (toluene-d_8)

[3]Clarified V-8 juice refers to V-8 (eight garden vegetables, Campbell Soup Company Ltd.) juice filtered through a pad of Celite.

[4]Details of the assignment are reported in Part 4 of this series.

at 60°C, δ: 1.0 (3H, s, C-3′ CH_3), 1.06 (3H, d, 6.5 Hz, C-2′ CH_3), 1.17 (3H, s, C-3′ CH_3), 1.82 (3H, s, $OOCCH_3$), 2.20 (3H, s, $OOCCH_3$), 2.60 (3H, s, $ArCH_3$), 4.21 (1H, q, 6.5 Hz, C-2′ H), 6.78 (1H, s, C-8 H); ^{13}C nmr ($CDCl_3$) at 55°C, δ: 14.3 (br),[5] 20.5, 21.0, 21.5, 22.4, 25.7 (br), 44.0, 92.4, 112.7, 115.9, 123.8, 124.8, 127.9, 134.7, 135.4, 137.6, 152.8, 153.4, 166.8, 168.0, 176.2; hrms, *m/z* calcd. for $C_{22}H_{20}O_8$ (M^+): 412.1158; found: 412.1164 (6), 384 (7), 370 (6), 342 (21), 328 (12), 300 (100), 285 (50).

*Sclerodin monoacetate (**3**a)*

Sclerodin (**3**, 3 mg) was dissolved in dichloromethane, and acetic anhydride (excess) and 4-*N*,*N*-dimethylaminopyridine (catalytic amount) were added at room temperature. After 30 min the reaction mixture was diluted with dichloromethane, then washed successively with 5% aqueous hydrochloric acid and water. The dichloromethane layer was dried (Na_2SO_4), filtered, and concentrated. Preparative thin-layer chromatography (benzene–acetone, 95:5) gave **3***a* (3 mg); tlc: R_f 0.44 (benzene–acetone, 95:5), blue fluorescence under uv light; ir ($CHCl_3$, cast): 2980, 1780, 1750, 1670, 1610, 1420, 1290, 1180, 1015 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.28 (3H, s, C-3′ CH_3), 1.49 (3H, d, 6.5 Hz, C-2′ CH_3), 1.53 (3H, s, C-3′ CH_3), 2.42 (3H, s, $OOCCH_3$), 2.86 (3H, s, $ArCH_3$), 4.73 (1H, q, 6.5 Hz, C-2′ H), 6.97 (1H, s, C-8 H), 12.14 (1H, s, OH); hrms, *m/z* calcd. for $C_{20}H_{18}O_7$ (M^+): 370.1052; found: 370.1045 (9), 328 (37), 313 (100), 285 (6), 269 (6).

*Sclerodin monoacetate (**3**b) and sclerodin diacetate (**3**c)*

Sclerodin (**3**, 10 mg) was dissolved in dichloromethane, and acetic anhydride (excess) and trifluoroacetic acid (0.5 mL) were added at room temperature. After 12 h the reaction mixture was diluted with dichloromethane and washed with water. The dichloromethane layer was dried (Na_2SO_4), filtered, and coevaporated with toluene. Preparative thin-layer chromatography (benzene–acetone, 95:5) gave **3***b* (2 mg) and **3***c* (8 mg). Monoacetate **3***b* was also prepared by hydrolysis ($NaHCO_3$, H_2O, MeOH; room temperature; 6 h) of diacetate **3***c*. Sclerodin monoacetate (**3***b*) showed the following properties: tlc: R_f 0.35 (benzene–acetone, 95:5), blue fluorescence under uv light; ir ($CHCl_3$, cast): 2980, 1780, 1750, 1670, 1610, 1300, 1180, 1030, 860 cm^{-1}; ^1H nmr ($CDCl_3$) at 55°C, δ: 1.26 (3H, br s, C-3′ CH_3), 1.45 (3H, br s, C-3′ CH_3), 1.50 (3H, d, 6.5 Hz, C-2′ CH_3), 2.47 (3H, s, $OOCCH_3$), 2.87 (3H, s, $ArCH_3$), 4.69 (1H, q, 6.5 Hz, C-2′ H), 6.98 (1H, s, C-8 H), 11.88 (1H, s, OH); ^1H nmr (toluene-d_8) at 65°C, δ: 1.0 (3H, s, C-3′ CH_3), 1.05 (3H, d, 6.5 Hz, C-2′ CH_3), 1.16 (3H, s, C-3′ CH_3), 2.17 (3H, s, $OOCCH_3$), 2.52 (3H, s, $ArCH_3$), 4.21 (1H, q, 6.5 Hz, C-2′ H), 6.56 (1H, s, C-8 H), 12.0 (1H, s, OH); hrms, *m/z* calcd. for $C_{20}H_{18}O_7$ (M^+): 370.1052; found: 370.1058 (12), 328 (33), 313 (100), 285 (5), 269 (5).

Sclerodin diacetate (**3***c*) showed the following properties: tlc: R_f 0.26 (benzene–acetone, 95:5), blue fluorescence under uv light; ir ($CHCl_3$, cast): 2980, 1778, 1760, 1724, 1605, 1600, 1290, 1015 cm^{-1}; ^1H nmr (toluene-d_8) at 65°C, δ: 1.0 (3H, s, C-3′ CH_3), 1.07 (3H, d, 6.5 Hz, C-2′ CH_3), 1.16 (3H, s, C-3′ CH_3), 2.13 (3H, s, $OOCCH_3$), 2.16 (3H, s, $OOCCH_3$), 2.55 (3H, s, $ArCH_3$), 4.23 (1H, q, 6.5 Hz, C-2′ H), 6.68 (1H, s, C-8 H); hrms, *m/z* calcd. for $C_{22}H_{20}O_8$ (M^+): 412.1158; found: 412.1161 (11), 370 (26), 328 (64), 313 (100).

*Scleroderolide α-methoxy-α-trifluoromethyl-α-phenylacetate (**8**)*

Pure scleroderolide (**1***a*, ca. 3 mg) was dissolved in dichloromethane (1 mL) containing 4-*N*,*N*-dimethylaminopyridine (excess) and the solution was added to α-methoxy-α-trifluoromethyl-α-phenylacetyl chloride (prepared from the corresponding (−)-acid and oxalyl chloride – dimethylformamide) at room temperature. After 20 min the reaction mixture was diluted with dichloromethane and washed successively with 5% aqueous hydrochloric acid and water. The dichloromethane layer was dried (Na_2SO_4), filtered, and concentrated to give the crude product. Preparative thin-layer chromatography (benzene–acetone – acetic acid, 90:10:0.1) gave **7** (2.4 mg); tlc: R_f 0.38 (benzene–acetone – acetic acid, 90:10:0.1), yellow spot; ^1H nmr ($CDCl_3$) δ: 1.36 (3H, s, C-3′ CH_3), 1.53 (3H, d, 6.5 Hz, C-2′ CH_3), 1.58 (3H, s, C-3′ CH_3), 2.80 (3H, s, $ArCH_3$), 3.81 (3H, s, OCH_3), 4.81 (1H, q, 6.5 Hz, C-2′ H), 6.95 (1H, s, C-8 H), 7.53 (3H, m, Ph H's), 7.80 (2H, m, Ph H's), 13.71 (1H, s, OH); hrms, *m/z* calcd. for $C_{28}H_{23}F_3O_8$ (M^+): 544.1345; found: 544.1348 (6), 342 (6), 314 (7), 189 (100).

*Anhydroscleroderolide diacetate (**9**)*

Pure scleroderolide (**1**, 6 mg) was dissolved in dichloromethane (4 mL), and acetic anhydride (excess) and 4-*N*,*N*-dimethylaminopyridine (excess) were added at room temperature. After 2 h the reaction mixture was diluted with dichloromethane and washed successively with 5% aqueous hydrochloric acid (10 mL) and water (10 mL). The dichloromethane layer was successively dried (Na_2SO_4), filtered, and concentrated. Preparative thin-layer chromatography (benzene–acetone – acetic acid, 90:10:1, double elution) gave **9** (45% yield); tlc: R_f 0.37 (benzene–acetone – acetic acid, 90:10:0.1), yellow spot; $[\alpha]_D$ −21.2° (*c* 0.17, $CHCl_3$); ir ($CHCl_3$, cast): 2980, 1774, 1738, 1590, 1570, 1188, 1032 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.39 (3H, s, C-3′ CH_3), 1.52 (3H, d, 6.5 Hz, C-2′ CH_3), 1.65 (3H, s, C-3′ CH_3), 2.44 (3H, s, acetyl CH_3), 2.84 (3H, s, $ArCH_3$), 4.76 (1H, q, 6.5 Hz, C-2′ H), 6.94 (1H, s, vinylic H), 7.09 (1H, s, C-8 H); hrms, *m/z* calcd. for $C_{22}H_{18}O_7$ (M^+): 394.1052; found: 394.1050 (18), 352 (100), 337 (67), 300 (20); cims, *m/z*: 412 (*M* + 18, 14), 394 (100).

*Preparation of scleroderolide (**1**) from sclerodione (**5**)*

Sclerodione (**5**, 4.3 mg) was dissolved in dichloromethane (3 mL) and *m*-chloroperbenzoic acid (3.4 mg) in dichloromethane (1 mL) was added at room temperature. After 5 h the reaction mixture was diluted with dichloromethane and washed with aqueous sodium bicarbonate. The dichloromethane layer was dried and concentrated to give a mixture of sclerodin (**3**) and scleroderolide (**1**). The aqueous layer was extracted several times with dichloromethane; the dichloromethane extracts were combined, and evaporated to dryness. Thin-layer chromatography of the residue showed a major yellow spot corresponding to scleroderolide. Acetylation (acetic anhydride – 4-*N*,*N*-dimethylaminopyridine) of this residue gave, after work-up (*vide supra*), scleroderolide monoacetate **1***a* (2 mg, 40% yield from **5**), identical with an authentic sample (tlc, ir, ^1H nmr, and hrms).

*Aerial oxidation of sclerodione (**5**)*

Sclerodione (**5**, 5 mg) was dissolved in dichloromethane (5 mL) in a loosely stoppered flask. After 5 weeks, separation of the reaction mixture by ptlc (dichloromethane–methanol, 49:1, double elution), gave sclerodin (**3**, 1 mg) and recovered sclerodione (3 mg). Sclerodin (**3**) was identical with an authentic sample (tlc, ir, ^1H nmr, and hrms).

X-ray crystallographic study of racemic scleroderolide monoacetate

Red-orange single crystals of racemic scleroderolide monoacetate suitable for X-ray diffraction analysis were obtained from CH_2Cl_2 – Skellysolve B. The crystal was roughly cubic with edges of 0.4 mm. Preliminary X-ray photographs showed triclinic symmetry. Precise lattice constants of a = 11.027 (2), b = 9.716 (1), c = 9.300 (1) Å, α = 77.44 (1), β = 91.34 (1), and γ = 117.97 (1)°, were determined by a least-squares analysis of the diffractometrically measured angular positions of 15 reflections. The results of the X-ray analysis show the space group for the crystals to be $P\bar{1}$, in which one molecule of scleroderolide monoacetate ($C_{20}H_{28}O_7$, M.Wt. = 370.44, V = 855.4 (2) Å^3, ρ_{calc} = 1.44 g/cm^3), μ = 8.8 cm^{-1}, forms the asymmetric unit. All unique diffraction data with $2\theta < 114°$ were surveyed using nickel-filtered CuK radiation (λ = 1.54178 Å) and a variable-speed ω-scan (1° scan width, 1.0°/min ≤ speed ≤ 29.3°/min) on a Syntex $P2_1$ diffractometer. After correction for Lorentz, polarization, and background effects, 1957 of a total of 2300 unique data (85.1%) were considered observed ($|F_o| > 3\sigma_F$) and used for the ensuing structure solution and refinement.[6]

[5]These signals are sharp at 75°C in toluene-d_8.

[6]All crystallographic computations and formulae are given in the Ph.D. thesis of Edward Van Dyke Arnold, Cornell University, 1982.

The structure of scleroderolide monoacetate was solved by standard multisolution direct methods.[7] All hydrogens were located by a difference synthesis following partial refinement. Block-diagonal least-squares refinement, with anisotropic oxygens and carbons and isotropic hydrogens, converged to a residual of 0.047 for the observed data.

Figure 1 shows a computer-generated perspective drawing of the final X-ray model of one enantiomer of scleroderolide monoacetate. The five-membered ring of scleroderolide monoacetate is in the C_2 conformation with the two-fold axis bisecting the C-5—C-6 bond. There is an intramolecular hydrogen bond between O-4 (H) and O-3 with an O-4—(H)—O-3 distance of 1.57 Å and OHO angle of 156°. The best least-squares plane through the 13 atoms of the three six-membered rings shows a maximum deviation of 0.095 Å from the plane for atom C-9. Although the substituents O-3, O-4, O-6, and C-3′ are also within 0.09 Å of this plane, O-2, C-7 Me, and O-9 are respectively 0.20, 0.16, and 0.18 Å away from this plane.

Tables of fractional coordinates and thermal parameters, bond distances, bond angles, torsion angles, and observed and calculated structure factors are available.[8]

Metabolites produced by the Scleroderris canker fungus, *Gremmeniella abietina*. Part 3. Some further metabolites

WILLIAM A. AYER AND M. SOLEDADE PEDRAS

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 8, 1986

WILLIAM A. AYER and M. SOLEDADE PEDRAS. Can. J. Chem. **65**, 754 (1987).

This article describes the metabolites of a strain of *Gremmeniella abietina* (Lagerb.) Morelet indigenous to Alberta. This strain does not produce the phenalenone derived metabolites isolated from the other strains of *G. abietina* examined to date. Only fatty acids and esters, glycerides, and sterol esters were produced. This raises a question regarding the identity of this particular strain. A greenish-yellow metabolite named Scleroderris green, isolated from a New Brunswick strain of *G. abietina*, is shown to have structure **12**. Scleroderris green (**12**) is structurally related to Scleroderris blue (**4**) and is produced when the latter compound is reduced with sodium bisulfite. Air oxidation of Scleroderris green (**12**) gives rise to Scleroderris blue (**4**). The structure of compound **12** was established by a study of the ^{13}C nmr spectra of the three pentamethyl derivatives (**8**, **9**, and **10**) produced when **12** is treated with ethereal diazomethane. It is suggested that the greenish discoloration of the wood of Scleroderris infected pine may be due to the presence of compound **12**.

WILLIAM A. AYER et M. SOLEDADE PEDRAS. Can. J. Chem. **65**, 754 (1987).

Dans ce travail, on décrit les métabolites d'une souche de *Gremmeniella abietina* (Lagerb.) Morelet qui est indigène à l'Alberta. Cette souche ne produit pas les métabolites dérivés de la phénalénone qui ont été isolés des autres souches de *G. abietina* qui ont été examinées jusqu'à maintenant. Il ne se produit que des acides gras et des esters, des glycérides ainsi que des esters de stérols. On démontre qu'un métabolite jaune-verdâtre, nommé le vert de Scléroderris et qui a été isolé d'une souche de *G. abietina* du Nouveau Brunswick, possède la structure **12**. Le vert de Scléroderris (**12**) possède une structure apparentée à celle du bleu de Scléroderris (**4**) et il se transforme en ce dernier lorsqu'on le réduit par du bisulfite de sodium. Une oxydation par de l'air du vert de Scléroderris (**12**) conduit au bleu de Scléroderris (**4**). On a déterminé la structure du composé **12** grâce à une étude des spectres rmn du ^{13}C des trois dérivés pentaméthylés (**8**, **9** et **10**) qui sont formés lorsqu'on traite le composé **12** par une solution éthérée de diazométhane. On suggère que la décoloration verdâtre du bois des pins infectés par le Scléroderris pourrait être du à la présence du composé **12**.

[Traduit par la revue]

In Parts 1 and 2 of this series (1, 2) we have described several metabolites produced in liquid culture by the Scleroderris canker fungus *Gremmeniella abietina* (Lagerb.) Morelet. The fungus *G. abietina* has been subdivided serologically into two races, the European and the North American.[1] The strain of the fungus used in the previous studies (1, 2), Canadian Forestry Service strain C-699, isolated in New Brunswick, is a member of the so-called European race. As part of our study of this plant disease we have compared the metabolites produced by different strains of this fungus collected in different parts of the world.[2] While most of these strains showed a similar chromatographic profile to that of strain C-699, the chromatographic profile of strain C-656, collected in Alberta, was distinctly different.[3] This report describes the metabolites of *G. abietina* strain C-656 as well as the isolation of a new metabolite from strain C-699.

Gremmeniella abietina strain C-656 was grown in still culture at 16–17°C on a medium of 10% V-8 juice containing added glucose. After four weeks the mycelium was harvested and extracted in a Soxhlet apparatus to give a brownish oily material, which was then fractionated by silica gel chromatography. The most polar fraction was readily identified, by its ir and ^1H nmr spectra, as a mixture of fatty acids. The high resolution mass spectrum (hrms) of the methylated (ethereal diazomethane) mixture revealed molecular ions corresponding to stearic ($C_{19}H_{38}O_2$), oleic ($C_{19}H_{36}O_2$), linoleic ($C_{19}H_{34}O_2$), and palmitic ($C_{17}H_{34}O_2$) acid methyl esters. The relative amount of each acid was estimated by integration of the ^1H nmr spectrum as follows (5): the resonance at δ 2.77 is due to the two doubly allylic hydrogens (C-11 H's) of linoleic acid. Since it integrates for 0.5 units and the total methyl groups (δ 0.89) for 3.0 units, this acid constitutes approximately 25% ($3/2 \times 0.5/3.0 \times 100$) of the mixture. The resonance at δ 5.30 (*CH*=*CH*), due to oleic and linoleic acids, integrates for 2.0 units, indicating that oleic acid comprises about 50% ($3/2 \times (2.0 - 1.0)/3.0 \times 100$) of the mixture. The remaining 25% is a mixture of stearic and palmitic acids.

The least polar fraction was similarly identified as a mixture of methyl linoleate (ca. 40%), methyl stearate, and methyl palmitate (ca. 35%).

The fractions of intermediate polarity contained di- and triglycerides, which were identified by means of their ^1H nmr, hrms, and chemical ionization mass spectra (cims). The ^1H nmr spectrum of the triglyceride fraction shows the characteristic signals of a triacylglycerol (5): δ 4.20 (2H, dd, 6, 12 Hz), 4.30 (2H, dd, 4.5, 12 Hz), and 5.36 (m, C-2 H) corresponding to five hydrogens of the glyceryl moiety, as well as the resonances due to the fatty acid residues (the signal at δ 5.36 overlaps with those of the olefinic protons). Although the hrms of this fraction did not reveal a molecular ion, analysis of the observed fragmentation pattern (6) provided evidence for the fatty acid composition of the triglycerides. Five major tetraoxygenated ion peaks, which represent the loss of an acyloxy group ($[M - RCOO]^+$ or $[M - RCOOH]^+$) were observed: m/z 604 ($C_{39}H_{72}O_4$), 603 ($C_{39}H_{71}O_4$), 602 ($C_{39}H_{70}O_4$), 600 ($C_{39}H_{68}O_4$), and 577 ($C_{37}H_{70}O_4$). These peaks indicate the presence of at least four different fatty acid residues in the triglyceride molecules. The acyl ions ($[RCO]^+$ or $[RCOH]^+$) detected (m/z 265 ($C_{18}H_{33}O$), 264 ($C_{18}H_{32}O$), 263 ($C_{18}H_{31}O$), 262

[1] For a good summary of all aspects of this disease see ref. 3.

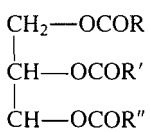
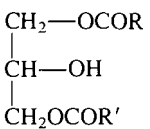
($C_{18}H_{30}O$), 239 ($C_{16}H_{31}O$)) indicate the presence of oleic, linoleic, linolenic, and palmitic acid residues. Thus this material is a mixture of triglycerides, which may be represented by the general structural formulae:



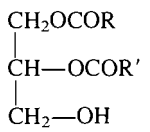
R, R′, R″ = $C_{17}H_{35}$, $C_{17}H_{33}$, $C_{17}H_{31}$, $C_{17}H_{29}$, $C_{15}H_{31}$

The 1,3-diglycerides can be distinguished from the 1,2-diglycerides by ^{1}H nmr (5). The ^{1}H nmr spectrum of the 1,3-diglycerides shows all of the glyceryl resonances in one multiplet (δ 4.18), whereas the ^{1}H nmr spectrum of 1,2-diglycerides shows four resonances (δ 3.76, 4.25, 4.35, and 5.10) for the glyceryl moiety. The cims of the 1,3-diglyceride fraction revealed it to be a complex mixture: *m/z* (relative intensity) 640 (16), 638 (72), 636 (87), 634 (51), 612 (73), 610 (79). These results indicate the presence of at least four different acyl residues corresponding to stearic, oleic, linoleic, linolenic, and palmitic acids. The general structural formulae of the components of the 1,3-diglyceride fraction may be represented as follows:



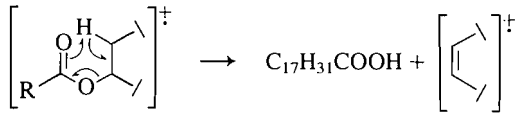
R, R′ = $C_{17}H_{35}$, $C_{17}H_{33}$, $C_{17}H_{31}$, $C_{17}H_{29}$, $C_{15}H_{31}$

Similar results were obtained with the 1,2-diglycerides. The cims clearly showed that this fraction was a mixture: *m/z* (relative intensity) 640 (13), 638 (16), 612 (88), 610 (18). The presence of stearic, oleic, linoleic, linolenic, and palmitic acid residues is consistent with these results. The general structural formulae of the components of the 1,2-diglyceride fraction may be represented as follows:



R, R′ = $C_{17}H_{35}$, $C_{17}H_{33}$, $C_{17}H_{31}$, $C_{17}H_{29}$, $C_{15}H_{31}$

Finally, the least abundant of the metabolites produced by strain C-656 was tentatively identified as a mixture of three sterol esters. The hrms of this fraction indicated two molecular ions: *m/z* 662 ($C_{46}H_{78}O_2$) and 660 ($C_{46}H_{76}O_2$) (confirmed by cims). The base peak at *m/z* 380 ($C_{28}H_{44}$) and a peak at *m/z* 382 ($C_{28}H_{46}$) suggested the loss of the same fragment ($C_{18}H_{32}O_2$) from the two molecular ions. This fragment is consistent with the loss of linoleic acid (7):

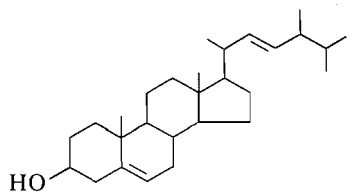


m/z 660 or 662 *m/z* 382 or 380

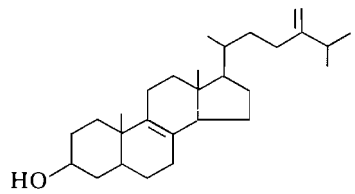
The ^{1}H nmr spectrum of this material is complex. It shows all the resonances attributable to a double unsaturated fatty acid (e.g., linoleic acid), as well as the following signals: δ 0.55 (s), 0.60 (s), 0.70 (s), 0.84 (vt), 0.92 (d), 0.98 (s), 4.64 (m), 5.2 (m). The ir shows carbonyl absorption at 1736 cm^{-1}.

The hrms of the neutral portion of the hydrolyzed (8) mixture (methanolic potassium hydroxide) showed a prominent peak at *m/z* 398 ($C_{28}H_{46}O$). A detailed analysis of the fragmentation pattern is precluded by the complexity of the spectrum. However, the major fragments support the hypothesis that it is a C_{28} sterol (8–10): *m/z* 383 (M − CH_3), 300 (M − C_7H_{14}), 271 (M − side chain − 2H), 255 (M − side chain − H_2O), 213 (M − side chain − H_2O − C_3H_6). The ^{1}H nmr spectrum of this hydrolyzed material is also consistent with a sterol mixture (11). It shows resonances at δ 0.54 (s), 0.61 (s), 0.70 (ca. 3H, s), 0.83 (ca. 6H, ap t, 6.5 Hz), 0.90 (ca. 3H, d, 6.5 Hz), 0.94 (s), 0.98–1.02 (m), 3.54 (m), 3.62 (m), 4.68 (<1H, br s); 4.72 (<1H, br s), 5.20 (ca. 2H, m), 5.37 (ca. 1H, m). On acetylation (12) (acetic anhydride – pyridine) the resonances at δ 3.54 and 3.62 shifted to δ 4.62 and 4.70 (acetyl methyls at δ 2.03 and 2.04).

A search of the literature revealed a similarity in the ^{1}H nmr chemical shifts between some 24-methylsterols (C_{28}) and our mixture. The major component in the mixture is a doubly unsaturated sterol: $C_{28}H_{46}O$, olefinic hydrogens at δ 5.20 (m) and 5.37 (m). The C-18 and C-19 hydrogens of $\Delta^{7,22}$ sterols are shifted upfield in relation to $\Delta^{5,22}$ isomers (e.g., δ 0.54 and 0.81 vs. δ 0.69 and 1.02) (11). Therefore the three singlets at δ 0.54, 0.61, and 0.70 (relative intensity 3:5:10) observed in the ^{1}H nmr spectrum of the mixture could be due to the C-18 hydrogens of three different sterols. The chemical shifts for the major component are consistent with those published (11, 13) for ergosta-5,22-diene-3β-ol (**1**). Although the resonances for the other components cannot be clearly assigned, the presence of signals at δ 4.68 (br s) and 4.72 (br s) (second major component) indicates the presence of a terminal methylene group (14). The second major component (C-18 hydrogens at δ 0.61) is consistent with ergosta-8,24(28)-diene-3β-ol (**2**) (14). A more definite assignment would require the separation of the components, which was not attempted because of the small quantities available.



1

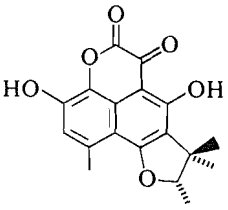


2

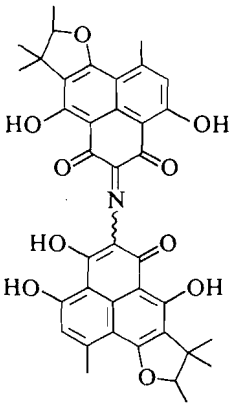
The strains of *G. abietina* previously studied (1, 2) (C-699 and C-708) produce metabolites possessing the phenalenone skeleton. We could not detect phenalenone metabolites in strain C-656 (Alberta). This raises a question regarding the identification of this strain. It is possible that the western fungus (C-656), which is only mildly pathogenic (15), represents a race (species?) different from those which occur in Eastern North America (C-699 and C-708) (15).

During the isolation of scleroderolide (**3**) (2) from the mycelium extract of *G. abietina* strain C-699, we observed that the thin-layer chromatograms (tlc) of some of the fractions obtained from column chromatography had a blue component,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.



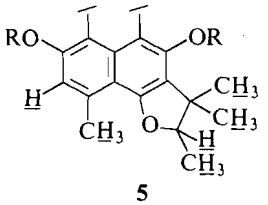
3



4

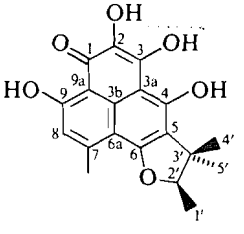
which seemed to increase in concentration with time. This blue component had an R_f identical with Scleroderris blue (**4**). This was unexpected since **4** is the least polar of the metabolites (1) isolated from *G. abietina*. We thus set about to isolate the compound responsible for this behaviour.

The mycelium methanolic extract from strain C-699 was washed with cold dichloromethane and the residue was vacuum dried to afford an amorphous greenish-yellow powder (mp > 350°C). This material, upon standing in solution, was transformed into blue material, which was identical with Scleroderris blue (**4**) by tlc comparison. Efforts to crystallize the greenish powder led to decomposition. The ^{1}H nmr spectrum of this material shows resonances consistent with the presence of fragment **5** (underlined hydrogens), as well as four downfield

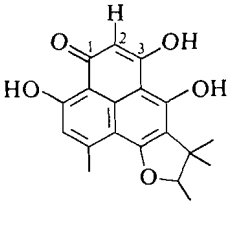


5

signals (δ 12–15, D_2O exchangeable). The hrms showed a prominent peak at *m/z* 326 ($C_{19}H_{18}O_5$) and a base peak at *m/z* 311 ($C_{18}H_{15}O_5$); the cims showed a base peak at *m/z* 327. These data suggested the molecular formula $C_{19}H_{18}O_5$, which would be consistent with a deoxyatrovenetin structure. Consideration of the biosynthesis of atrovenetin (**6**) (16) led us to consider structure **7** as a possibility. However, in the ^{1}H nmr



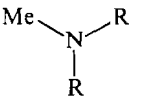
6



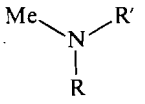
7

spectrum, we were unable to assign a signal attributable to the hydrogen at C-2. A structure such as **7** can exist in several tautomeric forms (the ^{1}H nmr is temperature dependent, indicating a dynamic equilibrium). To further study this material and to try at the same time to render it more stable, it was treated with an excess of ethereal diazomethane. After 12 h, the tlc of the reaction mixture showed three prominent spots. Preparative tlc of the crude reaction mixture yielded the three components. The hrms of each product indicated the presence of one nitrogen and suggested the molecular formula $C_{43}H_{45}NO_{10}$ (mol. wt. 735). Analysis of the ^{1}H and ^{13}C nmr spectra allowed the assignment of the "dimeric" structures **8**, **9**, and **10** to these derivatives.

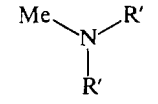
The ^{1}H nmr spectrum of the most polar component, **8**, showed all of the characteristic signals of fragment **5**. However, to be consistent with a molecular formula of $C_{43}H_{45}NO_{10}$, the signals must represent twice the number of hydrogens, i.e., it must be a dimeric structure. The remaining protons appear as follows: δ 3.68 (3H, s), 3.90 (6H, s), 4.03 (6H, s), 18.50 (2H, s). The diazomethane treatment had apparently led to the introduction of five methyl groups. Except for small differences in chemical shifts, the ^{1}H nmr spectrum of the least polar compound (**10**) is the same as that for **8**. The compound of



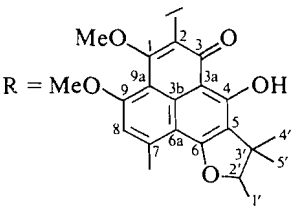
8



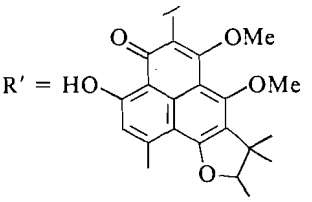
9



10



11*a*



11*b*

intermediate polarity (**9**) has a different ^{1}H nmr spectrum. Instead of showing signals of double intensity for fragment **5**, each signal is paired. The remaining protons are observed as follows: δ 3.68 (3H, s), 3.80 (3H, s), 3.87 (3H, s), 3.91 (3H, s), 4.04 (3H, s), 17.91 (1H, s), 18.45 (1H, s). It is noteworthy that this ^{1}H nmr spectrum is simulated by superimposing the spectra of compounds **8** and **10**. The ^{1}H nmr spectra of these three derivatives suggest that two of them have an element of symmetry that renders two fragments of type **5** equivalent, while in the third the symmetry element does not exist. This hypothesis is supported by the ^{13}C nmr spectrum: compound **8** shows 22 signals while compound **9** shows 43 signals (the spectrum of **10** was not obtained because of a lack of sufficient material).

From these symmetry considerations several conclusions may be drawn: (1) the nitrogen atom must be involved in linking two identical fragments; (2) the point of attachment in each fragment must be identical; (3) each fragment must contain two OCH_3 groups and the fifth methyl group must be an N-CH_3 group; (4) each fragment must have an internally hydrogen-bonded OH group. Thus the structures may be represented as $(C_{21}H_{21}O_5)_2NCH_3$. The fragments ($C_{21}H_{21}O_5$) must each have two OCH_3 groups, an OH group, and the structural features inherent in **5**. These requirements are satisfied by an atrovenetin-like structure (**6**) in which one of the oxygens (at C-1, 2, 3, 4, or 9) is replaced by nitrogen, while two others are methylated. Since there are two different symmetrical derivatives, as well as an unsymmetrical one, the site of N-substitution must be such as to leave an arrangement of OH groups whereby dimethylation can occur in two ways, leaving two different hydrogen-bonded OH groups. The chemical shifts (δ 18.50 and 17.91) and the sharpness of the OH signals in the ^{1}H nmr spectra suggest an *ortho*-acyl phenol unit. Only nitrogen substitution at C-2 can provide a structure in which this feature may appear in two

[a]In $CDCl_3$. [x,y]Carbon assignments may be interchanged.

different ways. Thus structures **8**, **9**, and **10** may be proposed for the three derivatives.

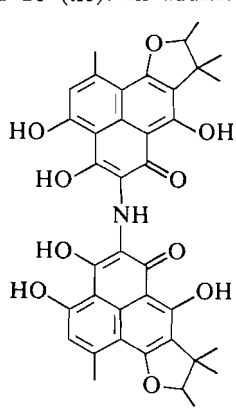
The structures were confirmed by a thorough analysis of the ^{13}C nmr spectra. The proton decoupled ^{13}C nmr spectrum of compound **8** shows 22 signals. All except one (δ 41.1, NCH_3) of the signals represent a pair of equivalent carbons. The signals may be divided into three groups: 5 sp^2 carbons bound to oxygen (δ 150–180); 8 other sp^2 carbons (δ 107–150); 9 sp^3 carbons (δ 14–91). The 9 sp^3 carbons (C-1′, 2′, 3′, 4′, 5′, $ArCH_3$, 2 × OCH_3, and NCH_3) and C-8 are readily assigned based on chemical shift and (or) multiplicity as well as by analogy to other metabolites (17). The remaining carbons were assigned by analysis of the 2-, 3-, and 4-bond $^{13}C-^1H$ coupling observed in the fully coupled spectrum (confirmed by selective ^1H decoupling) as follows. Since the C-8 hydrogen should have large (ca. 6 Hz) (18) coupling to both C-6a and C-9a and small (ca. 2 Hz) coupling (16) to C-7 and C-9, and since only C-6a and C-7 should be coupled to the $ArCH_3$, the assignment of C-6a, C-7, C-9, and C-9a can be made unambiguously. Because of the $^3J_{CH}$ coupling, the assignment of the carbons bearing the OCH_3 and CH_3 groups is possible by irradiation of the appropriate CH_3 hydrogens (δ 3.68, 3.90, and 4.03). Similarly the carbon bearing the OH group (C-3, 4)[4] is identified by its $^2J_{CH}$ coupling (ca. 3 Hz), while the $^3J_{CH}$ coupling serves to locate the α carbons. The C-6 assignment is made on the basis of chemical shift and is confirmed by a small (< 1 Hz) coupling to the C-2′ hydrogen. Of the three remaining carbons (3a, 3b, and 5), C-3b is assigned on the basis of chemical shift as well as its lack of long range coupling. Finally, C-5 is a multiplet due to $^3J_{CH}$ coupling to the C-4′ and C-5′ hydrogens, while C-3a appears as a doublet if an OH is present at C-4 (or C-3).

The complete ^{13}C nmr assignments for compound **8** are shown in Table 1. The following observations are pertinent with respect to the proposed structure. Since the resonance at δ 160.3 is coupled to both the C-8 hydrogen (δ 6.82) and to the lower field OCH_3 hydrogens (δ 4.03), a methoxyl substituent at C-9 is indicated. Significantly, the OH hydrogen (δ 18.50) shows coupling to four resonances: δ 107.7 (C-3a), 119.4 (C-5), 175.7, and 177.2. The resonances at δ 177.2 and 175.7 are not coupled to the OCH_3 hydrogens and therefore must represent a carbonyl carbon and an sp^2 carbon bearing an OH group. This strongly indicates nitrogen substitution at C-2 and thus structure **8**.

The proton decoupled ^{13}C nmr spectrum of **9** exhibits 43 signals. The presence of fragment **11***a* was assumed, since 22 of the signals are very close to the 22 signals observed for **8**, with respect to chemical shift (within 0.2 ppm), multiplicity, and long range coupling (confirmed by selective proton decoupling of the NCH_3 (δ 3.68), the lower field OH (δ 18.45), the lower field C-8 H (δ 6.83), and the lower field $ArCH_3$ (δ 2.88)). That the remaining 21 resonances are due to a fragment of structure **11***b* was confirmed by analysis of the long range $^{13}C-^1H$ coupling (selective proton decoupling of the NCH_3 (δ 3.68), the higher field OH (δ 17.91), the higher field C-8 H (δ 6.79), and the higher field $ArCH_3$ (δ 2.78)), as described above for compound **8**. In this case the OH (δ 17.91) is coupled to four resonances: δ 109.2 (C-9a), 121.5 (C-8), 176.5, and 178.2. The δ 178.2 and 176.5 signals are also coupled to the C-8 hydrogen, thus confirming their assignment as C-1 and C-9. This coupling is uniquely consistent with fragment **11***b*. The complete assignment for **9** is given in Table 1.

The structures **8** and **9** are unambiguously confirmed and that of **10** may be inferred since its ^1H nmr spectrum is in agreement with that of fragment **11***b* in **9**. Thus the structure of the parent compound, for which we suggest the trivial name Scleroderris green, must be **12** (several tautomers possible).

Structure **12** is closely related to the structure proposed (1) for Scleroderris blue (**4**). This structural relationship was confirmed as follows. Scleroderris blue was treated with sodium bisulphite (the blue colour gradually changed to violet, green, and then yellow). After 18 h the tlc of the crude reaction mixture showed a major spot corresponding to **12**. Treatment of the crude reaction mixture with diazomethane (excess) gave, after ptlc (petroleum ether – ethyl acetate, 4:1), three products identical with authentic samples of **8** (tlc, ir, ^1H nmr, hrms), **9** (tlc, ir, ^1H nmr, hrms), and **10** (tlc). In addition, a solution of **12**



12

[4]Because of strong intramolecular hydrogen bonding, C-3 and C-4 are indistinguishable.

(dichloromethane–methanol), on standing, gives a blue compound identical (tlc) with Scleroderris blue (**4**).

The wood of Scleroderris infected pine shows a characteristic yellowish green coloration (19). It is possible that compound **12** causes this discoloration.

Experimental

For general experimental details see part 2 (2).

Growth of Gremmeniella abietina *strain C-656 and extraction of metabolites*

Gremmeniella abietina (strain C-656) was grown in liquid still culture at 16–17°C, as reported previously (2). After 4 weeks the mycelium was separated from the broth, washed with cold methanol, and dried. The dry mycelium was extracted with ethyl ether (24 h) and twice with methanol (24 h each) in a Soxhlet apparatus. The ether and methanol extracts were separately concentrated *in vacuo* at 30°C.

Isolation of metabolites from G. abietina *strain C-656*

The crude mycelium ether extract of *G. abietina* C-656 gave ca. 0.1 g/L of crude metabolites and the combined crude methanol extracts gave 0.4 g/L. Both extracts were brownish oils (similar by tlc). The crude mycelium ether extract (0.8 g) was fractionated by flash column chromatography (20) on Merck Silica Gel 60 (40–63 μm) with the following solvent system: dichloromethane–methanol (49:1, 1.5 L), dichloromethane–methanol (46:2, 1 L), and methanol (0.5 L). Fractions of 125 mL were collected. Fractions 2–4 and 15 were further purified as indicated for the individual components.

Fatty acids

The fatty acids were eluted in the most polar fractions. Fractions 19–21 (50 mg) gave a single spot on tlc; tlc: R_f 0.16 (dichloromethane–methanol, 49:1); ir ($CHCl_3$, cast): 2925, 2855, 1711, 1460, 1280, 938, 720 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 0.89 (vt, 6.5 Hz, CH_3), 1.26–1.32 (m, $CH_2)_n$), 6.64 (m, CH_2CH_2CO), 2.0–2.08 (m, $CHCH$=), 2.34 (t, 8.0 Hz, CH_2CO), 2.77 (t, 6.5 Hz, =$CHCH_2CH$=), 5.30–5.42 (m, CH=CH); hrms, *m/z*: 97 (21), 95 (30), 83 (39), 82 (26), 81 (50), 69 (65), 68 (29), 67 (61), 57 (49), 56 (25), 55 (100); cims, *m/z*: 300 (*M* + 18 for 282, 26), 298 (*M* + 18 for 280, 74), 296 (*M* + 18 for 278, 87).

Methylation of fatty acids: the mixture of fatty acids (5 mg) was dissolved in dichloromethane (1 mL) and treated with excess ethereal diazomethane to give fatty acid methyl esters (5 mg); tlc: R_f 0.60 (petroleum ether – ethyl acetate, 9:1); hrms, *m/z*: 298 (25), 296 (27), 294 (34), 270 (13), 264 (95), 262 (14), 55 (100).

Fatty acid methyl esters

The fatty acid methyl esters were eluted in fractions 2–4 (80 mg). Preparative tlc (petroleum ether – ethyl acetate, 19:1, double elution) of these combined fractions gave a mixture of fatty acid methyl esters (10 mg); tlc: R_f 0.60 (petroleum ether – ethyl acetate, 9:1); ir ($CHCl_3$, cast): 3100, 2925, 2854, 1743, 1460, 1430, 1165, 720 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 0.89 (vt, 6.5 Hz, CH_3), 1.26–1.32 (m, $CH_2)_n$), 1.64 (m, CH_2CH_2CO), 2.0–2.08 (m, CH_2CH=), 2.28 (t, 8.0 Hz, CH_2CO), 2.75 (t, 6.5 Hz, =$CHCH_2CH$=), 3.67 (s, OCH_3), 5.30–5.40 (m, CH=CH); hrms, *m/z*: 298 (3), 296 (2), 294 (2), 270 (12), 264 (7), 74 (100).

Triglycerides

The triglycerides were eluted in fractions 2–4 (80 mg). Preparative tlc (petroleum ether – ethyl acetate, 19:1) of these combined fractions gave a mixture of triglycerides (30 mg); tlc: R_f 0.36 (petroleum ether – ethyl acetate, 9:1); ir ($CHCl_3$, cast): 3010, 2925, 2854, 1745, 1463, 1163, 720 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 0.89 (vt, 6.5 Hz, CH_3), 1.28–1.32 (m, $CH_2)_n$), 1.62 (m, CH_2CH_2CO), 2.05 (m, CH_2CH=), 2.32 (t, 7.0 Hz, CH_2CH_2CO), 2.78 (br t, 6.0 Hz, =$CHCH_2CH$=), 4.18 (dd, 6.0, 12 Hz, $OCH_2CH(O)CH_2O$), 4.30 (dd, 4.5, 12 Hz, $OCH_2CH(O)CH_2O$), 5.36 (m, CH=CH, $OCH_2CH(O)CH_2O$); hrms, *m/z*: 604 (45), 603 (80), 602 (63), 601 (40), 600 (43), 577 (78), 576 (39), 574 (25), 341 (7), 339 (28), 337 (8), 313 (19), 265 (24), 264 (36), 263 (32), 262 (89), 239 (11), 55 (100).

1,3-Diglycerides

The 1,3-diglycerides were eluted in fractions 6–10. Fraction 8 (10 mg) gave a single spot on tlc; tlc: R_f 0.45 (dichloromethane–methanol, 49:1); ir ($CHCl_3$, cast): 3460 (br), 2925, 2854, 1743, 1465, 1170, 720 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 0.90 (vt, 6.5 Hz, CH_3), 1.28–1.32 (m, $(CH_2)_n$), 1.62 (m, CH_2CH_2CO), 2.04 (m, CH_2CH=), 2.37 (t, 7.0 Hz, CH_2CH_2CO), 2.48 (d, 4.5 Hz, OH), 2.78 (br t, 6.0 Hz, =$CHCH_2CH$=), 4.18 (m, $OCH_2CH(OH)CH_2O$), 5.36 (m, CH=CH); hrms, *m/z*: 602 (2), 600 (2), 576 (2), 339 (39), 313 (27), 265 (23), 264 (26), 262 (35), 239 (15), 55 (100); cims, *m/z*: 640 (*M* + 18 for 622, 16), 638 (*M* + 18 for 620, 72), 636 (*M* + 18 for 618, 87), 634 (*M* + 18 for 616, 51), 612 (*M* + 18 for 594, 74), 610 (*M* + 18 for 592, 80).

1,2-Diglycerides

The 1,2-diglycerides were eluted in fractions 12–16 (50 mg). Preparative tlc (dichloromethane–methanol, 97:3) of fraction 15 gave a mixture of 1,2-diglycerides (6 mg); tlc: R_f 0.33 (dichloromethane–methanol, 49:1); ir ($CHCl_3$, cast): 3440 (br), 2925, 2854, 1740, 1463, 1170, 720 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 0.90 (vt, 6.5 Hz, CH_3), 1.28–1.32 (m, $(CH_2)_n$), 1.63 (m, CH_2CH_2CO), 2.03–2.08 (m, CH_2CH=, OH), 2.34 (m, CH_2CH_2CO), 2.79 (br t, 6.0 Hz, =$CHCH_2CH$=), 3.76 (t, 5.0 Hz, CH_2OH), 4.25 (dd, 6.0, 12 Hz, $OCH_2CH(O)CH_2OH$), 4.35 (dd, 4.5, 12 Hz, $OCH_2CH(O)CH_2OH$), 5.10 (m, $OCH_2CH(O)CH_2OH$), 5.36 (m, CH=CH); hrms, *m/z*: 604 (4), 602 (4), 576 (19), 341 (16), 339 (39), 313 (75), 265 (26), 264 (40), 262 (16), 239 (32), 55 (100); cims, *m/z*: 640 (*M* + 18 for 622, 13), 638 (*M* + 18 for 620, 16), 612 (*M* + 18 for 594, 88), 610 (*M* + 18 for 592, 18).

Sterol esters

The sterol esters were eluted in fractions 2–4. Preparative tlc (petroleum ether – ethyl acetate, 97:3, double elution) of these combined fractions gave a mixture of sterol esters (5 mg); tlc: R_f 0.55 (petroleum ether – ethyl acetate, 9:1); ir ($CHCl_3$, cast): 2954, 2928, 1736, 1460, 1175, 720 cm^{-1}; ^1H nmr ($CDCl_3$): see text; hrms, *m/z*: 662 (1), 660 (2), 535 (1), 382 (24), 381 (42), 380 (100), 337 (4), 282 (5), 255 (36), 253 (6); cims, *m/z*: 678 (*M* + 18 for 660, 69), 398 (100).

Hydrolysis of sterol esters: the mixture of sterol esters (4 mg), was dissolved in dichloromethane and 10% methanolic potassium hydroxide (excess) was added. After refluxing for 1 h, the reaction mixture was cooled, diluted with dichloromethane, washed with 5% hydrochloric acid, and concentrated. The resulting residue was fractionated by ptlc (petroleum ether – ethyl acetate, 4:1, double elution) to give a mixture of sterols (2 mg); tlc: R_f 0.26 (petroleum ether – ethyl acetate, 4:1); ir ($CHCl_3$, cast): 3400 (br), 2955, 2924, 2853, 1728 (w), 1460, 1370, 1060, 980 cm^{-1}; ^1H nmr ($CDCl_3$): see text; hrms, *m/z*: 400 (11), 298 (68), 396 (14), 383 (16), 363 (12), 314 (12), 300 (20), 271 (52), 255 (28), 69 (90), 55 (100).

Acetylation of sterols: the sterol mixture (2 mg) was dissolved in dichloromethane (1 mL) and acetic anhydride (excess) and pyridine (excess) were added at room temperature. After 24 h the reaction mixture was diluted with dichloromethane, washed with 5% hydrochloric acid, dried (Na_2SO_4), and concentrated to give a mixture of sterol acetates; tlc: R_f 0.70 (petroleum ether – ethyl acetate, 4:1); ir ($CHCl_3$, cast): 2955, 2860, 1730 (s), 1460, 1375, 1240, 1040, 970 cm^{-1}; ^1H nmr ($CDCl_3$): see text; hrms, *m/z*: 440 (16), 398 (16), 382 (20), 380 (100), 313 (19), 255 (38).

*Isolation of Scleroderris green (**12**)*

Scleroderris green (**12**) was isolated from the second methanol extract from *G. abietina* C-699. The crude mycelial extract was washed several times with cold dichloromethane and the residue was vacuum dried to afford ca. 200 mg of an amorphous greenish-yellow powder (mp > 340°C). Attempts at crystallization (CH_2Cl_2, EtOAc, MeOH, etc.) led to decomposition; tlc: R_f: 0.65 (benzene–acetone, 9:1), yellowish spot (with streaking), which turns blue on standing; uv (MeOH) λ_{max}: 214 (0.79), 259 (0.48), 396 (0.29) nm; ir ($CHCl_3$, cast): 3320 (br), 2920, 1617, 1380, 1280, 1060 cm^{-1}; ^1H nmr ($CDCl_3$) at 50°C, δ: 1.33 (6H, br s, C-3′ CH_3), 1.48 (6H, d, 6.6 Hz, C-2′ CH_3),

For personal use only.

1.56 (6H, br s, C-3′ CH_3), 2.84 (6H, s, $ArCH_3$), 4.69 (2H, q, 6.6 Hz, C-2′ H), 6.88 (2H, s, C-8 H), 12.44, 13.28, 13.42, 14.26 (ca. 4H, D_2O exchangeable); hrms, *m/z*: 340 (15), 326 (38), 311 (100), 269 (24); cims, *m/z*: 327 (100).

Methylation of Scleroderris green

Scleroderris green **12** (ca. 40 mg) was suspended in dichloromethane (10 mL) and was treated with excess ethereal diazomethane. After 12 h, the crude reaction mixture was evaporated to dryness and fractionated by ptlc (petroleum ether – ethyl acetate, 4:1, multiple elution), to give compounds **8** (8 mg), **9** (8 mg), and **10** (3 mg). Compounds **8** (orange crystals, mp 282–283°C) and **9** (red crystals, mp 275–277°C) were crystallized from dichloromethane–methanol.

Compound 8: tlc: R_f 0.29 (petroleum ether–ethyl acetate, 3:1), yellow spot; $[\alpha]_D$ −36.4° (*c* 0.44, $CHCl_3$); ir ($CHCl_3$, cast): 3400 (br), 2920, 1607, 1580, 1452, 1354, 1300, 1223 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 1.32 (6H, s, C-3′ CH_3), 1.46 (6H, d, 6.5 Hz, C-2′ CH_3), 1.54 (6H, s, C-3′ CH_3), 2.87 (6H, s, $ArCH_3$), 3.68 (3H, s, NCH_3), 3.90 (6H, s, OCH_3), 4.03 (6H, s, OCH_3), 4.64 (2H, q, 6.5 Hz, C-2′ H), 6.82 (2H, s, C-8 H), 18.50 (2H, s, OH); ^{13}C nmr ($CDCl_3$): see Table 1; hrms, *m/z* calcd. for $C_{43}H_{45}NO_{10}$ (M^+): 735.3043; found: 735.3035 (71), 704 (100); cims, *m/z*: 736 (100).

Compounds 9: tlc: R_f 0.35 (petroleum ether – ethyl acetate, 3:1), orange spot; $[\alpha]_D$ −78.6° (*c* 0.15, $CHCl_3$); ir ($CHCl_3$, cast): 3400 (br), 2920, 1607, 1580, 1455, 1354, 1299 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 1.27 (3H, s, C-3′ CH_3), 1.33 (3H, s, C-3′ CH_3), 1.46 (3H, d, 6.5 Hz, C-2′ CH_3), 1.47 (3H, d, 6.5 Hz, C-2′ CH_3), 1.52 (3H, s, C-3′ CH_3), 1.56 (3H, s, C-3′ CH_3), 2.78 (3H, s, $ArCH_3$), 2.88 (3H, s, $ArCH_3$), 3.68 (3H, s, NCH_3), 3.80 (3H, s, OCH_3), 3.87 (3H, s, OCH_3), 3.91 (3H, s, OCH_3), 4.04 (3H, s, OCH_3), 4.55 (1H, q, 6.5 Hz, C-2′ H), 4.64 (1H, q, 6.5 Hz, C-2′ H), 6.79 (1H, s, C-8 H), 6.83 (1H, s, C-8 H), 17.91 (1H, s, OH), 18.45 (1H, s, OH); ^{13}C nmr ($CDCl_3$): see Table 1; hrms, *m/z* calcd. for $C_{43}H_{45}NO_{10}$ (M^+): 735.3043; found: 735.3061 (100), 704 (80), 366 (24), 341 (29); cims, *m/z*: 736 (100).

Compound 10: tlc: R_f 0.48 (petroleum ether – ethyl acetate, 3:1), red spot; ir ($CHCl_3$, cast): 3400 (br), 2925, 1609, 1586, 1458, 1318, 1296 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 1.27 (6H, s, C-3′ CH_3), 1.46 (6H, d, 6.5 Hz, C-2′ CH_3), 1.52 (6H, s, C-3′ CH_3), 2.80 (6H, s, $ArCH_3$), 3.67 (3H, s, NCH_3), 3.75 (6H, s, OCH_3), 3.86 (6H, s, OCH_3), 4.56 (2H, q, 6.5 Hz, C-2′ H), 6.82 (2H, s, C-8 H), 17.91 (2H, s, OH); hrms, *m/z* calcd. for $C_{43}H_{45}NO_{10}$ (M^+): 735.3043; found: 735.3054 (100), 704 (69), 367 (39), 366 (44), 341 (26); cims, *m/z*: 736 (100).

Reduction of Scleroderris blue (4)

Scleroderris blue (**4**, 3 mg) was dissolved in dichloromethane–methanol (1:1, 2 mL) and aqueous sodium bisulfite (ca. 20 mg) was added with stirring at room temperature (the color of the reaction mixture changed from blue to violet, then green, and finally light yellow). After 18 h the reaction mixture was diluted with dichloromethane, washed with water (twice), dried, and concentrated. The tlc (benzene–acetone – acetic acid, 90:10:0.1) of the residue showed a major spot corresponding to Scleroderris green (**12**). To the residue (3 mg) in dichloromethane (1 mL) was added ethereal diazomethane (excess) at room temperature. After 12 h the solvents were evaporated and the residue was fractionated by ptlc (petroleum ether – ethyl acetate, 4:1, multiple elution) to give compounds **8** (0.5 mg), **9** (0.5 mg), and **10** (<0.3 mg). Compounds **8** and **9** were identical with authentic samples by tlc, ir, ^1H nmr, and hrms comparison; compound **10** was identical with an authentic sample by tlc.

Metabolites produced by the Scleroderris canker fungus, *Gremmeniella abietina*. Part 4.[1] Biosynthetic studies

WILLIAM A. AYER, M. SOLEDADE PEDRAS, AND DALE E. WARD
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 8, 1986

WILLIAM A. AYER, M. SOLEDADE PEDRAS, and DALE E. WARD. Can. J. Chem. **65**, 760 (1987).

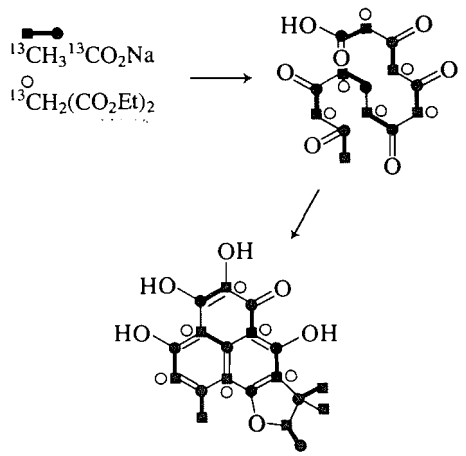
The biosynthetic origin of the carbon atoms of the most highly oxidized, polyketide derived, ring (carbons 1–3) of the *Gremmeniella abietina* metabolites sclerodione (**3**), scleroderolide (**4**), sclerodin (**5**), and Scleroderris green (**6**) has been studied. It is shown that both C-1 and C-3 of **3** and **4** are derived from C-1 of acetate, and that C-2 of scleroderolide (**4**) is derived from C-2 of acetate while C-3 is derived from C-1 of acetate. As expected, C-1 and C-3 of Scleroderris green (**6**) originate from the carboxyl carbon of acetate, while C-2 originates from the methyl carbon of acetate. Complete ^{13}C and ^{1}H nuclear magnetic resonance spectra of these metabolites are reported. It has also been shown that *ent*-atrovenetin (*ent*-**7***a*) is a metabolite of *G. abietina*.

WILLIAM A. AYER, M. SOLEDADE PEDRAS et DALE E. WARD. Can. J. Chem. **65**, 760 (1987).

On a étudié l'origine biosynthétique des atomes de carbone du cycle le plus oxydé (carbones 1–3) et dérivé d'un polycétide des métabolites du *Gremmeniella abietina* suivants : la sclérodione (**3**), le sclérodérolide (**4**), la sclérodine (**5**) et le vert de Sclérodérris (**6**). On a démontré que les carbones C-1 ainsi que C-3 des composés **3** et **4** sont dérivés du carbone C-1 de l'acetate et que le C-2 du sclérodérolide (**4**) est dérivé du C-2 de l'acétate alors que le C-3 est dérivé du C-1 de l'acétate. Comme on pouvait s'y attendre, les carbones C-1 et C-3 du vert de Scleroderris (**6**) ont leur origine dans le groupement carboxyle de l'acétate alors que le C-2 provient du carbone méthylique de l'acétate. On rapporte les spectres de résonance magnétique nucléaire ^{13}C et ^{1}H complets de ces métabolites. On démontre aussi que le *ent*-atrovenétine (**7***a*-*ent*) est un métabolite du *G. abietina*.

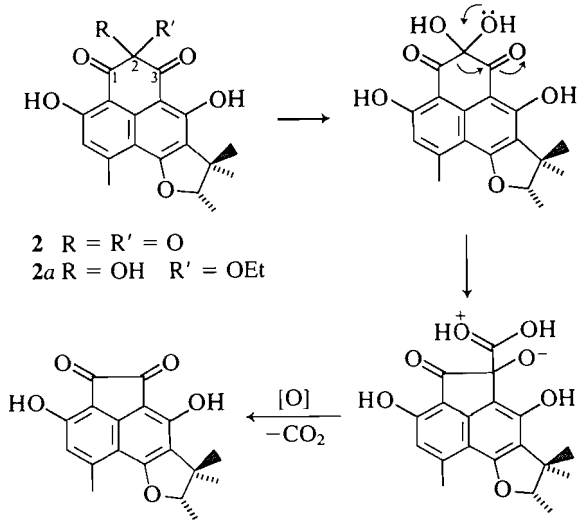
[Traduit par la revue]

We have previously reported (1–3) the isolation from *Gremmeniella abietina* of several metabolites, which contain a phenalenone nucleus fused to a dihydrofuran ring. Several structurally related metabolites have been isolated from other fungi.[2] Biosynthetic studies on metabolites of *Penicillium herquei* (e.g., atrovenetin (**1**)) have revealed a heptaketide origin for the phenalenone nucleus, whereas the dihydrofuran ring is mevalonate derived (Scheme 1) (5). The metabolites of *G. abietina* are expected to have a similar biosynthetic origin. Three of the metabolites (**3**, **4**, and **5**) have one carbon atom less than the parent phenalenones (e.g., **1** and **2**). In principle such a degradation could involve the loss of C-1, C-2, or C-3. We have previously speculated (6) that *ent*-atrovenetinone (**2**) could be a precursor of sclerodione (**3**), by loss of C-2. A possible pathway from **2** to **3** is illustrated in Scheme 2. Oxidation of **3** could lead to both sclerodin (**5**) and scleroderolide (**4**) (Scheme 3).



1

SCHEME 1



SCHEME 2

To examine the nature of this transformation we have studied the incorporation of [1-^{13}C]- and [2-^{13}C]acetate by *G. abietina* into compounds **3**, **4**, and **5**, as well as into the recently described Scleroderris green (**6**).

To follow the labelling pattern of ^{13}C enriched metabolites, it was first necessary to assign the ^{13}C chemical shifts for the metabolites. Since *ent*-atrovenetinone (**2**) is produced in small amounts, is unstable in solution (1), and since the stable ethanolate **2***a* is a mixture of epimers at C-2, we were prompted to utilize compound **6***a* rather than *ent*-atrovenetinone to represent metabolites with the intact phenalenone skeleton. Scleroderolide (**4**) was most conveniently isolated as the monoacetate **4***a*.

The ^{13}C nmr and ^{1}H nmr chemical shifts of **3**, **4***a*, **5**, and **6***a* are summarized in Tables 1 and 2. The ^{13}C nmr spectrum of **6***a* was assigned previously (3). Assignment of the ^{13}C nmr spectrum of sclerodin (**5**) was accomplished as follows. The

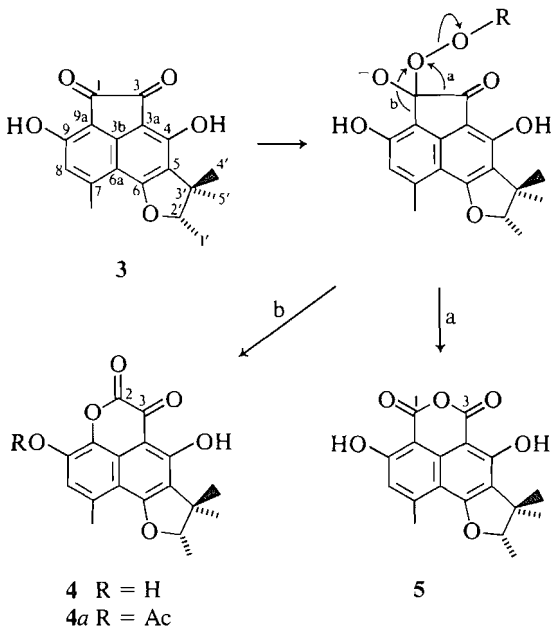
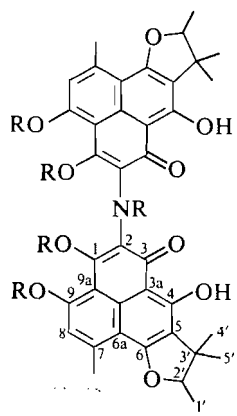


SCHEME 3

carbon shieldings in the proton decoupled spectrum may be subdivided into three groups: 5 sp^2 carbons bound to oxygen (δ 164–167); 7 other sp^2 carbons (δ 150–193); 6 sp^3 carbons (δ 14–93). The sp^3 carbons (C-1′, C-2′, C-3′, C-4′, C-5′, and $ArCH_3$) and C-8 are readily assigned on the basis of chemical shift, multiplicity, and by analogy to other metabolites (5). The remaining carbons of the phenalenone ring system are assigned by analysis of the 2-, 3-, and 4-bond $^{13}C-^1H$ coupling observed in the fully coupled spectrum (confirmed by selective proton decoupling experiments). Since the C-8 hydrogen should have



large (ca. 6 Hz) (7) coupling to both C-6a and C-9a and small (ca. 2 Hz) (7) coupling to C-7 and C-9, while only C-6a and C-7 should be coupled to the $ArCH_3$, the assignment of C-6a, C-7, C-9, and C-9a can be made unambiguously. The phenolic hydrogens at C-9 and C-4 are strongly hydrogen bonded and show coupling to C-1, C-9a, C-9 and C-3, C-3a, C-4, respectively. The previous assignment of C-9a allows unambiguous assignment of the phenolic hydrogens (C-9 OH, δ 11.43; C-4 OH, δ 11.64). Of the carbons coupled to the C-4 OH group, C-3a is assigned on the basis of chemical shift while C-4 is distinguished from C-3 on the basis of the magnitude of the coupling constants ($^2J_{CH}$ = 5 Hz, $^4J_{CH}$ = 2 Hz). Similarly, for the carbons coupled to the C-9 OH group the previous

[a]Shift (δ), (multiplicity, *J*(Hz), in $CDCl_3$).

assignment of C-9a and C-9 leads to the recognition of C-1 (confirmed by the magnitude of the coupling constants $^2J_{CH}$ = 5 Hz, $^4J_{CH}$ = 2 Hz). The remaining sp^2 carbon bound to oxygen is thus assigned as C-6 (confirmed by $^3J_{CH}$ to the C-2′ H). Of the two remaining carbons, C-3b is assigned due to its lack of long range coupling, whereas C-5 appears as a multiplet in the coupled spectrum.

The assignment of the ^{13}C nmr spectrum of sclerodione (**3**) was made in a similar fashion. However, in this case the phenolic hydrogens appear as very broad signals in the ^1H nmr spectrum (δ 7.48 and 7.79, $W_{1/2}$ = 16 Hz), precluding selective decoupling. Thus C-1 and C-3 are distinguished from C-4 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12

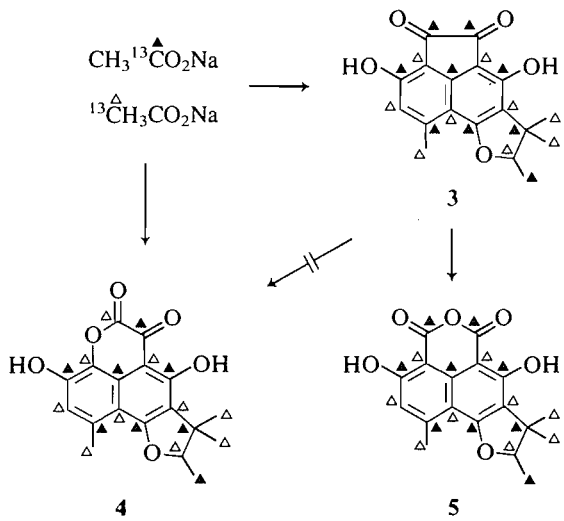


SCHEME 4

C-9 on the basis of chemical shift. While the assignment of C-9 (as with **5**) allows the assignment of C-4, C-1 and C-3 cannot be assigned unambiguously.

The assignment of the ^{13}C nmr spectrum of scleroderolide acetate (**4***a*) was made in a similar manner as for sclerodin (**5**). The acetate carbonyl (δ 168.2) is assigned by its two-bond $^{13}C-^{1}H$ coupling to the acetyl methyl hydrogens (δ 2.43). The C-2 carbonyl is assigned on the basis of its chemical shift (8) and its lack of long range coupling.

Gremmeniella abietina was grown in liquid still culture in the presence of sodium[1-^{13}C]acetate and, separately, in the presence of sodium[2-^{13}C]acetate. Compounds **3**, **4***a*, **5**, and **6***a* were isolated by chromatography.

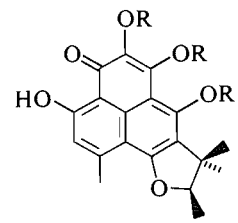
Examination of the proton decoupled ^{13}C nmr spectrum of compound **6***a*, isolated from the culture containing [1-^{13}C]-labelled acetate, showed enrichment (about 5% incorporation) at carbons 1, 3, 3b, 4, 6, 7, 9, 1′, and 3′ relative to the natural abundance spectrum. The use of [2-^{13}C]-labelled acetate led to enrichment at the remaining carbons (C-2, C-3a, C-5, C-6a, C-8, C-9a, $ArCH_3$, C-2′, C-4′, and C-5′). These results are consistent with those obtained with *P. herquei* (5) and confirm the polyketide–mevalonate origin of these metabolites.

Examination of the proton decoupled ^{13}C nmr spectrum of sclerodione (**3**), isolated from the culture containing [1-^{13}C]acetate, revealed the same labelling pattern as that of **6***a*; again carbons[3] 1, 3, 3b, 4, 6, 7, 9, 1′, and 3′ were enriched (about 3% incorporation) relative to the natural abundance spectrum. When sclerodione (**3**) was isolated from the culture containing [2-^{13}C]acetate, carbons 3a, 5, 6a, 8, 9a, $ArCH_3$, 2′, 4′, and 5′ were enriched. These results are fully consistent with the hypothesis of formation of sclerodione (**3**) by loss of C-2 from an intact phenalenone skeleton.

According to Scheme 3, oxidation of sclerodione (**3**), enriched at C-1 and C-3, would lead to sclerodin (**5**) also enriched at C-1 and C-3 (path a) and to scleroderolide (**4**) enriched at C-2 and C-3 (path b). The ^{13}C nmr spectrum of sclerodin (**5**), isolated from the culture containing [1-^{13}C]acetate, showed the same labelling pattern as that for **3** and **6***a* (i.e., C-1 and C-3 are enriched). The ^{13}C nmr spectrum for scleroderolide acetate (**4***a*) isolated from the same culture, however, failed to show the expected enrichment at C-2. These results were confirmed by incorporation of [2-^{13}C]acetate (C-2 of **4***a* is derived from C-2 of acetate). Thus sclerodione (**3**) may be a biosynthetic precursor to sclerodin (**5**) but not to scleroderolide (**4**) (Scheme 4). The pathway leading to scleroderolide (**4**) must involve oxidation at an earlier stage, perhaps prior to cyclization of the heptaketide chain. Interestingly, in vitro oxidation of sclerodione (**3**) with *m*-chloroperbenzoic acid gives both scleroderolide (**4**) and sclerodin (**5**) (2); however, air oxidation gives only sclerodin (**5**) (2).

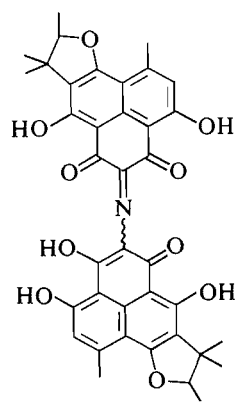
The oxidation of atrovenetin (**7**) to atrovenetinone (*ent*-**2**) (9) and **5** (10), as well as other unidentified products (**11**), has been reported. In our hands a dichloromethane–methanol solution of atrovenetin (**7**),[4] after standing for five weeks in the presence of air, gave rise to the enantiomers of compounds **2**, **3**, and **5** as the major products.

Examination of the hrms of crude methanol extracts of *G. abietina* revealed the presence of an ion corresponding to atrovenetin ($C_{19}H_{18}O_6$). Methylation (excess diazomethane) of the crude extract, followed by repeated chromatography, provided the enantiomer (*ent*-**7***a*) of atrovenetin trimethyl ether, indistinguishable by tlc, ir, ^{1}H nmr, ^{13}C nmr, and hrms from an authentic sample of **7***a*.[5]



7 R = H
7*a* R = Me

The presence of the enantiomer of atrovenetin in cultures of *G. abietina* raises the possibility that **2**, **3**, and **5** are produced by in vitro aerial oxidation. The possibility that the anhydride **5** is an isolation artifact has been mentioned previously (13), although in other cases (14) it seems to be of biological origin. Although the formation of some of compounds **2**, **3**, and **5** during the isolation process cannot be excluded, it seems unlikely that this is the only source of these substances; the air oxidation of **3** or **7** is a relatively slow process. It would



8

[3]For biogenetic reasons (see below) the ketonic carbonyls are numbered 1 and 3.

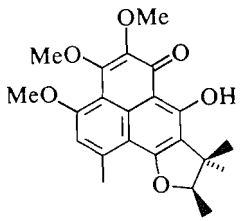
[4]Sample kindly provided by Professor L. C. Vining.

[5]Prepared by methylation of atrovenetin (12). This reaction gives two isomers of atrovenetin trimethyl ether (see Experimental). Structures **7***a* and **9** were assigned by analysis of ^{13}C nmr spectra, as described for **6***a*.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

appear that *G. abietina* catalyzes the oxidation of atrovenetin to other metabolites.

Another point that deserves consideration is the biogenesis of compound **6**. According to Narasimhachari and Vining (9) the blue green pigments of *P. herquei* did not form when sodium sulphite was present in the culture medium. This blue pigment possesses structure **8** (1), which may be formed by a ninhydrin-like reaction between atrovenetinone (**2**) and amino acids (1). Compound **6**, a reduced form of **8**, might be formed from *ent*-atrovenetin and *ent*-atrovenetinone (**2**), via atrovenetinone transamination. At this stage we do not know whether both **6** and **8** are produced in vivo by *G. abietina*. It is possible that **8** is an artifact derived from **6**.



9

Experimental

For general experimental details see part 2 of this series (2).

Nuclear magnetic resonance spectra

^{1}H nuclear magnetic resonance (^{1}H nmr) spectra and ^{13}C nuclear magnetic resonance (^{13}C nmr) spectra were measured on a Bruker WH-400 spectrometer. Solutions of 0.5–5% (w/v) in $CDCl_3$ (0.5 mL, 5-mm tube) were employed depending on availability of sample. For ^{1}H nmr, residual $CHCl_3$ in $CDCl_3$ was employed as the internal standard (assigned as 7.26 ppm downfield from tetramethylsilane (TMS)) and measurements are reported in ppm downfield from TMS (δ). For ^{13}C nmr, $CDCl_3$ was employed as the internal standard (assigned as 77.0 ppm downfield from TMS) and measurements are reported in ppm downfield from TMS (δ).

Incorporation of ^{13}C-labelled acetate

G. abietina C-699 was grown in liquid still culture (10 mL) in a medium of 10% V-8 juice and 1% glucose (15) in 2.8-L Fernbach flasks (1 liter of medium/flask), as reported previously (2). After 15 days of growth, a sterile solution of sodium [1-^{13}C]acetate (0.082 g, 1 mmol) in water (5 mL) was injected into each flask. After a further 7, and then 14 days, an additional 1.0 mmol of labelled acetate was injected into each flask. After a total of 38 days of growth the mycelium was removed by filtration (through cheesecloth), washed with cold methanol, and air dried in the dark (2 days). The dried mycelium was extracted in a Soxhlet extractor, twice with dichloromethane (12 and 24 h) and then twice with methanol (24 h each). The crude extracts were evaporated to dryness *in vacuo*, at room temperature. Compounds **3**, **4***a*, and **5** were isolated from the first crude dichloromethane extract (ca. 6.0 g), whereas compounds **6***a* and *ent*-**7***a* were isolated from the second crude methanol extract (ca. 250 mg).

The dichloromethane extract (700 mg) was fractionated by flash column chromatography (dichloromethane–methanol – acetic acid, 48:1:1, 3 L) and the fractions (125 mL) were coevaporated with toluene. The fractions were further purified as indicated for the individual components.

The second crude methanol extract showed two major components on tlc, one component corresponding to Scleroderris green (**6**) (higher R_f) and the other to atrovenetin (**7**).

The experiments with sodium [2-^{13}C]acetate were carried out in the same way as described above for sodium [1-^{13}C]acetate. The yields of the crude extracts were ca. 50% of the yields reported above.

Isolation of sclerodione (3)

Sclerodione (**3**) was eluted in fraction 5 (200 mg from 2.1 g of crude extract). Flash column chromatography (dichloromethane–methanol – acetic acid, 48:1:1) of this fraction gave crude sclerodione. Recrystallization from dichloromethane – petroleum ether gave sclerodione (20 mg), identical in all respects with an authentic sample.

*Isolation of scleroderolide monoacetate (4*a*)*

Scleroderolide (**4**) was more conveniently isolated as its monoacetate derivative **4***a*. Scleroderolide was eluted in fractions 6 and 7 in a very crude form. Flash column chromatography (dichloromethane–methanol – acetic acid, 48:1:1) of these combined fractions (300 mg, from 2.1 g of crude extract) gave crude scleroderolide (25 mg). Acetylation (acetic anhydride/pyridine/4-*N*,*N*-dimethylaminopyridine), followed by ptlc (benzene–acetone – acetic acid, 90:10:0.1, double elution) gave scleroderolide monoacetate (5 mg), identical in all respects with an authentic sample.

Isolation of sclerodin (5)

Sclerodin (**5**) was eluted in fractions 2 and 3. Flash column chromatography (petroleum ether – ethyl acetate, 4:1) of these combined fractions (600 mg, from 1.4 g of crude extract) gave crude sclerodin. Recrystallization from dichloromethane – petroleum ether gave sclerodin (20 mg), identical in all respects with an authentic sample.

*Isolation of pentamethyl Scleroderris green (6*a*)*

Pentamethyl Scleroderris green (**6***a*) was obtained on methylation (ethereal diazomethane) of the methanol extract. After 12 h the crude reaction mixture was evaporated to dryness and fractionated twice by ptlc (petroleum ether – ethyl acetate, 4:1, multiple elution) to give compound **6***a* (ca. 2 mg from 100 mg of crude extract), identical in all respects with an authentic sample.

Isolation of ent*-atrovenetin trimethyl ether (*ent*-7*a*)*

ent-Atrovenetin trimethyl ether (*ent*-**7***a*) was obtained on methylation (excess ethereal diazomethane) of the methanol extract. Fractionation of the crude reaction mixture by ptlc (petroleum ether – ethyl acetate, 4:1, multiple elution) gave a yellow residue (yellow fluorescence under uv light). Further purification by ptlc (benzene–acetone, 1:1) gave compound *ent*-**7***a* ($[\alpha]_D$ −103°), indistinguishable from authentic **7***a* (prepared from atrovenetin as follows) by tlc, ir, ^{1}H nmr, ^{13}C nmr, and hrms comparison.

Methylation of atrovenetin (7)

Atrovenetin (ca. 16 mg) was suspended in dichloromethane and excess ethereal diazomethane was added at room temperature. After 12 h the reaction mixture was evaporated and fractionated by ptlc (benzene–acetone, 19:1, double elution), to afford two major products **7***a* (ca. 4 mg, 22% yield) and **9** (ca. 8 mg, 44% yield).

*Atrovenetin trimethyl ether (7*a*):* tlc: R_f 0.35 (benzene–acetone, 19:1), yellow spot (yellow fluorescence under uv light); ir ($CDCl_3$, cast): 3240 (br), 2920, 1610, 1585, 1460, 1320, 1285 cm^{-1}; ^{1}H nmr ($CDCl_3$), δ: 1.28 (3H, s, C-3′ CH_3), 1.45 (3H, d, 7.0 Hz, C-2′ CH_3), 1.54 (3H, s, C-3′ CH_3), 2.80 (3H, s, $ArCH_3$), 3.85 (3H, s, OCH_3), 4.03 (3H, s, OCH_3), 4.09 (3H, s, OCH_3), 4.60 (1H, q, 7.0 Hz, C-2′ H), 6.84 (1H, s, C-8 H), 17.67 (1H, s, OH); ^{13}C nmr ($CDCl_3$), δ: 14.4 (C-1′), 22.1 (C-4a′), 26.2 (C-5′), 24.5 ($ArCH_3$), 44.3 (C-3′), 61.0, 62.3, 64.4 (3 × OCH_3), 90.5 (C-2′), 108.4 (C-6a), 109.3 (C-9a), 109.9 (C-3a), 121.3 (C-8), 126.9 (C-5), 127.8 (C-3b), 140.3 (C-2), 149.9 (C-7), 157.6 (C-4), 160.5 (C-3), 163.3 (C-6), 174.7 (C-9), 177.3 (C-1);[6] hrms, *m/z* calcd. for $C_{22}H_{24}O_6$: 384.1572; found: 384.1560 (100), 369 (79), 341 (67), 311 (13).

Atrovenetin trimethyl ether (9): tlc: R_f 0.32 (benzene–acetone, 19:1), yellow spot; ir ($CHCl_3$, cast): 3240 (br), 2920, 1610, 1585, 1455, 1355, 1300, 1260, 1220 cm^{-1}; ^{1}H nmr ($CDCl_3$), δ: 1.33 (3H, s, C-3′ CH_3), 1.48 (3H, d, 7.0 Hz, C-2′ CH_3), 1.57 (3H, s, C-3′ CH_3), 2.90 (3H, s, $ArCH_3$), 4.05 (6H, s, OCH_3), 4.11 (3H, s, OCH_3), 4.68 (1H, q, 7.0 Hz, C-2′ H), 6.88 (1H, s, C-8 H), 18.10 (1H, s, OH); ^{13}C nmr ($CDCl_3$), δ: 14.6 (C-1′), 20.5 (C-4′), 25.9 (C-5′), 24.1

Aerial oxidation of atrovenetin (7)

Atrovenetin (**7**, 20 mg) was suspended in chloroform–methanol (1:1) and exposed to sunlight in a loosely stoppered flask. After 5 weeks, separation of the reaction mixture by ptlc (dichloromethane–methanol, 49:1, double elution) gave three major fractions: R_f 0.90 (3 mg, 16%), R_f 0.55 (5 mg, 25%), and R_f 0.12 (4 mg, 22%). The R_f 0.90 compound was indistinguishable from sclerodin (**5**) by tlc, ^1H nmr, and hrms comparison. The R_f 0.55 compound was indistinguishable from atrovenetinone (**2**) by tlc and hrms comparison; its ethanolate (hot ethanol) was also indistinguishable from atrovenetinone ethanolate (**2***a*) by ir comparison. The R_f 0.12 compound was identical with sclerodione (**3**) by tlc, ^1H nmr, ^{13}C nmr, and hrms comparison.

Received August 22, 1986

WILLIAM A. AYER, SAMUEL K. ATTAH-POKU, LOIS M. BROWNE, and HELENA ORSZANSKA. Can. J. Chem. **65**, 765 (1987).

The metabolites formed in still cultures by *Ceratocystis minor*, one of the fungal species associated with the blue stain disease of pine, have been isolated and identified as ceratenolone (**5**), 6,8-dihydroxy-3-methylisocoumarin (**2**), 8-hydroxy-6-methoxy-3-methylisocoumarin (**8**), 3,4-dihydro-6,8-dihydroxy-3-methylisocoumarin (**10**), 3,4-dihydro-3-methyl-3,6,8-trihydroxy-3-methylisocoumarin (**12**), 3,4-dihydro-3-methyl-3,4,6,8-tetrahydroxyisocoumarin (**13**), and succinic acid. Ceratenolone (**5**), a new type of natural product, forms an intensely blue chelate with ferric ions. This chelate may be responsible for the blue coloration of the wood of pine infected by *Ceratocystis minor*.

WILLIAM A. AYER, SAMUEL K. ATTAH-POKU, LOIS M. BROWNE et HELENA ORSZANSKA. Can. J. Chem. **65**, 765 (1987).

On a isolé les métabolites qui se forment dans les milieux de culture du *Ceratocystis minor*, une des espèces de champignons reliés à la maladie des taches bleues du pin, et on les a identifiés comme étant la cératénolone (**5**), la dihydroxy-6,8 méthyl-3 isocoumarine (**2**), l'hydroxy-8 méthoxy-6 méthyl-3 isocoumarine (**8**), la dihydro-3,4 dihydroxy-6,8 méthyl-3 isocoumarine (**10**), la dihydro-3,4 méthyl-3 trihydroxy-3,6,8 isocoumarine (**12**), la dihydro-3,4 méthyl-3 tétrahydroxy-3,4,6,8 isocoumarine (**13**) et l'acide succinique. La cératénolone (**5**), un nouveau type de produit naturel, forme un chélate bleu intense avec les ions ferriques. Ce chélate pourrait être responsable de la coloration bleue du bois de pin infecté par le *Ceratocystis minor*.

[Traduit par la revue]

Introduction

The blue stain disease of conifers is a serious disease of pine that currently causes the death of over 40 million pine trees per year in Western Canada (1–3). The disease is spread by the mountain pine beetle (*Dendroctonus ponderosae* Hopk.), which lives symbiotically with a variety of microorganisms (1). Four species of blue stain fungi have consistently been isolated from diseased wood, including *Ceratocystis clavigera*, *C. huntii*, *C. ips*, and *C. minor*. In part 1 of this series we described the metabolites produced in liquid culture by the first three mentioned *Ceratocystis* species. The metabolites of *C. minor* were not included in our initial study since they had been the subject of an earlier investigation (4, 5). As a part of our earlier study we investigated the rate at which the various *Ceratocystis* species caused the blue staining of pine chips and pine bolts. We found that *C. minor* was the most active in this respect followed by *C. huntii*, then *C. clavigera*. 2,3-Dihydroxybenzoic acid (**1**), which forms an intensely blue complex with ferric ions and which induces blue staining of lodgepole pine shavings and debarked sapwood (1), was isolated as one of the metabolites of *C. huntii*. It was postulated that the blue stain associated with the fungal infection might be due to metal complexes of compound **1** (1). Since 2,3-dihydroxybenzoic acid was not reported as a metabolite of *C. minor* (4, 6), and since this fungus stains pine most rapidly, we decided to reexamine the metabolites produced by the fungus. The metabolites reported earlier (4–6), 6,8-dihydroxy-3-methylisocoumarin (**2**), 6,8-dihydroxy-3-hydroxymethylisocoumarin (**3**), and 3,6,8-trihydroxy-α-tetralone (**4**), although phenolic in nature, do not contain the 2,3-dihydroxybenzoyl unit found in many strongly iron-chelating compounds (7) often referred to as siderophores (8). In this article we report the isolation of several metabolites, including a new natural product that chelates very strongly with ferric ions, produced in liquid culture by *C. minor*.

Results and discussion

Ceratocystis minor (Hedgcock) Hunt was grown in liquid still culture using a modified malt extract medium. Extraction of the pale yellow culture broth with ethyl acetate gave a pale blue extract, which was separated into "neutral" and "acidic" fractions using sodium bicarbonate solution. The blue coloration disappeared during the bicarbonate treatment but reappeared when the alkaline solution was acidified. The pale blue acidic fraction could be decolorized by dissolution in dilute sodium hydroxide solution followed by reacidification. The colorless extract, however, showed a pale blue spot on thin-layer chromatography (tlc) when eluted with chloroform–acetone – acetic acid in the ratio 23:1:1. When the ratio was 97:2:1, no blue coloration was observed until the plate was sprayed with ferric chloride solution. The compound responsible for this behavior, which we have named ceratenolone, was separated by flash chromatography using the $CHCl_3$:Me_2CO:AcOH (23:1:1) solvent system and collecting the "blue" fraction, which was decolorized by treatment with dilute sodium hydroxide.

Ceratenolone, obtained as a viscous oil, has the molecular formula $C_{14}H_{20}O_3$, as determined by high resolution mass spectrometry (hrms). The ultraviolet (uv) spectrum shows maxima at 312 and 396 nm, shifted to 317 and 400 nm by the addition of base. The infrared (ir) spectrum shows H-bonded hydroxyl absorption in the 2600–3400 cm^{-1} region and absorption at 1662 and 1616 cm^{-1} in the double bond region. The ^1H nmr spectral data (see Experimental for details) revealed the presence of a methyl, an ethyl, and a *sec*-butyl group, all linked to fully substituted carbons. The methine proton of the *sec*-butyl group appears considerably downfield (δ 2.62), suggesting this group is linked to unsaturated carbon. The remaining hydrogens of ceratenolone appear as a singlet at δ 5.90, a doublet at δ 8.44 (J = 9.0 Hz), and a doublet at δ 16.36 (J = 9.0 Hz). On treatment with D_2O, the peak at δ 16.36 disappears and the signal at δ 8.44 becomes a singlet, suggesting the presence of an H-bonded hydroxymethylene group. The ^{13}C nmr spectrum shows signals for the alkyl groups mentioned above, a quaternary carbon (δ 58.6), and sp^2 carbons as doublets at δ 116.6 and 173.5 and as singlets at δ 109.4, 159.2, 199.8, and 206.2. The appearance of a strong peak at m/z 208 in the mass spectrum of ceratenolone, corresponding to the loss of ethylene from the molecular ion, suggested that the ethyl group is located

17

α to a carbonyl group (leading to loss by McLafferty rearrangement). At this stage it was possible to define the structural units present in ceratenolone (an enolized β-ketoaldehyde, an α,β-unsaturated ketone carrying a *sec*-butyl group, a quaternary carbon carrying a methyl and an ethyl group, one ring) but it was not possible to unambiguously determine their arrangement. The X-ray crystallographic study described below establishes the carbon skeleton and permits the assignment of structure **5** (the absolute configuration was not determined) to ceratenolone. The hydroxymethylene ketone form **5** is believed to be the major tautomer, rather than the aldo enol form **5***a*, because of the relatively large coupling constant (9 Hz) observed for the enolic hydrogen (9).

Treatment of ceratenolone with acetic anhydride – pyridine gave rise to a colorless, crystalline compound $C_{20}H_{28}O_7$, resulting from the incorporation of an acetoxyl and two acetyl groups. This derivative, which does not give a color reaction with ferric chloride, was shown by a single crystal X-ray diffraction study to possess structure **6**. Compound **6** presumably arises by acetylation of the enolic hydroxyl of **5** and 1,6-addition of acetic anhydride to the unsaturated carbonyl system. Diacetylacetoxyceratenolone (**6**) crystallizes from Skellysolve B as colorless prisms, mp 103–104°C. Figure 1 is a computer generated perspective drawing of the final X-ray model of diacetylacetoxyceratenolone (**6**).[2]

Ceratenolone represents a new structural type among natural products. Biogenetically, it may arise by condensation of two 4-methyltriacetic acid equivalents as illustrated in Scheme 1, with subsequent adjustment of the oxidation level. The enolized β-ketoaldehyde functionality presumably accounts for the iron chelating ability of ceratenolone. This chelate may be responsible for the blue coloration of the wood of pine infected with *C. minor*.

[2]The X-ray crystallographic study was carried out by R. G. Ball, Structure Determination Laboratory, Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2. Inquiries regarding the crystallographic results should be directed to Dr. Ball at the above address quoting report number SR:012505-03-84.

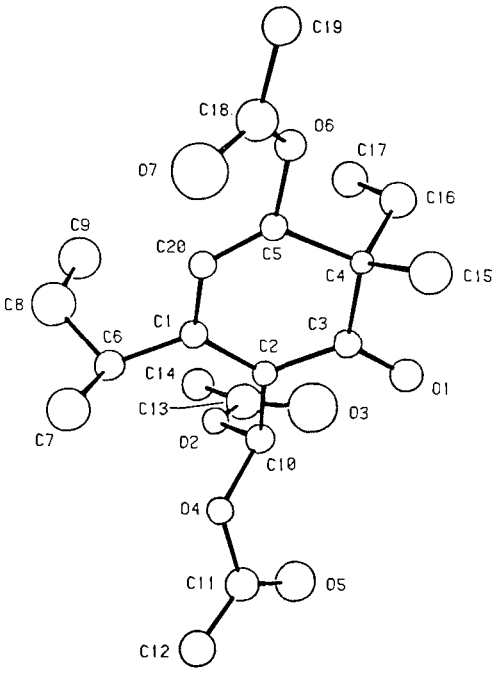

FIG. 1. Computer generated perspective drawing of compound **6**.

In addition to ceratenolone, several phenolic compounds and succinic acid are present in the acidic fraction of the broth extract. The previously reported metabolite of *C. minor*, 6,8-dihydroxy-3-methylisocoumarin (**2**), was isolated and identified by comparison of its spectral properties and those of its diacetyl derivative **7** with those reported (4–6). Four related methylisocoumarins were also isolated. The structures were established by comparison of the spectral data for the metabolite and its acetyl derivative with those of compounds **2** and **7** as follows. The least polar compound, **8**, is an O-methyl derivative of **2**. Since the ir spectrum of **8** shows the weak hydroxyl and low frequency carbonyl absorption (1683 cm^{-1}) characteristic

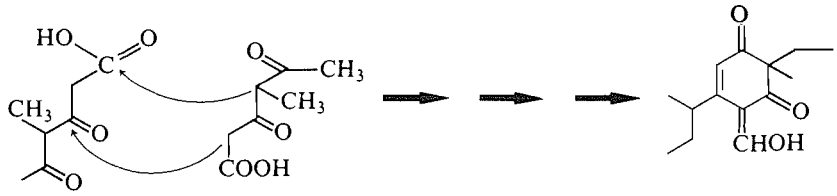
For personal use only.



SCHEME 1

of 8-hydroxyisocoumarins, it is the C-6 hydroxyl that is methylated. Acetylation of **8** afforded a monoacetyl derivative **9**. Compound **8**, which has previously been isolated from *C. fimbriata* (10), displays behavior on silica gel somewhat similar to that described earlier for ceratenolone. When a colorless ethyl acetate solution of **8** is adsorbed on silica gel it forms a pale pink band and elutes as a pale pink solution.

The second isocoumarin metabolite **10** is the dihydro derivative of **2**. In the ^{1}H nmr spectrum of **10** no signals characteristic of a vinyl proton or vinyl methyl are present; instead, a low-field methine (δ 4.68) coupled to a methyl group (δ 1.45) and two benzylic methylene protons (δ 2.85, 2.88) are observed. The spectral properties of compound **10**, which readily forms the diacetyl derivative **11** (acetic anhydride – pyridine), are identical with those reported (11–14).

A more polar metabolite, $C_{10}H_{10}O_5$ (**12**), is an hydrated derivative of **2** (11). The ^{1}H nmr spectrum of **12** shows the presence of a low-field methyl singlet (δ 1.65) and a benzylic methylene singlet (δ 3.09). Acetylation of **12** occurs with loss of acetic acid to give 6,8-diacetoxy-3-methylisocoumarin (**7**). The properties of **12**, which has been isolated previously from *Alternaria kikuchiana* (15), are identical with those reported (15–17).

The most polar component of the acidic fraction, $C_{10}H_{10}O_6$, was also the major component produced by *C. minor*. It was isolated as an inseparable mixture of epimers and was shown to be a dihydroxylated derivative (**13**) of compound **2**. Its tautomeric form **14** has previously been reported as a metabolite of *C. ulmi* (18). The ir spectrum of **13** shows intense hydroxyl (3400, 3300, 3055 cm^{-1}) and low frequency carbonyl (1635 cm^{-1}) absorption bands. The ultraviolet spectrum of **13** shows absorption maxima at 300, 267, 216, and 214 nm. Comparison of this data with that of tautomer **14** (18) and compound **17** (described below) supports the assignment of an isocoumarin structure to **13**. The ^{1}H nmr spectrum of **13** clearly shows two sets of signals for the major and minor epimer of the mixture (ratio 2:1). The major isomer shows four D_2O exchangeable protons (δ 5.92, 7.55, 10.60, 11.12), two *meta*-related aromatic protons (δ 6.22, 6.38), a low-field benzylic methine (δ 4.20), and a low-field methyl group (δ 1.52). The minor isomer shows similar proton resonances at δ 5.84, 7.38, 10.58, 11.10 (hydroxyl), 6.18, 6.50 (aromatic protons), 4.61 (benzylic methine), and 1.58 (methyl protons). The ^{13}C nmr spectrum of **13** confirmed that it was isolated as an epimeric mixture of lactols rather than as its keto acid tautomer. The lowest field signal (δ 168.4) in the spectrum is that arising from the lactol carbonyl. No signal characteristic of a ketone carbon is observed. Signals of a lactol carbon (δ 100.7), a benzylic carbinol carbon (69.1), six aromatic carbons, and a methyl carbon (δ 22.9, 24.4 indicating the isomeric mixture) are also present. The chemical shift assignments (see Experimental) are based on calculations using the principle of additivity of substituents. The observed values compare well with the calculated values. Acetylation of compound **13** gave a single triacetate derivative **15** in quantitative yield. Compound **15**, which is the only product formed, apparently results from the loss of acetic acid from tetraacetate **16**. The spectral properties of **15**, including its ^{13}C nmr spectrum, are consistent with its assigned structure.

The structures of compounds **2**, **8**, **10**, and **12** were further secured by correlation with the known compound **17** (19, 20). Catalytic hydrogenation of **8** afforded 3,4-dihydro-8-hydroxy-6-methoxy-3-methylisocoumarin (**17**). The ^{1}H nmr spectrum of **17** shows the presence of an intramolecular H-bonded phenolic proton (δ 11.26), two *meta*-related aromatic protons (δ 6.26 and 6.38), two benzylic protons (δ 2.88), an acyloxy proton (δ 4.69), a methoxyl group (δ 3.84), and a methyl doublet (δ 1.54). Nuclear Overhauser enhancement (nOe) studies confirm the placement of the substituents in **17**. Thus, irradiation of the benzylic methylene enhances the aromatic signal at δ 6.28 (H-5), and irradiation of the methoxyl protons causes enhancement of both aromatic hydrogen signals. The phenolic OH must then be located at C-8, in agreement with its H-bonded nature. The lactone carbonyl absorbs at 1655 cm^{-1}, confirming that it is also H-bonded. Treatment of compound **10** with ethereal diazomethane at −10°C gives compound **17**. Acetylation of **10** provides compound **11**, which may also be obtained by catalytic hydrogenation of compound **7**. Compound **7**, in turn, is prepared by acetylation of **2** and of **12**.

Examination of the neutral fraction of the broth extract of *C. minor* led to the isolation of methylisocoumarins **2**, **8**, and **10**. The mycelium of *C. minor* was extracted and separated into acidic and neutral fractions. Chromatographic separation of each of the fractions led to the isolation of small amounts of ceratenolone (**1**) along with compound **8** and appreciable amounts of triglycerides. The separation and characterization of the triglycerides was not pursued.

Experimental

High resolution mass spectra were recorded on an A.E.I. MS-50 mass spectrometer coupled to a DS 50 computer. Unless diagnostically significant, only peaks greater than 20% of the base peak are reported. Infrared spectra were recorded on a Nicolet 7199 FT spectrometer. High field ^{1}H nmr spectra were recorded on a Bruker WH-200 or WH-400 spectrometer with an Aspect 2000 computer system. Optical rotations were obtained on a Perkin Elmer 141 polarimeter. Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. E. Merck silica gel 60 (230–400 mesh) was used for flash chromatography. Analytical thin-layer chromatography (tlc) was carried out on BDH precoated plates of silica gel 60 PF 254, with visualization by ultraviolet light or 5% phosphomolybdic acid in 5% sulfuric acid, followed by careful charring on a hot plate. All solvents were distilled prior to use. Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C.

Fungal cultures

The blue stain fungi used in this study were obtained from Y. Hiratsuka, Northern Forest Research Centre, Edmonton, and deposited with L. Sigler, Curator, The University of Alberta Microfungus Collection (UAMH). *Ceratocystis minor* (Hedgcock) Hunt strain

C-839 (UAMH 4820) was isolated by A. Tsuneda from *Pinus contorta* growing in southern Alberta in June 1983.

Ceratocystis minor was maintained at 4°C in slant tubes containing 0.2% yeast extract in Difco potato dextrose agar. An aqueous suspension of mycelium was used to inoculate two potato dextrose – yeast extract agar plates. After 7–10 days at 17°C the culture was blended in a Waring blender with approximately 200 mL of sterile medium, and 20-mL aliquots were used to innoculate 10 × 1-L sterile modified malt extract medium in 2-L Fernbach flasks. (Modified malt extract medium: Difco malt extract 20 g, dextrose 20 g, peptone 1 g in water 1 L.) After inoculation, the still cultures were kept at room temperature for 8 weeks. The culture broth was decanted from the mycelium, concentrated *in vacuo* to about 1 L, and extracted by stirring with an equal volume of ethyl acetate for 24 h. The extraction procedure was repeated three times. The combined ethyl acetate extract was dried and concentrated to give crude broth extract. The mycelium was air dried, pulverized, and subjected to Soxhlet extraction with ethyl acetate. The ethyl acetate was dried and concentrated to give crude mycelial extract.

Isolation of metabolites

The broth extract (2.3 g) was redissolved in ethyl acetate (200 mL) and extracted with saturated sodium bicarbonate (3 × 15 mL). The bicarbonate extract was washed with ethyl acetate (3 × 20 mL), cooled with ice, acidified to pH 3 with 6 *N* hydrochloric acid, and extracted with ethyl acetate (3 × 50 mL). The ethyl acetate extract was dried (anhydrous sodium sulfate), filtered, and evaporated to give a viscous oil (1.6 g). The ethyl acetate extract left after bicarbonate extraction was washed with brine, dried, filtered, and concentrated to give neutral material (0.65 g). The acidic viscous oil (1.6 g) was dissolved in hot ethyl acetate (40 mL) and chloroform (10 mL) was added. The solution was allowed to cool and stored at 10°C for 48 h. The precipitate (0.560 g) was collected by filtration and dried *in vacuo*. Repeated precipitation from hot ethyl acetate afforded a solid material (0.200 g, **13**). Component **13** is an inseparable mixture of isomers (2:1 ratio) and the major component produced by *C. minor*. The mother liquor, obtained after precipitation of the major metabolite, was concentrated and subjected to flash column chromatography on silica gel. The following metabolites were obtained.

Ceratenolone (5)

Elution of the column with 5% ethyl acetate in Skellysolve B afforded a purple colored solution as the least polar fraction. Evaporation of the solvent afforded a purple oil, which was decolorized in the following way. Extraction with 5% aqueous sodium hydroxide, acidification of the aqueous extract with dilute hydrochloric acid, extraction with diethyl ether, and evaporation of the solvent gave a colorless oil. The oil was identified as the "blue compound" ceratenolone (**5**) (40 mg); R_f 0.80 ($CHCl_3$:acetone:acetic acid, 23:1:1); $[\alpha]_D$ 0; $[\alpha]_{360}$ +210° (*c* 0.33, MeOH); uv λ_{max} (MeOH): 312 (ε = 1920), 396 (ε = 755) nm; λ_{max} (MeOH + few drops aqueous NaOH): 317 (ε = 1359), 400 (ε = 1877) nm; λ_{max} (acidification (aqueous HCl) of previous alkaline solution): 300 ($\varepsilon \approx$ 1800) nm; λ_{max} (MeOH + $FeCl_3$): 550 nm; ir ($CHCl_3$ cast): 3400–2400 (weak, broad), 2968, 1662, 1616 cm^{-1}; ^1H nmr ($CDCl_3$, 400 MHz) δ: 0.78 (t, *J* = 7 Hz, 3H), 0.96 (t, *J* = 7 Hz, 3H), 1.24 (d, *J* = 7 Hz, 3H), 1.38 (s, 3H), 1.56 (m, 1H), 1.68 (m, 1H), 1.98 (m, 2H), 2.62 (m, 1H), 5.90 (s, 1H), 8.44 (d, *J* = 8 Hz, 1H), 16.36 (d, *J* = 8 Hz, 1H, exchanges D_2O); ^{13}C nmr ($CDCl_3$, 50 MHz) δ: 9.8 (q), 11.3 (q), 19.9 (q), 21.4 (q), 28.8 (t), 33.1 (t), 35.6 (d), 58.6 (s), 109.4 (s), 116.6 (d), 159.2 (s), 173.5 (d), 199.8 (s), 206.2 (s); hrms, *m/z* calcd. for $C_{14}H_{20}O_3$: 236.1429; found: 236.1421 (75), 221 (10), 208 (79), 193 (52), 190 (26), 179 (100); cims, NH_3, *m/z*: 237 (M^+ + 1).

Ceratenolone (10 mg) was dissolved in a mixture of acetic anhydride (1 mL) and pyridine (0.5 mL) and left at room temperature for 4 h. The reaction mixture was poured into water (5 mL) and the aqueous solution extracted with ethyl acetate. Evaporation of the ethyl acetate gave a semicrystalline residue (13 mg), which was triturated with cold Skellysolve B. The residue was crystallized from Skellysolve B to give compound **6** (6 mg); R_f 0.51 ($CHCl_3$:acetone:acetic acid, 23:1:1); mp 103–104°C; uv (MeOH) λ_{max}: 323 (ε = 8269) nm; ir ($CHCl_3$ cast): 2960, 1768, 1640, 1570 cm^{-1}; ^1H nmr ($CDCl_3$, 400 MHz) δ: 0.68 (t, *J* = 7 Hz, 3H), 0.87 (t, *J* = 7 Hz, 3H), 1.14 (d, *J* = 7 Hz, 3H), 1.28 (s, 3H), 1.54 (d, q, *J* = 7.7 Hz, 2H), 1.68 (d, q, *J* = 7.7 Hz, 1H), 1.93 (dq, *J* = 7, 7 Hz, 1H), 2.06 (s, 3H), 2.07 (s, 3H), 2.25 (s, 3H), 3.33 (ddq, *J* = 7, 7, 7 Hz, 1H), 6.27 (s, 1H), 7.89 (s, 1H); ^{13}C nmr (C_6D_6, 100 MHz) δ: 9.1 (q), 12.1 (q), 19.1 (q), 20.1 (q), 20.2 (q), 20.4 (q), 23.3 (q), 28.0 (t), 33.1 (t), 37.4 (d), 53.5 (s), 86.2 (d), 109.8 (d), 124.7 (s), 160.5 (s), 162.5 (s), 167.7 (s), 168.3 (s), 199.2 (s); hrms, *m/z* calcd. for $C_{20}H_{28}O_7$: 380.1836; found: 380.1834 (6), 338 (6), 278 (12), 236 (100).

8-Hydroxy-6-methoxy-3-methylisocoumarin (8)

Elution with 10% ethyl acetate in Skellysolve B afforded a waxy material. Crystallization of this material from diethyl ether – Skellysolve B afforded **8** (10 mg). This compound was also isolated from the neutral broth extract (40 mg) and from the mycelium extract (20 mg); R_f 0.8 (chloroform:acetone:acetic acid, 23:1:1); mp 128–129°C (lit. (10) mp 128–129°C); ir ($CHCl_3$ cast): OH is almost absent, very broad, 1683, 1644, 1620, 1165 cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz) δ: 2.25 (d, *J* = 0.5 Hz, 3H), 3.86 (s, 3H), 6.28 (d, *J* = 2 Hz, 1H), 6.46 (d, *J* = 2 Hz, 1H), 6.18 (q, *J* = 0.5 Hz, 1H), 11.12 (sharp s, 1H, D_2O exchanges); hrms, *m/z* calcd. for $C_{11}H_{10}O_4$: 206.0576; found: 206.0577 (100), 191 (33), 177 (11), 135 (35).

Compound **8** was treated with acetic anhydride in pyridine for 6 h at room temperature. Purification of the isolated crude product by filtration through a short column of silica gel in a pipette (6 in. long × 1/4 in. diameter), followed by crystallization from 10% ethyl acetate in Skellysolve B, afforded crystalline 8-acetoxy-6-methoxy-3-methylisocoumarin (**9**); R_f 0.75 (chloroform:acetone:acetic acid, 23:1:1); mp 167–168°C; ir ($CHCl_3$): 1765, 1755, 1719, 1665, 1610, 1365, 1152, 1180, 1050 cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz) δ: 2.20 (d, *J* = 1 Hz, 3H), 2.40 (s, 3H), 3.90 (s, 3H), 6.18 (d, *J* = 1 Hz, 1H), 6.62 (d, *J* = 2 Hz, 1H), 6.67 (d, *J* = 2 Hz, 1H); hrms, *m/z* calcd. for $C_{13}H_{12}O_5$: 248.0681; found: 248.0688 (12), 206 (100), 191 (18), 135 (10).

6,8-Dihydroxy-3-methylisocoumarin (2)

Elution of the column with 20% ethyl acetate in Skellysolve B and evaporation of the solvent, followed by crystallization from ethyl acetate – Skellysolve B, afforded pure compound **2** (10 mg). Compound **2** (20 mg) was also isolated from the neutral broth extract, R_f 0.5 (chloroform:methanol:acetone:acetic acid, 16:2:1:1); mp 241–242°C (lit. (4–6) mp 240–242°C); ir (CH_3OH cast): 3250, 1679, 1645, 1629, 1382, 1253, 1184 cm^{-1}; ^1H nmr (CD_3CN, 200 MHz) δ: 2.20 (d, *J* = 0.5 Hz, 3H), 6.32, 6.34, and 6.30 (m, 3H), 6.28 (d, *J* = 0.5 Hz, 1H), 11.6 (s, 1H); hrms, *m/z* calcd. for $C_{10}H_8O_4$: 192.0410; found: 192.0424 (100), 177 (49), 163 (5), 150 (10), 121 (27).

The acetyl derivative of **2** was prepared and purified as described above to afford pure 6,8-diacetoxy-3-methylisocoumarin (**7**); R_f 0.80 (chloroform:acetone:acetic acid, 23:1:1); mp 126–127°C; ir ($CHCl_3$ cast): 1774, 1730, 1665, 1614, 1367, 1354, 1189, 1163, 1135 cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz) δ: 2.24 (d, *J* = 0.8 Hz, 3H), 2.32 (s, 3H), 2.40 (s, 3H), 6.22 (d, *J* = 0.8 Hz, 1H), 6.90 (d, *J* = 2 Hz, 1H), 7.04 (d, *J* = 2 Hz, 1H); hrms, *m/z* calcd. for $C_{14}H_{12}O_6$: 276.0619; found: 276.0632 (8), 234 (32), 192 (100), 177 (10).

Hydrogenation of **7** in ethyl acetate over 10% palladium on carbon at room temperature and 1 atmosphere (101.3 kPa) pressure afforded the dihydro derivative, which is identical in all respects with compound **11** described below.

3,4-Dihydro-6,8-dihydroxy-3-methylisocoumarin (10)

Further elution of the column with 20% ethyl acetate in Skellysolve B gave a single compound, which was crystallized to afford pure compound **10** (10 mg). Compound **10** (10 mg) was also isolated from the neutral broth extract; R_f 0.42 (chloroform:methanol:acetone:acetic acid, 16:2:1:1); $[\alpha]_D$ +19.4° (*c* 0.35, CH_3OH); mp 214–215°C (lit. (11) mp 214–215°C); ir (Nujol mull): 3208, 1652, 1632, 1477, 1385, 1257, 1211 cm^{-1}; ^1H nmr (CD_3CN, 200 MHz) δ: 1.45 (d, *J* = 6 Hz, 3H), 2.85 (d, *J* = 4 Hz, 1H), 2.88 (d, *J* = 2 Hz, 1H), 4.68 (ddq, *J* = 2 Hz, *J'* = 4 Hz, *J''* = 6 Hz, 1H), 6.22 (s, 2H), 7.85 (br s, 1H, CD_3OD exchanges), 11.25 (s, 1H, CD_3OD exchanges);

For personal use only.

hrms, m/z calcd. for $C_{10}H_{10}O_4$: 194.0576; found: 194.0582 (100), 176 (21), 150 (87).

The diacetyl derivative of compound **10**, 6,8-diacetoxy-3,4-dihydro-3-methylisocoumarin (**11**), was prepared and purified in the usual manner; R_f 0.85 (chloroform:acetone:acetic acid, 23:1:1); $[\alpha]_D$ +58° (c 0.20, CH_3OH); mp 115–116°C; ir ($CHCl_3$ cast): 1772, 1719, 1615, 1367, 1252, 1186, 1131, 1113, 1086, 1061 cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz) δ: 1.48 (d, J = 4 Hz, 3H), 2.32 (s, 3H), 2.38 (s, 3H), 2.92 (d, J = 3 Hz, 1H), 2.95 (d, J = 6 Hz, 1H), 4.65 (m, 1H), 6.86 (d, J = 2 Hz, 1H), 6.97 (d, J = 2 Hz, 1H); hrms, m/z calcd. for $C_{14}H_{14}O_6$: 278.0786; found: 278.0788 (1), 236 (34), 194 (100), 150 (39).

Treatment of **10** with diazomethane in ether at −10°C for 1 h afforded the monomethyl derivative, which is identical in all respects with compound **17** described below.

*3,4-Dihydro-3-methyl-3,6,8-trihydroxyisocoumarin (**12**)*

Elution of the column with 40% ethyl acetate in Skellysolve B afforded an impure solid material. Preparative thin-layer chromatography of this material on silica gel (type 60 F-254; 0.25 mm thickness), followed by crystallization from ethyl acetate in Skellysolve B, afforded pure compound (**12**) (7.8 mg); R_f 0.20 (chloroform:methanol:acetone:acetic acid, 16:2:1:1); $[\alpha]_D$ 0° (c 0.25, CH_3OH); mp 160–161°C (lit. (15) mp 155–157°C); ir (Nujol cast): 3400, 3237, 1660, 1620, 1372, 1232, 1116, 1065 cm^{-1}; ^1H nmr (CD_3CN, 200 MHz) δ: 1.65 (s, 3H), 3.09 (br s, 2H), 5.15 (v br s, 1H, CD_3OD exchanges), 7.85 (br s, 1H, CH_3OD exchanges), 6.25 (s, 2H), 10.22 (br s, 1H, CD_3OD exchanges); hrms, m/z calcd. for $C_{10}H_{10}O_5$: 210.0545; found: 210.0529 (21), 192 (11), 150 (100), 122 (8), 43 (77).

Compound **12** was acetylated in the usual manner with acetic anhydride in pyridine and the product purified to afford a diacetate derivative, whose physical and spectral properties are identical with those of compound **7**.

*3,4-Dihydro-3-methyl-3,4,6,8-tetrahydroxyisocoumarin (**13**)*

Elution with 40% ethyl acetate, 0.5% acetic acid in Skellysolve B, followed by precipitation of the product from ethyl acetate and cooling at 10°C overnight, afforded a solid component (**13**) (50 mg), identical with the component obtained earlier from the acidic fraction by precipitation from ethyl acetate – chloroform solution. Component **13** exists as a mixture of two inseparable isomers (2:1 ratio by ^1H nmr); R_f 0.3 (chloroform:methanol:acetone:acetic acid, 14:4:1:1); mp 208–212°C; ir (Nujol cast): 3400, 3300, 3055, 1635, 1622, 1465, 1321, 1164 cm^{-1}; uv λ_{max} (MeOH): 214 (ε 13 541), 216 (ε 11 121), 267 (ε 6012), 300 (ε 3730) nm; ^1H nmr (DMSO-d_6, 200 MHz), major isomer, δ: 1.52 (s, 3H), 4.20 (d, J = 3 Hz, 1H, collapses to a singlet on addition of D_2O), 5.92 (d, J = 3 Hz, 1H, D_2O exchanges), 6.22 (d, J = 2 Hz, 1H), 6.38 (d, J = 2 Hz, 1H), 7.55 (s, 1H, D_2O exchanges), 10.60 (s, 1H, D_2O exchanges), 11.12 (s, 1H, D_2O exchanges); minor isomer, δ: 1.58 (s, 3H), 4.61 (d, J = 6 Hz, 1H, collapses to a singlet on addition of D_2O), 5.84 (d, J = 6 Hz, 1H, D_2O exchanges), 6.18 (d, J = 2 Hz, 1H), 6.50 (d, J = 2 Hz, 1H), 7.38 (s, 1H, D_2O exchanges), 10.58 (s, 1H, D_2O exchanges), 11.10 (s, 1H, D_2O exchanges); ^{13}C nmr (DMSO-d_6) δ: 168.4 (C-1), 164.2 (C-6), 162.8 (C-8), 143.9 (C-10), 107.9 (C-5), 104.9 (C-9), 101.5 (C-7), 100.7 (C-3), 69.1 (C-4), 24.4, 22.9 (CH_3); hrms, m/z calcd. for $C_{10}H_{10}O_6$: 226.0474; found: 226.0477 (9), 210 (15), 183 (25), 181 (44), 165 (100), 150 (58), 137 (59).

Acetylation of the epimeric mixture of component **13** with acetic anhydride in pyridine afforded only one product in quantitative yield. The triacetyl derivative was identified as 3-methyl-4,6,8-triacetoxyisocoumarin (**15**); R_f 0.70 (chloroform:acetone:acetic acid, 23:1:1), mp 175–176°C; ir ($CHCl_3$ cast): 1764, 1690, 1620, 1371, 1180, 1032, 1015, 915 cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz) δ: 2.32 (s, 3H), 2.34 (s, 3H), 2.36 (s, 3H), 2.42 (s, 3H), 6.90 (d, J = 2 Hz, 1H), 7.45 (d, J = 2 Hz, 1H); ^{13}C nmr ($CDCl_3$) δ: 168.2, 168.1, 167.9 ($COCH_3$), 162.4 (C-1), 156.5 (C-6), 149.1 (C-8), 113.9 (C-9), 139.0 (C-10), 138.2 (C-4), 137.0 (C-3), 116.8 (C-5), 112.9 (C-7), 21.2, 21.0, 20.6 ($COCH_3$), 16.3 (CH_3); hrms, m/z calcd. for $C_{16}H_{14}O_8$: 334.0684; found: 334.0683 (2), 292 (22), 250 (43).

Finally, elution with 40% ethyl acetate, 0.5% acetic acid in Skellysolve B, followed by crystallization from ethyl acetate, gave succinic acid.

*3,4-Dihydro-8-hydroxy-6-methoxy-3-methylisocoumarin (**17**)*

Catalytic hydrogenation of **8** (5 mg) in ethanol (2 mL) over 10% palladium on carbon at room temperature and 1 atmosphere pressure for 3 h gave a single product. Crystallization of the product from hexane gave compound **17**; R_f 0.75 (chloroform:acetone:acetic acid, 23:1:1); mp 75–76°C (lit. (20) mp 75–76°C); ir ($CHCl_3$): 1655, 1629, 1583, 1379, 1250, 1157, 1033, 803 cm^{-1}; uv λ_{max} (CH_3OH), 216 (ε 19 860), 267 (ε 12 580), 302 (ε 4890) nm; ^1H nmr ($CDCl_3$, 400 MHz) δ: 1.54 (d, J = 7 Hz, 3H), 2.88 (d, J = 6 Hz, 2H), 3.84 (s, 3H), 4.69 (m, 1H), 6.26 (d, J = 2 Hz, 1H), 6.38 (d, J = 2 Hz, 1H), 11.26 (s, 1H); nOe: irradiation of δ 1.54 (C-3 CH_3) gives 24% enhancement at δ 4.69 (H-3), irradiation of δ 2.88 ($ArCH_2$) gives 16% enhancement at δ 4.69 (H-3) and 26% enhancement at δ 6.26 (H-5), irradiation or δ 3.84 ($ArOCH_3$) gives 12% enhancement at δ 6.26 (H-5) and 5% enhancement at δ 6.38 (H-7); hreims, m/z calcd. for $C_{11}H_{12}O_4$: 208.0732; found: 208.0736 (100), 190 (20), 164 (89).

Kinetic study of the reaction between cystine and sulfide in alkaline solutions

DAVID K. LIU AND S. G. CHANG

Applied Science Division, Lawrence Berkeley Laboratory, University of California, Berkeley, CA, U.S.A. 94720

Received September 12, 1986

DAVID K. LIU and S. G. CHANG. Can. J. Chem. **65**, 770 (1987).

The reaction between cystine (CySSCy) and hydrogen sulfide ion (HS^-) in alkaline solutions has been studied by amino acid analysis and uv–visible spectroscopy. The reaction occurs in two reversible steps to form cysteine (CySH), *S*-thiocysteine ($CySS^-$), and disulfide (S_2^{2-}), as represented by the reactions $CySSCy + HS^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} CySH + CySS^-$ and $CySS^- + HS^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} CySH + S_2^{2-}$. The equilibrium and rate constants were pH dependent due to the presence of various charge types of reactants and products. The rate constants at 25°C, pH 10.0, and $\mu = 0.17$ *M* were determined to be: $k_1 = 3.7 \pm 0.4\ M^{-1}\ min^{-1}$, $k_{-1} = 5.5 \pm 0.6\ M^{-1}\ min^{-1}$, $k_2 = 6.1 \pm 0.5\ M^{-1}\ min^{-1}$, and $k_{-2} = 122 \pm 20\ M^{-1}\ min^{-1}$. When the rate constant k_1 is expressed as $k_1 = A \exp(-E_a/RT)$, values of $A = (4.7 \pm 0.3) \times 10^{11}\ M^{-1}\ min^{-1}$ and $E_a = 15.8 \pm 0.9$ kcal mol^{-1} were obtained. The ionic strength and pH dependence of k_1 were also studied.

DAVID K. LIU et S. G. CHANG. Can. J. Chem. **65**, 770 (1987).

Utilisant l'analyse des acides aminés et la spectroscopie uv–visible, on a étudié la réaction de la cystine (CySSCy) et les ions hydrosulfures (HS^-), en milieu alcalin. La réaction se produit en deux étapes réversibles conduisant à la cystéine (CySH), la *S*-thiocystéine ($CySS^-$) et le disulfure (S_2^{2-}) par les réactions représentées par les équations suivantes : $CySSCy + HS^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} CySH + CySS$ et $CySS^- + HS^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} CySH + S_2^{2-}$. Dû à la présence de divers types de réactifs et de produits, les équilibres et les constantes de vitesse varient avec le pH. A 25°C, avec un pH = 10,0 et $\mu = 0{,}17$ *M*, on a déterminé que les constantes de vitesses sont les suivantes : $k_1 = 3{,}7 \pm 0{,}4\ M^{-1}\ min^{-1}$, $k_{-1} = 5{,}5 \pm 0{,}6\ M^{-1}\ min^{-1}$, $k_2 = 6{,}1 \pm 0{,}5\ M^{-1}\ min^{-1}$ et $k_{-2} = 122 \pm 20\ M^{-1}\ min^{-1}$. Lorsqu'on exprime la constante de vitesse par l'équation $k_1 = A \exp(-E_a/RT)$, on obtient les valeurs suivantes : $A = (4{,}7 \pm 0{,}3) \times 10^{11}\ M^{-1}\ min^{-1}$ et $E_a = 15{,}8 \pm 0{,}9$ kcal mol^{-1}. On a aussi étudié la relation qui existe entre la valeur de k_1 et la force ionique et le pH.

[Traduit par la revue]

Introduction

The reaction between cystine and sulfide has been the subject of various investigations. Kuster and Irion (1) reported the isolation of a new amino acid when wool was treated with sodium sulfide, the identity of which was subsequently confirmed by Horn *et al.* (2) to be that of lanthionine. More recently, Rao and Gorin (3) and Gattner and Zahn (4) studied the same reaction under milder conditions and found cysteine and *S*-thiocysteine produced in two equilibrium steps. However, the equilibrium constants for the individual steps were not determined and little kinetic information was given in their accounts. Our interest in this system stems from recent discovery in our laboratory that ferrous–cysteine complex can effectively remove NO from flue gas (5). We have also demonstrated that the cystine formed in the process can be efficiently converted back to cysteine with HS^-/SO_3^{2-} under appropriate conditions (unpublished experiments). Therefore, a more complete understanding of the cystine–sulfide system is desirable both from a theoretical and practical viewpoint. In this paper we report the equilibrium and rate constants of the reaction between cystine and sulfide at various pH, temperatures, and ionic strengths.

Experimental

Materials

L-(−)-Cystine (Kodak) and L-(+)-cysteine hydrochloride monohydrate (MCB) were used as received. Sodium citrate dihydrate (Mallinckrodt), $Na_2S \cdot 9H_2O$ (Mallinckrodt) and $Na_2B_4O_7 \cdot 10H_2O$ (Baker) were used without further purification. Ninhydrin, stannous chloride, and ethylene glycol monomethyl ether were purchased from Pierce Chemical Co. and were used as received. Electronic absorption spectra were obtained on a Varian Cary 219 spectrophotometer.

Amino acid analysis

The concentrations of cystine, cysteine, and *S*-thiocysteine were determined by a combination of ion-exchange chromatography and quantitative photometric ninhydrin method, first developed by Moore and Stein (6). The amino acid analyzer used in this study was built in-house with the following components: A Rheodyne Model 7010 sample injection valve with a 500 μL sample loop, Eldex Model B-100-S and E-120-S high pressure single piston pumps, a Technicon Model 1 colorimeter with a 570 mm filter, and a Hewlett-Packard 680M strip chart recorder. The jacketed column (9 mm id) was packed with a sulfonated cation exchange resin (16 ± 2 μm) to a height of 13 cm and was thermostated at 55°C. The eluant employed was a pH 3.25 citrate buffer (0.2 *M* Na^+) with a flow rate of 1.5 mL min^{-1}, whereas the flow rate of the ninhydrin solution was set at 0.7 mL min^{-1}. The amino acid analyzer generally operated at a pressure of ~100 psi, and under such conditions the analysis time for each sample was ~30 min.

General procedure

In a typical kinetic experiment, cystine (0.0481 g; 0.2 mmol) was dissolved in 90.0 mL pH 10.0 borate buffer (0.05 *M* Na^+) and the solution was subjected to uv–visible spectroscopic and amino acid analyses. A 0.2 *M* Na_2S stock solution (10.0 mL) was then added to the above cystine solution and the reaction mixture was stirred under a N_2 atmosphere. The reaction mixture (1.0 mL) was taken out at designated time intervals and diluted ten times with the pH 3.25 citrate buffer for uv–visible spectroscopic and amino acid analyses. In the equilibrium studies, the reaction was allowed to proceed until no change in reactant and product concentrations was observed (generally less than 3 h). The concentrations of the amino acids were determined by comparing their peak areas to those of standard samples. The retention times for $CySS^-$, CySH, and CySSCy under present conditions were about 9, 21, and 28 min, and their relative sensitivities were 1.0:1.6:30.8, respectively.

In the temperature dependence experiments, the reaction mixtures

TABLE 1. Composition of equilibrium mixtures and equilibrium constant of reactions [3] and [4] at various pH at 25°C[a]

pH[b]	[CySSCy]	[CySH]	[CySS$^-$]	[HS$^-$]	[S_2^{2-}]	K_1	K_2
8.0	0.51	2.40	0.58	17.60	0.91	0.16	0.21
9.0	0.30	2.25	1.15	17.75	0.50	0.49	0.06
10.0	0.24	2.25	1.27	17.75	0.49	0.65	0.05
11.0	0.20	2.20	1.40	17.80	0.40	0.87	0.04
12.0	~0.05[c]	2.20	1.70	17.80	0.25	~4.2[c]	0.02

[a]All concentrations are in m*M*. Initial concentration of CySSCy and HS$^-$ are 2.0 and 20 m*M*, respectively. Results shown here are averages of at least two separate runs.
[b]pH attained by addition of HCl or NaOH to a 0.05 *M* Na^+ borate buffer.
[c]The equilibrium concentration of CySSCy is too low to be accurately determined (see Fig. 1; inset curve *2*); therefore the value of K_1 reported here is only approximate.

were kept in a controlled-temperature water bath. For ionic strength dependence studies, less concentrated borate buffers were used for $\mu < 0.17$ *M* whereas for $\mu = 0.01$ *M*, the solutions were not buffered but were adjusted to pH 10.0 by dropwise addition of 0.5 *M* NaOH. pH other than 10.0 were obtained by addition of concentrated HCl or 1 *M* NaOH to a 0.05 *M* Na^+ borate buffer.

Results and discussion

Previous works by Rao and Gorin (3) and Gattner and Zahn (4) established that the reaction between cystine (CySSCy) and sulfide in 0.1–0.2 *M* NaOH solution yielded cysteine (CyS$^-$), *S*-thiocysteine (CySS$^-$), and disulfide (S_2^{2-}) in two reversible steps:

$$[1] \quad \text{CySSCy} + \text{S}^{2-} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{CyS}^- + \text{CySS}^-$$

$$[2] \quad \text{CySS}^- + \text{S}^{2-} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \text{CyS}^- + \text{S}_2^{2-}$$

However, the only kinetic information given in these reports were the approximate half-lives (3) and the approximate rate constant (4) of the forward reaction in reaction [1]. Our discovery that cystine can be quantitatively converted to cysteine by HS^-/SO_3^{2-} prompted us to undertake a more detailed kinetic study of the above equilibria. Since in the pH range (7.8 to 12.0) of our study the predominant form of sulfide in solution would be HS$^-$ (7), reactions [1] and [2] should be rewritten as:

$$[3] \quad \text{CySSCy} + \text{HS}^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{CySH} + \text{CySS}^-$$

$$[4] \quad \text{CySS}^- + \text{HS}^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \text{CySH} + \text{S}_2^{2-}$$

It should be pointed out that different charge forms of CySSCy, CySH, and CySS$^-$ are also present under such conditions (8). This problem will be addressed below.

The reaction between CySSCy and HS$^-$ has been monitored by a combination of uv–visible spectroscopy and amino acid analysis (ion-exchange chromatography), as shown in Fig. 1. The absorption maximum at 332 nm associated with the equilibrium mixture starting with 2.0 m*M* CySSCy and 10.0 m*M* HS$^-$ at 25°C and pH 10.0 (curve *1*) had been previously ascribed to CySS$^-$ (3, 4). Our result here is consistent with their finding since neither CySSCy (curve *0*), CySH, or HS$^-$ (not shown) absorb appreciably at 332 nm. Furthermore, the fact that the magnitude of A_{332} at pH 10.0 and 12.0 correlates well with

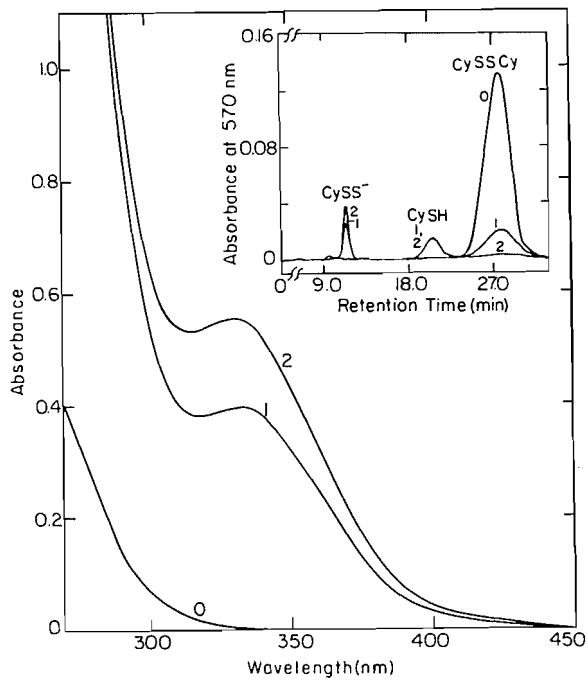

FIG. 1. Ultraviolet–visible spectral changes upon reaction of CySSCy with HS$^-$ at 25°C and $\mu = 0.17$ *M*. Curve *0*: 2.0 m*M* CySSCy in pH 10.0 borate buffer (0.05 *M* Na^+). Curve *1*: upon reaching equilibrium with 20.0 m*M* HS$^-$ at 3.0 h. Curve *2*: equilibrium mixture at pH 12.0. Inset shows the ion chromatograms corresponding to curves *0*, *1*, and *2*.

the equilibrium concentrations of CySS$^-$ as shown in the ion chromatograms (Fig. 1; inset) but not those of S_2^{2-} (Table 1) establishes that the absorption maxima at 332 nm is in fact due to CySS$^-$. From the known equilibrium concentrations of CySS$^-$ (Table 1), one can calculate using Beer's law the molar absorptivity of CySS$^-$ at 332 nm to be $370 \pm 15\ M^{-1}\,\text{cm}^{-1}$.

Determination of equilibrium constants K_1 *and* K_2 *at various pH*

The equilibrium concentrations of CySSCy and CySH in a given mixture can be determined by comparison of the peak areas in the ion chromatograms with those of standard samples. Since CySS$^-$ has not been isolated in a pure state, the equilibrium concentration can be calculated by mass balance using eq. [5]. We generally found a good agreement between the calculated value for $[\text{CySS}^-]_{eq}$ and the observed value from uv–visible spectroscopy (using $\epsilon_{332} = 370\ M^{-1}\,\text{cm}^{-1}$) or using

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

amino acid analysis (assuming a sensitivity factor 1/1.6 that of CySH). The equilibrium concentrations for HS^- and S_2^{2-} are calculated using eqs. [6] and [7], respectively.

$$[5] \quad [CySS^-]_{eq} = 2\{[CySSCy]_0 - [CySSCy]_{eq}\} - [CySH]_{eq}$$

$$[6] \quad [HS^-]_{eq} = [HS^-]_0 - \{([CySSCy]_0 - [CySSCy]_{eq}) + \tfrac{1}{2}([CySH]_{eq} - [CySS^-]_{eq})\}$$

$$[7] \quad [S_2^{2-}]_{eq} = \tfrac{1}{2}\{[CySH]_{eq} - [CySS^-]_{eq}\}$$

The composition of equilibrium mixtures at various pH are listed in Table 1. We have studied equilibria [3] and [4] in the pH range of 7.8 to 12.0 because (*i*) of the low solubility of CySSCy between pH 2 and 8 (9); and (*ii*) both CySSCy and CySH are known to decompose in strongly alkaline medium (10). Stricks and Kolthoff reported that CySSCy is stable in pH 11 to 13 solutions for at least 1 h between 12 and 37°C such that polarographic measurements were possible (8). However, we detected the decomposition of CySSCy within 15 min after preparation of the solution at pH 13.0 and 25°C by amino acid analysis. Therefore, determination of equilibrium and rate constants at pH $\geq$ 13 by the present analytical method is not feasible.

The equilibrium constants of reactions [3] and [4], K_1 and K_2, are calculated from eqs. [8] and [9], respectively,

$$[8] \quad K_1 = \frac{[CySH][CySS^-]}{[CySSCy][HS^-]}$$

$$[9] \quad K_2 = \frac{[CySH][S_2^{2-}]}{[CySS^-][HS^-]}$$

and their values at different pH are listed in Table 1. The equilibrium constant K_1 increases whereas K_2 decreases with increasing pH. The fact that the apparent equilibrium constants vary with pH can be explained by the presence of different charge forms of CySSCy, CySH, $CySS^-$, and HS^- at different pH. In order to determine the equilibrium constants due to specific charge forms, the absolute equilibrium constants would first have to be measured at pH ~ 14, where only a single charge form of each species is present. Equilibrium constants involving other charge forms could then be calculated from the absolute equilibrium constants at pH ~ 14 and the apparent equilibrium constants at other pH (8). Unfortunately, such procedure is not feasible here because of the rapid decomposition of CySSCy at pH $\geq$ 13.

Determination of rate constants k_1, k_{-1}, k_2, *and* k_{-2}

Method I

For two parallel reversible reactions such as [3] and [4], it can be shown (11) that the reaction rate can be expressed as

$$[10] \quad V = -\frac{d[CySSCy]}{dt} = \frac{k_1k_2[CySSCy][HS^-]^2 - k_{-1}k_{-2}[S_2^{2-}][CySH]^2}{k_{-1}[CySH] + k_2[HS^-]}$$

At the onset of the reaction, $[S_2^{2-}]$ and [CySH] are negligible compared to [CySSCy] and $[HS^-]$. Therefore the k_{-2}-containing term can be ignored and eq. [10] can be simplified to

$$[11] \quad V = \frac{k_1k_2[CySSCy][HS^-]^2}{k_{-1}[CySH] + k_2[HS^-]}$$

Inverting and multiplying eq. [11] by [CySSCy], one obtains

$$[12] \quad \frac{[CySSCy]}{V} = \frac{k_{-1}[CySH]}{k_1k_2[HS^-]^2} + \frac{1}{k_1[HS^-]}$$

The term on the left hand side of eq. [12] can be written as the reciprocal of the pseudo first-order initial-rate constant if HS^- is present in excess compared to CySSCy. Therefore eq. [12] becomes

$$[13] \quad \frac{1}{k_i} = \frac{k_{-1}[CySH]_0}{k_1k_2[HS^-]_0^2} + \frac{1}{k_1[HS^-]_0}$$

where k_i represents the pseudo first-order initial-rate constant, and $[CySH]_0$ and $[HS^-]_0$ are the initial concentrations of CySH and HS^-, respectively. The value of k_i at a given $[CySH]_0$ can be obtained from the initial slope of a plot of log $([CySSCy]_0/[CySSCy]_t)$ vs. t. Finally, a plot of $1/k_i$ vs. $[CySH]_0$ at constant $[HS^-]_0$ should yield a straight line with a slope of $k_{-1}/k_1k_2[HS^-]_0^2$ and an intercept of $1/k_1[HS^-]_0$, as shown in Fig. 2. From the slope and intercept of the plot and the values of K_1 and K_2 (Table 1), we have obtained $k_1 = 3.7 \pm 0.4\ M^{-1}\ min^{-1}$, $k_{-1} = 5.5 \pm 0.6\ M^{-1}\ min^{-1}$, $k_2 = 6.1 \pm 0.5\ M^{-1}\ min^{-1}$, and $k_{-2} = 122 \pm 20\ M^{-1}\ min^{-1}$ at 25°C, pH 10.0 and ionic strength (μ) of 0.17 *M*. Gattner and Zahn (4) reported $k_1 = 0.8\ M^{-1}\ min^{-1}$ at 20°C and unspecified μ in an unbuffered 0.1 *M* NaOH solution, whereas k_{-1}, k_2, and k_{-2} were all omitted in their approximation method.

Method II

Since $K_1 \gg K_2$ at pH $\geq$ 9 (Table 1), the values of k_1 and k_{-1} can alternately be determined by a method which only consider the first equilibrium (reaction [3]) and ignores the effect of the second equilibrium (reaction [4]). For an opposing reaction of second order such as reaction [3], it has been shown (12) that the reaction rate

$$[14] \quad \frac{dx}{dt} = \alpha + \beta x + \gamma x^2$$

where $x = [CySSCy]_0 - [CySSCy]_t$, $\alpha = k_1[CySSCy]_0[HS^-]_0$, $\beta = -k_1([CySSCy]_0 + [HS^-]_0)$, and $\gamma = k_1 - k_{-1}$. For $k_1 < k_{-1}$ ($K_1 = 0.65$ at pH 10.0; Table 1), the solution takes the form (13)

$$[15] \quad -\tanh^{-1}\frac{2\gamma x + \beta}{q^{1/2}} = \frac{q^{1/2}}{2}t - \theta$$

where $q = \beta^2 - 4\alpha\gamma$, and θ can be determined by the condition $x = 0$ at $t = 0$, or $\theta = \tanh^{-1}(\beta/q^{1/2})$. Therefore, from our knowledge of $[HS^-]_0$, $[CySSCy]_0$, $[CySSCy]_t$, and K_1, we can determine the values of k_1 and k_{-1} from the slope of a plot of $-\tanh^{-1}\left(\frac{2\gamma x + \beta}{q^{1/2}}\right)$ vs. t (since there is a k_1 term in the slope $(q^{1/2}/2)$.

Figure 3 shows plots of eq. [15] at different $[HS^-]_0$. The fact that all the data fit well as straight lines is consistent with (*i*) the reaction is first-order in CySSCy and HS^-, and (*ii*) the first equilibrium can be effectively separated from the second in the determination of k_1 and k_{-1}. The average values of k_1 and k_{-1} at 25°C, pH 10.0, and $\mu = 0.17\ M$ determined by this method are 3.2 ± 0.3 and 4.8 ± 0.5 $M^{-1}\ min^{-1}$, respectively, in good agreement to those determined by Method 1 under the same conditions. As a result, this simpler approach (eq. [14]) can be employed to study the effect of temperature, pH and ionic strength on the rate constant k_1.

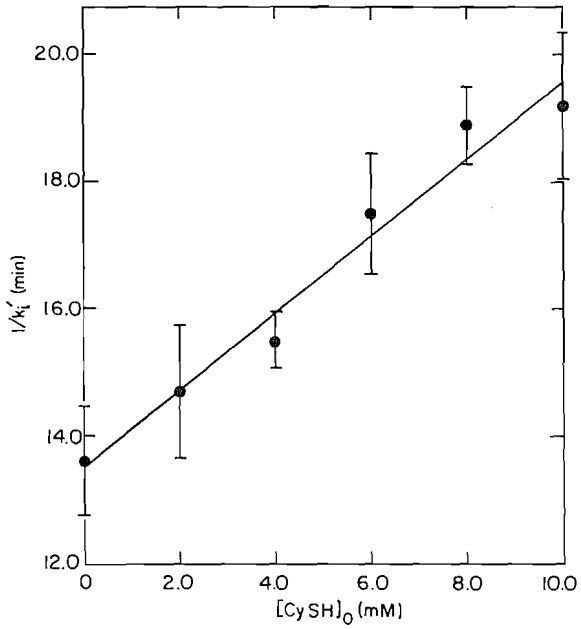

FIG. 2. Plot of $1/k_i$ vs. $[CySH]_0$ at constant $[HS^-]_0$. Reaction conditions are: $[CySSCy]_0 = 2.0$ mM and $[HS^-]_0 = 20.0$ mM, $T^0 = 25$°C, pH = 10.0, and $\mu = 0.17$ M.

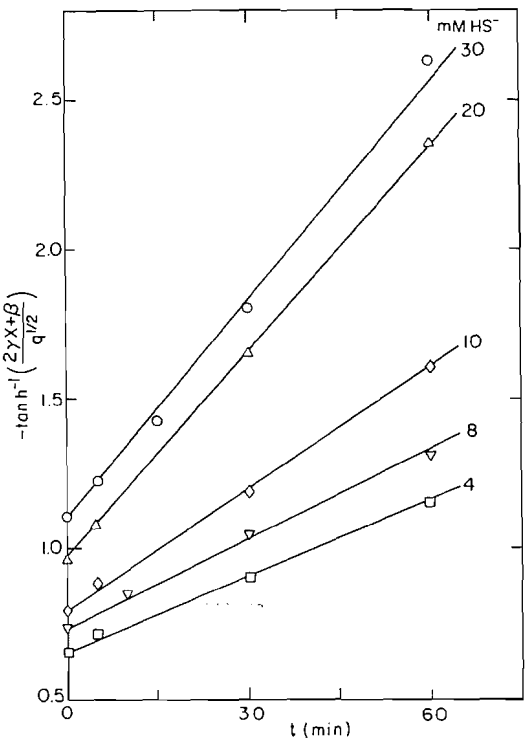

FIG. 3. Plot of $-\tanh^{-1}\left(\dfrac{2\gamma x + \beta}{q^{1/2}}\right)$ vs. t at different $[HS^-]_0$. Reaction conditions are $[CySSCy]_0 = 2.0$ mM, $T^0 = 25$°C, pH = 10.0, and $\mu = 0.17$ M.

Temperature, pH, and ionic strength dependence of k_1

The temperature dependence of the reaction between CySSCy and HS^- was studied in the range of 25 to 50°C, and an Arrhenius plot of the data is shown in Fig. 4(*a*). If the rate constant is expressed as $k_1 = A\exp(-E_a/RT)$, then least-square fit of the data yields $A = (4.7 \pm 0.3) \times 10^{11}$ M^{-1} min^{-1} and $E_a = 15.8 \pm 0.9$ kcal mol^{-1}. The value of E_a we obtained is slightly higher that of 12.8 kcal mol^{-1} obtained by Gattner and Zahn (4).

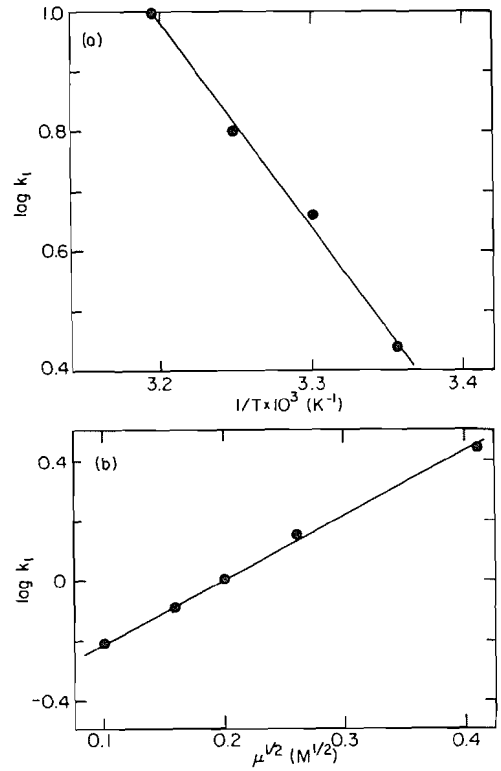

FIG. 4. (*a*) Arrhenius plot for k_1 at pH 10.0 and $\mu = 0.17$ M. (*b*) Ionic strength dependence of k_1 at pH 10.0 and 25°C.

The effect of ionic strength on k_1 was examined over the range of $\mu = 0.01$ to 0.17 M Brønsted's equation for the influence of ionic strength on reaction rate at 25°C in H_2O (12) can be expressed as

$$[16] \quad \log\frac{k_1}{k_1^0} = 1.02\, Z_A Z_B \mu^{1/2}$$

where k_1^0 is the limiting rate constant at $\mu = 0$, and Z_A and Z_B are the charges of the reactants. A plot of log k_1 vs. $\mu^{1/2}$ is shown in Fig. 4(*b*). The best fit of the data is a straight line with a slope of 2.11 ± 0.05 and an intercept of −0.42 ± 0.01, from which one can obtain $Z_A Z_B = 2.07 \pm 0.05$ and $k_1^0 = 0.38 \pm 0.01$ M^{-1} min^{-1}. Hence our result indicates that $CySSCy^{2-}$ react with HS^- at pH 10.0, which is consistent with predictions based on their acid dissociation constants (Fig. 5).

Finally, the effect of pH on k_1 has been studied over a pH range of 7.8 to 12.0, and the results are shown in Fig. 5. It is clear from the experimental results at k_1 does not have a simple $[H^+]$ dependence but is determined by the charge types of both cystine and sulfide at a given pH. To determine the contribution to k_1 from each pair of charged reactants, the absolute rate constant would first have to be determined at pH ~ 14 where only $CySSCy^{2-}$ and S^{2-} are present. The absolute rate constant for $CySSCy^{2-}$ and HS^- can then be calculated from the measured absolute rate constant at pH ~ 14 and the apparent rate constant measured at pH ~ 12, and so on. However, the rapid decomposition of cystine at pH ≥ 13 precludes such a systematic determination of absolute rate constants from being undertaken. However, some qualitative conclusions can be

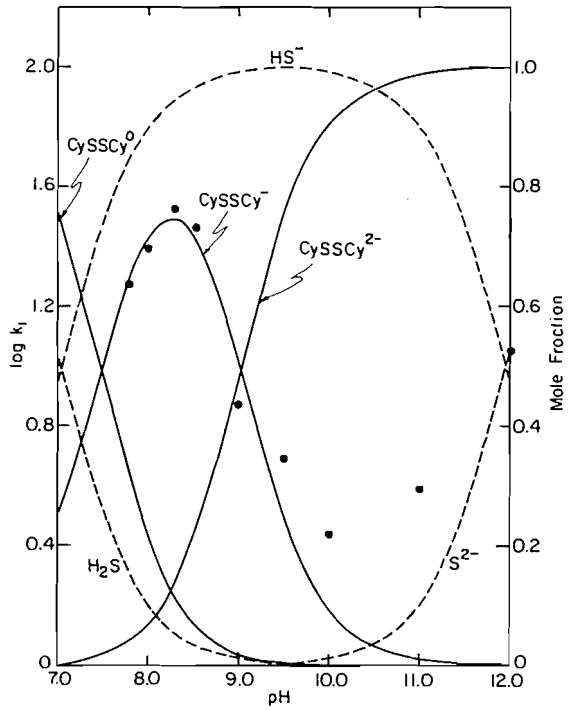

FIG. 5. pH dependence of k_1 at 25°C and μ = 0.17 *M*. The experimental data are represented by closed circles. The curves showing the mole fractions of various charge types of cystine and sulfide were computed using acid dissociation constants from refs. 13 and 14.

drawn from the results shown in Fig. 5. Since the value of k_1 at pH 12.0 (where $CySSCy^{2-}/S^{2-}$ and $CySSCy^{2-}/HS^-$ are present in roughly equal amounts) is greater than that at pH 10.0 (where the reactant pair $CySSCy^{2-}/HS^-$ is predominant), the rate constant for $CySSCy^{2-}/S^{2-}$ must be greater than that for $CySSCy^{2-}/HS^-$. Similarly, by comparing the values of k_1 at pH 10.0 and 8.7 (~70% $CySSCy^-/HS^-$ and ~20% $CySSCy^{2-}/HS^-$), and at pH 12.0 and 8.7, one can conclude that the rate constants for the charged reactant pairs are in the order: $CySSCy^{2-}/S^{2-} \sim CySSCy^-/HS^- > CySSCy^{2-}/HS^-$.

Synthesis of taxodione

ROBERT H. BURNELL,[1] MICHEL JEAN, AND DONALD POIRIER
Département de chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Received September 26, 1986

ROBERT H. BURNELL, MICHEL JEAN, and DONALD POIRIER. Can. J. Chem. **65**, 775 (1987).

Two syntheses of taxodione are described, as well as some of the model experiments that preceded them. The yields are low but comparable to most other syntheses of this extended quinone.

ROBERT H. BURNELL, MICHEL JEAN et DONALD POIRIER. Can. J. Chem. **65**, 775 (1987).

Deux synthèses de la taxodione sont présentées avec quelques séquences réactionnelles qui ont servi comme modèles. Les rendements globaux sont plutôt faibles mais ils sont comparables à ceux de synthèses déjà publiées.

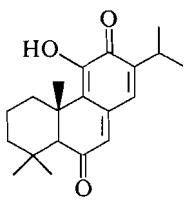
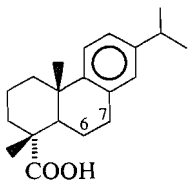
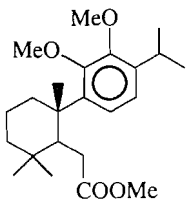
As an extension of certain diterpene syntheses under investigation in our laboratory (1), we were tempted to add our efforts to the several previous taxodione **1** syntheses (2). This extended



1



2



3

quinone showed interesting biological (3) activity, which precipitated the flurry of methods leading to its synthesis, but in most of the schemes the yields have been low.

During our synthesis and structure correction of 5-dehydronellionol trimethyl ether (1), we converted dehydroabietic acid **2** to the B-seco ester **3** but, for economy of time and effort, we had actually performed the original experimentation without reducing the carboxyl function at C.4 to the methyl. We now describe these transformations because some of the compounds also served as models in the taxodione field. By established procedures, methyl dehydroabietate was oxidized to the C.7 ketone, which, when subjected to Baeyer–Villiger conditions, afforded a 7-membered lactone and the latter, on acid catalysed methanolysis, gave the phenol diester **4**.

As in the previously reported sequence, a second oxygen function was introduced on the aromatic ring by oxidation with phenyl seleninic anhydride (4), which gave mainly the red *o*-quinone **5** and a small quantity of the *p*-quinone **6**. Catalytic hydrogenation of the *o*-quinone **5** gave an intermediate, which was immediately methylated *in situ* (Me_2SO_4, NaOH) under hydrogen to afford the di-*O*-methyl catechol derivative **7***a*. Of the four *O*-methyl groups in the latter, the two ethers and the pivalic type ester at C.4 are stable to aqueous base but the other ester was readily hydrolysed to the acid **7***b*.

Cyclization of the latter in trifluoroacetic anhydride led to the ketone **8***a*. As a taxodione model, the molecule still lacked an oxygen function at C.6, which we intended to introduce by oxygenation in strong base, but, on attempting this reaction on **8***a*, the newly introduced enol, as in **9**, cyclized spontaneously to the lactone **10***a*.

In our original scheme for this synthesis, we had hoped to force the cyclization of the acid **11***c* despite the unfavorable disposition of the substituents and to oxidize the aromatic ring to the *o*-quinone at a later stage. The cyclization, for which several literature equivalents exist (5), gave only the rearranged

products **12** and **13**, presumably via the *ipso* substituted intermediate **14** (or its equivalent). The double bond in compound **12** resisted conjugation.

The preparation of the dimethoxy ketone **15**, which we published earlier (1), represented a formal synthesis of taxodione, since this was an intermediate that Matsumoto used to prepare the corresponding $\Delta^{6,7}$-olefin, which in turn was transformed by Mori into taxodione in four steps (2). We felt that this sequence could be improved. Stirring the ketone **15** under oxygen in the presence of potassium *tert*-butylate

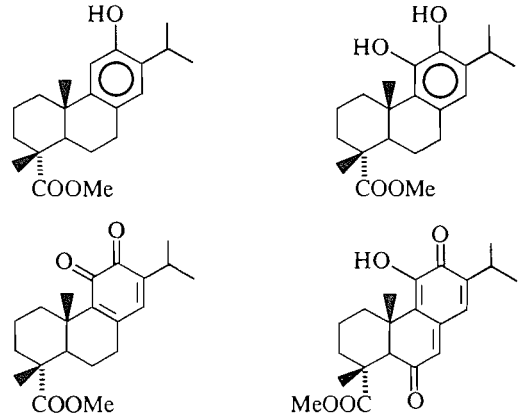
afforded the enolized α-diketone **16***a*. We had previously found that hydrogenation of such diketones gives several products, including appreciable quantities of the compound where both oxygen functions are lost by hydrogenolysis, but that this difficulty can be avoided to a large extent by methylation of the enolic carbonyl group (6). So after protecting this hydroxyl group as the methyl ether **16***b*, the product was catalytically hydrogenated to give the 6-methoxy-7-hydroxy compound **17** in which the configurations were assigned using the proton nmr vicinal coupling constants. Upon demethylating this material with boron tribromide and chromatographing the product slowly over silica gel, we obtained taxodione **1** directly in about 20% yield.

Another synthesis of a taxodione analogue described by Ohtsuka and Tahara (7) involves the transformation of an abietatriene type ester by an arduous route into an *o*-quinone, which on slow silica gel chromatography was oxidized directly to the taxodione chromophore in low but interesting yield (14%, see Scheme 1). The authors added that they were unable to prepare the appropriate *o*-quinone (*gem*-dimethyls at C.4) for the synthesis of taxodione itself.

This fortuitous synthesis was appealing so, as a trial system, we demethylated the ester **18***a*, which we had on hand from previous model studies, and subjected the acid **18***b* to oxidation by phenyl seleninic anhydride, which gave an excellent yield of the *o*-quinone **19** (87%). The latter was not too stable so, following the procedure suggested by Tahara *et al.*, we chromatographed it very slowly over silica gel, which caused the colour to change from red to orange to yellow. After further purification, we isolated a 58% yield of the lactone **20**, which showed the same uv absorption as taxodone **21** (8).

When ferruginol **22** was oxidized with phenyl seleninic anhydride the *o*-quinone **23** was isolated in 40% yield accompanied by the quinol **24** (13%). The latter could be dehydrated by refluxing in methanol containing hydrochloric acid but the probable intermediate **28***a* enolized to afford the conjugated olefin **25***a*. It was hoped to integrate the quinol **24** into the synthesis via the olefin **25***a* or the ketone **26**, prepared from it by rearrangement of the 6,7-diol, but their oxidation with phenyl seleninic anhydride led to intractable mixtures, even at low temperature. The *o*-quinone **23** was reduced catalytically and methylated while still under hydrogen, affording both the dimethoxy compound **27***a* and the monomethoxy **27***b*. Of course, the latter gave the former upon further methylation.



SCHEME 1

In their synthesis of taxodione, Mori and Matsui bypassed compound **27***a*, which was prepared in a completely different fashion (2*a*).

When the *o*-quinone **23** was slowly chromatographed following the Tahara method, we obtained up to 14% taxodione, but the yield was variable. In an effort to understand this oxidation of the quinone, which must be quite complex, we followed the uv–vis absorption as a function of time. Freshly dissolved in ethanol, the *o*-quinone absorbs at 264 and 424 nm; however, in chloroform there is an intense stable peak at 311 nm, which is exactly like that shown by taxodone **21**. In methanol solution, the 311-nm band diminishes over a period of a few days to the advantage of a peak at 278 nm but, after evaporation, the residue showed only the 311-nm peak, so no irreversible change had occurred. Taxodione has two very intense peaks at 320 and 332 nm (EtOH, ε = 25 000 and 26 000 respectively).

During the slow chromatography the first product we noticed was that showing the peak at 311 nm, and we could isolate this intermediate as a yellow oil in 69% yield after adsorbing the *o*-quinone on a small quantity of silica gel by evaporation of the solvent and then eluting the material from a conventional column. The uv spectrum suggests the taxodone chromophore while absorptions in the ir at 3300 and 1650 cm^{-1} confirmed the presence of a hydroxyl group and a highly conjugated carbonyl. The molecular ion in the mass spectrum at 300 *m/z* showed the new product to be isomeric with the original *o*-quinone, and only the mono-enolized structure **28***b* adequately fits the physical data. The other enol **29** would not only show a different uv absorption but the methyl groups in the sidechain would be displaced from their observed positions of δ 1.13 and 1.14. The stabilizing effect of the hydrogen bonding in **28***b* precludes enolization to the fully aromatic **25***b*. The intermediate **28***b* also gave taxodione on repeated slow chromatography in carbon tetrachloride in yields comparable to those obtained directly from the *o*-quinone.

Experimental

Unless otherwise stated, the conditions and instruments used to characterize the products were melting points, Electrothermal, uncorrected; ultraviolet spectra, ethanol solutions (log ε in parentheses), Hewlett Packard 8450 A; infrared spectra, carbon tetrachloride solutions, Beckman 4250 and Perkin Elmer 457; proton magnetic resonance spectra, deuteriochloroform solutions, TMS internal standard (multiplicity, integrated peak areas, coupling constants, and assignments in parentheses), Bruker HX 90; carbon-13 magnetic resonance spectra, deuteriochloroform solutions, TMS internal standard, Bruker WP 80; mass spectra, Hewlett Packard 5992. Elemental analyses were by Galbraith Laboratories, Knoxville. The high resolution mass spectra were recorded on an A.E.I. MS-30. Unless otherwise stated, dry

column chromatography implies the use of Merck Kieselgel 60F (70–230 mesh) and elution with hexane – ethyl acetate (proportions determined by prior thin-layer chromatography using Machery–Nagel Polygram precoated plastic sheets).

Ortho-quinone **5**

The phenol diester **4** (1.24 g, prepared following essentially the procedure described by Pelletier and Ohtsuka (9)) was dissolved in anhydrous THF (50 mL) and this solution was added dropwise to a suspension of freshly sublimed phenyl seleninic anhydride (2.60 g) in THF (50 mL) warmed to 50–60°C. After 60 min the mixture was poured into ice-water and extracted with ether, which was then well washed with a saturated sodium bicarbonate solution. The reddish crude product was chromatographed (silica gel; benzene – ethyl acetate 9:1) affording diphenyl diselenide (730 mg, yellow solid, mp 50–55°C), the *p*-quinone **6** (270 mg; 21%), and the *o*-quinone **5** (900 mg; 70%) as a viscous dark red oil; uv λ_{max}: 275 (sh), 414 (1800), and 580 (weak) nm; ir (CCl_4): 1730, 1685, 1675, and 1660 cm^{-1}; ^1H nmr δ: 1.11 (d, J = 7 Hz, iso-Pr methyls), 1.18 and 1.23 (2s, C.4-Me and C.10-Me), 2.26 and 2.28 (d, J = 5 Hz, CH_2—COOMe), 2.94 (sept, J = 7 Hz, iso-Pr CH), 3.51 (dd, J = 6 and 5 Hz, C.5-H), 3.59 and 3.75 (2s, COOMe), 6.72 (s, 2H, =CH); ^{13}C nmr: see Table 1; mass spectrum, m/z: 392 (M + 2), 390 (M^+), 362, 360, 332, and 181 (base). *Exact Mass* (hrms) calcd. for $C_{22}H_{30}O_6$: 390.2042; found: 390.2034.

The yellow *p*-quinone **6** was identified by comparison with a sample prepared in another context: ^{13}C nmr, see Table 1.

Reduction and methylation

The *o*-quinone (900 mg) in methanol (20 mL) was added to prehydrogenated Adams catalyst (40 mg) in methanol (10 mL) and hydrogenated at atmospheric pressure. When the red solution had become colorless, without opening to the atmosphere, sodium hydroxide (30% aqueous solution, total 18 mL) and dimethyl sulfate (total 7 mL) were added 1 mL at a time at intervals over a period of 50 h. After filtering and washing the catalyst, the organic solvent was evaporated to give the crude product **7***a*, which was purified by dry column chromatography (705 mg; 70%); ir (CCl_4): 1740 cm^{-1}; ^1H nmr δ: 1.18 (d, J = 7 Hz, iso-Pr methyls), 1.26 and 1.32 (2s, C.4-Me and C.10-Me respectively), 2.22 (d, J = 6 Hz, -CH_2COOMe), 3.28 (sept, J = 7 Hz, iso-Pr CH), 3.36 and 3.47 (2s, COOMe), 3.66 (t, J = 6 Hz, C.5-H), 3.79 and 4.09 (2s, Ar-OMe), 6.89 (ABq, Δν = 11.7, J = 8.5 Hz, arom. H); ^{13}C nmr, see Table 1; mass spectrum, m/z: 420 (M^+), 405, and 389. *Anal.* calcd. for $C_{24}H_{36}O_6$: C 68.54, H 8.63; found: C 68.26, H 8.02.

Hydrolysis ester **7**a → **7**b

To the ester **7***a* (570 mg) in methanol (25 mL) was added potassium hydroxide solution (25 mL of 10% aqueous) and the mixture was refluxed for 140 min. Most of the methanol was then evaporated under vacuum and the aqueous solution washed with ether to remove neutral materials. After acidification (concentrated HCl), ether extraction afforded the acid **7***b* as a yellow solid (538 mg; 97%), mp 112–114°C; ir (KBr): 3600–2400 (v br), 1730, and 1710 cm^{-1}; ^1H nmr δ: 1.17 (d, J = 7 Hz, iso-Pr Me), 1.24 and 1.29 (2s, C.4-Me and C.10-Me respectively), 2.25 (d, J = 6 Hz, -CH_2COOMe), 3.26 (sept, J = 7 Hz, iso-Pr CH), 3.36 (s, COOMe), 3.60 (t, J = 6 Hz, C.5-H), 3.76 and 4.00 (2s, Ar-OMe), 6.88 (ABq, Δν = 12.1, J = 8 Hz, arom. H), 9.80 (bs, D_2O, COOH); ^{13}C nmr, see Table 1; mass spectrum, m/z: 406 (M^+), 374, and 160 (base). *Anal.* calcd. for $C_{23}H_{34}O_6$: C 67.95, H 8.43; found: C 68.41, H 8.74.

Cyclization to the ketone **8**a

The acid **7***b* (300 mg) was stirred in trifluoroacetic anhydride (3 mL) for 12 h at room temperature. The mixture was poured into ice-water and the ether extract was washed with sodium bicarbonate solution until neutral, then evaporated and taken up in methanol (30 mL) and aqueous potassium hydroxide (3 mL of 10%). After 2 h at room temperature the product was obtained by adding water and extracting with ether. The ketone **8***a* was obtained as a wax (253 mg; 83%); ir (CCl_4): 1730 and 1690 cm^{-1}; uv λ_{max}: 272 (8000) nm; ^1H nmr δ: 1.22 and 1.25 (two d, J = 7 Hz, iso-Pr Me), 1.34 and 1.42 (2s, C.4-Me and C.10-Me respectively), 2.69 (d, J = 11 Hz, —CH_2—C(=O)—), 3.28 (sept, J = 7 Hz, iso-Pr CH), 3.68 and 3.87 (2s, Ar-OMe), 7.79

(s, arom. H at C.14); ^{13}C nmr, see Table 1; mass spectrum, *m/z*: 388 (M^+, 100%), 373, 358, 329, and 313. *Anal.* calcd. for $C_{23}H_{32}O_5$: C 70.33, H 8.08; found: C 70.10, H 8.30.

Formation of the lactone ***10****a*

At room temperature the ketone ***8a*** (240 mg) in *tert*-butanol (20 mL) was added to the solution resulting from dissolving potassium (1.5 g) in *tert*-butanol (40 mL). Oxygen was bubbled through the solution for 4 h, the reaction mixture was then acidified with 10% hydrochloric acid, and the product obtained by ether extraction. The ester **9** and the lactone ***10a*** are both present at this stage (tlc and spectra) in the ratio 3:7 but during the silica gel chromatography (benzene–EtOAc 9:1) the former disappears and only lactone ***10a*** was isolated (165 mg; 72%) as a white solid, mp 182–183°C: uv λ(EtOH): 251 (9600), 269 (11 600), and 306 (10 000) nm; ir (KBr): 1810 (lactone), 1680, 1660, and 1600 cm^{-1}; ^{1}H nmr δ: 1.27 and 1.29 (2d, total 6H, J = 7 Hz, nonequivalent iso-Pr Me), 1.67 and 1.69 (2s, C-Me at C.4 and C.10), 3.35 (sept, J = 7 Hz, iso-Pr CH), 3.89 and 3.95 (2s, Ar-OMe), 8.03 (s, arom. H at C.14); ^{13}C nmr, see Table 1; mass spectrum, *m/z*: 370 (M^+), 342 (100%), and 327. *Anal.* calcd. for $C_{22}H_{26}O_5$: C 71.33, H 7.08; found: C 71.50, H 7.12.

Demethylation of ***10****a to give* ***10****b*

A solution of boron tribromide (0.4 mL) in dichloromethane (1.0 mL) was added very slowly (during 3 h), with stirring, to the lactone ***10a*** (20 mg) in dichloromethane (2 mL) at room temperature. After 11 h, the solvent was removed by evaporation, the residue taken up in water, and ether extracted. Chromatography (silica gel; hexane – ethyl acetate 6:4) gave some starting material (3 mg) and then the catechol ***10b*** (14 mg; 76%), mp 268–270°C (yellow crystals); uv: 262 (9400), 340 (2700), and 424 (3600) nm; ir (KBr): 3470, 3420, 1800, 1670, 1645, and 1610 cm^{-1}; ^{1}H nmr δ: 1.25 (d, J = 7 Hz, iso-Pr Me), 1.59 and 1.67 (2s, C-Me), 3.1 (m, iso-Pr CH), 6.6 (br, 2H, D_2O), and 7.84 (s, arom. H); (in acetone-d_6: 1.26, 1.66, 1.78, 3.3, and 7.82); mass spectrum, *m/z*: 342 (M^+), 314, 299, 298, and 286 (100%). *Exact Mass* (hrms) calcd. for $C_{20}H_{22}O_5$: 342.1467; found: 342.1466.

Preparation of the acid ***11****c*

The phenol ester ***11a*** (described earlier (*1c*), 0.86 g), dimethyl sulfate (8.4 g), and anhydrous potassium carbonate (9.0 g) were refluxed in acetone (100 mL) for 20 h. Water was added to destroy excess dimethyl sulfate and most of the acetone was then evaporated before extracting the solution with ether. Chromatography (silica gel; hexane – ethyl acetate 9:1) afforded the methoxy ester ***11b*** (0.71 g; 80%); ir: 1740 cm^{-1}; ^{1}H nmr δ: 3.20 ($COOCH_3$) and 3.89 (Ar-OCH_3); ^{13}C nmr, see Table 1; mass spectrum, *m/z*: 346 (M^+), 315, 303, and 117 (100%), which was hydrolysed without further purification.

To the methoxy ester ***11b*** (2.44 g) in methanol (85 mL) was added sodium hydroxide (85 mL, 10% aqueous) and the mixture was refluxed for 20 h. Most of the methanol was evaporated and the product obtained by ether extraction. Chromatography (silica gel; hexane – ethyl acetate 4:1) gave the acid ***11c*** as a low-melting solid (1.78 g; 79%), mp 46–50°C; ir: 3200–2500 (acid), 1710, and 1610 cm^{-1}; ^{1}H nmr δ: 0.89, 0.97 and 1.31 (3s, Me-C), 1.20 (d, J = 7 Hz, iso-Pr Me), 1.89 (dd, J = 16 and 5 Hz, -C*H*—CO), 2.17 (dd, J = 16 and 6 Hz, CH—CO), 2.70 (sept, J = 7 Hz, iso-Pr CH), 3.50 (dd, J = 6 and 5 Hz, C.5-H), 3.84 (s, Ar, OMe), 6.7 and 7.16 (arom. H), 11.4 (bs, COO*H*, D_2O); ^{13}C nmr, see Table 1; mass spectrum, *m/z*: 332 (M^+, 100%), 317, and 289. *Anal.* calcd. for $C_{21}H_{32}O_3$: C 75.86, H 9.70; found: C 75.95, H 9.94.

ipso *Cyclization of acid* ***11****c*

The methoxy acid (308 mg) was stirred in trifluoroacetic anhydride (4 mL) at room temperature for 6 h. The mixture was decomposed with ice-water and the product obtained by ether extraction and well washed with aqueous potassium hydroxide. Chromatography (silica gel; hexane – ethyl acetate 4:1) afforded two products:

Nonconjugated enone ***12*** (162 mg; 56%); uv λ_{max}: 253 (10 000) and 304 (5200) nm; ir (film): 1680 and 1600 cm^{-1}; ^{1}H nmr δ: 0.91 and 1.49 (2s, Me-C), 1.23 (d, J = 7 Hz, iso-Pr Me), 2.85 (sept, iso-Pr CH), 3.64 (s, 2H, C═C—CH_2—C═O), 3.83 (s, Ar, OMe), 6.88, 6.94 (m), and 7.61 (d, J = 8 Hz, arom. H); ^{13}C nmr, see Table 1; mass spectrum, *m/z*: 314 (M^+), 299, 287, 272 and 177 (100). *Exact Mass* (hrms) calcd. for $C_{21}H_{30}O_2$: 314.2246; found: 314.2244.

Tertiary alcohol ***13*** (44 mg; 14%); uv λ_{max}: 253 (14 700) and 302 (6000) nmr; ir: 3460, 1670, and 1600 cm^{-1}; ^{1}H nmr δ: 0.86 (6H), 1.14 (2s, 3 × Me-C), 1.24 (d, J = 7 Hz, iso-Pr Me), 2.12 (dd, J = 6 and 5 Hz, C.5-H), 2.24 (s, OH, D_2O), 2.86 (sept, J = 7 Hz, iso-Pr CH), 3.83 (s, Ar-OMe), 6.84, 6.92 (m), and 7.59 (d, J = 8 Hz) (3 × arom. H); ^{13}C nmr, see Table 1; mass spectrum, *m/z*: 332 (M^+), 317, 314, 299, 289, and 177 (100). *Anal.* calcd. for $C_{21}H_{32}O_3$: C 75.86, H 9.70; found: C 76.02, H 9.89.

NOTE: When the alcohol **13** (91 mg) was refluxed in methanol (20 mL) containing hydrochloric acid (5 mL, 50%) for 5 h, the product was the tetraene **12** (83 mg; after chromatography: 96%).

Oxygenation of the ketone ***15*** *(→ diosphenol* ***16****a)*

Potassium (2.0 g) was dissolved in *tert*-butanol (50 mL) and stirred for 12 h. The ketone **15** (290 mg) dissolved in *tert*-butanol (25 mL) was then added at room temperature and oxygen was bubbled through the solution for 2 h. The mixture was then acidified with dilute hydrochloric acid (5%) and the weak acid product was extracted into ether and finally crystallized from hexane, affording the diosphenol ***16a*** (253 mg; 84%), mp 115–117°C (colorless plates, hexane); uv λ_{max}: 243 (8000), 279 (9600), and 322 (10 500) nm; ir: 3370, 3340, 1640, 1625, and 1585 cm^{-1}; ^{1}H nmr δ: 1.25, 1.29 (two d, J = 7 Hz, iso-Pr Me), 1.48 (6H) and 1.66 (3s, Me-C at C.4 and C.10 respectively), 3.33 (sept, J = 7 Hz, iso-Pr CH), 3.87, 3.94 (2s, Ar-OMe), 7.14 (s, enol OH, D_2O), 7.92 (s, arom. H); ^{13}C nmr, see Table 1; mass spectrum, *m/z*: 358 (M^+), 343, 330, 327, 315, and 273 (100). *Anal.* calcd. for $C_{22}H_{30}O_4$: C 73.71, H 8.44; found: C 73.75, H 8.31.

Methylation of the diosphenol ***16****a (→* ***16****b)*

The diosphenol (159 mg) was dissolved in ethanol (10 mL) and water (10 mL), and aqueous sodium hydroxide (8.0 mL of 30%) was added, followed by dimethyl sulfate (4.0 mL, dropwise). The mixture was stirred for 21 h and then more sodium hydroxide (4 mL of 30%) and dimethyl sulfate (2.0 mL) were added. After 26 h the solution was diluted with water and the product obtained by ether extraction. Chromatography (silica gel; hexane – ethyl acetate 19:1) gave some starting material (29 mg; 18%) and then the methylated product ***16b*** (89 mg; 54%), mp 104–106°C (from hexane): uv λ_{max}: 243 (20 000), 274 (30 000), and 299 (27 000) nm; ir: 1650 and 1600 cm^{-1}; ^{1}H nmr δ: 1.23, 1.26 (two d, J = 7 Hz, iso-Pr Me), 1.43 (6H) and 1.65 (2s, 3 × Me-C), 3.30 (sept, iso-Pr CH), 3.85 (6H) and 3.92 (2s, 3 × OMe), 7.92 (s, arom. H); ^{13}C nmr, see Table 1; mass spectrum, *m/z*: 372 (M^+), 357, 341, 329, and 287 (100). *Anal.* calcd. for $C_{23}H_{32}O_4$: C 74.16, H 8.66; found: C 74.01, H 8.76.

Hydrogenation of the methylated enol ***16****b (→* ***17****)*

The methylated product ***16b*** (22 mg) in methanol (15 mL) was introduced into a hydrogenation apparatus containing prehydrogenated 10% palladium on carbon (25 mg) in methanol (10 mL). After stirring under hydrogen for 12 h, the catalyst was filtered off, and the solution diluted with water and extracted with ether. After chromatography (silica gel; carbon tetrachloride – ethyl acetate 9:1) the colorless solid **17** was crystallized from hexane, mp 92–95°C (19.5 mg; 88%); ir: 3620, 3380, and 1615 cm^{-1}; ^{1}H nmr δ: 1.03, 1.17, and 1.60 (3s, C-Me), 1.21 (d, J = 7 Hz, iso-Pr Me), 2.28 (d, J = 12 Hz, C.5-H), 3.24 (sept, J = 7 Hz, iso-Pr CH), 3.58 (s, OMe at C.6), 3.74, 3.82 (2s, Ar-OMe), 3.98 (d, J = 5 Hz, C*H*OH), 4.56 (dd, J = 12 and 5 Hz, C*H*-OMe), 7.30 (s, arom. H); mass spectrum, *m/z*: 376 (M^+, 100), 361, 358, and 343. *Anal.* calcd. for $C_{23}H_{36}O_4$: C 73.36, H 9.64; found: C 73.11, H 9.64.

Taxodione ***1*** (demethylation and oxidation of **17**)

To the trimethoxy derivative **17** (27 mg) in dry dichloromethane (5 mL) cooled to 0°C was added boron tribromide (0.5 mL of 1 *M* solution in dichloromethane). After 2 h, more boron tribromide solution (0.5 mL) was added and the reaction stirred for 12 h at room temperature. The reaction mixture was poured into ice-water and extracted with ether that was well washed with saturated sodium

For personal use only.

bicarbonate solution. The crude oily orange product (26 mg) was slowly chromatographed over silica gel in carbon tetrachloride, twice, affording a fraction of pure taxodione (3.0 mg; 13%); ir: 3320, 1675, 1640, 1628, 1618, and 1600 cm^{-1}; mass spectrum, *m/z*: 314 (M^+), 299, 286, 271, and 149 (100). *Exact Mass* (hrms) calcd. for $C_{20}H_{26}O_3$: 314.1882; found: 314.1875.

Comparison of the product with an authentic sample obtained from Prof. Takashi Matsumoto (Hiroshima University) showed the two to be identical (ir, tlc; two solvent systems).

*Synthesis of lactone **20** (via o-quinone **19**)*

The methyl *O*-methyl-13-isopropylpodocarpate **18***a* (323 mg, prepared as described previously (1*a*) was dissolved in methylene chloride (20 mL) and, at −10°C and under nitrogen, boron tribromide (5 mL) in methylene chloride (10 mL) was rapidly added. After stirring for 1 h, water was added and the volatile solvent removed *in vacuo*. Ether extraction gave a brownish oil from which chromatography (silica gel; ethyl acetate) gave the substituted podocarpic acid **18***b* (256 mg; 83%), mp 252°C (colorless needles); ir: 3600–2400 (very br), 1690, 1600, 1575, and 1500 cm^{-1}; ^1H nmr, acetone-d_6, δ: 1.12 and 1.30 (2s, 2 × Me-C), 1.21 (d, *J* = 7 Hz, iso-Pr Me), 3.23 (sept, *J* = 7 Hz, iso-Pr CH), 6.81 and 6.86 (2s, arom. H at C.11 and C.14); ^{13}C nmr, see Table 1; mass spectrum, *m/z*: 316 (84, M^+), 301 (54), 255 (73), 213 (100), 199 (23), 185 (22), 171 (39), 157 (59), and 147 (55). *Anal.* calcd. for $C_{20}H_{28}O_3$: C 75.91, H 8.92; found: C 75.79, H 9.02.

Phenyl seleninic anhydride (466 mg) was suspended in anhydrous THF (50 mL) and warmed to 50°C. The phenol **18***b* (200 mg) in anhydrous THF (20 mL) was added drop by drop and stirring was continued for 2 h. The reaction mixture was diluted with chloroform (200 mL) and the solution washed many times with aqueous sodium bicarbonate and then with brine. The organic phase gave a red oil, which was chromatographed rapidly over silica gel to give the unstable red *o*-quinone **19** (182 mg; 87%); ^1H nmr δ: 1.12 and 1.19 (2d, 6H, *J* = 7 Hz, iso-Pr Me), 1.17 and 1.32 (2s, Me-C), 2.29 (m, iso-Pr CH), 6.46 (s, C.14-H).

The *o*-quinone **19** (182 mg) was adsorbed on a small quantity of silica gel by evaporation, introduced at the top of a silica gel column, and, very slowly, the product was eluted with carbon tetrachloride. The color changed from red to orange to dark yellow. This slow chromatography was repeated a second time and gave the lactone **20** (105 mg; 58%), mp 100–104°C (yellow needles, ethanol–water); uv: 268 (13 000), 311 (26 500), and 378 (2900) nm; ir: 3340, 1765 (lactone), 1645, 1625, and 1615 cm^{-1}; ^1H nmr δ: 1.16 and 1.18 (2d, 6H, *J* = 7 Hz, iso-Pr Me), 1.22 and 1.38 (2s, Me-C), 2.13 (d, *J* = 5 Hz, C.5-H), 3.08 (sept, *J* = 7 Hz, iso-Pr CH), 5.19 (dd, *J* = 5 and 5 Hz, C.6-H), 6.61 (d, *J* = 5 Hz, C.7-H), 6.92 (s, C.14-H), and 7.22 (s, OH, D_2O); ^{13}C nmr, see Table 1; mass spectrum, *m/z*: 328 (29, M^+), 300 (49), 285 (51), 272 (35), 257 (93), 229 (38), and 218 (100). *Anal.* calcd. for $C_{20}H_{24}O_4$: C 73.14, H 7.37; found: C 73.21, H 7.70.

*Oxidation of ferriginol **22** to o-quinone **23***

Ferruginol (300 mg) in anhydrous THF (20 mL) was oxidized by adding to a suspension of phenyl seleninic anhydride (760 mg) in THF (40 mL) warmed to 50°C as described above. Chromatography over silica gel afforded first the *o*-quinone **23** (127 mg; 40%), mp 143–144°C (dark red needles from hexane); uv: 264 (6100) and 424 (1750) nm; ir: 1670 and 1655 cm^{-1}; ^1H nmr δ: 0.90 and 0.94 (2s, *gem* Me), 1.11 (d, *J* = 7 Hz, iso-Pr Me), 1.24 (s, Me-C.10), 2.83 (sept, *J* = 7 Hz, iso-Pr CH), 6.42 (s, olefinic H); ^{13}C nmr, see Table 1; mass spectrum, *m/z*: 302 (8, *M* + 2), 300 (11, M^+), 258 (8), 257 (25), 231 (31), 229 (44), 217 (43), and 204 (65). *Anal.* calcd. for $C_{20}H_{20}O_2$: C 79.95, H 9.39; found: C 80.12, H 9.52.

A second fraction from the column contained the quinol **24** (40 mg; 13%), mp 177–179°C (lit. (2*c*) mp 181–182°C); ^{13}C nmr, see Table 1.

*Dehydration of the quinol **24***

The quinol (90 mg) was gently refluxed in methanol (50 mL) containing concentrated hydrochloric acid (1 mL) for 3 h. Dilution with water, removal of most of the methanol by evaporation, and then ether extraction afforded some starting material (10 mg) and then the olefin **25***a* (42 mg; oil, 50%, identical with the product obtained by boron tribromide demethylation of the known methyl ether); ir: 3600, 3385, 3030, 1650, and 1610 cm^{-1}; uv: 278 (10 500) nm; ^1H nmr δ: 0.97 and 1.04 (2s, *gem* Me), 1.20 and 1.24 (2d, *J* = 7 Hz, iso-Pr Me), 1.27 (s, Me-C), 3.17 (m, iso-Pr CH), 5.88 (dd, *J* = 9 and 3 Hz, olefinic H at C.6), 6.60 (s, arom. H at C.11), 6.88 (dd, *J* = 9 and 3 Hz, olefinic H at C.7), and 6.91 (s, arom. H at C.14); ^{13}C nmr, see Table 1.

*Formation of the ketone **26***

Following the Défaye–Duchateau procedure (10), a solution of the olefin **25***a* (84 mg) in acetone (30 mL) was treated with osmic acid (50 mg) in carbon tetrachloride (5 mL). The mixture was protected from light with aluminium foil and stirring was continued at room temperature for 1.5 days. The solvents were then evaporated and the black residue taken up in methanol (30 mL) and reduced by adding excess sodium borohydride and stirring for 24 h. After dilution with water and acidification with concentrated hydrochloric acid, the crude product (mixture of *cis*-diols) was obtained by ether extraction. The residue was taken up in dry benzene (35 mL) containing *p*-toluenesulfonic acid (4 mg) and then refluxed for 2 h. Extraction and chromatography gave the ketone **26** (43 mg; 48% from the olefin **25***a*): ir (film): 3380, 1690, and 1620 cm^{-1}; ^1H nmr δ: 1.12 and 1.18 (2s, *gem* Me), 1.28 (d, *J* = 7 Hz, iso-Pr Me), 1.34 (s, Me-C), 2.43 (s, C.5-H), 3.22 (m, iso-Pr CH), 3.61 (s, 2H, C.7-H), 5.08 (s, OH, D_2O), 6.81 and 6.92 (2s, arom. H); mass spectrum, *m/z*: 300 (100, M^+), 285 (92), 257 (36), 240 (63), 217 (22), 215 (36), and 201 (63).

NOTE: Attempts to oxidize this phenolic ketone **26** and the preceding olefin **25***a* with phenyl seleninic anhydride led to the complete destruction of the substrates.

*Reduction and methylation of the o-quinone **23***

The *o*-quinone **23** (59 mg) in methanol (50 mL) was introduced into an atmospheric hydrogenation apparatus containing prehydrogenated palladium on charcoal (20%, 50 mg) suspended in methanol (25 mL). Agitation under hydrogen rapidly changed the solution from red to colorless and then, without opening to the air, sodium hydroxide (2 mL of 30%) was added, followed by dimethyl sulfate (1 mL). The addition of base and dimethyl sulfate was repeated every half hour (total 8 mL and 4 mL respectively). After 24 h the reaction mixture was filtered, diluted with water, concentrated, and extracted with ether. Chromatography gave two products, first the *dimethoxy compound* **27***a* (15 mg; 23%); ir: 1615, 1570, and 1500 cm^{-1}; ^1H nmr δ: 0.95 (s, 6H, *gem* Me), 1.15 (d, *J* = 7 Hz, iso-Pr Me), 1.30 (s, Me-C), 3.75 and 3.80 (2s, O-Me), 6.68 (s, arom. H); mass spectrum: 330 (M^+). These properties are identical with those given by Mori and Matsui (2*a*).

The second fraction was the *monomethylated compound* **27***b* (28 mg; 45%); ir: 3500, 1615, and 1495 cm^{-1}: ^1H nmr δ: 0.97 (s, 6H, *gem* Me), 1.18 (d, *J* = 7 Hz, iso-Pr Me), 1.30 (s, Me-C), 3.75 (s, O-Me), 5.83 (s, OH, D_2O), 6.33 (s, arom. H); mass spectrum: 316 (M^+).

Methylation of **27***b* (NaOH, dimethyl sulfate) afforded **27***a*.

Formation of taxodione by slow chromatography

The *o*-quinone **23** (35 mg) was adsorbed by evaporation of the solvent onto a small quantity of silica gel and then introduced to the top of a conventional column of silica gel and slowly eluted with carbon tetrachloride. Evaporation of the eluate afforded a yellow oil, **28***b* (24 mg; 69%) uv:316 (7000) and 370 (1600) nm; ir (film): 3300, 1650, 1620, 1610, and 1560 cm^{-1}; ^1H nmr δ: 0.92 and 0.97 (s, 6H, *gem* Me), 1.13 and 1.14 (2d, 6H, *J* = 7 Hz, iso-Pr Me), 1.18 (s, Me-C), 3.07 (m, iso-Pr CH), 6.81 (m, 2H, C.7-H and C.14-H), and 7.48 (s, OH, D_2O); ^{13}C nmr, see Table 1; mass spectrum, *m/z*: 300 (35, M^+), 232 (35), 231 (50), 229 (70), 218 (45), 215 (40), and 204 (90).

When either the *o*-quinone **23** or the mono-enolized form **28***b* was subjected to repeated, slow chromatography (as described above), taxodione (identical with that described above) was formed in yields up to 15%. Attempts to accelerate this process by bubbling air through a solution of the *o*-quinone for 2 days produced no permanent change. Although the uv–vis spectrum of the solution showed an intense peak

at 311 nm, upon evaporation of the methanol only the *o*-quinone chromophore was evident. Bubbling oxygen through a methanol solution of the *o*-quinone led to its complete and rapid decomposition.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada and the Ministère de l'éducation du Québec for operating and equipment grants. A graduate bursary (F.C.A.R., Québec) is also gratefully acknowledged (D.P.).

Synthesis, characterization, and crystal and molecular structures of the coordination compounds, $[Me_2Ga\cdot O(C_5H_3N)CH_2NMe_2]$ and $[Me_2Ga\cdot O(C_9H_6N)]_2$

EMMANUEL C. ONYIRIUKA, STEVEN J. RETTIG, ALAN STORR,[1] AND JAMES TROTTER[1]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received August 18, 1986

EMMANUEL C. ONYIRIUKA, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **65**, 782 (1987).

Crystals of (2-dimethylaminomethyl-3-pyridolato)dimethylgallium are monoclinic, a = 13.443(3), b = 6.7563(3), c = 13.046(2) Å, β = 100.38(1)°, Z = 4, space group $I2/m$, and those of bis[(8-quinolinolato)dimethylgallium] are monoclinic, a = 9.7340(4), b = 12.7135(5), c = 9.6843(4) Å, β = 117.014(3)°, Z = 2, space group $P2_1/c$. Both structures were solved by conventional heavy atom methods and were refined by full-matrix least-squares procedures to R = 0.044 and 0.032 for 1485 and 1567 reflections with $I \geq 3\sigma(I)$, respectively. The structure of $[Me_2Ga\cdot O(C_5H_3N)CH_2NMe_2]$ consists of discrete monomeric molecules which contain tetrahedrally coordinated gallium atoms. The bidentate anionic 2-dimethylaminomethyl-3-pyridolate ligand coordinates Ga via the oxygen and amino nitrogen atoms (Ga—O = 1.892(3), Ga—N = 2.127(4), Ga—C = 1.950(5) and 1.939(6) Å). The structure of $[Me_2Ga\cdot O(C_9H_6N)]_2$ consists of centrosymmetric dimers which contain a nearly planar system of seven fused rings. The Ga atoms are five-coordinate, having distorted trigonal bipyramidal coordination geometry. The dimerization occurs via the formation of a central, planar, four-membered $(Ga—O)_2$ ring in which each asymmetrically bridging oxygen atom occupies an equatorial coordination site on one gallium atom and an axial site on the other. Important geometrical parameters for $[Me_2Ga\cdot O(C_9H_6N)]_2$ are Ga—O(eq) = 1.937(3), Ga—O(ax) = 2.297(3), Ga—N(ax) = 2.211(3), Ga—C(eq) = 1.948(6) and 1.945(5) Å, O(ax)—Ga—N(ax) = 149.7(1)°.

EMMANUEL C. ONYIRIUKA, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **65**, 782 (1987).

Les cristaux du (diméthylaminométhyl-2 pyridolato-3) diméthylgallium sont monocliniques, avec a = 13,443(3), b = 6,7563(3) et c = 13,046(2) Å et β = 100,38(1)°, Z = 4 et groupe d'espace $I2/m$ alors que ceux du bis[(quinolinolato-8) diméthylgallium] sont monocliniques, avec a = 9,7340(4), b = 12,7135(5) et c = 9,6843(4) Å et β = 117,014(3)°, Z = 2 et groupe d'espace $P2_1/c$. On a résolu les deux structures par les méthodes conventionnelles aux atomes lourds et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs de R = 0,044 et 0,032 pour respectivement 1485 et 1576 réflexions avec $I \geq 3\sigma(I)$. La structure du $[Me_2Ga\cdot O(C_5H_3N)CH_2NMe_2]$ consiste en molécules monomères discrètes qui contiennent des atomes de gallium coordonnés d'une façon tétraédrique. Le ligand anionique bidentate diméthylaminométhyl-2 pyridolate-3 se coordonne au Ga par le biais des atomes d'azote et d'oxygène (Ga—O = 1,892(3), Ga—N = 2,127(4), Ga—C = 1,950(5) et 1,939(6) Å). La structure du $[Me_2Ga\cdot O(C_9H_6N)]_2$ consiste en des dimères centrosymétriques qui contiennent un système pratiquement planaire de sept cycles fusionnés. Les atomes de Ga sont pentacoordonnés et ils possèdent une géométrie de coordination bipyramide trigonale déformée. La dimérisation se produit par le biais de la formation d'un cycle central, planaire et à quatre chaînons $(Ga—O)_2$ dans lequel chaque atome d'oxygène formant un pont asymétrique occup un site de coordination équatorial sur un atome de gallium et un site axial sur l'autre. Les paramètres géométriques importants pour le $[Me_2Ga\cdot O(C_9H_6N)]_2$ sont: Ga—O(eq) = 1,937(3), Ga—O(ax) = 2,297(3), Ga—N(ax) = 2,211(3), Ga—C(eq) = 1,948(6) et 1,945(5) Å et O(ax)— Ga—N(ax) = 149,7(1)°.

[Traduit par la revue]

Introduction

The complex bis(2-methyl-8-quinolinolato)chlorogallium, $GaCl(C_{10}H_8NO)_2$, was characterized as the first crystallographic example of a trigonal bipyramidal, five-coordinate gallium complex (1, 2). In a previous report (3), the *N*-methyldiethanolaminogallane dimer $[MeN(CH_2CH_2O)_2GaH]_2$ was characterized as the second such example. The related derivatives, $[Me_2NCH_2CH_2O\cdot GaH_2]_2$ and $[Me_2NCH_2CH_2O\cdot GaMe_2]_2$ (4), both dimeric five-coordinate gallium species, and the monomeric four-coordinate gallium complex $[H_2NCH_2CH_2O\cdot GaMe_2]$ (5) have subsequently been structurally characterized. Recently the study was extended to include derivatives incorporating a pyridyl "aromatic" ring, resulting in the structure analysis of the $[Me_2Ga\cdot OCH_2(C_5H_4N)]_2$ dimer (6). As part of our continued interest in four- and five-coordinate gallium compounds, we have extended our study to include the sterically more bulky quinolyl and 2-dimethylaminomethylpyridyl ring systems in these gallium complexes. The present account details the synthesis, characterization, and crystal structure determinations of (2-dimethylaminomethyl-3-pyridolato)dimethylgallium, $[Me_2Ga\cdot O(C_5H_3N)CH_2NMe_2]$, and bis[(8-quinolinolato)-dimethylgallium], $[Me_2Ga\cdot O(C_9H_6N)]_2$.

Experimental

Air-sensitive materials were handled in a glove box under oxygen-free dry nitrogen or on a high-vacuum line. Tetrahydrofuran (THF) was dried by refluxing over Na/benzophenone and was used immediately following distillation. Benzene was dried by refluxing over molten potassium followed by distillation. Trimethylgallium was prepared as described previously (7). 2-Dimethylaminomethyl-3-hydroxypyridine (Aldrich), and 8-quinolinol (Eastman Organic Chemicals) were used as supplied.

Preparation of $[Me_2Ga\cdot O(C_5H_3N)CH_2NMe_2]$

To a solution of trimethylgallium (1.01 g, 8.8 mmol) in THF was added an equimolar amount of 2-dimethylaminomethyl-3-hydroxypyridine in the same solvent. The reaction mixture was refluxed overnight (~24 h) until cessation of methane gas evolution.

$$Me_3Ga + HO(C_5H_3N)CH_2NMe_2 \xrightarrow[\Delta]{THF} [Me_2Ga\cdot O(C_5H_3N)CH_2NMe_2] + MeH$$

The solvent was removed *in vacuo* and the colorless residue was extracted with benzene followed by filtration. The desired compound was isolated as air- and moisture-sensitive pale-yellow crystals in ~80% yield. Mp ~62°C. *Anal.* calcd. for $[Me_2Ga\cdot O(C_5H_3N)CH_2NMe_2]$: C 47.85, H 6.83, N 11.16; found: C 48.05, H 6.76, N 10.96. ^{1}H nmr (C_6D_6, 400 MHz, $\tau(C_6H_6)$ = 2.84 ppm): τ 10.29 s ($GaMe_2$), 8.39 s

[a]Temperature 22°C, Enraf-Nonius CAD4-F diffractometer, graphite-monochromated Mo-K_α($\lambda_{K\alpha1}$ = 0.70930, $\lambda_{K\alpha2}$ = 0.71359 Å) or nickel-filtered Cu-K_α radiation ($\lambda_{K\alpha1}$ = 1.540562, $\lambda_{K\alpha2}$ = 1.544390 Å), takeoff angle 2.7°, aperture (2.00 + tan θ) × 4.00 mm at a distance of 173 mm from the crystal, scan range extended by 25% on both sides for background measurement, $\sigma^2(I) = S + 2B + [0.04(S - B)]^2$ (S = scan count, B = normalized background count), function minimized $\Sigma w(|F_o| - |F_c|)^2$ where $w = 1/\sigma^2(F)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, $S = (\Sigma w(|F_o| - |F_c|)^2/(m - n))^{1/2}$. Values given for R, R_w, and S are based on those reflections with $I \geq 3\sigma(I)$.

[b]Non-standard setting of $C2/m$. Equivalent positions in $I2/m$: (0, 0, 0), (1/2, 1/2, 1/2) ± [x, y, z; $-x$, y, $-z$].

(NMe$_2$), 6.40 s (—CH$_2$), ring protons appeared at 3.14 dd (J = 4.0, 8.0 Hz), 2.74 d (J = 8.0 Hz), and 1.94 dd (J = 2.0, 4.0 Hz).

The mass spectrum displayed strong signals corresponding to the parent P$^+$, and P − Me$^+$ ions at m/e 250 and 235, respectively. The most intense peaks in the spectrum (100%) were those attributable to the $[Me_2Ga\cdot O(C_5H_3N)]^+$ fragment ion signal at 192 (m/e values based on ^{69}Ga isotope).

Preparation of $[Me_2Ga\cdot O(C_9H_6N)]_2$

$$Me_3Ga + HO(C_9H_6N) \xrightarrow[\Delta]{THF} (1/2)[Me_2Ga\cdot O(C_9H_6N)]_2 + MeH$$

The coordination compound $[Me_2Ga\cdot O(C_9H_6N)]_2$ was prepared by an identical procedure to that described above, using 8-hydroxyquinoline as the active-hydrogen containing starting material. The air-sensitive lemon–yellow needles of the product were isolated in ~85% yield. Mp ~63°C. *Anal.* calcd. for $[Me_2Ga\cdot O(C_9H_6N)]_2$: C 54.16, H 4.92, N 5.74; found: C 54.58, H 4.61, N 5.97. ^{1}H nmr (C_6D_6, 400 MHz, τ(C_6H_6) = 2.84 ppm) τ 9.90 s ($GaMe_2$), ring protons at 3.58 dd (J = 4.0, 8.0 Hz), 3.31 dd (J = 2.0, 8.0 Hz), 2.71 m, 2.61 dd (J = 2.0, 4.0 Hz), and 2.57 dd (J = 2.0, 8.0 Hz).

The mass spectrum displayed a moderately strong signal corresponding to the monomer ion at m/e 243. Strong signals were displayed for P − Me$^+$ and P − 2Me$^+$ ions at 228 and 213, respectively, the former being the most intense signal (100%) in the spectrum.

X-ray crystallographic analyses

Crystallographic data for $[Me_2Ga\cdot O(C_5H_3N)CH_2NMe_2]$ and $[Me_2Ga\cdot O(C_9H_6N)]_2$ appear in Table 1. Unit-cell parameters were refined by least-squares on 2 sin θ/λ for 25 reflections with 2θ = 40–45° for $[Me_2Ga\cdot O(C_5H_3N)CH_2NMe_2]$ and 2θ = 70–90° for $[Me_2Ga\cdot O(C_9H_6N)]_2$. The intensities of three check reflections, measured each hour of X-ray exposure time throughout the data collections, showed only small random variations in each case. The data were reduced[2] and corrected for absorption using the Gaussian integration method (8, 9).

Both structures were solved by conventional heavy atom methods. The gallium coordinates were determined from the Patterson functions and those of the remaining non-hydrogen atoms from subsequent difference maps. Non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included as fixed contribu-

tors to the structure in idealized positions (based on observed positions with C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å) for $[Me_2Ga\cdot O(C_5H_3N)CH_2NMe_2]$ and were refined with isotropic thermal parameters for $[Me_2Ga\cdot O(C_9H_6N)]_2$. Neutral atom scattering factors for all atoms and anomalous scattering corrections for Ga were taken from ref. 10. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied for $[Me_2Ga\cdot O(C_9H_6N)]_2$ (11–13). The final value of g was 0.20(4) × 10^4.

Space group symmetry and structural considerations indicate that the $[Me_2Ga\cdot O(C_5H_3N)CH_2NMe_2]$ molecule must reside on a crystallographic mirror plane in the space group $I2/m$. It was immediately apparent that apart from the Ga atom, which does reside on the mirror plane, all remaining atoms are 1:1 disordered with respect to the mirror plane. Refinement was then attempted in the non-centrosymmetric space groups $I2$ and Im (both consistent with the systematic absences observed from film and diffractometer data: hkl, $h + k + l$ odd) in the hope that an ordered structure would result. In each case a similar disorder persisted. The refinement was carried out in the space group $I2/m$, all atoms in general positions being assigned occupancy factors of 0.5. The maximum parameter shift was associated with U_{33} for C(5), all other shifts being less than 0.2σ. The relatively large residual density near Ga may be due in part to imperfect modelling of the thermal motion for the superimposed Ga atoms.

Final positional and thermal parameters appear in Tables 2 and 8, respectively.[3] Bond lengths and angles involving non-hydrogen atoms are given in Tables 3 and 4, respectively, and intra-annular torsion angles in Table 5. Calculated hydrogen parameters, bond lengths and angles involving hydrogen, and a complete listing of torsion angles (Tables 7, 9–11), and measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

*Here and elsewhere in this report, primed atoms are related to those in Table 2 by inversion through the centre of symmetry at (1/2, 1/2, 1/2).

Results and discussion

Gallium alkyls are known to eliminate methane on reaction with active-hydrogen containing compounds. In a previous study, the dimeric complex $[Me_2NCH_2CH_2OGaMe_2]_2$ was structurally characterized as the product of the reaction of trimethylgallium with *N,N*-dimethylethanolamine (4). In a later study, the reaction of Me_3Ga with ethanolamine, a compound containing active hydrogen at both the oxygen and nitrogen ends of the molecule, resulted in preferential elimination of the hydroxyl hydrogen to yield the complex $H_2NCH_2CH_2OGaMe_2$ (5). This selectivity was not surprising since it is known that O—H groups coordinated to gallium alkyls eliminate alkanes much more rapidly at lower temperatures than do similarly coordinated N—H groups which require elevated temperatures for alkane elimination (14). With the notable exception of $H_2NCH_2CH_2OGaMe_2$, which has a structure consisting of monomeric molecules containing tetrahedrally coordinated gallium atoms (5), monomer units of similar Me_2Ga systems have been shown by X-ray crystallographic analysis to dimerize in the solid state

via the formation of four-membered $(Ga—O)_2$ rings giving distorted trigonal bipyramidal arrangements about each five-coordinate gallium atom (3, 4, 6, 15–18).

The reaction of 8-hydroxyquinoline with trimethylgallium afforded the coordination compound "$[Me_2GaO(C_9H_6N)]$". The ^1H nmr spectrum of this quinolinato complex in C_6D_6 solution (Fig. 1) is in accord with an overall planar structure for the complex in solution. In this configuration, the two methyl groups on gallium lie above and below the plane, hence a sharp singlet is observed for the —$GaMe_2$ group.

The crystal structure of $[Me_2Ga\cdot O(C_9H_6N)]_2$ consists of discrete centrosymmetric dimeric units (Fig. 2) which are separated by normal van der Waals distances. Although the mass spectrum shows the complex to be monomeric in the gas phase, the solid state structure reveals that dimerization via the formation of a four-membered $(Ga—O)_2$ ring has taken place. The resulting structure contains a system of seven fused rings which is planar to within 0.053(5) Å. Taken individually, only

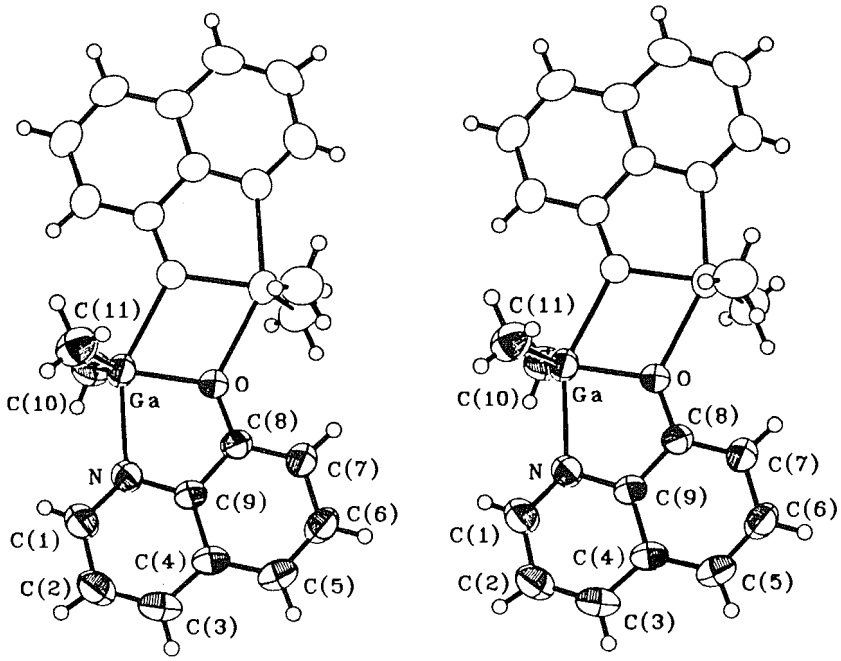

FIG. 2. Stereoscopic view of the bis[(8-quinolinolato)dimethylgallium] molecule; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned arbitrary thermal parameters for the sake of clarity. Shaded atoms comprise the asymmetric unit.

the two symmetry-related five-membered chelate rings are significantly non-planar (maximum deviation from the mean plane 0.027(3) Å), and have flattened Ga—envelope conformations. The quinoline moiety is slightly folded with an angle of 1.4(3)° between the normals to the mean planes of the two six-membered rings. The coordination about each Ga atom is trigonal bipyramidal, distorted primarily by the steric requirements imposed by the existence of the fused ring system. The Ga—N and Ga—O distances in $[Me_2Ga{\cdot}O(C_9H_6N)]_2$ are compared with those observed for other five-coordinate gallium complexes (1–4, 6, 15–25) in Table 6. The axial Ga—N distance is 2.211(3) Å, while those previously reported range from 2.104(3) to 2.779(3) Å with an average value of 2.361 Å. The equatorial and axial Ga—O distances, which occur in the central $(Ga—O)_2$ ring, are 1.937(3) and 2.297(3) Å, respectively. The corresponding ranges and averages for the seven other complexes which contain the same type of central $(Ga—O)_2$ ring are 1.911(3)–1.963(2) (mean 1.935 Å) for equatorial, and 2.012(6)–2.545(2) (mean 2.190 Å) for the axial Ga—O bonds. Those complexes with longer than average intracyclic axial Ga—O bonds all contain nearly planar, extended, fused-ring systems.

The coordination compound $[Me_2Ga{\cdot}O(C_5H_3N)CH_2NMe_2]$ was isolated as the product of the reaction of 2-dimethylamino-3-hydroxypyridine with trimethylgallium. The ^1H nmr spectrum of this compound in C_6D_6 solution (Fig. 3) is again consistent with an overall planar structure in solution, displaying singlets for the $—GaMe_2$, $—NMe_2$, and $—CH_2—$ groupings.

The mass spectrum of the compound $[Me_2Ga{\cdot}O(C_5H_3N)CH_2NMe_2]$ displayed as its highest mass peaks, a moderately strong parent ion (P^+) signal as well as a very strong $P - Me^+$ signal, suggestive of a monomeric species in the gas phase. The most intense signals were those corresponding to the loss of the "CH_2NMe_2" moiety from the monomer species.

The monomeric nature of $[Me_2Ga{\cdot}O(C_5H_3N)CH_2NMe_2]$ in the solid state was confirmed by the X-ray crystallographic analysis, which shows the structure to consist of discrete monomeric molecules containing tetrahedrally coordinated gallium

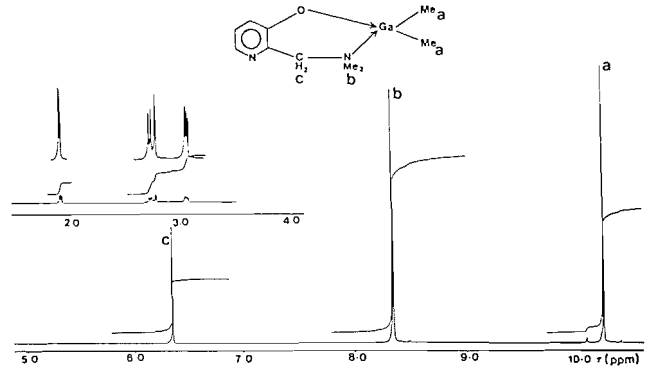

FIG. 3. 400 MHz ^1H nmr spectrum of $[Me_2Ga{\cdot}O(C_5H_3N)CH_2NMe_2]$ in C_6D_6 solution.

atoms (Fig. 4). This is somewhat surprising since similar dimethylamino compounds have been shown to dimerize in the solid state (4). The monomeric nature of the present compound is probably related to the steric constraints imposed by the unsaturation of the pyridine ring. Since the pyridine substituent atoms O and C(6) are constrained to lie approximately in the plane of the pyridine ring, four atoms of the six-membered chelate must be roughly coplanar. In order to minimize angular strain, the chelate ring adopts a steep and slightly twisted boat conformation in which the NMe_2 and $GaMe_2$ groups are nearly eclipsed. The partial staggering about the Ga—N bond which would be required for dimerization most likely results in too high a degree of ring strain. It is noteworthy that the presence of extensive $N—H\cdots O$ hydrogen bonding was sufficient to prevent the dimerization of $H_2NCH_2CH_2OGaMe_2$ (5) and $H_2NCH_2CO_2GaMe_2$ (26) in the solid state.

The Ga—N distance of 2.127(4) Å in $[Me_2Ga{\cdot}O(C_5H_3N)CH_2NMe_2]$ is as expected: longer than the bonds of 2.056(6) and 2.072(6) Å in the tetrahedral complex $H_2NCH_2CH_2OGaMe_2$ (5), similar to the values of 2.139(17) and 2.138(9) Å in (hexamethylenetetramine)bis(dimethylgallium) (27), and shorter than the bonds of 2.20(3) Å in Me_3GaNMe_3 (28) and 2.241(9) Å in

^{13}C magnetic resonance studies. 129.[1] Homoenolization in the camphenilone system. Examination of some 7-substituted derivatives

SRIYAWATHIE PEIRIS, ARTHUR J. RAGAUSKAS,[2] AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received October 7, 1986

SRIYAWATHIE PEIRIS, ARTHUR J. RAGAUSKAS, and J. B. STOTHERS. Can. J. Chem. **65**, 789 (1987).

The behavior of the 7,7-dimethyl, 7-spirocyclopropyl, and 7-isopropylidene derivatives of camphenilone under strongly basic conditions (*t*-BuO$^-$/*t*-BuOH/185°C) has been investigated to examine substituent effects on β-enolization in the [2.2.1] system. In each case, an equilibrium mixture of the initial ketone and its corresponding 5-substituted isomer was obtained, with the latter increasingly favored through the series. In each case the $^1H/^2H$ exchange processes were examined by experiments utilizing *t*-BuO$^-$/*t*-BuOD to establish the individual sites of deuterium incorporation in these ketones with ^2H and ^{13}C magnetic resonance. These data provide the stereoselectivities and relative rates of the exchange processes. The ^2H-induced effects in the ^{13}C spectra are discussed.

SRIYAWATHIE PEIRIS, ARTHUR J. RAGAUSKAS et J. B. STOTHERS. Can. J. Chem. **65**, 789 (1987).

Dans le but d'évaluer les effets des substituants sur la β-énolisation dans les systèmes [2.2.1], on a étudié le comportement des dérivés diméthyl-7,7, spirocyclopropyl-7 et isopropylidène-7 de la camphénoline dans des conditions fortement basiques (*tert*-BuO$^-$/*tert*-BuOH/185°C). Dans chacun des cas, on a obtenu un mélange à l'équilibre contenant de la cétone initiale et de son isomère correspondant substitué en position 5; la quantité de ce dernier augmente dans la série des composés étudiés. Dans chacun des cas, on a étudié les processus d'échange $^1H/^2H$ sous l'influence du *tert*-BuO$^-$/*tert*-BuOD; on a pu établir les sites individuels d'incorporation du deutérium dans ces cétones en faisant appel à la rmn du ^2H et du ^{13}C. Ces données nous ont permis d'établir les stéréosélectivités et les vitesses relatives des processus d'échange. On discute des effets du ^2H sur les spectres rmn du ^{13}C.

[Traduit par la revue]

Introduction

The discovery of β-enolization by Nickon and Lambert (1) arose from their examination of the fate of optically active camphenilone (**1***a*, 3,3-dimethylbicyclo[2.2.1]heptan-2-one) upon treatment with *t*-BuO$^-$/*t*-BuOH(D) at elevated temperatures. At 185°C, **1***a* was found to racemize (69% after 36 h, 88% after 48 h) and, in *t*-BuOD, racemization is accompanied by deuterium exchange at C-1 and -6 such that up to three deuterium atoms are incorporated in short reaction times, <48 h. Furthermore, the initial rate of deuterium incorporation is the same as the rate of racemization, establishing that proton abstraction leads to an intermediate that is symmetrical, or becomes symmetrical, before deuteration by solvent. This β-enolate intermediate may be represented as **2***a*, resulting from proton abstraction from C-6 in **1***a*. Ketonization of **2***a* can occur by cleavage (**a**) or (**b**) to yield **1***a* or its enantiomer **3***a*, respectively, which, in *t*-BuOD would pick up deuterium at C-6. In the early work, Nickon *et al.* (2) also studied the stereochemistry of the homoketonization process by examination of the cleavage of nor-**2***a*, generated from 1-acetoxynortricyclene at room temperature. In *t*-BuO$^-$/*t*-BuOD, deuteration occurred with high stereoselectivity (>94%) favoring the *exo* orientation, thereby signalling opening with inversion of configuration. Subsequently, the stereochemistry of ketonization of several β-enolates has been investigated and a general tendency for opening with inversion established (3).

The regioselectivity of β-enolate ketonization has been established for many systems (3) and the major governing factors appear to be relief of strain, product stability, and the stability of the incipient carbanion. Since the half-life for racemization of **1***a* is ca. 25 h at 185°C, this constitutes one of the more efficient isomerizations known to proceed through a β-enolate and, consequently, seemed to be a good system for an examination of substituent effects on the equilibrium **1** ⇌ **3**. For 7-

[b]Unequivocal assignments obtained from an INADEQUATE spectrum of a C_6D_6 solution.

substituted derivatives the regioselectivity of β-enolate cleavage could be biased toward formation of the 5-substituted isomers, thereby providing a viable preparative route to these derivatives; for example, 3,3,5,5-tetramethylnorcamphor (**3***b*) had not been described in the literature. We have recently found (4) that the 8-isopropylidene substituent in **4***d* gives regiospecific ketonization via path **b**, whereas **4***a* and **4***c* open exclusively by path **a**, demonstrating that conjugative stabilization of one of the incipient carbanionic centres can have a marked effect on the regiochemistry of homoketonization. For the camphenilone system, we have studied the fate of the 7,7-dimethyl (**1***b*), 7-spirocyclopropyl (**1***c*), and 7-isopropylidene (**1***d*) derivatives under typical homoenolization conditions and we wish to report our observations in this paper together with the results of an examination of the $^1H/^2H$ exchange processes in **1***b–d*.

Results and discussion

Preparation of materials

From an earlier study (4) 7-spirocyclopropylnorbornenone (**5**) was available and was readily hydrogenated over Pd/C to give 7-spirocyclopropylnorbornanone (**6**), which afforded 7,7-dimethylnorbornanone (**7**) upon hydrogenation over PtO_2, as described by Turro and Farrington (5). Both **6** and **7** were converted to their 3,3-dimethyl analogs **1***c* and **1***b*, respectively, by treatment with $NaNH_2/Et_2O/MeI$, and characterized by their ^{13}Cmr spectra (Table 1) and mass spectrometry. The ^{13}C assignments for **6** were established from the results of an INADEQUATE spectrum (6). In anticipation of the results of homoenolization of **1***c*, an alternative route to **3***c* was explored (Scheme 1). Treatment of 2-methyl-3-chloropropene with $NaNH_2$ in *t*-BuOH/THF gave methylene cyclopropane, which was reacted with cyclopentadiene to furnish the known olefin **8** (7). Hydroboration of **8** with borane – methyl sulfide complex furnished a 1:1 mixture of isomeric alcohols, which was oxidized quantitatively to the corresponding mixture of ketones **9** with pyridinium chlorochromate (PCC), but these mixtures were inseparable by gas liquid chromatography (glc) and thin-layer chromatography (tlc). Treatment of the ketone mixture

with $NaNH_2/Et_2O/MeI$, however, afforded a 1:1 mixture of **3***c* and **10**, which was readily separated by preparative glc. It may be noted that reduction of mixture **9** with LAH furnished a 1:1 mixture of the *endo*-alcohols **11** and **12**, which were easily separated by glc.

For the preparation of **1***d*, 7-isopropylidenenorbornenone (**13**), available from earlier work (4), was employed. Since hydrogenation of **13** has been reported to occur at both double bonds (8), it was anticipated that *exo*-3-methylation of **13** could render hydrogenation of the 5-double bond more favorable. Hence, **13** was converted to the corresponding enolate with LDA and quenched with methyl iodide to generate **14**, which was quantitatively hydrogenated over Pd/C to furnish **15**. Methylation of **15** using $NaNH_2/Et_2O/MeI$ gave **1***d* in 94% yield.

The ^{13}C shielding data for the compounds involved in the preparative procedures are collected in Table 1.

Homoenolization experiments

Initially the behavior of **1***b* under homoenolization conditions was examined following our usual procedures (9); **1***b*

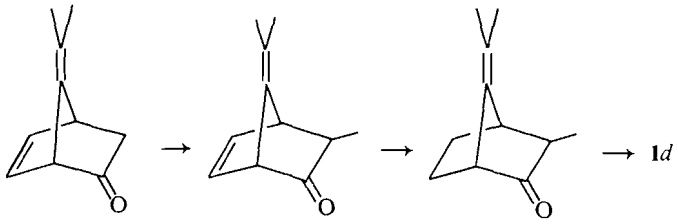
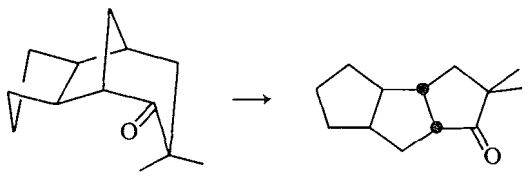
SCHEME 1



13 14 15 → 1d

was dissolved in anhydrous *t*-BuO$^-$/*t*-BuOH and aliquots were transferred to predried glass tubes under nitrogen, which were sealed and heated at 185°C for varying periods of time. The neutral product was isolated (>80% recovery) and analyzed by glc and ^{13}Cmr. While the chromatograms contained a single major band, the ^{13}C spectra clearly showed that the product is a mixture of two ketones with **1***b* as the major component. The minor compound was tentatively assigned structure **3***b*, the isomer expected from β-enolization of **1***b* via **2***b*, and the ^{13}C data offered permissive support for this structure. Confirmation of the identity of **3***b* was obtained later (see below). The proportions of each ketone in the neutral product, as a function of time, are listed in Table 2, from which it is apparent that **3***b* reaches a maximum concentration of ~16% after ~100 h at 185°C, which is presumably the equilibrium value. For additional evidence that the 5:1 ratio of **1***b* to **3***b* is the equilibrium mixture, two tubes containing a 1:1 mixture of **1***b* and **16** were heated at 200°C for 245 and 345 h. Under these conditions **16** is cleanly isomerized to **17** in 90% yield (10). The neutral

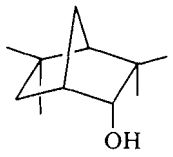


16 17

product in each case was the same, within experimental error, 42% (**1***b*), 8% (**3***b*), 5% (**16**), and 45% (**17**), which confirmed the initial results for **1***b* ⇌ **3***b* equilibration.

Under the same conditions, a series of experiments with **1***c* as the initial ketone gave a neutral product (>90% recovery) whose ^{13}C spectra contained two sets of signals attributable to **1***c* and **3***c* but the components of the mixture could not be separated by glc or tlc. Attempts to separate the mixture obtained by LAH reduction of the product were uniformly unsuccessful. Hence the relative proportions of the two ketones in the original product mixtures were determined from the ^{13}C spectra (Table 2). To confirm the 3:7 equilibrium distribution observed in these experiments, a series of runs with **3***c* was also carried out; these results are listed in Table 2. The behavior of the isomeric ketone **10** was also examined under these conditions but gave no indication of isomerization even after >400 h at 185°C, with >90% recovery of **10**.

With the proof that **1***c* and **3***c* are interconvertible under strongly basic conditions, attention was turned to the interconversion of **3***c* → **3***b*. Hydrogenation of the equilibrium mixture of **1***c* and **3***c* over PtO_2 in glacial acetic acid furnished a 37:63 mixture (by glc) of **1***b* and an alcohol exhibiting four methyl signals and lacking cyclopropyl absorption in its ^{1}H and ^{13}C spectra. Hence it could be concluded that hydrogenolysis of the spirocyclopropyl function occurred, as expected, together with reduction of the carbonyl group in **3***b*, which is much less hindered than that in **1***b*, and structure **18** was assigned to this



18

alcohol. Oxidation of **18** with PCC gave ketone **3***b* in 89% yield, having the identical ^{13}C spectrum as the isomerized product from **1***b*. Furthermore, this ketone was treated with *t*-BuO$^-$/*t*-BuOH at 185°C following our usual procedure and, after 85 h, gave a neutral product (>90% recovery) consisting of a 1:1 mixture of the same components found in the experiments with **1***b*, described above. These results confirm structure **3***b* for the isomeric ketone formed from **1***b* and illustrate a viable synthetic route from **1***c* → **3***b*.

The fate of **1***d* under strongly basic conditions was next examined and, from a series of experiments at 185°C, the neutral product, isolated in >90% yield, was found to contain two major components (>95% of the total product) that were readily separable by preparative glc. The relative proportions of **1***d* and the new component in the product were determined, as a function of time, by analytical glc and these results are

collected in Table 2. Precise mass measurements showed that the new component has the molecular formula $C_{12}H_{18}O$ and, therefore, is isomeric with **1***d*. The carbonyl carbon signal, δ_C 222.9, is 3.2 ppm downfield from that of **1***d*, indicative of reduced interaction with the double bond, as is the reduced shielding difference exhibited by the fully substituted olefinic carbons, 8.0 ppm vs. 17 ppm for **1***d*. These data are entirely consistent with isomerization of **1***d* → **3***d* and the carbon signals were readily assigned to **3***d*. The ^{1}Hmr spectrum provided further support for this structural assignment. Two sharp methyl singlets at δ 0.94 and 1.10, readily ascribed to the 3-methyl groups, were accompanied by the methyl signals of the isopropylidene group, δ 1.64 (bs), 1.73 (dd. J = 1.7 Hz). The latter are coupled to methylene patterns at δ 2.03 (*endo*-H-6, bd, J ~ 16 Hz), and 2.43 (*exo*-H-6, bd, J ~ 16 Hz) as shown by double irradiation experiments, which also revealed that irradiation of the δ 2.43 pattern collapsed a 4.5-Hz coupling in a one-proton multiplet, δ 2.73 (H-1, m, $\nu_{1/2}$ ~ 8 Hz). Irradiation of a one-proton multiplet at δ 2.92 (H-4, $\nu_{1/2}$ ~ 4 Hz) affected only the methylene patterns at δ 1.60 (*anti*-H-7, "dt", J ~ 10, 2 Hz) and 2.09 (*syn*-H-7, bd, J ~ 10 Hz). The ^{13}C shieldings are listed in Table 1; the individual assignments were confirmed by a series of experiments in *t*-BuOD.

These results show that derivatives **1***b–d* isomerize reversibly under strongly basic conditions in a manner analogous to that found for the racemization of camphenilone (**1***a*), presumably via an intermediate β-enolate that can be represented as **2**. In contrast to **2***a*, however, **2***b–d* are not symmetric and, consequently, different incipient carbanions are generated by cleavage of bonds **a** and **b**. For **2***d* it is evident that cleavage proceeds mainly via mode **b**, which furnishes an allylic carbanion. However, the cleavage is not regiospecific as is the case for **4***d* (4). The 5:95 equilibrium mixture of **1***d* and **3***d* shows that the latter is the more stable entity. It is interesting that a single isomer is generated by cleavage **b** since, upon formation of **3***d*, hydrogens at C-6 and the isopropylidene methyl carbons are the most acidic in the molecule and various allylic carbanions can form, as established by ^{1}H/^{2}H exchange experiments described below. Nevertheless, significant amounts of other double bond isomers of **3***d* were not detected. The presence of trace amounts of other isomers cannot be entirely discounted because two very small bands were visible by glc in the neutral product but were not investigated. The generation of some of the 5-isopropenyl isomer(s) was anticipated since sp^3 hybridization of C-5 in the [2.2.1] system will reduce the C-4,5,6 bond angle, but the interactions encountered by an 5-isopropenyl group must preclude its formation in significant amounts.

An inspection of molecular models of **1***b* and **3***b* suggests that the nonbonded interactions between closely lying methyl groups will be appreciably less for **1***b*. Consequently the marked preference for **1***b* in the equilibrium mixture seems reasonable and indicates an energy difference of ca. 1.5 kcal/mol for these two isomers at 185°C. While nonbonded interactions also appear to be less in **1***c* relative to those in **3***c*, the bond angle strain introduced by the spirocyclopropyl group at C-7 in the former may be expected to be greater than that produced by the corresponding substitution at C-5 in **3***c*. The 30:70 ratio of **1***c*:**3***c* at equilibrium indicates that **3***c* is the more stable by ca. 0.8 kcal/mol at 185°C. The preferential formation of **3***c* and its efficient separation from **1***c* by hydrogenation to the alcohol, which is readily oxidized to **3***b* in high yield, provided a preparative route (60% yield from **1***c*) to the latter. This was of interest since **3***b* was one of the tetramethylnorbornanones that had not been prepared heretofore.

H/D exchange experiments

To obtain additional information on the proton abstraction processes occurring in these systems, a series of experiments with each of **1***b–d* was carried out in *t*-BuO$^-$/*t*-BuOD at 185°C. The ^{13}C spectra of the recovered deuterated materials reveal the sites of H/D exchange through the characteristic ^{2}H-induced effects (11). Typically, in saturated systems, a deuterated carbon exhibits an upfield shift ($^1\Delta$) of 300–600 ppb (1 ppb = 0.001 ppm) with J_{CD} ~ 20 Hz, while geminal carbons (^{13}C–C-^{2}H) undergo two-bond shifts ($^2\Delta$) of 50–150 ppb with $J_{CCD} \leq 0.5$ Hz. Vicinal shifts are generally smaller, $^3\Delta$

10–20 ppb, but it has been recently recognized (11) that these exhibit a dependence on the dihedral angle (θ) relating the ^{13}C and ^{2}H nuclei extending the range of $^{3}\Delta$ to ~80 ppb for θ ~ 0°. The well-known angular dependence of vicinal couplings often provides a distinction between $^{2}\Delta$ and $^{3}\Delta$ shifts near 80 ppb since periplanar vicinal $^{13}C-^{2}H$ interactions generally exhibit resolvable couplings of ca. 1 Hz.

Samples of **1***d*-d_x and **3***d*-d_x were obtained from runs with **1***d*. The ^{2}H and ^{13}C spectra of **1***d*-d_x recovered after 0.5 and 1.5 h treatment only showed that extensive exchange occurred at the isopropylidene methyl sites. The ^{13}C spectra of the **3***d*-d_x samples (0.5, 1.5, 6, and 20 h) were more informative since the presence of deuterium at C-1 and -6 was clearly revealed, in addition to that at the isopropylidene methyl carbons. Generation of **3***d* via **2***d* in *t*-BuOD leads directly to deuterium incorporation at C-6, which becomes allylic, resulting in increased acidity of the 6-hydrogens and their ready exchange. This was confirmed by the C-6 absorption at 32 ppm, which consisted of a weak signal at δ_C 32.1 (CH_2) as well as a triplet and a barely discernible quintet arising from CHD and CD_2 species, respectively, with J = 20.5 Hz and $^{1}\Delta$ = 330 ppb/D. For the 6- and 20-h samples, a second set of these lines was apparent to signal the presence of deuterium at C-1 with $^{2}\Delta$ = 95 ppb. The C-1 pattern confirmed mono- and dideuteration at C-6 through its appearance as a four-line pattern with isotope-shifted components 70, 90, and 160 ppb upfield from the weak signal at δ_C 50.4 for the protio material. For the 0.5-h sample, the relative intensities were, in order of increasing field, 1:8:2:8, indicating that the initial incorporation at C-6 is stereoselective, presumably favoring *exo* deuteration, as is usual in related systems (3). Supporting evidence for this suggestion was provided by the C-7 absorption in which the δ_C 35.4 signal was accompanied by a prominent singlet, 18 ppb upfield, and a weak triplet, J ~ 0.9 Hz, 21 ppb upfield. The relative intensities of these components were approximately equal for the 1.5-h sample. These lines must be induced by *exo*- and *endo*-6-deuterons, respectively; since the latter is antiperiplanar to C-7, a resolvable vicinal coupling is expected (11). The relative intensities of these isotope-shifted components in the spectrum of the 0.5-h sample confirm the predominance of *exo*-6-deuteration initially, i.e., via cleavage of **2***d*. For the 6- and 20-h samples, a second set of the shifted components appeared 95 ppb upfield from the first set, arising from species bearing deuterium at C-1. Although the triplet for deuterated C-1 was indistinguishable from the noise in the 50-ppm pattern, the appearance of the second set of shifted components in the patterns for each of C-6 and C-7 established the occurrence of bridgehead exchange. The relatively rapid equilibration and allylic exchange, with the consequent rapid diminution of the deuterium pool, precluded the extraction of meaningful quantitative data on the rates and stereoselectivity of the processes involving **2***d*.

Although the mixtures of **1***b*-d_x and **3***b*-d_x obtained from the treatment of **1***b* with *t*-BuO^-/*t*-BuOD at 185°C could not be separated by glc, the individual signals for each carbon are nicely separated in the ^{13}Cmr spectra (Table 1) and the major sites of exchange in **1***b*-d_x could be identified. From the spectra of the products recovered after 4, 8, 16, and 32 h there was clear evidence of deuterium incorporation at C-1 and -6. After 4 h, a characteristic CHD triplet, J = 20.6 Hz, with $^{1}\Delta$ = 300 ppb, accompanied the original C-6 signal at δ_C 23.3, while the C-1 and -5 patterns, δ_C 59.4 and 23.5, respectively, each contained an isotope-shifted component, 60 and 115 ppb upfield. After longer reaction times, a second, less intense component appeared in each of the C-1 and -5 patterns with $^{2}\Delta$ = 85 and 90 ppb, respectively. In the spectra of the 16- and 32-h samples the C-6 absorption included a second, weak triplet, $^{2}\Delta$ = 105 ppb shifted by deuterium at C-1, which was also evidenced by the appearance of a shifted component in the C-7 absorption, δ_C 45.0, $^{2}\Delta$ = 85 ppb. The CD triplet for C-1 was, unfortunately, indistinguishable from the noise. The relative intensities of these various isotope-shifted components for C-1, -5, -6, and -7 indicated that incorporation at C-6 is stereoselective, favoring, presumably, *exo* exchange by ca. 6:1 over *endo* exchange, with the latter about three times slower than bridgehead exchange. To obtain better estimates of the relative rates of exchange and to check for lower incorporation levels at other centres, it was necessary to obtain pure samples of **1***b*-d_x. Hydrogenation of each of the mixtures over PtO_2 in HOAc afforded mixtures of **1***b*-d_x and **18**-d_x that were readily separated by flash chromatography to provide the requisite pure samples of **1***b*-d_x for examination by mass spectrometry, to determine the total deuterium content, and by ^{2}Hmr, to assess the incorporation level at the individual sites. The ^{2}Hmr spectrum of **1***b*-d_x that was recovered after 16 h with *t*-BuO^-/*t*-BuOD exhibited five signals at δ 2.08, 1.95, 1.50. 1.24, and 1.04. The two highest field signals coincide with two of the four methyl singlets in the proton spectrum of **1***b* and, by analogy with several related systems (3) can be assigned to the geminal 3-methyls, with that at highest field arising from the *endo*-methyl group since the rate of ^{2}H uptake was found to be slowest. For several related systems, it has been established (3) that β-methyl exchange is regioselective, favoring *exo* incorporation. The lowest field ^{2}H signal at δ 2.08 coincides with a broadened doublet, J ~ 5 Hz, in the proton spectrum and is readily assigned to the bridgehead H-1. The remaining pair of signals, therefore, arises from the 6-methylene deuterons. Both signals coincide with multiplets in the proton spectrum in which the lower field pattern is the more complex and is, therefore, attributable to the *exo*-6 proton since its *endo*-6 counterpart lacks significant coupling to H-1. The relative intensities of the 1- and 6-deuterium signals confirmed the relative rates of deuterium incorporation tentatively deduced from the ^{13}C spectra, as noted above, and in combination with the total ^{2}H content determined by mass spectrometry permitted estimates of the first-order rate constants for exchange at the various sites as: $7.5 \times 10^{-7}\,s^{-1}$ (C-1), $2 \times 10^{-5}\,s^{-1}$ (*exo*-6), $3 \times 10^{-6}\,s^{-1}$ (*endo*-6), $1 \times 10^{-7}\,s^{-1}$ (*exo*-3-Me), and $5 \times 10^{-8}\,s^{-1}$ (*endo*-3-Me).

As in the preceding case, the mixtures of **1***c*-d_x and **3***c*-d_x obtained upon homoenolization in *t*-BuOD could not be separated but there is little overlap of the ^{13}C signals from each in the mixtures and considerable information could be extracted. From the ^{13}C spectra of the mixtures recovered after 2, 4, 8, and 16 h at 185°C, there was clear evidence of deuterium incorporation at C-1 and -6 in **1***c*-d_x. The signal for C-7 at δ_C 32.3 was accompanied by an upfield component, $^{2}\Delta$ 75 ppb, whose intensity increased with reaction time and is attributable to deuterium incorporation at C-1. Similarly, the δ_C 23.6 pattern for C-5 contained an isotope-shifted signal, $^{2}\Delta$ 115 ppb, which grew more rapidly and arose from deuterium exchange at C-6. In the spectrum of the 2-h sample, the C-6 pattern consisted of the normal signal δ_C 24.7 and a shifted component, $^{2}\Delta$ 105 ppb, due to deuterium at C-1. For the later samples, characteristic triplets, $^{1}\Delta$ 310 ppb, J = 21.0 Hz, were increasingly apparent for species bearing deuterium at C-6 and at both C-1 and -6

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

such that, after 16 h, these triplets constituted virtually the entire absorption for C-6. Thus, although there is extensive deuterium incorporation at C-6, there was no evidence of a resolvable $^3\Delta$-shifted component in the absorption for C-7; this indicated that most of the deuterium at C-6 is *exo*, which is consistent with inversion of configuration upon cleavage of **2***c* via bond **a**. The ^{13}C patterns for **3***c*-d_x also provided clear evidence of deuterium incorporation at C-1 and -6. In each case, the C-7 absorption contained the original signal at δ_C 35.8 together with a $^2\Delta$ component 100 ppb upfield indicative of deuterium at C-1. In the later samples a third component appearing as a closely spaced triplet, $J \sim 0.8$ Hz, $^3\Delta$ 20 ppb, became evident. The spectrum of the 2-h sample revealed that >95% of the absorption for C-1, δ_C 51.9, was the isotope-shifted component, $^2\Delta$ 66 ppb, signifying nearly complete mono-deuteration at C-6. In addition, 95% of the absorption for one of the spirocyclopropyl methylene carbons, δ_C 13.9, was a triplet, $J \sim 0.8$ Hz, 90 ppb, upfield from the normal signal while the second spirocyclopropyl methylene signal, δ_C 11.0, was unaffected. However, in the later samples, a distinctly broadened ($\nu_{1/2}$ 1.6 Hz) component, $^3\Delta$ 70 ppb, became increasingly intense; in fact, the growth of this component was similar to that found for the closely spaced triplet in the C-7 absorption, noted above. These spectral changes shed light on the stereoselectivity of deuterium incorporation at C-6. After 2 h, the *exo*-6 proton is nearly completely exchanged and the large vicinal isotope shift and coupling exhibited by one of the spirocyclopropyl methylene carbons identifies that which is synperiplanar, i.e., *exo*. After longer reaction times, the incorporation of *endo*-6-deuterium is manifest in the appearance of vicinal effects in the absorptions for C-7 and the second spirocyclopropyl methylene carbon to which this deuterium is antiperiplanar and synperiplanar, respectively. These results are consistent with preferential cleavage of **2***c* via **b** proceeding with inversion of configuration. The spectrum of the 2-h sample contained a prominent triplet, $J = 20.5$ Hz, $^1\Delta$ 375 ppb, together with a weak singlet (<5% of the total intensity) at δ_C 35.4 for C-6. With increasing time, a second triplet, $^2\Delta$ 100 ppb, became increasingly prominent and was due to deuterium exchange at C-1. After 16 h, the latter triplet constituted >60% of the total intensity in the C-6 pattern. It should be noted that the absorption for fully deuterated C-6 species was not distinguishable from the noise.

To obtain estimates of the relative rates of exchange in **1***c*-d_x, the mixtures of **1***c*-d_x and **3***c*-d_x were hydrogenated over PtO_2 in HOAc to furnish mixtures of **1***b*-d_x and **18**-d_x, which were readily separated by flash chromatography. The ^2H content of the resulting pure samples of **1***b*-d_x was assessed by mass spectrometry and ^{2}Hmr as described above for the analogous samples from the experiments with **1***b*. With the assumption that the hydrogenolysis of **1***c*-d_x to **1***b*-d_x did not alter the ^2H distribution, approximate first-order rate constants for exchange at the various sites in **1***c* were estimated and these data are collected in Fig. 1 together with those for **1***b*, **19** (9), **20** (16), and **21** (17). From these results it is apparent that the rates of exchange at C-6 are comparable in **1***b*, **1***c*, and **19**, with *exo* exchange favored. It is interesting that bridgehead exchange at C-1 is significantly enhanced in **1***c* relative to that in **1***b* by a factor of 25, while this process proceeds at comparable rates in **1***b* and **20**. Bridgehead exchange in **1***c* approaches the rate found for **21**, indicating that the three-membered ring in each enhances the acidity of the 1-hydrogen in each case. Finally, it may be noted that the rates of deuterium exchange at

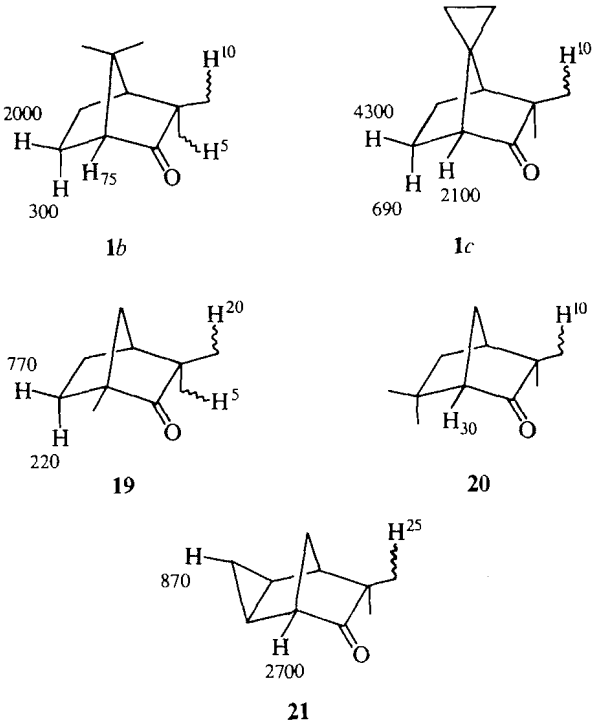

FIG. 1. Deuterium exchange rates ($k \times 10^8\ s^{-1}$) at the various sites in **1***b*, **1***c*, and **19–21** by β-enolization at 185°C in *t*-BuO$^-$/*t*-BuOD. The data for **1***c* were obtained by examination of samples of **1***b* from hydrogenolysis of **1***c* (see text).

the *exo*-methyl carbon are similar in the five systems. There was no evidence of γ-exchange at the cyclopropylmethylene sites in **1***c* although such hydrogens may be expected to be more acidic than their alicyclic counterparts. This contrasts sharply with the results for **21**, which exhibits deuterium incorporation at the less hindered of the two cyclopropylmethylene hydrogens, with $k \sim 8.7 \times 10^{-6}\ s^{-1}$, i.e., at a rate comparable to that found for the *endo*-6-hydrogen in **1***c* (17). This suggests that the carbonyl group in **21** enhances the acidity of the cyclopropylmethylene hydrogen due to the orientation of the three-membered ring relative to the carbonyl π system, which differs from that in **1***c*. It may be noted that the *endo* isomer of **21** also exhibits γ-exchange at the less hindered of the cyclopropylmethylene sites $k \sim 1.6 \times 10^{-5}\ s^{-1}$. Clearly the effect of the carbonyl group is dependent on the geometry of the system. Work is in progress to obtain more data on the reactivity of exchange in related systems, which may permit more definitive interpretation of the trends for both β- and γ-exchange.

Experimental

Gas–liquid chromatography was carried out on Varian 920 and 3700 instruments using columns of 10% Carbowax 20 M, 6% FFAP or 10% SE-30 in Chromosorb W, as indicated. Tetrahydrofuran (THF) and ether were dried over sodium and freshly distilled before use. Diisopropyl amine was distilled from CaH_2 and stored over 4A molecular sieves; methyl iodide was dried over 4A sieves. The ketones, 7-spirocyclopropylnorbornenone (**5**) and 7-isopropylidenenorbornenone (**13**), were employed as the starting materials for the preparation of **1***b–d* and have been described previously (4).

Infrared spectra were recorded with a Beckman 4250 instrument and mass spectra were obtained on a Varian MAT-311A system at 70 eV (direct inlet). Routine ^{1}Hmr spectra were recorded with a Varian EM-360 instrument while data for pure samples were collected with a Varian XL-200 spectrometer. The ^2H and ^{13}Cmr spectra were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

obtained using a Varian XL-300 system and comparison of the fully decoupled ^{13}C spectra with those recorded with either the APT (12) or DEPT (13) sequences identified the methyl, methylene, methine, and fully-substituted carbon signals. The INADEQUATE spectrum of **6** was obtained using the C13SAT sequence of the XL software with the XL-200 instrument: 3000 Hz sweep width (sp^3 carbons only), 12 s repetition rate, 32 000 points, and a 32K transform.

7-Spirocyclopropylnorbornanone (6)

To a solution of **5** (1.89 g) in 95% EtOH (24.2 mL) was added 10% Pd/C (73 mg) and the mixture hydrogenated in a Parr shaker (50 psi, H_2 pressure (1 psi = 6.9 kPa)) for 6 h. After removal of the catalyst by filtration, the solution was concentrated by evaporation and the residue taken up in *n*-pentane (30 mL), before washing with H_2O (2 × 15 mL) and drying over $MgSO_4$. Removal of the solvent gave **6** (1.80 g, 94% yield) as an oil, >99% pure by glc (Carbowax), which crystallized on standing, mp 65–66°C (lit. (14) mp 64°C); ir (film): 3070, 2960, 1750 cm^{-1}; ^{1}Hmr agreed with the literature (5); ^{13}Cmr (see Table 1). *Exact Mass* calcd. for $C_9H_{12}O$: 136.0888; found: 136.0890.

7,7-Dimethylnorbornanone (7)

The mixture composed of **6** (300 mg) in glacial acetic acid (11.5 mL) and Pt_2O (70 mg) was hydrogenated in a Parr shaker (50 psi, H_2 pressure) for 16.5 h. After the addition of H_2O (6 mL) the catalyst was removed by filtration and the acid neutralized by the addition of solid $NaHCO_3$. Extraction with *n*-pentane (4 × 30 mL), washing the combined extracts with 10% aqueous NaCl solution (2 × 40 mL), and drying over $MgSO_4$ before evaporation of the solvent afforded crude **7** as an oil, which was purified by flash chromatography (ether – petroleum ether, 10:90) to furnish **7** (300 mg, 98% yield); ir ($CHCl_3$): 2940, 1740 cm^{-1}; ^{1}Hmr agreed with the literature (5); ^{13}Cmr (see Table 1). *Exact Mass* calcd. for $C_9H_{14}O$: 138.1045; found: 138.1050.

3,3-Dimethyl-7-spirocyclopropylnorbornan-2-one (1c)

Ketone **6** (500 mg) in Et_2O (4 mL) was added to a stirred suspension of $NaNH_2$ (0.8 g) in Et_2O (20 mL) under nitrogen and the mixture stirred for 2 h under reflux. Methyl iodide (0.46 mL) was added slowly and then equivalent amounts of MeI were added at intervals of 2, 4, and 11 h. The mixture was refluxed for 2 h before cooling to 0°C and dilution with H_2O (12 mL). Pentane extraction in the usual fashion gave a yellow oil, which was purified by flash chromatography (Et_2O – petroleum ether, 5:95) to furnish **1***c* (320 mg, 52% yield); ir (CCl_4): 3070, 2960, 1742 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.27–0.52 (m, 2H), 0.73–0.97 (m, 2H), 1.06 (s, 3H, Me), 1.20 (s, 3H, Me), 1.45–1.65 (m, 2H), 1.75–2.15 (m, 4H); ^{13}Cmr (see Table 1). *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1201.

3,3,7,7-Tetramethylnorbornornan-2-one (1b)

Following the general procedure described for the preparation of **1***c*, **7** (300 mg) in Et_2O (4 mL) was reacted with $NaNH_2$ (0.5 g) in Et_2O (11 mL) at reflux for 2.5 h before the addition of MeI (0.5 mL). Further additions after 10 and 2.5 h followed by reflux for 7 h furnished a product (250 mg) after pentane extraction, which appeared by glc (Carbowax) to be a 4:1 mixture of **1***b* and 3,7,7-trimethylnorbornanone. This mixture was recycled through the methylation sequence to afford oily **1***b* (80 mg), which glc indicated to be >95% pure. Preparative glc provided pure **1***b* for characterization and for homoenolization studies; ir (film): 2960, 1850 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.04 (s, 3H, Me), 1.09 (s, 3H, Me), 1.13 (s, 3H, Me), 1.23 (s, 3H, Me), 1.47 (m, 1H), 1.68–2.10 (m, 5H); ^{13}Cmr (see Table 1). *Exact Mass* calcd. for $C_{11}H_{18}O$: 166.1358; found: 166.1356.

3,3-Dimethyl-5-spirocyclopropylnorbornan-2-one (3c)

(i) 5-Spirocyclopropylnorbornene (8)

Methylenecyclopropane (3.27 g), prepared from methallyl chloride and $NaNH_2$ in *t*-BuOH/THF as described by Conia and co-workers (15), cyclopentadiene (4.9 g), and hydroquinone (12 mg) were combined and aliquots were transferred to a series of thick-walled glass tubes (tube volume:solution volume, 5:1) that were sealed under vacuum. These were placed in an oil bath at 100°C and the temperature increased to 190°C over 3.5 h. After 19 h at 190°C the tubes were removed from the bath and cooled to room temperature before opening. The contents of the tubes were recovered by washing with pentane. Bulb-to-bulb distillation gave **8**, bp 28–30°C/18 Torr (1 Torr = 133.3 Pa), 3.98 g, 55% yield, whose physical properties were identical to those found by Adam *et al.* (7).[3]

(ii) 5- and 6-Spirocyclopropyl-3,3-dimethylnorbornan-2-ones (3c and 10)

Upon cooling a solution of **8** (3.9 g) in *n*-hexane (11 mL) to 0°C, 10 *M* borane – methyl sulfide solution (1.33 mL) was added dropwise, after which the ice bath was removed and the reaction mixture stirred for 6 h. Excess borane was destroyed by the slow addition of EtOH (12.7 mL) followed by the addition of 3 *M* NaOH aqueous solution (4.7 mL). The solution was cooled to 0°C before 30% H_2O_2 solution (4.7 mL) was slowly added. Then the reaction mixture was refluxed for 1.5 h. Upon cooling, the solution was diluted with H_2O (50 mL) and the organic layer removed by decantation. The aqueous phase was extracted with pentane (3 × 60 mL) and the combined extracts washed with brine before drying over $MgSO_4$ and evaporation of solvent. Distillation of the residue afforded a 1:1 mixture (by ^{13}Cmr) of two alcohols, bp 49–50°C/0.4 Torr, 3.05 g, 68% yield, which could not be separated by glc (Carbowax, FFAP, SE-30) or tlc. Precise mass measurement of the mixture indicated the expected molecular formula, $C_9H_{14}O$. *Exact Mass* calcd.: 138.1045; found: 138.1047.

The mixture of alcohols (1.0 g) in CH_2Cl_2 (9.6 mL) was added to a slurry of PCC (2.33 g), sodium acetate (0.18 g), Celite (2.33 g), and CH_2Cl_2 (9.6 mL), which was stirred for 3 h before isolation of the product by our usual pentane extraction. Removal of the solvent gave an oil (0.99 g, quantitative yield) whose ^{13}C spectrum indicated the presence of two isomeric ketones **9** but, again, glc and tlc failed to separate the two components. The expected molecular formula for the product, $C_9H_{12}O$, was obtained by precise mass measurement. *Exact Mass* calcd.: 136.0888; found: 136.0885.

Dimethylation of this mixture of ketones was accomplished following the general procedure described above. A slurry of $NaNH_2$ (1.9 g), Et_2O (30 mL), and mixture **9** (0.83 g) was refluxed for 2 h. Methyl iodide (0.76 mL) was then added and three further additions were made after 2 h (0.76 mL), 4 h (1.52 mL), and 11 h (1.52 mL). Before work-up, the mixture was refluxed for 5 h; however, the ^{13}Cmr spectrum of this product indicated the presence of both mono- and dimethylated material. Two additional cycles were required before a product consisting of a 1:1 mixture of two components (0.77 g, 77% yield) was obtained, which was readily separated by preparative glc (FFAP) to furnish pure samples of each dimethylated ketone.

3*c*: ir ($CHCl_3$): 3080, 2990, 1740 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.26 (m, 1H), 0.74 (m, 1H), 0.76 (m, 2H), 1.02 (s, 3H, Me), 1.17 (s, 3H, Me), 1.66 (bd, *J* = 12.4, *endo*-H-6), 1.79 (dd, *J* = 12.4, 5.3 Hz, *exo*-H-6), 2.67 (d″q″, *J* = 5.3, 1.8 Hz, H-1), 1.48 (m, H-4), 1.99 (dt, 11.4, 1.8 Hz, *anti*-H-7), 2.02 (d″q″, *J* = 11.4, 1.8 Hz, *syn*-H-7); ^{13}Cmr (see Table 1). *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1197.

10: ir (CCl_4): 3030, 2920, 1737 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.47 (m, 2H), 0.57 (m, 1H), 0.68 (m, 1H), 1.08 (s, 3H, Me), 1.10 (s, 3H, Me), 1.62 (dd, *J* = 12.2, 2.5 Hz, *endo*-H-5), 1.81 (dd, *J* = 12.2, 3.9 Hz, *exo*-H-5), 1.75 (t, *J* = 1.5 Hz, H-1), 1.89 (dt, *J* = 10.5, 1.5 Hz, *anti*-H-7), 2.02 (ddt, *J* = 10.5, 2.5, 1.5 Hz, *syn*-H-7), 2.30 (m, H-4); ^{13}Cmr (see Table 1). *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1201.

*5- and 6-Spirocyclopropyl-*endo*-2-norbornanols (11 and 12)*

To a slurry of LAH (42 mg) in Et_2O (4 mL) was added the 1:1 mixture of ketones **9** (100 mg), described above, in Et_2O (2 mL) and the reaction mixture was stirred overnight. Excess LAH was destroyed by the cautious addition of H_2O and the product isolated by ether extraction to yield a 1:1 mixture of alcohols **11** and **12** (70 mg, 70% yield), which was readily separated by preparative glc (Carbowax).

[3]The ^{13}C data, ir, mass, and ^{1}Hmr spectra for authentic **8** were kindly provided by Professor Adam for comparison with our material.

Separation of mixtures of ***1****c*/***3****c and* ***1****b*/***3****b by hydrogenation to* ***1****b and* ***18***

The 32:68 mixture of **1***c* and **3***c* (210 mg) from homoenolization of **1***c* for 187 h at 185°C was placed in a pressure vessel containing glacial acetic acid (7 mL) and PtO_2 catalyst (100 mg) and the mixture hydrogenated under 50 psi of H_2 for 33 h. After the addition of H_2O (10 mL), the mixture was neutralized with solid $NaHCO_3$ and the catalyst removed by filtration. The neutral solution was saturated with NaCl and extracted with pentane (3 × 20 mL) in the usual manner. Removal of the solvent gave an oil (200 mg), which glc analysis (FFAP) and ^{13}Cmr indicated to be a mixture of **1***b* and **18**. Flash chromatography (Et_2O – petroleum ether, 10:90) furnished pure samples of each, **1***b* (70 mg) and **18** (120 mg); ir (film): 3360, 2945, 1073 cm^{-1}. ^{1}Hmr ($CDCl_3$) δ: 3.74 (d, J = 4.5 Hz, H-2), 2.31 (bt, J = 4.5 Hz, H-1), 1.60 (m, 3H), 1.25 (m, 2H), 1.22, 1.11, 1.05, 1.03 (4 × Me); ^{13}Cmr (see Table 1). *Exact Mass* calcd. for $C_{11}H_{20}O$: 168.1514; found: 168.1517.

The same procedure was employed to separate the mixtures of **1***b*-d_x and **3***b*-d_x obtained upon homoenolization of **1***b* in *t*-BuO^-/*t*-BuOD at 185°C.

*3,3,5,5-Tetramethylnorbornan-2-one (****3****b)*

To a slurry of PCC (190 mg), sodium acetate (15 mg), Celite (190 mg), and CH_2Cl_2 (1.0 mL) was added a solution of **18** (100 mg) in CH_2Cl_2 (1.0 mL) and the reaction mixture was stirred for 3 h. The crude product was isolated by pentane extraction and purified by column chromatography on silica (eluent: ether – petroleum ether, 5:95) to give **3***b* (88 mg, 89% yield); ir (film): 2940, 1745 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.52 (d″q″, J = 5.8, 1.6 Hz, H-1), 2.00 (dt, J = 11.2, 1.8 Hz, *anti*-H-7), 1.94 (dq, J = 11.2, 1.8 Hz, *syn*-H-7), 1.83 (m, H-4), 1.76 (ddd, J = 13.2, 5.8, 1.2 Hz, *exo*-H-6), 1.39 (dd, J = 13.2, 1.8 Hz, *endo*-H-6), 1.23 (s, 6H), 1.17 (s, 3H, Me), 1.14 (s, 3H, Me); ^{13}Cmr (see Table 1). *Exact Mass* calcd. for $C_{11}H_{18}O$: 166.1358; found: 166.1362.

*3,3-Dimethyl-7-isopropylidenenorbornan-2-one (****1****d)*

*(i) 3-*exo*-Methyl-7-isopropylidenenorborn-5-en-2-one (****14****)*

To a stirred solution of LDA, prepared from diisopropyl amine (0.53 mL), THF (6 mL), and *n*-butyllithium in hexane (1.3 mL, 2.5 *M*) at −78°C, under an N_2 atmosphere was added dropwise a solution of 7-isopropylidenenorbornenone (400 mg) in THF (2 mL) and stirring was continued for 35 min before the addition of methyl iodide (0.35 mL). After stirring overnight at room temperature, the reaction mixture was diluted with 10% aqueous NaCl solution (10 mL) and the product extracted with pentane (4 × 15 mL). The combined extracts were washed with the NaCl solution (2 × 15 mL) and H_2O (15 mL) before drying over $MgSO_4$. Removal of the solvent afforded **14** (430 mg, 98% yield), which was pure by glc analysis (FFAP); ir (CCl_4): 3080, 2940, 1748 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 6.66 (dd, J = 5.8, 3.0 Hz, H-5), 6.24 (dddd, J = 5.8, 3.3, 1.2, 0.6 Hz, H-6), 3.53 (bdd, J = 3.3, 1.8 Hz, H-1), 3.32 (m, $\nu_{1/2}$ ~ 6 Hz, H-4), 2.14 (q, J = 7.4 Hz, *endo*-H-3), 1.68 (s, 3H, Me), 1.63 (s, 3H, Me), 1.04 (d, J = 7.4 Hz, *exo*-3-Me); ^{13}Cmr (see Table 1). *Exact Mass* calcd. for $C_{11}H_{14}O$: 162.1045; found: 162.1039.

*(ii) 3-*exo*-Methyl-7-isopropylidenenorboran-2-one (****15****)*

To a solution of **14** (220 mg) in 95% EtOH (3.26 mL) was added 10% Pd/C (80 mg) and the mixture hydrogenated in a Parr shaker at 760 Torr for 6 h. The catalyst was removed by filtration and the product isolated by pentane extraction (3 × 8 mL). The combined extracts were washed with 10% aqueous NaCl (2 × 10 mL) and H_2O (10 mL) and the aqueous fractions were reextracted with pentane (20 mL). After drying over $MgSO_4$, the pentane solution was concentrated to yield **15** (220 mg, 99% yield), which was pure by glc analysis (FFAP); ir (CCl_4): 2960, 1745 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.05 (m, H-1), 2.75 (m, H-4), 2.09 (q, J = 7.4 Hz, H-3), 1.75–1.90 (m, 2H), 1.73 (s, 3H, Me), 1.69 (s, 3H, Me), 1.48–1.58 (m, 2H), 1.02 (d, J = 7.4 Hz, *exo*-3-Me); ^{13}Cmr (see Table 1). *Exact Mass* calcd. for $C_{11}H_{16}O$: 164.1201; found: 164.1201.

A mixture of **15** (420 mg), $NaNH_2$ (840 mg), and Et_2O (8.4 mL) was heated under reflux for 2.5 h. Methyl iodide (1.0 mL) was then added and four further additions were made after 8 h (0.5 mL), 4 h (0.5 mL), 3 h (0.5 mL), and 2 h (0.3 mL). After refluxing for an additional 17 h, the reaction mixture was worked up to furnish an oil (430 mg, 94% yield) by pentane extraction, and glc analysis (FFAP) indicated purity of >98%. Preparative glc (FFAP) provided pure **1***d* for characterization and for homoenolization experiments; ir (CCl_4): 2970, 1747 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.05 (dd, J = 5.0, 1.5 Hz, H-1), 2.62 (dd, J = 4.5, 1.5 Hz, H-4), 1.5–1.9 (m, 4H), 1.72 (s, 3H, Me), 1.66 (s, 3H, Me), 1.07 (s, 3H, Me), 1.01 (s, 3H, Me); ^{13}Cmr (see Table 1). *Exact Mass* calcd. for $C_{12}H_{18}O$: 178.1358; found: 178.1361.

Homoenolization experiments

The general procedures for the rearrangement and exchange experiments, reported previously (9), were followed as illustrated for **1***b*. To a solution of *t*-BuO^-/*t*-BuOH (1.27 *M*, H_2O content = 50 μg/mL) was added **1***b*, to give a solution that was 0.26 *M* in ketone. To a series of 5-mL predried, thick-walled glass tubes were transferred 0.5-mL aliquots of the reaction solution; the tubes were degassed and sealed before immersion in an oil bath at 185°C. Tubes were removed at various times, cooled before opening, and the contents removed by washing with H_2O (10 mL). The organic product was isolated by pentane extraction (3 × 15 mL) and the combined extracts backwashed with H_2O (3 × 10 mL). The aqueous washings were reextracted with pentane (2 × 15 mL) and the pentane extracts dried over $MgSO_4$. Removal of the solvent by distillation afforded a neutral organic product, representing 80–90% yields from the various tubes, which consisted of two components according to the ^{13}C spectra, although only a single band was evident upon glc analysis (FFAP, Carbowax SE-30). The major component was the initial ketone and the minor component was **3***b*, identified by the synthesis of an authentic sample (see above). From the various runs, the results showed that a 6:1 mixture of **1***b*:**3***b* represented the equilibrium value. An 85-h run at 185°C with **3***b* as starting material gave a 1:1 mixture of **1***b* and **3***b* (>90% recovery), confirming the identity of the latter.

Analogous experiments with **1***c* also gave a neutral two-component product (>90% yield) inseparable by glc (FFAP, Carbowax, SE-30) but whose ^{13}C spectra showed the presence of **1***c* and **3***c*, which was identified by comparison with an authentic sample (see above). The same mixture of **1***c* and **3***c* resulted upon base treatment of either as the initial ketone showing the equilibrium mixture to be 30:70 (**1***c*:**3***c*). The isomeric ketone **10** was found to be stable under the strongly basic conditions. With >90% recovery after >300 h there was no evidence of isomerization. Homoenolization experiments with **1***d* resulted in a 95% conversion to **3***d*, which was identified on the basis of its spectroscopic properties (see text).

The results of these homoenolization runs are collected in Table 2.

For the exchange experiments, *tert*-butyl alcohol-*O*-d_1 (99% deuterated and <0.005 *M* in water) was employed and a series of runs for each of the ketones **1***b–d* was carried out: **1***b*, 4, 8, 16, and 32 h; **1***c*, 2, 4, 8, 16 h; **1***d*, 0.5, 1.5, 6, and 20 h, using the same batch of *t*-BuO^-/*t*-BuOD for each. The products from each run were examined by ^{13}Cmr to determine the ^{2}H-induced effects. To assess the deuterium incorporation as a function of reaction time, samples of the initial ketones were required for analysis by mass spectrometry and ^{2}Hmr. While preparative glc afforded the requisite samples of **1***d*-d_x from the **1***d*-d_x/**3***d*-d_x mixtures, a different method was required for the others. Pure samples of **1***b*-d_x were obtained from the mixtures of

1*b*-d_x/**3***b*-d_x and **1***c*-d_x/**3***c*-d_x by hydrogenation over PtO_2/HOAc, followed by flash chromatography as described above. Mass spectrometric analysis of each sample provided the overall deuterium content while integration of the ^{2}Hmr spectra gave the proportions of ^{2}H at the individual sites. From these results approximate rate constants for ^{2}H incorporation at each site were determined, as discussed in the text.

RENÉ T. BOERÉ, DAVID E. ESSER, CHRISTOPHER J. WILLIS, DOUGLAS W. STEPHAN, and TARAS W. OBAL. Can. J. Chem. **65**, 798 (1987).

The compound 2-thioanisole-1,1,1,3,3,3-hexafluoro-2-propanol, $CH_3S—C_6H_4—C(CF_3)_2OH$, HL^2, has been prepared, and shown to act (in the ionized form) as a hybrid, chelating, ligand. Neutral bis-complexes $M(L^2)_2$ are formed with Pd^{2+} and Pt^{2+}; the former reacts with $PdCl_4^{2-}$ to give the Cl-bridged dinuclear complex $(L^2)Pd(\mu\text{-}Cl)_2Pd(L^2)$, which may in turn be cleaved by PPh_3 or PPh_2Me to give $PdCl(L^2)(PR_3)$.

A complete structural determination has been made for $PdCl(L^2)(PPh_2Me)$; $C_{23}H_{20}ClF_6OPPdS$. Crystals are monoclinic, space group $P2_1/n$, a = 15.526(5), b = 12.966(9), c = 12.900(8) Å, β = 101.84°, V = 2542(2) Å^3, Z = 4. Least-squares refinement on F of 198 variables using 2801 observations converged at R_1 = 0.0434, R_2 = 0.0559. The complex consists of discrete square-planar molecules with phosphine and alkoxide *trans*-disposed. Bond lengths are Pd—O, 2.053(3); Pd—P, 2.242(1); Pd—Cl, 2.323(2); Pd—S, 2.252(2) Å. In the six-membered chelate ring, all atoms with the exception of Pd are close to coplanarity; there is a dihedral angle of 127.9° between the O—Pd—S plane and that of the aromatic ring.

Multinuclear nmr measurements are used to show that both *cis*- and *trans*-forms of complexes $PdCl(L^2)(PR_3)$ are present in solution, with inversion at coordinated sulfur occurring much more rapidly in the latter.

RENÉ T. BOERÉ, DAVID E. ESSER, CHRISTOPHER J. WILLIS, DOUGLAS W. STEPHAN et TARAS W. OBAL. Can. J. Chem. **65**, 798 (1987).

On a préparé le composé thioanisole-2 hexafluoro-1,1,1,3,3,3 propanol, $CH_3S—C_6H_4—C(CF_3)_2OH$, HL^2 et on a démontré qu'il peut agir (sous la forme ionisée) comme un ligand hybride et chélatant. Avec le Pd^{2+} et le Pt^{2+}, il se forme des bis-complexes neutres $M(L^2)_2$; le premier réagit avec le $PdCl_4^{2-}$ pour donner le complexe dinucléaire ponté par des Cl $[(L^2)Pd(\mu\text{-}Cl)_2Pd(L^2)]$ qui peut être clivé à son tour par le PPh_3 ou le PPh_2Me pour donner le complexe $PdCl(L^2)(PR_3)$.

On a déterminé complètement la structure du composé $PdCl(L^2)(PPh_2Me)$; $C_{23}H_{20}ClF_6OPPdS$. Les cristaux sont monocliniques, groupe d'espace $P2_1/n$, avec a = 15,526(5), b = 12,966(9) et c = 12,900(8) Å et β = 101,84°, V = 2542(2) Å^3 et Z = 4. Un affinement de 198 variables, par la méthode des moindres carrés sur F et utilisant 2801 réflexions, converge à R_1 = 0,0434 et R_2 = 0,0559. Le complexe consiste en des molécules discrètes plan-carré de phosphine et d'alcoolate disposé en *trans*. Les longueurs des liaisons sont: Pd—O, 2,053(2); Pd—P, 2,242(1); Pd—Cl, 2,323(2); Pd—S, 2,252(2) Å. Dans le cycle à 6 chaînons du chélate, tous les atomes, à l'exception du Pd, sont pratiquement coplanaires; l'angle dièdre entre le plan O—Pd—S et celui du cycle aromatique est égal à 127,9°.

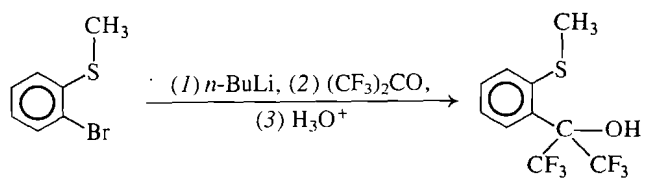
On a fait appel à des mesures rmn multinoyaux pour démontrer que les formes tant *cis* que *trans* des complexes $PdCl(L^2)(PR_3)$ sont présentes en solution et que l'inversion au niveau du soufre coordonné se produit beaucoup plus rapidement dans le dernier.

[Traduit par la revue]

Introduction

We have previously reported the synthesis of some fluorinated alcohols containing a thioether function, $RS—CH_2—C(CF_3)_2—OH$ (**1**), and their use (in the ionized form) as hybrid ligands to form neutral complexes $[M\{RSCH_2C(CF_3)_2O\}_2]$ (M = Pd, Pt; R = Me, Ph) (1) and cationic complexes $[M\{RSCH_2C(CF_3)_2O\}(PPh_3)_2]^+$ (2, 3). Five-membered chelate rings are formed, and the presence of the soft thioether stabilizes the bond from the hard alkoxide group to the soft transition-metal ions. The related diarylphosphino fluoro-alcohol $PPh_2CH_2C(CF_3)_2OH$ behaves similarly (4).

The conformations of the highly-substituted chelate rings in complexes of these ligands show a remarkable consistency, with four atoms (including the metal) coplanar and the fifth significantly out of plane (3, 4). We now report the preparation of a similar hybrid ligand with an aryl backbone, which coordinates through oxygen and sulfur to form six-membered chelate rings. Ligand alcohol **2**, 2-thioanisole-1,1,1,3,3,3-hexafluoro-2-propanol, (abbreviated HL^2) is prepared by the reaction sequence:



2

We have prepared Pd^{2+} and Pt^{2+} complexes of the ionized form of this alcohol and find it to be generally similar to alcohol **1**. However, the use of nmr data in conjunction with a solid-state X-ray structure on the palladium complex $[Pd(L^2)Cl(PPh_2Me)]$ shows that differences in the type and proportions of the isomers observed in solution may be related to the distinctly different chelate ring conformations adopted by **1** and **2**.

Experimental section

General experimental conditions have been described previously (1). New complexes were characterized by elemental analysis (data in Table 1, deposited)[1] and nmr spectra (Table 5, below). *n*-Butyl lithium and *o*-aminothiophenol were commercial samples (Aldrich).

TABLE 2. Summary of crystal and data collection parameters

Molecular formula	$C_{23}H_{20}ClF_6OPPdS$
Formula weight	631.27
Crystal class	Monoclinic
a	15.526(5) Å
b	12.966(9) Å
c	12.900(8) Å
β	101.84°
V	2542(2) Å^3
Z	4
d(calcd.)	1.65 g cm^{-3}
Space group	$P2_1/n$
Diffractometer	Syntex $P2_1$, four-circle
Radiation	Mo Kα, graphite monochromatized, λ = 0.71069 Å
Data collected	2θ of 4.5–45° ($\pm h$, $+k$, $+l$)
Temperature	24°C
θ Range	$4.5 \leq 2\theta \leq 45°$
Scan speed	2.0–5.0 deg min^{-1} (θ/2θ scan)
Scan range	1.0° below $K\alpha_1$; 1.1° above $K\alpha_2$
Crystal dimensions	0.35 × 0.37 × 0.44 mm
μ	9.35 cm^{-1}
Reflections collected	3689
No. unique data where $F_o > 3\sigma(F_o)$	2801
Variables	198
Final R_1[a]	0.0434
Final weighted R_2[b]	0.0559

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.
[b] $R_2 = \{\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2\}^{1/2}$.

Ligand synthesis

o-Bromothioanisole (16 g, 0.078 mol, prepared from *o*-aminothiophenol) (6) was dissolved in ether (20 mL) in a 250 mL three-necked flask attached to a vacuum/argon line and equipped with a serum-capped dropping funnel, magnetic stirrer, and serum cap. The solution was cooled to 0°C under ~10 cm Ar pressure and *n*-BuLi (50 mL of 1.55 *M* solution in hexane, 0.078 mol) introduced by syringe into the dropping funnel, then added dropwise over 2 h. Continuous stirring was necessary as the organolithium reagent precipitated. A separate vacuum flask equipped with serum cap was charged with anhydrous ether (50 mL) and hexafluoroacetone (13 g, 0.078 mol; and held at −78°C. The organolithium reagent was transferred in as a slurry using a double-ended stainless steel needle. After stirring 2 h at −78°C, the mixture was poured onto concentrated HCl (100 mL) on ice, extracted with ether, dried ($MgSO_4$), and distilled to yield 2-thioanisole-1,1,1,3,3,3-hexafluoro-2-propanol, HL^2, **2**, 17.5 g (78%), bp 80°C/1 mm, mass spectrum *m/e* 290 (parent ion). Nuclear magnetic resonance ($CDCl_3$ solution): δ(CH_3S) s, 2.45 ppm; δ(aromatic) m, 7.0–7.8 ppm; δ(CF_3) s, −74.96 ppm.

Complex preparation

(*i*) $Pt(L^2)_2$, **3**. K_2PtCl_4 (0.42 g, 1.0 mmol) was dissolved in water and HL^2 (0.58 g, 2.0 mmol) added, followed by KOH (2.0 mmol. In this and subsequent reactions, it was convenient to measure KOH by use of a standardized solution.) After stirring 48 h, solvent was removed by rotary evaporation and the residue extracted with CH_2Cl_2. Recrystallization from $CHCl_3$ gave $Pt(L^2)_2$, **3** (87% yield), colorless, mp 157–159°C.

(*ii*) $Pd(L^2)_2$, **4**. Starting from K_2PdCl_4 ($PdCl_2$ in aqueous KCl), the same route as that used for **3** gave the palladium analog **4**, orange, mp 278–281°C.

(*iii*) $Pd_2Cl_2(L^2)_2$, **5**. Attempts to prepare the Cl-bridged dinuclear complex by direct reaction of ligand with $PdCl_2$ in 1:1 molar ratio lead only to mixtures containing the bis-complex **4**. Successful synthesis was achieved by dissolving **4** in excess acetone, heating to reflux, and adding the stoichiometric amount of $PdCl_2$, dissolved in a minimum volume of aqueous KCl, dropwise under reflux. After reflux 1 h, acetone was removed by distillation until crystallization began, at which point an excess of water was added and the solution cooled to 0°C, when the bridged complex **5** precipitated in essentially quantitative yield; orange crystals from $CHCl_3$, mp 260–262°C.

(*iv*) Cleavage reactions of **5** using PPh_3: Bridged complex **5** (0.10 g, 0.12 mmol) and PPh_3 (0.073 g, 0.28 mmol) were stirred together in toluene (40 mL) at 20°C for 3 h, then slowly heated with stirring until solution was complete. After cooling to 0°C, the greenish-yellow precipitate was filtered off and washed quickly with hexanes, yielding $PdCl(L^2)(PPh_3)$, **6**, mp 190–195°C. Analytical data indicated a small degree of impurity, but attempts at recrystallization led to disproportionation.

Using PPh_2Me, the bridged complex **5** (0.42 g, 0.48 mmol) was dissolved in acetone and PPh_2Me (0.19 g, 0.97 mmol) added at 25°C; an immediate darkening in color was seen. Solvent was removed by rotary evaporation and the residue recrystallized from 60–80 petroleum ether/$CHCl_3$ to give $PdCl(L^2)(PPh_2Me)$, **7**, mp 192°C. Using $PPhMe_2$ in a similar reaction sequence led only to disproportionation reactions and formation of a mixture containing $Pd(L^2)_2$ and $PdCl_2(PPhMe_2)_2$. A similar result was obtained using $AsPh_3$.

Structure determination: X-ray data collection and reduction

Yellow blocks of compound **7**, chloro(2-thioanisole-1,1,1,3,3,3-hexafluoro-2-propoxy)(methyldiphenylphosphine)palladium(II), were obtained by slow evaporation from 60–80 petroleum ether/chloroform and a suitable crystal mounted in a capillary tube. Diffraction experiments were performed with a four-circle Syntex $P2_1$ diffractometer using graphite-monochromatized Mo Kα radiation. The initial orientation matrix was obtained from 15 machine-centered reflections selected from a rotation photograph, and these data used to determine the crystal system. Partial rotation photographs around each axis were consistent with a monoclinic crystal system. A total of 40 high-angle reflections ($15° < 2\theta < 25°$) were used to obtain the final lattice parameters and the orientation matrix. Machine parameters, crystal data, and data collection conditions are summarized in Table 2.

Observed extinctions were consistent with the space group $P2_1/n$, and $\pm h$, $+k$, and $+l$ data were collected in one shell. Three standard reflections were recorded every 197 reflections, and analysis of their intensity showed that no appreciable crystal decomposition occurred during data collection. The data were processed using the SHELX-76 package (7) on the computing facilities at the University of Windsor.

A total of 2801 reflections having $F_o^2 > 3\sigma(F_o^2)$ were used in the refinement. No absorption correction was applied to the data.

Structure solution and refinement

Neutral atom scattering factors were taken from Cromer and Waber (8). The Pd position was determined by the heavy-atom Patterson technique, and the remaining non-hydrogen atoms were located from successive difference-Fourier map calculations. Refinement was carried out by full-matrix least-squares techniques on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where the weight w is defined as $4|F_o|/\sigma^2(F_o^2)$ and F_o and F_c are the observed and calculated structure-factor amplitudes. Refinement with all non-hydrogen atoms assigned isotropic temperature factors gave $R_1 = 8.01\%$. Hydrogen-atom contributions for both methyl and phenyl were included, assuming C—H bond lengths of 0.95 Å, and hydrogen-atom temperature factors were fixed at 1.10× the isotropic temperature factor of the bonded carbon atom.

In the final cycles of full-matrix least-squares refinement, all non-hydrogen and non-carbon atoms were assigned anisotropic temperature factors and hydrogen-atom contributions were included but not refined. Final values of R_1 and R_2 were 4.34% and 5.59%, and maximum shift on any of the parameters in the final cycle was 0.003σ. A final difference-Fourier map showed no peaks of chemical significance, the largest peak being 0.95 eÅ^{-3} associated with the Pd atom.

Final atomic positions of non-hydrogen atoms for compound **7** are given in Table 3.

Anisotropic temperature factors are given in supplementary Table S-I, hydrogen-atom positions and temperature factors in Table S-II, bond angles and distances associated with the phenyl rings and the trifluoromethyl groups in Table S-III, and values of $10|F_o|$ and $10|F_c|$ in Table S-IV.[1]

Structure description

Selected interatomic distances and bond angles for compound **7** are shown in Table 4.

An ORTEP view of the molecule is shown as Fig. 1. (The phenyl ring in the ligand contains carbon atoms 11–16; phenyl rings on phosphorus contain carbon atoms 21–26 and 31–36.) The metal atom is in essentially square-planar coordination, with the two soft ligands, phosphine and thioether, *cis* to each other; we will therefore refer to the overall conformation as *cis*.[2] The bond angles at the metal are close to 90°, except for the S—Pd—O angle within the chelate ring, which is reduced to 83.8(1)°. Five of the atoms in the six-membered chelate ring are close to coplanarity, the exception being the Pd atom. The ring may therefore be described as "hinged" at the O—S axis with a dihedral angle of 127.9° between the plane defined by O—Pd—S and that containing O, C(1), S, and the aromatic ring; the CF_3 groups are disposed on opposite sides of the latter.

The effect of this ring conformation on the geometry at the coordinated sulfur atom is to swing the methyl group away from the phosphine coligand, making the S—Pd—P bond angle 92.3(1)°. In the platinum complexes $[Pt(PR_3)_2\{CH_3SCH_2C(CF_3)_2O\}]^+$, where the five-membered chelate is closer to planarity, the bite angle of the ligand is essentially the same as in **7** but the greater repulsion between the phosphine and S—CH_3 group increases the S—Pt—P angles to 94.6(1)° ($PR_3 = PPh_2Me$) and 97.28(7)° (PPh_3).

[1]Complete set of data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[2]In terms of CIP priority rules, it has the *Z* configuration.

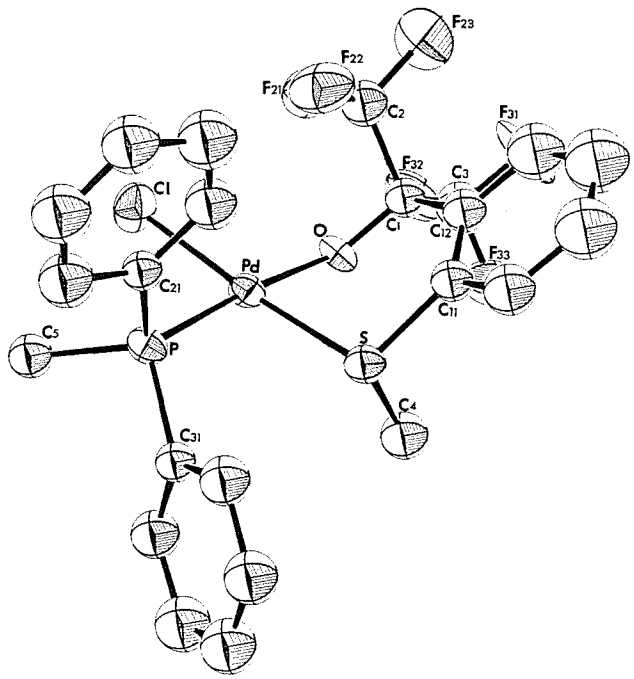

FIG. 1. An ORTEP view of **7**, $\{\overline{OC(CF_3)_2C_6H_4SMe}\}PdCl(PPh_2Me)$.

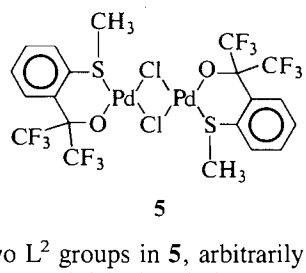
Results and discussion

Synthesis of complexes

The synthesis of ligand **2** proceeded smoothly, in accordance with our previous experience with compounds of this type. Neutral bis-complexes $M(L^2)_2$ were readily prepared with M = Pt^{2+} (**3**) or Pd^{2+} (**4**), but could not be isolated with Ni^{2+} or Co^{2+}; this also is consistent with precedent, since the hybrid ligands **1**, containing the same donor set, preferentially complex with the softer transitional-metal ions. In order to extend the range of complexes of **2** available for study, we then prepared the chloro-bridged dinuclear palladium complex **5** by the reaction of **4** with $PdCl_4^{2-}$ in acetone, an established route in palladium chemistry (10).

$$Pd(L^2)_2 + PdCl_2 \xrightarrow[H_2O/Me_2CO]{KCl}$$



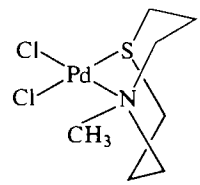
5

(The relative orientation of the two L^2 groups in **5**, arbitrarily shown as *trans* above, has not been established.) Limited success was achieved in preparing other palladium complexes by cleavage of **5** with other ligands. With tertiary phosphines, PPh_3 gave *cis*-$PdCl(L^2)(PPh_3)$, **6**, and PPh_2Me gave *cis*-$PdCl(L^2)$-(PPh_2Me), **7**. However, disproportionation generally accompanied recrystallization. Using $PPhMe_2$, disproportionation to $(PPhMe_2)_2PdCl_2$ and $Pd(L^2)_2$ was rapid, and $AsPh_3$ behaved similarly. Use of thioethers in cleavage reactions also led to disproportionation.

These results are essentially parallel to those reported a number of years ago by Livingstone for Pd^{2+} complexes of *o*-methylthiobenzoic acid, HL^3. This ligand forms bis-complexes $Pd(L^3)_2$ in a single geometric isomer (11, 12) and halo-bridged complexes $(L^3)Pd((\mu\text{-}X)_2Pd(L^3)$ (X = Cl, Br) (10, 12). Mixed-ligand complexes could not be isolated in the solid state, the product being $M(L^3)_2$ (10) and disproportionation was assumed to be rapid.

The structure of **7** (Fig. 1) shows the metal to be in square-planar coordination with the two soft ligands, phosphine and thioether, in *cis*-conformation. Metal–ligand bond lengths are within normal limits, with the mutually *trans* Pd—P and Pd—O bonds having the values 2.242(1) and 2.053(3) Å, respectively. A very similar situation is found in the perfluoropinacolato complex $(PEt_3)_2Pd(PFP)$ (14), where the respective bond lengths to Pd from phosphine and *trans* fluorinated alkoxide are 2.237 and 2.043 Å.[3] The C—O bond in the six-membered chelate ring in **7** is 1.359(7) Å, within the range of 1.34(1) (16), 1.341 and 1.388 Å (14), and 1.365(3) Å (17) found where a fluorinated alkoxide is chelated to Pd in five-membered rings, and in accord with the usual trend toward short C—O linkages in metal alkoxides.

The conformation adopted by the ligand may be compared with that observed in the $PdCl_2$ complex of the endocyclic thioether 5-methyl-1-thia-5-azacyclooctane (TACO) (18):



The geometry at sulfur and nitrogen in this complex is essentially identical to that in **7**, with the non-bonding pair on sulfur lying close to the coordination plane and bent in toward the metal in each, as is the *N*-methyl substituent in the TACO complex. A further consequence for **7** is that one of the CF_3 groups is directed toward the chloride coordination site, which it might be said to overhang.

Solution structures: nuclear magnetic resonance studies

The ^1H, ^{19}F, and ^{31}P nmr data for complexes **3–7** are shown in Table 5. We have previously demonstrated the power of using a combination of ^1H and ^{19}F data in identifying the constituents of isomeric mixtures of fluorinated alkoxides (2), and the same approach is used here.

For the ML_2 complexes **3** and **4**, *cis* and *trans* isomers are possible, and with slow inversion at the pyramidal coordinated sulfur, each of these may exist in solution as "*syn*" or "*anti*" diastereomers with respect to the disposition of the two CH_3—S substituents about the coordination plane of the metal (15). Interestingly, the proton spectra of $Pt(L^2)_2$, **3**, show that the product first isolated is a mixture of two isomeric species, **3***a* and **3***b*, which do not interconvert in solution. Fractional crystallization gives pure **3***a*. The equivalence of the ^{195}Pt coupling constants and the similarity in chemical shift of the two isomers agree with their being *syn* and *anti* forms of the *same* geometrical isomer, a situation we found for the analogous complex $[Pt\{CH_3SCH_2C(CF_3)_2O\}_2]$ (1). However, while in the latter case thioether inversion re-establishes an equilibrium population of diastereomers when the complex is redissolved, inversion for $[Pt(L^2)_2]$ is a higher-energy process, and equilibrium is not established after several days in solution at ambient temperature in the nmr tube. We attribute this lack of dynamic equilibration to the greater rigidity and steric bulk of the aromatic ligand, discussed below.

Each of the Pd^{2+} complexes of L^2, **4** and **5**, shows only a

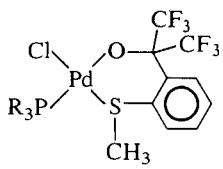
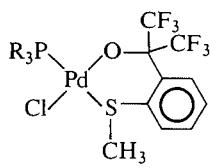
single species in solution at all times, and the CF_3 groups show only a single ^{19}F resonance. Equivalence of CF_3 groups on the nmr time-scale may occur through rapid thioether inversion, but this is unlikely because of the observed rigidity of the Pt^{2+} complex. More probable with this sterically crowded complex is a mechanism involving dissociation of the Pd—S bond. In strong contrast, the Pd^{2+} complexes of the more flexible ligand **1** show complex isomerism and inversion behaviour in solution (1, 2).

The mixed-ligand complexes **6** and **7** can exist as two geometric isomers, which we will designate as *cis* and *trans* with respect to the two soft ligands, CH_3—S and R_3P:



cis



trans

Since only one pyramidal sulfur atom is found in each complex, diastereomerism does not occur, but slow inversion at coordinated sulfur could lead to inequivalent CF_3 signals (9). In $CDCl_3$ solution, nmr signals attributable to the two geometric isomers are in fact observed for both **6** and **7**. The major species, comprising ~95% for **6** and ~80% for **7**, has a CH_3—S signal at 2.54 ppm split by about 1 Hz through coupling to ^{31}P. Selective decoupling of the major ^{31}P signal in each case collapses this doublet, as well as that due to the CH_3—P in the PPh_2Me complex **7**. The ^{19}F nmr spectrum shows inequivalent CF_3 groups, with the typical doublet-of-quartet pattern we have observed in such complexes with slow or stopped thioether inversion. The minor species in **6** and **7** have CH_3—S resonances at significantly lower field (2.83 ppm), with much larger coupling to ^{31}P. Selective decoupling of the minor ^{31}P signals again confirmed the coupling in these species. Their ^{19}F signals consist of a sharp singlet in **7** and a singlet (overlapping the signal from the major species) in **7**, indicating that the CF_3 groups are dynamically equivalent through rapid inversion at coordinated sulfur. We have previously demonstrated (2) that such spectral parameters are consistent with the major components of **6** and **7** in solution being the *cis*-isomers, the minor the *trans*-isomers. In particular, the lower barrier to inversion with R_3P, rather than Cl^-, *trans* to the thioether confirms this assignment.

We note again that, for the *cis*-isomer, anisotropic ring-current effects from the phenyl substituents on the adjacent phosphine cause an upfield shift in δ(CH_3—S) (2, 5). However, the proportions of the two isomers differ dramatically from those found for the complex $PdCl\{CH_3SCH_2C(CF_3)_2O\}(PPh_3)$, for which the *trans*-isomer predominates in $CDCl_3$ solution (2), and this may be attributed to the differing ring conformations in the two hybrid ligands. In the solid state, $PdCl(L^2)(PPh_2Me)$, **7**, has the *cis*-geometry corresponding to the major solution species. The unusual conformation adopted by the ligand (Fig. 1) causes the site *trans* to the thioether to be sterically crowded by an overhanging CF_3 group, and this may account for the predominance of the *cis*-isomers in both **6** and **7**.

An additional, surprising, point of difference is that the nmr spectra of **6** and **7** show the proportions of the isomers to be invariant with temperature and the nature of the solvent, whereas with the compound $PdCl\{CH_3SCH_2C(CF_3)_2O\}(PPh_3)$ the proportions of the isomers present are very sensitive to changes in temperature or solvent. It appears that the *cis*- and *trans*-forms of **6** and **7** are generated in the initial cleavage reactions of **5**, but are not sufficiently labile to undergo subsequent equilibration in solution. Their relative proportions are therefore fixed by kinetic, rather than thermodynamic, factors, and the isolation of pure crystals of *cis*-**7** for the structural determination is the result of an adventitious fractionation during recrystallization to give the major component of the mixture.

Received July 25, 1986

RAJ K. CHADHA, PETER C. HAYES, HASSAN E. MABROUK, and DENNIS G. TUCK. Can. J. Chem. **65**, 804 (1987).

$In(SPh)_3$ is readily prepared by the reaction of $InCl_3$ and NaSPh in methanol. The compound is a Lewis acid, forming 1:1 adducts with 2,2′-bipyridine, 1,10-phenanthroline, *N,N,N′,N′*-tetramethylethanediamine, bis(diphenylphosphino)ethane, and dimethylsulphoxide, and 1:2 adducts with pyridine, trimethylamine, and triphenylphosphine. Reaction with R_4NX (X = Cl, Br, I) or similar salts gives $R_4N[XIn(SPh)_3]$ salts, which are 1:1 electrolytes. The structure of $Ph_4P[BrIn(SPh)_3]$ has been determined by X-ray methods. The crystals are monoclinic, space group $P2_1/c$, with cell dimensions a = 9.964(3) Å, b = 13.477(3) Å, c = 30.359(7) Å, α = 98.30(2)°, Z = 4, R = 0.0622 for 2924 unique observed reflections. The anion has distorted tetrahedral symmetry in the $InBrS_3$ kernel, with In—Br = 2.527(2) Å, and In—S(av) = 2.450 Å. The vibrational spectra of $In(SPh)_3$ and its derivatives in the region 500–200 cm^{-1} are discussed.

RAJ K. CHADHA, PETER C. HAYES, HASSAN E. MABROUK et DENNIS G. TUCK. Can. J. Chem. **65**, 804 (1987).

On prépare facilement le composé $In(SPh)_3$ en faisant réagir le $InCl_3$ et le NaSPh dans le méthanol. Le composé est un acide de Lewis qui forme des adduits 1:1 avec la bipyridine-2,2′, la phénanthroline-1,10, la *N,N,N′,N′*-tétraméthyléthanediamine, le bis(diphénylphosphino)éthane et le diméthylsulfoxyde et qui forme des adduits 1:2 avec la pyridine, la triméthylamine et la triphénylphosphine. Sa réaction avec les composés R_4NX (X = Cl, Br ou I) ou des sels semblables conduit à des sels du type $R_4N[XIn(SPh)_3]$ qui sont des électrolytes 1:1. On a déterminé la structure du $Ph_4P[BrIn(SPh)_3]$ par diffraction des rayons-X. Les cristaux sont monocliniques, groupe d'espace $P2_1/c$, avec a = 9,964(3), b = 13,477(3) et c = 30,359(7) Å et α = 98,30(2)°, Z = 4 et R = 0,0622 pour 2924 réflexions uniques qui ont été observées. L'anion possède une symétrie tétraédrique déformée au niveau du noyau $InBrS_3$ et on a déterminé les distances In—Br = 2,527(2) et In—S(moyenne) = 2,450 Å. On discute des spectres vibrationnels du $In(SPh)_3$ et de ses dérivés dans la région de 500 à 200 cm^{-1}.

Introduction

The alkyl and arylthiolato derivatives of the Main Group metals have not been studied as extensively as have those of the transition elements, but there is nevertheless a significant literature on these compounds. The chemistry of $Sn(SR)_4$ and $R_nSn(SR')_{4-n}$, of tin(II) thiolates, and of the corresponding lead compounds, has been reviewed (1–4). The complexes formed with organomercury cations have also been investigated especially in terms of their solution chemistry (5–8). There is an absence of information on the complexes of gallium, indium, and thallium, although here, as with the other elements mentioned above, dithiolato complexes have been thoroughly studied. We have now investigated the preparation and properties of $In(SPh)_3$, which is a Lewis acid, giving rise to adducts with both neutral and anionic ligands. The crystal structure of the salt of one of these derivatives, $Ph_4P[BrIn(SPh)_3]$, has been determined by X-ray crystallography and the results are compared with those of related compounds.

Experimental section

General

All solvents were distilled and stored over appropriate drying agents. Benzenethiol and neutral ligands were used as supplied; tetraalkyl ammonium and other halides were dried at 110°C before use.

Indium analysis was by atomic absorption spectrophotometry, and halide analysis by Volhard titration. Microanalysis was by Guelph Chemical Laboratories Ltd. Spectroscopic methods were those described in previous papers (9).

Indium trichloride was prepared by passing a stream of chlorine gas and nitrogen over heated metal.

Preparation of $In(SPh)_3$

A solution of NaSPh (7.1 g, 54 mmol) in 50 mL methanol was added dropwise over 1 h to a refluxing solution of $InCl_3$ (4.00 g, 18 mmol) in 50 mL of the same solvent. A white solid, subsequently identified as NaCl, precipitated. Refluxing was continued for a further 2 h, and the solution allowed to cool to room temperature, during which time more NaCl precipitated. After filtration, the filtrate was taken to dryness *in vacuo* to yield a colourless oil which was dissolved in 50 mL hot benzene leaving a white residue. A white solid deposited when the benzene extract cooled, and was re-crystallized from *n*-pentane as a white powder (yield 4.8 g, 10.8 mmol, 60% based on $InCl_3$). *Anal.* calcd. C 48.9, H 3.4, S 21.7, In 26.0; found: C 47.8, H 3.6, S 20.5, In 26.3. The ^1H nmr spectrum (d_6-dimethylsulphoxide) showed a multiplet in the aromatic region (6.8–7.4 ppm from Me_4Si; cf. a much sharper multiplet at 7.0 ppm for PhSH in the same solvent, and the absence of RS*H* at 3.3 ppm. The strongest peak in the field-desorption mass spectrum is a manifold at m/e = 441–445, with the strongest peak at 442 corresponding to $^{115}In(SPh)_3$. Other ions of significance were at m/e = 333 ($In(SPh)_2^+$), 218 ($Ph_2S_2^+$), 109 (PhS^+), and 130 + 131 (not identified).

Tris(benzenethiolato)indium(III) is an air-stable white solid, mp 240–245°C, soluble in dimethylsulphoxide, pyridine, or methanol at room temperature, and in refluxing benzene, slightly soluble in acetonitrile or methylene dichloride, but insoluble in diethyl ether, petroleum ether, nitromethane, hexane, or cold benzene. A number of attempts were made to obtain crystals from various solvent mixtures, but without success. Sublimation *in vacuo* onto a cold finger gave a powder which analysed as $In(SPh)_3$.

Neutral adducts of $In(SPh)_3$

A series of adducts involving various neutral donors was prepared by a standard method exemplified by the case of 2,2′-bipyridine (bpy). When 0.18 g of bpy (1.15 mmol) was added to a stirred solution of $In(SPh)_3$ (0.5 g, 1.13 mmol) in methanol (30 mL), the solution became green. After further stirring for 4 h under dry nitrogen, the solution was filtered and the filtrate taken to dryness *in vacuo*. The residue was a yellow–green oil, which was triturated with diethyl ether to give a yellow solid which was washed twice with diethyl ether and then with benzene. Analysis (see Table 1) and nmr spectra

[b]Abbreviations, etc., as in Table 1.

showed that this solid is $In(SPh)_3 \cdot bpy$ (yield 0.6 g, 1.00 mmol, 89% yield).

Similar methods gave 1:1 adducts of $In(SPh)_3$ with 1,10-phenanthroline (phen) *N,N,N′,N′*-tetramethylethanediamine (tmen) and bis-(diphenylphosphino)ethane (dppe), and 1:2 adducts with pyridine, triethylamine, and triphenylphosphine. With dimethylsulphoxide in three-fold excess the product was $In(SPh)_3 \cdot dmso$. Analytical and nmr results are given in Table 1; infrared spectroscopy confirmed the presence of the neutral ligand in each case.

Anionic complexes

(*i*) $[XIn(SPh)_3]^-$ (X = Cl, Br, I). In a typical experiment, Ph_4PBr (0.20 g, 0.48 mmol) in methanol was added to a solution of $In(SPh)_3$ (0.21 g, 0.48 mmol) in the same solvent. A colourless precipitate immediately formed, and was collected, washed twice with methanol, and dried *in vacuo* (yield 0.34 g of $Ph_4P[BrIn(SPh)_3]$, 0.39 mmol, 82%). This material was recrystallized from either methanol/chloroform or diethyl ether/chloroform by slow evaporation of solvent to give well-formed colourless crystals which were dried *in vacuo*. Analytical and nmr results for this salt, and for other $[XIn(SPh)_3]^-$ salts prepared by similar methods, are given in Table 2.

(*ii*) $[In(SPh)_4]^-$. A solution of NaSPh (0.12 g, 0.90 mmol) in methanol (20 mL) was added dropwise over 30 min to a solution of $In(SPh)_3$ (0.40 g, 0.9 mmol) in benzene (50 mL). The resultant suspension was refluxed for 24 h and then filtered; the pale yellow filtrate was taken to dryness *in vacuo* to yield a yellow solid which was washed with benzene and dried *in vacuo*. This material, identified as $Na[In(SPh)_4]$, is soluble in hot methanol, and a solution of 0.50 g (0.88 mmol) and Et_4NCl (0.14 g, 0.88 mmol) in boiling methanol (50 mL) was stirred for 4 h, after which the precipitated NaCl was removed by filtration. Evaporation of the filtrate gave a white solid which was washed with benzene and dried *in vacuo*; this product is $Et_4N[In(SPh)_4]$.

Crystallographic analysis

A suitable crystal of $Ph_4P[BrIn(SPh)_3]$ (1), prepared by the method described above, was sealed in a capillary tube and mounted along the largest dimension in a Syntex $P2_1$ diffractometer. The cell dimensions (Table 3) were obtained from the least-squares refinement of the setting angles of 15 high angle reflections ($15° < 2\theta < 30°$). The density was determined by flotation in CCl_4/benzene mixtures.

Relevant information on the X-ray crystallographic experiment is given in Table 3. The intensities of three monitor reflections did not change significantly during the data collection. The results were corrected for Lorentz and polarization effects, and analytical absorption corrections were applied by the use of ABSORB. Details of the collection and reduction of the experimental data, and the sources of the scattering factors and computer programmes used have been described previously (10).

The systematic absences $h0l$ ($l = 2n + 1$) and $0k0$ ($k = 2n + 1$) identify the space group $P2_1/c$ unambiguously. The position of the indium atom was determined by a sharpened Patterson synthesis using SHELX, and the remaining atoms were revealed by subsequent difference maps. The structure was refined by blocked-matrix least-squares methods using 163 parameters in one block, and 169 in the other. The indium and bromine atoms were common to the two blocks, one of which contained P, the three S atoms, twelve C atoms, and a scale factor, and the other contained the remaining C atoms and a scale factor. The carbon atoms of the Ph_4P^+ cation were refined isotropically, and the remainder anisotropically. Hydrogen atoms were included in the final refinements in ideal positions (C—H = 0.95 Å, CCH = 120°), with isotropic U values set at 0.1 $Å^2$ greater than those found for the corresponding carbon atoms in the first refinement cycles. The refinement converged at $R = 0.0622$, and $R_w = 0.0628$. The function minimized in the initial least squares refinement was $(|F_o| - |F_c|)^2$; a weighting scheme of the form $w = 1/[\sigma^2(F) + \rho F^2]$

TABLE 3. Summary of crystal data, intensity collection, and structural refinement for $[(C_6H_5)_4P][BrIn(SC_6H_5)_3]$

Cell constants (a, b, c, α)	9.964(3), 13.477(3), 30.359(7) Å, 98.30(2)°
Cell volume (Å^3)	4034(2)
Crystal system	Monoclinic
Space group	$P2_1/c$
Molecular weight	860.7
Z	4
ρ_c, ρ_o (g cm^{-3})	1.42, 1.44
Crystal dimension (mm)	0.13 × 0.22 × 0.60
Absorption coefficient, μ(cm^{-1})	17.03
Minimum absorption correction	1.013
Maximum absorption correction	1.023
Radiation	MoKα, λ = 0.71069 Å
Monochromator	Highly oriented graphite
T (°C)	21 ± 1
2θ angle (°)	4–50
Scan type	Coupled θ (crystal)/2θ (counter)
Scan width	K_{α_1} − 1° to K_{α_2} + 1°
Scan speed (°min^{-1})	Variable, 2.02–4.88
Background time/scan time	0.5
Total reflections measured	8300 ($+h$, $+k$, $\pm l$)
Unique data used	2924 [$I > 3\sigma(I)$]
Number of parameters (NP)	163, 169
$R = (\Sigma\|\|F_o\| - \|F_c\|\|/\Sigma\|F_o\|)$	0.0622
$R_w = [\Sigma\omega(\|F_o\| - \|F_c\|)^2/\Sigma\omega\|F_o\|^2]^{1/2}$	0.0628
$\Delta\rho_{max}$(e Å^{-3})	0.6
Shift:error (max)	0.3

was used, with a final p-value of 0.0001, in calculating R_w. No evidence of secondary extinction was found.

The final coordinates for the non-hydrogen atoms are given in Table 4, and important bond distances and angles in Table 5. Tables of fractional coordinates and thermal parameters for hydrogen atoms, of anisotropic thermal parameters, and of observed and calculated structure factors have been deposited, as has a packing diagram of the unit cell.[1]

Results and discussion

Tris(benzenethiolato)indium(III)

The preparation of $In(SPh)_3$ follows a conventional route and calls for no comment. The compound is clearly a Lewis acid, forming derivatives with both monodentate and bidentate donor ligands, and with halide anions. The structure of $In(SPh)_3$ could not be determined by X-ray methods, since it proved impossible to obtain crystals, but by analogy with other indium(III) compounds with sulphur ligands, it is probable that there is an InS_3 planar kernel which then leads to cross-linking through In---S′ interactions to give InS_3S_2', where S′ is a sulphur atom on a neighbouring $In(SPh)_3$ unit. This type of interaction has been invoked to explain the behaviour of indium(III) complexes with bidentate sulphur donor ligands (11–13), where the parent molecule shows evidence of cross-linking which is broken down by the formation of adducts, and is a consequence of the tendency of indium(III) to expand its coordination number from three to four, five, or six with relatively small donor atoms such as oxygen or sulphur (14).

The neutral donors derived from $In(SPh)_3$ are, with one exception, of the type InS_3N_2 or InS_3P_2, and these are reasonably formulated as mononuclear five-coordinate species. An obvious analogue for the Ph_3P adduct is $InCl_3 \cdot 2Ph_3P$, which has been shown to have D_{3h} stereochemistry (15). The exception is $In(SPh)_3 \cdot$dmso, which is the only adduct we have been able to prepare with an oxygen donor. There are a number of possible structures for this compound, and it does not seem reasonable to opt for any one of these on the present evidence.

The salts of $[XIn(SPh)_3]^-$ are 1:1 electrolytes in various solvents, as shown by the conductivities (16) (see Table 6), and the anions are readily formulated as having InS_3X kernels. This has been confirmed by X-ray methods for $Ph_4P[BrIn(SPh)_3]$ (see below). The anion $[In(SPh)_4]^-$ presumably has a tetrahedral InS_4 core, being isoelectronic with $Sn(SPh)_4$, and may well also be a Lewis acid. This mode of four-coordination has already been reported for anionic complexes of indium with the bidentate dithiolate ligands 1,2-dicyanoethylene-1,2-dithiolato (= MNT^{2-}) and toluene-3,4-dithiolate (17).

Structure of $Ph_4P[BrIn(SPh)_3]$

Figure 1 shows the structure of both cationic and anionic units. The cation has the conventional distorted tetrahedral stereochemistry at phosphorus, with bond lengths and angles within the normal range for such molecules.

The anion also has pseudo-tetrahedral symmetry in the $InBrS_3$ kernel, with the sum of the bond angles being 656.3° (average 109.4°). The In—Br bond length of 2.572(2) Å is greater than that (18) of 2.479(3) Å in $InBr_4^-$, but less than the values (19) of 2.644(3) and 2.635(2) Å in $Me_2InBr_2^-$ (C_{2v} symmetry) or in the five-coordinate (20) $EtInBr_2 \cdot$tmen (2.531(2), 2.688(2) Å). Given the effect of both coordination number and neighbouring ligands, it is not possible to discuss these values in any detail. The three In—S bonds in $[BrIn(SPh)_3]^-$ give an average value of 2.450 Å, with one bond apparently longer at 2.470(4) Å than the other two. No other monodentate In—SR systems appear to have been studied, but results are available for a number of six-coordinate complexes involving bidentate

*Esd's on mean values have been calculated with the use of the scatter formula

$$\sigma = [\Sigma(d_i - \bar{d})^2/(N-1)]^{1/2}$$

where d_i is the ith and $\bar{d}$ the mean of N equal measurements.

dithio ligands. In the anion (21) $[In(MNT)_3]^{3-}$, the average In—S distance is 2.604 Å, within a range of 2.626(8)–2.585(8) Å, while in $In(S_2COEt)_3$ the corresponding values are 2.622(1) and 2.574(1) Å, distances which are comparable to those in other 1,1-dithiolate derivatives (22). The values for $In[S_2P(OEt)_2]_3$ are in the range (23) 2.59(11)–2.633(9) Å, and those for $In[S_2C{=}N(CH_2)_5]_3$ cluster closely around an average (24) of 2.588 Å. All of these results then give longer In—S bonds than those now reported, but any detailed comparison is obviously placed in question by the differences in both coordination number and ligand type. This caveat is strengthened by more recent results (25) for the compound In(dithizonate)$_3$, in which the local geometry at the metal is trigonal bipyramidal, with two bidentate and one monodentate ligand giving a InS_2N_2S' kernel. In this compound the In—S bond lengths are 2.477(3), 2.467(3), and 2.468(3), close to the distances found in the present work.

Structural parameters have also been reported (26) for $Sn(SPh)_4bpy$, in which the Sn^{IV}—S bond distances are 2.497(1)–2.502(1) Å, but again changes in coordination number apparently affect the bond length since in species with SnC_3S kernels, values of 2.420(8) Å and 2.44(2) Å have been reported for compounds with arylthiolate ligands (27). The general conclusion is that the present In—S bond distances are clearly compatible with those in other In^{III}—S compounds and in Sn^{IV}—S (and Cd^{II}—S) (28) structures, although no exactly comparable set of results is available.

The remaining structural features reported in Table 5 are very similar to those found in other benzenethiolate derivatives, and call for no discussion.

Vibrational spectroscopy

As noted above, we recorded the infrared spectrum of all products over the range 3500–600 cm^{-1} in order to establish

TABLE 6. Conductivity results for salts of $[XIn(SPh)_3]^-$ and $[In(SPh)_4]^-$

Salt	Solvent	Molar conductivity/ohm^{-1} cm^2
$Et_4N[ClIn(SPh)_3]$	CH_3OH	92
$Et_4N[BrIn(SPh)_3]$	dmso	56
$Et_4N[IIn(SPh)_3]$	CH_3OH	102
$Ph_4P[BrIn(SPh)_3]$	CH_3CN	147
$Ph_4As[ClIn(SPh)_3]$	CH_3CN	142
$Et_4N[In(SPh)_4]$	CH_3OH	97

[a]Standard ranges for 1:1 electrolytes in these solvents are CH_3OH 80–115, CH_3CN 120–160, dmso 50–70 ohm^{-1} cm^2 (cf. ref. 16).

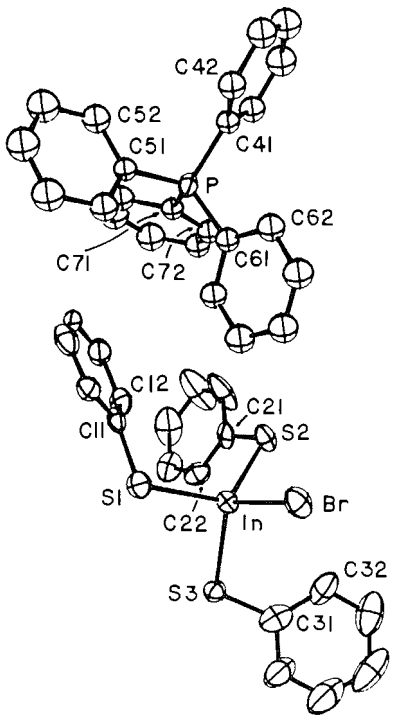

FIG. 1. Structure of cationic and anionic units in $Ph_4P[BrIn(SPh)_3]$.

the presence of the appropriate ligand, cation, etc. These results call for no comment, but the infrared and Raman spectra over the range 600–100 cm^{-1} do contain significant information. For the compound $In(SPh)_3$ there are only two bands in the infrared spectrum, at 332 m and 150 m, br, other than those readily identified as arising from vibrations of the SPh group. The Raman spectrum also shows features arising from the ligand together with emissions at 330 m and 317 s; no features could be identified below approximately 180 cm^{-1} due to the high background scatter in this region. We assign the vibrations in the 300–350 cm^{-1} region to ν_{as} (330) and ν_s (317) of In—$(SPh)_3$, with the lower frequency infrared band tentatively identified as a bending mode. The values for the stretching modes are in good agreement with earlier studies of indium complexes with —SR ligands (17, 29). These results do not permit any vigorous analysis in terms of local symmetry at the indium atom.

The vibrational spectra of the adducts of $In(SPh)_3$ with neutral ligands are too complex for analysis, but the situation is more favorable for the $[XIn(SPh)_3]^-$ anions. The relevant values are shown in Table 7, with assignments which are again in agreement with the results for $In(SPh)_3$, and with the earlier work noted above. The interpretation of the far infrared and Raman spectrum of $Ph_4As[ClIn(SPh)_3]$ and $Ph_4P[BrIn(SPh)_3]$ is hindered by the presence of cation bands, but we again observe ν(In—Cl) at 286(ir), 287(R) cm^{-1}, and ν(In—Br) at 198(ir), 200(R) cm^{-1}. In general, the vibrational spectra confirm the isostructural relationships between the anions of these salts.

N. P. RAO and RONALD E. VERRALL. Can. J. Chem. **65**, 810 (1987).

Ultrasonic velocity and density data of binary systems of water–2-butoxyethanol (BE), 2-butoxyethanol–benzene, and 2-butoxyethanol–decane are reported for temperatures of 25, 40, and 55°C. Adiabatic compressibility coefficients, apparent molar volumes, and apparent molar compressibilities were calculated from these data. Excess adiabatic compressibility properties were evaluated using volume fraction weighting of the individual component properties to estimate ideal mixture behavior. These results are compared with the data obtained based on the use of mole fraction weighting of the individual component properties for the ideal behavior value. A sharp ultrasonic velocity maximum and compressibility minimum is observed at low BE concentration in mixtures of water–BE at all temperatures. These maxima in ultrasonic velocity and minima in adiabatic compressibility are attributed to the formation of "clathrate-like" structures of water and alcohol. A shift of the velocity maximum towards lower concentrations of BE was observed with increase of temperature. A minimum in the ultrasonic velocity and a maximum in adiabatic compressibility coefficient values are observed in systems of BE–benzene and BE–decane. These results are discussed in terms of the breakdown of associated alcohol structures and the interstitial location of hydrocarbon molecules in alcohol aggregates.

N. P. RAO et RONALD E. VERRALL. Can. J. Chem. **65**, 810 (1987).

Opérant à des températures de 25, 40 et 55°C, on a mesuré les vitesses ultrasoniques et les densités des systèmes binaires eau/butoxy-2 éthanol (BE), butoxy-2 éthanol/benzène et butoxy-2 éthanol/décane. A partir de ces données, on a calculé les coefficients de compressibilité adiabatique, les volumes molaires apparents et les compressibilités molaires apparentes. Utilisant les poids relatifs des fractions du volume des propriétés des composantes individuelles pour évaluer le comportement du mélange idéal, on a évalué les propriétés de compressibilité adiabatique en excès. On compare ces résultats avec les données obtenues en se basant sur l'usage des poids relatifs des fractions molaires des propriétés des composantes individuelles pour évaluer le comportement du mélange idéal. A toutes les températures, on observe un maximum important de la vitesse ultrasonique et une compressibilité minimale à des faibles concentrations de BE dans les mélanges eau/BE. On attribue ces maxima dans la vitesse ultrasonique et ces minima dans la compressibilité adiabatique à la formation de structures de l'eau et de l'éthanol "ressemblant à des chlathrates". Lorsqu'on augmente la température, on observe un déplacement du maximum de la vitesse vers les concentrations plus basses de BE. Dans les systèmes BE/benzène et BE/décane, on observe un minimum dans la vitesse ultrasonique et un maximum dans les valeurs des coefficients de compressibilité adiabatique. On discute de ces résultats en fonction d'un bris des structures associées de l'alcool et de la position des molécules interstitielles d'hydrocarbures dans les agrégats d'alcool.

[Traduit par la revue]

Introduction

It has been shown that microphase structures occur in mixtures of water, alcohol, and oil (1–3). Water and alcohol mixtures themselves show unique minima and maxima in their thermodynamic properties at low alcohol concentrations (4–10). The formation of "clathrate-like" structures is believed to be the cause of these unusual properties in the case of alcohols having alkyl groups with 3- or 4-carbon atoms. The formation of such structures also are apparent in mixtures of water and other organic solvents (11–18). It has been observed that the addition of a hydrocarbon component changes the "clathrate-like" structures of the binary water–alcohol systems and gives rise to stable microphase structures (1–3). For example, surfactants have been found to have a large stabilizing effect on these microphase structures and they give rise to the formation of microemulsions and emulsions of relatively larger size (19). However, the formation and stability of these large aggregates are not well understood. A systematic study of these systems using ultrasonic techniques has been undertaken in our laboratory. Improved instrumentation for the measurement of ultrasonic velocity and density properties enables the accurate determination of adiabatic compressibility coefficients which can be used to provide qualitative information about the physical nature of the aggregates occurring in the liquid phase. As a preliminary step in this work, binary systems of water (W) – 2-butoxyethanol (BE), BE–benzene (BNZ), and BE–decane (DEC) have been investigated. Because of the unique miscibility behavior of BE and water at temperatures below 49°C, BE was used as the alcoholic component.

Excess adiabatic compressibility coefficients, ($\Delta\beta$), which are a measure of deviations from ideal solution behavior of a mixture, were evaluated by considering ideal solution behavior values based on both mole fraction and volume fraction weighted averaging of the individual component properties. However, closer examination of the physical nature of compressibilities suggests that, while many thermodynamic and physical properties of ideal solutions are represented by the mole fraction weighted averages of component properties, it is more appropriate to use volume fraction weighted averages of compressibility coefficients of pure solution components to estimate ideal behavior of this property (20–24). Large differences occur between the values of excess compressibility coefficients estimated by these two methods, especially when the molar volumes of the individual component differ considerably. Under these circumstances it would appear useful to consider correlating the excess ultrasonic velocity and compressibility properties as a function of volume fraction.

Apparent molar volumes and apparent molar adiabatic com-

pressibilities also have been calculated from density and ultrasonic velocity measurements over the complete composition range of these binary systems. These quantities are very sensitive to interactions between solute and solvent and to changes induced in the solvent by the solute as the concentration of the latter tends to zero. Trends in these properties with changes in temperature and composition can also offer some qualitative assessment of solution behavior in the intermediate composition range. A comparison of these properties for the three binary systems studied is presented and discussed.

Experimental section

Density measurements

The solution densities were measured with a SODEV flow digital densimeter Model 02D. This instrument, described by Picker *et al.* (25), is capable of measuring densities with an accuracy of 1 part in 10^6 g cm^{-3}. The densimeter was thermostated to ±0.001°C using a SODEV (Model-CT-C) temperature controller.

Ultrasonic velocity measurements

The ultrasonic velocities were measured at 4 MHz using a NUSONIC (Mapco, Model 6080) velocimeter based on the sing-around technique (26). The sample container is an insulated double-walled glass cell. The sample temperature was maintained to within ±0.001°C by circulating water from a SODEV (Model CT-L) temperature controller through the thermostating chamber of the cell. The ultrasonic velocities, u, in units of m s^{-1} are obtained from the average round-trip period of the ultrasonic wave in the fixed path length between the piezoelectric transducer and reflector. The period is expressed as a frequency, f, and the following relation is used to calculate u

$$[1] \quad u = fA(1 + \alpha' t)/(7 - (fB \times 10^{-6}))$$

where A is the sonic path length in meters, B is the electronic time delay in microseconds, f is the frequency in Hertz, α' is the coefficient of thermal expansion of the transducer holder, and t is the solution temperature in degrees Celsius. The constants A and B were obtained by calibrating the transducer probe with distilled water and aqueous sodium chloride solutions using the data of Del Grosso and Mader (27) and Sakurai *et al.* (28). The ultrasonic velocity measurements are accurate to ±0.02 m s^{-1}.

A region of high ultrasonic absorption is observed in binary mixtures of W–BE and the sing-around unit employed was unable to provide accurate ultrasonic velocity measurements in this range. Instead, a single crystal interferometer working at a frequency of 4 MHz was used to obtain ultrasonic velocities in this region. The accuracy in the interferometric velocity measurements is ±0.1 m s^{-1}.

The ultrasonic velocity obtained in the present work for 2-butoxyethanol at 25°C is 1305.37 m s^{-1}, a value 3.41 m s^{-1} higher than the value of 1301.96 m s^{-1} reported by Lara and Desnoyers (10). The purified (see below) alcohol was analyzed for water and other impurities using Karl Fischer and gas chromatographic techniques, respectively. The water content was found to be <0.03 wt.% and was accounted for when solutions with water were prepared. Its contribution to the ultrasonic velocity of BE would be to increase it by ca. 0.15 m s^{-1}, considerably less than the observed discrepancy reported above. A Tractor 222 gas chromatograph with dual FID/ECD detector was used to examine for the presence of other organic impurities. The glass column was packed with 10% carbowax 20M on 100/120 mesh supelcoport. No other impurities were detected with this unit, in particular 2-isobutoxyethanol, which has a different retention time on this column, was not observed. Furthermore, any presence of 2-isobutoxyethanol as an impurity can be ruled out because its presence should reduce the ultrasonic velocity since it has a reported (29) value of 1260 m s^{-1}. Notwithstanding the difference between the ultrasonic velocity of pure BE obtained in this work and that reported previously (10), there was good agreement with previously reported (10) ultrasonic velocity data for solutions of W–BE, particularly in the region of the ultrasonic velocity maximum (see Results section).

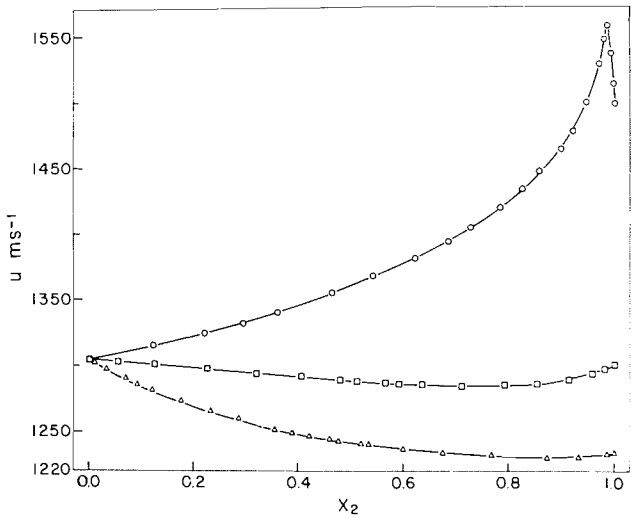

FIG. 1. Variation of ultrasonic velocity as a function of mole fraction of nonalcoholic component (2) in mixtures of (○) BE–W, (□) BE–BNZ, and (△) BE–DEC at 25°C (for the sake of clarity not all data points have been shown.)

Chemicals

2-Butoxyethanol (BE) and decane (DEC) were obtained from Aldrich Chemical Co. BE was further purified by fractional distillation under vacuum and kept over molecular sieves prior to use. Spectral grade benzene (BNZ) (BDH Chemicals) was used without further purification. All solutions were made on a weight basis using water obtained from a Millipore Super-Q system.

Results and discussion

Ultrasonic velocity and density data measured for the systems W–BE, BE–BNZ, and BE–DEC at 25, 40 and 55°C are given elsewhere.[3] A typical plot of the variation of ultrasonic velocity at 25°C as a function of mole fraction content of the nonalcoholic component is shown in Fig. 1. Adiabatic compressibility coefficients, β, are calculated from the relation

$$[2] \quad \beta = 100/(u^2 d)$$

where β is in units of bar^{-1}, d is the solution density (g cm^{-3}), and u is the ultrasonic velocity (m s^{-1}). The variation of β as a function of the mole fraction of the second component is shown in Fig. 2*A*–*C*. The W–BE system has a lower consolute temperature of 49°C. Because of this, a two phase region exists at higher temperatures and at 55°C extends over the concentration range $0.016 < X_{BE} < 0.13$. This region is shown as a dashed line in Fig. 2*A*. At 25°C, a velocity maximum and compressibility minimum is observed at $X_{BE} = 0.015$. This composition is in good agreement with the previously reported results of Lara and Desnoyers (10). Furthermore, the value of 1556.18 m s^{-1} obtained for the ultrasonic velocity maximum is in good agreement with the value of 1556.02 m s^{-1} obtained by the above authors.

The origin of this maximum at low alcohol concentration is believed to be due to long range order in water giving rise to hydrogen bonded structures which have numerous cavities that can accommodate other species. As the alcohol is added to water, alcohol molecules are assumed to occupy the cavities in the framework of the water aggregates. A denser packing of the molecules results in an increase in the ultrasonic velocity and a decrease in the compressibility of these solutions. This

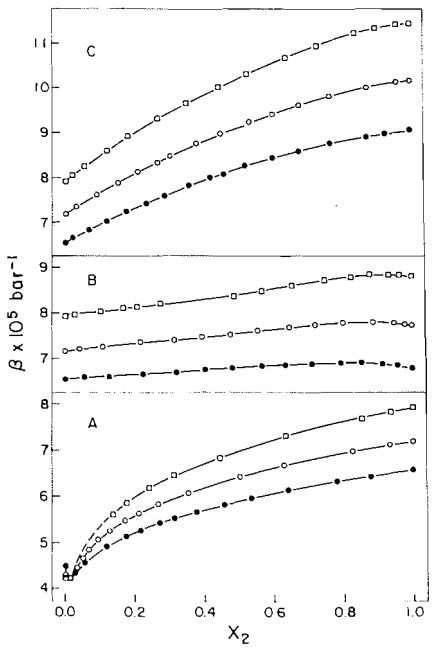

FIG. 2. Variation of the adiabatic compressibility coefficient as a function of mole fraction of component (2) in mixtures of (*A*) W–BE (2), (*B*) BE–BNZ (2), and (*C*) BE–DEC (2) ((●) 25, (○) 40, (□) 55°C).

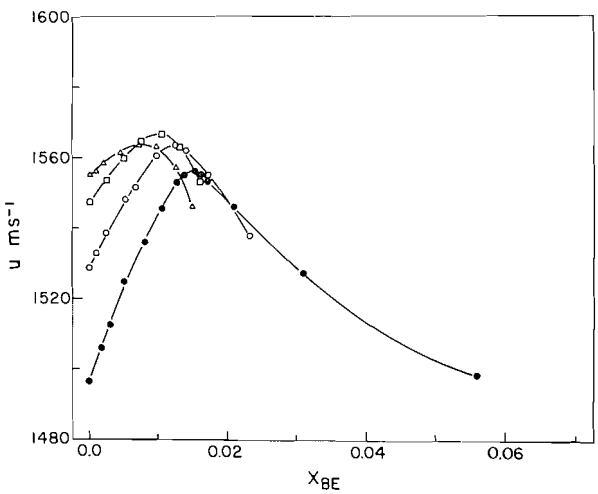

FIG. 3. Variation of ultrasonic velocity as a function of mole fraction of BE in mixtures of W–BE: (●) 25, (○) 40, (□) 55, (△) 70°C.

process continues until a concentration is reached at which all cavities are filled. A simpler argument for the increase in ultrasonic velocity is that the addition of alcohol to water causes a breakdown of the less dense hydrogen bonded structures of water. However, the results of inelastic light scattering experiments (30, 31) and ultrasonic relaxation and photon correlation spectroscopic studies (32) strongly suggest that "clathrate-like" structures are present in W–BE systems and therefore these structures are believed to contribute to the observed compressibility behavior at low BE concentrations rather than a decrease in the concentration of low density structures of water.

Figure 3 shows the variation of ultrasonic velocity as a function of mole fraction of BE at low alcohol concentrations in the binary system W–BE in the temperature range 25–70°C. A shift of the ultrasonic velocity maximum towards lower BE concentrations with increasing temperature is clearly illustrated. These maxima are postulated to correlate with the compositions at which "clathrate-like" structures of alcohol and water of well defined stoichiometry are found. This shift of the maximum to lower concentrations of BE implies that the number of possible cavities decreases at higher temperatures. It is consistent with the general view that the degree of hydrogen bonding in water decreases at higher temperatures and fewer "clathrate-like" structures would be expected to form.

The variation of the magnitude of the peak ultrasonic velocity also shows unusual behavior. It first increases with increasing temperature to above ca. 55°C and then decreases beyond this value. This trend is similar to that observed for water itself in which the creation of more compact structures with increasing temperature first produces an increase in sound velocity but, at some high temperature, the usual volume expansion property tends to dominate and thus leads to a decrease in the ultrasonic velocity. The same qualitative arguments can be used to describe the sound velocity maxima observed for the W–BE systems between 55 and 70°C.

In binary mixtures of BE–BNZ a velocity minimum and compressibility maximum (Fig. 2*B*) are observed at lower concentrations of BE. In the case of BE–DEC a velocity minimum is observed at all temperatures while, a compressibility maximum is apparent only at 55°C. The behavior of these systems can be better explained in terms of the excess adiabatic compressibility coefficients.

The usual procedure for obtaining the ideal isothermal solution property (β^{ideal}) is to take the mole fraction weighted contribution of the pure component properties represented by

$$[3] \quad \beta^{ideal} = \Sigma X_i \beta_i$$

where the suffix i represents the ith component.

However, from the fundamental definition of isothermal compressibility, it can be readily shown that the ideal solution value of this property is properly derived by taking the volume fraction (ϕ_i) weighted contributions of the isothermal compressibilities of the pure components. Considering the relationship between the isothermal and adiabatic compressibility coefficients, it has been shown (20–24) that the adiabatic compressibility coefficient of an ideal mixture can be expessed as

$$[4] \quad \beta^{ideal} = \Sigma\phi_i[\beta_i + TV_i\alpha_i^2/C_{p,i}] - T[\Sigma X_i V_i][\Sigma\phi_i\alpha_i]^2/[\Sigma X_i C_{p,i}]$$

where β_i, V_i, α_i, and $C_{p,i}$ are the adiabatic compressibility coefficient, molar volume, coefficient of thermal expansion, and heat capacity at constant pressure, respectively, of the pure i components and T is the absolute temperature. The excess adiabatic compressibility coefficients are defined as

$$[5] \quad \Delta\beta = \beta^{real} - \beta^{ideal}$$

which represents the excess of the given property of a real mixture over the value for an ideal mixture at the same temperature, pressure, and composition.

In the present work excess compressibility coefficients were calculated using both mole fraction weighted averaging (eqs. [3] and [5]) and volume fraction weighted averaging (eqs. [4] and [5]) for comparison. These data and the thermodynamic constants used in eq. [4] are given elsewhere.[3] Considerable differences are observed between the magnitudes of $\Delta\beta$ obtained from these two weighting methods. Figure 4*A* and *B* show a comparison of the excess adiabatic compressibility

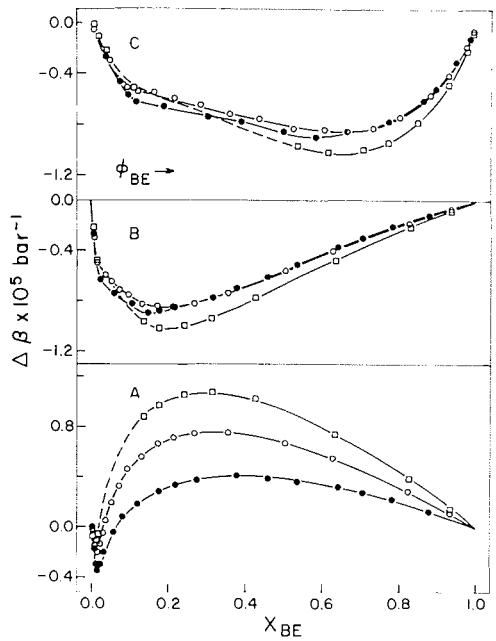

FIG. 4. Variation of excess adiabatic compressibility coefficient as a function of concentration of BE in mixtures of W–BE ((*A*) calculated from eqs. [3] and [5]; (*B* and *C*) calculated from eqs. [4] and [5]): (●) 25, (○) 40, (□) 55°C.

coefficients, calculated from mole fraction and volume fraction weighting, respectively, of the ideal solution behavior as a function of mole fraction of BE in W–BE binary solutions at 25, 40, and 55°C. Figure 4*C* shows the variation of $\Delta\beta$ obtained from the use of volume fraction weighting for the ideal solution as a function of volume fraction of BE. The dashed line in the 55°C curve for W–BE illustrates the extent of the two phase region encountered when working above the lower consolute temperature. The excess compressibility properties derived from the use of ideal solution properties based on mole fraction weighting (Fig. 4*A*) are generally positive with the exception of the low alcohol concentration range, i.e., $X_{BE} < 0.04$. However, excess compressibility coefficients derived from the use of volume fraction weighting of the ideal component contributions are negative throughout the complete composition range. The negative values of $\Delta\beta$ at very low BE concentrations in Fig. 4*A* and *B* are consistent with the view that BE molecules can occupy cavities in a hydrogen bonded framework of water molecules leading to decreased solution compressibility relative to the pure components.

The variation in $\Delta\beta$ values shown in Fig. 4 *A* and *B* exhibit considerable differences above $X_{BE} = 0.04$. In Fig. 4*A*, the values increase rapidly and eventually become positive at $X_{BE} > 0.07$ at all temperatures studied. This latter behavior is not in accordance with what would be expected for solutions containing such a high content of water. Generally, water compressibility is supposed to decrease with increasing temperature up to 64°C. It is also difficult to explain the rather sharp change in $\Delta\beta$ as being due to the positive contribution of the alcohol in conjunction with a sudden breakdown of "clathrate-like" structures of relatively lower compressibility. One would expect a gradual transformation of these well organized aggregates into merged types of aggregates leading to an increase in $\Delta\beta$, but extending over a wider alcohol composition range.

The variation of $\Delta\beta$ values (Fig. 4*B*) derived from use of eqs. [4] and [5] show a pattern more consistent with the formation and transformation of "clathrate-like" aggregates as the BE concentration is increased. The rapid decrease in $\Delta\beta$ values at low alcohol concentrations is consistent with the postulated (30, 31) "clathrate-like" structure of alcohols in water. However, the negative trend continues beyond this point ($X_{BE} = 0.015$) albeit with a reduced slope indicating that less compressible aggregates are being produced beyond the "clathrate-like" composition. Ito *et al.* (31) have proposed that in the composition range $0.015 < X_{BE} < 0.20$ both clathrate and water–alcohol aggregates with stoichiometric composition W_4BE exist. Presumably the latter structures become more prevalent as the BE concentration increases and the compressibility results reported here would appear to indicate that these W_4BE aggregates are compact and less compressible. Minima in $\Delta\beta$, depending upon temperature, are observed in the range $0.14 < X_{BE} < 0.20$. Beyond this range the increase in $\Delta\beta$ is almost linear with increasing alcohol concentration reflecting the increasing contribution of the more compressible alcohol component.

Since the compressibility coefficient is a measure of the relative change in volume with pressure, it seems appropriate to examine the variation of $\Delta\beta$ as a function of the volume fraction of BE in the binary mixtures. The results shown in Fig. 4*C* illustrate apparent differences in behavior from those exhibited in Fig. 4 *A* and *B*. However, on closer examination the results in Fig. 4 *B* and *C* are seen to be generally similar except that using ϕ_{BE} as the independent variable appears to more clearly illustrate the change in slope and the position of the minima in $\Delta\beta$ as compared to Fig. 4*B*. The excess compressibility coefficients are negative throughout the volume fraction range. A moderation of the decrease in slope of $\Delta\beta$ with ϕ_{BE} occurs at ca. $\phi_{BE} = 0.10$. Further decrease in $\Delta\beta$ continues to ca. $\phi_{BE} = 0.55$. Beyond this region the $\Delta\beta$ values become less negative as the influence of the more compressible alcohol component dominates the solution behavior. This result is consistent with the interpretation given previously with regard to the variation of $\Delta\beta$ as a function of X_{BE}.

The temperature variation of $\Delta\beta$ is unusual in the W–BE system. It is not so readily apparent in Fig. 4*B* but Fig. 4*C* shows that there is an inversion in the trend of $\Delta\beta$ with increasing temperature as the magnitude of ϕ_{BE} increases. Unfortunately, rather large ultrasonic absorption values at concentrations near the "clathrate-like" region prevented measurements of the ultrasonic velocity with the sing-around equipment. However, interferometric measurements were made to provide a few data points in this region. It is seen that at low BE concentrations $\Delta\beta$ values become less negative as temperature increases. This is in accordance with the expectations based on our discussion of Fig. 3. On the other hand, at $\phi_{BE} \geq 0.55$, $\Delta\beta$ becomes more negative with increasing temperature in the range 25–55°C. The trend is more pronounced at 55°C and suggests that the molecular arrangement of the molecules at higher temperatures is occurring with considerable economy of space leading to a reduction of compressibility relative to the ideal solution approximation.

Specific heat (33) and enthalpy of mixing (34) studies also have indicated the occurrence of clathrate structures at ca. 0.02 X_{BE}. Beyond this concentration microphase aggregates are predicted to occur and it is only at very high concentrations of BE that clathrate and microphase structures cease to exist. The variation of excess molar heat capacities and excess molar enthalpies of some normal alcohol–water and alkoxyethanol–water systems (35–38) are consistent with the variation of excess

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

adiabatic compressibility coefficients for BE(alkoxyethanol)–water observed in this work. The excess molar specific heat goes through a maximum at $X_{BE} = 0.2$ and then slowly decreases. The excess enthalpies, like the excess compressibility coefficients, show negative values that decrease sharply to a mole fraction of either alcohol or alkoxyethanol $\simeq 0.2$ and then slowly rise toward zero. The variation of the excess enthalpy of the 2-ethoxyethanol–water system with composition is exactly the same as the variation of the excess compressibility coefficient in the BE–W system (38). Both the excess enthalpies of 2-ethoxyethanol–water and the excess compressibilities of BE–W, at lower alcohol concentrations, decrease with increase of temperature. The results of the specific heat and enthalpy studies were interpreted as indicating that small additions of solute (alcohol or alkoxyethanol) are accommodated within the cavities in the hydrogen bonded network of water. In the intermediate compostion range stronger hydrogen bonding is believed to occur between water molecules as opposed to weaker bonding between the alcohols and water. Hence, a greater state of order exists within water in these systems as opposed to pure water itself. This is supported by light scattering studies (8) of water–*t*-butylalcohol (TBA) from which it is predicted that solvent-shared association complexes $[(H_2O)_{105}(TBA)_5]$ occur. The discussion of the behavior of the excess compressibility coefficient of BE–W systems obtained in this work is consistent with the conclusions drawn from the above studies.

Figure 5*A* shows the variation of $\Delta\beta$ calculated from the ideal solution approximation based on the use of eqs. [3] and [5] as a function of mole fraction of BNZ in the mixture BE–BNZ. The $\Delta\beta$ values are always positive and show a decrease with increasing temperature. Such temperature variation is unusual as generally organic liquids show an increase in compressibility with increase in temperature. Consequently the $\Delta\beta$ values would be expected to increase with increasing temperature. $\Delta\beta$ values (Fig. 5*B* and *C*) derived from ideal solution approximations based on volume fraction weighting (eqs. [4] and [5]) show negative values at lower BNZ concentration and an increase in the solution compressibility with increase in temperature, a result more in agreement with the expectation stated above. The negative values of $\Delta\beta$ observed in the BE rich region are believed to arise from BNZ occupying interstitial sites within associated structures of alcohol and to the structural change caused by the interaction between BNZ and BE. At higher concentrations of BNZ the associated alcohol structures no longer can exist and there is an increase in solution compressibility. At higher temperatures the association of alcohols is less favoured and consequently the occupation of interstitial sites by BNZ occurs to a lesser degree. This is reflected by the very shallow minimum in the $\Delta\beta$ curve at 55°C (Fig. 5*B*).

At low BE concentrations a maximum in the $\Delta\beta$ curve is observed at all temperatures. The peak value of the excess compressibility coefficient increases in magnitude and appears to shift to lower BNZ concentrations with increasing temperature. A graph of $\Delta\beta$ vs. ϕ_{BNZ} (Fig. 5*C*) shows this trend more clearly. This maximum in $\Delta\beta$ conceivably reflects the breakdown of self-associated alcohol aggregates of different association number. The shift of this peak to lower BNZ concentrations with increasing temperature indicates the greater disruptive effect of BNZ on the alcohol aggregates with increasing temperature. The discussion of the results of $\Delta\beta$ obtained from eqs. [4] and [5] for the BE–BNZ system are consistent with the

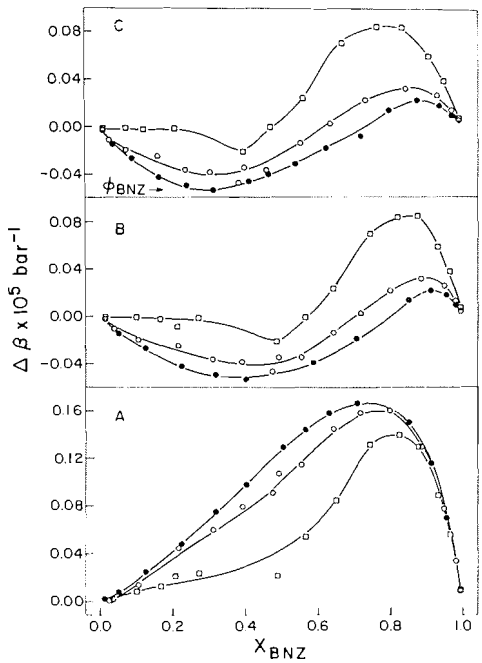

FIG. 5. Variation of excess adiabatic compressibility coefficient as a function of concentration of BNZ in mixtures of BE–BNZ ((*A*) calculated from eqs. [3] and [5]; (*B* and *C*) calculated from eqs. [4] and [5]): (●) 25, (○) 40, (□) 55°C.

interpretation of the variation of excess volume and excess compressibility coefficient property reported for 2-ethoxyethanol–hydrocarbon systems (39, 40).

The variation of $\Delta\beta$ calculated using eqs. [3] and [5] as a function of mole fraction of DEC in mixtures of BE–DEC is shown in Fig. 6*A*. All $\Delta\beta$ values are positive and show a normal increase with increase in temperature. $\Delta\beta$ values calculated from eqs. [4] and [5] (Fig. 6*B* and *C*) also are positive throughout the composition range but the maxima occur in the DEC-rich region. The reasons for the maxima are similar to those noted above for the case of BE–BNZ solutions, however, contrary to the results obtained with BE–BNZ, there is no minimum in the graphs of $\Delta\beta$ vs. X_{DEC}. This suggests that DEC does not fit interstitially into alcohol structures at lower DEC concentrations, possibly, because of the relatively larger size of the decane molecule.

The apparent molar volume ($\phi_{V,A}$) and apparent molar compressibility ($\phi_{K,A}$) properties of a solute component A defined in terms of mole fraction concentration units are calculated from the relations

$$[6] \quad \phi_{V,A} = M_0(X_0/X_A dd_0)(d_0 - d) + M_A/d$$

$$[7] \quad \phi_{K,A} = \beta\phi_{V,A} + X_0M_0(\beta - \beta_0)/(X_A d_0)$$

where d_0, X_0, M_0, and β_0 are the density, mole fraction, molecular weight, and adiabatic compressibility of the solvent, respectively, X_A and M_A are the mole fraction and molecular weight of the solute component; and d and β are the density and adiabatic compressibility of the solution mixture. Values of these properties calculated using eqs. [6] and [7] are given in the supplementary material. Typical results for the systems W–BE and BE–DEC are shown in Figs. 7–9. Figures 7 and 8 show the variation of apparent molar compressibilities and apparent molar volumes, respectively, of BE and water with composition.

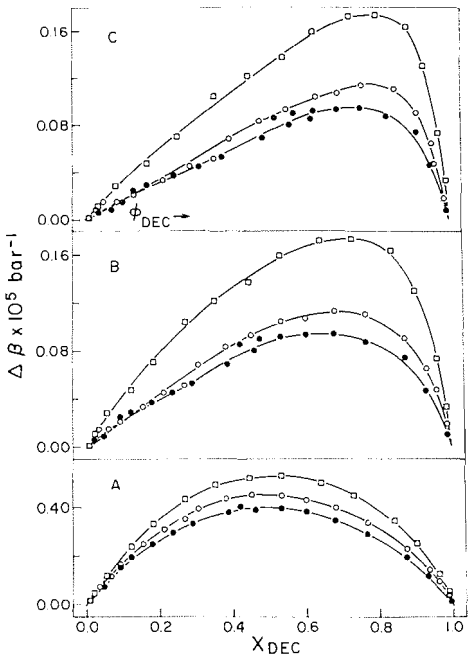

FIG. 6. Variation of excess adiabatic compressibility coefficient as a function of concentration of DEC in mixtures of BE–DEC ((*A*) calculated from eqs. [3] and [5]; (*B* and *C*) calculated from eqs. [4] and [5]): (●) 25, (○) 40, (□) 55°C.

From Fig. 7 it is seen that the change in apparent molar compressibility of water over the entire composition range is about five times smaller than that of BE. However, virtually all of this difference in magnitude between $\phi_{K,BE}$ and $\phi_{K,W}$ occurs at $X_{BE} < 0.05$. Thereafter the monotonic increase in $\phi_{K,BE}$ and $\phi_{K,W}$ as a function of their respective mole fraction contents are approximately the same over a wide composition range. Almost similar behavior arises with respect to the apparent molar volumes, Fig. 8. The sharp changes that occur in these properties at low BE mole fractions are consistent with the view that "clathrate-like" structures of BE in water are present at these low concentrations. This argument appears to be best supported by the rather sharp drop in the magnitude of $\phi_{V,BE}$ at $X_{BE} < 0.01$. The BE molecules appear to be occupying void space thereby giving rise to a marked decrease in their apparent molar volume property. As well, at high concentrations of BE, $\phi_{K,W}$ is negative showing that there is a breakdown of water aggregates and the water is being dispersed in linear and 2-dimensional hydrogen-bonded alcohol clusters leading to a reduction in the molar compressibility property of water.

A further comparison of Figs. 7 and 8 shows an interesting difference in behavior with respect to the variation of apparent molar volume and apparent molar compressibility with temperature at fixed compositions. The apparent molar volumes of both BE and water increase with increasing temperature. On the other hand the apparent molar compressibility of BE increases whereas that of water decreases with increasing temperature. It would appear that increasing temperature affects the molecular organization in these systems so as to increase the amount of free water and hence contribute to a closer packing of the molecules and a lower compressibility of the water component. The volumes show a trend expected on the basis of simple thermal expansion characteristics. On balance, it would appear that the temperature dependence of the adiabatic compressibility coefficient may be a better probe of "structural" characteristics of these solutions.

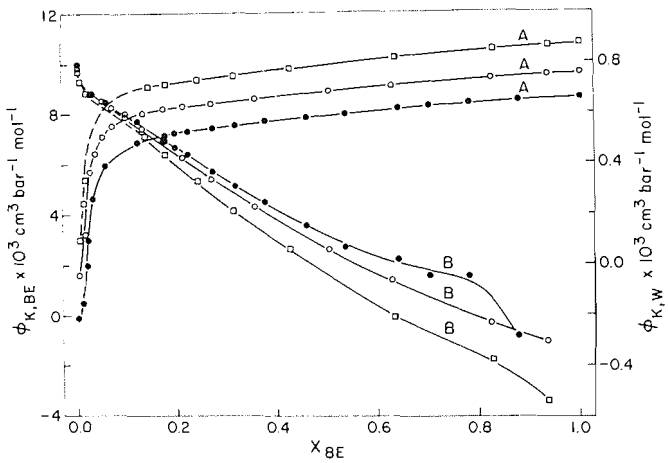

FIG. 7. Variation of apparent molar compressibility of BE (*A*) and W (*B*) in mixtures of W–BE: (●) 25, (○) 40, (□) 55°C.

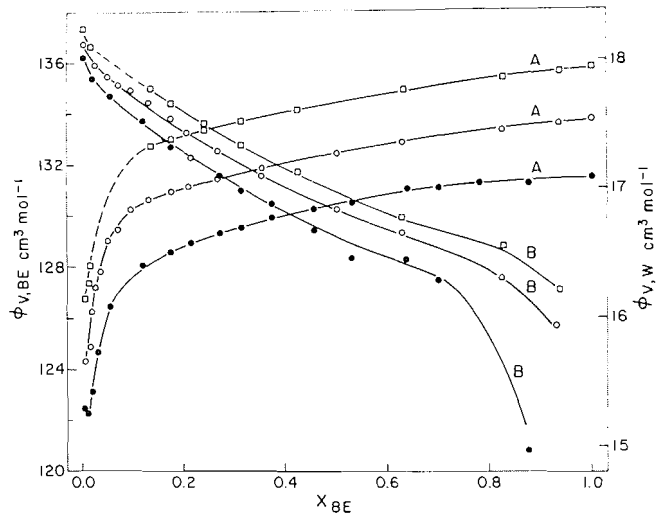

FIG. 8. Variation of apparent molar volume of BE (*A*) and W (*B*) in mixtures of W–BE: (●) 25, (○) 40, (□) 55°C.

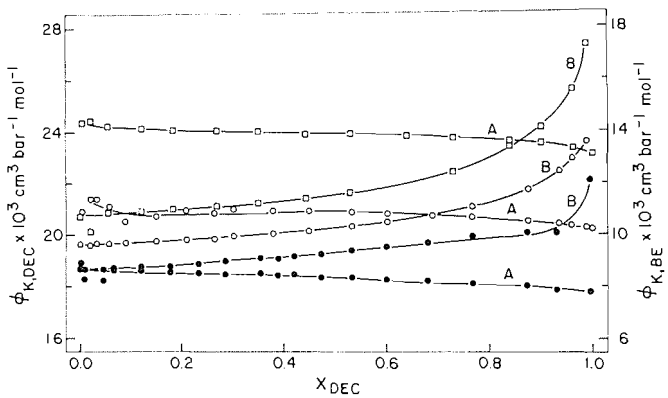

FIG. 9. Variation of apparent molar compressibility of DEC (*A*) and BE (*B*) in mixtures of BE–DEC: (●) 25, (○) 40, (□) 55°C.

The trends in the variation of apparent molar volumes and apparent molar compressibilities of BNZ in BE, BE in BNZ, DEC in BE and BE in DEC are similar at all temperatures. A typical example is shown in Fig. 9 for $\phi_{K,DEC}$ and $\phi_{K,BE}$. The magnitudes of these properties for the oil component are rela-

For personal use only.

tively constant across the entire composition range. Variations in the apparent molar properties of BE occur at lower compositions of BE, the variations being greater at the highest solution temperatures. The higher apparent molar compressibilities of BE at low BE concentrations, $X_{BE} < 0.20$, may reflect the breakdown of associated alcohol clusters in the bulk phase creating conditions of less efficient packing and hence relatively higher compressibility. The apparent molar volumes also show a similar behavior. The conclusions reached from an assessment of the behavior of apparent molar volume and apparent molar compressibility properties are consistent with those presented to describe the peaks observed in $\Delta\beta$ curves at low BE concentrations.

Conclusions

The presence of "clathrate-like" aggregates at low concentrations of BE in W–BE mixtures and changes in these aggregates as a function of temperature appear to correlate well with the variation of ultrasonic velocity maximum in these solutions. A more consistent interpretation of molecular association process can be made from the excess compressibilities obtained on the basis of using volume fraction weighted averaging of the individual component properties to evaluate ideal solution compressibility data. The transformation from "clathrate-like" to other types of alcohol–water aggregates can be described by the slope changes in the excess adiabatic compressibilities as a function of solution composition. The occupation of interstitial sites in alcohol aggregates by BNZ at high BE concentrations gives rise to minima in the excess compressibilities of BE–BNZ solutions. The breakdown of associated alcohol aggregates at lower BE concentrations by BNZ and DEC lead to maxima in the $\Delta\beta$ values. The apparent molar volume and compressibility behavior of the components of these solutions are also consistent with these qualitative conclusions.

Étude des mélanges eau–HF par spectroscopie infrarouge à transformée de Fourier

JALEH KHORAMI, RÉJEAN BEAUDOIN ET HUGUES MÉNARD[1]

Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Reçu le 28 juillet 1986

JALEH KHORAMI, RÉJEAN BEAUDOIN et HUGUES MÉNARD. Can. J. Chem. **65**, 817 (1987).

L'analyse des spectres infrarouges des mélanges HF–H_2O entre 10 et 97% en HF nous a permis de déterminer l'évolution des espèces ioniques de HF. Les résultats obtenus montrent la présence des ions $H_3O^+F^-$, H_3O^+, F^- ainsi que H_2O dans des solutions HF–H_2O à moins de 46% en poids de HF. À partir de 50% HF en poids, on a constaté l'apparition des bandes caractéristiques de HF_2^- dont les intensités augmentent avec la concentration jusqu'à 90% en HF. D'autre part, nous avons mis en évidence l'existence des polymères $(HF)_n$ dans les solutions à haute concentration en HF. Ces résultats expliquent le comportement électrochimique des solutions HF–H_2O que nous avons entreprises.

JALEH KHORAMI, RÉJEAN BEAUDOIN, and HUGUES MÉNARD. Can. J. Chem. **65**, 817 (1987).

An analysis of the ir spectra of HF–H_2O mixtures containing from 10 to 97% of HF has been used to determine the evolution of the ionic species of HF. The results indicate that water and the ions $H_3O^+F^-$, H_3O^+, and F^- are present in the solutions containing less than 46% w/w of HF. In the solutions containing at least 50% w/w of HF, bands characteristic of the ion HF_2^- start appearing and their intensity increases with the concentration of HF, up to a concentration of 90%. As well, polymers of $(HF)_n$ have been detected in the solutions containing the highest concentration of HF. These results can be used to explain the electrochemical behaviour of solutions of HF–H_2O.

[Journal translation]

Introduction

Les propriétés des mélanges eau–HF mesurées par voie électrochimique indiquent des changements importants au niveau de l'ionisation en solution (1–3) en passant des solutions diluées aux mélanges très concentrés. En particulier dans la région de 45 à 75% en poids de HF, plusieurs propriétés passent par un maximum ou une transition. La température d'ébullition (4), la conductivité (1), l'activité en ions fluorure (2, 3) et la densité (1) en sont des exemples.

L'étude des mélanges eau–HF par spectroscopie infrarouge effectuée par Giguère et Turrell (5, 6) permet d'établir de façon claire les espèces présentes jusqu'à 46% en HF. À plus grande concentration en HF, la compréhension des propriétés électrochimiques et physiques nécessite la connaissance des espèces ioniques et moléculaires en solution.

L'utilisation de la spectroscopie infrarouge nous permet donc de mettre en évidence l'évolution des espèces formées en solution avec la concentration croissante en HF de 10 à 90%. Par ces études, on mettra en évidence les espèces ioniques H_3O^+, HF_2^- et la probabilité de la formation des espèces polymériques du fluorure d'hydrogène. Ces résultats confirment et expliquent les propriétés particulières des mélanges eau–HF observées lors des études en électrochimie.

Partie expérimentale

Les solutions de HF sont préparées à l'avance. Les spectres ont été enregistrés à la température ambiante à l'aide d'un appareil infrarouge à transformée de Fourier Nicolet MX1 avec une résolution de 2 cm^{-1}. Le temps de balayage se situe entre 30 et 60 secondes.

Pour les mélanges eau–HF contenant moins de 46% en poids de HF, nous avons utilisé un film capillaire formé en pressant une fine goutte de liquide entre deux pastilles de KBr. À plus grande concentration en HF, nous avons utilisé la même technique avec des pastilles de AgCl à cause de la réactivité de la solution vis-à-vis le KBr. Le spectre est enregistré rapidement à cause de la haute pression partielle du HF.

Résultats et discussion

La figure 1 montre une superposition des spectres qui permet de voir l'évolution des bandes attribuées aux différentes espèces en solution.

1. Auteur à qui adresser toute correspondance.

Les tableaux 1–4 résument les attributions des bandes entre 4000 et 2500 cm^{-1}, 2500 et 1600 cm^{-1}, 1600 et 800 cm^{-1} et 800 et 400 cm^{-1}.

Région de 4000 à 2500 cm^{-1}

Lorsqu'on ajoute du HF à l'eau, on peut remarquer l'apparition d'un épaulement vers 2700 cm^{-1}.

L'intensité de cet épaulement augmente jusqu'à une concentration de HF 51% en poids et se déplace légèrement vers les fréquences plus élevées. À partir de 61% de HF, on observe une diminution de l'intensité pour cet épaulement par rapport au pic situé vers 3500 cm^{-1}.

Les deux bandes forment un ensemble qui s'étend entre 3700 et 2500 cm^{-1} pour les solutions plus concentrées en HF. Giguère et Turrell (5, 6) ont attribué cette bande vers 2700 cm^{-1} à une vibration ν_3 de H_3O^+ pour les mélanges contenant moins que 46% de HF. Cette bande qui est due à une liaison hydrogène très forte entre H_3O^+ et l'ion de fluorure en solution se déplace vers les fréquences plus basses en comparaison avec les mélanges similaires de HCl et l'eau qui se trouve vers 2900 cm^{-1}.

Pour ces mélanges, la force de liaison hydrogène entre les ions de Cl^- et H_3O^+ est considérée très faible.

Dans nos études, le déplacement et la diminution de l'intensité de la bande vers 2700 cm^{-1} sont peut-être dus respectivement à une baisse de la force de liaison hydrogène entre H_3O^+ et l'ion de fluorure et la décroissance des espèces ioniques H_3O^+ dans les solutions concentrées de HF.

D'autre part, on a remarqué que les bandes ν_1 et ν_3 de l'eau située dans cette région vers 3500 cm^{-1} persistent toujours et même augmentent d'intensité à partir des solutions contenant 61% de HF.

D'après les études suivantes qui montrent la disparition quasi totale des bandes caractéristiques de l'eau sur les spectres ir à partir de 61% en HF, cette bande vers 3500 cm^{-1} ne peut pas appartenir à l'eau.

Si on se réfère aux travaux de Couzi (7) qui ont été effectués pour HF gazeux et les travaux de Gennick *et al.* (8) pour HF dans un milieu aqueux en présence des ions d'alkylammonium ainsi que les études de Desbat et Huong (9) qui comparent

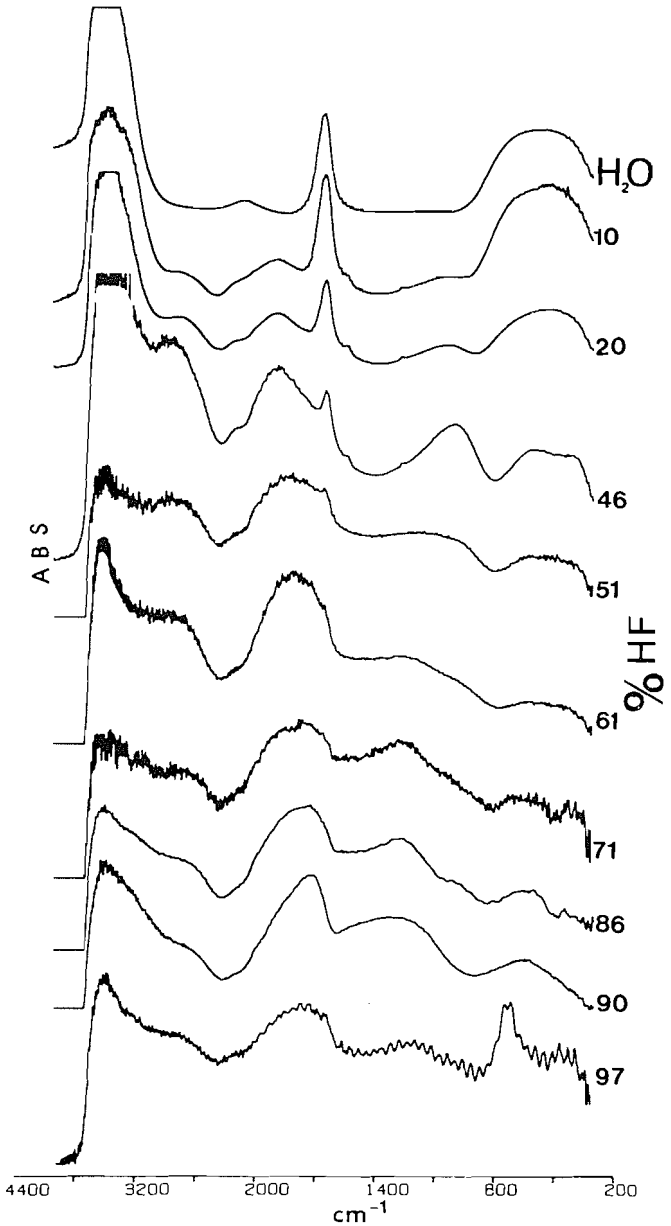

FIG. 1. Spectre infrarouge des mélanges HF–H_2O en poids.

les spectres ir des mélanges concentrés en HF et ceux de HF gazeux, on est convaincu que cette bande large située vers 3500 cm^{-1} est due à la formation des espèces de polymères ioniques de HF.

D'autre part, les études précédentes (10, 11) confirment nos résultats et montrent que les spectres infrarouges des mélanges concentrés en HF sont comparables à ceux du HF gazeux.

La région de 2500 à 1600 cm^{-1}

La comparaison des spectres infrarouges de l'eau (12) et des mélanges eau–HF jusqu'à 97% montre les points suivants :

1. Les vibrations de l'eau situées vers 1645 et 2125 cm^{-1} diminuent d'intensité avec l'augmentation de la concentration en HF à partir de 61% en HF; ces bandes caractéristiques disparaissent complètement pour donner leurs places à une bande de vibration large située entre 1600 et 2000 cm^{-1}. L'intensité de cette bande augmente et son maximum se trouve vers 1730 cm^{-1} aux hautes concentrations en HF.

2. On peut noter que, pour les solutions de 10 à 50% en HF, la disparition des deux bandes caractéristiques de l'eau est

suivie par l'apparition d'une bande dont le maximum est situé vers 1880 cm^{-1}.

Dans les solutions aqueuses de HF, la bande de vibration centrée à 1880 cm^{-1} est symétrique. Par analogie avec le spectre des autres acides minéraux (11), Giguère et Turrell (5, 6) ont attribué cette bande au pliage (bending mode) ν_4 de l'ion H_3O^+. Cette fréquence, beaucoup plus élevée que dans l'acide chlorhydrique (1750 cm^{-1}), a été attribuée à la formation de paires d'ions liés par liaison hydrogène. On peut représenter ces ions à partir de l'équilibre suivant :

$$H_2O + HF \rightleftarrows [H_3O^+ \cdot F^-] \rightleftarrows H_3O^+ + F^-$$

Cette fréquence, très élevée pour un pliage hors plan, est indicatrice d'une très grande force de rappel.

À partir de 50% en HF, on note un élargissement et le déplacement du pic à 1800 cm^{-1} vers 1730 cm^{-1}. La bande devient non symétrique et s'étend encore de 200 à 1600 cm^{-1}. Le maximum à 1730 cm^{-1} apparaît d'abord comme un épaulement et augmente d'intensité avec la concentration en HF jusqu'à 90%.

D'après les études effectuées par Emsley (12) sur les spectres infrarouges de HF_2^- et qui fait intervenir les résultats de recherches de différents auteurs, il est fort probable que l'apparition de l'épaulement vers 1730 cm^{-1} et le déplacement de la bande de vibration à 1880 cm^{-1} vers 1730 cm^{-1} sont dus à la formation de l'espèce ionique HF_2^- selon les équilibres suivants :

$$HF + F^- \rightleftarrows HF_2^-$$

$$[H_3O^+ \cdot F^-] + HF \rightleftarrows H_3O^+ + HF_2^-$$

La bande de vibration ν_3 de HF_2^- peut être retrouvée entre 1450 et 1900 cm^{-1}. Harmond *et al.* (13) ont observé cette bande à 1740 cm^{-1}.

D'après nos résultats de spectroscopie infrarouge, il est possible de prévoir les conclusions suivantes sur les espèces

ioniques et moléculaires dans les mélanges eau–HF:

1. La diminution à partir de 10% en HF et la disparition quasi-totale de l'eau «libre» à partir de 60% en HF.
2. L'apparition et l'augmentation de la concentration de la paire d'ions $H_3O^+ \cdot F^-$ de 10 à 50% en HF.
3. L'apparition à partir de 50% en HF et l'augmentation de la concentration de HF_2^- jusqu'à 85% en HF.

La région de 1600 à 800 cm^{-1}

Dans cette région de vibration, l'eau ne possède aucune bande en infrarouge. Par contre, on peut constater sur le spectre des mélanges eau–HF l'apparition d'un épaulement situé vers 1035 cm^{-1}. D'autre part, on peut noter qu'avec l'augmentation de la concentration en HF jusqu'à 50%, l'épaulement à 1030 cm^{-1} se transforme en un pic large dont le maximum se situe à 1000 cm^{-1}. À plus de 50% en HF, ce pic diminue d'intensité et on voit apparaître vers les fréquences plus élevées une bande large. À partir de 60% en HF, on observe une bande large centrée à 1260 cm^{-1} et dont l'intensité augmente jusqu'à 90% en HF. Le tableau 3 résume l'évolution des différentes bandes.

Les observations ci-dessus ainsi que les interprétations citées pour les bandes de vibration situées entre 1600 et 2500 cm^{-1} nous conduisent aux conclusions suivantes:

1. On peut interpréter l'apparition de l'épaulement à 1035 cm^{-1} dont l'intensité suit celle du pic à 1800 cm^{-1} à une bande de vibration de l'ion H_3O^+. Giguère (5) a attribué la faiblesse et la largeur anormalement élevée de cette bande au complexe $H_3O^+ \cdot F^-$. Dans les autres acides minéraux, ν_2 de H_3O^+ est beaucoup plus intense et centré à 1200 cm^{-1}. Cette particularité est consistante du point de vue du moment dipolaire de $H_3O^+ \cdot F^-$.
2. La diminution d'intensité de la bande centrée à 1035 cm^{-1} suivie de l'apparition de la bande à 1260 cm^{-1} qui augmente d'intensité avec la concentration en HF de la même façon que la bande à 1730 cm^{-1} doit être due à la formation et à l'augmentation de concentration de l'espèce HF_2^-. Selon Emsley (12), la bande ν_2 de HF_2^- est un mode de vibration dégénéré. Ceci pourrait expliquer la largeur importante de la bande à 1260 cm^{-1}.

La région de 800 à 400 cm^{-1}

Dans cette région de vibration, l'eau possède une bande large située entre 300 et 700 cm^{-1} avec un maximum centré à 500 cm^{-1}.

Sur les spectres infrarouges des mélanges eau–HF, on peut constater une diminution de l'intensité de ce pic et un élargissement avec l'augmentation de la concentration en HF. À partir de 46% en HF, on observe aussi l'apparition d'un épaulement puis d'un pic vers les fréquences plus élevées. On observe encore un maximum vers 650 cm^{-1} pour des concentrations de 78 à 90% en HF. Le tableau 4 résume l'évolution des bandes dans cette région.

Par ailleurs, on peut remarquer que l'apparition de l'épaulement et l'augmentation de ce pic, déplacé vers les fréquences plus élevées, suivent de façon évidente la présence et l'augmentation d'intensité des deux bandes vers 3500 et 2770 cm^{-1}. Ces deux bandes de vibration avaient été attribuées à la formation des espèces polymériques de HF avec l'augmentation de la concentration de HF jusqu'à 90%. Ces observations nous

TABLEAU 4. Les bandes de vibration observées dans la région entre 800 et 400 cm^{-1}

	650 cm^{-1}		475 cm^{-1}	
% HF (poids)	Intensité relative	Attribution	Intensité relative	Attribution
Eau	(550) TF, L	ν_L H_2O		
10	(550) TF, L	ν_L H_2O		
20	(550) F, L	ν_L H_2O		
46	(600) F	ν_L H_nF_n	F	ν_L H_2O
51	(610) M	ν_L H_nF_n	M	ν_L H_2O
61	(620) M	ν_L H_nF_n	f	ν_L H_2O
71	M	ν_L H_nF_n	—	—
78	M	ν_L H_nF_n	—	—
86	M	ν_L H_nF_n	—	—
90	F	ν_L H_nF_n	—	—
97	F	ν_L H_nF_n	—	—
HF	(700) F	ν_L H_nF_n	—	—

poussent à croire que l'apparition de cette bande de vibration à 650 cm^{-1} doit être liée à la formation des espèces polymériques en solution (14). D'autre part, dans HF gazeux, on observe des vibrations de déformation à 800 cm^{-1} attribuées aux multimètres du fluorure d'hydrogène.

Conclusion

À partir des mesures de spectroscopie infrarouge sur le système eau–HF, on peut déduire le points suivants :

1. Dans les mélanges eau–HF jusqu'à 50% en poids de HF, l'espèce ionique dominante est le H_3O^+ fortement lié à l'ion fluorure.

2. À partir de 50% en HF, la concentration de HF_2^- augmente pour atteindre au maximum entre 80 et 90% en HF.

3. Ces travaux nous ont montré aussi la probabilité de formation des espèces polymériques dans le système aqueux de HF, comme c'est le cas pour HF gazeux (7, 9) et en présence d'ions alkylammonium (8).

Il faut noter que les conclusions déduites de la spectroscopie infrarouge confirment les travaux effectués en électrochimie. La conductivité reste élevée jusqu'à 65% en HF; l'activité en ions fluorure baisse rapidement entre 45 et 65% en HF; le potentiel de réduction des métaux est affecté par une espèce en solution différente de l'ion fluorure entre 50 et 100% en HF.

The interaction of copper with tris(hydroxymethyl)aminomethane (TRIS) has been studied by optical and esr spectroscopic techniques. In solution, three different copper complexes are obtained as a function of pH. At pH 10 the room temperature esr parameters are $g_0 = 2.135$, $A_0 = 82$ G and nitrogen superhyperfine structure $A_N = 9.5$ G, characteristic of two nitrogen ligands; at pH 6.5, $g_0 = 2.147$, $A_0 = 65$ G and at pH 5.0, $g_0 = 2.180$, $A_0 = 44$ G. The high pH complex was crystallized and its molecular structure determined by X-ray methods. Space group and cell dimensions are $C2/c$, $a = 12.955(2)$ Å, $b = 10.793(1)$ Å, $c = 10.091(2)$ Å, $\beta = 116.62(1)°$, $V = 1261.4(6)$ Å^3, $Z = 4$, $D_c = 1.694$ g cm^{-3}, $R = 0.034$ for 938 reflections with $I > 3\sigma(I)$. The Cu^{2+} ion is located on the two-fold axis and coordinated to the oxygen and nitrogen atoms of two TRIS moieties; these ligand atoms form the rectangular base of a pyramid structure in which oxygen from a water molecule acts as the fifth ligand.

M. F. COLOMBO, L. AUSTRILINO, O. R. NASCIMENTO, E. E. CASTELLANO et M. TABAK. Can. J. Chem. **65**, 821 (1987).

Faisant appel à des techniques de spectroscopie optique ou rpe, on a étudié l'interaction entre le cuivre et le tris(hydroxyméthyl)aminométhane (TRIS). En solution, trois types différents de complexes de cuivre sont obtenus en fonction du pH : à un pH de 10 et à la température ambiante, les paramètres rpe sont les suivants : $g_0 = 2,135$, $A_0 = 82$ G et une structure hyperfine de l'azote $A_N = 9,5$ G qui sont caractéristiques de deux ligands azotés; à un pH de 6,5, $g_0 = 2,147$ et $A_0 = 65$ G et à un pH de 5,0, $g_0 = 2,180$ et $A_0 = 44$ G. On a cristallisé le complexe qui se forme à un pH élevé et on a déterminé sa structure par diffraction des rayons-X. Le produit cristallise dans le groupe d'espace $C2/c$, avec $a = 12,955(2)$ Å, $b = 10,793(1)$ Å et $c = 10,091(2)$ Å et $\beta = 116,62(1)°$, $V = 1261,4(6)$ Å^3, $Z = 4$, $D_c = 1,694$ g cm^{-3} et $R = 0,034$ pour 938 réflexions avec $I > 3\sigma(I)$. L'ion Cu^{2+} est situé sur l'axe binaire et il est coordonné aux atomes d'azote et d'oxygène des deux portions TRIS; les atomes de ces ligands forment la base rectangulaire d'une structure pyramidale dans laquelle l'oxygène d'une molécule d'eau agit comme cinquième ligand.

[Traduit par la revue]

Introduction

Due to the importance of the biological complexes of Cu(II) and its presence as an integral part of a number of proteins, several techniques have been used to obtain information about the binding structure and biological function of this ion. Because of the intrinsic complexity of high molecular weight systems, many model studies have been made of Cu(II) with aminoacids, small peptides and organic compounds (1).

Electron spin resonance and optical absorption spectroscopies have proved to be very useful in establishing the ligands bonded to the metallic ion, the bond symmetry and the degree of covalence in these complexes (2–4). These data are always more completely explained when the complexes formed in solution are also obtained and investigated in the solid state; in solution the copper ion often forms more than one complex for a given free ligand concentration. It is often extremely difficult to separate the complexes due to their labile character and this is why most of the work appearing in the literature is restricted to the discussion of data for samples prepared at high free ligand concentration, when the metallic ion is found as the most stable complex (5, 6).

The quantitative description and concentrations of the complexes formed in solution is made through the determination of equilibrium constants and formation curves. However, the equilibrium constants only give indirect structural information of the complexes; solid state epr and X-ray diffraction data can give a complete structural characterization (7).

In the present work the interaction of tris(hydroxymethyl)-aminomethane (TRIS) with copper is investigated with use of the epr and optical spectroscopies as well as X-ray crystallography. The choice of this compound was motivated first by its wide use as biochemical buffer and our detection of its ability to make quite strong copper complexes in competition with some biological molecules. This compound also has quite interesting properties in the solid state, where a transition is observed with the formation of a plastic crystal phase (8, 9). Further, the equilibrium constants were obtained for the Cu^{2+}—TRIS complexes in solution based on the experimental titration data and the assumption of several reaction equilibria (10). An attempt is made to characterize the complexes in solution by comparing the spectroscopic and titration data, and also to identify the complex obtained in the crystalline form by using epr and X-ray crystallography.

Experimental

Sample preparation

TRIS and $CuClO_4$ were obtained from Merck Co. and used without further purification. A solution of 0.05 *M* TRIS and 0.005 *M* $CuClO_4$ in distilled water has a characteristic blue color and the original pH value is around 8.5. The pH values in the range 3.0–12.0 (Corning Model 130 pH-meter) were adjusted with the use of concentrated solutions of NaOH and HCl so that dilution was avoided. Equal 0.5 mL aliquots at each pH value were collected from a stock of 50 mL for the measurements, and the samples were used both for electronic optical absorption and epr measurements at room temperature and at low temperature in the frozen state.

Single crystals were obtained from solutions of 1 *M* TRIS and 0.1 *M* $CuClO_4$. Generally, good crystals were obtained if the solution was maintained around pH 10.0.

Optical and esr spectroscopy

For the optical absorption measurements (350–700 nm) a spectro-

photometer Shimadzu UV-180 was used. Electron spin resonance measurements were performed in a Varian E-109 spectrometer at X-band (9.3 GHz). A rectangular cavity E-248 together with the temperature control accessory E-257 was used to obtain the spectra at room temperature and at −150°C. The signal modulation at 100 kHz was 4 G peak-to-peak and microwave power 10 mW, the power being adjusted to improve the resolution of the superhyperfine nitrogen lines. Single crystal spectra were obtained with the use of a Varian goniometer, measuring the spectra in three orthogonal crystal planes as a function of orientation of the magnetic field at room temperature.

Crystallography

A prismatic crystal with dimensions 0.52 × 0.10 × 0.10 mm was mounted on an Enraf Nonius CAD-4 diffractometer. Unit cell dimensions and the orientation matrix for data collection were obtained by least squares from 25 centered reflections. Crystal data are as follows

$Cu(TRIS)_2 \cdot H_2O$ fw = 321.81

Monoclinic, space group $C2/c$, a = 12.955(2), b = 10.793(1), c = 10.091(2) Å, β = 116.62(1)°, V = 1261.4(6) Å^3, Z = 4, D_c = 1.694 g cm^{-3}, μ(MoKα) = 1.68 mm^{-1}, λ(MoKα) = 0.71073 Å, T = 296 K.

Intensities were measured by the ω–2θ scan technique at a rate between 2.5 and 10.0° min^{-1}; the ω scan angle was (0.80 + 0.35 tan θ)°, extended at each side by 25% for background determination. From 1701 reflections measured, 1108 unique, 938 having $I > 3\sigma(I)$ ($\sigma(I)$ estimated from counting statistics) were used for structure determination and refinement. The intensity of one standard reflection ($3\bar{1}\bar{5}$) was essentially constant (variation of ±2%) over the duration of the experiment. Data were corrected for Lorentz, polarization, and absorption effects (maximum and minimum transmission factors 0.908 and 0.816).

The copper atom was readily located from a Patterson map and the rest of the structure was determined by alternate cycles of isotropic least squares and difference synthesis. The structure was refined by full-matrix least-squares, including H-atom coordinates, to final R factors R = 0.034 and R_w = 0.030. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with $w = 1/\sigma^2(F_o)$. Hydrogen atoms were assigned a common B factor which refined to a final value of 1.2(2) Å^2. All other atoms were treated anisotropically. A total of 118 parameters were refined, including χ in the extinction correction formula $F(\text{corrected}) = F_c[1.0 - \chi F_c^2/\sin\theta]$, which converged to the value $\chi = 1.46 \times 10^{-6}$. Complex scattering factors for non-H atoms (11, 12) and bonded H-atom scattering factors (13) were employed. Most calculations were carried out with the programs SHELX-76 (14) and ORTEP (15).

Results

The formation curves for the complex in solution were calculated using the equilibrium constants and reactions proposed in the work of Bai and Martell (10). These curves predicted eight possible different complexes as a function of pH (Table 1).

Optical absorption measurements

The optical spectra for the Cu^{2+}—TRIS system as a function of pH are presented in Fig. 1. A shift of the band to lower wavelengths occurs with the increase of pH. At pH 8.1 a splitting of the absorption band into two is apparent. Figure 2 presents the dependence of the wavelength of maximum absorption of the pH. The decrease of λ with increasing pH and a splitting above pH 8.0–8.5 are clearly observed.

In order to follow the appearance of the electronic bands the intensity of absorption at two different wavelengths as a function of pH was plotted (Fig. 3). The selection of the wavelengths was made using the fact that the high pH spectrum shows two bands at approximately 630 and 530 nm. Figure 3*a* shows that the maximum intensity at 630 nm occurs at pH 7.0, while above pH 9.5 the absorption intensity remains constant.

TABLE 1. Equilibrium constants for the complexes of Cu^{2+} with TRIS in solution at 25°C, 0.10 M ionic strength (10)

Complex	Equilibrium constant	log K	pH_{max}	Maximum* concentration (%)
ML^{2+}	K_1	3.95	5.4	31
ML_2^{2+}	K_2	3.68	5.8	22
ML_3^{2+}	K_3	3.47	6.4	29
ML_4^{2+}	K_4	3.0	7.6	75
$MH_{-1}L^{+}$	K_{1a}	−6.0	5.9	13
$(MH_{-1}L)_2^{2+}$	K_{ad}	2.2	6.5	16
$ML(H_{-1}L)^{+}$	K_{2a}	−6.32	6.0	2
$M(H_{-1}L)_2$	K_{2b}	−7.90	>9	>60

*The maximum concentrations were calculated from the formation curves and are given together with the corresponding pH value.

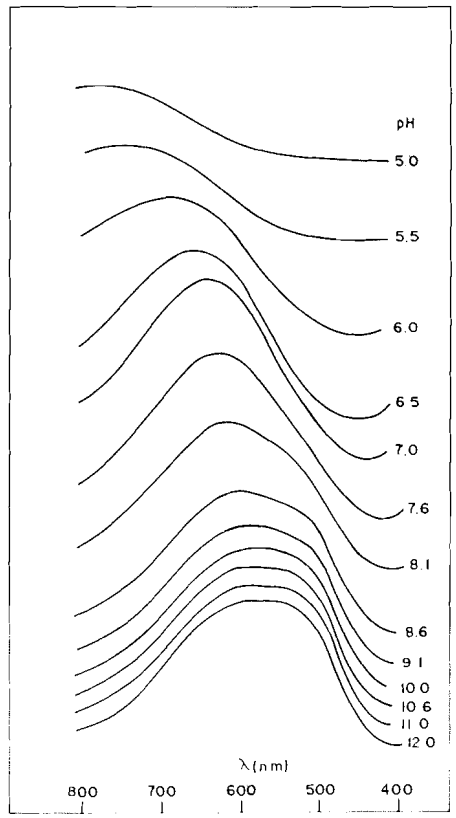

FIG. 1. Optical absorption spectra for the complexes Cu^{2+}—TRIS in solution as a function of pH.

From Fig. 3*b* the absorption at 530 nm increases with pH up to pH 9.0 and then it remains constant at approximately the intensity of the 630 nm band.

Electron spin resonance measurements

Figure 4 shows the room temperature esr spectra for the Cu^{2+}—TRIS system as a function of pH. At pH values above 8.0 a predominant spectrum is apparent with a superhyperfine splitting of the high field line into five lines probably due to two nitrogen ligands on the metal ion. From Fig. 4*b* it is evident that lowering the pH towards pH 7.0 leads to less of this complex and an increase in a second one where nitrogen structure is not resolved. This second complex has a greater value of g_0 and smaller value of A_0. We shall denote the different complexes starting from high pH so that the complex appearing above pH

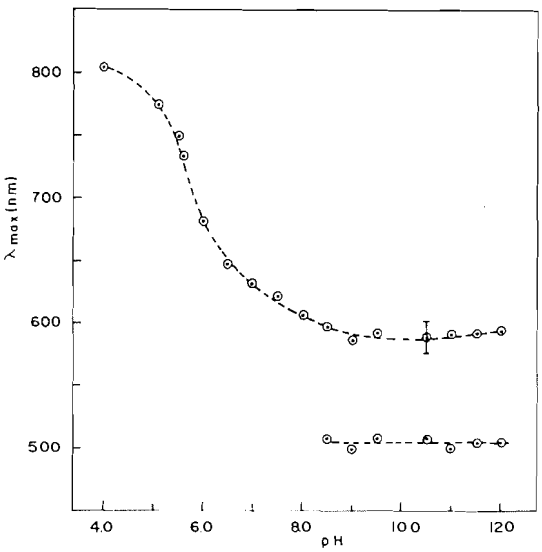

FIG. 2. Dependence of the wavelength for maximum absorption λ_{max} on the pH for the solution of Cu^{2+}—TRIS.

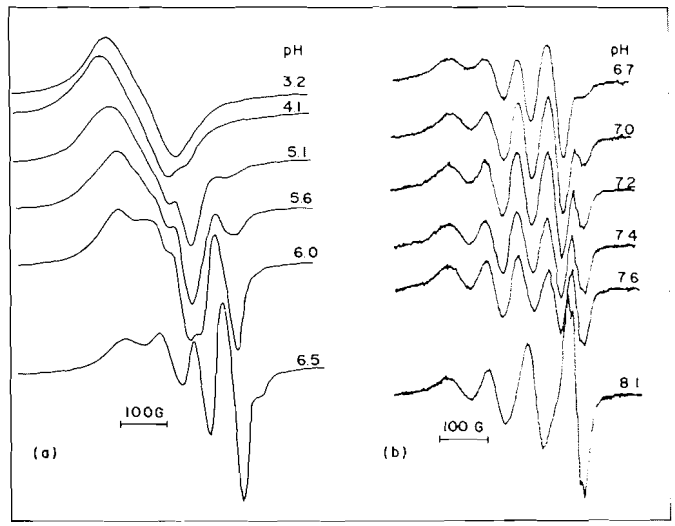

FIG. 4. Electron spin resonance spectra for the Cu^{2+}—TRIS solution as a function of pH at room temperature: (*a*) low pH range 3.2–6.5; (*b*) high pH range 6.7–8.1. Spectra above 8.1 do not change.

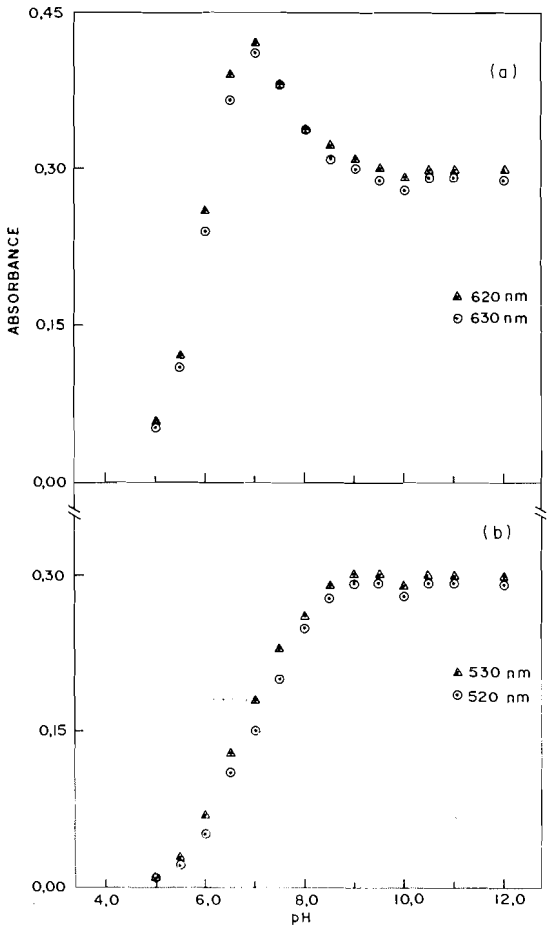

FIG. 3. Dependence of the intensity of the absorption at two different wavelengths which characterize the optical bands as a function of pH for the solution of Cu^{2+}—TRIS.

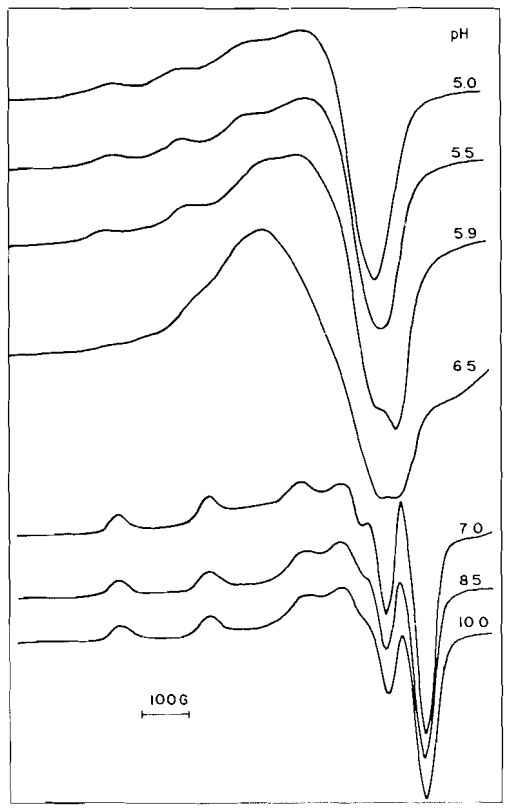

FIG. 5. Electron spin resonance spectra for the Cu^{2+}—TRIS frozen solution as a function of pH at −150°C.

8.0 will be **1**; the second complex around pH 7.0 will be **2**, etc.

Below pH 6.5, complex **1** disappears completely and the concentration of complex **2** is reduced; in fact, the amount of this complex is reduced dramatically at pH 5.6 (Fig. 4*a*). It is clear that at pH 6.0 and specially pH 5.6 there exists a complex **2** (small amount) and another lower pH complex (**3**). Further lowering of pH gives the hydrated copper ion as the predominant species. In order to further characterize the observed complexes esr spectra were taken at low temperature (Fig. 5). In the pH range 7.5–12.0 the spectrum practically does not change, this being a characteristic for the high pH species. The nitrogen hyperfine structure is not resolved at this low temperature. Complex **2** starts to show up near pH 7.0 and at pH 6.5 the contribution of complex **1** is very small (Fig. 5). The very broad line with poorly resolved hyperfine structure is probably due to the fact that complex **2** is highly charged and precipitates at low temperature or, alternatively, to dimer

TABLE 2. Electron paramagnetic resonance parameters for the complexes of Cu^{2+} with TRIS in solution as a function of pH

Complex	pH	g_0	A_0 (G)	A_N (G)	λ_{max} (nm)
1	10	2.135	82	9.5	587 508
2	6.5	2.147	65	—	650
3	5.0	2.180	44	—	775
Solvated ion	3.2	2.220	—	—	~800

*The parameters correspond to those for the pure complexes obtained through spectral subtraction (complexes **2** and **3**). The wavelength for maximum absorption was also included.

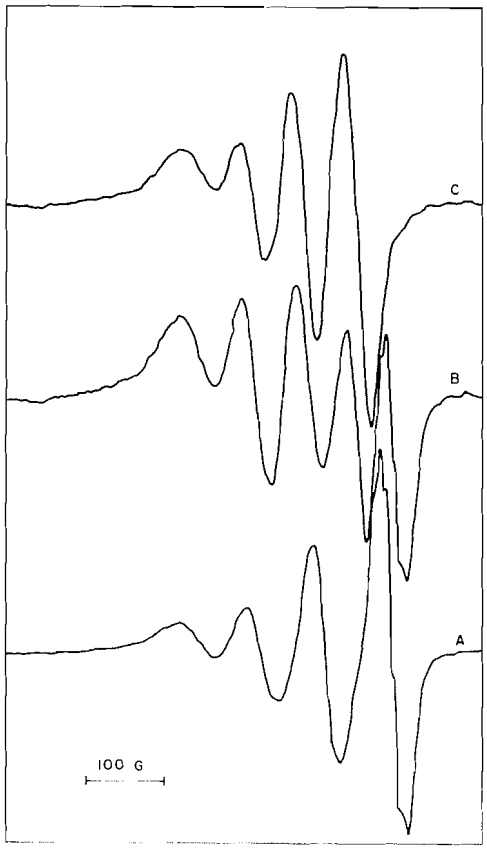

FIG. 6. Electron spin resonance spectrum for complex **2** (*C*) obtained through spectral subtraction using the experimental spectra at pH 10.0 (complex **1**, *A*) and at pH 7.6 (mixture of complexes **1** and **2**, *B*).

formation for complex **2**. It is interesting that the loss of resolution of copper hyperfine structure occurs in a very narrow pH range since both at pH 6.0 and pH 7.0 this structure again becomes resolved. The esr parameters for the complexes of Cu^{2+} with TRIS are listed in Table 2. From the spectra in Figs. 4 and 5 it is clear that the esr spectrum for **1** is pure and the parameters can be obtained with great accuracy. However, the parameters for complexes **2** and **3** can not be directly obtained due to the superposition of spectra for several complexes. To obtain the pure spectra of complexes **2** and **3**, a spectral subtraction was performed based on the relation $C = A - BX$, where *A* and *B* refer to spectra of the mixture of **1** and **2** and of pure **1**, respectively. The factor *X* is adjusted to obtain the best reproduction of the experimental spectrum (Fig. 6). The spectrum at pH 10.0 corresponds to pure complex **1** while at

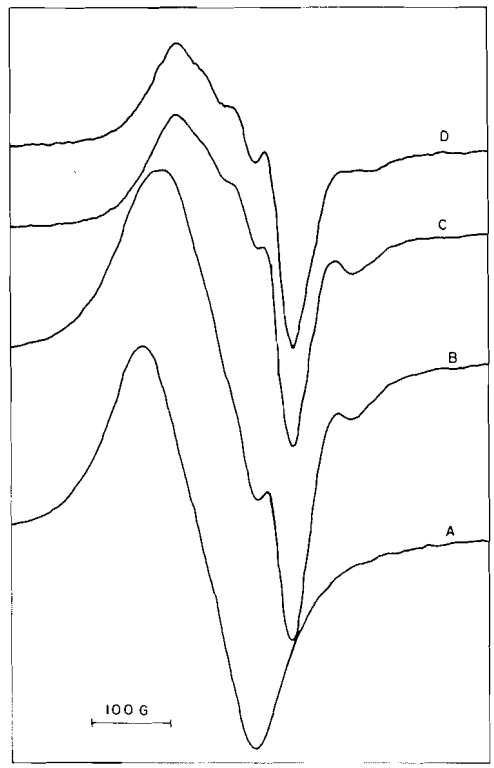

FIG. 7. Electron spin resonance spectrum for complex **3** (*D*) obtained through spectral subtraction using the experimental spectra at pH 3.2 (solvated ion *A*) and at pH 5.1 (mixture of solvated ion, complex **3** and small amount of complex **2**, *B*). The spectrum *C* was obtained from a subtraction of spectrum *A* from *B*; spectrum *D* takes in account the small amount of complex **2** in the spectrum *C*.

pH 7.6 corresponds to a contribution of both complexes. *X* turns out to be 0.45 for this case.

To obtain the spectrum of pure **3**, again the relation $C = A - BX$ was used where now *A* is the experimental spectrum at pH 5.1 and *B* is the experimental spectrum at pH 3.2, which corresponds to solvated free copper ion in solution. The result is shown in Fig. 7 ($X = 0.6$) from which it is clear that there is still a small contribution from complex **2**.

Single crystals for the high pH complex were obtained; the esr spectra and the angular variations in three orthogonal planes were measured (Fig. 8). A single esr line with no hyperfine structure is observed.

The angular variation was adjusted by the Zeeman Hamiltonian. The principal values for the g tensor are shown in Table 3. All these values are different, showing a small rhombic distortion in the symmetry of the complex.

Crystallography

Final atomic coordinates for non-hydrogen atoms and equivalent isotropic temperature factors are given in Table 4. The list of structure factors, anisotropic thermal parameters and hydrogen fractional coordinates have been deposited.[1] Bond distances and angles for the tris(hydroxymethyl)aminomethane moiety and for the coordination around the copper atom are given in Table 5.

The copper atom is located on a two-fold axis and is coordinated by an oxygen atom of a water molecule located on

the same two-fold axis. Five atoms coordinate the copper atom forming an approximate pyramid with a rectangular basis as depicted in Fig. 9, which has its base formed by a pair of oxygen and nitrogen atoms. The atoms of each pair are related by a two-fold axis and belong to two symmetrically related tris(hydroxymethyl)aminomethane groups. The vertex of the pyramid is formed by the oxygen atom located on the two-fold axis. In a unit cell there are four coordination complexes linked to one another by a system of hydrogen bonds (Fig. 10).

Discussion

The formation curves were obtained on the basis of the

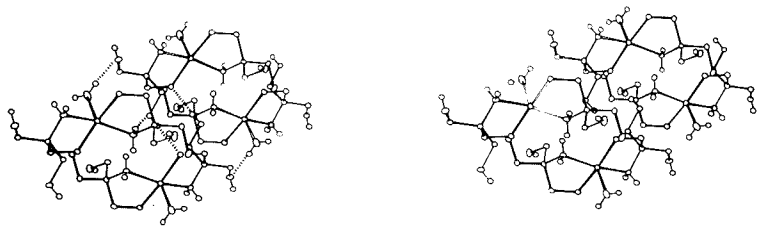

FIG. 10. Projection of the molecular packing showing the interaction through hydrogen bonds between four groups of the type depicted in Fig. 9.

TABLE 6. Relevant distances (Å) and angles (deg) in hydrogen bonds

Atoms	Distance O...O	Distance H...O	Angle O—H...O
O(3)—H(03)...O(1)	2.585(4)	0.72(4)	165.(1)
O(2)—H(02)...O(1)	2.716(4)	0.67(4)	175.(1)
O(W)—H(0W)...O(2)	2.752(4)	0.75(4)	162.(1)
N—H(N)...O(3)	3.113(5)	0.79(3)	168.(1)

equilibrium constants and reaction steps proposed for the Cu^{2+}—TRIS system (10).

The equilibrium analysis is rather complicated since eight different species are present in solution. Three species will be very predominant at different pH values: (*1*) the chelate complex $M(H_{-1}L)_2$ which above pH 9.5 is the only species present in solution; (*2*) the species ML_4 which near pH 7.6 is predominant and (*3*) the free solvated copper ion below pH 4.0. Together with the epr data, this analysis suggests that the highest pH complex observed by epr (complex **1**) could be assigned to the chelate since two nitrogen ligands show themselves in the room temperature spectrum. Our epr data show that the presence of this complex is significant down to pH 7.6 while the formation curves predict that at this low pH only ML_4 species would be significant. Therefore, our epr data seem to indicate that the formation curves in the region of pH above 7.2 should be displaced to lower pH, so that at pH 7.6 approximately 50% of the chelate species is present in the solution. This would require values for K_4 and K_{2b} to be lower and higher, respectively, than those given in ref. 10. Martell (10) considered the complete deprotonation of the hydroxyl groups, this leading to the structure corresponding to an uncharged species $M(H_{-1}L)_2$. This structure is essentially the same as the one obtained from X-ray crystallography except for the water molecule (see Fig. 9).

The epr results with the frozen solution suggest the occurrence of a rhombic distortion which is also observed for the high pH complex in the single crystal.

With regard to the optical spectra obtained at high pH it should be mentioned that similar complexes of aminoacids, where nitrogen and oxygen (carboxylate) ligands are involved, usually show a single broad band. In our case the splitting of the optical band is quite unusual; this could be explained alternatively in one of the following ways: (*a*) at high pH there is a coexistence of two different species, which have exactly the same epr spectrum, namely, $M(H_{-1}L)_2$ and $M(H_{-1}LL)^+$; the two optical bands are due to these different species and the formation curve for complex $(MH_{-1}LL)^+$ is wrong. (*b*) At high pH there is a single species with an optical band split in two bands. We believe this hypothesis should be preferred because upon freezing the splitting in the epr spectrum is not observed. Also, it is in closer agreement with the formation curves.

In the pH range between 6.0 and 7.5 the species which is predominant corresponds to our complex **2**. The equilibrium constant K_4 has to be corrected so that its maximum intensity would be shifted to pH 6.7 as indicated by the optical data (Fig. 4*a*).

Complexes of W(VI) and Mo(VI) with glycolic, lactic, chloro- and phenyl-lactic, mandelic, and glyceric acids studied by ^1H and ^{13}C nuclear magnetic resonance spectroscopy

M. Madalena Caldeira, M. Luisa Ramos, and Victor M. S. Gil
Department of Chemistry, University of Coimbra, 3049 Coimbra, Portugal

Received August 8, 1986

M. Madalena Caldeira, M. Luisa Ramos, and Victor M. S. Gil. Can. J. Chem. **65**, 827 (1987).

A proton and carbon-13 nuclear magnetic resonance study is reported on the number, stoichiometry, geometry, and stability of the complexes that form when sodium tungstate or sodium molybdate is mixed with each one of the following α-hydroxyacids in aqueous solution at pH values in the range 3–8: glycolic, lactic, chloro-3- and phenyl-3-lactic, mandelic, and glyceric acids. The predominant complexes have 1:2 composition and pK of formation of the order of −15 to −16.

M. Madalena Caldeira, M. Luisa Ramos et Victor M. S. Gil. Can. J. Chem. **65**, 827 (1987).

On rapporte une étude par rmn du ^1H et du ^{13}C sur le nombre, le stoechiométrie, la géométrie et la stabilité des complexes qui se forment lorsqu'on mélange du tungstate ou du molybdate de sodium avec l'un des α-hydroxyacides suivants, dans des solutions aqueuses dont le pH se situe entre 3 et 8 : acides glycolique, lactique, chloro-3 et phényl-3 lactiques, mandélique et glycérique. La composition des complexes prédominats est 1:2 et les pK de leurs formations sont de l'ordre de −15 à −16.
[Traduit par la revue]

Introduction

Very stable complexes are well known to form when α-hydroxycarboxylic acids are mixed with molybdate or tungstate salts in aqueous solution. Frequently, more than one complex can form, depending on the experimental conditions, namely the molar ratio of the complexing species and the pH of the solution. This explains most of the contradictory reports often found in the literature. In addition, the classical techniques used (potentiometry, conductimetry, polarimetry, spectrophotometry, cryoscopy) measure bulk properties that must somehow be separated into individual contributions.

Taking advantage of the fact that, at ordinary temperatures, ligand exchange is usually slow enough to enable distinct nmr spectra to be obtained for free and bound ligand in the various complexes, we have been carrying out a systematic study of such complexation reactions (the most recent paper in the series, ref. 1), as well as of complexes involving other oxo-ions: uranyl (2) and vanadate ions (3). The previous study with malic (CO_2H—CH_2—$CHOH$—CO_2H) (4), thiomalic (CO_2H—CH_2—$CHSH$—CO_2H) (1, 5), and tartaric (CO_2H—$CHOH$—$CHOH$—CO_2H) (6) acids is now extended to the following ligands:

A. Glycolic acid	$CH_2(OH)$—CO_2H
B. (L)-Lactic acid	CH_3—$CH(OH)$—CO_2H
C. (L)-Phenyl-lactic acid	C_6H_5—CH_2—$CH(OH)$—CO_2H
D. (D,L)-Chloro-lactic acid	CH_2Cl—$CH(OH)$—CO_2H
E. (L)-Mandelic acid	C_6H_5—$CH(OH)$—CO_2H
F. (D,L)-Glyceric acid	$CH_2(OH)$—$CH(OH)$—CO_2H

The system Mo(VI) + lactic acid will be only briefly mentioned in comparison with the tungsten counterpart, as the former was already included in ref. 1.

Experimental

Analytical grade sodium tungstate and sodium molybdate and commercially available hydroxyacids were used (unavailability of the optically active forms in two cases and failure in attempts to resolve the racemic mixtures preclude us from also using one of the optical isomers in such cases). To reduce the intensity of the OH nmr signal, the salts were dried at 120°C, the acids were lyophilized from a solution in deuterium oxide, and D_2O solutions were used throughout. Previous to use, lactic, chloro-lactic, and glyceric acid solutions in D_2O were heated in boiling water for 2 hours to accomplish depolymerization. The concentrations of the tungstate and molybdate solutions were established by weight and the acid solutions were standardized by potentiometry. The pH was adjusted by addition of solutions of DCl and NaOD: the pH* values quoted are the direct pH-meter readings (room temperature) after standardization with aqueous (H_2O) buffers. Whenever necessary, the ionic strength was kept approximately constant by making the solution 1 M in NaCl.

The ^1H and ^{13}C spectra were obtained on a Varian XL-200 nmr spectrometer at probe temperature (21 ± 1°C). The latter were recorded using proton-decoupling techniques with suppression of the nuclear Overhauser effect; in this manner, temperature fluctuations of the sample were reduced to ca. ±1°C. Dioxane and DSS were used as internal references, respectively, for ^{13}C and ^1H shifts. Typically, spectral widths of 10 000 Hz, acquisition times of 1.5 s, pulse delays of 8–12 s, and 2000 pulses were used when recording ^{13}C spectra.

Results and discussion

Proton and carbon-13 nmr spectra were obtained for D_2O solutions of various concentrations (in the range 0.02–1.0 M for ^1H spectra and 0.2–1.0 M for ^{13}C spectra) and of different molar ratios (3:1 to 1:3 or 1:4) of complexing species and of different pH* values. Since at low pH the signals are usually broad, suggesting extensive polymerization, and at pH > 8 complexation is almost nonexistent, the pH range covered was 3–7.5. The number and intensity of ligand (free and bound) signals, together with their changes with molar ratio and pH, enable the number of complexes to be established. Job's plots based on ^1H spectral intensities give the stoichiometry of the dominant complex in each case. When only one complex is formed, a formation constant is determined.

The ^{13}C and ^1H chemical shifts observed on complexation indicate the groups by which the ligand binds to the metal. Finally, vicinal proton–proton coupling constants are measured to give information on the conformation of the bound ligands C, D, and F.

We shall now briefly present the results obtained with each acid as ligand, dealing with the first ligand in the series (glycolic acid) in more detail, and compare with results in the literature, whenever existent, provided by other techniques.

(a) Glycolic acid

The ^1H nmr spectrum of glycolic acid is just one line (δ_H = 4.02 at pH* = 5.1) (apart from the contribution of the OH groups to the common OH signal), which gives rise to an AB spectrum when complexation to tungsten occurs; the center of

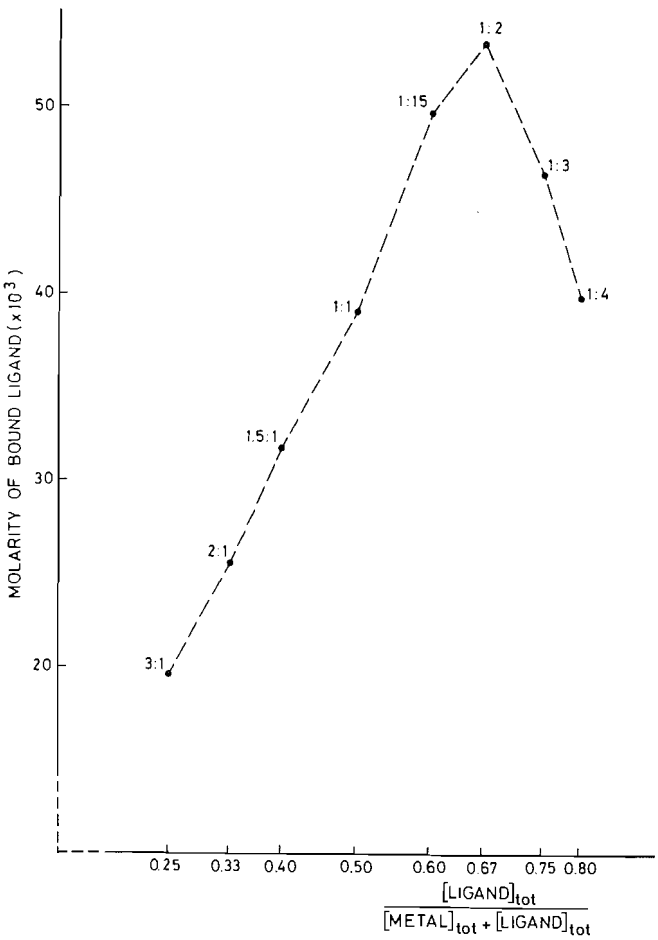

FIG. 1. Job's curve based on proton nmr spectral intensities for the system W(VI) + glycolic acid. Total concentration of complexing species 0.10 *M* (D_2O solutions, 1 *M* in NaCl, pH* = 5.1).

this spectrum is shifted by 1.08 ppm (to high frequency) with respect to free ligand (at pH* = 5.1) with $|\nu_A - \nu_B| = 0.17$ ppm and J_{AB} = 17.2 Hz. Only one complex is detected for the whole range of concentrations, pH, and molar ratios covered. The Job's plot given in Fig. 1 clearly shows that this is a 1:2 (metal:ligand) species.

A p*K* of formation of -15.7 ± 0.2 is obtained (from the measured concentrations of free and bound ligand for the various molar ratios, at pH* = 5.1, the ionic strength being kept approximately constant with NaCl 1 *M*) for the equilibrium

$$WO_4^{2-} + 2HY^- + 2H^+ \rightleftarrows WO_2Y_2^{2-} + 2H_2O$$

where the hydroxyacid is represented by H_2Y. In the calculation, due account was taken of the main equilibrium of polymerization of WO_4^{2-} for the conditions used (7)

$$12WO_4^{2-} + 18H^+ \rightleftarrows W_{12}O_{39}^{6-} + 9H_2O$$

with p*K* = −132.5; this is especially important for solutions having a higher content of metal ion.

That both the carboxylate and the hydroxyl groups are involved in chelation, with likely deprotonation of the OH group, is revealed by the proton and the carbon shifts. In particular, there is a big shift of the methylenic ^{13}C signal to high frequency on complexation. The δ_C values for the free ligand at pH* = 5.0 and the $\Delta\delta_C$ values upon complexation ($\Delta\delta$ = δ(complex) − δ(acid at same pH) are given in Table 1. At pH* = 7.2 similar shifts are observed (11.77 and 4.61) but at pH* = 3.0 they become 13.36 and 7.63, respectively, because the free ligand (pK_a = 3.8 (8)) is then almost entirely in the acid form (ionization of glycolic acid causes high frequency shifts of 1.42 and 3.22 ppm for the CH_2 and CO_2H groups, respectively).

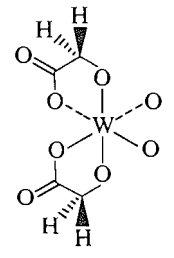
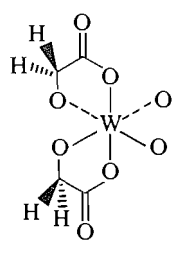
*Carbon 1 in the phenyl ring.

From the magnetic equivalence of the two ligand molecules we can conclude that the structure of a 1:2 monomeric pseudo-octahedral complex is either **I** or **II**.



I



II

If an analogy with the 1:2 complex of Mo(VI) with malic acid is allowed, for which the crystal structure was recently determined (9), then **I** is to be preferred. In both **I** and **II**, the two methylenic H nuclei become nonequivalent. It is noted that this nonequivalence is a result of the *cis*-MoO_2 arrangement and would not occur for a 1:2 *trans* dioxo species.

The effect of pH on the formation of the complex is illustrated by the following concentrations measured approximately by the nmr spectral intensities in a 0.003 *M*:0.067 *M* (metal:ligand) solution (1 *M* in NaCl): 6.0×10^{-2} *M* at pH* = 3.4, 5.4×10^{-2} *M* at pH* = 5.1, and 1.9×10^{-2} *M* at pH* = 7.2.

Only one complex is also detected in the case of molyb-

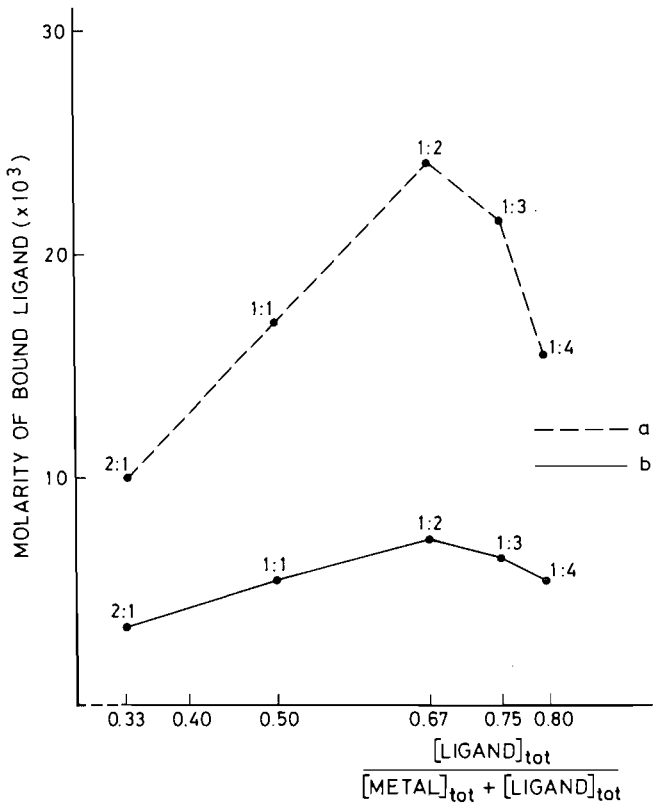

FIG. 2. Job's plots based on proton nmr spectral intensities for the system W(VI) + (L)-lactic acid: complexes *a* and *b*. Total concentration of complexing species 0.05 *M* (D_2O solutions, 1 *M* in NaCl, pH* = 5.0).

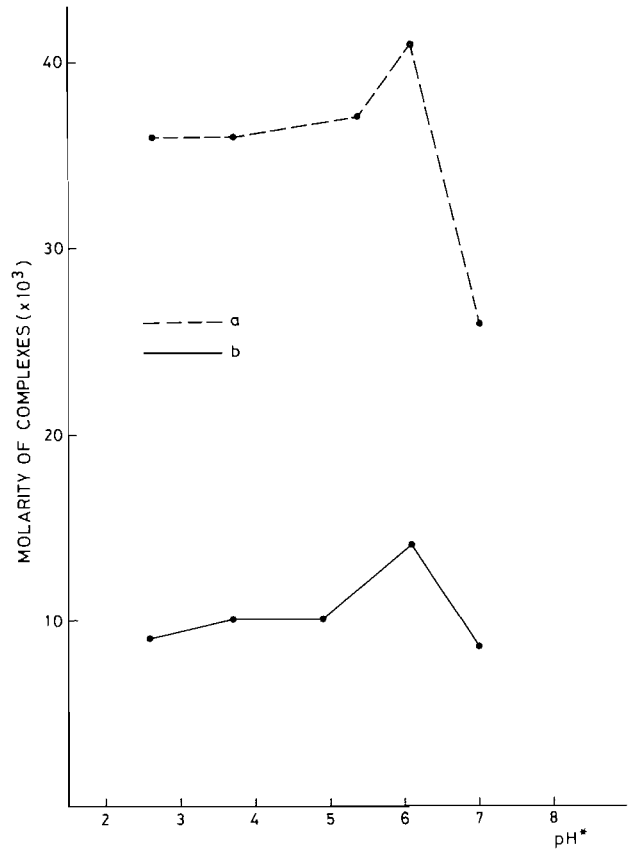

FIG. 3. Effect of pH on the concentration of the complexes (*a* and *b*) W(VI) + (L)-lactic acid (0.033 *M* : 0.067 *M* D_2O solution 1 *M* in NaCl).

denum. The proton nmr spectrum is broader than with tungsten and, instead of an AB pattern, a broad singlet (close to the OH residual signal) is observed. This broadening is due to partial reduction of Mo(VI) to paramagnetic lower oxidation states and (or) to more rapid exchange processes. The proton shift on complexation is 0.80 ppm; the carbon shifts are shown in Table 1.

Reliable integration of the signals in order to draw a Job's plot in this case was not feasible. But from qualitative inspection of the spectra and by analogy with W(VI), it seems safe to infer that the complex is again 1:2.

The formation of a 1:2 complex both with W(VI) and Mo(VI) was previously shown by the conductimetric and polarimetric studies of Brown (10), corroborated, in the case of Mo(VI), by Cadiot and Viossat using potentiometry (11) and, in the case of W(VI), by Wünsch and Nagen using uv spectrophotometry (12).

(b) Lactic, phenyl- and chloro-lactic, and mandelic acids

For lactic acid, both free and bound ligand give rise to A_3X spectra. In the case of W(VI), two complexes are formed, one being always dominant. The A doublet is almost not shifted upon complexation, but the X quartets are shifted by 0.94 and 1.08 ppm to high frequency, respectively, for the more and less abundant complex, at pH* = 5.0 (J_{AX} = 6.40 Hz and J_{AX} = 7.00 Hz, respectively); at this pH*, the δ_H values for free lactic acid are 1.34(A) and 4.12(X). Job's plots are shown in Fig. 2; the dominant complex is clearly a 1:2 species, but no stoichiometry can be unequivocally established for the weaker complex from these curves.

The effect of pH on the concentrations of the complexes is shown in Fig. 3; maximum complexation occurs at pH* $\simeq$ 6 for both cases.

The carbon shifts, at pH* = 5.0, for the most stable complex are presented in Table 1.

The structure of the complex is probably similar to that of the 1:2 complex of W(VI) with glycolic acid. We note, however, that the substitution of H in CH_2 by CH_3 leads to the possibility of formation of diastereomers. This may be the reason for the occurrence of two complexes in this case.

As expected, the use of (D,L)-lactic acid leads to additional signals of bound ligand due to the simultaneous involvement of D and L forms in the same complex.

For the system molybdenum + lactic acid only one complex is formed and its stoichiometry given by Job's method is 1:2 (1). A p*K* of formation of -14.7 ± 0.4 is calculated in the same way as done for tungsten + glycolic acid.

The proton shifts on complexation, at pH* = 5.1, are 0.07 and 0.74 ppm for CH_3 and CH, respectively; the carbon shifts are included in Table 1.

Complexation of W(VI) with lactic acid was previously mentioned in the literature (13, 14) but no quantitative study was reported. More abundant is the literature on the Mo(VI) + lactic acid system (15–17). Evidence for 1:2 complexation is found by applying various techniques. Cervilla and co-workers (17) suggested, in addition, the formation of 1:1 species at pH < 4.7 on the basis of spectrophotometry and cryoscopy; we could not corroborate those findings by nmr.

The results obtained with phenyl- and chloro-lactic acids and with mandelic acid are very similar to those for lactic acid as ligand, namely one complex with Mo(VI) of composition 1:2

TABLE 2. ^{1}H nuclear magnetic resonance parameters for W(VI) + phenyl-lactic acid and W(VI) + chloro-lactic acid (couplings in Hz)

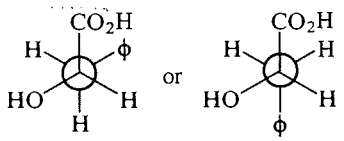
		δ_A	δ_B	δ_X	$\lvert J_{AB}\rvert$	J_{AX}	J_{BX}
(L)-Phenyl-lactic acid (pH* = 5.3)	Free ligand	2.75	2.96	4.27	14.0	8.2	3.9
	Complex *a* (dominant)	3.07	3.04	5.14	13.0	7.7	3.5
	Complex *b*	—	—	5.31	—	$J_{AX} + J_{BX}$ = 14.2	
(D,L)-Chloro-lactic acid (pH* = 5.2)	Free ligand	3.81	3.85	4.35	11.7	2.5	4.6
	Complex *a* (dominant)	3.87	4.00	5.17	12.1	2.6	4.2
	Complex *b*	—	—	5.29	—	$J_{AX} + J_{BX}$ = 9.3	

($pK = 16.0 \pm 0.3$ for (L)-phenyl-lactic acid, $pK = 14.8 \pm 0.6$ for (L)-mandelic acid as ligands) and two complexes with W(VI), one of composition 1:2 being largely dominant ($pK = 15.8 \pm 0.3$ for (L)-phenyl-lactic acid).

The tungsten(VI) – mandelic acid system had been previously studied by Richardson using potentiometry and conductimetry (19), by Brown using conductimetry and polarimetry (10), and by Banerjee and Bhattacharya using conductimetry and potentiometry (20); Richardson concludes that there is formation of a 1:3 complex and the others propose 1:2 complexation. The authors of refs. 10 and 20 show the formation of a 1:2 complex between Mo(VI) and mandelic acid, a result earlier pointed out by Souchay on the basis of a potentiometric study (21).

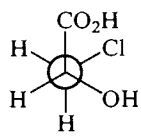
The carbon shifts are included in Table 1. The proton spectra of phenyl- and chloro-lactic acids are of the ABX type (plus the aromatic signals in the case of the former). The proton nmr parameters are given in Table 2 (due to overlap of the AB signals, only partial data could be obtained for the weaker complex).

The vicinal HH coupling constants of phenyl-lactic acid are not significantly altered by complexation, which points to a conformation of the bound ligand similar to the mean conformation of free ligand. A typical *gauche* coupling ($J_{BX} = 3.85$ Hz) and a typical *trans* coupling affected by an electronegative substituent, i.e., OH ($J_{AX} = 8.15$ Hz), suggest that the preferred staggered conformer of the acid is either



different from the conformation in the crystal (18).

The vicinal HH coupling constants for both free and bound chloro-lactic acid are particularly low, suggesting a conformation close to



in the complex and an important contribution of such a conformer in the rapidly rotating free ligand molecule.

TABLE 3. ^{1}H nuclear magnetic resonance parameters for W(VI) + (D,L)-glyceric acid (pH* = 5.2)

	δ_A	δ_B	δ_X	$\lvert J_{AB}\rvert$	J_{AX}	J_{BX}
Free ligand	3.71	3.81	4.14	12.1	6.4	2.8
Complexes: a_1	—	—	5.26	—	$J_{AX} + J_{BX}$ = 8.2	
a_2	—	—	5.24	—	$J_{AX} + J_{BX}$ = 8.2	
b_1	3.89	3.83	5.04	12.0	5.8	2.4
b_2	—	—	5.01	—	$J_{AX} + J_{BX}$ = 8.0	

Apart from the second-order pattern arising from the aromatic ring, which is little affected by complexation, the proton spectrum of mandelic acid is just one line, due to the C*H*(OH) group ($\delta_H = 5.02$ at pH* = 5.0). This shifts by 0.71 ppm on complexation to Mo(VI) and by 0.90 and 1.04 ppm respectively on formation of the more and the less stable complex with W(VI).

(c) (D,L)-Glyceric acid

There is now an additional OH group as potential coordinating site. Also, due to the use of the racemic mixture of glyceric acid, more complexes can form. In fact, two pairs of complexes a_1,a_2 and b_1,b_2 are detected with W(VI), the chemical shifts being very similar in each pair.

The ^{1}H nmr spectra are of the ABX type and the corresponding parameters are given in Table 3.

Since separate integration of the a_1 and a_2 signals and of b_1 and b_2 was not possible, Job's plots for $a_1 + a_2$ and for $b_1 + b_2$ were constructed; maximum intensity occurs in both cases for 1:2 composition.

Only one pair a,b of spectra (broader than with W(VI)) is observed with molybdenum(VI), also due to 1:2 complexes.

The carbon shifts are given in Table 1. The big difference between the shifts of CH_2OH and $CHOH$ on complexation is a clear indication that only the α OH group, together with CO_2H, is bound to the metal.

The vicinal HH coupling constants of bound and free ligand are not significantly different. One of the values is typical of a *gauche* coupling whereas the other is intermediate between a *trans* and a *gauche* coupling constant. For the free ligand, this means an about equal contribution of conformers **III**′ and **I**′ or

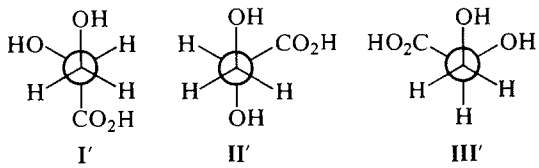
*Weaker complex.

III′ and **II′**:



However, the undecoupled $^{13}CO_2H$ signal (the Y part of a ABMY system) shows that $^3J_{CH(A)} + {}^3J_{CH(B)} + |^2J_{CH(X)}| = 9.0$ Hz, which, in view of the typical values for *trans*, *gauche*, and *geminal* ^{13}CH coupling constants in similar compounds (22), requires a significant contribution of **I′** (for which the carboxylic group is *gauche* to both H(A) and H(B)). We may, therefore, conclude in favour of the pair I′,III′.

The values of J_{AX} and J_{BX} for the bound ligand in b_1 and the sum $J_{AX} + J_{BX}$ in the other complexes are slightly smaller than for free ligand. This suggests a conformation intermediate between **I′** and **III′**, with stabilization of **III′** with respect to the free ligand.

Conclusion

Table 4 summarizes our findings relative to the number, composition, and, in some cases, approximate formation constants of the complexes formed between W(VI) or Mo(VI) and α-hydroxycarboxylic acids in aqueous solution (pH range 3–7.5).

Malic acid, with its second carboxylic group, was also included for comparison. The data were taken from refs. 4 and 23, after confirmation at 200 MHz and for dilute solutions (Fig. 4) of the results for W(VI) + malic acid previously obtained at ~1 *M* concentrations in a continuous wave 100 MHz spectrometer (23).[1]

[1]The new data requires that two corrections should be made to the initial work (23). Firstly, it was found that the position of the X signal of complex *b* (Fig. 4) is very sensitive to pH, shifting to higher frequency in acidic media, that being the real reason for the evolution of the spectrum with time reported in ref. 23. Secondly, carbon spectra were recorded and the shifts observed on complexation (10–12 ppm for *C*HOH, 5–6 ppm for the α CO_2H group, −1 to 0 ppm for the β CO_2H group) clearly show it is the α and not the β carboxyl group that is involved in chelation, together with the OH group (see also ref. 5).

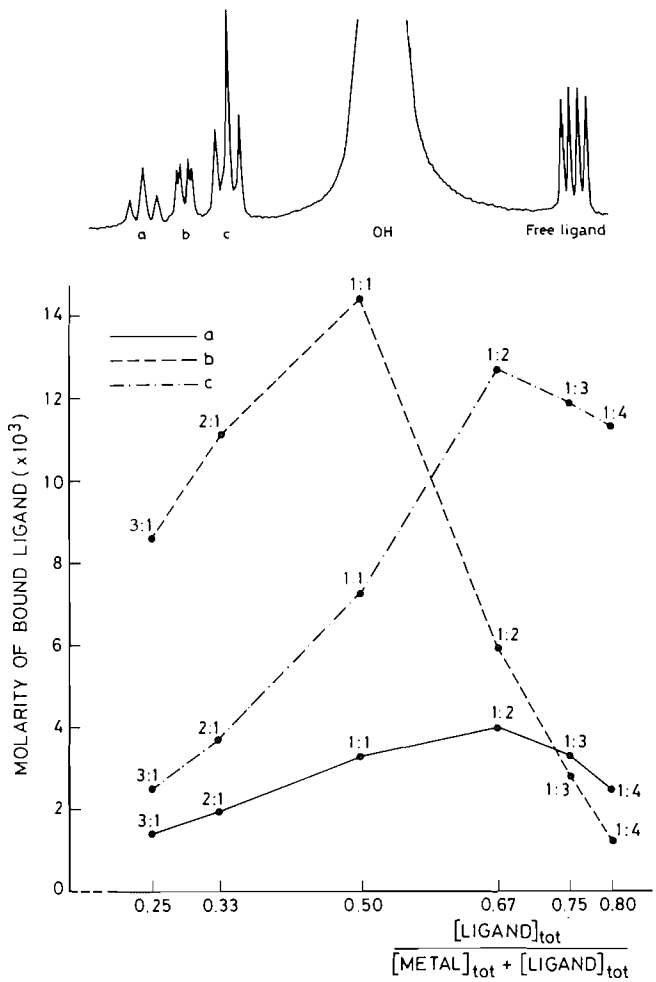


FIG. 4. The 200-MHz proton nmr *C*HOH signals for bound (complexes *a*, *b*, *c*) and free ligand in a 0.017 *M*:0.033 *M* WO_4^{2-} + (L)-malic acid solution in D_2O, and Job's plots as in Fig. 2 (pH* = 4.4).

The question marks in Table 4 refer to complexes of maximum concentration for the ratio indicated, in Job's plots, but which are not predominant in those conditions; in such cases, no stoichiometry can be directly inferred from the Job's method. Thus, for example, the weaker W(VI) + malic acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 80.58.250.72 on 09/07/12
For personal use only.

complex might be one of the 1:1 (or 2:2) complexes suggested by Cervilla *et al.* (24).

We note the occurrence of predominant 1:2 complexation in all cases (together with 1:1 complexation for malic acid). The weaker complexes indicated in Table 4 are presumably 1:2 diastereomers of the dominant complexes arising because of the asymmetric carbon atom; in accordance with this, glycolic acid leads to only one complex. The weaker complex is usually not detected when the metal is molybdenum.

A curious observation regarding the ^{13}C shifts on complexation of the acids to the metals is that $\Delta\delta_C$ for CO_2H is larger with W(VI), whereas $\Delta\delta_C$ for $CHOH$ is in general larger with Mo(VI). On the other hand, $\Delta\delta_H$ for $CHOH$ is smaller with Mo(VI).

Densities and apparent molar volumes of aqueous NaCl–KBr mixtures at 298.15 K. An alternative treatment

ALAN A. HUMFFRAY

Department of Physical Chemistry, University of Melbourne, Parkville, 3052, Victoria, Australia

Received September 2, 1986

ALAN A. HUMFFRAY. Can. J. Chem. **65**, 833 (1987).

In estimating properties of mixtures of electrolytes from those of the individual components, it is better to calculate the density directly using a mixing rule, rather than from the derived quantity, the apparent molar volume. Each component contributes to the density in proportion to its ionic strength fraction in the mixture; this simple mixing rule gives better agreement for NaCl–KBr mixtures than do Pitzer's equations, incorporating up to sixteen parameters. Some discrepancies in Kumar's published data (Can. J. Chem. **63**, 3200 (1985)) on NaCl–KBr mixtures are discussed.

ALAN A. HUMFFRAY. Can. J. Chem. **65**, 833 (1987).

Lorsqu'on évalue les propriétés de mélanges d'électrolytes par rapport à celles des composantes individuelles, il est avantageux de calculer la densité directement, en faisant appel à une règle de mélange, plutôt que d'utiliser une quantité qui est dérivée, comme le volume molaire apparent. Chaque composante contribue à la densité en proportion avec sa fraction de force ionique dans le mélange; cette règle de mélange simple conduit à une meilleure correspondance, pour des mélanges de NaCl/KBr, que les équations de Pitzer qui incorporent jusqu'à seize paramètres. On discute de quelques anomalies dans les données publiées par Kumar (Can. J. Chem. **63**, 3200 (1985)) pour des mélanges de NaCl/KBr.

[Traduit par la revue]

Introduction

Recently Kumar (1) has applied Pitzer's equations (2, 3) to the evaluation of the densities and apparent molar volumes of aqueous mixtures of NaCl and KBr, as well as to NaCl–$CaCl_2$ (4) and KCl–$CaCl_2$ (5). In the former case, with no common ion, a total of *sixteen* parameters was required for the calculations. These are the apparent molar volumes Φ_V^0 at infinite dilution, for NaCl and KBr, and the pressure derivatives of Pitzer's parameters $\beta^{(0)}$, $\beta^{(1)}$ and C^Φ, i.e. $(\partial\beta^{(0)}/\partial P)_T$, $(\partial\beta^{(1)}/\partial P)_T$, and $(\partial C^\Phi/\partial P)_T$ not only for NaCl and KBr, *but also for KCl and NaBr*, and the binary interaction parameters θ_{NaK} and θ_{ClBr} for interactions between ions of like charge. Although the total contribution to the apparent molar volume of the mixture from all the Pitzer parameters (i.e. the last fourteen listed above) is often not great, ranging from 0.6% at $I = 1$ *m*, $y_B = 1$ to 11.5% at $I = 4$ *m*, $y_B = 0$, the successful application of a treatment with so many parameters is a tribute to the essential soundness and usefulness of Pitzer's theory. (y_B is the ionic strength fraction of B, in this case KBr, in the mixture.) Unfortunately, for application to such a binary mixture with no common ion, measurements or tabulations of density as a function of concentration for *all four* electrolytes, NaCl, KBr, NaBr, and KCl are required, for evaluation of the parameters.

Young and Smith (6) showed previously that Wirth's results (7) for NaCl–KBr mixtures, at ionic strength up to 1 *m*, were well-fitted by eq. [1]

$$[1] \quad \Phi_V = \frac{n_A\Phi_A + n_B\Phi_B}{n_A + n_B}$$

where Φ_V, Φ_A, and Φ_B are the apparent molar volumes of the mixture (containing n_A mole of NaCl and n_B mole of KBr), and of NaCl and KBr, respectively, all at the same ionic strength. Since apparent molar volumes of individual electrolytes can be adequately represented as functions of (molar) concentration using only two (8, 9) or three (6) parameters, eq. [1] significantly reduces the number of parameters required, and, in particular, eliminates the need for data on NaBr and KCl. Equation [1] is shown below to fit the apparent molar volumes of mixtures with a precision comparable to that claimed by Kumar. In the process of comparison, some discrepancies were revealed in his data; these are discussed below.

Since the primary experimental results are the densities, or Δd ($= d - d_0$, where d and d_0 are the densities of the solution and water, respectively), it is surprising that so much emphasis in the past has been placed on the derived quality, apparent molar volume. Apart from Celeda (9), few workers have sought to utilise densities (or Δd) directly. Equation [1] implies a direct relationship between the density of a mixture and the densities of the component electrolytes at the same ionic strength, as outlined below. Application of this relationship avoids the inherent loss of precision in converting experimental densities into apparent molar volumes (10); as an example, Kumar's NaCl–$CaCl_2$ and KCl–$CaCl_2$ data show, at an ionic strength of 0.5 *m*, $y_B = 1$, Δd values of 15.01 (4) and 14.948 (5) mg cm^{-3} corresponding to Φ_V values of 20.40 (4) and 20.787 (5) cm^3 mol^{-1}, respectively, i.e. a variation of 0.4% in Δd leads to a 1.8% change in Φ_V.

Equation [1] may be written as

$$[2] \quad \Phi_V = \Sigma c_i\Phi_i/\Sigma c_i$$

where Φ_i is the apparent molar volume of component i at (molar) concentration c_i, and (molar) ionic strength $I = Q_i c_i$ ($Q = 1$ for 1:1, 3 for 2:1 electrolytes, etc.). The treatment is given in terms of molarities; if more convenient, molalities may be substituted, with appropriate changes in the equations where necessary. The relation between Φ_i and Δd_i is (10)

$$[3] \quad \Phi_i = \frac{1}{d_0}\left\{M_i - \Delta d_i \Big/ c_i\right\}$$

$$[4] \quad = \frac{1}{d_0}\left\{M_i - Q_i\Delta d_i \Big/ I\right\}$$

where M_i is the molecular weight of component i, and Δd_i ($= d_i - d_0$) is the density increment at ionic strength I. For a mixture, (increment Δd) eq. [3] becomes

$$[5] \quad \Phi_V = \frac{1}{d_0\Sigma c_i}\left\{\Sigma c_i M_i - \Delta d\right\}$$

Printed in Canada / Imprimé au Canada

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

Substitution of eq. [4] into eq. [2] gives

$$[6] \quad \Phi_V = \frac{1}{d_0 \Sigma c_i}\left\{\Sigma c_i M_i - \frac{1}{I}\left(\Sigma c_i Q_i \Delta d_i\right)\right\}$$

and, comparing [5] and [6],

$$\Delta d = \frac{1}{I}\left(\Sigma c_i Q_i \Delta d_i\right)$$

or

$$[7] \quad \Delta d = \Sigma y_i \Delta d_i$$

where $y_i = c_i Q_i / I$ is the ionic strength fraction of component i. Thus, the mixture rule for densities resembles that for apparent molar volumes (eq. [2]), with ionic strength fraction replacing mole fraction.

Equation [7] is shown below (Table 1) to fit Kumar's density measurements more precisely than eq. [1] fits the molar volumes, and significantly more precisely than Pitzer's equations, utilising all sixteen parameters.

Discussion

Inspection of Kumar's data on NaCl–KBr mixtures reveals that, although the densities and apparent molar volumes for KBr alone are in good agreement with those of Isano (11), the agreement of the tabulated densities for NaCl alone (at $y_B = 0$) is less satisfactory, both with results of other workers (3, 12), and with values calculated using the NaCl parameters quoted by Kumar in his Table 2 (1). For example, at $I = 4\ m$, $y_B = 0$, the observed Δd/mg cm^{-3} is 138.445, whereas Roger and Pitzer (3) quote a specific volume of 0.879457 cm^3 g^{-1} corresponding to $\Delta d = 140.018$, Romanklw and Chou (12) quote 139.793, and the value calculated from Kumar's parameters is 139.814. Evaluation of Φ_V from the first and last of these values leads to a difference of 0.33 cm^3 mol^{-1}, i.e. thirty three times the standard deviation of fit claimed. The observed densities at $I = 1\ m$ and 3 m are also too low, suggesting an error in a stock solution, but that at $I = 2\ m$ is too high!

For this reason, eqs. [1] and [7] were tested for conformity with Kumar's data, not by evaluating Φ_A, Φ_B and Δd_A, Δd_B from equations empirically fitted to experimental data (3, 6, 7, 10, 11), but by taking Φ_A and Δd_A, Φ_B and Δd_B from the tabulations at $y_B = 0$ and 1, respectively, and comparing calculated Φ_V for other values of y_B with the tabulated ones. Standard deviations for the difference between calculated and observed values are listed in Table 1, columns 2 and 4; in evaluating the standard deviations, calculations at $y_B = 0$ and 1 were not included.

Table 1, column 2 shows the fit for Φ_V is better at $I = 4\ m$, but somewhat poorer at $I = 1$ to 3 m than the fit claimed by Kumar (values in column 3, Table 1). This claimed precision, however, is not readily verified, because the parameters for KBr quoted in Kumar's Table 2 (1) are erroneous. The KBr densities from the reference (11) quoted by Kumar lead to the following values of the parameters with their standard deviations (Kumar's tabulated values in parentheses):

$$\Phi_V^0 = 33.94 \pm 0.27\ (34.08),\ 10^5\ (\partial\beta^0/\partial P)_T\ 1.35 \pm 0.66\ (4.93),\ 10^5\ (\partial\beta^1/\partial P)_T\ -1.22 \pm 3.83\ (9.18),\ 10^6\ (\partial C^\Phi/\partial P)_T\ -2.00 \pm 1.84\ (28.15)$$

The large standard deviations for the parameters, and the large standard deviation of fit (0.37 cm^3 mol^{-1}) arise from fitting a four parameter equation to only seven data points. Table 2 illustrates the improvement in calculating the apparent molar volume for KBr alone using these, rather than Kumar's published values.

TABLE 1. Standard deviations of fit for Φ_V and Δd*

	$\sigma(\Phi_V)$/ cm^3 mol^{-1}		$\sigma(\Delta d)$/mg cm^{-3}		
I/m	(*a*)	(*b*)	(*c*)	(*d*)	(*e*)
1	0.040	0.034	0.035	0.092	0.061
2	0.069	0.056	0.029	0.255	0.143
3	0.16	0.092	0.020	0.401	0.169
4	0.11	0.210	0.064	0.675	0.254

*(*a*), from eq. [1]; (*b*), Kumar's results (1); (*c*), from eq. [7]; (*d*), Kumar's results without mixing parameters θ_{ik}; (*e*) Kumar's results with mixing parameters θ_{ik}.

TABLE 2. Apparent molar volume of KBr solutions*

	Φ_V/cm^3 mol^{-1}		
I/m	(*a*)	(*b*)	(*c*)
1	35.59	35.61	39.81
2	36.42	36.40	45.07
3	36.98	37.00	51.41
4	37.47	37.46	59.00

*(*a*), calculated from measured density (11), by eq. [3]; (*b*), calculated from re-evaluated Pitzer parameters; (*c*), calculated from Kumar's parameters (Table 2, ref. 1).

Kumar's tabulated experimental density increments Δd correlate well (Table 1, column 4) with eq. [7]; columns 5 and 6 in Table 1 give Kumar's claimed standard deviations for comparison, column 5 without, and column 6 with, the mixing parameters θ_{ik}. Equation [7] gives a significantly better fit; the standard deviations are lower than those claimed by Kumar when the binary mixing parameters are included. The larger standard deviations for Kumar's procedure is undoubtedly at least partly attributable to the discrepancies discussed above.

A further test of equation [7], on systems for which $I \neq \Sigma c_i$, was performed on Kumar's data for KCl–$CaCl_2$ (5) and NaCl–$CaCl_2$ (4) mixtures. The agreement for KCl–$CaCl_2$ was excellent, the largest standard deviation in Δd being 0.025 mg cm^{-3} at $I = 3\ m$, for which Kumar's values were 0.258 mg cm^{-3} without θ_{KCa} and 0.101 mg cm^{-3} with θ_{KCa} (5). For NaCl–$CaCl_2$ mixtures, the agreement was less satisfactory, but at each ionic strength, the standard deviation was smaller than that quoted by Kumar.

Pitzer's equations incorporating the pressure derivatives have a useful role to play in dealing with mixed electrolyte solutions under elevated pressures, but, for calculating densities at atmospheric pressure, a simple mixture rule dependent on ionic strength fraction is more precise, and requires fewer parameters.

Cyclic nitronates from the diastereoselective addition of 1-trimethylsilyloxycyclohexene to nitroolefins. Starting materials for stereoselective Henry reactions and 1,3-dipolar cycloadditions[1]

MICHAEL A. BROOK[2] AND DIETER SEEBACH

Laboratorium für Organische Chemie der Eidgenössischen Technischen Hochschule, Universitätstr. 16, ETH-Zentrum, CH-8092, Zürich, Switzerland

Received September 11, 1986

MICHAEL A. BROOK and DIETER SEEBACH. Can. J. Chem. **65**, 836 (1987).

Induced by a stoichiometric excess of dichloro(diisopropoxy)-titanium, 1-trimethylsilyloxycyclohexene and (*E*)-nitroolefins (R—CH=CHNO$_2$, R = C_6H_5, *p*-$C_6H_4CH_3$, *p*-$C_6H_4OCH_3$, *p*-C_6H_4CN, CH_3) combine in CH_2Cl_2 solution at −90°C *preferentially* with relative topicity *ul*, opposite to the corresponding reaction of enolates or enamines. The primary products are the epimeric bicyclic nitronates **4–6**, which can be separated, and which are converted by KF in MeOH to the alkyl or aryl (nitroethyl)-substituted cyclohexanones **1** and **2** (Table 1). Instead of being solvolysed, the cyclic nitronates **4–6** can be used for nitroaldol additions to give the trisubstituted hexahydrobenzopyranols **15–19**. Alternatively, **4–6** can be used in 1,3-dipolar cycloadditions with acrylates to furnish the tricyclic compounds **22–31**. In either case, products with four asymmetric carbon atoms (not including acetal centres) are produced diastereoselectively. The addition described here is yet another example of an *ul* combination of trigonal centres induced by Lewis acids, overriding the influence of the configuration of the donor component.

MICHAEL A. BROOK et DIETER SEEBACH. Can. J. Chem. **65**, 836 (1987).

À −90°C et sous l'influence d'un excès stoechiométrique de dichloro(diisopropylate) de titane, le triméthylsilyloxy-1 cyclohexène et les nitrooléfines-(*E*) (R—CH=CHNO$_2$, R = C_6H_5, *p*-$C_6H_4CH_3$, *p*-$C_6H_4OCH_3$, *p*-C_6H_4CN et CH_3) en solution dans le CH_2Cl_2 se combinent avec une topicité relative *préférentielle ul* qui est opposée à celle observée au cours des réactions correspondantes des énolates ou des énamines. Les produits primaires sont les nitronates bicycliques épimères (**4–6**) qui peuvent être séparés et qui, sous l'influence du KF dans le méthanol, peuvent être transformés en nitroéthyl cyclohexanones substituées par des groupements alkyles ou aryles (composés **1** et **2** du tableau 1). Si on ne les solvolyse pas, les nitronates cycliques **4–6** peuvent être utilisés lors d'additions nitroaldoliques conduisant aux hexahydrobenzopyranols trisubstitués (**15–19**). Par ailleurs, les composés **4–6** peuvent être utilisés dans des cycloadditions dipolaires-1,3 avec les acrylates pour donner les composés tricycliques **22–31**. Dans chacun des cas, les produits contenant quatres atomes de carbone asymétriques (en ne comptant pas les centres des acétals) sont obtenus avec une diastéréosélectivité. L'addition décrite ici n'est qu'un autre exemple d'une combinaison *ul* de centres trigonaux qui est induite par des acides de Lewis et qui a plus d'importance que l'influence de la configuration des composantes du donneur.

[Traduit par la revue]

Introduction

Extensive investigations of the properties of compounds containing the nitro group have been undertaken (2). Their use in organic synthesis has been somewhat limited. This situation has been changing recently, as the utility of these compounds in selective carbon–carbon bond forming processes becomes apparent. One obvious limitation is the paucity of nitro group containing natural products. Presently, however, there are more and more methods available for cleanly converting the nitro group into the common functional groups (3).[3]

One particularly versatile type of nitro containing compounds are the nitroolefins (5). Our interest in these compounds stemmed from previous work, which showed that highly diastereo- (6, 7) and enantioselective Michael additions (8) of enamines (3, 6, 7) or of lithium enolates (9) to nitroolefins are possible.

Risaliti and co-workers (6) have demonstrated in a series of papers that enamines add to nitroolefins with relative topicity *lk*.[4,5] This preference is also observed, albeit to a somewhat lesser extent, with lithium enolates (2, 9) (Scheme 1). While the stereochemical course of the addition of lithium cyclohexenolate to 1-nitropropene can be reversed by changing the nitroolefin configuration (9*a*), this is not possible with β-nitrostyrene (9*b*; also D. Seebach and Th. Laube, ETH-Zürich, unpublished results). However, enantioselection in this Michael addition to nitroolefins can be achieved by choosing an appropriate chiral auxiliary (12; also T. Mukhopadyay, ETH-Zürich, unpublished results). In addition, enamines derived from prolinol ethers gave Michael adducts with up to 95% e.e. (enantiomeric excess) (8).

The other isomer, formally derived from an *ul* addition of the enamine to β-nitrostyrene, is accessible by acid-catalyzed equilibration of the *lk* product. This process is not synthetically useful, however, both because the isomerization is not complete (**1** → **1/2**, 2:1) and the separation of the products is relatively difficult (ΔR_f (silica gel, petroleum ether/ether) ca. 0.04). In an independent study, Mukaiyama and Stevens have found that *ul* addition occurs with the Sn(II) enolate of cyclohexanone and β-nitrostyrene (11).

The use of nitroolefins as a^2 reagents is of interest for synthesis because of the high stereoselectivity achievable in Michael reactions to them. However, the utility would be further increased if the inherent d^1 reactivity of the nitronates **3**, formed upon the addition of a nucleophile to a nitroolefin, could be exploited (Scheme 2). In this way, the nitroolefin functionality would be used for selective formation of two carbon–carbon bonds. Only a few examples of the combination of a^2 and d^1 reactions of nitroolefins have hitherto been described (14).

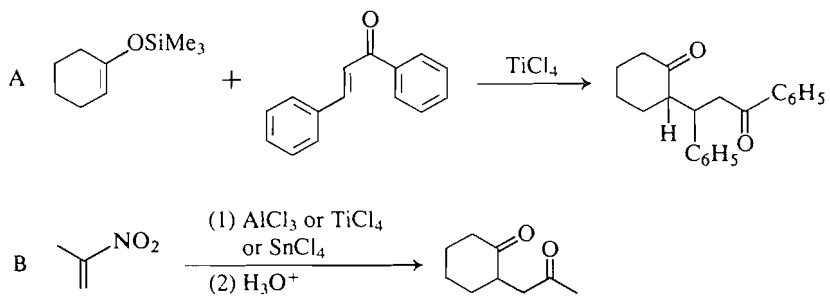

SCHEME 3

Our goal at the outset of this work was to develop both the a^2 and d^1 reactions of nitroolefins such that they occur diastereoselectively and enantioselectively. The present report describes our efforts to achieve diastereoselection.

The a^2 reaction

Results

It was hoped that the sense of diastereoselectivity of the reaction between nitroolefins and carbonyl compounds could be changed by switching from basic to acidic conditions. In place of Li enolates or enamines as nucleophiles, trialkylsilyl enol ethers would be used, with activation by Lewis acids.

Mukaiyama and co-workers first showed that silyl enol ethers will undergo the Michael addition with a variety of electrophiles in the presence of Lewis acids (15, 16) (Scheme 3A). Yoshikoshi and co-workers have demonstrated that 2-nitropropene, in the presence of a variety of Lewis acids, is also a good electrophile for the reaction (17) (Scheme 3B). In neither case was the stereochemical course of the reaction discussed.[6]

Our investigation of the Lewis acid mediated addition of silyl enol ethers to nitroolefins shows that the stereochemical course of the reaction depends strongly on the Lewis acid: the addition of 1-trimethylsilyloxycyclohexene to β-nitrostyrene at −90°C, in the presence of one equivalent of $TiCl_4$, gives rise to both diastereomeric Michael adducts **1** and **2**. In addition, however, two diastereomeric cyclic nitronates **4** and **5**, formally arising from a cycloaddition process, are isolated (Scheme 4). There was no overall discrimination between *lk* addition (**1** + **4**) and *ul* addition (**2** + **5**). These results contrast with the above-mentioned selective additions of the lithium enolate or morpholinoenamine of cyclohexanone to β-nitrostyrene (6, 9), which occur with relative topicity *lk* (up to >99:1). We chose to look optimistically at this apparently negative result, as an indication that further modification of the Lewis acid would lead to higher proportions of the hitherto less readily accessible product arising from an *ul* addition of the reactants. Systematic variation of the Lewis acid led to the discovery that the use of three equivalents[7] of $Cl_2Ti(O\text{-}iPr)_2$ resulted in the suppression of the formation of the Michael adducts **1** and **2**; instead, three silylated nitronates **4**, **5**, and **6** were isolated in good

[6]Heathcock has recently described stereochemical results for a variety of related Michael additions of silyl enol ethers (and ketene acetals) to α,β-unsaturated carbonyl compounds (18). The steric course of the reaction is governed by the nature of the silyl enol ether, by the nature of the Lewis acid, and not by the geometry of the silyl enol ether.

[7]Three equivalents were used to force the reaction to completion. While the reaction will take place with smaller quantities of the Lewis acid, it is more sluggish and some equilibration occurs, favouring the formation of the product of *lk* addition.

yield (Scheme 5). The products are easily separable,[8] mostly crystalline materials, which are indefinitely stable (**4***a*, **5***a* for more than 8 months at reduced temperatures in the absence of moisture).

The survival of the O—Si bond to exposure to an aqueous work-up and flash chromatography (19) is surprising in light of the facility with which trimethylsilyl ethers normally undergo hydrolytic cleavage (20). In fact, it is this instability to aqueous conditions that obviates their use as a protecting group. More interesting, however, is the diastereoselectivity of the reaction.

Table 1 shows the results of the addition of 1-trimethylsilyloxycyclohexene to five nitroolefins in the presence of three equivalents of $Cl_2Ti(O\text{-}i\text{Pr})_2$: with the exception of 1-nitropropene, the *ul* product **5** is favoured over the *lk* products **4** and **6**, by as much as 4:1. Dichloro(diisopropoxy)-titanium led to the highest selectivity for the *ul* addition of the Lewis acids tested. Varying the size of the alkoxy group on the titanium (OMe, OEt, O-*t*Bu), the alkyl group on silicon (Et), or the size of the R group of the nitroolefin (R = *i*Pr) led to *decreased* diastereoselectivities.

Hydrolysis of the three products **4**, **5**, and **6**, with KF/methanol, led to the known Michael adducts **1** and **2** (**4** and **6** → **1**, **5** → **2**, Scheme 5).[9] This proves the relative configuration at the newly formed carbon–carbon bond. The assignment of the *trans* ring junction (**4** and **5**) was made using nuclear Overhauser effect (nOe) measurements: irradiation with the frequency of the trimethylsilyl hydrogens led to a large enhancement of the phenyl signal with compounds **5***a* and **6***a*, but no enhancement with **4***a*. Knowing the relative configuration at the newly formed carbon–carbon bond, the ring junction must be *trans* for both **4***a* and **5***a*, and *cis* for **6***a*. By analogy, the *para*-substituted derivatives **4***b–d*, **5***b–d*, and **6***b–d* are assumed to have the same relative configurations at the bridgehead position.

The configuration of products **4***e*, **5***e*, and **6***e* was assigned by hydrolysis to the known Michael products (6, 9) and by spectroscopic comparison with the aromatic nitronates. All physical and spectroscopic data are consistent with the assigned structures.

Finally, it was possible to obtain crystals of **4***a* suitable for X-ray structure analysis. The *trans* fusion of the rings and the

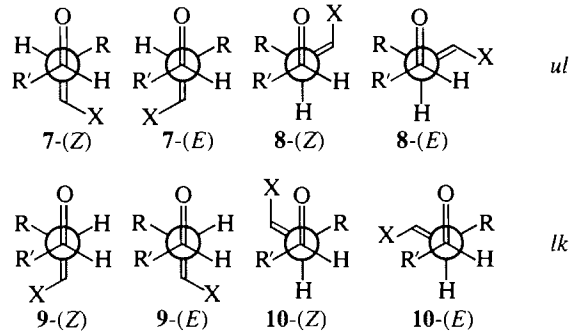
trans configuration of the $OSiMe_3$ and phenyl groups are clearly evident from Fig. 1.

Discussion

The configuration of the isomer formed upon the addition of a metal enolate (M = Li, BR_2) to an electrophile (aldehydes, nitroolefins, etc.) is dependent on the geometry of the enolate: with (*E*)-enolates the trigonal centres combine with relative topicity *lk*; with (*Z*)-enolates, with relative topicity *ul* (21, 22). So many examples of such a geometrical dependence on diastereoselectivity exist that this relationship has become the standard by which related aldol and Michael reactions are judged (21–24*a*).

However, over the last five years a series of reactions has been described for which this geometrical relationship does not hold. When other elements of the periodic table are employed in the aldol reaction, such as $OB(OR)_2$ (24, 25), Si (26), Sn (27), Ti (28), Zr (29), and $S[(Me_2N)_3S^+$, TAS] (30), products arising from an *ul* addition are obtained *regardless of the geometry of the enolate*. Complementarily, allyl derivatives of Si (31) and Sn (32, 33) add to aldehydes in an *ul* approach, again regardless of the geometry of the allylic double bond. To this series, and there are many other examples, can be added the Michael addition to aromatic nitroolefins presently under consideration; contrary to the "rule", an (*E*)-enolate (1-trimethylsilyloxycyclohexene) preferentially adds to the nitroolefin in an *ul* fashion, to varying extents (cf. the above-mentioned addition of Sn enolates to nitrostyrene (11)).[10]

[10]With 1-trimethylsilyloxycyclohexene, the alkyl nitroolefin, 1-nitropropene, reacted to give predominantly the *lk* addition product, but to a far lesser extent than is the case of Li cyclohexenolate (9*a*) or enamines (6*b*) as the nucleophiles.



SCHEME 6

Reactions in which diastereomeric starting materials lead to the same diastereomeric product can be useful for synthesis and are interesting mechanistically. Possible explanations for the *ul* preference that has been observed in the examples cited (1, 24–33) will be discussed below.

Lewis acid

Most of the reactions that are independent of the enolate/allylic double bond geometry are performed in the presence of a Lewis acid, either the metal on the donor itself, or one specifically added. The nature of the Lewis acid is critical in determining the steric course of the reaction. As described above, the change from $TiCl_4$ to $Cl_2Ti(O\text{-}iPr)_2$ in the Michael addition under discussion led to a change from no selectivity to *ul* selectivity. Keck *et al.* (34) have observed a complete reversal of diastereoselectivity in the addition of crotylstannanes to aldehydes, depending on the Lewis acid. In addition, Danishefsky and co-workers (35) have described a relationship between the Lewis acid strength and the diastereoselectivity of the hetero Diels–Alder reaction between (*E*,*Z*)-2,4-dimethyl-1-methoxy-3-trimethylsilyloxy-1,3-butadiene and benzaldehyde. With the stronger Lewis acid $TiCl_4$, a moderate *lk* selectivity is observed (Mukaiyama reaction, refs. 15, 16, 36). With the weaker Lewis acid $MgBr_2$, *ul* addition is preferred; cf. the present case: nonselective with $TiCl_4$, *ul* selective with the weaker Lewis acid $Cl_2Ti(O\text{-}iPr)_2$. At this point it appears to us difficult to assess the nature of the electronic interactions of the Lewis acid in the transition state.

Steric effects

A variety of transition state models has been proposed for those reactions in which an *ul* approach is observed. All of these fall into one of two classes; the open transition state (addition to aldehydes of allylsilanes (31), allylstannanes (32), TAS enolates (30*b*), or the Michael addition to α,β-unsaturated carbonyl compounds of silyl enol ethers and silyl ketene acetals (18*b*)) and the synclinal transition state (addition to aldehydes of allyl stannanes (33), of bulky lithium ester enolates (37), of trichlorotitanium enolates (tilt boat, 28*b*), of bis-cyclopentadienylchlorozirconium enolates (twist boat, 29*a*), and of enol boronates (24, 25)).

Arguments (30*b*, 31, 32) for an "open" transition state suggest that minimizing the steric interaction between R and R′ is the most important feature of the approach trajectory (i.e., **7**, **10** more favourable than **8**, **9**) (Scheme 6). The "open" *ul* transition state **7** was favoured over *lk*-**10** by the corresponding authors either for reasons that were not given (32) or because it was thought to involve a minimization of electrostatic repulsion between two oxygen atoms (30*b*). Let us consider these two factors separately.

The importance of the steric interaction between R and R′ is

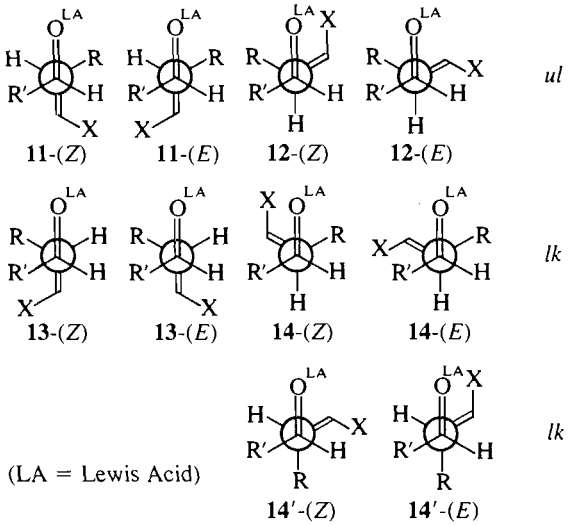
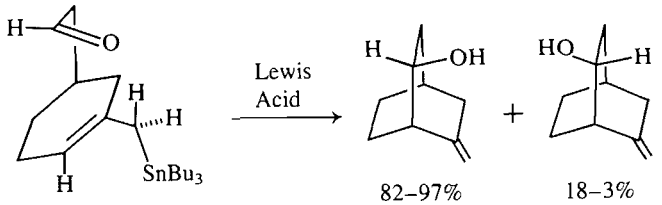
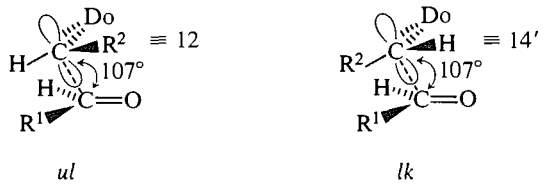


SCHEME 7



SCHEME 8



Priority sequence: =O > R^1 > H, Do > R^2 > H, =CX > R^2 > H
(Do = Donor)

SCHEME 9

overemphasized in our view. Taking butane as a model system, for example, a destabilization of only 0.8 kcal/mol occurs on going from the *anti* to the *gauche* orientation (38). Although the R, R′, and C=CHX groups are more sterically demanding than the methyl group of the model system, the forming carbon–carbon bond will also be longer in the transition state and these interactions will be less severe. Only when R or R′ is very bulky, for example, with α-substituted enolates or α,α,α-trisubstituted aldehydes, will the R/R′ steric interaction dominate the relative topicity of the approach of the donor and acceptor. Such interactions will favour a return to the "normal" reactivity in which (*E*)-enolates undergo *lk* addition and (*Z*)-enolates undergo *ul* addition to aldehydes.

In most cases in which the "open-chain" transition state was postulated, the Lewis acid was ignored. The location of the Lewis acid, particularly when its size is relatively large such as with TiX_4, will likely have a critical bearing on the relative energies of the transition states. Current evidence is compatible with a Lewis acid chelation to the aldehyde (in the aldol reaction) *trans* to the R′ group for steric reasons (33*b*, 39; see also ref. 15 cited in ref. 25*a*).[11] If one now compares the steric interactions, including the presence of the Lewis acid (Scheme 7), it seems likely that transition states **11** and **14** should be destabilized with respect to **12** and **13**.

In reactions for which chelation can occur between X (the donor) and the Lewis acid, for example with $TiCl_3$ enolates (28*b*), the synclinal transition state **12** should be favoured over **13**. However, even when this is not the case, as with allyl metal derivatives (31, 33), there is good evidence that a synclinal transition state is favoured.

In the transition state, partial charge will build up or disappear at the acceptor and donor ends. In nonpolar solvents, a common feature of the geometry independent reactions, solvation of these charges will not be efficient and the open transition state should be disfavoured. In support of this statement are the observations that the steric course of some aldol reactions (41, 42) changes from synclinal to open-chain on going from aprotic to protic solvents, the latter being better able to solvate charges.

Convincing evidence for a synclinal transition state comes from the work of Denmark and Weber (33). The Lewis acid catalyzed cyclization of an allylstannane to an aldehyde takes place with very high synclinal (*ul*) selectivity (Scheme 8). The authors (33*b*) concluded that the origin of the preference for a synclinal approach is not related to steric factors, but deferred further explanation.

Bürgi–Dunitz approach

Assuming that the reactants follow a synclinal approach for the reasons just given, it is still necessary to discriminate between an *ul*-**12** or *lk*-**14′** approach.[12] Bürgi and Dunitz have shown that nucleophiles attacking a carbonyl group approach the CO plane not at 90°, but canted at ca. 107° (43–45). When it is a nucleophile with enantiotopic faces, as is the present case, the closest approach of the reacting partners will occur when the proton, the smallest substituent on the trigonal centre of the donor, is antiperiplanar to the acceptor C=O bond (Scheme 9), the "antiperiplanar hydrogen rule" (7, 9). Based on the ability of the reactants to approach more closely in **12** than **14′**, the former should be the more favourable transition state.

Recently, Gennari and co-workers have performed semi-empirical calculations (MNDO) that have allowed an estimation of the energy difference between the *ul* and *lk* approaches (25*a*). By fixing the distance between the two bond forming carbon atoms at 2 Å, and assuming a synclinal approach, they have "modelled" the transition state of the aldol reaction of (*E*)- and (*Z*)-enolborates (dialkoxyenolboranes) and (*E*)-enolborinates (dialkylenolboranes) with benzaldehyde.

The calculations indicate that for the (*Z*)-enolborate, the *ul* approach (Scheme 7, **12**-(*Z*)), a twist boat, is favoured by 2.1 kcal/mol over the *lk* approach (Scheme 7, **14**-(*Z*) or **14′**-(*Z*)). For the (*E*)-enolborate, the half-chair, *ul* approach (Scheme 7, **12**-(*E*)) was more favourable by 2–3 kcal/mol than the *lk* approach (Scheme 7, **14**-(*E*) or **14′**-(*E*)). In contrast, the half-boat, *lk* approach was favoured by 1.2 kcal/mol over the *ul* approach for the (*E*)-enolborinate. This mechanistic

[11]X-ray analyses of boron (40*a*) and tin (S.E. Denmark, Illinois-Urbana, private communication) complexes with aromatic aldehydes show that the Lewis acid lies *trans* to the Ar group in the C—C=O plane. With titanium derivatives, the titanium is not forced to lie in the C—C=O plane. Helmchen and co-workers (40*b*) have shown, by the X-ray analysis of a $TiCl_4$-chelated ester, that there is a torsional angle (C—C=O—Ti) of >60°.

[12]Transition state **14** was discounted on steric grounds (*vide supra*), therefore its rotamer **14′** will be considered.

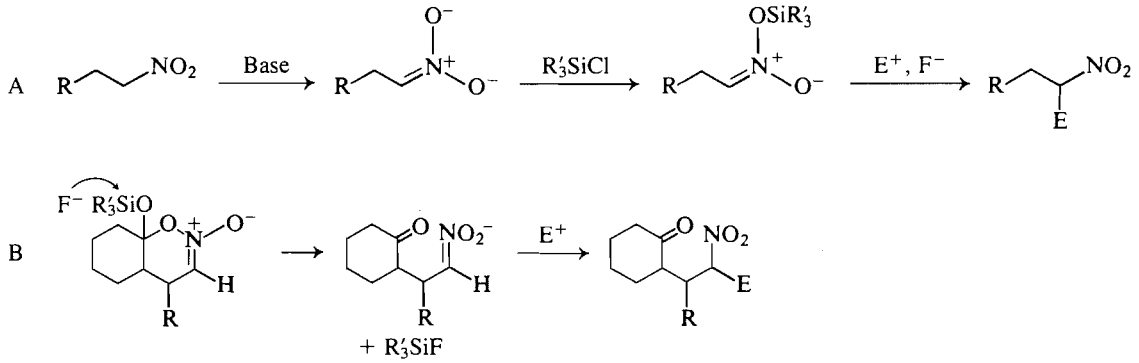


SCHEME 10

changeover, which correlates nicely with experimental observations, was ascribed by the authors to transannular interactions between the hydrogens and alkyl groups on the boron atom in the twist-boat *ul* approach.

Thus, the preference for a synclinal, *ul* approach of two trigonal centres, when the steric outcome does not display a dependence on the geometry of the nucleophile, can be traced to: (*i*) minimization of steric interactions, the most important of these being C=O-Lewis acid/R′ interactions; (*ii*) minimization of charge separation in nonpolar solvents (synclinal transition state); (*iii*) general preference for a synclinal approach (7, 33*b*) in the presence of Lewis acids, and (*iv*) optimization of the Bürgi–Dunitz trajectory.

The d^1 reaction

Results

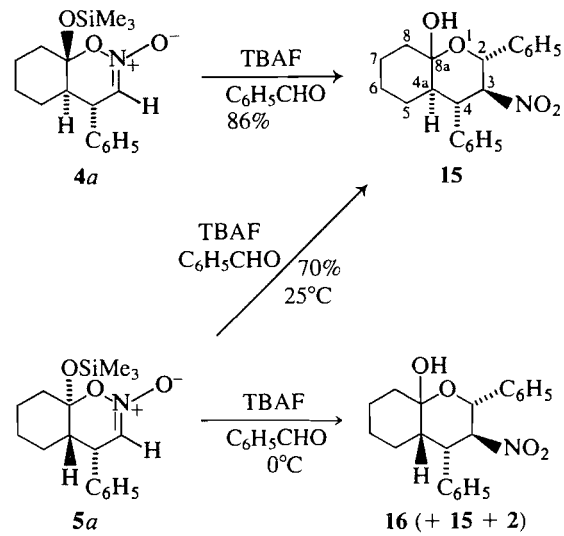
While nitroolefins are among the most reactive electrophiles (a^2 reagents), nitronates are nucleophiles (d^1 reagents). They are typically generated by treatment of nitroalkanes with base. A convenient alternative is the use of silyl nitronates from which nitronates may be generated by fluoride ion and combined *in situ* with suitable electrophiles (Scheme 10A) (46, 47).

Nucleophilic nitronate anions should be generated by fluoride ion from the O-silyl substituted cyclic nitronates **4–6**, as indicated in Scheme 10B. There is an additional way by which elaboration of the skeleton of cyclic nitronates could be achieved: they can react as 1,3-dipoles in cycloaddition reactions (48–50). These two types of reactivity have been tested with our cyclic nitronates and are described in the following sections.[13,14]

Henry reaction

The reaction of the cyclic nitronate **4***a* with benzaldehyde in the presence of a source of fluoride ion as catalyst, such as *n*-Bu_4NF (TBAF), results in the formation in high yield of the cyclic hemiacetal **15** (Scheme 11). The reaction is highly diastereoselective (95% ds); only traces of a second unstable isomer could be detected in the ^1H nmr spectrum.

The structure of **15** was established by ^1H nmr spectroscopy, which clearly shows the *trans,trans,trans* relationship of the three protons in the 2-, 3-, and 4-positions of the heterocyclic



SCHEME 11

ring. It is not clear whether the formation of the hemiacetal takes place during the reaction or upon work-up and purification. In the event, no open-chain products were detected. The relative configuration of the bridgehead positions was not assigned.

The diastereomeric nitronate **5***a* did not react as cleanly. There were two kinds of problems: (*i*) fluoride ion is a sufficiently strong base to epimerize the α-keto position at room temperature, and (*ii*) hydrolysis of the starting material; at lower temperatures the most reactive electrophile is the water present in TBAF solutions[15] (Scheme 11). The latter hydrolytic reaction is clearly uninteresting. The former reaction occurring with epimerization (**16** → **15**) would be of interest if the diastereomer with *u* configuration at C(4) and C(4a) were desired (for the numbering of **15**, see Scheme 11).[16,17] It should be possible in a single step to form the most stable product **15** from the mixture of cyclic nitronates **4***a*, **5***a*, and **6***a* and benzaldehyde.

[13]Many examples of cyclic nitronic esters are known, most of which result from the additions of enamines to substituted nitroolefins (for selected examples see ref. 51). In all cases for which the diastereoselectivity is known, the products of a *lk* addition are favoured and the rings are *cis*-fused.

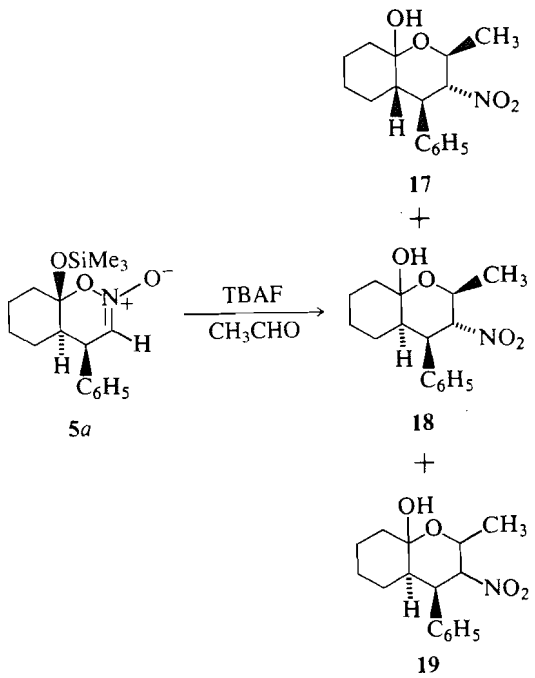
[14]Although the cyclic nitronates derived from enamines[13] have the potential to undergo 1,3-dipolar cycloadditions, it is less likely that conditions could be found for their participation in the Henry reaction.

[15]TBAF was used in the following forms: (*i*) commercial (Aldrich) solution, 1 *M* in THF; (*ii*) dried by azeotropic removal of water (benzene) and made up to 1 *M* solution in THF; (*iii*) dried at 100°C under high vacuum and made up to 1 *M* solution in THF; (*iv*) dried in the THF (1 *M* solution) over molecular sieves 3Å; and (*v*) supported on Kieselgel (Fluka).

[16]The product **16** of kinetic control was very labile, isomerizing to **15** under a variety of conditions. Therefore, analytically pure **16** could not be obtained.

[17]The epimerization must take place with an intermediate that has a free carbonyl group.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.



SCHEME 12

Several attempts were made to modify the conditions such that hydrolysis and epimerization could be avoided. However, a variety of other fluoride sources which are "dry", for example $(Me_2N)_3SF\cdot(TMSF)$ or KF/DMF, did not lead to improved results.

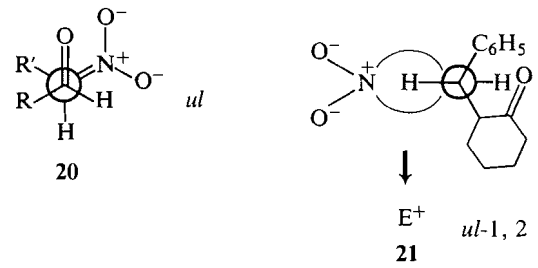
When acetaldehyde and the nitronate **5***a* were allowed to react, both epimerized (**17**) and nonepimerized (**18**)[18] products were obtained (Scheme 12). A third isomer **19** was also isolated.

The reactions take place with preferential coupling of the trigonal centres with relative topicity *ul* as is usual in the silyl nitronate modification of the Henry reaction[19] (47*a*), see **20** in Scheme 13. It is also remarkable that there appears to be a strong influence on the steric course of the reaction by the stereogenic centre adjacent to the nitronate double bond (47*b*), see the relative topicity *ul*-1,2 as depicted in **21** of Scheme 13. In two simple steps, a stereoselective construction of four new, adjacent, stereogenic centres, not including acetal centres, has been achieved!

1,3-Dipolar cycloadditions

Torssell and co-workers (49) have shown that silyl nitronates, like other nitronic acid esters, undergo 1,3-dipolar cycloadditions with a variety of olefins. This is also expected of the cyclic nitronates **4**, **5**, and **6**. Indeed, upon reaction of any of the three cyclic nitronates **4***a*, **5***a*, and **6***a* with acrylic acid derivatives, cycloadducts are formed in moderate to good yields and with good diastereoselectivities. Thus methyl acrylate, the most reactive of the dipolarophiles tested, reacted with **4***a*, **5***a*, and **6***a*, respectively, within 4–6 hours at room temperature to form the tricyclic compounds **22**, **24**, and **25** with the yields and diastereoselectivities given in Scheme 14. *p*-Bromophenyl acrylate reacted with **4***a* to give the crystalline material **23**.

The products **4***e*, **5***e*, and **6***e*, derived from 1-nitropropene, also react readily and stereoselectively with methyl acrylate



SCHEME 13

to give the tricyclic products **26**, **27**, and **28**, respectively (Scheme 15).

Although some modifications of the acrylic acid derivative are tolerated, β-substituted α,β-unsaturated esters do not yield the desired products; methyl crotonate and methyl cinnamate failed to react.[20] Acrylamide, however, will add to the nitronates **4***a* and **5***a* to give the tricyclic products **29** and **30**, respectively. Substitution at the α-position of the α,β-unsaturated ester is also possible: methyl methacrylate reacts with **5***a* to form the geminally disubstituted derivative **31** as a 1:1 mixture of diastereomers (Scheme 16).

Discussion

1,3-Dipolar cycloadditions are thought to be concerted processes (48) although a mechanism involving diradical intermediates has also been postulated (52). Like all dipolar cyloadditions, the reactions with nitrones generally take place with high stereoselectivity (53). In the case under consideration, there are four different approaches between the methyl acrylate and the bicyclic nitronate (*endo* or *exo*, α- or β-face, as drawn[21]). However, products arising from only two of these were isolated, with a pronounced preference (up to 13:1 or 93% ds) for one of the two.

In establishing the steric course of the reaction, it is first necessary to ascertain that isomerization does not occur during the reaction at the three stereogenic centres present in the starting material. The ^1H nmr measurements indicate that such isomerization does not take place. On going from **4***a* to **22** or **5***a* to **24**, the C(4)/C(4a) proton coupling constants (see Scheme 14 for numbering) changed from 11.1 to 12.2 Hz and from 9.2 to 6.9 Hz, respectively, about what is to be expected upon the loss of the double bond in the 6-membered ring. No information about the acetal centre could be obtained.

Subsequently, the relative configuration must be determined at the two stereogenic centres formed in the reaction. All attempts to establish this using nuclear Overhauser effect measurements failed. However, the configuration was assigned from the X-ray crystal structure analysis of **23** (Fig. 2). It can be seen that **23** arises from the *exo* addition of the acrylate to the diastereotopic face of the nitronate opposite to the $OSiMe_3$ group (α-face as drawn), an *lk*,*ul*-1,2 combination.

As the ^1H nmr spectra of **22** and **23** are virtually identical, with the exception of the protons of the ester functionality, it can be concluded that **22** has the same relative configuration as **23**. On the basis of the similarities of the ^1H nmr spectra, the relative configurations of the related products derived from **4***a* (**26** and **29**) are also assumed to be the same as **23**.

[18]In contrast to the product formed from benzaldehyde, the two bicyclic compounds **17** and **18** were stable crystalline materials.

[19]In the previous work (47), however, trimethylsilyl nitronates were found to add nonselectively to aldehydes.

[20]1-Nitropropene gave a complex mixture of products.

[21]The *lk*/*ul* nomenclature may be used to describe the approach of the reactants even though the new bond is not formed between the two centres with heterotopic faces: the four possible combinations are described (*lk*, *lk*-1,2), (*ul*, *lk*-1,2), (*ul*, *ul*-1,2), and (*lk*, *ul*-1,2), respectively.

The cycloadduct arising from the other diastereomer **24** is assumed also to have been formed via an *exo* α-face attack of the acrylate, as the steric shielding of the β-face of the starting material **5***a* is even more pronounced than in the case of **4***a*; both the OTMS and phenyl groups are axially disposed on the β-face. Analogously, the products **27** and **30**, derived from **5***a*, are assumed to have the same relative configuration as **24**. It was not possible to assign the configurations at the newly formed stereogenic centres in products **25** and **28**, which are derived from **6***a* and **6***e*, respectively.

A preference for an *exo* approach has also been observed in 1,3-dipolar cycloadditions of acrylates to nitronates in the work of Tartakovskii and co-workers (54), Carrié and co-workers (55), and Denmark *et al.* (14). The high selectivity for α-face attack, which is also common in reactions of this type, has been ascribed (14) to the kinetic anomeric effect (55*b*, 56). While such electronic effects are undoubtedly operating here, steric effects are also quite important. The crystal structure of the starting material **4***a* shows the β-face to be shielded by the OTMS group. In the case of the other diastereomer **5***a*, this shielding will be more pronounced as both the OTMS and phenyl groups will block the β-face. Therefore, on both steric

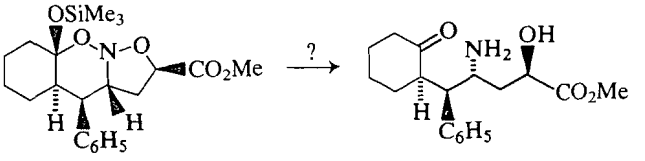
and electronic grounds the selectivity for α-face attack is very reasonable.

The tricyclic products **22–31** are formed in two steps from the nitroolefins. The overall diastereoselectivity with which the four stereogenic centres are formed is high and therein lies the utility of the sequence.



24

SCHEME 17

Reduction of the tricyclic compounds

It was hoped that the tricyclic compounds could be reduced to give useful polyfunctional starting materials for total synthesis (Scheme 17, shown for **24**). In the event, the N—O bonds proved much more rugged than anticipated and relatively severe conditions were required before any reduction was observed to take place. Using Raney nickel/KF as catalyst (49), the tricyclic compounds **24** and **27** (nitroso acetals) were reduced to the bicyclic lactams **33** and **34**, respectively (Scheme 18). The reduction of **24**, derived from β-nitrostyrene, was somewhat capricious, and in some cases the secondary amine **32** was isolated. This could be converted to the lactam **33** by potassium carbonate in methanol. The ^{1}H nmr spectra of compounds **32–35** indicate that no change occurs in the relative configuration of the stereogenic centres that were present in the starting material. The assignment of the *cis* ring junction in products **32–34** was based on the small coupling constants of the bridgehead hydrogens.

Surprisingly, the isomers **22** and **26** were not reduced under the same conditions. When the former was reduced with the more powerful reductant $LiAlH_4$, the N—O bonds remained untouched; only the ester was reduced, and after acetylation and chromatography over silica gel, the bicyclic derivative **35** was isolated (Scheme 19). Currently, other reagents are being sought that might achieve the desired reduction to the lactams in all cases.

Conclusion

The addition of silyl enol ethers to nitroolefins is a promising alternative to the traditional Michael addition. Firstly, it preferentially takes place with relative topicity *ul*, leading, after

hydrolysis, to the diastereomeric nitroalkylated ketone **2**, which is difficult to obtain by other means. Secondly, it results in the primary formation of the isolable, novel, silylated cyclic nitronates **4–6**. These can be used in Henry reactions or 1,3-dipolar cycloadditions to give highly functionalized species in which the relative configuration of four stereogenic centres, not including acetal centres, is set. Further work to extend the utility of these processes, and to make them enantioselective as well, is under investigation.

Experimental

General remarks

Tetrahydrofuran (THF) was purified by distillation from potassium–benzophenone. Except for the 1,3-dipolar cycloadditions and reductions, all reactions were carried out in a dry Ar atmosphere. For column chromatography, Merck or Fluka silica gel 60 (70–230 mesh) was used. Melting points (mps) were determined using a Büchi 510 apparatus. All mps are uncorrected. The following instruments were used: for ir, Perkin–Elmer 297 spectrophotometer, data in cm^{-1}; for ^1H nmr, Varian EM-390 (90 MHz) and Bruker WM 300-WB (300 MHz) spectrometers; unless otherwise indicated the reported spectra were recorded at 300 MHz; chemical shifts are given in parts per million (ppm) with the tetramethylsilane (TMS) signal at 0.0 ppm as the internal standard; multiplicities as s (singlet), d (doublet), t (triplet), qa (quartet), qi (quintet), sept (septet), m (multiplet); coupling constants (J) in Hz; for mass spectra, Varian MAT311 spectrometer (70 eV, electron impact).

Preparation of nitroolefins: General procedure 1 (ref. 57)[22]

To a mixture of the aromatic aldehyde (0.20 mol) and nitromethane (0.20 mol) in methanol (200 mL) at −10°C was added aqueous KOH (0.20 mol in 60 mL H_2O) at a rate such that the temperature remains below −5°C (+5°C for *p*-cyanobenzaldehyde). The mixture was poured into cooled 2 *N* HCl (150 mL, 10°C). The bright yellow precipitate was filtered, air dried, and recrystallized from hexanes–chloroform.

p-Methyl-β-nitrostyrene: yield, 53%; mp 102.0–102.5°C; ^1H nmr (90 MHz, $CDCl_3$): 2.40 (s, 3H), 7.25, 7.46 (ABqa, $4H_{arom}$, J = 8), 7.54 (d, 1H, J = 13), 8.02 (d, 1H, J = 13).

p-Methoxy-β-nitrostyrene: yield, 48%; mp 86.6–87.0°C; ^1H nmr (90 MHz, $CDCl_3$): 3.89 (s, 3H), 6.98, 7.55 (ABqa, $4H_{arom}$, J = 10), 7.55 (d, 1H, J = 14), 8.02 (d, 1H, J = 14).

p-Cyano-β-nitrostyrene: yield, 50%; mp 179.8–186.8°C (dec); ^1H nmr (90 MHz, $CDCl_3$): 7.62 (d, 1H, J = 13), 7.68, 7.84 (ABqa, $4H_{arom}$, J = 8), 8.04 (d, 1H, J = 13).

[22]β-Nitrostyrene is commercially available; 1-nitropropene was prepared using the method described in (37).

Michael additions of silyl enol ethers to nitroolefins: General procedure 2

To a solution of titanium tetraisopropoxide ($Ti(O\text{-}iPr)_4$, 15.0 mmol) in methylene chloride (400 mL) was added titanium tetrachloride ($TiCl_4$, 15.0 mmol). After stirring for 1/2 h, the solution was cooled to ca. −40°C and the nitroolefin (10.0 mmol) was added. The coloured solution (varying from light yellow to deep red depending on the nitroolefin) was cooled to −90°C and 1-trimethylsilyloxycyclohexene (11.0 mmol) was added. The now lighter coloured solution was allowed to react for 20 min – 1 h at which time it was poured into an ether/water bilayer (4:1, 800 mL), shaken, neutralized with saturated $NaHCO_3$ solution, extracted with ether, washed with water (2 × 500 mL, brine should be avoided), and the combined organic phases were dried under an argon atmosphere at 0°C with a 1:1 mixture of $NaHCO_3/MgSO_4$. The solvents were evaporated at 10 and then 0.1 Torr (1 Torr = 133.3 Pa) to give the crude oil, which was purified by flash chromatography (ether/petroleum ether mixtures as eluent).[23,24] The three compounds isolated, **4**, **5**, and **6**, were further purified by recrystallization from hexanes/chloroform.

Hydrolysis of the silylated cyclic nitronate: General procedure 3

To a solution of the nitronate **4**, **5**, or **6** (0.5 mmol) in methanol (10 mL) was added KF (2.5 mg, 40 μmol). After stirring at room temperature for 10 min – 3 h, the reaction mixture was extracted with ether, and washed with water (2×) and brine. The combined organic phases were dried over $MgSO_4$ and the solvents removed at 10 and then 0.1 Torr. The crude residue was purified by flash chromatography (petroleum ether/ether mixtures as eluent).

The Henry reaction: General procedure 4

To a cooled solution (0°C) of the aldehyde (0.2–0.4 mmol) and cyclic nitronate **4** or **5** (0.1–0.25 mmol) in THF (5–30 mL) was added TBAF in THF (5–10 mol%).[25]

After stirring for 6–16 h, the solution was allowed to warm to room temperature over 1 h. Following extraction with hexanes or ether, and washing with water (10×), the combined organic phases were dried over $MgSO_4$ and evaporated at 10 and then 0.1 Torr. The crude product (**4***a* → **15**, **5***a* → **15**–**19**) was purified by flash chromatography (petroleum ether/ether) and recrystallized from hexanes/chloroform.

1,3-Dipolar cycloadditions: General procedure 5

To a solution of the acrylate derivative (0.3–1.0 mmol) in CH_2Cl_2[26] at room temperature was added the cyclic nitronate (0.25–0.35 mmol). After stirring for 4–18 h, the solvents were removed at 10 and then 0.1 Torr. The crude residue was submitted to flash chromatography (petroleum ether/ether mixtures) to give the mixture of diastereomers. In the case of crystalline adducts, with the exception of **23**, recrystallization provided diastereomerically pure samples with sharp melting points.

Data of *l*,*u*,*u*,*l*-decahydro-4-phenyl-8a-[(trimethylsilyl)oxy]-isoxazolo[2,3-*b*][1,2]2-carbomethoxybenzoxazine, **22** (>95% ds, from **4***a*): yield, 96%; oil; ir ($CHCl_3$): 1740, 1249, 1168, 1078; ^{1}H nmr ($CDCl_3$): 0.27 (s, 9H), 1.05–1.29 (m, 3H), 1.49–1.65 (m, 4H), 1.75–1.86 (m, 2H), 1.94 (dt, 1H, J = 3.0, 11.6), 2.78 (dt, 1H, J = 10.6, 11.6), 3.52 (dd, 1H, J = 4.6, 12.2), 3.68 (s, 3H), 3.68–3.76

[25]Generally, commercial TBAF/THF (1 *M* Aldrich) was used without modification.

[26]With acrylamide, toluene was used as the solvent at 110°C. The compounds were purified by recrystallization.

Reduction of cyclic nitronates: General procedure 6

Raney nickel was prepared according to ref. 47 (p. 1117, procedure A). To a suspension of the activated Raney nickel (0.5 g) in methanol (40 mL) was added the cyclic nitronate (0.8–0.9 mmol) and KF (5 mg). The solution stirred overnight under an atmosphere of H_2 (1–20 atm; 1 atm = 101.3 kPa) at elevated temperatures (25–120°C). The solution was filtered through Celite (2×) and evaporated at 10 and then 0.1 Torr. The residue was recrystallized from ethyl acetate or $CHCl_3$/methanol.

Data of methyl *l,l,l,l*-octahydro-1*H*-indole-3-phenyl-2-[2-hydroxy]-propanoate **32** (H_2, 20 atm, 50°C, from **23**): yield, 88%; mp 192.1–192.6°C; ir (KBr): 3325, 1744, 1210, 1204, 1094; ^{1}H nmr ($CDCl_3$): 1.04–1.09 (m, 1H), 1.18–1.30 (m, 2H), 1.60–1.66 (m, 1H), 1.72–1.88 (m, 4H), 2.12 (ddd, 1H, J = 1.3, 9.2, 14.6), 2.28–2.33 (m, 2H), 2.49 (ddd, 1H, J = 3.6, 10.1, 15.1), 3.46 (dd, 1H, J = 3.1, 5.8), 3.69 (s, 3H), 4.11 (bs, 1H, OH), 4.56 (t, 1H, J = 10.1), 4.74 (dd, 1H, J = 3.6, 9.2), 7.18–7.36 (m, 6H); ms m/z: 303 (13%, M$^+$), 200 (100%).

Data of *l,l,l,l*-decahydro-2-hydroxy-9-phenyl-3*H*-pyrrolo[1,2-*a*]-indol-3-one, **33** (H_2, 1 atm, 25°C, from **23**): yield, 78%; mp 192.1–192.6°C; ir (KBr): 3355, 1676; ^{1}H nmr ($CDCl_3$): 1.01–1.26 (m, 4H), 1.49–1.64 (m, 3H), 1.75 (dt, 1H, J = 9.1, 11.2), 2.45 (d, 1H, J = 15.0), 2.57 (dt, 1H, J = 10.5, 12.5), 2.87 (ddd, 1H, J = 5.6, 7.6, 12.5), 2.98 (d, 1H (OH), J = 2.2), 3.07 (dd, 1H, J = 5.5, 10.5), 4.10 (bs, 1H), 4.41 (ddd, 1H, J = 5.5, 9.2, 10.2), 4.69 (dddd, 1H, J = 1.2, 2.2, 7.5, 10.5 (after D_2O exchange: ddd, 1H, J = 1.2, 7.5, 10.5)), 7.13–7.38 (m, 5H$_{arom}$); ms m/z: 271 (26%, M$^+$). *Anal.* calcd. for $C_{17}H_{21}NO_2$, *Mol. Wt.* 271.360: C 75.24, H 7.80, N 5.16; found: C 75.11, H 7.64, N 5.08.

Data of *l,u,u,l*-decahydro-2-hydroxy-9-methyl-3*H*-pyrrolo[1,2-*a*]-indol-3-one, **34** (H_2, 19 atm, 120°C, from **26**): yield, 61%; oil; ir ($CHCl_3$): 3520, 3360, 1687; ^{1}H nmr ($CDCl_3$): 0.96 (d, 3H, J = 6.9), 1.03–1.21 (m, 2H), 1.44–1.88 (m, 7H), 2.18 (m, 1H), 2.38 (d, 1H, J = 13.5), 3.02 (bs, 1H (OH)), 3.58 (dt, 1H, J = 5.5, 9.5), 3.87 (bs, 1H), 4.57 (ddd, 1H, J = 1.1, 7.4, 11.1); ms m/z: 209 (100%, M$^+$).

*Conversion of **32** to **33***

To a solution of K_2CO_3 (3 mg) in methanol (10 mL) was added **34** (10.0 mg, 0.03 mmol). After 24 h at room temperature, the solvent was evaporated at 10 Torr and the residue recrystallized from ethyl acetate to give **33** (83% yield).

*Reduction of **22** to the alcohol **35**, protected as the acetate*

To a suspension of $LiAlH_4$ (0.03 g, 0.8 mmol) in THF (10 mL) under

an argon atmosphere at 25°C was added **22** (0.164 g, 0.4 mmol). After 18 h, acetic anhydride (0.5 mL, 5.3 mmol) was added and the mixture stirred for 4 h. The solution was evaporated at 10 Torr. The ^{1}H nmr spectrum (90 MHz) of the crude residue showed the presence of the OTMS group in the product. The residue was submitted to flash chromatography (petroleum ether/ether, 1:1).

Data of 2-[(5-(acetoxymethyl)-2-isoxazolidin-3-yl)-phenylmethyl]-cyclohexanone, **35**: yield, 65%; oil; ir ($CHCl_3$): 1738, 1707, 1220, 1128; ^{1}H nmr ($CDCl_3$): 1.06–1.20 (m, 1H), 1.54–1.80 (m, 5H), 2.12 (s, 3H), 2.36–2.54 (m, 2H), 2.87 (d, 2H, J = 8.7), 3.36 (ddd, 1H, J = 5.0, 10.8, 13.0), 3.78 (d, 1H, J = 10.9), 4.11 (dd, 1H, J = 5.3, 12.0), 4.16 (dd, 1H, J = 4.8, 12.0), 4.63 (ddt, 1H, J = 4.8, 5.3, 8.7), 7.20–7.37 (m, $5H_{arom}$); ms m/z: 329 (32%, M^+), 256 (90%), 130 (77%).

Acknowledgements

We would like to thank Frl. B. Brandenberg (ETH) for conducting the nmr measurements, and Mr. R. Faggiani (McMaster) for performing, and Dr. C. J. L. Lock (McMaster) for helpful discussions regarding, the X-ray crystal structure analysis. The awarding of an N.S.E.R.C. Canada Postdoctoral Fellowship (1984–1985) to M.A.B. is gratefully acknowledged.

DANIELLE DRUET, LOUIS CLAUDE COMEAU, ROBERT VIANI, ANDRÉ BALDY, JACQUES ESTIENNE et MARCEL PIERROT. Can. J. Chem. **65**, 851 (1987).

L'étude cristallographique du triterpène $C_{32}H_{50}O_4$, extrait d'*Opilia celtidifolia*, confirme l'approche chimique de la structure moléculaire. Les cycles A, B, C et D adoptent une conformation chaise alors que le cycle E, du fait de la présence d'un groupement lactone ponteur entre les atomes de carbone C(17) et C(20), s'observe dans une conformation bateau. Les cinq cycles à six chaînons présentent des jonctions *trans*.

DANIELLE DRUET, LOUIS CLAUDE COMEAU, ROBERT VIANI, ANDRÉ BALDY, JACQUES ESTIENNE, and MARCEL PIERROT. Can. J. Chem. **65**, 851 (1987).

An X-ray crystallographic study of the triterpene $C_{32}H_{50}O_4$, isolated from *Opilia celtidifolia*, confirms the chemical analysis of the molecular structure. The rings A, B, C, and D are in the chair conformation, but ring E, due to a bridging lactone between the C(17) and C(20) carbon atoms, adopts a boat conformation. All five six-membered rings are *trans*-fused.

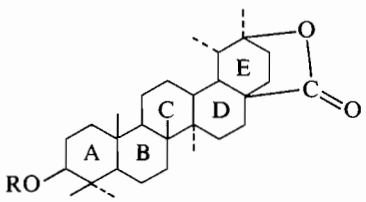
Introduction

Au cours de travaux effectués sur *Opilia Celtidifolia*, une Olacale de l'Afrique de l'ouest très utilisée en pharmacopée locale, nous avons isolé, après hydrolyse des glycosides, plusieurs aglycones triterpéniques. Aux côtés de l'hédéragénine (1) et de l'acide oléanique (2), nous avons pu caractériser un premier composé mineur dont nous avons établi la structure (3). Nous reportons ici l'étude chimique et structurale d'un second composé mineur : l'acétoxy-3β ursane olide-28,20βa **1***a*.



1 *a*: R = Ac
b: R = H

Résultats et discussion

Le composé **1***a* est isolé par chromatographie sur colonne de silice du mélange d'aglycones acétylées provenant de l'hydrolyse des glycosides d'*Opilia Celtidifolia*. **1***a* cristallise en aiguilles dans le mélange dichlorométhane–hexane (F = 314–321°C).

Les cristaux répondent positivement aux tests caractéristiques des triterpènes et négativement au test au tétranitrométhane. Une fraction des cristaux est hydrolysée par la potasse méthanolique afin d'établir les constantes physico-chimiques du composé **1***b*. Recristallisé du mélange dichlorométhane–hexane, celui-ci présente un point de fusion de 277–281°C.

Les analyses spectroscopiques ont été effectuées, pour plus de commodité, sur le derivé acétylé **1***a*. Le résultat de l'analyse centésimale et la présence en spectrométrie de masse d'un pic d'ion moléculaire à m/z = 498 conduisent à la formule brute $C_{32}H_{50}O_4$. La spectrométrie infrarouge montre qu'il s'agit d'un acétate (1725–1250 cm^{-1}) comportant vraisemblablement un pont lactone (1725–1160–1098 cm^{-1}). En spectrométrie de masse, le composé **1***a* donne la fragmentation caractéristique des triterpènes pentacycliques hydroxylés en 3 : les pics à m/z = 189 et 204 proviennent d'une coupure au niveau du cycle C (4, 5). D'autres fragments sont intéressants et notamment celui à m/z = 249 ($M^+ - 44$) venant confirmer la présence d'un pont lactone. Celui à m/z = 249, dont dérive le fragment à m/z = 204 par perte d'un groupement -CO_2H, permet de fixer une des positions du pont lactonique sur le carbone C(17) (5). La rmn du ^{1}H à 100 MHz, effectuée sur **1***a*, montre la présence de 6 groupements angulaires et d'un groupement méthyle porté par un carbone tertiaire. À δ = 2,04 ppm, un singulet (3H) dû au méthyle d'un groupement acétyle indique que le composé **1***a* ne possède qu'un seul hydroxyle acétylable. Le déplacement chimique du quadruplet à δ = 4,47 ppm (^3J = 10 Hz, ^3J = 6 Hz), correspondant au proton en α de la fonction acétyle, situe celle-ci en position 3β équatoriale. On n'observe aucun signal correspondant à un hydrogène en α de la fonction lactone, ce qui permet de conclure que celle-ci est portée par des carbones quaternaires. Le spectre du ^{13}C a été enregistré sur l'acétate **1***a* en utilisant la technique DEPT pour déterminer la nature des carbones présents dans la molécule. L'attribution des différents glissements chimiques figure dans le tableau 1, établi après détermination de la structure du composé par diffraction des rayons X.

La présence en rmn du ^{1}H d'un méthyle porté par un carbone tertiaire nous a orienté vers les dérivés de l'ursane dont l'un des méthyles en 19 ou 20 serait porté par un carbone rendu quaternaire, probablement par la présence d'un pont lactone. Une comparaison des caractéristiques physico-chimiques de notre composé **1***a* et de dérivés de l'ursane hydroxylés en 3 et comportant un cycle lactonique (6, 7) a permis de conclure que l'acétoxy-3β ursane olide-28,20 présentait de grandes similitudes avec notre composé : points de fusion identiques et

a et *b*, *c* et *d* peuvent être interchangées. Les valeurs de δ sont données en ppm avec le TMS comme référence interne.

valeurs des glissements chimiques des différents signaux en rmn du ^1H très proches.

La configuration absolue de la molécule n'a pas été déterminée dans cette étude. Toutefois, la connaissance de la configuration observée dans divers composés analogues de la même famille de triterpènes pentacycliques, et, notamment, celle du *p*-bromobenzoate-3 méthyl ursolate (8), permet la détermination de la stéréochimie de l'ensemble de la molécule. Cette configuration, à laquelle correspondent les coordonnées des atomes non hydrogènes mentionnés dans le tableau 3, se trouve portée sur la figure 1.

Les liaisons simples $C_{sp^3}—C_{sp^3}$ varient entre 1,487 et 1,593 Å, avec des limites paraissant anormales au regard de la valeur classique de 1,54 Å pour une liaison de ce type. En fait, dans la mesure où le rayon de van der Waals associé à un groupement méthyle est de l'ordre de 2,0 Å (9) et que les contacts de non liaison C(24)...C(25) et C(25)...C(26) sont respectivement de 3,25(1) et 3,11(1) Å, il existe dans la région des cycles A et B du noyau triterpénique une importante interaction stérique. Il s'observe en conséquence un allongement de certaines liaisons C—C, associé tout naturellement à un raccourcissement compensateur pour d'autres.

Les angles de valence varient de 107,1 à 118,3° avec une valeur moyenne de 111,2°. Les cycles A, B, C et D, en jonctions *trans*, présentent une conformation chaise avec respectivement pour meilleur plan moyen, les groupes d'atomes [C(1), C(3), C(4), C(10)], [C(6), C(7), C(9), C(10)], [C(8), C(9), C(12), C(13)] et [C(13), C(18), C(15), C(16)]. Le cycle E, également en jonction *trans*, s'observe dans une conformation bateau résultant du pontage de type lactone entre les atomes de carbone C(17) et C(20) situés respectivement à 0,757(7) et 0,640(7) Å au-dessus du plan moyen défini par le groupe d'atomes [C(18), C(19), C(21), C(22)].

L'existence d'une structure bicyclique ne semble pas en fait une condition nécessaire à l'adoption pour le cycle E de la conformation la moins favorable. En effet, les résultats relatifs à la structure du taraxasterol (10) semblent montrer que l'interaction stérique entre $C(12)H_2$ et $C(29)H_3$ est suffisante pour imposer la conformation bateau.

Aucune interaction intermoléculaire particulière au regard

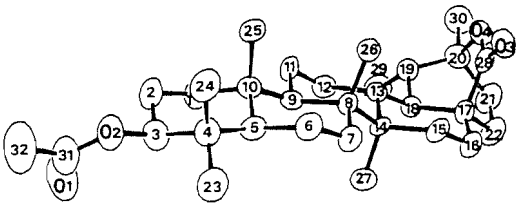

FIG. 1. Vue de la molécule (ellipsoïdes thermiques à 50% de probabilité) et indexation des atomes.

de la somme des rayons de van der Waals des atomes n'est à signaler.

Conclusion

D'après la littérature, l'hydroxy-3β ursane olide-28,20βa n'a jamais été isolé à l'état naturel dans une fraction aglycone provenant de végétaux, mais a été préparé à des fins analytiques (7) ou synthétisé par oxydation du formyl-3β époxy-28,20 ursane (6).

Certains auteurs (11–13) ont remarqué qu'une lactonisation pouvait se produire au cours de l'hydrolyse acide de glycosides dont l'aglycone possédait une fonction carboxylique en C(17) et une double liaison ou un groupement hydroxyle proche du -COOH.

Ces résultats doivent nous conduire à vérifier si l'aglycone **1***a* n'est pas issue d'une autre aglycone ayant subi une transformation chimique au cours de l'hydrolyse acide.

La conformation bateau du cycle E constitue un facteur déterminant pour une réaction d'estérification interne et les composés **2**, **3**, **4** ou **5**, **6** nous paraissent être de possibles précurseurs.

3 **4** **5** **6**

Partie expérimentale

Les points de fusion ont été pris sur microscope à platine chauffante de Reichert. Les spectres ir ont été effectués sur un appareil Leitz. Les spectres de rmn du ^1H et du ^{13}C ont été enregistrés sur Bruker AM 100 en solution dans le deutérochloroforme avec le TMS comme référence interne. Le spectre de masse a été déterminé sur L.K.B.

La fraction glycosidique (340 g) d'*Opilia Celtidifolia* est hydrolysée par 500 mL de mélange de Kiliani (eau – acide acétique – HCl, 275:175:50 v/v/v) à 100°C pendant 3 h. Les aglycones brutes (79 g) obtenues sont extraites au soxhlet pendant 72 h par de l'oxyde d'éthyle. Après évaporation du solvant, on récupère 40 g de résidu que l'on acétyle par 80 mL d'anhydride acétique en présence de 400 mL de pyridine anhydre, à température ambiante, pendant 48 h. Les réactifs sont ensuite éliminés sous pression réduite et la phase organique est reprise au dichlorométhane, lavée successivement au Na_2CO_3, à l'eau, par HCl 2 *N*, à nouveau à l'eau jusqu'à neutralité. Après séchage sur Na_2SO_4 et élimination du solvant, on obtient 41,2 g d'acétates

*$B_{eq} = (4/3)[a^2 \cdot B(1,1) + b^2 \cdot B(2,2) + c^2 \cdot B(3,3) + ab \cos\gamma \cdot B(1,2) + ac \cos\beta \cdot B(1,3) + bc \cos\alpha \cdot B(2,3)]$.

d'aglycones. Ceux-ci sont fractionnés par chromatographie sur colonne de silice (50 g de silice/1 g d'aglycones) avec comme éluant le mélange hexane – oxyde d'éthyle (90:10 v/v). À partir de 5 g d'aglycones acétylées, on isole en moyenne 55 mg de composé **1***a*. Après cristallisation dans le mélange dichlorométhane–hexane, l'acétate **1***a* présente les caractéristiques suivantes : *F* : 314–321°C; ir (KBr) : 1730, 1725, 1370, 1250, 1160, 1098, 1075, 1030, 980, 955, 950 cm^{-1}; rmn $^1H(CDCl_3)$ δ : 0,835 (s, 3H, CH_3); 0,846 (s, 6H, CH_3 × 2); 0,90 (s, 3H, CH_3); 0,93 (s, 3H, CH_3); 0,99 (d, 3H, ^3J = 7 Hz, —CH—CH_3); 1,31 (s, 3H, CH_3); 2,05 (s, 3H, CH_3—C(=O)—O—); 4,47 (q, 1H, ^3J = 10 Hz, ^3J = 6 Hz, —CH—OAc); rmn $^{13}C(CDCl_3)$: tableau 2; masse *m/z* : 498 (17), 470 (36), 454 (30), 438 (60), 423 (25), 395 (100), 249 (44), 233 (10), 234 (10), 204 (13), 189 (28). *Anal.* calc. pour $C_{32}H_{50}O_4$: C 77,11; H 10,04; O 12,85%; tr. : C 77,20; H 10,29; O 12,51%.

Quinze milligrammes d'acétate **1***a* sont hydrolysés pendant trois heures à reflux par 7 mL de potasse 2 *N* méthanolique. Après dilution, la fraction hydroalcoolique est extraite au dichlorométhane. L'extrait organique est lavé à l'eau, séché sur Na_2SO_4 et le solvant est éliminé. Le résidu (12 mg) est recristallisé du mélange dichlorométhane–hexane; *F* : 277–281°C; ir (KBr) : 1750, 1500, 1450, 1370, 1080, 1060, 950 cm^{-1}; rmn $^1H(CDCl_3)$ δ : 0,75 (s, 3H, CH_3); 0,82 (s, 3H, CH_3); 0,90 (s, 3H, CH_3); 0,93 (s, 3H, CH_3); 0,96 (s, 3H, CH_3); 0,98 (d, 3H, —CH—CH_3); 1,31 (s, 3H, CH_3); 3,20 (q, 1H, ^3J = 11 Hz, ^3J = 5,5 Hz, —CH—OH). *Anal.* calc. pour $C_{30}H_{48}O_3$: C 78,95; H 10,53; O 10,53%; tr. : C 78,82; H 10,50; O 10,68%.

Données cristallographiques

$C_{32}H_{50}O_4$ M_r = 498,7

Monoclinique, groupe spatial $P2_1$ avec *a* = 11,709(4), *b* = 7,774(4), *c* = 16,186(4) Å et β = 108,53(2)°, *U* = 1397(2) Å^3, D_c = 1,19 g cm^{-3}, *Z* = 2, MoKα radiation (λ = 0,71073 Å), μ = 0,71 cm^{-1}.

Les paramètres de la maille cristalline ont été déterminés à partir d'un affinement par moindres carrés des positions angulaires en θ de 25 réflexions dans l'intervalle 5,3–14,6°. La mesure des intensités a été effectuée sur diffractomètre CAD-4 Enraf–Nonius équipé d'un monochromateur au graphite, à température ambiante (293 K). Technique de scan ω/2θ de 0,91 à 10,06°min^{-1} sur un intervalle de (0,90 + 0,35 tg θ) degrés en ω avec un angle de balayage dans le rapport de 1/4 entre fond continu et pic de diffraction.

Aucune variation significative des intensités de trois réflexions standards ($70\bar{3}/1\bar{2}0/027$) mesurées toutes les heures n'a été observée lors de l'enregistrement des 3069 réflexions ($2\theta_{max}$ = 52°) effectué sur un cristal incolore de forme en aiguille (0,15 × 0,15 × 0,30 mm^3), h_{max} = ±14, k_{max} = 9, l_{max} = 20. Répondant au critère $I > 3\sigma(I)$, 1791 réflexions sont utilisées pour la résolution structurale.

Tous les calculs ont été effectués sur PDP 11/44, programmes SDP d'Enraf–Nonius (14). Correction des facteurs de Lorentz polarisation et résolution de la structure par méthodes directes (MULTAN (15)). Après affinement en matrice totale avec des facteurs d'agitation thermique anisotrope pour le atomes de carbone et d'oxygène, isotrope fixé à B = 5 Å^2 pour les atomes d'hydrogène aux positions calculées (C—H : 0,950 Å) non affinées, les facteurs de reliabilité *R* et R_w (pondération unitaire) prennent respectivement les valeurs finales de 0,046 et 0,047. Une valeur de 0,86 pour le facteur de reliabilité *S* corrobore le choix de la pondération. Les facteurs de diffusion sont ceux donnés par Cromer et Waber (16) corrigés de la dispersion anomale (17).

Une fonction Fourier différence ne présente alors pas de pic supérieur à 0,16 e Å^{-3}. Les tables relatives aux positions des atomes d'hydrogène, aux facteurs d'agitation thermique anisotrope des atomes

The aggregation of mononuclear [2,9,16,23-tetra(neopentoxy)phthalocyanato]cobalt(II) and of some related binuclear cobalt(II) phthalocyanine derivatives, in *o*-dichlorobenzene, has been studied by electronic absorption spectroscopy. Dimerisation constants and the calculated aggregate dimer spectra are reported.

W. A. NEVIN, WEI LIU et A. B. P. LEVER. Can. J. Chem. **65**, 855 (1987).

Faisant appel à la spectroscopie d'absorption électronique et opérant dans le *o*-dichlorobenzène, on a étudié l'aggrégation du [tétra(néopentylate)-2,9,16,23 phtalocyanato]cobalt(II) mononucléaire et de quelques dérivés apparentés binucléaires de la phtalocyanine de cobalt(II). On rapporte les constantes de dimérisation et les spectres calculés des dimères sous formes d'aggrégats.

Introduction

Extensive studies on the water-soluble tetrasulphonated phthalocyanines (TsPc) (1–10) have shown a tendency for these complexes to dimerise in aqueous solution, the extent of dimerisation depending strongly upon the nature of the central substituent in the phthalocyanine ring. Typically, the dimer has a Q band absorption at ca. 30–50 nm to the blue of the monomer Q band, due to exciton coupling between the two halves of the aggregate (11). At high concentrations, higher aggregates form which absorb in the same region as the dimer Q band, but with broader, lower intensity bands (1–3, 5, 6).

These aggregation phenomena are of considerable interest since coupling interactions between the Pc rings have important biological significance as models for similar porphyrin behaviour and may also have a direct influence on properties such as semiconductivity, photo- and electrocatalytic efficiency, and electrochromism. In particular there is intense interest in designing multi-electron redox catalysts by the purposeful construction of polynuclear species which are often prepared by difficult, time consuming, and low yield routes. Aggregation offers a facile procedure for generating multinuclear species which may prove to have useful properties different from their mononuclear components.

A major difficulty in evaluating dimerisation processes in aqueous solution is that the strong solvent–solvent interaction, rather than the dye–dye interaction is the dominant force causing the molecules to aggregate (12, 13). Hence, studies in solvents of low dielectric constant are desirable to maximise the Pc–Pc interactions. However, few studies have been carried out on Pc dimerisation in organic solvents. Monahan *et al.* (12–14) have shown that the degree of dimerisation of tetraalkyl phthalocyanines (PcX_4) increases in the order of central substituent: Cu ≪ Zn < VO in benzene, which is in contrast to the results for TsPc species in aqueous solution (Zn ≈ VO < Cu (3–5)).

We have recently reported a series of binuclear and tetranuclear phthalocyanines (15–18) based upon the organic-solvent soluble [2,9,16,23-tetra(neopentoxy)phthalocyanato]cobalt(II) (Co(II)TNPc). The complexes can exist in various conformations depending upon the nature of the bridging unit. For example, the EtMeO(5) and Cat(4) species (the latter linked by an O—O catecholate group) can close in a "clamshell"-like fashion (11, 15) while other binuclear phthalocyanines are constrained by the geometry of the bridge to have an open conformation. We present here data for the mononuclear control phthalocyanine, Co(II)TNPc, for an example of a "clamshell" (EtMeO(5)) and for an open conformation binuclear phthalocyanine (C(2)) (the number in parentheses is the number of bridging atoms). The binuclear species are EtMeO(5)-$[Co(II)TrNPc]_2$ (trineopentoxyphthalocyanine rings linked via $—OCH_2C(Me)(Et)CH_2O—$) and C(2)$[Co(II)TrNPc]_2$ (trineopentoxyphthalocyanine rings linked via $—CH_2CH_2—$).

Experimental

Electronic spectra were recorded with a Hitachi – Perkin Elmer Microprocessor model 340 spectrometer. Cobalt phthalocyanines were prepared following literature routes (15, 16). *N,N*-Dimethylformamide (DMF) was supplied by Aldrich (Gold Label). Tetrabutylammonium perchlorate (TBAP) (Kodak) was recrystallised from absolute ethanol and dried at 50°C under vacuum for 2 days. Solutions in *o*-dichlorobenzene (DCB, Aldrich Gold Label) were prepared by dilution of a freshly prepared stock solution of phthalocyanine. Spectra were run immediately after each dilution and solutions were shielded from room light to minimise any photodecomposition of the phthalocyanine.

Results and discussion

Figure 1 shows that for Co(II)TNPc in DCB solution, Beer's law was obeyed for the band at 678 nm (monomer Q band) up to a concentration of 2×10^{-5} *M*, above which the results show considerable deviation from linearity. Increasing the concentration of Co(II)TNPc caused an increase in intensity at 612 nm relative to 678 nm, indicating the formation of aggregates. The values of the molar absorptivities of the monomeric form of Co(II)TNPc, calculated from the linear portion of the Beer's law plot, are given in Table 1.

In the presence of 0.3 *M* TBAP, deviation from Beer's law occurred at lower concentrations of Co(II)TNPc and to a greater extent than for pure DCB solution (Fig. 1), while the absorbance at 612 nm increased further relative to 678 nm. This shows a greater tendency for aggregation as the ionic strength of the solution is increased, which was also noted for phthalocyanines in aqueous solution (3, 5–10). Figure 2*a* shows the variation of the spectrum of Co(II)TNPc in DCB with 0.3 *M* added TBAP, at concentrations of between 9×10^{-5} and 7×10^{-4} *M*. The spectrum of monomeric Co(II)TNPc is included for comparison. Note that the electronic spectrum, in DCB, of the monomeric species (ca. 5×10^{-6} *M*) is unperturbed in the presence of 0.3 *M* TBAP, indicating that no strong

TABLE 1. Electronic spectra of the monomeric phthalocyanine species in DCB

Species	λ_{max} nm ($\epsilon \times 10^{-4}\ M^{-1}\ cm^{-1}$)				
Co(II)TNPc	330 (6.54)	382 (2.49)	612 (3.45)	645 sh	678 (13.5)
EtMeO(5)[Co(II)TrNPc]$_2$	322 (10.8)	380 sh	626 (9.25)		674 (9.38)
C(2)[Co(II)TrNPc]$_2$	334 (9.67)	380 sh	628 (6.96)	645 sh	682 (10.3)

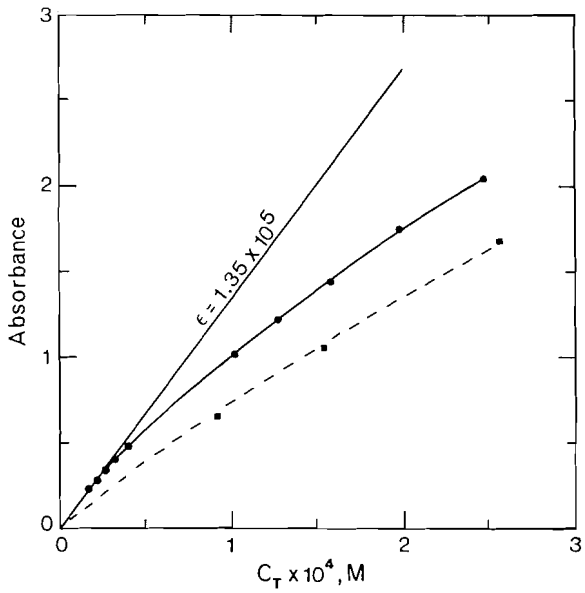

FIG. 1. Beer's law experiment (678 nm absorbance) for Co(II)TNPc in DCB solution (●) and DCB solution containing 0.3 M TBAP (■). The line marked $\epsilon = 1.35 \times 10^5$ defines Beer's law behaviour for Co(II)TNPc.

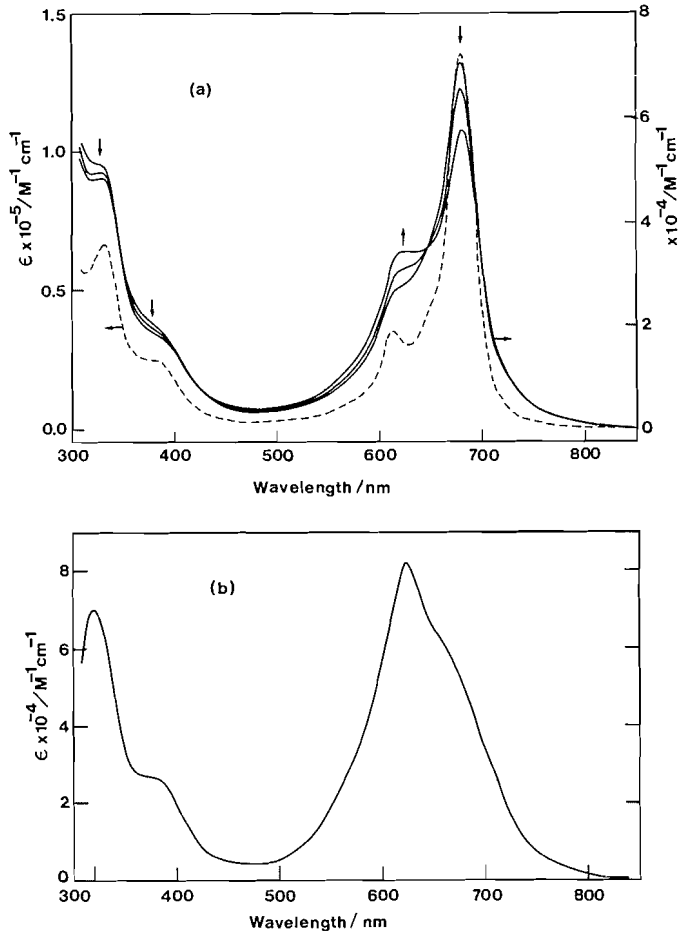

FIG. 2. (*a*) Electronic absorption spectra of Co(II)TNPc in DCB solution containing 0.3 M TBAP at concentrations of $9.2 \times 10^{-5}\ M$, $2.6 \times 10^{-4}\ M$, and $6.6 \times 10^{-4}\ M$ (—), and monomeric Co(II)TNPc in DCB solution (----). (*b*) Calculated spectrum of the aggregate dimer of Co(II)TNPc in DCB. ϵ_D(max) (625 nm) = $8.2 \times 10^4\ M^{-1}\ cm^{-1}$.

CoTNPc–TBAP interactions occur. The increased aggregation is probably due to a polarisation effect of the added electrolyte.

Addition of DMF to a solution of Co(II)TNPc in DCB reduces the aggregation, in agreement with previous work on metalloPcX$_4$ complexes in organic solvents (14), where the degree of aggregation was found to decrease with increasing dielectric constant of the solvent (DCB = 9.93, DMF = 36.7 (19)).

The dimerisation constant, K_D, for Co(II)TNPc in DCB was calculated from the uv–visible spectra using a computer program based upon the approximation method of West and Pearce (20), taking the spectrum at $< 2 \times 10^{-5}\ M$ to be that of the pure monomer. Data are given in Table 2. A plot of $\log_{10} C_M$ versus $\log_{10} C_D$, where C_M and C_D are the concentrations of monomer and aggregate dimer, respectively, at a given total concentration, C_T, of phthalocyanine, gave a straight line with a slope of 2 (statistical R coefficient > 0.99). This confirms the existence of a monomer(M)–dimer(D) (1) equilibrium excluding significant formation of trimers etc. at the concentrations studied.

$$[1] \quad 2\,M \rightleftharpoons^{K_D} D$$

An average value of $K_D = 2.57\ (\pm 0.05) \times 10^3\ M^{-1}$ was obtained.

Dimerisation constants of the binuclear complexes EtMeO(5)-[Co(II)TrNPc]$_2$ and C(2)[CoTrNPc]$_2$ in DCB were measured using phthalocyanine concentrations of 10^{-7}–10^{-4} and 10^{-6}–$10^{-4}\ M$, respectively. The spectra measured at $< 5 \times 10^{-6}\ M$ were taken as those of the pure monomeric forms. Absorption data used for calculation of the dimerisation constants are given in Tables 3 and 4, respectively. Plots of $\log_{10} C_M$ versus $\log_{10} C_D$ are shown in Fig. 3. In each case a straight line with a slope of 2 is obtained, showing that an equilibrium exists

[a]Cell pathlength = 0.1 cm; OD_{obs} = observed optical density; OD_M = corrected optical density of the monomeric species. $C_D = (C_T - C_M)/2$; $K_D = C_D/C_M^2$.

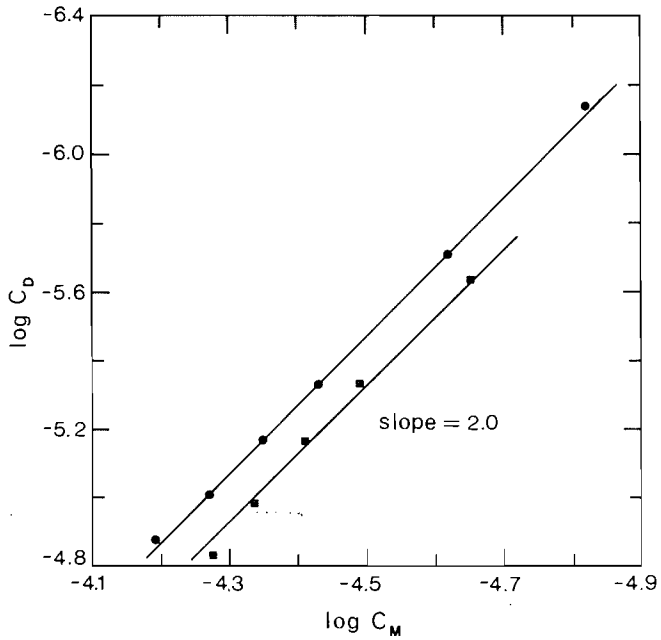

FIG. 3. Plots of log C_M versus log C_D for EtMeO(5)[Co(II)TrNPc]$_2$ (●) and C(2)[Co(II)TrNPc]$_2$ (■) in DCB solution. The solid lines are drawn with the theoretical slope of 2. The statistical R coefficient exceeds 0.99 for both plots.

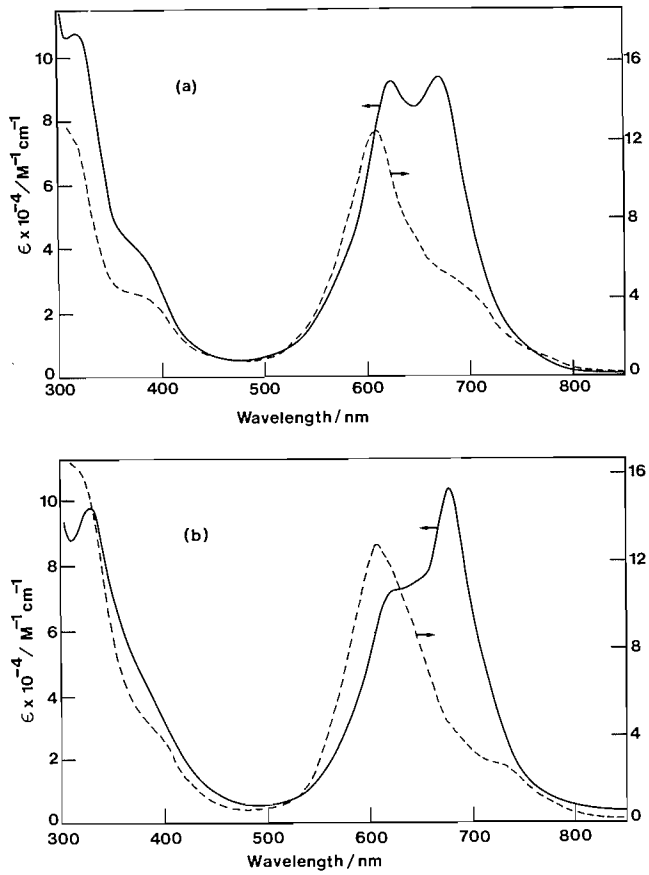

FIG. 4. Electronic absorption spectra of monomeric (—) and calculated aggregate dimer spectra, in DCB, of (*a*) EtMeO(5)[Co(II)TrNPc]$_2$ (ϵ_D(max)(610 nm) = $12.5 \times 10^4 M^{-1}$ cm^{-1}), and (*b*) C(2)[Co(II)TrNPc]$_2$ (ϵ_D(max) (605 nm) = $12.8 \times 10^4 M^{-1}$ cm^{-1}).

between a monomeric form and a dimer coupled via both rings of each binuclear molecule. Average values of K_D were calculated to be 3.3 ($\pm$0.2) $\times 10^3$ and 4.9 ($\pm$0.3) $\times 10^3$ M^{-1}, for EtMeO(5)[CoTrNPc]$_2$ and C(2)[CoTrNPc]$_2$, respectively.

The spectroscopic data can be used to derive the electronic spectra for the pure aggregate dimeric species following the method of West and Pearce (6, 7, 20). These spectra are shown in Figs. 2*b* and 4 and show the blue shifting to be anticipated as a consequence of the exciton coupling (11).

The values of K_D measured for these cobalt neopentoxy complexes in DCB are 2–3 orders of magnitude smaller than for CoTsPc in aqueous solution (1–4, 7). This is consistent with the 3–4 order of magnitude difference between K_D of $CuPcX_4$ in benzene (13, 14) and CuTsPc in water (3, 4, 6). In contrast, the K_D values of Zn and VO phthalocyanines are approximately of the same order for $MPcX_4$ in benzene (13, 14) and MTsPc in water (3–5).

Although the dimerisation constants of the cobalt neopentoxy phthalocyanine complexes are of the same order of magnitude, small differences are seen which may be related to the structural conformations of the molecules. Thus, the "open" conformation C(2) binuclear species appears to aggregate more readily than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

the EtMeO(5) binuclear species, which can form a "closed clamshell" conformation in solution, an effect which may inhibit inter-molecular aggregation.

A tetranuclear cobalt(II) phthalocyanine (18) has an unexpectedly high aggregation constant in DCB, some two orders greater than the binuclear species reported here. It is tentatively proposed that the geometry of the tetranuclear species permits two clamshell halves to inter-penetrate to form a quadruple stack. Presumably such an inter-penetrated quadruple stack is not geometrically permissible for the EtMeO(5) species.

Chimie des radioprotecteurs : synthèse d'alkylamino-2 éthanethiols encombrés sur l'atome d'azote

JOELLE LADURANTY, FRANCIS BARBOT ET LÉONE MIGINIAC[1]

Laboratoire de synthèse organique, Unité Associée 574 Centre national de la recherche scientifique, Université de Poitiers, 40, avenue du Recteur Pineau, 86022 Poitiers, France

Reçu le 30 juillet 1986

JOELLE LADURANTY, FRANCIS BARBOT et LÉONE MIGINIAC. Can. J. Chem. **65**, 859 (1987).

La mise au point de la synthèse d'alkylamino-2 éthanethiols portant un groupe tertiaire sur l'atome d'azote a été réalisée. L'action de magnésiens allyliques sur les thiazolidines, les alkyl-2 thiazolines et les thiométhyl-2 thiazolines s'est révélée une méthode de choix pour obtenir ces composés avec un groupe tertiaire comportant respectivement un, deux et trois motifs allyliques.

JOELLE LADURANTY, FRANCIS BARBOT, and LÉONE MIGINIAC. Can. J. Chem. **65**, 859 (1987).

Synthesis of 2-alkylaminoethanethiols with a tertiary group fixed to the nitrogen atom has been achieved. A very convenient method of access to such 2-alkylaminoethanethiols with one, two, and three allyl substituents is the reaction between allylic organomagnesium compounds and thiazolidines, 2-alkylthiazolines, and 2-methylthiothiazolines respectively.

Introduction

Au cours de ces dix dernières années, l'emploi des radioprotecteurs chimiques a pris un essor considérable. En effet, de tels composés sont d'une utilité potentielle dans le traitement du cancer : en radiothérapie, ils possèdent la propriété de protéger les cellules saines et, en chimiothérapie, ont également un effet bénéfique spécifique en «saturant» ces mêmes cellules et en minimisant ainsi la toxicité des antimitotiques utilisés (1, 2).

Ces travaux ont en particulier mis en évidence l'intérêt de la cystéamine **I** et de ses dérivés aliphatiques (1–8), ainsi que le rôle déterminant du vecteur. Cependant la cystéamine présente une certaine toxicité : certaines transformations, par exemple la formation de thiazolidines (9–12) ou bien celle de ponts disulfure (13, 14), permettent de la diminuer; le passage de la cystéamine à sa forme *S*-phosphorylée **II** (15–18) ou encore sa transformation en acides *S*-[(aminopropyl-3)aminoéthyl-2] et *S*-[(*N*-méthylaminopropyl-3)aminoéthyl-2] phosphorothioïques **III** et **IV** (15–17, 19) conduit également à des radioprotecteurs très intéressants :

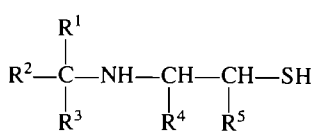
$H_2N—CH_2—CH_2—SH$ **I**

$H_2N—CH_2—CH_2—S—PO_3HNa$ **II**

$H_2N—(CH_2)_3—NH—CH_2—CH_2—SPO_3H_2$ **III**

$CH_3—NH—(CH_2)_3—NH—CH_2—CH_2—SPO_3H_2$ **IV**

La substitution d'un hydrogène de la fonction amine de la cystéamine par un groupe alkyle saturé, insaturé et (ou) fonctionnel, d'encombrement stérique notable, étant susceptible de jouer un rôle important sur les propriétés radioprotectrices (libération retardée de la cystéamine par déalkylation sélective par métabolisme) et sur la toxicité de la cystéamine, nous nous sommes proposés de mettre au point des méthodes simples et générales d'accès aux dérivés de type :

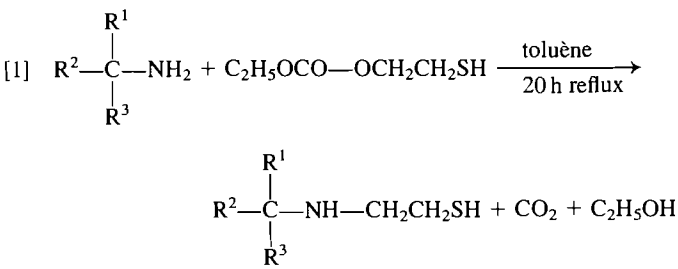


R_1, R_2, R_3 = alkyle, allyle, propargyle, alkyle fonctionnel
R_4, R_5 = H alkyle

1. Auteur à qui adresser toute correspondance.

I. Accès aux alkylamino-2 éthanethiols par action d'une amine primaire sur le mercaptoéthyl-2 carbonate d'éthyle

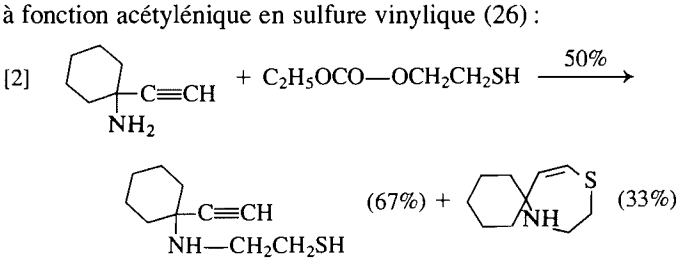
L'ouverture par une amine primaire (selon réfs. 21, 22) du thioépoxyde (produit peu stable) conduisant à des résultats décevants ou difficilement reproductibles, nous avons préféré utiliser le schéma réactionnel suivant :



En présence d'une base, le mercaptoéthyl-2 carbonate d'éthyle se décompose en thioépoxyde selon le mécanisme réactionnel proposé dans la réf 20.

Nos essais ont été réalisés avec l'amino-1 tétraméthyl-1,1,3,3 butane et l'amino-2 méthyl-2 propanol, ainsi qu'avec trois autres amines primaires à groupe tertiaire, préparées selon les réfs. 23–25, pour lesquelles R^1, R^2, R^3 = cycloalkyle, allyle, éthynyle, vinyle ou alkyle fonctionnel; nous avons également considéré le cas particulier d'une diamine primaire de type néopentylique, le diméthyl-2,2 diamino-1,3 propane.

Les résultats du tableau 1 montrent que la réaction a lieu dans tous les cas et conduit avec des rendements de 30–68% à l'aminothiol attendu; la réaction n'a lieu qu'une seule fois avec la diamine, malgré l'utilisation d'une quantité double de réactif. Enfin, signalons la cyclisation partielle *in situ* de l'aminothiol à fonction acétylénique en sulfure vinylique (26) :



Cette méthode permet donc d'atteindre des aminothiols secondaires à groupe alkyle encombré, lorsque l'amine primaire nécessaire est commerciale ou facile à préparer; cependant,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12

TABLEAU 1. Préparation d'amino-2 thiols par action d'amines primaires sur le mercaptoéthyl-2 carbonate d'éthyle

Amine	Produit obtenu		Rdt (%)
		**1**	58
		**2**	30
		**3**	50
		**4**	50
		**5**	68
		**6**	38

*Dans ce cas, l'amino-2 thiol attendu est accompagné du sulfure vinylique spirannique isomère **4'** (26).

cette dernière condition diminue beaucoup les possibilités d'application de cette méthode.

II. Accès aux alkylamino-2 éthanethiols par action d'un organomagnésien dérivant d'un halogénure α-insaturé sur une thiazolidine

Il a été montré qu'un *gem*-aminothioéther donne facilement une réaction avec les organométalliques, en particulier avec les organométalliques α-insaturés (27, 28), pour conduire à une amine et à un thiol :

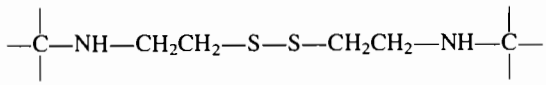
[3] $R'S{-}CH_2{-}N(R'')_2 \xrightarrow[(2)\ H_2O]{(1)\ RM} R'SH + RCH_2N(R'')_2$

Une telle réaction, appliquée à un *gem*-aminothioéther cyclique tel qu'une thiazolidine, devait nous permettre d'atteindre des aminothiols à groupe tertiaire.

A notre connaissance, seule l'action sur quelques thiazolidines de divers hydrures tels que $NaBH_4$ a été envisagée (31, 32) et a permis dans certains cas d'obtenir le produit résultant de l'ouverture du cycle.

Nous avons donc préparé par des méthodes usuelles (12, 29, 30) plusieurs thiazolidines et étudié leur réaction avec les magnésiens dérivant d'halogénures allyliques ou propargyliques :

[4] 
Les résultats du tableau 2 montrent que cette réaction a lieu dans tous les cas étudiés, le carbone C2 de la thiazolidine pouvant comporter des groupes saturés, insaturés ou fonctionnels. Les rendements (40–72%) en aminothiols isolés dépendent beaucoup des précautions prises lors de l'isolement (voir partie expérimentale); en effet, en opérant sans précautions particulières, il se forme par oxydation une quantité importante du disulfure correspondant :



Dans un seul cas, le rendement s'est révélé faible, sans doute par suite d'une décomposition lors de la distillation : il se forme vraisemblablement une cétimine β-éthylénique par élimination de butène-1 (pour une décomposition analogue, voir réfs. 33, 34), laquelle peut par exemple se cycliser en thiazolidine ou s'isomériser :

[5]

TABLEAU 2. Préparation d'amino-2 thiols par action de magnésiens α-insaturés sur les thiazolidines

Thiazolidine	RMgX	Produit obtenu		Rdt (%)
	$CH_2{=}CHCH_2MgBr$		**7**	40
			**8**	65
	$CH_2{=}C{=}CHMgBr$		**9**	43
	$CH_2{=}CHCH_2MgBr$		**10**	60
	$CH_2{=}CHCH_2MgBr$		**11**	18*
	$CH_2{=}CHCH_2MgBr$		**12**	65
	$CH_2{=}CHCH_2MgBr$		**13**	44
	$CH_2{=}CHCH_2MgBr$		**14**	72
	$CH_2{=}CHCH_2MgBr$		**15**	60

*Résidus abondants.

En résumé, cette réaction constitue donc une très bonne méthode de préparation d'alkylamino-2 éthanethiols secondaires à groupe tertiaire.

III. Accès aux alkylamino-2 éthanethiols par action d'un organomagnésien α-insaturé sur une thiazoline

Compte tenu des résultats précédents, il était intéressant d'essayer, à partir d'un substrat adéquat, d'introduire par voie organométallique deux, puis trois groupements allyles sur le groupe carboné rattaché à l'azote.

Nous avons donc envisagé de partir de thiazolines et d'étudier leur comportement vis à vis d'organomagnésiens allyliques; cette réaction peut se dérouler de la manière suivante en impliquant vraisemblablement d'ailleurs le passage à une thiazolidine *N*-métallée analogue à celles intervenant dans le paragraphe précédent :

[6] 
De même :

[7] 
À notre connaissance, l'action des magnésiens allyliques sur des thiazolines simples n'a pas été envisagée; signalons cependant les travaux récents relatifs à l'action de divers magnésiens sur les benzothiazoles (35–38).

Alors que les magnésiens saturés réalisent généralement une réaction de métallation au niveau du groupe R (36), les magnésiens allyliques conduisent généralement à une ouverture de cycle (35, 37), les auteurs n'isolant pas l'aminothiol résultant, mais directement le disulfure :

[8] 
En outre, les auteurs signalent l'arrêt possible à la benzothiazoline, en utilisant le dichlorométhane au lieu de l'éther (38).

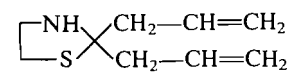
Nous avons préparé par des méthodes usuelles plusieurs alkyl-2 thiazolines diversement substituées (39–41; voir également la réf. 56) ainsi que deux thiométhyl-2 thiazolines (42–44), et étudié leur comportement vis à vis des magnésiens allyliques.

Les résultats obtenus dans cette étude figurent dans le tableau 3 et permettent de faire les remarques suivantes :

(*a*) La réaction a lieu dans tous les cas et permet d'atteindre les aminothiols attendus avec des rendements moyens (30–50%) avec une thiazoline non substituée sur la chaîne carbonée, et avec des rendements un peu plus faibles (20–40%) avec une thiazoline substituée. Le rendement est aussi plus faible lors de l'action du chlorure de méthallylmagnésium sur une thiazoline simple, la structure étant plus encombrée que dans le cas du groupe allyle. Là encore, les rendements en aminothiols isolés dépendent beaucoup des précautions prises lors de l'isolement (voir partie expérimentale).

À noter que contrairement à la réf. 38, l'action sur une thiazoline du bromure d'allylmagnésium, au sein de l'éther ou du dichlorométhane, conduit toujours au produit d'ouverture.

(*b*) La réaction permet également d'atteindre, à partir de la thiazoline non substituée en C2, des aminothiols à groupe secondaire. Ce résultat est intéressant, car il se forme le même dérivé que celui qui résulterait de l'action d'un hydrure sur la thiazolidine :



d'accès très difficile, puisqu'impliquant l'emploi d'une cétone β,β′-diéthylénique.

L'action des magnésiens allyliques sur les thiazolines permet donc de préparer aisément des aminothiols à groupe tertiaire comportant deux ou trois substituants allyliques.

Conclusion

Nous avons pu réaliser, dans des cas structuraux variés, la synthèse d'alkylamino-2 éthanethiols possédant un groupe tertiaire sur l'atome d'azote.

Nos résultats montrent également que la voie de synthèse

organométallique impliquant l'action d'organomagnésiens allyliques sur les thiazolidines, les alkyl-2 thiazolines et les thiométhyl-2 thiazolines est une méthode très intéressante, car générale et facile à mettre en oeuvre.

Partie expérimentale

Introduction

Les chromatographies en phase gazeuse ont été effectuées avec un appareil Intersmat IGC 12 M (détecteur à conductibilité thermique) équipé de colonnes analytiques de 2 m (diamètre : 0,63 cm), remplissage soit 20% SE 30, soit 20% Carbowax 20 M sur Chromosorb W.

Les spectres infrarouges ont été enregistrés sur les produits à l'état pur entre lames de chlorure de sodium avec un appareil IR 4240 Beckman. Intensités des bandes : F, forte; m, moyenne; f, faible; tf, très faible.

Les spectres rmn ont été enregistrés en solution dans CCl_4 à 60 MHz sur un appareil Perkin–Elmer R 24 A. Les déplacements chimiques sont exprimés en ppm par rapport au tétraméthylsilane utilisé comme référence.

Les analyses élémentaires ont été effectuées par le service central d'analyse du CNRS.

L'éther et le tétrahydrofuranne utilisés ont été préalablement desséchés et désoxygénés par distillation sur benzophénone/sodium, sous courant d'azote sec.

Préparation des magnésiens

Les bromures d'allylmagnésium, chlorure de méthallylmagnésium et bromure d'allénylmagnésium ont été préparés au sein de l'éther (45, 46).

Préparation des matières premières

(1) Amines primaires à groupe tertiaire

Les tétraméthyl-1,1,3,3 butylamine, diméthyl-1,1 hydroxy-2 éthylamine et diméthyl-2,2 diamino-1,3 propane sont des produits commerciaux utilisés après redistillation. Les amino-4 méthoxyméthyl-4 heptadiène-1,6 (23), amino-1 éthynyl-1 cyclohexane (24, 25, 47) et amino-1 vinyl-1 cyclohexane (25) ont été obtenus selon des méthodes usuelles.

(2) Thiazolidines

Elles sont obtenues selon les réfs. 29 et 30. Les cétones employées dans cette réaction sont des produits commerciaux (pentanone-2 et pentanone-3) ou ont été préparées selon des techniques usuelles : méthoxy-1 butanone-2 (52), thiométhyl-1 propanone-2 (49, 53), méthoxy-1 butanone-3 (48) et thiométhyl-1 butanone-3 (49–51).

Les constantes physiques des thiazolidines figurent dans le tableau 4.

(3) Alkyl-2 thiazolines

Elles sont préparées selon les réfs. 39–41. Les aminoalcools impliqués dans cette réaction sont des produits commerciaux (utilisés après redistillation) ou sont préparés selon des méthodes usuelles (54, 59).

Les constantes physiques des alkyl-2 thiazolines figurent dans le tableau 5.

(4) Thiométhyl-2 thiazolines

Elles sont préparées selon les réfs. 42–44. Leurs constantes physiques figurent dans le tableau 5.

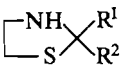
Modes opératoires

Première méthode

On opère sous atmosphère d'azote dans un ballon à trois tubulures de 250 mL équipé d'une ampoule, de deux réfrigérants ascendants (le premier à circulation d'eau, le second réfrigéré par un courant d'alcool refroidi à −30°C).

L'amine primaire (0,3 mol) en solution dans 50 mL de toluène anhydre est chauffée à reflux; 0,1 mol de mercaptoéthyl-2-carbonate d'éthyle est alors ajoutée par un goutte à goutte rapide et le milieu réactionnel est chauffé à reflux pendant 20 h environ. Après concentration du milieu réactionnel à l'évaporateur rotatif à l'aide d'un bain d'eau à 45°C environ, le résidu est distillé sous pression réduite la plus faible possible.

TABLEAU 4. Constantes physiques des thiazolidines



R^1	R^2	Réf. Litt.	Eb. (°C/Torr)	n_D^{20}	Rdt (%)
CH_3	nC_3H_7	29	87/16	1,5030	70
C_2H_5	C_2H_5	29	83/10	—	76
C_2H_5	CH_2OCH_3	—	63/0,07	1,5070	50
CH_3	CH_2SCH_3	—	78/0,05	1,5639	54
CH_3	$(CH_2)_2OCH_3$	—	55/0,05	1,5048	65
CH_3	$(CH_2)_2SCH_3$	—	103/0,5	1,5555	58

Deuxième méthode

(a) Cas d'un magnésien allylique. Dans un ballon à trois tubulures de 1000 mL préalablement séché à la flamme sous atmosphère d'azote, on place une solution de 0,06 mol de thiazolidine dans 220 mL d'éther. On introduit goutte à goutte, à t = 0–5°C, le magnésien, préalablement décanté, préparé selon la réf. 45 à partir de 13,0 g (0,535 mol) de Mg, 0,22 mol de bromure allylique et 190 mL d'éther.

À la fin de l'addition, le milieu réactionnel est chauffé à reflux pendant 2 h. Après retour à température ambiante, il est refroidi à t = 0–5°C et hydrolysé sous courant d'azote par addition lente d'une solution saturée de chlorure d'ammonium (420 mL).

Après décantation, extraction par 4 × 100 mL d'éther et séchage sur sulfate de magnésium, la phase organique est concentrée, puis l'aminothiol est distillé sous pression réduite la plus faible possible.

(b) Cas du bromure d'allénylmagnésium. À la solution du magnésien dérivant du bromure de propargyle, préparée à température inférieure à 18°C selon la réf. 46, à partir de 14,3 g (0,12 mol) de bromure de propargyle, 6,0 g de Mg broyé (0,247 mol) et de 85 mL d'éther, on additionne goutte à goutte une solution de 0,03 mol de thiazolidine dans 30 mL d'éther désoxygéné, en maintenant la température à 0–5°C. L'agitation est poursuivie pendant 2,5 h à une température inférieure ou égale à 18°C. Après l'hydrolyse *in situ* comme précédement et les traitements usuels, le résidu est distillé sous pression réduite la plus faible possible.

Troisième méthode

(a) Action du bromure d'allylmagnésium sur une alkyl-2 thiazoline. Une solution de bromure d'allylmagnésium (préparée sous azote, à 0–5°C, à partir de 19,4 g (0,16 mol) de bromure d'allyle, 10 g de Mg broyé (0,411 mol) et 140 mL d'éther est additionnée goutte à goutte (durée 2,5 h environ) à une solution de 0,04 mol d'alkyl-2 thiazoline dans 300 mL de dichlorométhane distillé, refroidie à 0–5°C. Après retour à température ambiante, le milieu est maintenu sous agitation pendant 2 h. Il est ensuite refroidi à 0°C et hydrolysé par addition lente d'une solution aqueuse saturée de chlorure d'ammonium (300 mL). Après les traitements usuels, le produit est distillé sous pression réduite la plus faible possible, en évitant les surchauffes. *N.B.* Dans le cas de l'action du chlorure de méthallylmagnésium sur une alkyl-2 thiazoline, on opère au sein de l'éther désoxygéné seul, la réaction risquant d'être incomplète au sein du mélange éther/dichlorométhane (38).

(b) Action du bromure d'allylmagnésium sur une thiométhyl-2 thiazoline. Une solution de bromure d'allylmagnésium (préparée sous azote à 0–5°C à partir de 24,2 g (0,2 mol) de bromure d'allyle, 12,6 g de Mg broyé (0,55 mol) et 170 mL d'éther) est ajoutée lentement sous azote, à 0–5°C, à une solution de 0,04 mol de la thiométhyl-2 thiazoline dans 170 mL de tétrahydrofuranne désoxygéné. Après retour à température ambiante, le milieu est chauffé à reflux pendant 2 h, puis laissé sous agitation pendant une nuit. Après refroidissement, une hydrolyse dans les mêmes conditions que précédemment est effectuée par addition d'une solution saturée de chlorure d'ammonium (400 mL). Après les traitements usuels, le produit brut est distillé sous pression réduite la plus faible possible.

ANTONIO DELGADO, DAVID MAULEON, CRISTINA MINGUILLON, MIGUEL FELIZ, MIQUEL A. PERICAS, and ANTONI RIERA. Can. J. Chem. **65**, 868 (1987).

The stereochemical assignment of *cis*- and *trans*-2-amino-1,2,3,4-tetrahydro-1-naphthalenols (**1**) can be performed by means of their conformationally restrained tricyclic tetrahydronaphtho[2,1-*d*]oxazol-2-one derivatives **2**–**6**. Thus, ^1H and ^{13}C nuclear magnetic resonance data of compounds **2**–**6** reveal differences between the *cis* and *trans* stereoisomers that are independent of the nature and number of the aromatic substituents. Conformational analysis of compounds **2**–**6** has been performed from the LAOCOON/3 analysis of their nuclear magnetic resonance spectra and MNDO theoretical results, through the use of the Karplus–Altona equation. Whereas the *trans* compounds exist in a rigid half-chair conformation, a 1:1 equilibrium of two interconverting half-chair conformers is found for the *cis* derivatives.

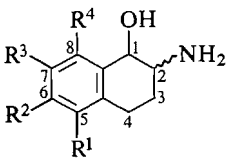
ANTONIO DELGADO, DAVID MAULEON, CRISTINA MINGUILLON, MIGUEL FELIZ, MIQUEL A. PERICAS et ANTONI RIERA. Can. J. Chem. **65**, 868 (1987).

On peut attribuer les configurations des amino-2 tétrahydro-1,2,3,4 naphtalénols-1-*cis* et -*trans* (**1**) en se basant sur leurs dérivés tricycliques, tétrahydronaphto[2,1-*d*]oxazolones-2 (**2**–**6**), qui sont restreints d'un point de vue conformationnel. Ainsi, les spectres rmn du ^1H et du ^{13}C des composés **2**–**6** présentent des différences, entre les isomères *cis* et *trans*, qui sont indépendantes de la nature et du nombre de substituants présents sur le cycle aromatique. En se basant sur une analyse à l'aide du programme LAOCOON/3 de leurs spectres rmn ainsi que sur des résultats théoriques analysés à l'aide de l'équation de Karplus–Altona, on a effectué une analyse conformationnelle des composés **2**–**6**. Alors que l'isomère *trans* existe sous une conformation rigide demi-chaise, les dérivés *cis* existent sous la forme d'un équilibre 1:1 de deux conformères demi-chaises qui se convertissent rapidement l'une dans l'autre.

[Traduit par la revue]

Introduction

In the course of studies of the adrenergic properties of conformationally restricted arylethanolamines, several isomeric pairs of substituted *cis*- and *trans*-2-amino-1,2,3,4-tetrahydro-1-naphthalenols **1** (see Fig. 1) have been described in the literature (1). Assignment of their stereochemistry is of major importance from a pharmacological standpoint and it has usually been carried out by ^1H nmr spectroscopy, on the basis of the H1 chemical shift[2] and the magnitude of the H1–H2 coupling constant (2). In the *trans* isomers H1 appears at 4–5 ppm as a doublet (J(H1–H2) = 8–10 Hz); in *cis* isomers this proton resonates at slightly lower field than in the *trans* compounds ($\Delta\delta$ = 0.2–0.3 ppm) and shows a H1–H2 coupling constant of about 3–5 Hz. However, the aforementioned criterion is not of general applicability. For instance, in a pair of *cis*-and *trans*-2-aminotetrahydro-1-naphthalenols prepared in our laboratories (**1**, $R^1 = R^4 = OCH_3$, $R^2 = R^3 = H$), we observed that the H1–H2 coupling constant was 4–5 Hz in each isomer, which did not allow an unambiguous stereochemical assignment. In fact, the observed values for J(H1–H2) depend on the position of the conformational equilibrium of the saturated ring. Only when this equilibrium in the *trans* isomer is shifted towards the di-pseudoequatorial conformer, will the J(H1–H2) values in the *cis* and *trans* derivatives be clearly different. Thus, we have considered of interest the development of a more reliable method for the stereochemical assignment of aminoalcohols **1**. In this context, we thought of the possibility of converting the aminoalcohols **1** into conformationally constrained tricyclic derivatives, so that the amino and hydroxyl groups in the parent compounds were forced to a fixed arrangement. The tetrahydronaphtho[2,1-*d*]oxazol-2-one derivatives **2**–**6** appeared quite suitable for this purpose since they can be easily obtained from aminoalcohols **1** under conditions where the stereochemistry of the starting material is preserved, and they possess the required rigidity.



1

FIG. 1. General structure of 2-amino-1,2,3,4-tetrahydro-1-naphthalenols (**1**). The *cis* and *trans* stereochemistry refers to the hetero functions on C1 and C2.

Although there is one example in the literature in which a pair of stereoisomeric 2-aminotetrahydro-1-naphthalenols of known stereochemistry have been converted into the corresponding tetrahydronaphtho[2,1-*d*]oxazol-2-ones by treatment with phosgene (3), the usefulness of such tricyclic derivatives to confirm the stereochemistry of the starting aminoalcohols has not been explored. In this paper we report the synthesis of the

3a,4,5,9b-tetrahydronaphtho[2,1-*d*]oxazol-2-one derivatives **2–6**, their spectroscopic study by nmr techniques, and the corresponding conformational analysis using the obtained coupling constants and the results of MNDO semiempirical SCF MO calculations on compound **2**.

Results and discussion

Synthesis

Synthesis of compounds **2–6** has been accomplished in each case from the corresponding *cis* or *trans* aminoalcohol according to the reaction sequence outlined in Scheme 2.

Thus, reaction of the starting aminoalcohol with phenyl chloroformate in pyridine afforded an intermediate urethane, which was converted to the requisite naphtho[2,1-*d*]oxazol-2-one by treatment with excess sodium hydride in tetrahydrofuran. Since both of these transformations are carried out in alkaline media, we do not expect any stereochemical changes and therefore the product will have the same stereochemistry as the starting aminoalcohol.

Spectroscopic studies

Chemical shifts of the H3a and H9b protons as well as the coupling constants between them are summarized in Table 1. As it can be observed, the *cis* or *trans* stereochemistry can be unambiguously established for each compound from the above data. Thus, two different sets of chemical shifts/coupling constant values can be observed, both being almost completely independent of the nature, position, and number of substituents on the aromatic ring. In *trans* derivatives **2–6**, the H9b chemical shift ranges in the interval of 5.08 ± 0.04 ppm whereas the H3a proton resonates at 3.68 ± 0.06 ppm and the mean H9b–H3a coupling constant is 11.14 ± 0.38 Hz. Similarly, *cis* derivatives show narrow chemical shift intervals of 5.64 ± 0.15 ppm for the H9b proton and 4.24 ± 0.05 ppm for the H3a proton, as well as an average H9b–H3a coupling constant of 8.25 ± 0.18 Hz.

The ^{13}C nmr spectra of compounds **2–6** have been recorded in $CDCl_3/CD_3OD$ solution (Table 2). Signals have been assigned on the basis of their multiplicity, chemical shifts, additivity effects due to the introduction of substituents upon the aromatic ring, and, in the case of C4 and C5 carbon atoms of the model compounds **2**, by means of $^{13}C-^1H$ heterocorrelation experiments. The ^{13}C nmr spectra confirm that the chemical shift of the cycloaliphatic carbon atoms in each diastereomeric series is independent of the nature of the substituents on the aromatic ring. Thus, empirical increments between carbon atoms of the same position in each diastereomeric pair can be obtained (Table 3). For example, C9b and C3a carbon atoms are deshielded at least 5.9 ppm in *trans* derivatives with respect to *cis* ones. This effect can be rationalized on the basis of the higher deshielding effect exerted by equatorial O and N groups upon the corresponding α and ipso carbon atoms, in comparison to the lower deshielding effect exerted upon the same carbon atoms when one of those groups adopts an axial disposition (4), which is the case for both possible conformations of the *cis* derivatives (see below).

In the light of the significant differences observed in the ^{1}H and ^{13}C nmr spectra of *cis*- and *trans*-naphtho[2,1-*d*]oxazol-2-ones, we can conclude that conversion of 2-aminotetrahydro-1-naphthalenols into their corresponding cyclic carbonyl derivatives is a good procedure for stereochemical assignment. These differences are independent of the nature of the aromatic

substituents and thus they can be useful for the assignment even in those aminotetralols which are conformationally distorted and not directly assignable by nmr, as was the case for **1** ($R^1 = R^4 = OCH_3$, $R^2 = R^3 = H$).

Conformational analysis

Compounds *trans*-**2–5** showed a great similarity in the ^1H nmr coupling patterns of the cycloaliphatic protons, and the same is true within the *cis* series **2–4**. Compounds *cis*-**2** and *trans*-**2** were taken as standards for simulation of the cycloaliphatic region of the high-resolution ^1H nmr spectra by means of the LAOCOON/3 program (5). After full optimization, their simulated spectra were superimposable with the experimental ones (RMS error was in both cases less than 0.2 Hz). The observed coupling constants and chemical shifts from the LAOCOON/3 analysis appear in Table 4.

To obtain information on these molecules, we decided to perform a theoretical study by using the semiempirical SCF MO method MNDO (6). For compound *trans*-**2**, only one stationary point could be located (Fig. 2). This is completely in accord with that observed by simple inspection of a Dreiding molecular model of *trans*-**2**, in which only one rigid half-chair conformer could be found.

On the other hand, MNDO predicts the existence of two different minima for *cis*-**2**, corresponding to the two half-chair conformers (Fig. 3). These are also observed by direct inspection of its Dreiding molecular model. The greater strain in *trans*-**2** is reflected in the MNDO results. Thus, *cis*-**2** ($\Delta H_f = -60.9$ kcal/mol) is predicted to be 10.5 kcal/mol more stable than the *trans* isomer ($\Delta H_f = -50.4$ kcal/mol). On the

*From MNDO calculations through the use of the Karplus–Altona equation.
†From MNDO calculations.

other hand, both possible conformers of *cis*-**2** are predicted to have very similar energy contents.

The Karplus–Altona equation (7) opens a way for perfoming a conformational analysis of *cis*-**2**. From the MNDO optimized geometries of both conformers of the *cis* stereoisomer we obtained the dihedral angles between vicinal protons on C-4 and C-5, and the corresponding coupling constants were then calculated by the Karplus–Altona equation. The results compare very well with the set of experimental coupling constants (RMS error = 0.36 Hz) and are summarized in Table 5. The selected set of coupling constants is the most reliable one that can be obtained by using the Karplus–Altona equation, since the C4—C5 part of the molecule is strain free and the substituents on these carbon atoms are well parametrized in the equation. On the other hand, a simple inspection of the computer-generated drawings of conformers *a* and *b* of *cis*-**2** (Fig. 3) showed that J(H4α–H5β) and J(H4β–H5α) were the coupling constants most sensitive to the conformational equilibrium. A population analysis was subsequently performed on the basis of these coupling constants and the results indicate in both cases a 1:1 equilibrium (estimated errors are below ±5%). It is noteworthy that these analyses afford an identical value within the margins of experimental error. On the other hand, the very small energetic difference between the calculated heats of formation (0.05 kcal/mol) of the conformers of *cis*-**2** also predicts an essentially equal population of both species.[3]

Finally, it has to be mentioned that neither *cis*-**6** nor *trans*-**6** showed ^{1}H nmr coupling patterns comparable to those of the corresponding *cis* and *trans* analogues **2**–**5**, and that the nmr spectrum of the cycloaliphatic protons in these compounds could not be successfully simulated by means of the LAOCOON/3 program. These results can be rationalized on the basis of the *peri* effect exerted by the C9-methoxyl group, which can sensibly modify the structural features of such compounds. However, as has been stated, this limitation does not preclude the use of naphtho[2,1-*d*]oxazol-2-one derivatives to confirm the stereochemistry of the corresponding 2-aminotetrahydro-1-naphthalenols.

Experimental

Melting points were determined in a capillary tube on a Buchi apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 1430 spectrophotometer. Proton magnetic resonance spectra were measured at 200 MHz with an FT Varian XL-200 spectrometer. Signal positions are reported in ppm downfield from tetramethylsilane (δ scale) as an internal standard, with $CDCl_3$ as solvent. The number of protons, multiplicity, coupling constants, and proton assignments are indicated in parentheses. The ^{13}C nmr spectra were measured at 50.3 MHz in the same spectrometer, with internal tetramethylsilane as a reference. Multiplicity of the signals was determined by the ADEPT program (8) (automatic distortionless enhancement by polarization transfer). Heteronuclear chemical shift correlation ^{13}C–^{1}H was determined by the HETCOR program (9). The calculations were performed by the standard MNDO semiempircal SCF MO method (6) as implemented in the MOPAC program (10). Microanalyses were performed by the Departamento de Química Orgánica Biológica, C.S.I.C., Barcelona.

*General procedure for the synthesis of substituted 3a,4,5,9b-tetrahydro-3*H*-naphtho[2,1-*d*]oxazol-2-one derivatives* **2**–**6**

To an ice-cooled solution of 1.50 mmol of the starting aminoalcohol **1**[4] in 8.5 mL of dry pyridine under a nitrogen atmosphere, 235 mg (1.50 mmol) of phenyl chloroformate was added dropwise. After stirring for 2 hours at 20°C, the reaction mixture was poured into water, acidified with 2 *N* hydrochloric acid, and extracted with 3 × 50 mL of dichloromethane. The organic layer was washed successively with 2 *N* sodium hydroxide solution, 2 *N* hydrochloric acid, and water. Evaporation of the solvent afforded an oil, which was dissolved in 20 mL of dry tetrahydrofuran and added dropwise over a suspension of 430 mg of sodium hydride dispersion (50–60% in oil) in 20 mL of dry tetrahydrofuran. After stirring for 12 h at room temperature, the

^{1}H nuclear magnetic resonance and molecular orbital studies of the structure and internal rotations in ethylbenzene

TED SCHAEFER, GLENN H. PENNER, AND RUDY SEBASTIAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received August 12, 1986

TED SCHAEFER, GLENN H. PENNER, and RUDY SEBASTIAN. Can. J. Chem. **65**, 873 (1987).

Rather extensive geometry-optimized computations at the STO-3G, 4-21G, 4-31G, and 6-31G levels of *ab initio* molecular orbital theory suggest that the fourfold component of the barrier to internal rotation about the C_{sp^2}—C_{sp^3} bond in ethylbenzene amounts to about 20% of the twofold component. The ^{1}H nuclear magnetic resonance spectral parameters, extracted by complete analyses of the spectra arising from the ten protons, are reported for ethylbenzene in acetone-d_6, CCl_4, CS_2, and perfluoromethylcyclohexane solutions. The long-range proton–proton spin–spin coupling constants demonstrate that the internal barrier is insensitive to the polarity of the solvent, in contrast to polar solute molecules such as benzyl fluoride. The coupling constants do not support a dependence of the internal barrier on the internal pressure of the solvent.

TED SCHAEFER, GLENN H. PENNER et RUDY SEBASTIAN. Can. J. Chem. **65**, 873 (1987).

Des calculs *ab initio* d'orbitales moléculaires ont été effectués d'une façon relativement approfondie aux niveaux STO-3G, 4-21C, 4-31G et 6-31G et on les a optimisés par rapport à la géométrie; les résultats suggèrent que la barrière à la rotation interne autour de la liaison C_{sp^2}—C_{sp^3} de l'éthylbenzène comporte une composante quadruple qui correspond à 20% de la composante binaire. On a déterminé les spectres rmn ^{1}H de l'éthylbenzène en solutions dans l'acétone-d_6, dans le CCl_4, dans le CS_2 et dans le perfluorométhylcyclohexane et on a déterminé les paramètres spectraux en procédant à des analyses complètes des spectres provenant des dix protons. Les constantes de couplage spin–spin, proton–proton à longue distance démontrent que la barrière interne n'est pas sensible à la polarité du solvant; ce résultat est en opposition avec ce qui est observé avec des molécules polaires comme le fluorure de benzyle. Les constantes de couplage ne présentent pas de relation entre la barrière interne et la pression interne du solvant.

[Traduit par la revue]

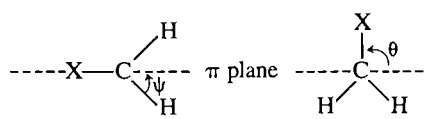
Introduction

Solvent perturbations of molecular conformational equilibria have been studied extensively (1–5). A well-known example is the *gauche–trans* equilibrium in *n*-butane. It was argued (6) that in the disordered liquid phase the intramolecular potential averages to that in the isolated molecule. Experimental data for the energy difference between the *trans* and *gauche* forms overlap for the liquid and gaseous states (1). Monte Carlo and molecular dynamics simulations and the so-called RISM calculations differ as to the effect of condensation or solvents on the equilibrium (2–4).

Because the *gauche* form of *n*-butane has a smaller volume (more globular) than the *trans* form, increased external or internal pressure (7, 8) should increase its population. At an external pressure of 3000 atm (1 atm = 101.3 kPa), Raman data are consistent with this idea (9), but do not prove it, whereas Monte Carlo simulations (10) suggest that pressures as high as 15 000 atm are needed to cause a significant change in population. From another viewpoint, the internal pressure of the liquid could cause a conformational shift. Internal pressures of common solvents range from about 2000 to 5000 atm and, if the volume difference between conformers is as large as 3 cm^3/mol, could then lead to an energy change of about 1 kJ/mol (7, 11). For *n*-butane in nonpolar solvents, the Raman (12) and neutron scattering (13) data suggest no change in the *gauche–trans* energy differences.

Turning to polar molecules, the general rule that a conformer with the greater dipole moment is favored in polar solvents (5) is confirmed by statistical mechanical calculations (1, 4). For example, the *gauche* conformer of 1,2-dichloroethane becomes about 4 kJ/mol more stable on condensation, both experimentally and theoretically (4).

Of course, as the barrier to interconversion between the conformers diminishes, the discussion in terms of energy differences between conformers becomes less meaningful. For example, in benzyl fluoride, conformer **1** (X = F) is ≤ 1 kJ/mol more stable than **2** in CS_2 solution (14), so that at ambient temperature a sensible discussion involves not an equilibrium between **1** and **2**, but the internal rotational potential, $V(\theta)$,



$\theta = 0°, \psi = 60°$ **1** $\theta = 90°, \psi = 30°$ **2**

defining rotation about the C_{sp^2}—C_{sp^3} bond. In fact, the use of $^nJ(^{13}C, ^{19}F)$, n = 2–5, $^nJ(^1H, ^1H)$, n = 4, 5, 6, and $^nJ(^1H, ^{19}F)$, n = 4, 5, 6, the long-range nuclear spin–spin coupling constants over n formal bonds between side-chain and ring nuclei, demonstrated that the twofold potential, V_2, governing this rotation, changes by 2 kJ/mol in passing from the nonpolar solvent CS_2 to the polar solvents acetone-d_6 or DMSO-d_6 (14). Conformer **2** becomes more stable than **1** in polar solvents. Qualitatively, this result is reasonable because **2** has a higher dipole moment than **1**.

Now, ethylbenzene is much less polar than benzyl fluoride and the dipole moments of **1** and **2** (X = CH_3) must differ by only a small amount. Hence any solvent effects on the internal rotational potential are expected to arise more from packing forces (internal pressure) than from electrostatic interactions. In consequence it is expected that $V(\theta)$ in ethylbenzene will be much the same in CS_2 and acetone solutions, which have very similar internal pressures (8) but quite different polarities. In a solvent such as perfluoromethylcyclohexane (PFMC), whose internal pressure is less than half that of CS_2, $V(\theta)$ might be altered if the volumes of **1** and **2** differ. The former conformer is expected to have a lower volume than that of **2**, which is analogous to the *trans* form of *n*-butane. Because $^6J(H, CH_2)$ is very precisely measurable at 300 MHz and because (15) it is

related to $V(\theta)$, this coupling constant can be taken as an indicator of such presumed changes in $V(\theta)$.

This paper reports precise analyses of the ^1H nmr spectra of ethylbenzene in CCl_4, CS_2, acetone-d_6, and PFMC solutions, covering a range of internal pressures and encompassing solvents of widely different polarity. Extensive molecular orbital calculations on $V(\theta)$ are also reported. Among other uses, the latter provide estimates of the intramolecular energies needed in statistical mechanical computations (1) of condensed phase perturbations. The barriers indicated by the long-range coupling constants are compared with theory.

Barrier computations by molecular orbital methods

The main purpose of these calculations was to establish the foldedness of the barrier to rotation about the exocyclic C_{sp^2}—C_{sp^3} bond in ethylbenzene. If, for example, the barrier is purely twofold, then $\langle \sin^2\theta \rangle$, as derived from $^6J(H,CH_2)$, is easily related via a hindered rotor model to the barrier, V_2. If a fourfold component also exists, then a given $\langle \sin^2\theta \rangle$ is compatible with a number of combinations of V_2 and V_4. A theoretical barrier can then suggest which of these combinations is the most probable.

Evidence exists for the usefulness of *ab initio* molecular orbital calculations of internal barriers for hydrocarbons containing the phenyl group. For example, STO-3G MO methods agree with experiment that the sixfold internal barrier in toluene is tiny (16). For styrene, experiment (17) has established a fourfold component amounting to 3.3 kJ/mol, about 25% of the magnitude of the twofold component of 12.8 ± 0.1 kJ/mol. STO-3G MO computations agree well with the magnitude of V_4 but overestimate V_2 by 3.5 kJ/mol (18). The 6-31G basis set yields an internal potential (19) effectively equal to that from experiment (17). Such computations demand rather full geometry optimization procedures.

In the present calculations for ethylbenzene, all bond angles and lengths were allowed to vary, with the constraint that the carbon and hydrogen atoms of the phenyl group remain in a plane. The angle θ was varied in 15° steps between 0° and 90°, except that at the 6-31G level only 0°, 45°, and 90° were used. The energies could be fit to potentials containing V_2 and V_4 terms, as in eq. [1].

$$[1] \quad V(\theta) = -V_2 \sin^2\theta + V_4 \sin^2 2\theta$$

	$-V_2$/kJ mol^{-1}	V_4	$-E_{90}$/a.u.
STO-3G	6.58(11)	0.78(12)	305.055 713
4-21G	7.70(11)	1.73(11)	308.134 706
4-31G	6.90(11)	1.45(11)	308.335 989
6-31G	6.04	1.19	308.664 033

The errors in parentheses are given at the 95% confidence level. These errors could be somewhat reduced by inclusion of a term in V_6. For example, for the 4-21G basis, such a fit gave V_2, V_4, V_6 as −7.85(5), 1.58(5), 0.37(5) kJ/mol, respectively. The present experimental data cannot distinguish between these numbers and those for a potential containing only V_2 and V_4. However, it is probable that the barrier is not purely twofold, containing a V_4 whose magnitude is about 20% of that of V_2.

Conformation **2** (X = CH_3) is clearly of lowest energy, in agreement with low-resolution microwave spectra (20). The computed structure **2** at the 6-31G level is given in Fig. 1 and will be of interest to microwave spectroscopists and other structural scientists.

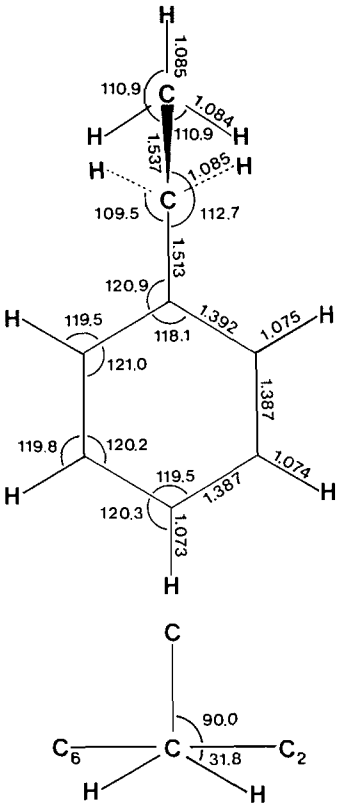

FIG. 1. The 6-31G structure of ethylbenzene in the conformation of lowest energy is displayed. The computed bond angles within the ring are remarkably close to those predicted (46, 47) from angular substituent parameters as given for a methyl substituent and determined mainly from X-ray crystallography. At the 6-31G level (48) these angular distortions from 120° in toluene are reproduced to within experimental error. The angle between the C(1)—C(4) vector and the C(1)—C(sp^2) bond is 1.6° in the sense that the methyl group moves away from the ring. The carbon atom of the methyl group lies in a plane perpendicular to the phenyl plane.

It is natural to assume that the barrier in ethylbenzene is steric in origin. In an attempt to discover how V_4 varies with various computed V_2 values, geometry optimized computations were carried out at the STO-3G level for various C_{sp^2}—C_{sp^3} bond lengths, the latter being changed in 10-pm steps between 105 and 185 pm. It was found that V_2 varied roughly as an inverse exponential function of bond length, decreasing as r increased, and that V_4 was linearly related to V_2. In fact, for 9 pairs of values, V_2/kJ mol^{-1} = −9.80 V_4 + 1.08 (r = 0.999), perhaps implying that when, in the high-energy conformation **1** (X = CH_3), the distance between the *ortho* C—H bond and the methyl group is large enough, the *ortho* C—H bond "sees" the methyl group as an "atomic entity" and no longer distinguishes among its individual C—H bonds.[1]

That the *ortho* C—H bond distinguishes between the C—H bonds of the methyl group in **1** (X = CH_3) is quite clear from the STO-3G values for rotation about the C_{sp^2}—C_{sp^3} bond. These rotational barriers are computed as 26.27(2) and −0.77(3) kJ/mol for V_3 and V_6, respectively, in **1** and as 15.05(7) and −0.01(8) kJ/mol in **2**. In ethane, V_3 and V_6 are 12.06(4) and 0.08(4) kJ/mol, respectively (22). Heat capacity data for ethylbenzene are consistent with 17.2 kJ/mol for V_3 (23), presumably corresponding to an ensemble average.

[1]The computed potential function for benzyl chloride is twofold (21), in line with the above interpretation.

TABLE 1. ^{1}H nuclear magnetic resonance spectral parameters for ethylbenzene at 300 K and 300.135 MHz

Parameter	$C_6F_{11}CF_3$[a]	CCl_4[b]	CS_2[b]	$(CD_3)C{=}O$[d]

[a]2.8 mol% in perfluoromethylcyclohexane, containing also 10 mol% C_6D_{12} and 0.5 mol% TMS.
[b]2.5 mol% in CCl_4 and C_6D_{12} and TMS as above.
[c]2.5 mol% in CS_2 and C_6D_{12}/TMS as above.
[d]2.5 mol% in acetone-d_6 and 0.5 mol% TMS.
[e]In Hz to high frequency of internal TMS. Numbers in parentheses are standard deviations in the last significant figure.
[f]Not iterated upon but estimated via decoupling experiments and simulations with various couplings and linewidths.
[g]Note that all peaks were assigned and that, of course, there are many degeneracies (ethyl group protons).
[h]There were no striking correlations involving the long-range couplings between side-chain and ring protons, except for one of 0.182 between $^4J(H,CH_2)$ and $\nu_2 = \nu_6$ for the $C_6F_{11}CF_3$ solution and one of −0.132 between $^4J(H,CH_2)$ and ν_{CH} in CS_2 solution.

Returning to the internal barrier about the C_{sp^2}—C_{sp^3} bond, it is not ascertainable at present which of the theoretical barriers is the most reliable. At 300 K, these potentials imply a $\langle\theta\rangle$ between 66 and 70° for a classical averaging procedure, which may be compared with a best fit value of 70° from electron diffraction patterns (24, 25).

Barriers derived from $^6J(H,CH_2)$ in solution

For toluene, $^6J(H,CH_2)$ has been written (26) as $^6J/\text{Hz} = {}^6J_{90}\sin^2\psi$, where $^6J_{90}$ is the magnitude of ^6J at $\psi = 90°$ and has a value of −1.204(4) Hz. In CS_2 solution (Table 1), ^6J is −0.455(1) Hz, so that the expectation value, $\langle\sin^2\psi\rangle$, is 0.378 if the methyl group does not alter the magnitude of $^6J_{90}$. From a hindered rotor model (15) relating the twofold potential to $\langle\sin^2\theta\rangle$, V_2 would then follow as 5.7 kJ/mol with **2** as the conformation of lowest energy. However, the magnitude of $^6J_{90}$ is reduced by electronegative substituents (14, 15, 21). On a scale on which the electronegativity of fluorine is 3.92 and that of hydrogen is 1.78 (27–29), $^6J_{90}$ is −0.95 Hz for fluorine (14). The electronegativity of the methyl group has been estimated by various methods (30–33). On the basis of the available data, it is here taken as 2.2 on the above scale. The assumption of a linear dependence of $^6J_{90}$ on electronegativity yields $^6J_{90}$ as −1.16 Hz. Then $\langle\sin^2\theta\rangle$ follows as 0.389 and the apparent V_2 as 5.0 kJ/mol. If the internal barrier about the C_{sp^2}—C_{sp^3} bond were purely twofold, then ^6J in CS_2 solution would imply its magnitude as $5.3_5 \pm 0.3_5$ kJ/mol.

However, the MO computations on the free molecule suggest substantial fourfold components. For the values quoted above, $\langle\sin^2\psi\rangle$, as obtained by a classical averaging procedure, is 0.355, 0.332, 0.345, and 0.360, respectively, for the STO-3G, 4-21G, 4-31G, and 6-31G basis sets. All these values are significantly lower than that obtained from ^6J (note that $\langle\sin^2\psi\rangle$ is 0.5 for a zero barrier and approaches 0.25 for a very large barrier).

One possible reason for the differences is that the barrier in solution is indeed lower than in the vapour phase. Consider the molecular volumes of **1** and **2**. Although these are not at all easy to calculate reliably (34), intuitively that of **1** is smaller than that of **2**. For *n*-hexane the molecular volume of the *trans* (extended) conformer has been estimated as 3.5 cm^3 less than that of the *gauche* conformer (34). If the difference between the conformers **1** and **2** of ethylbenzene is taken as 3 cm^3, an internal pressure of 4000 atm in CS_2 solution (8) will favor **1**, that is, will lower the internal barrier by about 1 kJ/mol.

A second possible reason is that the most flexible basis set employed above still overestimates the barrier magnitude, although it should be remembered that such a basis agrees very

well with the experimental barrier for another hydrocarbon, styrene. On the other hand, heat capacity measurements are consistent with an assumed V_2 of 4.85 kJ/mol (23) in the vapor. Gas phase electron diffraction data (24) give an internal barrier of 7 kJ/mol, assumed to be twofold, and, upon reconsideration, 9.2 kJ/mol (25). The charged core potential energy method relies on the calculation of one *ab initio* wave function, followed by electrostatic energy computations, and gives the barrier as 5.01 kJ/mol (35). In that work the GAUSSIAN 76 barrier was found to be 9.9 kJ/mol, presumably based on an STO-3G calculation.

In solution, ^{13}C spin-lattice relaxation times for 1,3-diethylpyridinium bromide in CD_3OD solution yield 5.9 ± 0.8 kJ/mol as the enthalpy of activation for rotation about the C_{sp^2}—C_{sp^3} bond (36), similar to the value of 5.9 ± 0.8 kJ/mol obtained by the same approach to 4-ethylaniline in $CDCl_3$ solution (37). Within experimental error these numbers agree with the apparent V_2 obtained from ^6J for ethylbenzene. However, the molecular polarizability studies for ethylbenzene in CCl_4 solution give V_2 as 9.6 kJ/mol (38). Yet the ^6J for ethylbenzene in this solvent (Table 1) is the same as in CS_2 and acetone-d_6 solutions (assuming an error of twice the standard deviations). In fact, the range of ^6J in the four solvents is only 0.014(3) Hz, implying no significant solvent effect on the barrier.

For toluene $^5J(H,CH_2)$ has been written (26) as the sum of a $\sigma-\pi$ component, proportional to $\langle\sin^2\theta\rangle$, and a σ component, proportional to $\langle\sin^2(\psi/2)\rangle$. For a twofold or fourfold barrier, the latter expectation value is 0.5, as for toluene itself. Hence any solvent dependence of ^5J should occur via changes in $\langle\sin^2\psi\rangle$. However, the $\sigma-\pi$ component of ^5J is only about one-third as large as that of ^6J in toluene. The observed changes in ^5J in Table 1 are consistent with the behaviour of ^6J.

$^4J(H,CH_2)$ in $C_6F_{11}CF_3$ and CS_2 solutions correlates significantly with other spectral parameters (footnotes in Table 1). Therefore, although ^4J appears to have a smaller magnitude in the former solution and is expected to have a predominant dependence (39) on $\langle\sin^2\psi\rangle$, it cannot be said that this appearance indicates a solvent dependence of the internal barrier.

Similar remarks apply to the coupling constants between protons situated on the phenyl group. For example, $^4J_{35}$ and $^5J_{25}$ are significantly correlated in $C_6F_{11}CF_3$ and CS_2 solutions. Consequently their sums are more reliable parameters and are indeed 2.043(3) and 2.048(3) Hz in the two solutions, so that an intrinsic solvent dependence of the two couplings is not established. In fact, $^5J_{25}$ has significant correlations with certain shift parameters in all the solutions in Table 1.

Derivatives of ethylbenzene

It is suggested that the barrier in ethylbenzene is influenced both by steric and hyperconjugative interactions (40), with C—C being larger than C—H hyperconjugation. In that event, **2** is stabilized by such an interaction. In 4-fluoroethylbenzene in acetone-d_6 solution (41), $^6J(CH_2,F)$ is 0.812(3) Hz, while $^6J(CH_3,F)$ is 1.149(3) Hz in 4-fluorotoluene in the same solvent (42). $^6J(CH_3,F)$ is predominantly a $\sigma-\pi$ coupling (42), implying that $\langle\sin^2\psi\rangle$ in 4-fluoroethylbenzene is 0.812(3)/2.298(6) or 0.353(3) if $^6J_{90}(CH_2,F)$ is not altered by the methyl group. An apparent V_2 of 7.5(3) kJ/mol is deduced. However, $^6J_{90}$ should probably be reduced by a factor of 1.16/1.20 (see discussion above), leading to an apparent V_2 of 6.5(3) kJ/mol. Both values are higher than for ethylbenzene in acetone-d_6, suggesting that C—C is a weaker hyperconjugative donor than C—H. This follows because the fluorine substituent is an π electron donor and would stabilize conformer **2**, in which the weaker of the two side-chain donors has a maximum interaction with the π electron system.

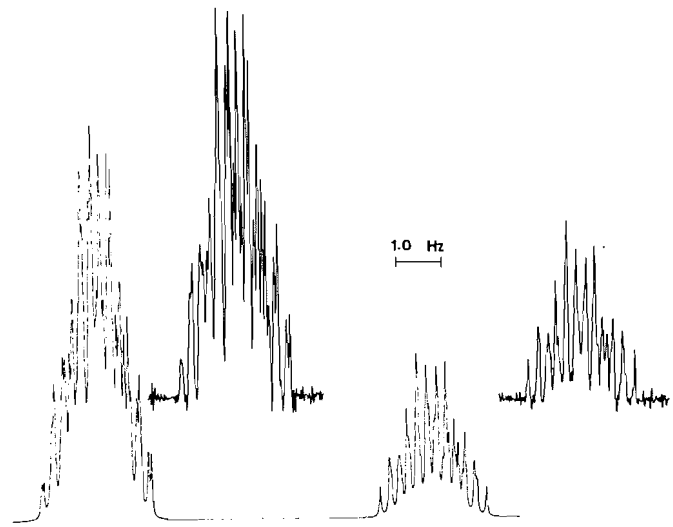

FIG. 2. Half of the observed and computed ^1H nmr spectrum of the methylene protons of ethylbenzene is displayed. The observed peaks arise from hundreds of transitions and the linewidth at half-height is about 0.06 Hz. The nmr sample contained 2.5 mol% ethylbenzene, 10 mol% C_6D_{12}, and 0.5 mol% TMS dissolved in CS_2. The probe temperature was 300 K and the carrier frequency was 300.135 MHz on the Bruker AM300 spectrometer.

Some support for a hyperconjugative contribution to the barrier in ethylbenzene comes from recent electron diffraction data on 4-ethylbenzaldehyde (43), from which the internal barrier is deduced as 1 kJ/mol *lower* than in ethylbenzene. In conformer **1**, the C—H bonds hyperconjugate more effectively than in **2**. Because the formyl group accepts π electron density from the ring, the reduction in barrier is expected if the C—H bonds are better donors than the C—C bond.

However, the apparent V_2 deduced from $^6J(CH_2,F)$ in 4-fluoroethylbenzene must be treated with circumspection because this coupling may contain a small contribution from other than a $\sigma-\pi$ mechanism (15). Indeed, the tenuousness of the barrier deduced from $^6J(CH_2,F)$ is indicated by the $^5J(H,CH_2)$ of 0.302(3) Hz for this compound. For 4-fluorotoluene, $^5J(H,CH_3)$ is 0.343(3) Hz and its increased magnitude relative to the 0.329(1) Hz in toluene (26) is attributable to an increased σ component (44). To within experimental error the ratios, $^5J(H,CH_2)/^5J(H,CH_3)$, are identical for the two types of compounds, implying the same barrier in ethylbenzene and its 4-fluoro derivative. Furthermore, to obtain 0.320(3) Hz in the 4-fluoroethylbenzene requires a $\langle\sin^2\psi\rangle$ of 0.378 and an apparent V_2 of 5.7 kJ/mol, the same as for ethylbenzene to within experimental error. A $^6J_{90}(CH_2,F)$ of 2.15 Hz follows from such a computation and is a reasonable number in view of the possible presence of a small non-$\sigma-\pi$ component.

Similar arguments can be made about $^4J(H,CH_2)$, and are complicated by considerations concerning the magnitude of the σ component in the presence of the methyl group (39). The observed value of −0.618(3) Hz in 4-fluoroethylbenzene (41) does not, in fact, support an increased barrier relative to the parent compound. In summary, the long-range coupling

constants do not establish a perturbation of the internal barrier in ethylbenzene by a 4-fluoro substituent.

Turning to 3,5-dibromoethylbenzene, $^6J(H,CH_2)$ is $-0.477(3)$ Hz for a solution in C_3D_6 (45) and is $-0.480(3)$ in CS_2 solution. In 3,5-dibromotoluene, as a 2.5 mol% solution in the CS_2/C_6D_{12}/TMS mixture, $^6J(H,CH_3)$ is $-0.613(2)$ Hz. In this molecule, therefore, $^6J_{90}$ is $-1.226(4)$ Hz. According to the previous discussion, $^6J_{90}$ in 3,5-dibromoethylbenzene then lies between -1.19 and -1.23 Hz, corresponding to a $\langle \sin^2 \psi \rangle$ of 0.395(10). Hence the apparent V_2 is 4.5(4) kJ/mol. This result indicates, at most, a very slight lowering of the barrier, it being $5.3_5 \pm 0.3_5$ kJ/mol for ethylbenzene in CS_2 solution. Rather more dramatic decreases in V_2 have been observed for the 3,5-dichloro derivatives of benzyl fluoride (14) and benzyl chloride (21).

Experimental

The spectral analytical procedures were identical to those described recently (26) and the footnotes in Table 1 give the relevant concentrations and temperatures. Figure 2 displays half of the observed and computed ^{1}H nmr spectrum of the methylene protons of ethylbenzene in CS_2 solution.

The molecular orbital concentrations used the program GAUSSIAN 82 (49) on an Amdahl 470/V7 system.

Conclusions

The long-range proton–proton coupling constants for ethylbenzene imply that the internal barrier to rotation about the C_{sp^2}—C_{sp^3} bond is independent of the polarity or internal pressure of the solvent. The barrier indicated by the coupling constants is slightly lower than that obtained from *ab initio* molecular orbital computations, which also suggest a significant fourfold, in addition to the dominant twofold, component.

The X-ray crystal structure of bis((*S*)-5,5-dimethylthiazolidine-4-carboxylic acid) protium chloride hydrate, **I**, has been determined. Crystals are orthorhombic, $P2_12_12_1$, with cell dimensions $a = 6.463(2)$, $b = 11.832(3)$, $c = 23.966(6)$ Å, and $Z = 4$. The structure was solved by standard methods and refined to $R = 0.073$, $R_w = 0.064$ for 2969 independent reflections. Compound **I** is composed of two zwitterion molecules bridged through a proton which causes a very short hydrogen bond, $O\ldots O' = 2.450(5)$ Å. The proton is located roughly halfway between the two carboxylate oxygen atoms, but is not on a special crystallographic position. Characteristic features of the infrared and Raman spectra, mass spectra, and ^1H and ^{13}C nmr spectra are discussed.

H. E. HOWARD-LOCK, C. J. L. LOCK, M. L. MARTINS, R. FAGGIANI et M. DUARTE. Can. J. Chem. **65**, 878 (1987).

Faisant appel à la diffraction des rayons-X, on a déterminé la structure cristalline de l'hydrate du chlorhydrate de l'acide bis((*S*)-diméthyl-5,5 thiazolidinecarboxylique-4) (**I**). Les cristaux sont orthorhombiques, $P2_12_12_1$, avec $a = 6{,}463(2)$, $b = 11{,}832(3)$ et $c = 23{,}966(6)$ Å et $Z = 4$. On a résolu la structure par les méthodes standards et on l'a affinée jusqu'à des valeurs de $R = 0{,}073$ et $R_w = 0{,}064$ pour 2969 réflexions indépendantes. Le composé **I** est formé de deux molécules zwitterioniques qui sont pontées par un proton qui provoque une liaison hydrogène très courte, $O\ldots O' = 2{,}450(5)$ Å. Le proton est situé approximativement au milieu des deux atomes d'oxygènes des carboxylates; toutefois, il ne se trouve pas dans une position cristallographique spéciale. On discute des caractéristiques principales des spectres infrarouge et Raman, des spectres de masse et des spectres rmn du ^1H et du ^{13}C.

[Traduit par la revue]

Introduction

We have been studying various derivatives of D-penicillamine and have reported that 2,2,5,5-tetramethylthiazolidine-4-carboxylic acid is an amino acid in the solid state rather than the zwitterion, and that even in aqueous solution about 5% exists as the amino-acid form (1). In contrast, thiazolidine-4-carboxylic acid is a zwitterion in the solid state and no amino-acid form is detectable in solution. We prepared and characterized a number of substituted thiazolidine-4-carboxylic acids in order to study the amino-acid–zwitterion equilibrium (2).

When attempting to prepare the sulfur-protected product of D-penicillamine with *N*-hydroxymethylacetamide, we were unsuccessful and instead isolated the title compound, **I**, bis((*S*)-5,5-dimethylthiazolodine-4-carboxylic acid) protium chloride hydrate, $[(C_6H_{10}NO_2S)_2H]Cl.H_2O$. Because the new compound fitted into our studies, we investigated compound **I** structurally and spectroscopically. We found that **I** is a salt containing a hemiprotonated zwitterion dimer, and that it contains a very strong hydrogen bond between two hemiprotonated zwitterion molecules. The hydrogen bond is very short and spectroscopic evidence suggests the hydrogen bond is symmetric, in which case it is one of the rare instances where a symmetrical hydrogen bond does not have the proton lying on a crystallographic symmetry element (3). We report this work here.

Experimental section

The D-(−)-penicillamine (free base) was of reagent grade, as supplied by Sigma Chemical Co., St. Louis, MI. *N*-Hydroxymethylacetamide was supplied by Alfa Products, Danvers, MA. The melting point of **I** was determined on a Gallenkamp capillary melting point apparatus and was not corrected. Chemical analyses were performed by the Guelph Chemical Laboratories, Ltd., Guelph, Ont. The pK's were obtained by titration of an aqueous solution of the salt against 0.01 *N* NaOH and 0.01 *N* HCl. The pH's were measured with a Corning Model 130 pH meter which was standardized with Scientific Products potassium hydrogen phthalate pH 4.00 buffer, BDH pH 7.00 buffer and Scientific Products boric acid/potassium hydroxide buffer, pH 10.00.

Preparation of bis(5,5-dimethylthiazolidine-4-carboxylic acid)protium chloride hydrate

N-Hydroxymethylacetamide, 0.6 g (0.005 mol) was added to 0.8 g (0.005 mol) D-penicillamine in 5 mL water. Dilute HCl was added to acidify the solution to pH < 2. The solution was stirred under nitrogen for 30 min, then the flask was stoppered and allowed to stand at room temperature. Following evaporation of the solution, a colourless oil was left. Upon standing overnight some separation of white solid from the oil was observed. Ethanol was added to dissolve the oil and the solid was filtered out. To the ethanol solution anhydrous diethyl ether was added and the mixture was left in the refrigerator. A white precipitate covered by a colourless oil was recovered. The oil dissolved in water readily, and the white precipitate was less soluble. The yield of white solid was 0.6 g (70%), mp 181–182°C (dec.).

Anal. calcd. C 38.2, H 6.7, N 7.4, O 21.2, S 17.0, Cl 9.4; found: C 37.2, H 6.9, N 7.8, O 20.3, S 18.4, Cl 9.4.

Long prismatic crystals for X-ray structure determination were obtained by slow crystallization from the reaction mixture over a period of one week.

Spectral measurements

Infrared spectra were recorded on both Nicolet 7199 FT-IR and Perkin-Elmer Model 283 spectrophotometers. The samples were ground with KBr at a concentration of approximately 1% by weight and then pressed into pellets. Spectra were calibrated with polystyrene. Raman spectra were excited by means of the $\lambda = 5145$ Å radiation from a Spectra-Physics Model 164-02 argon ion laser and recorded on a Spex 14018 double monochromator. Solid samples were contained in glass melting point tubes, and solutions in nmr tubes. The spectrometer was calibrated regularly against an indene standard and had previously been calibrated with a neon lamp; the wavelength readout scale was found not to change (± 1–2 cm^{-1}).

Solutions for nmr studies were prepared in D_2O and concentrations

were about 100 mg (solid) mL^{-1} of solvent. External tetramethylsilane was used as the reference. Proton nmr spectra were recorded on a Varian T60 spectrometer, and ^{13}C nmr spectra were recorded on a Bruker WP-80 spectrometer operating at 20.115 MHz.

Mass spectra were recorded on a VG Micromass 7070F mass spectrometer, with electron impact as the method of ionization.

Collection of the X-ray data and solution of the structure

A colourless, parallelepiped single crystal was sealed in a Lindemann capillary for the X-ray studies because we were worried about possible dehydration of the crystal. Precession photographs showed that crystals of **I** were orthorhombic. Unit cell parameters were obtained from least squares fit of χ, φ, and 2θ for 15 reflections in the range of $15.3° < 2\theta < 25.8°$ measured on a Syntex $P2_1$ diffractometer having graphite-monochromated MoKα_1 radiation ($\lambda = 0.70926$ Å at 22°C). Crystal data and other numbers related to data collection are summarized in Table 1. Intensities were also measured with use of the Syntex $P2_1$ diffractometer and a coupled θ(crystal)–2θ(counter) scan. The methods of determining scan rates and initial data treatment have been described (4, 5). Corrections were made for Lorentz and polarization effects but not for absorption. This will make a maximum error in F_o of <2.5%.

The structure was solved by direct methods with use of 85 reflections with $|E| > 1.68$ and 12 sets of starting phases. The chloride ion, and the rings were located in the subsequent E map. Full-matrix least-squares refinement followed by electron density difference syntheses revealed all the remaining atoms. The absolute configuration found, happened to be that expected on the basis of the known configuration of the starting product. No attempt was made to test the alternate configuration. At this stage the temperature factors of non-hydrogen atoms were made anisotropic and further full-matrix least-squares refinement, which minimized $\Sigma w(|F_o| - |F_c|)^2$ was terminated when the maximum (shift/error) fell below 0.1. Hydrogen atoms were included at the positions located in the difference maps but their positional parameters and temperature factors were not refined. Attempts to refine the hydrogen atoms were unsuccessful. Corrections were made for secondary extinction by the method of SHELX (6). Scattering curves were taken from ref. 7 and anomalous dispersion corrections from ref. 8 were applied to the curves for S and Cl. The atom parameters are listed in Table 2.[2]

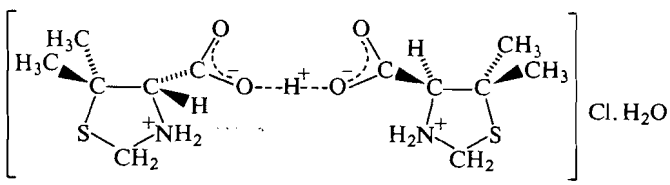
*B and A represent molecules with and without prime affixes.

Results and discussion

The reaction of *N*-hydroxymethylacetamide with cysteine produces a derivative with the sulfur protected by the acetamidomethyl group (9). When, in this work, a similar reaction was attempted with D-penicillamine, instead of the *S*-protected product, a protonated dimer of 5,5-dimethylthiazolidine-4-carboxylic acid, held together by a very short hydrogen bond, was separated from the reaction mixture. According to Veber *et al.* (9), only under extremely anhydrous conditions (in anhydrous HF at 0°C) is the yield of thiazolidine-4-carboxylic acid minimized. In the acidic solution, the *N*-hydroxymethylacetamide reagent must have broken down to generate formaldehyde (and acetamide); the reaction of the formaldehyde, so generated, with D-penicillamine in the acid solution gave **I**.



I

As expected, the dimer decomposes in aqueous (D_2O) solution and the ^1H nmr of the dimer is nearly identical to that of 5,5-dimethylthiazolidine-4-carboxylic acid prepared from formaldehyde (2), with a downfield shift of only 0.1 ppm for the C4-H peak at 3.95 ppm, presumably caused by a pH shift. Similar effects are seen in the carbon-13 spectrum where there is a downfield shift of 0.4 ppm of the C4 peak and a very small shift of the COOH carbon.

The hydrogen-bonded dimeric molecular cation is shown in Fig. 1. Each half of the cation is the hemi-protonated zwitterion form of (*S*)-5,5-dimethylthiazolidine-4-carboxylic acid. There are significant, but minor, differences in comparable bond

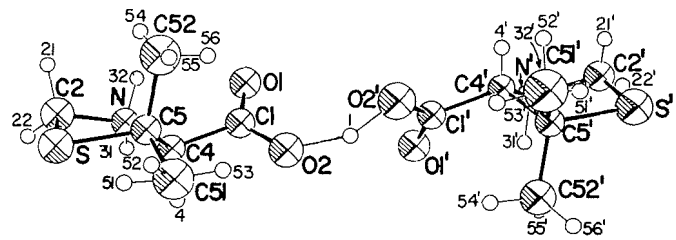


FIG. 1. The molecular cation bis((*S*)-5,5-dimethylthiazolidine-4-carboxylic acid)protium showing the atom numbering.

lengths and angles associated with the S—C2—N—C4 portion of the two rings, although others, particularly those in exocyclic fragments, do not differ significantly. The C5—S, C5′—S′ distances (1.828(5), 1.847(5) Å) are longer than the S—C2, S′—C2′ distances (1.784(5), 1.816(5) Å) presumably because of the greater repulsions of the methyl groups. In general, distances and angles are similar to those found in 2,2,5,5-tetramethylthiazolidine-4-carboxylic acid (1). Associated with the differences noted above there is a distinct difference in the conformation of the rings, as shown in Fig. 1. The unprimed ring has an envelope structure with C4 out of the plane, whereas the primed ring has a pseudo-C2, or $^4{}_3T$, structure. As can also be seen, the corresponding exocyclic torsional angles are very similar. N is nearly eclipsed with O1 and N′ with O1′, and these features have been invoked in the past as evidence of intramolecular hydrogen bonding (10). There is no evidence of this in the compound described here.

The two parts of the cation are joined by a very strong hydrogen bond (O2...O2′, 2.450(5) Å). This is in the range expected for symmetrical hydrogen bonds, although close to the upper limit. The hydrogen atom, H1, lies close to half-way between the two oxygen atoms O2 and O2′ but the errors in bond lengths and angles do not allow us to say with certainty that the bond is symmetric. The similarity of the C1—O1, C1—O2,

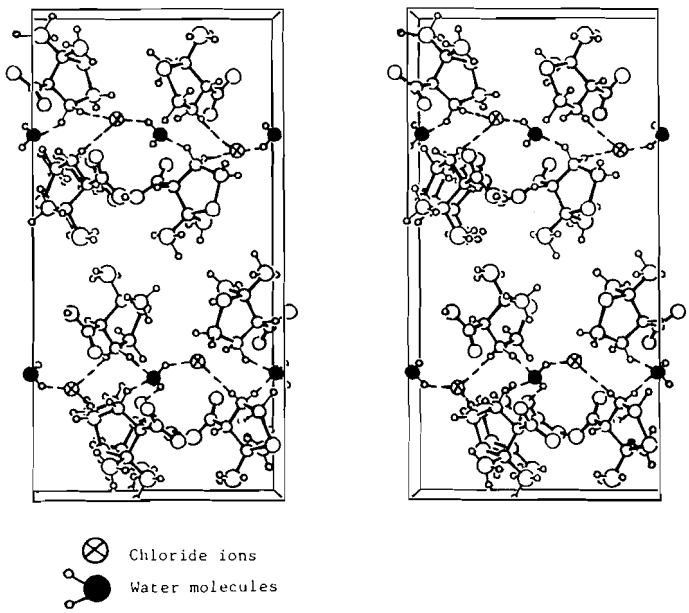

FIG. 2. The packing of the title compound in the unit cell. The hydrogen bonding network is shown by dotted lines. ***a*** and ***c*** are parallel to the bottom and sides of the page and the view is down ***b***.

and C1′—O1′ and C1′—O2′ distances, however, is consistent with a symmetric hydrogen bond. A similar strong (2.586(4) Å) but definitely asymmetric bond, found in (*R*)-2,2-dimethylthiazolidine-4-carboxylic acid caused considerable differences in the C—O lengths in the two carboxylate groups (11). The cation described here is one of the rare cases where the hydrogen atom in a very short hydrogen bond is not on, or disordered about, a crystallographic symmetry element, and thus the similarities in the two halves, noted above, are not artifacts of the space group.

The infrared and Raman spectral bands of **I** and its derivative obtained by D_2O exchange, **II**, are listed in Table 4. Many of the bands are assigned by comparison with the spectra determined recently for methyl-substituted thiazolidine-4-carboxylic acids (2) and for (*S*)2,2,5,5-tetramethylthiazolidine-4-carboxylic acid and its deuterated derivatives (1). A broad band at 3360 cm^{-1} (infrared) is typical of a weak hydrogen bond (O...O = 2.77 Å) and is assigned to hydrogen-bonded lattice water. The broad wing, 3100–2600 cm^{-1}, with multiple peaks on the low frequency side, is typical of these secondary amino acid compounds having zwitterion form (2), and includes absorption from ν_a and ν_s of the NH_2^+ group which is hydrogen bonded to the lattice water molecule, superimposed on the ν_a, ν_s bands of the CH_3, and CH_2 groups. The 2700–2300 cm^{-1} bands are combination bands. The NH...O bond lengths of 2.89 and 2.82 Å correlate with absorption frequencies of about 3100 cm^{-1} and new bands in **II** at 2240, 1990 cm^{-1} show H/D ratios of 1.36 and 1.42, which are reasonable for weak NH...O bonds (12). The carboxylate bands of the hemi-protonated groups are intermediate between those of carboxylate and carboxylic acid structures.

The most unusual feature of the spectra for **I** occurs in the infrared in the region below 1100 cm^{-1}; there is a very broad band, 1100–500 cm^{-1}, centred at ~800 cm^{-1}, with other peaks and windows superimposed on it. The general character of this band is not changed on D_2O exchange, but its maximum shifts to ~580 cm^{-1}. (νOH/νOD ratio = 1.38). This feature was not present in the 5,5-dimethylthiazolidine-4-carboxylic acid made with formaldehyde, nor indeed in any of our other substituted thiazolidines (2). We assign this band to antisymmetric stretching frequency (νOH) of the very strong hydrogen bond, O2...O2′ = 2.450(5) Å, linking the dimer through the carboxylate groups. We could not identify δ or γ for OHO(ODO), although this is expected to be one of the rare cases where ν is lower than both δ and γ (13). The Raman band at 302 cm^{-1}, which does not shift on deuteration, is assigned to the symmetric stretching frequency of this hydrogen bond; ν_s O...D...O is expected to have the same frequency as ν_s O...H...O because the proton (or deuteron) does not move in this mode.

In general, νOH frequencies are more difficult to assign for very strong O...H...O bonds than for weak or medium ones, because as the O...H...O distance becomes shorter, the OH band in the infrared spectrum becomes less prominent — lower in frequency, weaker in intensity, and ill-defined in shape. However, plots of νOH vs. O...O distance show good correlation for weak hydrogen bonds and a reasonably good one for strong hydrogen bonds. For a number of compounds containing strong hydrogen bonds, νOH is in the range 1800–700 cm^{-1}. In particular, the centred hydrogen bonds of acid salts of carboxylic acids have νOH below 1000 cm^{-1} (13). Thus there are precedents for our unusual assignment.

Moreover, our data for **I** and **II** show a parallel with data for sodium hydrogen diacetate and its deuterated derivatives, discussed by Novak (13) as an example of the special case of a symmetric, single-minimum potential for a short hydrogen bond. For that compound, the frequencies 720 (510), 1540 (1150), and 1285 (960) cm^{-1} were assigned to νOH (OD), δOH(OD), and γOH (OD) with H/D ratios of 1.41, 1.34, and 1.34, respectively. In addition, the ν_s O...H...O band was observed in the Raman spectrum at 320 cm^{-1}. (The ν_s O...D...O band was not mentioned, although it would be expected to have the same frequency, as we noted above.) The νOH/νOD isotopic ratio of 1.41 is much higher than that for strong O...H...O bonds of the double minimum type, and also higher than that for a free molecule (1.355). Thus deuterium substitution makes the O...O bond stronger, or at least does not weaken it, exactly as predicted for a single minimum potential (13).

The combination of the spectroscopic evidence with the crystallographic evidence, summarized above, indicates a very strong symmetric hydrogen bond. As we have noted, errors do not allow us to say that the bond is symmetric on the basis of the hydrogen atom position. We conclude that the title compound contains a strong single potential symmetric hydrogen bond which does not have crystallographic symmetry.

The packing within the unit cell is shown in Fig. 2. The dimeric cations lie roughly parallel to the [10$\bar{1}$] direction and are arranged in bilayers at $z = 1/4, 3/4$ with the halves of the bilayer at roughly $z = 1/8, 3/8$ and $z = 5/8, 7/8$. In the centre of the bilayers lie the chloride ions and the water molecules, and these are involved in an extensive and fairly strong hydrogen bonding network between both sides of the bilayer and in both the ***a*** and ***c*** directions. All the hydrogen atoms of the amine group are involved and there is one bond from the water molecule to O1. Between the bilayers, at roughly $z = 0, 1/2$, there are only van der Waals interactions involving methyl groups and sulfur atoms.

The mass spectra were measured of both the title compound and the corresponding partially deuterated species used for vibrational spectroscopy studies. The mass spectra are consis-

tent with deuteration of the exchangeable hydrogen atoms of the cation to 30–40%. Major peaks were observed in the mass spectrum at M/z = 161, 128, 116, 114, 100, 87, 82, 75, 69. The peak at 161 is caused by the 5,5-dimethylthiazolidine-4-carboxylic acid moiety, which is half the protonated cation. The peak at M/z = 128 is caused by loss of H_2O + CH_3, and that at M/z = 116 by loss of —CO_2H.

Practically all the other peaks can be explained by 1,4 or 2,5 cleavages, which are established pathways for thiazolidine fragmentation (1, 14). The small peak at M/z = 100 is caused by loss of N from the M/z = 114 fragment. Further loss of H_2O gives a peak at 82. No change in the 82:83 ratio is seen in the deuterated compound, confirming the fragment contains no NH(D) or OH(D) groups. Peaks at M/z = 87 and 75 correspond to the primary fragments of the 2,5 cleavage, although the $(CH_3)_2{}^+C$—SH has acquired a hydrogen atom by transfer. The peak at M/z = 69 is derived from M/z = 87 by loss of H_2O.

Extraction and transport of alkali metal salts by crown ethers and cryptands: estimation of extraction constants and their relationship to transport flux

THOMAS MURRAY FYLES
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received August 27, 1986

THOMAS MURRAY FYLES. Can. J. Chem. **65**, 884 (1987).

A method is described for the estimation of two phase extraction constants from stability constants for complexation of alkali metal cations by crown ethers and cryptands. The total free energy change for extraction of alkali metal salts from water to a non-polar organic solvent is evaluated as a sum of free energy terms for complexation, transfers of cation, anion, and complex between solvents, and ion pairing in the non-polar solvent. The method gives satisfactory agreement with a variety of published extraction constants and can be used predictively. As an example, the influence of extraction constant on transport flux was examined using calculated extraction constants and the rate data of Lamb *et al.* (J. Am. Chem. Soc. **102**, 6820 (1980)); rates are adequately modelled by a simple analysis of diffusion.

THOMAS MURRAY FYLES. Can. J. Chem. **65**, 884 (1987).

On décrit une méthode permettant d'évaluer constantes d'extraction à partir des constantes de stabilité des complexations des cations des métaux alcalins par des éthers couronnes et par des cryptands. On évalue le changement total d'énergie libre pour l'extraction des cations des métaux alcalins de l'eau vers un solvant organique non-polaire en faisant la somme des termes d'énergie libre pour la complexation, pour les transferts de cation, d'anion et de complexe entre les solvants et pour l'arrangement par paire des ions dans le solvant non-polaire. La méthode donne un bon accord avec un grand nombre de constantes d'extraction publiées et on peut l'utiliser pour faire des prédictions. Par exemple, utilisant les constantes d'extraction calculées et les vitesses rapportées par Lamb et ses collaborateurs (J. Am. Chem. Soc. **102**, 6820 (1980)), on a évalué l'influence de la constante d'extraction sur le taux de transport; on peut faire un modèle adéquat des vitesses en faisant à une analyse simple de diffusion.
[Traduit par la revue]

The transport of cations across artificial membranes using synthetic ionophores such as crown ethers or cryptands has received considerable attention over the past decade (1, 2). The focus of such studies varies from the assessment of the complexation selectivity of new ligands to the development of specific separation processes (1–3). The actual mechanism of the transport has received somewhat less attention but it is widely assumed that the transport is controlled by diffusion processes in the unstirred boundary layers adjacent to the organic/water interfaces. A recent report summarized the predictions of a simple diffusion model and concluded that the narrow range of reported rates was consistent with a diffusion mechanism (4). Our interest in this area has centred on crown ether carboxylic acids which can exhibit cation–proton counter-transport across artificial membranes (5, 6). This system has been examined in detail and it is clear that under the usual conditions of stirring the transport is *not* controlled by diffusion (5–7). We have identified the rate-limiting processes as adsorption and desorption of the carrier at the interface and have shown, as one consequence, how the transport selectivity depends on the interfacial surface charge (8).

In search of other systems which might be controlled by interfacial processes, we set out to compare the literature data with the predictions of the simple diffusion model (4). This search is immediately hampered by the paucity of data on two phase extraction constants. The use of extractions, particularly of metal picrates, to assess cation binding and selectivity has a long tradition in crown ether chemistry (9–11). However, such tests are often used qualitatively (% extraction) and, moreover, the extraction "constant" can depend on the experimental conditions (10, 12, 13). Whatever its value, the extraction constant (K_{ex}) plays a central role in artificial membrane transport. For a diffusion limited process, the rate should increase with K_{ex}, reach a maximum at a critical value of K_{ex} ($= K_{ex}(\max)$) and then *decrease* as K_{ex} increases further (4). The value of K_{ex} for optimal transport depends on the system examined (co- or counter-transport) and upon experimental conditions (initial concentrations, extent of transport). The selectivity of transport depends on the relationship of the extraction constants of the two substrates to $K_{ex}(\max)$, hence the "selectivity" is also a function of experimental conditions (4).

The phenomenon of maximum transport flux at a critical value of K_{ex} has been only rarely demonstrated (14, 15). More typically, transport flux is noted to be maximal at a critical value of *stability constant for complexation* in homogeneous solution (K_s) (1, 16, 17). These are not the same, if only for the trivial reason that the units of K_{ex} and K_s differ (M^{-2} vs. M^{-1} for 1:1 electrolytes). The oft quoted maxim of maximal transport rate at $\log K_s \sim 5$–6 (methanol) is more indicative of a restricted range of initial conditions than of a fundamental relationship (4). Nevertheless, there does appear to be some roughly linear relationship between K_{ex} and K_s. If the form of this relationship were known precisely, then the large compilations of data on K_s for a diverse assortment of ligands (18) would provide an equally large and diverse compilation of K_{ex} values. Direct experimental values would still be lacking but the survey problem discussed above would be greatly simplified.

Significantly, this problem of the relationship between K_{ex} and K_s, arose within the context of the report of Lamb *et al.* (17), on the relationship betwen K_s and transport rate. In their kinetic analysis, they incorporate additional diffusion distances at the organic/water interfaces for diffusion of uncomplexed ion pairs (1, 17). These distances are equivalent to the "relaxation" distances of Friedlander and Keller (19), which may be shown to be the formal equivalent of slow interfacial processes (20). These "relaxation" distances are essential to the kinetic model described by Lamb and co-workers (1, 17) and vary depending on the cation considered. Is this therefore another example of transport controlled by an interfacial process? Or are these relaxation distances merely adjustable parameters which render K_{ex} a linear function of K_s?

We approach this problem in a stepwise fashion. We first examine the relationship of K_s in a reference solvent to K_{ex} for extraction between water and a non-polar organic solvent. The free energy changes of the constituent equilibria are evaluated using a simple model of ionic solvation (21, 22) and an equally simple model of ion pairing (23). This permits the calculation of K_{ex} from a knowledge of K_s in the reference solvent. Having compared calculated with experimental values of K_{ex} in a number of cases, we calculate the values required for the transport system of Lamb *et al.* (17). These values, with the experimental transport fluxes, can then be directly compared with a simple diffusion model (4) and with the more complex model including relaxation distances (1, 17).

Results and discussion

The two equilibria we wish to relate are

[1] $L_s + M_s^+ \rightleftharpoons LM_s^+$

and

[2] $\overline{L} + M_w^+ + X_w^- \rightleftharpoons \overline{LMX}$

Reaction [1] defines K_s, the association constant for complex formation between a ligand L (crown ether, cryptand) and a cation M^+ (alkali metal) in some solvent (subscript s, reference solvent). This discussion is restricted to 1:1 electrolytes since many of the subsequent terms discussed are only valid for univalent ions; in principal further generalization is possible. The reference solvent will usually be methanol as the majority of ligands have reported values of K_s in this solvent (18). Reaction [2] defines the extraction constant K_{ex} where the cation M^+ and the anion X^- are in the aqueous phase (subscript w) and the ligand L and complex LMX are in the organic phase (overlined). Typically, the organic phase has a low dielectric constant (CH_2Cl_2, $CHCl_3$, benzene) so electrostatic ion pairing is assumed to occur to a large extent (13).

In order to relate [1] and [2], the following additional processes must be considered. We start from methanol as the reference solvent, reaction [3] below:

[3] $L_m + M_m^+ \rightleftharpoons LM_m^+ \qquad K_m$

(*i*) The cation must be transferred from methanol to water [4]

[4] $M_w^+ \rightleftharpoons M_m^+ \qquad K_{tr}^+$

(*ii*) The anion must be transferred from water to the organic solvent [5]

[5] $X_w^- \rightleftharpoons \overline{X^-} \qquad K_{tr}^-$

(*iii*) The ligand L and the complex LM^+ must be transferred between methanol and the organic solvent. As written, reaction [6] is not an elementary process but results in convenient cancellations (below).

[6] $LM_m^+ + \overline{L} \rightleftharpoons \overline{LM^+} + L_m \qquad K_{tr}^{cplx}$

(*iv*) The complex and anion must associate in the organic solvent [7].

[7] $\overline{LM^+} + \overline{X^-} \rightleftharpoons \overline{LMX} \qquad K_{ip}$

Summation of [3]–[7] produces [2]. In terms of evaluation of K_{ex} it is somewhat more convenient to deal with the corresponding free energy changes. The two forms are given as [8] and [9]

[8] $K_{ex} = K_m \times K_{tr}^+ \times K_{tr}^- \times K_{tr}^{cplx} \times K_{ip}$

or

[9] $\Delta G_{ex} = \Delta G_{cplx} + \Delta G_{tr}^+ + \Delta G_{tr}^- + \Delta G_{tr}^{cplx} + \Delta G_{ip}$

The first term, ΔG_{cplx} is available from the experimental values of $\log K_m$ (or in general $\log K_s$) (18). The second term, ΔG_{tr}^+, the free energy of transfer of the cation from water to methanol (or in general the solvent s), is also available from "experiment". The single ion value chosen requires an extra thermodynamic assumption, hence the numerical value will vary somewhat, depending on the nature of the assumption (21, 22, 24, 25). For consistency, we utilize the values of Abraham and Liszi (21, 22) (see Appendix I).

The free energy of transfer of the anion from water to the non-polar solvent, ΔG_{tr}^-, is calculated by the method of Abraham and Liszi (21, 22). The solvation energy of an ion is divided into an electrostatic term (ΔG_{el}) and a neutral term (ΔG_n). The free energy of transfer of the ion from water to the organic solvent is thus

[10] $\Delta G_{tr} = \Delta G_{el} + \Delta G_n - \Delta G_h^0$

where ΔG_h^0 is the hydration free energy of the ion. The ion, of radius a, is assumed to be covered with a first layer of solvent molecules to a radius b where $b - a$ is the radius of the solvent as calculated from the molar volume. The dielectric constant of the first layer is taken to be ϵ_1. This solvated ion is then immersed in the bulk solvent with the bulk dielectric constant ϵ_0. Thus, ΔG_{el} is given by [11]

[11] $$\Delta G_{el} = \frac{z^2}{2}\left[\left(\frac{1}{\epsilon} - 1\right)\left(\frac{1}{a} - \frac{1}{b}\right) + \left(\frac{1}{\epsilon_0} - 1\right)\frac{1}{b}\right]$$

where z is the ionic charge. For univalent ions, the radii a and b in Å and $\epsilon_1 = 2$ (21, 22) [11] gives [12] in kcal mol^{-1}.

[12] $$\Delta G_{el} = 166.2\left[\left(\frac{1}{\epsilon_0} - 1\right)\frac{1}{b} - \frac{1}{2}\left(\frac{1}{a} - \frac{1}{b}\right)\right]$$

The neutral term ΔG_n, is evaluated using [13]

[13] $\Delta G_n = ma + c$

where m and c are empirical solvent parameters derived from solvation energies of neutrals (21, 22). Values of the various parameters utilized are given in Appendix I and are those of Abraham and Liszi (21, 22). The ΔG_{tr}^- term can thus be evaluated from [10]. An additional correction for change of standard state from unit mole fraction $\Delta G_{tr}(\chi)$ to unit molar concentration $\Delta G_{tr}([\,])$ is required. Thus

[14] $$\Delta G_{tr}(\chi) - \Delta G_{tr}([\,]) = -RT \ln\left(\frac{M_1\rho_2}{M_2\rho_1}\right)$$

for a transfer from a solvent having molecular weight M_1 and density ρ_1 to a solvent having molecular weight M_2 and density ρ_2 (21, 25).

To evaluate the term ΔG_{tr}^{cplx}, the free energy change of equation [6], we proceed in the spirit of the Abraham and Liszi model. To a first approximation the ligand acts as the first solvation layer of the cation which remains approximately constant from solvent to solvent. The solvation energy of the complex ion is again composed of an electrostatic and a neutral term. If L and LM^+ are the same shape and size, then $\Delta G_n(LM^+) \sim \Delta G_n(L)$ in each solvent and in the summation will cancel. Of course, $\Delta G_{el}(L) = 0$ thus to this first approximation,

[15] $\Delta G_{tr}^{cplx}(S_1 \rightarrow S_2) = \Delta G_{el}^{cplx}(S_2) - \Delta G_{el}^{cplx}(S_1)$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

If the ligand is indeed the first solvation layer, ΔG_{el}^{cplx} will be given by [11] where b is the radius of the complex and ϵ_1 is the ligand dielectric constant. The actual value chosen for ϵ_1 is immaterial since [15] will result in cancellation of terms including ϵ_1. The complex radius, b, is potentially a more complex problem. Crystal structures are available for all the ligands considered in the subsequent comparisons, but we ignore this flurry of precise detail in favour of an approximate method proposed by Lehn (26). The approximate method has the advantage that it can be used for any ligand, whether crystalline or not, and gives an average value of the ligand thickness. Indeed averaging of some sort would be required from crystallographic data as most ligands have regions of different thickness. The method assumes that the ligand volume covers the cation in a spherical shell. The ligand volume (V_L) is derived as the sum of contributions for the volumes of various atoms and subgroups (V_w) in the ligand i.e. [16]

$$[16] \quad V_L = \sum^{n} V_w$$

where $V_w = 11.0$ Å^3 for O, $= 14.0$ Å^3 for N, $= 33.5$ Å^3 for CH_2 or CH_3, $= 125$ Å^3 for a benzene ring (26).

Thus, by simple geometry, the complex radius b is

$$[17] \quad b = \left(a^3 + \frac{3V_L}{4\pi}\right)^{1/3}$$

where a is the cation radius as used in [11]–[13].

This approximate method has both strengths and weaknesses. It is clearly a poorer picture for crown ethers than for cryptands and even cryptands do not completely cover the cation in a uniform spherical fashion. However, the method is simple, predictive and consistent with our view of the ligand as the first solvation sphere. Also the method gives a rough estimate, not readily available from crystal data, of the approximate size of an assembly of ligand, cation and the odd solvent molecule which fills the cracks in the first solvation shell. Clearly, we need only include those parts of the ligand adjacent to the binding site. Providing that a judicious choice of the parts of the ligand can be made, V_L may be calculated by [16] to give b via [17]. Equation [12] then gives ΔG_{el}^{cplx} for any solvent and the required term ΔG_{tr}^{cplx} can be calculated from [15], with the correction of [14] being applied here as well.

Turning finally to the ion pairing term ΔG_{ip}, we again begin from the assumption that the ligand covers the cation to produce a spherical ion of radius b as given by [17]. The association constant for electrostatic ion pairing with a spherical anion of radius c is then given by [18] (27).

$$[18] \quad K_{ip} = \frac{4\pi N d^3}{3000} \exp\left(\frac{e^2}{d\epsilon kT}\right)$$

where $d = b + c$, N is Avogadro's number, e is the electronic charge, ϵ the solvent dielectric constant, k is Boltzmann's constant, and T is the temperature. At 25°C and d in Å, K_{ip} is given by [19].

$$[19] \quad K_{ip} = 2.524 \times 10^{-3}\, d^3 \exp(560/\epsilon d)$$

to give

$$\Delta G_{ip} = -RT \ln K_{ip}$$

The assumptions made above will be most acceptable for cations which are well buried in the ligand, for non-coordinating anions such as picrate, perchlorate, or nitrate and for solvents with a sufficiently high dielectric constant so that ΔG_{ip} does not vastly outstrip the other terms in eq. [9]. Conversely, these assumptions will be less acceptable in a large number of real cases: large cations in small crown ethers and low dielectric solvents such as benzene. Additional corrections to [18] and [19] will thus be required. We can compare ΔG_{ip} for the "real" ligand with two other values: ΔG_{ip}^{ion} for the "naked" cation in the same solvent and ΔG_{ip}^{cplx} for a hypothetical complex in which the ligand completely covers the cation. The "real" value must lie between these two extremes as the real ligand is neither perfect, nor is the cation completely exposed to the anion. Real ligands therefore differ from ideal ligands to the extent to which they fail to provide complete coverage.

Consider a nearly ideal pair: cryptand 2.2.2/K^+. The ligand volume, V_L, is 700 Å^3 ([16]) with a ligand thickness ($b - a$) of 4.2 Å. A less ideal pair is 18-crown-6/K^+ with $V_L = 470$ Å^3 or only 67% (470/700) of the K^+ covered to a 4.2 Å depth. Viewed another way, the ΔG_{ip} of 18-crown-6/K^+ is about one third of the way from the ΔG_{ip}^{cplx} of a covered ion (at 4.2 Å thickness) to the ΔG_{ip}^{ion} of the naked cation. This then defines the approach to estimating ΔG_{ip} for cases where the simpler assumption becomes untenable.

Coverage of each cation with a 4.2 Å thick layer defines an optimum ligand volume for each cation

$$[20] \quad V_{opt} = \frac{4\pi}{3}\left(a + 4.2\right)^3$$

The value of ΔG_{ip} is then given by [21]

$$[21] \quad \Delta G_{ip} = \Delta G_{ip}^{cplx} + \left(1 - \frac{V_L}{V_{opt}}\right)\left(\Delta G_{ip}^{ion} - \Delta G_{ip}^{cplx}\right)$$

where ΔG_{ip}^{cplx} is given using [19] with $d = b + c$ and ΔG_{ip}^{ion} is given using [19] where $d = a + c$. The term V_L/V_{opt} can of course exceed 1; in these cases the ligand is assumed to be perfect and $\Delta G_{ip} = \Delta G_{ip}^{cplx}$.

There are thus two ways to estimate ΔG_{ip}. The first assumes a perfect, spherical ligand and [21] is ignored. This will be appropriate for solvents with $\epsilon > 4$ and picrate, perchlorate, and nitrate as counteranions. The second approach uses [21] and will be appropriate for solvents with $\epsilon < 4$ and coordinating anions. Examples of both approaches are given.

A referee has pointed out the inconsistency between the use of a one-layer model of solvation (eqs. [10]–[13]) with a contact model of ion pairing; should not the solvent layer around the anion be included as additional distance in the calculation of ΔG_{ip}? In principle, contributions from such solvent separated ion pairs should indeed be included. In addition, their importance will increase as the solvent dielectric constant increases. As discussed in the next section, the effect of this correction is minor (0.6 kcal) for the most polar of the solvents considered (CH_2Cl_2, $\epsilon = 8.93$). In view of the other adjustments to be made in the calculation of ΔG_{ip}, this particular correction is ignored.

Comparison of calculated and experimental values

The reliability of the methods outlined above can be readily seen by inspection of Tables 1 and 2. Table 1 unites data for extractions of metal picrates into CH_2Cl_2 and $CHCl_3$ with crown ethers and cryptands (12, 28, 29, 38) while Table 2 does the same for extractions into benzene and hexane (13, 29). In the former case the corrections of [21] are ignored. The results are quite satisfactory with an average value of ΔG_{ex}(calc) − ΔG_{ex}(expt) $= -0.28$ kcal/mol($\bar{x}$) and a standard deviation of $\sigma = 1.35$ kcal/mol. This corresponds to an average value of log K_{ex}(calc) − log K_{ex}(expt) of $\bar{x} = +0.21$ and $\sigma = -1.0$, i.e., K_{ex} is estimated to within an order of magnitude with a

slight tendency to over estimate. Not unexpectedly the cryptands have a smaller average displacement ($\bar{x} = -0.03$ kcal/mol) and standard deviation ($\sigma = 0.54$ kcal/mol) than do the crown ethers ($\bar{x} = -0.42$ kcal/mol, $\sigma = 1.62$ kcal/mol). Inclusion of corrections to ΔG_{ip} via [21] results in a minor shift of the average difference (to $\bar{x} = -0.54$ kcal/mol) but does not alter the standard deviation. This is a result of two effects: (*i*) $V_L \sim V_{opt}$ for many of the ligands on Table 1 and (*ii*) $\Delta G_{ip}^{ion} - \Delta G_{ip}^{cplx}$ is small (2–5 kcal). As a result, the corrections to ΔG_{ip} are modest.

In contrast the results in Table 2 clearly show that some correction to ΔG_{ip} via [21] is required. Ignoring [21] gives an average difference $\Delta G_{ex}(\text{calc}) - \Delta G_{ex}(\text{expt})$ of $\bar{x} = 3.8$ kcal/mol ($\sigma = 1.04$ kcal/mol). Including [21] gives $\bar{x} = -0.54$ kcal/mol ($\sigma = 1.00$ kcal/mol). The solvents of Table 2 were chosen to ensure very strong ion pairing effects (13) and the ligands in general are less bulky than those of Table 1. In addition $\Delta G_{ip}^{ion} - \Delta G_{ip}^{cplx}$ is large (~20 kcal/mol). The net result is corrections to ΔG_{ip} of 2–5 kcal/mol for the cases in Table 2. This is sufficient to shift $\bar{x}$ to a value similar to that of Table 1 while preserving the relatively narrow standard deviation.

On the basis of these results, it is reasonable to assume that the method as described in the preceding section can be used to predict K_{ex} to within an order of magnitude from stability constants in methanol. But *caution is essential* as can be readily demonstrated in several ways. Consider first the choice of the reference solvent. Methanol is convenient choice but in principle any solvent could serve and equations [3] to [7] should apply equally well. An exhaustive comparison for a variety of solvents of all the cases of Tables 1 and 2 is not essential; the results in Table 3 are sufficient to show that other reference solvents produce a divergent set of results even for three well behaved cases. Of the six reference solvents, only methanol gives acceptable results. All other reference solvents show systematic errors and increased scatter from the experimental values. This may be due to a variety of factors: (*i*) the method of Abraham and Liszi gives poorer estimates of ionic solvation energies for DMF and DMSO than for the other solvents (21).

[a]In kcal/mol at 25°C for extractions between $CHCl_3$ and H_2O. Experimental data of ref. 28.

As a result ΔG_{tr}^{cplx} will be more greatly in error in these cases. (*ii*) The entire set depends on the values of ΔG_{tr}^{+} utilized and the final values shift dramatically when values from different single ion scales are employed (21, 24, 25). (*iii*) The experimental values of stability constants may be more reliable in some solvents than in others. Systematic errors would only show in an inter-solvent comparison of this type. Whatever the reason, it is clear that the method outlined above may involve some convenient error cancellations for methanol which do not occur for other reference solvents.

The nature of these fortuitous cancellations can be partially uncovered by comparison of calculated and experimental values of ΔG_{ip} and ΔG_{tr}^{cplx}. Unfortunately, no completely comparable set of values is available from experiment so the two will have to be examined independently. Experimental values of ΔG_{ip} can be calculated from the data of Frensdorff for the extraction of Na^+ and K^+ picrates into CH_2Cl_2 (29). These values are 1.5–2.5 kcal more negative than those calculated by [21]. This might indicate acceptable agreement were it not for the fact that these cases already estimate ΔG_{ex} to be too negative by ca. 2 kcal/mol. Had experimental, rather than calculated values of ΔG_{ip} been used, the calculated value of ΔG_{ex} would have been ca. 4 kcal/mol more negative than the experimental value. Since ΔG_{ip} is too negative, this may be due to overestimating the importance of contact ion pairs compared to solvent separated ion pairs. As noted previously, the solvent layer around the anion should strictly be included in the calculation. This can only be part of the problem however as this correction amounts to only 0.3 and 0.6 kcal for the case of Na^+ and K^+ picrates in CH_2Cl_2 (29). Clearly the simple contact model, even including solvent, is inadequate.

Experimental values of ΔG_{tr}^{cplx} can be calculated for pairs of solvents from the stability constants for complexation in the two solvents and the ΔG_{tr}^{+} term for the cation complexed. Consider [22]–[25].

$$[22] \quad L(S_1) + M^+(S_1) \rightleftharpoons LM^+(S_1)$$

$$[23] \quad LM^+(S_2) \rightleftharpoons L(S_2) + M^+(S_2)$$

$$[24] \quad M^+(S_2) \rightleftharpoons M^+(S_1)$$

$$[25] \quad L(S_1) + LM^+(S_2) \rightleftharpoons LM^+(S_1) + L(S_2)$$

Reaction [22] and the reverse of [23] define the stability constants for complexation of M^+ by L in solvents S_1 and S_2. The summation of [22] and [23] with the transfer equilibrium [24] gives [25] which is identical to [6] where S_1 is the overline (organic) solvent.

Thus,

$$[26] \quad \Delta G_{tr}^{cplx} = \Delta G_{cplx}(S_1) - \Delta G_{cplx}(S_2) + \Delta G_{tr}^{-}(S_2 \rightarrow S_1)$$

The required transfer term ΔG_{tr}^{+} ($S_2 \rightarrow S_1$) can be evaluated from a cycle involving transfers to and from water hence "experimental" values of ΔG_{tr}^{cplx} can be determined from [26] (and corrected as previously using [14]). These "experimental" values depend on the single ion transfer values chosen as discussed above. As previously, we utilize the values of Abraham and Liszi (21) and combine these with the available data for the ligands of Tables 1 and 2 (18, 30) and the solvents water, methanol, DMF, DMSO, and acetonitrile. In each case methanol is chosen as S_1 (reference solvent). For 76 cases, the average value of ΔG_{tr}^{cplx} (calc by [12] and [13]) − ΔG_{tr}^{cplx} ("expt" by [26]) is $\bar{x} = 2.4$ kcal/mol ($\sigma = 1.15$ kcal/mol). It is therefore clear that eqs. [12] and [13] consistently provide values which are ca. 2 kcal/mol in error *on the positive side*. Although there is no solvent for which the summation of experimental values of ΔG_{tr}^{cplx} and ΔG_{ip} can be made, it is likely that the systematic errors uncovered in the analysis above persist and the summation results in a cancellation.

The calculation of ΔG_{tr}^{cplx} by [26] is similar to calculations by Abraham and Ling (31) and by Cox, Firman, Garcia-Rosas, and Schreider (32). The intent of these previous calculations was to examine the assumption that the ligand L provides a constant binding site in a range of solvents i.e., the point of departure for the calculation of ΔG_{tr}^{cplx} (above). To the extent that there are *consistent* errors in the calculated value of ΔG_{tr}^{cplx} and that the standard deviation is modest (1.15 kcal/mol) over such a large number of cases, the assumption seems to be reasonably well founded. Certainly the cation is exposed to the solvent (32, 33), certainly the exposure is greater for crown ethers than for cryptands (31, 32), certainly there are specific ligand–cation effects which are ignored in this analysis (30) and certainly there are also ligand–solvent effects which are also ignored (34, 35). Nonetheless, on average over a range of ligands and solvents, the assumption is tenable even if eqs. [12] and [13] fail to estimate the magnitude of ΔG_{tr}^{cplx} correctly.

In the final analysis, the method used to estimate ΔG_{ex} in Tables 1 and 2 is seen to be based on cancellations of errors but the values are internally consistent for methanol as a reference solvent. The systematic error in ΔG_{ip} due to [21] is apparently approximately cancelled by a systematic error in ΔG_{tr}^{cplx} [12] and [13]. Note however that the fundamental basis (eq. [8]) is exact and the errors arise only in the approaches used to calculate the contributing terms. More sophisticated models of ionic solvation, ligand structure, and ionic association could yield better results without alteration in the substance of the procedure.

Membrane transport and cation extraction

Turning finally to the basic rationale for the calculations outlined above, we wish to examine the system of Lamb *et al.* (1, 17) to discover if the kinetic parameters in the form of "relaxation distances" are essential for the analysis of the transport flux. The basic equation for the transport of M^+X^- from concentrated (in) to dilute (out) solution by crown ethers and cryptands across bulk liquid membranes, is given by Behr, Kirch, and Lehn (4) as:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

$$[27] \quad J = \frac{DL_0}{2l} K_{ex} \frac{S_{in}^2 - S_{out}^2}{(1 + K_{ex}S_{in}^2)(1 + K_{ex}S_{out}^2)}$$

where J is the flux of transported cation in moles per time per unit area, D is a general diffusion coefficient of the species $\overline{L}$ and $\overline{LMX}$ across the unstirred boundary layers of thickness l, K_{ex} is the extraction constant as defined by [2] and S_{in} and S_{out} are the concentration of the 1:1 salt MX on the two sides of the membrane. The flux will be maximal (J_{max}) when $J = DL_0/2l$ (4). Equation [27] strictly applies when the areas of the two interfaces and the volumes of the two phases are equal. Neither of these conditions apply with the cells utilized (17, 36) but corrections for area and volume ratios are readily incorporated (Appendix II). More critical is the correction for extent of transport; Behr, Kirch, and Lehn give an analysis in terms of a fixed fraction of transport (f) (4) whereas the experiment actually performed dealt in terms of a fixed lapse of time (24 h) (17). The fraction transported therefore depends on J up to the maximum fraction which could be transported (f_{max}) at the maximum rate (J_{max}). Thus f will vary as J/J_{max} between 0 and f_{max}.

The fluxes in ref. 17 were examined to determine J_{max}. The experimental data for alkaline earth cations cannot be treated, so these flux data were ignored. Of the remaining data, J_{max} (reported) is 550×10^{-7} mol/24 h/area of cell for 2.2.1/$RbNO_3$. This value is subject to some question as it lies about 40% higher than the next highest flux. For conditions of high source phase salt concentration and low carrier concentration, such as occur in this experiment, the maximum flux is expected to occur over a broad range of values of the extraction constant (4). The 2.2.1/$RbNO_3$ value thus appears to be anomalously high.

The next highest flux gives J_{max} (reported) $= 340 \times 10^{-7}$ mol/24 h/area of cell for DC18C6/KNO_3; a number of other fluxes lie near to this value as expected for a broad maximum. If this is indeed J_{max} then $f_{max} = 0.0425$, i.e., at J_{max} 4.25% of the initial amount of KNO_3 is transported in 24 h. Using this value, with the area and volume ratios (1, 17, 36) permits a theoretical curve of J/J_{max} as a function of log K_{ex} to be constructed (Appendix II). The theoretical curve is sketched in Fig. 1. The experimental points, taken from ref. 17, can be readily compared; the calculated values of K_{ex} are given in Table 4 for those cases where $J > 0.1\ J_{max}$ and the points J/J_{max}(expt), log K_{ex}(calc)) are plotted on Fig. 1 (circles). The calculated value of log $K_{ex} = 0.9$ for the system DB18C6/KNO_3 can be compared with an "experimental" value of log $K_{ex} = 0.4$ derived from the data of ref. 37 using a Michaelis–Menton analysis of the variation in rate as a function of substrate concentration (5, 8).

As is apparent from [5], K_{ex} depends on the anion chosen. This is the origin of the anion effect on transport rate (37). Roughly comparable data can be corrected for different carrier concentrations and interfacial areas and added to the set of values from ref. 17. The three triangles on Fig. 1 are the KBr, KNO_3, and KI values for the carrier DB18C6. This in effect is a duplicate determination of the KNO_3 flux and the two values are well within experimental error of one another.

It is evident that the theoretical curve and the calculated points are in rough agreement. Only the two points marked with full circles are outside experimental error in the transport rate and the estimated error of ± 1 log unit in K_{ex}. More significantly, if the error is assumed to lie entirely on the log K_{ex} axis, the average deviation between "experimental" and "theoretical" values is -0.10 kcal/mol with a standard deviation of 0.90 kcal/mol. This lies well within the errors expected for the calculation of K_{ex}. It is important to note that transport flux errors of $\pm 10\%$ are not insignificant. An example is provided for only the one point with error bars but the other points are all subject to the same uncertainty. As a consequence there is little point in examining the question of whether the model with relaxation distances provides a "better" fit.

The calculation of the theoretical curve assumes that the ligand remains entirely in the organic phase (L_0 = constant = 1×10^{-3} mol L^{-1} for this experiment (17)). However, a number

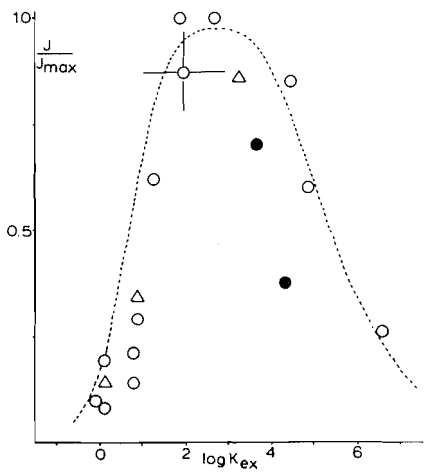

FIG. 1. Transport flux (J/J_{max}) as a function of log K_{ex}(calc). Circles – data of reference 17, triangles – data of reference 37. Error bars on one point apply to all points. The full circles lie outside of the errors in both J/J_{max} and log K_{ex}. Dashed line is the theoretical curve based on [27].

of the carriers utilized, notably 18C6 and 2.2.1, are significantly partitioned to the aqueous phase (28, 38). This acts to diminish L_0 and thus to diminish the flux. From available data on partition coefficients and stability constants for complex formation in water (18, 28, 38) one can estimate that up to 30% of the total amount of ligand is in the aqueous phase ($18C6/K^+$ and $2.2.1/Na^+$ as typical worst cases). Recalculation of the theoretical curve with $L_0 = 7 \times 10^{-4}$ mol L^{-1} results in only minor shifts in the curve shape and maximum. Since J_{max} is a linear function of L_0 however, the new curve must be below that of Fig. 1 with its maximum near 0.7. Stated another way, carriers which are partitioned to the aqueous phase will give points which lie below the calculated curve. Consistent with this analysis, the majority of the points lie below the curve with the most pronounced deviations occurring for $2.2.1/KNO_3$ and $2.2.1/NaNO_3$ (solid circles).

Is there a kinetic component to the transport in this system? Within the limits of the calculations and transport fluxes the answer is clearly "no". It is likely that the relaxation distances proposed previously (17) are simply artifacts of the linearization of K_m and K_{ex}. This conclusion is in general agreement with experiments in other cells (7) in which the transport of KNO_3 by DB18-6 is dependent upon stirring, and therefore primarily due to diffusion control. We continue the search for systems in which interfacial processes are slower than diffusion.

Effect of protonation on the ground state properties of retinal analogs: an *ab-initio* study

RAYMOND A. POIRIER, ARPITA YADAV, AND PÉTER R. SURJÁN[1]

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received August 18, 1986

RAYMOND A. POIRIER, ARPITA YADAV, and PÉTER R. SURJÁN. Can. J. Chem. **65**, 892 (1987).

The ground state properties (bond lengths, bond orders, net atomic charge distribution) of various *cis* and *trans* isomers of retinal analogs have been studied at *ab initio* SCF and correlated levels. The effect of protonation on the properties of the retinal Schiff base analogs has also been studied. Convergence in various properties has been observed with increasing chain length justifying the use of smaller analogs mimicking retinal. Convergence is, however, slower for the protonated retinal Schiff base analogs. The protonated retinal Schiff base analogs show an increased conjugation reflected in the bond orders, bond lengths, and in the decrease in the HOMO–LUMO gap. The nodal characteristics of the HOMO of the protonated retinal Schiff base analog also indicate a strong conjugation in the vicinity of the protonated nitrogen. Based on the results of calculations at the correlated level, the sudden polarization charge transfer mechanism is shown to be an artifact of HF-based methods used in the calculations.

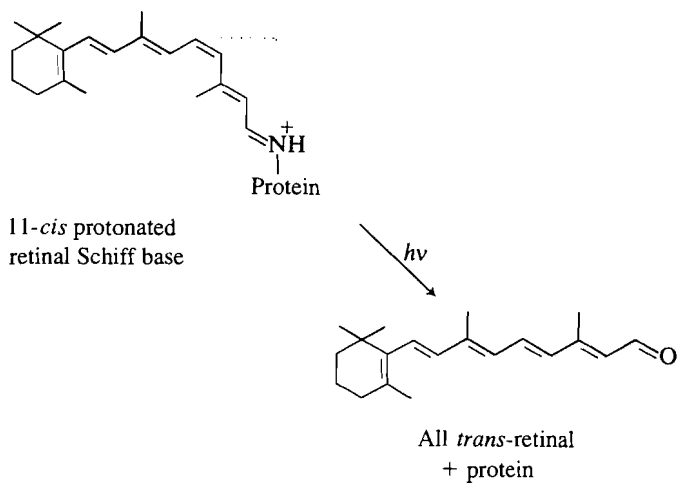
RAYMOND A. POIRIER, ARPITA YADAV et PÉTER R. SURJÁN. Can. J. Chem. **65**, 892 (1987).

Utilisant des méthodes *ab initio* en champ auto-cohérent et à des niveaux permettant d'établir une corrélation, on a étudié les propriétés à l'état fondamental (longueurs des liaisons, ordres des liaisons, distributions des charges atomiques nettes) des divers isomères *cis* et *trans* d'analogues du rétinal. On a aussi étudié l'effet de la protonation sur les propriétés d'analogues des bases de Schiff du rétinal. On a observé une convergence des diverses propriétés avec une augmentation de la longueur de la chaîne et cette observation justifie l'utilisation d'analogues plus petits qui reproduisent les propriétés du rétinal; toutefois, la convergence est plus lente pour les analogues protonés des bases de Schiff du rétinal. Les analogues protonés des bases de Schiff du rétinal présentent une plus grande conjugaison qui se réflète dans les ordres et les longueurs des liaisons et par une diminution de la différence entre la haute occupée et la basse vacante. Les caractéristiques nodales de la haute occupée de l'analogue protoné de la base de Schiff du rétinal suggèrent qu'il existe une forte conjugaison au voisinage de l'azote protoné. En se basant sur les résultats de ces calculs aux niveaux où l'on peut établir une corrélation, on démontre que la polarisation soudaine dans le mécanisme de transfert de charge n'a pas de signification physique et qu'elle est inhérente aux méthodes basées sur HF qui sont utilisées dans les calculs.

[Traduit par la revue]

I. Introduction

Recently a great deal of experimental (1–14, 18, 21) as well as theoretical (15–21) work has been done to understand the process initiated by the impinging of light on a visual pigment resulting in vision. It is well known that in both vertebrates and invertebrates, the protonated Schiff base (PSB) of 11-*cis* retinal is the chromophore group in the visual pigment rhodopsin (1). During this process the geometry of this retinal is changed from 11-*cis* to the all-*trans* form and in vertebrates the chromophore–opsin linkage is broken (2). In invertebrates the photocycle does not lead to rupture of the chromophore–opsin bond (13, 21). *In vivo* the photoreaction is followed by enzymatic processes regenerating the original 11-*cis* pigment. The impinging of light on retinal (that is, the primary event of the process) can be illustrated as follows:



This leads to a general statement that vision is initiated by photoisomerization of the retinal and occurs during the primary event (9). It has, however, even fairly recently been proposed that proton-transfer could be a fast competing process (3, 7, 8).

This photochemical reaction is not only important for the visual process, but has also been shown to be used for bioenergetics (14, 21). When grown under anaerobic conditions *Halobacterium halobium* develops a purple protein pigment, bacteriorhodopsin, whose role is to convert light energy directly into a gradient of hydrogen ions across the membrane which subsequently leads to the synthesis of ATP. Thus, very similar chromophoric systems are responsible in different organisms for different roles. There are, however, some basic structural differences between the systems. For the visual process the chromophore is the 11-*cis* retinal, whereas in bacteriorhodopsin, the chromophore is the all-*trans* retinal (10). For bacteriorhodopsin, the primary event is believed to be an all-*trans* to 13-*cis* isomerization and like invertebrates, the chromophore does not detach from the opsin during the photocycle.

Attempts to utilize computational chemistry for understanding this process in the past have been limited mainly to methods such as Hückel and Pariser–Parr–Pople (PPP) π-electron methods on simple polyenes (17, 18). Honig *et al.* (19) calculated the torsional potential of the cyclohexene ring for rotation around the C_6—C_7 and C_{12}—C_{13} bonds utilizing a LCAO—MO–CI semi-empirical method of PPP type corrected for the nearest neighbour overlap. Formerly, *ab-initio* calcula-

tions have been performed on a nonatetraenylidene methyliminium molecule using a minimal basis set (15).

Salem and Bruckmann (15) suggested a specific hypothesis that the lowest singlet excited state obtained by a $\pi-\pi^*$ excitation of the chromophore creates a sudden polarization within the molecule that triggers a sudden short-lived electrical signal, causing charge transfer from one end of the molecule to the other. However, this hypothesis is in contradiction with many experimental data (18). To our knowledge, geometry optimizations were not performed for any of these calculations.

Recent INDO-CISD (16) and MNDOC (20) calculations show that the retinal Schiff base ground state properties depend sensitively on protonation and on the charge environment. (All essential geometrical parameters were allowed to relax in the latter.) Ground state MNDOC calculations have shown that a protein, by protonating the retinal Schiff base and by providing one or two negative ions in the environment, can reduce double-bond isomerization barriers and can increase single bond barriers. The excited state INDO-CISD calculations predict a barrierless first excited singlet state potential surface for *cis–trans* isomerization of the retinal PSB chromophore.

As a first step it is important to understand the properties of retinal in its ground electronic state. In this paper we report *ab-initio* results on the ground state properties of various *cis* and *trans* isomers of retinal analogs. The geometries of the studied models have been fully optimized in all the cases. The effect of protonating the Schiff base on the ground state properties is studied. The use of smaller analogs mimicking retinal is justified by studying convergence in properties with increasing chain length.

II. Computational details

Closed Shell Hartree-Fock SCF calculations were performed using the MONSTERGAUSS program (22). A minimal STO-3G basis-set (23) was used throughout. In all cases the geometry optimizations were performed using the optimally conditioned method of Davidon and Nazareth (24) (the gradient length was required to be less than 5.0×10^{-4}). Bond orders (B_{ab}) were calculated according to the definition of Mayer (25). Correlational effects were taken into account in some cases within the same basis set by a simple model of strictly localized geminals (SLG) (26–28). This approach corresponds to a first order many-body perturbation theory with a correlated, but fully localized reference state. The latter is obtained by solving the two-electron Schrodinger equation exactly for each chemical bond, lone pair, etc., within a limited subspace of basis orbitals (hybrids) assigned to that bond. As a consequence, delocalization and dispersion interactions between different bonds are neglected by this model, but some interbond interactions like electrostatic inductive effects are accounted for. Obviously, the SLG method cannot describe any conjugational effect, thus its error can be considered as a measure of the conjugation.

III. Results and discussion[2]

In this study a series of the retinal chromophore analogs were investigated, starting with the smallest analog and then gradually increasing the chain length up to and including the double bond of the cyclohexene ring (excluding the methyl substituents). In each case full geometry optimizations were performed (no constraints) in order to determine the convergence as a function of chain length in some properties of the retinal analogs, such as, the bond lengths, bond orders, and charge distribution. Similarly, analogs of the retinal Schiff base (retinal SB) as well as the protonated retinal Schiff base (retinal PSB) were also studied.

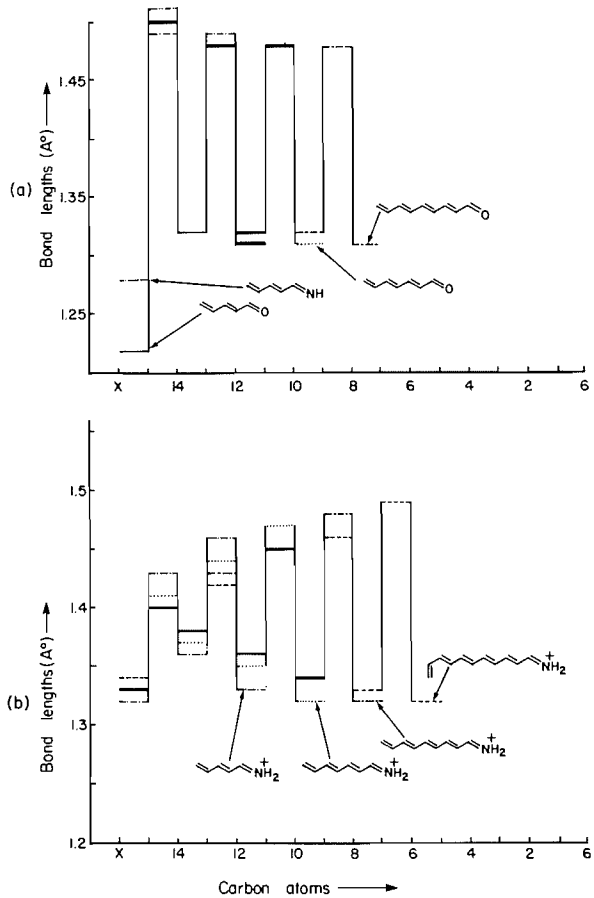

FIG. 1. Variation in the SCF optimized C—C bond lengths for the retinal, retinal SB (*a*) and retinal PSB (*b*) analogs. X = O or N. The numbering of carbon atoms is as defined in structure **I**. The different analogs are identified with different (dashed, dotted etc) horizontal lines, for each bond; the vertical lines are just visual guidelines. Thick horizontal solid lines indicate coincidence.

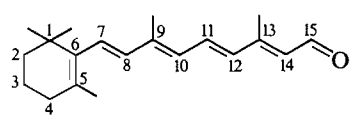
III.1 Bond lengths and bond orders

The C—C bond lengths for different analogs of retinal, retinal SB, and retinal PSB are shown in Fig. 1, and the C—C bond orders for the same analogs are given in Fig. 2. The numbering of carbon atoms has been kept the same as in retinal and is consistent throughout this paper. The numbering for the full retinal is as follows:



1

It is evident from Figs. 1 and 2, that there is a remarkable difference in the behaviour of the retinal SB analogs and that of retinal PSB analogs. Namely, in case of the former, bond length (r_{ab}) and bond orders (B_{ab}) are fairly independent of the chain length, that is, they show a *convergence* with increasing chain length. In turn, the same quantities in case of the retinal PSB show a slower convergence, that is, slightly more variation in

[2]Tables including the optimized geometries for the *cis* and *trans* isomers of retinal, retinal Schiff base, and protonated retinal Schiff base analogs may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

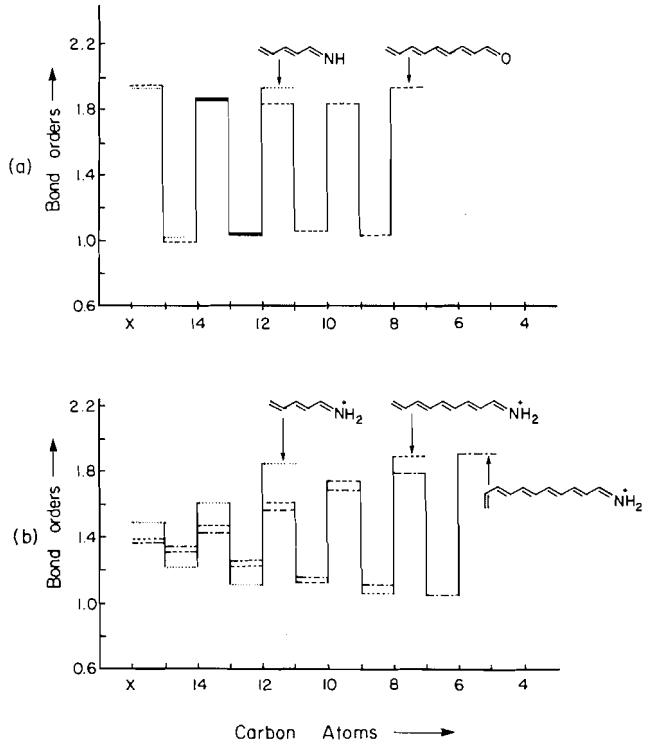


FIG. 2. Variation in the SCF optimized C—C bond orders for the retinal, retinal SB (*a*) and retinal PSB (*b*) analogs. For other notations, see Fig. 1.

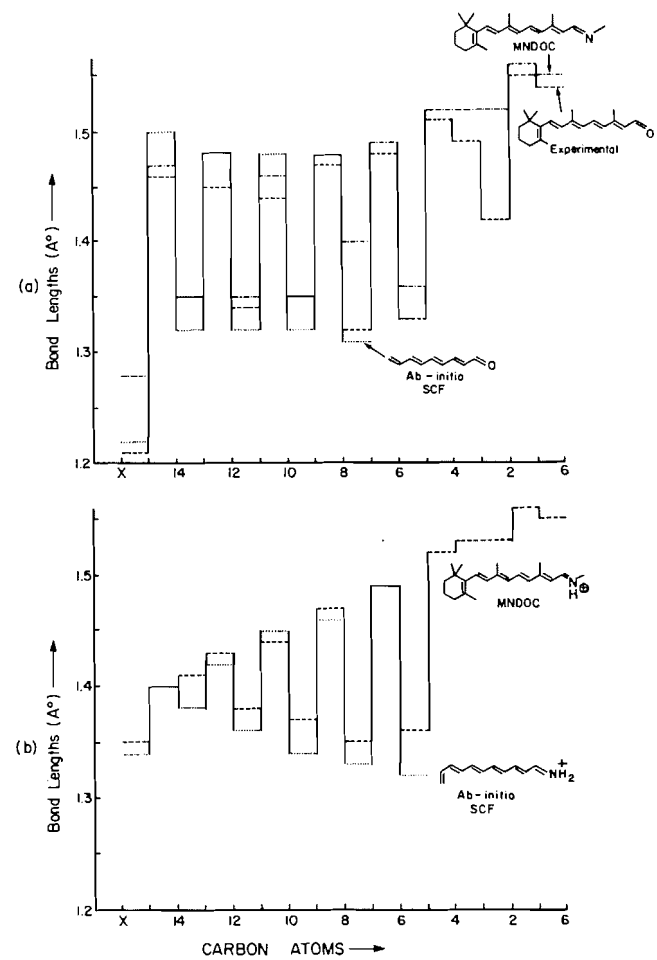

FIG. 3. Variation in the SCF and MNDOC optimized C—C bond lengths for different analogs of retinal, retinal SB (*a*) and retinal PSB (*b*). Experimental bond lengths (29) for retinal are also shown. For other notations, see Fig. 1.

r_{ab} and B_{ab}. As a consequence, the smallest analogs (up to three double bonds) do not give a good estimation for the corresponding properties of the larger retinal PSB analogs.

From Figs. 1 and 2 one can see that r_{ab} and B_{ab} values for the retinal SB analog are very similar to those for the retinal analogs, while the corresponding quantities for retinal PSB are rather different. In the case of the former two, the single and double bonds are easily identified indicating a limited conjugation along the whole chain. In other terms, the C—C bond lengths of the retinal and retinal SB show a strong regular alternation. On the other hand, the retinal PSB analogs show an increased conjugation around the NH_2^+ group manifested in a decreased alternation of bond lengths and bond orders. The conjugation subsequently dies off on moving towards the cyclohexene ring end of the molecule. Experimental results (29) show an increase in the frequency of the C_{14}—C_{15} stretch on protonation of the Schiff base, which is in agreement with the above results. The bond order of the C_{11}—C_{12} double bond is reduced considerably on protonation of the Schiff base thereby facilitating the rotation of the C_{11}—C_{12} double bond or in other words facilitates the *cis–trans* isomerization (c.f. Fig. 2).

In Fig. 3 the optimized geometries for the retinal and the retinal PSB analogs are compared with the experimental and the theoretical data available from semiempirical calculations. The bond lengths for the retinal analog are very close to the experimental geometry for retinal obtained by X-ray crystallography (30). The MNDOC results (20) for the retinal SB predict a very long bond length for the C_7—C_8 double bond and therefore predict the dihedral angle between the plane of the ring and the chain to be 83° which is larger than the experimentally observed angle of 62° (30). Also, MNDOC does not assign enough torsional stability to the C_6—C_7 π single bond to compete with the steric interaction between the methyl groups at C_1 and C_5 and the hydrogens at C_7 and C_8. The present *ab initio* results for the retinal PSB analog are in general agreement with the MNDOC results (c.f. Fig. 3), though the latter seems to overestimate most of the bond lengths.

III.2 Charge distribution

The net atomic charges for the different analogs of retinal, retinal SB, and retinal PSB are often studied because of their importance in understanding the energetics of the interaction between the chromophore and protein residual charges in simple electrostatic terms. The atomic charge distribution is also useful in monitoring the changes in the electronic structure of different analogs. We have determined the atomic charges by means of Mulliken's population analysis, which is expected to give reasonable relative values in the minimal basis set used throughout.

In Fig. 4 net atomic charges are plotted for various analogs of different chain lengths. An alternation pattern of the atomic charges can be observed in each case. The heteroatom is always strongly negative, C_{15} is positive, and the charge alternation on remaining carbon atoms decreases subsequently. However, similar to the cases of bond lengths and bond orders, the retinal and retinal SB analogs show a rather different behaviour as compared to retinal PSB. In the former case (Fig. 4*a*), the charges after C_{15} are all negative with a minor alternation,

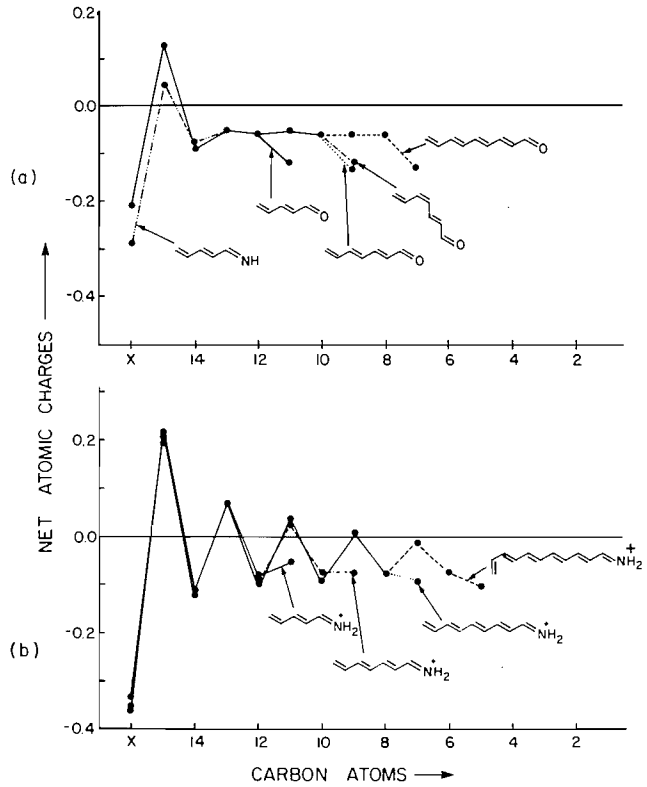

FIG. 4. Variation in the SCF net atomic charges on the C, N, or O atoms for different analogs of retinal, retinal SB (*a*) and retinal PSB (*b*). X = O or N. This numbering of carbon atoms is as defined in structure **I**.

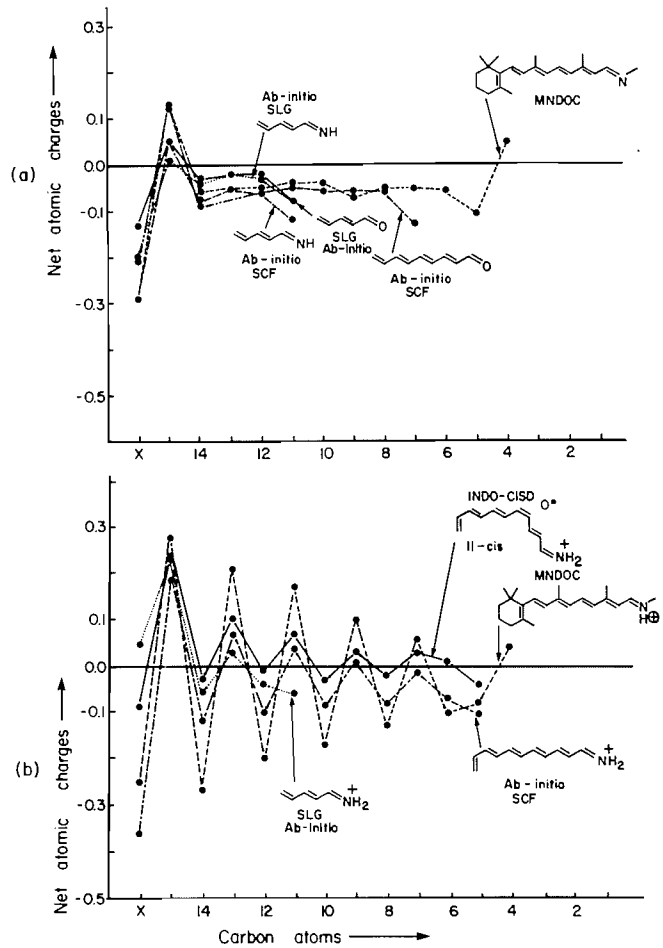

FIG. 5. Variation in net atomic charges on the C, N, and O atoms for retinal, retinal SB (*a*), and retinal PSB (*b*) analogs as obtained by *ab initio* SCF and SLG methods and semi-empirical MNDOC and INDO-CISD calculations. X = O or N, the numbering of carbons is as defined in structure **I**.

while in Fig. 4*b* for retinal PSB analogs we see a much larger alternation which keeps the odd-numbered carbon atoms slightly positive. The charge alternation according to our calculations is almost the same for *cis* and *trans* isomers.

The alternation of atomic charges along a chain introduced by a heteroatom as an "impurity" is well known; it can be understood by simple topological Huckel-type models (31) or, alternatively, on the basis of the induction of local dipoles. The reason of the remarkable difference between 4*a* and *b* is less obvious, though it has been studied formerly in several cases. In Fig. 5 we have collected some previous INDO-CISD and MNDOC results from the literature (16, 20). The charges obtained by the SLG wave function (cf. Section II) are also plotted. It turns out that all methods agree in the overall pattern of the charges though the MNDOC results seem to overestimate the actual values. The significance of the SLG method is important in this respect, because it does not take into account any delocalization or conjugation effects, and still shows a similar charge distribution. This implies that the essential difference between the charge distribution of retinal PSB and the retinal and retinal SB analogs reflected by Fig. 4 is not to be attributed to the increased conjugation of the former. The increased charge alternation in retinal PSB should be a consequence of the extra positive charge on N which induces larger local dipoles in the bonds over the whole molecule — an effect which is properly accounted for by the simple SLG wave function where the bonds are electrostatically coupled.

An interesting difference in the charge alternation pattern has been observed upon rotating the chromophore around the C_{11}—C_{12} "double bond" in excited state (16). The INDO-CISD calculations for the excited state predict an extra polarization at 90° of rotation around the C_{11}—C_{12} bond. However, the charges obtained by the properly correlated SLG wave function do not show the spurious extra polarization at 90° reported in refs. 15 and 16. The extra polarization is therefore most likely an artifact of the calculations. It should be emphasized that the HF-based methods are incapable of describing rotations around double bonds and do lead to charge polarization. Therefore, based on these results the sudden polarization charge transfer hypothesis can be eliminated as a possible mechanism in this process.

III.3 MO diagrams

Figure 6 shows the π molecular orbitals (MO's) for the analogs of retinal, retinal SB, and retinal PSB, in a simple diagrammatic representation. It clearly indicates that the π MO's in the retinal SB analog and the retinal analog have the same nodal characteristics. However, the nodal character of the HOMO changes in going from retinal SB to retinal PSB. The nodes in the HOMO of the retinal SB analog are located at the C_{14}—C_{15} and C_{12}—C_{13} bonds whereas in the case of retinal PSB analog the nodes are located at the C_{15}—N and C_{12}—C_{13} bonds. The strong conjugational effect on protonation near the NH_2^+ group end of the molecule is reflected by the nodal characteristics of the HOMO of the retinal PSB analog. The HOMO of the retinal PSB analog clearly shows conjugation

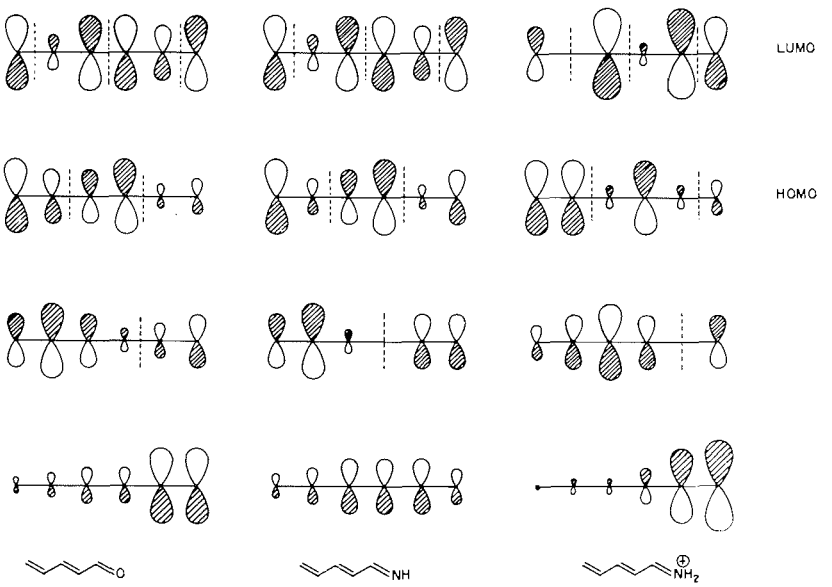

FIG. 6. Schematic representation of π-type MO's of retinal, retinal SB and retinal PSB analogs. The orbitals are drawn in order of ascending energy, the LUMO being at the top of the Figure.

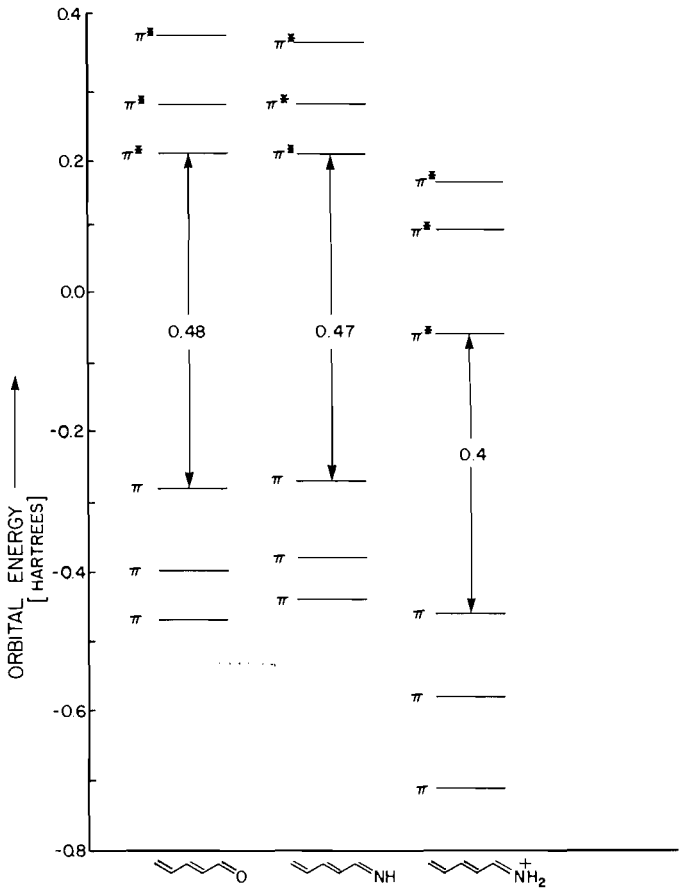

FIG. 7. π orbital energy diagram for retinal, retinal SB, and retinal PSB analogs.

between C_{13}—C_{14} and C_{14}—C_{15} bonds. Figure 7 shows the energy level diagram for the π MO's for the analogs containing three double bonds. In the retinal PSB analog the energy separation between the two highest filled π orbitals and two lowest antibonding π orbitals increases thereby reducing the gap between the HOMO and the LUMO. In other words, a red-shift in the π–π^* excitation energy is observed when the retinal Schiff base is protonated. The reason for this red shift is given by the increased conjugation of retinal PSB resulting in an equalization of "single" and "double" C—C bond lengths indicated by Fig. 1. We note that the larger analogs show the same trend (red shift upon protonation) with all the π–π^* orbital energy differences decreased due to the increased chain length.

IV. Conclusions

The results of the present paper are based on *ab-initio* STO-3G calculations, which reasonably describe the ground state properties of retinal. The conclusions can be summarized as follows:

(*1*) For the case of the retinal Schiff base and retinal analogs, convergence in bond lengths, bond orders, and atomic charges have been observed with increase in chain length showing that it is possible to mimic some properties of retinal with a smaller analog. This holds for protonated retinal Schiff base analogs only to a lesser extent.

(*2*) Protonation of the Schiff base causes more conjugational effects (i.e. elongation of double bonds and shortening of single bonds) in the vicinity of the NH_2^+ group which slowly dies off on moving towards the cyclohexene ring end of the molecule. This is reflected by the bond lengths and bond orders.

(*3*) Atomic charges alternate along the chain. This alternation is a result of induced local dipoles and is considerably stronger for protonated retinal Schiff base analogs.

(*4*) Regarding the studied properties various *cis* isomers show the same properties as the *trans* molecules.

(*5*) The change in nodal properties of the HOMO in the unprotonated retinal Schiff base and the protonated case is consistent with the conjugational effects and the difference in charge-distribution in the two cases.

(*6*) The protonated retinal Schiff base analog shows a red shift in π–π^* orbital energy difference, indicating a red shift in the corresponding excitation energy.

(*7*) The charge distribution of the studied models changes significantly at the SCF level when rotating around a double bond. This sudden charge polarization was shown to be an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

artifact of the closed shell HF calculations, which disappears if the properly correlated SLG wavefunction is used.

The systematic study of the various properties presented in this paper shows the analogy between retinal and retinal Schiff base, and the differences introduced on protonation. This is reflected by all the properties studied in this work.

Preparations and X-ray structure determinations are described for Ph_3SiSPh and $[W(CO)_4(\mu\text{-}SPh)]_2$. The compound Ph_3SiSPh crystallizes in space group *Pcab* with $a = 15.260$ Å, $b = 15.968$ Å, $c = 16.757$ Å, $Z = 8$, $d_{calc} = 1.20$ g cm^{-3} (MoKα1, λ = 0.70930 Å). The structure was solved with MULTAN and refined to the final $R = 0.050$ for 1933 significant reflections. The molecule has an unusual C—S—Si angle of 99.5° and a short Si—S bond length of 2.156 Å. The compound $[W(CO)_4(\mu\text{-}SPh)]_2$ crystallizes in the space group $P2_1/c$ with $a = 9.164$ Å, $b = 12.054$ Å, $c = 11.163$ Å, β = 111.63°, $Z = 2$, $d_{calc} = 2.35$ g cm^{-3} (MoKα1, λ = 0.70930 Å). The structure was solved with MULTAN and refined to the final $R = 0.062$ for 2748 significant reflections. The molecule is a dimer with a crystallographic center of symmetry. There is a short W—W distance (2.972 Å), a wide S—W—S′ angle (106.3°), a compressed W—S—W′ angle (73.67°) and there is distortion of a CO on each W due to the close approach of an *ortho*-H in a phenyl ring.

C. Robert Lucas, Michael J. Newlands, Eric J. Gabe et Florence L. Lee. Can. J. Chem. **65**, 898 (1987).

On décrit les préparations et les déterminations de structure par diffraction des rayons-X du Ph_3SiSPh et $[W(CO)_4(\mu\text{-}SPh)]_2$. Le composé Ph_3SiSPh cristallise dans le groupe d'espace *Pcab*, avec $a = 15{,}260$, $b = 15{,}968$ et $c = 16{,}757$ Å, $Z = 8$ et $d_{calc} = 1{,}20$ g cm^{-3} (MoKα1, λ = 0,70930 Å). On a résolu la structure à l'aide du programme MULTAN et on l'a affinée jusqu'à une valeur finale de $R = 0{,}050$ pour 1933 réflexions indépendantes. La molécule comporte une angle C—S—Si qui est inhabituel à 99,5° et une liaison Si—S relativement courte à 2,156 Å. Le composé $[W(CO)_4(\mu\text{-}SPh)]_2$ cristallise dans le groupe d'espace $P2_1/c$, avec $a = 9{,}164$, $b = 12{,}054$ et $c = 11{,}163$ Å, β = 111,63°, $Z = 2$ et $d_{calc} = 2{,}35$ g cm^{-3} (MoKα1, λ = 0,70930 Å). On a résolu la structure à l'aide du programme MULTAN et on l'a affinée jusqu'à une valeur finale de $R = 0{,}062$ pour 2748 réflexions indépendantes. La molécule est un dimère comportant une centre de symétrie cristallographique. On observe une distance W—W qui est courte à 2,972 Å, un angle S—W—S′ qui est grand à 106,3°, un angle W—S—W′ qui est comprimé à 73,67° et une distortion d'un CO de chacun des W qui est due à une approche d'un H en ortho d'une groupement phényle.

[Traduit par la revue]

Introduction

Recently, one of us has described the synthesis of a series of organometallic thioethers R_3MSR' (M = C, Si, Ge, or Sn) and their metal complexes with $W(CO)_6$ (1, 2). During studies of these compounds, it became apparent that structural evidence for p_π—d_π S → M π-bonding was probably accessible via an X-ray study of the ligands in which M = Si. It was also observed that decomposition of many of the complexes, $W(CO)_5(R_3MSR')$, to *cis*-disubstituted W(I) derivatives, $[W(CO)_4(SR')]_2$, was possible under appropriate conditions. This paper reports preparations and structures of the ligand Ph_3SiSPh and of $[W(CO)_4SPh]_2$, a W(I) decomposition product of the 1:1 complex between $W(CO)_6$ and Ph_3SiSPh.

Experimental

Reagents were obtained from the Aldrich Chemical Co. Inc., and were used without further purification. Spectroscopic data were obtained using the following instruments: ir, Perkin Elmer Model 283; nmr, Varian EM-360 or Bruker WP80 Fourier transform; mass spectra, VG Micromass 7070HS. X-ray diffraction data were collected using a Picker FACS-I four circle diffractometer with local (NRC) automation. Standard Schlenk techniques were used throughout and unless noted, procedures were carried out under an atmosphere of dry nitrogen. Analyses were performed by Canadian Microanalytical Service Ltd.

[1]NRCC No. 27026.

Preparative

(a) DABCO·HSPh

DABCO, (1,4-diazabicyclo[2.2.2]octane) (2.2 g, 20 mmol), was dissolved in dry toluene (15 mL) (freshly distilled from sodium) and thiophenol (2.1 mL, 20 mmol) was added portionwise. The precipitate of DABCO·HSPh which began to form after a few seconds was stirred for 2 h under a $CaCl_2$ drying tube. The suspension was filtered, transferred without washing to a Schlenk tube, covered with a glass wool plug, and placed under vacuum. After continuous pumping for 2 h at an oil pump, the solid was dry. Yield 3.1 g (70%), mp 95–97°C (lit. 97–98°C) (3).

(b) Ph_3SiSPh

DABCO·HSPh (3.1 g, 14 mmol) and Ph_3SiCl (4.1 g, 14 mmol) were suspended in dry benzene (42 mL) and stirred under a $CaCl_2$ drying tube for 2 days. The suspension was filtered and volatiles were removed from the filtrate under vacuum to leave a nearly colourless oil which crystallized upon standing. Crystals from hexane have mp 97–98°C (lit. 95–96°C) (3). Mass spectrum has major peaks at m/e = 368 $(Ph_3SiSPh)^+$, 259 $(Ph_3Si)^+$. Nuclear magnetic resonance in CCl_4 consists of a complex multiplet centered at 7.3 ppm from internal TMS.

(c) $[W(CO)_4SPh]_2$

Tungsten hexacarbonyl (5.3 g, 15 mmol) was dissolved in dry tetrahydrofuran (200 mL) in a Pyrex flask fitted with a double surface condenser, a magnetic stirrer, and a gas dispersion inlet tube. The top of the condenser was connected to an oil bubbler and the solution was irradiated for 4 h with a 100 W uv lamp while stirring and passing a stream of nitrogen bubbles through the solution. The lamp was switched off, Ph_3SiSPh (5.5 g, 15 mmol) was added, and the solution

was stirred for half an hour at which time water (1.0 mL, 55 mmol) was added. The solution was stirred a further half hour, volatiles were removed in vacuum on a warm water bath leaving a sticky residue and benzene (200 mL) was added. The mixture was stirred and refluxed overnight. The green solution was filtered, the off-white residue of $Ph_3SiOSiPh_3$ discarded and the filtrate taken to dryness in vacuum at 50°C. The residue was extracted several times with hexane, the extracts combined and concentrated and then chromatographed on Florisil using hexane as the eluant. The first green material to be eluted was discarded. The remaining green eluate was taken to dryness and placed in a sublimer at 40°C and 0.1 mm Hg to remove $W(CO)_6$. The residue was recrystallized from hexane. Yield 2.0 g (33%), mp 93°C (dec.). The mass spectrum shows a molecular ion peak at $m/e = 810$ and other peaks corresponding to sequential loss of all eight carbonyls. Nuclear magnetic resonance: ($CDCl_3$) multiplet 7.7 ppm from internal TMS. Infrared: (hexane) 2038 (s), 1979 (m), 1973 (m), 1964 (vs). *Anal.* calcd. for $C_{20}H_{10}O_8S_2W_2$: C 29.65, H 1.24, W 45.39; found: C 29.72, H 1.96, W 45.50.

X-ray studies

(a) Ph_3SiSPh

The compound crystallizes in the space group *Pcab* with a = 15.260(3) Å,[2] b = 15.968(2) Å, c = 16.757(2) Å, $Z = 8$ and d_{calc} = 1.20 g cm^{-3}. The space group was uniquely determined by the occurrence of systematic absences. The diffraction intensities of an approximately 0.25 × 0.35 × 1.0 mm crystal mounted in silicone grease inside an evacuated Lindemann capillary were collected at 295 K with graphite monochromatized MoKα radiation using the $\theta/2\theta$ scan technique with profile analysis (4) to $2\theta_{max} = 50°$ at a scan speed of 4°/min. A total of 3610 unique reflections were measured of which 1933 were considered significant with $I_{net} > 2.5\sigma(I_{net})$. Three standards were measured after every 100 reflections and no significant crystal decay was detected. Lorentz and polarization factors were applied but no absorption corrections were applied (μ = 2.13 cm^{-1}). Altogether, 440 systematic absences were measured, only three of which had significant intensities. No evidence for extinction was observed. The cell parameters were obtained by least-squares refinement of the setting angles of 90 reflections with $2\theta > 40°$ (MoKα1, λ = 0.70930 Å).

The structure was solved with MULTAN (5) plus a difference Fourier map, and refined by full-matrix least-squares with counting statistics weights. H-atom positions were calculated but their parameters were not refined. All heavier atoms were refined anisotropically. The final residuals are $R_F = 0.050$ and $R_W = 0.036$ for the significant data (R_F = 0.115 and R_W = 0.036 for all data). All calculations were performed with the NRCVAX system of programs (6). Scattering factors were taken from the International tables for X-ray crystallography (7).

The final atomic positional parameters and the equivalent isotropic temperature factors are listed in Table 1 while distances and angles are in Table 2. Anisotropic thermal parameters and final structure factors are available as supplementary data.[3] Figure 1 shows the molecule with the atomic numbering scheme.

(b) $[W(CO)_4SPh]_2$

The compound crystallizes in the space group $P2_1/c$ with a = 9.164(3) Å, b = 12.054(2) Å, c = 11.163(2) Å, β = 111.63(2)°, $Z = 2$ and d_{calc} = 2.35 g cm^{-3}. The space group was uniquely determined by the systematic absences. The diffraction intensities of an approximately 0.35 × 0.25 × 0.25 mm crystal glued to a glass fibre inside an evacuated Lindemann capillary were collected at 300 K with graphite monochromatized MoKα radiation using the $\theta/2\theta$ scan technique with profile analysis (4) to $2\theta_{max} = 60°$ at a scan speed of 4°/min. A total of 3356 unique reflections were measured of which 2748 were considered significant with $I_{net} > 2.5\sigma(I_{net})$. Three standards were measured after every 100 reflections and no significant crystal decay was detected. Lorentz and polarization factors were applied. It was not possible to calculate absorption corrections (μ = 10.5 mm^{-1}) because the mounting of the crystal made it impossible to measure the faces. No evidence for extinction was observed. Cell parameters were obtained by least-squares refinement of the setting angles of 58 reflections with $2\theta > 55°$ (MoKα1, λ = 0.70930 Å).

The structure was solved with MULTAN (5) and refined by full-matrix least-squares with counting statistics weights. H-atom positions were calculated and fixed in the refinement. The final residuals are $R_F = 0.062$ and $R_W = 0.062$ for the significant data (R_F = 0.072 and R_W = 0.062 for all data). All calculations were performed with the

NRCVAX system of programs (6). The final difference map showed two peaks with electron density equivalent to 5 e/Å^{-3} on the W—S and W—C(3) bonds about 0.9 Å from W which may be due to the lack of absorption correction. Scattering factors were taken from the International tables for X-ray crystallography (7). The final atomic positional parameters and the temperature factors are listed in Table 3 while distances and angles are in Table 4. Anisotropic thermal parameters and final structure factors are available as supplementary data.[3] Figure 2 shows the molecule with the atomic numbering scheme.

Results and discussion

Preparative

(a) Ph_3SiSPh

Although we have had difficulty with the preparation of Ph_3SiSPh described in ref. 3, the modified method (use of stoichiometric amounts of reagents and careful exclusion of moisture) reported herein works reproducibly in our hands and the properties of the substance obtained by this method agree with those of the material reported previously.

(b) $[W(CO)_4SPh]_2$

Preparations of bridged W(I) dimers $[M(CO)_4X]_2$ (X = PR_2 (8), I (9), SH (10), and SR (11); M = Mo or W) including $[W(CO)_4SPh]_2$ (12) have been reported previously and some of these W(I) compounds have been the subject of X-ray crystallographic structure determinations (9, 13). Generally, however, W(I) is less common than other oxidation states of tungsten and therefore all aspects of the formation, bonding, reactivity, and structure of its compounds are of interest. Isolation of $[W(CO)_4SPh]_2$ from solutions containing $W(CO)_5(Ph_3SiSPh)$ may seem surprising but in fact a series of steps, all previously demonstrated, could give rise to green $[W(CO)_4SPh]_2$.

[1] $W(CO)_6 + Ph_3SiSPh \rightarrow W(CO)_5(Ph_3SiSPh)$

[2] $2W(CO)_5(Ph_3SiSPh) + H_2O \rightarrow 2W(CO)_5(HSPh) + Ph_3SiOSiPh_3$

[3] $W(CO)_5(HSPh) \rightarrow W(CO)_5SPh + (1/2)H_2$

[4] $2W(CO)_5SPh \rightarrow [W(CO)_4SPh]_2 + 2CO$

Reaction [1] is a normal carbonyl substitution and requires no further comment whereas [2] involves hydrolytic cleavage of a Si—S bond analogous to that reported many years ago for uncomplexed R_3SiSR' (14). More recently, the latter process has also been observed by Vahrenkamp (15) during formation of $W(CO)_5SH_2$ from $W(CO)_5S(SiMe_3)_2$ by hydrolysis. During workup of our reaction, a white solid was obtained with mass and ir spectra corresponding to $Ph_3SiOSiPh_3$.[4]

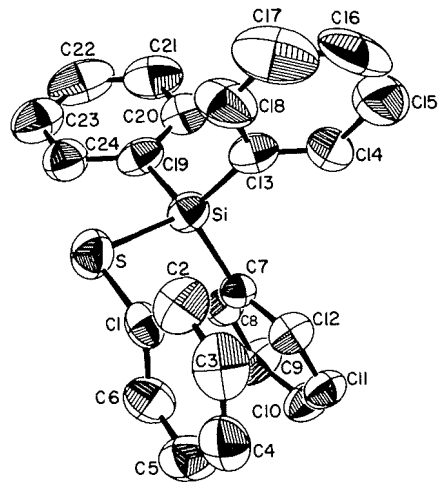

FIG. 1. ORTEP drawing of Ph_3SiSPh.

Reaction [3] represents a spontaneous process observed for ruthenium complexes of H_2S and EtSH (17) and for $W(CO)_5SH_2$ (10) while [4] is the equivalent of the dimerization of $W(CO)_5SH$ to $[W(CO)_4SH]_2$ reported by Vahrenkamp (10) which presumably involves a *cis*-labilizing effect in the monomer due to the lone pairs on sulfur (18).

Structural

(a) Ph_3SiSPh

The structure of Ph_3SiSPh (Fig. 1) is unremarkable except for the bond angle at S (99.5°) and the Si—S bond length (2.156 Å). Bond angles at sulfur in thioethers and organometallic thioethers are typically 105–109° (19, 20) and there are no close interactions between molecules in the unit cell of Ph_3SiSPh which would account for the significant closing of its C—S—Si angle. There is, however, a close approach of the phenyl ring on sulfur to one of those on silicon (Table 2). Van der Waal's forces of attraction between these two phenyl rings

[4]Mass spectrometry: molecular ion, M^+_{calc} = 534; M^+_{found} = 534. Infrared: corresponds to literature (16), in particular a strong, broad band at 1058 cm^{-1} due to Si—O stretching.

may therefore be the cause of the sharp angle at sulfur since the minimum distances between carbon atoms on the adjacent rings are about the same as the sum of the van der Waal's radii for carbon (2 × 1.70 Å) (21) (Table 2).

In our earlier spectroscopic studies (1, 2), evidence was presented for the presence of S → M p_π—d_π bonding in R_3MSR' (M = Si, Ge, Sn). Furthermore, the evidence suggested that this bonding was weak and unlikely to cause observable shortening of the M—S bond except perhaps when M = Si. This expectation has now been supported by experiment because when M = Ge or Sn, M—S bonds are usually found to be nearly the same (±0.01 Å) as those predicted by addition of covalent radii (20). In contrast, we find that when M = Si, shortening of 0.05 Å is observed (Table 2).

(b) $[W(CO)_4SPh]_2$

The molecule is a dimer with a crystallographic center of symmetry as shown in Fig. 2. Each W atom is six-coordinated to four CO groups and two S atoms which form a distorted octahedron. A phenyl ring is attached to each S atom which in turn coordinates to the two symmetry-related distorted octahedra with an S—W—S′ angle of 106.3(1)° and an S—W—C(3) angle of 163.8(4)° indicating maximum deviations of 16.3° from a right angle between the two coordinated sulfurs and 16.2° from a linear arrangement of S—W—CO. The distance between the planes of the two phenyl rings is 1.97(1) Å.

The compound contains formal W(I) which should be paramagnetic. The fact that a normal unshifted and unbroadened nmr spectrum is obtained suggests, however, that the substance is diamagnetic. Formation of a W—W bond would give such a diamagnetic compound in which each tungsten atom has achieved 18 valence electrons. Consistent with this hypothesis, the bond angles at W and S in the W_2S_2 ring are obtuse and acute, respectively, and the W—W distance is 2.972(1) Å which may be compared to the W—W distance of 3.222 Å in $[(\eta^5\text{-}C_5H_5)W(CO)_3]_2$ (22). The average W—S distance of 2.48 Å is substantially shorter than the distance of 2.59 Å found in the singly bridged W(O) ion $[W(CO)_5(\mu\text{-}SC_6Cl_5)W(CO)_5]^-$ (23). The *trans* influence relative to CO of the sulfur ligand is seen from the difference between the average length of the metal–carbonyl bonds *trans* to sulfur (1.95 Å) and that of the *cis* bonds (2.05 Å).

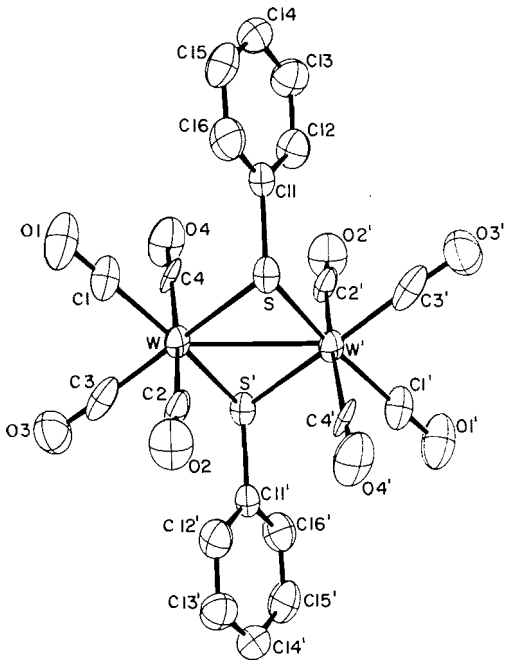

FIG. 2. ORTEP drawing of $W_2(CO)_8(SPh)_2$.

The tendency for binuclear tungsten carbonyl complexes with single sulfur bridges to distort to relieve CO repulsions between the two halves of the molecule has been noted for $[W(CO)_5(\mu\text{-}SH)W(CO)_5]^-$ (24) and it may be that distortion of two of the carbonyls that are *cis* to both sulfurs in $[W(CO)_4SPh]_2$ is due to the fact that the double sulfur bridges hold the two halves of the molecule in a nearly eclipsed conformation (OC(2)—W—W′—C(4′)O torsion angle 2.67°). It is more likely, however, that the distortion of just one of those carbonyls in each half of the molecule is due to close contact between the O of the distorted carbonyl and one of the *ortho*-H's of the phenyl ring (H(12)—O(2′) = 2.670 Å); sum of van der Waal's radii 2.70 Å (21). The very wide S—W—S′ angle (106.3°) has little effect on the rest of the octahedron but is matched by a correspondingly small W—S—W′ angle (73.67°), consistent with the presence of a W—W bond. The W—W distance (2.972 Å), W—S average (2.478 Å), W—C_{eq} average (1.954 Å) and W—C_{ax} average (2.056 Å) are very similar to the corresponding distances in the Mo(I) compound $[Mo(CO)_4\text{-}\mu\text{-}SBu']_2$ (Mo—Mo 2.984 Å; Mo—S 2.48 Å; Mo—C_{eq} 2.01 Å; Mo—C_{ax} 2.05 Å) (25) and to those in $[W(CO)_4\text{-}\mu\text{-}SMe]_2$ (W—W 2.97 Å; W—S 2.47 Å; W—C_{CO} 1.98–2.03 Å) (13). Comparable distances in $[\eta^5\text{-}(C_5H_5)M(CO)_3]_2$ (M = Mo or W) are Mo—Mo 3.235 Å; W—W 3.222 Å; W—CO 1.975, 1.956, 1.996 Å; Mo—CO 1.984, 1.964, 1.983 Å (22).

Detection of the isotopes of lithium using the Faraday effect

SHI-LIAN JING AND ROGER STEPHENS[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received September 11, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

SHI-LIAN JING and ROGER STEPHENS. Can. J. Chem. **65**, 903 (1987).

Lithium is atomised in an air–acetylene flame within a longitudinal magnetic field. Birefringent and dichroic signals are separately measured using a pulsed hollow cathode source. The arrangement is found to give isotopic selectivity and is useable down to concentrations of about 10 μg/mL. The signal ratio of birefringence: dichroism is found to be approximately independent of sample concentration at the high and low extremes of the calibration curve. However, severe distortions occur at intermediate concentrations. In addition, a reversal of signal magnitudes is observed between ^{6}Li and ^{7}Li. This effect is attributed primarily to a distortion of the source profile as a result of self-absorption.

SHI-LIAN JING et ROGER STEPHENS. Can. J. Chem. **65**, 903 (1987).

Le lithium est atomisé dans une flamme air/acétylène comportant un champ magnétique longitudinal. On peut faire des mesures séparées des signaux biréfringent et dichroïque en utilisant une source à cathode creuse et pulsée. On a trouvé que cet arrangement donne une bonne sélectivité isotopique et qu'on peut l'utiliser jusqu'à des concentrations aussi faibles que 10 μg/mL. On a trouvé que, aux limites extrèmement élevée ou basse de la courbe de calibration, le rapport des signaux de biréfringence/dichroïsme est pratiquement indépendant de la concentration de l'échantillon. Toutefois, il se produits d'importantes distortions aux concentrations intermédiaires. De plus, on observe un renversement des amplitudes des signaux entre le ^{6}Li et le ^{7}Li. On attribue principalement cet effet à une distortion du profil de la source qui provient d'une auto-absorption.

[Traduit par la revue]

Introduction

Magneto-optic rotation (MOR) has been used for the selective detection of the isotopes of lead (*1*). The technique employed the ratio of birefringence to dichroism in a Voigt optical configuration as a measurement parameter. The particular advantage of this approach is an ability to identify the different isotopes with an apparatus which uses a conventional, commercially available light source and atomiser: the method can tolerate the overlap of the hyperfine components of the atomic spectra without recourse to the use of isotopically pure sources and low pressure atomisers in order to optimise spectroscopic resolution.

The ratio parameter is isotopically sensitive because the shape of an atomic line profile changes as the isotopic composition of the atomic vapor is altered. Since birefringence and dichroism show a different functional dependence on the form of the profile their ratio is automatically responsive to such variations. The ratio parameter is otherwise robust, being largely independent of source intensity and of background absorption by non-atomic species, and with a reasonable tolerance towards limited changes in the sample concentration.

One disadvantage of the original apparatus proved to be a need for high sample concentrations in order to obtain adequate signal-to-noise (S/N) ratios. Subsequently this problem became even more apparent during an attempt to extend the technique to lithium. In spite of the known suitability of the isotopes ^{6}Li, ^{7}Li for selective detection by conventional spectroscopic methods (*2–4*), which implies that the differences between their respective response functions should be unusually large, the S/N ratio of the MOR apparatus remained poor. The present work examines the origin of this problem, and describes an instrumental modification which improves the sensitivity of the technique by one to two orders of magnitude.

Theory

Three main reasons are responsible for the poor S/N ratio observed in earlier experiments. The first lies in the use of a flame atomiser of short path length. The flame offers a convenient way to obtain a stable, continuous signal, but does not represent the most efficient way to atomise a sample. This point will not be expanded on here. The second reason arises from the optical configuration employed in the original apparatus, which lacked the flexibility to allow the S/N ratio to be optimised for any particular combination of atomiser background emission, source intensity, optical bandwidth etc. which might be encountered in a given experiment. Finally, attention must be given to the effect of magnetic field strength. In any MOR apparatus the field strength controls the S/N ratio of the birefringent and dichroic signals. In an isotopic system it also influences the degree of discrimination between the different isotopic responses. These are independent requirements which tend to place conflicting demands on the value of the field strength to be used. For instance, a field which gives the best selectivity may be so low that the individual birefringent and dichroic signals are too weak to give a satisfactory S/N ratio unless high sample concentrations are available (a situation previously encountered with ^{206}Pb (*1*)).

The sensitivity losses caused by the last two factors can be offset by use of a Faraday optical configuration. At low field strengths the signals from the Faraday effect are stronger than from the Voigt, for reasons given elsewhere (*5*). The need to compromise between the requirements of selectivity and sensitivity is correspondingly less severe. The converse is also true: if the best selectivity is obtained at a field strength exceeding that for optimum sensitivity then the Voigt configuration becomes preferable (it should be noted that the field strengths which give the best selectivity are unlikely to be identical in the two configurations).

The ability of the Faraday configuration to allow for an optimisation of the birefringent and dichroic signals to suit any particular experimental situation is shown by the following argument. Consider the optical system which is shown schematically in Fig. 1. The Jones matrix, $\mathbf{J}$, of this system is given by:

$$[1] \quad \mathbf{J} = \mathbf{P}_y\mathbf{R}(\theta)\mathbf{r}\mathbf{U}^{-1}\mathbf{F}\mathbf{U}\mathbf{P}_x$$

where $\mathbf{P}_x$, $\mathbf{P}_y$, $\mathbf{F}$, $\mathbf{r}$ are respectively the Jones matrices of

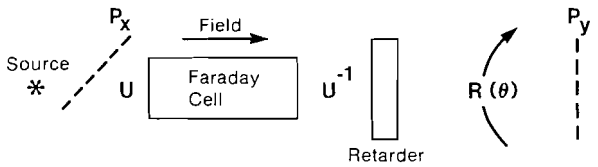

FIG. 1. Schematic MOR apparatus. $\mathbf{P}_x$, $\mathbf{P}_y$: polariser and analyser. $\mathbf{U}, \mathbf{U}^{-1}, \mathbf{R}(\theta)$ show the locations of the transformation matrices relative to the positions of the optical components.

polarisers P_x and P_y, of the Faraday cell, F, and of the retarder, r; $\mathbf{R}(\theta)$ is the rotation matrix which describes the displacement of P_y by some angle θ from an orthogonal position relative to P_x; and $\mathbf{U}, \mathbf{U}^{-1}$ are the similarity transform matrices between linear and circular basis vectors.

Writing the complex refractive index of the vapor in the Faraday cell as $\tilde{n} = n' + in''$ gives

$$\mathbf{F} = \begin{pmatrix} e^{i\tilde{n}_+ l} & 0 \\ 0 & e^{i\tilde{n}_- l} \end{pmatrix}$$

where l is the path length, and the subscripts +, − specify right and left handed circular components. Hence

$$[2] \quad \mathbf{F} = e^{i(\tilde{n}_+ + \tilde{n}_-)l/2} \begin{pmatrix} e^{i\Delta\tilde{n}l/2} & 0 \\ 0 & e^{i\Delta\tilde{n}l/2} \end{pmatrix}$$

where $\Delta\tilde{n} = \tilde{n}_+ - \tilde{n}_-$. Similarly, if 2δ is the retardance of r then

$$[3] \quad \mathbf{r} = \begin{pmatrix} e^{i\delta} & 0 \\ 0 & e^{-i\delta} \end{pmatrix}$$

Substitution of eqs. [2] and [3] into [1] allows eq. [1] to be evaluated as:

$$[4] \quad I = (1/4)I_0 e^{-(n''_+ + n''_-)l} \times [(\cosh \Delta n''l + \sin 2\delta \sin 2\theta \sinh \Delta n''l) - (\cos \Delta n'l \cos 2\theta + \cos 2\delta \sin 2\theta \sin \Delta n'l)]$$

where I is the transmitted intensity and I_0 is the unpolarised source intensity. The two terms in the inner brackets are the contributions from dichroism ($\Delta n''$) and birefringence ($\Delta n'$), respectively.

If r is a sinusoidal modulator with a peak retardance of $2\delta_0$ and circular frequency ω then $\delta = \delta_0 \sin \omega t$. The first and second harmonics contained in eq. [4] are then given by:

$$[5] \quad \begin{aligned} I_\omega &= (1/2)I_0 e^{-(n''_+ + n''_-)l} \sin 2\theta \, J_1(2\delta_0) \sinh \Delta n''l \sin \omega t \\ I_{2\omega} &= (1/2)I_0 e^{-(n''_+ + n''_-)l} \sin 2\theta \, J_2(2\delta_0) \sin \Delta n'l \cos 2\omega t \end{aligned}$$

where $J_1(2\delta_0)$, $J_2(2\delta_0)$ are the Bessel functions of order 1,2.

As $\tilde{n} \rightarrow$ unity then $\Delta\tilde{n} \rightarrow 0$, and the background transmission of eq. [4] becomes

$$[6] \quad I_B = (1/2)I_0 \sin^2 \theta$$

This result illustrates a significant advantage of the type of optical system shown in Fig. 1, namely that it produces a selective modulation of the signal of interest. Thus its use makes it relatively easy to reach a S/N ratio which is limited by shot noise rather than flicker, since it is technically feasible to employ a value of ω which is high enough for the flicker carried by I_B in eq. [6] to lie below shot noise. At the same time flicker noise caused by instability of the modulator (i.e. of δ_0) falls as the signal of interest falls, since the modulated terms in eq. [5] are all connected to $\Delta\tilde{n}$. The S/N behavior of this type of optical configuration is discussed at greater length elsewhere (6).

In practice additional terms are present in eq. [6]. These originate with the background emission from the atomiser or from non-resonance emission from the source (for example, if a wide aperture optical system of low resolving power is used). Given this extra input of stray light then optimisation of the S/N ratio is achieved by increasing θ. Equation [5] shows that the dichroic and birefringent signals increase simultaneously. Thus their S/N ratios both increase with θ until the background intensity contribution of eq. [6] becomes comparable to that of the other background sources, after which the S/N ratio becomes approximately constant (7). Thus the experimental adjustment of θ provides the means to simultaneously optimise the S/N ratios of both of the signals in eq. [5] for any particular conditions of background illumination. An application of the results of earlier work on optical linearisation shows that this use of θ as a linearising factor to improve the S/N ratio is almost ideal provided that θ is small (8). In other words one can probably find other types of (passive) optical system which will allow a comparable performance to be attained. However, the only way to achieve a significant improvement over the S/N ratios given by eqs. [5] and [6] is by a manipulation of the value of $\Delta\tilde{n}$, through some change in the way in which the optical anisotropy is introduced.

Finally it will be noted that a complete optimisation of the birefringent and dichroic signals in eq. [5] cannot be achieved simultaneously. This conclusion is quite general (8); it arises in the particular system considered here through the occurrence of the Bessel functions $J_1(2\delta_0)$, $J_2(2\delta_0)$ in the coefficients of the modulated birefringent and dichroic term. No single value of δ_0 exists which will allow $J_1(2\delta_0)$, $J_2(2\delta_0)$ to be maximised at the same time.

Experimental

The apparatus used here is shown in Fig. 2. The offset angle, θ, was applied to the analyser. The magnetic field was produced by a pair of air-cored coils driven by single half-cycles of the ac mains. The hollow cathode source (IL) was synchronised with the field coil to produce an emission pulse of 500 μs duration at the peak of the field. The pulse current was fixed at 80 mA. Observations were made over the duration of the emission pulse by gating the phototube pre-amplifier to the lamp supply. Details of this type of arrangement have been given (9). The field coils accommodated an air–acetylene burner with a 2.6 cm path length. In the Faraday configuration the peak field available was 0.2 Tessla.

The variable retarder shown in Fig. 2 was a PEM 80 photoelastic modulator (Hinds International, Portland, OR), ω = 50 kHz. Thus the birefringent and dichroic signals of eq. [5] appeared at frequencies of 100 kHz and 50 kHz, respectively. The value of δ_0 for the PEM was set empirically to give equal values of $J_1(2\delta_0)$, $J_2(2\delta_0)$ by inserting known static dichroic and birefringent optical elements in place of the burner head in the manner described previously (1).

Lamp emission at 670.8 nm was isolated by a 1/4 m monochromator (Oriel #7240, reciprocal dispersion = 6.4 nm/mm, slitwidth = 3 mm) and detected by an IP 28 photomultiplier. Electrical signals were taken through the gated pre-amplifier to 50 kHz and 100 kHz synchronous detectors which were phase-locked to the PEM. These circuits were built in the laboratory.

The isotopes ^{6}Li, ^{7}Li were supplied as their hydroxides by Stohler Isotope Chemicals, Montreal. Solutions were prepared in dilute HCl (Fisher; ACS reagent grade).

Results

The dependence of the S/N ratios of the birefringent and dichroic signals on the linearisation angle θ are shown in Fig. 3. The responses are quite normal, showing an initial,

approximately linear increase followed by a slow reduction. The shapes of the response curves and the relatively large value of the optimum angle are characteristic of a shot noise limited measurement at a high background light level (7). A shot noise limited response of some form is to be expected: flicker in this type of modulation system can be detected using a laser source (6), but the flux from a hollow cathode lamp is normally insufficient for flicker to become significant relative to shot noise. The high level of stray light apparent from these data is the direct result of the use of a flame atomiser. All subsequent measurements in the Faraday configuration were made at a fixed offset angle of 10°.

The signal dependence on magnetic field strength, given in Fig. 4, shows that no particular selectivity advantage is obtained by working below the maximum available field strength. It is of interest to note that the results show dichroism to be stronger than birefringence for ^{6}Li, and *vice versa* for ^{7}Li. This observation demonstrates the isotopic selectivity of the measurement. However it also represents an exact reversal of the expected form of the response, since the lamp cathode (natural Li) would be expected to emit essentially the spectrum of ^{7}Li. The reason for the reversal lies partly in the frequency shift of the pressure broadened flame line, and partly in the use of a pulsed measurement by the present apparatus. The high pulse current through the source produces self-absorption of the lamp emission profile, which leads to a broadening and splitting of the emission lines. The quantitative explanation of the mechanism by which self-absorption reverses the response functions of the two isotopes will be given in more detail elsewhere.

The enhanced sensitivity of the present apparatus relative to the system based on the Voigt configuration is illustrated by their respective signals, shown in Fig. 5. It is clear that a considerable improvement in performance is obtained. This improvement allows a corresponding extension to be obtained at the low concentration end of the calibration curves. The results (Fig. 6) show that the ratio parameter is approximately independent of sample concentration at the high and low ends of the concentration range, in agreement with earlier results (1), and therefore allows isotopic composition to be determined

without an exact knowledge of the sample concentration. However, the numerical values of the calibration constants at the two extremes do not coincide. Furthermore the fluctuations within the transition range are potentially quite drastic. Thus the stability of the ratio parameter towards variations in sample concentration is of only limited extent. Measurements can be made at one or other end of the concentration range but they cannot be mixed, while measurements in the transition range should be avoided altogether unless the sample concentration is known accurately.

The dependence of the signal ratio (birefringence:dichroism) on isotopic composition is shown in Fig. 7. Measurements were made at a fixed concentration of 2.3 m*M* (~15 μg/mL). This value lies approximately in the centre of the low concentration range data of Fig. 6, where the ratio parameter is relatively insensitive to concentration changes. The results suggest that the technique can be expected to distinguish variations in the proportion of ^{7}Li by perhaps ±5% relative to natural Li.

Conclusions

The present experiments have shown that the problem of poor sensitivity in the determination of isotopic composition by MOR can be largely overcome. The use of a Faraday optical configuration, linearised response functions, and the selective high frequency modulation of both birefringent and dichroic signals comprise the main features of the design. The system is built around standard, commercially available optical components, and the simplicity of the original system remains largely unchanged.

Two problems are evident as a result of the present work. The most serious of these is the limited range over which the response parameter remains independent of sample concentration. This increases the difficulties in developing a technique which will operate without the use of calibration standards. The second problem is the extent of the sensitivity of the measurement to self-absorption in the source, which suggests in general that calibration constants will be influenced by changes in the shape of the source profile. This behaviour is unsurprising and, given the excellent stability of modern hollow cathode sources, it seems likely that if the problem cannot be overcome it can at least be controlled simply by accurate regulation of the lamp supply. The trends observed in Fig. 6 imply that the sensitivity to the shape of the source profile may be less apparent at high concentrations.

Finally, it will be noted that the optical design described here is close to optimal, for the reasons outlined in the derivation of eq. [5]. Therefore it is concluded that the solution concentrations required to obtain the present results are approaching the lower limit to be expected for an apparatus which separately measures birefringence and dichroism by optical rotation in a flame atomiser. Small gains can be anticipated by, for example, increasing the field strength or improving the duty cycle of the source. Large improvements in performance appear likely to require more extensive adaptation, for instance through the use of non-flame atomisation.

The ^{1}H nuclear magnetic resonance spectra for CCl_4 solutions are analyzed for 2-(thiocthyl)phenol, 2,3-dimethoxyphenol, and 8-hydroxythiochroman. The chemical shifts of the hydroxyl protons in these compounds, in 2,3-dihydroxyanisole, and 2-hydroxybenzyl methyl ether are discussed in terms of stereospecific intramolecular OH hydrogen bonds to lone-pair electrons on oxygen and sulfur. The O—H...O hydrogen bonds can be adequately discussed in terms of equivalent lone pairs on oxygen. There is very little difference between the hydrogen bond energies for 2,3-dihydroxyanisole and 2,3-dimethoxyphenol. In the latter the central hydrogen bonded methoxy group lies nearly perpendicular to the ring plane. The O—H...S hydrogen bonds are best described in terms of nonequivalent, 3*s* and 3*p*, lone pairs on sulfur. It is estimated that an O—H...3*s* hydrogen bond is at least 8 kJ/mol weaker than an O—H...3*p* hydrogen bond. The former is predominant in the thiochroman derivative and the latter in the thioethylphenol, in which the thioethyl group prefers a plane perpendicular to the benzene ring. The long-range benzylic coupling constants in the thiochroman derivative indicate inversion of the saturated ring between distorted half-chair conformations. The boat conformation can be ruled out.

TED SCHAEFER, DAVID M. MCKINNON, RUDY SEBASTIAN, JAMES PEELING, GLENN H. PENNER et RICHARD P. VEREGIN. Can. J. Chem. **65**, 908 (1987).

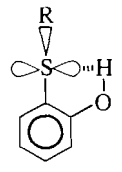
On a analysé les spectres de résonance magnétique nucléaire du ^{1}H, déterminés en solution dans le CCl_4, du thioéthyl-2 phénol, du diméthoxy-2,3 phénol et de l'hydroxy-8 chromane. On discute des déplacements chimiques des protons hydroxyles de ces composés ainsi que ceux du dihydroxy-2,3 anisole et de l'hydroxy-2 benzyl méthyl éther en fonction des liaisons hydrogènes OH intramoléculaires stéréospécifiques vers les paires d'électrons libres de l'oxygène et du soufre. On peut discuter d'une façon adéquate des liaisons hydrogènes O—H...O en fonction des paires équivalentes d'électrons libres sur l'oxygène. Il y a peu de différences entre les énergies des liaisons hydrogènes du dihydroxy-2,3 anisole et du diméthoxy-2,3 phénol. Dans ce dernier cas, le groupement méthoxyle central, qui est impliqué dans le liaison hydrogène, est pratiquement perpendiculaire au plan du cycle. La meilleur façon de décrire les liaisons hydrogènes O—H...S implique l'utilisation des paires libres non-équivalentes, 3*s* et 3*p*, du soufre. On évalue qu'une liaison hydrogène O—H...3*s* est plus faible que la liaison hydrogène O—H...3*p* et que la différence d'énergie est d'au moins 8 kJ/mol. Le premier type prédomine dans le dérivé thiochromane et le dernier type prédomine dans le thioéthylphénol, dans lequel le groupement thioéthyle se retrouve préférentiellement dans un plan perpendiculaire au plan du noyau benzénique. Les constantes de couplage benzylique à longue distance dans le dérivé thiochromane indiquent qu'il se produit une inversion du cycle saturé entre des conformations demi-chaises déformées. On peut exclure la présence de la conformation bateau.

[Traduit par la revue]

Introduction

An interesting aspect of hydrogen bonds concerns their formation along lone-pair directions (1–4). For example, intermolecular O—H...O bonds in the solid state, sampled over many such bonds, do not display a preference for the tetrahedral[2] lone-pair directions when the acceptor atom is divalent, but do prefer the plane of such lone pairs (1, 3). This observation is consistent with MO computations (5), which indicate that the proton donor molecule can move in this plane without a large loss in energy of interaction, and with experimental electron density maps of the lone-pair region of an epoxide (2). In the gas phase, F—H...O bonds display a (weak) preference for the lone-pair directions (6, 7). For N—H...O=C bonds in solids, formation along the direction of the sp^2 lone pairs is apparent (3). According to Taylor and Kennard (1), the directionality of sp^2 lone pairs may well be more marked than for sp^3 lone pairs.[3] In solution, the directionality of intermolecular X—H...Y bonds is less easily measured and has not been described.

However, *intramolecular* hydrogen bonding to a specific lone pair is known for O—H...S bonds in molecules in solution (10, 11). In benzenethiol the stable conformation is the one in which the S—H bond lies in the benzene plane and the barrier to internal rotation about the C—S bond is 3.4 kJ/mol (12), reflecting some $3p...\pi$ conjugational stabilization of the planar form. However, for 2-hydroxybenzenethiol, **1** (R = H), long-



1

range spin–spin coupling constants in CCl_4 solution demonstrate that the S—H bond prefers a plane perpendicular to

[1]University of Petroleum and Minerals, Dhahran, Saudi Arabia.

[2]Canonical molecular orbitals for divalent oxygen compounds distinguish between a mainly 2*s* lone pair and a mainly 2*p* lone pair perpendicular to the R—O—R plane. The tetrahedral localized lone pairs can be derived from the canonical orbitals by unitary transformations.

[3]Some theoretical approaches consider the deformation of the lone pair caused by formation of the hydrogen bond (8, 9).

the benzene ring (10). This result is most simply interpreted as a consequence of a stereospecific hydrogen bond to the directional $3p$ lone pair on sulfur. The barrier to rotation about the C—O bond is much larger than about the C—S bond (stronger conjugation), so that it is energetically favorable to twist the $3p$ lone pair into the benzene plane to yield the O—H...S bond (10). Such a bond also has marked conformational consequences for **1** (R = CH_3, C_6H_5, and S—C_6H_5) (11).

In the gas phase the geometry of the complexes, H_2S,HCl and H_2S,HF, can be interpreted in an entirely analogous fashion, the X—H...S direction being very nearly perpendicular to the H_2S plane (13, 14). This model is consistent with the observation that electrophiles approach sulfur atoms along the hypothesized $3p$ lone-pair directions, whereas nucleophiles do so in the plane perpendicular to this lone pair (15).

It appears, therefore, that the stereospecificity observed for O—H hydrogen bonds to oxygen can be interpreted in terms of equivalent lone pairs, while those to divalent sulfur are best discussed in terms of nonequivalent lone pairs. A reason for this distinction may lie in the relative extensions of the orbitals in oxygen and sulfur atoms. Detailed computations (16) show that the $2s$ and $2p$ valence electrons in first row atoms occupy more or less the same region of space (the $2p$ lobes do not extend much beyond the $2s$ sphere while, of course, retaining their directionality). In atoms of higher rows (sulfur) the p valence orbitals extend[4] significantly beyond the s valence orbitals. Consequently, their preferred electrostatic interactions with the X—H donor rationalize the structures discussed above for gaseous intermolecular and (solution) intramolecular hydrogen bonds to sulfur.

Returning to divalent oxygen, the actual angle between the (approximately) tetrahedral lone-pair directions may well vary from molecule to molecule. Thus, in the complex formed by oxirane and H—F, the angle between the lone pairs, as probed by the H—F direction, is 144°, instead of 109° for an sp^3 lone pair (17). In fact, the indicated angle is midway between those expected for a $2s$–$2p$ model and an sp^3 model. Furthermore, for phenol it is usual to invoke something very close to a $2s$–$2p$ model, the $2p$ orbital in the planar molecule being available for conjugation with the π system of the ring. Naturally, if the angle between the equivalent orbitals is very large (as large, say, as in oxirane), then conjugation is still substantial ($\sin^2\theta$ is then 0.9) in the planar form of phenol and is 0.1 for the perpendicular form, θ being the angle by which a lone pair twists away from the plane of the ring).

The ambiguity introduced by these considerations may have its origins in the very similar extensions of the $2s$ and $2p$ orbitals in the oxygen atom. One experimental fact, that the methyl group prefers to lie near the double bond, as in vinyl ether, or near that ring C—C bond with the larger mobile bond character, as in anisoles (18–20), is consistent with the equivalent lone-pair model if it is assumed that the two lone pairs are repelled by the π electrons in a C=C bond (proximity). However, an alternative interpretation (21, 22) has it that the lower energy arises from a structure that completes an aromatic sextet.

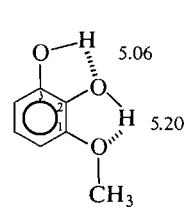
An attempt at discrimination between the two models might proceed as follows. If O—H...O intramolecular hydrogen bonds were as strongly directional as O—H...S bonds, then in 2-hydroxyphenol they would favor a conformational analogous to **2**. Of course, the rotation about the C—O bond is more strongly hindered than about a C—S bond in such compounds, so that the preferred directionality of an O—H...O bond might be masked. Alternatively, if, say, the central methoxy group in 2,3-dimethoxyphenol lay perpendicular to the benzene plane, then the hydrogen bond might be stronger than in 2,3-dihydroxyanisole because the p-type lone pair on oxygen-2 would now penetrate a region favoring its interaction with the O—H bond.

There is evidence (23, 24*a*,*b*) that the ^{1}H nmr chemical shift, δ(OH), measures the strength of an intramolecular O—H...X hydrogen bond in *ortho*-substituted phenols. The shift to high frequency on hydrogen bond formation is caused by the depletion of charge at hydrogen (25). In the measurements below, δ(OH) values for selected derivatives of phenol are examined from the viewpoint of intramolecular hydrogen bonding to specific lone pairs on oxygen and sulfur.

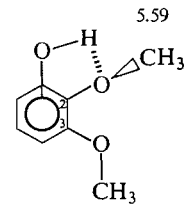
Results and discussion

Divalent oxygen

In 2,3-dihydroxyanisole, **2**, in CCl_4 solution, δ_2(OH)/ppm is 5.20 and δ_3(OH) is 5.06. This molecule has the indicated conformation at 300 K in CCl_4 solution (see Experimental) and is chosen for comparison with **3**. The latter, forming part of a



2



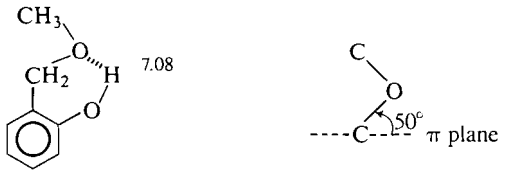
3

larger molecule in the solid state (26), displays an out-of-plane orientation of the methoxy group attached to C(2). The C(1)—C(2)—O—C(H_3) torsion angle is 107(2)°, showing a 17(2)° deviation from a plane perpendicular to the benzene plane, whereas the other methoxy group lies in the benzene plane. Such a conformation is consistent with the ^{1}H nmr spectral parameters of **3** in CCl_4 solution and δ(OH) is 5.59 ppm at 300 K. In a number of 1,2,3-trimethoxy aromatic compounds, the 2-methoxy group has a perpendicular conformation (27, 28).

The empirical relationship (23), $\Delta\delta(OH) = -0.4 \pm 0.2 + E/\text{kcal mol}^{-1}$, relates $\Delta\delta$(OH), measured relative to δ(OH) of phenol, to the strength of the intramolecular O—H...X bond in phenol derivatives.[5] Therefore the intramolecular hydrogen bond in **3** is 1.9 ± 0.8 kJ/mol stronger than in **2**. If the ether oxygen atoms in **2** and **3** are considered to possess equivalent lone pairs, then in **2** the O—H...O bond is bifurcated, the O—H bond lying in a plane bisecting the angle between the lone pairs (but recall the remarks above concerning sp^3 pairs). For the near-perpendicular orientation of the 2-methoxy substituent, one of the lone pairs is proximate to the O—H bond. In this model, the slightly stronger hydrogen bond in **3** arises from the latter situation and is consistent with the remarks in the introduction concerning weak stereospecificity for sp^3 lone

[4]The sulfur atom is much more polarizable than the oxygen atom, so that it is conceivable that the approaching O—H dipole distorts the higher-energy $3p$ orbital more than the $3s$ orbital, leading to the conformational effects discussed above.

[5]In this paper, $\Delta\delta$(OH) need only measure relative strengths within O—H...O and within O—H...S bonds. See Appendix.



4

pairs. A dihedral angle of 90° instead of the observed value of 107° would have favored the $2s$–$2p$ model.

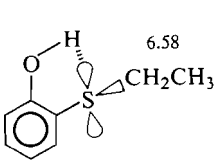
In **2** and **3**, the hydrogen bond completes a five-membered ring and the distance between the oxygen atoms is about 2.7 Å. In **4**, the known conformation (29) also has 2.7–2.8 Å for this distance, considered as a rigid conformation. However, this geometry is much more favorable to formation of a "linear" hydrogen bond. According to the δ(OH) of 7.08 ppm, the hydrogen bond is 6.2 ± 0.8 kJ/mol stronger than in **3**. Because the internal barrier to rotation about the C_{sp^2}—C_{sp^3} bond in benzyl alcohol in solution is only 1.3 ± 0.8 kJ/mol (30, 31) and is very similar in benzylmethyl ether,[6] the ether moiety can easily accommodate itself to formation of an optimum hydrogen-bonding interaction with the phenolic hydroxyl group. Examination of models in which the methyl group points away from the ring indicates that the hydrogen bond involves only one of the equivalent lone pairs (all bonds and lone pairs staggered, with the usual parallel 1:3 arrangements (22) of C—H bonds in the ether linkage). Furthermore, the empirical relationship above implies 11.7 ± 0.8 kJ/mol as the energy of the hydrogen bond (δ(OH) is 4.3 ppm for phenol). The combined molecular mechanics and nmr approach (32) agrees with this energy, as does an STO 3G MO computation (32), which, however, has θ as 33°.

One further comparison seems apt. In **4** and in salicylaldehyde the H...O distances (33–36) are deducible as 1.70–1.75 Å, but the energy of the hydrogen bond in salicylaldehyde is at least 15 kJ/mol greater (from δ(OH) and MO calculations) than in **4** (36, 37). This result is consistent with the higher stereospecificity found for hydrogen bonds to sp^2 lone pairs in the solid state (1, 3). In **2** the H...O distance is closer to 2.2 Å, helping to account for its relatively weak hydrogen bond.

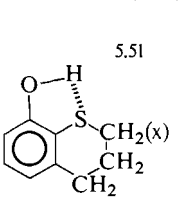
In summary, the chemical shifts of the hydroxyl protons in **2**–**5** are consistent with the hypothesis of weak stereospecificity of intramolecular O—H...O bonds to ether oxygen atoms relative to those involving carbonyl groups, entirely analogous to observations on intermolecular O—H...O bonds in the solid.

O—H...S bonds for divalent sulfur

As noted above, the model involving nonequivalent lone pairs on divalent sulfur, the $3p$ orbital being more extended than the $3s$ orbital, provides an easy rationalization of the conformation of **1** and of the geometry of intermolecularly hydrogen bonded complexes of H_2S. In **5**, chosen to mimic the electronic environment of the sulfur atom in **6**, δ(OH) is 6.58.



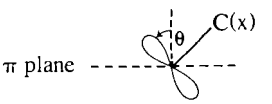
5



6

[6]Unpublished work in this laboratory.

In **6** the $3p$ orbital on sulfur is probably not strictly perpendicular to the aromatic plane. The ^{1}H nmr spectrum (see Experimental) suggests an inverting saturated ring on the nmr time scale, which does not mean, of course, that the $3p$ orbital is necessarily perpendicular on average. In an analogous oxygen compound, θ (see **7**) is perhaps as large as 20° (38). Accordingly, the



7

O—H...S bond in **6** will not be pure O—H...$3s$ in nature. In **6**, δ(OH) is 5.49, certainly implying a weaker hydrogen bond than in **5**. In the latter, formation of the hydrogen bond twists the C_{sp^2}—S bond into a plane perpendicular to the benzene plane. δ(OH) does not measure the energy of twisting (loss of $3p...\pi$ conjugation), which may be estimated as at least 4 kJ/mol (see Experimental), the barrier to internal rotation in phenyl methyl sulfide being over 5 kJ/mol (39). The empirical relationship above yields 4.6 ± 0.8 kJ/mol as the difference in the hydrogen bond strengths between **5** and **6**. Addition of 4 kJ/mol, and remembering that θ is not zero in **6**, **7**, suggests a *minimum* of 8 kJ/mol as the difference in energy between O—H...$3p$ and O—H...$3s$ hydrogen bonds for divalent sulfur[7] in which they complete a five-membered ring. In summary, intramolecular hydrogen bonding to sulfur, as well as the intermolecular geometries previously mentioned, are best discussed in terms of a $3s...3p$ model, unlike the bonds to oxygen, where equivalent lone pairs appear adequate as a model.

STO 3G MO computations

STO 3G MO calculations on planar and perpendicular (**1**) conformations of the thiomethyl group in 2-hydroxythioanisole, allowing all bond angles and lengths to vary but constraining the benzene ring to be planar, gave the perpendicular form as 8.4 kJ/mol lower in energy. For thioanisole itself such computations agree with experiment about the energy difference between the stable planar and the perpendicular conformations (39). The present result happens to agree with the difference in the O—H...$3s$ and O—H...$3p$ hydrogen bond energies estimated on the basis of δ(OH) in **5** and **6** above. Another calculation kept the perpendicular conformation of the thiomethyl group but turned the hydroxyl group away from the former. This conformation was 9.2 kJ/mol higher in energy than the hydrogen bonded form.

For 2-hydroxyanisole, the planar hydrogen bonded conformer is computed as 8.6 kJ/mol more stable than the perpendicular conformer. Unfortunately the internal barrier to rotation about the C_{sp^2}—O bond in anisole itself is uncertain (41*a*).

Experimental

Compounds

Both 2,3-dihydroxyanisole, **2**, and 2,3-dimethoxyphenol, **3**, came from Aldrich, while 2-(ethylthio)phenol, **5**, was a gift from Ethyl Corporation (41*b*). The 8-hydroxythiochroman, **6**, was made by the following procedure. Cyclization of 3-(2-nitrophenylthio)propanoic acid, prepared from 2-nitrophenylthiocyanate, gave 8-nitrothiochroman-4-one by cyclization in polyphosphoric acid, which was the most effective of many reagents tried. The nitroketone was converted directly under Clemmensen-type conditions to 8-aminothiochroman,

[7]The δ(OH) values suggest that O—H...S bonds are stronger than O—H...O bonds for divalent atoms, as is also deduced from Schroeder–Lippincott potential functions (40).

both carbonyl and nitro functions being reduced. The amine was converted to the phenol by diazotization. Yields were low (14%), probably because of reaction of the diazonium group with the sulfide function. The phenol is a colorless oil and gave a satisfactory ^{1}H nmr spectrum.

Nuclear magnetic resonance samples and spectra

All ^{1}H nmr spectra were measured in CCl_4 as a solvent. Compound **2** was prepared as a 0.9 mol% solution, containing some tetramethylsilane (TMS) to provide an internal lock on an HA100 nmr spectrometer. Compound **4** was measured as a 0.5 v% solution in CCl_4, containing some C_6D_{12} as an internal lock material for a WH90 nmr spectrometer (29). The concentrations of **3**, **5**, and **6** are given in the tables below. All solutions were transferred to 5 mm od nmr sample tubes, were degassed by several freeze–pump–thaw cycles, and were then flame-sealed.

For **2**, the ^{1}H nmr spectrum was calibrated at 100 MHz by continuous wave techniques at a probe temperature of 305 K by a procedure described in detail previously (42). The ^{1}H nmr spectra of **3**, **5**, and **6** were accumulated at 300 K on an AM300 nmr spectrometer. Wide sweepwidth survey spectra were obtained in order to reference the spectra with respect to TMS. Each spectral region was then examined in detail, with sweepwidth and data region adjusted to give acquisition times of about 40 s. As many as 16 scans were acquired. Before transforming the FIDs, using a small amount of gaussian multiplication, zero-filling to twice the original data region was done. Peak widths at half-height were typically well below 0.1 Hz. Figure 1 gives the ^{1}H nmr spectrum of the 3-methoxy protons in **3**. The smaller splitting is 0.09 Hz in magnitude.

Spectral analyses

The programs PANIC, provided as part of the software on the AM300, and NUMARIT (43) were used in the analyses of the ^{1}H nmr spectra. That for **2** was not highly precise and the spectral parameters are therefore not recorded here. The hydroxyl proton chemical shifts are given above in the structural formula for **2**. The chemical shift assignments followed from the characteristic through-space coupling constant (44) of −0.25(2) Hz between the methyl protons and the proton placed *ortho* to the methoxy group, having this magnitude for a preferred orientation of the latter as indicated in **2**. The assignment of the other two ring protons was then straightforward and that of the two hydroxyl protons followed from their stereospecific couplings over five bonds (45, 46) to these two ring protons for the conformation depicted in **2**. An alternative conformation, in which the central hydroxyl proton is hydrogen bonded to its neighbouring hydroxyl group, was excluded because no coupling was observable from it to the proton *ortho* to the methoxy group. Confirmation of this conclusion was found in the typical (47) aromatic-solvent-induced-shifts (ASIS) found at sites near a methoxy substituent (0.5 mol% in C_6D_6).

Tables 1, 2, and 3 contain the ^{1}H nmr spectral parameters for **3**, **5**, and **6**. Those for **4** are available elsewhere (29). The assignments for **3** in Table 1 followed from the characteristic coupling constants for the 3-methoxy (44) and the hydroxyl protons (45), the stereospecificities of which imply the conformation displayed in **3**. Again, the spectral data for 2-(thioethyl)phenol in Table 2 leave little doubt that the conformation is that shown in structure **5**. Thus, the virtual absence of through-space coupling between the methylene protons and the ring proton placed *ortho* to the ethyl group is consistent (11, 48) with a perpendicular conformer. The ring proton chemical shifts of **5** and of 2-hydroxythioanisole, **1** (R = CH_3), differ by only 0.02 ppm on average (11), as expected if their conformations are analogous (11, 49). See ref. 11 for a detailed approach to the proof that the thioanisole derivative has conformation **1**. It may also be noted that the mean difference of the coupling constants in **5** and **1** (R = CH_3) is less than 0.008 Hz, certainly consistent with similar conformations for the two molecules.

Turning to 8-hydroxythiochroman, **6**, the spectral parameters in Table 3 show that the peaks arising from the methylene protons were not fully analyzed. Two methylene groups gave rise to bands interpretable as roughly 1:2:1 triplets, each of whose components consisted of many peaks. The triplet components were spaced by approximately 6.5 Hz, arising from fluxionally averaged vicinal proton–proton coupling constants. The shift assignments followed from the known long-range coupling constants of benzylic (50) and thioanisole (51) protons. Unfortunately, the intermolecular exchange of the hydroxyl proton was too fast (an acidic or basic impurity was presumably present, but the amount of **6** was too small to encourage further purification procedures) to observe the characteristic coupling constant to H-6 over five bonds. However, the chemical shift of 5.49 ppm is characteristic of a hydrogen bond and is treated as such above.

The long-range coupling constants between the benzylic and aromatic protons allow a decision as to the conformation of the saturated part of the molecule. As noted above, the coarse features of

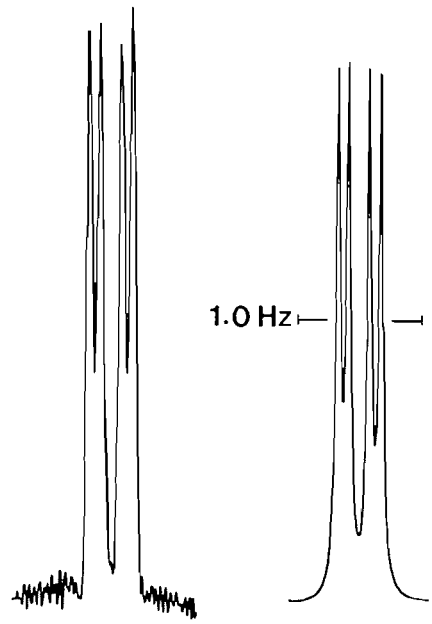

FIG. 1. The experimental and computed ^{1}H nmr spectra of the 3-methoxy protons for 1.6 mol% solution of 2,3-dimethoxyphenol in CCl_4 at 300 K and 300.135 MHz. They illustrate a linewidth of 0.04 Hz, a coupling to H-4 of 0.267(1) Hz, and one of 0.091(1) Hz to H-5. These coupling magnitudes show that the 3-methoxy group is lying in the benzene plane (19). The ^{1}H nmr spectrum of the 2-methoxy group is a singlet with a linewidth of 0.04 Hz.

TABLE 1. The ^{1}H nmr spectral parameters for 2,3-dimethoxyphenol, **3**, as a 1.6 mol% solution in CCl_4/C_6D_{12}/TMS[a] at 300 K and 300.135 MHz

[c]Standard deviations in the last significant figure are given in parentheses.
[d]For the aromatic protons.

the ^{1}H nmr spectra of the methylene protons indicate a conformational averaging process at 300 K. From models it may be concluded that the saturated ring is inverting between pure boat, distorted half-chair, or undistorted half-chair forms. Now assume that the barrier to inversion is rather larger than kT, as seems reasonable (52), so that the benzylic coupling constants can be discussed in terms of a two-site model. Define ϕ as the angle by which the benzylic C—H bond twists out of the aromatic plane. In toluene, eqs. [1]–[3] describe (50, 53) the

$$[1]\quad {}^6J/\text{Hz} = -1.20\langle\sin^2\phi\rangle$$

$$[2]\quad {}^5J/\text{Hz} = 0.336\langle\sin^2\phi\rangle + 0.322\langle\sin^2(\phi/2)\rangle$$

$$[3]\quad {}^4J/\text{Hz} = -1.08\langle\sin^2\phi\rangle - 0.32\langle\cos^2\phi\rangle$$

ϕ dependence of $^{4,5,6}J(H,CH_3)$, in which angular brackets indicate average values.

^6J is discussed first. From Dreiding models it appears that ϕ is very near 15° and 75° for the two benzylic C—H bonds in the distorted half-chair form. Then $\langle\sin^2\phi\rangle$ is very near 0.5. Accordingly, ^6J is calculated as −0.60 Hz from eq. [1], rather close to the observed value of −0.594(1) Hz. For an undistorted half-chair form, ϕ values are 30° and 90°, yielding $\langle\sin^2\phi\rangle$ as 0.625, implying ^6J as −0.75 Hz. Finally, in a pure boat form, the ϕ values are 5° and 65° or perhaps 0° and 60°, with the consequence that $\langle\sin^2\phi\rangle$ is 0.414 or 0.375; hence ^6J should lie between −0.45 and −0.50 Hz. The choice among the three forms seems clear.

Turning to ^5J, it must be noted that ϕ is defined as 0° when the C—H bond of the sidechain and the *meta* C—H bond in the ring point towards the same side of the ring and as 180° when the bonds point away from each other (50). For the distorted half-chair conformation, ϕ becomes 15° and 105°. Hence $\langle\sin^2(\phi/2)\rangle$ is 0.323 and eq. [2] yields ^5J as 0.27 Hz. The observed value is 0.285(1) Hz. The pure boat and undistorted half-chair conformations imply ^5J as <0.25 Hz and 0.30 Hz, respectively. The choice of the correct conformation is less unequivocal here but the distorted half-chair, given by ^6J, is at least as compatible with ^5J as the undistorted form. It might be noted that eq. [1] is better established (50) than eq. [2].

Finally, eq. [3] is probably the least reliable as a conformational indicator for **6**. The coefficient of $\langle\sin^2\phi\rangle$ depends on the mutual atom–atom polarizability (53) and in **6** will surely differ from its value in toluene. Although eq. [3] reproduces ^4J in toluene exactly (5), it is clear that ^4J in a variety of *ortho* substituted toluene derivatives is generally about 10% higher in magnitude (54–56) than would be expected from eq. [3]. Yet it is unclear how such an increase should be divided between the two terms in eq. [3]. Furthermore, a resonance structure that contributes to marked double-bond character of the intervening aromatic C—C bond can cause a dramatic increase in the magnitude of ^4J. Thus, in 2-nitro-4-methylphenol, ^4J(H-3,CH_3) is −1.00 Hz (53) and is attributed to the importance of structure **8**, while ^4J(H-5,CH_3) is −0.62 Hz. A similar structure for **6** involving a hydrogen bond to sulfur can also be conceived, but it is impossible to deduce a priori how much it would contribute to an increase in the magnitude of ^4J. However, if the distorted half-chair is taken as the

8

correct conformation of **6**, so strongly indicated by ^6J (whose value in toluene derivatives is remarkably insensitive to substituents), then the coefficient of $\langle \sin^2 \phi \rangle$ in eq. [3] becomes -1.40 Hz. This result assumes that the coefficient of $\langle \sin^2 \phi \rangle$, the σ-electron contribution, is unchanged from its value in toluene. A similar approach to **8** yields the coefficient of $\langle \sin^2 \phi \rangle$ as -1.7 Hz, the larger magnitude being expected for this rather more strongly hydrogen-bonded molecule. These considerations then imply a ^4J of -1.0 Hz for an undistorted half-chair, and -0.62 Hz for a pure boat conformation of **6**. The latter can be discarded on the basis of all three coupling constants. On the basis of our extensive experience with such long-range coupling constants, it seems clear that **6** exists as rapidly inverting, distorted half-chair conformations at 300 K in CCl_4 solution. These conformations agree with structure **7** and are similar to the solid state structure of the analogous compound containing oxygen in place of sulfur.

In view of the long-range coupling constants of the methyl protons in thioanisole (51), those involving the corresponding methylene protons in **6** and given in Table 3 will contribute to the eventual elucidation of the coupling mechanisms for these poorly understood parameters.

Appendix

A referee suggests that the empirical relationship between the energy of the hydrogen bonds and the chemical shift is rather tenuous and that therefore the quoted energies should be expressed more tentatively. While we cannot state the real accuracy of the derived energies, we believe that the order of the energies is reliable and that it is consistent with the arguments presented. In this connection it is interesting that a recent (60) study demonstrates a linear dependence of $\Delta\delta$(OH) on the computed charges for the atoms in the hydroxyl groups of a large variety of phenol derivatives. There also appears to be a direct proportionality between δ(OH) and the stretching frequency of the O—H bond, the latter being linearly related to the computed O—H bond length (60). It is also interesting that a linear relationship (61) exists between the (isotropic) chemical shift of the hydroxyl proton and the H...O distance in the O—H...O bond in crystals containing a large variety of such bonds. It is therefore noteworthy that the Badger and Bauer rule (62), relating the enthalpy of formation of intermolecular hydrogen bonds to the infrared frequency shifts, holds well for *closely related* compounds (63).

Speciation of soluble manganese in lakewater with Chelex-100 and polyacrylate resin, XAD-7

ALFIO CORSINI, GWEN WADE, CHI-CHUNG WAN, AND SHAREEN PRASAD
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 30, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

ALFIO CORSINI, GWEN WADE, CHI-CHUNG WAN, and SHAREEN PRASAD. Can. J. Chem. **65**, 915 (1987).

Two fractions of (soluble) manganese in Lake Ontario water have been detected and measured with the aid of sequential preconcentration on the polyacrylic ester resin, XAD-7, and Chelex-100. One fraction, consisting of free Mn(II), was retained on the XAD-7 column; the second fraction, consisting of one or more unidentified forms, was retained on Chelex-100. After elution from the columns, the concentration of manganese in each fraction in the lakewater was determined by graphite-furnace AAS. Because both fractions are retained by Chelex-100, the second fraction could also be determined by difference on passage of two separate aliquots through Chelex-100 and XAD-7. Analysis of samples from three locations in the western basin of Lake Ontario showed that about 12–22% of total (soluble) manganese was present as free Mn(II).

ALFIO CORSINI, GWEN WADE, CHI-CHUNG WAN et SHAREEN PRASAD. Can. J. Chem. **65**, 915 (1987).

Faisant appel à la préconcentration en série sur de la résine polyacrylique XAD-7 et sur du Chelex-100, on a détecté et mesuré deux fractions de manganèse (soluble) dans l'eau du lac Ontario. Une fraction, comportant le Mn(II) à l'état libre, est retenue sur la colonne de XAD-7; la deuxième fraction, contenant une ou plusieurs formes qui n'ont pas été identifiées, est retenue par le Chelex-100. Après l'élution des colonnes, la concentration du manganèse, dans chacune des fractions d'eau du lac, a été déterminée par spectroscopie AA dans une fournaise de graphite. Les deux fractions étant retenues par le Chelex-100, on peut aussi déterminer la deuxième fraction par différence, lors du passage de deux aliquots séparés à travers des colonnes de Chelex-100 et de XAD-7. Des analyses effectuées sur des échantillons provenant de trois endroits différents dans le bassin ouest du lac Ontario démontrent que de 12 à 22% du manganèse soluble total est présent sous la forme de Mn(II).

[Traduit par la revue]

Introduction

Because the bioavailability and toxicity of trace metals in natural waters is strongly dependent on chemical form, speciation of trace metals has become an area of increasing significance. Manganese is an essential trace element for plant and animal life and its distribution in natural waters has received considerable attention (1–5). It is found in soluble and suspended particulate forms and in sediments. The fraction that passes through a 0.45 μm filter is operationally considered as "soluble" manganese and that retained on the filter as particulate manganese (2). In ocean and fresh waters, manganese is found as free and bound Mn(II) and as Mn(IV) dioxide. In oxic waters Mn(II) is readily oxidized, particularly above pH 6, to colloidal MnO_2 so that much of the manganese is in the particulate phase. MnO_2 is also produced by the catalytic action of oxidizing bacteria (6); colloidal forms of Mn(III) may also exist. In anoxic waters the proportion of soluble manganese as Mn(II) is increased (4). In seawater, small amounts of Mn(II) chloride complexes may exist and in fresh water, Mn(II) maybe present as sulfate and organic complexes and may also remain adsorbed onto colloidal iron and manganese oxides. Computational methods suggest that in both seawater and fresh waters, the predominant form of soluble Mn(II) is the free hydrated ion (7) although the action of bacteria and algae on Mn(II) were not taken into account in these studies.

In an earlier report (8), a procedure involving two columns of the polymethylmethacrylate resin, XAD-7, was described for the preconcentration of trace metals in natural waters. In this procedure, the sample was acidified to pH 1–2 and passed through the first column to remove organic complexing species such as humic substances. The effluent was then adjusted to pH 8 and passed through the second (analytical) column to concentrate the trace metals. These were subsequently eluted with a small volume of dilute HNO_3 and determined by graphite-furnace AAS. Two methods of calibration were used, external standard-curve and standard additions calibration. It was noted in this work that samples of Lake Ontario water contained at least two forms of (soluble) manganese. This conclusion was indicated by the fact that the two-column procedure utilizing standard-curve calibration returned a much lower value for total soluble manganese than the two-column procedure utilizing standard additions. Although breakthrough of manganese from the analytical column occurred in both procedures, rapid equilibration of the low-level Mn(II) spikes in the standard additions procedure negated the effect on recovered manganese. Indeed, the result for total soluble manganese by this procedure was in good agreement with results obtained by two independent methods; i.e., direct injection of the sample into the furnace, and preconcentration on Chelex-100, prior to measurement. Identification of the species was not made. In the present report, more detailed evidence is presented to show that the combination of XAD-7 and Chelex-100 columns can differentiate soluble fractions of manganese in natural waters. For Lake Ontario samples tested, one fraction was retained by both XAD-7 and Chelex-100 and was identified as free Mn(II). A second fraction, consisting of one or perhaps more forms of soluble manganese, was retained by only Chelex-100; it was polarographically inactive and was not identified.

Experimental

Reagents and solutions

Distilled-deionized water (DDW) was used throughout. All other common reagents were reagent grade or better (e.g., Baker Instra-analyzed HNO_3 and NH_3). Mn(II) stock solutions (5 μg/L to 1 mg/L) were prepared by appropriate dilution of 1000-mg/L standard solutions (Fisher Scientific). A solution of Mn(III) (~30 μg/L) was prepared by dissolving 150 μg of Mn(III) acetate in 1 L of DDW at pH 8. A solution of colloidal MnO_2 was made by shaking a mixture of precipitated MnO_2 and DDW at pH 8, filtering to remove the excess solid,

For personal use only.

and passing the filtrate through a 0.45 μm membrane filter. NH_4Cl solutions were purified before use by passage through a Chelex-100 column to remove any trace amounts of manganese present.

The Lake Ontario samples (from Stations 3, 14, and 302, western basin) were supplied by Canada Centre for Inland Waters (CCIW), Burlington, Ontario. Aliquots were centrifuged to remove visible suspended particles and also filtered through 0.45 μm membrane filters prior to use. Portions of these aliquots were acidified to pH 1.7 to preserve the integrity of the trace metal content on storage.

Apparatus

All glass and polypropylene laboratory ware was cleaned as described previously (8). Atomic absorption measurements were made with a Perkin-Elmer Model 373 instrument equipped with a HGA-2200 graphite furnace. The wavelength (279.5 nm), slit width (0.2 nm), and lamp current (20 mA) were those recommended in the application manual. The drying temperature was 100°C for 20 s, charring temperature 1000°C for 20 s, and atomization temperature 2600°C for 7 s. During atomization, the Ar gas "interrupt mode" was used because of the very low concentrations involved. Sample volumes (20 μL) were manually injected with an Eppendorf micropipette. Concentrations of Mn in the samples were obtained from standard external calibration curves and by standard additions.

Ultraviolet irradiation to destroy organic material in the lakewater samples was carried out with a Rayonet Photochemical Reactor equipped with a 0.5 kW Hg lamp. Sample aliquots (100 mL in quartz cells) were exposed to intense 254 nm radiation for 8 h.

Differential pulse polarograms were obtained with a Metrohm Model E506 Polarecord instrument equipped with an E505 polarography stand which included the dropping-mercury and AgCl/Ag reference electrodes. The differential pulse mode (50 mV pulse), was used. Other settings were drop time, 1.2 s; sensitivity 2.5×10^{-10} A/mm.

Millipore membrane filters (MF) with pore sizes 0.45, 0.22, and 0.025 μm were used for filtration of samples. Filtration of a 100-mL aliquot through the 0.025 μm filter required about 20 h, under vacuum.

Column preparation

XAD-7, supplied as 20–50 mesh (Rohm and Haas), was ground and sieved to 80–100 mesh. The resin was cleaned and borosilicate columns (1 × 20 cm, Bio-Rad) were packed to a 3-cm height (0.5 g resin) and conditioned exactly as described by Wan *et al.* (8). Retained Mn(II) was eluted with 5 mL of 1% v/v HNO_3. After elution, the column was rinsed with dilute ammonia and DDW for future use. Chelex-100 resin (Rohm and Haas) was slurry-packed in borosilicate columns (1 × 4 cm bed height, 200–400 mesh, 0.5 g resin). The columns were conditioned with 50 mL of pH 8.0 buffer prior to percolation of samples or test solutions and were eluted with 25 mL of 14% v/v HNO_3.

Mn concentration

The total soluble manganese content of the Station 3, 14, and 302 samples was determined by several different methods: by direct injection of the sample (without preconcentration) into the graphite furnace; by preconcentration on a Chelex-100 column using external calibration; and by the two-column XAD-7 preconcentration method using both external and standard additions calibration. These methods have been used previously (8).

Breakthrough curves

Separate aliquots (100 mL) of lakewater samples were percolated through the XAD-7 and Chelex-100 columns at a flow rate of 1 mL/min. After passage of these samples, a 100-mL aliquot of a Mn(II) test solution (100 μg/L) was percolated through each column. The solutions and columns were at pH 8.0. A 0.5-mL increment of the effluent was taken at regular intervals and analyzed by GFAAS, to give data for construction of breakthrough curves. A breakthrough curve was also obtained for an aliquot of Station 3 lakewater which had been irradiated in the Rayonet apparatus. The sample was percolated sequentially through the XAD-7 and Chelex-100 columns.

DP polarography

Solutions were adjusted to pH 8.0 with dilute ammonia. They were made 0.01 *M* in NH_4Cl (supporting electrolyte) and Triton X-100 (10 drops/100 mL of solution) was added. Dissolved oxygen was removed by displacement with nitrogen and a nitrogen atmosphere was maintained during measurement. Solutions measured were as follows: test solutions of Mn(II) up to 150 μg/L; a solution of colloidal MnO_2 and a solution containing about 150 μg/L of Mn(III) acetate; test solutions containing soil humic acid and Mn(II); lakewater samples, some spiked with Mn(II) up to 100 μg/L; and the effluents of spiked lakewater samples that had been passed through the XAD-7 and Chelex-100 columns.

Filtration

Aliquots (100 mL) of Station 3 water (pH 7.9) were centrifuged to remove visible particulate matter and then filtered under vacuum through 0.45, 0.22, and 0.025 μm membrane filters. Afterwards, the 0.22 and 0.025 μm filters were soaked in 5 mL of 1% HNO_3 to dissolve any trapped manganese-bearing species (other than MnO_2, which is insoluble in 1% HNO_3) and the manganese was determined by GFAAS. Corresponding blank solutions were prepared by soaking unused filters in the same manner. The manganese in the blanks was <0.1 μg/L. The manganese content in the filtrate from the 0.025 μm filtration was also measured, after preconcentration at pH 8 on a XAD-7 column.

Results and discussion

For the preconcentration of trace metal ions, XAD-7 functions as a weak-acid ion-exchange resin of low capacity, about 30 μmol/g of 80–100 mesh dry resin (8). This capacity is more than adequate for the concentration of trace metals found in most natural waters.

The total soluble concentration of manganese in water from three locations in Lake Ontario was determined by three methods and is given in columns 2, 3, and 4 of Table 1. In the two-column XAD-7 procedure by both calibration methods, early breakthrough of manganese occurred through the analytical column (pH 8.0) when applied to the Station 14 and 302 samples; however, only the results by the calibration curve method are significantly low in comparison to those by the direct and Chelex-100 procedures. A typical breakthrough curve for the analytical column and Station 14 sample is shown in Fig. 1. To prove that the breakthrough was not due to insufficient capacity of the XAD-7 column, 100 mL of a standard solution containing 10 μg/L of Mn(II) (about eight times the total manganese concentration in the Station 14 lakewater) was percolated through the XAD-7 column after passage of 100 mL of lakewater. No breakthrough was observed. Therefore, the capacity was sufficient and the breakthrough species was not free Mn(II). Furthermore, when either a separate Station 14 sample or the effluent from the analytical XAD-7 column or the standard Mn(II) solution was passed through the Chelex-100 column, there was no breakthrough of manganese species (Fig. 1). This experiment demonstrates conclusively that soluble manganese in lakewater can be (operationally) speciated into two fractions, one which is retained by both XAD-7 and Chelex-100, and one which is retained by Chelex-100 but not XAD-7. Furthermore, it is reasonable to conclude that neither form involves colloidal MnO_2 in significant amounts. This conclusion is based on the following observations: (*a*) colloidal MnO_2 is inactive to Chelex-100, and (*b*) the results in Table 1 show that the soluble manganese content determined by the Chelex-100 method is only slightly lower than (or, in view of experimental error, arguably about the same as) the content yielded by direct GFAA measurement without column inter-

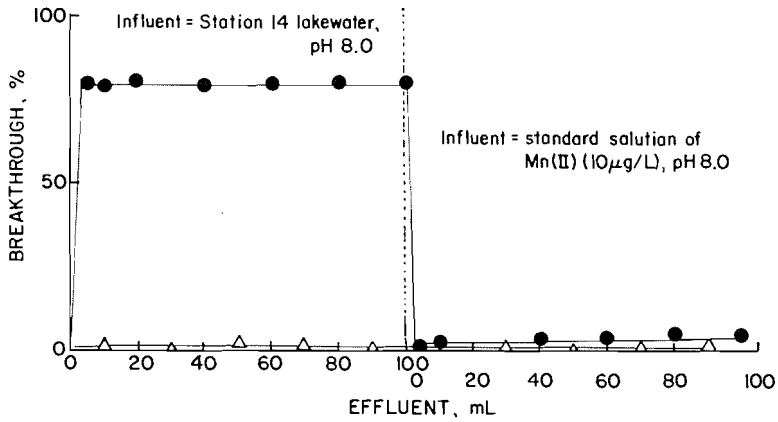

FIG. 1. Breakthrough curves for Mn in Lake Ontario water on a 1 × 3-cm XAD-7 analytical column (0.5 g, 80–100 mesh) (●), and a 1 × 4-cm Chelex-100 column (0.5 g, 200–400 mesh) (△). Flow rate = 1 mL/min.

TABLE 1. Soluble Mn in Lake Ontario waters, western basin[a]

Location	Direct analysis (μg/L)	Chelex-100 calib. curve (μg/L)	XAD-7 stand. add (μg/L)	Two-Column calib. curve (μg/L)
Station 3	0.50 ± 0.08	0.50 ± 0.05	Not done	0.11 ± 0.01[b]
Station 14	1.26 ± 0.14	1.13 ± 0.03	1.07 ± 0.02	0.15 ± 0.03
Station 302[c]	0.89 ± 0.08	0.72 ± 0.04	0.80 ± 0.02	0.12 ± 0.01

[a]Results are at least in duplicate; precision measure is one standard deviaton; all samples were previously filtered through 0.45 μm filters.
[b]Station 3 sample at natural pH (7.9) passed through one XAD-7 column only.
[c]Data from ref. 8.

cession. If MnO_2 is present in the samples, the bulk of it must have been removed by the 0.45 μm filter so that little or none is present in soluble form.

The two-column procedure requires acidification of the sample to about pH 1.7 and passage through a precolumn of XAD-7 to remove potentially complexing organic ligands such as humic substances (8). When the breakthrough experiments were repeated with unacidified samples passed through only the XAD-7 analytical column, the observations were essentially the same as for acidified samples (Station 3 sample, Table 1). In summary, 12–22% of total (soluble) manganese is retained on the XAD-7 column. This species is likely free Mn(II). It is a common form of manganese in lakewater; also, XAD-7 has been shown to retain free Mn(II) in standard solutions at pH 8, but not Mn(II) complexed to organic ligands such as humic material or colloidal forms of manganese (8).

Differential pulse polarography provided further evidence that the species retained by XAD-7 is free Mn(II). In Fig. 2, curves (*a*) and (*b*) represent, respectively, Station 3 water adjusted to pH 8.0 and the same sample spiked to 100 μg/L with Mn(II). In curve (*b*), the peak at −1.44 V is at the same potential as that for a standard solution of Mn(II) in DDW at pH 8.0 and, significantly, is only about 20% in height. About 80% of the spike has been converted to a polarographically non-labile form or forms. This conversion, of course, is why the standard addition two-column XAD-7 method returns a quantitative result for total soluble manganese. In curve (*a*), the natural concentration of Mn(II) (~0.1 μg/L) is simply too low for observation.

After passage of the spiked sample through the analytical

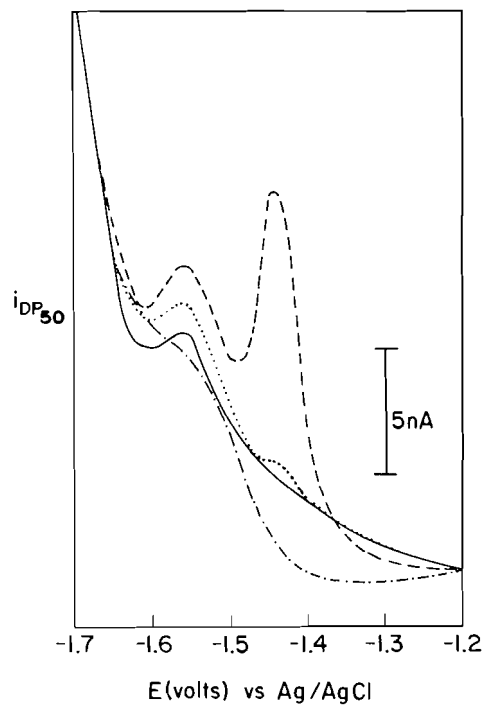

FIG. 2. Differential pulse polarograms of (*a*) Station 3 lakewater (—); (*b*) Station 3 sample spiked to 100 ppb with Mn(II) (---); (*c*) Sample in (*b*) after passage through XAD-7 column (····); (*d*) effluent from XAD-7 column in (*c*) passed through Chelex-100 column (-·-·-). Pulse = 50 mV; sensitivity = 2.5 × 10^{10} A/mm; droptime = 1.2 s; pH = 8.0, T = 21 ± 2°C.

For personal use only.

XAD-7 column, only a residual peak at −1.44 V was observed (curve (*c*)), which was completely eliminated when the XAD-7 effluent was passed through Chelex-100 for the primary purpose of removing the second species (curve (*d*)). The peak at −1.56 V in curves (*a*), (*b*), (*c*) was diminished to a broad shoulder after passage of the XAD-7 effluent through Chelex-100. It is tempting to attribute the removed peak to the second species; however, this attribution cannot be made since the 80% conversion of the 100 ppm Mn(II) spike should have resulted in a far more intense peak at −1.56 V in curves (*b*) and (*c*) than in curve (*a*), for which the peak height would represent 0.4 μg/L of the second species. No firm polarographic evidence was found over the potential range −0.2 to −1.7 V for the manganese species inert to XAD-7. Of interest, the peak at −1.56 V was not observed in the solutions of humic acid, colloidal MnO_2 or Mn(III) acetate, although the last solution did yield a small Mn(II) peak at −1.44 V due to disproportionation of Mn(III) to Mn(II) and Mn(IV). The peak at −1.56 V remains unidentified.

The possibility that the unidentified manganese fraction consists of organic complexes of Mn(II) was considered. Organic complexes of trace metals break through the XAD-7 column (8). This possibility is not likely here, however, because the first column in the two-column procedure removes the bulk of organic substances. Also, Fe(III) and Cu(II) form more stable complexes but these ions did not break through the analytical XAD-7 column in the two-column procedure (see last column, Table III, ref. 8). Moreover, after intense uv irradiation of a separate sample to destroy organic matter, the breakthrough of manganese on XAD-7 and Chelex-100 was essentially as shown in Fig. 1. Another possibility is that the second fraction is colloidal Mn(III) produced by oxidation of Mn(II) at the surface of algae cells; however, in view of the rapid equilibration of Mn(II) spikes in the lakewater samples, this seems unlikely. More likely, the fraction consists of Mn(II) adsorbed on colloidal particles of iron oxides which, in view of the high concentration of iron in the western basin (8), would most certainly be present. Knox and Turner have made a similar suggestion regarding colloidally-bound manganese for an estuary water (9). Such colloidally-associated manganese was found to be polarographically inactive. Some evidence for colloidally-bound manganese was obtained by filtration of 100-mL aliquots of Station 3 water through a 0.025 μm membrane filter. Substantial amounts of manganese were retained on the filter, corresponding to 0.7 μg/L, but the precision on three replicates was inexplicably poor (±0.5 μg/L). Dissolution of the entrapped manganese species by 1% HNO_3 converted it to free Mn(II) and so it was inappropriate to test the activity of the species towards Chelex-100 and XAD-7. Presumably, if the species is colloidally-bound Mn(II), it would be kinetically labile to Chelex-100 but not to the low-capacity XAD-7 column. The concentration of manganese in the filtrate was 0.21 ± 0.02 μg/L, corresponding reasonably well, considering the low levels, to the concentration trapped on the XAD-7 column (0.11 μg/L, Table 1). This species is active to both XAD-7 and Chelex-100 and is therefore indicated as Mn(II). No significant amount of manganese was recovered from the 0.22 μm filter.

In summary, the combined use of XAD-7 and Chelex-100 columns for preconcentration provides a useful approach for the detection and quantitative estimation of free Mn(II) and a second fraction of soluble manganese species in lakewater. The manganese in this fraction may be colloidally adsorbed Mn(II).

Versatile thin layer spectroelectrochemical cell employing specular reflectance

A. Scott Hinman and Brad J. Pavelich
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received June 26, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

A. Scott Hinman and Brad J. Pavelich. Can. J. Chem. **65**, 919 (1987).

A versatile thin layer spectroelectrochemical cell employing specular reflection of the incident light beam from the electrode surface is described. Its application to in-situ uv–vis and FTIR characterization of the products of electrochemical reactions and to thin layer voltammetry and coulometry as well as conventional cyclic voltammetry is demonstrated for the oxidation of tetraphenylporphinatozinc in dichloroethane/tetrabutylammonium perchlorate solution. The advantages and disadvantages of this type of cell as compared to more conventional sandwich type optically transparent thin layer electrodes are discussed.

A. Scott Hinman et Brad J. Pavelich. Can. J. Chem. **65**, 919 (1987).

On décrit une cellule spectroélectrochimique en couche mince qui est versatile et qui utilise la réflexion spéculaire d'un faisceau de lumière incidente provenant de la surface de l'électrode. Utilisant l'oxydation du tétraphénylporphinatozinc dans une solution de dichloroéthane/perchlorate de tétrabutylammonium, on a démontré l'application de cette cellule à la caractérisation par uv–vis et FTIR in-situ des produits des réactions électrochimiques, à la voltamétrie et à la coulométrie en couche mince ainsi qu'à la voltamétrie cyclique conventionnelle. On compare les avantages et les désavantages de ce type de cellule avec ceux des électrodes en couches minces plus conventionnelles, de type sandwiches et optiquement transparentes.
[Traduit par la revue]

Introduction

Recent literature shows a continuing interest in the design of thin layer electrochemical cells, especially those applicable to simultaneous spectrophotometric measurements (1–10). Particular emphasis has been placed on minimizing the resistance-induced potential distribution in the thin layer cavity, and on increasing the effective pathlength to improve spectral sensitivity. While the applicability of specular reflectance to thin layer spectroelectrochemical studies was reported as early as 1970 (11), the great majority of cells used for this purpose employ optically transparent electrodes, most often a gold minigrid, in a sandwich configuration of the general type described by DeAngelis and Heineman (12). Thin layer cells adapted for simultaneous specular reflectance measurements have more recently received attention as a result of their use for determining the infrared spectra of molecules within the thin layer cavity (13). Such cells can also be used in uv–visible studies and promise several advantages in this regard. In this paper we report on the design of a thin layer spectroelectrochemical cell employing reflectance of the light beam from the electrode surface, and demonstrate its utility for uv–visible and infrared spectral measurements as well as both conventional and thin layer voltammetric studies. The relative merits of this type of cell as compared to those employing optically transparent thin layer electrodes (OTTLE's) are discussed.

Cell design

The basic cell configuration is similar to that developed by Pons and co-workers for in-situ FTIR spectroelectrochemistry (13). The reader is referred to ref. 13 for optical considerations involved in in-situ infrared spectroelectrochemistry and references to the original literature. The important modifications to the basic Pons design included in our cell entail the provision for reproducible thin layer cavity thickness and greatly reduced sample volume requirement (5 mL). Also, the optical window seals directly to the cell body and does not require the use of epoxy cement or other sealing compound.

Figure 1 illustrates cross-section and front views of the cell and electrode assemblies. The cell body is constructed from a solid Teflon cylinder 50 mm in diameter and 50 mm in length.

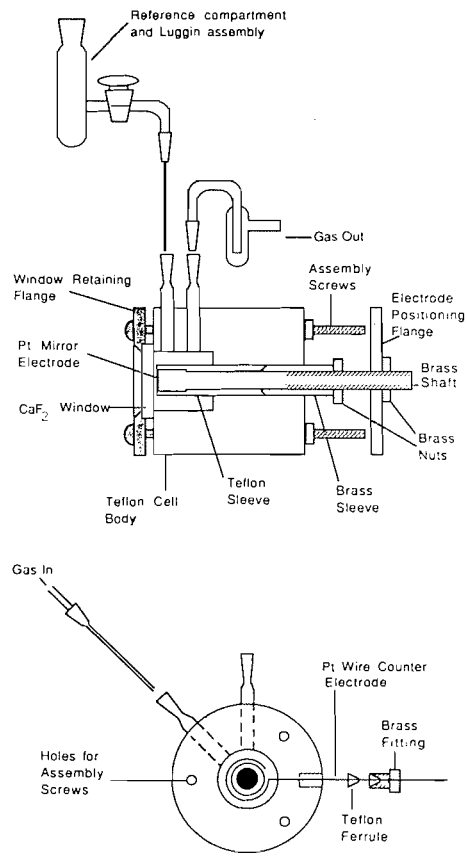

FIG. 1. Cross section of assembled cell and electrode assembly (upper drawing) and front view of cell with window and retaining flange removed (lower drawing).

A hollow concentric cylinder 20 mm × 20 mm is machined into it to form the sample compartment. A second cylindrical hole 11 mm in diameter is drilled concentrically through the remaining length of the cell body to accept the working electrode. Three holes are drilled radially into the sample compartment and ground glass joints (5/30 standard taper) are press fitted into these to accept Luggin capillary and degassing

accessories. A fourth hole provides for the Pt wire counter electrode. This is bent into a circle through which the working electrode can pass. The counter electrode is sealed by means of a Teflon ferrule and brass fitting which threads into the side of the cell body.

A 25 mm × 4 mm cylindrical calcium flouride window has been employed in this work. Although a variety of window materials may be used, CaF_2 has the advantages of being mechanically strong, resistant to scratching, stable to most aqueous and nonaqueous solvents, and transparent from approximately 1000 cm^{-1} in the infrared through to the near-uv region of the electromagnetic spectrum. The window is positioned in a machined brass flange and fastened to the cell by means of three bolts running the length of the cell assembly. The window seals directly against the front surface of the Teflon cell on tightening the fastening bolts.

The electrode is constructed from a brass shaft 80 mm in length. This is machined to a diameter of 6 mm except for a 1 cm length at one end which has a 7 mm diameter. A Pt disk cut from 0.5 mm thick Pt foil is silver soldered to this larger diameter end of the brass shaft while the other end is threaded for a length of 30 mm. The Pt disk is machined to a diameter 0.002 inches in excess of that of the shaft. This excess provides a leak-free seal to a Teflon sleeve 30 mm in length with an outside diameter of 11 mm. The inner diameter of the Teflon sleeve is machined to provide a press fit to the brass shaft. The difference between the 6 and 7 mm diameter sections of the brass shaft and a similar difference in the inside diameter of the Teflon sleeve prevent the sleeve from sliding forward on the electrode assembly. The Teflon sleeve is machined flush to the surface of the Pt disk after pressing it on. The Pt is then polished to a mirror finish on 0.3 μm alumina polishing powder. The end of the Teflon sleeve away from the electrode surface is chamfered inward at an angle of 45°. When the electrode assembly is inserted into the cell assembly a similarly chamfered brass sleeve 11 mm o.d. and 30 mm in length spreads the edges of the Teflon sleeve outward against the cell body to provide a leak-free seal. Pressure on the brass sleeve is provided by means of a nut threaded on to the electrode assembly and butting up against the back of sleeve. This is adjusted so that the electrode assembly may be easily slid forward and backwards in the cell assembly while still maintaining the seal. The maximum forward position of the electrode within the cell assembly is fixed by means of a lock nut and brass flange threaded on to the back of the electrode. The flange butts up against the cell assembly fastening bolts which provide a fixed reference position with respect to the cell window. Once the lock nut and flange have been adjusted to a suitable position, the thin layer of solution between the electrode surface and the window may be replenished by simply pulling the electrode back and pushing it forward again. This operation can be done while maintaining reproducible thin layer cavity thickness, as discussed below.

Experimental

A Cary model 16 uv–vis double beam scanning spectrometer was employed for spectroscopic studies in the visible region. A 25 mm hole was drilled into the side of the sample compartment along with three smaller holes to accept the cell assembly fastening bolts. The cell was then bolted directly to the side of the sample compartment. The sample beam was diverted with the aid of two 90° prisms, as illustrated in Fig. 2*a*. Absorbance spectra of the solution in the thin layer cavity were then recorded in double beam mode with an air reference. The reference beam was attenuated with the aid of an adjustable iris diaphragm to bring the absorbance on scale.

In-situ FTIR studies were performed with a Nicolet 5DX FTIR spectrometer employing the standard detector supplied with the instrument. The cell was placed in the sample compartment along with two planar front surfaced gold mirrors. The mirrors served to deflect the infrared beam onto the electrode and back to the detector, as illustrated in Fig. 2*b*. The cell was filled with the solution of interest and the thin layer thickness was adjusted to the desired value. (We have most often obtained best results with the electrode pushed ahead until it is in direct contact with the window. This serves to minimize solvent absorbance and increase the signal-to-noise ratio. The thin layer thickness in this case is determined by the accuracy with which the cell is machined.) A number of background energy spectra of the light reflected from the electrode surface were collected and signal averaged with the potential controlled at a value where no reaction occurs. The same number of spectra were then signal-averaged with the potential controlled at a value facilitating the reaction of interest. These were then ratioed against the background spectrum to give the normal %T versus wavenumber display. In this mode of operation, ir bands due to the reactant appear with greater than 100% T values, while bands due to the products of the electrochemical reaction have values less than 100%. (Solvent and supporting electrolyte bands are normally ratioed out, but can appear if they change their concentration in the double layer region or adsorb onto the electrode surface (13).)

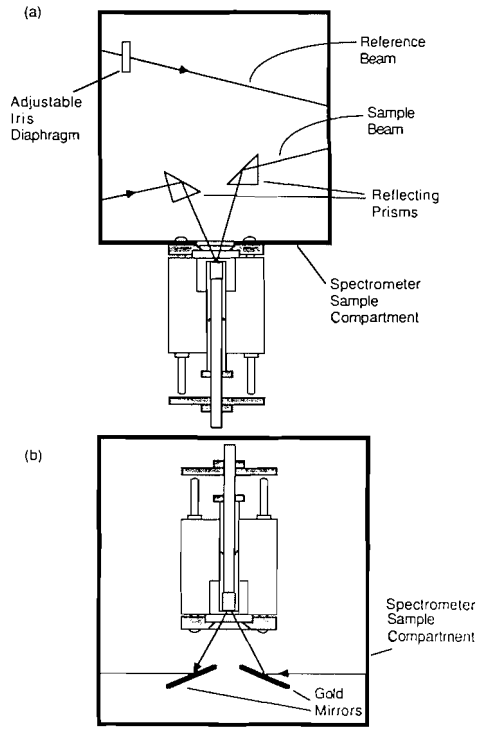

FIG. 2. Cell assembly and optical layout used for (*a*) Cary model 16 uv–vis spectrometer and (*b*) Nicolet 5DX FTIR spectrometer.

All solutions, reagents, and electrochemical equipment were used as described previously (2). The gas inlet tube illustrated in Fig. 1 extends directly into the solution in the sample cavity of the cell. Solutions were degassed by bubbling argon into the solution for approximately 2 min with the electrode pulled back. The bulb in the gas outlet port was filled with solvent, preventing diffusion of oxygen back into the cell when the argon flow was shut off. When operating in a thin layer configuration, a slow stream of argon could be maintained, as the resulting turbulence in the bulk solution had no effect on the voltammetry associated with the thin layer cavity. No pretreatment of the polished working electrode was performed other than rinsing with the solvent in use prior to the experiments.

Results and discussion

Figure 3 illustrates thin layer and conventional cyclic voltammetry obtained for 5,10,15,20-tetraphenylporphinatozinc(II) (TPPZn) in 1,2-dichloroethane containing 0.2 *M* tetra-*n*-butyl-

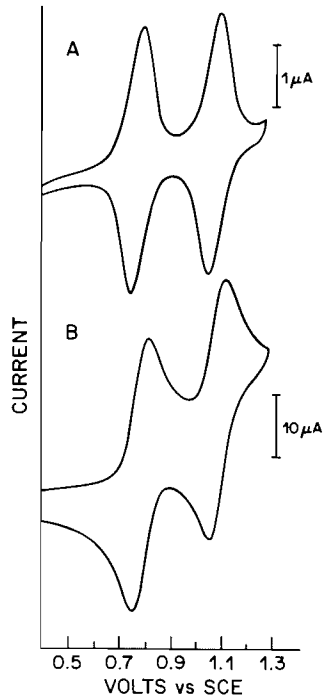

FIG. 3. Thin layer (*a*) and diffusion controlled (*b*) cyclic voltammograms for 0.48 m*M* TPPZn in $C_2H_4Cl_2$/0.2 *M* TBAP. Scan rates are (*a*) 2 mV/s and (*b*) 20 mV/s. The potential scale is vs. aqueous SCE.

ammonium perchlorate (TBAP). The two faradaic processes evident are well known and correspond to successive reversible formation of the porphyrin π-cation radical and π-dication (14). In the thin layer voltammogram the forward and reverse peaks are separated by 60 mV as compared to an ideal value of 0 (15), and the peak widths at half-height are 105 mV, as compared to a 90 mV theoretical value (1). The discrepancy between the theoretical and observed values results from resistance-induced potential distribution across the electrode surface (1). Although the resistance effects in this cell are fairly severe, the resolution between successive redox processes is still excellent even though their half-wave potentials are only separated by 300 mV. Also, the performance of this cell is still far superior to that obtained for TPPZn in the same media by us (2) and others (16) with more conventional cells employing minigrid electrodes in a sandwich configuration. It should be noted that near ideal thin layer voltammetric behaviour in this highly resistive solvent media has been reported by us (2) employing a 1 mm diameter thin layer electrode in a configuration similar to that described in this paper, and by Kadish and co-workers (3, 4) using a thin minigrid strip with two counter electrodes placed parallel and on either side of the strip. Theoretically, small reductions in the diameter of the electrode would lead to significantly improved performance (1). The relatively large 7 mm diameter employed in the present case is desirable, however, because it provides a larger area on which to focus the incident light beam, and thus simplifies the optics required. The beam diameter of the Nicolet 5DX FTIR spectrometer at its focal length is 8 mm, and a reduction of the electrode diameter below the 7 mm value we have used would probably require the inclusion of a beam condenser in the optical system to maintain the signal-to-noise ratio.

One problem encountered in designing thin layer cells is the provision of a means with which to change the solution in the thin layer cavity. With most conventional OTTLE cells, this requires careful and tedious rinsing of the thin layer cavity. With the present cell, changing the solution in the thin layer is readily accomplished by simply pulling the electrode assembly back and pushing it forward again until the electrode positioning flange butts up against the cell assembly bolts. To test the reproducibility of the thin layer thickness, five successive determinations of the charge required for complete 1-electron oxidation of a 1.0 m*M* TPPZn solution were carried out using thin layer chronocoulometry (2), pulling the electrode back and pushing it forward again between each run. The charges observed on successive runs all agreed within 2% of each other. This precision is readily obtainable by inexperienced workers employing thin layer thicknesses of ca. 50 μm. (The thin layer thickness is readily calculated from knowledge of the geometric area of the electrode and the quantity of charge required to bring about complete electrolysis of a solution of known concentration contained in the thin layer cavity.) At smaller thin layer thicknesses, this degree of precision is more difficult to obtain, and requires some practise. In particular, care must be taken not to rotate the electrode as it is pulled back and pushed forward again. We have been using the cell routinely for a year now, and an accuracy of 5% is readily obtainable in coulometric analyses when the thin layer volume is first calibrated with a solution containing a known concentration of electroactive species. While this is probably not as good as may be obtainable with cells employing fixed thin layer thicknesses, it is more than adequate for determining *n* values, the purpose for which thin layer coulometry is most often employed.

Figure 3*b* illustrates conventional cyclic voltammetry for TPPZn in the same solution as that used to obtain the thin layer voltammogram in Fig. 3*a*. These were obtained with the electrode pulled back to the rear of the cell sample compartment. Also, in the thin layer voltammogram, the luggin capillary reference probe was placed in the ground glass port closest to the window, while the port closest to the back of the cell was used in conventional cyclic voltammetric experiments. This allowed closer proximity of the luggin probe to the electrode. (The plane of the circular wire counter electrode lies between the two ground glass ports on top of the cell assembly. Hence the luggin probe may always be positioned to lie between the counter and working electrodes.) Although the peak currents were found to vary linearly with the square root of sweep rate throughout the range studied (10 to 200 mV s^{-1}) in accordance with theory, the peak separation varied between 68 and 92 mV, exceeding the 59 mV theoretical value for reversible charge transfer, even though electronic positive feedback compensation was employed to the fullest extent possible while maintaining potentiostat stability. In previous work (17) employing ac methods, one of us determined the standard heterogeneous rate constant for the first oxidation of TPPZn at Pt in the same solvent system to be $k^0 = 5.4 \times 10^{-2}$ cm s^{-1} with an associated diffusion coefficient of $D = 3.4 \times 10^{-6}$ cm^2 s^{-1}. Using this same diffusion coefficient, the cyclic voltammetric peak separations (18) lead to values of $k^0 = (6.0 \text{ to } 6.8) \times 10^{-3}$ cm s^{-1}, nearly an order of magnitude less than expected. The larger than expected peak separations probably result as much from uneven potential distribution at the electrode surface as uncompensated solution resistance, since all points on the planar working electrode are not equidistant from the circular wire counter electrode. Still, the agreement with theory is adequate for most purposes, and it is usually not possible to do conventional cyclic voltammetry at all in cells employing a fixed thin layer cavity thickness.

Figure 4 illustrates visible absorption spectra obtained at varying potentials throughout the first one-electron oxidation of

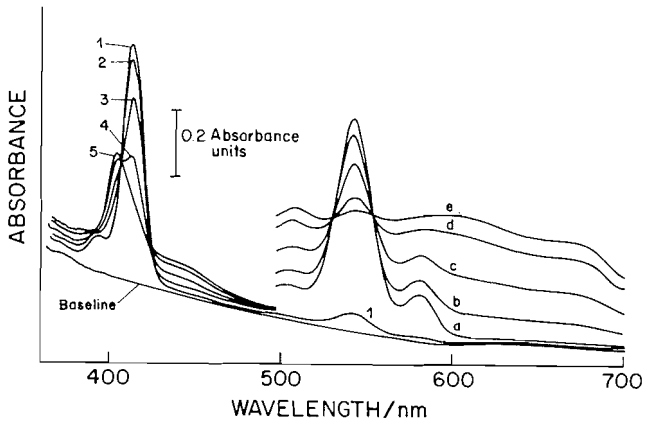

FIG. 4. Visible spectral changes observed for step-wise one electron oxidation of 1.14 mM TPPZn in $C_2H_4Cl_2$/0.2 M TBAP. Applied potentials vs. aqueous SCE are 650 mV, *1*, *a*; 740 mV, *2*, *b*; 780 mV, *3*, *c*; 820 mV, *4*, *d*; 860 mV, *5*, *e*. Spectra *a* through *e* were obtained after pulling the electrode back slightly to increase the absorbance, and utilized the same spectrometer sensitivity as *1* through *5*.

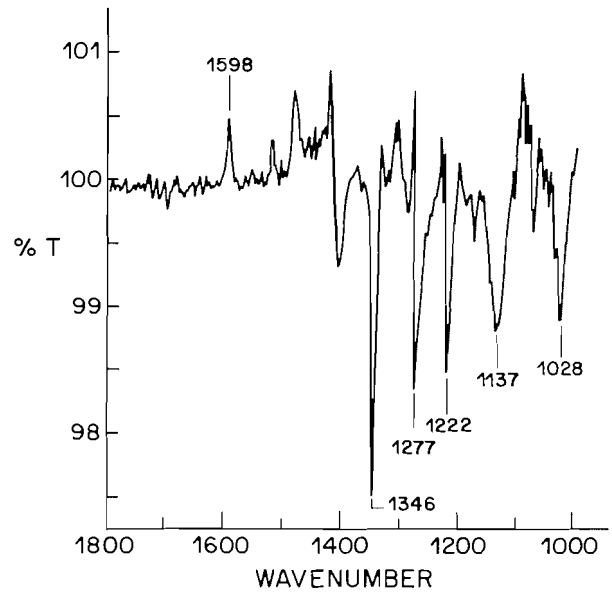

FIG. 5. In-situ FTIR spectra observed for one electron oxidation of 2.0 mM TPPZn in $C_2H_4Cl_2$/0.2 M TBAP. The base potential at which the reference spectrum was collected was 500 mV. The sample spectrum was collected after complete oxidation at 900 mV vs. aqueous SCE.

TPPZn. Spectra *a* through *e* were obtained at the same potentials and spectrometer sensitivity as *1* through *5*, respectively, after pulling the electrode back slightly to increase the thin layer thickness until adequate absorbance in the 500 to 700 nm range was observed. A comparison of the absorbance of the bands at 547 and 585 nm in spectrum *1* with the same bands in *a* demonstrates the dramatic variation in spectral sensitivity possible using thin layer cells employing specular reflectance. In OTTLE cells with fixed path length, generation of the spectra in Fig. 4 would have required the use of two solutions of different concentration.

The optical pathlength is given by eq. [1], as readily derived from geometric considerations (19).

$$[1] \quad l = 2d/\cos\theta$$

Here, d is the thickness of the thin layer cavity, and θ is the angle of incidence defined with respect to a perpendicular from the electrode surface. The molar absorptivity for TPPZn in dichloroethane/0.2 M TBAP was determined in a conventional uv–vis cell to be $2.25 \times 10^4\ M^{-1}\ cm^{-1}$ at 547 nm. From this value the optical pathlength l was determined to be 22 μm for spectra *1* through *5* in Fig. 4, and 240 μm for spectra *a* through *e*. From eq. [1], the thin layer thicknesses were less than 11 and 120 μm for these spectra. (A more precise calculation of d from eq. [1] requires knowledge of the angle of incidence, and subsequently the refractive index of the solution.) Kuwana and co-workers (9) have discussed a cell employing a gold minigrid which can be used in either a thin layer configuration or a semi-infinite linear diffusion configuration. It should be pointed out that cells employing their basic design might also have some applicability to obtaining thin layer spectra with varying optical pathlength, although this was not demonstrated. The degree to which the pathlength can be varied in a reflectance type cell cannot be realized utilizing optically transparent electrodes, however, as the light beam passes through the thin layer solution only once. Also, the use of a minigrid electrode limits the smallest obtainable pathlength to the thickness of the minigrid itself.

Although the greater sensitivity inherent in cells employing specular reflectance facilitates their use where variable optical sensitivity is desirable, precise knowledge of the optical pathlength is less readily available than in cells employing a fixed pathlength. Since there must always be a certain degree of variability in d, and since an exact knowledge of θ requires that the refractive index of the solution be known, the pathlength must be calibrated each time the cell is used if accurate determination of the molar absorptivities of the products of the electrochemical reaction is desired. In the case where the reactant has significant absorbance in the spectral region observed, this poses little problem, as the absorbance prior to the application of any potential to the electrode may be used for the calibration. The problem is more serious where the reactants do not absorb, in which case the pathlength must most often be deduced from the absorbance of a separate solution of known absorbance. Because the variability in pathlength is a factor $2/\cos\theta$ times the variability in the thin layer thickness, the resulting imprecision in the determination of molar absorptivities is a more serious problem than that in determining coulometric n values.

Figure 5 illustrates in-situ FTIR spectra associated with the first one-electron oxidation of TPPZn. The electrode was pushed into contact with the cell window to minimize solvent absorbance as discussed previously. The background spectrum was obtained at a potential of 0.5 V vs. SCE, while the sample spectrum ratioed against it was obtained after complete oxidation at 0.90 V. Each spectrum was the result of signal averaging 128 scans. (Each scan requires approximately 1 s.) Of particular interest is the strong absorbance at 1277 cm^{-1} observed for the TPPZn cation-radical. Absorbance bands very close to this value have been observed (20) for cation radicals of a number of metal–TPP complexes and have emerged as an important criterion for distinguishing between metal-centered as opposed to ring-centered oxidation of these complexes. Previous observation of this band, however, has required isolation of the oxidized species and determination of its solid-state vibrational spectrum. This, of course, is less convenient than in-situ characterization, and may not be possible in cases where the products have limited lifetime. It is noteworthy that this band is readily observable even though the solvent absorbs quite extensively in this region.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

Also of note in Fig. 5 is the relatively strong absorbance at 1137 cm^{-1}. This band is not observed in spectral ratios recorded at the same potential in solutions of solvent and supporting electrolyte alone. It lies within the region anticipated for coordinated perchlorate (21) and thus suggests coordination of perchlorate anion to the zinc–porphyrin cation radical. Coordination of perchlorate to $TPP^{+\cdot}Zn$ has been observed in the X-ray crystal structure of the isolated cation radical (22), but its coordination in solution was not directly inferred.

Conclusions

The utilization of specular reflectance in thin layer electrochemical cell design can lead to a number of important advantages with respect to the use of optically transparent electrodes. Firstly, the pathlength is greater by a factor of $2/\cos\theta$, for cells with the same thin layer thickness, leading to an inherently greater sensitivity. Secondly, the pathlength is variable, making the cell applicable to studies in solutions of a wider range of concentrations. Thirdly, and perhaps most importantly, is the great versatility of this type of cell design. Hence, both conventional and thin layer voltammetric studies can be carried out, and the cell design is amenable to studies in the ir as well as uv–vis spectral regions. The availability of relatively inexpensive bench-top FTIR spectrometers designed for routine analysis, such as that used in the present study, should lead to more common use of this type of cell.

In fairness, the disadvantages of this type of cell design must also be pointed out. These are primarily that the precision affordable in coulometric studies and determination of molar absorptivities, while probably adequate for most purposes, may not be as good as that attainable with fixed thickness thin layer cells. Also, the construction of the cell requires more precise machining and probably more cost than most conventional OTTLE cells. It should be kept in mind that the reflectivity of Pt, and a variety of other metals, decreases sharply in the uv (note the sloping baseline in Fig. 4), and the resulting lower optical throughput can limit the applicability of reflectance type cells in this spectral region (11). We feel, however, that for most applications these disadvantages are outweighed by the advantages.

Spectroscopic evidence for surface hydronium (H_3O^+) ions on hydrated single crystals

SIMONA BĂDILESCU AND CAMILLE SANDORFY
Département de Chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3J7

Received August 21, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

SIMONA BĂDILESCU and CAMILLE SANDORFY. Can. J. Chem. **65**, 924 (1987).

Evidence has been obtained by attenuated total reflection Fourier transform infrared spectroscopy (ATR-FTIR) for the existence of hydronium ions on the surfaces of hydrated single crystals. The band near 1740 cm^{-1} due to the ν_4 (e) bending vibration of the hydronium ion has been identified on silicon, germanium, thallium bromide iodide (KRS-5), and zinc selenide single crystals. The protonating capability of these hydronium ions was demonstrated with pyridine derivatives.

SIMONA BĂDILESCU et CAMILLE SANDORFY. Can. J. Chem. **65**, 924 (1987).

Nous avons mis en évidence la présence d'ions hydronium sur les surfaces de monocristaux hydratés par des mesures de spectroscopie infrarouge par transformée de Fourier utilisant la technique de la réflexion totale atténuée. La bande ν_4 (e), vers 1740 cm^{-1} due à une vibration de déformation de l'ion hydronium a été retrouvée sur des surfaces de monocristaux de silicium, germanium, bromure-iodure de thallium et séléniure de zinc. Les spectres montrent que ces ions hydronium peuvent protoner les dérivés de la pyridine.

Introduction

The existence of the hydronium ion as a discrete chemical species in strong acid hydrates was established long ago (1). The equivalence of the three protons in the crystalline monohydrates of several inorganic acids was confirmed by nmr spectroscopy (2) and the precise molecular geometry of the H_3O^+ ion has been determined later by X-ray and neutron diffraction studies (3, 4).

The fundamental vibrations of H_3O^+ were identified (5–11) in various mineral acid solutions and assigned on the basis of a pyramidal structure by analogy with the isoelectronic NH_3 molecule. Normal coordinate treatment of the hydronium ion was accomplished by Basile *et al.* (12, 13) using the neutron diffraction data on solid *p*-toluenesulfonic acid monohydrate. In spite of the strong polarity of the ion, the vibrational spectrum of hydronium perchlorate could be obtained from the Raman spectra too. The infrared spectra of hydrogen halide solutions were examined by Taylor and Vidale (14) and Giguère and Turrell (15) who emphasized the role of the ionic charge in the strong hydrogen bonding nature of H_3O^+. For a detailed discussion of the spectroscopic aspects we refer to Williams (16) and Giguère (17).

Recently, we have examined the capability of the thallium bromide iodide (KRS-5) crystal to adsorb water, and we have identified some diagnostic bands (18) by FT-IR-ATR spectroscopy. The hydrated crystal surface was used as a substrate for hydration studies on mononucleotides and a methodology to maintain a constant and precisely controlled hydration degree on the surface was developed (19). Subsequently, we have examined the proton-donor ability of the adsorbed water (20). The influence of the lack of smoothness of the crystal surface on the dissociation of the adsorbed water has been noted.

Using ATR spectroscopy, Chabal and co-workers (21, 22) showed that water adsorption on silicon surfaces is dissociative and that hydride formation occurs upon molecular chemisorption of water on annealed surfaces. These results were in agreement with those of Ibach *et al.* (23) obtained by electron energy loss spectroscopy. Binding structures that may result from the dissociation of water molecules on silicon surfaces were discussed (24).

Our previous results indicated the possibility of the existence of the hydronium ion (H_3O^+) as a distinct chemical entity on the surface of the hydrated KRS-5 single crystal. The narrow band located at 1744 cm^{-1} in the ATR spectra of the hydrated thallium bromide iodide single crystal can be assigned to the asymmetrical bending mode ν_4 (e) of the surface hydronium ions. This band, appearing in a "window" of the strong water absorption in the transmission spectrum, is much more obvious in the ATR spectrum. In the OH stretching region a strong, broad band centered around 3760 cm^{-1} was observed.

In order to ascertain the assignment of these bands we have extended our studies to different internal reflection elements during various proton-acceptor systems. We were also interested in the study of hydrogen bonding interactions of the surface hydronium ion. This study reports a preliminary spectroscopic surface study (FT-IR-ATR) of some hydrated ATR single crystals, both with and without proton-acceptor compounds.

Experimental

Spectra were recorded on a Nicolet 5DXB FT-IR spectrometer equipped with a DTGS detector. Collection times for the spectra (100 co-added interferograms) were less than 2 min. The instrument was flushed with dry nitrogen during all measurements. Background spectra of the internal reflection elements (ATR single crystals) were recorded on a Perkin–Elmer Model 783 double beam grating spectrophotometer as well. Wide slit programs (resolution 3.2 cm^{-1}) and noise filter were used to reduce the noise level. The spectra were recorded with base line adjustment, without scale expansion.

The Model 300 ATR attachment (Barnes Analytical) was used. Commercially available (Barnes Analytical and Harrick Scientific Corp.) new KRS-5, ZnSe, Ge, and Si ATR plates (50 × 10 × 3 mm) were used to record the background spectra. Measurements were made over angles of incidence ranging from 30 to 55°. KRS-5 crystals were hydrated by keeping them for a day in an atmosphere of constant relative humidity.

Pyridine, 2,4,6-trimethylpyridine, and dioxan were used. Dioxan was deposited onto the crystal from aqueous solutions ($\sim 10^{-3}$) using a Hamilton microsyringe. Due to its higher volatility under vacuum, pyridine was deposited from a concentrated solution and the procedure was repeated three times for each side of the crystal. Water was removed under vacuum. Trimethylpyridine was deposited from a dilute chloroform-*d* solution. Crystals were cleaned with the proper solvent and distilled water. In some experiments cleaned crystals were heated up to 80°C in a vacuum oven. The cleanliness of the crystal was checked by the background spectrum.

TABLE 1. Frequencies of the ν_4 (e) bending vibration of the hydronium ion (H_3O^+) on the surfaces of ATR single crystals*

Crystal	Background spectra	Sample spectra			
		Py	2,4,6-Py	Oxonium of dioxan	Pyrimidinium (18)
Ge	1739	1738	1728	1740 1725	
Si	1722	1730	1728		
ZnSe	1737	1735	1727	1740 1725	
KRS-5	1740	1735	1728		1740

*Py = pyridinium, 2,4,6-Py = 2,4,6-trimethylpyridinium.

Results and discussion

Figure 1 shows the ATR spectrum of the silicon single crystal recorded on a Perkin-Elmer 783 double beam spectrophotometer. The most important feature of the spectrum is the narrow band located at 1720 cm^{-1} which stands out much clearer than in our previous spectra taken with the KRS-5 crystal. The silicon crystal is thinner than the others (2 mm compared to 3 mm) allowing a higher number of reflections and therefore an increased sensitivity. No shift or distortion of the band with changes in the angle of incidence was detected. The absorption bands of the silicon crystal (lattice bands) were recorded in order to show the relative intensities. In the water stretching and bending regions it is difficult to make precise assignments for the silicon crystal.

Background spectra of the germanium and zinc selenide crystals (25 × 10 × 3 mm) were recorded with the FT-IR instrument. The spectra show weak narrow bands at 1739 and 1737 cm^{-1}, respectively. Table 1 shows the band frequencies corresponding to the four single crystals (for the KRS-5 single crystal spectrum, see Fig. 1 in ref. 18). As already mentioned, the intensity of this band in the KRS-5 crystal depends strongly on the roughness of the surface. Generally, in the presence of defects on the surface, the 1740 and 3760 cm^{-1} bands are stronger than on a new crystal. In all cases (excepting the silicon crystal) the background spectra indicate the presence of the broad ν_2 water band accompanying the narrow high-frequency band, but the hydronium band is more intense.

The narrow band at 1720–1740 cm^{-1} has the right frequency to be assigned to the asymmetrical bending vibration ν_4 (e) of H_3O^+. It is in the same range as for crystals and for acid solutions (see above). The hydronium ions must result from the dissociation of some of the water molecules on the surface according to $2H_2O = H_3O^+ + OH^-$. The ions would then be adsorbed on the surface and further stabilized by hydrogen bonding with water molecules.

In order to examine this band further we added different compounds having proton acceptor capabilities. The results are presented in Figs. 2, 3, 4, and in Table 1. The general pattern of the spectra corresponds to the pyridinium ion and not to the molecule (25, 26). For the assignment of the bands of the pyridine molecule adsorbed on acidic solid surfaces we used the data of Parry (27) and Kirina *et al.* (28, 29). In this part of the work, however, we were interested more in the behaviour of the hydronium bands than in the acceptor's bands.

The first observation concerns the intensity of the ν_4 hydronium band. In all systems the relative intensity of the bands of the hydronium ion and of the acceptor molecules are of comparable intensity. The spectra were obtained by comparing the sample data with the corresponding background spectra. What we observe is an increase in the intensity of the band in the presence of the acceptor molecule. This is an important argument for the assignment of the band. Therefore any assignment involving crystal bands (overtones, impurities) is ruled out. The band centered around 1640 cm^{-1} (Fig. 2) receives contributions from the pyridinium ion (ν(C=NH$^+$)

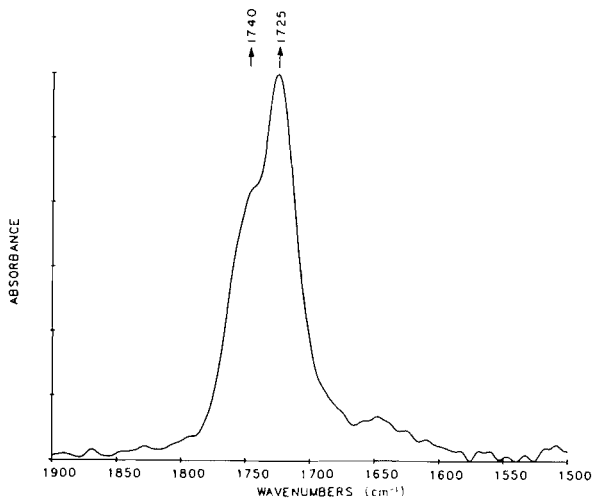

FIG. 4. ATR spectrum of dioxan adsorbed on a zinc selenide crystal.

and ν(C=C)) and also from the bending vibration of water. Similar results were obtained using the zinc selenide crystal under the same conditions. However, it is interesting to observe the different ratios of the bands at about 1735 and 1630 cm^{-1} corresponding to the hydronium and pyridinium ions, respectively, on the germanium and zinc selenide surfaces. On the germanium surface the 1735 band is much stronger while on the zinc selenide surface the relative intensities of the 1735 and 1630 bands are very nearly the same, indicating a higher degree of protonation of pyridine than on the germanium crystal (Fig. 2). We have already observed the decrease of the intensity of the hydronium band with the degree of protonation for Schiff bases (30). It is interesting to note that the heating of the crystal (pyridine adsorbed on zinc selenide) to 50°C during 2 h leaves the intensity of the pyridinium band unchanged. The results are supported by those obtained with a stronger base.

2,4,6-Trimethylpyridine. Figure 3 shows a strong band at 1636 cm^{-1} corresponding to the pyridinium ring and a weaker hydronium band at 1727 cm^{-1}. Figure 3 also shows some interesting features in the region corresponding to the stretching bands. An intense and broad band is present at about 2470 cm^{-1}. This is likely to correspond to the stretching vibration of an OH bond of the hydronium ion involved in a strong hydrogen bond. The N^+—H vibration may also contribute to it. The weaker band at 1983 cm^{-1} could be tentatively assigned to a combination involving the symmetrical bending vibration and a libration. The former can be assigned to a pronounced shoulder which is seen at about 1280 cm^{-1} in all our spectra. Figure 4 shows the 1900–1500 cm^{-1} region of the spectrum corresponding to dioxan adsorbed on a hydrated zinc selenide crystal. In this system the hydronium band is a double band with frequencies at 1740 and 1725 cm^{-1}. Table 1 shows that the ν_4 frequency of the hydronium ion depends more on the proton-acceptor molecule than on the crystal material; with the exception of the silicon crystal, the frequency of the hydronium ion is decreasing (compared to the free crystal) in the presence of the acceptor molecule. A lower frequency corresponds to a weaker hydrogen bond in the system.

The water environment of the hydronium ion on the crystal surface stabilizes the ion. It was established by diffraction studies that each of the three hydrogen atoms is strongly bonded to a water molecule; therefore the real structure of the ion corresponds to the formula $H_3O^+.3H_2O$ (17).

The counterion in these systems can be only the OH^- ion coordinated by the oxygen atom to the metal atom of the crystal. The hydronium ion in the crystal force field, stabilized by the water environment, is a stable, well-defined entity. The proton-acceptor molecules act as proton "sponges" displacing the dissociation equilibrium. The resulting protons are divided between the two possible acceptor sites — water and pyridine, for example.

Conclusion

The presence of the hydronium ion on the surface of some single crystals has been revealed by FT-IR-ATR spectroscopy. The bending vibration ν_4 (e) of the hydronium ion on different crystal surfaces has been assigned and the possible pattern of associations has been discussed. The hydronium ion protonates certain proton-acceptor molecules like pyridine derivatives.

The direct electrochemical synthesis of dialkyldithiocarbamate and diethyldithiophosphate complexes of main group and transition metals

CORRADO GELOSO, RAJESH KUMAR, JAIME ROMERO LOPEZ-GRADO,[1] AND DENNIS G. TUCK[2]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received September 18, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

CORRADO GELOSO, RAJESH KUMAR, JAIME ROMERO LOPEZ-GRADO, and DENNIS G. TUCK. Can. J. Chem. **65**, 928 (1987).

Dialkyldithiocarbamate derivatives $(R_2NCS_2)_nM$ of a number of metals (M = Fe, Co, Ni, Cu, Ag, Zn, Cd, In, Tl) have been synthesised in good yield by electrochemical oxidation of appropriate sacrificial anodes in non-aqueous solutions of either the corresponding tetraalkylthiuram disulphide $(R_2NCS_2)_2$ (R = Me, Et) or a mixture of carbon disulphide plus the secondary amine R_2NH (R = Et, *i*-Pr; R_2NH = piperidine). Similar experiments with solutions of $(EtO)_2P(S)SH$ (= HL) gave ML_n derivatives (M = Fe, Co, Ni, Cu, Ag, Au, Zn, Cd, Hg, Ga, In, Tl) while in the presence of HL + 1,10-phenanthroline, ML_n.phen derivatives were obtained for M = V, Mn, Fe, Co, Zn, and Ga.

CORRADO GELOSO, RAJESH KUMAR, JAIME ROMERO LOPEZ-GRADO et DENNIS G. TUCK. Can. J. Chem. **65**, 928 (1987).

On a synthétisé avec de bons rendements les dérivés dialkyldithiocarbamates $(R_2NCS_2)_nM$ d'un certain nombre de métau (M = Fe, Co, Ni, Cu, Ag, Zn, Cd, In, Tl) en mettant en jeu l'oxydation électrochimique d'anodes sacrifiées appropriées dans des solutions non-aqueuses soit des disulfures de tétraalkylthiurames correspondants $(R_2NCS_2)_2$ (R = Me, Et) soit d'un mélange de disulfure de carbone plus l'amine secondaire R_2NH (R = Et, *i*-Pr; R_2NH = pipéridine). Des expériences semblables avec des solutions de $(EtO)_2P(S)SH$ (= HL) conduisent aux dérivés ML_n (M = Fe, Co, Ni, Cu, Ag, Au, Zn, Cd, Hg, Ga, In, Tl) alors que, en présence de HL + phénanthroline-1,10, on obtient des dérivés ML_n.phen (M = V, Mn, Fe, Co, Zn et Ga).

[Traduit par la revue]

Introduction

The chemistry of metal complexes involving bidentate sulphur donor ligands continues to be of considerable importance in analytical chemistry, and in the preparative and the structural aspects of coordination chemistry. Alkyl dithiocarbamates, $R_2NCS_2^-$, are among the more important examples of such ligands, and some authors have reviewed these and related metal complexes (1, 2). The present work represents a continuation of studies in this laboratory of the preparation of metal salts of weak acids by electrochemical oxidation of a sacrificial anode in non-aqueous media. Earlier examples of such direct syntheses have lead to neutral and anionic thiolates (3–5), thiocyanates (6), phenylacetylene copper(I) (7), β-diketonates (8, 9), and carboxylates (10). We have now shown that the anodic oxidation of typical transition or Main Group metals into solutions of a tetraalkylthiuram disulphide $(R_2NCS_2)_2$, or a mixture of a secondary amine R_2NH with carbon disulphide, gives the $(R_2NCS_2)_nM$ derivatives in almost quantitative yield.

Dialkyldithiophosphate complexes represent another group of derivatives of bidentate sulphur donor ligands which are themselves the anions of weak acids (11). The present paper also reports the efficient direct electrochemical synthesis of a series of transition and Main Group metal complexes of diethyldithiophosphate from the parent acid.

Experimental

Materials

Solvents were dried by refluxing over calcium hydride (acetonitrile) or anhydrous magnesium sulphate (acetone). Carbon disulphide was dried over phosphorus pentoxide. All other organic reagents were used as supplied, as were metals used as anodes.

Analysis and spectroscopy

The metal content of the products was determined by atomic absorption spectrophotometry, and microanalysis on selected compounds was performed by Guelph Chemical Laboratories Ltd.

Infrared spectra were recorded on Perkin-Elmer IR 180 or Nicolet 5DX instruments; ^1H nmr spectra were obtained with a Perkin-Elmer EM 360 spectrometer at 60 MHz, and ^{31}P spectra on a Bruker CXP instrument.

Electrochemical synthesis

Dialkyldithiocarbamate complexes

Two different methods were used in the synthesis of $M(S_2CNR_2)_n$ complexes, but in each case, and in the preparation of diethyldithiophosphate derivatives described below, the cell was a 100-mL tall-form beaker fitted with a rubber bung through which the electrical leads entered the cell. The anode consisted of a rod or foil, as supplied, with the foils suspended on a platinum wire. The cathode was a platinum foil (12). Gallium anodes were prepared by the method described earlier, which in essence is melting the metal in a glass tube around a platinum wire (13). A stream of dry nitrogen served to stir the solution phase during electrolysis.

The two cells used can be summarized as:

(*i*) $Pt_{(-)}/CH_3CN$ (or acetone) + $(R_2NCS_2)_2/M_+$

(*ii*) $Pt_{(-)}/CH_3CN + R_2NCS_2H/M_{(+)}$

In case (*i*), the solutions of tetraalkylthiuram disulphide (R = Me, Et) were prepared immediately prior to electrolysis, the conditions of which are reported in Table 1. For (*ii*), solutions of $R_2NC(S)SH$ were prepared *in situ* by dropwise addition of excess CS_2 to a stirred solution of R_2NH (R = Et, *i*-Pr, or R_2NH = piperidine). The conditions for these experiments are set out in Table 2.

Isolation of dialkyldithiocarbamate complexes

The formation of an insoluble product at the anode was generally visible within a few minutes, although in some cases longer periods were required. Hydrogen gas evolved at the cathode when solutions of $R_2NC(S)SH$ were used. At the end of the electrolysis, the solid product was collected, washed several times with acetonitrile and then petroleum ether, and dried *in vacuo*.

Problems were encountered with anodes of gallium and thallium in

the isolation of products, and these cases are discussed below. No reaction was observed with anodes of mercury.

Diethyldithiophosphate complexes

The cells here were of the form $Pt_{(-)}/CH_3CN + (EtO)_2PS_2H/M_{(+)}$, but in all other respects, the experiments followed those described above for dialkyldithiocarbamate complexes. The details of cell composition, etc. are shown in the top section of Table 3 while in the bottom section we report the conditions for preparing various ML_n.phen adducts by anodic oxidation using acetone solutions of $(EtO)_2PS_2H$ + 1,10-phenanthroline.

Isolation of diethyldithiophosphate derivatives

The $M[S_2P(OEt)_2]_n$ compounds precipitated as the electrolysis proceeded, and these solids were collected, washed with acetonitrile and then diethyl ether, and dried *in vacuo*. Similar procedures gave a number of ML_n.phen adducts, which were washed with acetone and then *n*-pentane before drying *in vacuo*. Certain specific observations are noted below.

Results and discussion

Dialkyldithiocarbamate compounds

The studies reported above show that the preparation of $M(S_2CNR_2)_n$ compounds of both transition and Main Group elements by direct electrochemical synthesis from the metal can be satisfactorily achieved by two related routes. The first of

these uses the appropriate tetraalkylthiuram disulphide as the source of the ligand, which has the advantage of employing a stable (and in some cases commercially available) starting material. The products, listed in Table 4, are generally those of the metals concerned in conventional oxidation states, and many of these compounds have been previously prepared by other workers (see ref. 1 and references therein). As noted earlier, the yields were essentially quantitative, based on the quantity of metal dissolved from the sacrificial anode; in most cases, the product is insoluble in the solution phase of the cell, making recovery a simple operation. The conditions described in Table 1 suggest that fairly wide variations in solvent and solute concentration have little or no effect on the synthesis, and given these variations, it seems reasonable to suggest that the method is a general one. The present experiments were carried on a small scale, but the yield is easily increased by using larger cells and/or using a number of cells in series.

In keeping with our previous practice, we have measured the electrochemical yield defined as the quantity of metal dissolved per Faraday of electricity (E_F, mol F^{-1}). For Fe, Co, Ni, Zn, and Cd, the E_F values were 0.5 ± 0.05 mol F^{-1}, corresponding to the processes

$$\text{cathode: } (R_2NCS_2)_2 + 2e \rightarrow 2R_2NCS_2^-$$

$$\text{anode: } 2R_2NCS_2^- + M \rightarrow M(S_2CNR_2)_2 + 2e$$

and for all but one of these metals (i.e., iron), the products are indeed the ML_2 species. With Cu, Ag, In, and Tl, E_F values of 1.0 ± 0.1 mol F^{-1} imply analogous reactions to form ML, although Table 4 shows that only with silver is this the only product identified. For the remaining elements one can reasonably postulate that the formation of ML at the anode is followed by the oxidative addition reactions

$$CuL + (1/2)L_2 \rightarrow CuL_2$$

$$ML + L_2 \rightarrow ML_3 \qquad (M = In, Tl)$$

and an analogous process presumably explains why FeL_3 is isolated despite an E_F value which indicates the formation of FeL_2 at the anode. Such oxidation steps have been observed in other electrochemical syntheses (cf. refs. 4, 9).

The reactions of anodic gallium, indium, and thallium require discussion in this context. Gallium electrodes were prepared by the method described elsewhere (13), and in view of the low melting point of the metal, electrolysis (see Table 1) was carried out with the cell cooled in ice. Under these conditions a white solid deposited on the anode as electrolysis proceeded, and this in turn caused a decrease in current. No significant quantities of solid deposited in the cell and the product could only be collected by scraping the anode subsequent to electrolysis; this material contained the $R_2NCS_2^-$ ligand (as shown by the infrared spectrum) but elemental analysis on the Ga/$Me_2NCS_2^-$ product (C 7.14, H 2.2, N 3.3) showed that this is highly contaminated, probably with gallium metal from the anode. Under these circumstances, the electrochemical synthesis offers no advantages over the standard methods. With indium, the products are the conventional ML_3 species, formed via the unstable InL^I (see above), but with thallium the detailed behaviour depends on the $R_2NCS_2^-$ ligand being used. With R = Me, the solution gradually became yellow–orange as electrolysis proceeded, and eventually coloured crystals of $Tl(S_2CNMe_2)_3$ deposited (see Table 4). When R = Et, the same yellow–orange colour developed in the solution phase, but a white solid also deposited after about 10 min; this solid is the thallium(I) compound $Tl(S_2CNEt_2)$. Concentration of the filtrate at the end of the electrolysis yielded yellow–orange crystals of $Tl(S_2CNEt_2)_3$. These results confirm the oxidative mechanism proposed above, requiring the formation of In^I or TL^I species at the anode, followed by oxidation in the solution phase. Similar reactions have been observed recently in a number of systems involving the electrochemical synthesis of complexes of Group III elements with sulphur donor ligands.[3]

The synthesis of $M(S_2CNR_2)$ compounds can also be simply achieved by mixing solvent with R_2NH and CS_2, cooling to dissipate the heat generated in the formation of $R_2NC(S)SH$, and then proceeding with the synthesis. The electrochemical behaviour of these systems (see Table 2) differs only in that hydrogen is evolved at the cathode, as in other HL systems, so that the sequence of reactions is

$$\text{cathode: } nR_2NCS_2H + ne \rightarrow \left(\frac{n}{2}\right)H_2(g) + nR_2CNS_2^-$$

$$\text{anode: } nR_2NCS_2^- + M \rightarrow M(S_2CNR_2)_n + ne$$

The products of these syntheses were characterised by elemental analysis, comparison of melting points with literature values, and infrared spectroscopy which established the presence of the ligand (cf. ref. 1).

Diethyldithiophosphate compounds

As with dialkyldithiocarbamates, we have investigated the electrochemical oxidation of transition and Main Group metals in the presence of $(EtO)_2PS_2H$. With some exceptions, the compounds produced (Table 5) are analogous to the dithio-

carbamate species, and the E_F values are also similar, with $E_F = 0.5 \pm 0.05$ mol F^{-1} for iron, cobalt, nickel, zinc, and cadmium, and $E_F = 1.04 \pm 0.05$ mol F^{-1} for copper, silver, indium, and thallium. As noted earlier, the compounds were characterised analytically and spectroscopically; the infrared spectra demonstrated the presence of the $(EtO)_2PS_2$-ligand with the characteristic ν(P—S) modes in the 530–650 cm^{-1} region (cf. ref. 11). The proton nmr spectra of the diamagnetic complexes, in d_6-DMSO solution, showed a splitting of the CH_2 resonance, which is at ca. 4 ppm from Me_4Si; the CH_3 resonance at ca. 1.5 ppm was the conventional triplet. In the case of InL_3, which was studied in detail, we observed two quartets ($J = 7$ Hz) separated by 10.5 Hz (J(P—H)). The ^{31}P spectra (Table 5) show significant shifts from neat $(EtO)_2PS_2H$ for which the resonance is at 82.5 ppm. The resonance frequencies are in general close to those reported for these or similar complexes (17, 18), given the different solvents used, and confirm the bidentate coordination of ligand to metal.

The following points may be noted about the preparative work. With vanadium, electrolysis gave rise to a green solution, which eventually threw down a black solid which we were not able to characterise. Similarly, with chromium, substantial quantities of metal were dissolved, but an intractable black solid deposited from the dark yellow solution, while with manganese a colourless solution formed and a black deposit formed on the cathode. With iron, the product is a Fe^{II} derivative, rather than the Fe^{III} dithiocarbamate, perhaps reflecting the absence of an oxidising L_2 unit in solution. No product was isolated when gold was the anode. Thallium yielded only TlL (cf. comments on iron above).

When 1,10-phenanthroline was present in the electrolyte solution adducts were obtained (Table 5); some of these compounds have been reported previously (11). No doubt many other adducts of this and other donor ligands could be prepared by this simple and direct method.

Solvolytic rearrangement studies with (*E*)- and (*Z*)-2-anisyl-1,2-ditolyl[2-^{13}C]vinyl bromides

CHOI CHUCK LEE AND DAVE WANIGASEKERA
Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received October 1, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

CHOI CHUCK LEE and DAVE WANIGASEKERA. Can. J. Chem. **65**, 933 (1987).

Reaction of (*E*,*Z*)- or (*E*)-2-anisyl-1,2-ditolyl[2-^{13}C]vinyl bromides ((*E*,*Z*)- or (*E*)-**6**-Br-2-^{13}C) with HOAc–AgOAc gave a 1:1 mixture of (*E*)- and (*Z*)-2-anisyl-1,2-ditolyl[1,2-^{13}C]vinyl acetates ((*E*,*Z*)-**6**-OAc-1,2-^{13}C), with about 37.4% scrambling of the label from C-2 to C-1 arising from degenerate 1,2-anisyl shifts in the 2-anisyl-1,2-ditolyl[2-^{13}C]vinyl cation (**6**-2-^{13}C). No detectable amount of 1-anisyl-2,2-ditolylvinyl acetate was formed, indicating no nondegenerate 1,2-tolyl shift in cation **6** to give the more stable 1-anisyl-2,2-ditolylvinyl cation (**10**) in the reaction with HOAc–AgOAc. Reaction of (*E*)-**6**-Br-2-^{13}C with 2,2,2-trifluoroethanol (TFE) in the presence of 2,6-lutidine gave as major product 1-anisyl-2,2-ditolyl[1,2-^{13}C]vinyl 2,2,2-trifluoroethyl ether (**10**-OTFE-1,2-^{13}C) and a 1:1 mixture of (*E*)- and (*Z*)-2-anisyl-1,2-ditolyl[1,2-^{13}C]vinyl 2,2,2-trifluoroethyl ethers ((*E*,*Z*)-**6**-OTFE-1,2-^{13}C) as minor products, the ratio of **10**-OTFE to (*E*,*Z*)-**6**-OTFE being about 80:20. Scrambling on the ^{13}C label in the major product, **10**-OTFE-1,2-^{13}C, was 48.8 ± 0.9% and scrambling in the minor products, (*E*,*Z*)-**6**-OTFE-1,2-^{13}C, was 47.2 ± 1.4%. The present work with cation **6** completes the series of nine possible triarylvinyl cations, with various combinations of phenyl (Ph), *p*-tolyl (Tol), and (or) *p*-anisyl (An) as the three aryl groups, that can give rise to degenerate 1,2-aryl shifts across the double bond, and the present results are discussed in conjunction with data from previous work on the other eight triarylvinyl cationic systems.

CHOI CHUCK LEE et DAVE WANIGASEKERA. Can. J. Chem. **65**, 933 (1987).

La réaction des bromures d'anisyl-2 ditolyl-1,2 [^{13}C-2] vinyles-(*E*,*Z*) ou -(*E*) (**6**-Br ^{13}C-2-(*E*,*Z*) ou -(*E*)) avec HOAc–AgOAc conduit à un mélange 1:1 des acétates d'anisyl-2 ditolyl-1,2 [^{13}C-1,2] vinyles-(*E*) et -(*Z*) (**6**-OAc ^{13}C-1,2-(*E*,*Z*)) comportant 37,4% de répartition au hasard du marqueur de la position C-2 vers C-1; cette distribution proviendrait de migrations-1,2 dégénérées des groupements anisyles qui conduisent au cation anisyl-2 ditolyl-1,2 [^{13}C-2] vinyle (**6** ^{13}C-2). On n'a pas pu mettre en évidence la présence de quantités détectables d'acétate d'anisyl-1 ditolyl-2,2 vinyle; ce résultat indique que, dans la réaction avec le HOAc–AgOAc, il ne se produit pas de migration-1,2 non-dégénérée du tolyle du cation **6** qui conduirait au cation plus stable anisyl-1 ditolyl-2,2 vinyle (**10**). La réaction du **6**-Br ^{13}C-2-(*E*) avec le trifluoro-2,2,2 éthanol (TFE), en présence de lutidine-2,6, conduit à l'éther trifluoro-2,2,2 éthylique de l'anisyl-1 ditolyl-2,2 [^{13}C-1,2] vinyle (**10**-OTFE ^{13}C-1,2) comme produit principal et à un mélange 1:1 des éthers trifluoroéthyliques des anisyl-2 ditolyl-1,2 [^{13}C-1,2] vinyles-(*E*) et -(*Z*) (**6**-OTFE ^{13}C-1,2-(*E*,*Z*)) comme produits mineurs; le rapport des produits **10**-OTFE/**6**-OTFR-(*E*,*Z*) est d'environ 80:20. La répartition au hasard du marqueur ^{13}C dans le produit majeur, **10**-OTFE ^{13}C-1,2, est d'environ 48,8 ± 0,9% alors que dans les produits mineurs, **6**-OTFE ^{13}C-1,2-(*E*,*Z*), cette valeur est d'environ 47,2 ± 1,4%. Le présent travail avec le cation **6** complète la série de travaux entrepris sur les neuf cations triarylvinyles possibles avec les diverses combinaisons de phényle (Ph), *p*-tolyle (Tol) et (ou) *p*-anisyle (An) comme les trois groupements aryles et qui peuvent donner lieu à des migrations-1,2 dégénérées de groupements aryles à travers la double liaison. On discute des résultats obtenus dans le présent travail de concert avec les données obtenues dans les travaux antérieurs avec les huit autres systèmes cationiques triarylvinyles.

[Traduit par la revue]

Introduction

The early literature on vinyl cations, including rearrangements in these cations, has been reviewed (1, 2), and more specifically, work on degenerate rearrangements in triarylvinyl cations arising from 1,2-aryl shifts across the double bond, detected with use of isotopic labels as typified by eqs. [1] and [2], has been summarized in 1980 (3).

[1] $(Ar)_2C^*{=}\overset{+}{C}Ar \rightleftarrows Ar\overset{+}{C}^*{=}C(Ar)_2$

[2] $Ar(Ar')C^*{=}\overset{+}{C}Ar \rightleftarrows Ar\overset{+}{C}^*{=}C(Ar')Ar$

In the case of eq. [2], a nondegenerate rearrangement from a less stable to a more stable vinyl cation, which may occur before and after the degenerate rearrangement, as illustrated in eq. [3], is also possible.

[3] $Ar(Ar')C^*{=}\overset{+}{C}Ar \rightleftarrows Ar\overset{+}{C}^*{=}C(Ar')Ar$

$\downarrow$ $\downarrow$

$Ar'\overset{+}{C}^*{=}C(Ar)_2$ $(Ar)_2C^*{=}\overset{+}{C}Ar'$

With various combinations of phenyl (Ph), *p*-tolyl (Tol), and (or) *p*-anisyl (An) as the three aryl groups, nine triarylvinyl cationic systems, represented by structures **1** to **9**, are capable of giving rise to degenerate 1,2-aryl shifts across the double bond. In addition, cations **2**, **3**, and **6** should also be able to give a nondegenerate 1,2-phenyl or 1,2-tolyl shift to a more stable

$(Ph)_2C{=}\overset{+}{C}Ph$	$Ph(Tol)C{=}\overset{+}{C}Ph$	$Ph(An)C{=}\overset{+}{C}Ph$
1	**2**	**3**
$Tol(Ph)C{=}\overset{+}{C}Tol$	$(Tol)_2C{=}\overset{+}{C}Tol$	$Tol(An)C{=}\overset{+}{C}Tol$
4	**5**	**6**
$An(Ph)C{=}\overset{+}{C}An$	$An(Tol)C{=}\overset{+}{C}An$	$(An)_2C{=}\overset{+}{C}An$

cation as shown in eq. [3], while with cations **4**, **7**, and **8**, only the degenerate rearrangement as given in eq. [2] should occur because a 1,2-tolyl or 1,2-anisyl shift in these latter systems would not give a more stable cation. Up to the present, some work has been done on eight of these nine triarylvinyl cationic systems (3–5). The one exception is that no degenerate or

For personal use only.

nondegenerate rearrangement studies have been made so far on the 2-anisyl-1,2-ditolylvinyl cation (**6**). In the present work, we have investigated the reaction of (*E*)- and (*Z*)-2-anisyl-1,2-ditolyl[2-^{13}C]vinyl bromides ((*E*)- and (*Z*)-**6**-Br-2-^{13}C) with HOAc–AgOAc or with 2,2,2-trifluoroethanol (TFE) in the presence of 2,6-lutidine, determined the extents of rearrangements in cation **6** generated from these reactions, and compared the results with those previously reported for other triarylvinyl cationic systems.

Results and discussion

A mixture of (*E*)- and (*Z*)-2-anisyl-1,2-ditolyl[2-^{13}C]vinyl bromides ((*E*)- and (*Z*)-**6**-Br-2-^{13}C) was prepared via a series of reactions analogous to those described for the preparation of (*E*)- and (*Z*)-2-phenyl-1,2-ditolyl[2-^{13}C]vinyl bromides ((*E*)- and (*Z*)-**4**-Br-2-^{13}C) (6). Reaction of 1,2-ditolyl[1-^{13}C]ethanone (6) with AnMgBr gave 1-anisyl-1,2-ditolyl[1-^{13}C]ethanol, which, in turn, was treated with Br_2 in HOAc to give an approximately 4:1 mixture of (*E*)- and (*Z*)-**6**-Br-2-^{13}C. After separation by fractional crystallization from absolute ethanol, the higher melting isomer was tentatively assigned the (*E*) or *trans* configuration (4, 7) and this major product, (*E*)-**6**-Br-2-^{13}C, was utilized in most of the subsequent solvolytic reactions.

An old criterion for differentiating between geometrical isomers is based on the assumption of a higher melting point for the more symmetrical isomer (7). For triarylvinyl derivatives with two identical aryl groups, the *trans* isomer would have a higher melting point. From observations of the chemical shifts in the ^{1}H nmr spectra of *cis* and *trans* pairs of triarylvinyl derivatives, it was suggested that for the lower melting *cis* isomer, the methoxy protons of an anisyl group should appear at higher field and the methyl protons of a tolyl group should appear at lower field than those for the corresponding *trans* isomer (4, 8, 9). For (*E*)- and (*Z*)-1,2-dianisyl-2-tolylvinyl bromides ((*E*,*Z*)-**8**-Br), a crystallographic study did show that the lower melting isomer with methoxy absorptions at higher fields and a methyl absorption at lower field was indeed the (*E*) or *cis* isomer (4). In the trifluoroethanolysis of (*E*)- and (*Z*)-1,2-diphenyl-2-tolylvinyl bromides ((*E*,*Z*)-**2**-Br) (5), the product with a methyl absorption at lower field was found by crystallographic study to be the expected (*Z*)- or *cis*-1,2-diphenyl-2-tolylvinyl 2,2,2-trifluoroethyl ether ((*Z*)-**2**-OTFE) (10). However, the crystal structures of *cis*- or (*Z*)- and *trans*- or (*E*)-**2**-Br showed that the lower melting isomer with methyl absorption at lower field was the *trans* isomer, opposite to predictions based on melting point and nmr (11). The present assignment of the higher melting major product with methyl absorption at higher field as *trans*- or (*E*)-**6**-Br is, therefore, only tentative. Even if this assignment were incorrect and the major product was the (*Z*) isomer, conclusions drawn from data derived from subsequent solvolytic studies should still be valid since both (*E*)- and (*Z*)-**6**-Br would give rise to the same vinyl cation **6**.

The reaction of a 4:1 mixture of (*E*)- and (*Z*)-**6**-Br-2-^{13}C or pure (*E*)-**6**-Br-2-^{13}C with HOAc in the presence of AgOAc gave an essentially 1:1 mixture of (*E*)- and (*Z*)-2-anisyl-1,2-ditolyl[1,2-^{13}C]vinyl acetates ((*E*,*Z*)-**6**-OAc-1,2-^{13}C). Some scrambling of the ^{13}C label from C-2 to C-1 was observed and this arose from 1,2-anisyl shifts in cation **6**, giving rise to (*E*,*Z*)-**6**-OAc-2-^{13}C and (*E*,*Z*)-**6**-OAc-1-^{13}C. No 1-anisyl-2,2-ditolylvinyl acetate (**10**-OAc) was formed, indicating no nondegenerate 1,2-tolyl shift in cation **6** under the acetolysis conditions. The same observation has been made previously

Tol(An)C*=C(Br)Tol
(*E*,*Z*)-**6**-Br-2-^{13}C

Tol(An)C*=C(OAc)Tol
(*E*,*Z*)-**6**-OAc-2-^{13}C

Tol(AcO)C*=C(An)Tol
(*E*,*Z*)-**6**-OAc-1-^{13}C

that, in reactions with HOAc–AgOAc, no nondegenerate rearrangement took place for (*E*)- or (*Z*)-1,2-diphenyl-2-tolylvinyl bromide ((*E*)- or (*Z*)-**2**-Br) (5) or (*E*)-2-anisyl-1,2-diphenylvinyl bromide ((*E*)-**3**-Br) (12).

Each sample of (*E*,*Z*)-**6**-OAc-1,2-^{13}C derived from the acetolysis reactions was treated twice successively (13) with $LiAlH_4$ to give a mixture of *erythro*- and *threo*-2-anisyl-1,2-ditolyl[1,2-^{13}C]ethanol (**11**-1,2-^{13}C), which was analyzed by

$(Tol)_2C{=}C(OAc)An$
10-OAc

Tol(An)C*HC*H(OH)Tol
11-1,2-^{13}C

^{13}C nmr to give the extent of scrambling of the ^{13}C label from C-2 to C-1, using the intensity ratio method with the methoxy absorption containing ^{13}C in its natural abundance as an internal standard (13). The results, as summarized in Table 1, show a remarkably reproducible extent of 37.4–37.5% scrambling for the reaction of (*E*,*Z*)- or (*E*)-**6**-Br-2-^{13}C in HOAc–AgOAc, the scrambling being the result of 1,2-anisyl shifts in cation **6**. The formation of a 1:1 mixture of (*E*)- and (*Z*)-**6**-OAc-1,2-^{13}C with the same extent of scrambling from reaction of either (*E*,*Z*)-**6**-Br-2-^{13}C or (*E*)-**6**-Br-2-^{13}C would indicate the formation of the dissociated, linear 2-anisyl-1,2-ditolylvinyl cation **6** as intermediate in these reactions, a conclusion that is in agreement with those drawn previously in support of dissociated, linear triarylvinyl cations (3–5).

In preliminary work with unlabeled material, the reaction of (*E*,*Z*)- or (*E*)-**6**-Br with 2,2,2-trifluoroethanol (TFE) in the presence of 1.2 equivalents of 2,6-lutidine gave, according to ^{1}H nmr, 1-anisyl-2,2-ditolylvinyl 2,2,2-trifluoroethyl ether (**10**-OTFE) as the major product and a 1:1 mixture of (*E*)- and (*Z*)-2-anisyl-1,2-ditolylvinyl 2,2,2-trifluoroethyl ethers ((*E*,*Z*)-**6**-OTFE) as minor products, the ratio of **10**-OTFE to (*E*,*Z*)-**6**-OTFE being about 80:20. The formation of **10**-OTFE is attributable to a nondegenerate 1,2-tolyl shift in cation **6** to give the more stable 1-anisyl-2,2-ditolylvinyl cation (**10**) analogous to the general processes illustrated in eq. [3]. This behavior is also similar to that observed previously for the trifluoroethanolysis of (*E*,*Z*)-**2**-Br (5) or (*E*)-**3**-Br (12) in which the major product was derived from a nondegenerate 1,2-phenyl shift in cation **2** or **3**.

The reaction of (*E*)-**6**-Br-2-^{13}C with TFE–2,6-lutidine gave rise to **10**-OTFE-1,2-^{13}C and (*E*,*Z*)-**6**-OTFE-1,2-^{13}C, some scrambling of the isotopic label between C-2 and C-1 being observed in both major and minor products. This mixture of products was degraded by ozonolysis to give a mixture of labeled and unlabeled ditolyl and anisyl tolyl ketones and these ketones were then analyzed by gc–ms to give the extents of scrambling of the ^{13}C label from C-2 to C-1 in both **10**-OTFE-1,2-^{13}C and (*E*,*Z*)-**6**-OTFE-1,2-^{13}C, using procedures as previously described for the determination of the extents of scrambling in the trifluoroethanolysis of (*E*,*Z*)-**2**-Br-2-^{13}C (5).

Given in Scheme 1 are the processes involved in the trifluoroethanolysis of (*E*)-**6**-Br-2-^{13}C, the ozonolysis of the solvolysis products, and the m/z values for the molecular ions and base peaks of the ketones derived from the degradation. From the gc–ms analysis, the mass spectral data in the regions

[a] I_1, I_2, and I_s are the integrated intensities of the ^{13}C nmr absorptions for C-1, C-2, and CH_3O of the anisyl group at 76.5, 59.1, and 54.1 ppm, respectively. [b] I_1^* and I_2^* are the ^{13}C enrichments at C-1 and C-2, respectively, calculated from the intensity ratios; for an illustration of the calculations, see ref. 13.

of the molecular ions and base peaks for the unlabeled and labeled anisyl tolyl ketones and ditolyl ketones are summarized in Tables 2 and 3. After correcting for $[M + 1]^+$ absorptions and for the fact that the ^{13}C enrichment in the original reactant, (*E*)-**6**-Br-2-^{13}C, was 90%, an illustration of the calculations for these corrections having been given previously (5), the relative intensities for the unlabeled anisyl tolyl ketone at *m/z* 226 and 135 gave the extent of scrambling of the ^{13}C label from C-2 to C-1 in the minor products, (*E*,*Z*)-**6**-OTFE-1,2-^{13}C, and the relative intensities for the labeled ditolyl [^{13}C]ketone at *m/z* 211 and 120 gave the extent of scrambling of the label from C-1 to C-2 in the major product, **10**-OTFE-1,2-^{13}C. It is seen that the scrambling from C-2 to C-1 in (*E*,*Z*)-**6**-OTFE-1,2-^{13}C arising from degenerate 1,2-anisyl shifts in cation **6** was 47.2 ± 1.4% (Table 2), and the scrambling in **10**-OTFE-1,2-^{13}C arising from nondegenerate 1,2-tolyl shifts that took place before and after the degenerate rearrangement was 48.8 ± 0.9% (Table 3).

The rearrangement processes in Scheme 1 are shown again in Scheme 2 with the mean % scramblings ± standard deviations given in parentheses. Since the ratio of **10**-OTFE-1,2-^{13}C to (*E*,*Z*)-**6**-OTFE-1,2-^{13}C was 80:20, in the product mixture, the relative distribution of the unrearranged **10**-OTFE-1-^{13}C and the rearranged **10**-OTFE-2-^{13}C would be 0.80(51.2 ± 0.9) = 41.0 ± 0.7% and 0.80(48.8 ± 0.9) = 39.0 ± 0.7%, respectively. Similarly, the relative distribution of the unrearranged (*E*,*Z*)-**6**-OTFE-2-^{13}C and the rearranged (*E*,*Z*)-**6**-OTFE-1-^{13}C would be 0.20(52.8 ± 1.4) = 10.6 ± 0.3% and 0.20(47.2 ± 1.4) = 9.4 ± 0.3%, respectively. These distributions are also given in Scheme 2. It is of interest to note that the ratios of **10**-OTFE-1-^{13}C/(*E*,*Z*)-**6**-OTFE-2-^{13}C, or (41.0 ± 0.7)/(10.6 ± 0.3) = 3.9 ± 0.2, and **10**-OTFE-2-^{13}C/(*E*,*Z*)-**6**-OTFE-1-^{13}C, or (39.0 ± 0.7)/(9.4 ± 0.3) = 4.1 ± 0.2, are the same within experimental error, and this finding would indicate that the extents of nondegenerate 1,2-tolyl shifts from cation **6** to the more stable cation **10** are essentially the same before and after the degenerate 1,2-anisyl shifts in cation **6**. A similar conclusion was also obtained from the data derived from the trifluoroethanolysis of (*E*,*Z*)-**2**-Br-2-^{13}C (5). Again similar to the results obtained with (*E*,*Z*)-**2**-Br-2-^{13}C (5), the formation of **10**-OTFE-2-^{13}C as observed in the present work constitutes another demonstration of the occurrence of successive 1,2-aryl shifts, since this product was derived from a 1,2-anisyl shift in cation **6**-2-^{13}C to **6**-1-^{13}C followed by a 1,2-tolyl shift to **10**-2-^{13}C. Previously, using doubly labeled substrates (14, 15), successive 1,2-aryl shifts in triarylvinyl cations have also been demonstrated.

With the present work on cation **6**, isotopic scramblings arising from degenerate 1,2-aryl shifts have been determined for all of cations **1**–**9** generated in HOAc–AgOAc. Scrambling data from reactions in TFE–2,6-lutidine are also known for most of these nine cations. These results are summarized in Table 4. In the cases for which reactions with TFE–2,6-lutidine

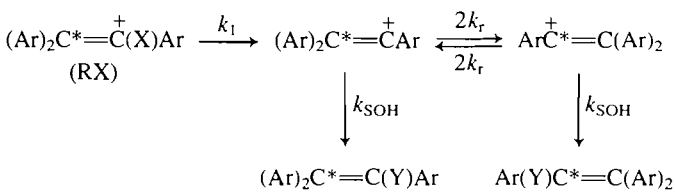
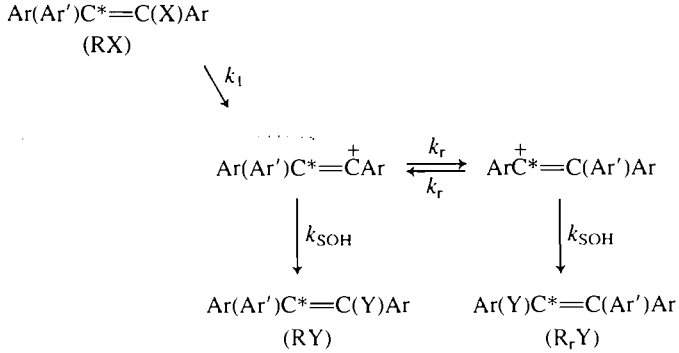
[a] $C^* = {}^{13}C$ or ${}^{14}C$; $Ph^* = C_6D_5$; $An^* = CD_3OC_6H_4$.
[b] Mean value after complete reaction, the maximum extent of scrambling between C-2 and C-1 being 50%.
[c] Calculated from eq. [4] or [5], using the mean % scrambling values.
[d] From reaction with CF_3COOH–CF_3COOAg.
[e] From the present work.
[f] From reaction with HOAc–NaOAc.
[g] This value is probably too high (4) since it would suggest a greater extent of 1,2-phenyl shift in cation **7** than the analogous 1,2-tolyl shift in cation **8**; difficulties may be due to overlapping of peaks in the analysis by ^1H nmr (19).
[h] Unpublished work of David Tsui carried out in this laboratory using ^{13}C labelling; a much lower extent of scrambling was observed than the 26.5% in the preceding entry.
[i] Reported as 35 ± 2% rearrangement (19), with 100% rearrangement corresponding to 33.3% scrambling of the labeled An* from C-2 to C-1; the 35 ± 2% rearrangement would be equivalent to about 18% scrambling, assuming the maximum scrambling between C-2 and C-1 is 50%.
[j] Reported as 100% rearrangement (19) with 33.3% scrambling of the labeled An* from C-2 to C-1, and this would be equivalent to about 50% scrambling between C-2 and C-1.



SCHEME 3

$$[4] \quad [RY]/[R_rY] = 1 + (k_{SOH}/2k_r)$$



SCHEME 4

$$[5] \quad [RY]/[R_rY] = 1 + (k_{SOH}/k_r)$$

have not been carried out, scramblings observed in reactions with CF_3COOH–CF_3COOAg are included in Table 4 as illustrations of the extents of scrambling from solvolyses in a medium of low nucleophilic character. For the scrambling processes as depicted in Scheme 3 or 4, at complete reaction, eq. [4] or [5], respectively, would apply (21). Some values of k_{SOH}/k_r, calculated from eq. [4] or [5], are included in Table 4 for those cations for which eq. [4] or [5] holds.

Some generalizations may be made from the data summarized in Table 4. First of all, it is seen that the extent of scrambling for a given cation generated from reaction in TFE–2,6-lutidine or CF_3COOH–CF_3COOAg is much greater than the corresponding scrambling for the same cation generated from reaction in HOAc–AgOAc. This is not surprising since in solvents of low nucleophilic character, such as TFE or trifluoroacetic acid (TFA) (22), the cation would have a longer lifetime, thus allowing for more 1,2-shifts and giving rise to a greater amount of scrambling. For a given set of cations that differ only in the migrating aryl group, with the aryl groups at the migration origin and migration terminus remaining the same, such as cations **1**, **2**, and **3**, **4**, **5**, and **6**, or **7**, **8**, and **9**, an increasing extent of scrambling follows the order of increasing migratory aptitude, i.e., the order in the extent of scrambling is **3** > **2** > **1**, **6** > **5** > **4**, and **9** > **8** > **7**, in accord with the expected order of migratory aptitude of An > Tol > Ph.

A more quantitative evaluation of migratory aptitudes may be made utilizing the k_{SOH}/k_r values given in Table 4 (21). For cations **1** and **2** from reactions with HOAc–AgOAc, for example, k_{SOH}/k_r may be more specifically designated as k_{SOH}/k_r^{Ph} and k'_{SOH}/k_r^{Tol}. If one were to assume that the rate constants for the capture of cations **1** and **2**, k_{SOH} and k'_{SOH}, were the same in the HOAc–AgOAc medium, then $(k_{SOH}/k_r^{Ph})/(k'_{SOH}/k_r^{Tol}) = k_r^{Tol}/k_r^{Ph} = 25/3.5 = 7.1$. Similarly, for cations **1** and **3**, $k_r^{An}/k_r^{Ph} = 25/0.16 = 156$, giving rise to relative migratory aptitudes for Ph:Tol:An of 1:7.1:156. For cations **4**, **5**, and **6**, again generated from reactions with

For personal use only.

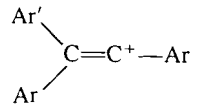
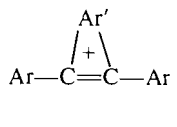
HOAc–AgOAc, $k_r^{Tol}/k_r^{Ph} = 57/11 = 5.2$, and $k_r^{An}/k_r^{Ph} = 57/0.67 = 85$, giving relative migratory aptitudes for Ph:Tol:An of 1:5.2:85. While these two sets of values do show some variations, on an energy scale, the differences are only minor. Moreover, since the calculations were based on the assumption that k_{SOH} for different cations was identical, and since the k_{SOH}/k_r values were calculated from the mean % scramblings, which may show considerable deviations, the results for the two sets of migratory aptitudes may be regarded as showing reasonable agreement.

Another comparison of the scrambling data in Table 4 may be made by keeping the migrating group the same while varying the aryl groups at the migration origin and migration terminus. From reactions with HOAc–AgOAc for which data from all nine cations are available, for cations **1**, **4**, and **7** with the same migrating Ph group, and with Ph, Tol, and An, respectively, as the α-aryl substituent, the extents of scrambling follow the order of **1** > **4** > **7**. Similarly, for cations **2**, **5**, and **8** with the same migrating Tol group, and cations **3**, **6**, and **9** with the same migrating An group, the extents of scrambling again follow the order of **2** > **5** > **8** and **3** > **6** > **9**. In each of these sets of cations, the one that gives the most or the least extent of scrambling, respectively, has an α-phenyl or an α-anisyl substituent, indicating that, other factors being equal, the more stable triarylvinyl cation gives rise to a lesser extent of scrambling. This generalization may be explained by assuming that the more stable the initial triarylvinyl cation (**12**), the lower is its energy and the higher would be the activation energy in going from **12** to transition state **13**, thus giving rise to a lesser extent of scrambling. Such an explanation has also been discussed previously (6).

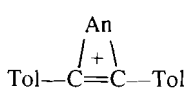


12

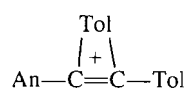


13

Finally, let us consider cations **2**, **3**, and **6**, all of which are capable of giving rise to both degenerate and nondegenerate rearrangements as depicted by eq. [3]. Summarized in Table 5 are the relative yields obtained under different conditions for the structurally unrearranged product from capture of the cation that may have undergone degenerate 1,2-aryl shifts, and the structurally rearranged product that resulted from a nondegenerate 1,2-aryl shift from a less stable to a more stable cation. It is seen from Table 5 that the relative yields of products are highly dependent on the reaction media. For all three cations, **2**, **3**, and **6**, no nondegenerate rearrangement to the more stable cation was observed for reactions in HOAc–AgOAc, while for reactions in TFE–2,6-lutidine, the major product was derived from the more stable cation resulting from a nondegenerate 1,2-aryl shift. With cation **6**, for example, the anisyl-bridged transition state **14** for the degenerate 1,2-shift may be of lower energy than the tolyl-bridged transition state **15** for the



14



15

nondegenerate 1,2-shift; thus the degenerate 1,2-shift may be a faster process than the nondegenerate 1,2-shift to give a more stable cation. However, since the nondegenerate rearrangement, such as from cation **6** to the more stable cation **10** (Scheme 1), is not likely to be readily reversible, the possibility of the nondegenerate 1,2-shift as under equilibrium control and the degenerate 1,2-shift as under kinetic control may not apply.

As suggested in our studies on cation **2** (5, 23), the nucleophilic character of the reaction medium and the lifetime of the cation in that medium may play an important role in determining whether nondegenerate 1,2-shifts would take place. In HOAc–AgOAc, the lifetime of a cation is short and only the faster degenerate 1,2-shifts could occur, while in TFE-2,6-lutidine, a medium of low nucleophilic character, the cationic lifetime is long, thus allowing a major part of the cation to proceed via slower nondegenerate 1,2-shifts to give a more stable cation. In solvents such as HOAc–H_2O and EtOH–H_2O (Table 5), the lifetime of a cation would be intermediate between the lifetimes in HOAc–AgOAc and TFE–2,6-lutidine, and only a small extent of nondegenerate 1,2-shifts could take place, resulting in the formation of only a minor amount of product derived from the more stable cation.

Experimental

1-Anisyl-1,2-ditolyl[1-^{13}C]ethanol

To a Grignard solution prepared from 9.0 g (48 mmol) of *p*-bromoanisole and 1.5 g (62 mmol) of Mg in 300 mL of dry tetrahydrofuran (THF), and cooled in an ice bath, was added dropwise and with stirring over a period of 1 h a solution of 5.4 g (24 mmol) of 1,2-ditolyl[1-^{13}C]ethanone, prepared from 90% enriched [^{13}C]$BaCO_3$ (6), in 75 mL of dry THF. The resulting material was stirred at room temperature for 1 h, heated under reflux for 2 h, and then poured into 200 mL of H_2O containing 25 g of NH_4Cl and 5 mL of concentrated NH_4OH. The organic layer was washed with H_2O (3 × 25 mL) and, after drying over $MgSO_4$, the solvent was removed under reduced pressure to give 5.2 g (77%) of 1-anisyl-1,2-ditolyl[1-^{13}C]ethanol, which was crystallized from methanol, mp 101–102°C. A similar preparation with nonlabeled material gave 1-anisyl-1,2-ditolylethanol, which also melted at 101–102°C; ^{1}H nmr δ($CDCl_3$): 2.23 (shoulder, OH), 2.23, 2.29 (6H, 2s, $2CH_3$), 3.48 (2H, s, CH_2), 3.69 (3H, s, CH_3O), 6.56–7.28 (12H, m, Ar). *Anal.* calcd. for $C_{23}H_{24}O_2$: C 83.10, H 7.28; found: C 83.59, H 7.19.

(E)- and (Z)-2-anisyl-1,2-ditolyl[2-^{13}C]vinyl bromides ((E,Z)-6-Br-2-^{13}C)

To a solution of 5.0 g (18 mmol) of 1-anisyl-1,2-ditolyl[1-^{13}C]ethanol in 50 mL of HOAc was added dropwise and with stirring 4.0 g (25 mmol) of Br_2 in 20 mL of HOAc over a period of 0.5 h. During this time, the reaction mixture was maintained below 50°C by periodic cooling in a water bath, and any HBr that was produced was flushed out with N_2. The resulting mixture was stirred overnight at room temperature and the yellow solid product that was formed was collected by filtration, then washed with 10% $Na_2S_2O_3$ solution and with H_2O. The yield of the dried product was 5.5 g (78%), consisting of an approximately 4:1 mixture of (*E*)- and (*Z*)-**6**-Br-2-^{13}C according to ^{1}H nmr. Fractional crystallization from absolute ethanol gave the pure (*E*) isomer, which was used in most of the solvolytic reactions.

The similarly prepared unlabeled (*E*,*Z*)-**6**-Br were separated by fractional crystallization from absolute ethanol to give the major product, tentatively assigned the (*E*) structure, with a higher mp of 116–117°C, and the minor product, (*Z*)-**6**-Br, mp 104–105°C. For (*E*)-**6**-Br, ^{1}H nmr δ($CDCl_3$): 2.17, 2.23 (6H, 2s, $2CH_3$), 3.75 (3H, s, CH_3O), 6.72–7.30 (12H, m, Ar). *Anal.* calcd. for $C_{23}H_{21}OBr$: C 70.23, H 5.38; found: C 70.78, H 5.49. For (*Z*)-**6**-Br, ^{1}H nmr δ($CDCl_3$): 2.25, 2.35 (6H, 2s, $2CH_3$), 3.75 (3H, s, CH_3O), 6.40–7.20 (12H, m, Ar). *Anal.* calcd. for $C_{23}H_{21}OBr$: C 70.23, H 5.38; found: C 70.79, H 5.36.

Reaction with HOAc–AgOAc

In a typical experiment, 900 mg (2.3 mmol) of (*E*)-**6**-Br-2-^{13}C and

TABLE 5. Relative yields of structurally unrearranged product, Ar(Ar′)C=C(Y)Ar, and structurally rearranged product, Ar′(Y)C=C(Ar)$_2$, from cations **2**, **3**, and **6**, Ar(Ar′)C=$\overset{+}{C}$Ar

3	80% EtOH – 20% H_2O	12	94	6
3	TFE–2,6-lutidine	12	15	85
6	HOAc–AgOAc[b]		100	0
6	TFE–2,6-lutidine[b]		20	80

[a]For **2**, Ar = Ph, Ar′ = Tol; for **3**, Ar = Ph, Ar′ = An; for **6**, Ar = Tol, Ar′ = An.
[b]From the present work.

420 mg (2.5 mmol) of AgOAc in 25 mL of HOAc containing about 5% Ac_2O were heated under reflux for 24 h. The resulting mixture was filtered and the filtrate was evaporated to dryness under reduced pressure by a rotary evaporator. The residue was redissolved in 100 mL of ether, washed with H_2O (2 × 20 mL), 5% $NaHCO_3$ (2 × 20 mL), and again with H_2O (1 × 10 mL). After drying over $MgSO_4$, the ether was removed, giving 650 mg (74%) of product the ^{1}H nmr spectrum of which showed it to be an approximately 1:1 mixture of (*E*)- and (*Z*)-**6**-OAc-1,2-^{13}C.

From a larger scale experiment with unlabeled (*E*,*Z*)-**6**-Br, fractional crystallization of the product mixture, with methanol as solvent, gave only one pure product, tentatively assumed to be (*Z*)-**6**-OAc, mp 168–169°C; ^{1}H nmr δ($CDCl_3$): 1.99 (3H, s, AcO), 2.77, 2.34 (6H, 2s, $2CH_3$), 3.75 (3H, s, CH_3O), 6.60–7.30 (12H, m, Ar). *Anal.* calcd. for $C_{25}H_{24}O_3$: C 80.61, H 6.50; found: C 80.96, H 6.48. From the ^{1}H nmr spectrum of the original product mixture, data for the other isomer, (*E*)-**6**-OAc, were deduced; δ($CDCl_3$): 2.00 (3H, s, AcO), 2.27 (6H, s, $2CH_3$), 3.79 (3H, s, CH_3O), 6.60–7.30 (12H, m, Ar). No other acetoxy or methoxy absorption was presented in the product mixture, indicating no formation of 1-anisyl-2,2-ditolylvinyl acetate (**10**-OAc).

Erythro- *and* threo-*2-anisyl-1,2-ditolyl[1,2-^{13}C]ethanol (**11**-1,2-^{13}C)*

Each sample of (*E*,*Z*)-**6**-OAc-1,2-^{13}C obtained from a reaction in HOAc–AgOAc was diluted with some unlabeled (*E*,*Z*)-**6**-OAc as carrier and then reduced twice successively with $LiAlH_4$ as previously described (13) to give **11**-1,2-^{13}C for analysis of the extent of scrambling with ^{13}C nmr (13). A second treatment with $LiAlH_4$ was necessary to ensure complete reduction of any 2-anisyl-1,2-ditolylethanone that may be present after the first $LiAlH_4$ treatment (13). Typically, from 900 mg (2.4 mmol) of (*E*,*Z*)-**6**-OAc-1,2-^{13}C, 450 mg (58%) of *erythro*- and *threo*-2-anisyl-1,2-ditolylethanol-1,2-^{13}C (**11**-1,2-^{13}C) was obtained, mp 124–126°C; ^{1}H nmr δ($CDCl_3$): 2.17 (1H, s, OH), 2.25, 2.33, 2.37 (6H, 3s, $2CH_3$, *erythro* and *threo*, 2.33 overlapping), 3.72, 3.82 (3H, 2s, CH_3O, *erythro* and *threo*), 4.26 (1H, d, J = 7.8 Hz, CH at C-2), 5.30 (1H, d, J = 7.8 Hz, CH at C-1), 6.57–7.35 (12H, m, Ar). According to the relative intensities of the CH_3O absorption at 3.72 and 3.82 ppm, the *erythro* to *threo* ratio was about 2:1, the major component being assumed to be *erythro* since this diastereomer has the An and OH as well as the two Tol groups at the *anti* orientation in the most stable conformation. Analysis of the *erythro* and *threo* mixture gave the following results: *Anal.* calcd. for $C_{23}H_{24}O_2$: C 83.10, H 7.28; found: C 83.28, H 7.24.

Reaction in TFE–2,6-lutidine

Typically, 900 mg (2.3 mmol) of (*E*)-**6**-Br-2-^{13}C in 15 mL of TFE containing 300 mg (2.8 mmol) of 2,6-lutidine in a sealed glass ampule was heated in an oil bath at 120 ± 2°C for 4 days. After cooling, the content was transferred to a round bottom flask and the excess solvent was removed by distillation under reduced pressure. The residual yellow oil was redissolved in 100 mL of ether and the solution was washed successively with H_2O (3 × 15 mL), 1 *M* HCl (1 × 10 mL), and H_2O (1 × 10 mL). After drying over $MgSO_4$, the ether was removed under reduced pressure to give 580 mg (61%) of a mixture of **10**-OTFE-1,2-^{13}C and (*E*,*Z*)-**6**-OTFE-1,2-^{13}C as an oil. Ozonolysis of this product mixture gave a mixture of labeled and unlabeled ditolyl and anisyl tolyl ketones, which was analyzed to give the isotopic scramblings by gc–ms as previously described (5).

In a larger scale experiment using unlabeled (*E*,*Z*)-**6**-Br, the ^{1}H nmr spectrum of the product mixture gave three methoxy absorptions with a major peak at δ 3.77 ppm, assigned to **10**-OTFE, and two other smaller peaks of equal intensity at 3.71 and 3.81 ppm, assigned to (*E*,*Z*)-**6**-OTFE, the ratio of **10**-OTFE to (*E*,*Z*)-**6**-OTFE being about 80:20. From fractional crystallization of the product mixture using methanol as solvent, only the major product, **10**-OTFE, was isolated as colorless crystals, mp 103–104°C; ^{1}H nmr δ($CDCl_3$): 2.25, 2.36 (6H, 2s, $2CH_3$), 3.77 (3H, s, CH_3O), 3.90 (2H, q, J = 8.4 Hz, CH_2), 6.65–7.30 (12H, m, Ar). *Anal.* calcd. for $C_{25}H_{23}O_2F_3$: C 72.80, H 5.62; found: C 72.79, H 6.65.

A ^{13}C and ^{15}N nuclear magnetic resonance study of solid ammonium thiocyanate

ROSS M. DICKSON, MICHAEL S. MCKINNON, JAMES F. BRITTEN, AND RODERICK E. WASYLISHEN[1]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received October 6, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

ROSS M. DICKSON, MICHAEL S. MCKINNON, JAMES F. BRITTEN, and RODERICK E. WASYLISHEN. Can. J. Chem. **65**, 941 (1987).

The static ^{13}C nmr powder pattern for solid ammonium thiocyanate is analyzed to obtain the ^{13}C chemical shielding anisotropy, 321 ± 7 ppm, and the $^{13}C-^{14}N$ dipolar splitting, 1295 ± 25 Hz. Slow magic angle spinning ^{15}N nmr experiments are analyzed to obtain a nitrogen chemical shielding anisotropy of 415 ± 15 ppm. The $^{13}C-^{14}N$ dipolar splitting leads to an effective C—N bond length of 1.19 ± 0.01 Å, in good agreement with the value of 1.176 Å reported from accurate X-ray and neutron crystallographic studies. In solid NH_4NCS absolute values of the average shielding constants $\sigma(N\underline{C}S)$ and $\sigma(\underline{N}CS)$ are 52 and 34 ppm, respectively. Comparison of calculated and observed $\sigma_{\parallel}{}^{d}$ values indicates that intermolecular interactions decrease the ^{13}C and ^{15}N shielding constants by approximately 10 and 30 ppm, respectively.

ROSS M. DICKSON, MICHAEL S. MCKINNON, JAMES F. BRITTEN et RODERICK E. WASYLISHEN. Can. J. Chem. **65**, 941 (1987).

Dans le but de déterminer l'anisotropie du blindage chimique du ^{13}C, 321 ± 7 ppm, ainsi que le couplage dipolaire $^{13}C-^{14}N$, 1295 ± 25 Hz, on a analysé le patron de poudre de la rmn ^{13}C statique du thiocyanate d'ammonium. On a aussi analysé des expériences des tournoiement lent de l'angle magique en rmn du ^{15}N pour obtenir l'anisotropie de blindage chimique de l'azote, 415 ± 15 ppm. Le couplage dipolaire $^{13}C-^{14}N$ conduit à une longueur réelle de la liaison C—N de 1,19 ± 0,01 Å; cette valeur est en bon accord avec la valeur de 1,176 Å qui a été obtenue par des études précises faites par diffraction des rayons-X et des neutrons. À l'état solide, les valeurs absolues des constantes moyennes de blindage $\sigma(N\underline{C}S)$ et $\sigma(\underline{N}CS)$ sont respectivement 52 et 34 ppm. Une comparaison des valeurs calculées et observées pour $\sigma_{\parallel}{}^{d}$ indique que les interactions intermoléculaires diminuent les constantes de blindage ^{13}C et ^{15}N par des valeurs respectives de 10 et 30 ppm.

[Traduit par la revue]

Introduction

Static powder lineshapes contain, in theory, information on all solid-state carbon-13 nmr interactions: chemical shielding anisotropy (CSA), dipole–dipole couplings (DD), and indirect couplings (J) (1–3). The principal challenge in powder nmr is to extract these observables from a powder spectrum or to devise ingenious experiments that allow one to separate these interactions so that they can be observed individually (1–10).

In this study we present a simple analysis of the static spin-1/2 powder pattern that results when the spin-1/2 nucleus has an axially symmetric CSA and is dipolar coupled to a quadrupolar nucleus (I = 1). The analysis is applied to the ^{1}H decoupled ^{13}C nmr powder spectrum of solid ammonium thiocyanate, NH_4NCS (Fig. 1). The ^{13}C chemical shielding anisotropy for this simple ion has not been previously reported. Also, the C—N bond length that we calculate from the observed dipolar coupling can be compared with values obtained from accurate X-ray and neutron diffraction measurements (11). Previously, Kaplan *et al.* (12) carried out a similar analysis for the cyano carbon of solid acetonitrile at 83 K; however, to our knowledge details of the analysis have not been presented. Carbon-13 nmr spectra of the cyano group in a single crystal of $K_2Pt(CN)_4Br_{0.3}\cdot 3H_2O$ have been presented by Stoll *et al.* (13). As well, Ripmeester *et al.* (14) have used ^{13}C nmr to study a single crystal of the acetonitrile–hydroquinone clathrate.

In the present study we have also obtained natural abundance ^{13}C and ^{15}N nmr spectra of NH_4NCS by magic angle spinning (MAS) and cross-polarization (CP) techniques (1–3). The observed ^{13}C nmr spectrum was an asymmetric doublet and was analyzed using known procedures (14–19). The spinning sidebands observed in the ^{15}N nmr spectra of NH_4NCS obtained with slow MAS were analyzed to obtain the ^{15}N CSA using the graphical procedure of Herzfeld and Berger (20). The values of σ (^{13}C and ^{15}N) obtained here for the thiocyanate ion are compared to the corresponding values observed for other linear molecules with a C_∞ axis (21, 22). The importance of these shielding constants in defining an absolute shielding scale is discussed. On an absolute shielding scale the bare nucleus has a shielding constant of zero.

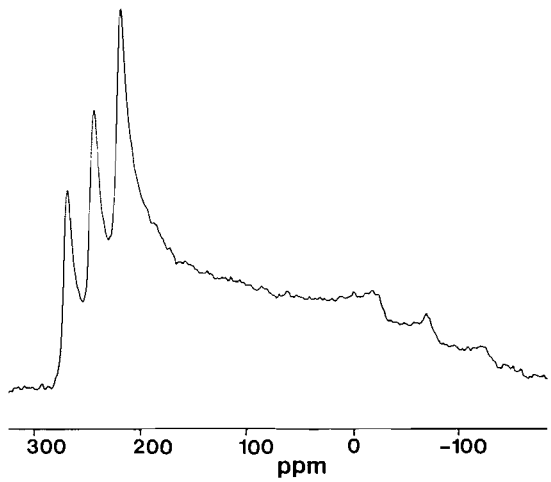

FIG. 1. Static carbon-13 powder spectrum of solid NH_4NCS obtained with high-powered proton decoupling and cross-polarization.

Experimental

Natural abundance ^{13}C and ^{15}N nmr spectra of NH_4NCS were obtained at 50.323 and 20.300 MHz, respectively, using a Bruker MSL-200 spectrometer (B_0 = 4.70 T). Powder samples (≈0.5 g) were packed into aluminum oxide rotors and all spectra were recorded at 20°C with high-power proton decoupling and cross-polarization using the Hartmann–Hahn match. Proton and ^{13}C 90° pulse widths were

4 μs. The static ^{13}C spectrum in Fig. 1 was obtained with 48 K scans using a contact time of 10 ms and a recycle time of 5 s. The acquisition time was 0.041 s and a sensitivity enhancement corresponding to 100-Hz line broadening was applied before Fourier transformation. Carbon-13 chemical shifts were referenced with respect to external adamantane, which has shifts of 38.56 ppm ($\underline{C}H_2$) and 29.50 ppm ($\underline{C}H$) with respect to TMS (23).

Carbon-13 MAS spectra were obtained with acquisition times of 0.205 s and recycle times of 4 s. Similarly the ^{15}N MAS spectra were acquired with 10 ms contact time and 5 s recycle delay. Proton ^{15}N 90° pulse widths were 5 μs. All spectra were obtained at ambient temperature.

Spectral simulations were done with FORTRAN 5 computer programs run on a CDC Cyber 170/730 operating under NOS 2.2. The program used to simulate the carbon–nitrogen dipolar splitting in the CP-MAS ^{13}C nmr spectrum was adapted from ref. 17*c*.

Results and discussion

(a) The static ^{13}C nuclear magnetic resonance spectrum

Here we briefly outline the theory necessary to analyze the ^{13}C nmr spectrum shown in Fig. 1. For the ^{13}C spin of the thiocyanate ion, three basic interactions must be considered: the Zeeman interaction, the chemical shielding anisotropy, and the ^{13}C–^{14}N dipolar interaction. The carbon (I) spin Hamiltonian is given in eq. [1] (24):

$$[1]\quad h^{-1}\hat{H}_C = -\nu_C[1 - \sigma_{iso} + \Delta\sigma(1/3 - \cos^2\theta)]\hat{I}_z + R[(1 - 3\cos^2\theta)\hat{I}_z\hat{S}_z - (3\sin\theta\cos\theta)\hat{I}_z\hat{S}_x]$$

with

$$\nu_C = (\gamma_C/2\pi)B_0, \qquad R = \frac{\gamma_C\gamma_N\hbar}{2\pi}\left\langle\frac{1}{r^3}\right\rangle\left(\frac{\mu_0}{4\pi}\right)$$

and θ being the angle between the C—N bond (ion symmetry axis) and the static magnetic field B_0. Here r is the C—N bond length, γ_C and γ_N are the magnetogyric ratios of carbon and nitrogen respectively, $\Delta\sigma = \sigma_\parallel - \sigma_\perp$ is the chemical shielding anisotropy, and $\sigma_{iso} = (2\sigma_\perp + \sigma_\parallel)/3$. All other symbols have their usual meanings. Note that in Fig. 1, the ^{13}C nmr spectrum of NH_4NCS appears on a chemical shift axis, δ, where by definition δ = 0 ppm is the isotropic chemical shift of TMS.

If we use the Zeeman states for the nitrogen spins (S), then we obtain three carbon transitions, one corresponding to each nitrogen state:

$$\nu_{+1} = \nu_C(1 - \sigma_{iso}) + (\nu_C\Delta\sigma/3 - R)(1 - 3\cos^2\theta)$$

$$[2]\quad \nu_0 = \nu_C(1 - \sigma_{iso})$$

$$\nu_{-1} = \nu_C(1 - \sigma_{iso}) + (\nu_C\Delta\sigma/3 + R)(1 - 3\cos^2\theta)$$

This gives rise to a powder pattern that is simply a sum of three axially symmetric CSA powder patterns, which may be individually simulated as described by Mehring (1). When $\Delta\sigma \geq 3R$, it appears as in Fig. 2. If we define the zero of frequency to be $\nu_C(1 - \sigma_{iso})$, the extrema of each powder pattern are at

$$\nu_{+1}: \nu_C\Delta\sigma/3 - R \quad \text{and} \quad -2\nu_C\Delta\sigma/3 + 2R$$

$$[3]\quad \nu_0 : \nu_C\Delta\sigma/3 \quad \text{and} \quad -2\nu_C\Delta\sigma/3$$

$$\nu_{-1}: \nu_C\Delta\sigma/3 + R \quad \text{and} \quad -2\nu_C\Delta\sigma/3 - 2R$$

corresponding to θ = 90° and θ = 0°, respectively. As illustrated in Fig. 2, this would allow one to read $\Delta\sigma$ and R directly from the powder pattern.

The assumption in this analysis that Zeeman spin functions describe the nitrogen spin states is not necessarily valid. If the

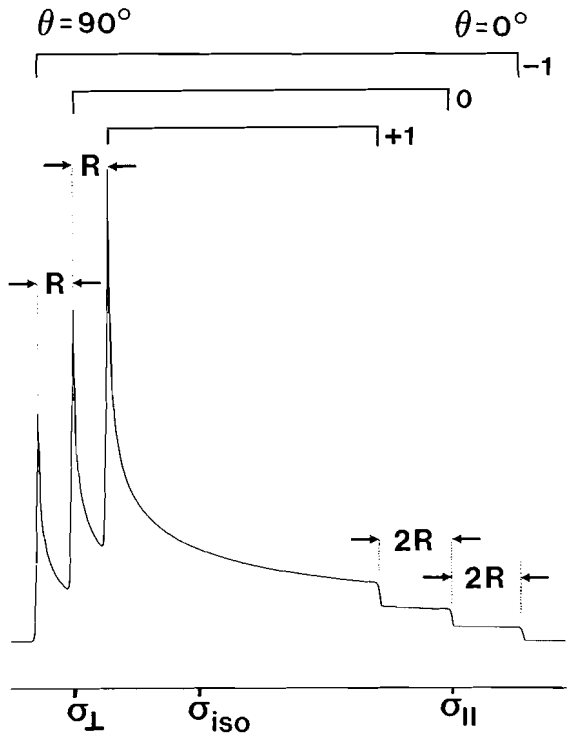

FIG. 2. Simulated NH_4NCS carbon-13 static powder pattern. The extrema of the three components arising from the three nitrogen-14 spin states (−1, 0, +1) are indicated. The nitrogen quadrupolar perturbation on the carbon dipolar Hamiltonian has not been considered in this simulation.

^{14}N quadrupole coupling constant is not negligible compared to the ^{14}N Larmor frequency, then linear combinations of Zeeman spin functions must be used, and the expectation value for $\hat{S}_z$ depends on the orientation of the nitrogen electric field gradient in the static magnetic field. This expectation value can be calculated from the eigenvectors of the ^{14}N Hamiltonian matrix, which is constructed from eq. [4] using a basis set of Zeeman spin functions (14).

$$[4]\quad \hat{H}_N = -\gamma_N\hbar B_0\hat{S}_z + (3/4)e^2qQ\{[\hat{S}_z^2 - (1/4)[\hat{S}_+\hat{S}_- + \hat{S}_-\hat{S}_+]](\cos^2\theta - 1/3) + (1/4)[\hat{S}_+^2 + \hat{S}_-^2]\sin^2\theta + (1/4)[\hat{S}_+\hat{S}_z + \hat{S}_z\hat{S}_+ + \hat{S}_-\hat{S}_z + \hat{S}_z\hat{S}_-]\sin(2\theta)\}$$

This equation assumes axial symmetry of the electric field gradient at the nitrogen nucleus, a reasonable approximation since the measured asymmetry of the ^{14}N quadrupole coupling is 0.0296 (25). For the singularity at θ = 0°, we find the Zeeman states are unmixed since the electric field gradient tensor is aligned with the Zeeman interaction, and so the shoulders of the powder pattern (Fig. 2) are separated by $2R$ irrespective of the nitrogen quadrupole coupling. For the singularity at θ = 90°, the expectation value of $\hat{S}_z$ varies with the ratio, Z/A, the magnitude of the Zeeman interaction to the quadrupole interaction, as shown in Fig. 3: $Z = \gamma_N B_0/2\pi$ and $A = e^2qQ/h$. This expectation value directly scales the splitting of the 90° peaks in the ^{13}C powder pattern in Fig. 2. Thus we can see that when $Z \geq 2A$, this splitting is very nearly R. In the present experimental case, $Z/A = 6.3$, hence the expectation value of $\hat{S}_z$ is greater than 0.998, and so the 90° splitting is $\geq 0.998R$.

From Fig. 1 we find the ^{13}C chemical shielding anisotropy

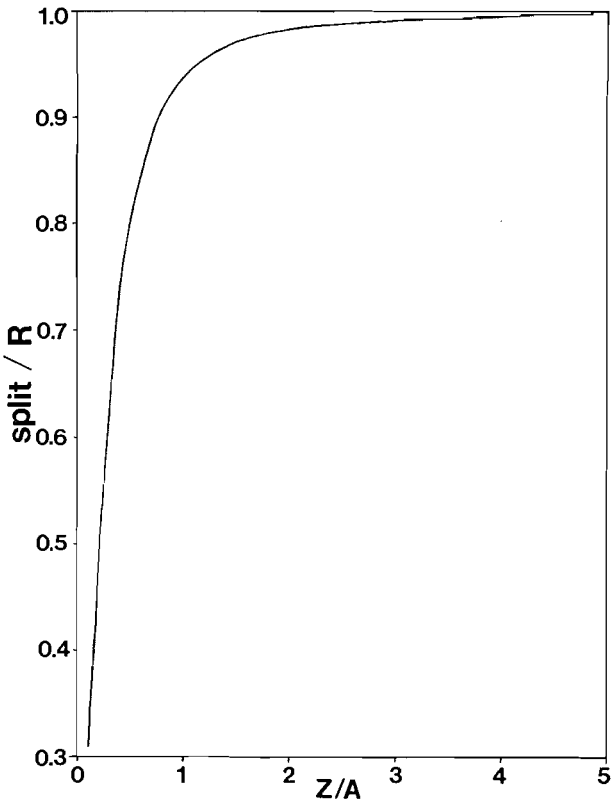

FIG. 3. Apparent dipolar splitting in the singularities corresponding to $\theta = 90°$ in the powder pattern in Fig. 2 as a function of the relative sizes of the nitrogen-14 Zeeman and quadrupole interactions.

in NH_4SCN is 321 ± 7 ppm and the isotropic chemical shift, $\delta_{iso} = 133$ ppm. This value of $\Delta\sigma$ is comparable to the results of Beeler *et al.* (21) on linear neutral molecules. The isoelectronic OCS has $\Delta\sigma = 365$ ppm. Moreover, for NH_4NCS, $\delta_{\parallel} = 133$ ppm − (2/3)321 ppm = −81 ± 5 ppm is quite close to the −90 ppm value reported by Beeler *et al.* for $\delta_{\parallel}$ in six linear molecules. See part (*c*) below for further discussion.

The apparent dipolar coupling constant $R = 1295 \pm 25$ Hz allows the calculation of an effective C—N bond length, $r_{CN} = 1.190 \pm 0.008$ Å. The lower limit on the bond length determined in the present study, 1.182 Å, is only 0.006 Å longer than the value of 1.176 ± 0.001 Å determined by neutron diffraction (11). There are several factors that could account for the small discrepancy noted here and these will be discussed below.

1. Since the neutron diffraction measurements were carried out at 81 K (11) and the nmr powder pattern was obtained at 293 K, the dipolar splitting should be corrected for librational motion (26–29). Motion of the linear thiocyanate ion at 293 K will partly average the dipolar interaction and reduce the dipolar splitting by a factor of approximately $(3\cos^2\delta - 1)/2 \simeq (2 - 3\delta^2)/2$ where δ^2 is the mean-square libration angle (14). The reduction in R leads to an apparent internuclear separation that is too large. One can estimate δ^2 from the known temperature dependence of the principal components of the ^{14}N quadrupolar coupling tensor (25). Using the procedure of Barten (30*a*), we estimate $\delta_x^2 = \delta_y^2 \simeq 5 \times 10^{-3}$ rad^2, which results in a corrected value for R of 1305 Hz ($r = 1.187 \pm 0.008$ Å).

2. A second source of error in the nmr method is the neglect of indirect nuclear spin–spin coupling in the above analysis. The indirect nuclear spin–spin interaction arises through a polarization mechanism involving the electrons; it is anisotropic and expressed by a second rank tensor (1, 31). In the case of a linear molecule or ion, the splitting between the $m = 0$ and $m = \pm 1$ peaks (Fig. 2) becomes $\pm(2R - J_{\parallel})$ for $\theta = 0°$ and approximately $\pm(R + J_{\perp})$ for $\theta = 90°$ (14). If $J_{\perp}(^{14}N,^{13}C) = -40$ Hz then the corrected value of R would be 1345 ± 25 Hz; hence $r = 1.176 \pm 0.008$ Å. In general, the average value of one-bond $^{14}N,^{13}C$ indirect spin–spin couplings rarely exceeds ±20 Hz (32–35); however, it is possible that the magnitude of the principal components of the J tensor could be substantially larger. For example, in the case of the acetonitrile–hydroquinone clathrate Ripmeester *et al.* (14) have suggested that $J_{\parallel}(^{14}N,^{13}C) = 301 \pm 20$ Hz and $J_{\perp}(^{14}N,^{13}C) = -130 \pm 11$ Hz. Studies of acetonitrile in partially oriented systems indicate anisotropies in $^1J(^{14}N,^{13}C)$, $\Delta J = J_{\parallel} - J_{\perp}$, of 144 ± 78 Hz (36). Molecular orbital calculations suggest that $\Delta J(^{14}N,^{13}C)$ in acetonitrile is less than 40 Hz (36, 37). In summary, it is very difficult to obtain reliable values of indirect coupling constant anisotropies (38, 39); this is clearly illustrated in a recent study by Jokisaari *et al.* (39).

3. Finally, it is important to note that diffraction studies and nmr measure two different averages. The diffraction measurements measure $\langle r \rangle$ while the dipolar coupling depends on $\langle r^{-3} \rangle^{-1/3}$ (29, 40).

Clearly the small discrepancy in r determined by neutron diffraction and ^{13}C nmr can readily be accounted for by correcting the observed dipolar splitting for librational motion of the thiocyanate ion, and by considering the possible influence of indirect spin–spin coupling.

Concerning the motion of the thiocyanate ion, it has been reported that in solid KSCN the SCN^- ion is undergoing rapid overall reorientation at room temperature (41). This suggestion was based on the observation of a relatively sharp, ≃10 ppm, ^{13}C nmr spectrum obtained from a static sample. We have been unable to reproduce this observation and propose that the line narrowing resulted from water-solvated NCS^- ions on the surface of KSCN, which is very hygroscopic. The earlier suggestion of rapid reorientation of the thiocyanate ion in solid KSCN is also incompatible with the structure determined by X-ray diffraction (42).

(b) Magic angle spinning experiments

(i) ^{13}C nuclear magnetic resonance

The observed CP-MAS ^{13}C nmr spectrum of NH_4NCS is shown in Fig. 4*a*. The isotropic shift is 133.1 ± 1 ppm from TMS, very similar to the value in aqueous solution, 133.8 ppm (43). The observed doublet (splitting 199 ± 10 Hz) is caused by residual dipolar splitting arising from the large ^{14}N quadrupole interaction described above. Under conditions where the quadrupolar interaction may be treated as a perturbation of the Zeeman interaction, the magnitude of the splitting observed in the MAS spectrum is directly proportional to e^2qQ/h and R, but inversely proportional to the square of the strength of the applied field B_0. This phenomenon has been observed by numerous workers and is well understood (14–19).

The spectrum in Fig. 4*b* was calculated using the method of Hexem (17) with $B_0 = 4.70$ *T*, $e^2qQ/h = 2.284$ MHz, $\eta_Q = 0.0296$ (25). A splitting of 199 ± 10 Hz was calculated with $r_{CN} = 1.16 \pm 0.02$ Å. Although the calculated spectrum reproduces the gross features of the observed spectrum, the detailed line shape of the low frequency peak is not in good agreement with experiment. The calculated peak centred at approximately −100 Hz is actually a doublet when more

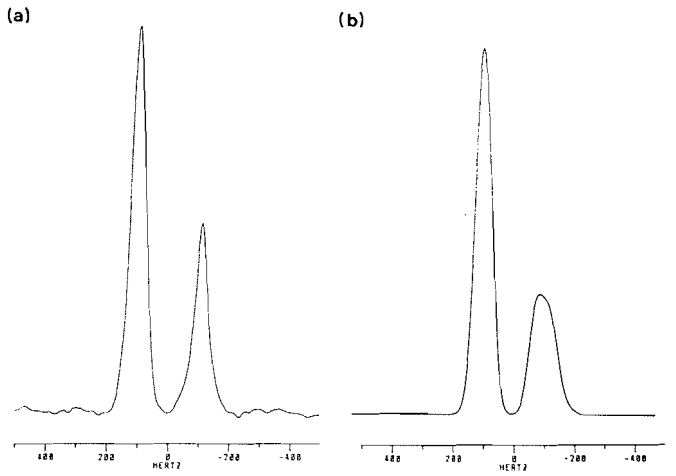

FIG. 4. (*a*) CP-MAS carbon-13 nmr spectrum of NH_4NCS, rotating at 3.6 kHz. (*b*) Simulated lineshape with 50-Hz Gaussian broadening.

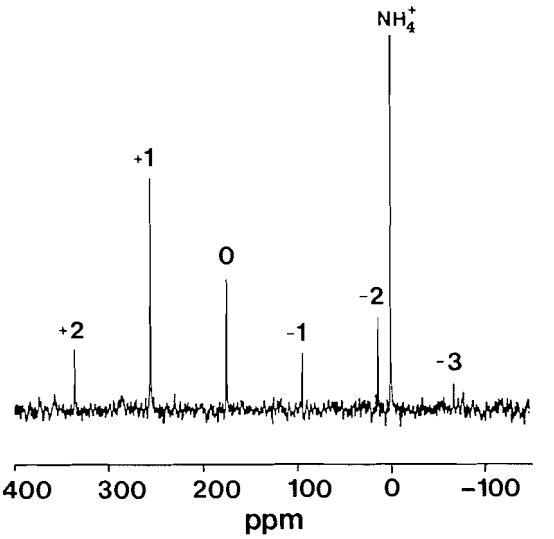

FIG. 5. CP-MAS nitrogen-15 nmr spectrum of NH_4NCS, rotating at 1.63 kHz.

realistic Gaussian line broadenings of 15–30 Hz are applied. Since our simulation program reproduces the calculated spectra of several other groups (for example, refs. 14, 16, 17) we are confident in the calculated spectrum. However, it is important to point out that the calculated spectrum does not take into account indirect spin–spin coupling. In the high field limit the MAS ^{13}C resonance will be a 1:1:1 triplet with splitting equal to $(J_{\parallel} + 2J_{\perp})/3$. Depending on the sign and magnitude of J it is possible that the low frequency portion of the spectrum might be influenced to a greater extent than the high frequency portion. This is the only explanation that we have for the sharp low frequency component observed in Fig. 4*a*. Initially we thought that the principal component of the nitrogen electric field gradient tensor might not be colinear with the C—N dipolar axis; however, this is inconsistent with the small observed asymmetry parameter, $\eta = 0.030$, obtained from nqr (25), and the nearly cylindrical symmetry of the electron density about the C—N bond (11). We did carry out line shape calculations varying the angle, β, between eq_{zz} and r_{CN}. The line shape is essentially independent of β for angles between 0° and 15°; the main effect of increasing β is to decrease the large splitting (see Fig. 6 of ref. 17*b*). Also, we found the ^{13}C MAS line shape to be very dependent on the angle between the spinning axis and B_0, as predicted by the calculations of Zumbulyadis *et al.* (16). The magic angle was adjusted by mixing KBr with NH_4NCS and using the ^{79}Br resonance of KBr as described by Frye and Maciel (44).

It is interesting to note that the observed splitting in the CP-MAS ^{13}C spectrum is directly proportional to e^2qQ/h, while the splittings in the static spectrum for $\theta = 0°$ and 90° are independent and almost independent, respectively, of e^2qQ/h. Therefore if one wishes to obtain an estimate of the ^{14}N quadrupole coupling constant from a ^{13}C spectrum it is desirable to have both the static and the MAS spectrum.

(ii) ^{15}N nuclear magnetic resonance

The CP-MAS ^{15}N spectrum of NH_4NCS, rotating at 1.63 kHz, is shown in Fig. 5. The ^{15}N resonance corresponding to the thiocyanate nitrogen is centered at 174.9 ppm to high frequency of that due to the ammonium ion in NH_4NCS. This difference in ^{15}N chemical shifts is in excellent agreement with the observations of Ratcliffe *et al.* (45). The large intensity of the spinning sidebands observed for the thiocyanate nitrogen indicates that the ^{15}N CSA (in Hz) is large compared to the rate of sample spinning. As described in Herzfeld and Berger (20), one can use the intensities of these sidebands to determine the ^{15}N CSA. Analyzing the intensities measured at 1.63 kHz and at 3.02 kHz we obtain $\Delta\sigma = \sigma_{\parallel} - \sigma_{\perp} = 415 \pm 15$ ppm. An independent estimate of the ^{15}N shielding anisotropy was also obtained from a static powder pattern. The singularity corresponding to $\sigma_{\perp}$ was 311 ± 10 ppm to high frequency of the ammonium ion resonance, or 136 ± 10 ppm from σ_{iso}, so $\Delta\sigma = 3(136 \pm 10 \text{ ppm}) = 408 \pm 30$ ppm. The poor signal-to-noise ratio precluded direct measurement of the low frequency singularity.

From the ^{15}N nmr powder pattern observed for the ammonium ion resonance we estimate $\Delta\sigma \leqslant 10$ ppm.

We have referenced the ^{15}N chemical shifts of solid NH_4NO_3 with respect to those of external NH_3 (liq.) at 298 K. The ammonium ion resonance in NH_4NO_3 is 23.8 ± 0.3 ppm to high frequency of that in liquid ammonia, thus $\delta_{iso}(\underline{N}H_4NCS) = 36.1$ ppm and $\delta_{iso}(NH_4\underline{N}CS) = 211.0$ ppm (45). Note $\delta_{iso}(NH_3(liq.)) = 0$ (33). In a saturated aqueous solution of KNCS, $\delta(\underline{N}CS) = 211.9$ ppm (34).

(c) ^{13}C and ^{15}N chemical shielding in molecules of C_{∞} symmetry

In Ramsey's theory (46), total chemical shielding at a nucleus may be expressed as a sum of diamagnetic and paramagnetic parts, eq. [5].

$$[5] \quad \sigma = \sigma^d + \sigma^p$$

The diamagnetic term depends on only the ground state electronic wavefunction and can be accurately calculated using molecular orbital theory or the approximate method devised by Gierke and Flygare (47). The paramagnetic term depends on both the ground and excited electronic states and consequently is much more difficult to calculate using molecular orbital theory. Fortunately, σ^p is closely related to the spin-rotation tensor, which can, in principle, be obtained from molecular beam measurements (48, 49).

Using the procedure outlined above, absolute chemical shielding scales have been derived for both carbon and nitrogen (50, 22). The carbon shielding scale is based on the absolute value derived for carbon monoxide, $\sigma_{iso}(CO) = 3.2 \pm 0.3$ ppm (50*c*,*d*). Using this shielding constant and the observed ^{13}C chemical shift of carbon monoxide with respect to TMS, the absolute value of $\sigma_{iso}(TMS)$ is 185.4 ppm (50*b*). Similarly, an

TABLE 1. Experimental and calculated carbon shielding constants in a series of linear triatomics

Molecule	Experimental[a]		Calculated	
	$\sigma_\perp$	$\sigma_\parallel$	$\sigma_\parallel{}^{d\,b}$	$\sigma_\parallel{}^{d\,c}$
OCO	−59.6	275.4	284.2	296.5
OCS	−89.6	275.4	286.7	298.9
SCS	−146.6	277.4	290.5	301.3
NCS^-	−55.0	266.0	—	296.7

[a]Reference 21, except for NCS^- (this study).
[b]Reference 53.
[c]Calculated using the method described in refs. 47–49; bond lengths used in the Flygare calculations: OCO: 1.163 Å; SCS: 1.553 Å; OCS: 1.157 Å; OCS: 1.560 Å; NCS$^-$: 1.176 Å; NCS$^-$: 1.649 Å.

absolute nitrogen shielding scale has been derived that leads to an absolute nitrogen shielding in liquid ammonia (300 K), σ_{iso} = 244.6 ppm (22).

It is interesting that for a nucleus in a linear molecule the paramagnetic contribution to shielding along the symmetry axis is zero (51, 52), i.e., $\sigma_\parallel{}^p = 0$; therefore the parallel component of the shielding anisotropy is given by $\sigma_\parallel{}^d$. If $\sigma_\parallel{}^d$ can be accurately calculated, an absolute shielding scale can also be derived from an experimental determination of $\Delta\sigma = \sigma_\parallel - \sigma_\perp$, via eq. [6].

$$[6] \quad \sigma_{iso} = (3\sigma_\parallel{}^d - 2\Delta\sigma)/3$$

In Table 1 we have compared absolute values of $\sigma_\perp$(C) and $\sigma_\parallel$(C) obtained here for NCS^- with those recently reported for several related linear molecules (21). Also in Table 1 calculated values of $\sigma_\parallel{}^d$ obtained from the *ab initio* calculations of Amos and Battaglia (53) are compared with those calculated using the method of Gierke and Flygare (47–49). Unfortunately, *ab initio* calculated values of σ^d for the NCS^- ion are unavailable in the literature. There are a number of features of Table 1 that deserve comment:

1. The observed values of $\sigma_\perp$ in these related molecules show considerable variation while the observed values of $\sigma_\parallel$ show little variation. The value of $\sigma_\parallel$ for the NCS^- ion is within 12 ppm of the corresponding values observed for other triatomics.

2. The observed values of $\sigma_\parallel{}^d$ are 9–13 ppm smaller than *ab initio* calculated values. This difference must arise in part from intermolecular interactions in the solid state (54, 55). The calculated values of course pertain to isolated molecules.

3. The approximate values of $\sigma_\parallel{}^d$ we calculate using the method of Gierke and Flygare are uniformly about 12 ppm larger than the *ab initio* values.

In the case of linear nitrogen-containing molecules one also finds a very small variation in *ab initio* calculated $\sigma_\parallel$ (N) values (56, 57). For N_2, HCN, and ONN the calculated values are 338.8, 336.9, and 342.0 ppm respectively (56). Similarly for N_2, HCN, ONN, and SCN^- the method of Gierke and Flygare (47–49) gives 349, 348, 349, and 350 ppm, respectively. Again the method of Gierke and Flygare consistently gives values which are 7–10 ppm too large. The value of $\sigma_\parallel$ that we observe for SCN^- in this study, $\sigma_{iso} + 2/3(\Delta\sigma) = 34 + 2/3\,(415) =$ 311 ppm, is about 30 ppm smaller than the value expected from *ab initio* calculations. As found above for the ^{13}C shielding constants, intermolecular interactions on the ^{15}N shielding constant are most likely responsible for this discrepancy.

If observed $\sigma_\parallel$(C) and $\sigma_\parallel$(N) values are to be used in establishing better absolute shielding scales, it would appear from this study that some effort must be made to account for the influence of intermolecular effects (50*a*, 51, 54, 55).

Acknowledgements

We wish to thank Dr. J. A. Ripmeester for his interest in this study, and the Natural Sciences and Engineering Research Council of Canada for financial support in the form of an undergraduate summer research scholarship (R.M.D.), a post-doctoral fellowship (M.S.M.), and operating and equipment grants (R.E.W.). High performance liquid chromatography as an analytical tool for the determination of sulfate in coconut and caffeine in tea

RASIAH S. RAMAKRISHNA, M. DIAS, S. PALAMAKUMBURA, AND M. JEGANATHAN

Centre for Analytical Research and Development, Chemistry Department, University of Colombo, Colombo, 3 Sri Lanka

Received October 21, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

RASIAH S. RAMAKRISHNA, M. DIAS, S. PALAMAKUMBURA, and M. JEGANATHAN. Can. J. Chem. **65**, 947 (1987).

The need for a rapid method for detecting sulphate sulphur in coconut and caffeine in manufactured tea initiated a study to compare high performance liquid chromatography with classical methods. We compare the methods in their applicability in rapid and selective analysis of coconut water, plant tissues, and soil, as well as of caffeine in tea samples from different regions. We present a statistical correlation between the methods and discuss the significance of our results.

RASIAH S. RAMAKRISHNA, M. DIAS, S. PALAMAKUMBURA et M. JEGANATHAN. Can. J. Chem. **65**, 947 (1987).

La nécessité d'avoir une méthode rapide pour déterminer le soufre à l'état de sulfate dans la noix de coco et la caféine dans le thé manufacturé nous a amené à comparer la chromatographie liquide à haute performance (CLHP) et les méthodes classiques. On a comparé les méthodes pour leurs facilités relatives d'application dans des analyses rapides et sélectives de l'eau de coco, des tissus de plantes et des sols ainsi ainsi que de caféine dans des échantillons de thé provenant de diverses régions. On présente une corrélation statistique entre les méthodes et on discute de la signification des résultats obtenus.

[Traduit par la revue]

Introduction

The Centre for Analytical Research and Development, CARD, established in 1980, at the University of Colombo, Sri Lanka, resulted from a collaborative project with the Trace Analysis Research Centre, TARC, Dalhousie University, Canada. The primary objective of the project has been using analytical chemistry in research of relevance to development efforts in Sri Lanka. Projects of importance to agriculture, industry, mineral resources development, food, nutrition, and environmental studies have been carried out. This paper reports the development and use of high performance liquid chromatography (hplc) in the analysis of sulfate sulphur in coconut, and caffeine in tea, both of which are national export commodities.

The recent change from ammonium sulphate to urea as fertilizer for coconut in Sri Lanka required studies of the sulphur status in coconut, since sulphur deficiency in coconut plants manifests characteristic symptoms (1–3). Conventional methods, such as gravimetry, turbidimetry and titrimetry, are tedious and time consuming, and are subject to operator error. A high performance liquid chromatographic procedure was found to be rapid and selective for routine determinations of SO_4^{2-}, and to allow simultaneous determinations of Cl^- and NO_3^- ions, of significance to studies of nutrient status. Correlation between classical methods, hplc, and the use of hot water as an extractant were also investigated along with the inter-method variability.

Several classical and spectrophotometric methods have been used for the quantitative estimation of caffeine in "manufactured tea" (4–12). The use of liquid chromatography enables more rapid estimation. Excess polyphenolic compounds, as found in tea, cause "peak broadening" (13). Both polyphenolic compounds and caffeine absorb strongly at 270 nm (14), the optimum wave length for caffeine in the hplc detector.

The reproducibility of hplc analyses of caffeine is improved if the polyphenolic material is removed from the tea extract using polyvinylpyrrolidone (PVP) as an adsorbent. The analysis of caffeine using hplc on chloroform extracts of tea, hplc on water extracts of tea following PVP pre-column treatment to remove polyphenolic material, and the modified Smith Conacher Rees' (S.C.R.) spectrophotometric method (9) were investigated. Statistical inter-method comparisons were also discussed.

Experimental

Apparatus

Spectrophotometer: A "MSE spectroplus-D" incorporating a grating monochromator was used with 1-cm matched silica cells. A Waters hplc system with a model-450 variable wavelength detector was used, along with a model-6000 A isochromatographic pump (flow rate, 2 cm^3/min at 2000–2500 psi) and a solvent programmer with gradient elution. The sample injection system consisted of a model U-6K injector (100 μL injection volume). The columns consisted of two Vydex anion exchange columns for estimation of sulphate sulphur and a Waters C_{18}μ Bondapak reverse phase analytical column, together with a polyvinylpyrrolidone (PVP) pre-column (10 cm × 0.2 cm) containing 150 mg of washed PVP and pH adjusted to 3.5 for optimum performance for the estimation of caffeine.

The mobile phases consisted of (*i*) 10^{-2} *M* phthalic acid — sodium borate solution at pH 6 for the estimation of sulphate sulphur and (*ii*) 30% methanol and 70% deionised distilled water, adjusted to pH 3.5 with glacial acetic acid, filtered through Whatman-40 filter paper and degassed in an ultrasonic bath, for the estimation of caffeine.

The variable wavelength detector was set at 254 nm for the estimation of sulphate sulphur, and at 270 nm for caffeine.

Estimation of sulphate sulphur in coconut

Rain water

Rain water (200 cm^3) was reduced to 10 cm^3 in a silica dish on a sand bath, transferred to a 25-cm^3 volumetric flask and made up to the mark. The sulphate content was estimated both by hplc and turbidimetry.

Total sulphur in leaf and kernel samples of coconut

A 1:1 $HNO_3/HClO_4$ acid mixture (25 cm^3) was added to 1-g samples and digested until $HClO_4$ acid fumes were visible (an additional 25 cm^3 $HClO_4$ was required for the kernel samples to obtain a clear solution). (CAUTION. $HClO_4$ fumes should be vented through a water scrubber or in a hood designed for wash-down.) The solution was cooled, filtered into a 50-cm^3 volumetric flask, and made up to volume. Aliquots were used for the estimation of sulphur by hplc and turbidimetry.

Water extractable sulphur in leaf and kernel samples of coconut

Samples (1–2 g) were ashed overnight at 450°C, and then digested with 5 cm^3 distilled water for 1 h at either room temperature, 60°C, or 100°C on a water bath. The extracts were next mixed in a "test tube mixer", filtered into 50-cm^3 volumetric flasks and made up to volume. Aliquots were taken for analysis of sulphur by hplc and turbidimetry.

Coconut water

"Nut water" (25 cm^3) was evaporated to dryness, ashed at 450°C

overnight, dissolved in water, filtered, and made up to 50 cm^3. Aliquots were used for estimation by turbidimetry and hplc.

Extractable sulphur in soil

Air-dried, sieved soil (20 g) was extracted with 50 cm^3 of extracting solution ("100 ppm P" solution) and 1 g activated charcoal for 30 min in a mechanical shaker. The samples were filtered, 25 cm^3 aliquots transferred to silica basins, 2 cm^3 of 3% H_2O_2 added, and the contents evaporated to dryness. The basins were then heated in an oven at 110°C for 1 h, the residue taken up in a 25 cm^3 volumetric flask in distilled water, and the sulphate determined by hplc and turbidimetry.

Standardisation of hplc for sulphur in coconut

Aliquots (100 μL) of separate solutions containing 10 to 50 μl g cm^{-3} each of SO_4^{2-}, Cl^-, and NO_3^- were injected to obtain calibration plots. Peak heights were found to be linearly dependent on anion concentrations.

Turbidimetry

An aliquot was treated with 5 cm^3 of 50% acetic acid, 5 cm^3 of 25% HNO_3, and 1 cm^3 of H_3PO_4 in a 50 cm^3 volumetric flask and diluted to about 45 cm^3 with distilled water and well mixed. $BaCl_2$-"Tween 80" reagent (5 cm^3) was added and the solution made up to volume and mixed. The solution was again mixed after 1 h and the turbidity measured against a reagent blank at 420 nm. A calibration plot was made using standard sulphate solutions prepared from 0.02 *M* $MgSO_4.7H_2O$.

Modified S.C.R. procedure (9)

Individual 1-g portions of tea and 2 cm^3 chloroform were wetted with 5 cm^3 ammonia in a separating funnel. The resulting mixture was extracted four times with 25 cm^3 portions of chloroform. The separated organic layers were each washed with 10 cm^3 portions of 1% KOH, dried over anhydrous Na_2SO_4, filtered into a 100-cm^3 volumetric flask, and made up to mark. Aliquots of this solution were diluted 1:10 and the absorbance measured at 272 nm. The caffeine content was read off a calibration plot prepared from standard caffeine solutions over the concentration range of 1 to 30 ppm.

High performance liquid chromatography using chloroform extraction

Individual 1-g portions of tea were extracted with 25 cm^3 portions of chloroform and the extract evaporated to dryness on a water bath. The residue was dissolved in distilled water, filtered, and together with washings made up to 100 cm^3; 100 μL of the resulting solution was injected into the hplc system.

High performance liquid chromatography using water extraction

Individual 1-g portions of tea were extracted with 80 cm^3 of boiling water for 4 min, filtered, and made up to 100 cm^3. A 2-cm^3 aliquot of this filtrate was passed through a 10 cm × 0.2 cm column containing about 150 mg of polyvinylpyrrolidone (PVP). The filtrate along with the distilled water washings was made up to 10 cm^3 in a volumetric flask; 100 μL of this solution was injected into the hplc system.

Standardisation of the hplc procedure for caffeine

Five standard solutions of caffeine with progressive increase in concentrations were prepared. For each solution 100-μL portions were injected into the hplc in duplicate.

Results and discussion

Sulphate determinations

The analyses of processed coconut water, leaf, kernel, and soil samples for sulphate sulphur are normally carried out by gravimetry, turbidimetry or titrimetry. Studies of the variability among these methods showed that whereas tetrimetry is subject to much operator error, turbidimetry is affected by the nature of stabilizing agents, as well as by other factors that influence dissolution of the barium sulphate precipitate (15). In addition, turbidimetry involves several experimental steps and suffers from interferences from other ions.

The hplc procedure was found to be rapid. A total of about 100 samples could be analysed per working day, whereas only about 20 samples could be so analysed using turbidimetry. In addition, hplc enables determination at 254 nm of Cl^- and NO_3^- in addition to sulfate; both are of importance to the nutritional status of coconut.

The detection limits for both turbidimetry and hplc were found to be about 1 ppm.

The hplc procedure gave higher values. The lower values observed with turbidimetry could be due to the interferences from other ions, as well as the possibility of the precipitate dissolving due to the introduction of various acids during the development of turbidity. Butters and Chenery (15) studied a number of factors that influence uniform precipitation of the solution, such as the quantity and size of the barium chloride crystals, type and concentration of acids, time and speed of stirring or inverting, time of standing, and the choice of optical filter. The manual method requires skill and considerable care, whilst automation requires standardisation of the procedure to obtain uniform sized particles.

Often a drift is found in the hplc base line due to adsorption of barium sulphate on the inner walls of the colorimetric flow cell. The higher values obtained with hplc could thus be an indication of the absolute values of the sulphur content.

Application of the hplc procedure to leaf samples required use of water extracts with ashed samples, since the normal acid digestion procedure introduces high Cl^- concentrations that mask both NO_3^- and SO_4^{2-}, thus making measurements difficult.

TABLE 2. Average leaf sulphur content, estimated by turbidimetry and hplc using different extractants

Extractant	Turbidimetry (μg cm^{-3})	% of value using $HNO_3/HClO_4$ digestion	hplc (μg cm^{-3})	% of value using HNO_3 digestion
Cold water	896 ± ($n = 30$)	57.7	982 ± ($n = 30$)	63.3
Hot water, 60°C	940 ± ($n = 30$)	60.5	1024 ± ($n = 30$)	65.9
Hot water, 100°C	950 ± ($n = 28$)	61.2	1104 ± ($n = 24$)	71.1

TABLE 3. Comparison of three methods on the recovery of 20 mg of pure caffeine, added to 1-g portions of decaffeinated tea

Method	Amount taken (mg/g)	Amount found (mg/g)	Recovery (%)
Modified S.C.R.	20.10	20.09	100.00
	20.30	20.10	98.01
	20.40	20.10	98.52
hplc, $CHCl_3$ extraction	20.00	20.01	100.05
	20.12	20.06	99.70
	20.06	20.01	99.75
hplc, water extraction with PVP pre-column	20.00	19.78	98.90
	20.00	19.97	99.85
	20.00	20.01	100.06

Correlation values using water extraction at different temperatures with 30 ashed leaf samples are given in Table 1. The correlation coefficient for turbidimetry with hplc was best for cold water extracts ($r = 0.9118$), and for water extracts at 60°C ($r = 0.8381$). However, use of water extraction at 100°C gave poor correlation ($r = 0.4496$).

Table 2 shows average leaf sulphur content using different extractants and the total sulphur content in %, as obtained by double acid digestion. Extraction at 60°C for estimation of sulphur requires careful temperature control. Extraction at 100°C is simple and convenient for large numbers of samples.

Several samples (n) of coconut leaf were extracted with boiling water and analysed in duplicate using both turbidimetry and hplc. A paired "t" test between the duplicate samples obtained by each of these methods showed no significant differences between them ($t = 1.54$, $n = 28$ and $t = 0.92$, $n = 24$ for turbidimetry and hplc, respectively). Further, significant intraclass correlations were found between duplicate samples by both turbidimetry ($r = 0.54$) and hplc ($r = 0.43$). These results support the reproducibility of boiling water extraction for the determination of the sulphur content in coconut leaves by both turbidimetric and hplc procedures.

A study of extraction conditions for soil for hplc and turbidimetry showed that the highest correlation ($r = 0.9947$) was found when boiling water was used as the extractant.

In summary, these results show that hplc is suitable for the estimation of sulphate in coconut water, as well as in boiling water extracts of coconut plant tissues and soil. The fact that water can be utilized as the extracting medium is of biological interest and is more economical for monitoring studies of the sulphur status of coconut.

Caffeine determinations

The spectrophotometric procedure, as well as the use of hplc, to determine caffeine in food and beverages normally involves prior extraction with chloroform (16, 17). Enhanced extraction of caffeine has been reported with an aqueous medium (7). However, the large quantities of polyphenolic compounds present in tea interfere in the determination of caffeine in aqueous extracts because both compounds absorb at 270 nm, the wavelength often used in uv detectors for hplc. Use of a pre-column of polyvinylpyrrolidone (PVP) to remove the polyphenolic compounds was found to give sharper hplc peaks, without interfering with determination of the caffeine present.

Known amounts of pure caffeine added to a decaffeinated solution of tea were quantitatively recovered after passage through a PVP column. Pure caffeine when added to a tea extract showed caffeine peak enhancement corresponding to the amount being added after passage through a PVP column.

Recovery studies carried out on pure samples of caffeine showed that PVP does not retain caffeine (Table 3). All three methods investigated were found to give a high degree of recovery on pure caffeine samples (Table 3). Eleven 1-g subsamples of Sri Lanka "up country" tea were analysed for caffeine by the three methods described. Statistical analysis of the results showed that all three methods were comparable at the 5% level of significance ($p = 0.05$). However, it was impossible to compare methods involving chloroform and water extracts for hplc (Table 4).

The correlation coefficient between the modified S.C.R. procedure and hplc using water extraction with a PVP pre-column ($r = 0.923$), was the most significant, whilst the correlation coefficient between the hplc procedure with chloroform and with water extraction was the least significant ($r = 0.816$).

The coefficient of variation, in %, for each of the methods using PVP pre-column, was: Modified S.C.R. procedure, 3.72; hplc using $CHCl_3$ extraction, 6.02; and hplc using water extraction, 3.21. For the hplc procedure with PVP pre-column the detector sensitivity at 270 nm was 0.15 absorption units at full scale (AUFS) for a 1 ppm solution of caffeine.

Mean levels of caffeine of several samples of manufactured tea from different regions in Sri Lanka and from other countries were each analysed in triplicate, to quantitatively estimate the percentage of caffeine present, using the three methods described. The results obtained are given in Table 5.

TABLE 4. Inter-method comparison of results obtained for the analysis of caffeine using 11 replicates of a sample of Sri Lanka "up country" tea

Methods	T value	Degrees of freedom	Significant limit, p	Significance at $p = 0.05$	Correlation coefficient
Modified S.C.R. vs. hplc using $CHCl_3$ extract	0.73	10	0.48	Not significant	0.86
Modified S.C.R. vs. hplc using water extraction with PVP pre-column	−1.63	10	0.12	Not significant	0.92
hplc using $CHCl_3$ extraction vs. hplc using water extraction with PVP pre-column	−2.81	10	0.01	Significant	0.82

Received November 19, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

A. Martin de P. Nicholas and Roderick E. Wasylishen. Can. J. Chem. **65**, 951 (1987).

Rotational correlation times for the end-over-end rotation of the C_3 symmetry axis of the nitrate anion in the temperature range 3–80°C are studied by nuclear magnetic resonance spectroscopy for a variety of nitrate salts in aqueous solution. The counterion is found to retard the rotation of the anion in the following order: $Sc^{3+} > La^{3+} > Pb^{2+} > Ca^{2+}$, $Sr^{2+} > Al^{3+}$, K^+, Na^+, $(CH_3)_4N^+ > Zn^{2+}$, Mg^{2+}, Li^+, NH_4^+, H_3O^+. This relative order is discussed in terms of the association of the nitrate ion with the cation. Oxygen-17 nmr spin-lattice relaxation times in combination with ^{14}N nmr T_1 values are used to derive rotational diffusion constants for the in-plane rotations of the nitrate anion. In all cases the in-plane rotations are found to be slower than the corresponding end-over-end motion.

A. Martin de P. Nicholas et Roderick E. Wasylishen. Can. J. Chem. **65**, 951 (1987).

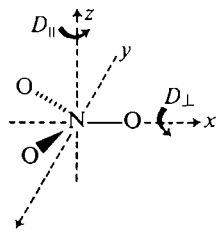
Opérant à des températures allant de 3 à 80°C et faisant appel à la spectroscopie rmn d'une variété de nitrates en solution aqueuse, on a déterminé les temps de corrélation rotationnelle pour la rotation d'un bout à l'autre de l'axe de rotation C_3 de l'anion nitrate. On a trouvé que le contre ion retarde la rotation de l'anion dans l'ordre suivant : $Sc^{3+} > La^{3+} > Pb^{2+} > Ca^{2+}$, $Sr^{2+} > Al^{3+}$, K^+, Na^+, $(CH_3)_4N^+ > Zn^{2+}$, Mg^{2+}, Li^+, NH_4^+, H_3O^+. On discute de cet ordre relatif en fonction de l'association de l'ion nitrate avec le cation. On a utilisé les temps de relaxation spin-réseau de la rmn du ^{17}O de concert avec les valeurs T_1 de la rmn du ^{14}N pour obtenir les valeurs des constantes de diffusion rotationnelle pour les rotations dans le plan de l'anion nitrate. Dans tous les cas, on a trouvé que les rotations dans le plan sont plus lentes que le mouvement correspondant d'un bout à l'autre.

[Traduit par la revue]

Introduction

Nuclear magnetic resonance spectroscopy is one of several techniques available for studying the rotations of ions in solution (1–4). The ease of application and sensitivity of this method make it an attractive choice, especially for studying more dilute solutions. Recently we have shown (5) the importance of using ^{14}N and ^{17}O nmr spin-lattice relaxation measurements to study the rotations of the nitrate and carbonate anions in aqueous solution in the presence of the sodium cation. We found rotations of the carbonate ion to be more hindered than those of the nitrate anion because of stronger cation–anion pairing and stronger anion–solvent interactions (hydrogen bonding). Some evidence for ion association was found for $NaNO_3$ at solute concentrations of 1 *M*; however, ion pairing is much more important for the divalent carbonate anion.

James and Frost (6–8) used Raman spectroscopy to derive rotational correlation times for the nitrate anion and to study ion–solvent interactions in a variety of nitrate salts at anion concentrations ≥ 1 *M*. However, it is important to study the anion rotations by several techniques because of the inherent limitations in the various approaches used (5, 9). As well, more dilute solutions, where viscosity effects are small, should be investigated. Here, nmr spectroscopy is used in a systematic study of the effects of monovalent (NH_4^+, Li^+, H_3O^+, K^+, and $(CH_3)_4N^+$), divalent (Pb^{2+}, Zn^{2+}, Ca^{2+}, Sr^{2+}, and Mg^{2+}), and trivalent (Sc^{3+}, La^{3+}, and Al^{3+}) cations on the end-over-end rotations of NO_3^- at anion concentrations of approximately 0.1 and 1.0 molar in aqueous solution. Our results are discussed in terms of ion pairing and compared with previous results obtained using Raman spectroscopy and Rayleigh scattering experiments. In some cases, for 1 *M* solutions, the temperature dependence of anion rotations is determined. Oxygen-17 relaxation data for solutions ≥ 1 *M* together with the ^{14}N data permitted measurement of both $D_\parallel$ and $D_\perp$ (**1**). Here $D_\parallel$ and $D_\perp$ represent rotational diffusion constants parallel and perpendicular to the ion plane. In-plane rotations have not been probed previously by other techniques, and hence our results should be of interest.



1

Theory

Under conditions of extreme narrowing the relaxation rate $(1/T_1)$ of a quadrupolar nucleus of spin I is given by (5, 10–15):

$$[1] \quad 1/T_1 = \frac{3\pi^2}{10}\frac{2I+3}{I^2(2I+1)}(e^2Qq_{xx}/h)^2\tau_{eff}$$

where (e^2Qq_{xx}/h) is the principal x component (in Hz) of the quadrupolar coupling tensor and τ_{eff} is an effective rotational correlation time, which includes a contribution from the asymmetry parameter, $\eta_q = (q_{yy} - q_{zz})/q_{xx}$ (11–13).

Assuming that the rotations of the nitrate anion can be described by small step rotational diffusion, the effective rotational correlation time obtained from ^{17}O spin-lattice relaxation data is given by eq. [2]:

$$[2] \quad \tau_{eff} = \{[4 + (\eta_q - 1)^2]D_\perp + (\eta_q + 1)^2 D_\parallel\}/4D_r$$

where

$$D_\perp = D_{xx} = D_{yy}$$
$$D_\parallel = D_{zz}$$
$$D_r = 3D_\perp(D_\perp + 2D_\parallel)$$

For the symmetrically bonded ^{14}N of the NO_3^- ion, the largest

For personal use only.

principal component of the electric field gradient tensor is perpendicular to the ion plane, $q_{xx} = q_{yy} = -(1/2)q_{zz}$, corresponding to $\eta_q = 3$; hence the relaxation rate is given by the more familiar equation (eq. [3]), which is a simplified form of eq. [1]:

$$[3] \quad 1/T_1(^{14}N) = 1.5\pi^2(e^2Qq_{zz}/h)^2\tau_{2R}$$

where e^2Qq_{zz}/h is the nuclear quadrupole coupling constant, QCC, (in Hz) and τ_{2R} is the rotational correlation time for rotations of the C_3 axis ($\tau_{2R} = \tau_\perp$). Oxygen-17 and nitrogen-14 quadrupolar coupling constants for the nitrate anion in the solid state are available from nuclear quadrupole resonance (16) and nmr experiments (17), respectively.

Experimental

The nmr measurements were performed on a Nicolet 360 NB (B_0 = 8.48 T) spectrometer using a broad-band variable-temperature 10-mm probe. All spin-lattice relaxation time measurements were made using the inversion recovery pulse sequence (IRCA), which uses compensating pulses (18) as previously described (5).

T_1's were calculated from peak heights obtained at twelve or more D_1 values, using a nonlinear three-parameter least-squares fitting procedure available on the Nicolet software (19).

Solutions of the nitrates were prepared by weighing out appropriate amounts of laboratory reagent grade chemicals and diluting volumetrically with distilled water. The solutions of $Al(NO_3)_3$ and $Sc(NO_3)_3$ were maintained at a pH of 2 to suppress hydrolysis (20).

Results and discussion

(a) Effect of cations on τ_{2R} of NO_3^- at ambient temperature

The effect of cations on the measured ^{14}N T_1 values and derived rotational correlation times, τ_{2R}, for the nitrate anion in aqueous solution at anion concentrations of 1 and 0.1 *M* is given in Table 1. The τ_{2R} values were calculated using eq. [3] taking QCC(^{14}N) = 745 kHz (21, 22), and are the same rotational correlation times measured by other spectroscopic methods (1, 9). A rotational correlation time, τ_{2R}, of 0.94 ps for a "free nitrate ion" in aqueous solution was calculated from the $T_1(^{14}N)$ of 130 ms obtained for a 0.01 *M* aqueous solution of ammonium nitrate. Identical results were obtained for a 0.01 *M* solution of sodium nitrate at the same temperature, 23 ± 2°C. For comparison, the effective rotational correlation time for water at 25°C has been estimated to be approximately 2.6 ps (23).

Table 1 shows that the end-over-end rotations of the nitrate anion are significantly affected by the cations Sc^{3+}, La^{3+}, Pb^{2+}, Sr^{2+}, and Ca^{2+} even in a dilute solution of concentration 0.1 *M* in nitrate. The influence of the cation on nitrate anion rotations varies from being very small for H_3O^+, NH_4^+, Li^+, Mg^{2+}, and Zn^{2+} to being very large for Sc^{3+}, La^{3+}, and Pb^{2+} where evidence for ion pairing was reported previously (24–28). These effects are a result of cation–anion and cation– and anion–solvent interactions, which retard rotations of the nitrate ion. At anion concentrations of 1 *M*, where the population of cation–anion associated species will be large relative to 0.1 *M*, the τ_{2R} values increase as expected.

The τ_{2R} values deduced in this work suggest the following order in the ability of the cations to coordinate with the nitrate anion and retard its end-over-end rotation: $Sc^{3+} > La^{3+} > Pb^{2+} > Ca^{2+}$, $Sr^{2+} > Al^{3+}$, K^+, Na^+, $(CH_3)_4N^+ > Zn^{2+}$, Mg^{2+}, Li^+, NH_4^+, H_3O^+. This order is in general agreement with previous studies of the extent of ion pairing of cations with the nitrate anion in aqueous solution (29, 30).

It should be pointed out that the observed T_1 values and hence the calculated τ_{2R} values in Table 1 represent an average value for all species present (see section (*c*) below). If the lifetime of a particular nitrate-associated species is long with respect to its rotational correlation time, then τ_{2R} for *that* species will be related to its hydrodynamic volume. The contribution that each species makes to any given τ_{2R} value in Table 1 will depend on the relative population of that species and its lifetime. Species with a lifetime on the order of 1 ps or less will have little effect on the observed T_1 values and resulting τ_{2R} value.

TABLE 1. The effect of the counter ion on the $T_1(^{14}N)$ and $\tau_{2R}(\tau_\perp)$ of the nitrate anion in aqueous solution[a]

	$T_1(^{14}N)$/ms		τ_{2R}/ps	
Cation	0.1 *M*[b]	1.0 *M*[c]	0.1 *M*	1.0 *M*
H_3O^+	127.3	116.5	0.96	1.04
NH_4^+	121.8	112.4	1.00	1.08
Mg^{2+}	122.2	103.2	1.00	1.18
Li^+	115.4[d]	105.7	1.05[d]	1.15

The $T_1(^{14}N)$ results in Table 1 indicate that the NH_4^+ does not associate with the nitrate anion. Previous work suggests this to be true even at high NH_4^+ concentration (6). The weak complexing power of NH_4^+ is apparently due to its tetrahedral shape, which enables it to fit into the hydrogen-bonded network without disrupting the water structure around the nitrate anion (31). Also, the structure-forming H_3O^+, Li^+, Mg^{2+}, and Zn^{2+} cations all possess a strong first hydration sphere and are not readily susceptible to attack by the nitrate anion, a well-known weak ligand. These cations are strongly hydrated because of their large charge to size ratio (32). Thus, the NH_4^+ ion and strongly hydrated cations are not susceptible to association with the nitrate anion, and hence do not significantly affect the rotation of this ion in solution at concentrations of less than 1 *M* NO_3^-.

For the nitrates of Na^+, K^+, and $N(CH_3)_4^+$ the τ_{2R} values increase slightly as the solute concentration increases from 0.1 *M* to 1 *M*. The implication is that the population of ion pairs must be small. The rate constant for dissociation of the $Na^+NO_3^-$ ion pair has been estimated to be 12×10^{10} s^{-1} (lifetime ≈ 7.7 ps) in 2 *M* sodium nitrate (33).

The behaviour of the nitrate ion for aqueous solutions of $Ca(NO_3)_2$ compared to those of $Mg(NO_3)_2$ is striking. For a 0.5 *M* $Ca(NO_3)_2$ solution the τ_{2R} value is 2.64 ps compared to 1.18 ps for a 0.5 *M* $Mg(NO_3)_2$ solution. Such a difference in these two salts was not evident in the Raman study of James and Frost (7); however, other work (27–30) has clearly indicated that the ion-pairing ability of Ca^{2+} should be considerably greater than that of Mg^{2+}, as implied in the present study. It is of interest to mention that from the analysis of depolarized

Rayleigh scattering line shapes of 0.9 *M* $Ca(NO_3)_2$, Whittle and Clarke (27) have found evidence for a slowly reorientating nitrate species ($\tau_{2R} \approx 50$ ps), which they tentatively assigned to a contact pair, $CaNO_3^+$. This species accounted for approximately 20% of the integrated intensity of the reorientational spectrum at a concentration of 0.9 *M*. If their analysis is valid, our results would indicate that the population of contact pairs is less than 10% at 0.5 *M* $Ca(NO_3)_2$. The data in Table 1 indicate very similar behaviour for the nitrate ion in $Sr(NO_3)_2$ and $Ca(NO_3)_2$.

The inability of Al^{3+} to significantly influence the rotational correlation time of the nitrate ion is in accord with previous nmr (34) and Raman (35) studies, which find no evidence for contact ion pairs.

The long τ_{2R} values observed here for the nitrates of lead, lanthanum, and scandium indicate significant concentrations of species such as $Pb(NO_3)^+$, $La(NO_3)^{2+}$, and $Sc(NO_3)^{2+}$. In fact recent ^{207}Pb nmr chemical shift data indicate that for a 0.5 *M* $Pb(NO_3)_2$ solution 25% of the nitrate ions are complexed with lead, $Pb(NO_3)^+$ (24). The longer τ_{2R} values observed for La^{3+} and Sc^{3+} imply a larger fraction of cation–nitrate associated species for aqueous solutions of these salts. The previously reported Raman value of τ_{2R} for the nitrate ions of 0.33 *M* $La(NO_3)_3$, 1.65 ps (8), is not in accordance with our results or with the known ion-pairing ability of La^{3+} (36). For aqueous solutions of $La(NO_3)_3$ at 25°C Irish and co-workers (36) have found the step stability constants $\beta_1 = 1.51$ and $\beta_2 = 0.14$. It is important to note that in aqueous solution the average coordination number of La^{3+} is 8; hence when the nitrate ion is associated with the lanthanum cation the overall ion rotation is expected to be impeded relative to a complex of coordination number 6. Previous ^{45}Sc nmr studies (37, 38) indicate extensive cation–anion association in the case of $Sc(NO_3)_3$, in agreement with our results.

The results in Table 1 indicate that ^{14}N nmr T_1's can be a useful probe to study ion pairing in solution. Clearly, the main advantage of the ^{14}N nmr technique over the Raman technique is its ability to measure τ_{2R} over a wide range of solute concentrations, from approximately 0.01 *M* to saturated solutions. Also, we believe that in studying cation – nitrate ion association ^{14}N nmr is generally more informative than nmr studies of the metal nuclide since the interpretation of metal nuclide relaxation data is difficult (e.g. ^{25}Mg nmr studies of $Mg(NO_3)_2$ (39, 40)).

The main assumption that we have made in calculating the τ_{2R} values in Table 1 is that the nitrogen-14 quadrupolar coupling constant in aqueous solution is the same as the value measured in the solid state. Calculations by Gourdji *et al.* (21, 22) indicate that the electric field gradient at the nitrogen nucleus in the nitrate ion is primarily intraionic in origin and that the contribution of neighbouring ions is 5% or less. Also, the excellent agreement in τ_{2R} values obtained for the nitrate ion in 1 *M* $NaNO_3$ by nmr (5) and by recent Raman fluctuation spectroscopic studies (41) indicates that the ^{14}N QCC in aqueous solution and in the solid state are very similar. Finally, we do not expect ion pairing to dramatically influence the value of the ^{14}N QCC used here because nqr studies of the nitrate ion in a variety of zinc imidazole complexes indicate that the factor QCC (^{14}N) $[(1 + (\eta^2/3)]^{1/2}$ is within 10–20% of the value found in solid $NaNO_3$ (42).

(b) Temperature dependence of ^{14}N T_1 (3–80°C)

The temperature dependence of the ^{14}N T_1 data is illustrated in Fig. 1 with a plot of log T_1 (^{14}N) against $1/T$, where T is the absolute temperature. Since the rate of nitrogen relaxation ($1/T_1$) is directly proportional to τ_{2R} (eq. [3]), the temperature dependence of T_1 is equivalent to that of τ_{2R}. For many molecules in solution the rotational correlation time shows an Arrhenius behaviour, and the temperature dependence of τ_{2R} is given by eq. [4]

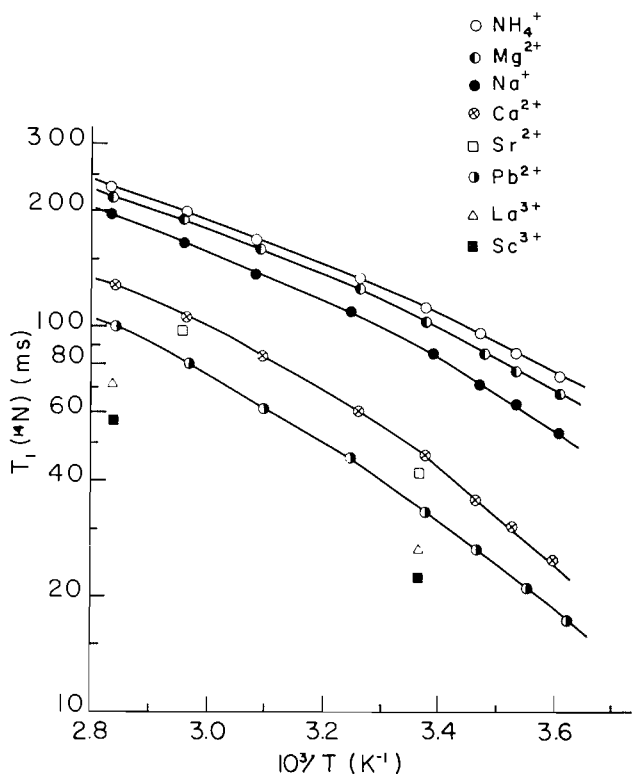

FIG. 1. Plots of log T_1(^{14}N) vs. $10^3/T$ for a variety of nitrate salts in aqueous solution at an anion concentration of 1.0 *M*.

[4] $\tau_2 = \tau_{2,0} \exp(E_a/RT)$

where E_a is an activation energy that should be related to the barrier to rotation (43). The relationship between E_a and the barrier to rotation has been discussed by a number of workers (43–47).

The results in Fig. 1 clearly indicate that log T_1 is not linearly related to the inverse of temperature; hence τ_{2R} is not simply related to temperature by a simple equation of the form of eq. [4] over the entire temperature range investigated. This type of behaviour is common for most transport properties of water (48, 49) and it has been found that two separate equations of the form of eq. [4] are often reasonably accurate over a low temperature range (0–25°C) and a high temperature range (35–80°C). We have arbitrarily separated our data in this way and the results are summarized in Table 2.

The nitrate counterions in Table 2 may be divided into three groups: those which do not associate with the nitrate ions or only very weakly so (NH_4^+, Li^+, Mg^{2+}, and Zn^{2+}), those which associate weakly ($(CH_3)_4N^+$ and Na^+), and finally those for which association is relatively strong (Ca^{2+} and Pb^{2+}). The average low temperature activation energies for each of these three groups of cations are 3.8, 4.45, and 5.55 kcal mol^{-1}, respectively. The corresponding average high temperature (30–80°C) E_a values are 2.55 kcal mol^{-1} (NH_4^+, Li^+, Mg^{2+}, Zn^{2+}), 2.85 kcal mol^{-1} ($(CH_3)_4N^+$, Na^+), and 3.75 kcal mol^{-1} (Ca^{2+}, Pb^{2+}). As expected, one finds that in any given

0.1 *M*	121	1.01	—
0.4 *M*	106	1.15	—
1 *M*	87	1.40	1.44
2 *M*	66	1.84	1.60
4 *M*	41	2.97	1.90(3.5 *M*)

[a]Reference 53 (at 29°C).
[b]At 23°C.
[c]At 22°C.

temperature range the activation energies consistently increase as ion association increases. This is expected because, as ion association increases, the nitrate ion on average finds itself associated with a larger, less mobile entity, for example in a species such as $[(H_2O)_5PbNO_3]^+$.

Several explanations for the larger activation energies at low temperature relative to those at high temperatures have been advanced (45–47); however, we do not wish to speculate on this point here.

(c) Concentration dependence of ^{14}N T_1

The concentration dependence of the ^{14}N T_1 (and hence the rotational correlation times) for the nitrate anion in the presence of the counterions Na^+ and NH_4^+ is given in Table 3. The values of τ_{2R} increase with increasing concentration. While the variation in τ_{2R} is large for the Na^+ salt it is small for the NH_4^+ salt, where ion pairing is small even at very high concentrations as already discussed (31). In principle it should be possible to obtain an estimate of the equilibrium constant for the formation of an ion pair and the T_1 for this ion pair from the concentration dependence of T_1 (50).

In the presence of association the observed T_1 values is a composite of the T_1 values for the free and complexed nitrate anion. In the region of motional narrowing when the rate of chemical exchange ($M^{n+} + NO_3^- \rightleftharpoons (MNO_3)^{(n-1)+}$) is slow relative to the rates of molecular reorientation of the nitrate anion and the ion-pair complex, T_1 is given by (51):

$$[5] \quad 1/T_1 = (1/T_1)_{free}(1 - A) + (1/T_1)_{complexed}(A)$$

where A is the mole fraction of the complexed nitrate anion. When the rates of exchange are fast relative to the reorientation rates (51):

$$[6] \quad T_1 = (T_1)_{free}(1 - A) + (T_1)_{complexed}(A)$$

If we assume that $1/T_1$ varies linearly with the macroscopic viscosity at a given temperature, then the T_1 term in eqs. [5] and [6] must be replaced by $T_1\eta_{rel}$, where η_{rel} is the macroscopic viscosity of the solution relative to that of pure water.

In practice it is difficult to determine A and $T_{1\,complexed}$ from relaxation data alone. As already mentioned, the equilibrium constant for dissociation of $Pb(NO_3)^+$ is known from ^{207}Pb nmr (24), hence it is instructive to apply the above analysis to this system. The value of $(T_1)_{free}$ can be obtained by studying very dilute solutions. At 23°C we estimate $(T_1)_{free}$ = 130 ms, corresponding to a rotational correlation time of 0.94 ps. Using the ^{14}N T_1 data for 0.5 and 0.05 *M* $Pb(NO_3)_2$ at 23°C, and obtaining the A values from K_{assoc} = 1.233 (24), we find that eq. [5] fits the data better than eq. [6]. As expected, this indicates relatively slow exchange rates for the ion-pair equilibrium. It must be noted that the exchange rate is still fast in the nmr chemical-shift time scale. Using eq. [5], we estimate $(1/T_1)_{complexed}$ = 9 ± 4 ms. Assuming QCC($^{14}NO_3^-$) is not affected by association, we obtain τ_{2R} ($[PbNO_3]^+$) = 14 ± 6 ps. This is to be compared with a value of ca. 50 ps estimated for $\tau_{2R}([CaNO_3]^+)$ using Rayleigh scattering (27). If the stick boundary condition applied to the rotation of the $M(H_2O)_5NO_3^+$ complex, 50 ps would seem more reasonable! However, because of the assumptions and errors involved in calculating both of these values, we do not care to speculate on the interpretation of these values.

(d) Anisotropy of reorientation

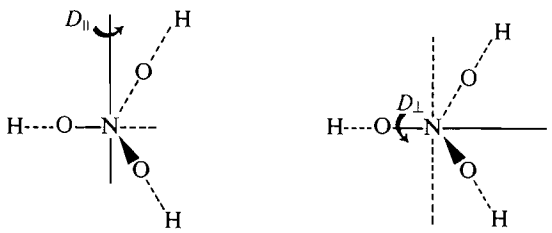
In this section effective rotational correlation times derived from ^{17}O nmr T_1 data are used to extract information about the influence of temperature, nature of the cation, and the cation concentration on the anisotropy of reorientation of the nitrate anion. The results are summarized in Table 4. The τ_{eff} values were calculated by using eq. [1] and taking QCC(^{17}O) = 12.57 MHz (52). The ratios of $D_\parallel/D_\perp$ derived from the correlation times using eqs. [1]–[3] and $\eta_q = -0.747$ (52) are listed in column 6 of Table 4. We did not attempt ^{17}O T_1 measurements at temperatures where the line width exceeded ca. 200 Hz, because of the large experimental errors anticipated under these circumstances (5). It must be noted that errors of 10 and 5% in the ^{17}O T_1 values and the QCC (^{17}O), respectively, correspond to an error of ca. 30% in the $D_\parallel/D_\perp$ ratio. Nevertheless, the relative error in this ratio is probably much less, and study of its variation with temperature, the counterion, and counterion concentration is of interest because it is difficult to obtain $D_\parallel/D_\perp$ by any other technique. Our results may be summarized as follows:

1. For a 3 *M* aqueous solution of NH_4NO_3, variable temperature ^{14}N and ^{17}O nmr results (Fig. 2) indicate $D_\parallel/D_\perp \approx 0.51 \pm 0.06$, essentially independent of temperature.

TABLE 4. An analysis of the anisotropy of the reorientation of the nitrate anion in aqueous solution

Cation	Temperature/°C	$T_1(^{14}N)$/ms	$T_1(^{17}O)$/ms	τ_{eff}/ps	$D_\parallel/D_\perp$
3 *M* NH_4^+	4	57.3	1.82	3.67	0.53
	9	64.5	2.09	3.20	0.54
	15	72.7	2.42	2.76	0.57
	24	90.5	2.81	2.38	0.50
	34	105.8	3.28	2.04	0.50
	47	130.5	4.03	1.66	0.49
	61	154.2	4.61	1.45	0.46
	72	176.7	5.45	1.23	0.49
1 *M* H_3O^+	24	116.5	2.84	2.35	0.29
1 *M* NH_4^+	25	114.7	3.15	2.12	0.39
1 *M* Na^+	22	85.2	2.48	2.69	0.44
0.5 *M* Zn^{2+}	26	100.1	2.74	2.44	0.38
0.5 *M* Ca^{2+}	47	79.0	2.41	2.77	0.48
0.5 *M* Pb^{2+}	50	61.1	1.88	3.55	0.49
0.33 *M* La^{3+}	80	71.0	2.39	2.79	0.59
1 *M* NH_4^+	25	114.7	3.15	2.12	0.39
3 *M* NH_4^+	24	90.5	2.81	2.38	0.50
4 *M* NH_4^+	24	83.2	2.70	2.47	0.55
8 *M* NH_4^+	24	54.3	2.03	3.29	0.71
0.5 *M* Zn^{2+}	26	100.1	2.74	2.44	0.38
1.5 *M* Zn^{2+}	24	58.0	2.02	3.31	0.62

Previously, similar results were obtained for 1 *M* $NaNO_3$ where $D_\parallel/D_\perp \approx 0.45 \pm 0.03$ (5). As discussed in our earlier study (5), it is difficult to account for the observation that in-plane rotations are slower than end-over-end rotations. One naive explanation would be that three N—O...H—O hydrogen bonds must be broken for in-plane rotation (**2**) compared to two for an end-over-end rotation (**3**).



2. Assuming that $D_\parallel/D_\perp$ is approximately independent of temperature (see results for the ammonium ion), it appears that the anisotropy of the motion decreases (i.e., $D_\parallel/D_\perp \rightarrow 1$) as ion association increases. For example, comparing samples which are 1 *M* in nitrate for the following cations, in approximate order of their ability to associate with the nitrate anion, gives:

Cation:	H_3O^+	NH_4^+	Zn^{2+}	< Na^+	< Ca^{2+}	< Pb^{2+}	< La^{3+}
$D_\parallel/D_\perp$:	0.29	0.39	0.38	0.44	0.48	0.49	0.59

These results are precisely what one would expect. For the systems where ion association is relatively strong, there will be a significant population of complexes of the type $[(H_2O)_nMNO_3]^{x+}$. These large complexes are expected to be more spherical than an isolated nitrate ion; hence the rotations should be more isotropic, as observed.

3. For cations that only associate weakly with the nitrate ion the ratio $D_\parallel/D_\perp$ increases with solute concentration. For example, in the case of NH_4NO_3, $D_\parallel/D_\perp$ increases from approximately 0.4 to 0.7 as the concentration increases from 1 *M* to 8 *M*. Similarly for $Zn(NO_3)_2$, $D_\parallel/D_\perp$ increases from 0.38 to 0.62 when the nitrate ion concentration increases from 1 *M* to 3 *M*. An increase in the salt concentration corresponds to a decrease in the number of water molecules available to hydrate the nitrate anion. In fact, the ratio of the molar concentration of H_2O to that of NO_3^- decreases from a high of 53 for 1 *M* solution to ca. 4 for the 8 *M* solution. That is, the $D_\parallel/D_\perp$ ratio is sensitive to amount of water available in the medium and increases with decreasing water content. This is in accordance with the hypothesis that hydration of the nitrate anion is the major factor responsible for a $D_\parallel/D_\perp$ ratio of less than unity.

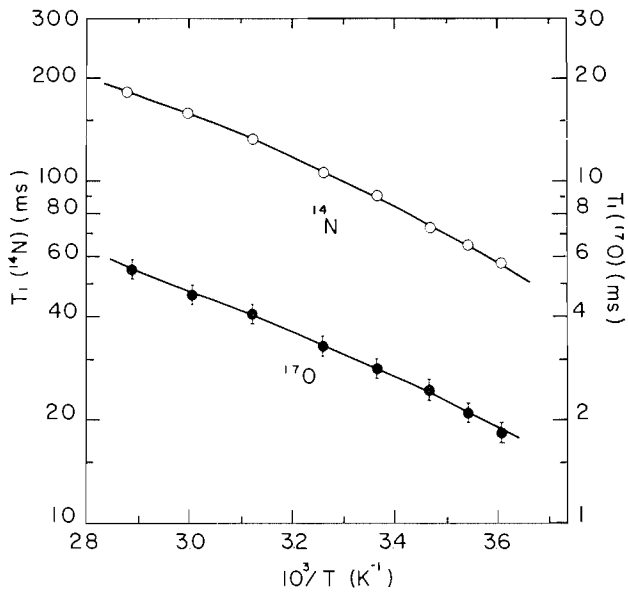


FIG. 2. Plots of log $T_1(^{14}N)$ and log $T_1(^{17}O)$ vs. $10^3/T$ for the nitrate anion in an aqueous solution of 3 *M* NH_4NO_3.

4. The nmr ^{14}N and ^{17}O T_1 values for the nitrate anion given in Table 4 are fairly well correlated (correlation coefficient $r = 0.96$) and their relationship is given by:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

[7] $T_1(^{17}O) = 0.027T_1(^{14}N) + 0.36$

This relationship, which is valid for the nitrate ion, may be used to obtain *approximate* ^{17}O T_1 values from the corresponding ^{14}N values. These initial estimates are useful in setting up appropriate delay values (D_1) in the ^{17}O T_1 IRCA experiment. The T_1 values are in units of ms.

Conclusions

In this study we have demonstrated the utility of ^{14}N and ^{17}O nmr in characterizing rotations of the nitrate anion in aqueous solution. We believe the nmr technique complements the results obtained by other techniques and we encourage others to apply this technique. The ^{14}N T_1 measurements are relatively straightforward on almost any modern multinuclear nmr spectrometer; however, natural abundance ^{17}O relaxation measurements are less routine and require a substantial amount of spectrometer time. Oxygen-17 labelling of the nitrate ion would permit one to significantly extend the present study.

Acknowledgements

We wish to thank Marco Gruwel for several helpful discussions regarding anisotropic rotational diffusion. All nmr spectra were obtained at the Atlantic Regional NMR Centre, Dalhousie University. We are grateful to NSERC for financial support in helping establish and maintain this centre and for an operating grant (R.E.W.).

A method for direct determination of molybdenum in seawater has been developed, and uses linear sweep voltammetry after adsorptive accumulation of the Erichrome Blue Black R (EBBR) complex on a static mercury drop electrode. To an acidified (pH 1.6) seawater (SW) sample, 6.0×10^{-6} *M* EBBR is added and preconcentration by adsorption is carried out for 30 s at a potential of −0.05 V vs. the Ag/AgCl/SW reference electrode. The potential is then scanned in the negative direction, giving a current peak for the reduction of the Mo—EBBR complex at −0.17 V. Under these conditions the limit of detection is 0.50 ng/mL. Experimental results for Mo in seawater using this technique agree well with certified values for two reference seawater samples (NASS-1, CASS-1).

S. N. WILLIE, S. S. BERMAN, J. A. PAGE et G. W. VANLOON. Can. J. Chem. **65**, 957 (1987).

On a développé une méthode directe pour la détermination du molybdène dans l'eau de mer; cette méthode fait appel à la voltamétrie à balayage linéaire, après une accumulation par adsorption du complexe de l'Erichrome Bleu Noir R (EBNR) sur une électrode à goutte de mercure statique. A un échantillon acidifié (pH de 1,6) d'eau de mer (EM), on ajoute $6{,}0 \times 10^{-6}$ *M* de EBNR et on effectue une préconcentration par adsorption pendant 30 s, à un potentiel de −0,05 V vs l'électrode de référence Ag/AgCl/EM. On effectue un balayage du potentiel dans la direction négative qui donne un pic du courant pour la réduction du complexe Mo—EBNR à −0,17 V. Utilisant ces conditions, la limite de détection est 0,50 ng/mL. Les résultats obtenus pour le Mo dans l'eau de mer, en utilisant cette technique, sont en bon accord avec les valeurs certifiées pour deux échantillons d'eau de mer (NASS-1, CASS-1).

Introduction

Anodic stripping voltammetry (ASV) is well suited for the determination of trace metals in seawater, but has been limited to the analysis of elements, most notably Zn, Cd, Pb, and Cu, which may be readily reduced and then reoxidized at the Hg electrode. However, a recent approach which significantly widens the scope of voltammetric analysis involves the use of adsorptive accumulation as a preconcentration technique. This technique requires the addition of reagent(s) to form a surface-active complex with the analyte species of interest; accumulation on the electrode surface then results due to adsorption under an applied potential.

Adsorptive accumulation voltammetry techniques have been reported for Ti (1) and Al (2) using solochrome violet RS, Mn (3) using eriochrome black T, and the lanthanides (4) using *o*-cresolphthalexon. The application of this technique to the determination of a number of trace elements in seawater has also been reported, Ni (5) using the dimethylglyoxime (DMG) complex, Cr (6) using diethylenetriaminepentaacetic acid (DTPA), and Fe, V, Cu, and U (7–10) using catechol to form chelates. A method for determining Mo in seawater has been described (11) which uses 8-hydroxyquinoline to form a complex.

The present work reports an alternate procedure for the analysis of Mo after formation of a complex with 3-hydroxy-4-[2-hydroxy-1-naphthylazo]-1-naphthalene sulphonic acid monosodium salt (Eriochrome Blue Black R or EBBR). EBBR is an *o,o'*-dihydroxyazo compound that has found extensive application as an indicator in EDTA titrations of a variety of metals (12). This dye and related compounds have also been recommended for the direct polarographic analysis of metals including Al, Fe, Ga, Mg, V, Zn, and the lanthanides (13).

In preliminary experiments (14) it was found that EBBR could be adsorbed onto a hanging Hg drop electrode in both its free state and also as metal complexes. By scanning the electrode potential in a negative direction, separate current peaks for the uncomplexed dye and metal complex could be observed. The latter peak height was found to be proportional to the concentration of metal ion in the solution.

This paper describes the analytical conditions required for the determination of Mo in seawater. The advantage of the present approach is that direct analysis is possible, without separate preconcentration such as co-precipitation (15, 16), ion exchange (17), or solvent extraction (18).

Experimental

Apparatus

An EG&G Princeton Applied Research Model 174A polarographic analyser was used in conjunction with a static mercury drop electrode Model 303 and a Model 305 stirrer. Voltammograms were recorded using a Hewlett Packard Model 7004B recorder. A Commodore Vic 20 computer was interfaced with the 174A to control the timing of the electrolysis cycle.

The borosilicate glass cell supplied with the unit was used and did not produce any observable contamination. Solutions were stirred with a Teflon-coated stirring bar (14 mm × 3 mm) at "slow" speed (500 Hz).

The auxilary electrode was a Pt wire and the reference electrode was an Ag/AgCl electrode immersed in acidified seawater (SW) (pH 1.6) and separated from the analyte solution by a Vycor plug. The potential of the Ag/AgCl/SW reference was −0.010 V vs. a conventional SCE at 25°C. All potentials quoted in this work are referenced to the Ag/AgCl/SW electrode.

Reagents

Water used in dilutions was triply distilled to remove trace metals.

Eriochrome Blue Black R, EBBR (also known as Mordant Black 17, Calcon or Solochrome Dark Blue), C.I. 15705, was supplied by G. Fredrick Smith Chemical Co. and used directly without further purification.

Stock solutions of the EBBR reagent were prepared daily by dissolving 20 mg dye in dilute aqueous ammonia (50 μL aqueous NH_3 (28%) in 50 mL H_2O) and then acidifying with 0.5 mL of acetic acid to inhibit decomposition (19). Acetic acid was used since it was found that hydrochloric acid precipitated the EBBR. The final dye solution was then filtered through Whatman #30 filter paper.

The concentration of the dye solution was determined by completely dissolving an appropriate weighed amount of dye in ethanol to make a standard solution. A spectrophotometric calibration curve at 510 nm was prepared by dilution of the standard solution with ethanol and water, keeping the ethanol concentration constant in the final solutions. The stock dye solution was diluted with ethanolic solution so that its absorbance was within the calibration range. The ethanol/water concentration was kept the same as in the standards. It was found that approximately half of the dye had dissolved in the stock solution to give a EBBR concentration of 6.0×10^{-4} *M*. Using this value a Job Plot was constructed; this indicated a Mo:EBBR combining ratio of 1:1 in accordance with what has been previously reported (19).

A 1000 μg/mL Mo standard was prepared from $(NH_4)_6Mo_7O_{24}\cdot H_2O$ (BDH, reagent grade) after drying at 100°C. A working solution of 10.0 μg/mL Mo was prepared by dilution with distilled water.

A concentrated aqueous buffer system was prepared from high purity aqueous ammonia and acetic acid. The acetic acid was purified by sub-boiling distillation from a quartz still using reagent grade acid as a feed stock. Aqueous ammonia (28%) was prepared by isopiestic distillation in a closed system. Appropriate amounts of acetic acid and ammonia were then mixed to give a 4.5 *M* $CH_3COO^-NH_4^+$ aqueous buffer.

A National Research Council of Canada (NRCC) open ocean seawater sample, NASS-1 (20), was used as a reference material. The sample had not been filtered and had a salinity of 35.07‰. A NRCC coastal seawater reference material, CASS-1, was also analysed. This sample, which has a salinity of 31.8‰, was filtered through a 0.45 μm membrane filter. Both seawater reference materials had been acidified to pH 1.6 with high purity NHO_3, immediately after collection and were stored in precleaned polyethylene bottles.

Procedure

All voltammetric operations involving cell and solution manipulations were performed in a laminar flow clean hood to minimize contamination.

For analysis, a 10.0 ± 0.1 mL sample of seawater (pH 1.6) was deaerated for 8 min using purified N_2 gas. Using a micropipet 100 μL of the aqueous 6.0×10^{-4} *M* EBBR solution was then added to the cell. The solution was allowed to equilibrate, with stirring, for 1 min before a fresh mercury drop (size "M") was dispensed and the potential applied to initiate adsorptive accumulation. The accumulation period (τ) was restricted to 30 s at a potential of −0.050 V with stirring, after which a further 10 s equilibration without stirring was allowed. The voltammogram was then recorded at a scan rate of 50 mV/s from −0.050 V to −0.550 V with no filtering of the signal. A single peak corresponding to reduction of the adsorbed Mo complex occurred at −0.170 V. Calibration was achieved by the method of standard additions using peak height measurements to quantify the analytical signal. A fresh mercury drop was dispensed for each calibration measurement.

Blanks analysed in triply distilled water were below the limit of detection in this method.

Results and discussion

Free EBBR may be adsorbed onto a Hg electrode under conditions of applied potential (Fig. 1). After adsorptive accumulation, scanning the potential in the negative direction

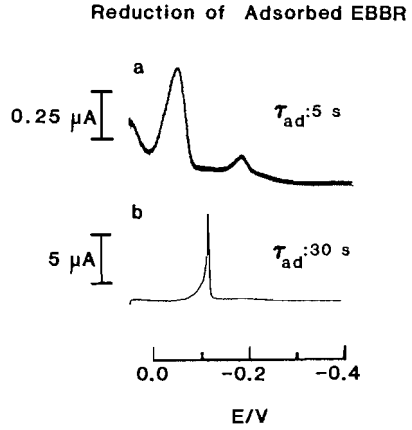

FIG. 1. Reduction peaks for EBBR in seawater at pH 1.6, [EBBR] = 6.0×10^{-6} *M*, ν 50 mV/s, E_{ad} +0.02 V. (*a*) τ_{ad} 5 s, (*b*) τ_{ad} 30 s.

results in a peak due to reduction of the adsorbed dye. A seawater sample with 6.0×10^{-6} *M* EBBR gave a reduction peak at −0.070 V after a few seconds of accumulation. Corresponding direct polarographic analysis of the same solution resulted in a wave with $E_{1/2}$ = −0.100 V for the EBBR.

The mechanism of reduction for the *o,o'*-dihydroxyazo dyes on a mercury electrode has been extensively studied by Florence and co-workers (21–23). Although this work pertains to solochrome violet RS and other aromatic azo compounds, it can be assumed that the same 4-electron reduction mechanism occurs for EBBR.

Figure 1 shows the reduction peak for the free dye after adsorption at a potential of +0.050. For Fig. 1*a*, the adsorption time was 5 s and a relatively broad, rounded peak occurred. Over a range of accumulation times from 0 to 20 s, the height of this peak varied directly with τ. However, for values of τ longer than 20 s, the character of the peak changed significantly to give a sharp spike with maximum peak current which was independent of the deposition time.

Laviron (24) observed similar behavior with the reduction of adsorbed *trans*-4',4"-pyridyl-1,2-ethylene. The phenomenon of narrow peaks was explained as the result of formation of a compact layer on the mercury surface, with attractive forces between the closely packed molecules. Due to the high density and strong intermolecular forces, reduction is difficult and occurs at more negative potentials. Once a fraction of the molecules are reduced, the intermolecular forces weaken, the reaction rate increases, and the rest of the molecules are reduced almost simultaneously, resulting in a large, narrow peak.

In the case of long adsorption times or large bulk concentrations (C_0*), the amount of adsorbed material is above the critical value required to form a compact layer. At low adsorption times a compact layer does not form; instead, the adsorbed material is spread out over the electrode surface with minimal interaction between molecules. The adsorbed species is then reduced over a broader potential range.

A current peak due to reduction of the Mo—EBBR complex was found after adsorptive accumulation. This reduction peak occurred at a potential approximately 0.07 V more negative than that for the adsorbed free dye and may be seen as a very small peak at about −0.17 V on Fig. 1*a*. To observe the voltammetry of the Mo complex without interference from the uncomplexed EBBR, an accumulation potential of −0.05 V was chosen. Under these conditions, reduction of the free dye was not observed on the voltammogram (Fig. 2).

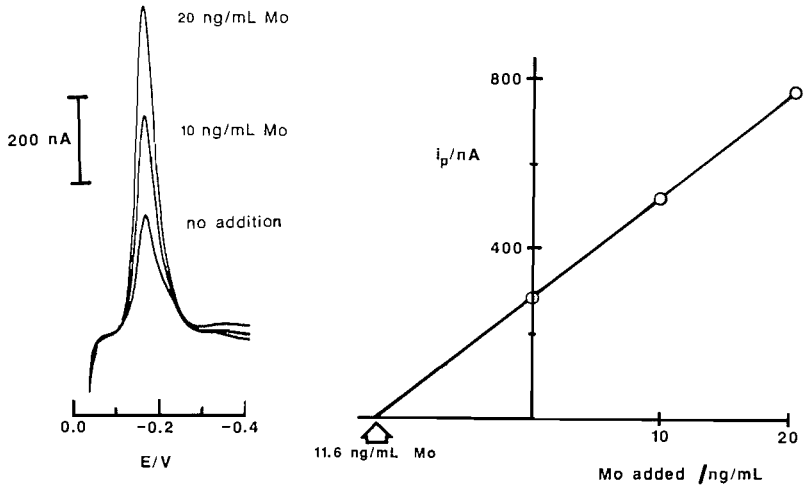

FIG. 2. Voltammograms and standard addition calibration for Mo in NASS-1, [EBBR] = 6.0×10^{-6} *M*, ν 50 mV/s, E_{ad} −0.05 V.

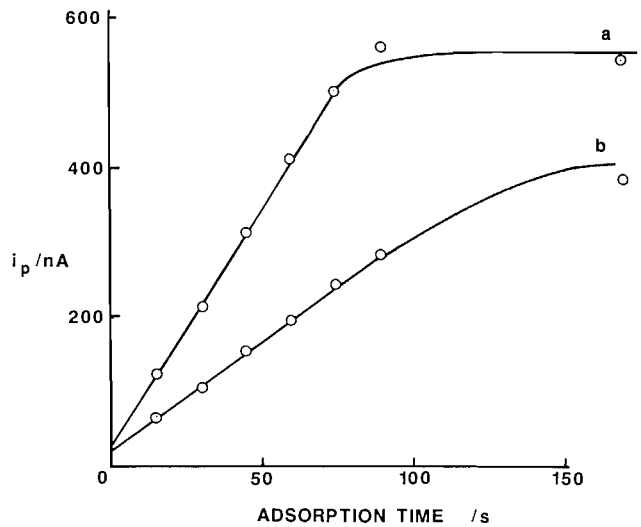

FIG. 3. Effect of adsorption time on peak height: seawater pH 1.6, [EBBR] = 6.0×10^{-6} *M*, E_{ad} −0.050 V, ν 50 mV/s. (*a*) 13 ng/mL Mo, (*b*) no Mo added.

Effect of pH

The peak potential for both the adsorbed dye and the Mo-complex became more negative with increasing pH. The reduction peak for the uncomplexed dye occurred over the pH range 1 to 6 without any decrease in height. However, the current peak for the reduction of the Mo complex decreased sharply at pH values greater than 3.

It is known that EBBR is insoluble in the presence of chloride at low pH (19), therefore, to avoid potential problems, a sample pH of 2.8 was initially chosen. However, no precipitation was observed in seawater at pH 1.6 unless the sample was allowed to stand overnight. Subsequent analyses were therefore performed at pH 1.6. This was convenient since the seawater had previously been acidified to this pH, and thus no addition of buffer was required prior to analysis.

Peak height vs. adsorption time

Figure 3 shows the effect of adsorption time on the measured peak current for Mo in seawater for a spiked (13 ng/mL) and an unspiked sample. The spiked sample reached a limiting current plateau at accumulation periods longer than 90 s. The current plateau for the peak may occur when there is complete surface coverage of the mercury drop with adsorbed species. As complete coverage of the electrode surface is to be avoided when performing standard addition calibrations, adsorption times were kept short (30–60 s).

Peak height vs. EBBR concentration

A seawater sample with 50 ng/mL Mo achieved a limiting current of 280 nA with a minimum of 6.0×10^{-6} *M* dye after 30 s accumulation time. A seawater sample with no Mo spike reached a limiting 40 nA with a minimum of 1.8×10^{-6} *M* EBBR after the same accumulation time.

The limiting current is reached when the EBBR is present in sufficient excess to quantitatively convert Mo in the sample to the dye complex. For analysis, a EBBR concentration of 6.0×10^{-6} M was used. This was sufficient to achieve the limiting maximum peak current for spikes with up to 50 ng/mL Mo(VI). Samples would normally not be expected to exceed this concentration value.

Peak height vs. scan rate

A linear relationship between peak current for the adsorbed Mo—EBBR complex and scan rate was obtained between 5 and 200 mV/s, when the other parameters were kept constant. This correlation agrees with theoretical predictions for redox reactions of an adsorbed species (24).

As scan rate increased, it became increasingly difficult to draw a baseline for measuring peak height. A scan rate of 50 mV/s was chosen as a compromise to give adequate response and precision.

Peak height vs. Mo concentration

Using the conditions described in the experimental section above, a linear relationship between peak height and concentration of added Mo was found (Fig. 2). The linear dynamic range was from 0 to 5×10^{-7} mol L^{-1} Mo and the sensitivity over this range was 15×10^{-3} A M^{-1} s^{-1}. When oxine was used as a complexing agent for adsorptive accumulation voltammetry of Mo (11), non-linear calibration curves were obtained if the solution was stirred during the accumulation step. An unstirred solution gave linear response curves up to 3×10^{-7} mol L^{-1} but the sensitivity was only 1.1×10^{-3} A M^{-1} s^{-1} under these analytical conditions.

Interferences

A number of metals gave reduction peaks at potentials near

†Reference 25.

those of Mo when analysis was done at pH 2.8 (other conditions as in Table 1). Some of these metal complexes formed only slowly at room temperature and therefore, in each case, solutions were heated to 60°C and then cooled prior to analysis. When the pH was reduced to 1.6, all of the peaks except that due to Mo disappeared. The ions Co(II), Cu(II), Cr(III), Cr(IV), Al(III), Sn(IV), Ni(II), Fe(III), Zn(II), Pb(II), Te(IV), In(III), W(VI), and U(VI) were tested at both pH values and gave no response, nor did they interfere with the Mo peak itself.

Limit of detection

The limit of detection, calculated as the concentration corresponding to three times the standard deviation of the *y*-intercept from the standard addition calibration curve, was determined to be 0.5 ng mL^{-1}. This could be reduced further by utilizing longer adsorption times, but since seawater Mo concentrations are typically near 10 ng mL^{-1}, there was no need to seek lower values. The detection limit in the oxine method was 0.3 ppb after a 1 min accumulation period.

Analysis of standard seawater samples

The Mo value in NASS-1, a reference seawater (20), has been determined by two independent analytical techniques — isotope dilution spark source mass spectrometry and graphite furnace atomic absorption spectroscopy (GFAAS). For NASS-1, the mean of six determinations by the present method was 11.6 ng/mL, std. dev. 1.2 ng/mL, which compares favorably with the reference value of 11.5 ± 1.9 ng/mL. For CASS-1, the mean of six values was 9.1 ng/mL, std. dev. 0.6 ng/mL, which again compares favorably with the reference value of 9.6 ± 0.5 ng/mL determined by GFAAS.

Determination of total tin in National Research Council of Canada marine reference materials[1]

R. E. STURGEON,[2] J. W. MCLAREN, S. N. WILLIE, D. BEAUCHEMIN, AND S. S. BERMAN
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received November 3, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

R. E. STURGEON, J. W. MCLAREN, S. N. WILLIE, D. BEAUCHEMIN, and S. S. BERMAN. Can. J. Chem. **65**, 961 (1987).

An intralaboratory determination of total Sn in three National Research Council of Canada reference materials, i.e., estuarine sediments BCSS-1 and MESS-1 and lobster hepatopancreas TORT-1 was undertaken. Samples were solubilized by acid mineralization and analyzed by stable isotope dilution inductively coupled plasma mass spectrometry, direct solution injection graphite furnace atomic absorption spectrometry (GFAAS), and hydride generation-GFAAS. The materials were homogeneous at the 500 mg subsample size. Good agreement was obtained amongst the results from the three instrumental methods of analysis. Certified values of total Sn in these materials are 1.85 ± 0.20 μg/g in BCSS-1, 3.98 ± 0.44 μg/g in MESS-1, and 139 ± 11 ng/g in TORT-1. The above uncertainties represent 95% tolerance limits for an individual (500 mg) subsample.

R. E. STURGEON, J. W. MCLAREN, S. N. WILLIE, D. BEAUCHEMIN et S. S. BERMAN. Can. J. Chem. **65**, 961 (1987).

Une détermination intralaboratoire du Sn total dans trois matériaux de référence du Conseil National de Recherches du Canada, soit les sédiments BCSS-1 et MESS-1 provenant d'estuaires, et l'hépatopancréas de homard TORT-1, fut entreprise. Des échantillons furent mis en solution par minéralisation acide et ensuite analysés par spectrométrie de masse à plasma à couplage inductif, au moyen de la dilution isotopique; par spectrométrie d'absorption atomique à four de graphite (SAAFG), avec injection directe des solutions; et par génération d'hydrure/SAAFG. Les matériaux sont homogènes au niveau de sous-échantillons de 500 mg. Un bon accord fut obtenu entre les résultats des trois méthodes instrumentales d'analyse. Les valeurs certifiées pour le Sn total dans ces matériaux sont 1,85 ± 0,20 μg/g dans BCSS-1; 3,98 ± 0,44 μg/g dans MESS-1; et 139 ± 11 ng/g dans TORT-1. Les incertitudes ci-dessus représentent des limites de tolérance de 95% pour un sous-échantillon individuel (500 mg).

Concentrations of total tin in many environmental samples vary from 100 μg/g (sediments) through low ng/g (biota) to the pg/g (aquatic) range (1). Growing concern over the accumulation of (toxic) anthropogenic alkyltin compounds and their degradation products in the environment (2, 3) has fostered development of sensitive analytical approaches for the determination of this element (1). Meaningful results (e.g. refs. 4–7) have been obtained only recently, however, due to the attention devoted to control of sample contamination.

Although the average crustal abundance of tin is only 3 μg/g (1), it is one of the most highly enriched metals in atmospheric particulate matter (7, 8). Additionally, tin is a ubiquitous contaminant in laboratory sampling vessels (including quartz and many plastics) and stringent control of airborne and reagent contamination as well as vessel surface cleanliness is imperative if accurate analyses are to be achieved.

Considering the difficulties associated with the accurate determination of tin at trace levels (1), and the paucity of international interest in this element in the past, it is not surprising that there are no biological or environmental materials presently available which are certified for their tin content (9). Systematic use of (certified) reference materials is the best way to evaluate measurement accuracy in such circumstances and a close correspondence between these materials and the test samples is desirable if valid inferences are to be made from comparative measurements.

This report summarizes work undertaken in our laboratory to determine the concentration of total Sn in three marine reference materials currently available from the National Research Council of Canada (NRCC), i.e., estuarine sediments BCSS-1 and MESS-1 and lobster hepatopancreas, TORT-1.

Use of several different analytical methods for this determination, wherein none of the methods would be expected to suffer identical interferences, should serve to minimize measurement error and provide a reliable estimate of the true value of the analyte concentration in the sample.

Experimental

Instrumentation

Determinations of total tin were made by graphite furnace atomic absorption and inductively coupled plasma mass spectrometry.

A Perkin-Elmer Model 5000 atomic absorption spectrometer was fitted with an HGA-500 graphite furnace and Zeeman effect background correction. Sample solutions were delivered to the furnace with a Perkin-Elmer AS-40 autosampler. Solid pyrolytic graphite (L'vov) platforms were used in conjunction with pyrolytic graphite coated grooved tubes. A Perkin-Elmer hollow cathode lamp served as the line source.

In addition to quantitation by direct injection of dissolved samples into the furnace, the volatile hydride of Sn was generated and trapped on a preheated graphite tube from which it was subsequently atomized. A conventional hydride generation cell was used and a quartz tube, leading from the outlet of the cell, served to transfer the hydride into the graphite tube (10).

A SCIEX ELAN 250 inductively coupled plasma mass spectrometer (Perkin-Elmer SCIEX Ltd., Thornhill, Ont.) was used for isotope ratio measurements in the analysis of dissolved samples using a stable isotope dilution technique. The only modifications to the instrument were the addition of a mass flow controller (Model 5850, Brooks Instrument Division, Emerson Electric, Hatfield, PA) to the nebulizer gas line and a Minipuls II peristaltic pump (Gilson, Middletown, WI) to the sample delivery tube.

Reagents

A 1000 mg/L stock solution of Sn, prepared by dissolution of high purity tin shot (Spex Industries, Metuchen, NY) in sub-boiling distilled nitric acid, served as the primary working standard.

Isotopically enriched (89.2%) ^{117}Sn was purchased from Oak Ridge

[1]NRC No. 27144.

National Laboratory in the form of SnO_2. A solution was prepared by fusion of 25 mg SnO_2 with 500 mg lithium tetraborate and 100 mg lithium carbonate in a platinum crucible placed in a muffle furnace at 900°C for 2 h. Overnight dissolution of the melt was effected in dilute nitric acid. The isotope abundances in this solution were checked against the values provided by Oak Ridge to assure that there was no significant contamination by the flux. The concentration of the ^{117}Sn solution was subsequently verified by a reverse spike isotope dilution analysis.

High purity mineral acids were prepared by sub-boiling distillation in quartz (HCl, HNO_3, $HClO_4$) and polypropylene stills (HF).

A 1% m/v sodium tetraborate(III) solution was prepared daily by dissolution of 0.25 g pellets of $NaBH_4$ (Alpha Inorganics) in deionized distilled water (DDW).

A 2000 mg/L solution of Pd (in HCl) was used as a matrix modifier for direct AAS determination of Sn, as suggested by Voth-Beach and Shrader (11).

Sample preparation

All sample preparations were conducted in a clean laboratory equipped with laminar-flow benches and fume cupboards providing a class 100 working environment.

Complete dissolution of the estuarine sediments can be obtained using closed vessel techniques without the danger of loss of any volatile analyte species. However, because of their limited sample capacity for organic materials, the Lorran vessels could not be used for the digestion of TORT-1. Dry ashing of this material is unsuitable due to potential losses of volatile organotin compounds as well as formation of insoluble SnO_2 in the sample residues. Wet ashing with mixed acids in clean quartzware was found to be unsatisfactory because of the resultant high blanks (up to 75 ng).

Sediment samples (BCSS-1 and MESS-1) were solubilized in LORRAN Teflon pressure decomposition vessels (H.K. Morrison and Sons Ltd., Mount Uniacke, N.S.). Nominal 0.5 g samples were mixed with 3 mL HNO_3, 3 mL HF, and 2 mL $HClO_4$ and the vessels submerged for 3 h in a water bath at 100°C. After cooling, the contents were quantitatively transferred to 50 mL Teflon PFA beakers and evaporated directly on a hot plate (with an ir lamp as an additional heat source) to incipient dryness. A further 1 mL HF and 1 mL $HClO_4$ were added and the samples again taken to near dryness. A final addition of 1 mL HCl and 1 mL HNO_3 followed by gentle warming and dilution to 50.0 mL with DDW resulted in complete solubilization of the sample. An initial white-colored sediment (presumably slightly soluble perchlorate salts) completely dissolved after the samples were permitted to stand for 12 h.

Duplicate samples were taken from each of four bottles of both sediments. Two blanks were run concurrently with each set of four sample decompositions.

The biological reference material TORT-1 was solubilized by addition of 20 mL HNO_3 to nominal 0.5 g samples in PFA beakers. The vessels were covered with Teflon watch covers and heated on a hot plate under reflux conditions for at least 4 h. The covers were then removed, 1 mL HF and 1 mL $HClO_4$ added to each, and the samples evaporated to near dryness. A further 5 mL HNO_3 and 1 mL $HClO_4$ were then added and the solutions again taken to near dryness. The surface temperature of the hot plate is approximately 190°C during these steps. Following a final 1 mL addition of $HClO_4$ with heating to near dryness, the residues were dissolved in 1 mL HCl and diluted to 25.0 mL with DDW.

Duplicate samples were taken from each of four different bottles of TORT-1. Two blanks were run concurrently with each set of four sample decompositions.

Isotopically spiked solutions of MESS-1, BCSS-1, and TORT-1 were prepared by adding an appropriate aliquot of the ^{117}Sn solution to the sample at the beginning of the acid digestion procedure. The mass of the ^{117}Sn spike was adjusted to make the $^{118}Sn/^{117}Sn$ ratio close to unity. Blank solutions were spiked with one-tenth the amount of ^{117}Sn added to the samples. Sets of four samples (along with two blanks) of each reference material were analyzed by the isotope dilution technique.

Procedure

The GFAAS furnace program and instrument conditions for direct injection analysis were as recommended by Slavin *et al.* (12) with the exception that 20 μg Pd was used as the matrix modifier (11). Calibration was by the method of additions using two incremental spikes of natural tin standard.

Volatile SnH_4 was produced by the addition of 2 mL 1% $NaBH_4$ to the hydride generation cell containing 20 mL 0.1 *M* HCl and 20 μL dissolved BCSS-1 or MESS-1 solution or 200 μL dissolved TORT-1 solution. The hydride was deposited at 800°C onto the tube wall of the graphite furnace and subsequently atomized at 2700°C. A detailed description of this technique has been presented by Sturgeon *et al.* (10, 13). Calibration was achieved against the response from simple aqueous standards treated in an identical manner.

The ELAN 250 ICP-MS was operated with a standard ICP-AES torch, with plasma, auxiliary and nebulizer gas flow rates of 14, 2.0, and 0.9 L min^{-1}, respectively. The torch box was positioned as close as possible to the sampler (i.e., 17 mm from sampler tip to top of RF load coil). The mass spectrometer was operated with low resolution and each ratio determination involved a total of 150 measurements of 0.1 s duration at m/z 118 and m/z 117. Fifty measurements were made at the assumed peak centers, while a further 100 were made at ±0.1 u. The use of the stable isotope dilution technique in ICP-MS has previously been described in applications to coastal seawater (14), river water (15), and marine sediment reference materials (16).

Prior to performing the isotope dilution analyses, $^{117}Sn/^{118}Sn$ isotope ratios were measured for a 100 μg/L natural abundance tin solution to check for mass discrimination and for several unspiked solutions of each of the samples to check for possible isobaric interferences from molecular species. The following values were obtained: 100 μg/L Sn standard, 0.317 ± 0.002; TORT-1 solution, 0.319 ± 0.005; MESS-1 solution, 0.314 ± 0.003. None of these differ significantly from the accepted value based on natural abundances (0.3171) not only confirming that mass discrimination is negligibly small, but also suggesting that there are no significant isobaric interferences on either of the Sn isotopes.

All sample weights were corrected for moisture content and results reported on a dry weight basis. A sample of TORT-1 reference material (not subsequently used for analysis due to possible contamination) was dried to constant weight by placing it in a vacuum oven at room temperature for 24 h. Similarly, samples of BCSS-1 and MESS-1 were dried to constant weight by heating overnight at 105°C.

Results and discussion

Maher (17) as well as Burns *et al.* (18) have reported that organotin compounds in biological materials and aqueous solutions can be quantitatively converted to Sn(IV) by acid digestion and that concentrated HNO_3 does not produce insoluble SnO_2 (17). The efficiency of recovery of total Sn from TORT-1 samples was verified by undertaking a $HNO_3/HClO_4$ digestion of 250 mg subsamples in closed 120 mL Savillex Teflon PFA vessels. Decomposition was effected by heating for 30 min at 60–70 psig (internal pressure in the vessel) using a MDS-81D microwave digestion system (CEM Corp. Indian Trail, NC). Analyses by ICP-MS using the isotope dilution technique (ID ICP-MS) produced results which were not significantly different from those obtained on samples digested in open PFA beakers.

Analytical blanks and methodological detection limits

Procedural blanks for ID ICP-MS were equivalent to 180 ± 30 ng/g for the sediments and 12 ± 4 ng/g for TORT-1. These blanks reflect the cumulative contamination from all

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

sources, including reagents, contact with vessels, and sample handling with the major amount arising from the nitric acid. No measurable blanks were obtained by direct GFAAS since the Sn concentrations in these solutions were below the detection limit for this technique. For hydride generation GFAAS, the primary source of the blank was the generation cell. No effort was made to clean up the $NaBH_4$ reagent. In this case the "cell blank" was determined to be 0.110 ± 0.024 ng, irrespective of the addition of 20 μL aliquots of sediment blank solution or 200 μL aliquots of TORT-1 blank solution.

Corresponding methodological detection limits (concentration corresponding to 3 × standard deviation of the blank) for Sn in sediments as determined by hydride generation GFAAS and ID ICP-MS are 0.36 μg/g (based on a 20 μL sample aliquot) and 0.09 μg/g, respectively. The detection limit for direct GFAAS, 0.9 μg/g, was estimated from the precision of determination of Sn in BCSS-1. Methodological detection limits for the determination of Sn in biological tissue (i.e., TORT-1) are 0.018 μg/g for hydride generation GFAAS (based on a 200 μL sample aliquot) and 0.012 μg/g for ID ICP-MS. Concentrations of Sn in dissolved TORT-1 were too low to permit accurate quantitation by direct GFAAS.

Detection limits may be further improved by decreasing the magnitude and variability of the procedural blank. Improvements in instrumental sensitivity by factors of 2 may be possible but will not significantly change the performance of the system. Complete sample decompositions in the Teflon pressure vessels in combination with microwave heating may serve to decrease dissolution blanks. Hydride generation GFAAS detection limits may be improved by cleaning up the $NaBH_4$ reagent through coprecipitation of Sn with added lanthanum or sodium hydroxide (e.g. ref. 19).

Analytical results

Results for the determination of Sn in BCSS-1, MESS-1, and TORT-1 are presented in Table 1 and are reported on a dry weight basis.

Of the eight test portions of MESS-1 and BCSS-1 taken for analysis by ID ICP-MS, one result was statistically rejected from each data set (by application of a simple *t*-test).

Of the eight test portions of MESS-1 and BCSS-1 taken for analysis by direct GFAAS and by HG-GFAAS, one was physically lost during preparation and one direct GFAAS result was statistically rejected.

No ID ICP-MS results for TORT-1 were rejected (only six test portions were initially taken for analysis). Of the eight test portions of this material taken for analyses by HG-GFAAS, one sample was physically lost during mineralization and one analytical result was statistically rejected. In general, good agreement is evident amongst the various techniques. The mean of results reported for the direct solution analysis of BCSS-1 by GFAAS is biased low. The reason for this is not clear, considering the acceptable results obtained on these same solutions by hydride generation GFAAS and the good performance of direct solution analysis of MESS-1 by GFAAS. The lower concentration of Sn in the solutions of BCSS-1 was not favorable in that the determination was being attempted at only 2-fold above the estimated detection limit for this technique. It is clear that hydride generation-GFAAS is the preferred optical spectroscopic method in this case (as well as for determinations in TORT-1 solutions).

Results from different bottles showed no significant differences compared to results from subsamples within bottles. The subsampling uncertainty (on 500 mg test portions) is thus equal to or less than the measurement uncertainty. Thus, heterogeneity of the materials does not contribute significantly to the overall analytical uncertainty when 500 mg test portions are used. It is probable that smaller subsamples may be utilized without the subsampling error exceeding the specified tolerance limits (20, 21).

TABLE 1. Analytical results for total tin, μg/g[a]

Technique	Sample		
	MESS-1	BCSS-1	TORT-1
GFAAS	3.9 ± 0.3 (8)	1.5 ± 0.3 (6)	ND[b]
HG-GFAAS	4.0 ± 0.2 (8)	1.9 ± 0.2 (7)	0.144 ± 0.016 (6)
ID ICP-MS	3.9 ± 0.2 (7)	1.78 ± 0.06 (7)	0.141 ± 0.006 (6)
Certified values[c]	3.98 ± 0.44	1.85 ± 0.20	0.139 ± 0.011

[a]Mean and standard deviation of (*n*) replicate determinations.
[b]Not determined.
[c]95% tolerance limit for an individual subsample.

Conclusions

With the exception of direct GFAAS results for BCSS-1, comparable data for total Sn concentrations were obtained by all three instrumental analytical techniques. Good agreement with certified values, i.e., 1.85 ± 0.20 μg/g in BCSS-1; 3.98 ± 0.44 μg/g in MESS-1, and 139 ± 11 ng/g in TORT-1 in the three reference materials was also demonstrated. The above uncertainties represent 95% tolerance limits for an individual subsample. That is, 95% of samples, 500 mg or greater, from any bottle would be expected to have concentrations within the specified range 95% of the time. It should be noted that certified values are based on the data presented here as well as on additional data not cited in this study.

Release of certified values for total Sn in these reference materials is significant in that they represent the first available environmental samples for which certified concentrations of this element (9) are given.

Received September 17, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

ROBERT A. BAUMANN, MARRY SCHREURS, CEES GOOIJER, NEL H. VELTHORST, and ROLAND W. FREI. Can. J. Chem. **65**, 965 (1987).

The feasibility of time-resolved quenched phosphorescence as a detection method for chromate based on paired-ion reversed phase high performance liquid chromatography is shown. After separation detection is achieved by monitoring the time-resolved phosphorescence signal of biacetyl at 515 nm. Optimization of the time-resolution parameters of the luminescence detector results in a limit of detection of 1.4×10^{-7} *M* (2 ng on column) for chromate standard solutions. The linearity of the method is three orders of magnitude. Chromatograms of tapwater and surface water samples spiked with chromate show the potential applicability of the method for real samples.

ROBERT A. BAUMANN, MARRY SCHREURS, CEES GOOIJER, NEL H. VELTHORST et ROLAND W. FREI. Can. J. Chem. **65**, 965 (1987).

On démontre la possibilité d'utiliser la phosphorescence piégée et résolue en fonction du temps comme méthode de détection du chromate; la méthode est bassé sur la chromatographie liquide à haute performance en phase inversée sur des ions pairés. Après la séparation, la détection se fait en observant, à 515 nm, le signal de la phosphorescence, résolue en fonction du temps, du biacétyl. Une optimisation des paramètres de la résolution en fonction du temps permet d'atteindre une limite de détection de $1{,}4 \times 10^{-7}$ *M* (2 ng sur la colonne) de solutions standard de chromate. La linéarité de la méthode s'étend sur trois ordres de grandeur. Les chromatogrammes d'échantillons d'eaux d'aqueduc ou de surface dans lesquels on a ajouté du chromate permettent de démontrer le potentiel d'application de la méthode à des échantillons réels.

Introduction

The speciation of metal ions with respect to their toxic properties is of great importance in clinical, toxicological, and environmental analysis. In the case of chromium, the trivalent cation Cr(III) is an essential trace element to man. It is present in natural waters at the ppb level and plays a role in biochemical processes of aquatic plants and animals (1). On the other hand, the chromate ion Cr(VI) is an enzymatic poison which leads to hepatic and renal damage by exposure (2). Furthermore, Cr(VI) is a suspected carcinogen. The maximum allowable concentration in drinking water established in 1963 by the World Health Organization is 50 ppb. Sources of chromium pollution are metallurgic, glass, ceramic, textile, and tannery industries. It is extensively used in electroplating, as a corrosion inhibitor and in chrome tanning liquors (3).

Most analytical methods used for the speciation of Cr(III) and Cr(VI) are based on an off-line separation and/or a preconcentration step by means of extraction or ion-exchange with subsequent detection of the different species by atomic absorption (4–7) or emission (8) spectrometry. Recently, separation by paired-ion reversed phase high performance liquid chromatography (hplc) of Cr(III) and Cr(VI) followed by inductively coupled plasma emission detection has also been published (9, 10). Additionally, reversed phase hplc separations of Cr(III)/Cr(VI) as dithiocarbamate complexes combined with uv (11, 12) or electrochemical (13) detection are known. Furthermore, a post column reaction detection method with a lead dioxide solid phase reactor has been reported (14).

In the present paper the selective determination of chromate after separation on a paired-ion reversed phase hplc system with the recently developed quenched phosphorescence detection method is described. With this detector Cr(III) gives almost no response. For the first time the possibility of time resolution is quantitatively examined by measuring the influence of the instrumental parameter settings of the commercially available detector on the sensitivity of the method. To show their influence theoretically the well-known Stern–Volmer equation for dynamic quenching has to be modified. Relevant analytical data obtained for chromate standard solutions are given. Chromatograms of spiked tapwater and spiked surface water samples clearly indicate the selectivity and sensitivity of the quenched phosphorescence detector for real samples.

Theoretical

Quenched room temperature phosphorescence in liquids (qrtpl) has been developed in our lab as a detection method in hplc (15, 16). It is based on the measurement of the phosphorescence of biacetyl (2,3-butanedione) present in the deoxygenated mobile phase. Analytes able to interact with biacetyl in the excited triplet state cause a decrease of the phosphorescence signal. In the past use was made of a luminescence detector with a continuum excitation source and the phosphorescence emission signal was monitored continuously. In absence of quenchers a constant phosphorescence signal with intensity I_0 is observed, corresponding to a triplet lifetime τ_0 of biacetyl. In presence of a dynamic quencher, τ_0 is decreased to τ and I_0 to I according to Stern-Volmer.

$$[1] \quad \frac{I_0}{I} = \frac{\tau_0}{\tau} = 1 + k_q \tau_0 [Q]$$

In eq. [1] k_q is the bimolecular rate constant of the quenching reaction ($M^{-1}\ s^{-1}$) and [Q] the quencher concentration (*M*).

Until recently, the possibility of time resolution on the microsecond time scale in quenched phosphorescence detection, to exclude scattering and background fluorescence, was not invoked. The Perkin–Elmer LS-2 luminescence detector applied in our experiments can be operated in a pulsed-source – time-resolved phosphorescence mode. The emission signal is gated, during a time interval t_g, after the source flash by a delay time t_d. Under these conditions the signal intensities in absence

and presence of quenchers I_0' and I' are given, respectively, by the time integrals

$$[2] \quad I_0' = \int_{t_d}^{t_d+t_g} B_0 \exp(-t/\tau_0)dt$$

and

$$[3] \quad I' = \int_{t_d}^{t_d+t_g} B_0 \exp(-t/\tau)dt$$

where $B_0\, e^{-t/\tau_0}$ and $B_0 e^{-t/\tau}$ are the phosphorescence decay curves. For biacetyl, B_0, the radiation flux, is the product of an instrumental constant, the rate of light absorption at the applied excitation wavelength, the efficiency of intersystem crossing, and the rate constant of the phosphorescence process (15). In our experiments t_g is about $5\tau_0$. Under these conditions more than 99% of I_0' falls within the upper integration limit $t_d + t_g$, of course the same holds for I' since $\tau < \tau_0$. This means that $t_d + t_g$ can be replaced by an integration to infinity so that eqs. [2] and [3] give

$$[4] \quad \frac{I_0'}{I'} = \frac{\tau_0}{\tau} \exp(-t_d/\tau_0 + t_d/\tau)$$

Combination of eqs. [1] and [4] leads to

$$[5] \quad \frac{I_0'}{I'} = (1 + \tau_0 k_q[Q]) \exp(t_d k_q[Q])$$

Thus in the time-resolved mode a modified Stern–Volmer expression is obtained; the intensity ratio is the product of a linear and an exponential term. The influence of the latter decreases when t_d is shortened. This is an important conclusion in view of the linearity of calibration curves, as can be seen in Fig. 3.

As noted before, if $t_d + t_g$ is much larger than τ_0 this sum can be replaced by infinity and I_0' from eq. [2] can be written as

$$[6] \quad I_0' = B_0\tau_0 \exp(-t_d/\tau_0)$$

so that

$$[7] \quad \ln I_0' = \ln(B_0\tau_0) - t_d/\tau_0$$

Experimental

Chemicals

All reagents used were analytical grade. K_2CrO_4, $NaH_2PO_4.H_2O$, and sodium hydroxide were purchased from Merck (Darmstadt, F.R.G.). Acetonitrile (hplc) grade was obtained from Baker (Deventer, The Netherlands); biacetyl from Aldrich (Beerse, Belgium), and tetrabutylammoniumchloride (TBACl) from Ventron (Karlsruhe, F.R.G.). Deionized water was distilled twice before use.

Instrumentation

Batch experiments were carried out as described previously (17). A description of the hplc system was published in ref. 18.

The Perkin–Elmer LS-2 luminescence detector was employed in the pulsed-source – time-resolved phosphorescence mode. For excitation of biacetyl a broad band filter with maximum transmission at 400 nm was used; the emission wavelength was 515 nm.

Results and discussion

Batch experiments

For most metal ions that occur in more than one oxidation state, as for instance platinum and tin, the ion in the lowest oxidation state has the highest quenching constant (16, 17). This can be readily conceived if the quenching of the biacetyl phosphorescence is caused by electron transfer. For chromium this is obviously not the case. Bimolecular quenching constants of chromate under various conditions, measured as described before (17), are given in Table 1. Rather unexpected, they are about one order of magnitude larger than the value found for Cr(III). The quenching mechanism for chromate could be based on energy transfer instead of electron transfer, which is only possible if chromate possesses an excited electronic state with a lower energy than the triplet state of biacetyl. Table 1 shows that the influence of the pH on k_q is small; with decreasing pH from 7 to 4, k_q increases slightly. In the pH-range 0.75–6.45 $HCrO_4^-$ is the dominating species, while above pH = 6.45 mainly CrO_4^{2-} is present in solution (19).

TABLE 1. k_q values of chromate under various conditions

	Solvent	k_q (M^{-1} s^{-1})
Chromate	Water/acetonitrile 50/50 (v/v)	8.5×10^8
	Water	7.5×10^8
	2×10^{-3} *M* phosphate buffer pH 7	3.5×10^8
	2×10^{-3} *M* phosphate buffer pH 6	5×10^8
	2×10^{-3} *M* phosphate buffer pH 5	8×10^8
	2×10^{-3} *M* phosphate buffer pH 4	8×10^8
Cr^{3+}	Water/acetonitrile 16.3/83.7 (v/v)	5.8×10^7 (17)

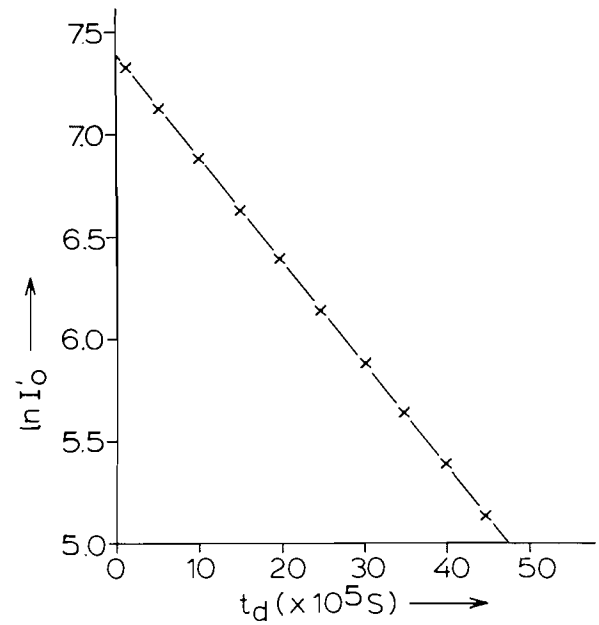

FIG. 1. ln I_0' vs. t_d for the determination of the phosphorescence lifetime τ_0 of biacetyl. t_g = 1.00 ms.

Time-resolved phosphorescence detection

In order to investigate the influence of the delay time t_d and the gating time t_g on the phosphorescence intensity measured in absence of quenching analyte we refer to the theoretical section.

Equation [7] predicts a straight line upon plotting ln I_0' versus t_d with intercept ln $B_0\tau_0$ and slope $-1/\tau_0$. Figure 1 shows such a plot obtained for a freshly prepared mobile phase after deoxygenation under flow conditions (t_g = 1.00 ms). The calculated lifetime of biacetyl τ_0 is 0.20 ms.

In Fig. 2 the influence of t_g on I_0' is visualized (measured at t_d = 0.01 ms, the minimum instrumental setting). When t_g becomes larger than 1.0 ms, corresponding to $t_g \approx 5\tau_0$, I_0' reaches a plateau; then the approximations of eqs. [2] and [3] apply.

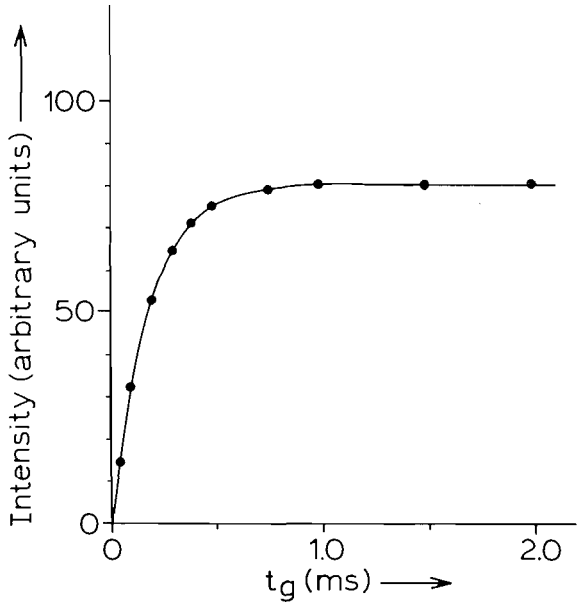

FIG. 2. I_0' vs. t_g; t_d = 0.01 ms.

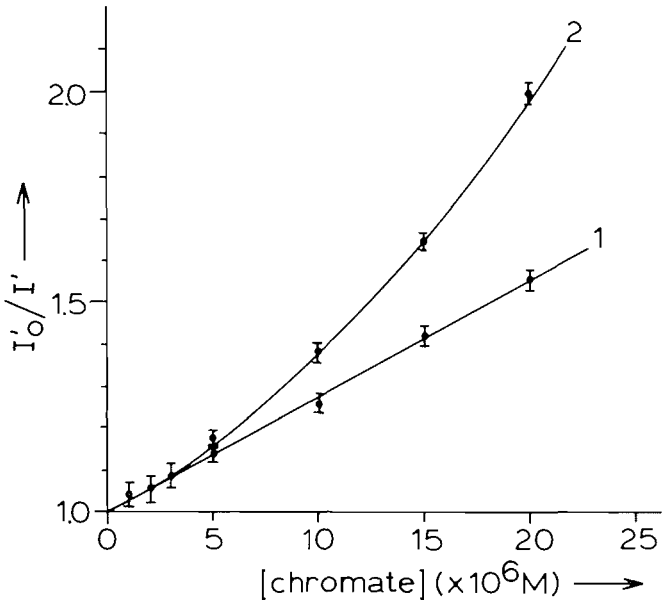

FIG. 3. I_0'/I' plotted against the chromate concentration. (*1*) t_d = 0.01 ms; (*2*) t_d = 0.25 ms. In both cases, t_g = 1.00 ms. The intensity ratios are calculated from actual chromatograms.

Equation [5] predicts a non-linear dependence of I_0'/I' and [Q] because of the presence of an exponential term in the Stern–Volmer equation for the time-resolved mode. The role of this term will depend on t_d. This is shown in Fig. 3. The deviation from linearity is negligible for t_d = 0.01 ms but is very strong if t_d is 25 times larger. The latter curve increases exponentially for higher chromate concentrations.

Of course the experimental settings t_d and t_g not only influence the signal but also the noise of the system. The optimum choice for t_g can be readily derived from Fig. 2: for t_g about 0.9–1.0 ms the signal-to-noise ratio (S/N) will be the most favourable. Further increase of t_g does not improve the signal but only implies a higher noise level. For the choice of t_d two points must be taken into account. If only shot noise is

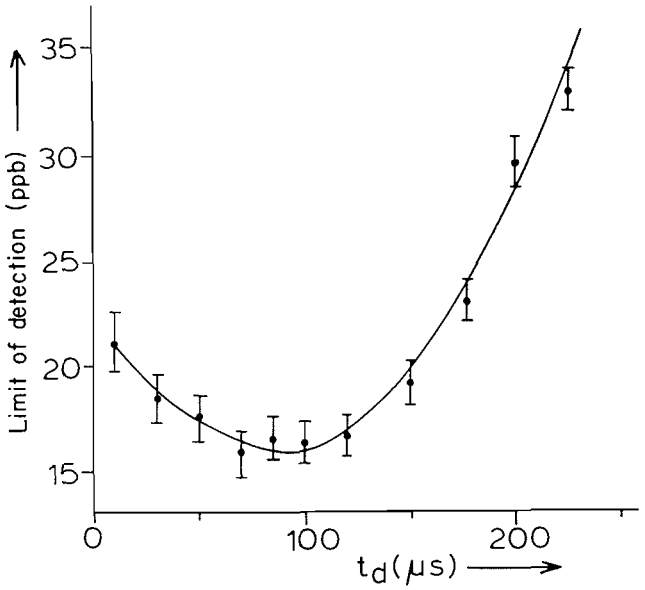

FIG. 4. Limit of detection (lod) of chromate vs. t_d to estimate the maximal signal-to-noise ratio. t_g = 1.00 ms. The injected chromate concentration is 100 ppb. Chromatographic conditions: column 12 cm × 4.6 mm inner diameter; 5 μm ODS. Spherisorb; mobile phase 95/5 (v/v) water/acetonitrile, 2×10^{-3} *M* phosphate buffer pH 7.1, 2×10^{-4} *M* TBACl and 5×10^{-3} *M* biacetyl. Injection volume 100 μL; flow rate 1.0 mL min^{-1}.

considered S/N is proportional to $(I_0')^{1/2}$; hence t_d must be chosen as short as possible because I_0' is proportional to $\exp(-t_d/\tau_0)$, see eq. [6]. On the other hand, an increase of t_d leads to a decrease of scattering and background fluorescence resulting in a lower noise level. Experiments have shown that the best value for t_d is 0.10 ms, which is in line with our earlier reported source pulse duration of the LS-2 instrument of about 0.08 ms (20). In Fig. 4 the limit of detection (lod) of chromate is depicted as a function of t_d (S/N = 3). The chromate concentration used was small (100 ppb) to assure working in the (quasi) linear range of the calibration curves. The gain in lod is about 30% when t_d is increased from 0.01 to 0.10 ms.

Summarizing we conclude that for routine analysis with the quenched biacetyl phosphorescence system a combination t_d = 0.01 and t_g = 1.00 ms can be used. To achieve the lowest limits of detection, t_d must be set equal to 0.1 ms.

Chromatographic experiments and application to real samples

The use of paired-ion, reversed phase hplc for the separation of Cr(III) and chromate has been described by several authors (9, 10, 14). When TBACl as ion pairing reagent is added to the mobile phase chromate is retained on a reversed phase type column while Cr(III) elutes in the solvent front. The mobile phase was buffered at pH 7.1 because of the favourable chromatographic properties of the divalent CrO_4^{2-} ion (21). At this pH chromate is almost quantitatively present as CrO_4^{2-} (20). In Fig. 5 a chromatogram is given for a 200 ppb (1.7×10^{-6} *M*) chromate standard solution. Peaks 1 and 2 are attributed to quenching impurities. The lod measured as a signal-to-noise ratio of 3 under optimal detector conditions (t_d/t_g resp. 0.10/1.00 ms) is 16 ppb (1.4×10^{-7} *M*), see also Fig. 4. For routine analysis, when a large linear range is required usually, t_d and t_g are set equal to 0.01 and 1.00 ms, respectively. In that case, the lod is 21 ppb. The calibration curve is linear over three orders of magnitude (r = 0.998, n = 7)

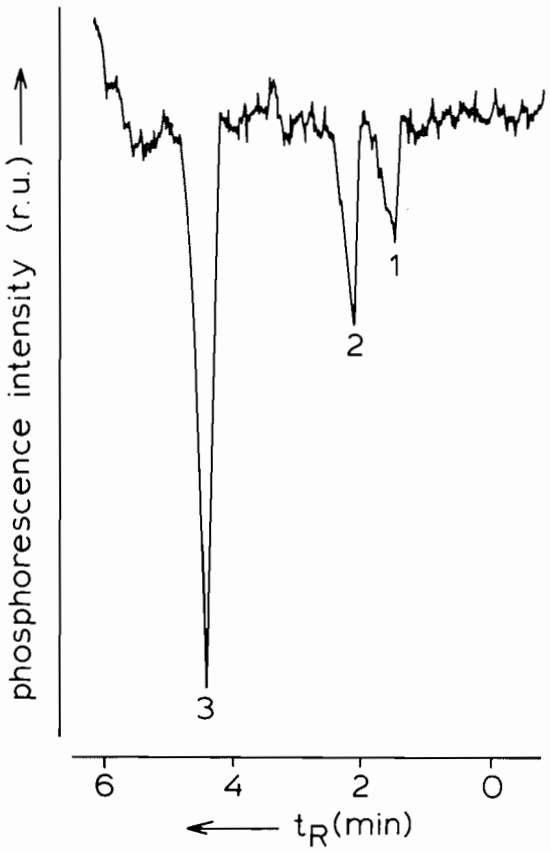

FIG. 5. Chromatogram of a 200 ppb (1.7×10^{-6} *M*) standard solution of chromate. (*1*) and (*2*) are quenching impurities, (*3*) is the chromate peak. Chromatographic conditions as in Fig. 4.

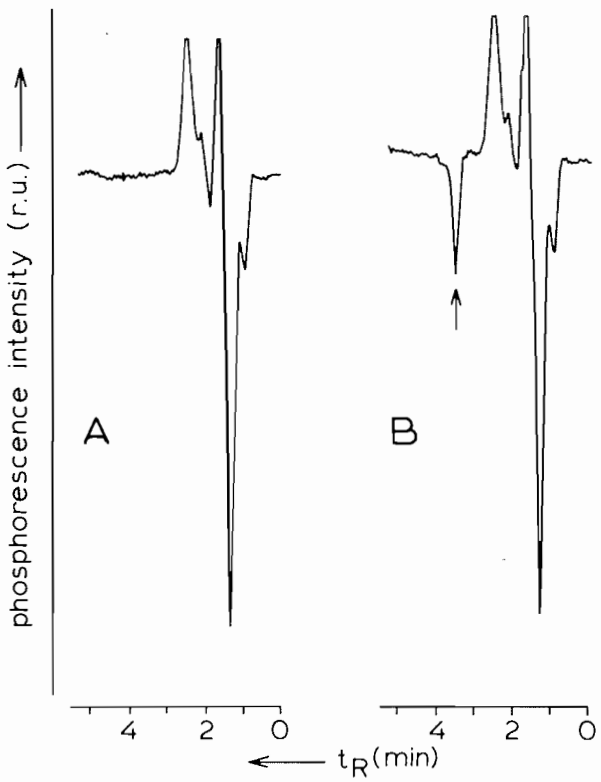

FIG. 6. Chromatogram of a blank tap water sample (*A*) and of a tap water sample spiked with 1×10^{-5} *M* chromate (B). The positive peaks in the chromatograms in Figs. 6 and 7 are attributed to impurities present in the samples exhibiting native fluorescence or sensitized phosphorescence of biacetyl. The negative peaks are caused by quenching compounds. Chromatographic conditions as in Fig. 4.

when I_0'/I' vs. [Q] is plotted. At the 50 ppb level the relative standard deviation is 4.2% and at the 500 ppb level 1.7%, both based on eight repetitive injections.

To show the potential applicability of the method to real samples tapwater and surface water samples were spiked with chromate, filtered over a 0.2 μm filter and after deoxygenation injected onto the column. In Fig. 6 chromatograms are given of a blank and a spiked tap water sample respectively. To improve the shape of the chromate peak, 3% acetonitrile was added to the spiked sample before injection. If this was not done, peak tailing was observed, caused probably by interaction of chromate with residual silanol groups on the silica matrix (22). Addition of a small amount of acetonitrile appeared to suppress this effect. The recovery of chromate was 60% at the 1×10^{-5} *M* level and 42% at the 5×10^{-6} *M* level. These low recoveries are probably due to reducing components present in tap water that react with chromate, or due to sorption onto or reaction with the filter used. Chromatograms of a blank and a spiked surface water sample are shown in Fig 7. In this case, the recovery of chromate was 85% at the 5×10^{-6} *M* level.

Figures 6 and 7 additionally indicate the selectivity of the detection method at hand. Both the chromatograms of the blanks for tap water and surface water are relatively clean; from this point of view sample preparation can be done quite easily.

The dependence of the recovery from the spiked amount of chromate makes it difficult to calculate a limit of detection for real samples. However, as the chromate peak is clearly separated from matrix interferences in all water samples, 20 ppb, corresponding to 2 ng absolute, seems a realistic value in view of the results of standard solutions. It is emphasized

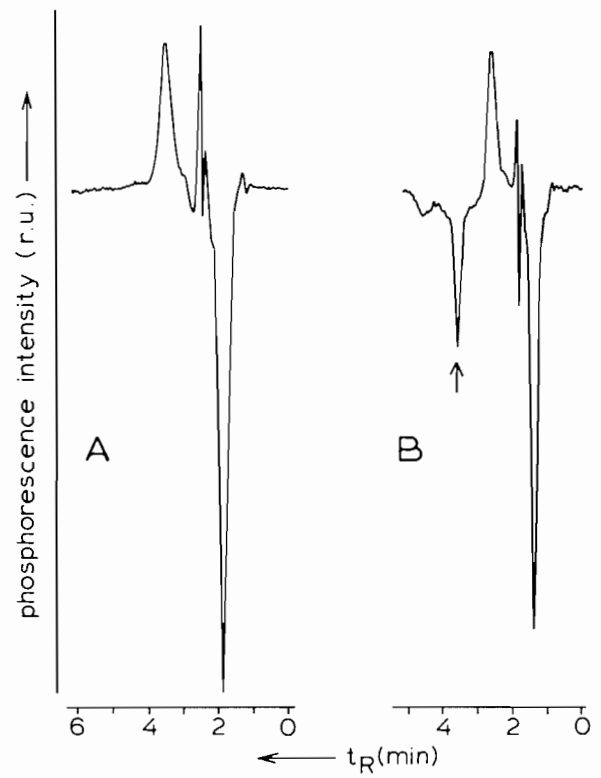

FIG. 7. Chromatogram of a blank surface water sample (*A*) and of a surface water sample spiked with 5×10^{-6} *M* chromate (*B*). Chromatographic conditions as in Fig. 4.

TABLE 2. Comparison of lod values for chromate obtained with different hplc methods

Detection method	Limit of detection (ng/mL)	Reference
Electrochemical (as diethyldithiocarbamate complex)	4	13
Colorimetric (as 1,5-diphenylcarbazide complex)	100	14
Direct current plasma (dcp) emission spectroscopy	7	10
Quenched rtpl	16	This work

that in originally chromate containing samples the concentration remains stable once an equilibrium situation has been reached.

In Table 2 a comparison in sensitivity is made between our method and other recently described hplc methods which deal with the separate detection of chromate; the lod's are essentially the same (4–17 ng) except for the colorimetric method (100 ng). Although the dcp (direct current plasma) detection method (10) claims a slightly lower lod than our method, a dcp emission spectrometer is not easily available in most laboratories. The electrochemical detection method as described by Bond and Wallace (13) has the disadvantage that the complex formation of chromate with diethyldithiocarbamate is extremely slow, resulting in a time-consuming sample pretreatment procedure.

Conclusions

The quenched phosphorescence detection method can be used in combination with paired-ion reversed phase hplc for the detection of chromate in water samples. The sensitivity of the method achievable with the commercially available Perkin–Elmer LS-2 detector should be sufficient for the control of drinking water quality (50 ppb limit) if time-resolution is applied and the instrumental parameters are chosen carefully.

The liquid crystalline polysiloxane substrate offers unique selectivity when used in capillary column gas chromatography. The separation and identification of priority pollutants along with other compounds is very difficult but important. In particular, the separation of isomeric organic compounds having similar volatilities could not be obtained on capillary columns using conventional stationary phases. The complete separation of *ortho*, *meta*, and *para* isomers of certain disubstituted benzenes as well as polycyclic aromatic compounds was achieved on a capillary column using a liquid crystalline polysiloxane stationary phase. The complete separation of octachlorodibenzodioxin from octachlorodibenzofuran was also obtained on this column which is not possible on columns of identical lengths using conventional stationary phases. The separation of polycyclic aromatic compounds in a complex sample of airborne particulate matter extract on the liquid crystal column is demonstrated.

K. P. NAIKWADI, A. M. MCGOVERN et F. W. KARASEK. Can. J. Chem. **65**, 970 (1987).

Le polysiloxane à l'état de cristal liquide, utilisé comme substrat en chromatographie en phase gazeuse avec des colonnes, offre une sélectivité unique. La séparation et l'identification des polluants prioritaires de même que celle d'autres composés est difficile, mais importante. En particulier, la séparation de composés organiques isomères possédant des volatilités semblables ne peut être réalisée à l'aide de colonnes capillaires remplies de phases stationnaires conventionnelles. La séparation complète des isomères *ortho*, *méta* et *para* de certains dérivés benzéniques disubstitués, de même que celle de composés aromatiques polycycliques a pu être réalisée sur une colonne capillaire contenant du polysiloxane à l'état de cristal liquide comme phase stationnaire. Utilisant cette colonne, on a aussi réalisé la séparation complète de l'octachlorodibenzodioxine de l'octachlorodibenzofuranne; cette séparation ne peut toutefois pas être réalisée à l'aide de colonnes de longueurs semblables remplies de phases stationnaires conventionnelles. On démontre, à l'aide de la colonne à cristaux liquides, comment on peut séparer les composés aromatiques polycycliques contenues dans un échantillon complexe de substances extraites de matières solides transportées dans l'air.

Introduction

Liquid crystalline compounds have been used as stationary phases in packed column gas chromatography (GC) for the last two decades. Their application for the separation of a variety of isomeric organic compounds has been reviewed several times (1–5). The continued research and interest in these phases resulted in the development of high temperature liquid crystals suitable for use in packed columns for separation of isomeric polycyclic aromatic compounds (PAC) (6–8). Capillary columns are highly efficient compared to packed columns and the separation of several hundred compounds can be carried out as reported previously (9). The use of high temperature monomeric liquid crystals in capillary columns presents several difficulties (10). Their use by blending with polymeric silicone phases in capillary columns resulted in moderate selectivities and higher efficiencies than packed columns (11, 12). The synthesis of new liquid crystalline compounds and separation of disubstituted benzene isomers (13), insect sex pheromones (14), and the effect of the chemical structure of liquid crystalline compounds on separation potential is reported in the literature (8). Recently, polymeric liquid crystals were developed for use in capillary columns (15–20). These phases can be coated in capillary columns by dynamic or static coating techniques. Their application in supercritical fluid chromatography has been reported previously (21).

In this paper, the application of a liquid crystalline polysiloxane stationary phase in a fused silica capillary column for the separation of various isomeric organic compounds will be shown. The novel application of this column for the separation of pac in airborne particulate matter will be demonstrated.

Materials and methods

A fused silica capillary column (20 m × 0.25 mm) coated with a liquid crystalline polysiloxane stationary phase (SB-Liquid Crystal) was obtained from Lee Scientific, Salt Lake City, Utah (U.S.A.). The column was coated by the static method (film thickness ca. 0.15 μm) and crosslinked using azo-*t*-butane. All the standard PAC were obtained from Aldrich Chemical Co. The halogenated standards were obtained from Ultra Scientific, Rhode Island (U.S.A.). The gas chromatograph was a Hewlett Packard model 5880 equipped with a flame ionization detector and cool on-column injector. The GC/MS system was a Hewlett Packard 5987A along with an HP 1000 data system. The data acquisition and storage system allows mass chromatograms to be reconstructed at any mass in the scan range. The library search system includes probability-based matching (PBM) based on 78 000 reference mass spectra. The airborne particulate matter extracts were separated into acidic, basic, and neutral groups of compounds by acid–base extraction.

The separation of neutrals into aliphatic, polycyclic aromatic, and polar compounds was achieved using a Varian 5000 Liquid Chromatograph with a Vista 401 data system. The data system has a capacity to recalculate and replot the stored data of a particular analysis. A semipreparative Spherisorb silica (10 μm) column (250 × 9.4 mm i.d., Tetrochem, Toronto, Canada) was employed with a 100 μL sample loop. The solvent gradient programme used consisted of 100% hexane for 30 min, programmed to 100% dichloromethane over 20 min, held for 10 min and programmed back to 100% hexane in 10 min. A constant flow rate, 2 mL/min was used. During this gradient programme four fractions were collected at elution times, start to

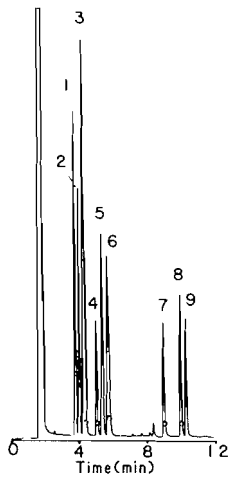

FIG. 1. Chromatogram of a mixture of disubstituted benzene isomers. Peaks: *1*, *m*-bromochlorobenzene; *2*, *o*-bromochlorobenzene; *3*, *p*-bromochlorobenzene; *4*, *m*-bibromobenzene; *5*, *o*-dibromobenzene; *6*, *p*-dibromobenzene; *7*, *o*-bromonitrobenzene; *8*, *m*-bromonitrobenzene; *9*, *p*-bromonitrobenzene. Temperature: 100°C for 1 min then programmed 3°C/min.

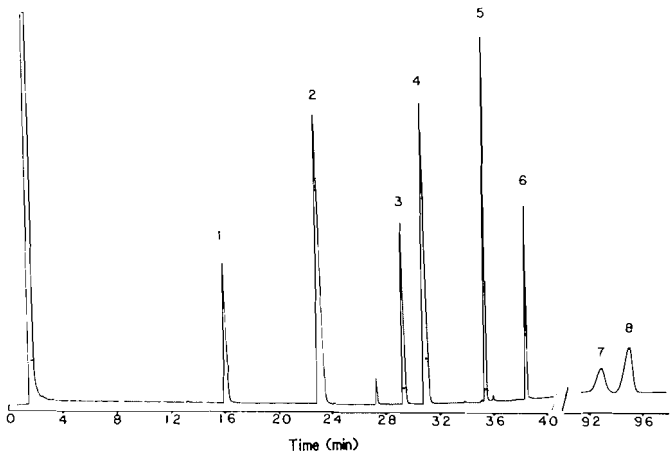

FIG. 2. Chromatogram of chlorinated compounds. Peaks: *1*, 2,2-dichlorobiphenyl; *2*, 2,2′,5,5′-tetrachlorobiphenyl; *3*, 2,3,4,5,6-pentachlorobiphenyl; *4*, 2,2′,4,4′,5,5′-hexachlorobiphenyl; *5*, 3,3′,4,4′-tetrachlorobiphenyl; *6*, 1,2,3,4-tetrachlorodibenzodioxin; *7*, octachlorodibenzodioxin; *8*, octachlorodibenzofuran. Temperature: 100°C for 1 min then programmed 3°C/min to 270°C.

14, 20, 35, and 80 min. First and last fractions consisted of nonpolar and highly polar compounds, respectively. Polycyclic compounds were collected between 14 to 20 and 20 to 35 min and designated as pac fraction I and pac fraction II, respectively. The separation and identification of pac's were carried out using a polymeric liquid crystal column in GC/MS.

Results and discussion

Disubstituted benzene isomers

The baseline separation of three isomers each of bromochloro, bromonitro, and dibromo disubstituted benzenes is shown in Fig. 1. The separation of these isomers using conventional packed or capillary columns is very difficult. The *ortho* isomer has a different volatility than the respective *meta* and *para* isomers, hence its separation is possible from the latter two isomers. However, *meta* and *para* isomers have identical volatilities resulting in their coelution on conventional columns. Based on the mechanism of separation on liquid crystal stationary phases it is possible to separate the *ortho*, *meta*, and *para* isomers using packed columns, but the *ortho* isomer may coelute with either the *meta* or *para* isomer. A capillary column coated with a polymeric liquid crystal stationary phase gives baseline separation of *ortho*, *meta*, and *para* isomers because of the high efficiency of the capillary column along with the traditional advantage of selectivity of the stationary phase.

Polychlorinated biphenyls, dioxins, and furans

The separation and identification of polychlorinated biphenyls (PCB), polychlorinated dibenzodioxins (PCDD), and polychlorinated dibenzofurans (PCDF) is very challenging. In particular, the separation of pentachlorobiphenyls from the tetrachlorodibenzodioxins (TCDD) has special importance because of the acute toxicity of the latter. The identification of TCDD is extremely difficult when there is a large number of pentachlorobiphenyl isomers because of strong interference that occurs even in the selected-ion-monitoring mode in mass spectrometry.

Hence, there is a need to develop a technique or column which can separate these isomers. We have attempted the separation of the 1,2,3,4-TCDD isomer from standard PCB isomers (Fig. 2). From the chromatogram it is clear that TCDD is retained longer than the tetra-, penta-, and hexachlorobiphenyls. However, it coelutes with the PCB isomers on the DB-5 column. Due to the lack of a large number of isomers of PCB and TCDD, it is difficult to predict the retention trends for all isomers on this liquid crystalline column.

Octachlorodibenzodioxin and octachlorodibenzofuran are also very difficult to separate. Their partial separation can be obtained using a 60 m conventional capillary column, while they can be separated completely on the 20 m capillary column using the polymeric liquid crystal stationary phase (Fig. 2).

Polycyclic aromatic compounds

Polycyclic aromatic compounds comprise the largest class of chemical carcinogens known to enter the environment through various sources. The separation of isomeric PAC's is

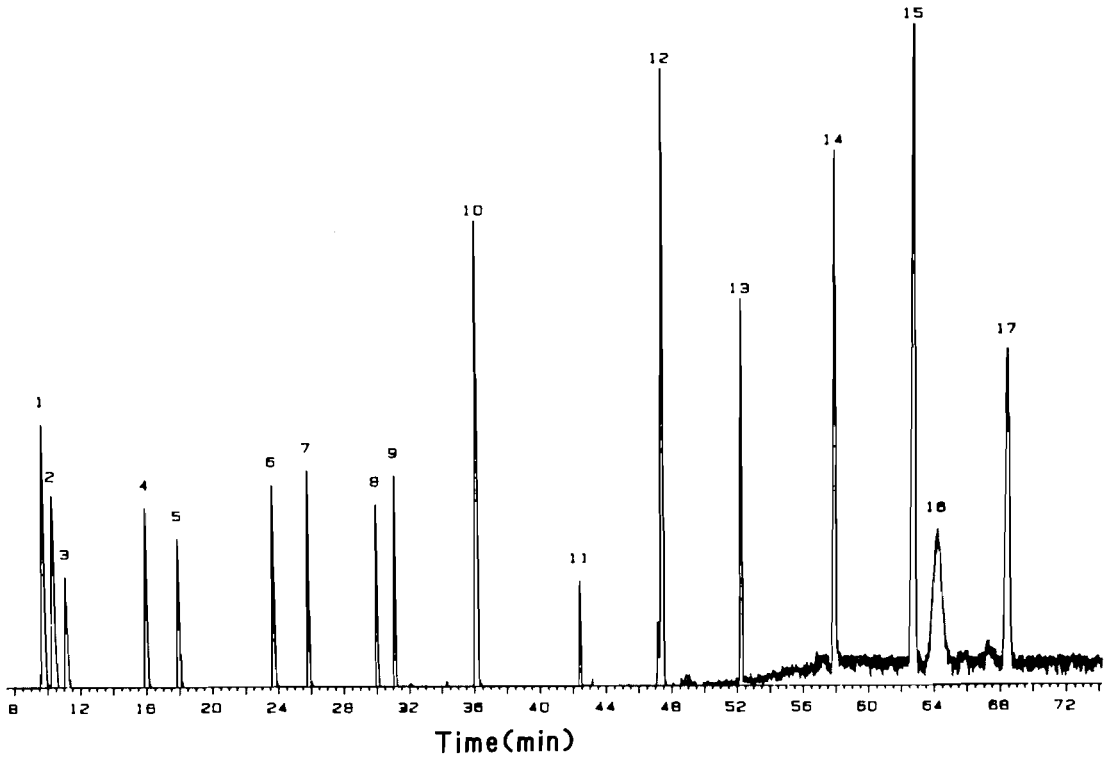

FIG. 3. Total ion current trace of mixture of standard PAC. Peaks: Table 1, other conditions as in Fig. 2.

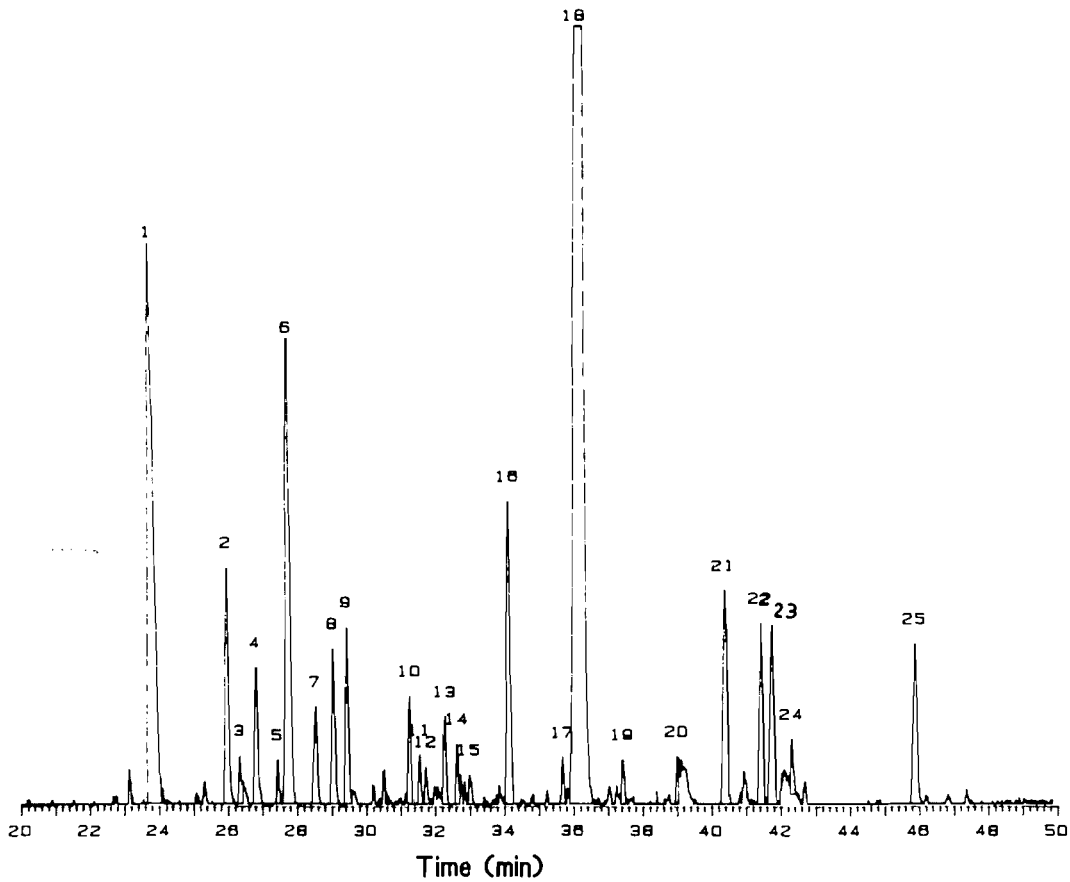

FIG. 4. Total ion current trace of PAC fraction I. Peaks as in Table 2, other conditions as in Fig. 2.

very difficult by gas chromatography using capillary columns coated by conventional stationary phases. The liquid crystalline stationary phases can separate isomeric PAC's based on their length-to-breadth ratio. The separation of a three-to-five ring standard pac mixture is shown in Fig. 3. The complete separation of phenanthrene/anthracene, triphenylene/chrysene and benzo(*e*)pyrene/benzo(*a*)pyrene was easily obtained. A list of the standard compounds separated is given in Table 1.

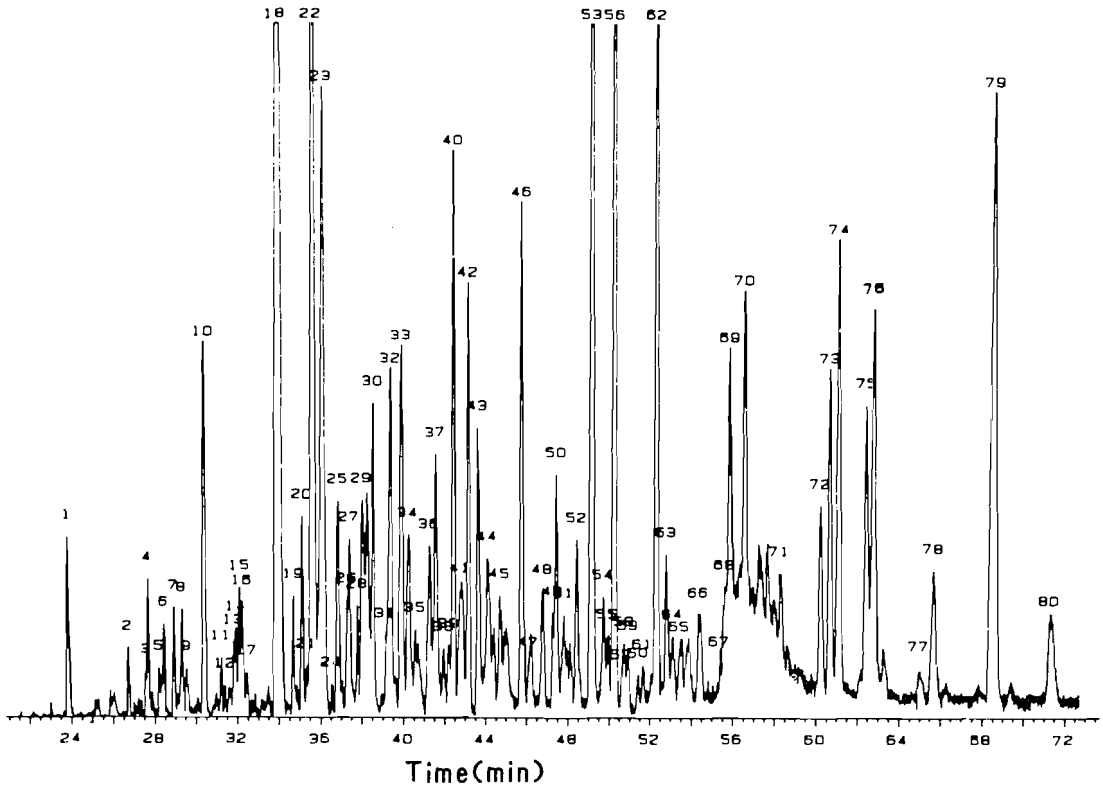

FIG. 5. Total ion current trace of PAC fraction II. Peaks as in Table 2, other conditions as in Fig. 2.

The retention time values and retention trends observed for standards were used for the identification of pac's present in airborne particulate matter along with the reference spectra obtained by pbm.

A normal phase, silica column in hplc was used to separate aliphatic compounds from aromatics. Reproducible separations were observed as compared to those obtained by open column chromatography. The separations achieved on silica column were based on the polarity of solutes, where increase in elution time was observed with increase in number of rings in the polycyclic aromatic compounds. A large number of three-ring PAC's were eluted in PAC fraction I, while PAC fraction II consisted of three-to-five-ring PAC's (Table 2). The total-ion-current (TIC) traces of these fractions are shown in Figs. 4 and 5.

It is very difficult to identify the pac isomers even using a pbm search. All identifications are based on the retention times of standard compounds injected at identical conditions, the mass spectral data of compounds in the sample compared with reference mass spectra, and the elution trend of various compounds on liquid crystal stationary phases in gas chromatography. A little work has been done regarding the application of liquid crystalline stationary phases for the separation of very complex mixtures (17, 19, 20). Our results show the practical application of capillary columns using a polymeric liquid crystal stationary phase for the separation of a large number of organic compounds in a complex environmental sample of airborne particulate matter.

Surface photochemistry: Semiconductor mediated reactions of some 1,2-diarylcyclopropanes[1]

PHILIP A. CARSON AND PAUL DE MAYO

Photochemistry Unit, Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received October 6, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

PHILIP A. CARSON and PAUL DE MAYO. Can. J. Chem. **65**, 976 (1987).

1,2-Diphenylcyclopropane (**1**) was found to be oxidized on illuminated ZnO in the presence of air while 1-(*p*-methoxyphenyl)-2-phenylcyclopropane (**2**) and 1,2-bis(*p*-methoxyphenyl)cyclopropane (**3**) were found to be similarly oxidized on illuminated CdS. Compounds **2** and **3** were found, also, to undergo a rapid photochemical *cis–trans* isomerization on CdS whereas **1** did not undergo such isomerization. An electron transfer mechanism involving formation of the radical cations of the substrates is proposed.

PHILIP A. CARSON et PAUL DE MAYO. Can. J. Chem. **65**, 976 (1987).

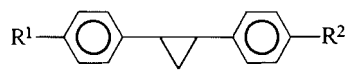
On a trouvé que, en présence d'air, le diphényl-1,2 cyclopropane (**1**) peut être oxydé sur du ZnO illuminé; par ailleurs, on a trouvé que le (*p*-méthoxyphényl)-1 phényl-2 cyclopropane (**2**) et le bis(*p*-méthoxyphényl)-1,2 cyclopropane (**3**) peuvent aussi être oxydés sur du CdS illuminé. On a aussi trouvé que les composés **2** et **3** subissent une isomérisation *cis–trans* photochimique rapide sur le CdS; toutefois, le composé **1** ne subit pas de telle isomérisation. On propose que la réaction se produit par un mécanisme de transfert d'électron impliquant la formation de cations radicaux des substrats.

[Traduit par la revue]

Introduction

Photocatalysis on semiconductors has recently become an area of intensive investigation. In addition to the more extensively studied use of electron transfer reactions at semiconductors for inducing the photolysis of water as a means of solar energy storage, recent attention has been paid to the use of semiconductors for initiating electron transfer processes in organic media. Numerous reports of semiconductor catalyzed electron transfer photoreactions of organic molecules have been made, involving oxidative (both addition of O_2 and loss of hydrogen) and non-oxidative (e.g. isomerization) reactions. Among the more popular semiconductors are ZnO, TiO_2, and, because of its good spectral response in the visible region, CdS. Examples of non-oxidative reactions on CdS are, *inter alia*, the dimerization of phenyl vinyl ether (1), the *cis–trans* isomerization of styrene derivatives and other olefinic substances (2), and a [2 + 2] retrocycloaddition of a cage compound (3). We wish now to report the semiconductor-mediated reactions of some 1,2-diarylcyclopropanes.

1,2-Diarylcyclopropanes are known to undergo electron transfer reactions in homogeneous systems. Thus, 1,2-diphenylcyclopropane (**1**) is reportedly oxidized by addition of $^3O_2$ to its radical cation, which can be generated in CH_3CN solution by electron transfer to excited 9,10-dicyanoanthracene (DCA) (4); 1-(*p*-methoxyphenyl)-2-phenylcyclopropane (**2**) and 1,2-bis(*p*-methoxyphenyl)cyclopropane (**3**) have both been shown to isomerize and to undergo oxidation using similar conditions (4). The band gap of CdS is 2.4 eV, which corresponds to an adsorption maximum of 520 nm (5). The position of the valence band of CdS, determined in acetonitrile, is +1.55 V vs. SCE (5*a*) and this value has been taken as being close to the value in methylene chloride, the solvent used exclusively in the experiments reported here. Thus, *trans*-**1** and both the *cis* and *trans* isomers of **2** and **3**, having oxidation potentials (Table 1) less positive than the potential of the valence band of CdS, fulfil the electrochemical requirement for electron transfer to illuminated CdS.



1: $R^1 = R^2 = H$
2: $R^1 = H$, $R^2 = OCH_3$
3: $R^1 = R^2 = OCH_3$

Several molecules, which have been shown to react by electron transfer using homogeneous sensitizers, have also been shown to react using semiconductor dispersions (refs. 3 and 7, 1 and 8, 3 and 9, 1 and 10). The latter have the advantage (to compensate for their frequent lesser photoefficiency) of not being involved in irrelevant chemistry themselves, as frequently happens with aromatic sensitizers. By virtue of these precedents, and because they meet the electrochemical requirements for electron transfer to CdS, cyclopropanes **1**, **2**, and **3** seemed excellent candidates for electron transfer studies at illuminated semiconductors.

Experimental

Samples were prepared using CH_2Cl as solvent (Baker or Fisher; spec. grade), which was used as received or after filtration through alumina. In the latter case (used in studies on **3**) 50 mL of Baker CH_2Cl_2 were percolated through 25 g alumina (Aluminum Oxide, Neutral, Baker, Brockman activity grade 1) in a 1 cm i.d. burette.

All reaction vessels and magnetic stirbars were washed by rinsing with concentrated HCl followed by washing 3× with water, 1× with acetone, 3× with water, 3× with 10% NH_4OH, 3× with distilled water, and 3× with acetone.

A solution of ca. 10.0 mg of cyclopropane in CH_2Cl_2 was added to a 5.00-mL volumetric flask (containing any additional compounds such as quenchers) and diluted to 5.00 mL with CH_2Cl_2. ([**1**] = 10.3×10^{-3} *M*; [**2**] = 8.9×10^{-3} *M*; [**3**] = 7.8×10^{-3} *M*.) This solution was then poured into a Pyrex reaction vessel containing ca. 30 mg of CdS and a magnetic stirbar. All samples were stoppered and wrapped in aluminum foil until irradiation. Samples containing **1** or **2** but not **3** were sonicated 5 min prior to irradiation or dark reaction.[2]

Irradiation was conducted using either a 1-kW Xe (PRA) lamp

[1]Publication No. 371 from the Photochemistry Unit, The University of Western Ontario.

[2]Sonication was a factor not easily monitored and might contribute to the difficulty found in obtaining reproducibility. Strict attention to detail was essential to achieve such reproducibility as was obtained.

operating at 840 W or a 150-W Xe lamp (PRA) operating at 140 W. Compressed air was used as a coolant and a water filter was employed to remove ir radiation. The output of both lamps was checked periodically with a Scientech 364 power energy meter and was found to remain satisfactorily constant. Corning cut-off filters were used such that no light was absorbed by the substrate. Samples were stirred magnetically during both irradiated and dark reactions. Unless degassed, samples containing **1** or **2** were open to the atmosphere through a condenser while samples containing **3** were stoppered and sealed with Teflon tape. For degassed samples, three freeze–thaw cycles were used before sealing to a residual pressure of $<2 \times 10^{-5}$ Torr (1 Torr = 133.3 Pa).

After irradiation the CdS was removed by filtration through Celite and cotton wool and the product analysed using a Varian 3700 gas chromatograph equipped with a flame ionization detector connected to a Hewlett Packard 3390A integrator. The mass balance was monitored by the use of calibrated internal standards (normal alkanes) added prior to irradiation. The CdS (usually Fisher) was used as received unless otherwise specified.

Because of difficulties with reproducibility, a more rigorous procedure was employed in reactions of **3**. To ensure homogeneity of **3**, *cis*-**3** was ground to a fine powder and mixed well. All samples were prepared, transported, and manipulated in the dark. Two filters were used in series, having cut-off wavelengths of 400 and 430 nm. The sample holder was a rigidly fixed aluminum block, and the lamp, the sample, and its holder, as well as the path of light between the lamp and the sample, were completely shielded to eliminate stray light. The stirring rate and stirrer position were optimized and kept constant and the lamp was run for 45 min prior to irradiation.

The products of oxidation were isolated by thin-layer chromatography and derivatives were prepared (ethanolic 2,4-dinitrophenylhydrazine). Potassium ferrioxalate actinometry was used (12). A Corning 558 filter and a Corning cut-off filter (430 nm) were used to allow only wavelengths between 430 and 480 nm to enter the sample cell. A wire mesh screen was used to reduce the light intensity where required. The *cis* → *trans* conversion was kept below 15% to minimize the reverse reaction. The approximate quantum yield for the photoisomerization of **3** (using Strem Luminescent CdS) was 3.3 ± 0.2, assuming all incident light was absorbed.

Cyclopropane preparation

The preparation of compounds **2** and **3** closely followed the method described by Overberger *et al.* (13*a*). Compound **1** was formed as a liquid (30% *cis*, 70% *trans*) and was chromatographed until it was transparent to 350 nm. Compound **2** was formed in 10% yield as a 95:5 mixture of the *trans* and *cis* isomers. Crystallization (methanol) resulted in the separation of >99% *trans*-**2**, mp 80.0–80.5°C. Direct irradiation of *trans*-**2** (Pyrex) resulted in a 50% conversion to *cis*-**2**. Purification by chromatography (CH_2Cl_2; silica gel) and crystallization (methanol) resulted in crystals (25% *cis*, 75% *trans*-**2**), used for experimentation. A sample of 95% pure *cis*-**2** isomer was prepared (oil) by preparative gas chromatography (10% OV-101 on Chromasorb W 80–200 mesh, 200°C).

Compound **3** was formed (57%, based on bis-(*p*-methoxy)chalcone) as a mixture of (14% *cis* and 86% *trans*) isomers. Greater than 99% isomerically pure *cis*-**3** and *trans*-**3** were separated by fractional crystallization from methanol; *trans*: mp 69.5–69.8°C (lit. (13) mp 70.5–71.0°C); *cis*: mp 57.5–58.0°C (lit. (13) mp 56.0–58.0°C).

Results

Compound *cis*-**3**, in the presence of CdS, isomerized rapidly (50% conversion in 15 min, 150-W lamp) to the *trans* isomer when irradiated at wavelengths longer than 430 nm. The ^{1}H nmr analysis confirmed the identity of the product. The mass balance for isomerization was over 95%. In the absence of CdS there was no reaction following irradiation, after the elimination of an acid catalysed isomerization by prior percolation of the solvent through alumina.

On Fisher CdS a fast dark reaction of **3** occurred (40% conversion in 1 h), which was quenched by addition of 1,2,4,5-tetramethoxybenzene (QMB). There was no dark reaction of **3** on CdS from other suppliers. Drying Fisher CdS under vacuum at 100°C or wetting it by storage in a highly humid environment had no significant effect on the dark reaction, while washing three times with distilled water and drying at 100°C in air for 24 h decreased but did not eliminate this process (Table 2). The residue obtained by evaporating the wash water weighed about 1% of the mass of the CdS sample and was found, by itself, to cause a dark reaction of **3**. Addition of Fe^{3+} in amounts equal to and 100 times greater than the supplier's assay of Fe^{3+} content in Fisher CdS (0.007%) to an inactive CdS sample (Strem Luminescent) was found not to induce a dark reaction.

The light-induced reaction of **3** on CdS could be entirely quenched by degassing or partially quenched by the addition of the electron donors (Table 3) (QMB), 1,2,4-trimethoxybenzene (TMB), 1,4-diazobicyclooctane (DABCO), and diisopropyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

amine (DIPA). Approached from both sides, the equilibrium composition for the photoisomerization of **3** on Strem Luminescent CdS was 95% *trans*, 5% *cis*.

Reproducibility of the reaction of **3** was a continuing problem. Using Fluka purissim, Aldrich Gold Label, or Strem Luminescent cadmium sulfide samples, photoreactions of **3**, conducted using a single stock solution and using the special procedure described for **3**, had an error of ± 10%, limiting the extent of any quantitative work. The acid sensitivity of **3** is known (15).

Compound **2** was found to isomerize on both illuminated Fisher CdS and in the dark on the same CdS. The reaction under irradiation was six times faster than in the dark. This dark reaction limited the scope of investigation using **2**. The light reaction of **2** was quenched by addition of QMB but the dark reaction remained. The equilibrium composition was found to be 95% *trans*, 5% *cis*. In contrast, no reaction of **1** occurred after 4 h of irradiation with a 1-kW lamp in the presence of Fisher CdS.

Irradiation of **1** in the presence of air and ZnO at $\lambda > 340$ nm resulted in the formation of three products. These were separated by tlc, and identified as benzaldehyde, acetophenone, and chalcone (1,3-diphenylpropenone). No reaction occurred in the absence of semiconductor. A freshly prepared product mixture was found to contain material that formed a red spot on a tlc plate when sprayed with acidic iron ammonium sulfate and ammonium thiocyanate, indicating the presence of a peroxide (11). This spot had a very much greater R_f than did either perbenzoic acid or hydrogen peroxide, which also turned red under this treatment.

Prolonged irradiation of **3** in the presence of CdS resulted in oxidation to form *p*-anisaldehyde, characterized as its 2:4 dinitrophenylhydrazone, and *p*-methoxyacetophenone, tentatively identified by its gc retention time and nmr spectrum. Prolonged irradiation of **2** also resulted in oxidation to form many unidentified products.

Discussion

All of the reactions induced by irradiation in the presence of semiconductor were quenched by the addition of electron donors. This is taken as evidence of electron transfer mechanisms involving formation of the radical cations of the cyclopropanes.

Cyclopropanes **2** and **3** but not **1** underwent rapid photoisomerization on CdS and were oxidized by prolonged irradiation. Compound **1**, on the other hand, was only efficiently oxidized on ZnO. This observation is not unexpected, since the oxidation potential of *cis*-**1** may be higher than the valence band of CdS in CH_2Cl_2, (i.e., electron transfer may be endergonic, hence slow (16)) and the oxidation potential of *trans*-**1** is very close. The actual position of the valence band of CdS in CH_2Cl_2 is not known.

On ZnO, which has a valence band potential (+2.4 V vs. SCE) (5*a*) higher than the oxidation potential of **1**, oxidation of **1** occurred, producing chalcone, benzaldehyde, and acetophenone: the same products were formed by homogeneous photocatalysis (4). It has been proposed that the DCA-sensitized oxidation of 1,2-diarylcyclopropanes proceeds via addition of either superoxide ($O_2^{\ddagger}$) or triplet oxygen to the cyclopropane radical cation to form a dioxolane (4). Prolonged irradiation or thermolysis of the dioxolane prepared from **3** was reported to yield 1,3-bis(4-methoxyphenyl)-1-hydroxypropan-3-one, *p*-anisaldehyde, and *p*-methoxyacetophenone (4*c*). An analogous route to the similar oxidation products from **1** and **3** using semiconductor catalysts is supported by the oxidation of **1** on ZnO, where there is evidence for the formation of a peroxide that was neither hydrogen peroxide nor perbenzoic acid, and which may be a dioxolane.

A mechanism can be proposed for the oxidation of **1**, **2**, and **3** on illuminated semiconductors. The radical cation is formed by electron transfer from the substrate to the photogenerated hole, while $O_2^{\ddagger}$ can be generated by electron transfer from the conduction band to oxygen.[3]

The *cis* and *trans* isomerization of compounds **2** and **3** on illuminated CdS occurred rapidly, while no isomerization of **1** was observed on either ZnO or CdS (4, 17). The radical cation of 1,2-diphenylcyclopropane **1** has been shown to maintain bonding between c_1 and c_2: CIDNP effects observed during photoinitiated electron transfer to chloranil or 9-cyanophenanthrene show that the radical cation of **1** is formed, but that it does not isomerize (17). In **1**, bearing no electron donating groups to stabilize the radical cation, there is a strong interaction in the benzylic π orbitals, resulting in the formation of a relatively strong one-electron, two-centre bond (17, 18). In cyclopropanes **2** and **3**, delocalization of the positive charge of the radical cation is provided by the electron donating groups, resulting in a weaker bond and a lower barrier to *cis–trans* isomerization.

The equilibrium compositions reached in the CdS catalysed isomerization of **2** and **3** are the same as that found in the homogeneous electron transfer reaction. This composition resembles that expected for a thermodynamic equilibrium between the *cis* and *trans* closed shell isomers. If every step of the radical cation route from one isomer to the other follows the principle of microscopic reversibility, then indeed these equilibria will be identical, but this has yet to be demonstrated. For comparison, acid catalyzed isomerization of **3** results in an equilibrium composed of 96% *trans*-**3** (15*a*). In contrast, triplet sensitization of **3**, where the principle does not hold, leads to a photostationary state containing ~70% *cis* isomer.[4]

The quantum yield for the photoisomerization of **3** on CdS was determined to be 3.3 ± 0.2 (at < 15% conversion), showing that the radical cation mediated reaction proceeds via a chain mechanism, propagated as follows:

[1] $\quad c^{\ddagger} \rightleftharpoons t^{\ddagger}$

$$t^{\ddagger} + c \rightleftharpoons t + c^{\ddagger}$$

The oxidation potential of *cis*-**3** is 0.95 V vs. SCE, while that of *trans*-**3** is 0.85 V vs. SCE. Even with slight endergonicity, chain propagation can, apparently, compete favourably with termination reactions (16) such as back electron transfer from the electron in the semiconductor conduction band.

Quenching by good electron donors is evidence supportive of an electron transfer mechanism for the reaction of **3**. Such quenching is more effective when the oxidation potential of the quencher is less than that of the substrate (1, 2, 19). This is interpreted as quenching by electron transfer to the radical cation of the substrate. It is therefore surprising that quenching by TMB, having an oxidation potential higher than that of **3**, is as efficient as quenching by QMB. This may be explained in at least two ways. The quenching may occur primarily by quenching of the valence band hole. Any electron donor with an oxidation potential low enough for electron transfer to CdS,

[3]This electron transfer is electrochemically allowed. E_{red} O_2 = −0.82 V vs. SCE (14*c*); conduction band = −0.85 V vs. SCE (5).

[4]Sensitization of **3** with benzophenone led to *cis–trans* isomerization. When approached from both sides, the equilibrium composition neared 70% *cis*. Other products were formed (~5%).

particularly one adsorbed strongly on the catalyst, may quench by this process, thus preventing initiation of the radical cation chain mechanism. Alternatively, quenching may still be occurring by less than diffusion controlled quenching of the radical cations themselves, thus terminating the chain reaction. Fifty per cent quenching by QMB was observed at concentrations as low as $5 \times 10^{-6} M$, which was less than 0.1% of the concentration of **3**, so it is unlikely that the quenching occurred by preferential occupation of all the active surface sites on CdS.

Some observations lend credence to the suggestion that it is the valence band hole which is quenched. Quenching by the amines 1,4-diazobicyclooctane and diisopropylamine, presumably by electron transfer, was more effective than quenching by the methoxybenzenes, and this was true for either electron donors with oxidation potentials above that of **3** (TMB, DIPA) or for donors with oxidation potentials below (QMB, DABCO). The amines may quench the reaction in part by occupying the more active sites on the catalyst, thus preventing adsorption and electron transfer by 3; the amine will, because of stronger adsorption on the CdS surface, be more effective in transferring an electron to the valence band hole than **3** or the methoxybenzenes. Quenching by the amines may not only be by electron transfer, but also by the neutralization of any acidic sites on the CdS surface: the reaction does not persist when the illumination ceases.

Quenching by termination of the radical cation chain requires that there be endergonic electron transfer from the quencher to **3**. This is not impossible, since the chain is itself propagated by an endergonic electron transfer, but is not likely in view of the expected reversibility of such electron transfer and the substantial quenching by QMB at concentrations 1000 times lower than that of the substrate. Further, endergonic quenching should be less efficient than exergonic: this was not observed either for the methoxybenzenes or amines. ΔG for the chain propagation steps and for this endergonic quenching is approximately 2–3 kcal/mol^{-1}. For such a change in free energy the rate constant for electron transfer in homogeneous systems might be expected to be near 10^8–10^9 L mol^{-1} s^{-1} (20) as against 10^{10} for an exergonic process.

Molecular oxygen probably plays a role in the stabilization of the electron-hole pair, possibly by prolonging the lifetime of the e^-/h^+ pair by accepting a photogenerated electron from the semiconductor conduction band to form adsorbed superoxide ($O_2^{\cdot-}$) (3, 21, 22, 23). Return of electrons trapped in chemisorbed oxygen to the conduction band is extremely slow at room temperature in the dark (26). An alternative rationalization of the effect of oxygen is that it may, as a strongly adsorbed electron acceptor, cause greater polarization in the charge depletion layer of CdS and in the layer of adsorbate than in its absence (22, 24, 25). The increased electric field would increase the band bending, accelerating the charge separation of the hole and electron and lowering the potentials of the conduction and valence bands.

In conclusion, it may be pointed out that one of the disadvantages of the use of homogeneous electron transfer photocatalysts is that they may react chemically with the substrate (for one example among many see ref. 27). In addition, back electron transfer from the sensitizer radical anion to the substrate radical cation may result in formation of an excited state of the substrate: this has been observed, for instance, for the 1,4-dicyanonaphthalene sensitized reaction of **1** (17). Both of these complications are avoided by the use of semiconductor catalysts, which act only to form the radical cation. Back transfer to give the substrate triplet plus two doublets on the semiconductor does not yet appear to have been observed. Disadvantages of heterogeneous systems can be low efficiency, especially if a chain is not involved, and a possible susceptibility to irrelevant surface-catalysed side reactions.

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

JOHN A. COXON, STAVROS NAXAKIS, and UTPAL K. ROYCHOWDHURY. Can. J. Chem. **65**, 980 (1987).

The visible $A^2\Pi \rightarrow X^2\Pi$ band system of PCl^+ has been recorded photoelectrically with a resolution of 0.006 nm. Fourteen $^2\Pi_{1/2}$–$^2\Pi_{1/2}$ and six $^2\Pi_{3/2}$–$^2\Pi_{3/2}$ sub-bands of $P^{35}Cl^+$ in the $v' = 0$ and 1 progressions with $10 \leq v'' \leq 20$ have been rotationally analysed. The measured positions of 1214 lines have been fitted directly by least squares to obtain a set of reliable constants for the two states that reproduce the entire data. These constants include the first estimated spin–orbit coupling constants for both states. The reliability of these estimates is discussed. The equilibrium internuclear separations are $r_e(X) = 0.1900$ and $r_e(A) = 0.2334$ nm.

JOHN A. COXON, STAVROS NAXAKIS et UTPAL K. ROYCHOWDHURY. Can. J. Chem. **65**, 980 (1987).

Opérant à une résolution de 0,006 nm, on a enregistré le spectre photoélectronique du système des bandes visibles $A^2\Pi \rightarrow X^2\Pi$ du PCl^+. On a analysé, d'un point de vue rotationnel, quatorze sous-bandes $^2\Pi_{1/2}$–$^2\Pi_{1/2}$ et six sous-bandes $^2\Pi_{3/2}$–$^2\Pi_{3/2}$ du $P^{35}Cl^+$, avec des progressions de $v' = 0$ et 1 et $10 \leq v'' \leq 20$. On a fait concorder directement les positions mesurées pour 1214 raies en faisant appel à la méthode des moindres carrés; on en a déduit un ensemble de constantes dignes de confiance pour les deux états et ces constantes permettent de reproduire l'ensemble des données. Ces constantes incluent la première évaluation de constantes de couplage spin–orbite des deux états. On discute de la fiabilité de ces évaluations. Les séparations internucléaires à l'équilibre sont $r_e(X) = 0{,}1900$ et $r_e(A) = 0{,}2334$ nm.

Introduction

Spectroscopic information on diatomic Group 5 monohalide cations with 11 valence electrons (e.g. NF^+, PF^+, PCl^+) is rather limited, although the corresponding Group 6 diatomic cations such as O_2^+ (1), SO^+ (2–4), SeO^+ (5), and S_2^+ [2] are relatively well characterised. The ground electronic states of NF^+ (6) and PF^+ (unpublished results quoted in ref. 7) have been identified by photoelectron spectroscopy. A band system of PF^+ has been analyzed vibrationally by Douglas and Frackowiak (8). Very recently, work in this laboratory has led to the first spectroscopic observations of PCl^+ (9) and $AsCl^+$ (10) through vibrational analyses of their visible $A^2\Pi \rightarrow X^2\Pi$ band systems. Until now, the only analysis of a rotationally resolved spectrum for the Group 5 monohalide cations was limited to five red-degraded bands of PF^+ (8). The present paper reports the first rotational spectroscopic analysis of the $A^2\Pi$–$X^2\Pi$ system of PCl^+.

In our low resolution study of this system of PCl^+, excited by the reaction of discharged helium with PCl_3, an extensive band spectrum was observed over the range 400–700 nm. In view of the weakness of the source, it was necessary to limit the present work to a selected group of fourteen of the most intense bands of $P^{35}Cl^+$. No attempt was made to investigate any bands of the less abundant isotopic species $P^{37}Cl^+$, even though several heads had been readily identified in the low resolution spectrum. For all fourteen bands of $P^{35}Cl^+$, the recorded spectra were exceptionally clean and free of overlap from any other species. The bands studied belong to the $v' = 0$ and 1 progressions in the ranges $v'' = 11$–20 and $v'' = 10$, 12–14, respectively. The molecular constants of the Hamiltonians of the two electronic states were fitted directly to the measured line positions of individual bands. Multiple estimates of these constants, which include the first estimates of the spin–orbit coupling constants, were reduced by the method of merging (11, 12) to a reliable set of single-valued constants that reproduce the entire data.

Experimental

The experimental arrangement has been described in detail elsewhere (3). PCl_3 vapour from a side-arm reservoir was introduced into a fast flow system, 5 cm downstream of a helium discharge between two cylindrical tantalum foil electrodes. The flow of PCl_3 vapour was controlled by a Teflon needle valve to optimize the brightness of the visible conical flame. The flow system was pumped by a 160 $m^3\ h^{-1}$ rotary pump (Leybold-Heraeus E150), and the system pressure was maintained at about 500 Pa. A 1.26 m scanning monochromator (Spex 1269), equipped with a 2400 groove mm^{-1} grating blazed at 500 nm, was used for recording the spectra. The slit height and width were 10 mm and 20 μm, respectively. The data acquisition system was fully automated (13) under control of a PDP 11/23 computer (Digital MINC). A uranium hollow cathode lamp was used for wavelength calibration. In a typical calibration for an individual sub-band, 25 uranium lines were fitted with a standard deviation of about 0.0008 nm.

Data fitting

The $A \rightarrow X$ system of PCl^+ is an example of a Hund's case (*a*) → case (*a*) transition. The ground states of numerous other 11-valence electron diatomics are all regular with large spin–orbit coupling constants, in accord with the electron configurations. It is assumed by analogy that the $X^2\Pi$ state of PCl^+ is also regular. The spectrum at low resolution (9) shows well separated sub-bands for both $P^{35}Cl^+$ and $P^{37}Cl^+$ in accord with the selection rules $\Delta\Sigma = 0$ and $\Delta\Omega = 0$ for such transitions. With the assumption of a regular ground state, the present work identifies the sub-bands as $^2\Pi_{1/2}$–$^2\Pi_{1/2}$ and $^2\Pi_{3/2}$–$^2\Pi_{3/2}$, with the more intense $\Omega = 1/2$ sub-bands lying at shorter wavelengths.

The 0–16, 0–17, and 0–18 bands are overlapped by only very weak bands from $v' \geq 1$, and are well separated from corresponding $P^{37}Cl^+$ bands. Both sub-bands were recorded in each case, and showed well-resolved rotational structure even at low *J*-values. Accordingly, these three bands were selected for preliminary assignment by the method of combination

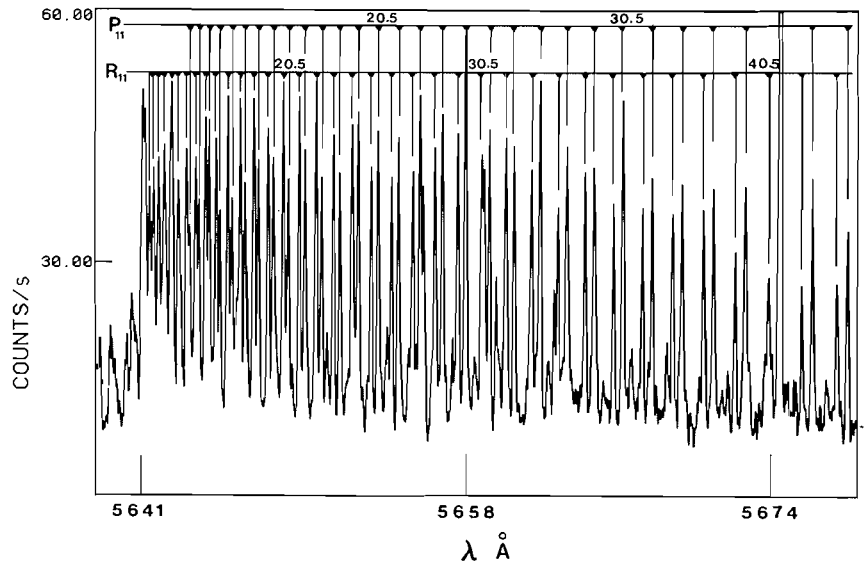

FIG. 1. The $A^2\Pi_{1/2}$–$X^2\Pi_{1/2}$ 0–17 sub-band of $P^{35}Cl^+$. The trace was recorded photoelectrically from the flame of the $He_2^+ + PCl_3$ reaction. The spectral resolution is about 0.006 nm.

differences. Trial sets of combination differences for the upper $v' = 0$ level were formed, leading to unequivocal identification of the P_1,R_1 and P_2,R_2 branch structures and relative J numbering. Absolute J numbering was readily established by the requirement for D_0' to be close to the theoretical value of $4B_e^3/\omega_e^2$. Even at the highest J values, there was no evidence with the spectral resolution (~0.006 nm) of the present work for any Λ-doubling.

Of the 14 bands analyzed, both sub-bands were recorded for only six of the strongest bands in the $v' = 0$ progression with $13 \leq v'' \leq 18$. For these bands, estimates of seven constants (ν_0, B', D', A', B'', D'', A'') could be obtained by fitting directly the measured line positions of both sub-bands. The calculated line positions were given as the differences of the eigenvalues of a standard $^2\Pi$ Hamiltonian (14, 15) containing different parameter values for the upper and lower states. The ability to determine A' and A'' directly in such fits is due to the significantly different values of $Y = A/B$ for the two states, leading to different J dependences of the spin–orbit splittings (16). For the remaining eight bands, only the P_1,R_1 structure of the stronger $^2\Pi_{1/2}$–$^2\Pi_{1/2}$ sub-bands has been assigned. For these bands, A' and A'' were constrained in the fits at approximate values given by preliminary fits of the other bands, and only five constants were adjusted (ν_0, B', D', B'', D''). Errors in the constrained A' and A'' will have negligible effect on the fitted rotational parameters, and are correlated strongly with the band origin estimates.

For several of the bands, the R(J) and P($J - n$) lines were blended over a range of lower J values ($n = 6$ for the 0–20 and 0–19 bands; $n = 5$ for the 0–15, 0–13, 0–12, 1–14, and 1–13 bands). For the 0–14 band, such blending of the R(J) and P($J - 5$) lines occurred for all J values. Although satisfactory fits for individual bands is often possible when the measured positions of such blends are included as data for both transitions, the fitted constants are generally in poor agreement with the constants obtained from bands with resolved structure. The non-linear fitting program used in the present work was modified so that blended line positions were adequately modelled. Calculated blend positions were obtained as intensity-weighted means of the individual R(J) and P($J - n$) positions, with weights taken as the squares of the relative intensities. The relative intensities were calculated from the line strengths and the experimental Boltzmann rotational temperature of 300 K.

Results

A portion of the $^2\Pi_{1/2}$–$^2\Pi_{1/2}$ sub-band of the 0–17 band is shown in Fig. 1. This is a fairly typical trace, and illustrates the quality of the spectra for all the sub-bands recorded in the present work. The two branches, P_{11} and R_{11}, are readily identified, and show little blending with overlapping weak structure of other bands. There is no indication for the presence of a Q branch. Blending of the two branches near the head occurs only at very low J values; such blending occurs over larger J ranges in some of the other $\Omega = 1/2$ and $\Omega = 3/2$ sub-bands. The 0–17, $\Omega = 1/2$ sub-band shown in Fig. 1 was assigned up to $P_{11}(56.5)$ and $R_{11}(61.5)$. At these highest values of J, there was no indication of any broadening of the lines from Λ-doubling.

Table 1 provides a summary of the bands investigated in the present work. The standard deviations ($\hat{\sigma}$) of the final least-squares fits for individual bands (or sub-bands) are tabulated along with the numbers of lines fitted. For the 0–13 to 0–18 bands, both sub-bands were analysed, and values of A' and A'' were estimated from the fits. For all other bands, only the stronger $\Omega = 1/2$ sub-bands were analysed, and A' and A'' were constrained at the values shown in Table 1. The standard deviations lie in the range 0.030 to 0.053 cm^{-1}, in accord with the estimated measurement precision. Fitted band origins are also listed in Table 1; as described in the following section, these estimates were obtained after merging the results for individual bands.

The individual band fits of Table 1 yielded 82 estimated constants, many of which are multiple estimates of the same constants. Single-valued estimates for all the constants were obtained by merging (11, 12) the individual band constants to a new set of 47 constants (Merge 1). Since the estimates of D_v'' in this output set showed no systematic change with v'', it was decided to reduce these 11 constants to a single vibrationally independent parameter D'' (Merge 2). This merge was very

18	0.256255(87)	282.63(251)
19	0.254763(89)	
20	0.253044(87)	

[a]The results, in cm^{-1} units, are from Merge 2; see text. Values in parentheses are estimated standard errors, in units of the last digit of the corresponding constant. The fitted value $D'' = 1.68(28) \times 10^{-7}$ cm^{-1} was also obtained in this fit.

satisfactory; the variance of the equivalent single step merge to the 37 output parameters of Merge 2 is $\hat{\sigma}^2 = (1.837)^2$ with $f = 45$ degrees of freedom. The upper and lower state constants from this merge are listed in Tables 2 and 3, respectively; the band origins are listed in Table 1.

A third merge was performed in which the ground state rotational constants were represented by a polynomial expansion in $(v'' + 1/2)$. Three coefficients were estimated, B_e'', α_e', and γ_e''. However, this merge was not so satisfactory; the variance of the equivalent single step merge to the 29 output parameters, $\hat{\sigma}^2 = (2.762)^2$ with $f = 53$ degrees of freedom, is appreciably larger than that of Merge 2. There was no significant improvement when either the expansion of B_v'' was carried out to higher order or when the constraint of Merge 2 was not adopted. The result is indicative of small systematic error in some of the estimated B_v''. Nevertheless, the results of Merge 3 provide the best estimates of the equilibrium rotational parameters of the $X^2\Pi$ ground state of PCl^+; these are listed in Table 4, together with other fitted parameters given by Merge 3. Calculated line positions for all the bands analysed in this work have been obtained with the parameters of Merge 2. The calculations include lines that were not measured, and are listed[3] in Table 5 together with the corresponding residuals (observed − calculated positions). The root-mean squares of the residuals for individual bands have been listed in Table 1,

A_{17}	280.3(35)		
A_{18}	279.5(35)		

[a]The results, in cm^{-1} units, are from Merge 3; see text. Values in parentheses are estimated standard errors, in units of the last digit of the corresponding constant.

[3]Table 5 is too extensive to reproduce here; copies may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

and are generally very similar in magnitude to the corresponding standard deviations. This indicates that the parameters of Merge 2 reproduce the entire data very satisfactorily.

Discussion

It is apparent from Table 1 that for all four bands with $v' = 1$, only five fitted constants were obtained from the $\Omega = 1/2$ sub-bands. Not only are the corresponding $1-v''$, $\Omega = 3/2$ sub-bands considerably weaker, they are also overlapped by $0-v''$, $\Omega = 1/2$ sub-bands of the less abundant $P^{37}Cl^+$ ion. Despite this problem, it was possible to make tentative assignments of the P_{22} and R_{22} branches for one of the bands, 1–12. However, attempts to fit these data simultaneously with the $\Omega = 1/2$ transitions were not successful. It was concluded that the $^2\Pi_{1/2}$ and $^2\Pi_{3/2}$ components of $v' = 1$ were associated with different (effective) rotational constants. The possibility that incompatibility between the data for the two sub-bands was due to an unknown error in calibration of the 1–12, $^2\Pi_{3/2}$–$^2\Pi_{3/2}$ sub-band was ruled out since the separations of the R(J) and P($J - 5$) lines were also inconsistent with the B_1' value of the $^2\Pi_{1/2}$ component. A fit of the $^2\Pi_{3/2}$–$^2\Pi_{3/2}$ 1–12 sub-band alone was very satisfactory ($\hat{\sigma} = 0.039\ cm^{-1}$). This fit determined only ν_0 and B_1', with D_1', A_1', B_{12}'', D_{12}'', and A_{12}'' constrained at the values given by Merge 2. The results of this fit, which gave $\nu_0(^2\Pi_{3/2}) = 21013.97(1)$ and $B_1'(^2\Pi_{3/2}) = 0.18692(2)\ cm^{-1}$, are included in Table 5. It is apparent that not only is the fitted B_1' significantly different from that for $^2\Pi_{1/2}$, but also that the fitted origins for the two sub-bands differ by more than $2\ cm^{-1}$. This would imply that A_1' is about $2\ cm^{-1}$ less that A_0'. Since such a large vibrational dependence of a spin–orbit coupling constant would not be expected, the results suggest the existence of an unidentified perturbation of $v = 1$ in the $A^2\Pi_{3/2}$ state.

As shown in Table 4, the variation of A_v'' with v'' is well established with A'' decreasing by $\sim 0.56\ cm^{-1}$ per quantum with increasing v''. The value of A_{17}'' is somewhat out of line with this trend. These statements can be made confidently despite the $\sim 3.5\ cm^{-1}$ standard errors of the spin–orbit coupling constants, since the relative A_v'' values, as well as the differences, $A_v'' - A_0'$, are determined with much greater accuracy. It is possible, in fact, that the absolute values of A_v'' and A_0' are considerably less reliable than is suggested by the quoted standard errors. As mentioned earlier, the ability to discriminate between A'' and A' derives from the different J *dependences* of the spin–orbit splittings. However, the different J dependences for the upper and lower states of a $^2\Pi$–$^2\Pi$ transition may be due only in part to different Y (A/B) values. For a transition in which both Y values are large, the magnitudes of such J dependence become small, and comparable to higher order effects (centrifugal distortion of spin–orbit coupling and second order spin–rotation, which are strongly correlated (14)). As a consequence, the absolute magnitude of the fitted spin–orbit coupling constants obtained from a $^2\Pi$–$^2\Pi$ transition can depend significantly on the corresponding γ (or A_D) values. The precision of the present data did not afford determinations of γ_v for either state, so that to some extent, A' and A'' are effective parameters that absorb unknown spin–rotation/centrifugal distortion effects. Although data of better precision from a future study or from the photoelectron spectrum of PCl might resolve this problem, it is still interesting to comment on the values given in Table 4. The spin–orbit coupling constant in the ground $^2\Pi$ state of PF^+ is well determined (8) from a $^2\Sigma$–$X^2\Pi$ transition as $323.95\ cm^{-1}$. For the isoelectronic species SiF and SiCl, the ground state A'' values are 161.9 (17) and 207.2 (18) cm^{-1}, respectively. If a similar halogen dependence holds for PF^+ and PCl^+, A'' for PCl^+ would be $\sim 370\ cm^{-1}$, considerably larger than the effective value in Table 4. This topic thus merits further investigation.

Selective extraction of trace metals associated with hydrous aluminum oxides

JANECE SLAVEK AND WILLIAM FREDERICK PICKERING
Chemistry Department, University of Newcastle, N.S.W., 2308, Australia

Received September 29, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

JANECE SLAVEK and WILLIAM FREDERICK PICKERING. Can. J. Chem. **65**, 984 (1987).

In soil/sediment analysis, subdivision of trace metal content into different categories is usually based on selective extraction schemes. To assess the disposition of metal ions bound to aluminum hydrous oxides in such schemes, suspensions of $Al(OH)_3$ gel, gibbsite, or alumina were loaded with up to 5 μmol of Cu, Pb, Cd, or Zn ions prior to being extracted for 24 h with one of fifteen different chemical solutions. The percentage of sorbed ion retrieved varied along the reagent sequence: NaCl, $CaCl_2$ < $MgCl_2$, NH_4NO_3 < CH_3COONH_4, Na citrate, $Na_4P_2O_7$ < EDTA, DTPA < CH_3COOH, $H_2C_2O_4$, HCl, HNO_3. In each system, the recovery value varied with the initial surface loading (a function of sorption pH) and reflected changes in metal species form, e.g., bonded M^{2+}, (MOH^+), $M(OH)_2$. With low loading levels up to 40% was displaced by salt solutions; with 1 to 2 μmol sorbed, as little as 10% was displaced by acids or complex formers but this increased to ~90% with higher loadings. The relationship between sorption pH, amount sorbed, and extraction value was complex, and since in selective extraction schemes classification is based on recovery values, changes in initial retention parameters (e.g. system pH) lead to varying fractions of the different metal ions being classified as "ion exchangeable", "chemisorbed", and "incorporated in the lattice".

JANECE SLAVEK et WILLIAM FREDERICK PICKERING. Can. J. Chem. **65**, 984 (1987).

Lors de l'analyse des sols et des sédiments, la subdivision des échantillons en diverses catégories d'éléments contenus à l'état de trace est généralement basée sur des schémas d'extractions sélectives. Pour évaluer la disponibilité des ions métalliques liés à des oxydes hydratés d'aluminium dans de tels schémas, on a chargé des suspensions de $Al(OH)_3$, de gibbsite ou d'alumine avec des quantités allant jusqu'à 5 μmol d'ions Cu, Pb, Cd ou Zn avant de les extraire pendant 24 h avec l'une des solutions chimiques décrites plus loin. Les pourcentages d'ions adsorbés que l'on a pu récupérer varient selon la séquence suivante des réactifs : NaCl, $CaCl_2$ < $MgCl_2$, NH_4NO_3 < CH_3COONH_4, citrate de Na, $Na_4P_2O_7$ < EDTA, DTPA < CH_3COOH, $H_2C_2O_4$, HCl, HNO_3. Dans chacun des systèmes, la quantité de produit qui est récupérée varie avec le chargement initial de la surface (qui est une fonction du pH de l'adsorption) et elle est un reflet des changements dans la forme des espèces métalliques, comme M^{2+}, (MOH^+) ou $M(OH)_2$. Lorsque les quantités de métaux qui sont chargées sont faibles, des niveaux allant jusqu'à 40%, les métaux sont déplacés par les solutions de sels. Lorsqu'on fait adsorber de 1 à 2 μmol, il n'y a que 10% des métaux qui sont déplacés par les acides ou par les composés pouvant former des complexes; toutefois, cette quantité croit jusqu'à 90% avec des chargements plus élevés. La relation entre le pH d'adsorption, la quantité adsorbée et la valeur de récupération est complexe; puisque la classification des schémas d'extractions sélectives est basée sur les valeurs de récupération, des changements dans les paramètres de rétention initiale (comme le pH du système) conduisent à des fractions variables d'ions métalliques différents qui sont classifiés comme "échangeables", "chemisorbés" ou "incorporés au réseau".

Introduction

Only a small fraction of the trace element content of soils and sediments is liable to be "biologically active". In recognition of this, analysts have developed a series of chemical extraction schemes which attempt to subdivide total contents into segments which bear labels such as "detrital (or residual)", "non-detrital", "ion exchangeable", "bound to carbonates", "organically bound", or "associated with hydrous oxides". In respect to the latter group, most of the extended "fractionation" procedures include steps which help identify the fraction of total element content associated with the Mn(IV) and/or Fe(III) oxide components (1, 2). None of the analytical methods, however, attempt to identify the amount associated with hydrous aluminum oxides, a soil/sediment component formed during weathering of alumino-silicate minerals or via hydrolysis of leached aluminum salts. The Al–hydroxy species can control the pH of acid soils (3) and can sorb both metal ions (4, 5) and anions (e.g. F^- (6)).

The omission of analytical procedures for identifying the Al-bound metal fraction could arise from the bland assumption that treatments which disrupt Fe(III) or Mn(IV) oxides should simultaneously release ions bound to Al oxides. Alternatively, it may arise from limited knowledge of sorbed metal ion behaviour.

The chemical and structural form of the Al species found in environmental samples depends on the source, and the conditions prevailing during the aging cycle. The hydrogel $[Al(OH)_3]$ formed by hydrolysis of Al(III) salts (pH 3 to 9) spontaneously loses water to form the polyhydroxide known as β-aluminum hydroxide. On aging, this gradually converts to boehmite (AlOOH) and gibbsite ($Al_2O_3 \cdot 3H_2O$) (7, 8). These transitions are accompanied by: (*i*) a change from amorphous to crystalline structural form. During the structural rearrangement, incorporation of favored ion (e.g. Mg, Ni, Zn) can occur, and it has been postulated (9) that this results in two types of cation adsorption, namely, specific and non-specific (i.e. displaceable by Ba^{2+}); (*ii*) a significant decrease in acid or base solubility; and (*iii*) a reduction in the adsorptive capacity for metal ions (e.g. freshly precipitated gel's capacity for Zn^{2+} (~160 mmol/kg) was found to be tenfold that of aged oxide, and corresponded to a tenfold difference in surface area (10)).

During the sorption of metal ions H^+ are displaced, and the specific sorption of divalent cations to fresh gel may involve coordination to two (or even three) surface —OH groups. Metal ion uptake tends to vary from very little to near total uptake over a narrow (1–2 unit) pH range, and if selectivity is defined in terms of the pH required for 50% retention (pH_{50}), then the sequence is Cu(4.8) > Pb(5.2) > Zn(5.6) > Ni(6.3) > Co(6.5) > Cd(6.6) > Mg(8.1) > Ca > Sr(9.2) > Ba (4.5).

On α-Al_2O_3, sorption of Zn, Mn, Co, or Ba from $<10^{-7}$ *M* solutions follows a log adsorption isotherm, with the pH required for 50% retention being virtually independent of

*Substrates: A, $Al(OH)_3$ gel, aged 24 h; B, α-Al_2O_3. With gibbsite, Al detected was extremely low; e.g. <1% with acid solutions.

concentration (e.g. for Zn, $pH_{50} \sim 6.8$) (11). With Cd sorption, the pH_{50} value shifts to lower regions (e.g. 8.0 to 6.7) when the α-Al_2O_3 suspension concentration is increased (e.g. from 2 to >20 g/L) (12).

γ-Al_2O_3 uptake behaviour is altered by the presence of nitrolotriacetate (NTA), yielding an affinity sequence such as Cu > Zn > Cd > Pb, Ni (13).

In the corundum-type structure of α-Al_2O_3 a layer of Al atoms lies between two layers of oxygen atoms; the γ modification has a spinel-type structure in which the O atoms have an approximate face-centred cubic order with Al atoms occupying half of the octahedral interstices.

It has been proposed (14) that synthetic Fe and Al hydrous oxides serve as useful models for some of the species found in the environment, and in view of the role that these materials can play in soil/sediment chemistry, improved understanding of metal ion desorption processes was deemed to be highly desirable. The results obtained in systematic examinations of the Fe and Mn systems have been published (15, 16). This paper outlines the extraction behaviour observed using hydrous Al oxides loaded with varying amounts of Cu, Pb, Cd, or Zn ions, and a selection of the reagents used in analytical speciation schemes.

Experimental

Adsorbents

A suspension of $Al(OH)_3$ was prepared (as required) by slowly adding NaOH solution to vigorously stirred M/60 $Al(NO_3)_3$ until the pH was ~7. The suspension was kept well stirred and aliquots taken for transfer to vials (~13 mg solid/10 cm^3).

A suspension of A.R. aluminum hydroxide powder (May and Baker, 36% H_2O) containing 2 g L^{-1} was prepared as required. XRD examination of the powder showed it to be predominantly gibbsite.

Suspensions of alumina (2 g L^{-1}) were prepared from chromatography grade Al_2O_3, supplied by May and Baker.

Extraction procedure

Aliquots (10 cm^3) of $Al(OH)_3$ gel or solid suspension (i.e. 13 mg $Al(OH)_3$ gel or 20 mg crystalline solids) were transferred to acid-washed glass vials. An appropriate volume of 0.01 *M* NaOH was then added to raise the system pH and ensure adsorption of a high proportion of the 5 μmol of M^{2+} subsequently added (as 10.0 cm^3 of 5×10^{-4} *M* $Me(NO_3)_2$ solution). With fresh gel and alumina there was a marked pH effect on uptake in the vicinity of pH_{50} and accordingly the amounts sorbed varied between individual vials. Each test solution was diluted to 25.0 cm^3 with demineralised water and the vial was capped before being mixed overnight in an end-over-end stirring unit. The pH of the systems stabilized after about 12 h of mixing.

After this equilibration period, the solid phase was collected on a 0.45 μm (25 mm diameter) membrane (using an Amicon Vacuum manifold unit) and washed with 5.0 cm^3 water. The pH of each aqueous phase was measured using a Philips® Meter, Model 9407, and the Pb, Cu, Zn, or Cd content was determined using a Varian® AA875 Atomic Absorption Spectrometer and appropriate C_2H_2, air flame conditions. (For Al determinations a C_2H_2–N_2O flame was utilised.)

Each filter membrane plus transferred solid was returned to the original vial, and 30.0 cm^3 of extracting solution (selected from the range listed on Table 1) was then added. Care was taken to ensure minimal loss of solid to the walls of the filter vessel. To compensate for random losses or experimental variations, each extraction study was replicated (i.e. more than six samples per reagent). To identify loading effects, most studies were repeated using different initial NaOH additions (i.e. system pH values), in order to vary the amount of M^{2+} sorbed by the substrates. As the pH required for onset of significant adsorption varied with substrate nature and the metal ion involved, suitable conditions had to be determined from trial runs.

The vials containing the solid, membrane, and extractant solution were equilibrated overnight at 25°C in the end-over-end mixer before being centrifuged (and filtered when necessary) to yield a clear aqueous phase which could be analysed for metal content. The AAS unit was calibrated by adding known amounts of metal ion to the same extractant solution as involved in the test study.

The percentage recovery of metal ion was calculated by comparing the μmol M^{2+} found in the extractant against the μmol sorbed in the uptake stage.

Determination of the Al content of extractant solutions provided an indication of the solubility of the substrate in the various reagents, and these results are summarized on Table 1.

Results

With $Al(OH)_3$ gel and Al_2O_3, the effect of pH on uptake followed the pattern reported by earlier workers, that is, uptake increased from low values to near total retention over a narrow

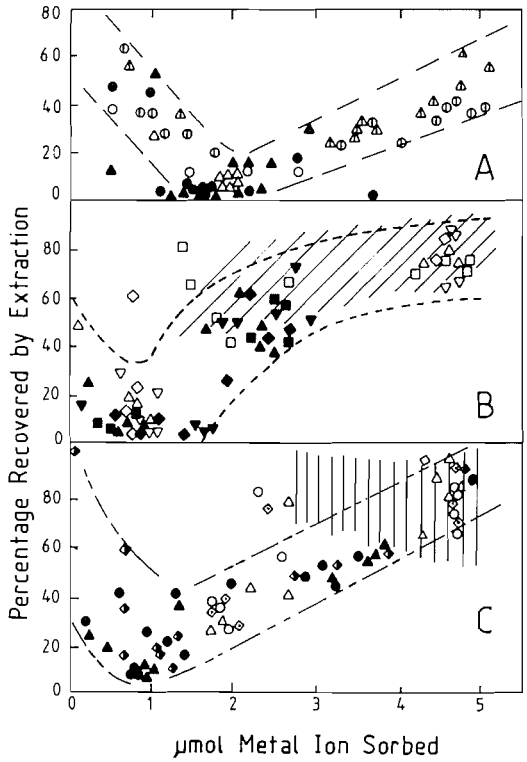

FIG. 1. Effect of amount of metal ion sorbed by substrates on the percentage recovered by 24 h extraction at 25°C. *A*, Cd displaced by NH_4NO_3 (●, ○, ⓘ) or CH_3COONH_4 (▲, △, ⧋). Symbol shading represents data using gibbsite, Al_2O_3 or $Al(OH)_3$ gel, respectively. *B*, Zn displaced using different acid solutions, e.g. HCl (■, □), HNO_3 (◆, ◇), CH_3COOH (▲, △), or $(COOH)_2$ (▼, ▽). The extraction values found using $Al(OH)_3$ gel as substrate fell within the zone defined by sloped shading. *C*, Cu displaced using different complex forming extractants e.g. EDTA (●, ○), DTPA (▲, △), or sodium citrate (◆, ◇). The recoveries obtained using the same reagents on $Al(OH)_3$-sorbed metal ion fell within the area outlined by vertical shading.

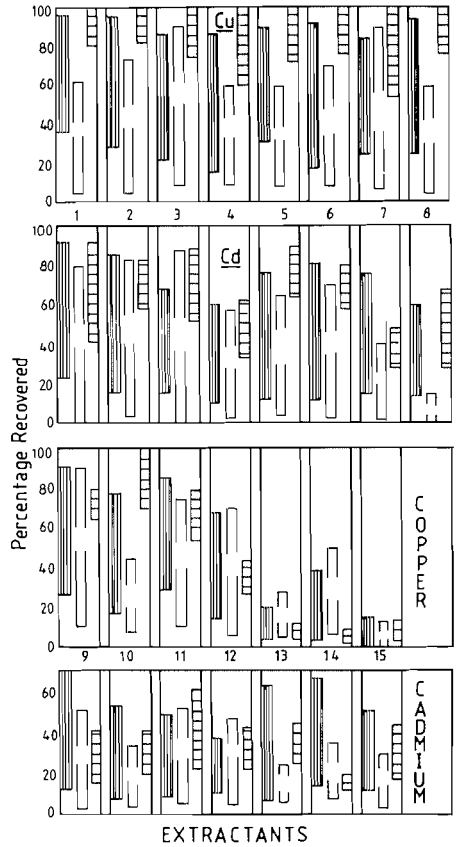

FIG. 2. Block diagram showing the effect of substrate and extractant type on the percentage of sorbed Cu or Cd recovered. Each rectangle indicates the spread of recovery values obtained (covers different amounts sorbed) and shading indicates the substrate: vertical (|||||), Al_2O_3; horizontal (≡≡≡), $Al(OH)_3$ gel; and open box, gibbsite. Reagent code: *1*, 0.5 *M* HCl; *2*, 1 *M* HNO_3; *3*, 0.5 *M* CH_3COOH; *4*, 0.25 *M* CH_3COOH/0.25 *M* CH_3COONH_4; *5*, 0.5 *M* $H_2C_2O_4$; *6*, 0.1 *M* $H_2C_2O_4$/0.18 *M* $(NH_4)_2C_2O_4$; *7*, 0.005 *M* EDTA; *8*, 0.005 *M* DTPA; *9*, 1 *M* sodium citrate; *10*, 0.1 *M* $Na_4P_2O_7$; *11*, 1 *M* CH_3COONH_4; *12*, 1 *M* NH_4NO_3; *13*, 1 *M* $MgCl_2$; *14*, 0.5 *M* NaCl; and *15*, 0.05 *M* $CaCl_2$.

pH range. However, in the presence of the aluminum substrates, metal ion hydrolysis continued overnight, as shown by a drop in pH which ranged from ~1 pH unit using gel to ~0.3 pH units with Al_2O_3 suspensions. These changes, plus aging effects caused the pH_{50} values to vary marginally from those quoted in the Introduction. With gibbsite, slow partial dissolution of the solid (possibly accompanied by secondary formation of gel) led to wide variations (e.g. 15%) in uptake at most pH values. Hence plots of amount sorbed versus pH yielded broad zones rather than steeply sloping curves.

Due to the significant effect of pH on metal ion uptake in all of the systems studied, each replicate tended to adsorb different amounts of metal ion, and this was found to lead to variations in the amount of sorbed metal ion recovered by extraction.

Figure 1 shows the effect of amount sorbed on the percentage recovered in three different systems, and highlights the distinct minimum in uptake values discerned in some of the extraction studies. This minima is considered to correspond to maximum uptake of a MOH^+ species. At higher loadings increasing amounts of $M(OH)_2$ should exist. With lead sorbed on $Al(OH)_3$, the minimum release zone was followed at higher coating levels by an abrupt increase in the percentage extracted. In many of the copper and zinc studies, the percentage of metal ion retrieved increased almost linearly as coating levels increased. By contrast, recovery values using the chloride salts of Na, Ca, or Mg, tended to continually decline as the amount of metal ion initially sorbed increased, that is, there was a gradual change from the maximum values shown on Figs. 1 and 2 (reagents *13* to *15*) to the lower limits indicated by the rectangles.

The trends were complex, and explanation difficult, hence detailed consideration of this aspect has been deferred to a later publication.

The loading effect contributed significantly to the range of recovery values reported in Figs. 2 and 3. On these diagrams the spread of values obtained is indicated by the length of the rectangular plots. Figure 2 highlights the effect (if any) of substrate nature on the extractability of sorbed copper and cadmium ions (Pb and Zn responses were generally similar to one or other of these two studies).

Figure 3 summarises the effect of metal ion on the amount recovered by different extractants using partially aged $Al(OH)_3$ as substrate.

Other factors, besides "loading effects", contributed to the broad spread of results. Perusal of the points shown on Fig. 1, shows that recoveries varied widely even when the amount sorbed by replicates varied little. Partly to blame are experi-

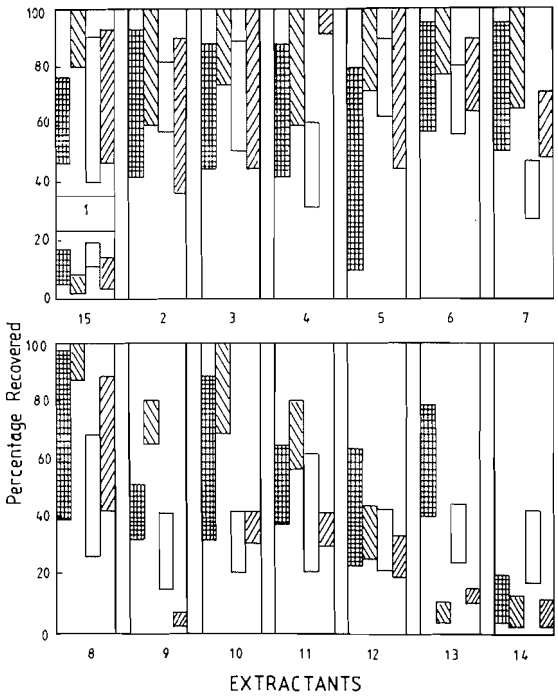

FIG. 3. Diagrams showing the ability of different extractants to retrieve metal ions sorbed on $Al(OH)_3$ gel. Metal ion code: Pb, ▦; Cu, ▧; Cd, □; and Zn, ▨. Reagent code, *1* to *15*, same as for Fig. 2.

mental design limitations (e.g. gel filtration problems, colloid loss during substrate isolation, aging effects, and calculations based on analysis differences). Similar problems were encountered in earlier studies using Fe(III) and Mn(IV) oxides (15, 16), but in these investigations precision was far better (e.g. ±5 to 10% deviation from a mean value).

The "solubility" of the substrate also contributed to system behaviour. As noted in the Introduction, changes in gel structure during aging reduces solubility. In our study, aging (~48 h total) plus chemical interaction with metal ions at the surface reduced gel solubility in acids by about 25% (cf. Table 1). The values quoted are the mean of 5 to 20 determinations, with reproducibility being around ±10%. Variations in matrix dissolution could have contributed to varying amounts of "occluded and/or chemi-sorbed metal ion" being retrieved.

The alumina solubility was quite low, and with gibbsite suspensions (which only slowly reach saturation values (17)), dissolved Al was close to the AAS detection limit. With these materials, metal ion recovery levels were often lower than observed with gel, but loading effects blurred any substrate based trends.

Discussion

Selective extraction of metal ions sorbed on aluminum hydrous oxides

A primary aim of this study was to elucidate the conditions required for release of any metal ion associated with aluminum oxide or hydroxide species in soils and/or sediments.

The diverse results obtained in this controlled study indicate, however, that sorbed metal ions are bonded by several different mechanisms, and the initial loading was only occasionally fully retrieved (cf. upper limits of rectangles drawn on Figs. 2 and 3).

The reagents used included strong acids and EDTA, systems recommended for distinguishing between detrital and non-detrital metal fractions.

The detrital fraction consists mainly of fragments of the original ground rock (in which metals are usually present in lattice structures); the non-detrital material contains weathering products of fine particle size with a high sorptive capacity for metal ions. The sorbed ions may be bound through electrostatic attraction (ion exchangeable), by less definable weak bonding or by compound formation (chemisorption). The reagents tested included many recommended for identifying ion exchangeable fractions, weakly sorbed material and bound to the hydrous oxides of Fe and Mn(IV).

In terms of extraction behaviour, the responses could be grouped under four major headings, namely, *acids*, *complex forming ligands*, *ammonium salts*, and *chloride salts*.

The last two groups embrace reagents used (by some) to evaluate the ion exchange capacity of soils or to estimate the amount of ion exchangeable metal ion present in sediments. A study of Figs. 2 and 3 show that up to 80% of sorbed Pb, Cu, or up to 60% of Cd was occasionally displaced by these reagents. The recovery value varied with the nature of the substrate (Fig. 2), element of interest (Fig. 3), the amount initially sorbed (Fig. 1) and the reagent selected. One ion in this group (Mg^{2+}) was very effective in displacing Pb^{2+}, a result that suggests that a high proportion of sorbed lead was non-specifically bonded.

The enhanced ability of ammonium salts to effectively displace sorbed metal ions may be due to preferential sorption of the small NH_4^+ ion (ionic radius ~ 2.5 Å), complemented by the tendency of Cu, Cd, and Zn to form ammine complexes (with H^+ transfer to surface hydroxyl groups). With acetate salts, formation of aceto-complexes may also contribute to recovery values.

The effective stability of any metal complexes formed, relative to substrate bonding strength, strongly influenced the amount recovered, as shown by the variable responses observed using chelating agents (e.g. EDTA, DTPA, citrate) and complex formers (e.g. oxalate, pyrophosphate). All these reagents form complexes whose structure, charge, and effective stability is a function of system pH and ligand concentration. Some products had limited solubility (e.g. Zn^{2+} with citrate, Pb^{2+}, and $(COOH)_2$). As shown in Table 1, these reagents also partially dissolved gel substrates.

If one accepts the oft assumed premise that complex-forming ligands release both displaceable and chemi-sorbed metal ions, while chloride salts release only the exchangeable fraction, then comparison of the recoveries listed on Figs. 2 and 3 indicates that up to half of the Cu, Pb, and Zn was chemi-sorbed; with Cd non-specific sorption appears to have predominated.

Acid reagents also had the potential to release both weakly held and chemi-sorbed ions, through a combination of substrate dissolution and preferential sorption of H^+ (aided by metal complex formation when using acetic and oxalic acid systems). The total recovery predicted was not achieved, however, due to part of the sorbed material becoming incorporated in a crystal lattice or converted into a sparingly soluble product. The fraction in this category was influenced by the amount of metal ion initially sorbed (cf. Fig. 1).

Specific sorption persists down to quite low initial metal ion concentrations, with at least three bonding modes still involved. In anodic voltammetry studies, using $\mu g\ L^{-1}$ levels of metal ion and acetate buffer solutions, it was found (18) that added $Al(OH)_3$ gel sorbed significant amounts of the nanomoles of metal ion present (even though it existed in solution primarily as aceto-complexes). Sorption by α-Al_2O_3 from $<10^{-7}$ *M*

solutions (11) and uptake by γ-Al_2O_3 in the presence of the chelating agent NTA (13) was noted earlier.

With metal ions sorbed on alumino-silicates (e.g. kaolin, illite, montmorillonite) extraction behaviour resembled that reported in this paper in many respects. Most of the sorbed metal ion was strongly held, with pH 3 ammonium oxalate being the most efficient releasing agent, followed by EDTA and acid solutions (19).

Analytical schemes

The absence of specific mention of aluminum-bound metal ion in any of the published selective extraction procedures (cf. refs. 1 and 2) is now understandable, since no single reagent appears to have the capacity to consistently achieve optimum release of this particular sub-category.

Treatment of sediments by any of the published sequential procedures would lead to Al associated material appearing in different segments of the scheme, e.g., a significant part could appear with the ion exchangeable fraction, some would be classified as weakly sorbed, part would be released with the Fe, Mn hydrous oxide sediment, and varying amounts would be detected in the "residual" sub-group.

At this point, it should also be noted that satisfactory procedures for differentiating between extractable forms of Al have yet to be developed. It has been reported, for example, that the approach used for extractable Fe (based on oxalate, dithionite, and pyrophosphate extractions) was less useful for distinguishing between the various forms of Al in soils (20). A more recent study demonstrated that a 4 h extraction with acidified (pH 3) ammonium oxalate was the most efficient single procedure for assessing the amount of translocated Al, Fe, and Si present as inorganic compounds in the non-crystalline weathering products found in podzol B horizon samples (21). A pyrophosphate extraction provided an estimate of the organic bound Al fraction. For evaluating the amount of poorly ordered alumina gels in samples, extraction with cold 5% Na_2CO_3 has been proposed (22).

As shown in our investigation, the precision of determinations based on "selective extraction" can be quite poor. With real samples, this variability may be matched by sampling errors or sample heterogeneity. In addition, only a small fraction of the trace element content may be bonded to Al species.

Bonding modes

Factors which contribute to the observed extraction behaviour include the different types of bonding sites at the surface of aluminium oxide/hydroxide substrates, variations in the chemical form of the sorbed metal ion, ion diffusion into gel structures, and surface charge. Freshly precipitated Al gel has a zero point charge value of around 9.4 (4) while the value quoted for α-Al_2O_3 is 8.8 (11) and since the system pH in the sorption studies was lower than these values the substrates should have maintained a net positive charge during the various sorption cycles.

As pH increases (and more metal ions are sorbed) chemisorption (involving bonding to Al—OH sites) becomes more pronounced. This is preceded or accompanied by proton loss from coordinated water molecules, yielding hydroxy species in which the average $OH^-:M^{2+}$ ratios vary from near zero to two (when all the initial M^{2+} has been sorbed or precipitated). To explain the minima in extraction values noted in some studies (cf. Fig. 1), the solubility of one of the intermediate species (e.g. $\overline{S}MOH$ where $\overline{S}$ is substrate surface) must be lower than that of other species.

In the presence of kaolinite, illite, or montmorillonite clay particles the term $pM + pOH$ remained virtually constant, up to the pH_{50} point (23). This suggested that the sorbed species was probably a polymer having the general formula $(MOH)_x$. When over half of the total metal content had been sorbed/precipitated the term $pM + 2pOH$ became constant, which implied that both sorbed metal ion and precipitated excess had the empirical formula $M(OH)_2$. The presence of particulate matter tends to lower the pH required for metal—hydroxide formation, and the pH associated with 50% precipitation (pH_{50}) varies with substrate composition (for example, using 10^{-4} *M* solutions Pb (or Cd) pH_{50} values range from 3.1 (or 5.8) on hydrous Fe oxide (5) to 5.9 (or 7.3) on clay minerals (19)).

Terminology in extraction studies

For quantitative recovery of sorbed metal ions, an extractant must have the capacity to dissolve aged metal hydroxy polymers, disrupt chemisorption bonds, release occluded material, and displace electrostatically attracted species.

Any reagent capable of performing some, of all, of these tasks in respect to aluminum bound species, will undoubtedly have the potential to displace the same element from other substrates, particularly clays and hydrous iron oxides. Accordingly selective extraction of the aluminum bound fraction appears to be an unattainable goal.

This conclusion highlights the inappropriateness of some of the terminology used in chemical extraction studies. Categories such as hydrous oxide bound, organic bound have limited significance (due to varied bonding modes) and it would be preferable to standardise on a reagent based system (e.g. acetate-buffer soluble; released by pH 3 ammonium oxalate; released by HNO_3, H_2O_2 attack; and so on).

For reasons outlined in review articles, it is equally important to closely specify experimental conditions, for example, reagent concentration, solid-to-liquid ratios, time of contact, and temperature.

Selective extraction procedures have useful applications, but their limitations have also to be recognised.

The apparent molar volumes and heat capacities of aqueous mixtures of neutral polymers and ionic surfactants were measured at 25°C. The polymers chosen were poly(vinylpyrrolidone) (PVP) and poly(ethyleneoxide) (PEO) and the surfactants were the C_8, C_{10}, and C_{12} homologs of sodium alkylsulfates and the C_{10}, C_{12}, and C_{16} homologs of alkyltrimethylammonium bromides. The polymer–surfactant interactions depend on the nature of both components and on the chain length of the surfactant. The thermodynamic properties of the cationic surfactants are essentially the same in the absence and presence of polymer indicating little surfactant–polymer interaction. On the other hand, the thermodynamic properties of anionic surfactants are shifted, upon the addition of polymers, in the direction of enhanced hydrophobic association. The effect increases with the surfactant chain length and with the polymer concentration. The effect is larger with PVP than with PEO.

GÉRALD PERRON, JOSÉE FRANCOEUR, JACQUES E. DESNOYERS et JAN C. T. KWAK. Can. J. Chem. **65**, 990 (1987).

Opérant à 25°C, on a mesuré les volumes molaires apparents et les capacités calorifiques de mélanges aqueux de polymères neutres et d'agents de surface ioniques. Les polymères choisis sont la poly(vinylpyrrolidone) (PVP) et poly(oxyde d'éthylène) (POE) alors que les agents de surface sont les homologues C_8, C_{10} et C_{12} des alkylsulfates de sodium et les homologues C_{10}, C_{12} et C_{16} des bromures d'alkyltriméthylammonium. Les interactions polymère/agent de surface dépendent de la nature de chacun de composants et sur la longueur de la chaîne de l'agent de surface. En présence ou en l'absence de polymères, les propriétés thermodynamiques des agents de surface cationiques sont essentiellement les mêmes; ces résultats indiquent qu'il y a peu d'interactions entre le polymère et les agents de surface. Par ailleurs, l'addition de polymères déplace les propriétés thermodynamiques des agents de surface anioniques dans la direction d'une augmentation de l'association hydrophobe. L'effet augmente avec la longueur de la chaîne de l'agent de surface et avec la concentration de polymère. L'effet est plus important avec la PVP qu'avec le POE.

[Traduit par la revue]

Introduction

The interaction of macromolecules and amphiphilic small molecules is of importance in a wide variety of biological systems and industrial processes. Polymer–surfactant systems are also of considerable interest for fundamental studies, because they combine the effects of ionic, dipolar, and hydrophobic interactions, and the aggregates formed provide a new microenvironment, for instance, for hydrophobic solutes. In recent years, polymer–surfactant solutions have been the topic of a large number of investigations, and the solution aspects of these mixtures have been reviewed extensively (1–4). Most of these studies are concerned with the determination of binding isotherms, using techniques such as dialysis equilibrium, surface tension, selective ion electrodes, etc. Generally, it is found that the binding of ionic surfactants by polyions of opposite charge starts at concentrations as much as two orders of magnitude lower than the critical micelle concentration (cmc) of the surfactant. On the other hand, in the case of non-ionic polymers, binding of ionic surfactants occurs close to the cmc. In both cases, hydrophobic interactions between the bound surfactant ion play an important role in the overall aggregation process, as is perhaps most clearly shown in the dependence of the binding constant on the alkyl chain length of the surfactant (5, 6).

In view of the extensive work on binding isotherms, it is perhaps surprising that the determination of thermodynamic parameters other than free energies or activities in these systems has been relatively neglected. Goddard's review (4) only mentions a few direct calorimetric measurements of enthalpies in neutral polymer – ionic surfactant solutions (5, 7). In aqueous electrolyte and non-electrolyte solutions and in micellar systems, the direct determination of thermodynamic quantities such as enthalpies, volumes, and heat capacities has been applied widely. In particular, partial molar volumes and partial molar heat capacities have been shown to be sensitive indicators of hydrophobic interactions in micellar aggregation and in microemulsions (8, 9). In the case of ternary systems such as those considered here, the relevant thermodynamic quantities are more easily expressed in terms of transfer functions (10).

In the present study, the apparent molar volumes and heat capacities of anionic and cationic surfactants have been measured in dilute solutions of two typical water-soluble polymers, poly(vinylpyrrolidone) (PVP) and poly(ethylene oxide) (PEO), and compared with the corresponding properties in water. Any interaction between the surfactant and the polymer should be reflected as a shift in the cmc of the surfactant

and in the thermodynamic properties in the pre- or post-micellar region. These two non-ionic polymers have been chosen because they have been shown to interact with anionic surfactants, and their solution properties are well known (11). In addition, interactions between these polymers and the anionic surfactants (sodium octyl-, decyl-, and dodecyl sulfate) occur in sufficiently high concentrations to make the direct measurement of molar volume and heat capacity possible.

Experimental

The two techniques used for the measurement of the differences in densities (12) and of relative changes in heat capacities per unit volume (13–15) using a commercial SODEV densimeter (Model 01D) and flow microcalorimeter (Model CPC) have been well described in the literature. The apparent molar quantities of the component i, $V_{i,\phi}$ and $C_{p,i,\phi}$, are calculated from

$$[1] \quad V_{i,\phi} = M_i/d - 1000(d - d^*)/mdd^*$$

and

$$[2] \quad C_{p,i,\phi} = M_i c_p + 1000(c_p - c_p^*)/m$$

M_i is the molar mass of solute i, m the molality in moles per kg of (polymer) solution, and $d - d^*$ is the difference in densities, where the asterisk stands for the reference solvent (pure H_2O or H_2O–polymer solution). The difference in specific heat capacities, $c_p - c_p^*$, is calculated from the relative change in heat capacities per unit volume σ and the densities d (15).

Under the best conditions, differences in densities can be obtained to 3 ppm and relative changes in heat capacities per unit volume to 0.5%. This limits the precise measurements of apparent molar quantities to concentrations above 0.01 mol kg^{-1}.

Sodium octyl- and decylsulfate (NaC_xSO_4) (Eastman Kodak) and sodium dodecylsulfate (BDH, Specially Pure Biochemical) were recrystallized from absolute ethanol. Decyltrimethylammonium bromide ($C_{10}Me_3NBr$) (Eastman Kodak) and $C_{12}Me_3NBr$ and $C_{16}Me_3NBr$ (Sigma Chemicals) were recrystallized from spectrograde acetone. The purified surfactants were washed with diethylether and dried under vacuum at temperatures lower than 60°C to minimize possibilities of decomposition. They were then cooled and kept under vacuum over P_2O_5. Purity of surfactants was checked by surface tension. Note that for octyl- and decylsulfate molar volume in the dilute region, as measured here, is one of the best indicators of purity.

The polymers were used as received; PEO from Polyscience, sample 2L3811, approximate molecular weight 100 000 and PVP from GAF Corporation, sample Plasdone K-25 approximate molecular weight 35 000.

All solutions were prepared by mass using deionized distilled water. The majority of solutions were prepared from a stock solution of the ternary system and diluted with a polymer solution. All measurements were made on the ternary system (water + polymer + surfactant) relative to the binary solution (water + polymer). In the case of PEO, some stock solutions were heated at 55°C for half an hour before dilution to ensure complete dispersion of the polymer. Measurements with these samples were identical, within experimental uncertainty, to the samples that had not been heated.

Results and discussion

The original data for the densities and heat capacities and the derived apparent molar quantities for the surfactants in water and in the polymer solutions, as a function of the surfactant molality, are available from the Depository of Unpublished Data.[2] The microcalorimeter and densimeter were placed in series using the same temperature controller. As a consequence the densities were measured at 24.67°C and the heat capacities at a mean temperature of 25.00°C. The error introduced by this difference in temperature is negligible. Whenever possible, the data in water were compared with values previously measured in our laboratory and the agreement was inside the experimental uncertainty.

Polymers in water

From the data on the binary polymer solutions, it is possible to calculate the apparent molar quantities for the repeating unit of the two polymers. These values can then be compared with those of the literature and with those calculated by group additivity using data on related solutes in water. These results are compared in Table 1. In comparing our present data to those of Riedl (16) and the data collected by Molyneux (11), we note that our values both for $V_{2,\phi}$ and $C_{p,2,\phi}$ agree with those of Riedl within measurement error. Our value for $V_{2,\phi}$ for PVP agrees well with the average given by Molyneux, however in the case of PEO our value is slightly lower (equivalent to 0.824 $cm^3\ g^{-1}$ where Molyneux's average is 0.834). In part this may be due to the concentration difference (up to 0.4 wt% in this work, 2% for most of the data quoted by Molyneux). More importantly, we note that for PEO the measured values for $V_{2,\phi}$ and $C_{p,2,\phi}$ are close to the values calculated from Cabani's group additivity principle (17). This indicates that the polymer is extended and fully hydrated in water, the properties of the polymer in water being equal to the sum of those of the individual groups in water (given the high molecular weight, end effects can reasonably be neglected). The situation is less clear with PVP. The measured value for $C_{p,2,\phi}$ for this polymer is significantly below the group additivity value, and far below the measured value for 1-*n*-vinyl-2-pyrrolidone (17). Intramolecular hydrophobic interactions are known to result in lower molar heat capacity values, thus the lower than expected molar heat capacity for PVP in aqueous solution is an indication of such interactions in the aqueous polymer solution. On the other hand, such interactions

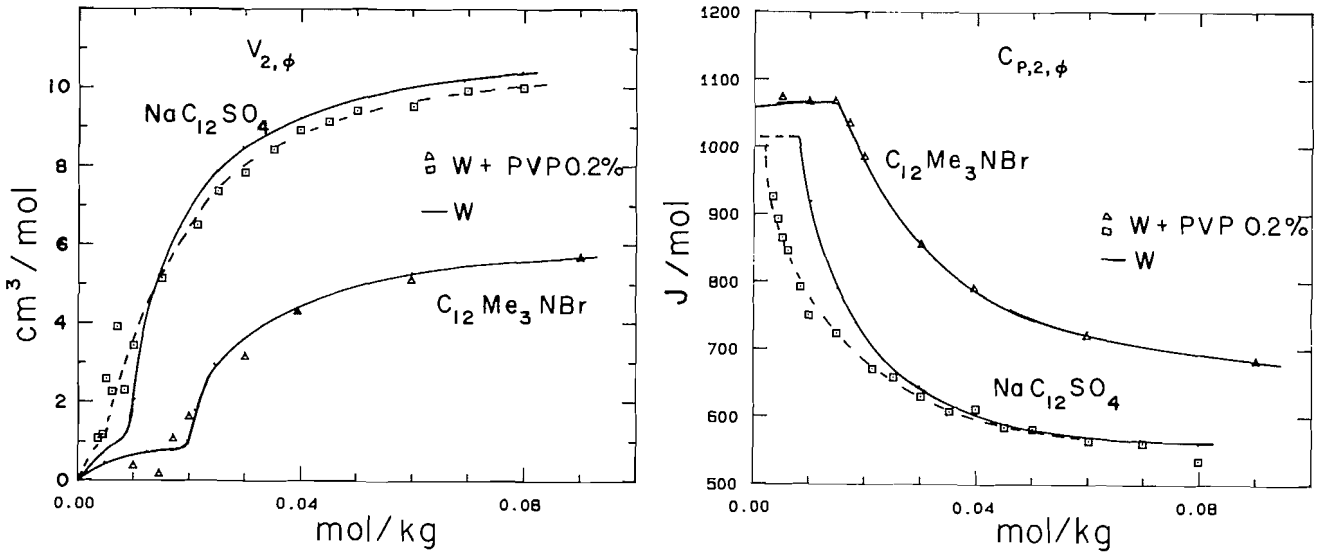

FIG. 1. Apparent molar volumes and heat capacities of typical anionic and cationic surfactants in water (full lines) and in 0.2% PVP (□,△).

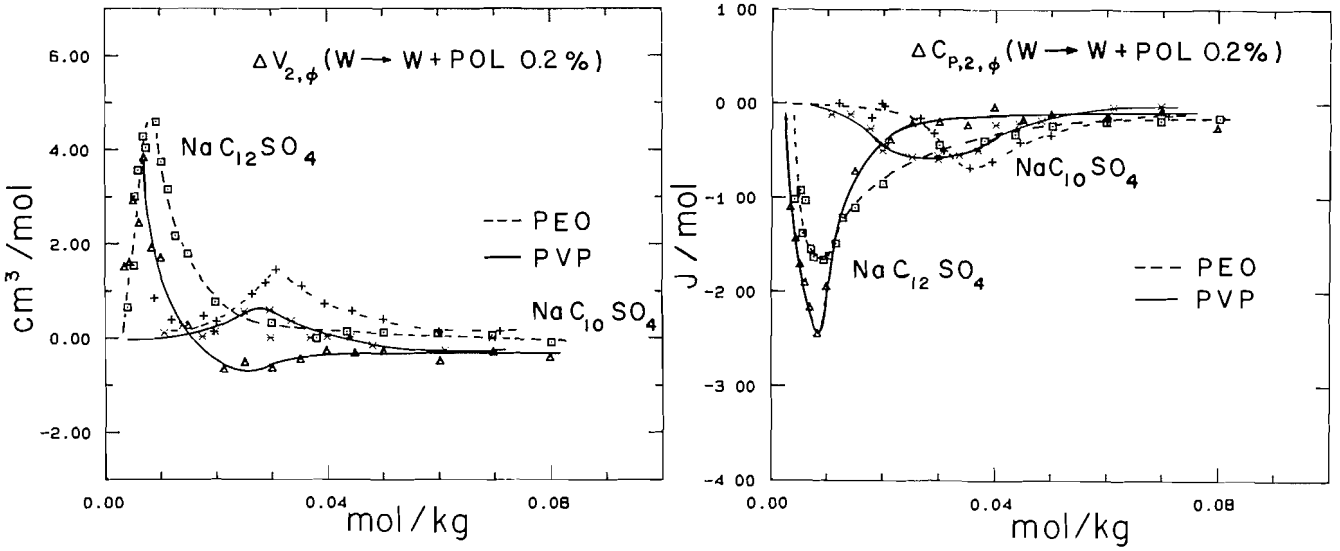

FIG. 2. Changes in apparent molar volumes and heat capacities of sodium alkylsulfates in 0.2% PVP and PEO relative to data in water.

should lead to higher molar volumes (8), contrary to what is observed. Molyneux (11) noted that the low molar volume of PVP in solution, compared to the molar volume of the bulk polymer, is an indication of the "compacting effect" of the polymer on the solvent. A more detailed study of volume changes associated with hydrophobic interactions in these systems would probably be worthwhile.

Polymer–surfactant interactions

Examples of trends of $V_{i,\phi}$ and $C_{i,i,\phi}$ as a function of m, for two types of surfactants in water and in water + polymer solution are shown in Fig. 1. With the cationic surfactants $C_{10}Me_3NBr$ and $C_{12}Me_3NBr$ the values with and without polymer coincide, indicating negligible polymer–surfactant interactions. This is in agreement with what is normally reported for interactions between neutral polymers and cationic surfactants with chloride or bromide counterions (2). Efforts to determine any binding in these systems using surfactant selective electrodes also gave negative results.[3]

[3]N. Ohno and J. C. T. Kwak. Unpublished results.

In the case of anionic surfactants large differences are observed when polymer is added, especially in the region of the cmc. In this region, the data in the polymer solution are more positive for the volumes and more negative for the heat capacities. These changes are as expected for enhanced micellization or hydrophobic interactions (8). As can be seen more clearly in Fig. 2, the deviations start at a definite free surfactant concentration, consistent with the notion of a "first critical concentration" (2, 4, 20, 21), go through a maximum and return close, but not always equal, to zero at high added surfactant concentrations. Unfortunately the calorimetric measurements in particular for SDS do not yield an accurate value for this point of first binding. On the other hand, binding isotherms determined by other methods in particular for SDeS are not very clear (18), making a comparison of the results for the first critical concentrations as obtained by calorimetry and by binding measurements difficult (4, 5, 7, 18–21).

Effect of surfactant chainlength

Differences between the properties of binary systems (water + surfactant) and ternary systems (water + polymer +

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12

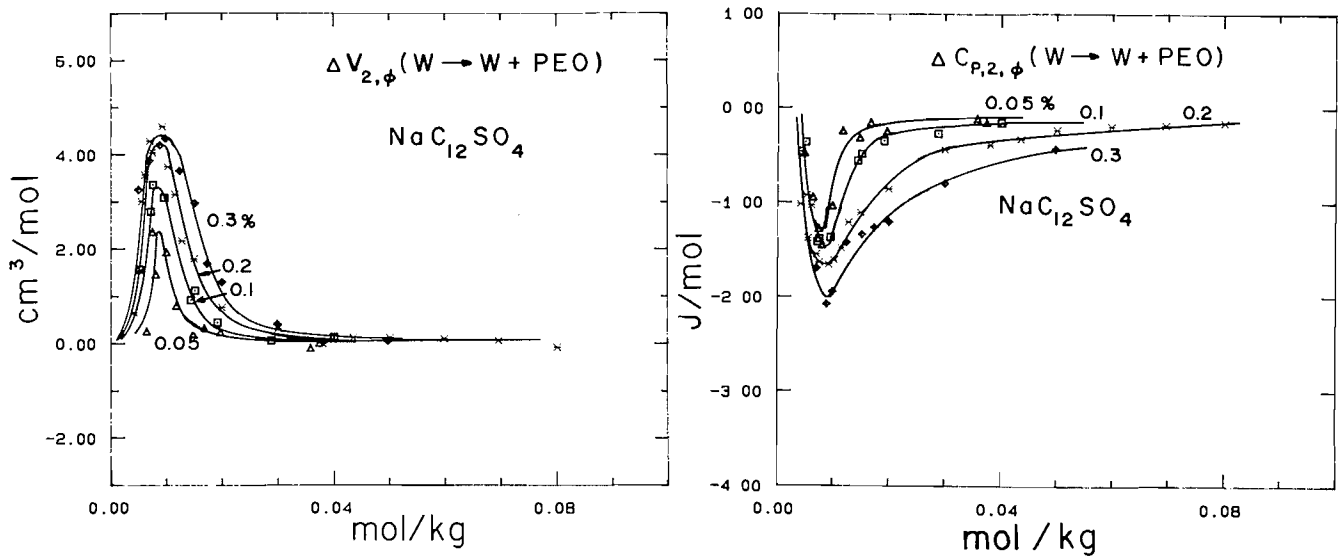

FIG. 3. Changes in apparent molar volumes and heat capacities of sodium dodecylsulfate in PEO of varying concentration relative to data in water.

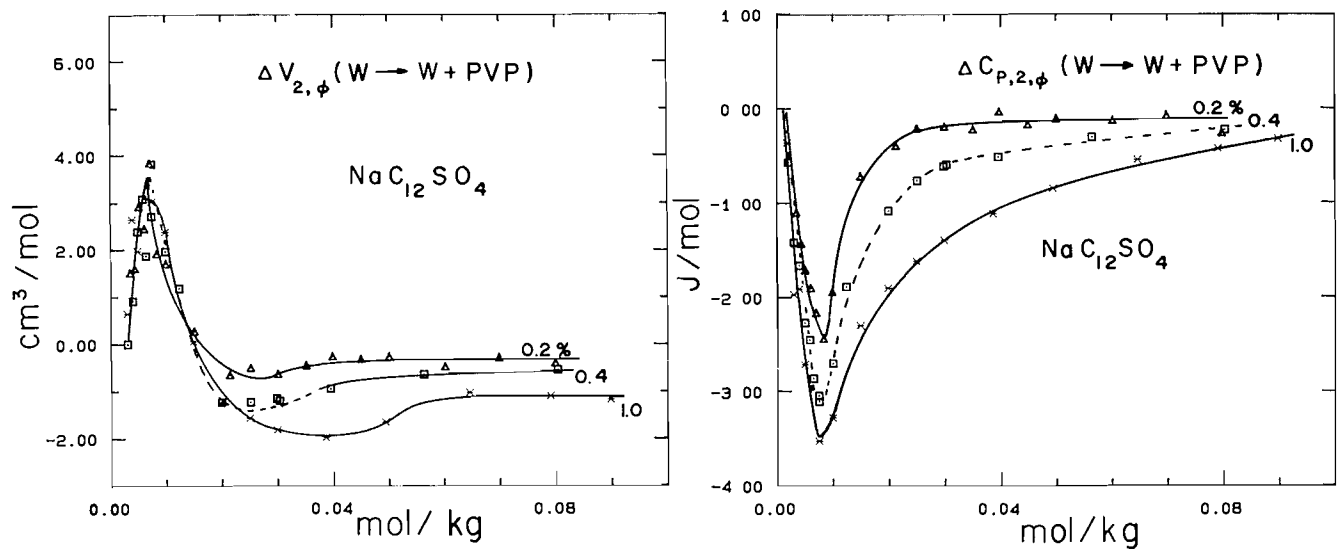

FIG. 4. Changes in apparent molar volumes and heat capacities of sodium dodecylsulfate in PVP of varying concentration relative to data in water.

surfactant) are more relevant than the actual values of those properties in understanding polymer–surfactant interactions. Transfer or difference functions can be defined as:

$$[3]\quad Y_i(\mathrm{W} \rightarrow \mathrm{W} + \text{polymer}) = Y_{i,\phi}(\mathrm{W} + \text{polymer}) - Y_{i,\phi}(\mathrm{W})$$

where W stands for the solvent water. Transfer functions for volume and heat capacity of the surfactant, as defined above, are plotted in Fig. 2 as a function of surfactant concentration, and for a fixed 0.2% (by weight) polymer concentration. In these and subsequent figures the data for sodium octylsulfate are omitted, because the effects are small compared to sodium decylsulfate since the ratio polymer to surfactant is too small (0.2% of polymer for a surfactant that has a cmc of 0.3 mol kg^{-1}). However, even for sodium octylsulfate the effects are measurable.[2] The surfactant chain length dependence is clear both in the magnitude of the effect and in the concentration of first binding. In comparing the results for PEO and PVP, we note that a 0.2 wt% solution corresponds to a 0.045 mol of repeating unit kg^{-1} for PEO and 0.018 mol kg^{-1} for PVP. This difference in concentration should not influence the concentration where binding first occurs but it will affect the overall stoichiometry and the magnitude of the deviation, as discussed in the next section. In general, we find that binding of the alkylsulfates starts at lower surfactant concentrations with PVP than with PEO and that the magnitude of the effect on $V_{2,\phi}$ and $C_{p,2,\phi}$ is larger with PVP.

Effect of polymer concentration

Figures 3 and 4 show the effect of polymer concentration on the volume and heat capacity transfer functions as defined by eq. [3] for sodium dodecylsulfate with PEO and PVP. The transfer functions show two effects: (*1*) The shift of the cmc. There is a definite lower critical binding concentration, this concentration is independent of polymer concentration, but lower for PVP than for PEO. (*2*) The effects above the cmc.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

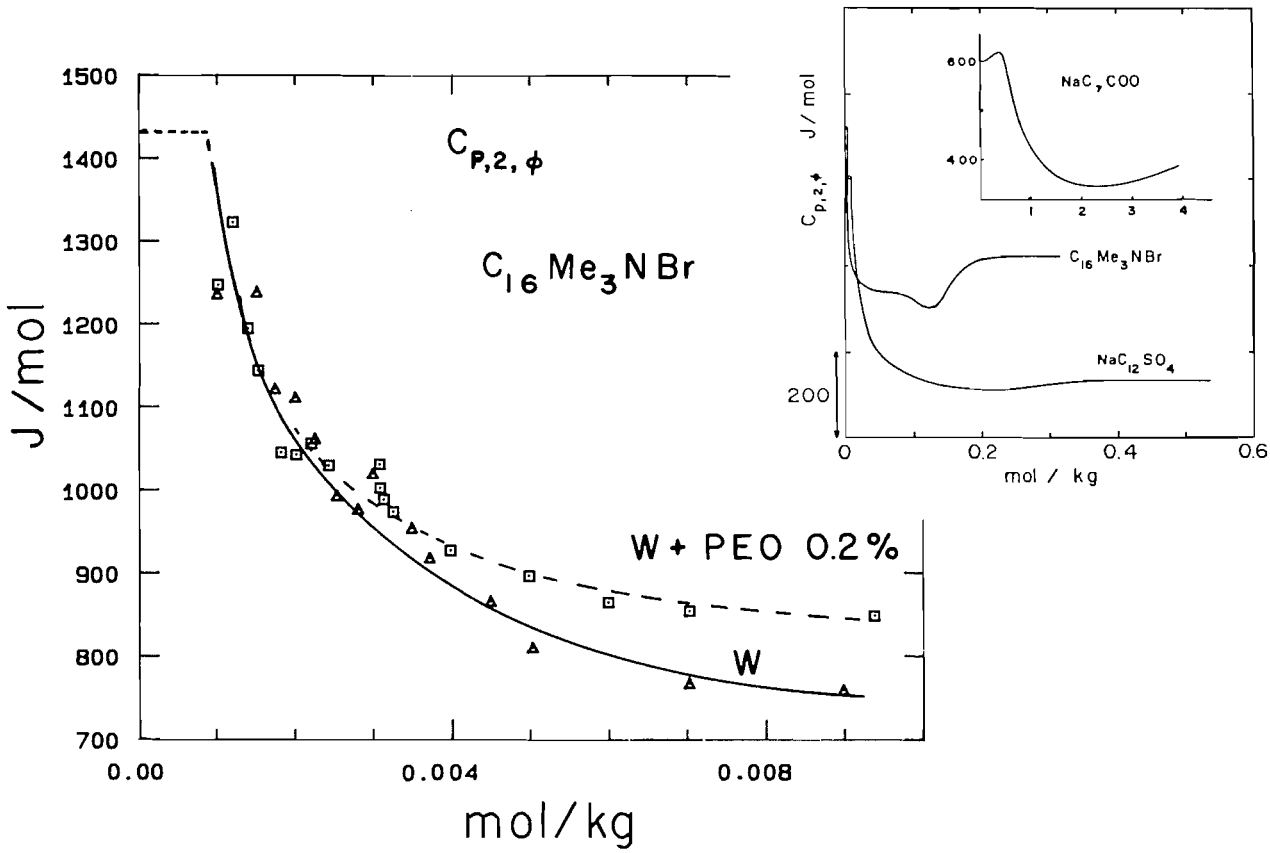

FIG. 5. Apparent molar heat capacities of cetyltrimethylammonium bromide in water and in 0.2% PEO. Insert from ref. 24.

The transfer volume in PEO solution returns to zero at high surfactant concentration. This is not the case for PVP, where negative transfer volumes are observed above the cmc. This effect increases with increasing PVP concentration.

In general, we conclude that the interactions are stronger with PVP than with PEO, as is clear in particular from the C_p data. This observation is supported by the lower critical binding concentration with PVP. In addition, the volume data at high surfactant concentration point at a micelle–polymer interaction for PVP but not for PEO. The negative sign of the transfer volume in this region would indicate lower hydrophobic interaction and may be related to the unusual molar volume of PVP itself.

The system $C_{16}(CH_3)_3NBr$(HTAB)–PEO

We have already seen that PVP and PEO do not shift the cmc of C_{10} and C_{12} cationic surfactants. In the case of a C_{16} alkyl chain length the cmc is too low to allow volume or heat capacity measurements. However, with this surfactant the region far above the cmc can be studied. We did not observe any change in the apparent molar volume of CTAB upon addition of PEO, although there is a small but significant effect on the heat capacity at surfactant concentrations above 0.003 mol kg^{-1} (Fig. 5). This effect was not observed for PVP. Note that there is considerable and unavoidable scatter in the data at the lowest concentrations. At higher concentrations, however, the data become much more accurate. Thus, we conclude that there is some interaction between PEO and CTAB micelles, an interaction which is not observed with PVP. Quirion and Desnoyers (24, 25) have shown that CTAB, like other surfactants such as sodium dodecylsulfate, undergoes a post-micellar transition at high concentration and that this transition is shifted to lower concentrations in the presence of additives such as alcohols. The increase in heat capacity of CTAB in the post-micellar region, in the presence of PEO, is most probably related to such a shift.

Conclusions

We have shown that thermodynamic measurements can be applied to the study of polymer–surfactant interactions in the same way as they have been applied to micellar systems. Direct apparent molar volume and molar heat capacity measurements give additional information to the more generally used binding measurements, and are particularly useful to show the effects of hydrophobic interactions. The binding of anionic alkylsulfate type surfactants by PVP and PEO can be demonstrated by this technique, and in general the results are in agreement with conclusions obtained from binding isotherms (2, 4, 5, 19, 21, 26). We did not observe any effects associated with binding or polymer–micelle interactions in systems containing C_{10} and C_{12} chain length cationic surfactants and PVP and PEO. Earlier negative results of direct binding studies[3] were attributed to differences in the micellar surface between alkylsulfate- and alkyltrimethylammonium surfactants (22, 23).

Received October 31, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

ROBERT L. BENOIT, DIANE LEFEBVRE, and MONIQUE FRÉCHETTE. Can. J. Chem. **65**, 996 (1987).

The ionization constants of the conjugate acids BH_n^{n+} of two bases widely used in synthesis, 1,8-bis(dimethylamino)naphthalene (PS), and 1,4-diazabicyclo[2.2.2]octane (DABCO), have been obtained in Me_2SO and water. The partition coefficients of both bases B and their heats of solution and protonation have also been determined. The basicity of PS is dramatically reduced when passing from water to Me_2SO while the basicity of DABCO remains unchanged, thus making DABCO the stronger base in Me_2SO. The solvent effect on the base strength is analyzed in terms of free energy and enthalpy of transfer for B and H^+, and for BH^+, from water to Me_2SO. The entropy-controlled much stronger solvation of PS in Me_2SO is in line with that of aromatic compounds while the increased solvation of DABCO in water is due to H-bonding of its two nitrogens. PSH^+, like H^+, is better solvated by Me_2SO while $DABCOH^+$ does not show a definite preference for one solvent. The calculated enthalpy of solution of gaseous PSH^+ is abnormally low when compared to that of $DABCOH^+$ and of related BH^+ ions, thus indicating that the proton of PSH^+, in a strong intramolecular H-bond, does not normally H-bond to the solvent. Our results suggest that the proton sponge acid–base system could be used as a convenient reference to determine the free energy and enthalpy of transfer of H^+ between solvents.

ROBERT L. BENOIT, DIANE LEFEBVRE et MONIQUE FRÉCHETTE. Can. J. Chem. **65**, 996 (1987).

Les constantes d'ionisation des acides conjugués BH_n^{n+} du bis(diméthylamino)-1,8 naphtalène (PS) et du diaza-1,4 bicyclo[2.2.2]octane (DABCO), deux bases largement utilisées en synthèse, ont été obtenues dans le Me_2SO et l'eau. Les constantes de partage des deux bases B et leurs chaleurs de solution et protonation ont aussi été déterminées. On note une diminution remarquable de la basicité du PS lorsque l'on passe de l'eau au Me_2SO, alors que la basicité du DABCO n'est pas affectée, de telle sorte que le DABCO devient la base la plus forte dans le Me_2SO. On analyse l'effet du solvant sur la force des bases à partir des énergies libres et enthalpies de transfert de B et H^+, et de BH^+, de l'eau au Me_2SO. La solvatation plus forte du PS dans le Me_2SO, controlée par un terme entropique, est analogue à celle des composés aromatiques alors que la solvatation accrue du DABCO dans l'eau est due à des liaisons-H avec les deux azotes. PSH^+, comme H^+, est mieux solvaté par le Me_2SO tandis que $DABCOH^+$ n'a pas de préférence nette pour l'un des solvants. L'enthalpie de solution calculée pour l'ion gazeux PSH^+ est anormalement basse si on la compare à celle du $DABCOH^+$ et d'ions BH^+ voisins, ceci indique que le proton de PSH^+, engagé dans une liaison-H intramoléculaire forte, ne forme pas de liaison-H normale avec le solvant. Ces résultats nous suggèrent d'utiliser le système acide–base du PS comme référence simple pour déterminer l'énergie libre et l'enthalpie de transfert de H^+ entre les solvants.

Introduction

In aqueous solution 1,8-bis(dimethylamino)naphthalene (proton sponge) shows an unusually high basicity for an aromatic amine (1, 2). Since it was first proposed by Alder *et al.*, this high basicity has generally been attributed to steric strain in the neutral base which is effectively relieved in the conjugate acid where the proton is intramolecularly H-bonded to the two nitrogen atoms (3). Proton sponge (denoted PS) is of interest not only for its high basicity but also for its weak *nitrogen* nucleophilicity due to steric hindrance resulting from the vicinity of the two bulky dimethylamino groups (1). In fact with strong electrophiles PS reacts preferably as a *carbon* nucleophile (4). The unusual rates of proton transfer between PS, and related compounds, and their conjugate acids have also attracted wide interest (5).

As a continuation of our comparative thermodynamic study of the protonation of nitrogen bases in water and Me_2SO (6) we recently examined the behaviour of a series of aliphatic α,ω-diamines in both solvents (7) and searched for possible evidence in solution of the intramolecular H-bonded monoprotonated form observed in the gas phase. During this work we looked briefly at two other diamines, PS and DABCO (1,4-diazabicyclo[2.2.2]octane), and also at related quinuclidine. While we found that the basicity of DABCO is little changed when passing from water to Me_2SO, the pK_a of PSH^+ shows a dramatic decrease of some 4.5 units in Me_2SO so that

PS

1,4-diazabicyclo[2.2.2]octane
DABCO

DABCO becomes a better base than PS in Me_2SO. Terrier and Hallé (8), during the course of recent preparative work, also observed the superior basicity of DABCO over PS in Me_2SO.

Because of the synthetic utility of PS and DABCO and the wide use of Me_2SO as reaction medium, we have further explored our preliminary findings and compared more fully the thermodynamics of protonation of PS and DABCO in water and Me_2SO. In addition, we evaluated the part played by solvent effects on PS and PSH^+ in modifying the intrinsic high basicity of PS and shed some light on the interactions between the intramolecular H-bonded proton in PSH^+ and both solvents.

Experimental

Materials

Proton sponge (Aldrich) was twice recrystallized in ethanol, washed with water, and dried under vacuum at room temperature. Purity of the compound as checked by titration with trifluoromethanesulfonic acid in Me_2SO was 101 ± 1%. DABCO (MCB) was purified by sublimation at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

75°C then dried under vacuum at room temperature and kept in a desiccator over P_4O_{10}. Its purity was 99 ± 1% as determined by HCl titration. Tetraethylammonium perchlorate (Eastman Kodak) was recrystallized in a 4:1 water–ethanol mixture and dried under vacuum at room temperature. NaCl (McArthur), trifluoromethanesulfonic acid (Aldrich) and H_2SO_4 (Baker) were used as received. HCl (0.1 *M*) and NaOH (0.1 *M*) were from BDH. Buffer solutions were prepared from reagent grade chemicals. Finally, Me_2SO (BDH, analytical reagent) and *n*-heptane (A & C American Chemicals), were used without further purification. Me_2SO-d_6 was from Cambridge Isotope Laboratories.

pK_a determinations

Potentiometric titrations of Me_2SO solutions of PS and DABCO (5×10^{-3} to 1×10^{-2} *M*) with standardized 0.1 *M* HCF_3SO_3 in Me_2SO were carried out at 25.0 ± 0.1°C as previously described (6). The solutions were made initially 0.100 *M* in NEt_4ClO_4 to keep the ionic strength constant.

A spectrophotometric procedure was used to determine the pK_a value for PSH^+ in water. The spectrum of PSH^+ (pH < 9.0) shows an absorption band with a maximum at 285 nm, two small shoulders at 275 and 295 nm, and negligible absorption above 335 nm. When the pH is increased this band decreases in intensity and a new one appears at longer wavelengths (λ_{max} = 335 nm). Absorbance measurements were made at 335 nm on PS solutions containing 10^{-1}–10^{-3} *M* NaOH and 0.11 *M* NaCl. Because of the slow rate of dissolution and low solubility of PS in water, the PS aqueous solutions (10^{-4}–10^{-5} *M*) were obtained by dilution of 10^{-2}–10^{-3} *M* solutions in Me_2SO. Preparation of PS solutions by neutralization of PSH^+ solutions with NaOH, or extraction of *n*-heptane solutions of PS with NaOH proved unsatisfactory. The absorbances were measured with a PMQII Zeiss spectrophotometer using 2 cm thermostated cells. The values of K_b, the basicity constant, and of the molar absorptivity ε of PS were obtained at 25°C from the absorbances at 335 nm by the graphical procedure used by Hibbert (2). This ε value, 6500 ± 200 M^{-1} cm^{-1}, was used to calculate K_b at other temperatures from additional measurements made at 5-deg intervals up to 55°C. The solutions were less stable at higher temperatures and the absorbances increased on standing.

Solubility and partition coefficient determinations

The solubility of PS in water is very low ($\sim 1 \times 10^{-5}$ *M*) and is difficult to determine directly. On the other hand, the solubility of PS in Me_2SO is high (~0.8 *M*), while that of DABCO is high in both water and Me_2SO (>2 *M*), so that the saturated solutions of the bases in both solvents may not behave ideally. Thus, in order to avoid the problems inherent in determining the activities of both PS and DABCO in their saturated solutions in water and Me_2SO, we determined the partition coefficient of PS and DABCO between water and Me_2SO using *n*-heptane as the common immiscible reference solvent.

First, the partition coefficient of PS between *n*-heptane and Me_2SO, $P_{h/s}$, was obtained by determining potentiometrically the concentration of PS in the Me_2SO phase after equilibration of three 50 mL samples of 2.2×10^{-2} *M* PS solution in *n*-heptane with 50 mL Me_2SO, and also of two 50 mL *n*-heptane with 50 mL 0.7–1.0 $\times 10^{-2}$ *M* PS in Me_2SO. The equilibrium concentration of PS in *n*-heptane was calculated by difference. Since it was not practical to determine directly $P_{h/w}$, the partition coefficient of PS between *n*-heptane and water, $P_{h/w}$ was obtained indirectly from experimental values of the distribution coefficient $D = (PS)_h/[(PS) + (PSH^+)]$ at several pH and the relation

$$[1] \quad \log D = \log P_{h/w} - pK_a + pH$$

which is valid for pH ≪ pK_a. Then, 50 mL of 3.3–0.12 $\times 10^{-3}$ *M* PS solutions in *n*-heptane were equilibrated with 50 mL of five buffer solutions (pH 4.80, 5.74, 6.29, 6.86, 6.99). The equilibrium PS concentration in *n*-heptane was determined by spectrophotometry at 327 nm with ε = 9020 and that of PS (i.e. PSH^+) in water was calculated by difference.

The determination of the partition coefficients of DABCO, $P_{h/s}$, and $P_{h/w}$ did not present any difficulty. First, 20 mL samples of 0.172 *M* DABCO solution in Me_2SO were equilibrated with 20 mL of *n*-heptane, and the Me_2SO phase was analyzed potentiometrically with standard HCl after flooding with water. The equilibrium DABCO concentration in *n*-heptane was found by difference. Second, 2 mL portions of 1.51 *M* DABCO solutions in water were equilibrated with 25 mL of *n*-heptane; then 20 mL of this *n*-heptane solution was analyzed for DABCO by equilibrating with 20 mL water and titrating the aqueous phase with standard acid.

Calorimetric measurements

The heats of solution of PS in Me_2SO, and of DABCO in water and in Me_2SO were measured at 25.0°C with a LKB Model 8725-2 isoperibol calorimeter as previously described (6), the amount of base dissolved being known from the weights of the glass ampoules. For each base, three to five separate determinations were made at different concentrations by dissolving 3–10 $\times 10^{-4}$ mole of base in 100 mL of solvent. The heats of neutralization of the solid bases were determined similarly using an excess of 0.1 *M* HCF_3SO_3 in Me_2SO or 0.1 *M* HCl in water. For DABCO the heat of neutralization for the first protonation was subsequently determined by dissolving a known excess of DABCO in 2.4–5.2 $\times 10^{-3}$ *M* HCF_3SO_3 in Me_2SO. Some difficulties were experienced in determining the heat of neutralization of PS in aqueous 0.1 *M* HCl because the PS particles dissolve slowly and have a tendency to float. In order to improve the accuracy, 0.35 *M* HCl and H_2SO_4 solutions were also used. The heat of solution of PS in water could only be determined indirectly from its heat of neutralization, and from its heat of protonation which was, in turn, obtained from the variation of pK_a with temperature.

Nuclear magnetic resonance measurements

The second protonation of PS was studied by ^{13}C nmr. Spectra of 0.3 *M* solutions of PS were recorded rapidly between 10–18 *M* H_2SO_4 because some decomposition takes place on standing. The quaternary carbons were easily singled out and other carbons were identified from literature data on aniline and dimethylaniline (9). The ^{13}C spectra were acquired at 28°C on a Bruker WP-80 spectrometer operating at 20.2 MHz. Data acquisition and Fourier transformation were performed with 8 K data point. ^{13}C chemical shifts were measured relative to external dioxane in D_2O and converted to the Me_4Si scale with $\delta_{Me_4Si} = \delta_{dioxane} + 67.40$ ppm. ^{13}C spectra in Me_2SO were also taken on 0.2 *M* PS solutions to which HCF_3SO_3 was added to obtain molar ratios of acid-to-base equal to 0, 0.25, 0.50, 1.00, and 2.00. Similar molar ratio experiments were carried out on 0.1 *M* PS solutions in Me_2SO-d_6 for the recording of ^1H spectra. A Bruker WH-90 spectrometer operating at 90.0 MHz was used and ^1H chemical shifts were determined using Me_4Si as internal reference. The protonation of DABCO was also studied by ^{13}C nmr using the molar ratio method, first by adding HCF_3SO_3 to a 0.2 *M* DABCO solution in Me_2SO, then by adding $HClO_4$ to 0.1 *M* DABCO in water.

Results

pK_a and free energies of transfer

The ionization constants K_a of the protonated bases PSH^+, $DABCOH^+$, and $DABCOH_2^{2+}$ in Me_2SO were obtained from the potentiometric neutralization data by using a program described previously (6). Our pK_a values for BH_n^{n+} are given in Table 1 together with the very accurate values of Paoletti *et al.* (10) for $DABCOH^+$ and $DABCOH_2^{2+}$ in water. No corrections were made for the effect of ionic strength, which would be small for such reactions.

The basicity constant K_b and molar absorptivity of PS in water at 25°C were determined from absorbance measurements in 10^{-3}–10^{-1} *M* NaOH by using the graphical procedure of Hibbert (2). The corresponding pK_a value in Table 1 was then deduced from $pK_b = 1.8 \pm 0.1$ and the dissociation constant of water at 0.11 ionic strength. The pK_a for PSH_2^{2+} was obtained from the ^{13}C nmr data in 10–18 *M* H_2SO_4 by using the excess acidity method and the program developed by Cox as previously described (11).

TABLE 1. Ionization constants K_a of BH_n^{n+} ions at 25°C

BH_n^{n+}	pK_a		ΔpK_a
	Me_2SO	H_2O	
PSH^+	7.47 ± 0.04	12.0 ± 0.1	−4.5
PSH_2^{2+}		−9.0 ± 0.2	
ϕNMe_2H^+ [a]	2.5	5.2	−2.7
Me_3NH^+ [b]	8.4	9.8	−1.4
Quinuclidine H^+ [c]	9.8	11.0	−1.2
$DABCOH^+$	8.93 ± 0.05	8.82 ± 0.01 [d]	+0.1
$DABCOH_2^{2+}$	2.97 ± 0.05	2.97 ± 0.01 [d]	0

The free energy of transfer ΔG_t^0 (hypothetical 1 *M* solution as standard state) from water to Me_2SO for both PS and DABCO was obtained from the partition coefficient $P_{s/w}$ calculated in turn from the partition coefficient between Me_2SO and *n*-heptane, $P_{h/s}$, and the partition coefficient, $P_{h/w}$, between water and *n*-heptane. For PS, we determined $P_{h/w}$ from the experimental relation between the distribution coefficient *D* and pH, $\log D = 6.8 \pm 0.1 + pH$ ($4.8 \leq pH \leq 7.0$). By comparison with eq. [1] and with $pK_a = 12.0 \pm 0.1$ we find $\log P_{h/w} = 5.2 \pm 0.2$. Since we obtained $P_{h/s} = 1.9 \pm 0.1$, we calculate $P_{s/w} = 10^{4.9 \pm 0.2}$ and $\Delta G_t^0(PS) = -28 \pm 1$ kJ mol^{-1}. For DABCO, we determined directly $P_{h/s} = 0.37 \pm 0.01$ and $P_{h/w} = 5.3 \pm 0.5 \times 10^{-4}$ so that $P_{s/w} = 10^{-2.82 \pm 0.05}$ and $\Delta G_t^0(DABCO) = +16.1 \pm 0.3$ kJ mol^{-1}.

The values of the free energies of transfer $\Delta G_t^0(BH^+)$ of the conjugate acids BH^+, from water to Me_2SO, are calculated by means of relation [2] derived from the thermodynamic cycle relating protonation processes in both solvents.

$$[2] \quad \Delta G_t^0(BH^+) = \Delta G_t^0(B) + \Delta G_t^0(H^+) + \Delta G_{ps}^0 - \Delta G_{pw}^0$$

where ΔG_{ps}^0 and ΔG_{pw}^0 are the free energies of protonation in both solvents calculated from the pK_a values in Table 1. The free energy of transfer of the proton, −19 kJ mol^{-1}, is based on an extrathermodynamic assumption (12).

The $\Delta G_t^0(BH^+)$ values are, respectively, −21 and −3 kJ mol^{-1} for PSH^+ and $DABCOH^+$; the errors are unknown, since they depend on the validity of the extrathermodynamic assumption. All of our free energies of transfer are listed in Table 2.

Protonation enthalpies and enthalpies of transfer

The plots of the heats of solution of DABCO in water and of both bases in Me_2SO and Me_2SO solutions of 0.1 *M* HCF_3SO_3 against the number of moles dissolved were linear and the least-squares slopes gave $\Delta H_s^0(B)$ or $\Delta H_w^0(B)$ [3] and $\Delta H_{ns}^0(B)$ or $\Delta H_{nw}^0(B)$ [4] according to

$$[3] \quad B(c) = B(s \text{ or } w)$$

$$[4] \quad B(c) + H^+(s \text{ or } w) = BH^+(s \text{ or } w)$$

$$[5] \quad DABCO(c) + 2H^+(s) = DABCOH_2^{2+}(s)$$

$$[6] \quad B(s \text{ or } w) + H^+(s \text{ or } w) = BH^+(s \text{ or } w)$$

ΔH_{ps}^0, the enthalpy for the first protonation of DABCO (eq. [6]) in Me_2SO was obtained by subtracting from Q_{ns}, the heat change found for dissolving n_b moles of DABCO in n_a moles of acid ($n_b \gg n_a$), $Q_s = n_b \times \Delta H_s^0(B)$, and by taking $\Delta H_{ps}^0 = (Q_{ns} - Q_s)/n_a$. The heat of neutralization of PS (reaction [4]) in water, ΔH_{nw}^0, is an average of values determined in 0.1–0.35 *M* HCl and H_2SO_4. The pK_b values for PS were determined at 5-deg intervals between 25 and 55°C from absorbance measurements at 335 nm on three series of solutions with 2.5, 5.0, and 10.0×10^{-3} *M* NaOH. The pK_b values were plotted against $1/T$ to give by a least-squares procedure the associated enthalpy value, -11 ± 4 kJ mol^{-1}, which, in turn, was combined with the enthalpy for the dissociation of water at 25°C and 0.11 ionic strength to give the enthalpy of protonation $\Delta H_{pw}^0 = -65 \pm 4$ kJ mol^{-1} according to [6].

Then ΔH_w^0 for PS was obtained from

$$[7] \quad \Delta H_w^0(B) = \Delta H_{nw}^0(B) - \Delta H_{pw}^0(B)$$

A similar equation was used to calculate this time ΔH_{ps}^0 for PS and DABCO in Me_2SO. The ΔH_{pw}^0 values used for DABCO were from Paoletti *et al.* (10). The values of the enthalpy of solution and protonation of PS and DABCO are listed in Table 3.

The values of the enthalpies of transfer of PS and DABCO, $\Delta H_t^0(B)$, were calculated from the enthalpies of solution of both bases in water and Me_2SO. $\Delta H_t^0(BH^+)$ was obtained from eq. [8] for $DABCOH^+$ and from eq. [9] for PSH^+ taking $\Delta H_t^0(H^+) = -25.5$ kJ mol^{-1} (12).

$$[8] \quad \Delta H_t^0(BH^+) = \Delta H_t^0(B) + \Delta H_t^0(H^+) + \Delta H_{ps}^0 - \Delta H_{pw}^0$$

$$[9] \quad \Delta H_t^0(BH^+) = \Delta H_t^0(H^+) + \Delta H_{ns}^0 - \Delta H_{nw}^0$$

The enthalpies of transfer are given in Table 4.

Enthalpies of transfer from the gas phase to Me_2SO and water

The enthalpies of protonation of both PS and DABCO in the gas phase ΔH_{pg}^0 according to

$$[10] \quad B(g) + H^+(g) = BH^+(g)$$

have been determined by several groups of workers (13–15). The values of ΔH_{pg}^0, i.e. minus the proton affinity, given in Table 3, are averages and based on PA = 207 kcal mol^{-1} for NH_3, 224 kcal mol^{-1} for pyridine, and 229 kcal mol^{-1} for trimethylamine. Thus, the ΔH_{pg}^0 values taken for PS and DABCO are respectively, 1030 and 970 kJ mol^{-1}, these values being rounded to the nearest 5 kJ mol^{-1}.

We can now obtain the valuable enthalpies of transfer of BH^+ ions from the gas phase to water, $\Delta H_{gw}^0(BH^+)$, and to Me_2SO, $\Delta H_{gs}^0(BH^+)$, by using relations derived from the thermodynamic cycles relating protonation processes in the gas phase and Me_2SO or water. For example, from eqs. [4] and [10], we derive

$$[11] \quad \Delta H_{gs}^0(BH^+) = \Delta H_{gc}^0(B) + \Delta H_{gs}^0(H^+) + \Delta H_{ns}^0 - \Delta H_{pg}^0$$

$\Delta H_{gs}^0(H^+)$ is taken as −1155 kJ mol^{-1} which is based on $\Delta H_t^0(H^+) = -25$ kJ mol^{-1} and $\Delta H_{gw}^0(H^+) = -1130$ kJ mol^{-1} (−270 kcal mol^{-1}) (12). ΔH_{gc}^0 is $-\Delta H_{sub}^0$, the enthalpy of sublimation. ΔH_{sub}^0 is calculated for DABCO as +65 kJ mol^{-1} from a literature value at 65°C (16) corrected to 25°C (17). ΔH_{sub}^0 for PS was estimated as follows. The enthalpy of fusion of PS ($t_f = 48$°C) was estimated as +20 kJ mol^{-1}, from a heat of solution in Me_2SO, +25 kJ mol^{-1}, minus a small enthalpy of solution of a non-associated liquid in Me_2SO taken as +5 kJ mol^{-1} (18). The enthalpy of vaporization ΔH_v^0 of liquid PS at 25°C, +70 kJ mol^{-1}, was obtained from a correlation line between ΔH_v^0 and normal boiling points t_b for tertiary amines (19) and an estimated $t_b \sim 320$°C. Finally, ΔH_{sub}^0 is obtained as +90 kJ mol^{-1} which is interestingly near the value for

TABLE 5. ^{13}C shift values[a] (ppm) of PS, PSH$^+$, and PSH_2^{2+} in Me_2SO and water

	C-1	C-2	C-3	C-4	C-9	C-10	CH_3
PS (Me_2SO)	151.3	113.8	126.5	122.5	120.9	138.4	45.3
PSH$^+$ (Me_2SO)	145.6	122.8	128.0	130.0	120.0	135.9	46.9
PSH$^+$ (H_2O)	144.3	121.9	127.8	130.0	118.9	135.8	46.6
PSH_2^{2+} (H_2O)	135.4	124.4	128.2	135.4	116.9	138.3	51.5

[a]Standard deviation usually better than 0.1 ppm.

1,8-dimethylnaphthalene, +83 kJ mol^{-1} (20). Although our ΔH_{sub}^0 value is obviously a crude estimate, the error is not unlike that on PA values, 5–10 kJ mol^{-1}. Our calculated enthalpies of transfer from the gas phase are listed in Table 4.

Nuclear magnetic resonance data

The ^{13}C limit chemical shift values obtained for PSH$^+$ and PSH_2^{2+} from our data in 10–18 *M* H_2SO_4 are summarized in Table 5. The ^{13}C shift values for PS and PSH$^+$ in Me_2SO are also given. The spectra corresponding to Me_2SO solutions containing molar ratios of acid to PS between 0 and 1 showed signals for both PS and PSH$^+$. Apparently the exchange between the nonprotonated and protonated forms is too slow to be observed on the nmr time scale at room temperature. ^{1}H signals for both PS and PSH$^+$ were also observed in solutions with molar ratios of acid to PS between 0 and 1 and the proton of PSH$^+$ appeared at unusually low field, 18.36 ppm. Further addition of acid did not cause shift of the PSH$^+$ proton, so that the exchange between PSH$^+$ and protonated Me_2SO (HCF_3SO_3 is a strong acid in Me_2SO) is also slow. The PSH$^+$ spectrum shows a doublet signal for the methyl protons. The splitting (J = 2.4 Hz) is due to coupling with the PSH$^+$ proton.

In contrast, the study of the protonation of DABCO by ^{13}C nmr, using the molar ratio method, indicated exchange between DABCO and both protonated species both in water and in Me_2SO. The plots of the ^{13}C shifts against the molar ratio of acid-to-base consisted of three straight lines whose intersections corresponded to molar ratios 1.0 and 2.0. The C-1 shift values for DABCO, DABCOH$^+$, and $DABCOH_2^{2+}$, deduced from the graphs, are respectively 48.2, 45.3, 44.1 ppm in Me_2SO and 46.0, 44.9, and 44.4 ppm in water.

Discussion

Ionization constants and free energies of transfer

We will consider the ionization constants K_a of PSH$^+$ and DABCOH$^+$ first, since they are our initial raw data. We will then discuss the solvent effect on K_a in terms of free energy of transfer of B and BH$^+$.

The data in Table 1 show that on passing from water to Me_2SO the pK_a change is −4.5 for PSH$^+$ and +0.1 for DABCOH$^+$, thus confirming our preliminary findings that while in water PS is a much better base than DABCO, the reverse holds true in Me_2SO. Our previously determined ΔpK_a for dimethylaniline (−2.7) and for trimethylamine (−1.4) (18) listed in Table 1 for comparison, suggest that, at least in part, the pK_a changes for PSH$^+$ and DABCOH$^+$ in Me_2SO are in line with what is expected for related amines in the aromatic and aliphatic series. However, PS and DABCO must have some additional specific structural factors which would account for their ΔpK_a being larger than for the simple parent amines considered. For DABCO at least, it is clear that its diamine nature plays a part in explaining its ΔpK_a = +0.1 since its monoamine analog, quinuclidine, has a ΔpK_a = −1.2 (Table 1) very close to that of Me_3N, −1.4.

The very weak basicity of PSH^+ is noteworthy with a corresponding pK_a value of -9.0 ± 0.2 (half protonation in 15.2 *M* H_2SO_4, $m^* = 1.12 \pm 0.04$ (11)). The extraordinary stability of PSH^+ (1) with respect to protonation and deprotonation as shown by both its pK_a values, is totally different from what is observed both for $DABCOH^+$ (Table 1) and for BH^+ ions in the α,ω-diamines series where there is no "dicoordination" of the proton (7).

Turning now to the free energies of transfer of B and BH^+ in Table 2, we note first the highly contrasted ΔG_t^0 values for both bases, PS and DABCO. The high and negative $\Delta G_t^0 = -28$ kJ mol^{-1} for PS is typical of aromatics behaviour with their very low solubility in water and high solubility in Me_2SO. The situation is completely reversed for DABCO with $\Delta G_t^0 = +16$ kJ mol^{-1}, indicating that DABCO is more strongly solvated by water through H-bonding to both nitrogens. Looking next at the values of $\Delta G_t^0(BH^+)$, we find that PSH^+ exhibits a strong preference for Me_2SO while $DABCOH^+$ is only slightly better solvated by Me_2SO. To conclude this free energy analysis of the solvent effect on the base strength, the much reduced basicity of PS when passing from water to Me_2SO comes from three nearly equal contributions of some 23 kJ mol^{-1}, those on PS and H^+ being opposed by that on PSH^+. For DABCO, the absence of solvent effect on its basicity is due to nearly equal and opposite effects on the neutral base and H^+.

Enthalpies of transfer

Our values of the enthalpies of transfer ΔH_t^0 of PS, DABCO, PSH^+, and $DABCOH^+$ from water to Me_2SO (Table 4) present interesting results when compared with previous data (18, 21) for aliphatic and aromatic amines. First, the small ΔH_t^0 for PS is typical of what is observed for aromatics[1] (for C_6H_6, $\Delta H_t^0 = -0.3$ kJ mol^{-1}) so that, given the high negative value of ΔG_t^0, there must be a very large compensating positive entropy of transfer, as is common to aromatics, and which reflects the peculiarities of water as a solvent. For DABCO, ΔH_t^0 is large and positive indicating much stronger interactions with water, as was already clear with ΔG_t^0. Again the ΔH_t^0 value for DABCO is near that for the aliphatic amine Me_3N; the ΔS_t^0 values for both bases are also positive (21) and almost identical. The negative ΔH_t^0 values for all the BH^+ ions which are listed in Table 4 indicate some 15–20 kJ mol^{-1} stabilization in Me_2SO though much less for $DABCOH^+$.

Finally, if we turn our attention to the enthalpies of transfer of a series of BH^+ ions from the gas phase to Me_2SO in Table 4, we draw some highly valuable conclusions. We note first that the values of $\Delta H_{gs}^0(BH^+)$ for very different nitrogen bases, B = DABCO, Me_3N, Py, and ϕNMe_2 are all within -280 ± 5 kJ mol^{-1} while $\Delta H_{gs}^0(PSH^+)$ is some 40 kJ mol^{-1} less exothermic. We previously found (18, 21) that the exothermic heat of solution of substituted ammonium ions decreases with the number of N—H protons which can H-bond to Me_2SO, the size of the substituent being of lesser importance. The average decrease of the heat of solution of the gaseous ions per H-bond was about 35 kJ mol^{-1}. Then it is clear that while $DABCOH^+$, Me_3NH^+, PyH^+, and ϕNMe_2H^+ all form one H-bond with Me_2SO, PSH^+ does not normally H-bond to the solvent. If the solvation of the PSH^+ cation is non-specific, its heat of solution $\Delta H_{gs}^0 = -239$ kJ mol^{-1} should be near that of ions such as the tetraalkylammonium. Unfortunately, these latter values are not well established because they depend on some assumptions for the calculation of lattice enthalpies of related salts (22). Our comparisons of enthalpies of solution of BH^+ ions in Me_2SO (Table 4) could have been made with water as the solvent. The values of $\Delta H_{gs}^0(BH^+)$ are easily calculated from our data in Table 4 with $\Delta H_{gw}^0(BH^+) = \Delta H_{gs}^0(BH^+) - \Delta H_t^0(BH^+)$. For B = Me_3N, Py, and ϕNMe_2, we obtain an enthalpy of solution in water of -262 kJ mol^{-1} while for DABCO the value is more exothermic, -280 kJ mol^{-1}, largely because of H-bonding of the second nitrogen of this diamine to water (there was no such H-bonding with Me_2SO). For B = PS, $\Delta H_{gw}^0(PSH^+) = -224$ kJ mol^{-1} which is much less exothermic and is close to the rough estimate given by Taft (-210 kJ mol^{-1}) (23) for "limiting physical ion–dipole and ion – induced dipole solvation of univalent cations which do not involve specific cation–molecule chemical bonding". We, therefore, conclude that the proton of PSH^+ is involved in a strong intramolecular H-bond which precludes H-bonding to water, or even to more basic Me_2SO as we have seen. Further support of this point comes from the remarkable correlation of Taft *et al.* (23) which suggests that the solvation behaviour of PSH^+ in water is more like that of resonance-stabilized carbonium ions.

The exceptionally slow rate of proton transfer from PSH^+ to OH^- also implies that there is an unusually strong intramolecular H-bond in PSH^+ (2). The lack of exchange on the nmr time scale between PS, PSH^+, and acids in Me_2SO and other solvents (1, 24) is as well indicative of unusual properties of the proton in PSH^+ and the ^1H nmr spectra of PSH^+ in Me_2SO is compatible with the presence of a strong H-bond with H^+ in a bridge between the nitrogen atoms.

The proton sponge acid–base system as a reference

There is a most interesting consequence of the apparent lack of specific chemical interactions between PSH^+ and Me_2SO or water, and presumably between PSH^+ and other solvents. We propose to use the PSH^+/PS acid–base system as a reference system to obtain values of $\Delta G_t^0(H^+)$, the free energy of transfer of H^+ between solvents, and hence obtain values of ΔG_t^0 for other cations and anions. Equation [2] can be rearranged to give

$$[12] \quad \Delta G_t^0(H^+) = \Delta G_{p1}^0 - \Delta G_{p2}^0 + \Delta G_t^0(PSH^+) - \Delta G_t^0(PS)$$

where t stands for transfer from solvent 1 to solvent 2 and ΔG_{p1}^0 and ΔG_{p2}^0 are the free energies of protonation in solvents 1 and 2, respectively. Assuming

$$[13] \quad \Delta G_t^0(PSH^+) = \Delta G_t^0(PS)$$

we obtain

$$[14] \quad \Delta G_t^0(H^+) = \Delta G_{p1}^0 - \Delta G_{p2}^0$$

For example, with water and Me_2SO we calculate from our data in Table 1 $\Delta G_t^0(H^+) = -26$ kJ mol^{-1}. The extrathermodynamic assumption corresponding to eq. [13] is equivalent to supposing first that PS is an excellent neutral analog[2] of PSH^+ and second that the electrostatic contribution $\Delta G_t^{elec}(PSH^+)$ is negligible (12). The first assumption is the direct consequence of our finding that PSH^+ does not give any specific interaction with the solvent, and the second assumption is reasonable as long as the solvent dielectric constant is not too low. Although more data with other solvents are obviously needed to assess completely the validity of our proposed extrathermodynamic assumption, it is interesting to note that the corresponding $\Delta G_t^0(H^+)$ value for the transfer from water to Me_2SO, -26 kJ mol^{-1}, is in acceptable agreement with the $\Delta G_t^0(H^+)$

[1]For naphthalene, $\Delta H_t^0 = -11$ kJ mol^{-1}.

[2]Interactions between nitrogens of PS and water, or other H-bond donor solvents, are likely to be minimal.

value -19 kJ mol^{-1} deduced from the widely used TATB assumption, i.e. $\Delta G_t^0(As\phi_4^+) = \Delta G_t^0(B\phi_4^-)$, considering that the ferrocene assumption used by electrochemists gives a -32 kJ mol^{-1} value (12) and the Hammett type hypothesis $\Delta G_t^0(BH^+) = \Delta G_t^0(B)$ where B is a Hammett base) leads to -9 kJ mol^{-1} (12). One advantage of our proposed assumption is its directness: we only need the pK_a values of the PSH^+/PS system in both solvents to calculate $\Delta G_t^0(H^+)$ while the other assumptions usually require a large number of experimental determinations which lead to an increased margin of error. It is clear that the PSH^+/PS system can also be used as a reference to establish an enthalpy scale for the transfer of H^+ between solvents. By assuming

[15] $\Delta H_t^0(PS) = \Delta H_t^0(PSH^+)$

we calculate for $\Delta H_t^0(H^+)$ (eq. [8]) -16 kJ mol^{-1} for the water–Me_2SO transfer, a value which also is in reasonable agreement with -25 kJ mol^{-1} deduced from the TATB assumption. Here, again, our extrathermodynamic assumption leads to more directly accessible values of $\Delta H_t^0(H^+)$ than does the TATB assumption.

The significance of the variability in analytical results for lead, copper, nickel, and zinc in street dust

JACK E. FERGUSSON
Department of Chemistry, University of Canterbury, Christchurch, New Zealand

Received October 17, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

JACK E. FERGUSSON. Can. J. Chem. **65**, 1002 (1987).

Street dust has frequently been used as a material for the monitoring of trace element pollution, and in particular for the metal lead. The value of the analytical data, as a measure of pollution, depends on understanding the spatial, temporal, and bulk characteristics of the dust. The influence of each of these factors on the variability of trace element analytical results has been investigated in order to determine whether or not the variations reflect differing pollution levels. The concentrations of the four metals Pb, Cu, Ni, and Zn have been measured in street dust collected from a variety of situations. Coefficients of variation >20% (particularly for lead) for a series of samples have been taken as a guide to real differences in lead levels between samples in the series. An important factor in the variability of heavy metal levels in dust is the distribution of particle size within a sample. Concentrations of the trace metals fall and then rise as the particle size decreases from 1000 μm down to silt sized particles.

JACK E. FERGUSSON. Can. J. Chem. **65**, 1002 (1987).

On utilise fréquemment la poussière des rues comme matériel permettant d'évaluer la pollution par les éléments à l'état de traces et, en particulier, par le plomb métallique. La valeur des données analytiques, comme mesure de la pollution, dépend de la compréhension des caractéristiques spaciales, temporales et globales de la poussière. Afin de déterminer si les variations sont réellement un reflet de différents niveaux de pollution, on a étudié l'influence de chacun de ces facteurs sur la variabilité des résultats analytiques des éléments à l'état de traces. On a mesuré les concentrations de quatre métaux (Pb, Cu, Ni et Zn) dans des échantillons de poussières recueillis dans diverses situations. On considère que les coefficients de variation >20%, observés pour une série d'échantillons et particulièrement pour le plomb, révélent la présence de différences dans les niveaux de plomb contenus dans divers échantillons de la série. Un facteur important dans la variabilité des niveaux des métaux lourds dans la poussière est la distribution des grosseurs des particules à l'intérieur d'un échantillon. Les concentrations des métaux présents à l'état de trace commencent par diminuer puis augmentent quand la grosseur des particules passe de 1000 μm à des particules de la grosseur des boues.

[Traduit par la revue]

Introduction

Street dust has frequently been used as a material for the monitoring of heavy metal pollution, and especially for the metal lead. A cursory glance at reported results indicates that a wide range of concentrations have been found for different elements in the dust (1–4). The question has been raised (5) as to whether the analytical results are reliable indicators of pollution, because of the variability of the levels over short distances and periods of time, and problems of sampling and analysis.

There are a number of factors that can influence the level of a trace element in street dust.

1. The method of taking the sample is important, and a number of these are reported. Samples are taken from pavements or gutters, with brushes or scoops or by suction, and from areas of different sizes such as 1 m^2 or 5 m^2 (4, 6–11).

2. The precision and accuracy of the analysis establishes the lower limit of variability between samples (12). The limit is the number, below which the variability must be attributed to analytical variation and not environmental or pollution factors.

3. The variability in the results will be influenced by spatial considerations, such as the distance of samples from each other, and the nature of the surrounding environment (6, 11, 13).

4. A temporal variability in trace element levels can be expected because of the effect of seasonal factors, such as wind and rain. In addition street cleaning and the duration of exposure is important (7, 11, 12).

5. The size of the particles in street dust vary from large (>1 mm) down to clay particle size. Owing to temporal changes and different sources of the dust (1, 11, 14, 15), some fractionation of the particles can occur influencing the variability of trace metal levels (1, 2).

6. Contamination of the street dust samples during collection and analysis may also influence the variability of the levels found. This is probably less of a problem when the levels of the trace elements are relatively high.

The analytical, spatial, source, temporal, and particle size aspects of street dust are considered in this present study in order to arrive at an estimate as to when variability reflects a real difference in trace element levels. For this purpose the coefficient of variation (expressed as a percent),

$$\text{cv} = (\text{standard deviation}/\text{mean}) \times 100\%$$

will be used as a measure of variability. The cv allows comparisons to be made irrespective of the level of concentration of an element in the dust, and it is also possible to compare different elements as it is independent of units. The elements Pb, Cu, Ni, and Zn are investigated in some samples, and Pb in all samples.

Experimental

Sampling

Street dust was sampled using a 3–5 cm brush and a plastic scoop. Each sample at each site was collected within a square metre, though not all the material within the 1 m^2 was taken. The samples were taken from pavements and gutters, being careful not to include soil, e.g. samples were not taken close to a grass berm. Care was taken not to discriminate on the basis of particle size when sampling. The samples were then transferred to clean plastic bags.

Treatment of samples

Each sample was oven dried at 110–120°C for 6–8 h, or at 60°C

[d]99% confidence limits.

overnight. Samples were then sieved through 1 mm or 500 μm or 250 μm sieves as required. Around 1 g samples were digested for 30 min in 20 mL 4 *M* AR HNO_3 and then filtered through acid washed Whatman 40 or 540 filter papers. A few samples were re-digested a further time. In addition some samples were treated with a mixture of AR HF (7 mL) and AR $HClO_4$ (0.7 mL) in platinum crucibles after first igniting the dust in the crucibles to red-heat. The acid mixture was heated to 200–230°C until fuming had ceased (i.e. all the $HClO_4$ had gone) and the residue taken up in 4 *M* AR HNO_3 and filtered as before.

Atomic absorption analysis

The elements Pb, Cu, Ni, and Zn were determined using flame AAS (Varian Techtron AA1475) at wavelengths Pb, 217.0 nm; Cu, 324.7 nm; Ni, 352.4 nm; and Zn, 213.9 nm. Background correction was used for lead and zinc. Multielement standards were prepared in 0.4 *M* AR HNO_3.

Description of samples

Reference materials

No street dust reference material was availabe. An IAEA sediment sample SD-N-1/2 (16), recently used in an interlaboratory study, has been used as a primary reference material. The accepted levels are (overall mean, range of accepted laboratory means): Pb, 120, 93–154; Cu, 75.9, 53.4–92.0; Ni, 30.6, 21.0–45.0; Zn, 434, 342–549 $\mu g\ g^{-1}$. Our analytical results are given in Table 1. Internal reference samples of street dust were prepared by grinding a composite sample to a fine powder in a tungsten carbide mill. A soil sample was treated similarly. The analytical results for Pb, Cu, Ni, and Zn on these materials are given in Table 1.

Street dust samples

A number of street dust samples were collected at various times.

(*a*) A set of 10 samples were collected at the same time. The ten samples were taken 0.5 m apart over a length of 5 m. Two such sets were collected, one from the pavement and one from the gutter.

(*b*) Samples were taken from 20 sites around an intersection involving three T junctions, and controlled by traffic signals. Samples 1–14 were taken along the main thoroughfare, and samples 15–20 were taken from the side streets, two from each street. The 20 sites were sampled at monthly intervals for eight months.

(*c*) Street dust samples were taken from various sites around the city, corresponding to industrial, residential, commercial, and heavy-traffic carrying areas. Samples were also collected from different cities.

(*d*) Street dust samples after drying were fractionated into a range of sizes, being careful not to alter the size of the particles by the sieving. The nylon sieve sizes (measured under a calibrated microscope) were (mean ± standard deviation): 963 ± 38, 564 ± 14, 213 ± 14, 165 ± 13, 111 ± 11, 54 ± 7, 33 ± 8 μm. A study of the fraction <33 μm under the calibrated microscope, indicated that most of the particles were in the 10–20 μm range. Some samples were also separated on the basis of density, using tetrabromoethane (density = 2.67 $g\ mL^{-1}$).

Results and discussion

Reference materials

The results of the analysis of the IAEA material and internal reference materials are given in Table 1. The measurements were done on samples either at different times over a 3 to 4 year period, whenever the material was used as a control in a batch of analyses, or prepared and analysed on the same day.

For the IAEA standard the coefficient of variation, cv, is <10% for the four metals (<6% for Pb, Cu, and Zn), and except for Ni the cv's for the internal reference materials are (9% ≪ 6% for Pb and Zn).

A second extraction of the samples with HNO_3 removed very little more of the metals into solution. The mean and (standard deviation) for six samples indicate that of the extractable metal

ions 99% (0.9) Pb, 99% (0.5) Cu, 97% (2.1) Ni, 99% (2.3) Zn (i.e. cv's < 2%) are removed by the first extraction. This does not mean that all the metal in the dust has been removed as a $HF/HClO_4$ digestion indicates that around 98% Pb, 89% Cu, 86% Ni, and 95% Zn is obtained by the nitric acid digestions. Therefore it appears that little of the variability in the analytical results arises from inconsistent extractions, particularly for hot, strong acid extractions.

A coefficient of variation < 10% may therefore be considered as encompassing experimental and extraction errors in analysis, and any inhomogeneity in the sample.

Spatial effect

Two sets of ten samples of dust, each set taken from a 5 m spread and samples 0.5 m apart have mean lead levels (in $\mu g\ g^{-1}$) of 2280, 3430, standard deviations 320, 270, ranges 1830–2680, 2800–3800, and coefficient of variation 14%, 7.9%, respectively. The results are similar to those reported by Day (12). The cv's calculated from his data are 14% and 5.8%. The variability is relatively low, and in two of the four cases close to the analytical variability. This suggests that the level of lead in a spot sample taken from the sites are reasonably representative of the level in the material at the site (over a 5 m distance). These results indicate that for lead a total variability of 20%, as measured by the coefficient of variability, includes the analytical and sample variability for a particular site.

The mean, standard deviation, and cv for 20 sampling sites around an intersection involving three T junctions are given in Table 2, one sample per month for eight months. The data for the first five months are given in the columns labelled A. During that time the weather conditions, in particular rainfall, were relatively uniform. It may be seen from the data that the cv's for lead at each site range from 4.7% to 43% with 16 of the sites having a cv < 20%. For Cu, Ni, and Zn the number of sites with cv < 20% are 13, 18, and 13, respectively. The results for Pb and Ni suggest a reasonable constancy in their levels for most sites over the five months, and a somewhat lesser constancy for Cu and Zn.

Source of trace elements

From previous studies of the sources of trace elements in dust, soil appears to be the major contributor, around 75–90% (1, 14, 17). Because of the high contribution of soil to street dust it could be expected that the variability of the levels of elements originating primarily from the soil is less than for pollution-type elements. This is found to be the situation. For the soil-based elements Mn, Ti, Al, Ce, La, and Sm, the cv range for 11 samples taken from five cities (1) is 22–54%, and for 12 samples from one city (17) 11–24%. For the three pollution based elements, Pb, Cu, and Zn, the cv ranges are 71–107% and 66–74%, respectively.

TABLE 3. Size distribution of particles in street dust

Size range μm	Mean[a] %	Standard deviation	cv%	Range
963–563	17.1	10.5	62	2.6–30.7
563–213	29.1	9.2	32	11.1–43.9
213–165	13.9	5.1	36	7.2–25.4
165–111	14.4	8.1	56	5.0–36.5
111–54	13.1	4.5	34	6.5–19.3
54–33	6.1	3.9	63	1.7–16.7
<33	6.2	4.6	74	0.5–13.6

[a]12 samples, mass of each sample: 702.4, 332.7, 172.4, 221.3, 203.9, 260.1, 258.7, 409.7, 211.2, 1227.8, 226.8, 65.7 g. Total mass for each size fraction: 590.7, 1099.6, 711.5, 591.1, 620.7, 366.2, 313.0 g.

Temporal effect

The data in columns B in Table 2 are the means, standard deviations, and cv's for the same 20 sites over eight months (the original 5 months + the next three). Severe flooding occurred between the fifth and sixth month sampling periods. A significant reduction occurred in the levels of some of the heavy metals, especially lead. The cv's < 20% for Pb, Cu, Ni, and Zn in this case are 5, 13, 18, and 10, respectively. There is a clear temporal effect for lead due to the rainfall (3, 7), and little overall change for the other metals.

Size effect

Street dust consists of a wide range of particle sizes, and the % size distribution within samples is not constant. Over 12 sites covering industrial, residential, heavy-traffic and commercial areas, the % mass distribution of dust in different size ranges are listed in Table 3. There is a large variability for each size fraction. In addition the amount of sample >963 μm is as variable. The different distributions would be of little consequence if the concentrations of the heavy metals did

[a]Mean (W) = weighted mean, mean (S) = straight concentration mean, sd = standard deviation for mean (S), cv = coefficient of variation.

not vary with size, but this is not the case, as indicated by representative data for three of the sites given in Table 4. Each element displays the same size/concentration profile, i.e. a minimum in concentration around the 213–165 μm range. The profiles are of the same general form for the other nine samples, but less so for the samples taken from industrial areas. The form of the profile does not relate simply to the surface area of the particles.

The straight concentration means are greater than the weighted means, but surprisingly close. However, the cv's for the means generally show a wide variability. Therefore significant variability may occur between samples as a result of differences in the distribution of sizes within the samples. This could well be one of the factors which influences the actual level obtained (1, 2, 4, 7, 11, 15). Sampling methods, street cleaning, and rain and wind could all produce some fractionation of the dust in the street. The fall in lead levels after a flooding event suggests that some fractionation has occurred, removing a greater proportion of either the large size particles or smaller size particles, or both. The size fraction <33 μm was mainly made up of particles 10–20 μm. It appears that the finest particles in street dust (i.e. clay size) are not sampled by the method used, and probably by most methods reported in the literature.

The density of the dust particles may influence natural and man-made fractionation processes. From the twelve city-wide sites dense material (>2.67 g mL^{-1}) decreased regularly from 12% to 5% of the total sample, as the particle size decreased, whereas the light material (<2.67 g mL^{-1}) increased from 83% to 95%. There is proportionately more light material in the smaller-sized particles, and it could be that these particles are the ones preferentially lost during rain storms, reducing the lead content of the remaining dust. It is known that the lead levels in the dense dust fraction are significantly greater than in the light material (2, 7). This contributes to the higher levels of lead in the larger particles.

Concluding remarks

It appears that the factors that may influence the variability of levels of trace elements in street dust are spatial, temporal, source, particle size, and particle density. For any sample all these factors may contribute to the actual trace element levels, and their variability. However, provided the particle size is taken into account, and there is knowledge of the temporal and sampling factors that may have influenced the sample, and for a cv > 20% there is reason to be confident in the reliability of the trace element concentrations as a measure of pollution levels. Of the four metals studied this conclusion is only clearly applicable to lead, a widely dispersed pollution element.

Received August 27, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

MIHIR K. BISWAS, ARNOLD JARCZEWSKI, and KENNETH T. LEFFEK. Can. J. Chem. **65**, 1007 (1987).

The reaction of tetramethylguanidine (TMG) with trinitrocumene (TNC) and trinitroethylbenzene (TNEB) in dimethylformamide solvent has been studied with respect to products and kinetics. For TNC only σ-complex formation with the benzene ring was observed, for which the equilibrium constant, rate constants, and activation parameters were measured. For TNEB, both σ-complex formation and proton transfer from the α-carbon atom of the ethyl group were observed. The equilibrium constants, rate constants, and activation parameters were separately determined for each reaction and a primary deuterium isotope effect, k_H/k_D = 13.6 (at 20°C), was found for the proton transfer. The reaction parameters are compared to those for proton transfer from TNT to tetramethylguanidine in DMF solvent.

MIHIR K. BISWAS, ARNOLD JARCZEWSKI et KENNETH T. LEFFEK. Can. J. Chem. **65**, 1007 (1987).

Dans le but de déterminer la cinétique et la nature des produits des réactions, on a étudié les réactions de la tétraméthylguanidine (TMG) avec le trinitrocumène (TNC) et avec le trinitroéthylbenzène (TNEB), dans le diméthylformamide. Dans le cas du TNC, on n'a observé que la formation du complexe σ avec le noyau benzénique dont on a mesuré la constante d'équilibre, les constantes de vitesses ainsi que les paramètres d'activation. Dans le cas du TNEB, on a observé la formation d'un complexe σ ainsi qu'une réaction de transfert de proton du carbone σ du groupement éthyle. Pour chacune de ces réactions, on a déterminé les constantes d'équilibre, les constantes de vitesse et les paramètres d'activation; de plus, on a trouvé que l'effet isotopique primaire du deutérium, k_H/k_D = 13,6 (à 20°C). On a comparé les paramètres réactionnels avec ceux observés antérieurement pour le transfert de proton du TNT à la tétraméthylguanidine dans le DMF.

Introduction

The reaction of 1,1,3,3-tetramethylguanidine (TMG) with 2,4,6-trinitrotoluene (TNT) in dipolar aprotic solvents has been shown to be a proton transfer from the methyl group (1, 2), and a number of primary deuterium kinetic isotope effects have been measured for the proton transfer reaction with various bases and solvents (3–7). Nevertheless, it has also been noted (3, 6, 7) that nucleophilic attack by some bases could take place on the benzene ring to yield a σ-complex. The ring attack took place at the 3 position instead of the 1 position as originally observed by Meisenheimer (8).

In this work, the methyl group in TNT is replaced by ethyl and isopropyl to observe how enhanced steric hindrance and reduction of acidity alter the balance between the two possible reactions of the base, i.e., proton abstraction from the α-carbon of the side chain and nucleophilic attack on the benzene ring. By observing which hydrogen atoms in the substrate molecules are preferentially replaced by deuterium under basic conditions and by measuring equilibrium constants, rate constants, primary kinetic isotope effects, and activation parameters of the reactions, it should be possible to determine the factors that lead to one reaction dominating the other.

Results and discussion

The trinitrocumene reaction

Sym-trinitrocumene (TNC) reacts with 1,1,3,3-tetramethylguanidine (TMG) base in DMF solvent to give a coloured product with λ_{max} at 454 and 505 nm. An analogous reaction in the same solvent with sodium hydroxide or alkoxide ions gave a product with absorption maxima at 448 and 495 nm. However, the rates of these latter reactions are very much faster than that of TMG.

When TNC was treated with NaOD or TMG-*d* in DMF solvent, followed by DCl in D_2O, the product was TNC deuterated in the 3 and 5 positions of the benzene ring. This result and the similar λ_{max} of the products suggests that TMG, NaOH, and NaOAlk give rise to the same type of product, a σ-complex, as shown in eq. [1] for the TMG reaction.

The slowness of the TMG reaction compared to that of the alkoxides may result from several factors, e.g. the large degree

TABLE 1. The optical densities of the reaction of trinitrocumene* with tetramethylguanidine in DMF solvent at 25°C

10^2[TMG] (M)	1.53	2.04	2.55	3.06	3.57	4.60
OD at 450 nm	0.691	0.816	0.964	1.094	1.149	1.400

*Initial concentration of TNC = 5.16×10^{-4} M.

of steric hindrance of both the substrate and reagent molecules, the weak nucleophilicity of TMG, the weak basicity of TMG in DMF solvent due to the electron-donor character of DMF, and the reduced acidity of the proton on the α-carbon atom of the isopropyl group relative to that of the methyl protons in trinitrotoluene.

The equilibrium constant for the reaction was determined by the Hildebrand–Benesi method (9) from the optical densities shown in Table 1. These results fitted eq. [2]

$$[2] \quad [A]/OD = 1/K\varepsilon[B] + 1/\varepsilon$$

in which [A] is the concentration of TNC, [B] is the concentration of [TMG], OD is the optical density, K is the equilibrium constant, and ε is the molar absorptivity. The correlation coefficient was 0.996, with $K = 22.8 \pm 3.0$ dm^3 mol^{-1} and $\varepsilon = 5100$ dm^3 mol^{-1} cm^{-1} at 25°C. The reasonably good correlation coefficient suggests that there are no competing reactions.

Terrier[3] has suggested, by analogy with similar reaction systems (11), that the σ-complex in eq. [1] is deprotonated by a second molecule of TMG. Such a reaction probably does take place to some extent and is no doubt part of the mechanism for deuterium exchange of the ring hydrogen. However, the σ-complex should be rather a weak acid with high steric hindrance. The experimental fit of the optical density data to eq. [2], rather than to the equation derived from a reaction involving two TMG molecules, provides evidence that the deprotonation of the σ-complex proceeds only to a very limited extent.

The pseudo-first-order rate constants were measured at several temperatures by monitoring the optical density at 450 nm using an excess of TMG. The values of the k_{obs} were fitted to eq. [3] and the forward (k_f) and backward (k_b) rate

$$[3] \quad k_{obs} = k_f[TMG] + k_b$$

constants were calculated from a linear least-squares fit. The results are shown in Table 2. The k_f values yielded $\Delta H^{\ddagger} = 13.0 \pm 0.7$ kcal mol^{-1}, $\Delta S^{\ddagger} = -18.8 \pm 2.5$ cal mol^{-1} deg^{-1}. The equilibrium constant at 25°C calculated from k_f and k_b is 25.7 ± 2.4 dm^3 mol^{-1}, in good agreement with the above non-kinetic determination.

The trinitroethylbenzene reaction

The reaction of trinitroethylbenzene (TNEB) with sodium ethoxide in DMF gives a product with λ_{max} at 433 and 502 nm. This is similar to the reaction of sym-trinitroanisol with ethoxide in ethanol, which showed λ_{max} at 410 and 490 nm (12).

The reaction of TNEB with TMG is a fast reaction giving a product with λ_{max} at 447 and 508 nm, very similar to the reaction with trinitrocumene. This reaction, particularly for the deuterated substrate, is most clearly visible at lower TMG base concentrations, and the similarity of the absorption maxima of the products to those of the trinitrocumene reaction suggest σ-complex formation. At higher TMG base concentrations the initial orange colour from the above two absorptions changes slowly to a blue product. This product has three absorption maxima at λ_{max} 363, 514, and 785 nm. This absorption spectrum is similar to the product of the reaction of trinitrotoluene with TMG in acetonitrile (1) and in dimethylformamide (2), and is characteristic of a proton transfer reaction (4, 5).

In the case of the reaction of deuterated TNEB with TMG, the initial fast reaction is particularly clear since the subsequent deuteron transfer is very much slower.

The absorption peak at 363 nm does not overlap with the initial peak at 447 nm, so it is possible to measure the rate of the second reaction without interference by monitoring this peak with time. The nature of this reaction as a proton transfer was established by deuterating TNEB with TMG-*d* or diethylamine-*d*, the product of which exchange is TNEB deuterated 90% on the α-carbon atom of the ethyl group, although some deuteration also took place at the 3 and 5 positions of the ring.

The equilibrium constants for the proton and deuteron transfer reactions were calculated from the optical density measurements shown in Table 3, by the Hildebrand–Benesi method (9). The correlation coefficients for a fit to eq. [2] were 0.946 and 0.987 for the proton and deuteron reaction respectively. K_H^{25} was 540 ± 110 dm^3 mol^{-1} and K_D^{25} was 525 ± 45 dm^3 mol^{-1} with the molar absorptivity in the range of 5000–5500 dm^3 mol^{-1} cm^{-1}.

The first- and second-order rate constants were determined using excess TMG base by monitoring the optical density at 363 nm for both the normal and deuterated TNEB substrate. The observed pseudo-first-order rate constants, k_{obs}, were fitted to eq. [3] and the forward (k_f) and backward (k_b) rate constants for the proton transfer equilibrium were calculated by a linear least-squares fit.

The results are shown in Table 4, together with the isotope effects k_H/k_D. The activation parameters derived from the second-order rate constants are collated in Table 5.

An extra series of runs was carried out using deuterated TNEB substrate and deuterated TMG as the base at 30°C. This gave $k_f = 1.38 \pm 0.06 \times 10^{-3}$ mol^{-1} s^{-1}, and $k_b = 5.9 \pm 0.3 \times 10^{-5}$ s^{-1}, in satisfactory agreement with the rate constants for normal TMG, indicating no rapid isotopic scrambling in this reaction.

The initial fast reaction between TNEB and TMG was monitored at 447 nm for several base concentrations in large excess over that of TNEB. The results are collated in Table 6. The absorbance value at the end of these kinetic runs was used to calculate an approximate value for the equilibrium constant for this reaction, using eq. [2]. This calculation gave $K^{20} = 7.5 \pm 3.0$ dm^3 mol^{-1}, in good agreement with K^{20} calculated from k_f/k_b of 7.9 ± 1.6 dm^3 mol^{-1}.

The activation parameters derived from the second-order rate constants are $\Delta H^{\ddagger} = 5.2 \pm 0.7$ kcal mol^{-1}, $\Delta S^{\ddagger} = -31.4 \pm 2.5$ cal mol^{-1} deg^{-1}.

A summary of the reaction parameters that have been determined for the σ-complex and proton transfer reactions of trinitrocumene, trinitroethylbenzene, and trinitrotoluene (2) in DMF solvent are collected in Table 7.

The proton transfer reaction is not observed for trinitrocumene because the second-order rate constant for that reaction is probably at least 10^5 times slower than that for the σ-complex reaction. For trinitroethylbenzene, although the σ-complex reaction is kinetically favoured, the proton transfer reaction has a much larger equilibrium constant and, therefore, is observed at long reaction times. For trinitrotoluene, the equilibrium

constant for the σ-complex reaction will be quite small and thus that reaction is not observed in the presence of the proton transfer reaction, which is quite fast and has a large equilibrium constant.

Experimental

Materials

2,4,6-Trinitrocumene (TNC) was prepared by a double nitration of cumene, the first carried out by the procedure of Fittig *et al.* (13) using a 1:6 mixture of 90% HNO_3 and 98% H_2SO_4. The oily product of this reaction was extracted with dichloroethane and renitrated by the procedure of Kamlet *et al.* (14). The oily product (15 g) was dissolved in a mixture of 60 mL 90% HNO_3 and 300 mL 98% H_2SO_4 and the solution was stirred at 80°C when a vigorous reaction started. The temperature was raised slowly to 120–130°C, and the reaction allowed to proceed for 45 min. The reaction mixture was poured onto ice and the resulting white solid product was recrystallized from ethanol, mp 109–110°C; nmr δ: 8.53 (s, 2H), 1.36, 1.47 (d, 6H), 3.33 (h, 1H).

2,4,6-Trinitroethylbenzene (TNEB) was prepared by the procedure of Gay-Lussac and Ficheroulle (15). Ethylbenzene (20 g) was added dropwise to a mixture of 54 mL 100% HNO_3 and 250 mL 30% oleum at 20°C. After the addition, the mixture was warmed to 45°C for 2 h and then to 85°C for 5 h. After cooling to room temperature, the reaction mixture was poured onto ice. The crude trinitroethylbenzene was washed several times with cold $NaHCO_3$ solution and then with water. Recrystallization from ethanol gave yellow needles, mp 38.5°C; nmr δ: 8.76 (s, 2H), 2.98, 3.09 (g, 2H), 1.41 (t, 3H).

Tetramethylguanidine was dried over NaOH and fractionally distilled. The fraction distilling at 161°C was collected.

Dimethylformamide (DMF) was purified by the method of Zaugg and Schaefer (16). Reagent grade benzene (400 mL) was added to reagent grade DMF (2 L) and the mixture was distilled at atmospheric pressure until the boiling temperature reached 130°C. The undistilled liquid was transferred under nitrogen to storage bottles and 20–30 g P_2O_5 was added per litre of DMF. The bottles were shaken for 3–4 h, after which the DMF was transferred, under nitrogen, to fresh storage bottles containing 50 g BaO per litre of DMF. The bottles were shaken for a further 1–2 h. The DMF was then decanted and distilled under nitrogen at 20–25 Torr pressure (1 Torr = 133.3 Pa), using a capillary nitrogen bleed. The distillate was redistilled in the same manner and the middle cut of about 1 L was collected and stored under nitrogen.

Deuteration of 2,4,6-trinitrocumene

Trinitrocumene (0.25 g) was dissolved in dry freshly distilled DMF (25 mL), and D_2O (25 mL) was added. To this solution 0.1 M NaOD (7 mL) was added dropwise with stirring. After 2 h the reaction mixture was neutralized with a few drops of dilute DCl in D_2O and poured into excess D_2O. Very fine yellow crystals formed and this material was recrystallized from ethanol-d. This procedure was repeated 3 times, giving a product, mp 109.5–110°C. The nmr spectrum showed no

$(\Delta S_D^{\neq} - \Delta S_H^{\neq})$ (cal mol^{-1} deg^{-1})	−0.6 ± 0.5	

signal at δ = 8.53 for the ring protons, whereas the aliphatic proton signals integrated in the ratio of 1:6 as for normal TNC.

TNC was also deuterated using TMG as base by a method similar to that used by Caldin and Mateo (10). After two exchanges the ring protons were about 50% replaced by deuterium, based on nmr signals.

Deuteration of 2,4,6-trinitroethylbenzene

The deuteration was carried out with both TMG-*d* and diethylamine-*d* as the base. 2,4,6-Trinitroethylbenzene (0.24 g) was dissolved in dry, freshly distilled DMF, and a base solution consisting of 1 mL of base in 5 mL DMF was added dropwise with stirring. After 3 h the reaction mixture was neutralized with a few drops of dilute DCl in D_2O. The solvent was removed under vacuum and then D_2O (20 mL) was added to dissolve the amine hydrochloride. The TNEB-*d* was extracted with chloroform and the extract washed several times before being evaporated to dryness, to yield an oil product of TNEB-*d*. This was washed several times with D_2O and then crystallized from ethanol-*d* at −7°C. All the operations were performed under dry, pure N_2.

The product obtained using diethylamine-*d* as the base gave nmr signals indicating more than 90% deuteration of the α-carbon atom of the ethyl group and about 50% deuteration of the benzene ring. The TMG-*d* base gave slightly less deuteration of the α-carbon of the ethyl group and about 80% deuteration of the ring. The diethylamine-*d* product was used in the kinetic runs.

Kinetic and equilibrium measurements

The kinetic runs and equilibrium measurements were carried out using a Cary 219 spectrophotometer with the cell block thermostat to ±0.1°C. The kinetic runs were completed under pseudo-first-order conditions with the base concentration in 50-fold to 400-fold excess. Pseudo-first-order rate constants were calculated from the traces of absorbance vs. time using the Guggenheim method and the second-order rate constants were calculated by a linear least-squares fit of the variation of k_{obs} with base concentration. The activation parameters were calculated by a linear least-squares fit of ln k/T vs. $1/T$.

^{63}Ni β range and backscattering in confined geometries[1]

K. W. MICHAEL SIU[2] AND WALTER A. AUE[3]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received October 17, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

K. W. MICHAEL SIU and WALTER A. AUE. Can. J. Chem. **65**, 1012 (1987).

To know the spatial distribution of ion pairs resulting from ^{63}Ni β radiation in the gas phase is important for a variety of theoretical and practical reasons, in particular those concerning the electron capture detector. Literature estimates of this distribution vary by about one order of magnitude, yet this parameter is necessary for the modelling of this detector. The ^{63}Ni-induced, initial ion pair distribution was therefore measured in a variety of gases with two techniques: a conventional one based on the electrical saturation current at variable interelectrode distances, and an unconventional one based on luminescence from a plastic scintillator. The data are analyzed in terms of two ranges, d^{50} and d^{95}, that describe the distances from a planar radioactive foil within which 50% and 95% of the total gas-phase ionization occur. The data from the electrical measurement show unexpected evidence of strong β backscattering and secondary electron emission from the counter-electrode. Under these (non-exponential) conditions, d^{50} values in the common detector gases nitrogen and argon/methane vary from 0.5 to 1.0 mm, depending on the nature of the counter-electrode. Calculations based on the quasi-exponential range found at longer distances in electrical measurements yield values of about 2.5 mm (which are low because of geometric measurement bias). In contrast, the data from the luminescence measurement are almost completely exponential and d^{50} values for argon (+5% methane) and nitrogen are 2.8 and 3.8 mm, respectively. The d^{95} values vary from 12 to 16 mm for the luminescence, to 6 and 9 mm for the (less reliable) electrical measurement; all at ambient conditions. The luminescence data are considered closer to the "true" (unimpeded) charge distribution, while the ionization data may be closer to the initial charge topography inside an electron capture detector of confining geometry. All range data, however, are short enough to advise modelling the detector as a system with strongly heterogeneous charge distribution. No evidence was found for some of the very large range estimates found in the literature.

K. W. MICHAEL SIU et WALTER A. AUE. Can. J. Chem. **65**, 1012 (1987).

Connaître la distribution spaciale des paires d'ions provenant de la radiation β du ^{63}Ni est important pour diverses raisons théoriques et pratiques, en particulier celles concernant le détecteur à capture d'électrons. Les valeurs de la littérature, pour cette distribution, varient par environ un ordre de grandeur; pourtant ce paramètre est nécessaire à la réalisation d'un modèle de ce détecteur. La distribution initiale des paires d'ions, induite par le ^{63}Ni fut donc mesurée dans divers gaz au moyen de deux techniques : l'une conventionnelle, basée sur le courant de saturation électrique à des distances interélectrodes variables; et l'autre peu conventionnelle, basée sur la luminescence d'un scintillateur en plastique. Les données sont analysées en fonction de deux distances, d^{50} et d^{95}, qui décrivent les intervalles jusqu'à une feuille radioactive planaire, à l'intérieur desquels se produit 50% et 95% de l'ionisation totale en phase gazeuse. Les données provenant des mesures électriques montrent qu'il y a évidence inattendue de forte diffusion β rétrograde et d'émission secondaire d'électrons par la contre-électrode. Dans ces conditions (qui ne sont pas exponentielles), les valeurs de d^{50} dans l'azote et un mélange argon/méthane, des gaz usuels pour ce détecteur, varient de 0,5 à 1,0 mm, selon la nature de la contre-électrode. Des calculs basés sur le domaine quasi-exponentiel que l'on trouve à de plus grandes distances, lors des mesures électriques, donnent des valeurs d'environ 2,5 mm (qui sont basses à cause d'un biais associé aux mesures géométriques). Par contre, les données provenant des mesures de luminescence sont presque complètement exponentielles et les valeurs de d^{50} pour l'argon (5% de méthane) et l'azote sont respectivement 2,8 et 3,8 mm. Les valeurs de d^{95} varient de 12 à 16 mm pour la luminescence, à 6 et 9 mm pour les mesures électriques (moins fiables); le tout, aux conditions ambiantes. Les données provenant de la luminescence sont considérées plus proches de la valeur "vraie" (inaltérée) de la distribution de charge, tandis que les données provenant de l'ionisation sont possiblement plus proches de la topographie initiale de la charge à l'intérieur d'un détecteur à capture d'électrons de géométrie restreinte. Toutefois, toutes les données de distances sont suffisamment courtes pour indiquer que le modèle du détecteur devrait consister en un système ayant une distribution de charge nettement hétérogène. On n'a trouvé aucune évidence de quelques-unes des très grandes valeurs de distances trouvées dans la littérature.

Introduction

It is of basic interest to know the boundary and the density gradient of the plasma that surrounds a β emitter in the gas phase. It may also be of considerable practical importance.

Such is the case with the weak β emitter ^{63}Ni, the isotope of choice for the electron capture detector (ECD). The ECD is the most prominent of all selective detectors used in conjunction with gas chromatography, and it has played a role in the discovery and monitoring of almost every major area of environmental concern from DDT to Freons to PCB's.

Despite this prominence, the mechanism by which the ECD responds to electron-capturing analytes is not very well understood. As it turns out, one of the key impediments to understanding the mechanism of the ECD is the inadequately known range and distribution of ^{63}Ni β particles. Their energy spectrum has been reported (1), but literature estimates of their range in nitrogen or argon/methane — the typical carrier gases for electron capture detection — vary by roughly one order of magnitude. Experimental estimates are generally shorter than

theoretical ones, particularly in regard to the half range (the thickness of the zone in which the first 50% of ionization occur).

A brief selective review of some recent measurements and frequently cited literature values may illustrate this point. Ayala *et al.* assessed the maximum range as 7.9 cm, presented a β distribution plot and estimated "that ca. 30% of the distribution for Ni-63 is within 1.4 cm" (2). Grimsrud and Connolly measured the steady-state positive ion distribution of a Ni-63 disc at atmospheric pressure by mass spectrometry and showed approximately 50% of the ions occurring within 1 mm from the foil (3). Further, they developed an equation relating radiation intensity and distance. Their calculation showed the ion-pair production rate at the center of a cylindrical foil of 5 mm radius and 20 mm length to be 0.44 times that at 0.5 mm from the wall (in argon at 200°C). Popp *et al.* reported the extent of ionization in nitrogen as 15 mm (4). Pellizzari, in a widely quoted review article (5), spoke of a zone of electrons 6–8 mm thick. Simon and Rork measured the variation in saturation current in air between concentric spheres up to about 5 cm. From their data it appears that 50% of the ionization occurs within about 5 mm of the radioactive foil in concentric spherical and 3 mm in coaxial cylindrical geometries (6). (The latter should not be confused with typical coaxial cylindrical ECD's in which the foil is not the inner but the outer cylinder.) Our own group used impedance matching to locate the "centre of ionization", an estimated 1 mm away from a planar foil (7).

Even allowing for the fact of different conditions and criteria in the studies cited above, their results are too far apart to be used with confidence in certain considerations involving the ECD. The importance of usable data is particularly pronounced in the following contexts. First, certain physicochemical constants derived from the ECD depend on the volume in which the measured processes are assumed to occur. Second, any modelling of ion reactions and distributions inside the ECD must start with the initial ionization of the carrier gas. Third, the choice of dimensions in constructing new ECD models has to take into account the topography of the plasma. Fourth, the interpretation of certain experimental probes of the ECD's response mechanism depends in a crucial manner on the density distribution of its electrical charges.

The latter point is of particular interest to us. In an attempt to ascertain that an ECD could function (and function well) under conditions where it was impossible for analyte-derived anions to be neutralized by cations in the gas phase, we designed a detector in which the effluents from the gas chromatographic column could react with electrons close to the anode, but were not allowed near the radioactive cathode. Clearly, the choice of dimensions became crucial in this case. For instance, the radioactive foil in one of these constructions was located about 1.2 cm away from electron-capturing analytes (8). If it were indeed correct that "ca. 30% of the distribution for ^{63}Ni is within 1.4 cm" (2), i.e. if 70% of the β's reached *beyond* 1.4 cm, then our premise of no contact between cations and anions would no longer be valid and the recent criticism ((9) of our experiment would appear justified.

Furthermore, a clear definition of the extent and density distribution of the ECD plasma could help to distinguish between two currently held, opposing viewpoints: One considers the detector a bipolar, more or less homogeneous system where the plasma fills the entire detector volume (5, 10). Owing to this, the model is often referred to as a "stirred-reactor" model although, quite obviously, there is no physical stirring involved (11). The other viewpoint sees the ECD as containing both bipolar and unipolar regions — a limited plasma region near the radioactive cathode, and a plasma-free region populated only by electrons and (analyte-derived) anions near the anode (7). Speculation based on these two models leads to different mechanisms by which detector response arises. Obviously, a valuable first step toward attributing response to one or the other mechanism (or a mixture of the two) would be to define the spatial distribution of ionizing events caused by β radiation.

For these reasons it seemed appropriate to measure again the specific ionization produced by a typical ^{63}Ni foil, under conditions that would to some extent resemble those of electron capture detectors.

In addition, our initial choice of measurement technique was influenced by two considerations. First, we wanted to use a generally recognized approach. Our earlier work was based on impedance matching which, though convenient and appropriate for an ECD that relies on impedance for response, had no predecessor in the literature. Also, this measurement of choice was to be backed up by a second, different technique of probing the same radioactive source.

Second, the important measurements were to be those particularly relevant to the ECD. We would not measure the *maximum* range of the radiation, which is primarily of interest to nuclear physicists and best investigated by means other than those involving a gas phase. Rather, we wanted to know at which distances from the foil 50% and 95% of the ionization would take place. These distances, d^{50} and d^{95}, characterize in an immediately apparent way how rapidly the plasma density decreases with increasing distance from the foil, and how far the plasma extends for any practical purpose. In contrast, data for the last 5% of ionization carry large error limits and are of little consequence for the ECD.

Radioactive foils are shaped into cylinders, cups, or planes for use in the ECD. It was felt that a parallel-plane ECD configuration was the most facile and tractable one in terms of future use of plasma distribution data.

Two types of measurements were to be employed toward that goal: a direct and conventional one based on ionization, and an indirect and less conventional one based on luminescence. Similar to approaches taken by several other groups, the conventional electrical measurement would involve moving the radioactive foil toward the counter-electrode and observing, by saturation current, the decrease in gas-phase ionization events as more and more β particles struck the electrode. The less conventional, photoelectric measurement — for which we found no precedent in the ECD field — would consist of moving the radioactive foil toward a semitransparent scintillator disc and monitoring, from the disc's opposite side, its increase in luminescence. It was hoped that roughly comparable, hence confirmatory results would be produced by the two different approaches.

What results was one to expect? The discrepancies in the literature are far larger than appears justified for a relatively simple (but important) problem. This suggests that part of it may be conceptual: There are significant differences between the idealized concept of unimpeded β rays emanating from a pure ^{63}Ni monolayer, and the experimental situation of a conventional radioactive foil located inside an electron capture detector. Measuring the maximum range does not recognize these differences; measuring d^{50} and d^{95} values does.

Although fairly self-evident or even trivial, it may be appropriate to mention some factors that influence the density of initial ionization in the present context. Almost all of these tend

to compress the initial 50% or 95% of the plasma in comparison with an idealized setting. The factors are radioactive layer thickness, angular β distribution, energy dependence of the ion pair yield, scattering in the gas phase, and backscattering and secondary electron emission in solid phases (inside the foil, from materials surrounding the foil, and from the counter-electrode). These will be dealt with in turn.

Radioactive layer thickness

A typical (New England Nuclear) foil for ECD's has about 15 mCi ^{63}Ni deposited as a layer of 10 mCi/mg specific activity on a gold backing measuring 0.5 × 1.5 in. It is easy to calculate from these data that the radioactive layer, at 0.31 mg/cm^2, is on the average 3.5×10^{-4} mm thick. (Judged solely by density correlation, this would correspond to a 2.5 mm thick zone of nitrogen gas at STP.) This means that a significant portion of the β particles does not reach the foil surface and that the average (but not the maximum) β range is reduced. The thicker the layer, the shorter the half range d^{50} (this "half range", though like the radioactive "half life", the most descriptive parameter characterizing an exponential decay, is unfortunately not nearly as constant). Severe contamination of the foil in an ECD would obviously exert a similar effect.

Angular β distribution

β Emission occurs randomly in all directions. Those β particles that emerge at oblique angles to the foil, will on the average travel longer paths through the solid, and therefore shorter ones through the gas phase, than those that are emitted in a perpendicular direction. Again, this reduces the half range.

Ion pair yield

The number of ion pairs formed per unit pathlength — the specific ionization — is dependent on β energy. β Particles from ^{63}Ni, with a maximum energy of 67 keV, are among the weakest known. In the low-energy region, the specific ionization increases dramatically with decreasing energy. To illustrate, the literature data shown in Fig. 1 suggest that a β particle generates about 8 times as many ion pairs per mm at 6.7 keV than at 67 keV (12).

To express the above argument differently: since weaker β particles produce denser ionization but expend the same energy per ion pair created, they travel disproportionately shorter distances. This gas-phase effect is synergistic with the angular distribution effect mentioned earlier, in reducing the half range.

Scattering in the gas phase

β Rays are easily scattered. The more scattering occurs, the shorter is the half range.

Scattering and secondary electron emission in solid phases

Scattering is, of course, not restricted to the gas phase but will occur on any material that happens to bar the path of a β particle — for instance, the radioactive layer and its backing as well as (if they are situated close enough) the walls of the detector and the counter electrode. Backscattering inside the foil itself is sporadically mentioned in the ECD literature; backscattering (reflection) and secondary electron emission from the detector wall and the counter electrode has, to our knowledge, never before been considered in an ECD-related context.

Secondary electrons are the result of inelastic collisions between the primary electrons (β particles) and the solid material. Provided the primary is of high enough energy, more than one secondary electron may be produced per incident. The efficiency of the scattering and emission processes depends strongly on the atomic number of the solid and the angle of incidence: the heavier the material and the larger the angle of incidence, i.e. the more shallow the impact, the larger is the number of secondary electrons created (13–15). Gas-phase ionization resulting from such secondary electrons occurs very close to the surface.

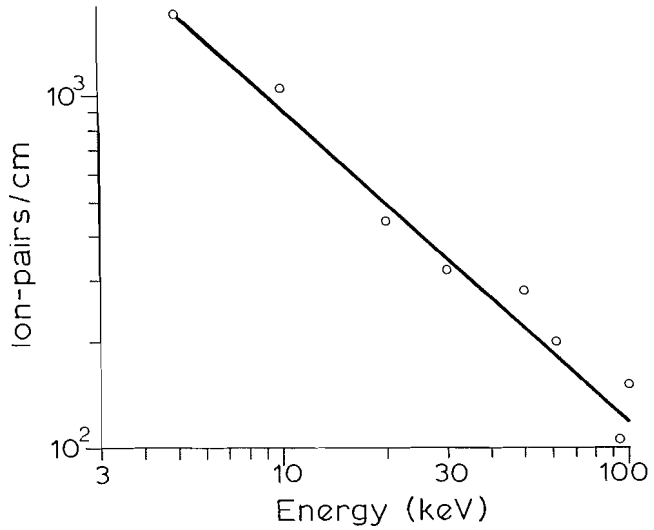

FIG. 1. Variation of specific ionization with actual β energy. Data taken from ref. 12.

All the scattering and secondary electron emission effects reduce the half range. Backscattering inside the foil, whether inside the ^{63}Ni layer or on the gold backing, leads to weaker β particles (of shorter range) emerging from the foil. If a counter electrode or constraining detector wall is situated close to the foil, scattering and secondary electron emission will produce more gas-phase ion pairs there than would have been present without the constraint.

Also, short distances can promote scattering to a disproportionately larger degree. Consider, for instance, a parallel-plate configuration in which the counter-electrode is being moved toward the foil. In the beginning, only β rays travelling roughly perpendicular to foil and electrode will be able to bridge the gap. As the gap decreases, increasingly more β particles leaving the foil and arriving at the electrode at *oblique* angles will enter the process. Thus, the average β impact will be not only more energetic but also more shallow, leading to increased scattering and secondary electron emission. If such an arrangement were to be used to determine half range, a counter-electrode with strong scattering ability would have to move closer to the foil to collect half of the maximum current than a (fictional) electrode simply absorbing the β particles.

Experimental

The ionization current measurement

The set-up used to measure the saturation current at different interelectrode distances is shown in Fig. 2. It is designed to represent a parallel-plate ECD free of confining walls. The design is similar to the one used earlier for impedance matching (7).

Two different ^{63}Ni foils were tested. These were rectangular plates measuring ca. 6 × 5 mm; one with a gold, the other with a nickel backing. Both originated from 0.5 × 1.5 in. conventional ECD foils of nominal 15 mCi activity (New England Nuclear). The radioactive plates were mounted on a stainless-steel disc of 8 mm diameter, which had been silver-soldered onto a threaded rod. By turning the rod through the compressed PTFE (polytetrafluoroethylene) ferrule, the

For personal use only.

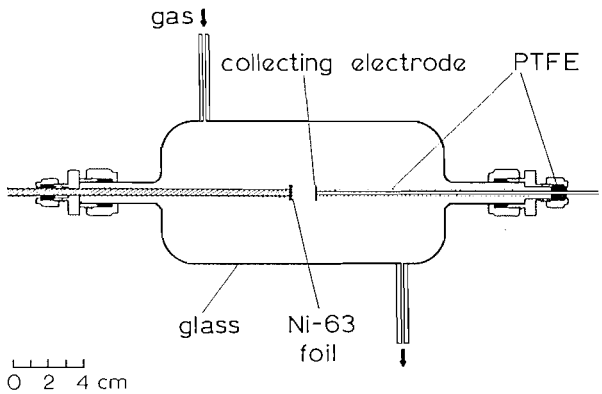

FIG. 2. Apparatus used for the ionization current measurement.

assembly could be easily moved toward, or away from, the stationary counter-electrode.

This counter-electrode was also a stainless-steel disc of 8 mm diameter, similarly soldered onto a rod. Electrodes of different scattering power were made by mounting a graphite disc, or a piece of lead foil, on the steel disc.

To permit measurements at elevated temperatures, the glass vessel was first covered with several layers of grounded aluminum foil (for electromagnetic shielding and improved heat distribution) and then tightly wrapped with two heating tapes in opposite directions. A small window was left open to allow the examination of electrode alignment. To improve reproducibility, the apparatus was routinely "baked" overnight prior to any measurement at temperatures higher than ambient.

Initially, the set-up was polarized, and the saturation current measured, in two configurations. These were expected to (and did) yield the same results in the initial series of experiments. In part for convenience, they were used interchangeably thereafter. In one configuration, the ^{63}Ni foil was polarized negative with respect to ground and the counter-electrode was connected directly to an electrometer. In the other configuration, the ^{63}Ni foil was at ground and the counter-electrode was biased to ca. +300 V by a battery box whose negative terminal provided the input to the electrometer. Measurements were made at least in duplicate, with triplicate and quadruplicate sampling being not infrequent.

The luminescence measurement

Figure 3 shows the set-up used to measure β-induced luminescence. The ^{63}Ni foil-and-rod assembly described above was re-used here, augmented by a PTFE "piston". This piston kept the foil parallel to the scintillator disc and prevented any contact between the two by virtue of a ca. 0.2 mm thick rim. The scintillator was of the conventional, transparent plastic type used in low-energy β counting.

The PMT (photomultiplier tube) was a Hamamatsu R268 unit polarized to −700 V. Two electrometers were used interchangeably. One was a conventional unit, the other a laboratory-made, inexpensive "electrometer substitute" (16).

β Ranges were studied in a variety of gases — some chosen for their common use in electron capture detection, others for their convenient molecular weight. These gases (minimum % purity or grade in parentheses) included nitrogen (99.998%), argon +5% methane ("high purity"), hydrogen (99.99%), helium (99.999%), methane (99.97%), sulfur hexafluoride (99.99%), difluorodichloromethane (99%), and butane (99.5%).

Results and discussion

While the current ECD debate calls for direct measurement of the ^{63}Ni β range — particularly the half range d^{50} — it also calls for an appreciation of the extent to which the data derived from such measurements can be affected by definitions and instrumental circumstances. Furthermore, it calls for consideration of factors that could conceivably account for significant

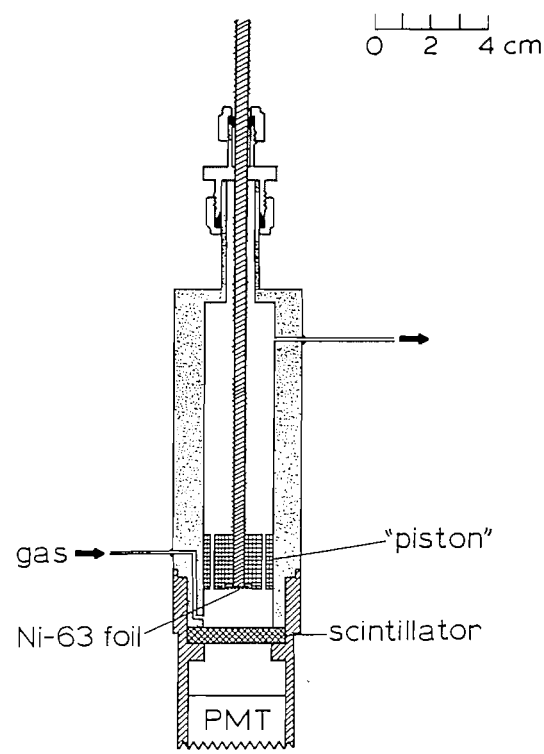

FIG. 3. Apparatus used for the luminescence measurement.

changes in half range when a foil is moved from a measurement device to an electron capture detector.

The 95% range is this study's expedient substitute for the true maximum range. Values for d^{95} — in contrast to the ideal d^{100} — can still be measured with some confidence. On the other hand, d^{50} values invite direct comparison with detector dimensions, i.e. they allow a crude but immediate assessment of a detector's likely charge heterogeneity.

The half range d^{50} will depend on the particulars of the ^{63}Ni source — i.e. whether it is a flat or cylindrical, a thinly or thickly coated, a large or small piece of foil — and the geometry and nature of materials that surround it in a detector. Even with a given source, however, and with the simplest and least obstructed geometry imaginable, the circumstances of the measurement set-up will have an influence on the results. Therefore we shall postpone reporting the data and first discuss implications of the way in which they were obtained.

Factors involved in the luminescence measurement

What was actually measured in this experiment was the photomultiplier current, originating from the combined luminescence in both the scintillator and the gas under investigation. Very little light was in general emitted by the gas, and its contribution was routinely subtracted from the total signal by baseline extrapolation. The validity of such linear extrapolation was confirmed by measurements with the scintillator disc removed from the apparatus. Since the luminescence was normally measured through — hence was attenuated by — the plastic scintillator, the two baselines differed by a small factor. It, however, was considered minute compared to other types of errors.

Another, entirely negligible error arose from the fact that, when the foil and the scintillator were close together, the β particles penetrated farther into the scintillator. Consequently photons were emitted more close to the PMT, resulting in a

For personal use only.

higher light level. Considering the relative densities of a gas and a solid, this *axial* displacement factor must have been extremely small.

The *radial* displacement bias, however, was considered to be far from negligible. It is easy to see why. When the foil and the scintillator almost touched, the luminescing area seen by the PMT was little larger than the foil itself. However, as the two moved apart, the luminescence spread in the scintillator until it reached the confines of the disc (this, incidentally, can be easily seen with dark-adapted eyes). Any photons emitted from the peripheral regions — because of the longer distance, the more oblique angle to the photocathode, and the larger attenuation by the not perfectly transparent disc — contributed less than their share to the overall measurement. This effect decreased the half range (i.e. the observed half range was shorter than the true one).

Further, any β ray travelling beyond or outside the confines of the disc was completely lost to the light measurement. Since this occurred primarily when the foil and the scintillator were far apart, the effect decreased the 95%.range and, to a smaller extent, the half range as well.

Since intimate contact between the foil and the scintillator was to be avoided, the light output at zero distance was determined by extrapolation. As will be shown later, luminescence in the measurement of *light* gases did level off at very short distances. Thus it may have been erroneous to do so. However, the error — which would have decreased the half range — was considered to be extremely small.

More important at very close distances may have been the backscattering of β particles from the scintillator disc. The effect was not as large as backscattering from the counter-electrode in the ionization measurements — the average atomic number of the scintillator was only about 3 — but it was not negligible. Furthermore, surface charges on the electrically insulating scintillator could have had some repulsive effect. Both processes, since they occurred primarily at very short distances, increased the half range.

Perhaps the most basic question is one to which we cannot provide an answer: to what extent, and how far down in energy, can we assume a quantitative relationship between ionization and luminescence? The premise of using luminescence in the given context was, of course, that it accurately represented the ion pairs that *would have been* formed in the volume to which access was now barred by the scintillator. Aside from requiring a homogeneous, clean disc, this condition also required that the cross section for luminescence inside the disc had to represent precisely the cross section for ionization in the gas phase, and that this relationship had to be kept strictly intact throughout the available β energy range.

In a gas, the ionization cross section increases by about one order of magnitude at low — and, for ^{63}Ni, relevant — energies. Considering the importance of very weak β particles for the d^{50} measurement, one may need to be reassured of a strictly linear relationship between energy and luminescence — or, more precisely expressed, between the number of ion pairs created in the gas phase on one hand and the number of equivalent photons emitted in the plastic scintillator on the other.

It is well known, of course, that the energy expended in creating one ion pair in the gas phase is remarkably independent of the β energy (12). It is also known that the intensity of the light flash from a scintillator, for instance in γ ray spectrometry, is proportional to the energy of the incident γ photon (17). However, it is not entirely clear whether these general relationships can be extrapolated to the low-energy range while still satisfying the exact correlation demanded by this study. As will be seen later, the half ranges measured by luminescence differed considerably from those measured by ionization. Yet, it appears that this was not primarily due to a faulty correlation between ionization and luminescence, but that a variety of other effects were responsible for most of the discrepancy.

Factors involved in the ionization measurement

The same radioactive foils were used in the luminescence and ionization measurements. However, the target of the β particles — the plastic scintillator and the various counter-electrodes — differed not only in nature but also in size.

In designing the measurement set-up, dimensions were chosen similar to those that one might expect in a parallel-plate ECD, but any wall constraint was removed to avoid possible interference by a charged insulator surface. The design addressed possible multiple-purpose use in future experiments and took into account that an earlier study had shown the centre-of-ionization to be located only about one mm away from the foil (7).

This meant (judging mainly from hindsight) that some of the β particles, particularly those of greater energy and more oblique angles of emission as well as those emitted from the boundary regions of the foil, *did* have some chance to miss the target, i.e. travel beyond the plane of the counter-electrode without being intercepted. More gas phase ions would thus be created, leading to a decrease in d^{95} and, to a much smaller degree, in d^{50} values. How large this geometric effect was depended on conditions: at short distances and with heavy gases it was negligible, at long distances and with light gases it was significant.

A measurement of the distances at which 50% and 95% of the current were collected presumed knowledge of I_{max}, the maximum ionization current. I_{max} was taken to be the saturation current at distances considerably larger than d^{95}, i.e. the current that would remain constant during further increases in distance and voltage. Unfortunately, but not unexpectedly, this current was not perfectly independent of experimental circumstances. While this did not influence the half range to any significant degree, the d^{95} values were likely to carry some error because of it. Also, the I/d curve displayed a very gentle slope as it approached the I_{max} value, thus increasing the error in measuring d^{95}. One of the causes for small current fluctuations, which became particularly important at long interelectrode distances, could have been the presence of small amounts of electron-capturing substances. Even such trivial an influence as the magnetic field induced by a.c. resistance heating had to be reckoned with as a cause for variations in current. Although the described arrangement of crossed heating tapes largely eliminated the originally noticed aberration, a very small effect might have persisted.

On the other hand, it was the actual measurement of distance that introduced most of the error at *very close* range. Keeping the electrodes parallel and measuring a gap between them of a few tenth of a millimetre was difficult.

Summing up the paragraphs above, the various criticisms and caveats that have emerged from a closer consideration of the two experimental approaches should make it abundantly clear that the range data obtained were approximate ones. This will also become evident from the significant difference between the luminescence and the ionization sets of measurements. Yet, the uncertainty in the results needs to be viewed in the proper perspective.

First, as will be discussed later in more detail, the dimensions

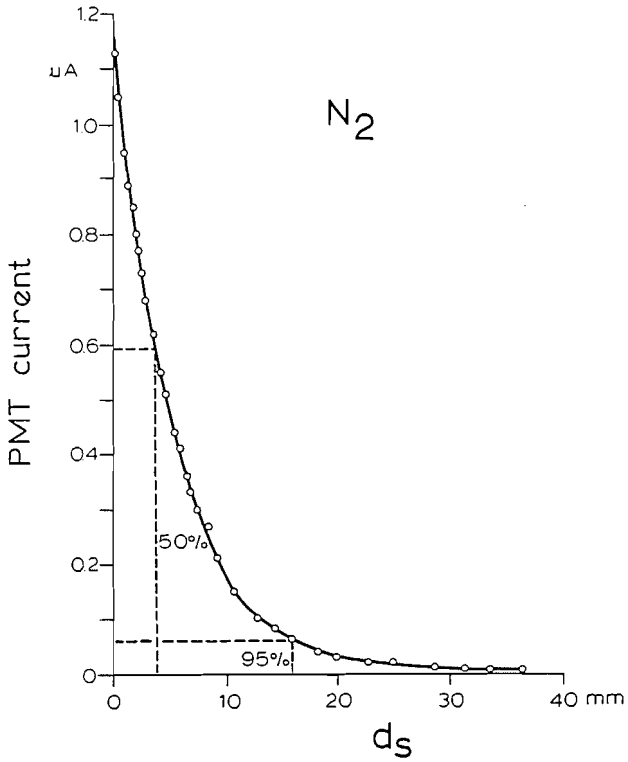

FIG. 4. Luminescence plot for nitrogen at ambient conditions.

and materials used in constructing an ECD are likely to produce changes in d^{50} and d^{95} values greater than the discrepancies between ionization and luminescence measurements reported here. Second, and more importantly, the literature of electron capture detection cites range values more than an order of magnitude apart — a much greater error than that arising from a comparison of the two techniques used in this study. Third, the use of *two* measurement techniques is likely to produce larger error limits and more reliable results.

Luminescence measurements

Figure 4 presents the result of a typical experiment, i.e., a plot of photomultiplier current versus the distance d_s ("s" for scintillator) between the foil and the disc. β Particles from the foil lose some of their energy by inelastic collision with gas (in this case nitrogen) molecules during their flight toward the disc. On entering the scintillator, a constant proportion — or so it is hoped — of their residual energy is converted to light and monitored. At 50% and 95% of the (extrapolated) maximum PMT current, the "directly measured" values of d_s^{50} and d_s^{95} are obtained. Table 1 lists these values for a series of gases ranging from the very light to the very dense, including the two common ECD carriers nitrogen and argon/methane.

The function displayed in Fig. 4 appears exponential in nature and it is therefore easy to calculate the number of ion pairs generated per second in any volume element ("slice") parallel to the foil. As shown in Appendix 1, the profile of the PMT current is identical in shape to that of the *initial* ion-pair distribution. In the particular case of Fig. 4, to convert the former to the latter, the ordinate covering the range from 0 to 1.2 μA PMT current can be replaced by one reading 0 to 3.1×10^9 ion pairs $s^{-1}\,mm^{-1}$. (Note that such a plot yields only the *number* of ion pairs created at a certain distance from a foil of particular activity and dimension; it does not provide immediate information on the ion pair *concentration*.)

Since this initial ion pair distribution does, however, provide a reasonable first step toward modelling the ECD, it may be appropriate to include here a few comments on the implications of such an approach.

TABLE 1. Ranges measured by luminescence

Gas	Molecular weight	Direct[a] d_s^{50}	Direct[a] d_s^{95}	Indirect[b] d_s^{50}	Indirect[b] d_s^{95}
H_2	2	10.2	38.0	8.0	34.3

SF_6	146	1.0	5.0	1.1	4.8

[a]Direct measurement in mm, taken from PMT current plot.
[b]Indirect measurement in mm, calculated from semilogarithmic PMT current plot via linear regression analysis of slope.

To begin with, there are geometric effects to be considered. For instance, the initial ion pair density is constant at a constant distance from a planar foil only if that foil is infinitely large. In our set-up, ionization density in a particular parallel slice was highest in the middle — opposite the centre of the foil — and decreased toward its periphery, with profiles depending on the distance of the imagined slice from the foil.

Then there is recombination. Given a strictly second-order reaction with micro-homogeneity (no columnar effects interfering) and assuming that there is as yet no gas flow, no diffusion, no polarizing potential and, of course, no analyte, the distribution of charges would remain exponential — though the half range would double.

In the next step, however, the electrical potential imposed for operating the detector — for making any electrical measurement, in fact — must disturb the initial or steady-state distribution drastically. So must the introduction of analyte, with the concomitant generation of slow anions proportional to local electron concentrations. So must the neutralization reaction, reflecting the local concentrations of cations and anions. Furthermore, both charged and neutral species must be subject to diffusion and transport by the carrier gas, though to different extents. All of that, and more, will influence the charge distribution. (It is not surprising that the stirred-reactor concept of the ECD has proven so popular.)

Thus, knowing the initial ion-pair distribution represents only a simple (yet necessary) first step in the complex modelling sequence of the detector's charge topography. Still, the fact that the initial distribution is exponential should make the task easier.

Of course, this exponential relationship comes as no surprise. The absorption of β energy in metals — gases are generally less well characterized — is known to be largely exponential and conform to the relationship (18)

$$A = A_0 \exp(k_a l)$$

where A_0 is the activity (e.g. counts per second) measured without an absorber, A is the activity measured through an absorber of thickness l, and k_a is the absorption coefficient and an approximately linear function of the absorber's density. It may be added that this equation applies to β particles with their characteristic energy distribution; in contrast, monochromatic electrons will exhibit a linear rather than an exponential

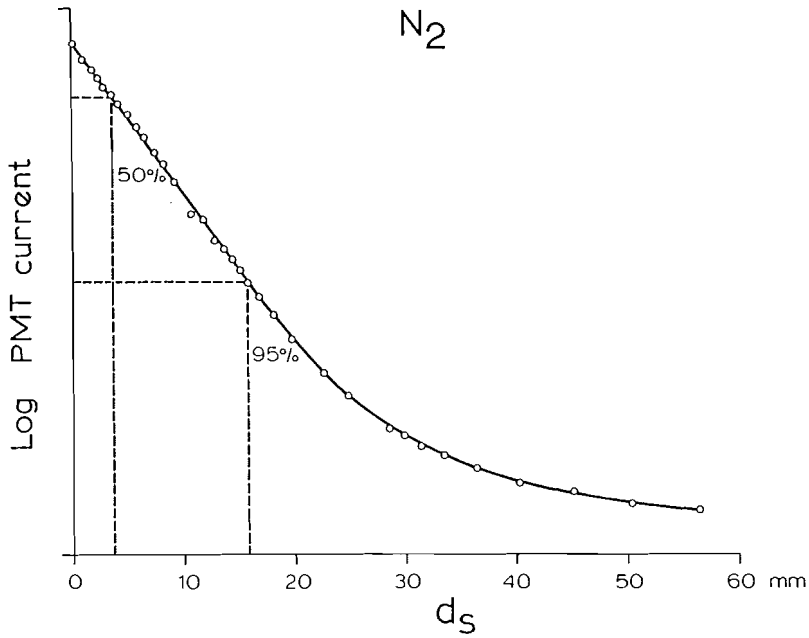

FIG. 5. Semilogarithmic luminescence plot for nitrogen at ambient conditions; data as in Figure 4.

dependence (14). In view of different energy distributions from different isotopes and the distinct upper limit in energy of any β radiation, clearly the above equation can only approximate the true distribution *within a certain range*. That becomes also obvious if one considers its mathematical equivalence to, *inter alia*, Beer's law and the integrated form of the first-order rate equation.

To find out how far this equation is obeyed by ^{63}Ni β particles moderated by a gas and monitored by their energy (as opposed to their numbers), the data of Fig. 4 were replotted in the semi-logarithmic format of Fig. 5. About 97% of the energy distribution fits the exponential pattern which, for the purpose of this study, can be rewritten as

$$\ln i = -kd + \ln i_{max}$$

where i is the photocurrent measured at the distance d between the foil and the scintillator disc, and i_{max} is the (extrapolated) photocurrent at distance 0. The slope k can be obtained directly from the plot or by linear regression analysis of its data points. The latter method has been used to arrive at "indirectly" measured ("calculated") values of d^{50} and d^{95}, some of which are shown in Table 1. (Note that $\ln 2/k$ equals d^{50}, $\ln 20/k$ yields d^{95}, and d^{95}/d^{50} is supposed to be 4.32.)

The "indirect" values thus calculated and the values obtained by "direct" measurement of the plot do differ, mainly because of deviations from the exponential relationship at the upper and lower ends.

The deviation at the upper end of the graph requires a low-density gas such as hydrogen or helium to show up clearly. (We do not know to what extent this can be attributed to backscattering from the scintillator.) The effect is demonstrated in Fig. 6. Incidentally, the plots for hydrogen and helium are almost identical, despite the fact that the two gases differ by a factor of two in density. A possible explanation is that the mean energy loss per unit path length, according to the Bethe-Bloch equation (12), is proportional to the ratio of atomic number over atomic weight. This ratio varies little amongst elements with the exception of hydrogen, for which it is about twice as large.

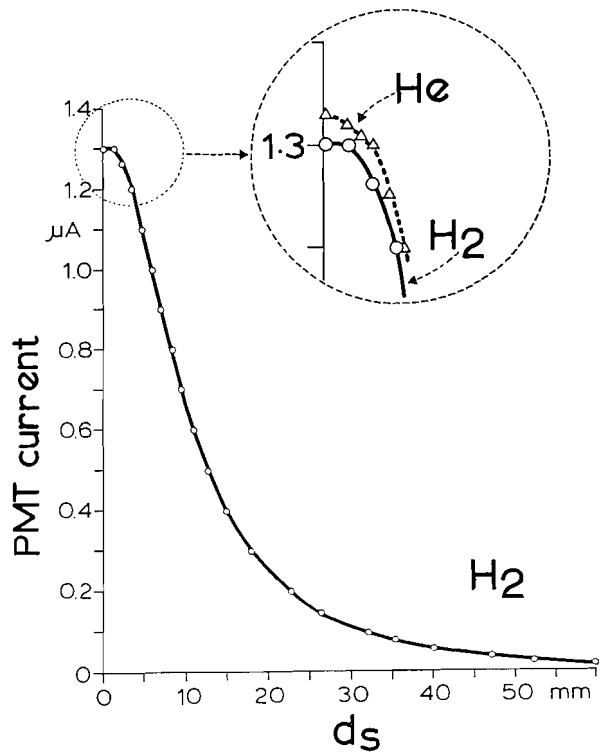

FIG. 6. Luminescence plots of hydrogen and helium at ambient conditions.

Hydrogen aside, the d_s^{50} and d_s^{95} values for different gases follow approximately the expected inverse proportionality with molecular weight, as shown in Figs. 7 and 8. The data are thus fairly consistent (though that does not, per se, establish their accuracy). Perhaps their greatest value in the present context is that they can be trusted to show how far the bulk of ^{63}Ni β particles can reach in the most favourable geometry. Hence we consider the luminescence data to be more characteristic of an "ideal" β range measurement — though not necessarily of a

For personal use only.

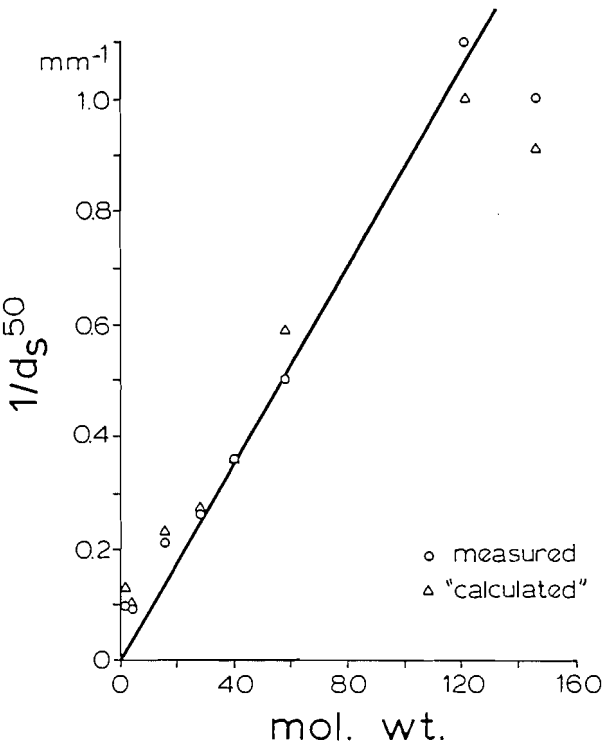

FIG. 7. Plot of $1/d_s^{50}$ versus molecular weight of different gases (listed in the experimental section) at ambient conditions. "Measured" data taken directly from i/d_s plot; "calculated" data derived from same plot via linear regression analysis.

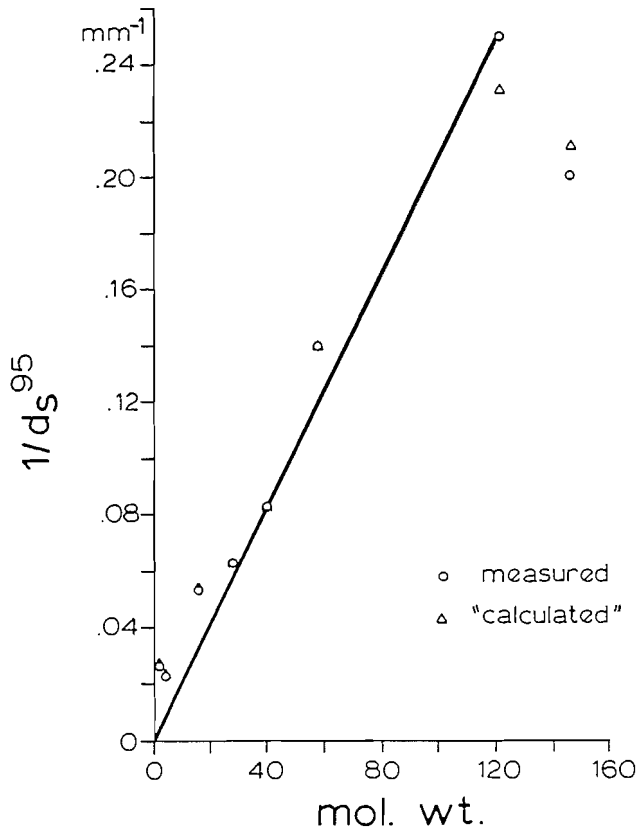

FIG. 8. Plot of $1/d_s^{95}$ versus molecular weight of different gases; similar to Fig. 7.

typical ECD arrangement — than the ionization data which are to follow.

Numerically, the luminescence data fall somewhere in the middle of the range estimates mentioned in the literature. Thus, in the common ECD carrier gases argon/methane and nitrogen at room temperature, approximately 95% of the total β energy from a planar foil is dissipated within 12 and 16 mm, and 50% is expended within 2.8 and 3.8 mm, respectively. We are not aware of any similar *luminescence* measurements in the ECD literature. However, as a formal comparison, our data are closest to ionization-based results obtained by Simon and Rork (6) in the context of smoke detectors. Estimated from the graphs in their paper, the d^{50} distances in air were approximately 5 mm for concentric-sphere and 3 mm for coaxial-cylinder geometry. (A parallel-plate configuration would be expected to yield a value somewhat less than 3 mm on geometric grounds.) Also close comes the statement of Popp *et al.* that all radiation from their foil was absorbed in nitrogen within 15 mm (4). There is no evidence for the claim of Ayala *et al.* (2) that 70% of β particles travel distances in excess of 1.4 cm.

In the context of this study, the luminescence data provided the *largest* range values even though these were still well within the requisites of the "space-charge" mechanism (7), and well within the premise for experiments using "separated" cation and anion chambers (8, 19). In the latter, the configuration most often used employed a cylindrical foil about 12 mm away from an aperture of 8 mm diameter leading to the anion chamber (8). We can now estimate that the β energy, which could have been transmitted through the aperture, was clearly below one percent, i.e. negligible — and that the recent criticism (9) of these experiments can therefore be safely dismissed.

While the luminescence measurements carry the appeal of an independent probe, the electron capture detector is, of course, based on the monitoring of charge, not light. If only for this reason, the following measurements of the ionization current could be considered more germane to the subject at hand.

Ionization measurements

When a large enough potential is maintained between a radioactive foil and an anode separated by a gas phase, and when that anode is located beyond the range of radiation, all accessible charges are collected from the gas phase, and the electrical current is the maximum one possible. (This statement accepts columnar recombination (20) as unavoidable but — given the very much larger voltages that would be necessary to diminish *that* reaction — remains correct for all practical purposes.)

However, when the anode is moved toward the radioactive foil and, as a consequence, starts intercepting β radiation, the ionization current from the gas phase decreases. Neglecting the extremely small contribution of the β particles' own charge, an arrangement of this sort can be used to map the unimpeded β energy distribution by current monitoring. This is the basis for most of the β range measurements in the literature. Their implicit premise is that the anode simply and totally absorbs any β particle that happens to hit it.

If, on the other hand, backscattering and secondary electron emission were to occur such that the gas phase would gain additional ion pairs, the measured current would have to be adjusted for this effect before it could be used to establish the ion pair distribution in an *uninterrupted* gas phase. To our knowledge, there is no reference in the ECD literature to elastic or inelastic scattering of β's on the anode or confines of the

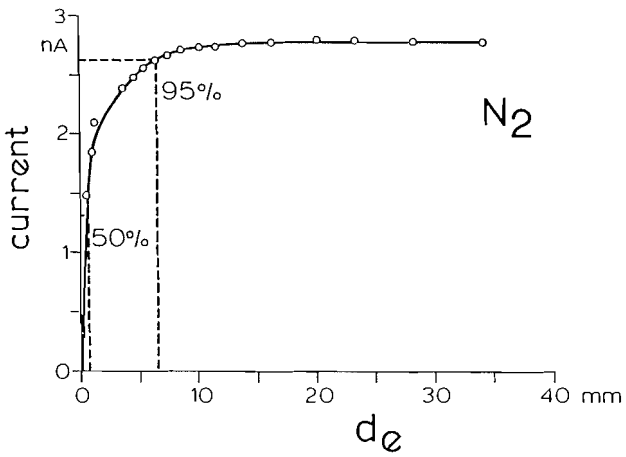

FIG. 9. Ionization current plot for nitrogen at ambient conditions; steel counter-electrode.

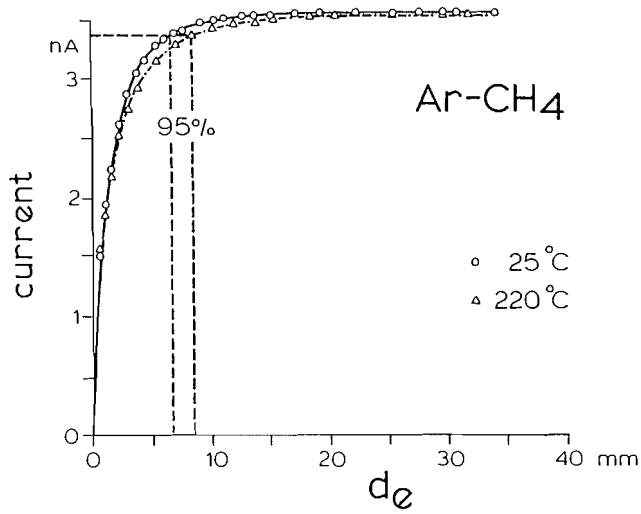

FIG. 10. Ionization current plot for argon/5% methane at two temperatures.

measurement apparatus nor, for that matter, on the anode or the walls of an electron capture detector. For the latter, the converse is true: data from an uninterrupted distribution would have to be adjusted for scattering effects, and estimates of ion pair distributions inside the ECD would have to take into account the nature and geometry of its relevant construction elements.

If scattering effects exist, they should be most easily observable in ionization measurements with heavy metal counter-electrodes located at very short distances from the foil and light gases in between — i.e. under conditions that produce the most shallow β impacts on the most heavy targets.

Figure 9 shows a typical run of ionization current versus distance between the foil and a stainless-steel counter-electrode in nitrogen at ambient temperature and pressure. Steel is not the heaviest of metals and nitrogen not the lightest of gases — though both are typical of the ECD — and yet there occur significant scattering effects.

Most evident is how close the counter-electrode has to approach the foil before the current drops to half its maximum value. The d_e^{50} value ("e" for electrode or electrical) is only 0.8 mm, compared with the d_s^{50} of 3.8 mm from the luminescence measurement. Furthermore, the d_e^{95}/d_e^{50} ratio jumps to 8.3 — indicating that the exponential function, which the luminescence data displayed, is not applicable to the ionization measurements. Similar behaviour is exhibited by a variety of test gases under a variety of circumstances: in every case, the saturation current decreases less than expected (from an exponential point of view) at short interelectrode distances.

Figure 10 shows two of these runs, carried out in argon/methane at two temperatures. Not only do the data fail to satisfy the exponential criterion $d^{95}/d^{50} = 4.32$, but they also deviate from the expected inverse proportionality with density. At 220°C, one expects the characteristic ranges to be about 1.6 times as large as those at room temperature. However, d_e^{95} increases only by a factor of about 1.3, and d_e^{50} hardly changes.

For the d_e^{95} measurements, the increased "fly-by" of β particles in a less dense medium — i.e. their crossing the plane of a counter-electrode which is too small to intercept them — contributes strongly to the discrepancy between 1.6 and 1.3. Furthermore, d_e^{95} values rely in a crucial manner on the I_{max} measurement and hence their error limits may be rather large. A variety of additional high-temperature runs were therefore done, using nitrogen or argon/methane as carrier gases, steel or graphite as counter-electrodes, and 220 or 298°C as temperatures. They suggest that some scattering is still present at longer distances but that the predominant reason for the discrepancy is indeed a geometric artifact of the measurement technique.

The d_e^{50} measurements, however, are *not* subject to the fly-by error to any significant extent — the interelectrode distance is too small compared to the electrode dimensions for that. Also, the measurements have been carefully repeated several times with essentially the same results.

We can see only one reasonable interpretation for these results: a considerable fraction of β energy hitting the counter-electrode must be turned back into the gas phase rather than being picked up by the solid phase, thus leading to a higher ionization yield between the two electrodes. That this yield increases disproportionately as the interelectrode distance decreases is to be expected. The yield of both elastic and inelastic processes, i.e. backscattering of electrons and secondary electron emission, is strongly angle-dependent, and the average angle of incidence on the counter-electrode increases as the interelectrode gap decreases. (We are using here the conventional angle-of-incidence definition (21): A zero degree angle means perpendicular impact, a 90 deg angle means grazing the surface.)

What is somewhat surprising, however, is the lack of such backscattering effects being mentioned in literature reports (including one from our own group (7)) of β range measurements. The clear premise there is that, once a β particle hits the counter-electrode, it is "lost" — i.e. it does not contribute any further to the observed current. While this does not introduce any errors in a maximum-range measurement, it will clearly do so the larger the angle of incidence and the shorter the interelectrode distance become.

Aside from its angular dependence, a characteristic feature of electron scattering and secondary electron emission is their increase with the atomic number of the scattering medium. This can, in fact, serve as an easy test for the presence of scattering. If several counter-electrodes of the same shape but different material are used, the electrodes with higher atomic numbers should be better able to scatter, elastically and inelastically, the β particles. Hence they should lead to shorter d_e values. (Analysts who electroplate the conducting inner surfaces of their ECD's with gold to reduce analyte decomposition may, if circumstances are right, wind up also with the benefits accruing from additional electrons and a shorter half range.)

TABLE 2. d_e^{50} values in mm with different gases and counterelectrodes[a]

Gas	Graphite [6]	Steel [26]	Lead [82]
H_2	2.3	0.6	
CH_4	1.6	0.6	
N_2	1.0	0.8	0.5
$Ar–CH_4$	1.0	0.9	0.5

[a]Atomic number in square brackets.

Indeed, counter-electrodes made of graphite (atomic number 6), steel (ca. 26), and lead (82) clearly demonstrate the expected effect. As shown in Table 2 for various gases (and as expected), the difference in scattering between materials of low and high atomic number shows up best in a light gas like hydrogen. (While graphite with its lower scattering power leads to half-range values that reflect the expected decrease with increase in gas density, steel does not. However, d_e^{95} values for steel — e.g. 17.4 mm for hydrogen, 10.4 mm for methane, and 6.6 mm for nitrogen — are less subject to scattering and do follow the expected trend.)

Though not as pronounced as in hydrogen, the effect of the atomic number of the counterelectrode material is still quite noticeable in the conventional carrier gas nitrogen, with d_e^{50} values of 1.0 mm for graphite, 0.8 mm for steel, and 0.5 mm for lead. It may be remembered at this point that the earlier measurement of the "centre-of-ionization" by (extrapolated) impedance matching was done with a similar steel arrangement and yielded a similar value, namely ca. 1 mm (7). This value is also in essential agreement with the (steady-state, we presume) measurement of a 1 mm half range in front of a mass spectrometer aperture by Grimsrud and Connolly (3). Using their data, Grimsrud and Connolly further calculated the ion pair generation rate and distribution in a cylindrical geometry. In view of β backscattering and other effects, it would be most interesting to obtain experimental verification of their results. Unfortunately, measurements of cylindrical geometries are inherently more difficult to carry out than those of parallel plates.

One may note that, at an interelectrode gap of 1 mm, border effects such as β particle fly-by are minimized and the system approaches the performance of an infinitely large parallel-plate geometry. It should be further noted that the atomic number of graphite used in the electrical measurement and the (average) atomic number of the scintillator plastic used in the luminescence measurement, differ only by a factor of two — yet the half ranges were measured as 1 mm and 3.7 mm, respectively. This strongly suggests that some backscattering must have occurred on the scintillator at short distances and that (though in part offset by errors in extrapolation to distance zero), the measured half range of 3.7 mm must have been too large.

At longer distances, border effects become increasingly important. Also, the average angle of incidence decreases and with it the scattered β particle fraction. Hence one would expect the d_e^{50} values to be more dependent on counter-electrode density than the d_e^{95} values. Figure 11 demonstrates that this is indeed so. Arguments can be made along similar lines in order to explain the somewhat smaller temperature dependence observed with denser electrodes as well as the fact that (as for instance shown in Fig. 10) the temperature dependence decreases with decreasing interelectrode gap.

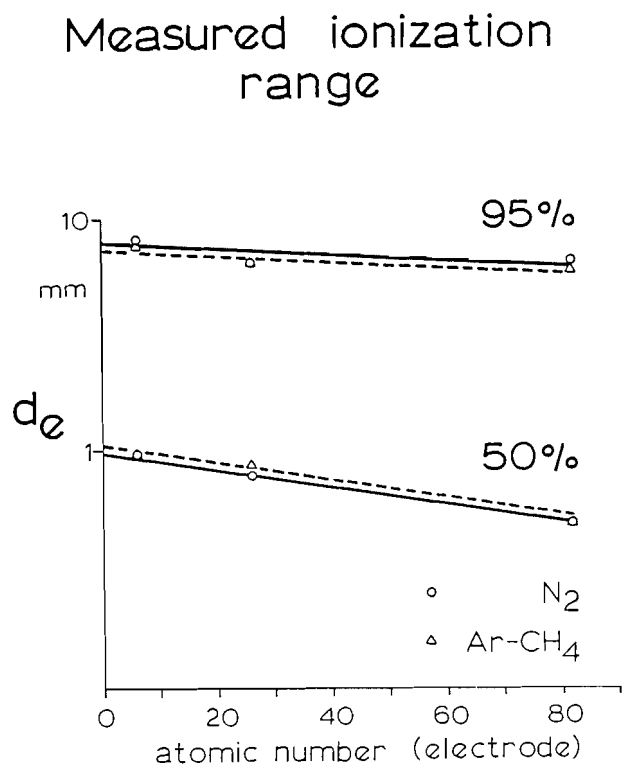

FIG. 11. Variation of d_e^{50} and d_e^{95} values with atomic number of graphite, steel, and lead counter-electrodes, for nitrogen and argon/5% methane at ambient conditions.

These scattering effects make for an interesting dilemma. Clearly, they represent an artifact of the measurement technique, and hence an annoying bias as far as the measurement of "true" β ranges is concerned. Yet, the important characteristic one wishes to establish for an ECD is the distribution of charges *within that particular detector*. Thus it may be that the present ionization measurement, however crude and fraught with dependence on geometry, is actually more relevant to conventional detector construction and function than a precise knowledge of unimpeded β topography.

Scattering could prove not only relevant but also helpful to the ECD. A case in point: ^{63}Ni is used in ECD's because of its superior thermal and chemical stability; yet some properties of the earlier favorite tritium — e.g. a shorter range allowing a smaller detector design — would still be useful to have. As a matter of speculation, then, one could perceive of, for example, a gold-plated screen or perforated plate that would be of slightly larger size than, and be located parallel to and about 1 mm away from, a ^{63}Ni foil. This screen would be designed to intercept most β particles but pass most secondary electrons (given a suitable potential). In effect, this arrangement could drastically reduce and unify the β range and allow, for instance, the construction of a relatively compact, *parallel-plate* ^{63}Ni-ECD. A *constant* β range, i.e. one essentially independent of carrier gas and temperature, could be used to advantage in a variety of scientific problems, not all of which need necessarily be related to the electron capture detector.

In retrospect, one may also note that scattering effects did most likely help the earlier "centre-of-ionization" measurement to succeed. As mentioned before, the matching of impedances — i.e. determining the interelectrode distance at which the impedances for regular and reversed electrical field became

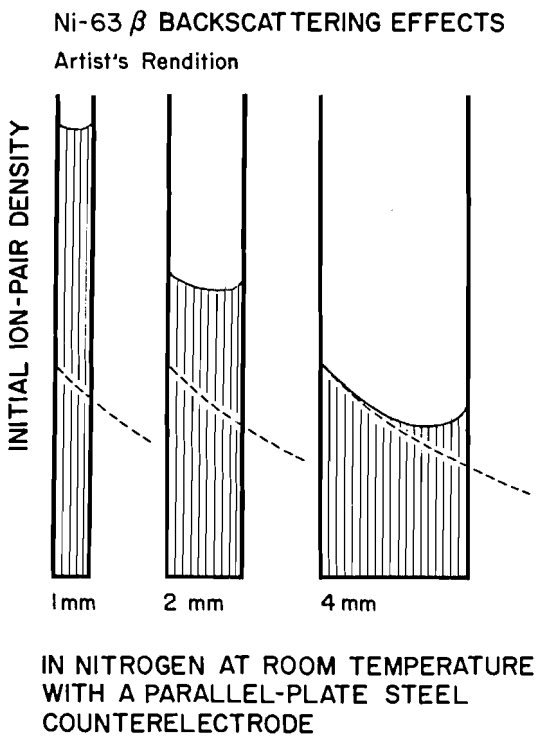

FIG. 12. Artist's rendition of β-induced ion-pair density under scattering conditions in a parallel-plate ECD with adjustable steel counter-electrode at three different interelectrode distances in nitrogen. Unimpeded ion-pair distribution indicated by dashed line. See text for explanation.

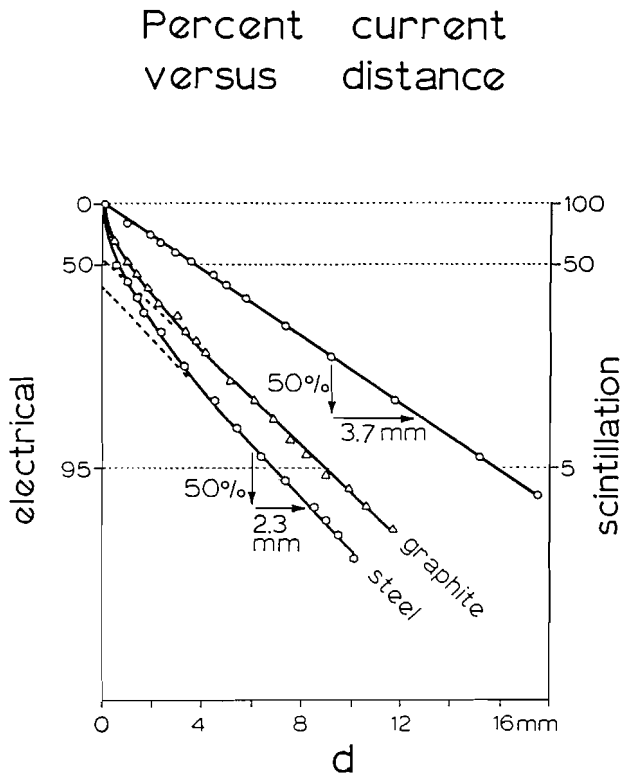

FIG. 13. Ionization current and photomultiplier current plots in semi-logarithmic format for nitrogen at ambient conditions. See text for explanation.

equal — did require some extrapolation. In fact, without scattering those two impedances could have never become quite the same: on the average, it would always be easier for the impedance-determining cations to drift to the foil than to the counter-electrode. However, backscattering from the latter does create additional cations (and electrons) in its immediate vicinity. When the electrodes are in close proximity to each other, one could visualize between them an almost homogeneous plasma (in the absence of an electric field). As a matter of ancillary interest, this is portrayed — with the help of data from ionization plots but still remaining highly speculative in its details — in the "artist's rendition" of Fig. 12.

Given the essential correctness of this rendition, it points to yet another use to which scattering effects can be put. With closely spaced electrodes, an ECD could indeed assume a fairly homogeneous initial ion-pair distribution. Such an ECD could approach, as closely as appears possible, the homogeneous (stirred-reactor) state preferred by kineticists. In addition, it would meet both conditions for ECD response according to the classical theory (5, 10): A high concentration of electrons for effective electron capture; and a high concentration of cations to allow — via the preferential neutralization of analyte-derived anions — the capture effect to be observed.

Comparison of luminescence and ionization results

The luminescence data follow an exponential relationship and can be used directly as an ion-pair density profile. The ionization data do not, but can be converted to the same format for the ease of comparison by plotting them as percent of maximum current. Figure 13 shows such a plot for nitrogen at room temperature, with two ionization profiles for graphite and steel counter-electrodes on the left and a luminescence profile on the right. (Additional ionization profiles for different gases and a steel counter-electrode are given in Fig. 14.)

The plots of Fig. 13 are normalized in the sense that all start from the same point at interelectrode distance zero: the ionization profiles with zero electrical current, the luminescence profile with (extrapolated) maximum photomultiplier current. Both ordinates list the respective currents as percent of maximum.

As discussed before and as expected, the ionization data show distinctive evidence of scattering while the luminescence data show little if any. (Note, however, the evidence of Fig. 6 where the low-density gases hydrogen and helium allow a closer inspection.) Scattering by the counter-electrode leads to a shorter half range, and scattering by the scintillator to a longer one. Thus, if one were to estimate the extent of scattering at small distances and deduct it from the data, the ionization profiles would become linear (as suggested by the dashed lines) and move up (by virtue of the normalization). The luminescence profile would, perhaps, show a slightly steeper slope — and the three plots would move closer together.

Even with all these adjustments made, however, the ionization and the luminescence curves are not likely to coincide. The primary reason for this is the difference in target areas between the plastic scintillator and the counter-electrodes. Secondary (and minor) reasons could be the differently dimensioned cells and the, perhaps, not exactly proportional ionization and luminescence yields.

The ionization profiles show a quasi-exponential (i.e. in Fig. 13, linear) region at longer distances from the foil. There,

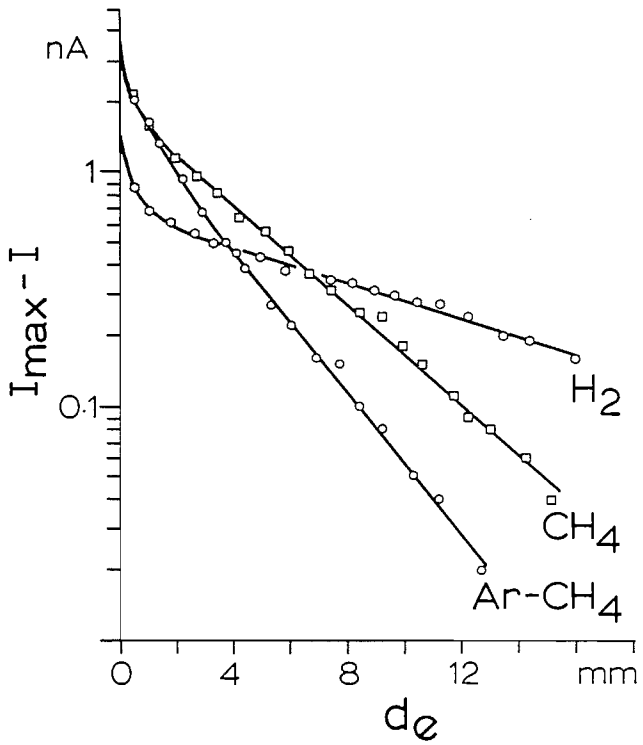

FIG. 14. Semilogarithmic plots of ($I_{max} - I$) versus d_e for three gases with steel counter-electrode under ambient conditions.

a 50% drop in current corresponds to ca. 2.2 mm for steel and 2.5 mm for graphite counter-electrodes. Taking scattering and geometric arguments into account, it seems reasonable to suggest that the "true", unimpeded β distribution would have a half range d^{50} between the 2.5 mm for ionization and the 3.8 mm for luminescence measurements, but would lie very close to the latter.

Further measurements that would eliminate much of the geometric bias and some of the scattering (but would move the apparatus farther away from resembling an ECD) could be made with an "infinite plate" counter-electrode — consisting, for instance, of a low-density, conductive plastic. However, as far as the ECD is concerned, this is not really necessary: the experimental numbers are already close enough to serve as a reasonable base for future calculations and simulations.

Yet, it bears stressing that a real-life ECD — depending on the shape of the foil and its surroundings — may have a very different (and non-exponential) initial ion-pair distribution. When scattering effects prevail, this distribution is likely to be steeper, i.e. the half range is likely to be shorter, than the one found with unimpeded β particles.

Appendix 1

If the photomultiplier current truly reflects the energy of the β particles entering the scintillator, the residual β energy E, arriving per second on the scintillator, can be represented as

[1] $E = E_0 \exp(-k' d_s)$

where E_0 is the maximum β energy available. Since the average energy spent in creating an ion pair is fairly independent (12) of the energy of the ionizing β particle, N^i, the number of ion pairs created per second in the gas volume between the foil and the scintillator (i.e. from $d_s = 0$ to d_s) is given by

[2] $N^i = w(E_0 - E)$

where w is a constant. Substituting [1] into [2] yields

[3] $N^i = wE_0[1 - \exp(-k' d_s)]$

The local ion-pair generation rate N (ion pairs created per second per unit length) at d_s can be found by differentiating N^i with respect to d_s

$$N = dN^i/d(d_s)$$

[4] $N = wE_0k' \exp(-k' d_s)$

[5] $N = N_0 \exp(-k' d_s)$

where $N_0 = wE_0k'$ is the ion-pair generation rate adjacent to the foil. Thus the initial ion-pair generation rate or, differently

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

expressed, the initial ion-pair distribution drops off exponentially with increasing distance from the foil.

Furthermore, from [4], the total number of ion pairs created per second, N_{inf} from $d_s = 0$ to d_s = infinite, can be calculated as

$$[6] \quad N_{inf} = \int_0^\infty dN^i = \int_0^\infty N d(d_s)$$

Substituting [5] into [6]

$$N_{inf} = N_0 \int_0^\infty \exp(-k' d_s) d(d_s)$$

$$[7] \quad N_{inf} = N_0/k'$$

However,

$$[8] \quad N_{inf} = I_{max} \times 6.023 \times 10^{23}/96500$$

where I_{max} is the maximum current available from the foil. Therefore, the initial ion-pair distribution is calculable if I_{max} and k', two measurable parameters, are known.

Cyclic single drop square wave polarography at spherical electrodes — the reversible case

LOUIS RAMALEY[1] AND WEE TEE TAN[2]

Trace Analysis Research Centre, Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received November 5, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

LOUIS RAMALEY and WEE TEE TAN. Can. J. Chem. **65**, 1025 (1987).

The influence of electrode sphericity and the results of sweep reversal are examined for square wave voltammetry and the square wave polarography in which an entire polarogram is obtained on a single drop. An expanding sphere treatment obtained by adding a spherical correction to expanding plane theory gives the best fit to the experimental data. Amalgam forming reactions fit the simple theory developed to a lesser extent than other reactions, especially on the reverse sweep. The shape of the differential polarogram is not significantly affected by sphericity and the reverse peak potential is approximately equal to the forward peak potential. Small differences in these potentials are due to the distortion of the square wave by the stairstep used for the sweep and the distortion of the polarogram due to drop growth. The ratio of the forward and reverse peak currents depends on the phasing of the square wave and stairstep in all cases and on other parameters for a growing drop.

LOUIS RAMALEY et WEE TEE TAN. Can. J. Chem. **65**, 1025 (1987).

On a examiné l'influence de la sphéricité de l'électrode et les résultats de l'inversion du balayage sur la voltamétrie à onde carrée et sur la polarographie à onde carrée dans lesquels le polarogramme complet est obtenu sur une goutte unique. Le meilleur accord avec les données expérimentales est obtenu en utilisant un traitement de sphère en expansion, qui est obtenu par l'addition d'une correction sphérique à la théorie du plan en expansion. Les réactions qui conduisent à un amalgame se produisent à un degré moindre que les autres réactions, principalement lorsqu'on renverse la balayage, et elles peuvent être expliquées par la théorie simple qui a été développée. La forme du polarogramme différentiel n'est pas affectée d'une façon importante par la sphéricité et le potentiel maximum de la réaction inverse est approximativement égal au potentiel maximum de la réaction normale. Les petites différences observées dans ces potentiels sont dues à la distortion de la vague carrée par les échelons utilisés pour le balayage ainsi qu'à la distortion du polarogramme qui est causée par la croissance de la goutte. Le rapport des courants maxima normaux et inverses dépend de la phase de la vague carrée et de l'échelon dans tous les cas et sur d'autres paramètres d'une goutte qui croît.

[Traduit par la revue]

Introduction

Until recently the ability to perform pulse electrochemical experiments at high sweep rates was limited to laboratories possessing rather specialized, lab-built equipment. The advent of new, commercial instrumentation (Bioanalytical Systems, Inc., and EG&G Princeton Applied Research) has altered this situation, leading Osteryoung and Osteryoung (1) to predict that square wave voltammetry (SWV) will become widely applied both for mechanistic studies and chemical analysis. In SWV a stationary test electrode is employed and the potential excitation waveform consists of a square wave of peak-to-peak amplitude ΔE and half-period τ superimposed on a staircase wave of step height E_s and length 2τ, as shown in Fig. 1. With the new instrumentation the step length can be in the low millisecond range, providing sweeps rapid enough to be carried out on a single drop at a dropping mercury electrode (dme). This latter experiment is referred to as single drop square wave polarography (SDSWP).

Drake *et al.* (2) have indicated that cyclic differential pulse voltammetry (DPV), where the sweep direction is reversed one or more times during the experiment, might be very useful in the study of electrode processes and in chemical analysis. Several experimental examples were presented. SWV may be looked upon as a special case of DPV in which the pulse waveform has a 50% duty cycle. Thus DPV and SWV will have many of the same characteristics. Gajda and Horák (3) applied a square wave superimposed on a linear sweep to a dme with a long drop time (100 s) and obtained low analytical detection limits. They reversed the sweep in some of their work but did not systematically study the effect of this reversal. Okamoto (4) first derived a theory for cyclic SDSWP assuming a small amplitude (<10 mV) square wave superimposed on a triangular sweep. The slow scan limit, an assumption that the linear sweep is too slow to distort the square wave, was implicit in his work. Theory and experiment agreed better on the forward than on the reverse sweep. All told, very little has been published on cyclic pulse voltammetry.

Recently interest has revived concerning the effect of electrode geometry on current–voltage curves. Some time ago a paper by Beigler and Laitinen (5) showed that the assumption of plane geometry for spherical electrodes led to errors under certain conditions when determining kinetic parameters from faradaic impedance measurements. This led to a series of papers by Smith and his group (6–10) on the effect of sphericity in first and second harmonic ac polarographic experiments. This has special relevance to reactions at mercury electrodes since these electrodes are almost always spherical. Somewhat later Bond *et al.* (11, 12) discussed the effect of electrode sphericity on the results of first and second harmonic ac voltammetry, considering the cases where the product of the reaction is soluble in solution and in the mercury electrode. More recently Bond and Oldham (13) have analyzed the behaviour of potential step experiments at spherical electrodes and concluded that distortions occur in the current–voltage curves (*vis-a-vis* those at planar electrodes) even for simple, reversible reactions. Myland and Oldham (14) and Tokuda *et al.* (15), and Myland *et al.* (16) came to the same conclusion in the cases of linear sweep voltammetry and cyclic voltammetry, respectively.

Using a perturbation approach involving the inverse of the electrode radius as the perturbation parameter, Goodisman (17) has formulated a general theory for spherical corrections in the voltammetry of nernstian systems. For the case of SWV, O'Dea

et al. (18) and Whelan *et al.* (19) have noted that the shape of the voltammogram for differential or net current (the normal display) was unaffected by electrode radius for disk electrodes. Thus edge effects appeared to play little role in this regard. Finally Aoki *et al.* (20) have derived equations assuming the small amplitude limit ($n\Delta E < 10$ mV) for square wave voltammograms at electrodes of various geometries for reversible reactions. Their results indicate that the shape of the differential voltammogram should be independent of electrode geometry. This is in contrast to the current–voltage curves for normal pulse polarography (13) and linear sweep voltammetry (14–16).

In this paper we present a theoretical treatment for SWV and SDSWP at spherical electrodes which makes no assumption regarding either square wave amplitude or sweep rate. Results are given for both instantaneous and average current, the latter being the normal method of data measurement in chemical analysis. The treatment is extended to include sweep reversal. Theory and experiment are compared for systems in which the product is soluble both in solution and in the electrode, but the theory is strictly applicable only to the solution soluble case for reversible electrochemical reactions.

Theory

In the following it will be assumed that the elctrode reaction

[1] $\quad O + ne \rightarrow R$

is reversible, that diffusion is semi-infinite, that R is not present before the experiment, and that R is soluble in solution rather than in the electrode. Under these conditions the theory for the instantaneous current flowing to a stationary, planar electrode has been presented at various levels of sophistication (21–23). The method used by Rifkin and Evans (23) for pulse methods is quite general and provides results for any sequence of pulses with no restrictions on time symmetry or amplitude. Ramaley and Tan (24) have extended the treatment to include the expanding plane geometry and both average and instantaneous current. For the case of a stationary spherical electrode, presented in detail in the appendix, a general equation is developed for any pulse sequence. However, in the discussion to follow only the square wave pulse sequence will be examined because this waveform symmetry allows simpler nomenclature and because it is the most useful analytically (1).

For instantaneous current measurement, the measurement will be made at a constant fraction, β, of the square wave half-period, τ, where

[2] $\quad 0 \leq \beta \leq 1$

For average current measurement, which requires gated integration over a constant time period, integration will start at a fixed fraction, β_a, of τ and cease at a second fixed fraction, β_b, where

[3] $\quad 0 \leq \beta_a < \beta_b \leq 1$

The potential of the jth half-cycle of the pulse sequence is given by

[4] $\quad E_j = E_i + \text{Int}\,([j-1]/2)E_s + (-1)^j\Delta E/2$

where E_i is the potential applied before the pulse sequence begins and the term Int $([j-1]/2)$ represents the greatest integer not exceeding $[j-1]/2$.

In SWV and SDSWP the normal procedure is to establish the phase of the square wave such that at the time of the stairstep, the pulse potential changes in the same direction as the stairstep, as depicted in Fig. 1. The current that flows on the first half-cycle after the step is referred to as the forward current

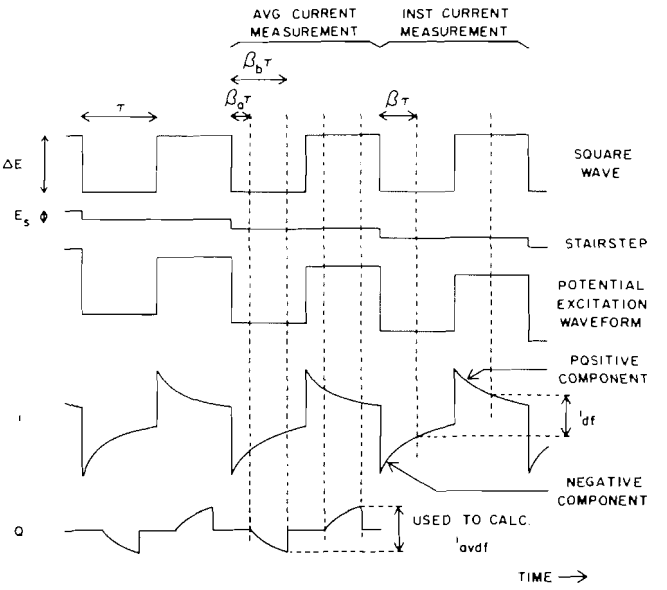

FIG. 1. Potential, current, and charge waveforms used and observed in SWV and SDSWP.

and that on the second as the reverse current. The difference between these two currents, the differential or net current, provides the current–voltage curve normally associated with these techniques. This paper will deal with sweep reversal in which it is customary to designate the current before reversal as the forward current and that after as the reverse current. Some confusion may arise due to the various meanings of forward and reverse current. Hereafter, forward current will signify that flowing on either half-cycle of the square wave before sweep reversal, the reverse current to that flowing after reversal. The negative current component will refer to the current flowing on the negative half-cycle of the square wave and the positive component to that flowing on the positive half-cycle, regardless of the manner of synchronizing the square wave and stairstep. The usual electrochemical convention that cathodic current is positive will be observed. The waveforms in Fig. 1, however, depict the current and charge as these are measured experimentally.

The differential current is obtained from the individual negative and positive current components using

[5] $\quad i_{df} = i_{j-1} - i_j \qquad$ with $j = 2, 4, 6, \ldots$

The following are useful in simplifying the equations for the various cases and geometries:

[6] $$Q_j = \frac{\exp\,[(E_j - E_{1/2})nF/RT]}{1 + \exp\,[(E_j - E_{1/2})nF/RT]}$$

[7] $\quad E_{1/2} = E^{0\prime} + (RT/2nF)\ln\,(D_R/D_O)$

where $E^{0\prime}$ is the formal potential for reaction [1], D_R and D_O are the diffusion coefficients of R and O, respectively, and the other symbols have their usual meanings,

[8] $\quad G = nFAD_O^{1/2}C^*/\pi^{1/2}\tau^{1/2}$

where A is the electrode area and C^* is the concentration of O in the bulk of solution, and

[9] $\quad H_k = (j - k + \beta)^{1/2}$

[10] $\quad H_k^a = (j - k + \beta_a)^{1/2}$

[11] $\quad H_k^b = (j - k + \beta_b)^{1/2}$

The equations for the currents flowing to a stationary, planar electrode on the jth half-cycle of the square wave are (21–24):

$$[12]\quad i_p = G\sum_{k=1}^{j}(Q_{k-1} - Q_k)/H_k \qquad \text{(inst. current)}$$

$$[13]\quad (i_p)_{av} = \frac{2G}{(\beta_b - \beta_a)}\sum_{k=1}^{j}(H_k^b - H_k^a)(Q_{k-1} - Q_k) \qquad \text{(avg. current)}$$

$$[14]\quad (i_p)_{df} = G\sum_{k=1}^{j}(Q_k - 2Q_{k-1} + Q_{k-2})/H_k \qquad \text{(diff. inst. current)}$$

$$[15]\quad (i_p)_{avdf} = \frac{2G}{(\beta_b - \beta_a)}\sum_{k=1}^{j}(H_k^b - H_k^a) \times (Q_k - 2Q_{k-1} + Q_{k-2}) \qquad \text{(diff. avg. current)}$$

and those for currents flowing to a stationary, spherical electrode are (see Appendix):

$$[16]\quad i_s = i_p + \frac{nFAD_OC^*}{r_0}(1 - Q_j) \qquad \text{(inst. current)}$$

$$[17]\quad (i_s)_{av} = (i_p)_{av} + \frac{nFAD_OC^*}{r_0}(1 - Q_j) \qquad \text{(avg. current)}$$

$$[18]\quad (i_s)_{df} = (i_p)_{df} + \frac{nFAD_OC^*}{r_0}(Q_{j-1} - Q_j) \qquad \text{(diff. inst. current)}$$

$$[19]\quad (i_s)_{avdf} = (i_p)_{avdf} + \frac{nFAD_OC^*}{r_0}(Q_{j-1} - Q_j) \qquad \text{(diff. avg. current)}$$

where r_0 is the radius of the electrode and Q_0 and Q_{-1} are both unity. Equations [12]–[19] may be applied to a dme with varying degrees of approximation by using the following substitution for the electrode area

$$[20]\quad A = (36\pi)^{1/3}(mt'/\rho)^{2/3}$$

where t' is the time from the beginning of drop life, m is the mass flow rate of mercury, and ρ is the density of mercury.

For comparison the equations for the expanding plane theory as applied to a dme (24) are shown below:

$$[21]\quad i_{xp} = (7/3)^{1/2}(36/\pi^{1/2})^{1/3}nF(m/\rho)^{2/3} \times [t_d + (j - 1 + \beta)\tau]^{4/3}D_O^{1/2}C^*\left\{\sum_{k=1}^{j}(Q_{k-1} - Q_k)\Big/ ([t_d + (j - 1 + \beta)\tau]^{7/3} - [t_d + (k - 1)\tau]^{7/3})^{1/2}\right\} \qquad \text{(inst. current)}$$

$$[22]\quad (i_{xp})_{av} = \frac{(12/7)^{1/2}(36/\pi^{1/2})^{1/3}nF(m/\rho)^{2/3}D_O^{1/2}C^*}{(\beta_b - \beta_a)\tau} \times \sum_{k=1}^{j}\{([t_d + (j - 1 + \beta_b)\tau]^{7/3} - [t_d + (k - 1)\tau]^{7/3})^{1/2} - ([t_d + (j - 1 + \beta_a)\tau]^{7/3} - [t_d + (k - 1)\tau]^{7/3})^{1/2}\} \times (Q_{k-1} - Q_k) \qquad \text{(avg. current)}$$

where t_d is the time between the beginning of drop life and the start of the experiment. The equations for the differential current do not simplify to any extent after appropriate substitution of [21] or [22] into [5] and so are not listed.

Experimental

A conventional three-electrode operational amplifier potentiostat interfaced to and controlled by a minicomputer was used to obtain data. A potentiostat almost identical to that employed has been described elsewhere (25, 26). The computer system, which was also used to perform the theoretical calculations, consisted of a Hewlett-Packard 21MX-M minicomputer with a magnetic tape operating system.

Unthermostated borosilicate glass cells of 20 mL capacity were employed. A conventional saturated calomel electrode (sce) was connected to the cell through a side arm filled with supporting electrolyte. The dme consisted of a 10 s capillary sealed above a 6 mm soft glass tube which was in turn drawn to a fine tip. Electrical contact was made through the soft glass tube below the capillary. This arrangement avoids the shielding and capillary resistance of the normal dme. No drop dislodging device was employed; the breaking of a light beam by the free falling drop signalled the beginning of a new drop and was used to synchronize the sweep electronics. All measurements were carried out between 23 and 25°C.

All chemicals were reagent grade and were used without additional purification except KCl which was crystallized once from distilled water. Cadmium(II) in a 1.00 *M* KCl medium was employed as an example of an amalgam forming system and Fe(III) in 0.500 *M* $K_2C_2O_4$ at pH 5.0 served as an example in which both halves of the redox couple are soluble in solution. Stock Fe(III) solutions were prepared by oxidation of the iron in $Fe(NH_4)_2(SO_4)_2\cdot 6H_2O$, taken as a primary standard, with concentrated nitric acid; Cd(II) solutions were prepared from $Cd(NO_3)_2\cdot 4H_2O$ and were standardized by EDTA titration. Laboratory distilled water was run through activated charcoal and distilled once more from an all-glass still before use.

Results and discussion

Results derived from theory

As seen from eqs. [16]–[19], the current flowing to a spherical electrode can be visualized as that flowing to a planar electrode plus an additional term or "correction" for sphericity. For the individual current components the spherical term is the same as that for a single pulse or step (13) and is the result predicted by the general voltammetric treatment of Goodisman (17). This term is a function only of the applied potential, E_j (through Q_j), and does not depend on time or any previously applied potentials. Since Q_j is unity when E_j is positive to $E_{1/2}$, the spherical term will be maximum at negative potentials and will disappear as the potential returns to its initial value in a cyclic experiment.

The magnitude of the spherical term relative to the planar term will depend on r_0, β or β_a and β_b, and τ (sweep rate), increasing with decreasing r_0 and increasing β and τ. The latter occurs because the spherical term is independent of β and τ and the planar term decreases with increasing β and τ. Sphericity will have a larger effect on average current measurements, again because the spherical term is unaffected by integration whereas the planar term usually decreases when integration is employed.

For differential or net current, the spherical term depends on $(Q_j - Q_{j-1})$ or ΔE. Thus if ΔE is small ($n\Delta E < 10$ mV), this term will be much smaller than that for the individual current components and may be considered negligible, as proposed by Aoki *et al.* (20). Since dQ/dE is maximum at $E_{1/2}$ and falls to zero on either side of $E_{1/2}$, the differential spherical correction will be maximum at and symmetrical about $E_{1/2}$. Even for large ΔE, the spherical term will be smaller for net current than for individual current and will distort the net current–voltage curve much less. This line of reasoning can be applied to any geometry (20) where the current can be represented as the sum of a planar term and a time independent geometrical "correction".

Typical values of the relative spherical correction for differential current are presented in Table 1. The insensitivity of the

TABLE 1. Relative spherical corrections in SWV*

10	2	0.2
10	0.0625	1.0
50	0.0625	1.1

*r_0 = 0.45 mm, E_s = −2 mV, n = 2, D_0 = 1 × 10^{-5} cm^2/s, T = 25°C, β_a = 0.5, β_b = 1.

correction to the magnitude of ΔE is explained by noting that an increase in ΔE causes increases in both the planar and spherical terms to approximately equal extents, leaving the relative correction almost unchanged.

The discussion above is strictly applicable only to the case where O and R share the same diffusion space and $D_O = D_R$. However, it should be a good approximation as long as $D_O \cong D_R$, the usual case experimentally. Brydon and Oldham (27) have shown that using a mean value for the diffusion coefficients when $D_O \cong D_R$ leads to the mathematical result that the surface concentrations of O and R are a function only of potential. This supports the soundness of the approximation. For amalgam forming reactions O and R do not share the same diffusion space and the approximation is much worse, regardless of the values of D_O and D_R.

Equations [12]–[19], [21], [22] assume a fixed time symmetry (50% duty cycle) but make no restrictions on pulse amplitude or direction. Thus the theory does not have to be extended to include sweep reversal. The reversal potential, E_λ, is given by

$$[23] \quad E_\lambda = E_i + \text{Int}([\lambda - 1]/2)E_s$$

where λ is the value of j, taken as even, at which reversal takes place. Prior to reversal eq. [4] is used to calculate E_j and after reversal the following may be used

$$[24] \quad E_j = E_\lambda - \text{Int}([j - \lambda + 1]/2)E_s + (-1)^j \Delta E/2$$

A cyclic square wave voltammogram for a reduction at a stationary spherical electrode is shown in Fig. 2. As expected, the forward and reverse peak potentials for the differential current appear to be the same; however, the reverse peak current is lower than the forward peak current. It was first pointed out by Ramaley and Krause (21) that the stairstep must distort the square wave on which it is superimposed. For example, a −2 mV stairstep synchronized with the positive pulse of a 10 mV square wave produces an 8 mV positive step and a 10 mV negative step, averaging 9 mV per step. Christie *et al.* (22) pointed out that sensitivity increased if the stairstep and square wave were synchronized such that both steps occurred in the same direction (as in Fig. 1). For the E_s and ΔE values above, a 10 mV positive and 12 mV negative step, averaging 11 mV, would result from this phasing. Although correct, this comment on phasing is somewhat academic since differences in phasing can be offset by changes in ΔE to produce exactly the same results (e.g. a 12 mV ΔE will produce the same current with the first phasing above as the 10 mV ΔE does with the second), indicating that synchronization is not important in achieving higher sensitivity.

The reverse current in Fig. 2 is lower than the forward current because the negative stairstep and negative pulse are synchronized together on the forward sweep, but on the reverse sweep the stairstep is positive, though still synchronized with

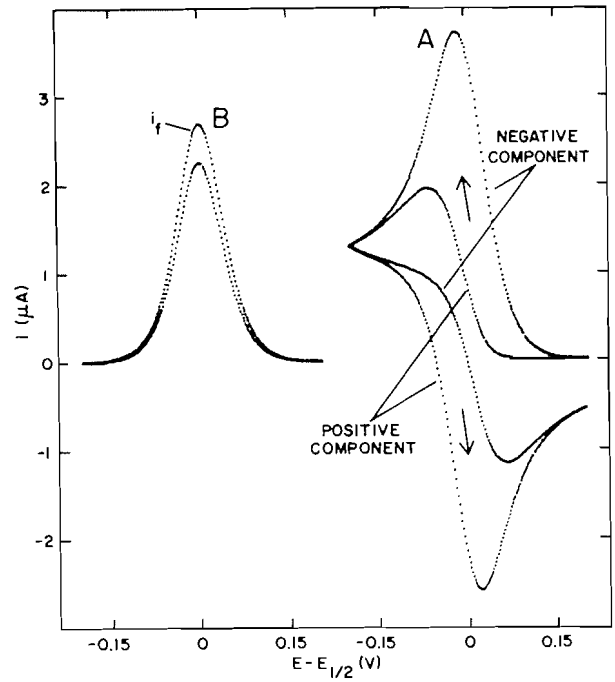

FIG. 2. Cyclic square wave voltammograms at a spherical electrode. Synchronization scheme [24], *A*, individual currents, *B*, differential current, E_s = −2 mV, ΔE = 10 mV, n = 1, r_0 = 0.5 mm, β_a = 0.5, β_b = 1, D_O = 1 × 10^{-5} cm^2/s, C^* = 1 × 10^{-4} M, sweep rate = 1 V/s, T = 25°C.

the negative pulse. This may be overcome by extending the stairstep at E_λ to a time equal to 3τ, synchronizing the positive stairstep with the positive pulse. For this case

$$[25] \quad E_j = E_\lambda - \text{Int}[j - \lambda]/2)E_s + (-1)^j \Delta E/2$$

after reversal. Figure 3 shows the voltammograms obtained for this synchronization. The reverse differential current is now

*Same conditions as in Table 1, except sweep rate = 1 V/s.

slightly larger than the forward current. When this current is computed using eq. [25] with j even, the individual currents used in the calculation occur across a potential step of ΔE for the forward sweep and $(\Delta E + E_s)$ for the reverse sweep. This causes the calculated differential current in the reverse sweep to be slightly larger. For the same reason, the spherical correction will be slightly higher in the reverse direction. If the subtraction scheme after reversal is changed so that

[26] $i_{df} = i_j - i_{j-1}$ with j odd

the two values in the calculation always occur across a step of ΔE and the forward and reverse differential currents are equal.

Peak potentials were obtained from experimental data or data generated from eqs. [12]–[19], [21], [22] by regression analysis. This is most simply done by fitting a small number of data, e.g. nine points, centred on the peak to a parabola using linear regression analysis. The peak maximum is then obtained from the parameters calculated in the analysis. Since the shape of a reversible square wave polarogram closely approximates the first derivative of the dc polarogram, especially at small ΔE, a better fit is obtained using a function of the form of that derivative. Such a function is

[27] $i = \{(4i_{pk})\exp[K(E - E_{pk})]\}/\{\exp[K(E - E_{pk})] + 1\}^2$

The parameters i_{pk}, the peak current, E_{pk}, the peak potential, and K, a constant related to the peak half-width, must be evaluated by non-linear regression analysis (28). Both methods provide the same results at high resolution ($E_s \leqq 2$ mV) but the parabolic fit degrades at lower resolution.

For a stationary spherical electrode the peak potential on both the forward, $(E_{pk})_f$, and reverse, $(E_{pk})_r$, sweeps is very close to $E_{1/2}$ at high resolution. However, as E_s is increased, the values move away from $E_{1/2}$, $(E_{pk})_f$ moving toward negative values, and $(E_{pk})_r$ moving identically for the scheme of eq. [24] and toward positive values and to a greater extent for eq. [25], as shown in Table 2. This latter shift is more apparent than real and is mainly due to the method of data handling and plotting in our computer programs. It is convenient to use the potential of the stairstep for odd j as the average electrode potential for data analysis regardless of synchronization scheme. With the scheme of eq. [24] individual current measurements are made at potentials which average to this potential both before and after reversal. When the scheme of eq. [25] is used after reversal, the stairstep occurs between the two current measurements and the average potential is offset from the assumed potential by $E_s/2$. This is approximately the difference between the values of $(E_{pk})_r$ for the two schemes.

Increasing E_s also increases any difference between $(i_{pk})_f$ and $(i_{pk})_r$ in the different schemes. These problems are worst for small ΔE, where the distortion is largest. The use of small ΔE provides the narrowest and most ideal peak shapes; however, the best values for $E_{1/2}$ are obtained using large ($\geqq$50 mV) values of ΔE.

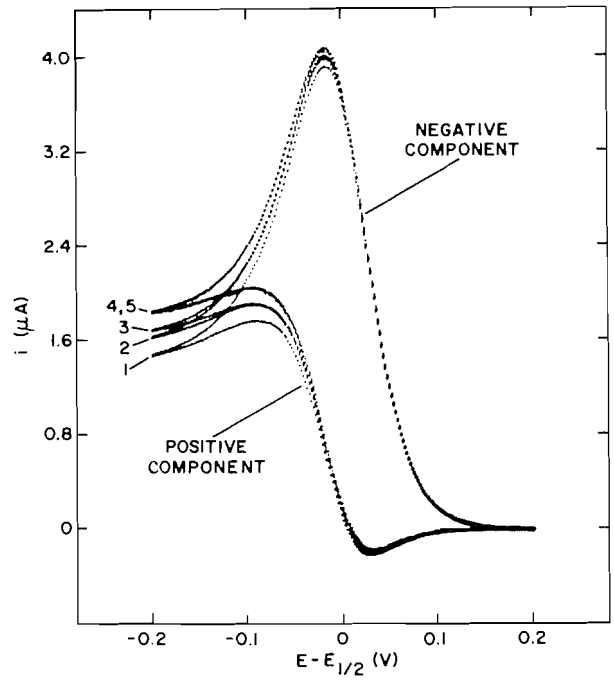

FIG. 4. Forward current components in SDSWP; *1*, planar theory; *2*, spherical theory; *3*, expanding plane theory; *4*, spherically corrected expanding plane theory; *5*, experiment; 4.00 × 10^{-4} *M* Fe(III); 0.500 *M* $K_2C_2O_4$; pH = 5.0; E_s = −2 mV, ΔE = 10 mV; sweep rate = 0.125 V/s, t_d = 0.992 s, β_a = 0.0625, β_b = 1, m = 0.001837 g/s, T = 23°C.

These phasing problems do not occur for a square wave superimposed on a linear sweep. However, the linear sweep produces a higher background due to the continuous flow of current needed to charge the double layer. This is especially evident at high sweep rates.

Experimental results with the Fe(III)/(II) system

All experimental work was done with a dme and most used the synchronizing scheme of eq. [24] after reversal. However, recently we have built an instrument (29) in which the potential excitation waveform is generated in software and the synchronizing scheme of eq. [25] can be employed. Experimental work with the two schemes agrees very well with predictions based on the theory presented above.

It has previously been shown (24) that both the planar (with the area calculated from eq. [20]) and expanding plane theories produce results which agree very well with experiment for the differential current. Differences appeared only when the individual current components were examined. This also holds true for spherical electrodes and for currents measured on the reverse sweep. All theories produce forward and reverse differential polarograms that are for all practical purposes identical to experiment. However, differences, which depend on the experimental parameters, are noted for the individual components. At high sweep rates ($\geqq$1 V/s), the electrode size changes little during the experiment and the expanding plane results are almost identical to the area corrected plane results. At large delay times, the drop is large and the spherical correction is small so that again the planar theories provide good agreement with experiment. The conditions used in obtaining the data shown in Figs. 4 and 5 were chosen such that both the drop

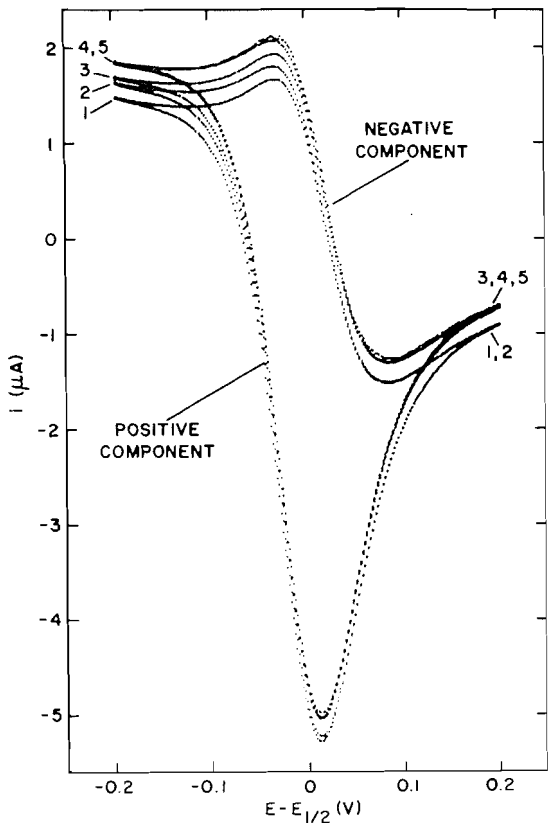

FIG. 5. Reverse current components in SDSWP. Same conditions and designations as in Fig. 4.

expansion and sphericity would cause deviations from simple area corrected planar theory.

In addition to the results of the planar, spherical, and expanding plane theories, those of a combination of expanding plane theory with a spherical correction are shown in these figures. This combination is obtained by the addition of the spherical correction term of eq. [17] to the right side of eq. [22]. Delmastro and Smith (6) noted that corrections for sphericity and expansion were almost independent of each other and that a reasonable treatment for an expanding sphere might be the combination of an expanding plane with a simple stationary spherical correction. McCord and Smith (10) later used this approach in obtaining data on quasireversible reactions using second harmonic ac polarography with good results.

A diffusion coefficient of 6.12×10^{-6} cm^2/s, which produced identical experimental and theoretical differential polarograms, was used to generate the theoretical curves of Figs. 4 and 5. This agrees well with the value of 6.31×10^{-6} cm^2/s obtained by Olmstead and Nicholson (30), but is somewhat higher than that of Myland *et al.* (31), 4.8×10^{-6} cm^2/s. This latter value was measured in 1.0 *M* $K_2C_2O_4$, whereas the concentration used in this work is 0.50 *M*.

As seen in the figures, area corrected planar theory gives the worst agreement and spherically corrected expanding plane theory the best, and quite satisfactory, agreement with experiment for both the forward and reverse sweeps. Expanding plane theory appears to be slightly superior to spherical theory, but this will depend on the experimental parameters chosen, holding only when the expansion "correction" is larger than the spherical correction. These results appear to substantiate the proposal of Delmastro and Smith (6) regarding the approximate

expanding sphere treatment. The reverse currents are larger than the forward currents mainly due to electrode expansion.

Variations in ΔE, E_λ, and the synchronizing scheme do not affect the agreement between theory and experiment. However, at higher sweep rates ($\geqq$1 V/s), even though the differential polarograms are still accurately predicted by theory, the agreement in the case of the individual components begins to degrade slightly. The cause of this is not presently known.

The positions of the peaks in and the shapes of the individual component polarograms depend on n, E_s, ΔE, and β(s) (24). However, the shapes of and the peak positions in differential polarograms depend very little on these parameters except that the peak shape is a strong function of n. Small variations in $(E_{pk})_f$ and $(E_{pk})_r$ as a function of E_s were discussed above. In addition a small difference in $(E_{pk})_f$ and $(E_{pk})_r$ was noted both for theory and experiment as a function of sweep rate, as shown in Table 3. This is unusual because (*a*) the greatest differences appear at the slowest sweep rates and (*b*) τ does not appear in the summations in eqs. [12]–[19] so that the peak potentials should not depend on τ. If the calculations are performed for stationary electrodes, the peak positions are independent of τ. Therefore the effect shown in Table 3 must be due to distortion of the polarograms by drop growth. As sweep rate increases, growth has a smaller effect on the polarogram and the effect decreases.

Much of the data taken in this study involved the averaging of the results from a number of drops, usually 16 or 25, to improve the signal-to-noise ratio. A depletion effect was sometimes noted when comparing single drop and multidrop results. The magnitude of this effect depended on the time the electrode potential was held negative to $E_{1/2}$ and was thus a function of sweep rate and reversal potential for cyclic work or final potential for linear sweep work. Decreases as large as 7% in peak current for multidrop experiments at sweep rates of 0.05 V/s were observed and thus caution should be used in sensitive experiments when averaging is employed.

Experimental results with the Cd(II)/Cd·Hg system

The data for the reduction of Cd(II) in experiments similar to those for Fe(III) are shown in Figs. 6 and 7. A value of 8.22×10^{-6} cm^2/s for D_O was needed to properly fit the data. A range of 6.8 to 7.7 $\times 10^{-6}$ cm^2/s has been reported for Cd(II) in 1.0 *M* nitrate and chloride media (13). Values of 7.3×10^{-6} cm^2/s (14) and 8.11×10^{-6} cm^2/s (15) have also recently been used for 1.0 *M* KCl electrolytes. Again the spherically corrected expanding plane approach provided the best fit to the experimental data. This fit, although not as good as with Fe(III), is satisfactory for the forward sweep. However, none of the models fit the data on the reverse sweep very

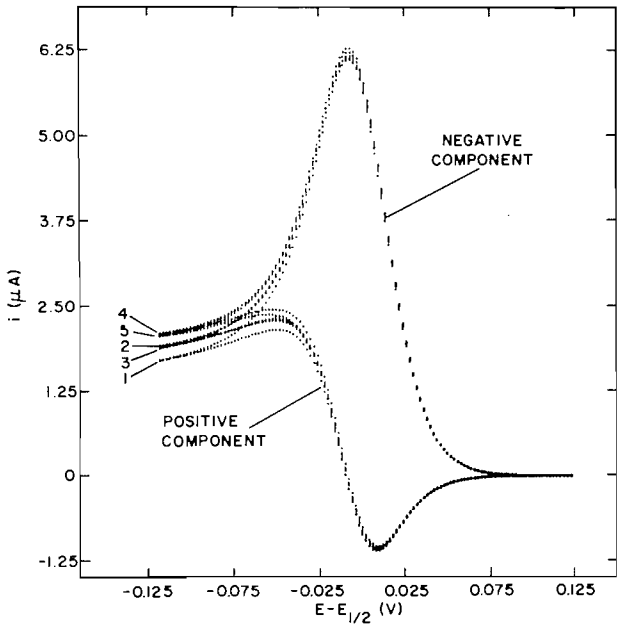

FIG. 6. Forward current components in SDSWP; 2.00×10^{-4} *M* Cd(II), 1.00 *M* KCl, other conditions and designations as in Fig. 4.

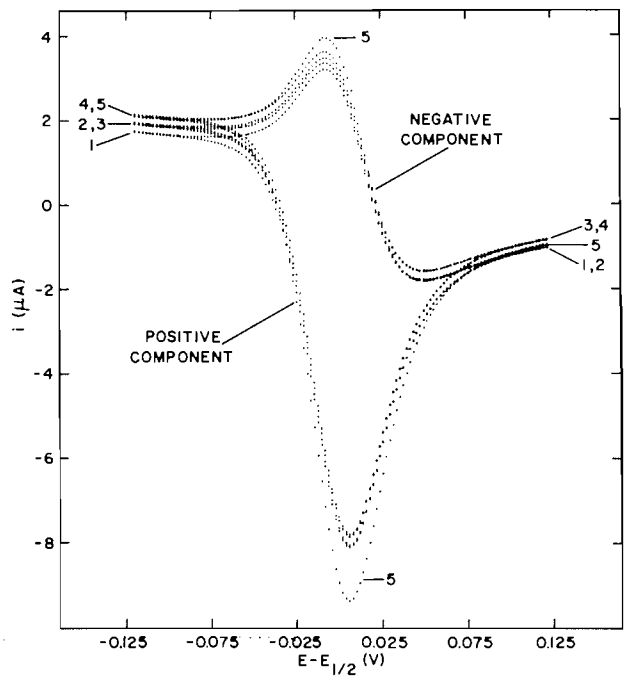

FIG. 7. Reverse current components in SDSWP. Same conditions as in Fig. 6.

well, either for individual or differential polarograms. The experimental current is invariably larger than that predicted by theory. The need for a diffusion coefficient larger than generally accepted and higher reverse currents are typical for systems involving diffusion into the mercury drop (6, 9, 12), when the theory for a solution soluble reduced species is applied.

The effect of changes in E_λ is shown in Fig. 8 for the synchronization scheme of eq. [24]. When reversal is carried out at or near $E_{1/2}$, the reverse current is smaller than the forward current as expected. However, reverse current can become considerably larger than forward current when E_λ is negative to $E_{1/2}$. For the data shown at $E_\lambda = -0.912$ V, the

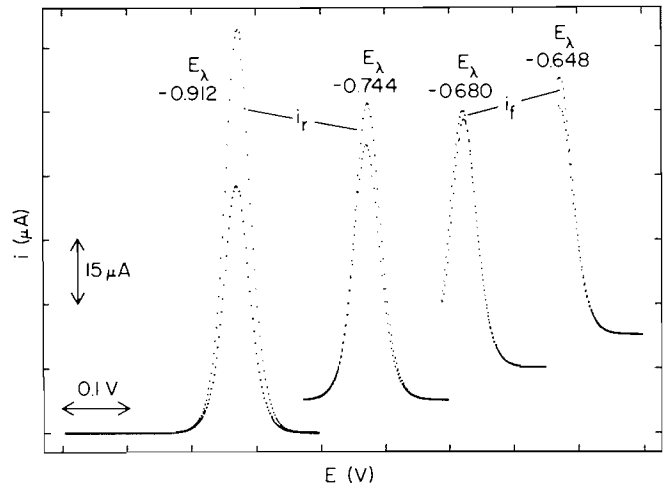

FIG. 8. Effect of reversal potential on differential polarograms. 1.00×10^{-3} *M* Cd(II), 1.00 *M* KCl, synchronization scheme [24], $E_s = -2$ mV, $\Delta E = 10$ mV, $E_{1/2} = -0.646$ V (sce), sweep rate = 0.0977 V/s, $t_d = 3.0$ s, $\beta_a = 0.125$, $\beta_b = 1$, $m = 0.00125$ g/s, $T = 23$°C.

reverse current is 63% higher than the forward current. This is due to a combination of drop growth and stripping from the spherical drop. For the reduction of Fe(III) under identical conditions where only drop growth is involved, the increase in reverse current over forward current is 33%. This phenomenon depends on sweep rate as well as reversal potential. As for ac polarography (9), amalgam formation does not affect the differential peak shape, with a half width of 90/n mV, or peak position on either the forward or reverse sweeps.

Appendix

For electrode reaction [1] Fick's second law of diffusion for spherical symmetry can be written (32)

$$[28] \quad \frac{\partial v(r,t)}{\partial t} = D_O \frac{\partial^2 v(r,t)}{\partial r^2}$$

where r is the radial distance from the centre of the electrode and

$$[29] \quad v = rC_O$$

where C_O is the concentration of the oxidized component.

The initial and boundary conditions that prevail are as follows:

$$[30] \quad C_O = C^* \qquad \text{for } t < 0$$

$$[31] \quad C_O \rightarrow C^* \qquad \text{as } r \rightarrow \infty \qquad \text{for } t \geqq 0$$

and at $r = r_0$,

$$C_O = C_1 \qquad 0 < t < t_1$$
$$C_O = C_2 \qquad t_1 < t < t_2$$
$$\vdots$$
$$C_O = C_j \qquad t_{j-1} < t$$

These can be reformulated as

$$[32] \quad C_O = \sum_{k=1}^{j} I_k C_k \qquad \text{at } r = r_0$$

where $I_1 = 1$ for $0 < t < t_1$, zero otherwise, $I_2 = 1$ for $t_1 < t < t_2$, zero otherwise, etc.

For use with the variable, v, [30], [31], and [32] become

$$[33] \quad v = v^* = rC^* \qquad \text{for } r \geqq r_0,\ t < 0$$

$$[34] \quad v \rightarrow v^* \qquad \text{as } r \rightarrow \infty \qquad \text{for } t \geqq 0$$

$$[35] \quad v = \sum_{k=1}^{j} I_k v_k \qquad \text{at } r = r_0$$

Solution is achieved by transforming [28], [33], [34], and [35] into Laplace space, where [28] becomes a simple differential equation. The resulting equation is solved for the transformed variable, $\bar{v}$, and then reverse transformed. After substitution of [29] the result is

$$[36] \quad C_O = C^* + \frac{r_0}{r}\sum_{k=1}^{j}(C_k - C_{k-1}) + \frac{r_0}{r}\sum_{k=1}^{j}(C_{k-1} - C_k)\,\text{erf}\left(\frac{r - r_0}{2D_O^{1/2}(t - t_{k-1})^{1/2}}\right)$$

where $C_{k=0}$ is C^* and $t_{k=0}$ is zero.

The Laplace transformations require the use of the unit finite impulse function or Heaviside unit function. Danielsson *et al.* (33) have questioned the use of this function (or the superposition principle) in the derivation of equations for use in pulse voltammetry. They conclude that its application is valid as long as the electrochemical system can be separated into a potential dependent part which may be non-linear and a linear part. These conditions prevail here. As usual, current is obtained from Fick's first law of diffusion

$$[37] \quad i = nFAD_O(\partial C_O/\partial r)_{r=r_0}$$

Application of [37] to [36] provides

$$[38] \quad i_j = \frac{nFAD_O^{1/2}}{\pi^{1/2}}\sum_{k=1}^{j}\frac{(C_{k-1} - C_k)}{(t - t_{k-1})^{1/2}} + \frac{nFAD_O(C^* - C_j)}{r_0}$$

As long as both halves of the redox couple are soluble in the solution, the electrode reaction is reversible, and $D_O = D_R$, the concentrations at the electrode surface are a function only of the applied potential (6) and are not influenced by prior potentials. Under these circumstances

$$[39] \quad C_k = \frac{C^*(\exp[(E_k - E_{1/2})nF/RT])}{1 + \exp[(E_k - E_{1/2})nF/RT]} = C^*Q_k$$

which leads to

$$[40] \quad i_j = \frac{nFAD_O^{1/2}C^*}{\pi^{1/2}}\sum_{k=1}^{j}\frac{Q_{k-1} - Q_k}{(t - t_{k-1})^{1/2}} + \frac{nFAD_OC^*(1 - Q_j)}{r_0}$$

Average current is obtained by applying the law of the mean to [40] resulting in

$$[41] \quad (i_j)_{av} = \frac{2nFAD_O^{1/2}C^*}{\pi^{1/2}(t_b - t_a)}\sum_{k=1}^{j}[(t_b - t_{k-1})^{1/2} - (t_a - t_{k-1})^{1/2}](Q_{k-1} - Q_k) + \frac{nFAD_OC^*(1 - Q_j)}{r_0}$$

Equations [40] and [41] are completely general in that any potential or time sequence may be applied without regard to symmetry in either sequence. When a pulse train, symmetric in time, is employed (this case includes SDSWP and SWV, among other techniques) the following equations apply:

$$[42] \quad t_{k-1} = (k - 1)\tau \qquad \text{for all cases}$$

$$[43] \quad t = (j - 1 + \beta)\tau \qquad \text{for instantaneous current}$$

$$[44] \quad t_a = (j - 1 + \beta_a)\tau \qquad \text{for average current}$$

$$[45] \quad t_b = (j - 1 + \beta_b)\tau \qquad \text{for average current}$$

On appropriate substitution of the above into [40] and [41], eqs. [16] and [17] result.

Analytical chemists and dinosaurs

Received September 28, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

R. R. BROOKS. Can. J. Chem. **65**, 1033 (1987).

The role of the analytical chemist in the development of the extraterrestrial impact theory for mass extinctions at the terminal Cretaceous Period is reviewed. High iridium concentrations in Cretaceous/Tertiary boundary clays have been linked to a terrestrial impact from an iridium-rich asteroid or large meteorite some 65 million years ago. Other evidence in favour of the occurrence of such an impact has been provided by the detection of shocked quartz grains originating from impact and of amorphous carbon particles similar to soot, derived presumably from wordwide wildfires at the terminal Cretaceous. Further evidence provided by the analytical chemist involves the determination of isotopic ratios such as $^{144}Nd/^{143}Nd$, $^{187}Os/^{186}Os$, and $^{87}Sr/^{86}Sr$. Countervailing arguments put forward by the gradualist school (mainly palaeontological) as opposed to the catastrophists (mainly chemists and geochemists) are also presented and discussed.

R. R. BROOKS. Can. J. Chem. **65**, 1033 (1987).

On présente une revue du rôle joué par les analystes dans le développement de la théorie des impacts extraterrestes sur les extinctions en masse qui se sont produites à la fin de la période crétacée. On a lié le fait que l'on retrouve des concentrations élevées d'iridium dans les argiles du limite entre les périodes crétacée et secondaire à une collision qui se serait produite il y a environ 65 millions d'années entre la terre et un astéroïde ou un gros météorite riche en iridium. D'autres indications en faveur d'une telle collision sont fournis par la détection de grains de quartz commotionnés provenant de cet impact ainsi que de particules amorphes de charbon, semblables à celles de la suie, qui pourraient provenir de feux grégeois qui se seraient produits au niveau mondial à la fin de la période crétacée. D'autres indications proviennent de résultats obtenus par les analystes lors de la détermination des rapports isotopiques $^{144}Nd/^{143}Nd$, $^{187}Os/^{186}Os$ et $^{87}Sr/^{86}Sr$. On présente et on discute aussi des arguments mis de l'avant par l'école gradualiste (principalement paléontologique) qui est en opposition à l'école des catastrophistes (principalement des chimistes et des géologues).

[Traduit par la revue]

Introduction

A famous benchmark paper by Alvarez *et al.* (1) in 1980 ushered in a new era of research (and controversy) concerning events which may have occurred on earth some 65 million years ago at the end of the Cretaceous period. One day in 1977 outside the town of Gubbio in the Italian Appennines, Walter Alvarez of the Berkeley campus of the University of California found a layer of clay that clearly marked the end of the fossil-rich Cretaceous limestone and the beginning of the fossil-poor Tertiary limestone that overlaid it. This layer corresponds to the Cretaceous–Tertiary (K–T) boundary and will be so designated in this review. Alvarez's father, the Nobel Laureate Luis Alvarez, had the clay analysed by analytical chemists Frank Asaro and Helen Michel at Berkeley, and found up to 8 ng/g (ppb) iridium in the sample (1): i.e. about 30 times the background level. Later, further iridium anomalies were detected in K–T boundary clays from Stevns Klint, Denmark, and from Woodside Creek, New Zealand (1).

Because iridium is abundant in meteorites (and in the earth's mantle), but rare in crustal rocks, it was proposed that the earth had been struck by a large (10 km diameter) chondritic (with character of stony meteorites) asteroid or meteorite. It was further suggested that this impact caused the ejection of a vast amount of dust that stayed in the atmosphere for about 6 months, resulting in the blotting out of the sun's rays with consequent cessation of photosynthesis, breakdown of food chains, and the extinction of 70% of all life forms on earth, including the dinosaurs.

It is probable that public interest in the subject has been stimulated precisely because such large and extravagant life forms such as dinosaurs had been involved. The ammonites were also rendered extinct but their demise has not captured the public imagination to any degree. It is also noteworthy that the

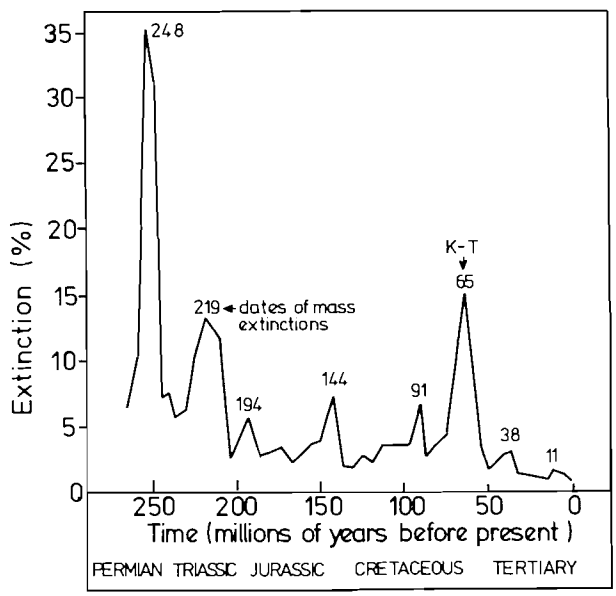

FIG. 1. Disappearance of families of marine animals from the fossil record (2). Copyright 1986 by the American Association for the Advancement of Science. Reprinted by permission.

K–T extinctions are by no means the greatest to have occurred. The Permian–Triassic (P–T) extinctions were far greater.

Some indication of the relative magnitude of past extinctions has been given by Raup and Sepkoski (2) who showed the existence of about eight of these events occurring in 26 million year (m.y.) cycles. These findings are shown in Fig. 1 but since they represent only marine families rather than individual taxa, the percentages are lower than would be obtained if the total of all biota were considered. For example, the 35% extinction

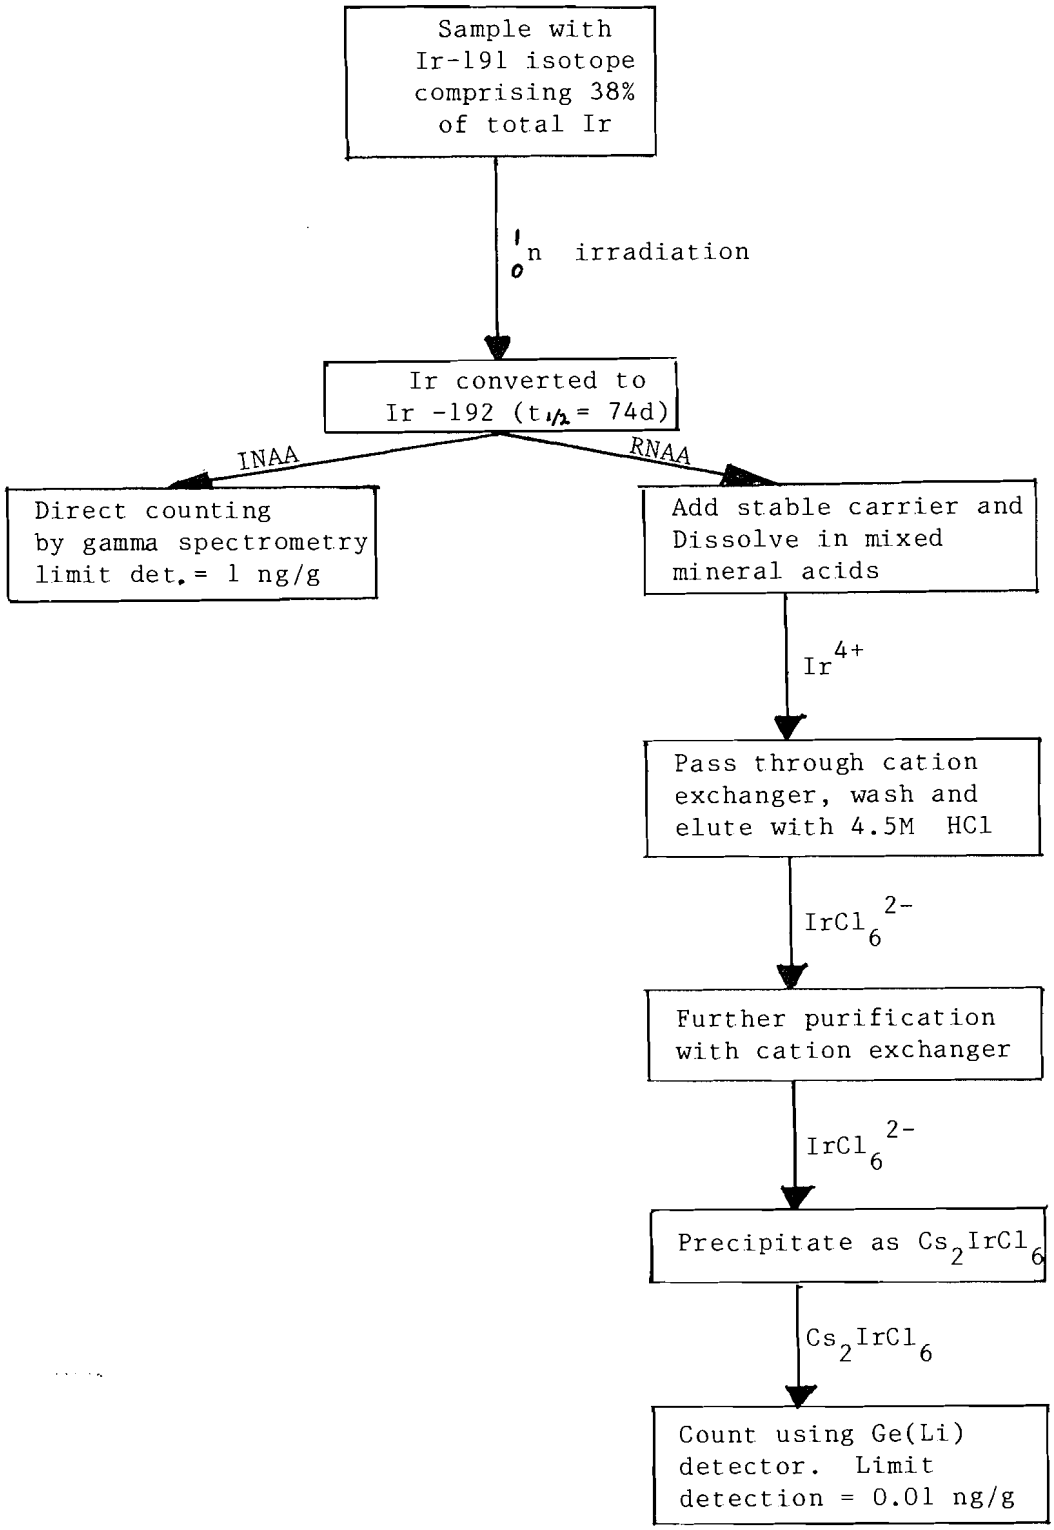

FIG. 2. Analytical scheme for determination of iridium by two types of neutron activation analysis.

of families at the P–T boundary represents 96% of all taxa involved. Using the data of Raup and Sepkoski, some scientists have proposed that the apparent periodicity of mass extinctions was caused by the sun having a dark companion ("Nemesis") with a 26 m.y. orbit. This star passing through the Oort cloud of comets every 26 m.y. would cause some to be dislodged from their regular orbits so that a shower of comets (rather than a single asteroid) would impact the earth at regular intervals. This theory will not be considered further since the chemical composition of cometary cores and asteroids are similar, and the nature of the bolide(s) is immaterial to the arguments which follow.

The original work of Alvarez *et al.* (1) has stimulated considerable research, discussion, and controversy worldwide, which in October 1981 resulted in a conference on the subject at Snowbird, Utah (3), in which perhaps as much heat as light was generated.

Some workers (4–6) have been strongly critical of the

TABLE 1. Iridium abundances (ng/g) in various rock types

Rock type	Iridium content
K–T boundary clays	1–130
Crustal rocks	0.02–0.1
Upper mantle	1–8
Ocean floor basalts	0.001–0.1
Terrestrial impact melts	0.02–70
Lunar magmatic rocks	0.001–0.1
Lunar impact rocks	0.02–70
Chondrites (stony meteorites)	200–1000
Siderites (iron meteorites)	0.1–100 000 (0.01%)

Alvarez theory, but evidence is accumulating that an impact probably did occur on earth some 65 m.y. ago, though it may not have been partially or totally responsible for mass extinctions at this time. The evidence of such a collision having taken place has resulted mainly from the work of analytical chemists and it is therefore appropriate that the subject should be reviewed in this journal. It is also fitting that the review should appear in an issue in honour of D. E. Ryan since he himself has been involved in these studies.

Evidence for an impact at the terminal Cretaceous can be divided into four main categories of studies on K–T boundary clays. These are (*1*) the presence of anomalously-high iridium concentrations; (*2*) mineralogical studies showing the presence of shocked quartz grains and of extraterrestrial material; (*3*) the presence of amorphous carbon particles of similar morphology to soot; (*4*) the existence of isotopic ratios (such as $^{187}Os/^{186}Os$) indicating an extraterrestrial origin for some of the constituents of boundary clays. The following review will be concerned mainly with these four categories of evidence.

The iridium anomaly

The abundance of iridium in various rock types is summarised in Table 1. Clearly, concentrations of this element in meteorites are very much higher than in the earth's crust or even in its upper mantle.

Until recently, iridium was almost always determined by neutron activation analysis and this is still the most popular method, though it is being replaced to some extent by plasma source mass spectrometry (see below). An analytical scheme for neutron activation is given in Fig. 2. There are two main procedures which may be followed. The first of these is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

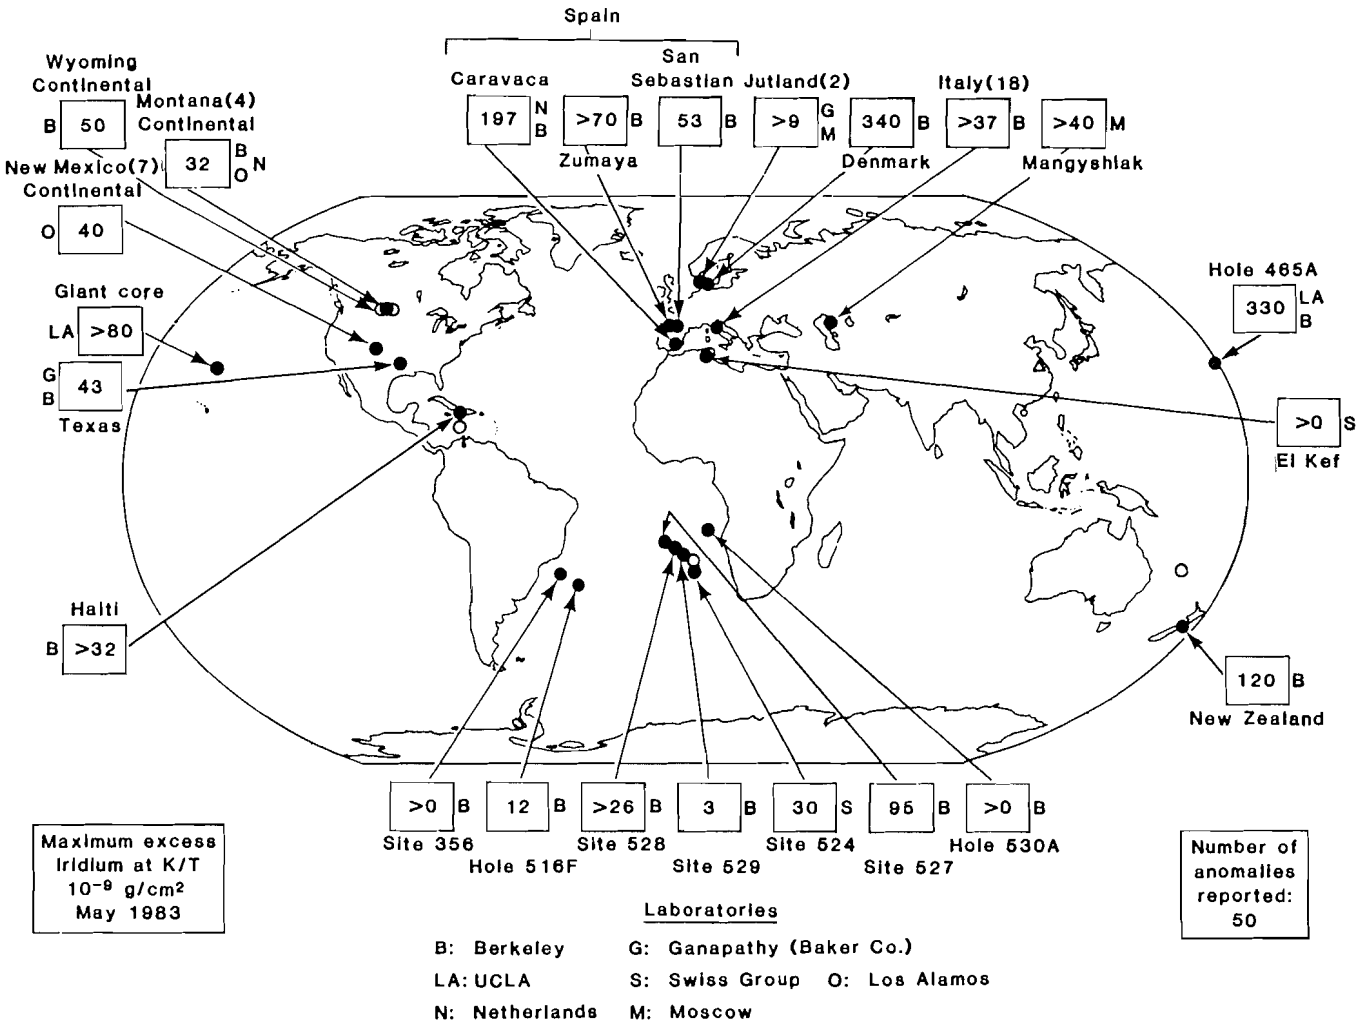

FIG. 4. Distribution of K–T boundary sites containing anomalously high iridium concentrations (8). Copyright 1984 by the American Association for the Advancement of Science. Reprinted by permission.

instrumental neutron activation (INAA) in which the sample is irradiated with neutrons to convert stable ^{191}Ir to radioactive ^{192}Ir (half life of 74 days). After an appropriate cooling period, the activity of the isotope is determined by γ spectrometry. The limit of detection is about 1 ng/g (ppb). For lower iridium concentrations, recourse has to be made to radiometric neutron activation (RNAA) in which the sample is first irradiated and then a stable carrier of ^{192}Ir is added. The sample plus carrier is then dissolved in a mixture of mineral acids ($HNO_3/HF/HClO_4$) so that the iridium is converted to the Ir^{4+} state. The solution is passed through a cation exchanger to absorb the iridium. After washing, the iridium is eluted with hydrochloric acid as the anionic $IrCl_6^{2-}$ complex. Following a further stage of purification in a second cation exchanger, the iridium is precipitated as Cs_2IrCl_6. The precipitate is filtered and dried and its activity measured. The detection limit is about 10 pg/g (ppt). It is clear that without the help of the analytical chemist, this work on iridium would have been impossible to carry out, as it is only in the past 10 years that neutron activation techniques have become sufficiently sensitive to determine iridium at the sub-ppb level. It should also be mentioned that the only reason that iridium was used as a marker for K–T impacts was because it is the most readily determined of all the platinum metals. The others are also present in K–T boundary clays with about the same abundance, but their limits of detection are higher than for iridium.

Apart from iridium, there are usually elevated concentrations of other siderophile (iron-loving) elements in K–T boundary clays. Examples of these are cobalt, chromium, and nickel. This is illustrated in Fig. 3 which gives abundance data for the Woodside Creek K–T sequence in New Zealand (7). It should be noted that it is customary to present data on a decalcified ($CaCO_3$-free) basis. This is to avoid criticisms that the elevated levels are merely due to subsequent dissolution of limestone after the initial deposition.

Since the original discovery of anomalous iridium levels in K–T boundary clays at Gubbio, Stevns Klint, and Woodside Creek, over 70 other such occurrences have been recorded worldwide including Alberta and Saskatchewan (37). The distribution of these anomalies, recorded worldwide (8), is shown in Fig. 4. It is particularly noteworthy that only one of these sites is on land in the Southern Hemisphere (Woodside Creek in New Zealand). Further investigations in New Zealand have resulted in the identification of four more K–T boundary sites with anomalously-high iridium levels (9, 10). It is usually more meaningful to express values as integrated mass of iridium per cm^2 of earth surface (ng/cm^2). This system has been used in Fig. 4. The most recent discovery of a K–T boundary in New Zealand (Flaxbourne River) gives an integrated iridium signature of nearly 150 ng/cm^2 (10). There is no apparent trend in the data of Fig. 4 which would indicate a specific location for the original impact. Since the oceans cover 70% of the earth's

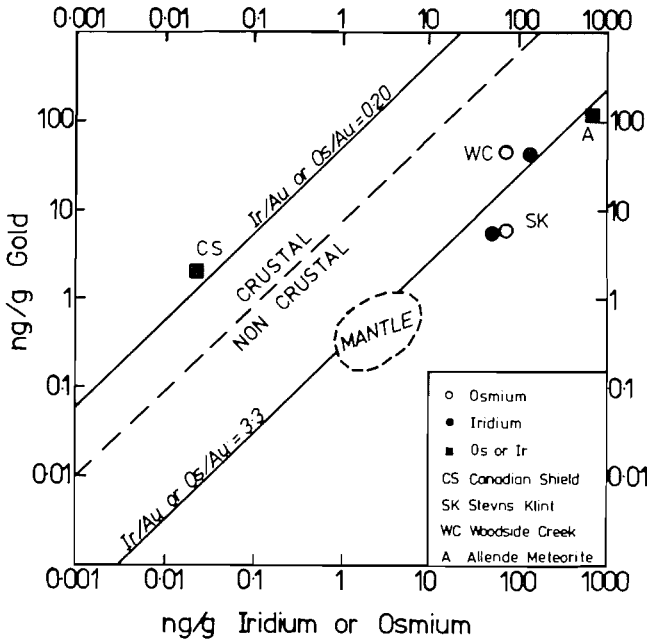

FIG. 5. Plots of gold vs. iridium or osmium in crustal, meteoritic, and K–T boundary material. CS = mean for Canadian Shield, SK = Stevns Klint, WC = Woodside Creek, A = Allende carbonaceous chondrite (25). Copyright 1986 by Macmillan Journals Ltd. Reprinted by permission from Nature, vol. 322, pp. 816, 817.

surface however, this impact is likely to have occurred in the sea and a crater would be hard to discover.

One of the earlier critics of the Alvarez theory (4) suggested that the iridium in the K–T boundary clays could have been derived from the water column itself during a period of unusual ocean chemistry. However, discoveries of iridium anomalies in a continental K–T section in New Mexico (11, 12) have answered this objection.

Because of the very low iridium levels in boundary clays, extreme care has to be taken to avoid contamination during the analytical procedures. For example, an iridium "anomaly" was once reported for samples handled by an analyst wearing a platinum ring with 10% iridium (8). We ourselves have noticed a distinct memory effect for osmium determinations after successive fusions in a zirconium crucible which appeared to be otherwise clean.

Despite vehement criticisms from some quarters, a broad concensus is emerging, at least among geochemists, that the elevated iridium levels found at most K–T boundary sites probably resulted from an impact (or impacts) with extraterrestrial material during the terminal Cretaceous. The possibility of the iridium having been derived from volcanic activity remains a distant option. The lava of deep-seated volcanoes does indeed contain iridium, but the levels are so low that vulcanism on an unimaginable scale would have had to have occurred to account for present levels of this element in boundary clays.

A useful geochemical "signature" in geological materials is the Ir/Au ratio. From Fig. 5 it will be noted that a ratio of 0.2 is typical of crustal rocks whereas extraterrestrial material clusters around a value of 3.3 The same is true of the Os/Au ratio.

Because of the great expense of neutron activation procedures, particularly RNAA, it is advisable for analysts to screen samples by first determining marker elements such as cobalt, chromium, and nickel which can be readily quantified by atomic absorption (AAS) or plasma emission (ICP) spectrometry. Only samples with anomalous concentrations of all or some of these elements will then need to be analysed for iridium.

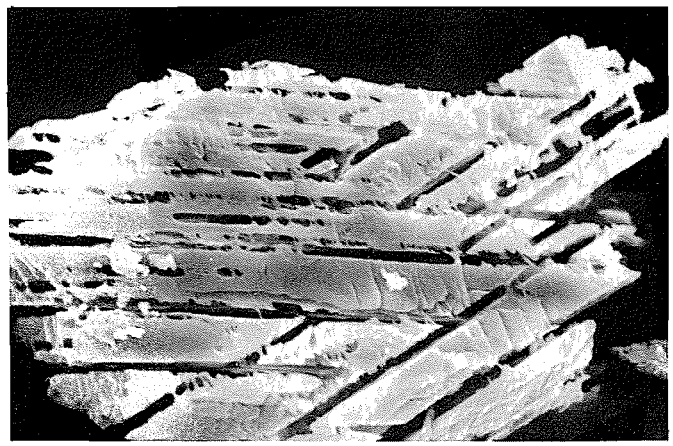

FIG. 6. Photograph of shocked quartz grain (30 μm × 20 μm) — courtesy of B. F. Bohor.

Shocked quartz and magnesioferrite

The second piece of evidence that an impact may have occurred on earth 65 m.y. ago has been provided by the discovery of shocked quartz grains in K–T boundary clays (13–16). Shocked quartz is usually associated worldwide with meteoritic impact craters. The grains have characteristic lamellar features as is shown in Fig. 6. The grains are isolated by removing the clay fraction by washing with water. The residual quartz is etched with hydrofluoric acid and examined under a scanning electron microscope (SEM). The worldwide abundance, maximum grain size, and distribution of shocked quartz has also been studied (15) and is shown in Fig. 7. The map shows the continents as they were at the terminal Cretaceous. There is a clear trend for maximum grain size and abundances to be greatest in North America and to show a steady decrease in a southeasterly direction with minimum values in New Zealand. This trend seems to indicate that the impact may have occurred in the vicinity of North America, since the larger grains should have deposited closest to the impact site. The ratio of shocked to unshocked quartz grains also shows a decrease along the southeast-trending direction.

The presence of extraterrestrial magnesioferrite at the K–T boundary at Caravaca in Spain and Umbria in Italy has also been demonstrated (17, 18). Material from the former site was washed to remove clay particles and the ferromagnetic material was removed with a magnetic separator. The composition of the separated material was similar to that of magnetic alloys injected into rocks in impact craters.

Soot particles in K–T boundary material

Further evidence favouring an asteroidal/meteoritic impact during the terminal Cretaceous has been provided by work at the University of Chicago (19, 20). Clay samples from three K–T boundary sites contained 0.36–0.58% graphitic carbon, morphologically similar to soot particles. It was proposed that the soot was derived from worldwide forest fires following the event. This amount of soot (0.021 g/cm^2) would have greatly enhanced the "winter" caused by dust particles in the atmosphere. A very good correlation between iridium levels and the abundance of soot paricles has also been demonstrated (20).

The findings of the Chicago group were hotly disputed by

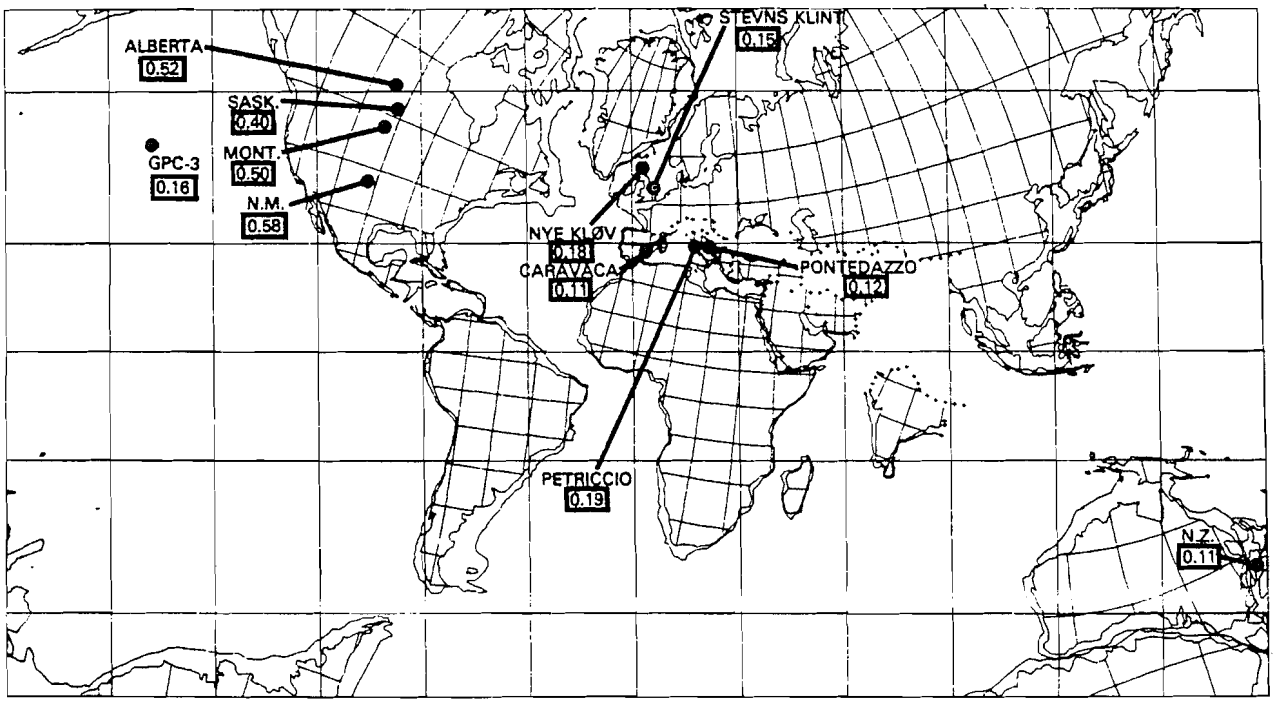

FIG. 7. Geographical distribution of shocked quartz grains in K–T boundary sites throughout the world. Values are maximum grain size and the continents are shown as they were at the K–T transition time (15).

some other scientists (21) who suggested that the high carbon content of the Stevns Klint material resulted from dissolution of the limestone (condensed section). The same mechanism would account for both the high carbon and iridium contents. In a rebuttal of these arguments (22), it was pointed out that redissolution of the carbonate layer would have required condensation of a 600 m thickness of rock to only 10 mm, and that the original limestone would have had to have contained 99.95% calcium carbonate.

Isotopic studies

Further compelling evidence for the past occurrence of an impact at the terminal Cretaceous has again been provided by the analytical chemist. The ratio $^{187}Os/^{186}Os$ is diagnostic of rock type. The ratio of these two isotopes in cosmic material 4.5×10^9 years BP (before present) is believed to have been 0.8:1.0. The ratio is now about 1.0:1.0 in material which has been cycled through the mantle due to production of ^{187}Os from decay of the long-lived isotope ^{187}Re. The earth's crust is, however, greatly enriched in rhenium compared with osmium so that the decay process has resulted in a much greater abundance of ^{187}Os in crustal rocks a ratio of about 26–30:1. Figure 8 shows the range of values which would have resulted within the limits of 2.0–3.8 billion years BP for the probable separation of the earth's crust from the mantle.

The original work on the osmium isotopes (23) was carried out by use of an ion probe mass spectrometer in which the sample surface is bombarded with a fast-moving ion beam which dislodges atoms and ions from the sample as gas phase species. The secondary ions then pass through a mass spectrometer. The technique is highly sensitive and permits analyses at the ng/g level. $^{187}Os/^{186}Os$ isotopic ratios of about 8 have been reported for oceanic manganese nodules (i.e. material derived from the sea water column) and 1.3 to 1.6 for K–T boundary clays (13).

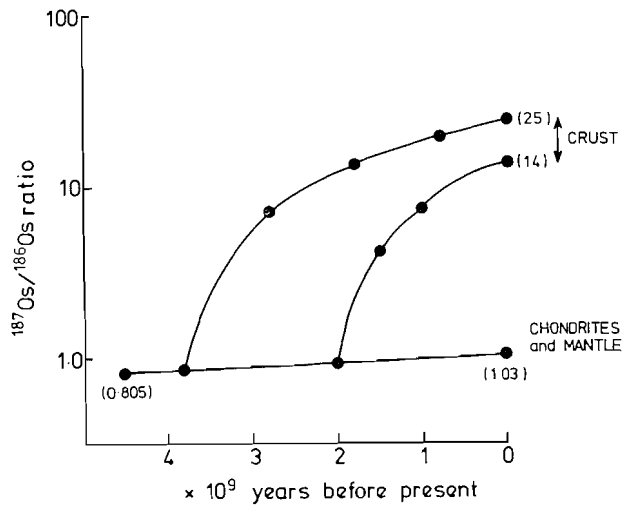

FIG. 8. $^{187}Os/^{186}Os$ ratios in chondritic meteorites, and the earth's mantle and crust expressed as a function of age — courtesy of R. D. Reeves.

A new analytical tool has been developed which offers great promise for determining isotopic ratios in geological materials. This is plasma source mass spectrometry (ICP-MS) in which an inductively-coupled plasma source is fed directly into a quadrupole mass spectrometer (24). Abundances of a large number of isotopes can be obtained very quickly and with very low detection limits (ca. 1 ng/mL). The technique has been used to determine the $^{187}Os/^{186}Os$ ratio in K–T boundary clay from New Zealand (25) for which a value of 1.12 was obtained. The same procedure was used to determine total osmium which is difficult to determine sensitively by IANA. As shown in Fig. 3, the Os/Au ratio afforded yet another means of determining extraterrestrial components of K–T boundary

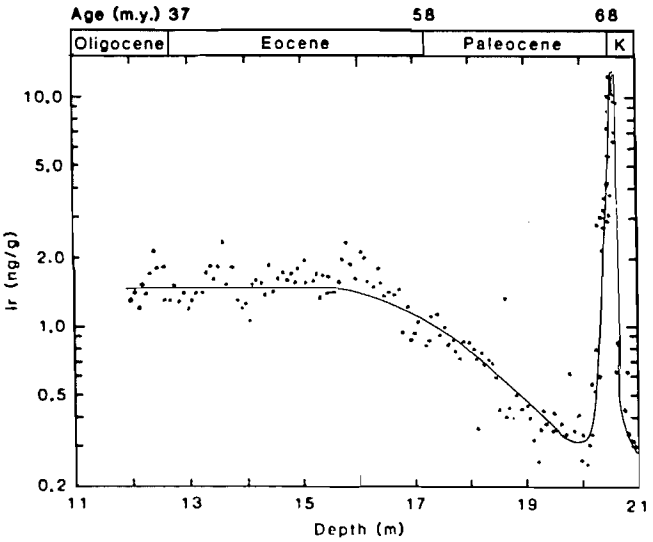

FIG. 9. Profile of iridium concentrations in a Pacific core. The only significant positive anomaly is at the K–T transition (34). Copyright 1986 by the American Society for the Advancement of Science. Reprinted by permission.

material. The ratio lies along the 3.3 isoratio line and the values are clustered close to those for the Allende carbonaceous meteorite. Though mantle rocks lies along the same line, values are clustered to the centre of the plot and do not overlap those for the K–T boundary clay.

The simplicity, cheapness, and very high sensitivity of the ICP-MS technique renders it a suitable alternative and competitor to neutron activation procedures for determining elements at very low abundances, though it does suffer from the disadvantage of requiring a solution rather than a solid.

Other isotopic ratios which may be used to establish the origin of material in K–T boundary clays are $^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$ (26). Recent isotopic studies at the Caravaca K–T marine sequence in Spain shows that the boundary clay was of terrestrial rather than of marine origin. This indicates fallout from dust ejected into the atmosphere.

Summary of evidence for an impact at the terminal Cretaceous

Because of the continuing discussion concerning the reality of an impact (or impacts) at the terminal Cretaceous (a paper by Alvarez (36) is a useful source for this), it will now be appropriate to first review the evidence in favour of such an event.

1. Iridium and other noble metals are enriched up to 1000-fold at the K–T boundary at more than 70 sites worldwide (8).

2. $^{187}Os/^{186}Os$ ratios, though not ruling out the possibility of a mantle source, indicate the probability of an extraterrestrial source for this element (25).

3. $^{144}Nd/^{143}Nd$ and $^{87}Sr/^{86}Sr$ ratios indicate a terrestrial origin for the clay found in K–T marine sections, thus pointing to aerial fallout as a source (26).

4. The presence of soot particles in K–T boundary material, which may have originated from worldwide fires after an impact (19).

5. Shocked quartz (13–16) and spherules resembling microtektites (27) have been found in K–T boundary clays.

The countervailing arguments by proponents of gradualism rather than catastrophism have been based on four main arguments:

1. Iridium in boundary clays was accumulated from the sea water column (4).

2. The iridium anomaly may have been derived from dissolution of limestone and in any case the iridium input may not have been constant over geological time (6).

3. Vulcanism may have been a source of iridium since it is known that this element can be found in lava and other volcanic emanations (28).

4. Shocked quartz is not necessarily always associated with impacts.

An answer to the first and second of these arguments has already been given above. As regards the third argument, vulcanism could indeed be a source of some of the iridium, but to have provided enough of this element to give the concentrations found uniformly worldwide in boundary clays, would have involved a degree of volcanic activity far beyond human comprehension. Even the basalts of the Deccan Traps in India, proposed by some to have been a source of such iridium, contain only 0.005 ng/g of this element.

As regards the final argument, a few shocked quartz grains have apparently been found in a volcanic formation (29). The discoverers do, however, admit that the abundance of these grains is very low and have ascribed this to annealing of shocked particles due to the high temperature involved. The same arguments must however also apply to shocked quartz associated with a K–T impact: i.e. if annealing does occur, the abundances of these grains at K–T sites would have been even greater than recorded, since the energy involved in the impact is many orders of magnitude greater than that of any volcanic event. It is always possible to find some support in favour of negation of any well-tried theory. For example, dinosaur bones have been reported from Hell Creek, Montana, in a stratum some 1.3 m above the putative K–T boundary (30). This has been advanced as proof that dinosaurs outlived the terminal Cretaceous. Other workers have, however, pointed out that the strata at Hell Creek are too muddled and reworked by ancient streams for any great credence to be placed on the observations. If the recent finding of shocked quartz in a volcanic environment is not to attract this same lack of credence, many more findings and observations will have to be made before current thinking on the origin of shocked quartz is to be seriously challenged.

Evidence for iridium anomalies at non-K–T boundaries

Since the original discovery of elevated iridium levels at the K–T boundary, there has been an active interest in finding such anomalies at other geological boundaries involving the transition from one period to another. The oldest boundary at which an anomaly has been found is at the junction of the Frasnian–Fammenian stages of the Devonian (365 m.y. BP). A value of 0.3 ng/g has been reported for material from this boundary (31). Though this is low, the iridium value is several times higher than local background. The iridium is, however, said to have been scavenged by a fossil cyanobacterium, *Frutexites* sp., and does not represent aerial contribution from an impact.

Mass extinctions at the Ordovician/Silurian (O–S) boundary (435 m.y. BP), when 22% of all marine families became extinct, are second in magnitude only to those of the Permian–Triassic (P–T) transition. In a thorough study of iridium and other elements in O–S boundary material from Anticosti Island, Quebec (32), anomalous iridium levels (60 pg/g) were indeed found. However, when expressed on a decalcified basis, the

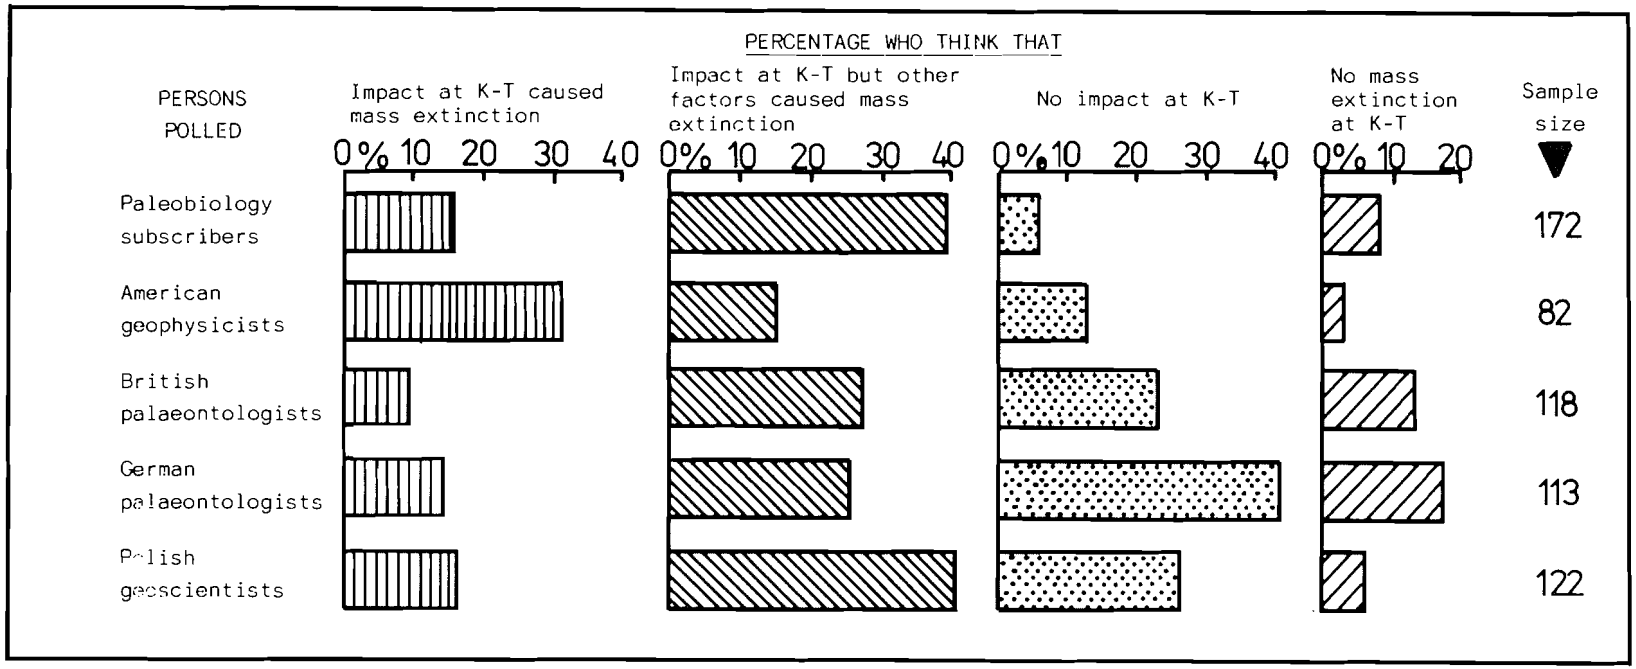

FIG. 10. Results of a poll of opinions among scientists carried out in 1984. Percentages do not add up to 100 because many respondents did not have an opinion (35). Reprinted by permission of Geology and the senior author.

levels were no longer anomalous. There is therefore no evidence for an impact to have occurred on earth at this time.

A claim by a Chinese group to have discovered 8 ng/g iridium at the P–T boundary (33) was apparently based on erroneous analytical techniques, though the work was reported in good faith. There are at present no reliable data supporting an iridium anomaly at this boundary.

Our knowledge of iridium levels in rocks whose ages span the period 33–67 m.y. BP: i.e. late Cretaceous and younger, has been enhanced by a recent paper (34) which presents data for iridium abundances in 149 samples from a continuous 9 m Pacific core of abyssal clay. The data are given in Fig. 9. Background iridium deposition fell to 0.3 ng/g in the Paleocene and rose to a maximum of 1.7 ng/g in the Eocene. A well-defined peak occurred only at the terminal Cretaceous. The annual global influx of meteoritic material is calculated at 78 000 tonnes. Superficially it seems that the K–T boundary represents the only significant impact event during this period, but it must be remembered that the samples were taken at average intervals of 6 cm, and much finer sampling would have been needed to detect smaller iridium anomalies.

Current status of the impact theory

As to whether or not there is general concensus among scientists about the reality of an asteroidal/meteoritic impact some 65 m.y. ago, depends on who is consulted. It will be very obvious that nearly all the evidence in favour of such an event having occurred is chemical. The analytical chemist is therefore ranged against some palaeontologists in a continuing controversy. This is illustrated (Fig. 10) by a recent survey (35) of opinions from scientists of different disciplines. Apparently 40% of subscribers to the palaeontological publication *Journal of Paleobiology* believed that an impact did indeed occur at the K–T transition, but only 15% believed that this impact was responsible for mass extinctions at that time. Initially many palaeontologists disbelieved in the reality of the impact itself, but were forced to change their views because of the compelling evidence put forward by chemists. Chemists will not, however, be able to prove beyond reasonable doubt that an impact caused mass extinctions. This is a matter for the palaeontologists to decide and is likely to remain controversial for many years to come. I feel, however, that we as chemists deserve some credit for having been able to read the message contained in iridium-rich boundary clays: a message that the Rosetta Stone of modern instrumentation has enabled up to decipher.

Alkylammonium lead halides. Part 1. Isolated PbI_6^{4-} ions in $(CH_3NH_3)_4PbI_6 \cdot 2H_2O$

BEVERLY R. VINCENT,[1] KATHERINE N. ROBERTSON, T. STANLEY CAMERON, AND OSVALD KNOP
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received October 14, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

BEVERLY R. VINCENT, KATHERINE N. ROBERTSON, T. STANLEY CAMERON, and OSVALD KNOP. Can. J. Chem. **65**, 1042 (1987).

The yellow $(CH_3NH_3)_4PbI_6 \cdot 2H_2O$ ($P2_1/n$, a = 10.421(3) Å, b = 11.334(2) Å, c = 10.668(2) Å, β = 91.73(2)°, Z = 2) contains isolated PbI_6^{4-} octahedra, $CH_3NH_3^+$ cations of two types and H_2O molecules. The cations and the water molecules are hydrogen-bonded to form *cat* 1···H_2O···*cat* 2 units arranged in centrosymmetric (*cat* 1···H_2O···*cat* 2)$_2^{4+}$ pairs; the centres of these composite units and the Pb atoms form a distorted NaCl-type lattice. The Pb—I bond lengths in the PbI_6^{4-} anions are compared with those in $[Pb(II)I_6]^{\epsilon}$ complexes containing shared I atoms and the effect of the sharing on the bond lengths is discussed. A scheme is proposed for the extensive three-dimensional hydrogen bonding in the structure.

BEVERLY R. VINCENT, KATHERINE N. ROBERTSON, T. STANLEY CAMERON et OSVALD KNOP. Can. J. Chem. **65**, 1042 (1987).

Le composé jaune, $(CH_3NH_3)_4PbI_6 \cdot 2H_2O$ ($P2_1/n$, a = 10,421(3), b = 11,334(2) et c = 10,668(2) Å, β = 91,73(2)° et Z = 2) contient un octaèdre isolé de PbI_6^{4-}, des cations $CH_3NH_3^+$ de deux types et des molécules de H_2O. Les cations et les molécules d'eau sont liés par des ponts hydrogènes qui forment des unités *cat* 1···H_2O···*cat* 2 qui sont arrangées en paires centrosymétriques (*cat* 1···H_2O···*cat* 2)$_2^{4+}$; les centres de ces unités composites et les atomes de Pb forment un réseau déformé du type NaCl. On compare les longueurs des liaisons Pb—I des anions PbI_6^{4-} avec celles observées dans les complexes $[Pb(II)I_6]^{\epsilon}$ contenant des atomes I partagés et on discute de l'effet du partage sur les longueurs des liaisons. On propose un schéma pour expliquer le réseau important de liaisons hydrogènes tridimensionnelles que l'on retrouve dans cette structure.

[Traduit par la revue]

Dropwise addition of a concentrated aqueous solution of $Pb(NO_3)_2$ to an aqueous solution containing CH_3NH_3I in 12-fold molar excess yields a black precipitate of $CH_3NH_3PbI_3$ when the addition is carried out above ca. 40°C. With the solutions below this temperature a pale yellow crystalline solid, originally believed to be hydrated $CH_3NH_3PbI_3$ (1), is obtained instead; it forms also by spontaneous conversion of the black $CH_3NH_3PbI_3$ precipitated above 40°C when the latter is cooled below this temperature in contact with the mother liquor. This yellow solid was of concern to us at first only as a potential contaminant of $CH_3NH_3PbI_3$ then under investigation (ref. 2 and to be published), but the suspicious closeness of the temperature limit given (1) for its formation to the upper transition temperature of solid $CH_3NH_3PbI_3$, ~54°C (to be published), eventually prompted us to investigate the yellow solid in some detail.

The ir spectrum of the yellow material indeed indicated the presence of water of hydration. With the preparation of larger quantities of the compound and further chemical characterization under way, we proceeded with the crystal-structure analysis, in the expectation that the composition could be established independently in this way.

The main features of the structure emerged almost immediately, owing to the presence of the heavy scatterers Pb and I. After several cycles of refinement it became clear that the compound was not a hydrate of $CH_3NH_3PbI_3$, but the hitherto unreported compound $(CH_3NH_3)_4PbI_6 \cdot 2H_2O$ (**1**) and, to our knowledge, the first compound shown to contain *isolated* Pb(II)I_6 octahedra (cf. Table 1).[2] The composition was subsequently confirmed by chemical analysis.

The structure of **1** consists of a distorted fcc array of PbI_6^{4-} ions interspersed with $CH_3NH_3^+$ cations of two types and water molecules of a single type (Fig. 1). Each water molecule is hydrogen-bonded to a cation 1 and a cation 2 to form *cat* 1···H_2O···*cat* 2 units (see below), which occur in centrosymmetric pairs. If the structure is regarded as an assembly of such (*cat* 1···H_2O···*cat* 2)$_2^{4+}$ dimers and PbI_6^{4-} octahedra, the centres of the ions are situated on a distorted NaCl-type lattice.

The centrosymmetric PbI_6 octahedron is quite regular (Table 2), testifying to the stereochemical inactivity of the lone pair on the Pb(II) atom. The Pb—I bond lengths range from 3.195 to 3.231 Å, with a mean of 3.217(16) Å (3.223(10) Å when corrected for thermal motion). This range, 0.036(2) Å, is relatively narrow compared to the variation of bond length in PbI_6 octahedra containing shared I atoms (Tables 1 and 3); in the extreme case of anhydrous and hydrated $APbI_3$ (**5**–**8**) the difference between the longest and the shortest Pb—I bond in the same PbI_6 octahedron is ~0.4 Å (see below).

The H atoms could not be found in difference Fourier maps and direct evidence of hydrogen bonding is thus lacking. However, the N···O distances of 2.90 Å almost certainly correspond to N—H···O bonds. The N(1)—O—N(2), C(1)—N(1)—O, and C(2)—N(2)—O angles are 112°, 102°, and 136°, respectively, and assuming that C—N—H = 109.5° and N—H = 1.02 Å, we have H_N···O ~ 1.90 Å, N—H—O ~ 168° for cation 1 and H_N···O ~ 2.04 Å, N—H—O ~ 141° for cation 2, values not exceptional for N—H···O bonds (9). Since the N—H···O bonds are stronger than O—H···I or N—H···I bonds, cation 1 and cation 2 may be regarded as hydrogen-bonded to the water molecule to form discrete cationic units $H_3N(1)$—H···OH_2···H—$N(2)H_3$, which in turn are linked by N—H···I and O—H···I bonds to the PbI_6 octahedra.

The shortest O···I separations in **1**, 3.63–3.65 Å (Table 4), are well within the range 3.59–3.67 Å reported for O···I^- distances in iodide hydrates (9). If the coordination of the O atom is assumed to be approximately tetrahedral, examination

[1]Holder of NSERC (1983–1987), Killam (1984–1987), and Sumner (1986–1987) graduate fellowships.

[2]The rhombohedral Cs_4PbI_6 (3, 4) is almost certain to be isostructural with K_4CdCl_6 (5) and therefore to contain isolated PbI_6^{4-} octahedra of C_{3i} symmetry. However, the structure of this iodide has not yet been reported.

*e, equatorial; a, axial. For the notation $I_{p/q}$ see text. ⟨Pb—I⟩, mean of the six Pb—I distances in the complex, with the standard deviation in parentheses.

†Cubic high-temperature form isotypic with the room-temperature phases of the cubic perovskites $CH_3NH_3PbCl_3$ and $CH_3NH_3PbBr_3$; ⟨Pb—I⟩ = Pb—I (σ = 0.001 Å) refers to ~57°C (to be published).

‡$CsPbI_3$ is isostructural, ⟨Pb—I⟩ = 3.24(12) Å (3).

§Depends on the polytype.

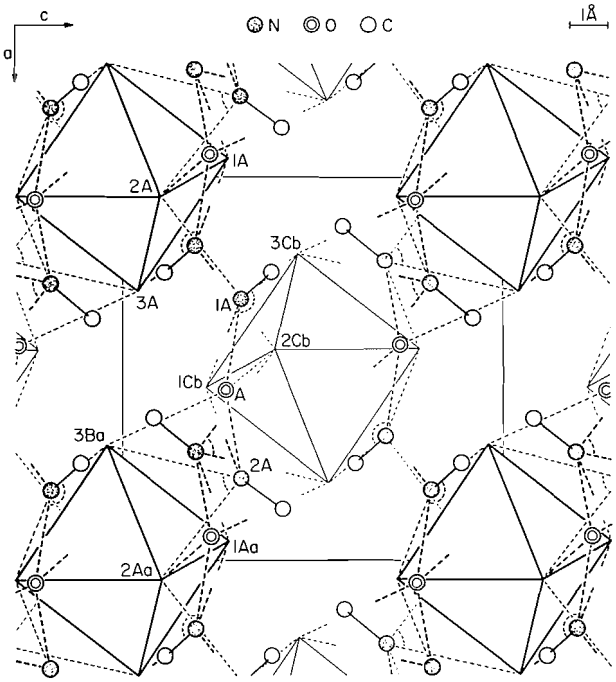

FIG. 1. $(CH_3NH_3)_4PbI_6 \cdot 2H_2O$: projection of the structure on (010) (the β angle of 91.7° is approximated by 90°). Broken arcs indicate N—H···I bonds presumed bifurcated. For symmetry code see Table 4.

of the N—O—I and I—O—I angles (Table 4) shows that a reasonable hydrogen-bonding scheme results when N(1) and N(2) are taken to be the donor and I(2C) and I(3B) the acceptor atoms of the hydrogen bonds (Fig. 2). Although the deviations of some of the N—O—I angles from tetrahedral are large, the OH_4 tetrahedron is likely to be closer to regular than these deviations might suggest, owing to the nonlinearity of the N—H···O (and probably also O—H···I) bonds.

In the absence of accurate knowledge of the positions of the H_N atoms bonded to the oxygen the description of the bonding engagement of the remaining H_N atoms can only be tentative. The shortest N···I distances, 3.54–3.72 Å (Table 4), are comparable to the N···I^- distance in Et_3NHI, 3.60(3) Å, which is reliably known and which corresponds to an N—H···I^- bond straight by symmetry (10). However, the two shortest N(1)···I distances, N(1)···I(3C) and N(1)···I(1C), correspond to

†Corrections based on a rigid-body motion model add 0.005 Å to Pb—I(1) and 0.006 Å to Pb—I(2) and Pb—I(3). Corrections to the I—Pb—I angles do not exceed 0.02°.

C(1)—N(1)—I angles of 94° and 157°, respectively, indicating that if N—H···I bonds are involved here, they must be appreciably bent. Placing an H_N atom on a straight line defined by N(1) and the midpoint of I(1C) and I(3C) would result in a bifurcated N(1)—H···2I bond with the N(1)—H vector ca. 110° from the N(1)···O line and a C(1)—N(1)—H angle of 129°. While these values are not close to ideal, it is clear that the N(1)—H···I bond in the direction of the two nearest I atoms is either strongly bent or bifurcated.

Similar considerations of other short N···I distances and of plausible hydrogen-bonding geometries have produced the overall hydrogen-bonding scheme illustrated in Figs. 1 and 2. Although the proposed scheme is tentative in the specific assignment of the N—H···I bonds, it does indicate that (*1*) not all (and perhaps none) or the hydrogen bonds can be close to straight; (*2*) the two strongest hydrogen bonds are those linking the two cations to the water molecule to form identifiable *cat* 1···H_2O···*cat* 2 units; (*3*) the cations and the water molecules cross-link the PbI_6 octahedra to form a three-dimensional edifice; and (*4*) all the I atoms participate in hydrogen bonding. These conclusions would stand even if some re-positioning of the proposed N—H···I bonds was required

†The esd's are 0.003 Å for the N···O and 0.001 Å for the N···I distances.

as a result of an actual location of the H atoms by neutron diffraction or single-crystal nmr.

The engagement of every I atom in at least two N—H···I bonds tends to find support in the result of a TLS analysis on the PbI_6 octahedron. The rigid-body motion model accounts moderately well for the observed thermal parameters: $R(U_{ij})$ = 7.3%, and the rms discrepancy for U_{ij} is 0.0018 compared to the rms discrepancy for esd(U_{ij}) of 0.0005. The mean amplitudes about the principal axes of libration are small and quite similar, 1.9°, 2.5°, and 2.8°, which reflects a largely isotropic hindering potential to librational motion. The translational component of the motion is quite small and nearly isotropic.

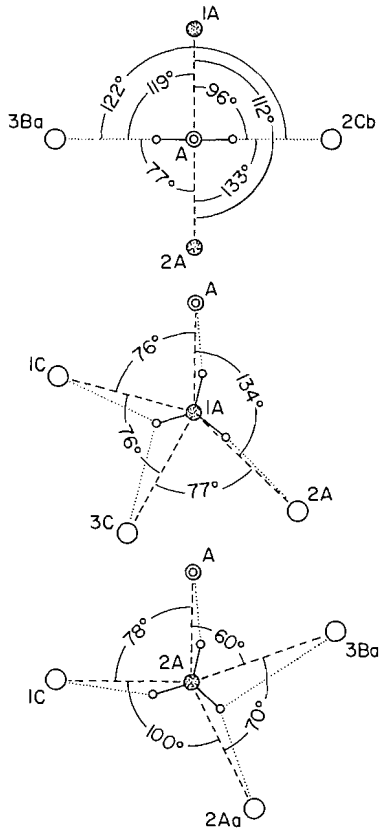

FIG. 2. Schematic representation of the hydrogen-bonding scheme proposed for $(CH_3NH_3)_4PbI_6 \cdot 2H_2O$. Symbols as in Fig. 1. Dashed lines, donor···acceptor distances; dotted lines, H···acceptor bonds. For symmetry code see Table 4.

Bond lengths in $[Pb(II)I_6]^\epsilon$ complexes

Since a $[Pb(II)I_6]^\epsilon$ octahedron in a crystal may be linked to another such octahedron or octahedra, its I atoms may participate in more than one Pb—I bond each. The connectivity of the octahedron can be represented by $[PbI_{p_1/q_1}I_{p_2/q_2}\cdots]^\epsilon$, $\Sigma(p_i/q_i) = 2 - \epsilon$, $\Sigma p_i = 6$, where q_i is the number of Pb atoms forming a bond to the ith I atom, p is the number of I atoms of the same type, and ϵ is the charge on the complex. The length of an individual Pb—I bond in the octahedron will then depend on p, q, and ϵ. This is illustrated in Table 3. The number of Pb—I bond lengths reported to date is too small for a detailed analysis, but it is clear that the bond length at constant q increases with increasing anionic charge $|\epsilon|$ and, at constant ϵ, with increasing q, as would be expected. However, the variation is not independent of the symmetry and connectivity of the octahedron: the configuration and the p/q values of the other Pb—I bonds also play a rôle. Thus in **5**–**7** the shortest (p/q = 1/1) and the longest (p/q = 1/3) bonds are both axial. They average 3.032(6) and 3.435(46) Å, respectively, but their *means* average 3.234(17) Å, i.e. they are close to the mean for the C_s complex (Table 1) and to the overall mean of the Pb—I distances in the $[PbI_6]^\epsilon$ complexes of Table 1, 3.216(78) Å. This "*trans*" effect reflects an extreme unbalance of the bond strength across the Pb atom in the infinite double chain of PbI_6 octahedra and renders the individual bond lengths involved untypical for the particular combination of q and ϵ. Similarly, the *means* of the *trans* bonds involving the $I_{2/2}$ and $I_{2/3}$ atoms in **5**–**7** average 3.239(4) Å, but here the two bond lengths *trans* to each other differ by much less.

The overall mean of the individual bond lengths in **1**–**7** and **9** is 3.216(78) Å (high–low spread, 3.153–3.462 Å), that of all the *trans*-pair means is 3.216(29) Å (high–low spread, 3.153–3.247 Å), and that of the ⟨Pb—I⟩ means for the eight octahedra is 3.216(26) Å (high–low spread, 3.153–3.239 Å). It would thus appear that the ⟨Pb—I⟩ values for different $[PbI_6]^{\epsilon}$ octahedra are quite similar and, furthermore, that the bond-length compensation is accomplished by pairwise averaging of Pb—I bonds *trans* to each other.

Table 1 details the geometries of the $[PbI_6]^{\epsilon}$ complexes of different types reported to date. This list of types is far from exhaustive, for in principle any geometrically permissible combination $[PbI_{p_1/q_1}I_{p_2/q_2}\cdots]^{\epsilon}$ can occur. In particular, $[PbI_{4/1}{}^{e}I_{2/2}{}^{a}]^{3-}$ would represent an infinite chain of octahedra linked by *trans* corners; however, an example of this or any other such trivalent anion is yet to be found.

Experimental

A quantity of **1** was prepared by hot precipitation of $CH_3NH_3PbI_3$ (as in ref. 1) and allowing the solution and the precipitate to cool slowly to room temperature. On standing overnight in contact with the mother liquor the black solid had converted completely to small pale yellow crystals of good quality. A batch of handpicked crystals constituted the sample used in this investigation.

The compound is difficult to obtain completely dry because of a risk of dehydration on prolonged drying in air and of decomposition when washing with organic liquids. The presence of residual accidental water rendered chemical analysis difficult. Nevertheless, determination of Pb as $PbCrO_4$ (in triplicate) gave 17.5(1) wt% Pb, in reasonable agreement with theory (18.3 wt% Pb).[3] The water content was determined from the weight loss on dehydrating a sample under mechanical-pump vacuum at the bp of acetone. The low weight percentage of H_2O in **1** necessitated a large sample (3.3 g) and only one determination was therefore made, resulting in 4.05 wt% H_2O (theory for $2H_2O$, 3.18 wt%). The low analytical figure for Pb corresponds to at most 2.8 extra H_2O molecules per formula unit, while the H_2O analysis corresponds to ca. 0.6 extra H_2O molecules. The discrepancy stems from the variable residual water content of the samples, crystal size playing a rôle in the removal of accidental water by rapid air drying. In spite of their shortcomings these analytical results clearly support the composition of **1** as determined by the crystal-structure analysis, in particular as regards the number of H_2O molecules of hydration, which cannot be less than two.

Water decomposes **1** immediately with the formation of PbI_2. Heating in air or pumping at room temperature dehydrates **1** to a black mixture of $CH_3NH_3PbI_3$ and CH_3NH_3I. Treating this dehydration product with acetone or MeCN yields dark yellow solutions, from which **1** is recovered by evaporation of the solvent (in large crystals when MeCN is used). Recombination of the dehydration product to **1** in nitromethane is limited by low solubility but otherwise proceeds as in acetone or MeCN. Treating **1** with nitromethane results in an initial slight blackening of the solid followed by reappearance of the yellow colour; evaporation of the colourless solution yields **1**. The starting compound is also recovered when **1** is treated with acetone or MeCN and the solvent evaporated, but in this case the solid first turns rapidly and completely black while the solution is yellow.

Crystal data

$C_4H_{28}I_6N_4O_2Pb$ fw = 1132.9

Monoclinic, $P2_1/n$ (no. 14) (systematic absences: $h0l$, $h + l = 2n + 1$; $h00$, $h = 2n + 1$; $0k0$, $k = 2n + 1$; $00l$, $l = 2n + 1$); $a = 10.421(3)$ Å, $b = 11.334(2)$ Å, $c = 10.668(2)$ Å, $\beta = 91.73(2)°$, $V = 1259.5(5)$ Å^3, $Z = 2$, $\rho_c = 2.987$ g/cm^3, $F(000) = 992$ e.

Structure determination

Radiation, Mo $K\alpha_1$, $\lambda = 0.70926$ Å (graphite monochromator); crystal, 0.1 mm radius sphere in sealed capillary; $\mu_{Mo} = 140.4$ cm^{-1}; limits of transmission, 0.27–0.54. Reflections (CAD-4 four-circle diffractometer): total counted, 2562; total unique, 1749; total used ($I_o \geq 3\sigma(I_o)$), 1425. Scattering factors for neutral atoms and corrections for anomalous scattering taken from ref. 11. Weighting schemes: SHELX, $w^{-1} = \sigma^2|F_o| + 0.00542F_o{}^2$; CRYSTALS, $w^{-1} = \sigma^2|F_o|$. Temperature factor, $T = \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$.

The structure was solved and a preliminary refinement carried out using the SHELX system (12) and intensities not corrected for absorption. Absorption corrections were then applied and the refinement completed using CRYSTALS (13); the latter system was also used in the TLS analysis. The final R value (based on 1425 unique reflections corrected for absorption) was 4.29%, $R_w = 4.36\%$. The C, N, and O atoms could be clearly distinguished; the hydrogen atoms were not seen. The final difference maps were flat, without recognizable residual features.

The positional and thermal parameters are listed in Table 5, structure factors in Table 6,[4] and interatomic distances and bond angles in Tables 2 and 4.[5]

Received October 20, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

BYRON KRATOCHVIL, NORINE MOTKOSKY, M. JOHN M. DUKE, and DENNIS NG. Can. J. Chem. **65**, 1047 (1987).

The biological reference material TORT-1, lobster hepatopancreas, was analyzed for aluminum by instrumental neutron activation analysis (INAA) and graphite furnace atomic absorption spectroscopy (GFAAS). After correction of the INAA results for interferences from ^{28}Al produced by $^{31}P(n,\alpha)^{28}Al$ and $^{28}Si(n,p)^{28}Al$ reactions, and use of HNO_3 plus HF for sample dissolution for the GFAAS analyses, the methods gave similar results of 43 ± 3 and 42 ± 2 μg/g respectively for 200 to 300-mg test portions. Analysis of six portions from each of six bottles of TORT-1 showed no statistical difference at the 95% confidence level for the between and within bottle variances. Therefore, the material can be considered homogeneous for aluminum if 200- to 300-mg test portions are taken. The variance was greater and the average lower when 30-mg test portions were analyzed for aluminum by GFAAS. The pattern of the results, together with the need for HF in the dissolution procedure, suggests the presence of aluminum-containing microparticulate mineral matter, perhaps silicate material, in the material.

BYRON KRATOCHVIL, NORINE MOTKOSKY, M. JOHN M. DUKE et DENNIS NG. Can. J. Chem. **65**, 1047 (1987).

Faisant appel à l'analyse instrumentale par activation neutronique (AIAN) et à la spectroscopie par absorption atomique avec fournaise de graphite (SAAFG), on a analysé l'aluminium contenu dans le produit biologique de référence TORT-1, un hépatopancréas de homard. Après correction des résultats de AIAN pour les interférences provenant du ^{28}Al qui est produit par les réactions de $^{31}P(n,\alpha)^{28}Al$ et $^{28}Si(n,p)^{28}Al$ et l'utilisation de HNO_3 plus HF pour dissoudre l'échantillon pour les analyses par SAAFG, les méthodes donnent des résultats semblables de 43 ± 3 et 42 ± 2 μg par gramme respectivement pour des essais sur des échantillons de 200 à 300 mg. Les analyses effectuées sur six échantillons provenant de chacune des six bouteilles de TORT-1 ne présentent pas de différences statistiques, au niveau de confiance de 95%, pour des variations entre bouteilles et à l'intérieur de la même bouteille. Si on utilise des échantillons de 200 à 300 mg pour faire les essais, on peut donc considérer que le matériel est homogène pour l'aluminium. Lorsqu'on a analysé l'aluminium sur des échantillons de 30 mg par la SAAFG, les variations étaient plus grandes et la moyenne plus basse. L'ensemble des résultats, couplé au fait qu'il est nécessaire d'utiliser du HF pour dissoudre l'échantillon, suggère qu'il contient probablement substances minérales porteuses d'aluminium, comme des silicates, à l'état de microparticules.

[Traduit par la revue]

Introduction

Accurate determination of trace aluminum in biological materials is difficult. Problems include contamination or loss during sample collection and preparation for measurement, and bias and scatter in the measurement steps. As a result, only two of the biological standard reference materials presently available from the U.S. National Bureau of Standards, Pine Needles SRM 1575 and Tomato Leaves SRM 1573, are certified for aluminum. For Bovine Liver SRM 1577a, a provisional value of 2 μg/g is given, but values ranging from 1.8 to 65 μg/g have been reported in the literature (1).

The marine biological reference material TORT-1 of the National Research Council of Canada, prepared from acetone-extracted lobster hepatopancreas, has been certified for 15 trace elements, but not for aluminum because of the poor reproducibility of results obtained by various methods in different laboratories. A study was therefore made of the homogeneity and concentration of Al in this material using two methods, instrumental neutron activation analysis (INAA) and graphite furnace atomic absorption spectroscopy (GFAAS). A third method, inductively coupled plasma emission spectroscopy, has also been used to determine Al in biological matrices (2), but was not studied here.

The determination of trace aluminum in biological and environmental materials is of increasing interest. Acid rain has been connected with elevated levels of aluminum in water; aluminum is reported to affect fish at concentrations as low as 100 μg/L (3). Also, concern about the neurotoxicity of aluminum is growing, and it has been implicated in the development of senility, and of Alzheimer's disease (4).

Experimental

GFAAS measurements

Apparatus

The atomic absorption measurements were made on a Perkin Elmer Model 5000 spectrophotometer with background correction, an HGA 2200 furnace, and an AS-1 autosampler. Pyrolytic graphite tubes with platforms (Perkin Elmer Part No. B012-1091) were used (5). Operating conditions are given in Table 1. The argon purge gas flow was continued during atomization at the normal (40 mL/min) setting for 7 s. Peak areas were recorded on a Perkin Elmer PRS-10 printer sequencer. Working curves were linear over the range 0 to 3.7×10^{-6} *M* aluminum (0 to 2 ng Al per 20 μL injection). A typical working curve had a slope of 0.215 ± 0.016 absorbance units per μg injected and an intercept of 0.08 ± 0.06 ng Al for two replicates each of 3 standards and a blank (uncertainties are one standard deviation). Blanks carried through the same procedure as the samples were run on the instrument after every few measurements and the absorbance for the appropriate blank subtracted from the sample

TABLE 1. Operating conditions for graphite furnace atomic absorption measurements of aluminum

Parameter	Value
Wavelength	308.2 nm
Integration time	6 s
Spectral slit width	0.7 nm
Drying temperature and time	110°C, 30 s
Ashing temperature and time	1400°C, 40 s
Atomization temperature and time	2550°C, 6 s
HCL current	25 mA

absorbances to correct for blank components including drift and furnace deterioration. Each injection of 20 μL was repeated two or three times.

Reagents

Distilled water was further purified by passage through a column of mixed strong acid and strong base ion exchange resins (Amberlite MB-3, Rohm and Haas Co.). The nitric acid for sample dissolution was double sub-boiling distilled in quartz (Seastar Chemicals, Sidney, B.C., Canada). All other chemicals were either analytical or reagent grade. A certified standard solution of aluminum (Spex Industries 1000 μg/mL) was used to prepare the calibration curves and for standard additions.

Sample preparation

Six bottles of TORT-1, obtained from the Marine Standards Analytical Program, Division of Chemistry, National Research Council, Ottawa, Canada, were tumbled end-over-end for 2 to 2½ h. Approximately 5-g portions were then removed from each bottle and dried in glass weighing bottles for 24 h at room temperature (23–24°C) in a vacuum oven (National Appliance Co., Model 5851-6) at approximately 0.06 mm Hg. The vacuum was produced with a pump (Welch Co.) separated from the oven by a dry ice – acetone cold trap. Previous studies have shown these drying conditions to be optimum (6). The dried samples were stored in closed weighing bottles in a desiccator over magnesium perchlorate.

To check the methods, U.S. National Bureau of Standards standard reference materials Oyster Tissue SRM 1566 and Pine Needles SRM 1575 were also analyzed. These materials were dried in the same way as TORT-1.

For the study of small samples approximately 35-mg portions of the biological materials were weighed to ±0.01 mg on a Mettler H-51 semimicro balance and transferred into Teflon thick-walled, screw-capped decomposition vessels of about 20-mL capacity (H. K. Morrison and Sons, Mt. Uniacke, N.S., Canada). About 3 mL of concentrated HNO_3 and 0.2 mL concentrated HF (1 mL HF for NBS SRM 1575 Pine Needles) were added to each vessel and the cover tightly secured. The vessels were placed in a boiling water bath for 3 h, then removed, wiped immediately, and allowed to cool to room temperature. After cooling, the contents of each vessel were transferred into a Teflon bottle containing a solution of 0.185 g H_3BO_3 (0.93 g for Pine Needles) in 5 mL of water. The amount of H_3BO_3 added is determined by the amount of HF used in the dissolution step, since its purpose is to remove excess HF as fluoroborate. The solutions were diluted to approximately 15 mL for TORT-1, 25 mL for Oyster Tissue and 100 mL for Pine Needles. The final volumes were determined by weighing the solutions and by determining their densities from the weights of 1-mL portions.

The standard-additions solutions were prepared by pipetting 1 mL of 0.0547 *M* $Mg(NO_3)_2$ and 2 mL of sample solution into four or five 30-mL Teflon bottles followed by 0 to 0.6 mL of standard Al solution (1 μg per mL). The Al standard was added with a variable micropipet (Socorex 60–100 μL). Three or four standard additions were made to each digested sample. The solutions were then diluted to about 10 mL and the final volume determined by weight as described above.

For large samples approximately 300-mg portions of TORT-1 were weighed into the Teflon decomposition vessels and 3 mL HNO_3 and 1 mL HF were added. After 6 h digestion in a boiling water bath the vessels were removed, wiped, and allowed to cool. The digestion mixture was added to a polypropylene 100-mL volumetric flask containing 0.93 g H_3BO_3 dissolved in about 20 mL of water. The solution was diluted to volume, transferred to a Teflon bottle, and 2-mL portions taken for preparation of the standard-additions solutions as described before. All solutions were run on the atomic absorption spectrophotometer immediately after preparation. Plots of absorbance against aluminum added were drawn and the *x*-axis intercept, obtained by least-squares calcuation, was used to calculate the aluminum present in the sample solution.

INAA measurements

Approximately 200-mg portions of biological reference material were weighed into nitric acid-washed 400-μL polyethylene micro-centrifuge tubes. The tubes were heat-sealed and then enclosed in second larger polyethylene vials for irradiation. Standards were prepared from commercial atomic absorption standard solutions (Alpha) by pipetting 5 to 100 μL of stock solution onto Whatman #1 filter paper that had been rolled and inserted into micro-centrifuge tubes.

Irradiation and counting

The irradiation and counting operations were carried out at the SLOWPOKE II reactor facility of the University of Alberta. Conditions used for the analysis were: 120-s irradiation at 1×10^{11} n cm^{-2} s^{-1}, 10-s delay, and 180-s count 6 cm from an unshielded detector.

Counting of the 1779 keV γ radiation of ^{28}Al (half-life 2.24 m) was carried out with an Ortec 86 cm^3 active volume Win-15 coaxial Ge(Li) detector coupled to a Nuclear Data (ND) 660 multichannel analyzer with an Ortec 572 amplifier and ND 575 ADC. The detector specifications include a relative efficiency of 18.5%, and a measured FWHM of 2.1 keV and peak-to-Compton ratio of 53:1, for the 1332 keV photopeak of ^{60}Co. Signals were assigned to one of 4096 channels and the spectral data were stored on floppy discs for later analysis.

The specific activity (counts/μg) for Al was determined for the irradiation-decay counting period described, and the mass of Al in the NBS standards and TORT-1 was determined via an adaptation of the comparator (semi-absolute) method for INAA (7), that is, by dividing the 1779-keV photopeak area of the unknowns by the specific activity of Al. Deadtime corrections (8) for the decay of short-lived radioisotopes were applied; in addition, a correction factor for random summing effects was calculated and applied following the procedure of Wyttenbach (9).

The measurement of aluminum using the 1779 keV photopeak of ^{28}Al produced via the reaction ^{27}Al(n,γ)^{28}Al suffers a nuclear interference from the fast neutron reaction ^{31}P(n,α)^{28}Al. The interference factor for this reaction, that is, the mass of phosphorus that would produce the equivalent activity of 1 μg aluminum irradiated and analyzed under identical conditions, was empirically determined by irradiating and counting P and Al standards (10). Potassium dihydrogen phosphate and aluminum AA standards were irradiated for 120 s in the SLOWPOKE reactor at a thermal flux of 2.5×10^{11} n cm^{-2} s^{-1}. After a decay period of 30 s each test portion was counted for 180 s live-time at 6-cm geometry using the Win-15 coaxial Ge(Li) detector. The potassium phosphate standard was also analyzed for aluminum by GFAAS. A concentration of 7 μg Al per g was found and a correction made for this amount when calculating the interference factor. Analysis of twelve standards gave a corrected phosphorus interference factor to aluminum of 668 ± 30 (1 std. dev.) μg/g. From the certified NRC phosphorus content of TORT-1, 0.879% ± 0.021% (95% tolerance limits), and this interference factor, the phosphorus is calculated to produce an activity equivalent to 13.2 ± 0.6 μg Al per g of TORT-1. This interference was subtracted from the total aluminum determined by INAA for all TORT-1 test portions.

A similar correction was made for the ^{28}Si(n,p)^{28}Al interference reaction. The interference, based on a measured silicon concentration

TABLE 2. Analytical results in μg/g for aluminum in TORT-1 by INAA and GFAAS[a]

Method	Sample size (mg)	Bottle Number 5	155	811	881	887	908	Average

of 231 ± 33 μg/g in TORT-1 by GFAAS and an interference factor of 192, is equivalent to 1.2 μg Al per g of TORT-1 (10). The aluminum results from the INAA measurements were corrected for the phosphorus and silicon interferences, therefore, by subtracting a total of 14.4 μg/g from all measured aluminum values. The additional uncertainty in the result for Al introduced by this correction is about 0.7 μg/g.

When phosphorus and silicon concentrations are not known from other measurements it is possible to determine these elements concurrently with aluminum by irradiating a second test portion with epithermal and fast neutrons. This allows the contribution of phosphorus and silicon to the ^{28}Al activity to be estimated. Procedures using this approach have been reported (11–14). It was not used here because the amount of phosphorus present was already known from the certificate data, and because the level of silicon was so small a GFAAS measurement was more convenient and precise.

All spectral analyses were performed off-line in batch mode using standard Nuclear Data software (with modifications made by personnel at the SLOWPOKE facility).

Results and discussion

The results of the analyses of TORT-1 for aluminum are summarized in Table 2, and of the NBS standard reference materials SRM 1566 Oyster Tissue and SRM 1575 Pine Needles in Table 3.

Initial results for aluminum in TORT-1, using the HNO_3 dissolution procedure that was successful for the determination of lead and cadmium (15), were not satisfactory. Values tended to be low and erratic on 300-mg portions. Reproducibility was achieved only after HNO_3 was replaced by a mixture of HNO_3 and HF, and magnesium nitrate was added to the solutions before measurement by GFAAS. The presence of magnesium has been reported previously to reduce early loss of aluminum during the sample charring stage (16–18). Scatter for 30-mg portions analyzed by GFAAS remained larger than expected on the basis of the 300-mg results, however, even with the addition of HF (Table 1). This variability may be caused by non-uniform distribution of aluminum in the material, but this has not been proven. The averages for 30-mg portions are significantly lower than for 200- to 300-mg portions, with occasional values higher than would be expected for a Gaussian distribution. Preliminary data on 30-mg portions by INAA indicate values of the same order as for the 300-mg portions. Work on this aspect of the problem is continuing. Figure 1 shows the distribution patterns for 200- to 300-mg test portions by the two methods and for the two test-portion sizes by GFAAS.

Data for aluminum in reference materials similar in composition to TORT-1 are rare. Table 2 shows results of a limited number of analyses of SRM 1566 Oyster Tissue and SRM 1575 Pine Needles. Results for aluminum in both materials agree reasonably well between the two methods; those for Pine Needles agree with the NBS certified value and with values reported in the literature. One literature value has been reported for Oyster Tissue; NBS does not give a certified value. The literature value is somewhat higher than ours.

A one-way analysis of variance of the results for the 200- and 300-mg test portions in Table 2 indicates that there is no difference in the between and within bottle variances for aluminum by either method at the 95% confidence level. Furthermore, no statistical difference is observed at the 95% confidence level between the average values obtained by the two analytical methods.

Although the average values for the 30-mg portions are much lower than for the larger sample sizes, the scatter is much higher. An F test indicates that the variances for the 30- and 300-mg analyses by GFAAS differ significantly at the 95% confidence level ($F = 6.25$, $F_{.95} = 5.05$ for $\upsilon_1 = \upsilon_2 = 5$ d.f.), so the 30-mg data set cannot be compared with the 300-mg set by analysis of variance. The same conclusion holds when variances of the 30- and 200-mg portions are compared.

In summary, our best estimate of the aluminum content of

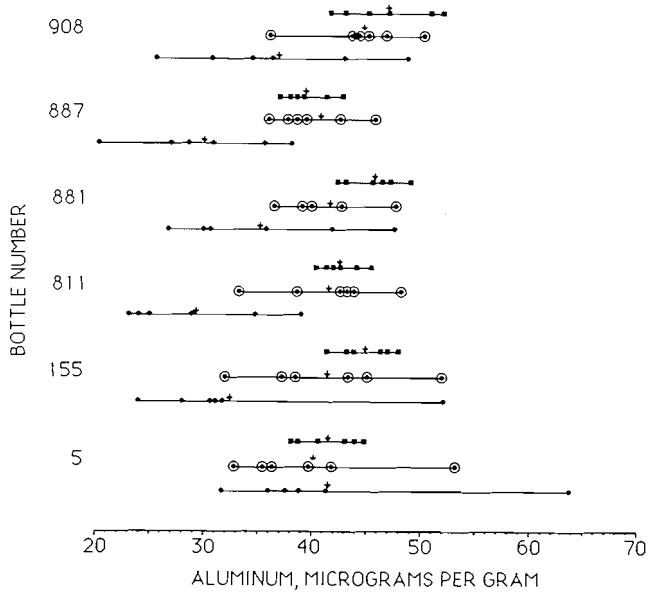

FIG. 1. Distribution of individual analytical results for Al in randomly selected bottles of TORT-1 certified reference material by graphite furnace atomic absorption spectroscopy (GFAAS) and by instrumental neutron activation analysis (INAA). The short vertical arrows above each data set identify the average value of that set. (■) INAA, 200-mg test portions; (○) GFAAS, 300-mg test portions; (●) GFAAS, 30-mg test portions.

TORT-1 is 43 ± 3 μg/g, where the ±3 denotes one standard deviation based on 72 analyses. The results indicate that TORT-1 is homogeneous for aluminum when 200 to 300 mg or larger test portions are taken, but that homogeneity is suspect at the 30-mg level. Also, dissolution in HNO_3 alone is not adequate to dissolve all the aluminum-containing material; addition of HF is necessary. This requirement differs from previous studies of lead and cadmium in TORT-1, where HNO_3 alone was shown to be sufficient to release both metals from the matrix (15).

Pulse cyclic voltammetry. I. Static solutions

GORDON N. ECCLES AND WILLIAM C. PURDY
Department of Chemistry, McGill University, 801 Sherbrooke St. West, Montreal, P.Q., Canada H3A 2K6

Received September 28, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

GORDON N. ECCLES and WILLIAM C. PURDY. Can. J. Chem. **65**, 1051 (1987).

By using pulse cyclic voltammetry rather than cyclic voltammetry at a relatively high scan rate, an increase in sensitivity and a lowering of the detection limit by more than a factor of two are demonstrated for the ferricyanide–ferrocyanide couple at a carbon electrode. The test for reversibility based on peak shape or symmetry comparison is enhanced significantly with pulse cyclic voltammetry. Another reversibility test, by observing peak variations as a function of scan rate, was applied to pulse cyclic voltammetry and was found to be as diagnostically informative as the cyclic voltammetry test. These tests are illustrated by a study of the hydroquinone–quinone couple.

GORDON N. ECCLES et WILLIAM C. PURDY. Can. J. Chem. **65**, 1051 (1987).

Dans le cas du couple ferricyanure/ferrocyanure à une électrode de carbone, on démontre que l'utilisation de la voltamétrie cyclique pulsée plutôt que la voltamétrie cyclique à des taux de balayage relativement élevés augmente la sensibilité et diminue la limite de détection par un facteur qui est plus grand que deux. Avec la voltamétrie cyclique, on augmente considérablement le test pour la réversibilité qui est basé sur la forme du maximum ou sur une comparaison de la symétrie. On a aussi appliqué un autre test de réversibilité, basé sur les variations des maxima observés en fonction du taux de balayage, à la voltamétrie pulsée et on a trouvé que ce test permet un aussi bon diagnostique que le test de la voltamétrie cyclique. On illustre ces tests par une étude du coupe hydroquinone/quinone.

Introduction

Cyclic voltammetry (CV) is a well documented electroanalytical technique offering a wealth of information for the study of redox couples, reaction kinetics, and the mechanism of many electrochemical reactions (1–4). Its use, however, has been restricted primarily to the gathering of qualitative information. Quantitative determinations are better made by other electroanalytical techniques such as differential-pulse (5, 6) and square-wave voltammetry (5, 7, 8). By comparison these latter techniques offer increased sensitivity over CV due to their ability to effectively separate charging current, which contributes largely to the background, from the faradaic current and interpretation of the peak readout is much simpler. In multicomponent analysis well-defined peaks are simpler to resolve as opposed to the semi-peak readout for CV. It would, therefore, be plausible to expect the same benefit when using CV with pulsed techniques. The present work was undertaken to confirm this model using the ferricyanide–ferrocyanide couple as the example.

When a new redox couple is studied with the aim of evaluating the reaction mechanism, cyclic voltammetry can provide critical information about the electrochemical reversibility of the electrode reaction. The usual procedure involves measuring either peak separations or peak height ratios for the anodic and cathodic peaks as a function of scan rate (3, 4). If a couple is reversible, the separation will equal $59/n$ mV, where n is the number of electrons involved in the electrode reaction, and the peak height ratio will be close to unity. A somewhat simpler method is to examine the symmetry or shape of the response curves obtained for each scan direction (1). If the couple is reversible, then the curves for the two scan directions will be superimposable. When a redox couple is slightly or quasi-reversible, the shapes of a cyclic voltammogram are not sufficiently different to determine reversibility at a glance. In contrast, pulse cyclic voltammetry (PCV) emphasizes peak symmetry differences. This effect will be illustrated with the data collected for the hydroquinone–quinone couple.

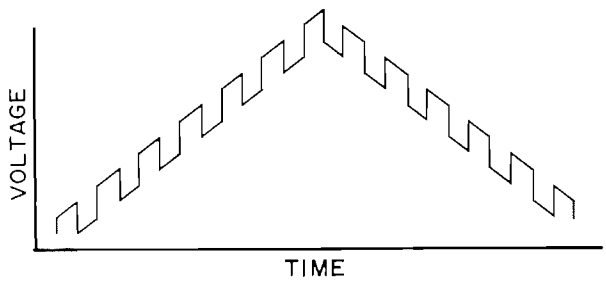

FIG. 1. Working electrode waveform.

Experimental

Electrochemical apparatus

The microprocessor-controlled potentiostat used to carry out CV and pulse cyclic voltammetry (PCV) has been described previously (9). The work described in that paper was based on the waveform shown in Fig. 1. A square wave is superimposed on a linear sweeping voltage and the data are obtained prior to each pulse transition. This type of waveform offers electrochemical information in two time domains. In addition to the conventional CV time scale, another short time scale is obtained from the negative and positive going pulses. During the lifetime of a pulse in this waveform the potential continues to ramp, introducing a charging current component. Additional equipment required includes an IBM PC with 640 kbytes of memory, an IBM colour monitor, a HP 7470 2-pen plotter, and a three-electrode cell consisting of an SCE reference, platinum wire auxiliary, and a low temperature isotropic carbon (LTIC) working electrode (1.57 cm^2, available from Carbomedics Inc., Austin, TX). This cell was fitted with a nitrogen gas purging system.

The software language used to operate the instrument and manipulate the data was written in TURBO Pascal-87. The program is menu-driven and communicates interactively with the operator for smooth operation.

Chemicals

Reagent grade chemicals were used in preparation of all solutions. A 2.00 m*M* stock solution of potassium ferricyanide was prepared by dissolving the salt in 1 *M* potassium nitrate. Solutions of 1.00, 0.400, 0.200, and 0.080 m*M* were subsequently prepared by diluting

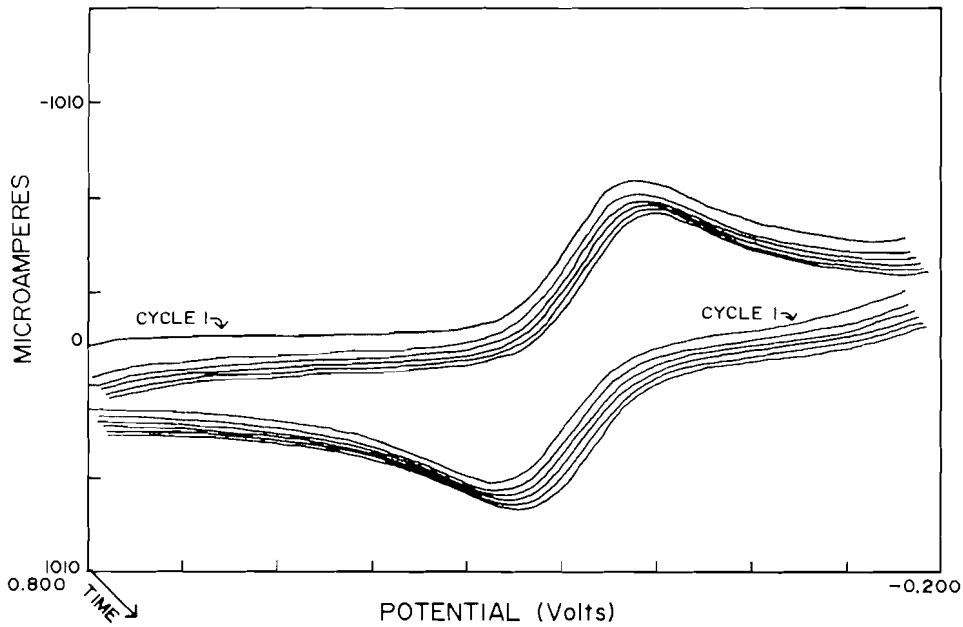

FIG. 2. Multiple scan cyclic voltammogram of 2 m*M* ferricyanide in 1 *M* potassium nitrate. Number of cycles = 6. Data acquisition frequency = 120 Hz. Voltage ramp = 1 V/s.

the appropriate volume of the stock solution in 1 *M* potassium nitrate. Solutions of quinone and hydroquinone, 1 m*M*, were prepared by dissolving the required weights in 1 *M* sulfuric acid.

Procedure

Cyclic and pulse cyclic voltammograms were obtained for various concentrations of ferricyanide in 1 *M* potassium nitrate. The sequence was to purge each solution with nitrogen gas for 15 min, hold the working electrode at 0.800 V for several minutes, and then apply the waveform. A total of two runs containing six consecutive cycles was obtained for each concentration in both modes of operation.

Cyclic and pulse cyclic voltammograms were obtained from 1 m*M* solutions of quinone and hydroquinone in 1 *M* sulfuric acid at various scan rates. The sequence was similar to the one described above except the holding potential for the quinone solution was −0.200 V. One run containing five consecutive cycles was obtained for each solution in both modes of operation.

All the data were stored on a hard disk in the computer and processed later by outputting the response current vs. potential curves to a plotter.

Results

CV and PCV as a quantitative tool

It is rare to continue the waveform in a CV experiment for more than two or three cycles (4). In fact, much of the diagnostic information available from a cyclic voltammogram can be obtained from the first cycle. In quantitative work using an LTIC electrode, however, it is best to use the data collected after completion of this cycle. This is illustrated by the results of a multiple scan CV of 2 m*M* potassium ferricyanide in 1 *M* potassium nitrate shown in Fig. 2. To reduce confusion from overlapping lines, the forward and reverse scan results are arbitrarily spaced apart on the response current axis. The residual current becomes reproducible after completion of the first cycle and as a consequence the analyte signal does as well. Therefore there is little advantage to continuing the scan beyond the third cycle.

A PCV experiment on the same redox couple is shown in Fig. 3. It is difficult to observe a background current difference between the first cycle and subsequent cycles and this would indicate that PCV can be used for quantitative work on the first cycle. It is appropriate here to discuss the format and information obtained in this plot. The data presented on the left half of the figure were acquired from the forward scans. These curves represent the current obtained by calculating the absolute difference between a point acquired during a forward pulse and another during the respective reverse pulse. In an identical manner, the data on the other side of the switching potential (right half of the figure) were obtained from the pulses applied during the reverse scan.

The peak currents for both CV and PCV experiments for various concentrations of potassium ferricyanide were plotted and are shown in Fig. 4. The two upper curves, acquired from PCV data, show the expected increase in sensitivity in comparison to CV data. The pulsed data show a drop in signal at 2 m*M* which is probably due to departure from the dynamic range of this technique at this scan rate. The linear regression equation for the forward-scan peak in PCV excluding the data for 2 m*M* ferricyanide (top curve) was $y = -16.37 + 493.34x$ with a correlation coefficient of 0.998. The equation obtained for the forward-scan peak in CV (second from the bottom) was $y = -10.06 + 327.36x$ with a correlation coefficient of 0.9997. The detection limits obtained were 0.4×10^{-5} *M* and 1×10^{-5} *M* for PCV and CV.

Comparison of CV and PCV response curve symmetry differences for the hydroquinone–quinone redox couple

Consistent with the above, a multiple CV scan of the hydroquinone–quinone couple shows reproducibility after the first cycle (Fig. 5). The shapes of the forward and reverse scan peaks obtained during these cycles do not appear sufficiently different to test reversibility of the couple and further information is needed using one or both of the measurement techniques described above.

An alternative method of presenting PCV data which is diagnostically more informative is to plot the raw data obtained during the forward and reverse pulses. This gives an insight in

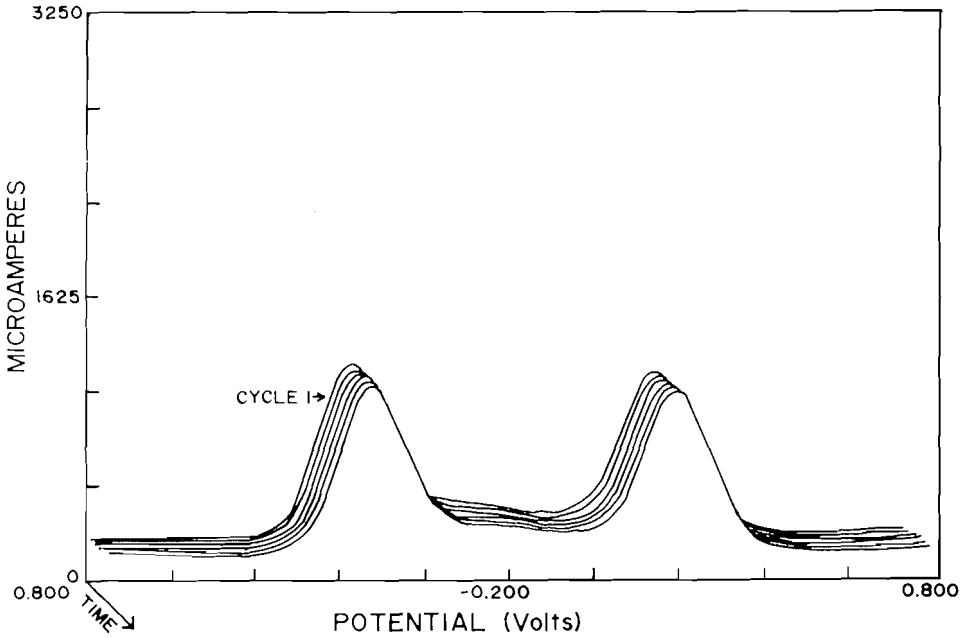

FIG. 3. Multiple scan pulse cyclic voltammogram of 2 m*M* ferricyanide in 1 *M* potassium nitrate. Number of cycles = 6. Data acquisition frequency = 130 Hz. Square wave frequency = 65 Hz. Square wave amplitude = 100 mV. Voltage ramp = 1 V/s.

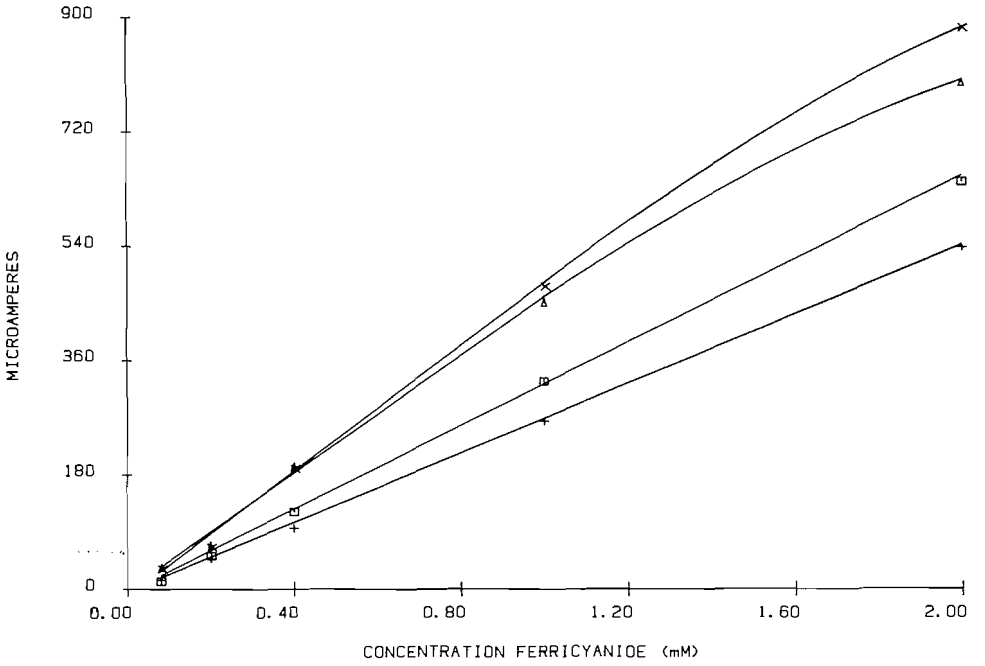

FIG. 4. Comparison of pulse cyclic and cyclic voltammetry calibration curves for various concentrations of ferricyanide: (●) PCV reduction, (△) PCV oxidation, (□) CV reduction, (×) CV oxidation.

two time domains (see Fig. 6). For clarity, in this and the following two figures the third run is plotted to give the pulsed cyclic voltammogram. The two peaks on the left-hand side of Fig. 6 (or to the left of the −0.200 V switching potential) describe what is occurring during the forward scan. The major peak (in the negative microampere region) represents the reduction current for the reduction of quinone to hydroquinone and is obtained from the upward pulses of the applied waveform. The minor peak represents the oxidation of the generated hydroquinone during the downward pulses (short time scale).

On the right-hand side of Fig. 6 the major peak (long time scale) is the oxidation current obtained from the downward pulses in the reverse scan. The poorly defined hump in the upper trace was the contribution of reduction current taken in the short time scale. It is clear from the difference plot of these data (Fig. 7), that the height of the reverse-scan peak exceeds that of

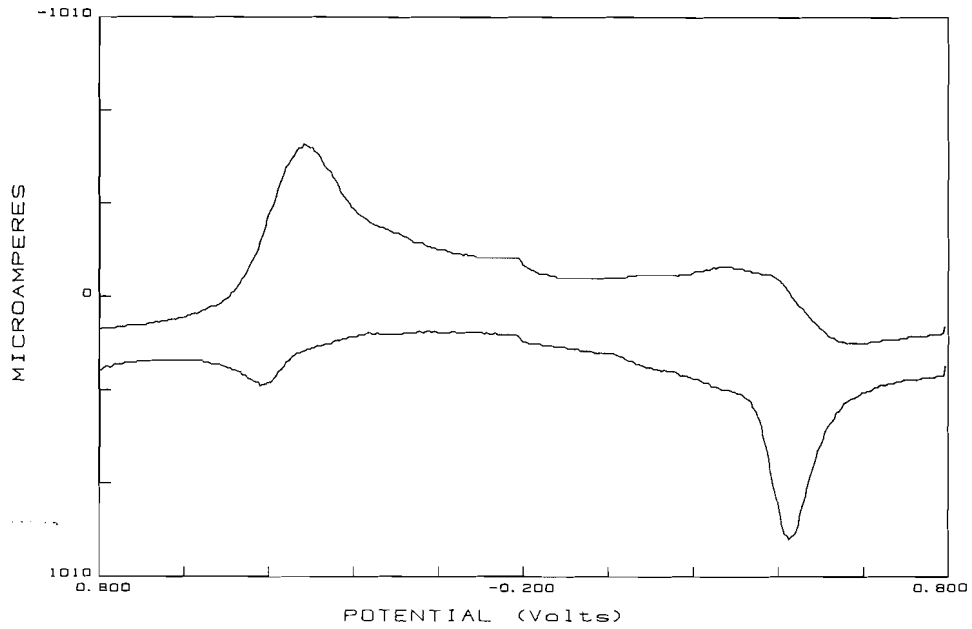

FIG. 6. Third cycle of a multiple scan pulse cyclic voltammogram of 1 m*M* quinone in 1 *M* sulfuric acid. Number of cycles = 5. Data acquisition frequency = 130 Hz. Square wave frequency = 65 Hz. Square wave amplitude = 100 mV. Voltage ramp = 100 mV/s.

the forward scan and that the shapes are different. This signifies that this redox couple is irreversible at the scan rate studied. Further tests are required to determine whether the couple is slightly or quasi-reversible. Nevertheless the plot does indicate at a glance that the couple is not reversible, a feature that the cyclic voltammogram of the same couple (Fig. 5) does not as convincingly provide. It follows then, that a difference current plot of a hydroquinone solution would likely show irreversibility as well. Figure 8 confirms this and also indicates that the forward-scan difference peak current is greater in magnitude than the peak in the reverse scan. This is exactly opposite to what was observed with the quinone solution.

The variation of peak positions as a function of scan rate for CV and PCV difference plots to determine reversibility were obtained for the solutions hydroquinone and quinone. The results tabulated in Table 1 indicate that peak separations

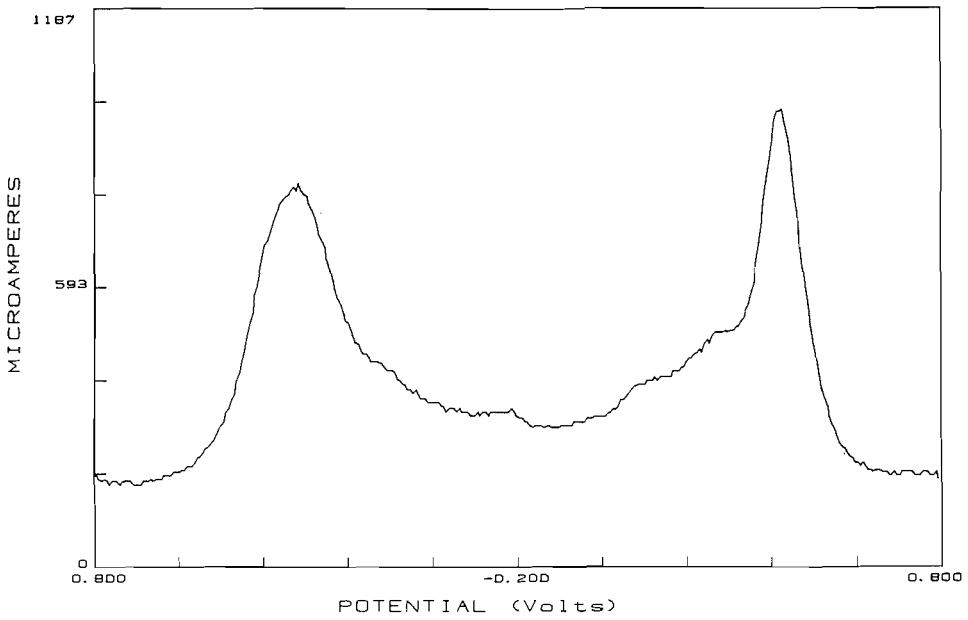

FIG. 7. Third cycle of a multiple scan difference pulse cyclic voltammogram of 1 m*M* quinone in 1 *M* sulfuric acid. Number of cycles = 5. Data acquisition frequency = 130 Hz. Square wave frequency = 65 Hz. Square wave amplitude = 100 mV. Voltage ramp = 100 mV/s.

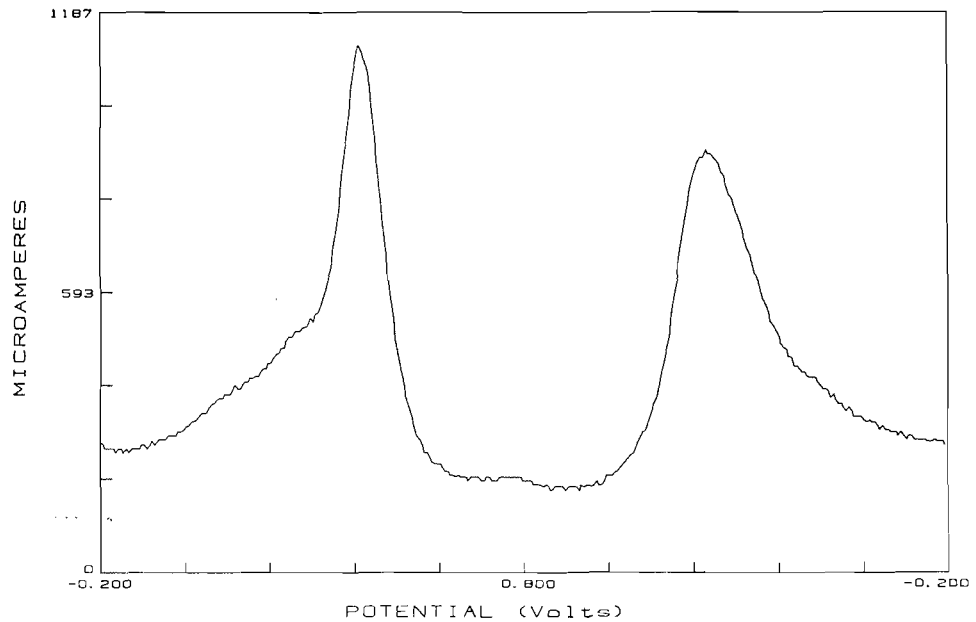

FIG. 8. Third cycle of a multiple scan difference pulse cyclic voltammogram of 1 m*M* hydroquinone in 1 *M* sulfuric acid. Number of cycles = 5. Data acquisition frequency = 130 Hz. Square wave frequency = 65 Hz. Square wave amplitude = 100 mV. Voltage ramp = 100 mV/s.

are narrower but do expand with increasing scan rate for the PCV data. This confirms that this test of reversibility is another useful diagnostic tool that PCV has to offer.

To investigate the use of PCV as a quantitative tool for a solution of hydroquinone, the calibration curve may be best obtained from the major peak during the forward scan in terms of sensitivity (Fig. 8). Linear sweep square-wave voltammetry would, as the forward scan, yield the same type of curve. In contrast, however, a pulse cyclic voltammogram of a quinone solution (Fig. 7) exhibits the major peak during the reverse scan, indicating an ability that the linear sweep technique lacks. A range of scan rates was applied to 1 m*M* solutions of quinone and hydroquinone using CV and PCV. The peak currents for both the forward and reverse scans for CV were plotted against the log of the scan rate. Included on each plot are four PCV curves; two forward and reverse difference current curves and

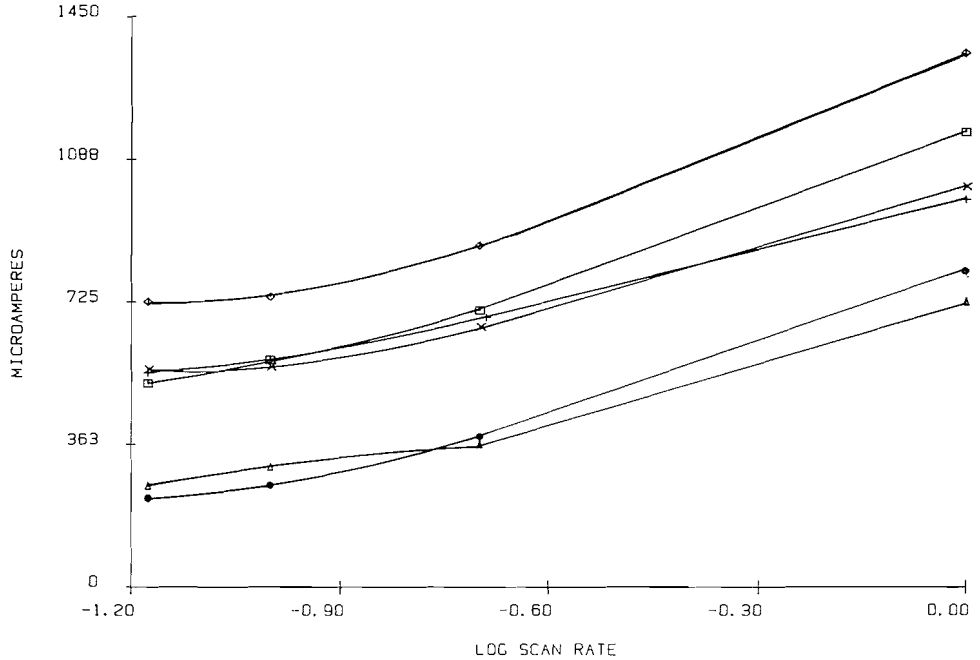

FIG. 9. Response vs. log scan rate for 1 m*M* quinone using cyclic and pulse cyclic voltammetry: (●) CV reduction, (△) CV oxidation, (□) PCV reduction, (+) PCV oxidation, (×) PCV difference reduction, (◇) PCV difference oxidation.

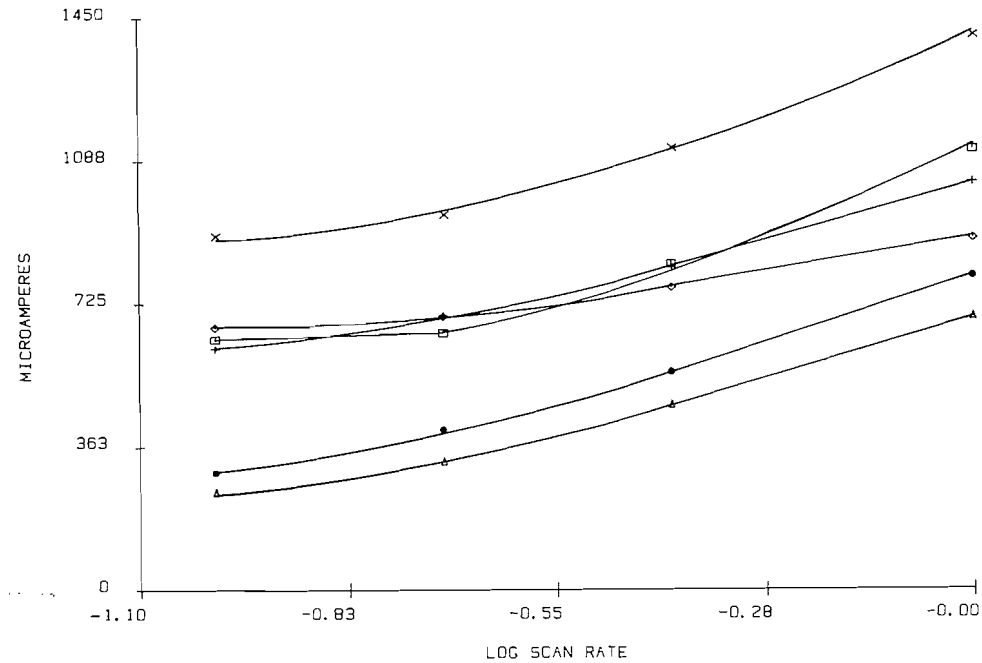

FIG. 10. Response vs. log scan rate for 1 m*M* hydroquinone using cyclic and pulse cyclic voltammetry: (●) CV reduction, (△) CV oxidation, (□) PCV reduction, (+) PCV oxidation, (×) PCV difference reduction, (◇) PCV difference oxidation.

the raw data curves plotted against log scan rate (Figs. 9 and 10). By examining both plots it can be concluded that at the scan rates studied, the PCV difference oxidation peak for either solution offers the greatest sensitivity for quantitative work and indeed CV offers the least.

Conclusions

PCV and CV offer quantitative information if the second or third cycle is used for data analysis as was shown using the ferri–ferrocyanide couple on an LTIC electrode. The detection limit of ferricyanide was found to be 0.4×10^{-5} *M* using PCV and 1×10^{-5} *M* using CV at a scan rate of 1 V/s. The relative sensitivity of these two techniques was shown to be greater for PCV experiments. Present work includes the use of signal averaging and fourier smoothing techniques to further increase the sensitivity.

PCV emphasizes shape or symmetry contrast as a test of reversibility for the quinone–hydroquinone redox couple

TABLE 1. Peak separation as function of scan rate for hydroquinone and quinone using CV and PCV data

Scan rate (V/s)	Peak separation (V)			
	Hydroquinone		Quinone	
	CV	PCV	CV	PCV
1.000	0.245	0.148	0.270	0.169
0.400	0.208	0.112	0.235	—
0.200	0.184	0.077	0.220	0.121
0.100	0.184	0.054	0.183	0.099
0.067	0.139	—	0.156	0.063

studied. The difference current plots obtained, provide a rapid conclusive test. In contrast, CV data for the same couple were not as informative. Another popular CV test of reversibility using peak separation as a function of scan rate was applied and ratified by PCV data obtained on the same redox couple. It was also shown that the major peak for either a solution of quinone or hydroquinone was due the oxidation of hydroquinone. In the case of the quinone solution the hydroquinone was generated during the forward-scan of the applied waveform.

Received January 29, 1986[1]

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

K. M. WILSON-YANG and GEORGE BURNS. Can. J. Chem. **65**, 1058 (1987).

The once colourful mural paintings at the Beni Hasan tombs (ca. 2100 B.C.), an important Egyptian archaeological site, are covered with an obscuring grey deposit. Qualitative observations made over the past 150 years were assembled and correlated with each other by us. Cumulatively, they indicate that recently the development of this layer has accelerated. To study this surface degradation, X-ray photoelectron spectra of fragments from the painted walls have been collected. Empirical XPS sensitivity factors have been employed to treat the data semiquantitatively. Three types of surfaces were identified. The first surface consists of $CaCO_3$ and SiO_2 as major constituents, and was the only surface identified previously. Our XPS data indicate that it also contains Al_2O_3, NaCl, MgO, sulphates, and phosphates as minor and trace components. The second surface consists predominantly of aluminium silicates. The third surface consists mostly of calcium carbonate. A preliminary mechanism for opaque layer formation is proposed herein. It suggests that the principal physicochemical processes are adsorption of water in the presence of carbon dioxide, followed by dissolution of the substrate walls upon which the murals were painted. This mechanism is consistent with our finding that mural deterioration is recent; it also indicates that deterioration is progressive, continuous, and cumulative. Further experiments are designed to verify the proposed mechanism. Two mechanisms proposed earlier are found to be inconsistent with at least some of our findings. Relatively recent efforts in removing obtrusive surface layers with dilute HCl were found to be performed carefully; there was no evidence of excess chlorides on cleaned surfaces. However, this finding does not provide a guarantee that murals were undamaged by HCl below the surface. It does suggest that progressive damage due to the formation of hygroscopic $CaCl_2$ on the surface has been avoided.

K. M. WILSON-YANG et GEORGE BURNS. Can. J. Chem. **65**, 1058 (1987).

Les peintures murales très colorées des tombes de Beni Hasan (environ 2100 B.C.), un site archéologique égyptien important, sont couvertes par un dépot gris qui les rend moins claires. On a rassemblé et établi des corrélations entre les diverses observations qualitatives qui ont été faites au cours des 150 dernières années. Ces observations prises d'une manière cumulative indiquent que le développement de cette couche s'est récemment accéléré. Dans le but d'étudier cette dégradation de la surface, on a recueilli les spectres photoélectroniques par rayons-X de fragments provenant de la peinture des murs. Dans le but de faire un traitement semi-quantitatif des données, on a utilisé des facteurs empiriques pour la sensibilité des SPX. On a identifié trois types de surfaces. Les constituants principaux de la première sont le $CaCO_3$ et le SiO_2; il s'agit de la seule surface qui avait été identifiée antérieurement. Nos données de SPX indiquent qu'elle contient aussi du Al_2O_3, du NaCl, du MgO, des sulfates et des phosphates, comme constituants mineurs et à l'état de traces. La deuxième surface est formée principalement de silicates d'aluminium. La troisième surface consiste essentiellement en carbonate de calcium. On propose un mécanisme préliminaire pour la formation de la couche opaque. Ce mécanisme suggère que le principal processus physico-chimique est l'adsorption de l'eau, en présence de bioxyde de carbone, qui est suivie d'une dissolution des murs qui agissent comme substrats et sur lesquels les murales avaient été peintes. Ce mécanisme est en accord avec nos observations selon lesquelles la détérioration murale est récente; il indique aussi que la détérioration est progressive, continue et cumulative. Dans le but de vérifier le mécanisme proposé, on envisage d'autres expériences. On a trouvé que deux mécanismes proposés antérieurement ne sont pas en accord avec un certain nombre de nos observations. Des efforts ont été déployés récemment dans le but d'enlever les couches superficielles qui créent des obstructions et, pour ce faire, on procède à des lavages avec du HCl dilué; nos observations, à l'effet que l'on ne retrouve pas de résidus d'ions chlorures sur les surfaces nettoyées, démontrent que que cette opération peut être effectuée avec soins. Toutefois, ces observations ne fournissent aucune garanties relativement aux dommages que le HCl aurait pu faire subir aux murales en-dessous de la surface. Ces observations suggèrent toutefois que l'on a pu éviter les dommages progressifs qui auraient pu être causés par la formation de $CaCl_2$ hygroscopique sur la surface.

[Traduit par la revue]

Introduction

The tombs at Beni Hasan, near Minya in Middle Egypt, date from circa 2400 B.C. to 1700 B.C. (6th Dynasty, Old Kingdom, to 12th Dynasty, Middle Kingdom). They are cut in levels in cliffs on the east bank of the Nile, and number over 400. The tombs in the uppermost level, carved from a single stratum of polycrystalline calcite (nummulitic limestone) have attracted much interest (1, 2). Of the 39 upper level tombs, 12 have fine murals dating from circa 2180 B.C. to 1786 B.C. (First Intermediate Period to Middle Kingdom) and are not only important artistically but also constitute a significant record of ancient Egyptian life. The First Intermediate Period is the "dark age" of Egyptian history which immediately followed the earliest known breakdown of a major advanced civilization. Complete disintegrations of major civilizations, and the socio-economic chaos which follows them, are now known to have occurred a number of times in the past; there is much evidence and concern that they continue to occur even at present (3). Although these phases of history attract the considerable attention of scholars in a number of disciplines, they are still poorly understood, because historic evidence from the "Time of Troubles" (3) is often irretrievably lost. Predictably, historic sources from the First Intermediate Period are also scarce. Therefore, it is particularly important to preserve such historic monuments. Yet, ancient artifacts deteriorate with time and, in the case of Beni Hasan, even the basic physicochemical processes which are responsible for such deterioration, are still inadequately identified. No comprehensive conservation and restoration efforts can be undertaken unless these processes are precisely determined; otherwise preservation efforts may only

further damage these ancient sources of information and destroy this great work of art.

A physicochemical investigation of this site was prompted by the presence of an ubiquitous, almost opaque layer on the wall surfaces. Figure 1 illustrates the general appearance of this layer and its cross-section. The earliest mechanism for opaque layer formation was suggested on the basis of visual assessments (4). It proposes that the formation of these layers was initiated by the percolation of water through rock; calcium carbonate and calcium sulphate are carried from any underlying plaster to the surface and deposited as the water evaporated. The idea that water flow could be involved, was novel because it was not obvious that moisture could play an important role in physicochemical processes in the arid regions of Egypt, and to that extent, the mechanism (4) had merit. Nonetheless, it is unlikely that water *percolation* was involved because there was no evidence of extensive water flow. There are no stalactites or stalagmites in these cave-like tombs. No irregularities or discontinuities associated with flow-lines or cracks are seen; on the contrary, the surface is disfigured in a continuous manner.

In a more recent study (5, 6), X-ray diffraction (XRD) analysis of the opaque surface layer showed that it was composed, not of sulphates, as was suggested in the first mechanism (4), but predominantly of $CaCO_3$, SiO_2, and feldspar. Isolated resistivity measurements made within the walls showed no water (5). On the basis of this information, a second, alternative, mechanism was suggested, in which CO_2-saturated, dew-point condensation on the wall surfaces dissolves calcium carbonate present in deposited dust (5, 6). Silica and other less soluble dust constituents are then sealed within a carbonate matrix formed as $CaCO_3$ precipitates. There is a considerable difference between the two mechanisms

TABLE 1. Sample description and provenance

in ref. 4 and refs. 5, 6, especially because the first mechanism predicts disintegration of the substrate upon which the murals were painted while the second does not.

The time of formation of this surface layer was placed in the early part of the Christian era (5), because habitation of these tombs appears to have been commonplace at that time and therefore, the partial pressure of CO_2, P_{CO_2}, and relative humidity, RH, were high (5). Although this suggestion appeared reasonable, it was not based on experimental findings. However, a review of empirical and historical evidence (2) suggests an alternative explanation. In 1798, it was reported that the murals were well-conserved throughout (7). By 1890, deterioration was recognized and it was noted that many of the painted records were indecipherable (7). In the 1930's, copyists referred to a salty coating which made the assessment of colour difficult; however, it was noted that the pigmentation could be uncovered by lightly touching the coating with a brush (8). In 1981, it was reported that the disfiguring coating had coalesced and could no longer be brushed off (2). These findings do not preclude a possibility that at least some opaque layers had been formed in the early Christian era, as was earlier (5) suggested. However, the second mechanism (5, 6) does not account for the recent acceleration of opaque layer formation, and therefore, does not explain the existence of the bulk of it. It can be concluded that neither one of the existing mechanisms (4–6) explains the nature or the dynamic development of the opaque layer.

X-Ray photoelectron spectroscopy

To begin a systematic study of the degradation phenomena now occurring in the Beni Hasan tombs, X-ray photoelectron spectroscopy (XPS) was employed here. This technique makes it possible to examine the first few nanometers of surfaces and is therefore suitable for study of the growth of the obtrusive surface layer. A representative selection of six painted fragments from these tombs was so studied.

The use of the powerful XPS technique in the archaeometric studies of surfaces has been limited. However, this method of analysis has been employed to investigate oxidation states and compositions of unprepared surfaces with or without Ar^+ etching (9, 10).

The inherent heterogeneity of archaeological surfaces makes it difficult to secure representative and accurate data. It is possible, however, to treat data semiquantitatively. Simple intensity ratios (9) and ratios correlated with known weight percentages (11) have been used in pottery analyses. Inter-element comparisons of Egyptian pigments have been made from intensity ratios corrected using empirical sensitivity factors (10) or photoelectric cross-sections (12). In this paper, recent sensitivity factors (13), with a correction for detector efficiency, are used to reduce the data semiquantitatively.

Experimental

Red and yellow pigmented fragments of painted surfaces were cut from different areas of six of the thirty-nine upper level tombs at Beni Hasan using a clean, stainless-steel scalpel handled with disposable plastic gloves. The sample size was, on the average, approximately 3 mm × 1 mm × 0.5 mm. The samples were stored in pre-cleaned plastic screw-topped vials (Provial and Nalgene) packed with glass wool and sealed with strips of Parafilm. The number of collected samples was representative, but limited; the Beni Hasan tombs are considered an Egyptian National Treasure, and only limited but judicial intrusion on our part was justifiable.

Six samples were chosen from the total set for analysis by XPS (Table 1). These samples are representative of surface appearance, colour, and physical position. Samples 1 and 2 have yellow and red paint layers, respectively. Both samples appear irregular with some smooth, glaze-like patches. Sample 3, at one time painted red, is severely disfigured by a uniform white layer. Sample 4 has a black surface and originates from a heavily encrusted tomb which had evidence of severe smoke damage. Sample 5 is a fragment of red painted surface which had been cleaned on site with HCl about 10 years earlier (4). Sample 6 was originally yellow in colour and was taken from a portion of the wall which was slightly slanted in such a way as to prevent direct deposition of dust by gravity alone.

All Beni Hasan tombs face west and have access to the exterior by either open doors or windows. There is a noticeable decrease in disfigurement of the murals with height above the tomb floors. Therefore, all samples were taken from selected heights above floor level (Table 1).

To remove loose dirt and packing material, the surfaces were lightly vacuumed with a Pasteur pipette packed with glass wool attached through a control valve and trap to a mechanical pump.

XPS spectra were obtained on a McPherson ESCA-36 photoelectron spectrometer in the Surface Science Laboratory at the University of Western Ontario. An Mg X-ray anode operated at 200 W was used and data collection was under the control of a PDP-8E computer. Samples were mounted on the 8-place sample stage by Cu pins and secured thereon by a conducting Ag paste. Sample 4, due to its relatively large size (Table 1), was mounted by means of an Al mask. Typically, spectra were collected for 1 h over the full energy range of 0–1000 eV. Narrow energy range spectra, 10 eV in width, were obtained for Ca, N, S, P, and Si in sample 4 and for the carbon region in all samples except in sample 3. These latter spectra were collected for ten scans of the relevant energy region. Analysed areas were approximately 5 mm^2 maximum.

Results

Figure 2 provides the full energy range spectrum for sample 2. Energy resolution for this application of XPS has been assessed as 1.4 eV based on the fwhm of the Au($4f_{7/2}$) line[2] at 83.2 eV. However, when experimental fwhm from these heterogeneous surfaces are used, the resolution is approximately 2.3 eV. The accuracy of the spectra was found to be ±1 eV, based on the

energies of the hydrocarbon C(1*s*) and the silica Si(2*p*) peaks at 285 eV and 103 eV, respectively. These peaks were found in each spectrum. The uncertainty of ±1 eV is predominantly due to charging differences between samples. Table 2 compares literature binding energies with experimental energies for the major peaks of each detected element and provides oxidation state assignments. The experimental energies of some confirming peaks are given also. No unusual difficulties were encountered in making assignments.

In order to obtain semiquantitative intensity comparisons, peak height ratios versus the O(1*s*) peak in each spectrum were taken. Peak heights rather than peak areas were used since it was found from short energy range spectra that the peak widths were constant at 2.3 eV fwhm. The ratios were further modified by a weighting factor. Each weighting factor is a product of improved empirical sensitivity factors (13) and a correction term which compensates for the energy dependence of the spectrometer detection efficiency. Mole ratios were found from the following expression:

$$[1] \quad \frac{n_i}{n_{O(1s)}} = \left(\frac{h_i}{h_{O(1s)}}\right)\left(\frac{S_{O(1s)}}{S_i}\right)\left(\frac{E_{O(1s)}}{E_i}\right)^2$$

For every element i, S_i is the empirical sensitivity factor (13),

E_i is the kinetic energy of the emitted photoelectron from i, h_i is the peak height, and n_i is the number of moles. Results are presented in Table 3.

The sensitivity factor, S_i, reflects the influence of sample area and photoelectric cross-section on the measured intensity. It also contains contributions from the energy and the matrix dependence of the photoelectron mean-free path as well as the probability of detecting a photoelectron, i.e. the transmission factor. The transmission factor is a function of spectrometer design (14) and detector efficiency. Electron angular distributions and the competition of shake-off and shake-up events (15) are also included in the value of S_i. They are considered minor in this application (15).

The literature values S_i are valid only for flat, homogeneous solids without surface contamination, measured on the spectrometer type used in the literature (13). However, reliable use of the literature S_i values is possible through several compensating features of the data treatment procedure used here. The energy factor, $(E_{O(1s)}/E_i)^2$, removes the E^{-1} dependence (13, 14) of the spectrometer transmission factor of the retarding-voltage spectrometers used by Wagner (13) and replaces it with an E dependence (13, 14) for the double-focussing spherical-sector instrument (16) employed in this study. Roughness features are extremely varied on these surfaces and can be as great as 1000 times the X-ray mean-free path. Normalizing to the O(1*s*) peak decreases those intensity variations between samples which are due to irregularities in the surfaces. Variation in sample size is also compensated by this normalization process.

The literature values of $S_i/S_{O(1s)}$ (13) do not completely remove the variation in photoelectron mean-free paths due to heterogeneous matrices. However, it has been found that the ratio of the photoelectron mean-free paths is only slightly matrix dependent (13, 17).

We estimate 20% precision for the reported mole ratios based on a 10% precision for each S_i (12) and a 10% error in peak height measurements. As a gauge of accuracy, mole ratios versus oxygen were calculated from the pure compounds (Table 3): using these maximum values as criteria, the experimental mole ratios are correct within an order of magnitude.

Discussion

The oxidation state assignments (Table 2) and the semi-quantative mole ratios (Table 3) make it possible to differentiate between samples on the basis of surface composition. Surface hydrocarbon, an expected XPS artifact (18, 19), is prominent in all samples. The sources of this carbon peak cannot be elucidated from these spectra; carbon may arise from sample handling, the pre-analysis atmosphere and from hydrocarbon impurities in the surface deposit. Organic nitrogen is seen also and likewise may arise from varied sources. Iron, which is the principle pigment constituent, was not detected in any of the six samples studied. This finding indicates that the

surface deposit screens the pigment layer from analysis by XPS. The experimental limit of detection of Fe based on twice the average peak height of the background has been estimated as 0.09 Fe/O; this is the upper limit of the Fe versus O mole ratio in the surface layer.

Samples 1–4 have surfaces which consist of calcium carbonate and silica, i.e. essentially limestone and sand. The composition of these four samples is similar to those studied earlier (5, 6) using XRD. However, because the XPS technique is more sensitive than XRD, Al_2O_3, MgO, NaCl, sulphates, and phosphates are also detected by us.

The carbon-to-oxygen mole ratios for carbonate in samples 3 and 4 are comparable to that of pure carbonate (Table 3). The carbon-to-oxygen ratios of samples 3 and 4 are greater than the corresponding ratios for samples 1 and 2 based on the 20% precision estimate. Samples 3 and 4 have the most damaged surfaces of all the samples. However, they are visually dissimilar to each other. Sample 3 is white to the point of opacity whereas sample 4 is severely blackened because it originated from a tomb which had suffered smoke damage. The similarity in the XPS surface compositions of these two samples suggests that the layer formation process in these samples is the same and the deposit seen by XPS in sample 4 was formed after the wall surfaces were damaged by smoke. The latter point confirms previous conclusions based on descriptive evidence (2) for recent layer development and suggests that this aspect of the second mechanism proposed earlier (5, 6) is not supported by our experimental findings.

Sample 5 contains only SiO_2, Al_2O_3, and a just detectable amount of Cl on its surface, which is unlike the predominant composition of the previously mentioned four samples. The surface from which sample 5 was taken had been cleaned with HCl approximately 10 years ago to remove the disfiguring layer. This finding strongly suggests that the silica and alumina are recent deposits, again verifying earlier conclusions (2).

There has been considerable concern (5) that the use of HCl to clean the surfaces may damage the painted walls by dissolving the underlying rock:

$$CaCO_3(s) + 2HCl \rightarrow CaCl_2(s) + H_2O + CO_2$$

However, it can be seen (Table 3) that three of the five uncleaned samples have greater chloride contents than does sample 5. This suggests that damage associated with residual HCl and the formation of hygroscopic $CaCl_2$ is negligible in the sample studied.

Sample 6 represents another extreme in composition. Calcium and carbonate with minor amounts of phosphate and chloride make up the surface in this instance. The carbon-energy range spectra of samples 5 and 6 are shown in Fig. 3. Note the lack of a carbonate peak in sample 5.

No specific correlations were found between sample heights above the floor (Table 1) and composition. Since XPS provides information on the first few nanometers of a surface, it is planned to look for these correlations using bulk-analysis techniques.

Present results identify the mechanism of the surface-layer formation at Beni Hasan with a reasonable degree of certainty. Normally, the initial step of degradation is the deposition of dust or sand on the surface of murals; sample 5, which is the most recently exposed fresh surface, exemplifies this early stage of deterioration. The presence of deposited particles increases the amount of adsorbed water. Under these circumstances, diffusion processes are initiated at the liquid–solid interface

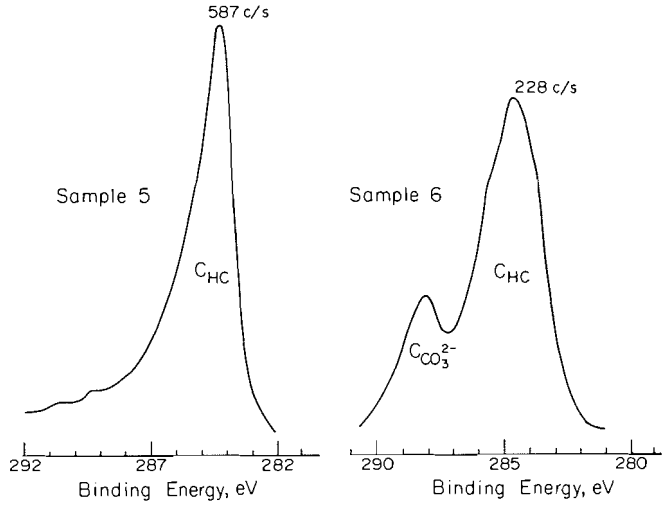

FIG. 3. Carbon energy region of samples 5 and 6 showing the absence of carbonate in sample 5.

along particle boundaries. These processes occur both above and at dew-point temperatures. Thus, at 50% RH, in the presence of particulates, capillary condensation may supply solvent (20). Subsequently, water diffuses through the murals to the limestone walls, a continuous and progressive process which dissolves $CaCO_3$. The presence of CO_2 from the air acidifies the adsorbed water and therefore accelerates deterioration. Daily fluctuations in temperature and humidity make it possible for Ca^{2+} to diffuse to the surface; this leads to the formation of the surface observed on our samples 1–4.

If wall surfaces are slanted so that direct particle deposition on the murals from the air is not favoured, water adsorption still may take place. This process should be less extensive and will involve a smaller effective surface area. In such cases, a third type of surface is formed in which the obtrusive layer consists predominately of calcium carbonate (sample 6).

This mechanism suggests that calcite walls, upon which murals were painted, deteriorate progressively and cumulatively. However, it should be pointed out that we lack *direct* evidence for such type of deterioration. Further investigations have been designed to elucidate this point and examine the nature of the surface deposit to a greater depth than is attainable by XPS.

The key difference between the mechanism proposed here and the earlier mechanism (5, 6) is that the latter attributes carbonate layer formation to dissolution and reprecipitation of $CaCO_3$ dust particles from the air, while the new mechanism predicts an accelerating disintegration of the substrate upon which murals were painted. In support of the new mechanism, our results (sample 5) indicate that there is no detectable carbonate deposit in recent dust deposits. The experimental limit of detection for carbonate has been calculated, based on twice the average background, as 0.004 carbon-to-oxygen ratio. Therefore, the recent deposits on sample 5 contain only an insignificant amount of carbonate. This implies that $CaCO_3$ is not necessary to initiate layer formation. However, this does not exclude the possibility that at least some of the $CaCO_3$ deposit was generated by dissolution of $CaCO_3$ dust from calcite and therefore some carbonate dust may be present. Nonetheless, the tombs are open to the natural elements for a considerable period of time, and Egyptian dust is a result of persistent winds from the Sahara, which carry with them often minute, all-pervasive

particles of sand. This sand is predominantly silica or silicates and contains practically no carbonates. The earliest mechanism (4) which involved water percolation leading to the subsurface removal of material, is, as noted in the introduction, inconsistent with observations (5). It was originally rejected (5) on the basis of isolated resistivity measurements and the absence of sulphates. Our mechanism supports the conclusion of earlier work (4) to the extent that both mechanisms predict dissolution of the substrate. However, the mechanism of ref. 4 and the present mechanism diverge at this point: we substitute diffusion of solvent water through the surface, a more pervasive and dangerous process, for percolation of water through the rock wall. The suggestion (4) that percolation brings out sulphate from the substrate to become a dominant component of the surface, is inconsistent with our measurements because only a negligible amount of sulphate (Table 3) is detected by us.

In the context of the current mechanism, the absence of sulphates in the opaque surface implies that gypsum-based plasters were not used in the Beni Hasan tombs studied by us. Gypsum plasters are known to have been used throughout Egypt in preceding and succeeding dynasties (21), however. The absence of these plasters could imply a deterioration of painting technology in the Beni Hasan area, at least in the "Time of Troubles" when the tombs presently investigated, were constructed. Additional experiments have been designed to investigate more extensively the apparent absence of sulphate plasters.

The rate of layer formation as prescribed by the present mechanism is strongly dependent on environmental and climatic factors. Since the ambient temperature defines the saturation water-vapour pressure, at low temperatures both capillary condensation and dew-point condensation are probable. Beni Hasan is situated in the coldest part of Egypt; it is too far north to be influenced by the equatorial climate and is not moderated by the Mediterranean Sea. Winter lows at Beni Hasan can reach near 0°C. The solubility of CO_2 also increases with decreasing temperature. Continuous monitoring of climatic conditions, such as relative humidity and temperature, would contribute towards a quantitative understanding of surface-deposit growth. Increases in dust and sand deposition, in P_{CO_2} (22), and in condensation should accelerate the growth of the opaque surface layers. All of these parameters increase as a result of extensive visitor access. Capillary condensation increases with relative humidity which is associated with the pronounced increases in irrigation in the Nile Valley that followed construction of the Aswan Dam in 1965. Therefore, the recent increase in the rate deterioration of the Beni Hasan murals (2) appears to be associated with increases in both irrigation and tourism.

The yield of the five-step preparation of 1,6:2,3-dianhydro-4-*O*-benzyl-β-D-allopyranose from 1,6-anhydro-β-D-glucopyranose has been raised to 33% from 12% by modifying conditions or methods for four of the steps. It has been demonstrated that nucleophilic addition to the former compound provides a general route to 1,6-anhydro-3-deoxy-3-substituted-β-D-glucopyranose derivatives, although reactions with large nucleophiles proceed either slowly or not at all. A number of nucleophiles, including chloride, fluoride, cyanide, alkylsulfide, and dimethylamine, gave this type of product in good yield (73–87%). The conditions used to introduce a chloro group, a catalytic amount of tetraethylammonium chloride in 1,1,2,2-tetrachloroethane at reflux, had not previously been used for carbohydrate epoxides. The methyl substituted product was obtained in highest yield with dimethyl magnesium. By-products from this reaction included the products of a Witting rearrangement and of an elimination. All addition products were present in the $^1C_4$ conformation.

T. Bruce Grindley, Gerry J. Reimer, Jaroslav Kralovec, Robert G. Brown et Max Anderson. Can. J. Chem. **65**, 1065 (1987).

En modifiant les méthodes ou les conditions expérimentales de quatre des étapes, on a pu augmenter de 12 à 33% le rendement global de la synthèse en cinq étapes du dianhydro-1,6:2,3 *O*-benzyl-4 β-D-allopyrannose à partir de l'anhydro-1,6 β-D-glucopyrannose. On a démontré que l'addition de nucléophiles sur le premier composé fournit une méthode générale d'accès aux dérivés de l'anhydro-1,6 déoxy-3 β-D-glucopyrannoses substitués en position 3, même si les réactions des nucléophiles volumineux se produisent lentement ou pas du tout. Avec un certain nombre de nucléophiles comprenant les ions chlorure, fluorure et cyanure ainsi que la diméthylamine et les sulfures d'alkyles, on a pu obtenir ce type de produit avec un bon rendement (73–87%). Les conditions utilisées pour introduire le groupement chloro, une quantité catalytique de chlorure de tétraéthylammonium dans du tétrachloro-1,1,2,2 éthane, n'avaient jamais été utilisées jusqu'à maintenant pour ouvrir des époxydes de carbohydrates. Pour obtenir le meilleur rendement du produit substitué par un groupement méthyle, il faut utiliser le diméthylmagnésium. Parmi les sous-produits de cette réaction, on retrouve des produits provenant d'une transposition de Wittig ainsi que d'une élimination. Tous les produits d'addition existent dans la conformation $^1C_4$.

[Traduit par la revue]

Introduction

There has been considerable interest in 3-deoxy-3-substituted-D-glucose derivatives over a period of time. 3-Amino-3-deoxy-D-glucose (kanosamine), a component of the antibiotics kanamycin (1), nebramycin (2), and hikizimycin (3) has been synthesized by a number of groups (4–6). 3-Fluoro-3-deoxy-D-glucose has been an attractive synthetic target because of the continuing interest in deoxyfluoro-D-glucose derivatives for positron emission tomography (7). Pougny and Sinay prepared 3-deoxy-3-*C*-methyl-D-glucose by a different route during the synthesis of a pheromone (8).

Our interest in 3-substituted-D-glucose derivatives was sparked by observations by one of us that 3-*O*-methyl-D-glucose affected the amino acid uptakes and rates of growth of certain yeasts and fungi (9). We wanted to obtain a variety of other 3-substituted-D-glucose derivatives for study and thus required a general synthetic route. The most commonly used synthetic approach to 3-deoxy-3-substituted-D-glucose derivatives has involved nucleophilic displacement of sulfonate derivatives of 1,2:5,6-di-*O*-isopropylidene-D-allofuranose. This reaction works well for good nucleophiles (5, 7) but has not been reported for carbon-based nucleophiles.

An attractive approach to the synthesis of substituted deoxy sugars is the addition of nucleophiles to epoxides (10). These reactions occur under milder conditions than those used for displacements of secondary sulfonates and hence allow use of a greater variety of nucleophiles. The regiochemistry and stereochemistry of the product from an epoxide fused to a pyranose sugar is fixed by the favoured *trans*-diaxial opening (11). To prepare 3-deoxy-3-substituted-D-glucose derivatives, the pyranose ring must be in the less stable $^1C_4$ conformation. 1,6-Anhydro derivatives provide a convenient source of pyranose sugars fixed in this conformation (12). Additions to a blocked derivative of either 1,6:3,4- or 1,6:2,3-dianhydro-β-D-allopyranose would be appropriate. However, a convenient synthetic route to the 4-*O*-benzyl derivative (**6**) of the latter compound has been published (13) and a few reactions with nucleophiles have been tried, with it and with its unblocked precursor.

Two types of results were obtained from these reactions.

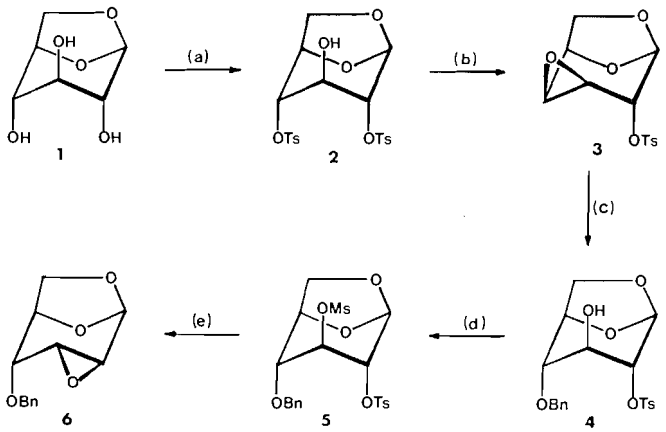


SCHEME 1. Conversion of **1** to **6**: (a) TsCl/pyridine; (b) NaOMe/MeOH; (c) BnOH, $BF_3 \cdot Et_2O$, benzene, 50°C; (d) MsCl/pyridine; (e) NaOMe/MeOH, −18°C.

The parent compound, 1,6:2,3-dianhydro-β-D-allopyranose gave only decomposition on reaction with a potassium hydroxide solution, in contrast to the addition reactions observed with 1,6:2,3-anhydrohexoses having different stereochemistry (14). The decomposition reaction may have proceeded by a retroaldol reaction (14). Compound **6** formed an alkene on reaction with potassium *tert*-butoxide (14), as did the closely related 1,6:2,3-dianhydro-4-deoxy-β-DL-*ribo*-hexopyranose with *n*-butyl lithium (15). More promisingly, compound **6** gave the product of nucleophilic addition with sodium azide in 2-ethoxyethanol (16) and with sodium methoxide in methanol (17).

The original five-step preparation of 1,6:2,3-dianhydro-4-*O*-benzyl-β-D-allopyranose from 1,6-anhydro-β-D-glucopyranose (**1**) (readily available by pyrolysis of starch) had an overall yield of 12% (13). In this publication, we report improvements to the synthesis of **6** and also demonstrate that a wide variety of nucleophiles add to **6**.

Results and discussion

Improvements in the synthesis of 1,6:2,3-dianhydro-4-O-benzyl-β-D-allopyranose

The five-step sequence proceeding from 1,6-anhydro-β-D-glucopyranose (**1**) to 1,6:2,3-dianhydro-4-*O*-benzyl-β-D-allopyranose (**6**) is shown in Scheme 1. Some improvements to this scheme have appeared since it was initially published (13). In particular, the yield of the first step was raised to 79% by using toluenesulfonyl anhydride as the sulfonating reagent (18).

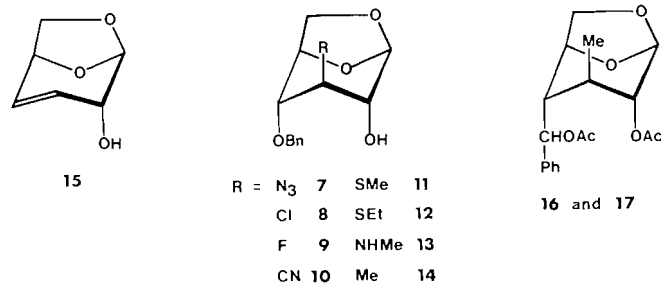
The yield of step two was raised to 82% here, from 55% reported initially (19), by adding the sodium methoxide solution very slowly. The third step, opening the 3,4-epoxide ring, was originally performed with benzyl alcohol and *p*-toluenesulfonic acid as an acid catalyst in 62% yield (20). A number of methods were investigated for improving this step. Use of a Lewis acid catalyst, boron trifluoride etherate, gave the best yield (78%). Other Lewis acid catalysts, including the highly recommended phosphorotungstic acid (21), were less effective, as were base-catalysed conditions.

The yield of step four was increased to a slight extent (from 76 to 81%) by conducting the reaction at a lower temperature under nitrogen. The yield of the last step was significantly improved (from 61 to 80%) by adding the sodium methoxide slowly and performing the reaction at −20°C. An alternative improvement consisted of changing the reaction medium (16). These changes in the last four steps raised the overall yield for the five-step process to 33% from 12%.

Nucleophilic additions to 1,6:2,3-4-O-benzyl-β-D-allopyranose

The preferred site for attack by nucleophiles on 1,6:2,3-dianhydro-4-*O*-benzyl-β-D-allopyranose (**6**) is expected to be at carbon-3 since oxiranes open to give diaxially substituted six-membered rings preferentially (11). Because diequatorial products have been obtained with other 1,6:2,3-dianhydrohexopyranoses using the soft nucleophile, sodium benzyl sulfide (22), caution was observed in product identification. All products obtained here by nucleophilic addition to **6** were characterized by high-field ^1H and ^{13}C nmr spectroscopy. The spectral results are shown in Tables 1–3. Most ^1H nmr signals were assigned by means of extensive decoupling experiments. The H-3 signal was assigned by consideration of substituent chemical shift effects. The signals for H-2 and H-4 were distinguished in some spectra by D_2O exchange of the coupled OH-2 signal. The ^{13}C nmr signals were assigned by analogy with literature assignments of other 1,6-anhydro-β-D-glucopyranose derivatives (23) and by consideration of chemical shift changes as substituents change. In some cases, the chemical shifts of the de-*O*-benzylated derivatives were considered.[1]

A product with the *gluco* stereochemisty has the skeletal protons, H-1 to H-5, in equatorial orientations if the compound adopts the $^1C_4$ conformation observed for **1** (25). As a result,



these protons gave rise to narrow signals with multiple small (<2.5 Hz) splittings due to vicinal and long-range couplings. Sometimes these splittings were resolved either in the original or in the decoupled spectra; often they were not. In general, the magnitudes of the coupling constants matched those reported by Cerny and co-workers (25) for **1**, although in certain compounds the magnitudes of some long-range couplings were somewhat different. The product of a diequatorial opening would be evident through the observation of a large $J_{2,3}$ value in its ^1H nmr spectrum. Similarly, products with the *gluco* configuration that adopted a conformation different than **1** would give spectra with coupling constants of different magnitudes. All compounds obtained here by nucleophilic additions to **6** gave similar patterns of coupling constants (see Table 2).

Approach to the epoxide ring of **6** by a nucleophile is likely to be hindered by the axial CH_2 group of the 1,6-anhydro bridge, particularly if the attacking nucleophile is large. Cerny *et al.* (16) have reported that **6** did not react with methanolic ammonia whereas other 1,6:2,3-dianhydrohexopyranoses did.

Compound **6** reacted with sodium azide in ethanol at reflux

to give 1,6-anhydro-3-azido-3-deoxy-β-D-glucopyranose (**7**) in somewhat higher yield (86%) than obtained at reflux in 2-ethoxyethanol (16).

Addition of chloride ion directly to epoxides is difficult because Cl^- is inherently much more stable than an alkoxide ion (26). Successful reagents supply an electrophile to neutralize the oxyanion. Those used to add chloride to carbohydrate epoxides include HCl in acetone (27), which is known to hydrolyze 1,6-anhydro rings, and (chloromethylene)dimethyliminium chloride (28), which yields chloro *O*-formyl derivatives. The reagent employed here was 1,1,2,2-tetrachloroethane containing a catalytic amount of tetraethylammonium chloride. Buddrus has shown in reactions with simple epoxides that the alkoxide intermediate formed from the addition of chloride abstracts a proton from 1,1,2,2-tetrachloroethane (26). Loss of chloride gives 1,1,2-trichloroethene. This method was found here to be a good one for the addition of chloride to **6** (recrystallized yield 73%) and would presumably work for other complex epoxides.

Fluoride was added to **6** in excellent yield (87%, recrystallized) using a standard reagent (29), potassium hydrogen fluoride in ethylene glycol. Cesium fluoride was less effective. Since both this reaction and subsequent deblocking steps can be performed rapidly,[1] this reaction is another potential method for obtaining ^{18}F labelled sugars for positron emission tomography.

Cyanide was added to **6** using diethylaluminum cyanide, a reagent previously used for addition to several epoxides (30), including carbohydrate ones (31). This reagent gave a 5:1 mixture of diaxial and diequatorial adducts with methyl 3,4-

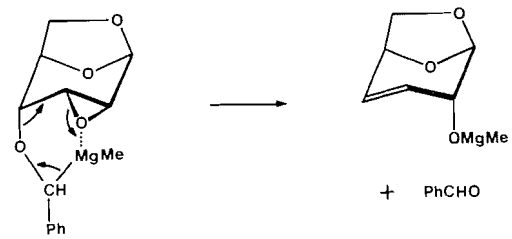
[a]In ppm from internal tetramethylsilane in chloroform-*d* solutions.

anhydro-2,6-di-*O*-benzyl-α-D-galactopyranoside, a substrate which is strongly biased conformationally but which has an axial methoxyl group in a 1,3-diaxial relationship to the incoming cyanide group (31). A second product was not detected here.

The sulfur-containing nucleophiles, sodium thiomethoxide and sodium thioethoxide, similarly added to **6** at C-3. High-field ^1H nmr spectra of the crude products did not contain any signals attributable to the product of diequatorial addition. This outcome is in contrast to results obtained in the reaction of sodium benzyl sulfide with different 1,6:2,3-dianhydrohexopyranosides (22). A methylamino group was introduced in excellent yield (80%) by reaction of **6** with aqueous methylamine under pressure at 150°C.

The reactions of a number of reagents used to add methyl groups to epoxides have been investigated. However, the results of reaction of **6** with nucleophilic methyl groups were consistent with the suggestion that the epoxide group of compound **6** is relatively hindered. The best yield (32%, isolated by chromatography) of 1,6-anhydro-4-*O*-benzyl-3-deoxy-3-*C*-methyl-β-D-glucopyranose (**14**) was obtained by reaction with dimethyl magnesium in dioxane at reflux for 14 h. This yield is in contrast to the excellent yield obtained in the reaction of dimethyl magnesium with the unhindered epoxide ring in 1,6:2,3-dianhydro-4-*O*-benzyl-β-D-mannopyranose (32). This product was accompanied by benzyl alcohol (14%) and three interesting by-products, 1,6-anhydro-3,4-dideoxy-β-D-*erythro*-hex-3-enopyranose (**15**) (3%) and, following acetylation, an approximately 1:1 mixture of the two diastereomers of 2-*O*-acetyl-1,6-anhydro-3,4-dideoxy-4-*C*-acetoxyphenylmethyl-3-*C*-methyl-β-D-glucopyranose (**16** and **17**) (7%). A reaction conducted at 20°C gave lower yields of **14** (19%) and higher yields of benzyl alcohol (22%) and **15**. The benzyl alcohol probably arises from a process that results in sugar decomposition, since the overall product yields were low.

The structure of compound **15** was derived from the analytical and spectral data. The ^{13}C nmr chemical shifts indicated that an alkene was present and the ^1H nmr coupling constants



SCHEME 2. Possible mechanism for the formation of **15**.

showed that the double bond was between carbons 3 and 4. The ^1H nmr spectral data were very similar to those reported from 100-MHz ^1H nmr spectra of the racemic modification of **15** (15). A probable mechanism for the formation of **15** is shown in Scheme 2. This mechanism would result in the release of benzaldehyde, which would be methylated under the reaction conditions. The ^1H nmr spectrum of the crude chromatographic fraction containing benzyl alcohol showed methyl and methine signals at the same chemical shifts as those of 1-phenylethanol (33), having one-fifth the intensity of those of benzyl alcohol.

The two remaining products came from a Wittig rearrangement (34) of the initial adduct (**14**). Compounds **16** and **17** were obtained by acetylation followed by chromatographic separation. Their structures followed from the spectral (see Tables 1–3) and analytical data. The ^{13}C nmr spectra established that **16** and **17** each contained two secondary aliphatic deoxy carbons. Observation of quartets at 1.42 and 2.03 ppm and doublets at 1.87 and 1.77 ppm, each attributable to one hydrogen in the ^1H nmr spectra of **16** and **17**, respectively, was in agreement with this conclusion. The absence of observable coupling constants between H-1, H-2, H-3, H-4, and H-5 indicated that the configurations at the corresponding carbons were the same as in compounds **7**–**14**. The configurations at the new chiral centre (C-4′) could be established tentatively from the chemical shift of H-5. The chemical shift of H-5 was relatively constant in all of the products of nucleophilic addition to **6** (**7**–**14**), 4.57–4.64 ppm. In the ^1H nmr spectra of **16** and **17**, the signals of H-5 appeared at 4.77 and 3.99 ppm, respectively.

The magnitudes of $J_{4,4'}$ were 10.2 and 10.6 Hz in the spectra of **16** and **17**, respectively, indicating that the predominant conformation about the C-4—C-4′ bond had H-4 and H-4′ *anti* in both compounds. As a result, the phenyl group is *anti* to C-5 in one compound and *gauche* in the other. The most likely explanation for the marked upfield shift for H-5 in the ^{1}H nmr spectrum of **17** is that the phenyl group is *gauche* to C-5 and shields H-5. On this basis, **17** is (4′*R*)-2-*O*-acetyl-1,6-anhydro-3,4-dideoxy-4-*C*-acetoxyphenylmethyl-3-*C*-methyl-β-D-glucopyranose and **16** is the 4′*S* isomer. In contrast to the current result, Schollkopf found that the chiral centre in lithiobenzyl *sec*-butyl ether mostly racemized during the Wittig rearrangement in tetrahydrofuran at −60°C (34).

Reaction with lithium dimethyl cuprate gave lower yields of the *C*-methyl product than did reaction with dimethylmagnesium, while a higher order cuprate, $Me_2Cu(CN)Li_2$ (35), did not react with **6**.

Product conformations

All of the 1,6-anhydro-4-*O*-benzyl-3-deoxy-3-substituted-β-D-glucopyranose derivatives prepared here exist predominantly in the $^1C_4$ conformation in solution, as does the parent compound **1**. In contrast, 3-amino-1,6-anhydro-3-deoxy-β-D-glucopyranose (**18**) is present in solution as an approximately 1:1 mixture of the $^1C_4$ and $B_{O,3}$ conformations (16), and its hydrochloride and other cationic derivatives exist predominantly in the latter conformation. Both compounds are present in the chair conformation in the solid state (36, 37). One explanation considered for the unusual conformation of **18** was that the NH_2 group was larger than an OH group (16). Compound **14**, which contains the still larger methyl group, was observed to adopt the chair conformation in solution. Thus, the size of the 3-substituent does not appear to have a particularly important influence on the conformations of these derivatives.

An interesting phenomenon observed in the ^{1}H nmr spectra of several of these derivatives (**9**, **10**, **11**, and **12**) measured in chloroform-*d* solutions was that the OH group on C-2 was coupled to H-2. The coupling constants ranged from 11.6 to 12.5 Hz. A Karplus type relationship has been reported for H—C—O—H fragments and similarly large values of coupling constants have been observed in situations where hydrogen bonding causes the H—C—O—H conformation to be close to *anti* (38). In crystals of **1**, OH-2 adopted an *anti* orientation to H-2, perhaps as a result of weak intramolecular hydrogen bonds to both O-4 and O-5 (39).

Experimental

General methods

Most general methods were as in ref. 40. Accurate masses were obtained on VG-7070 or Dupont CEC 21-110B mass spectrometers.

*1,6:3,4-Dianhydro-2-*O*-p-toluenesulfonyl-β-D-galactopyranose (3)*

A solution of sodium methoxide in methanol (1.15 L of 0.60 *M* solution, 0.7 *M*) was added dropwise over 1.4 h to a stirred solution of the 1,6-anhydro-2,4-di-*O*-*p*-toluenesulfonyl-β-D-glucopyranose–pyridine (1:1) complex (**2**) (19) (85.5 g, 0.155 *M*) in dry methanol (1.76 L). After being stirred 11 h, the reaction mixture was neutralized to pH 7 (pH meter) by adding 5% aqueous hydrochloric acid dropwise. Removal of methanol left an aqueous mixture, which was extracted with chloroform (2 × 500 mL). The combined chloroform extracts were washed with water (100 mL), dried ($MgSO_4$), and concentrated to about 200 mL. Methanol (500 mL) was added and the solution kept at 5°C for 12 h. The white crystals of the title compound (**3**) were filtered, washed with methanol, and dried under vacuum (0.1 Torr; 1 Torr = 133.3 Pa) at 56°C; mp 148°C (lit. (19) mp 148–150°C); $[\alpha]_D^{22}$ −41° (*c* 2.70, chloroform) (lit. (19) $[\alpha]_D$ −40°). An average yield of 77% was obtained from six reactions (lit. (19) 55%, (41) 70%).

*1,6-Anhydro-4-*O*-benzyl-2-*O*-p-toluenesulfonyl-β-D-glucopyranose (4)*

Compound **3** (326.4 g, 1.09 *M*), benzyl alcohol (350 mL, 3.38 *M*), and freshly distilled boron trifluoride etherate (21 mL, 0.17 *M*) were stirred under nitrogen in benzene at 50°C for 24 h. The cooled solution was washed with sodium bicarbonate solutions (1 *M*, 2 × 400 mL) and water (200 mL), then dried ($MgSO_4$) and evaporated. The solid produced was separated from unreacted benzyl alcohol by filtration, washed with ether, and dried (56°C, 0.1 Torr, 12 h). The combined filtrate and washings were concentrated to dryness at 100°C and 1 Torr. The remaining solution was diluted with an equal amount of ether, then kept 12 h at 5°C and filtered, total yield 348.9 g, 78% (lit. (20) 62%); mp 124–125°C (lit. (20) mp 126–127°C); $[\alpha]_D^{22}$ −19° (*c* 2.09, chloroform) (lit. (20) $[\alpha]_D$ −18°).

*1,6:2,3-Dianhydro-4-*O*-benzyl-β-D-allopyranose (6)*

A solution of sodium methoxide in methanol (3.4 L of 1.32 *M*) was added dropwise over 5 h to a solution of 1,6-anhydro-4-*O*-benzyl-3-*O*-methanesulfonyl-2-*O*-toluenesulfonyl-β-D-glucopyranose (**5**) (335.5 g, 0.692 *M*) in dry chloroform (1 L), cooled to −18°C, and stirred under nitrogen. The reaction mixture was stirred a further 11 h at 25°C, then neutralized with an aqueous 10% HCl solution (pH meter), and concentrated. The residue was extracted with hot chloroform (1.5 L and 2 × 0.5 L). The combined extracts were washed with water, dried ($MgSO_4$), and concentrated. The resulting syrup was diluted with ethyl acetate (0.4 L) and petroleum ether (30–60°C) (0.5 L). The colorless crystalline product was removed by filtration and washed with pentane; yield 130.2 g, 80%; mp 75–79°C (lit. (12) mp 74–76°C); $[\alpha]_D^{24}$ +119° (*c* 3.00, chloroform) (lit. (12) $[\alpha]_D$ +127°, (42) +121°).

*1,6-Anhydro-3-deoxy-3-azido-4-*O*-benzyl-β-D-glucopyranose (7)*

Compound **6** (20.22 g, 86.3 mmol), ammonium chloride (35.6 g, 0.67 *M*), and sodium azide (35.8 g, 0.55 *M*) were mixed with ethanol (95%, 400 mL) and water (100 mL), then heated under reflux for 30 h. The cooled reaction mixture was filtered and the precipitate washed with ethanol. The combined filtrate and washings were concentrated to an orange solid, which was taken up in chloroform (100 mL). The chloroform solution was washed with water (2 × 100 mL), dried ($MgSO_4$), and concentrated to a light yellow syrup. The syrup was diluted with ethyl acetate (30 mL) and pentane (50 mL), then kept at 5°C for 12 h. The large colorless prisms of compound **6** were collected and washed with pentane, yield 20.47 g, 86%; mp 76–77°C (lit. (16) mp 74–76.5°C); $[\alpha]_D^{20}$ −12.1° (*c* 8.50, chloroform) (lit. (16) $[\alpha]_D$ −13°).

*1,6-Anhydro-4-*O*-benzyl-3-chloro-3-deoxy-β-D-glucopyranose (8)*

1,6:2,3-Dianhydro-4-*O*-benzyl-β-D-allopyranose (**6**) (2.34 g, 10 mmol) and tetraethylammonium chloride (0.25 g, 1.5 mmol) were mixed in dry 1,1,2,2-tetrachloroethane (25 mL), then stirred at 110°C for 12 h. The solvent was removed by steam distillation. An ethereal solution of the residue (25 mL) was washed with water (3 × 10 mL), dried ($MgSO_4$), decolorized with charcoal, and concentrated to 10 mL. The crystalline product was recrystallized from ether to give the title compound (**8**), 1.98 g, 73%; mp 75–78°C; $[\alpha]_D^{26}$ −51.1° (*c* 1.25, acetone); M − Cl, calcd. for $C_{13}H_{15}O_4$: 235.097; found: 235.097; M − HCl, calcd. for $C_{13}H_{14}O_4$: 234.089; found: 234.091.

*1,6-Anhydro-4-*O*-benzyl-3-deoxy-3-fluoro-β-D-glucopyranose (9)*

Compound **6** (2.34 g, 10 mmol) and potassium hydrogen fluoride (4.70 g, 7 mmol) were refluxed in ethylene glycol for 5 h. The cooled mixture was poured into an aqueous solution of potassium carbonate (5%, 200 mL), which was stirred 5 min, then extracted with chloroform (5 × 20 mL). The combined extracts were washed with water (3 × 10 mL), dried ($MgSO_4$), and concentrated. Crystallization and then recrystallization from ether gave the title compound (**9**) as colorless crystals, 2.21 g, 87%; mp 106–108°C; $[\alpha]_D^{26}$ −67.5° (*c* 1.31, acetone); H,F coupling constants, to H-2, -3, -4, -6_{endo}, and -6_{exo}: 12.3, 42.4, 13.1, 0.9, and 2.1 Hz, respectively; C,F coupling constants, to C-2, -3, and -4: 22.6, 181.6, and 26.3 Hz, respectively.

For other spectral data, see Tables 1–3. *Anal.* calcd. for $C_{13}H_{15}FO_4$: C 61.41, H 5.95, F 7.47; found: C 61.30, H 5.94, F 7.06.

*1,6-Anhydro-4-O-benzyl-3-cyano-3-deoxy-β-D-glucopyranose (**10**)*

A solution of diethyl aluminium cyanide (25 mL, 1.0 *M* in toluene, 25 mmol) was added to a solution of epoxide **6** (2.34 g, 10 mmol) in dry benzene (50 mL) and the solution was stirred under nitrogen at reflux for 2 h. The cooled reaction mixture was poured onto an ice-cold HCl solution (0.1 *M*, 250 mL) with stirring. The organic layer was washed with brine, dried ($MgSO_4$), decolorized with charcoal, and concentrated. The crude product was recrystallized from chloroform to give colorless crystals of the title compound (**10**); 2.12 g, 81%; mp 134–136°C; $[\alpha]_D^{26}$ −85.3° (*c* 1.08, acetone). *Anal.* calcd. for $C_{14}H_{15}NO_4$: C 64.36, H 5.79, N 5.36; found: C 64.37, H 5.56, N 5.35.

*1,6-Anhydro-4-O-benzyl-3-deoxy-3-methylthio-β-D-glucopyranose (**11**)*

A mixture of epoxide **6** (240 mg, 1 mmol) and sodium thiomethoxide (140 mg, 2 mmol) in tetrahydrofuran (5 mL) was refluxed 6 h. The product mixture was poured into water (150 mL) with stirring and the aqueous solution was extracted with ether (5 × 20 mL). The combined extracts were washed with water (3 × 10 mL), dried ($MgSO_4$), and concentrated. The syrupy product (**11**) was purified by chromatography on silica using chloroform as eluent; yield: 229 mg, 81%; $[\alpha]_D^{25}$ −38.7° (*c* 1.06, chloroform). *Anal.* calcd. for $C_{14}H_{18}O_4S$: C 59.55, H 6.43; found: C 59.76, H 6.49.

*1,6-Anhydro-4-O-benzyl-3-deoxy-3-ethylthio-β-D-glucopyranose (**12**)*

A suspension of sodium (100 mg, 4 mmol) in a solution of ethanethiol (1.25 g, 20 mmol) in tetrahydrofuran (4 mL) was stirred under reflux until all the sodium had reacted (3 h). A solution of epoxide **6** (240 mg, 1 mmol) in tetrahydrofuran (3 mL) was added and the solution was refluxed 4 h. The product mixture was cooled and water (5 mL) was added. The organic layer was separated and the aqueous solution extracted with ether (3 × 10 mL). The combined organic layers were washed with water (3 × 5 mL), dried ($MgSO_4$), and concentrated. The syrupy product (**12**) was purified by chromatography on silica using chloroform as eluent; yield, 249 mg, 84%; $[\alpha]_D^{25}$ −30° (*c* 2.33, chloroform). *Anal.* calcd. for $C_{15}H_{20}O_4S$: C 60.79, H 6.80; found: C 60.93, H 6.89.

*1,6-Anhydro-4-O-benzyl-3-deoxy-3-methylamino-β-D-glucopyranose (**13**)*

A solution of epoxide **6** (240 mg, 1 mmol) in 40% aqueous methylamine (20 mL) was kept at 150°C in a sealed tube for 24 h. The product mixture was extracted with chloroform (3 × 20 mL). The combined extracts were washed with water (3 × 5 mL), dried ($MgSO_4$), and concentrated. The residue was purified by column chromatography on silica gel using chloroform as eluent. The solid obtained was recrystallized from ethanol to give colourless crystals of **13**; yield: 201 mg, 76%; mp 61–62°C; $[\alpha]_D^{25}$ −34.3° (*c* 0.97, chloroform). *Anal.* calcd. for $C_{14}H_{19}NO_4$: C 63.38, H 7.22, N 5.28; found: C 63.20, H 7.09, N 5.30.

*Reaction of 1,6:2,3-dianhydro-4-O-benzyl-β-D-glucopyranose (**6**) with dimethyl magnesium*

A fresh solution of dimethyl magnesium (43) (0.5 *M* (24)) in ether (1 L) (containing very little chloride ion, 0.01 *M*) was added to a solution of compound **6** (7.97 g, 34 mmol) in dry dioxane (500 mL) under nitrogen. The ether was distilled until the distillation head temperature reached 70°C, then the reaction was heated under reflux for 13.6 h. The stirred reaction mixture was cooled in an ice bath and saturated aqueous ammonium chloride (75 mL) was added. The reaction mixture was filtered and the filtrate concentrated to a volume of 50 mL. The residue was diluted with chloroform (30 mL) and the solution washed with saturated sodium bicarbonate solutions (2 × 40 mL), dried ($MgSO_4$), and concentrated to a brown oil (7.21 g). The oil was separated into two fractions by column chromatography on silica gel (266 g) using ethyl acetate – petroleum ether (30–60°C) 1:1 as eluant.

The first fraction (R_f 0.43 using the same eluant) was a syrup, 1,6-anhydro-4-*O*-benzyl-3-deoxy-3-*C*-methyl-β-D-glucopyranose (**14**); 2.73 g, 32%; $[\alpha]_D^{20}$ −59° (*c* 5.10, chloroform); *m/z*: 250 (0.6%), 192 (1.1%), 147 (12%), 146 (7%), 143 (3%), 141 (4%), 118 (6%), 113 (8%), 91 (100%). *Exact Mass* calcd. for $C_{14}H_{18}O_4$: 250.1205; found: 250.1202.

The second fraction (0.89 g) was a mixture, which was separated into two fractions by column chromatography on silica gel (40 g) using hexanes – 2-propanol 3:2 as eluant. The slower moving fraction, a solid (R_f 0.55 using pentane – 2-propanol 3:2 as eluant), was recrystallized from ethanol–water to give colorless needles of 1,6-anhydro-3,4-dideoxy-β-D-*erythro*-hex-3-enopyranose (**15**); mp 50–52°C; $[\alpha]_D^{22}$ −238° (*c* 2.70, chloroform); ir (solution in chloroform): 3595, 3470 (OH stretch), 3057 (CH stretch of alkene) cm^{-1}. *Anal.* calcd. for $C_6H_8O_3$: C 56.25, H 6.29; found: C 56.33, H 6.24.

The faster moving fraction (0.57 g), a mixture, was kept with acetic anhydride (1 mL) and pyridine (1.5 mL) for 24 h. Normal work-up gave a slightly yellow oil, 0.45 g. The two components were separated by column chromatography on silica gel (37 g) using ethyl acetate – hexanes 3:7 as eluant.

The faster moving component (R_f 0.44) (110 mg) was a syrup, one diastereomer of 2-*O*-acetyl-4-*C*-(acetoxyphenylmethyl)-1,6-anhydro-3,4-dideoxy-β-D-glucopyranose (**16**); $[\alpha]_D^{25}$ −36.5° (*c* 1.13, chloroform).

The slower moving component (R_f 0.32) (120 mg) was a solid, which was recrystallized from 95% ethanol to give long needles of the other diastereomer of 2-*O*-acetyl-4-*C*-(acetoxyphenylmethyl)-1,6-anhydro-3,4-dideoxy-β-D-glucopyranose (**17**); mp 152–154°C; $[\alpha]_D^{25}$ −80.8° (*c* 1.36, chloroform). *Anal.* calcd. for $C_{18}H_{22}O_4$: C 64.66, H 6.63; found: C 64.52, H 6.72.

Preparation of integrated chemical sensors using commercial VLSI technology

PAUL G. GLAVINA AND D. JED HARRISON[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 31, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

PAUL G. GLAVINA and D. JED HARRISON. Can. J. Chem. **65**, 1072 (1987).

The fabrication of ion sensitive field effect transistors (ISFET) and microelectrode arrays for use as chemical sensors using a commercial CMOS fabrication process is described. The commercial technology is readily available through the Canadian Microelectronics Corporation; however, several of the recommended design rules must be ignored in preparing chemical sensors using this process. The ISFET devices show near theoretical response to K^+ in aqueous solution (55 mV slope) when coated with a K^+ sensitive membrane. An extended gate ion sensitive device is presented which offers advantages in encapsulation of ISFET sensors. The source-drain current of both devices show a linear response to log a_{K^+} in contrast to ISFETs previously reported that have high internal lead resistances. Al and poly-Si microelectrode arrays are fabricated commercially and then Pt is electrodeposited on the microelectrodes. The resulting arrays show good cyclic voltammetric response to $Fe(CN)_6^{4-}$ and $Ru(NH_3)_6^{3+}$ and are relatively durable.

PAUL G. GLAVINA et D. JED HARRISON. Can. J. Chem. **65**, 1072 (1987).

On décrit la fabrication, à l'aide du processus de fabrication commercial CMOS, de transistors à effet de champ sensibles aux ions (TECSI) et de revêtements de microélectrodes qui peuvent être utilisées comme sondes chimiques. La technologie commerciale est facilement disponible par le biais de la Corporation canadienne de microélectronique; toutefois, plusieurs des règles recommandées doivent être ignorées lors de la préparation des sondes chimiques. Les TECSI qui sont recouverts d'une membrane sensible aux ions K^+ présentent une réponse qui est pratiquement théorique pour le K^+ en solution aqueuse (pente de 55 mV). On propose un dispositif, sensible aux ions et offrant plus de possibilités, qui offre des avantages pour l'encapsulation des sondes TECSI. Le courant source-drain de chacun de ces dispositifs présente une réponse linéaire par rapport aux log a_{K^+} et ce résultat est en opposition avec ceux obtenus antérieurement avec d'autres TECSI qui avaient des résistances élevées du fil interne. On a fabriqué commercialement des revêtements de microélectrodes en Al et en poli-Si et on a procédé à l'électrodéposition du Pt sur des microélectrodes. Les revêtements qui en résultent présentent de bonnes réponses pour la voltammétrie cyclique du $Fe(CN)_6^{4-}$ et du $Ru(NH_3)_6^{3+}$ et ils sont relativement durables.

[Traduit par la revue]

There is an increasing interest in the design and fabrication of chemical sensors which may function as remote, implantable, or field portable transducers in the determination of biologically or environmentally important species (1, 2). One of the keys to development of advanced sensors is the determined exploitation of Si integrated circuit processing technology. Most of the devices that have been reported in the literature have been fabricated at research facilities which offer considerable flexibility in materials selection and processing steps (1, 2). However, the significant cost of establishing microlithographic capability limits the access of many researchers to this technology. It is important to develop means of using commercially available fabrication facilities to prepare integrated sensors, which may then require modest post-processing steps (3). In addition to increasing access to researchers, this is also an important step to the eventual commercialization of integrated chemical sensors, since it will significantly reduce the initial capital investment required to produce devices.

The Canadian Microelectronics Corporation (CMC), funded through the Natural Sciences and Engineering Research Council, has been established to encourage research in microelectronics and act as a liaison with Northern Telecom. Through the CMC the CMOS-1b (5 μm minimum feature dimension) and the CMOS-3 (3 μm dimension) Si fabrication processes of Northern Telecom are available to Canadian researchers. There are presently more than 25 Canadian universities equipped with design stations that submit projects to this facility. However, to our knowledge these projects have not involved chemical sensors. Utilization of a commercial facility for chemical sensor fabrication presents a number of difficulties. A significant feature of most chemical sensors is the need for access of the sensing element to the environment; this requires unique fabrication considerations since a standard CMOS process is designed to protect the device from the environment. Additionally, the most commonly used materials for interconnects and metallization are P-doped polycrystalline Si (poly-Si) and Al. Many electrochemical sensors utilize other materials as electrodes (1, 2), and poly-Si and Al are not compatible with many applications.

In this paper we present techniques we have used to design and fabricate ion sensitive field effect transistors (ISFETs) and microelectrode arrays using the Northern Telecom CMOS-1b process. Microelectrode arrays and interdigitated electrodes have been previously demonstrated to be integral components of a variety of chemical sensors (2) such as the chemical transistor (4) and chemiresistors (5). We have developed techniques for the fabrication of Al or poly-Si microelectrodes using the CMOS-1b process, followed by electrodeposition of Pt, resulting in microelectrode arrays that can be used in aqueous solution. In the fabrication of ISFETs the use of the Northern Telecom process introduces several features not usually found in ISFET design. These include the use of an overglass layer to protect and passivate the Al interconnects, and the consequent ability to use low impedance contacts to the transistor source and drain. These features lead to linear device output, which is important in simplifying the signal processing stage.

Experimental

Integrated devices were fabricated by Northern Telecom using the poly-Si gate CMOS-1b process. Access to this facility is provided through the VLSI Implementation Centre (VLSIIC) of the CMC. Mask layout was performed using the graphics editor program KIC (6)

as a VLSI design tool, running on a VAX-11/780 using the UNIX operating system. Design stations consisting of DEC UT240 and AED graphics terminals provided by the CMC were used. The file in CIF format was transferred to VLSIIC using the CDN-net electronic mail network. Several of the designs were prepared on a different system using the CADDS 2/VLSI graphics editor operating on a Computervision Model 4001 mainframe computer. The output format was Calma GDS-II (Version 3) which was converted to CIF format using software written in the Department of Electrical Engineering, University of Alberta. The files were sent on magnetic tape to VLSIIC.

The semiconductor dies received from CMC were bonded in 40 pin dual in-line packages (DIP) by Northern Telecom. An HP 4145A Semiconductor Parameter Analyzer (on loan from the CMC) with a 16658A test fixture was used to test the characteristics of the reference FETs paired to each ISFET on the Si chip. To test devices in solution the bonding wires and contact pads were encapsulated with Epon 828 resin, hardened with Epon V-40 (1:1 ratio) (Miller Stephenson Co., Connecticut), and cured for 24 h. The DIP was then made into a "beaker" by attaching a 1 cm × 1.25 cm glass ring to the assembly with epoxy. Several drops of a polyvinylchloride, dioctyladipate, valinomycin, and $KB(C_6H_5)_4$ mixture in tetrahydrofuran (BDH, distilled), prepared according to Bond *et al.* (7), was evaporated on the surface of the chip to prepare K^+ sensitive ISFETs. Transistor and diode characteristics were obtained for the ISFETs using a Pine Instruments RDE-4 bipotentiostat and a Kipp and Zonen BD90 $x-y$ recorder. To obtain transistor characteristics, the reference and counter electrode terminals of the RDE-4 were connected to the device source/substrate contact. The device drain was connected to working electrode K1, and a saturated calomel reference electrode (SCE) was connected to working electrode K2. Sweeping the potential of K1 (500 mV/s) acts to vary V_{DS} (see Fig. 2), while the potential of K2 is varied in stepwise fashion to obtain a family of curves with different values of V_g. Diode characteristics (8) were obtained by connecting the ISFET as above, but the SCE was also connected to K1 (see Fig. 2*b*). K^+ test solutions were adjusted to constant ionic strength with 0.1 *M* NaCl.

Electrical response times of the K^+ sensitive ISFETs were evaluated using a square wave from a PAR 175 waveform generator, input into the Pine RDE-4 potentiostat, to modulate either V_g or V_{DS}. The current response, I_{DS}, was recorded with a Tektronix Model 2430 digital storage oscilloscope. The response time (to 100% of the final value) of the Pine potentiostat was determined to be ~30 μs; sufficient for this application. Chemical response time of the ISFETs to an increase in K^+ concentration was evaluated under conditions of fixed V_g and V_{DS}. A small volume (~0.3 mL) of 10^{-4} *M* KCl was first introduced into the "beaker" on the DIP, and then ~0.7 mL of 1 *M* KCl was vigorously injected from a pipette. The change in I_{DS} during this procedure was recorded on the Tektronix oscilloscope, and on an $x-y$ recorder.

Microelectrode arrays were encapsulated as described for ISFET devices. To electroplate Pt on interdigitated Al fingers, the Al was first etched with a 25% aqueous solution of 25:1 H_3PO_4:HNO_3 for 12 min and rinsed thoroughly with doubly distilled H_2O. The Al array was then briefly exposed to the air before exposing to the plating solution. For both Al and poly-Si surfaces, Pt was electrodeposited in 5 m*M* K_2PtCl_4 (Strem), 1 *M* $NaClO_4$ (G. F. Smith) at −0.8 V vs. SCE for about 7 min, and the devices were rinsed in doubly distilled H_2O. Reagent grade $K_4Fe(CN)_6$ (J. T. Baker), $Ru(NH_3)_6^{3+}$ (Strem), KCl and NaCl (GIC), were used as received.

A Cambridge S250 Scanning Electron Microscope equipped with a Kevex 7000 Energy Dispersive X-ray Analyzer was used to obtain electron micrographs. Samples were Au-coated to ~200 Å thickness. A Bausch and Lomb Microzoom microscope with a Wild MPS-12 camera adaptor and a Wild Mikrophot MPSO5 light meter was used to obtain optical micrographs.

Results

The ion sensitive field effect transistor and related devices have been the subject of intense research activity (1, 2*a*, 3, 8–10). We have used the Northern Telecom CMOS-1b process to fabricate two types of ISFET devices. Figure 1 shows a schematic representation of an ISFET (device 1) with an opened gate region on the left hand side which can be subsequently coated with an ion-sensitive material and exposed to solution. On the right hand side is a reference transistor which remains insulated from solution and shares a common drain with the ISFET; it can be used to characterize the transistor assembly.

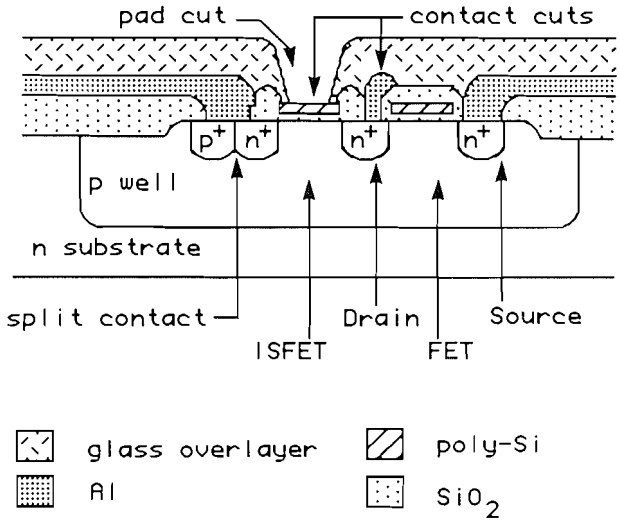

FIG. 1. Schematic of the opened gate ISFET (left) and a paired reference FET (right) prepared in the same p-Si device well (device 1) using the Northern Telecom CMOS-1b process. A split contact is made to the ISFET source and the p-well substrate to short these terminals together. The symbols p^+ and n^+ refer to heavily doped p and n type regions, respectively. The source contact for the FET is on the opposite side of the device, and both the FET and ISFET share a common drain. Contact cuts through the SiO_2 are made over the source and drain diffusions as well as over the ISFET gate. A pad cut is made over the ISFET gate down to the poly-Si layer through the overglass layer which protects and passivates the Si chip.

The transistors are designed with a split contact, Fig. 1, that shorts together the n^+ source diffusion and the p^+ substrate diffusion contacts as indicated in the circuit diagrams, Fig. 2. In the fabrication process SiO_2 is thermally grown over the entire wafer following definition of the source, drain, and gate. Contact cuts are etched through the oxide to regions that are subsequently metallized, allowing electrical contact to the transistor. To prepare an ISFET a contact cut is also made over the gate region of the transistor. This removes the SiO_2 layer over the poly-Si which defines the gate area. This step violates a CMOS-1b design rule (11) but is compatible with the actual fabrication process (11*a*). The wafer is then aluminum coated and the metal interconnect layer is patterned microlithographically. In this step Al is removed from the contact cut over the gate by not defining this region in the Al patterning mask. Although this violates another design rule (11*b*), X-ray fluorescence spectra indicate Al is successfully removed from the gate. The final step in the Northern Telecom CMOS-1b process involves chemical vapour deposition of a pyrox overglass from SiH_4, PH_3, and O_2. This layer serves to passivate the device and protect it from the environment. Bonding pads are formed by etching through to the metallized regions, and in this step a region of appropriate dimensions is etched out over the ISFET gate, down to the poly-Si layer. This step also breaks a design rule (11*c*).

An alternative device configuration (device 2) has also been

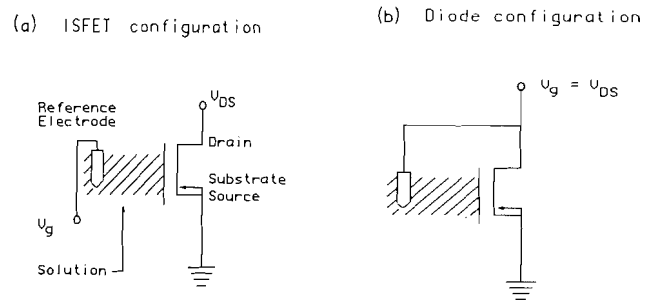

FIG. 2. (*a*) The configuration of an ISFET is shown. A solution replaces the metal contacts to the device gate. The potential of a reference electrode in solution is controlled by varying V_g with respect to the source and substrate potential. The drain-source voltage V_{DS} is set independently. (*b*) In the so-called diode configuration the reference electrode potential $V_g = V_{DS}$ relative to the source and substrate. In this configuration the square root of the drain-source current is proportional to V_g.

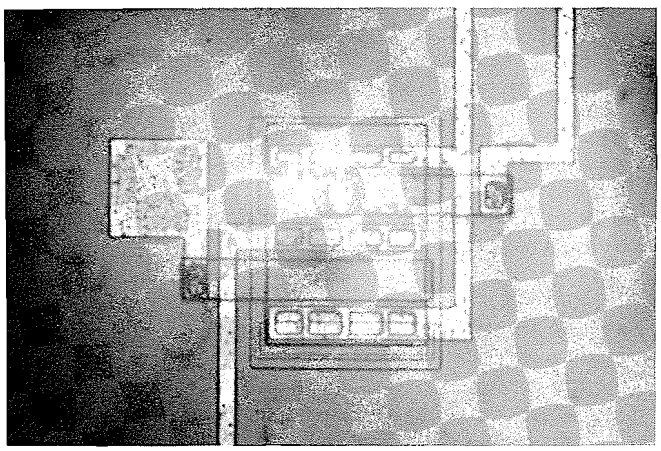

FIG. 3. Photomicrograph of the extended gate ISFET (device 2) with paired reference FET. The poly-Si lead of the ISFET gate is contacted to an exposed Al pad away from the sensitive gate region in contrast to the device configuration of Fig. 1.

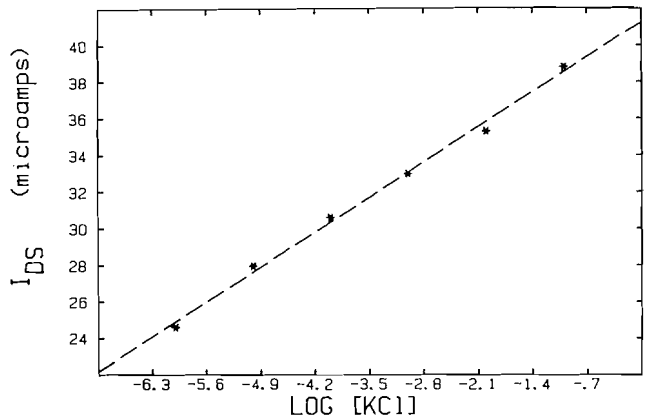

FIG. 4. Response of device 1 opened gate ISFET to log [KCl]. Drain source current, I_{DS}, was measured at constant $V_{DS} = 1.0$ V with 2.0 V applied as V_g. Ionic strength was adjusted to 0.1 *M* with NaCl.

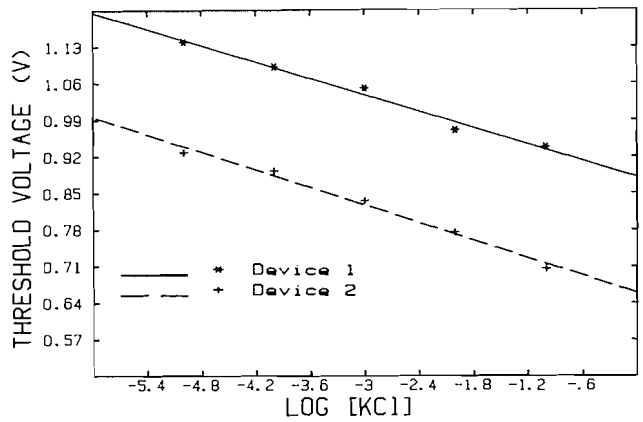

FIG. 5. Values of the threshold voltages, V_{Th}, as a function of log [KCl] for opened gate (device 1) and extended gate (device 2) configurations. V_{Th} with respect to an SCE was determined at each concentration from plots of $\sqrt{I_{DS}}$ versus V_g with the device operated in the diode configuration.

fabricated and is shown in Fig. 3. In this device the relatively fragile FET gate is not directly exposed to solution. Instead the poly-Si layer over the gate is extended beyond the device, and a contact cut is made to the poly-Si layer where a 50 μm × 50 μm Al pad is defined in the metallization step. Following device passivation with the pyrox overglass, the pad area is re-opened using the final lithographic step that also opens the bonding pads. In this design the chemically sensitive region can be located a considerable distance from the active Si device, and connected to the gate via poly-Si or Al leads producing an "extended" gate.

Devices 1 and 2 may be coated with organic ion sensitive membranes, which impart selectivity to a specific ion (2*a*). Coating the exposed transistors with a mixture of polyvinylchloride, dioctyladipate, and valinomycin (7) produces devices with good sensitivity and selectivity for K^+ in aqueous solution. Operating device 1 at a constant value of V_{DS} and apparent gate voltage V_g (see Fig. 2*a*) results in the drain-source current, I_{DS}, varying linearly with log [K^+], as shown in Fig. 4. This configuration results in a signal which is low impedance and provides immediate amplification of the response to K^+. The sensor may also be operated in the diode configuration (8), with the reference electrode shorted to the drain, Fig. 2*b*. In this configuration $\sqrt{I_{DS}}$ is proportional to V_g, for devices with no significant internal resistance, and a plot of $\sqrt{I_{DS}}$ versus V_g should be linear, with the threshold voltage, V_{Th}, given by the voltage axis intercept. The threshold voltage represents the value of V_g at which the conductivity in the channel under the gate becomes sufficient for the current, I_{DS}, to flow. It has been shown that V_{Th} measured with respect to a reference electrode is proportional to log (ion activity) (2*a*). For devices 1 and 2 coated with K^+ sensitive membrane, plots of $\sqrt{I_{DS}}$ vs. V_g are linear, and values of apparent V_{Th} vs. SCE as a function of [K^+] are readily attained. Figure 5 shows that for both device types V_{Th} varies linearly with log [K^+], and a slope of 55 mV is obtained, in reasonable agreement with the 59 mV slope predicted by the Nernst equation. The two devices show about 200 mV difference in the value of apparent V_{Th} at a given concentration. A similar variation in V_{Th} is observed for the reference transistors paired to each ISFET, and apparently represents normal variation between transistors for the CMOS-1b process, rather than a real difference between the design properties of devices 1 and 2.

The response of I_{DS} to a step function perturbation of either V_g or V_{DS} was evaluated for devices 1 and 2. Operating at

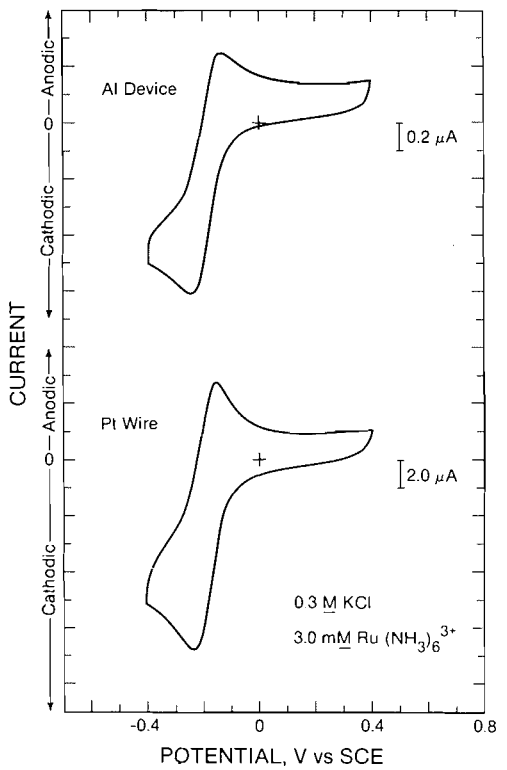

FIG. 6. Cyclic voltammetry at 50 mV/s of $Ru(NH_3)_6^{3+}$ at Pt electroplated Al microelectrodes, fabricated using the Northern Telecom CMOS-1b process, compared to that at a Pt wire electrode (0.01 cm^2).

constant V_{DS} a step in V_g from 1.8 to 2.2 V results in I_{DS} reaching 95% of the final value in 15 ms for device 1 and 10 ms for device 2. A step change in V_{DS}, with fixed V_g equal to 1.75 V, requires 3 ms and 4 ms for devices 1 and 2 to settle to 95% of the final value. The response times observed are shorter by a factor of two than those previously reported for ISFET devices with K^+ membranes (12). When bias voltages are held constant and the concentration of K^+ is stepped from 10^{-4} *M* to 0.7 *M* the final value of I_{DS} is attained in 90 ms. This represents an upper limit on the response time of the ISFET, since it is difficult to evaluate the time required for mixing of solutions with the procedure used.

Microlithographic patterning of conducting electrode arrays is an attractive route to developing a variety of electrochemical sensors (4, 5). The conducting interconnect layers in most commercial processes are Al or doped poly-Si, yet neither of these materials is overly satisfactory for electrochemical applications. We have used the CMOS-1b and CMOS-3 facilities to produce Al interdigitated fingers, and poly-Si microelectrode arrays, and have subsequently electrodeposited Pt on the electrodes to prepare them for electrochemical applications.

Immediately prior to electrodeposition of Pt on Al substrate arrays, an active Al surface is prepared by etching the array in an acid solution. This fresh Al surface is briefly exposed to air (~60 s) allowing formation of a thin oxide, and approximately 1 to 10 mmol/cm^2 of Pt is then electrodeposited from the plating solution, at a potential of −0.7 V vs. SCE. Figure 6 compares the cyclic voltammetry for $Ru(NH_3)_6^{3+}$ observed at a bulk Pt electrode and a platinized Al microelectrode array in 0.1 *M* KCl. The peak-to-peak separation is ~10 mV greater at the Pt-coated Al device, which is consistent with a voltage drop across the thin aluminum oxide layer formed during preparation

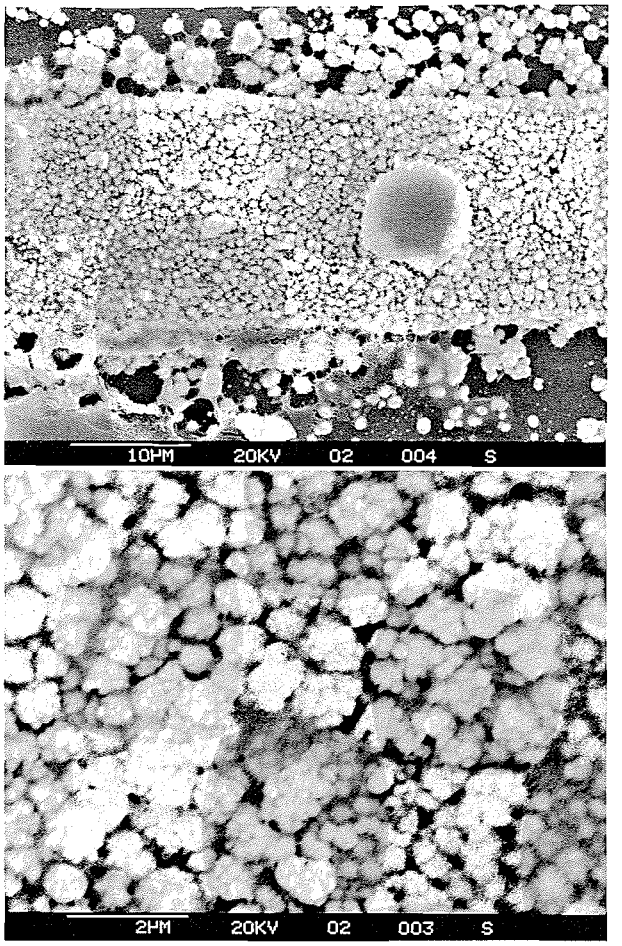

FIG. 7. Electron micrographs of Pt electrodeposit on the Al microelectrode substrate. The upper micrograph shows small Pt particles, identified by X-ray fluorescence (XRF), deposited over an Al lead, with larger Pt particles scattered nearby. A large featureless nodule is also observed on the electrode. XRF identifies Al and Cl as its constituents, indicating corrosion of the Al substrate. The lower micrograph shows a close-up of the Pt particles deposited on the Al leads.

of the surface for Pt electroplating. There is no significant background oxidation current for Al observed at the positive potential extreme, and the platinized electrodes can be cycled more than 50 times with no significant change in the electrochemistry. However, excursions to potentials at which H_2 or O_2 is evolved result in loss of Pt from the electrodes.

The nature of the Pt deposit on Al was examined by scanning electron microscopy (SEM). Figure 7 shows that Pt is deposited uniformly on the Al, and displays a microcrystalline structure. However, larger Pt nodules are observed deposited over the SiO_2 substrate between Al leads. Spreading of the Pt deposit beyond the electroactive area has been observed previously for Pt deposition at Au microelectrodes, and has been used to narrow the inter-electrode separation to as little as 0.2 μm (13). Unfortunately, there is a tendency for the separate fingers of the interdigitated Al leads to short together as Pt is deposited and we have not been able to isolate Al electrodes separated by less than ~40 μm. The other feature of concern is the large nodule in the centre of the Al lead, Fig. 7. Energy dispersive X-ray fluorescence under the SEM probe identifies Al and Cl as two of the major components. This structure clearly results from corrosion of the Al layer. While it is often not a problem,

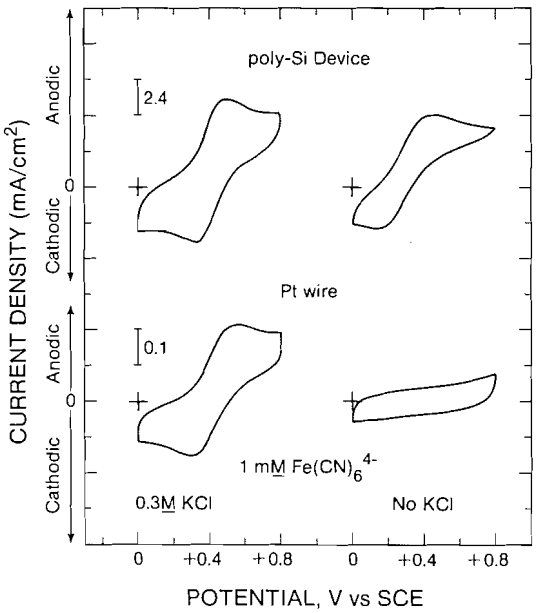

FIG. 8. Cyclic voltammetry at 50 mV/s of 1 m*M* $Fe(CN)_6^{4-}$ in 0.3 *M* KCl at Pt electroplated poly-Si microelectrodes compared to the response at a Pt electrode (0.01 cm^2). Also shown is the response to 1 m*M* $Fe(CN)_6^{4-}$ in the absence of supporting electrolyte. The Pt electrode response is severely distorted by *IR* drop in solution, while the Pt coated poly-Si electrodes show response typical of microelectrodes in high resistance media.

in some cases an entire electrode finger is destroyed by this corrosion process.

We have also prepared microelectrode arrays consisting of P-doped poly-Si electrodes 20 μm wide, 190 μm long, separated by 20 μm, and all connected to a common bus. The poly-Si layer was exposed using the contact cut and bonding pad steps in the CMOS-1b microlithographic process. Again these steps involve breaking of CMOS-1b design rules (11*b*, *c*). It proved possible to electrodeposit Pt on poly-Si without need for an etching step to activate the poly-Si. The cyclic voltammetric response to $Fe(CN)_6^{4-}$ of a Pt coated poly-Si electrode array is shown in Fig. 8, and compared to that at a bulk Pt electrode. There is no significant difference in peak-to-peak separation for the bulk and the electrodeposited Pt electrodes. The platinized electrode arrays can be cycled more than 50 times in $Fe(CN)_6^{4-}$ solution with no change in the cyclic voltammograms. The observed current densities at the electrodes are significantly different, based on the projected geometric areas of the bulk Pt electrode (1×10^{-2} cm^2) and the microelectrode array (4.2×10^{-4} cm^2). The projected area does not account for surface roughness factors, which are clearly important in evaluating the true area of the platinized array, Fig. 9. However, enhanced current density is expected due to cylindrical diffusion (14) to the electrodes in the array, as has been reported previously for microelectrodes of similar geometry (15). Evidence for microelectrode behaviour at the poly-Si device is shown by the response to $Fe(CN)_6^{4-}$ in absence of supporting electrolyte, for which a reasonably well defined cyclic voltammogram is observed, Fig. 8. This contrasts with the distorted response observed at a bulk Pt electrode of macroscopic dimensions in the same solution.

Electron micrographs of electrodeposited Pt on poly-Si arrays are shown in Fig. 9. The poly-Si electrodes are relatively uniformly covered, and there is much less deposition on

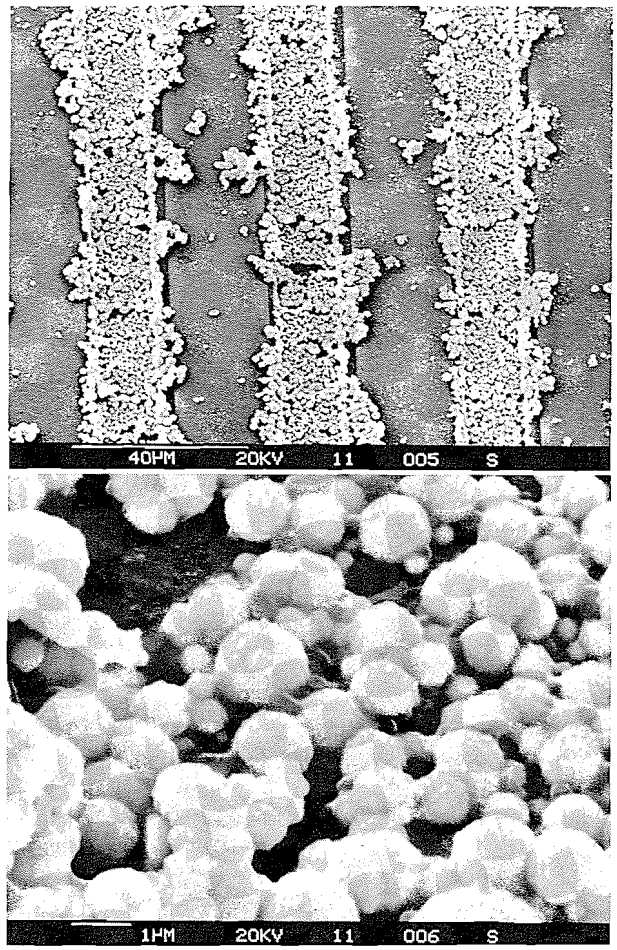

FIG. 9. Electron micrographs of Pt electrodeposited on poly-Si microelectrodes. Lower micrograph shows close-up of Pt deposit on the poly-Si lead indicating much less dense packing obtained on poly-Si relative to Al (Fig. 8).

the insulated region between electrodes than is found for Al electrode arrays. Some Pt growth between electrodes does occur, but it occurs much less frequently, and isolation of electrodes separated by 20 μm is readily achieved. A close up of the Pt deposit, Fig. 9, shows it is less uniform than on Al electrodes, and appears to have a different structure. The corrosion problems observed with Al electrodes are not observed on poly-Si, due to rapid passivation of Si arising from oxide growth at positive potentials.

Discussion

The commercial CMOS-1b fabrication process can be used successfully to produce a variety of sensor devices. In fabricating an ISFET using the CMOS-1b process the gate material exposed to solution is conducting poly-Si, in contrast to most ISFETs (2, 8–10) which have insulating SiO_2 or Si_3N_4 layers on the gate. The data in Figs. 4 and 5 for K^+ membrane coated devices demonstrate that the presence of poly-Si on the gate does not affect device performance. However, unlike Si_3N_4 coated ISFETs (2*a*), device 1 with poly-Si on the gate and no organic membrane coating does not exhibit Nernstian response to pH.

Protection of the Al interconnects using a pyrox overglass decreases problems associated with packaging of ISFETs. With pyrox passivation low resistance Al contact leads can be used to

For personal use only.

directly contact the source and drain of the devices, as has been done for the devices presented here. This approach differs from that used with many ISFETs reported in the literature (2, 8–10, 16, 17) which have high internal source and drain resistances due to the use of n^+ diffusions as the contact leads for source and drain. The effect of the internal resistance is non-linearity in the response of I_{DS} to log a_{K^+} when a device is operated at constant V_g. Additionally, when such devices are operated in the diode configuration (Fig. 2*b*) $\sqrt{I_{DS}}$ varies in a non-linear fashion with V_g. Non-linearity of ISFET response due to the internal resistance of n^+ diffusion leads has led to considerable efforts (16–18) to design compensatory circuitry and feedback control to obtain a linear output. The devices presented here, using low resistance Al contacts and a passivating overglass, obviate the need for much of the additional complex circuitry and matching of transistors used for other devices, since I_{DS} is linear over the range of concentration for which the membrane responds in a Nernstian fashion, Fig. 4.

Figure 5 demonstrates that the extended gate configuration of device 2 is as satisfactory as the more common exposed gate configuration of device 1. One of the difficulties associated with preparing ISFETs is packaging of the device to prevent transistor failure. The standard ISFET configuration of device 1 presents a particularly severe challenge, since it is the gate oxide which is most sensitive to environmental damage. The configuration of device 2 separates the device and the active chemically responsive element on the Si die. This extended gate structure should be more easily packaged and more durable.

Microelectrode arrays have been used to prepare a number of types of chemical sensors (4, 5). It is clear that noble metal electrodes prepared by vapor deposition and subsequent microlithographic patterning are superior to the electrodeposited Pt electrodes presented here. However, the approach presented provides access to microelectrode arrays for many researchers who do not have independent microlithographic capabilities.

Despite deposition of a layer of Pt on the Al electrode substrate, corrosion of the Al layer remains a problem, particularly in the presence of Cl^-. While cyclic voltammetry, Fig. 6, indicates that Al corrosion is not rapid, the large Al and Cl containing nodules observed in electron micrographs, Fig. 7, provide evidence that corrosion occurs. This is expected unless the Pt coating is totally non-porous, due to galvanic effects. The deposition of multiple metal layers on Al has been shown (19) to produce smooth Ni films and a similar procedure to produce better Pt deposits is under examination. Overall, the anodic self-passivating nature of the Si/SiO_x system makes the poly-Si arrays the preferred substrate for Pt coated electrochemical arrays.

The porous nature of the Pt deposit and the deposition conditions used are the probable cause for loss of Pt coating from the arrays during H_2 and O_2 evolution. Formation of gas in pockets inside the Pt film could lead to mechanical disruption of the film. The Pt was plated at a potential at which H_2 is not evolved, to allow determination of the amount deposited coulometrically. This differs from many methods for Pt deposition during electroplating. One consequence of a high overvoltage is a mechanically more durable Pt film, as weakly adhered material is immediately lost due to mechanical disruption by the gas bubbles formed.

The peak separation observed in the cyclic voltammetry for $Ru(NH_3)_6^{3+}$ reduction at the Pt coated, Al substrate electrodes, Fig. 6, indicates a kinetic barrier to electron transfer. This most likely arises from the presence of a thin Al oxide at the Al/Pt interface, resulting in a resistive potential drop (*IR* drop) which causes increased peak separation. The Pt-plated, poly-Si substrate arrays show no increase in peak separation in cyclic voltammetric scans at 50 mV/s, compared to a bulk Pt electrode. However, at sufficiently high scan rates the native oxide, SiO_x, present on the poly-Si surface would be expected to introduce some resistive losses. The presence of an *IR* drop at the electrode substrate/Pt interface reduces the applicability of these arrays to kinetic studies, but is unlikely to interfere with most sensor applications, such as electrochemical detection in liquid chromatography. The arrays should also make suitable substrates for moderately thick coatings ($\gtrsim 10$ μm) used in the preparation of chemiresistors. However, the surface roughness probably makes the arrays unsuitable for use with thin films (< 1 μm).

There are presently more than 25 Canadian universities with the capability to design and submit integrated circuitry for fabrication through the CMC. The methods of preparation of chemical sensors we have developed are compatible with this commercial process. Not only will chemical sensor fabrication using the Northern Telecom CMOS-1b process open this field to a variety of researchers, but the development of means to utilize a commercial facility is an important step in furthering commercialization of integrated sensors.

The efficiency of an HGA-400 for production and containment of atomic vapour was determined for several elements using relatively high heating rates. Two different atomization efficiencies β_1 and β_2 were experimentally determined by two variations of a method. Assuming that atomization in the HGA-400 can be described by consecutive, first-order reactions $D \xrightarrow{k_1} B \xrightarrow{k_2} C$, the method consisted of making the absorbance signal profile (at least the decay part of it) appear at constant tube wall (at the centre) temperature and determining first-order rate constants for atom formation and atom loss, k_1 and k_2, respectively. Two atomization efficiencies were calculated: β_1 and β_2, which gave the fraction of analyte which was present as atomic vapour at the peak of the absorbance signal profile. Experimental atomization efficiencies reported for Al, Cu, Co, Fe, Ag, and Ga average: β_1 0.42 and β_2 0.30, with a range from 0.30 to 0.50 for β_1 and from 0.18 to 0.43 for β_2. Significance of the results and limitations of the two variations of the method in terms of validity of their underlying assumptions have been brought out in a critical assessment of the atomization efficiencies measured by the two variations of the method. In both the variations of the method, the heating rates used were much higher than those used by some other authors, with the result that in agreement with the prediction of the theory, the atomization efficiencies measured in this work were considerably higher than those reported by those authors.

C. L. CHAKRABARTI, D. FERRAROTTO, S. J. CATHUM et C. J. RADEMEYER. Can. J. Chem. **65**, 1079 (1987).

On a déterminé l'efficacité d'un HGA-400 pour produire et contenir la vapeur atomique de plusieurs éléments à des taux élevés de chauffage. Utilisant deux variations d'une même méthode, on a déterminé expérimentalement deux efficacités différentes d'atomisation, β_1 et β_2. Faisant l'hypothèse que l'atomisation dans un HGA-400 peut être décrite par les réactions consécutives, du premier ordre $D \xrightarrow{k_1} B \xrightarrow{k_2} C$, la méthode consiste à faire apparaître le profil du signal d'absorption (au moins sa portion de dégénérescence) à température constante de la paroi du tube (au centre) et à déterminer les constantes de vitesse du premier ordre pour la formation des atomes et pour la perte des atomes, soit respectivement k_1 et k_2. On a calculé les deux efficacités d'atomisation β_1 et β_2 qui donne la fraction de l'analyte qui est présente sous la forme de vapeur atomique au maximum du profil du signal d'absorption. La moyenne des efficacités expérimentales d'atomisation rapportées pour Al, Cu, Co, Fe, Ag et Ga sont $\beta_1 = 0{,}42$ et $\beta_2 = 0{,}30$ et les valeurs de β_1 varient de 0,30 à 0,50 alors que celles de β_2 varient de 0,18 à 0,43. La signification de ces résultats et les limitations des deux variations de la méthode en fonction de la validité des hypothèses sousjacentes ont été déterminées grâce à une évaluation critique des efficacités d'atomisation qui ont été mesurées par les deux variations de la méthode. Dans chacune des variations de la méthode, les taux de chauffage utilisés étaient beaucoup plus élevés que ceux utilisés par d'autres auteurs; il en résulte, en accord avec les prédictions de la théorie, que les efficacités d'atomisation mesurées dans ce travail sont beaucoup plus élevées que celles rapportées par d'autres auteurs.

[Traduit par la revue]

Introduction

Atomization efficiencies of some commercial graphite furnaces have been studied by several authors (1–4). However, the differences in the published results of different authors indicate that the problem of atomization efficiency still remains unresolved. Probably, part of the problem lies in the definition of atomization efficiency of graphite furnaces. Sturgeon and Berman (1) measured the absolute atomization efficiencies of the HGA-2200 for nine elements by determining electron concentrations using microwave attenuation techniques. Relative values of atomization efficiencies subsequently calculated by the authors (1) for several elements were, however, subject to uncertainties in the *gf* values (from the literature) used in the calculation (5). van den Broek and de Galan (2) calculated the overall atomization efficiencies of two graphite furnaces (CRA-63 and HGA-72) for the atomization of Ag, Pb, Mn, and Cd. They concluded that, under common operating conditions, atomization efficiencies averaged less than 10% for the above elements. Smets (3) in his study of atom formation in and dissipation from an open strip atomizer made the following estimate of the atomization efficiency (taking into account the relative oscillator strengths of the atomic resonance lines): 1 for Au, Ag, Cu, Fe, Mn, and Mg, and less than 0.1 for Al. Kitagawa *et al.* (4) spectroscopically determined the atomization efficiency of a glassy carbon tube atomizer for Cu and calculated relative atomization efficiencies for Cr and Ag based on the absolute value established for Cu.

The objective of the present work was to determine atomization efficiencies of an HGA-400 for several elements using relatively high heating rates and to make a critical assessment of the atomization efficiencies.

Theory

For simplicity, we shall confine our analysis to the passage of an atomic vapour through the analysis volume, without considering all other chemical reactions and physical processes that lead to formation of atomic vapour in and loss of atomic vapour from the graphite furnace. We shall also ignore any complicating processes that may accompany the transport of the material through the analysis volume and shall further assume that all of the element we are determining is in the atomic state while inside the analysis volume. The above assumptions are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

admittedly valid only for a limited number of elements which are completely atomized in graphite furnace and the ionization of which can be ignored at the atomization temperature used. These simplifying assumptions allow considerable simplification of the mathematical formulation of the model.

Assuming that consecutive, first-order reactions that occur during atom formation in and atom loss from the HGA-400 can be described by the following model (6):

$$[D] \xrightarrow{k_1} [B] \xrightarrow{k_2} [C]$$

where [D] represents the concentration of the pre-atomization analyte species; [B] represents the concentration of the absorbing analyte atomic vapour formed; [C] represents the concentration of the analyte atomic vapour that is lost from the analysis volume; k_1 and k_2 are then identified as the first-order rate constants for analyte atom formation and loss, respectively. At all times the concentrations are related by:

$$[1] \quad [D]_t + [B]_t + [C]_t = [D]_0$$

where the subscript t and 0 represent the time and the initial concentration (at time $t = 0$), respectively. The above model yields the differential eqs. [2] and [4].

$$[2] \quad \frac{d[D]}{dt} = -k_1[D]$$

By solving eq. [2] one gets eq. [3]:

$$[3] \quad [D] = [D]_0 \exp(-k_1 t)$$

$$[4] \quad \frac{d[B]}{dt} = k_1[D] - k_2[B]$$

In the limit, [D] tends to zero, which is identified with the exhaustion of the supply of the pre-atomization species D. At this point, eq. [4] simplifies to:

$$[5] \quad \frac{d[B]}{dt} = -k_2[B]$$

Since absorbance is proportional to the concentration of the absorbing species, B, the rate constant for the atom loss, k_2, can be determined from this part of the absorbance signal profile. A plot of the logarithm of absorbance vs. time should be linear, yielding the rate constant k_2 from the slope.

Extrapolation of this straight line plot to zero time (i.e., t_0) will give the concentration of B (resulting from complete conversion of $[D]_0$ into [B]) necessary to produce the decay of the signal by diffusion process alone. However, eq. [4] shows that the rate of formation of B is equal to the difference between the rate of conversion of species D into species B and the rate of loss of species B by concentration diffusion. The difference between the extrapolated absorbance and the experimental absorbance at any time t is equal to the concentration of the pre-atomization species D. Equation [2] suggests that a plot of the natural logarithm of this difference vs. time should be linear, with a slope equal to the rate constant for atom formation k_1.

If the kinetic parameters are evaluated, the shape of the absorbance signal profile may then be determined by solving eq. [4]. The use of the solution of eq. [2] with the initial concentration of the species D and $[D]_0$ and with no B present initially, gives the following solution of eq. [4]:

$$[6] \quad [B]_t = \frac{[D]_0 k_1}{k_1 - k_2}[\exp(-k_2 t) - \exp(-k_1 t)]$$

where $[B]_t$ represents [B] at time t. The concentration of B, which is initially zero, at first increases and reaches a maximum when $d[B]/dt$ is zero; the system is then said to have reached a stationary state.

$[B]_t$ can be related to the measured absorbance by using a pre-exponential factor p:

$$[7] \quad \text{Absorbance} = \frac{p[D]_0 k_1}{k_1 - k_2}[\exp(-k_2 t) - \exp(-k_1 t)]$$

where p is a function of the oscillator strength (a constant) of the analysis line and the efficiency of formation of analyte atoms. The p is therefore directly related to atomization efficiency. The atomization efficiency, which can be increased by forming analyte species that is readily vaporized and atomized, and by increasing the heating rate which increases k_1 and shifts the absorbance signal profile (at least the decay part) into the isothermal region of the tube wall temperature curve, thereby making the analyte atom loss by concentration diffusion only, which makes k_2 relatively small and constant at constant temperature.

The time t_{max} is identified with the time required to attain the absorbance maximum. Use of high heating rates coupled with moderately high atomization temperatures should yield $k_1 \gg k_2$. The resulting low t_{max} value (0.1–0.2 s) should yield $k_1 t_{max} \gg k_2 t_{max}$. Equation [7] is then reduced to:

$$[8] \quad \text{Absorbance} \simeq p[D]_0$$

yielding high atomization efficiency.

On differentiating eq. [6] we obtain the following expression for the time t_{max} required for the attainment of the stationary state:

$$[9] \quad k_1 \exp(-k_1 t_{max}) = k_2 \exp(-k_2 t_{max})$$

or

$$[10] \quad t_{max} = \frac{1}{k_1 - k_2} \ln \frac{k_1}{k_2}$$

The maximum concentration of B is seen to be:

$$[11] \quad [B]_{t=t_{max}} = [D]_0 \exp(-k_2 t_{max})$$

where $[D]_0$ is the initial concentration of D. The efficiency of atomization, β_1, is defined here as the fraction of analyte present as atomic vapour at t_{max} (the time when this fraction is a maximum) and is given by

$$[12] \quad \beta_1 = \frac{[B]_{t=t_{max}}}{[D]_0} = \exp(-k_2 t_{max})$$

It is important to note that this definition of atomization efficiency does not take into account those atoms that are lost by the process:

$$[B] \xrightarrow{k_2} [C]$$

in going from time $t = 0$ to $t = t_{max}$. It is a measure of those atoms that are present at t_{max}.

An alternative method of calculating the atomization efficiency can be derived from the above definition of β_1. This atomization efficiency (to be called β_2) is defined as the number of atoms, N_{max}, present as atomic vapour at t_{max} over the total number of atoms present in the injected sample, N_0 (i.e., at time = t_0).

$$[13] \quad \beta_2 = \frac{N_{max}}{N_0}$$

For personal use only.

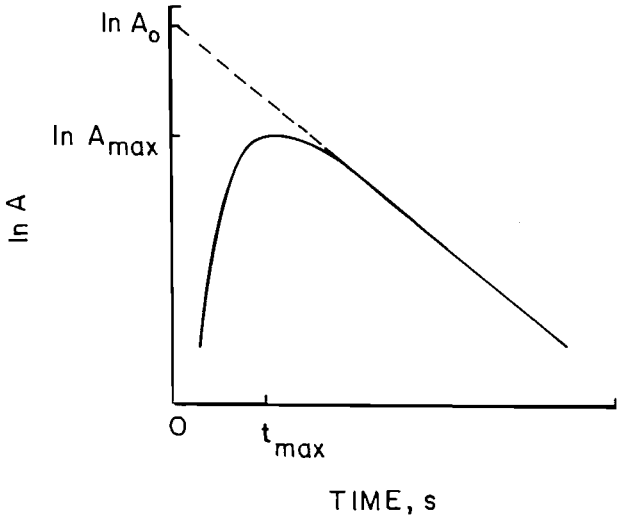

FIG. 1. Plot of natural logarithm of absorbance vs. time (linear scale). A_{max} and A_0 are absorbance at time $t = t_{max}$ and t_0, respectively.

However,

$$[14] \quad p = \frac{A_{max}}{N_{max}}$$

where A_{max} is the absorbance at time $t = t_{max}$.

As stated earlier, extrapolation of the straight line plot to zero time (i.e., t_0) will give the concentration of B necessary to produce the decay of the absorbance signal by diffusion process alone. Therefore,

$$[15] \quad p = \frac{A_0}{N_0}$$

where A_0 is the absorbance at time $t = t_0$. A_{max} and A_0 are defined in Fig. 1.

The final result is that the atomization efficiency, β_2, can be obtained readily from the equation:

$$[16] \quad \beta_2 = \frac{A_{max}}{A_0}$$

Theoretically, having been derived from the same definition, β_1 should be equal to β_2.

Because k_2 is weakly dependent on temperature, it is important for the calculation of β_1 that the descending part of the absorbance signal profile be located in the isothermal region of the tube wall (at the centre) temperature vs. time curve. The k_2 values are calculated from the data points from the tail end of the experimental trace.

It can be seen from eq. [12] that $\beta_1 \simeq 1$ when $k_2 t_{max} \ll 1$. Hence, for the highest atomization efficiency, both k_2 and t_{max} must be made as small as possible. The time t_{max} is sensitive to heating rate; generally, relatively high heating rates yield small t_{max} values. However, the rate constant k_2 for atom loss by concentration diffusion increases with increasing temperature, although k_2 is less sensitive to higher temperatures than k_1 (7). This method employs relatively high heating rates coupled with moderately high atomization temperatures to keep both k_2 and t_{max} values small so as to approach the condition $k_2 t_{max} \ll 1$. As can be seen later, with the maximum heating rate available with the modified HGA-400 (about 7 K ms^{-1}), this attempt has been only partly successful.

TABLE 1. Experimental and analytical parameters*

Element	Wavelength (nm)	Mass of elements (pg)	Charring temperature (K)

Experimental

Apparatus

A modified Perkin-Elmer atomic absorption spectrometer, model 503, equipped with a Deuterium-Arc Background Corrector and an HGA-400 atomizer was used. The atomizer was fitted with a laboratory-made power supply capable of supplying variable heating rates up to about 7 K ms^{-1}, with independent control of the heating rates and temperatures. The details of the modified instrument have been published earlier (8). High temperatures of the graphite tube were measured with an Ircon 1100 series automatic optical pyrometer (Ircon Inc. Skokie, IL). Low temperatures were measured with an Ircon series 300 pyrometer (Ircon Inc.). Perkin-Elmer pyrolytically coated graphite tubes (part no. 091504) were used. Graphite tubes were replaced with new tubes after about 12 firings. Argon gas was used in the gas-stop mode of operation at the atomization step. Absorbance and temperature profiles were recorded with a four-channel, Nicolet digital oscilloscope, series 4094, with two plug-in units, model 4562 (Nicolet Instrument Co. Madison, WI).

Hollow-cathode lamps of cobalt (Perkin-Elmer), aluminium (EEL), and copper, silver, iron, and gallium (the last four by Westinghouse) were operated at the lamp current recommended by the manufactures.

Reagents

Chemically pure metals or their salts were used to prepare standard solutions. Stock solutions of cobalt and iron were prepared separately by dissolving an appropriate mass of the metal in nitric acid (ULTREX, J. T. Baker Chemical Co.) and diluting the solution to 1000 μg mL^{-1} with ultrapure water. The stock solution for silver was prepared by dissolving an appropriate mass of silver nitrate in ultrapure water. Stock solutions for gallium and copper were prepared separately by dissolving the metals in concentrated nitric acid (ULTREX) and 50% (v/v) nitric acid, respectively, with heating. The final solutions were made by dilution to 1000 μg mL^{-1} with ultrapure water. The stock solution for aluminium was prepared by dissolving the metal in 20% HCl (ULTREX) with heating. The final solution was made by dilution to 1000 μg mL^{-1} with ultrapure water. All stock solutions were made 1% (v/v) in HNO_3.

All test solutions were prepared by diluting the stock solutions to desired concentrations with ultrapure water immediately prior to use. They contained 1% (v/v) HNO_3 (ULTREX). Ultrapure water of resistivity 18.3 megohm-cm was obtained direct from a Milli-Q2 water purification system (Millipore Corporation).

Procedure

Sample solutions were injected into the atomizer using a 10 μL Eppendorf pipet fitted with disposable plastic tips. High heating rates and moderately high atomization temperatures were used in order to shift the atomic absorbance signal profile (at least the decay part) into the isothermal region of the tube wall (at the centre) temperature vs. time curve so that the assumption of consecutive, first-order reactions was valid. The absorbance values were corrected for blanks.

Experimental and analytical parameters

Table 1 summarizes the experimental and analytical parameters used.

Results and discussion

Table 2 summarizes the atomization efficiency values of a selected group of elements at various heating rates and atomization temperatures. The heating rates listed were calculated from the tube wall temperature curve (such as the one shown in Fig. 2) using its nearly-straight-line segment which encompasses the appearance temperature of the element. For example, in Fig. 2, the appearance temperature of Al was 2420 K and the heating rate was calculated as follows.

$$\text{Heating rate} = \frac{(2560 - 2420)\text{K}}{(200 - 160)\text{ms}} = 3.5\ \text{K ms}^{-1}$$

The reason for using the above segment of the tube wall temperature curve was that the heating rate so calculated was what the analyte actually experienced at the appearance time of the signal and at times immediately following the appearance time. The above heating rate was greater than the average heating rate over the entire period of rise in the tube wall temperature shown in Fig. 2. The heating rate is one of the important factors that determine the rate of atom formation during the rising part of the atomic absorption signal profile (9–11), and hence, affects atomization efficiency strongly. The gas temperature, which like the tube wall temperature, was time- and space-dependent, roughly followed the tube wall temperature in the immediate vicinity of the spot on the tube wall surface where the test solution was placed (12, 13) — the tube wall temperature of that spot and the gas temperature in its immediate vicinity determined the rate of atom formation at the appearance time and at times immediately following the appearance time.

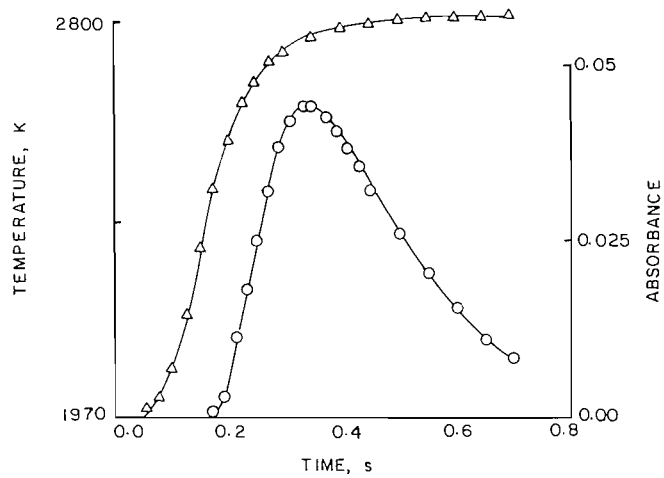

FIG. 2. Absorbance profile of aluminium and the corresponding temperature profile of the graphite furnace. △: tube wall temperature measured with the automatic optical pyrometer. ○: 0.1 ng of Al in 1% (v/v) HNO_3 aqueous solution. Atomization temperature = 2800 K. Heating rate = 3.5 K ms^{-1}.

Most of the absorbance profiles were located more than 70% within the isothermal region of the tube wall temperature vs. time curves. This was achieved by using the highest possible heating rates and moderately high atomization temperatures.

Figure 3 shows the absorbance signal profile of aluminium vs. the time drawn using a logarithmic scale for the ordinate. The rate constant for aluminium atom loss, k_2, was obtained from the slope of line B, which was drawn from the experimental data points at the tail of the absorbance signal profile.

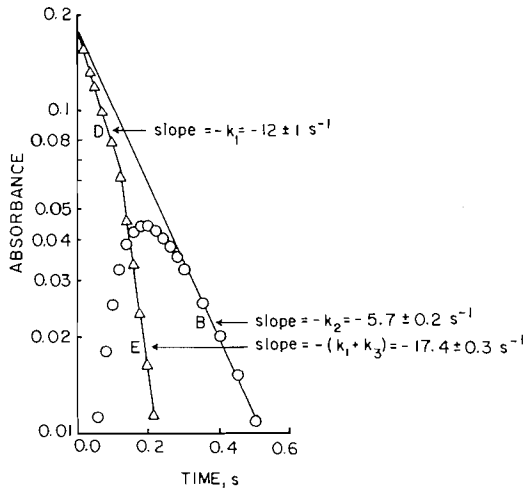

FIG. 3. Plot of absorbance (logarithmic scale) vs. time (linear scale) for aluminium shown in Fig. 2. Curve B: Loss of $Al_{(g)}$: $Al_{(g)} \xrightarrow{k_2} C$. Curve D: Formation of $Al_{(g)}$: $AlO_{(g)} \xrightarrow{k_1} Al_{(g)} + (1/2)O_{2(g)}$. Curve E: Formation of $Al_{(g)}$ by dissociation of $AlO_{(g)}$, and loss of the latter:

$$\begin{array}{l} AlO_{(g)} \xrightarrow{k_1} Al_{(g)} + (1/2)O_{2(g)} \\ \downarrow k_3 \\ C' \end{array}$$

Atomization temperature = 2800 K. Heating rate = 3.5 K ms^{-1}.

The value of the slope of line B was calculated by least-square linear regression involving the last few data points on the decay part of the absorbance signal profile. The points of line D represent the "concentration" of the species D. The curve D has been plotted using the difference between the extrapolated absorbance and the experimental absorbance vs. time, plotted on the same axes, and shows two intersecting straight lines of different slope. These intersecting straight lines correspond to two different modes of loss of the species D. The straight line, D, corresponding to the earlier times and having the lower absolute slope, gives the value of the rate constant, k_1, for the reaction $D \xrightarrow{k_1} B$. The straight line, E, corresponding to later times and having a slightly steeper slope yields the sum of the rate constants ($k_1 + k_3$) for the two modes of loss of the species D, as shown below:

$$[17] \qquad \begin{array}{l} D \xrightarrow{k_1} B \xrightarrow{k_2} C \\ \downarrow k_3 \\ C' \end{array}$$

where C′ is the product of the other loss process of species D. Any D taking the path indicated by the arrow marked k_3 will not yield an atomic absorption signal. The mathematical treatment adopted above is admittedly a simplified treatment of a more complex process, but has the merit of showing the correct temperature dependence of the rate constants. However, where two straight-line segments are observed (as for aluminium) a more rigorous mathematical treatment is necessary if the mechanism is as shown above; the slower must be treated like B above, then the faster extracted from the differences.

Following the treatment described in ref. 6 the following mechanism for aluminium atomization involving three first-order rate processes is proposed.

$$\begin{array}{lll} AlO_{(g)} & \xrightarrow{k_1} & Al_{(g)} + (1/2)O_{2(g)} \\ \downarrow k_3 & & \downarrow k_2 \\ C' & & C \end{array}$$

The above mechanism shows that a part of the $AlO_{(g)}$ is lost as $AlO_{(g)}$ (with a rate constant k_3), a part is dissociated to $Al_{(g)}$ (with a rate constant k_1), and the $Al_{(g)}$ is then lost (with a rate constant k_2). This mechanism is in agreement with what has been observed in another study from this laboratory (14). Smets (3) has also reported that the mechanism of aluminium atomization is by dissociation of $AlO_{(g)}$.

The β_1 and β_2 values in Table 2 are internally consistent; the β_1 values are consistently larger than the β_2 values. Probably, the large extrapolations involved in obtaining the A_0 values result in their over-estimation and in lower β_2 values from eq. [16].

Table 3 shows the values of k_1, k_2, and measured t_{max} at various final, steady-state atomization temperatures. Precision values of the rate constants are not shown since values of precision from least-square regression calculations depend on the number of points included, whereas the value of the rate constant itself does not. However, the precision of any rate constant value can be no better than 5% relative standard deviation, as the absorbance values used in the calculation of rate constants have this order of relative precision.

The t_{max} values used in calculating the β_1 values in Table 3 were measured graphically from Fig. 1 since the measured t_{max} values had a smaller uncertainty than the t_{max} value calculated from eq. [10]. The uncertainty in the measured t_{max} arose

TABLE 3. First-order rate constants for atom formation and atom loss

Element	Atomization temperature (K)	Rate constants (s^{-1}) k_1	k_2	Measured t_{max} (s)

from manually locating the appearance time and the time corresponding to A_{max} (Fig. 1); the digital oscilloscope calculated the difference (t_{max}) in the above times. If t_{max} values were calculated from eq. [10], it would have required use of the k_1 and k_2 values, each of which had an uncertainty of at least 5% relative standard deviation. The k_1 values were also subject to unknown systematic error as they were calculated from the absorbance values from the rising part of the absorbance signal profile which was located in the non-isothermal region of the tube wall temperature curve (Fig. 2). Also, there are further complications in determining k_1 values in the case of an element such as Al in which there is an additional, first-order loss process (identified as C′ in mechanism 17 given earlier) having a rate constant k_3. In such a case, eq. [10] must be modified as shown below (6).

$$[18] \quad t_{max} = \frac{\ln (k_1 + k_3) - \ln k_2}{k_1 + k_3 - k_2}$$

The measurement of t_{max} with the digital oscilloscope was preferred because it avoided the complications that would arise in the above mathematical formulation of t_{max} in terms of the two rate constants involved in the loss of species D, and thereby simplified the task considerably. This was in addition to lower uncertainty in measuring t_{max} graphically from Fig. 1 than that in calculating t_{max} from eqs. [10] or [18]. However, by using still higher heating rates as used in ref. 6, the location of the entire absorbance signal profile can be shifted to the isothermal region of the tube wall temperature curve; in that case, t_{max} can be readily evaluated also from eq. [10] or [18] since the uncertainty and error in measuring k_1 from the absorbance signal profile would then be comparable to those in measuring k_2 and t_{max} from the same absorbance signal profile.

Comparison with the atomization efficiency values reported by other authors

Sturgeon and Berman (1) used an HGA-2200 and van den Broek and de Galan (2) used an HGA-72 and a CRA-63, whereas this work was done with an HGA-400. Also, before comparison can be made, it must be noted that the efficiency values determined in this study were for the HGA-400, and were only applicable under the specific experimental conditions, especially the heating rates used in this work. The most important difference between this work and those of the above authors was that the heating rates used in this work were much higher (Table 2) than those used by the above authors (1, 2). Regardless of whether atomization was isothermal or non-isothermal, higher heating rates increased k_1 values much more than k_2 values, and hence decreased t_{max} values by eq. [10]. Equation [12], which shows $\beta_1 = \exp(-k_2 t_{max})$, holds good as long as the decay of analyte atom is by a first-order rate process with a rate constant k_2. Fulfillment of the above condition required only that the tail end of the absorbance signal from which the experimental data points for evaluating k_2 values were taken must be located in the constant-temperature region of the temperature vs. time curve. As Table 2 shows, this condition was certainly fulfilled by all the elements in this work. It can be predicted from eq. [12] that much higher heating rates used in this work should produce higher β_1 values than those reported by the other workers (1, 2) who used much lower heating rates. The β_1 values reported in this work confirm the above prediction.

Sturgeon and Berman (1) defined the absolute atomization efficiency of the HGA-2200 for a particular point in time (conveniently at the time of maximum signal) as the ratio of the sum of the number of neutral and ionized analyte atoms to the number of analyte atoms initially introduced into the furnace. Since all of the elements in this work have ionization energies of about 6 eV or higher, loss of neutral atoms by ionization in the HGA-400 at the atomization temperatures used can be considered negligible. Table 4 shows that most of the atomization efficiencies reported by Sturgeon and Berman (1) are of the same order of magnitude as those of this work.

TABLE 4. Comparison of mean atomization efficiency values of this work with those reported by the other authors (1, 2)

Element	This work* β_1	This work* β_2	Sturgeon and Berman† (1) β	van den Broek and de Galan§ (2) β_{theor}	van den Broek and de Galan§ (2) β_{expt}

Ga	0.30	0.18	0.06	—	—

*Used HGA-400.
†Used HGA-2200.
§Used HGA-72. β = Atomization efficiency.

van den Broek and de Galan (2) reported that atomization efficiency of the HGA-72 for Ag — a theoretical value of 0.45 and experimental value of 0.20. These authors (2) defined the atomization efficiency as N_{max}/N_0 — the ratio of the maximum number of atoms, N_{max} (obtained from the measured peak absorbance), and the amount of analyte injected into the furnace, N_0. Table 4 shows that the atomization efficiencies reported by van den Broek and de Galan (2) are similar to those in this work.

It should be noted that not only were the atomizers of the above authors (1, 2) different from the HGA-400 used in this work, but also the experimental and analytical parameters, especially the heating rates used, were different.

Critical appraisal of the atomization efficiency values, β_1 and β_2

The atomization efficiency values, β_1 and β_2, were obtained from the same theory and were subject to the assumptions made in developing the theory. However, as stated earlier, the two methods that were used to obtain β_1 and β_2 values had different sources of uncertainties and errors. The β_1 values were affected by uncertainties in k_2 (Fig. 3) and in t_{max} values (Fig. 1) used in solving eq. [12]. The β_2 values were affected by uncertainties in measuring A_{max} and A_0 used in solving eq. [16].

Since all k_2 values were obtained from the last few experimental data points at the tail end of the absorbance signal which was located in the isothermal region of the tube wall temperature curve, and since these experimental data points related to the time when atom loss by concentration diffusion was the only process occurring, it can be concluded that the k_2 values listed in Table 3 are fairly good. The line from which k_2 was calculated (Fig. 3) was reasonably straight, especially at the last few data points at the tail end of the absorbance signal. However, as explained earlier, k_2 values had an uncertainty of about 5% relative standard deviation, which, added to the uncertainty in manually locating t_{max}, was transmitted to β_1 values. The uncertainty in β_2 was mainly due to the measurement of A_0 values since large extrapolation from the tail end of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

absorbance signal were required for the determination of A_0 (Fig. 1). As can be seen from Table 2, β_2 is usually very close in magnitude to β_1, but in each case β_2 is less than β_1. As explained in the theory, it is reasonable to expect the β_1 and β_2 values to have approximately the same magnitude. The above difference was probably due to the sources of uncertainty mentioned above. Since the uncertainty in measuring k_2 and t_{max} was not nearly as large as that due to large extrapolations in calculating A_0, the β_1 values seem to be a more reliable estimate of the fraction of analyte present as atomic vapour at t_{max} than the β_2 values.

The β_1 values were obtained by solving eq. [12], i.e., by using the k_2 and t_{max} values, and were therefore not affected by uncertainty in the k_1 values. The k_1 values were, however, subject to larger uncertainty and errors than the k_2 values because the k_1 values were obtained from the experimental data points (Fig. 3) lying in the non-isothermal region of the tube wall temperature curve (Fig. 2). In contrast, the k_2 values were obtained from the last few experimental data points at the tail end of the absorbance signal (Fig. 3) in order to make sure that the only process occurring at those times was loss of analyte atoms by concentration diffusion at constant temperature. In view of the above, the β_1 values are more reliable than the β_2 values. It is to be noted that the k_1 values were not used in calculating β_1 and β_2 values. However, from the k_1 and k_2 values in Table 3 and from eq. [7], one finds that under the experimental and analytical parameters used in this work, elements such as Cu, Co, Fe, and Ag for which the condition $k_1 \gg k_2$ is more closely approached than elements such as Al, and Ga, yield greater β_1 values than the latter group of elements.

Conclusions

1. Kinetic parameters can be used to determine atomization efficiencies of graphite furnaces.
2. As expected from the theory, significantly higher heating rates than what are usually provided for in commercial graphite furnaces yield significantly higher atomization efficiencies than those reported for some commercial graphite furnaces.

Received October 24, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

B. K. Afghan, J. Carron, P. D. Goulden, J. Lawrence, D. Leger, F. Onuska, J. Sherry, and R. Wilkinson. Can. J. Chem. **65**, 1086 (1987).

Analytical methodology for polychlorinated dioxins and furans (PCDDs and PCDFs) in environmental samples is not standardized. Many variations exist for the extraction, cleanup, quantitation, and confirmation of these compounds and reported detection limits and recoveries vary over several orders of magnitude. This paper describes research carried out at the Canada Centre for Inland Waters over the past seven or eight years to develop reliable methodology at ultratrace levels (10^{-12}–10^{-15} g/g) applicable to a wide range of environmental samples. Extraction techniques are described for biological tissue (fish, clams, leaches, eggs), fly ash, sediments, and water. Detailed cleanup procedures for the various matrices consist of most or all of the following: gel permeation chromatography liquid/liquid extraction with Na_3PO_4, liquid/liquid extraction with H_2SO_4, basic alumina chromatography, and carbon fibre chromatography. Preliminary screening of the cleaned extracts is achieved by gas chromatography equipped with a mass selective detector and positive identification by gas chromatography/mass spectrometry operated in electron impact and chemical ionization modes and with full scan and multiple ion detection. Custom software permitting the analysis of a wide range of compounds in a single run by gc/ms is reported. The presence of specific isomers of PCDDs and PCDFs is confirmed by high resolution gas chromatography/mass spectrometry. A radioimmunoassay screening procedure for PCDDs in environmental samples is also described.

Les méthodes d'analyse des dioxinnes et des furannes polychlorés (DPC et FPC) ne sont pas standardisées. Plusieurs variations existent pour l'extraction, le nettoyage, la quantification et la confirmation de la présence de ces composés; de plus, les limites de détection ainsi que les taux de récupération rapportés varient par plusieurs ordres de grandeur. Dans ce travail, on décrit les études effectuées au cours des 7 à 8 dernières années au centre canadien des eaux intérieures dans le but de développer une méthodologie applicable à des niveaux d'ultratraces (10^{-12} à 10^{-15} g/g) et à un grand éventail d'échantillons prélevés dans l'environnement. On décrit des techniques d'extraction pour des tissus biologiques (poissons, moules, eaux de lessivage et oeufs), des suies, des sédiments et des échantillons d'eau. Les diverses méthodes détaillées proposées pour le nettoyage de diverses matrices comportent la plupart ou toutes les techniques suivantes: chromatographie par perméation de gel; extraction liquide/liquide avec du Na_3PO_4; extraction liquide/liquide avec du H_2SO_4; chromatographie standards sur de l'alumine ou des fibres de charbon. On a effectué des essais préliminaires sur des extraits lavés en faisant appel à la chromatographie en phase gazeuse couplée à un détecteur sélectif de masses; on a procédé à l'identification positive par chromatographie en phase gazeuse couplée à la spectrométrie de masse, opérée soit dans le mode d'impact électronique ou d'ionisation chimique et avec un balayage complet et une détecteur ionique multiple. On rapporte le développement de logiciels faits sur mesure pour permettre l'analyse d'un grand nombre de composés dans une seule expérience de cg/sm. On peut confirmer la présence d'isomères spécifiques des DPC ou des FPC en procédant à la chromatographie en phase gazeuse couplée à la spectrométrie de masse opérée à haute résolution. On décrit aussi une méthode radioimmunologique permettant de vérifier la présence des DPC dans des échantillons provenant de l'environnement.

[Traduit par la revue]

Introduction

The presence of polychlorinated dioxins and furans (PCDDs and PCDFs) in the environment is cause for concern to public, government, and municipalities in industrialized societies. This is mainly due to the pronounced toxicity of the 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD) isomer to certain biological species (1). Many agencies have established guidelines for these compounds and recently the Ontario Ministry of Environment has recommended a maximum daily human intake for 2,3,7,8-TCDD or its toxic equivalent of PCDDs and PCDFs of less than 10 pg/km of body weight (2).

Methods for determining PCDDs and PCDFs in various types of samples have been well documented (2, 3). A recent worldwide survey conducted by the Ontario Ministry of the Environment has shown a proliferation of extraction, cleanup, quantitation, and confirmation techniques for analysis of these compounds (4). The reported range of detection limits and recoveries obtained for various types of samples are shown in Table 1 (4). The large range of reported detection limits and recoveries can be attributed to variations in the size of samples, complexity of samples, the amount of determinand in relation to the amount of interfering substances in samples together with

TABLE 1. Reported limits of detection (lod) and range of percent recovery for PCDDs by laboratories responding to worldwide survey (4) (all values in parts per trillion: 10^{-12} g/g)

Sample type	Compound	Range of lod	Range of % recovery
Soil	2,3,7,8-TCDD	0.1–1000	10–179
	OCDD	1.0–500	0–184
Fish	2,3,7,8-TCDD	0.1–1000	6–150
	OCDD	1.0–100	10–110
Water	2,3,7,8-TCDD	0.0005–300	40–110
	OCDD	0.0001–50	40–116
Fly ash	2,3,7,8-TCDD	0.1–300	10–118
	OCDD	1.0–100	37–122

variations in the procedures used for cleanup and quantitation of the PCDDs and PCDFs.

Work at the Canada Centre for Inland Waters for the past seven or eight years has been directed at systematic development of analytical capability to detect and determine hazardous substances including PCDDs and PCDFs down to 10^{-12} g/g with a high degree of reliability and confidence. Developed methodologies had to be applicable to a wide range of environmental samples. This initially involved designing and constructing a special laboratory facility to (*a*) minimize errors due to cross contamination of samples during cleanup and pretreatment and (*b*) provide maximum safety to personnel when handling hazardous chemicals such as 2,3,7,8-TCDD during method development and/or sample analysis (5). Several methods for extraction, cleanup, quantitation, and confirmation of PCDDs and PCDFs at parts-per-trillion (ppt) and parts-per-quadrillion (ppq) levels have been developed to analyze chlorophenol formulations, fish tissues, sediments, and fly ash (6, 7). The methodologies were also applied to a study of the formation and fate of PCDDs and PCDFs during chlorophenol combustion (8).

This paper presents the recent work carried out by the authors in areas of large volume extraction of contaminants at ultratrace levels (10^{-12} to 10^{-15} g/g) from water, the application of radioimmunoassay as a screening technique for PCDDs, improvements in the cleanup of environmental samples and the use of hydrogen negative ion chemical ionization mass spectrometry to obtain improved precision and increased reliability for PCDDs analysis.

Experimental

Apparatus and equipment

(a) Glassware

Consists of Erlenmeyer flasks, separating funnels, Allihn filters, round bottom flasks, micro syringes, centrifuge tubes, disposable glass pipettes, and chromatographic columns.

(b) Extraction and concentration and filtering apparatus

Consists of rotary evaporators, vortex evaporator, homogenizers, soxhlet apparatus, centrifugation apparatus capable of accommodating 250 mL centrifuge cups and 4500–5000 rpm, gas tight syringes capable of accepting disposable filter units (25 mm diameter × 0.2 μm porocity).

(c) Gel permeation liquid chromatographic system

Assembled using suitable injection valve, 5 mL sample loop, 60°A Styragel column, uv detector with 254 nm filter, and a solvent delivery system capable of constant flow with medium and low back pressure.

(d) Alumina column cleanup apparatus

Consists of 2 cm id × 35 cm glass column with Teflon stopcock with a glass wool plug. A 30 g alumina column (Brockman activity 1, 80–200 mesh, activated at 550°C for 6 h and deactivated with 1%-w:w distilled–deionized water) is used. A 2 cm layer of sodium sulfate was added to cover the alumina in order to maintain its activity. The column must be prepared just prior to use.

(e) Carbon–fibre system

This system consists of a solvent delivery system capable of constant flow at low back pressure, solvent selector value allowing selection of five or six solvents, fraction collector, and controller, and a 6-port switching valve equipped with 1 mL sample loop. The carbon–fibre column consists of 4 mm id × 7.2 cm annealed glass and fitted with zero dead volume fittings and 2 μm stainless steel frits. The column packing is prepared as described below:

Glass fibre filter paper (0.6 g) (type GA200, Toyo Roshi Co. Ltd.) is weighed in a suitable size beaker, 0.05 g of activated carbon (PX-21, Amoco Research Corp) is added along with 100 mL methylene chloride. The mixture is shredded and mixed with a Polytron, so that the fibres are of a size capable of retaining the carbon particles. This slurry of carbon fibres is then packed, using an aspirator, into a 7.2 cm, 6 mm od, annealed glass tube, equipped with zero dead volume fittings and 2μ frits.

(f) Gas chromatography – mass spectrometry apparatus

Preliminary screening and subsequent positive identification, confirmation, and quantitative analysis are carried out using a wide variety of instruments and columns. The details of specific instruments and the operating conditions are described in the analytical protocols section of this paper.

(g) Continuous-flow extractors

A variety of continuous extractors have been developed to cover the various sampling procedures that may be required. They are designed primarily as portable units for use in the field, however, they can also be setup on board ship or in the laboratory. All the extractors are basically mixer–settlers in which the incoming water is passed through a chamber where it is mixed with solvent.

The extractors were produced in two sizes, "large" to extract up to 1 L/min and "small" to extract up to 0.5 L/min. The water can be sampled as "whole water", i.e. with no separation of particulates or as "clarified water" by extracting the effluent of a continuous flow centrifuge. The suspended solids can also be collected and analyzed at the same time. The flow rate through the extractor and total sampling time can be adjusted so that there is sufficient material for analysis of corresponding suspended sediment and clarified water. For long sampling times (one week) the solvent can be stripped from the extractor effluent water and recirculated so that no solvent make up is required.

(h) Apparatus for radioimmunoassay

Incubator, refrigerator, freezer, γ counter, and refrigerated centrifuge are essential to carry out the assay.

(i) Reagents and materials for radioimmunoassay

Antiserum to TCDD, raised in rabbits as described by Albro *et al.* (9), antiserum to rabbit γ-globulin raised in goats, ^{125}I-labelled 1-*N*-(5-iodovaleramido)-3,7,8-trichlorodibenzo-*p*-dioxin, detergent solution, bovine γ-globulin, rabbit γ-globulin, phosphate buffer saline, antibody diluent, and second antibody reagent.

(j) Internal (spiking) standard

A mixture of ^{13}C-labelled dioxins consisted of 50 pg/μL of 2,3,7,8-^{13}C TCDD, and 100 pg/μL each of 1,2,3,7,8-^{13}C-PCDD, 1,2,3,4,6,7,8-^{13}C-HpCDD, and ^{13}C-OCDD in toluene. The ^{13}C hexa isomer was not available at our laboratory.

Sample extraction techniques

(a) Tissue extraction (fish, clams, leeches, and eggs)

Homogenized tissue (10 g) is subsampled into a 500 mL Erlenmeyer flask and spiked with 25 μL internal standard. After the addition of 100 mL 1 *N* HCl the contents of the flask are mixed by swirling and allowed to stand for 30 min. A 100 mL aliquot of toluene is added and

For personal use only.

the flask is placed on the wrist shaker overnight. The density of the resulting emulsion will determine the next analytical step. Light to medium emulsions that show some separation are transferred to a separatory funnel and allowed to separate. The lower aqueous layer, solids and emulsion remnants are then placed into stainless steel centrifuge cups and homogenized with an additional 100 mL of toluene, followed by centrifugation to break emulsions. Dense or persistent emulsions may be directly transferred to the centrifuge cups and centrifuged at 4000–4500 rpm for 10–15 min prior to decantation into a separatory funnel and subsequent separation. This separation, homogenation centrifugation scheme is repeated twice with 100 mL of toluene and the extracts are combined for further cleanup steps.

(b) Fly ash and sediments

An appropriate size sample (1–10 g) is spiked with 25 μL internal standard, treated with 100 mL 1 *N* HCl and allowed to stand 1 h. The mixture is then filtered and washed with 100 mL of distilled deionized water. The filtrate is extracted three times with 50 mL portions of toluene. The solids are mixed with sodium sulfate to obtain a free flowing mixture and soxhlet extracted for 6 h with 300 mL of toluene. The toluene extracts are combined for further cleanup.

(c) Water

A 50–200 L sample size, depending upon the concentration factor required, is extracted with 300 mL of dichloromethane using a continuous-flow extractor. The extraction is carried out by passing the sample through the extraction chamber where it is mixed with dichloromethane. The water phase is separated and passed to waste through a small packed column, the solvent is recirculated back into the mixing chamber. The effluent water contains dissolved solvent (about 1.5% by volume) which is replenished by adding solvent to the top of the small packed column through which the effluent water is passing, thus giving a counter-current extraction with clean solvent. The packing is "Teflon" Raschig rings which also serve, by virtue of the solvent wetability of "Teflon", to break any emulsions and coalesce small solvent drops.

In all extractions a metering pump is used to meter surrogate standard solution into the water sample flow as it enters the extractor. In this way for every sample extracted the recovery of the surrogate standards gives an immediate measure of the material balance obtained in the extraction–analytical process. The surrogate standards are chosen so that they have similar extraction characteristics to the analytes of interest and are compatible with the chromatographic procedure and detection system used. For example, when analyzing for PCDDs, where a mass detector is used, isotopically labelled dioxins such as ^{13}C are ideal surrogates.

Extraction of small volumes of water (1–4 L size) is carried out using the separatory funnel technique. A sample is spiked with 25 μL of internal standard solution. The spiked sample is then extracted with dichloromethane. The extract is concentrated and exchanged to hexane or chloroform depending upon the type of cleanup required to eliminate interferences that may be encountered.

Cleanup procedures

(a) Liquid /liquid extraction using trisodium phosphate

The sample extracts are treated with 100 mL of 0.05 *M* trisodium phosphate ($Na_3PO_4 \cdot 12H_2O$) for 2 min followed by a wash with 100 mL deionized water.

(b) Liquid/liquid extraction using sulphuric acid

The sample extracts are treated with 100 mL of 1 *N* sulphuric acid (H_2SO_4) for 2 min followed by a wash with 100 mL deionized water.

(c) Mercury treatment

Approximately 0.5 mL triple-distilled mercury is added to the concentrated organic extract (5 mL) and vigorously shaken until formation of a black precipitate ceases. The chloroform extract is filtered using a 0.2 μm nylon filter and a 5 mL gas-tight syringe. Additional chloroform is used to wash the mercury until a volume of 12 mL is reached.

(d) Gel permeation chromatography (gpc)

The sample extract is evaporated to dryness, and the residue, reconstituted in small volumes of chloroform, is filtered through a 0.2 μm nylon filter until a volume of 12 mL is reached. Aliquots (4.5 mL) are injected into the gpc system operated at 5 mL/min using chloroform as a mobile phase. The previously calibrated fraction containing the PCDDs and PCDFs is collected. This procedure is repeated for the entire sample volume and the fractions are combined for further cleanup.

(e) Alumina chromatography

The extract from each sample is evaporated to dryness and the residue is dissolved in 1 mL of 1% methylene chloride in hexane. The residue is transferred to the basic alumina column with solvent washings. The column is eluted with a total of 200 mL 1% (v:v) methylene chloride:hexane (fraction 1) and subsequently with 150 mL 50% (v:v) methylene chloride hexane (fraction 2). Fraction 2, containing PCDDs and PCDFs, is evaporated and the residue redissolved in 0.9 mL 50% (v:v) methylene chloride:cyclohexane.

(f) Carbon–fibre chromatography

The concentrated extract from the alumina cleanup is injected into the carbon–fibre cleanup system and eluted at 4 mL/min in succession as follows: 20 mL 50% (v:v) methylene chloride:cyclohexane, 30 mL ethyl acetate, 20 mL 4% benzene in ethyl acetate, 20 mL 20% benzene in ethyl acetate, and 30 mL 50% benzene in ethyl acetate. The carbon fibre is then back eluted with 30 mL toluene. The toluene fraction containing the PCDDs and PCDFs is concentrated to dryness and reconstituted with 25 μL ^{37}Cl-labelled 2,3,7,8-TCDD in toluene for high resolution gas chromatography/low resolution mass spectrometry analysis.

Isolation of dioxins from environmental samples

Isolation procedures vary with type, nature, and concentration of interfering substances in the environmental sample. The detailed sequence of the sample pretreatment, extraction, and cleanup procedures is determined by the sample type. Figure 1 illustrates the schematic, depending upon the matrix, employed for isolation of dioxin and related compounds prior to analysis.

Analytical protocols

Preliminary screening using gas chromatography with mass selective detector

The system employing an HP5880A gas chromatograph fitted with a 30 m × 0.25 mm id SPB-5 capillary column and HP5970 mass selective detector is used on a routine basis.

The end of the column is inserted directly into the source of an HP 5970 mass selective detector (msd) used in the electron impact (EI) mode at 70 eV. The electron multiplier is set at 2200 V and the dwell times at 200 ms.

Screening of the samples for the presence of dioxins is done in the single ion monitoring (sim) mode by monitoring the three most intense ions in the molecular cluster and the (M − COCl) ion for each congener group over pre-determined time windows (Table 2). These chromatographic windows are determined by running a mixture of all available dioxin isomers and by monitoring simultaneously the most intense ion for each congener group. The detection of the four specified ions in the correct ratios and at the right retention times provides confirmation of the presence of a particular dioxin isomer in the sample which is then subjected to the quantitation procedure.

The quantitative analysis protocol described here is similar to that reported by Norstrom *et al.* (10). It involves quantitation by monitoring, for the correct congener group and over its specified time window, the most intense ion in the molecular cluster of the unlabelled and ^{13}C-labelled (internal standard) dioxin (Table 3). Use is made of the quantitation and reporting software provided with the HP 59970 data acquisition system. The quantitation is based on the ^{13}C internal standards which automatically correct for losses of material during the clean up and for chromatographic variations between injections. A mixture consisting of equal concentrations of unlabelled and ^{13}C-labelled dioxins is first run in order to calibrate the system. The amount of each labelled dioxin is the same as that initially spiked in the sample. After integration of each ion peak, the system automatically updates the calibration table and creates a response ratio (unlabelled/labelled) versus concentration ratio calibration curve for

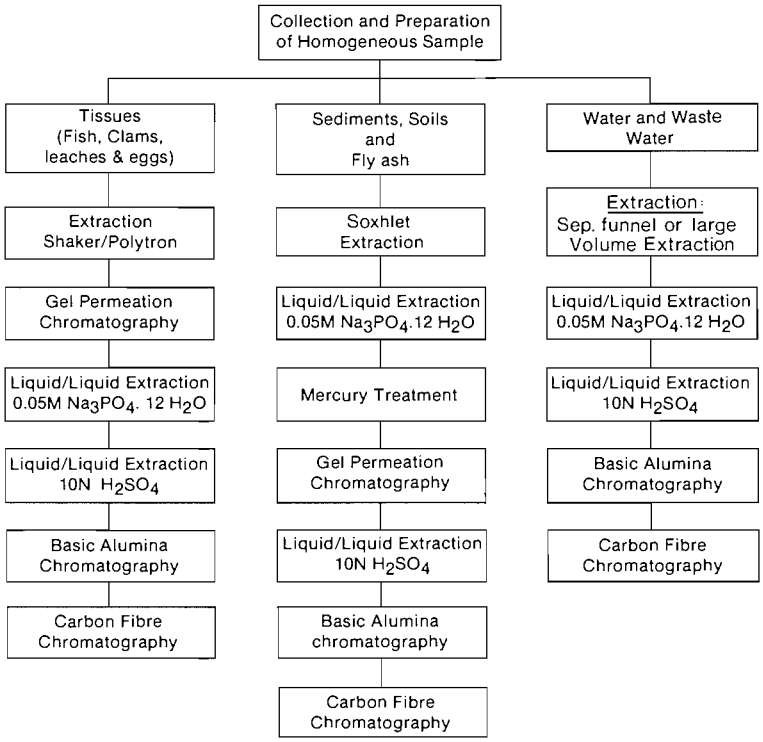

FIG. 1. Sample extraction schematic.

TABLE 2. Nominal masses of the three most intense ions in the molecular cluster of unlabelled dioxins and of the corresponding COCl loss

Congener	Time window (min)	Nominal masses of monitored molecular ions			M-COCl
Tetra	13.0–17.0	319.9	321.9*	323.9	258.9*
Penta	17.0–20.0	353.9	355.9*	357.8	292.9*
Hexa	20.0–23.0	387.8	389.8*	391.8	326.8*

*Most intense ion in cluster.

TABLE 3. Nominal masses of the three most intense ions in the molecular cluster of ^{13}C-labelled dioxins

^{13}C Dioxin	Three most intense ions in molecular cluster		
Tetra	331.9	333.9*	335.9
Penta	365.9	367.9*	369.9
Hexa	399.9	401.9*	403.8
Hepta	435.8*	437.8	439.8
Octa	469.8	471.8*	473.8

*Most intense ion in cluster.

each isomer specified in the table. The ratios found for the sample are then compared with the curves and the concentration of each specified dioxin determined. Recoveries are determined by running an external standard.

(b) Positive identification

A Finnigan 4500 gas chromatograph/mass spectrometer is used for routine confirmation. The cleaned sample extracts are injected into the system using a standard H.P. injector in the splitless mode at 260°C. The gas chromatographic separations are performed using a 60 m × 0.32 mm id fused silica column coated with SP2331 to a film thickness of 0.2 μm. To achieve maximum sensitivity, the exit end of the capillary column is inserted directly into the ion source while maintaining the transfer line area at 250°C. Mass spectra are acquired in various modes such as full scan (fs) and multiple ion detection (MID) using both electron impact and negative ion chemical ionization. The following gas chromatographic and mass spectrometric conditions are used during the preliminary identification of PCDDs.

Gas chromatography conditions	
Carrier gas	Hydrogen at 14 psi head pressure
Initial temperature	80°C
Initial time	2 min
Program at 15°C/min to	200°C
Program at 4°C/min to	250°C
Final holding time	40 min

Mass spectrometry conditions		
Parameter	Electron impact	Chemical ionization
Ion source temperature	150°C	50°C
Manifold assembly temperature	100°C	100°C
Reagent gas	—	Hydrogen
Ion source pressure	—	0.7 to 1.0 Torr
Emission current	0.36 mA	0.36 mA
Electron voltage	70 eV	70 eV
Electron multiplier set at	1100 V, 3 kV on the dynodes for both modes	
Electron multiplier gain		$\times 10^{-7}$ A/V

The acquired data are processed using a Finnigan SUPER INCOS data system. A supplementary data system, developed under contract

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 78.46.186.204 on 09/07/12
For personal use only.

for use in our laboratory, is also employed to carry out quantitation using multiple peak scanning mode. The latter system utilizes customized software to enable sufficient sensitivity and selectivity to be obtained for PCDDs through use of an integrated selected ion signal.

(c) Custom software

Custom software permitting the analysis of a wide range of compounds in a single run was developed under contract for use in our laboratory (11). The data system operates on a Zenith Z-100 computer controlling the Finnigan 4500 gc/ms system. The data system is highly automated and yet allows for operator interaction for optimization of sensitivity and selectivity and for verification of results. The sensitivity of the custom software falls between single ion monitoring and full scan mode of operation. It targets in on specific compounds in relationship to an internal standard rather than general time window in the chromatogram. Quantitation is achieved using the response factor of a single characteristic ion (base peak) relative to an internal standard. The identity of the compound is verified by monitoring up to six confirming ions. The system also includes a quality assurance protocol to monitor long-term performance of the gc/ms system and continuously updates the detection limits of individual compounds.

(d) Isomer specific confirmation

A Varian MAT 311A mass spectrometer directly coupled to a Carlo Erba Model 4160 gas chromatograph is utilized for confirmation. The gc is equipped with a 60 m × 0.25 mm id open tubular column (otc) coated with Silar 10C. The carrier gas is helium with a linear velocity of 27 cm/s. The ms is equipped with a combination electron impact (EI) and chemical ionization (CI) source but operated only in the electron impact mode. Each four channels of the hardware multiple ion detection device can be individually controlled for selection of acceleration voltage, range output, signal bandwidth, background baseline level, and integration rate. The intensities of the selected masses are monitored on a four-channel recorder. The adjustable integration rate can accurately reproduce open tubular column peaks of less than 2 s width at half peak height.

The high voltage unit is monitored using a KEITHLEY Model 191 digital multimeter to calculate the exact acceleration voltage required for the specific masses to be monitored. The magnet is set at perfluorokerosene (PFK) peak at m/z 318.9793 and the resolution is adjusted to between 5 500 and 7 000 mass resolution. The high voltage unit is monitored and used for calculating the exact acceleration voltages for the masses and ions given below.

Ion	Mass (m/z)
$C_{12}H_4O_2{}^{35}Cl_4$	319.8965
$C_{12}H_4O_2{}^{35}Cl_3{}^{37}Cl$	321.8936
$C_{12}H_4O_2{}^{37}Cl_4$	327.8847
$^{13}C_{12}H_4O_2{}^{35}Cl_4$	333.9337

The calculated values are introduced into sim channels.

Using the Silar 10C column, we are able to resolve 18 baseline separated peaks from a mixture of 22 tetrachlorodebenzo-*p*-dioxin isomers. The column is also suitable for isomer specific confirmation of 2,3,7,8-TCDD.

(e) Radioimmunoassay procedure

A procedure recommended by Albro *et al.* (9) is employed. The organic extract is passed through appropriate cleanup steps to reduce interferences and concentrated to 10 μL or less per sample. The residue is solubilized by sonication in a detergent–buffer mixture and incubated with a previously optimized dilution of antiserum from rabbits. A threefold excess of a radiolabelled derivative of trichlorodibenzo-*p*-dioxin over what can be bound by the amount of antiserum used is added and incubation is continued until equilibrium binding occurs. An optimum amount of antiserum to rabbit γ-globulin prepared in goats is then added to precipitate the bound radiolabel. After precipitation is complete, the sample is centrifuged. The supernate is drained off and the pellets radioassayed to a γ counter. The presence of chlorinated dibenzo-*p*-dioxins in the sample extract results in decreased radioactivity being precipitated relative to procedural blanks, and the decrease is a measure of the amount of analyte present.

Results and discussion

Comparison and choice of extraction techniques

Considerable work has been reported on the concentration and/or extraction of dioxin and related compounds at ultratrace levels (ng to pg/L, ng/kg) from a wide variety of environmental samples. Adsorption, solvent extraction, homogenization, and sonication have been used with numerous combinations of different solvents. In spite of the above, a wide variation in extraction efficiency and inability of certain techniques to quantitatively extract dioxins is universally recognized. Therefore, work was initiated to critically evaluate various techniques and select a narrow range of extraction techniques for different types of matrices. The choice of extraction technique was found to depend upon the type of sample and relative concentration of interferences in the samples. Improved recoveries of PCDDs in fish tissue and sediments have been obtained when samples were pretreated with hydrochloric acid and extracted with toluene using mechanical agitation or soxhlet respectively. Sediments with high sand or gravel content can be satisfactorily extracted using sonication with organic solvents such as methylene chloride or toluene. Air particulates and fly ash must be soxhlet extracted after pretreatment with hydrochloric acid and filtration. Our work confirms the earlier findings of Hutzinger *et al.* (1) who have critically evaluated various extraction techniques in a wide variety of environmental samples.

Cleanup procedures

The cleanup scheme utilized for PCDD analysis of environmental samples has evolved from the methodology previously developed for the analysis of 2,3,7,8-TCDD in fish tissue samples (6). Certain fish species and sediment samples require a more comprehensive and exhaustive clean-up scheme to remove interfering compounds. The removal of sulphur compounds prior to gel permeation chromatography is necessary to prevent their deposition within the system and a resulting deterioration of efficiency. Phenolic compounds are one of the most prolific groups of chemical compounds found in nature, and their removal from sediment extracts greatly enhances the stability and resolution of the gpc step. Previously, a micro alumina column employing neutral alumina had been used to separate aliphatics from aromatics (6, 7), however, it was found that certain fish extracts were contaminated with polychlorinated biphenyls at a level sufficiently high to result in a break-through of material which in turn led to failure of the carbon fibre isolation procedure. A higher capacity aluminia column similar to that employed by Norstrom *et al.* (10), was incorporated into the cleanup process for a more reliable removal of PCBs. It was also found that a more stable elution pattern resulted if a six-solvent elution scheme similar to that established by Stalling *et al.* (12, 13) was employed with the carbon fibre system.

The detailed sequence of the cleanup procedure is determined by the nature of the sample and the type of its extract (Fig. 1). The choice and the order of cleanup steps, to eliminate interfering substances, is determined by the nature of samples, extraction technique employed and the relative concentration of interfering substances in the extract. Sediment samples, dumpsite samples containing organic matter, sludges, and fly ash required the most extensive cleanup. However, other types

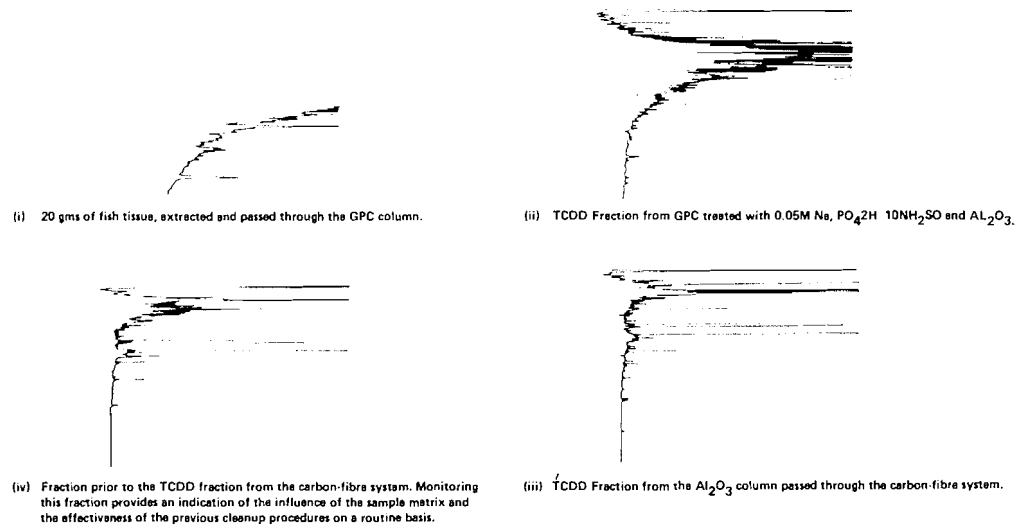

FIG. 2. Chromatograms showing effect of sequential cleanup steps.

of samples can be analyzed by eliminating some of the cleanup steps described in the experimental part of this paper. Figure 1 illustrates the recommended cleanup steps for various types of samples.

The effectiveness of individual cleanup steps to eliminate interferences is shown in Fig. 2. In this example, 25 g of fish tissue extract was carried through the cleanup procedure illustrated in Fig. 1. After each major step an aliquot was taken, corresponding to approximately 0.8 g of fish tissue, and injected into a capillary gas chromatograph. It can be seen that each step significantly reduces the background interferences and thus enables more accurate quantitative analysis of PCDD.

Radioimmunoassay technique for dioxins

Conventional methods for the analysis of PCDDs, which combine gas chromatography with mass spectrometry following extensive extraction and cleanup procedures, are excessively time consuming and expensive when used for routine environmental monitoring. A gas chromatography – mass spectrometry laboratory with two operators, could be realistically expected to process a maximum of 10 samples a day; with an individual analysis, including isomer confirmation, costing between $500 and $1000. These are serious limitations when considered from the perspective of an environmental surveillance or monitoring program. In the event of an environmental accident involving the release of PCDDs into the environment, a requirement would exist for the short-term analysis of large numbers of environmental and biological samples, to be followed in all probability by an intensive monitoring program. Such demands would severely stress existing PCDD analytical facilities.

The inclusion of an effective screening test in the analytical protocol for PCDDs could resolve some of the foregoing problems by eliminating those samples that are free of PCDD from further time consuming conventional analyses. A screening method for PCDDs need not be isomer specific. Rather, positive samples from the screening step could be subsequently analyzed for specific PCDD isomers, using conventional techniques. Three screening methods have been proposed for the detection of PCDDs: radioimmunoassay (9), aryl hydrocarbon hydroxylase (AHH) induction assay (14), and cytosol receptor assay (15). For reasons that have been adequately described by Albro *et al.* (9), radioimmunoassay was considered to offer the best potential for eventual incorporation into an analytical protocol for the routine analysis of PCDDs.

Based on the classical antigen-antibody reaction, radioimmunoassay is a relatively simple, powerful, and adaptable technique for the rapid determination of trace levels of organic compounds. Originally developed for the micro-determination of proteinaceous substances, radioimmunoassay is also extensively used in the detection and determination of steroidal hormones and other low molecular weight organic molecules. Immunoassays have been proposed for the detection of several environmentally important compounds in addition to PCDDs (9): PCBs (16), dieldrin and aldrin (17), atrazin (18), benomyl and methyl 2-benzimidazolecarbamate (19), diclofop-methyl (20), 2,3,7,8-tetrachlorodibenzofuran (21), and 2,4-D and 2,4,5-T (22). Recently, the International Union of Pure and Applied Chemistry, reporting on improved cost effective approaches to pesticide residues analysis, concluded that immunochemical methods, while being traditionally unfamiliar to the residue chemist, offer exciting possibilities for newer, cost effective approaches (23).

Developed by Albro and co-workers (9), the radioimmunoassay for PCDDs is a double antibody procedure with a reported detection limit of approximately 25 pg of 2,3,7,8-TCDD, and a reliable sensitivity in human fat of 100 pg ($P < 0.05$) (24). The precision of the radioimmunoassay for PCDDs remains to be determined for other sample types. The assay uses detergent micelles to solubilize the highly insoluble PCDD molecules which are then incubated, in a competitive binding reaction, with an ^{125}I-labelled dioxin derivative and antibodies raised in rabbits against 2,3,7,8-TCDD. When equilibrium binding has been reached, bound and free labelled hapten are separated, and the bound radioactivity is quantified. A decrease in bound radioactivity, relative to the control tubes, is proportional to the amount of PCDD present. Concentrations of unknowns are interpolated from a standard curve.

A preliminary evaluation of the radioimmunoassay for PCDDs was undertaken in order to confirm that the procedure has potential for the detection of PCDDs in fish extracts, a matrix routinely analyzed for PCDDs at CCIW. A set of fish samples (Table 4) consisting of a variety of tissue homogenates that had been previously extracted and prepared for TCDD

analysis using a deactivated florisil cleanup procedure (R. Thomson, personal communication) was analyzed using radioimmunoassay and gc–ms. The radioimmunoassay analyses were undertaken by Dr. C. Mituma, SRI International, Menlo Park, CA, USA.

Three of the fish extracts (lake trout #2 fraction D, rainbow trout fraction D, and lake trout #7 fraction E) had high TCDD contents, observations that were confirmed by the radioimmunoassay analyses. Overloading of the low capacity florisil probably caused carryover of TCDD from the D fraction, where it would be expected to elute from the column, to the F fraction where it was detected using radioimmunoassay in the lake trout #2 sample. The discrepancies between the TCDD levels detected in the extracts using gc–ms and radioimmunoassay are unimportant, since radioimmunoassay is proposed as a pre-screening method rather than for quantitative determination. Furthermore, radioimmunoassay is responsive to PCDD isomers other than 2,3,7,8-TCDD (9) and to some PCDF isomers (9).

Several contradictions are apparent between the gc–ms and radioimmunoassay results. No TCDD was detected in the lake trout #1 fraction D, and ocean haddock fraction D samples using gc–ms, whereas >20 and 12 ng respectively were detected using radioimmunoassay. The presence of positive interferences, PCDDs other than 2,3,7,8-TCDD, or cross-reacting PCDFs in the sample extract, or the failure to detect TCDD using the gc–ms protocol in use at that time could cause such an effect. Fraction E of the acid-digested lake trout #7 sample, was the only sample tested that gave a false negative result using radioimmunoassay. The remainder of the samples, in which no TCDD was detected using gc–ms, yielded zero or low readings using radioimmunoassay.

These preliminary data demonstrate that radioimmunoassay can detect TCDD in fish samples. However, the problem of low level false positive results obtained using radioimmunoassay requires investigation to clarify whether it is due to positive interferences, assay variability, or the presence of PCDDs other than 2,3,7,8-TCDD. Selection and optimization of an appropriate simplified cleanup procedure would help to eliminate positive interferences from sample extracts. The use of matrix blanks and control samples covering a range of analyte concentrations would further reduce the effect of low level positive interferences and assay variability and instability in the radioimmunoassay for PCDDs. The detection of PCDDs other than 2,3,7,8-TCDD, or of PCDFs, is not a problem, since the presence of such compounds in environmental samples is also cause for concern. Samples containing such interferences should be further analyzed using gc/ms.

Efforts to date have focussed on evaluating the potential of radioimmunoassay for the detection of PCDDs in samples from aquatic environments, interfacing the radioimmunoassay procedure with appropriate cleanup procedures and evaluating its performance when so interfaced, and investigating various means of improving the responsiveness, and precision of the radioimmunoassay. Some basic changes to the original radioimmunoassay procedure have resulted. The modified assay, which uses dimethylsulfoxide (DMSO) as the solubilization agent, will be described in a later publication.

Confirmatory techniques using gc/ms

Standard electron impact ionization at 70 eV is the most widely used form of ionization in conventional mass spectrometry. The majority of gc/ms operators use this mode for the confirmation of PCDDs and PCDFs.

Recently, several other modes of mass spectrometry involving chemical ionization with reagent gases such as methane, oxygen-doped methane, and isobutane have been used to improve sensitivity and in some cases isomer specificity (25–27).

All PCDDs available in our laboratory were analysed using full scan (FS) and also multiple ion scanning (MID) modes of detection. Preliminary data acquired using electron impact and pulsed positive ion negative ion chemical ionization (PPINICI) indicated that TCDDs were most sensitive using the electron impact – multiple ion detection mode, while the H_2 negative ion chemical ionization/multiple ion detection mode provided enhanced sensitivity for the other PCDDs ranging from penta to octa chlorinated isomers.

In the past, the use of negative ion chemical ionization with hydrogen as reagent gas has not been exploited. Presumably this is because it is not as good a reagent gas as methane or isobutane and in the presence of water molecules the H_3O^+ ions formed would compete for sample molecules and result in poor reproducibility of the chemical ionization spectra (28). In addition, hydrogen is a difficult gas to pump from the mass spectrometer system.

In our laboratory, we initially used methane as reagent gas with helium as the gc carrier gas. The use of negative ion chemical ionization gave rise to a significant enhancement, compared to the more conventional electron impact mode, of mass spectrometry for the penta to octa substituted isomers of PCDDs. Because methane contaminates the ion source, the instrument sensitivity declines throughout the decay. Substituting hydrogen for methane gives results that are about 70% as sensitive as for methane but additional benefits accrue which more than make up for this decrease in sensitivity. These advantages are: (*a*) the use of hydrogen allows the He gc carrier gas to be replaced resulting in improved gas chromatography peformance; (*b*) the ion source does not become contaminated with the reagent gas and does not show a loss in sensitivity with time. Time-consuming source cleanups are eliminated.

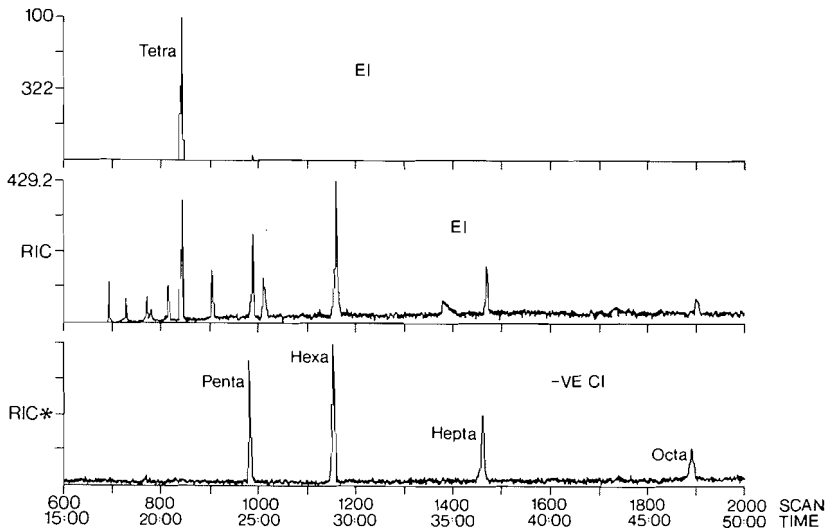

FIG. 3. Ion chromatogram with H_2 NICI scanning from 240 to 480 amu for dioxin standard mixture. Tetra shown at mass 322 for top mass chromatogram.

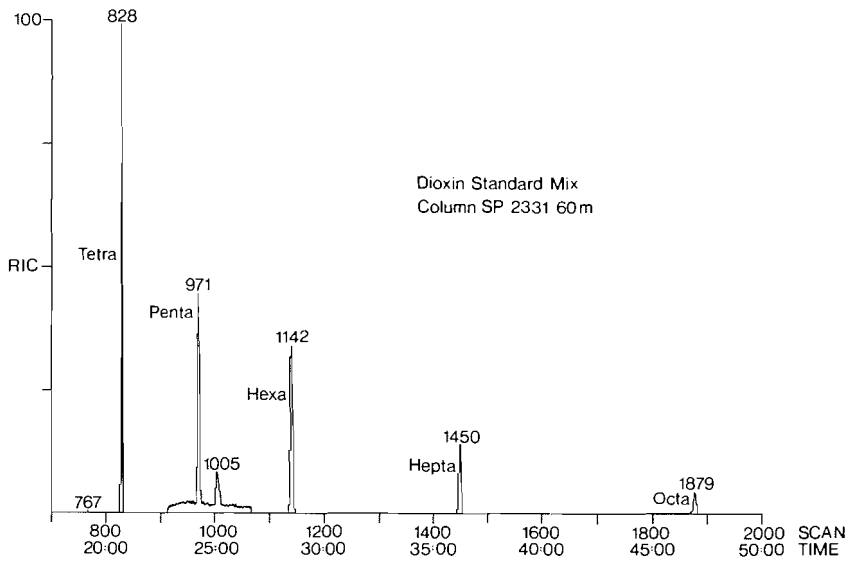

FIG. 4. Ion chromatogram with electron impact multiple ion scan for dioxin standard mixture.

Changing ion volumes, alternate and negative ion chemical ionization electron impact modes of operation can be used with no apparent loss of sensitivity; (*c*) analysis of sample extracts produce significantly lower background noise using H_2 negative ion chemical ionization mass spectrometry compared to the electron impact mode. However, similar background noise is observed when standard solutions of PCDDs are run in both modes; (*d*) the spectra for PCDDs using electron impact and H_2 negative ion chemical ionization are similar in fragmentation of the M and M–Cl clusters. Because of this it is possible to use a common multiple ion detection descriptor(s) with the data system and later reconstruct a dual display for both modes of operation, thereby enabling a direct comparison of spectra for peaks within ± 1% retention time of each other; (*e*) the use of multiple ion detection both electron impact and H_2 negative ion chemical ionization provides an additional confirmatory step to increase the confidence of PCDD identification.

All PCDDs available in our laboratories are analyzed using full scan as well as multiple ion detection modes. Data acquired for electron impact, positive ion chemical ionization and negative ion chemical ionization indicates that 2,3,7,8-TCDD is more sensitive using the electron impact – multiple ion detection mode, while H_2 negative ion chemical ionization mode provides enhanced sensitivity for the penta–octa chlorinated PCDDs. Figures 3–5 and Table 5 present data for a selected isomer mix run under different mass spectrometric conditions. These results indicate that the combination of HP OV-1 and H_2 negative ion chemical ionization in multiple ion scanning mode provide maximum sensitivity for the majority of the higher chlorinated PCDDs. However, the HP OV-1 column does not resolve as many dioxin isomers as the SP2331 column under the conditions described in the experimental section.

With the current protocol, qualitative and confirmatory analysis of PCDDs consist of running the sample extract several times using gc–ecd, gc–msd, hrgc–lrms with various modes of ionization followed by a final reconfirmation of results using magnetic sector hrgc/ms.

Analysis of environmental matrices

Our earlier work was aimed at developing a reliable analytical

method, using mild cleanup steps with least derivatization potential, for TCDDs in environmental samples. The application of this procedure to the analysis of other homologues and complex matrices such as polluted sediments, fly ash and samples from dumpsites indicated that certain samples could not be analyzed, as indicated by low recoveries of spiked labelled isomers (6, 7).

The modifications reported in this paper enabled us to analyze the above samples with increased accuracy and precision. The modifications which enabled improved recoveries included changes in alumina chromatography, addition of mercury cleanup step and change in the order of cleanup procedures. Table 6 and Figs. 6 and 7 illustrate the type of recoveries and mass-chromatograms obtained by the proposed method using highly contaminated samples. Furthermore, the modified procedure was also found to be satisfactory for analysis of a wide variety of tissue samples (e.g. herring gull eggs, clams, leachates, and fish with high lipid content). The results of replicate analysis of herring gull egg pool samples are shown in Table 7 which illustrates the concentration in ng/kg, of native dioxins found in each replicate. The mean values with standard deviation are also given for each isomer. It should be noted that the native dioxins are reported as the 2,3,7,8-TCDD, 1,2,3,7,8-PCDD, and 1,2,3,4,6,7,8-H7CDD isomers. There is only one OCDD. Table 8 lists the recoveries of the method spike and of the samples internal standard. No recoveries are reported for ^{13}C hexa since we do not have that labeled isomer.

A few comments can be made about the analysis. The ms chromatograms were very "clean" with no interference presence except in the case of samples #1 and #2. An interference was

masking the octa M − COCl confirmation ion in those samples. But this was not the case for samples #3 and #4 in which the confirmation ion was clearly detectable thus allowing confirmation of octa in the samples.

Very low levels of native hepta were found in all the samples, typically 1.9 ng/kg, which correspond to a signal-to-noise ratio of about 10. Accordingly, the M − COCl confirmation ion could not be detected and confirmation was based on the three most intense ions in the molecular cluster and the retention time of the peak. Traces of the other hepta isomer also appeared to be present in all the samples but its presence was not confirmed.

The lower recoveries for the higher chlorinated dioxins were linked to a loose frit in the carbon fibre column. This resulted in small carbon particles finding their way into the collection flask and sticking to the wall along with minute quantities of dioxins. Since the highest chlorinated dioxins, especially octa, adsorb strongly to carbon, they could not be recovered completely by the toluene washings. To confirm the above, the loose frit in the carbon fibre system was repaired and the performance of the system was tested using the internal (spiking) standard. A 1 mL aliquot of 50% (v:v) methylene chloride:cyclohexane, containing 25 μL of the internal (spiking) solution, was injected into the carbon fibre cleanup system and the toluene fraction containing PCDDs and PCDFs was analyzed using gas chromatography with mass selective detector. The repaired system afforded recoveries of over 95% for all the spiked dioxin isomers.

Overall, because of the very good efficiency of the cleanup and of the use of an internal standard, the results were considered quite reliable. Our laboratory also participated in an interlaboratory comparison study which demonstrated that the results obtained, using a herring gull egg pool, were comparable to the reference values for the sample.

Further work is in progress to validate the above methodology which will include: (*a*) estimation of practical detection limits for each type of matrix at 95% confidence level, (*b*) determination of the mean recoveries of a series of representative samples from each matrix using three levels of labeled dioxin isomers and varying sample size, (*c*) determining the scope of the methods by analyzing samples across Canada and determining the success rate for the procedure, and (*d*) by "blind" analysis of blanks, reference samples, and fortified replicate samples covering the range of matrices described in this paper.

Binding of isocyanides to five-coordinate, durene-capped hemes

SHANTHA DAVID, BRIAN R. JAMES, AND DAVID DOLPHIN
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received November 14, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

SHANTHA DAVID, BRIAN R. JAMES, and DAVID DOLPHIN. Can. J. Chem. **65**, 1098 (1987).

Solution data at 20°C are presented for the binding of *t*-butylisocyanide and tosylmethylisocyanide (TMIC) to the five-coordinate hemes Fe(porp)(Cy_2Im), where Cy_2Im = 1,5-dicyclohexylimidazole and porp = the dianion of some durene-capped porphyrins with variable length linking methylene straps on either side of the durene moiety (4/4, 5/5, or 7/7 methylenes). The ^{t}BuNC and TMIC ligands are used to probe the steric nature of the distal binding site under the cap, in particular the respective "central" and "peripheral" effects as defined by Traylor *et al.* The binding constants range from $1.1 \times 10^9\ M^{-1}$ for the 7/7—TMIC system to immeasurably small for the 4/4—^{t}BuNC system, this range spanning data reported in the literature for related anthracene- and adamantane-capped systems.

SHANTHA DAVID, BRIAN R. JAMES et DAVID DOLPHIN. Can. J. Chem. **65**, 1098 (1987).

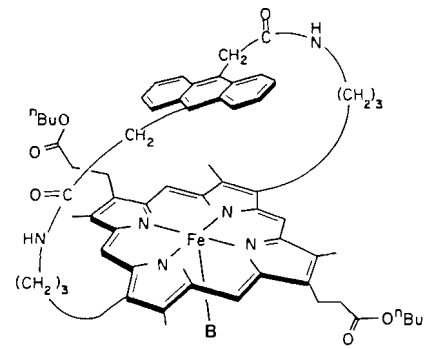
On rapporte des données relatives à la complexation des isocyanures de tert-butyle et de tosylméthyle (ICTM) avec des hèmes penta-coordonnées Fe(porp)(Cy_2Im) dans lesquels Cy_2Im = dicyclohexyl-1,5 imidazole et porp = le dianion de porphyrines «cappées» par un durène rattaché par des unités méthyléniques de longueurs variables (4/4, 5/5 ou 7/7 méthylènes). On a utilisé les ligands tert-BuNC et ICTS comme sondes pour la nature stérique du site de complexation «distal» et en particulier pour les effets respectifs «central» et «périphéral» définis par Traylor et ses collaborateurs. Les constantes de complexation vont de $1,1 \times 10^9\ M^{-1}$ pour le système 7/7—ICTM à un niveau tellement faible qu'il ne peut être mesuré pour le système 4/4—tert-BuNC; cet éventail de valeurs recouvre les données rapportées dans la littérature pour les systèmes «cappés» par de l'anthracène ou de l'adamantane.

[Traduit par la revue]

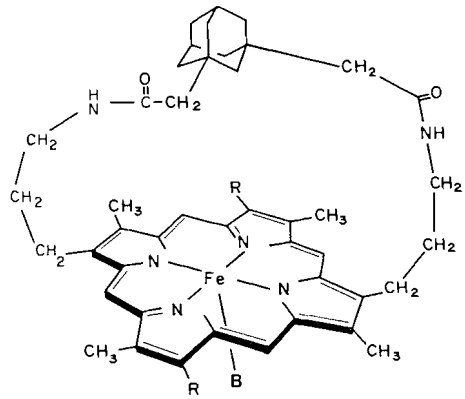
Introduction

Protein residues that surround the heme moiety in hemoproteins can play a crucial role in determining the nature of the axial coordinated ligand(s). Further, for example in reversible O_2-carrying hemoproteins, the protein environment around the distal binding pocket controls (via steric and electronic effects) the extent of O_2-coordination, both in absolute terms and relative to other ligands such as CO (1). Extensive studies (2–7) involving the ligation of various isocyanides (RNC), including bulky ones, have proven useful for gaining an overall appreciation of the structural nature of the binding pocket within protein systems. More recently, isocyanide ligation studies have been extended to model hemes, where Traylor *et al.* (1, 8) have compared the affinities of sterically hindered five-coordinate anthracene (**1**) and adamantane (**2**) model hemes toward ^{t}BuNC and tosylmethylisocyanide (TMIC, see Fig. 1), two structurally dissimilar isocyanides which differ with respect to their relative steric requirements on coordination to the iron(II) centre (Fig. 1). Low affinity of a hindered heme toward ^{t}BuNC, with branching in the third atom away from the iron, is considered to result from a "central steric effect" imposed by a crowded distal environment directly above the metal; in the case of TMIC, a reduced affinity is considered to result largely via a "peripheral steric effect" because the bulky tosyl moiety lies off the Fe—C≡N—C axis.

We decided to probe, using the isocyanides, the steric nature of the distal binding sites within the five-coordinate durene-capped hemes (**3**). The syntheses of the base porphyrins (9, 10), as well as the *in situ* generation of Fe(porp) and Fe(porp)B species from the isolated hemin (Fe^{III}) chlorides (11), have been described (porp = the dianion of the durene-capped porphyrin, and B = an imidazole base). The bulky 1,5-dicyclohexylimidazole, Cy_2Im, was chosen as axial base B because it is unable to coordinate under even the largest 7/7 cap (11). The affinities for the isocyanides are found to reflect decreasing



1: anthracene-capped 5-coordinate heme; B = imidazole base.



2: adamantane-capped 5-coordinate heme; B = imidazole base; R = $CH_2CH_2CO_2CH_2Ph$.

flexibilities of the durene cap in the trend 7/7 > 5/5 > 4/4, and indeed the 4/4 system binds neither ^{t}BuNC or TMIC. Preliminary binding constant data for some of the systems

[a]Data at 20°C in toluene (for the present durene work), or in benzene or toluene for the other systems (1, 8).
[b]MeIm = *N*-methylimidazole; equilibrium constant for binding of CO to this complex = $6\times10^{5}\ M^{-1}$ at 20°C in toluene (1).
[c]Equilibrium constants for binding of CO to these complexes in toluene at 20°C are 6.6×10^{7}, 8.6×10^{7}, and $4.3\times10^{6}\ M^{-1}$ for the 7/7-, 5/5-, and 4/4-systems, respectively (13, 19).

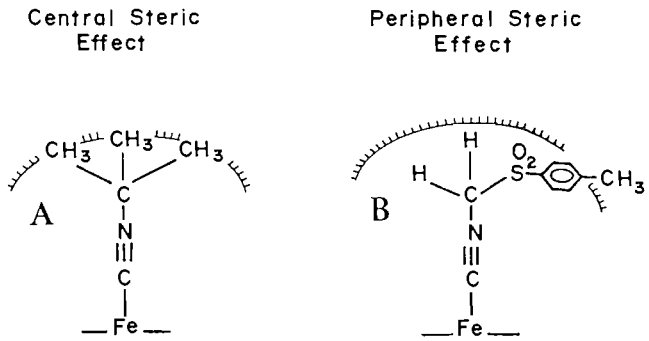

FIG. 1. Distal site steric effects resulting from coordination of bulky isocyanides within a heme binding pocket: **A**, *t*-butylisocyanide; **B**, tosylmethylisocyanide (via ref. 8).

described here were initially presented at recent conferences (12, 13).

Experimental

Toluene (reagent grade) was distilled over CaH_2 immediately prior to use. Cy_2Im was prepared according to a procedure described by Traylor *et al.* (1). ^{t}BuNC, TMIC, and ^{n}BuNC (Aldrich) were used as received. All spectrophotometric titrations were carried out under N_2, which had been passed through Ridox (Fisher) and molecular sieve columns to remove trace O_2 and H_2O.

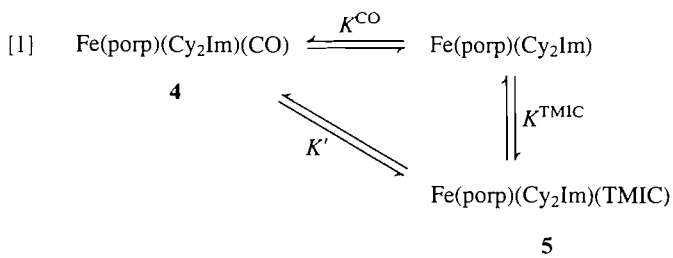
The 5-coordinate ferrous complexes Fe(porp)(Cy_2Im) were prepared in toluene, and transferred directly into specially designed tonometers as described previously (11, 14); aliquots of the appropriate isocyanide in deoxygenated toluene were then added by a syringe via a septum plug in the tonometer and the heme solution was then equilibrated at 20°C in a Cary 17 spectrophotometer, the spectra being recorded in the 250–700 nm region.

Results

Durene—7/7 and —5/5 systems

Titration of toluene solutions of Fe(porp)(Cy_2Im), at about $3\times10^{-6}\ M$, with aliquots of the concentrated (1.0 *M*) ^{t}BuNC solutions to give [^{t}BuNC] $\geq 2\times10^{-5}\ M$, afforded directly the values for the isocyanide binding, K'^{BuNC}. A large excess of Cy_2Im (0.3 *M*) was maintained in solution to ensure that the equilibrium changes observed corresponded exclusively to the binding of ^{t}BuNC on the capped side of the heme, without complication caused by displacement of the Cy_2Im axial base: the binding constants of this imidazole to all three durene systems are in the range $(2.0–6.0)\times10^{3}\ M^{-1}$ at 23°C in toluene (11), and thus negligible amounts of the 4-coordinate hemes are present under the chosen conditions. Additions of ^{t}BuNC gave spectral changes with excellent isosbestics (and typical of a change in coordination from five to six (11)), and analyses of the data in the 420 nm region were made according to standard methods using Hill plots (15–17); the plots gave slopes of 1.00 ± 0.06, consistent with the binding of one ^{t}BuNC ligand, and the *K* values (±10%) listed in Table 1.

The two larger cap 5-coordinate hemes show an affinity for TMIC too high to be measured by direct titration with the isocyanide, at least at the heme concentration used ($\sim3\times10^{-6}\ M$); even at additions of TMIC as low as $5\times10^{-6}\ M$, formation of the 6-coordinate Fe(porp)(Cy_2Im)(TMIC) was essentially complete, implying $K^{TMIC} > 10^{6}\ M^{-1}$. The K^{TMIC} values were thus determined using competitive ligation methods using both TMIC and CO, analogous to the procedure described by Traylor *et al.* (1). From preliminary trial experiments, it became clear that binding of TMIC is comparable with, or stronger than, that of CO, and thus relative concentrations of TMIC and CO can be chosen to study the equilibrium *K'* for the overall displacement, reaction [1],



where $K' = K^{TMIC}/K^{CO}$.

The titrations are carried under a constant CO pressure (and concentration) which is chosen such that the carbonyl **4** is fully formed prior to the addition of the TMIC. Figure 2 illustrates the data for one such titration at a CO partial pressure of 24 Torr, which corresponds to a concentration of $2.4\times10^{-4}\ M$ (18). Again, a high [Cy_2Im] was maintained to ensure that neither TMIC nor CO displaced the axial imidazole base, and the isosbestic spectral changes observed both in the Soret (Fig. 2) and visible regions (500–600 nm) are entirely consistent with the equilibrium in which TMIC simply replaces CO under the cap.

The equilibrium expression for *K'* leads to eq. [2],

[2] $\log [\mathbf{5}]/[\mathbf{4}] = \log K' + \log [\text{TMIC}] - \log [\text{CO}]$

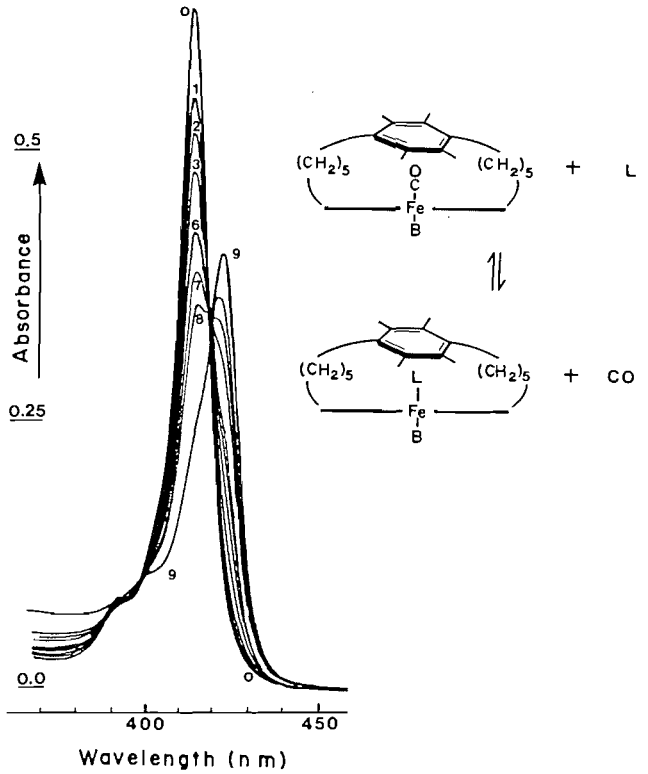

FIG. 2. Spectrophotometric titration (Soret region) of Fe(durene—5/5)(Cy_2Im)(CO) with TMIC at 20°C in toluene, under a CO pressure corresponding to [CO] = 2.4×10^{-4} *M*. Curves *0–9* (*4* and *5* are not shown) correspond to added [TMIC] = 0.0, 4.84, 6.92, 9.00, 11.10, 13.50, 16.90, 23.50, 33.59, and 200×10^{-4} *M*, respectively; B = Cy_2Im, L = TMIC.

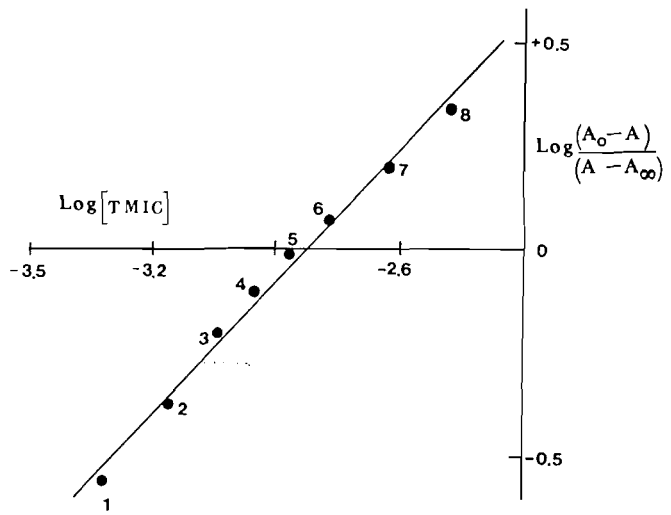

FIG. 3. Hill plot for the data of Fig. 2 at 415 nm (see text). The slope of the least-squares line drawn is 1.1, and the intercept on the *x* axis = log [CO] − log *K'*, which yields *K'* = 0.167; using $K^{CO} = 8.6 \times 10^7\ M^{-1}$ (Table 1) gives $K^{TMIC} = 1.4 \times 10^7\ M^{-1}$.

and a Hill plot of log [**5**]/[**4**] vs. log [TMIC] (Fig. 3) allows for an estimation of *K'*, and hence K^{TMIC} (±20%, Table 1). The [**5**]:[**4**] ratio is given simply by $(A_0 - A)/(A - A_\infty)$, where A_0 and A_∞ are the absorbances for pure **4** and pure **5**, respectively, and *A* is the absorbance of mixtures of **4** and **5** at any given [TMIC]; the slopes of the Hill plots were 1.0 ± 0.1.

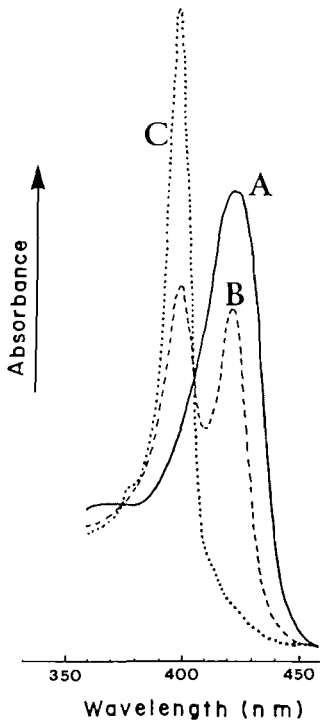

FIG. 4. Spectral trends for coordination of isocyanides to Fe(durene—4/4) species. **A** (—) is the spectrum of Fe(durene—4/4)(Cy_2Im); **B** (---) is the spectrum obtained on adding 0.02 *M* 'BuNC or TMIC to **A**; **C** (····) is the spectrum obtained on adding TMIC (at 10^{-3} *M*) to *in situ* Fe (durene—4/4), and is considered to be that of Fe(durene—4/4)(TMIC).

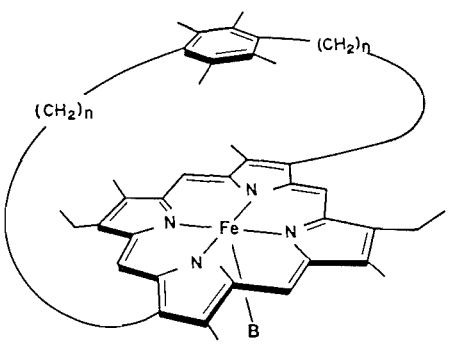
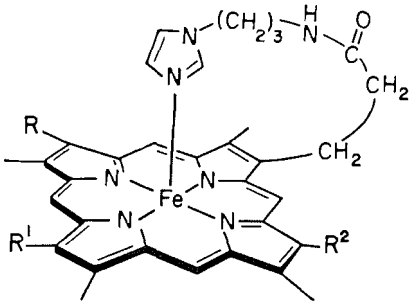
Durene—4/4 system

For the 5-coordinate Fe(durene—4/4)(Cy_2Im) species, a high [RNC] of ~0.02 *M* was necessary before any spectral change was observable at all, in contrast to the larger cap systems where binding was evidenced even for 'BuNC in the 10^{-5} *M* range. However, the blue shift to 400 nm observed for the 4/4-system (Fig. 4) is unlike the red shift changes seen for the coordination of isocyanides under the larger caps (ref. 11, and for example Fig. 2); indeed, the blue shift is similar to that obtained when TMIC is added to the 4-coordinate durene—4/4 heme in the absence of any other ligand (Fig. 4). Thus it seems certain that addition of 'BuNC or TMIC at sufficiently high concentration to Fe(durene—4/4)(Cy_2Im) results only in replacement of the imidazole by the isocyanide with no binding under the cap. Further support for this conclusion comes from qualitative binding studies with ^{n}BuNC, a sterically less



3: durene-capped 5-coordinate heme; B = imidazole base; *n* = 4, 5, 7, correspond to the durene—4/4, —5/5, and —7/7 species.



4: chelated protoheme; $R^1 = CH{=}CH_2$, $R^2 = CH_2CH_2CO_2CH_3$.

demanding isocyanide (1, 7); this readily binds to Fe(durene—4/4)(Cy_2Im) and gives the red-shifted spectral changes typically found for binding under the cap and formation of a 6-coordinate Fe(porp)(Cy_2Im)(RNC) (see above and ref. 11). The $K^{^nBuNC}$ value was about 50 M^{-1}.

Discussion

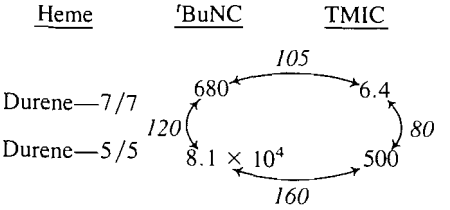
The data for the binding of the isocyanide probes TMIC and 'BuNC to the durene systems and anthracene and adamantane species, as well as to an unencumbered system (chelated protoheme, **4**), are summarized in Table 1. The chelated protoheme (1, 8), which encompasses a covalent attachment of the imidazole base to a side-chain of the porphyrin periphery, has an open, unhindered face for optimum binding of any isocyanide, and the terms "peripheral and central reduction factors" have been coined for other model hemes to indicate binding constants of TMIC and 'BuNC, respectively, relative to those for the chelated protoheme (1, 8). It is first noted that the data for the various durene systems reveal reduction factors of a very wide range that covers those reported for the anthracene and adamantane systems.

The data for the durene—7/7 and —5/5 systems are also shown in Scheme 1 which incorporates relative factors for these two systems. The most significant finding is the substantial reduction for the binding of 'BuNC relative to TMIC for both hemes (105- to 160-fold). According to Traylor's differentiation for the relative steric requirements of these isocyanides (1, 8), the results are readily interpreted in terms of a "central" steric effect imposed by the durene moiety in both heme systems. Examination of the consecutive reduction factors in the series: chelated protoheme → 7/7 → 5/5 reveals that the binding of 'BuNC is retarded 680-fold by the initial introduction of the central durene cap in the 7/7-complex, with a less pronounced reduction in affinity (120-fold) on shortening to the 5/5 strap. In the case of TMIC, however, peripheral steric interaction largely arises within the more enclosed environment of the 5/5-capped heme, 80-fold relative to an affinity reduction of 6.4-fold for the 7/7-complex.

Of interest, a further decrease in binding pocket size to the 4/4—durene capped heme severely retards coordination of either bulky isocyanide, where spectral changes characteristic of ligation under the cap are not observed. The less sterically demanding ^{n}BuNC can coordinate under the 4/4-cap.

It is interesting to note here a distinction between the durene—4/4 and anthracene—6/6 systems. Although the Fe(durene—4/4)(Cy_2Im) species shows a much reduced affinity for 'BuNC relative to that of Fe(anthracene—6/6)(MeIm), at least 150-fold, the durene heme shows about a 7-fold higher affinity for CO (Table 1). The pronounced porphyrin skeletal distortion inherent in the durene—4/4 heme complex presumably results in a "basket-shaped" 5-coordinate system where access to the iron is not obstructed significantly for a small diatomic (Fig. 5). In the case of the anthracene—6/6 system, the amide functions, which link the cap to the porphyrin periphery, probably add considerable rigidity to the distal hindrance provided by the cap, to the extent that accessibility to the metal is diminished even for diatomics. This suggestion is strongly supported by data that show a higher rate of CO association to the 5-coordinate durene—4/4 heme than to the anthracene system: $k = 3.0 \times 10^6\ M^{-1}\ s^{-1}$ (19) vs. $3.0 \times 10^4\ M^{-1}\ s^{-1}$ (1), both in toluene at 20°C. Nevertheless, the potential flexibility of the anthracene cap, having a larger number of adjoining atoms than the durene—4/4 heme, allows for coordination to some degree of even the bulkiest isocyanide, 'BuNC. The extremely restrictive distal cavity imposed by the tight cap in the durene—4/4 system does not allow for the required orientation for coordination of the bulky isocyanide.

These findings on the binding of the isocyanides to the durene-capped hemes will be invaluable in attempting to understand factors (steric and electronic) that govern the relative binding characteristics (kinetic and thermodynamic) of CO and O_2 to these hemes (19).



SCHEME 1. The relative factors (shown in *italics*) between the central and peripheral reduction factors for binding of 'BuNC and TMIC to the iron(II) durene—7/7 and —5/5 systems (shown in normal type).

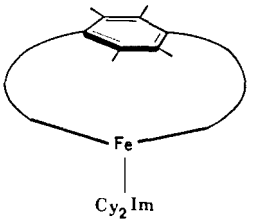


FIG. 5. Suggested "basket-shaped" conformation of distorted Fe(durene—4/4)(Cy_2Im) that could provide for greater accessibility of the Fe atom for incoming CO.

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

A. S. KHAN, W. G. BALDWIN, and A. CHOW. Can. J. Chem. **65**, 1103 (1987).

The distribution of alkali metal picrates between water and polyester-based polyurethane foam in the presence of dicyclohexyl-18-crown-6 was studied. The order of extraction coefficients of the alkali metals is governed by the ratio of the cation size to that of the crown ether, although the degree of extraction may depend on the nature of the organic phase. The extraction of alkali metals by polyurethane foam from an aqueous solution in the presence of crown ether and a bulky anion can be considered as an ion pair extraction of MCrA by an organic solvent.

A. S. KHAN, W. G. BALDWIN et A. CHOW. Can. J. Chem. **65**, 1103 (1987).

On a étudié la distribution des picrates de métaux alcalins entre l'eau et des mousses de polyuréthanes contenant des polyesters, en présence de la dicyclohexyl 18-couronne-6. L'ordre des coefficients d'extraction des métaux alcalins est lié au rapport entre la taille du cation et celle de l'éther couronne, même si le degré d'extraction peut dépendre de la nature de la phase organique. On peut considérer que l'extraction des métaux alcalins, d'une solution aqueuse par de la mousse de polyuréthane, en présence d'un éther couronne et d'un anion volumineux, correspond à l'extraction d'une paire d'ions MCrA par un solvant organique.

Due to their reluctance to form stable complexes with most complexing agents, the separation of alkali metals has been accomplished usually by ion exchange chromatography. Alternative precipitation procedures are not very selective and are generally not suitable for small quantities of alkali metals. Extractions of alkali metals reported before 1968 are almost all based on the ion association principle and used bulky anions (e.g. polyiodide (1), tetraphenyl borate (2), and phenols (3)). However, following the discovery of the complexing ability of macrocyclic polyethers (crown ethers), several studies on the solvent extraction of alkali metals by crown ethers have been reported.

The stability constants of various crown ether – cation complexes have been measured both in aqueous and in organic media by calorimetric titration techniques (4), by potentiometric measurements (5), and by spectrophotometric methods (6). On the basis of these studies, it has been concluded that the stability of the metal – crown ether complex is determined by the fit of the metal ion into the cavity of the ligand together with the charge of the cation and the nature of the solvent. Pedersen and Frensdorff (7) have reported that crown ethers containing five to ten oxygen atoms, each separated from the next by two carbon atoms, are the most effective complexing agents.

Jawid and Ingman (8) studied the extraction into dichloromethane of ion-pairs formed by alkali metal complexes of dicyclohexyl-18-crown-6 with a series of anions and concluded that the efficiency of extraction increases with large and highly polarizable anions. Frensdroff (9) has reported the extraction of sodium and potassium picrates from water into methylene chloride and into hexane using both isomer A and isomer B of dicyclohexyl-18-crown-6 (DCHC-6). He reported a higher value of K_{ex} for the potassium/picrate system containing isomer A than for that containing isomer B and also found that K_{ex} is one hundred times smaller in hexane than it is in methylene chloride. Jaber *et al.* (10) also have reported the extraction of alkali and alkaline earth metal picrates into methylene chloride using DCHC-6.

Sadakane *et al.* (11) studied the extraction of alkali metal picrates into benzene using dibenzo-18-crown-6 and found that the K_{ex} value increases, passes through a maximum at potassium, and then falls off as the size of the alkali metal cation increases further. They also noticed higher extraction of the cation in more polar solvents. Takeda and Goto (12) studied the extraction of monovalent metal picrates with 15-crown-5 and 18-crown-6 into benzene, and reported the following order for K_{ex} using 18-crown-6:

$$Tl^+ > K^+ > Rb^+ > Ag^+ > Cs^+ > Na^+ \gg Li^+$$

Although enhancement of extraction with increase in polarity of organic phase has been observed by most workers, Danesi *et al.* (13) have reported some interesting results from a study of the extraction of alkali metal picrates into different mixtures of nitrobenzene and toluene using dibenzo-18-crown-6. In 50:50 and 30:70 mixtures of nitrobenzene and toluene (dielectric constant, D = 15.6 and 10.6), K_{ex} was decreased with respect to pure nitrobenzene (D = 35). On the other hand, they observed an increase in the extraction for a 5:95 mixture of nitrobenzene and toluene (D = 3.4).

It is generally accepted that esters are more polar than ethers and it would be expected that this is also true for polyester versus polyether, although experimental values for the dielectric constants are not available. The use of polyester foam for the extraction of alkali metal cations was initiated because of the prospect of improving the degree of extraction over that obtained using polyether foam (14).

Experimental

Apparatus and reagents

Absorption measurements were made using a model 306 Perkin-Elmer atomic absorption spectrophotometer, analyzing for rubidium and cesium, or an Evans Electroselenium Ltd. flame photometer, analyzing for sodium and potassium. Measurements of pH were made using a Fisher Accumet model 520 digital pH meter.

Dicyclohexyl-18-crown-6 (DCHC-6) was obtained from Aldrich Chemical Co. and was used without further purification. No attempt was made to separate the two isomers, therefore the results are valid only for the isomeric mixture whose composition is not available from the supplier. Sodium chloride, potassium chloride, rubidium chloride, and cesium chloride salts were reagent grade. A 0.05 M solution of

picric acid was prepared from BDH reagent grade picric acid and standardized potentiometrically with sodium hydroxide. Water used was doubly distilled and deionized.

The polyester type polyurethane foam employed in this study is marketed as "Displo"$^{T.M.}$ foam plugs by Scientific Products, McGraw Park, IL, and was obtained locally from Canlab, Winnipeg.

Procedures

Polyurethane foam was cut into cubes weighing approximately 0.2 g each, soaked in 0.5 *M* HNO_3 for 12 h, washed several times with distilled water until free from acid, washed with acetone in a Soxhlet apparatus for 6 h, and finally air dried.

For each experiment, 40 mL of sample solution was equilibrated with a 0.2 g foam cube for 6 h at room temperature using the procedure described previously (14). The amount of metal extracted was determined by measuring the concentration before and after extraction with the foam, using atomic absorption or flame emission.

The distribution coefficient for metal ion is given by the ratio of the concentration of the metal ion on the foam to the concentration of the metal left in the solution at equilibrium and is equal to

$$[1]\quad D = \frac{\text{amount of metal on foam}}{\text{weight of foam}} \times \frac{\text{volume of solution}}{\text{amount of metal left in solution}}$$

Defined in this way, D has the units of volume per weight, i.e., of mL/g or L/kg.

The distribution coefficients between polyester-based polyurethane foam and water for crown ether, DCHC-6, and for picric acid were determined using the method previously reported (14). The average distribution coefficient for DCHC-6, (K'), was found to be 19 ± 7 L/kg while the value for picric acid, (D'), was determined to be 106 ± 19 L/kg.

Trial experiments showed little or no extraction of the metal ions if either the crown ether or picric acid was absent from the alkali metal solution.

Results and discussion

Extraction mechanism

Metal – picrate ion pairs have been extracted into both organic solvents like nitrobenzene (15) and into polyurethane foam (16). Similarly, the extraction of metal ions from aqueous solutions containing both picrate and crown ethers have been reported (14). Thus, the equilibria between an aqueous solution containing metal cation, M^+, the picrate anion, A^-, crown ether, Cr, and polyurethane foam can be written as:

$$M^+ + A^- \rightarrow MA_f \qquad K_{1ex} = [MA_f]/[M^+][A^-]$$

$$M^+ + Cr + A^- \rightarrow MCrA_f \qquad K_{2ex} = [MCrA_f]/[M^+][Cr][A^-]$$

where MA and MCrA denote the two ion pairs, the subscript f indicates the foam phase and the absence of subscript denotes the aqueous phase. The overall extraction equilibria can be analyzed in terms of the following equilibria:

(*i*) Ion-pair formation between metal ion and picrate ion

$$M^+ + A^- \rightarrow MA \qquad K_3$$

(*ii*) Extraction of the ion-pair between the two phases

$$MA \rightarrow MA_f \qquad K_{3ex}$$

(*iii*) Complexation of the metal ion with the crown ether

$$M^+ + Cr \rightarrow MCr^+ \qquad K_4$$

(*iv*) Ion-pair formation between the metal/crown ether complex and the picrate ion

$$MCr^+ + A^- \rightarrow MCrA \qquad K_5$$

(*v*) Distribution of the ion-pair between the two phases

$$MCrA \rightarrow MCrA_f \qquad K_{5ex}$$

(*vi*) Dissociation of the ion-pairs and the complexes in the organic phase

$$MCrA_f \rightarrow MCr^+{}_f + A^-{}_f \qquad K_{5d^*}$$

$$MCr^+{}_f \rightarrow M^+{}_f + Cr_f \qquad K_{4d^*}$$

$$MA_f \rightarrow M^+{}_f + A^-{}_f \qquad K_{3d^*}$$

The distribution relation is then:

$$D = \frac{\text{total metal on the foam per unit weight of foam}}{\text{total metal in solution per unit volume of solution}}$$

$$= \frac{[M^+{}_f] + [MA_f] + [MCr^+{}_f] + [MCrA_f]}{[M^+] + [MA] + [MCr^+] + [MCrA]}$$

Assuming equilibrium between crown ether in the aqueous solution and crown ether "dissolved" in the foam,

$$[Cr_f] = K'[Cr]$$

where [Cr] is the concentration of crown ether not complexed with the metal ion; $[Cr_f]$ is the "concentration" of crown ether in the foam. Similarly

$$[A_f] = D'[A]$$

Substituting,

$$[2]\quad D = \frac{K_{3d^*}K_{3ex}K_3/D' + K_{4d^*}K_{5d^*}K_{5ex}K_5K_4/D'K' + K_{5d^*}K_{5ex}K_5K_4[Cr]/D' + K_{3ex}K_3[A^-] + K_{5ex}K_5K_4[Cr][A^-]}{1 + K_3[A^-] + K_4[Cr] + K_5K_4[Cr][A^-]}$$

In deriving the above equation, the formation of only 1:1 complexes has been assumed. If complexes of higher stoichiometry are important, additional terms must be incorporated. In particular, if polynuclear complexes are important, one or more terms involving the metal ion concentration are required; that is, the distribution ratio, D, will vary with the concentration of the metal ion.

Extraction equilibrium constants

To test for polynuclear complexes, the extraction was studied as a function of crown ether concentration at three different total metal concentrations. In Fig. 1 it can be seen that the plots of log D as a function of the log of the initial crown ether concentration are coincident for the three different initial concentrations of potassium ion, indicating that the extraction is independent of metal ion concentration. This observation suggests that polynuclear species are not important in these solutions. This is consistent with the conclusions reached in the earlier study (14) of polyether-based polyurethane foam extraction.

To compare the extraction of alkali metal ion complexes by polyester-based polyurethane foam to the results obtained by the earlier study of polyether-based foams, the distribution coefficient, D, was studied as a function of initial crown ether concentration at constant metal ion and picric acid concentration (Fig. 2). The results show that the extraction of the cations

Plots of log *D* vs. log [crown ether] for the distribution of alkali metal picrates between polyester foam and aqueous solution: Na^+ (◆), K^+ (●), Rb^+ (▲), Cs^+ (■), [cations] = 1×10^{-4} *M*, [picric acid] = 4×10^{-3} *M*. Weight of foam 0.20 g; volume of solution 40 mL; temperature 25.00 ± 0.05°C. K^+ slope 1.03 ± 0.04, intercept 5.10 ± 0.099, correlation coefficient 0.998; Rb^+ slope 1.03 ± 0.04, intercept 4.87 ± 0.101, correlation coefficient 0.998; Cs^+ slope 0.953 ± 0.032, intercept 3.832 ± 0.075, correlation coefficient 0.997; Na^+ slope 1.16 ± 0.06, intercept 3.780 ± 0.15, correlation coefficient 0.994.

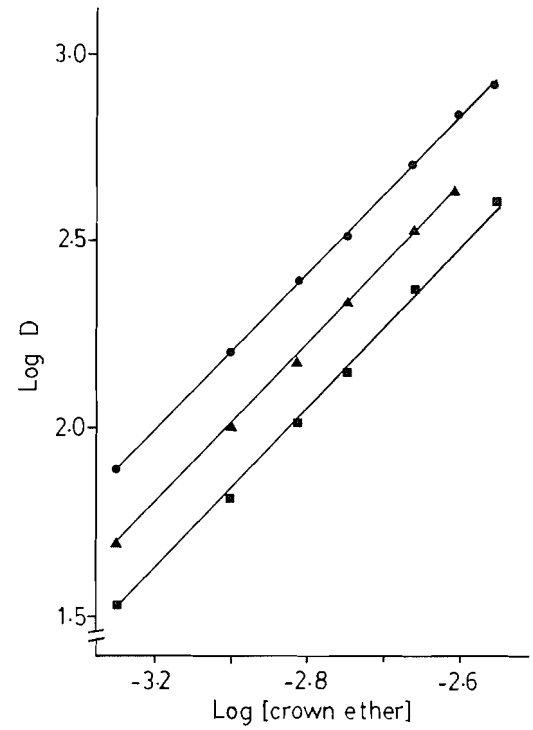

FIG. 3. Extraction of potassium as a function of initial concentration of crown ether at different initial concentrations of picric acid: [picric acid] = 2×10^{-3} *M* (■), 4×10^{-3} *M* (▲), 8×10^{-3} *M* (●); [potassium] = 1×10^{-4} *M*; volume of solution 40 mL; weight of foam 0.20 g; temperature 25.00 ± 0.05°C. 2×10^{-3} *M* slope 1.11 ± 0.03, intercept 5.162 ± 0.073, correlation coefficient 0.999; 4×10^{-3} *M* slope 1.05 ± 0.02, intercept 5.146 ± 0.067, correlation coefficient 0.999; 8×10^{-3} *M* slope 1.03 ± 0.01, intercept 5.298 ± 0.035, correlation coefficient 1.000.

studied increases with the increase in crown ether concentration and that the sequence of the extraction of alkali metal picrates using DCHC-6 is $K^+ > Rb^+ > Cs^+ > Na^+$. This same sequence was observed with polyether-based foam, but the magnitudes of extraction observed then were significantly lower, e.g., for K^+, $D = 536$ L/kg in polyester versus $D = 220$ L/kg in polyether foam for solutions both initially 4×10^{-3} *M* in picrate. The order of extraction can be attributed to the ability of DCHC-6 to complex these cations, whereas the higher magnitude of extraction is most likely due to the greater polarity of the polyester foam. This result is consistent with solvent extraction studies reported. Sadakane *et al.* (11) reported a higher extraction of potassium picrate using dibenzo-18-crown-6 in polar solvents such as isobutyl methyl ketone and nitrobenzene than in nonpolar benzene, while Frensdorff (9) reported that methylene chloride is a better solvent than benzene for the extraction of potassium picrate using dibenzo-18-crown-6.

The linear plots of approximately unit slope (Fig. 2) for the extraction of all alkali metal cations into polyester foam suggest a 1:1 crown ether:cation stoichiometry for the extracted complexes. Unit slope has been reported by several authors for the extraction of monovalent cations into various organic solvents using 18-crown-6 and its derivatives (11, 12, 17, 18). Takeda *et al.* (12, 17) studied the extraction of several monovalent metal picrates by 15-crown-5 and 18-crown-6 into benzene, and on the basis of slope analysis concluded that both crown ethers form 1:1 complexes with all metal cations studied.

Experiments were carried out under varied crown ether and

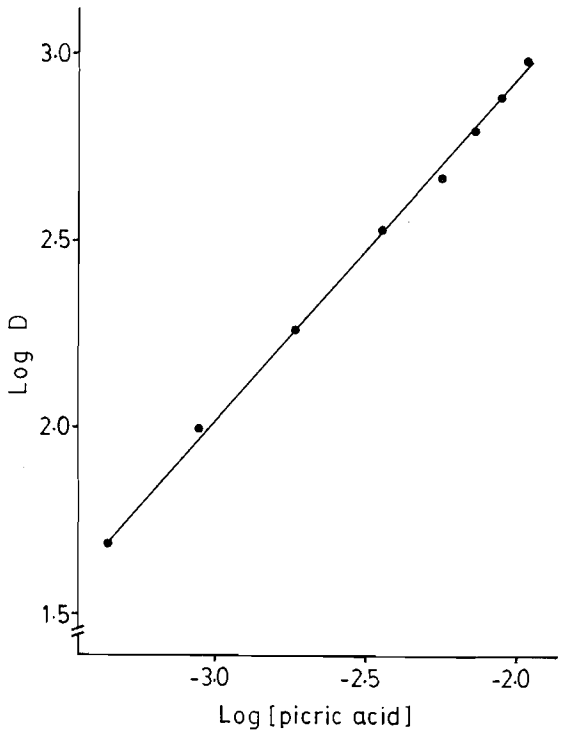

FIG. 4. Distribution ratio of potassium between polyester foam and aqueous picric acid solutions: $K^+ = 1 \times 10^{-4}$ *M*, DCHC-6 = 4×10^{-3} *M*; weight of foam 0.20 g; volume of solution 40 mL; temperature 25.00 ± 0.05°C; slope 0.912 ± 0.017; intercept 4.766 ± 0.043; correlation coefficient 0.999.

picrate concentrations to confirm the validity of 1:1 stoichiometry of complex formation between crown ether and metal cation over a wide range of picrate (anion) concentration. The extraction of potassium by DCHC-6 into polyester-based polyurethane foam was studied under three sets of experimental conditions differing in the initial concentration of picric acid. The results are shown in Fig. 3, where the logarithm of the distribution coefficient is plotted against the logarithm of the initial crown ether concentration. The linear plots of approximately unit slope further demonstrate that a 1:1 complex of crown ether and potassium is formed under these conditions of crown ether and picrate.

To verify the relationship between the metal ion and picrate ion, the extraction of potassium ion by DCHC-6 into polyester-based polyurethane foam was studied at constant potassium ion and at constant crown ether concentrations while varying the initial concentration of picric acid. The results of this experiment are shown in Fig. 4, where the logarithm of the distribution coefficient is plotted against that of the initial picric acid concentration. The linear plot of approximately unit slope suggests that the complex extracted has a stoichiometric ratio of picrate to metal ion of 1:1 under these conditions.

Evaluation of equilibrium constants

To evaluate the equilibrium constants using eq. [2], it is necessary to have an estimate of the concentrations of both the crown ether and the picrate which are in the aqueous solution and not bound to metal. Although these values can not be easily determined experimentally, the concentrations can be estimated. Yamane *et al.* (15) have reported values for the ion pair constants, K_3, and the extraction equilibrium constants, K_{3ex}, while Izatt *et al.* have given values for the metal – crown ether complex formation constants, K_4. The ion pair constants, K_5, have been estimated previously (14).

From the literature and the experimental results, the values of most of the constants needed can be obtained. However, there remains the difficulty of deciding the "free" (i.e. not bound to metal) concentrations of both picrate and crown ether in aqueous solution. These values have been estimated under five sets of assumptions: (*1*) The extraction of "free" or bound picrate and DCHC-6 is negligible with respect to the total concentrations. Therefore the "free" picrate and DCHC-6 concentrations are equal to the initial concentrations of these compounds. In the aqueous solution the amount of metal bound is also negligible. For this assumption $K_3[A^-]$, $K_4[Cr]$, and $K_5K_4[Cr][A^-] \ll 1$, $[A^-] = [A^-]_{initial}$, and $[Cr] = [Cr]_{initial}$. (*2*) Both the amount of bound metal and also the amounts of bound picrate and crown ether in the aqueous solution are negligible compared to the "free" concentrations. The "free" concentrations of picrate and DCHC-6 are corrected for the amount of these species extracted in the absence of metal ion. In this assumption, $K_3[A^-]$, $K_4[Cr]$, and $K_5K_4[Cr][A^-] \ll 1$, and $[Cr] = [Cr]_{initial}/(1 + K'w/v)$ and $[A^-] = [A^-]_{initial}/(1 + D'w/v)$, where w = weight of foam and v = volume of solution. (*3*) Similar assumptions as in *1* are made for "free" picrate and crown ether but consideration is given to the metal ion bound to only one of picrate or DCHC-6. For this assumption, $[A^-] = [A^-]_{initial}$, $[Cr] = [Cr]_{initial}$, and $K_5K_4[Cr][A^-] \ll 1$. (*4*) The same assumptions for "free" crown ether and picrate are made as in *2*, but also assumes that metal bound only to picrate or only to crown ether is important. Only $K_4K_4[Cr][A^-] \ll 1$. (*5*) A reduction in the concentrations of "free" picrate ion and DCHC-6 is made by accounting for the amount of each extracted in a 1:1:1 complex with the metal ion as well as that extracted in the absence of any metal. Further, it is assumed that $K_4[A^-]$ and $K_4[Cr]$ are not negligible compared to one. For this assumption, $K_5K_4[Cr][A^-] \ll 1$.

Table 1 shows representative data calculated using these assumptions with eq. [2]. Since in all cases, regardless of the set of assumptions used, the intercept is within one standard deviation of zero or is negative, it is reasonable to assume that there is negligible dissociation of the extracted complex in the foam and no significant extraction of the metal ion into the foam either on its own or bound only to picrate or only to crown ether. Therefore eq. [2] can be simplified to

$$D = \frac{K_{5ex}K_5K_4[Cr][A^-]}{1 + K_3[A^-] + K_4[Cr] + K_5K_4[Cr][A^-]}$$

Assumptions *1–4* effectively allow a plot of $D(1 + K_3[A^-] + K_4[Cr])$ versus the concentration of either initial crown ether or initial picrate, keeping the other constant. The slope is then the product of $K_{5ex}K_5K_4$ times the concentration of either DCHC-6 or picrate which was fixed for the calculation. With assumption *5*, it is necessary to plot $D(1 + K_3[A^-] + K_4[Cr])$ versus the product of the concentrations of both crown ether and picrate since these are varied simultaneously as the amount of metal extracted varies.

Despite the significant differences in the assumptions used it is interesting to note that the data in Table 1 gives values for the extraction coefficient K_{2ex} ($= K_{5ex}K_5K_4$) which are quite consistent (within a factor of three) for the individual metal ions.

The simplest assumption, *1*, overestimates the "free" concentrations and therefore leads to the lowest value for the

extraction coefficient. The extraction coefficient calculated using assumption *5* is the highest value and is most likely as it reflects a closer approximation to the actual concentrations of the species in the solution.

In Table 2, the "best" values (i.e. those resulting from assumption *5*) are listed. From several replicates done using potassium ion the uncertainty in its extraction coefficient can be estimated at about 25%. A similar uncertainty is assumed for the other ions in the listed values.

Conclusions

This study has demonstrated the ability of polyester-based polyurethane foam to extract alkali metal cations from aqueous solution using DCHC-6 in the presence of picrate ions. The ratios of the distribution coefficients for the alkali metals are about 1:3:21:40 for Na^+:Cs^+:Rb^+:K^+ from the data used for Fig. 2. This indicates that each of the ions should be separable from the others and that a column of polyester-based polyurethane foam could be used to separate all of these ions.

The efficiency of the extraction depends on the nature of the organic phase, with extraction into the more polar polyester foam being greater than into the less polar polyether foam. The same order of K_{ex} of alkali metals obtained for both polyester and polyether foams suggests that although the degree of extraction may depend on the nature of the organic phase, the order of extractability may be governed by the ratio of the cation size to that of the crown ether cavity. Similar results have been reported for ion pair extraction of metal – crown ether – picrate

in various organic solvents (7, 8, 11). This similarity suggests that the extraction of alkali metals from an aqueous solution by polyurethane foam in the presence of crown ether and a bulky anion, can be considered as an ion pair extraction of MCrA by an organic solvent. However, in contrast to previous reports (19) that polyether is a better extractor than is polyester foam, it is clear from the $K_{5ex}K_5K_4$ values (Table 2) that the opposite is true here. This study also reveals that there is no appreciable dissociation of the extracted complex in the polyester foam. It is hoped that these studies have led to a better understanding of the mechanism of extraction with the use of polyurethane foam.

How does the geometry of the tetrahedral $XF_{4-n}Cl_n^{\epsilon}$ (X = Al, Si, P) species depend on composition, or *ab initio si certum nescio*

S. C. Choi, Russell J. Boyd, and Osvald Knop
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received November 2, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

S. C. Choi, Russell J. Boyd, and Osvald Knop. Can. J. Chem. **65**, 1109 (1987).

The molecular parameters of the isoelectronic tetrahedral species NaF_4^{3-}, MgF_4^{2-}, $AlF_{4-n}Cl_n^-$, $SiF_{4-n}Cl_n$, $PF_{4-n}Cl_n^+$, SF_4^{2+}, and ClF_4^{3+} have been investigated by *ab initio* calculations at the 6-31G* level. The bond lengths and the critical radii of X in XF_4^{ϵ} are found to decrease monotonically with the formal oxidation state m of X up to and including X = S but show an upturn at X = Cl. The relative position of the critical point in the X—F bond, $r_c(X)/(X—F)$, remains relatively constant for m = 1–3; for m = 4–6 the critical point moves gradually closer to X, but for m = 7 it shifts appreciably away from X. The increase in the electron density at the bond critical point of XF_4^{ϵ} (and probably also of XCl_4^{ϵ}) is represented reasonably closely by a power function am^b. The effect of progressive replacement of F in XF_4^{ϵ} (X = Al, Si, P) by Cl on the bond lengths and angles depends on the sign of ϵ. For $\epsilon = -1$, X—F and X—Cl decrease and FXF increases; for ϵ = 0 and 1, X—F and X—Cl increase and FXF decreases. These changes increase in magnitude, in their respective directions, with $|\epsilon|$. Relationships between the bond lengths and the bond angles are described. The excess total electronic energies $\Delta E = E(XF_{4-n}Cl_n^{\epsilon}) - \frac{1}{4}(4-n)E(XF_4^{\epsilon}) - \frac{1}{4}nE(XCl_4^{\epsilon})$ are negative for all three X; they are largest (and approximately symmetric with respect to n) for Al, smaller (and asymmetric) for P, and very small for Si. The amount of charge transferred from F or Cl to X varies in a complicated manner with m and n, and the rates of transfer of charge with n in an $XF_{4-n}Cl_n^{\epsilon}$ molecule are not the same for F and Cl. More than one unit of charge is transferred from a halogen atom to X in ClF_4^{3+} and PCl_4^+.

S. C. Choi, Russell J. Boyd et Osvald Knop. Can. J. Chem. **65**, 1109 (1987).

Utilisant des calculs *ab initio* au niveau 6-31G*, on a étudié les paramètres moléculaires des espèces tétraédriques isoélectroniques NaF_4^{3-}, MgF_4^{2-}, $AlF_{4-n}Cl_n^-$, $SiF_{4-n}Cl_n$, $PF_{4-n}Cl_n^+$, SF^{2+} et ClF_4^{3+}. On a trouvé que, dans XF_4^{ϵ}, les longueurs des liaisons ainsi que les rayons critiques de X diminuent d'une façon monotone avec l'état d'oxydation formel m de X, jusqu'à X = S; toutefois, ces valeurs augmentent lorsque X = Cl. La position relative du point critique de la liaison X—F, $r_c(X)/(X—F)$, demeure constante pour m = 1 à 3; toutefois, pour m = 4 à 6, le point critique se déplace graduellement vers X alors que pour m = 7, il s'éloigne considérablement de X. L'augmentation de la densité électronique au point critique de la liaison des composés XF_4^{ϵ} (et probablement aussi dans les composés XCl_4^{ϵ}) peut être représentée d'une façon assez raisonnable en faisant appel à une fonction du type am^b. Si on remplace progressivement des F par des Cl dans les composés XF_4^{ϵ} (X = Al, Si, P), l'effet qui se fait sentir sur les longueurs ainsi que sur les angles de liaison dépend du signe de ϵ. Pour $\epsilon = -1$, les liaisons X—F et X—Cl diminuent alors que FXF augmente; pour ϵ = 0 et 1, les longueurs X—F et X—Cl augmentent alors que FXF diminue. Ces changements augmentent en amplitude, dans leurs directions respectives, avec $|\epsilon|$. On décrit les relations qui existent entre les longueurs des liaisons et les angles de liaisons. Pour chacun des X, les énergies électroniques totales en excès, $\Delta E = E(XF_{4-n}Cl_n^{\epsilon} - \frac{1}{4}(4-n)E(XF_4^{\epsilon}) - \frac{1}{4}nE(XCl_4^{\epsilon})$ sont négatives; ces valeurs sont les plus grandes (et approximativement symétriques par rapport à n) pour les composés du Al, alors qu'elles sont plus petites (et asymétriques) pour les composés du P et qu'elles sont très faibles pour les composés du Si. La quantité de charge qui est transférée du F ou du Cl vers X varie d'une façon compliquée avec m et n; dans une molécule $XF_{4-n}C_n^{\epsilon}$, les variations des vitesses de transfert de charges avec n ne sont pas les mêmes avec F et avec Cl. Dans les cas des composés ClF_4^{3+} et PCl_4^+, il y a plus d'une unité de charge qui est transférée d'un atome d'halogène X.

[Traduit par la revue]

The purpose of this investigation is to discover, and subsequently predict, trends that may exist in the geometric and other molecular parameters in series of isoelectronic tetrahedral $XF_{4-n}Cl_n^{\epsilon}$ species. Experimentally determined values of bond lengths and bond angles for the mixed species are available only for X = C, Si, and Ge (refs. 1–15; Table 1). They are generally of insufficient accuracy and show a considerable scatter. However, they do suggest that the X—F and X—Cl bond lengths increase with n. The low accuracy makes comparisons of the FXF and ClXCl angles even more tentative, but it is thought (e.g. ref. 13) that in $CF_{4-n}Cl_n$ the FCF angle is always the smallest. It came therefore as a surprise when it turned out, in our recent investigation of $AlF_{4-n}Cl_n^-$ species by *ab initio* calculations, that the opposite is true in this case: the Al—F and Al—Cl bond lengths *decrease* with increasing n, and for the bond angles actually present the sequence, for a given n, is FAlF > FAlCl > ClAlCl. This finding demonstrated that it was desirable not only to verify, by calculation, the trends believed to exist for X = C, Si, and Ge, but also to extend the calculations for Al to at least X = P. We have now investigated the complete series for X = Al, Si, P and, in addition, the pure species NaF_4^{3-}, MgF_4^{2-}, SF_4^{2+}, and ClF_4^{3+}, with the results reported below. The corresponding systematic calculations for X = B, C, and N are contemplated for the near future; they are required for determining the importance of orbital size for the trends now established for elements of the second row.

Method

The main objective was to obtain an internally consistent systematic comparison of equilibrium molecular geometries that on a reasonable expectation would be closely similar. The 6-31G* basis set was thought well suited for the task in hand, as mean absolute differences between the experimental and theoretical bond lengths were expected, from previous experience, to be about 0.01–0.02 Å (23). This basis set, or more precisely, the 6-31G* set for fluorine (24) and 66-31G* for the second-row elements (23), was therefore used for all calculations. The validity of this choice is borne out by the good

[a]Bond lengths in Å, bond angles in deg. Bond lengths in crystals will depend on the bond strengths of the Hal ligands and would have to be extrapolated to "free"-species values if they are to be compared with the calculated values.
[b]Abbreviations as follows: ed, electron diffraction; mw, microwave spectroscopy; xl, crystal structure.
[c]Estimated from AlO_4^{5-} (cf. ref. 17).
[d]Mean of Al—Cl distances in nine compounds, corrected for therml motion.
[e]At −145°C.
[f]Assumed.
[g]Mean of 12 values from three compounds, corrected for thermal motion.
[h]Uncorrected mean of P—Cl distances in $(PCl_4)VCl_5$.

agreement between the observed and the calculated values of the bond lengths for X = Si (Tables 1 and 2; see below).

The calculations were carried out using the GAUSSIAN 80 set of programs (25) on a Perkin-Elmer 3230 computer. Net atomic charges were computed from standard Mulliken population analyses (26) and bond critical points were investigated using the AIMPAC series of programs (27). Complete geometry optimizations, subject to the symmetries listed in Table 2, were performed for all species.

The energies, bond lengths, and bond angles are listed in Table 2, critical radii, net charges, and electron densities at the critical points in Table 3.

Notation

The symbols used are defined as follows: f, number of degrees of freedom; m, oxidation state of X; p, number of data; ϵ, charge on the $XF_{4-n}Cl_n^{\epsilon}$ molecule; τ, the tetrahedral angle; E, total electronic energy (au); $\Delta E(n)$, excess energy (au), $\Delta E(n) = E[XF_{4-n}Cl_n^{\epsilon}] - [1 - (n/4)]E(XF_4^{\epsilon}) - (n/4)E(XCl_4^{\epsilon})$; $E_f(0)$, $E_f(4)$, energy of formation (au) of XF_4^{ϵ}

and XCl_4^{ϵ}, respectively: $E_f(0) = E(XF_4^{\epsilon}) - E(X^{m+}) - 4E(F^-)$, $E_f(4) = E(XCl_4^{\epsilon}) - E(X^{m+}) - 4E(Cl^-)$; $\epsilon(X)_n$, $\epsilon(F)_n$, $\epsilon(Cl)_n$, net charges (e) on X, F, and Cl, respectively; $\epsilon(X)_n + (4 - n)\epsilon(F)_n + n\epsilon(Cl)_n = \epsilon = m - 4$; $r_c(X)_n^F$, $r_c(X)_n^{Cl}$, critical radius (Å) of X in an X—F and an X—Cl bond, respectively; $r_c(F)_n$, $r_c(Cl)_n$, critical radii of F and Cl, respectively; $r^{iv}(X^{m+})$, Shannon's (28) effective ionic radius (Å) of X^{m+} in 4-coordination; $\rho(r_c)_n^F$, $\rho(r_c)_n^{Cl}$, electron density (au) at the critical point in an X—F and an X—Cl bond, respectively; $\rho(r_c)_0$ for XF_4^{ϵ}, $\rho(r_c)_4$ for XCl_4^{ϵ}.

Validity of the results

Because of the paucity of experimental results for $XF_{4-n}Cl_n^{\epsilon}$ species we can assess the overall accuracy of our calculated values of the molecular parameters only with reference to Table 1. The experimental values of bond lengths listed there correlate linearly ($r^2 = 0.996$) with the calculated values to a σ of 0.016 Å. This must be regarded as a satisfactory agreement. The discrepancies originate mainly in the bond lengths in crystals, which are subject to a variety of constraints not considered in the calculations. It may be noted that the agreement of the observed and the calculated X—Hal distances, where the former are available, is significantly better than for previous theoretical calculations.

No estimate can be provided for the absolute accuracy of the $E(XF_{4-n}Cl_n^{\epsilon})$, but where values for the single atoms close to the Hartree–Fock limit are available (29, 30), the differences are not negligible (Table 4).

The 6-31G* energies $E(X^{m+})$ can be adequately represented by $E(X^{m+}) = -128.483722 - 31.158188m - 2.0027179m^2$ ($r^2 = 1.000$, $\sigma = 0.0075$ au ~ 4.7 kcal/mol $\sim 0.002\%$ of the m = 0–8 range). This representation is approximately of the form $-a(m + b)^2 \sim -2(m + 8)^2$. A significant reduction of σ is obtained by omitting Ne^0 (m = 0) from the regression ($\sigma = 0.0040$ au). A cubic regression including Ne^0 improves σ only marginally, but if Ne^0 is not included, a dramatic drop in σ results:

TABLE 4. Electronic energies (au) of selected atoms and ions

Atom	E(6-31G*)	E(~HF limit)[a]	Difference
Ne^0	−128.47441	−128.54705	0.07264

Ar^{8+}	−505.92316	(−505.96783)	(0.04467)
F^0	−99.36496	−99.40930	0.04434
F^-	−99.35048	−99.45937	0.10889
Cl^0	−459.44796	−459.48187	0.03391
Cl^-	−459.52600	−459.57670	0.05070

[a]These values are from ref. 29; those in parentheses (somewhat lower level of theory) are from ref. 30.

[1] $E(X^{m+}) = -128.52000 - 31.130826m - 2.0084983m^2 + 0.00036657m^3$

($r^2 = 1.000$, $\sigma = 0.0006$ au ~ 0.38 kcal/mol). Considering the magnitude of $E(X^{m+})$, this goodness of fit (and for that matter even that for the parabolic regression) must be regarded as remarkable. The reason for the $E(Ne^0)$ value not fitting satisfactorily into this regression is at present not understood.[1]

The ionization potential of Na calculated from the E values of Table 4 is within 4% of the experimental value, but the electron

[1]A cubic regression of the E(~HF limit) values of Table 4 on m gives a similar result: $r^2 = 1.000$, $\sigma = 0.0018$ au for m = 0–8, and $r^2 = 1.000$, $\sigma = 0.0008$ au for m = 1–8.

affinities calculated for F and Cl agree poorly with experiment even for E(~HF limit):

Parameter	Value		
	6-31G*	~HF limit	Expt.
Na (ionization potential), eV	4.957	4.952	5.139
F (electron affinity), eV	−0.394	1.363	3.448
Cl (electron affinity), eV	2.124	2.581	3.613

However, because of our particular choice of basis set, the deficiencies of the model used in the energy optimization, which manifest themselves with high visibility in the parameters deriving directly from the E values for single atoms, appear to be much less reflected in the values of the geometric parameters of the $XF_{4-n}Cl_n^{\epsilon}$ species. It should be noted that the smooth trends of the parameters described below emerge on assembling the results of calculations performed separately for each of the individual species. We therefore believe that these trends are real and that they are at least qualitatively correct. In the circumstances even qualitative knowledge is of value, for some of the $XF_{4-n}Cl_n^{\epsilon}$ species investigated here may be accessible experimentally only with difficulty or not at all, and a more extensive theoretical treatment at a higher SCF level or beyond does not appear to be imminent.

In the following the results of the 6-31G* level calculations are presented as statements of fact, but it is of course clear that the validity, in the absolute sense, of any of the assertions is restricted to the framework of the present study and is subject to the limitations of the basis set employed. The parameter sets are examined for trends and correlations both by graphical display and analytically. Where p is sufficiently large, an attempt is made to represent the visually identified trend by fitting the data set to a function which is compatible with the constraints imposed by the particular situation. Where the analytical representation has a high degree of fidelity (as judged by r^2 and σ), it is regarded as an adequate approximation to the (unknown) true correlation function and usable for numerical comparisons and for further phenomenological manipulation. Otherwise it merely serves to display the qualitative features of a trend. This is so *a fortiori* when $f = 0$; the function is then used only for convenience of interpolation. In yet other cases a surmised correlation is presented only graphically after free-hand smoothing.

Results and discussion

Total electronic energy

The availability of the E values, $E(0)$, for all the members of the XF_4^{ϵ} series permits an examination of the regularity of the variation of $E(0)$ with m. A cubic regression yields

$$[2]\quad E(0) = -525.12659 - 32.0264635m - 2.0506510m^2 - 0.01394827m^3$$

($r^2 = 1.000$, $\sigma = 0.0173$ au ~ 11 kcal/mol ~ 0.006% of the $E(0)$ range for $m = 1$–7). This approximation is useful in that it gives estimates of $E(0)$ for NeF_4^{4-} and ArF_4^{4+}, of importance in connection with the stability of these species (see Energy of formation).

Excess energy ΔE(n)

The excess energy measures the stability, in terms of the total electronic energy, of the mixed species relative to mixtures of XF_4^{ϵ} and XCl_4^{ϵ} of the appropriate molar ratios. Its variation with n, ϵ, and n,ϵ is shown in Fig. 1. The skewness of the $\Delta E(n)$ vs. n curves increases sharply from Al to P: γ_1(Al) = 0.05, γ_1(Si) = 0.15, γ_1(P) = 0.60. Since $\Delta E < 0$ for all three elements, the mixed species are always more stable. The stability increases, in magnitude, toward $n = 2$ with decreasing ϵ, and in composition, toward $n = 0$ with increasing ϵ. However, examination of the shape of the ΔE vs. n curve for $\epsilon = 1$ (and to a less certain extent, for $\epsilon = 0$) reveals that a sign inversion of ΔE may exist. If it does (and this cannot be established with certainty from the present results limited to $m = 3$–5), it would occur at $n \sim 3.8$ for $\epsilon = 1$; for $\epsilon = 2$ it could be expected at a significantly lower value of n, probably below $n = 3$. In that case $SFCl_3^{2+}$ would be unstable relative to $\frac{1}{4}SF_4^{2+} + \frac{3}{4}SCl_4^{2+}$. This interesting possible evolution will have to be verified by extending the calculations beyond $m = 5$.

As the position of ΔE_{min} in the ΔE vs. n,ϵ contour map shifts, with increasing ϵ, toward $n = 0$ and, with decreasing ϵ, quasi-asymptotically toward $n = 2$, the species most stable relative to $XF_4^{\epsilon} - XCl_4^{\epsilon}$ mixtures of the same molar ratio would seem to be SF_3Cl^{2+} for $\epsilon = 2$ and $MgF_2Cl_2^{2-}$ for $\epsilon = -2$.

The $|\Delta E|_{max}$ value is smallest for Si (~0.25 kcal/mol), about 1/16 that of $|\Delta E(Al)|_{max}$ and about 1/6 of $|\Delta E(P)|_{max}$, i.e. the SiF_4–$SiCl_4$ system is almost indifferent to formation of the mixed species. On the other hand, it is surprising that for P the preferential stability of the mixed species returns: $|\Delta E(P)|_{max} > |\Delta E(Si)|_{max} < |\Delta E(Al)|_{max}$.

Bond lengths

The Al—F and Al—Cl bond lengths decrease non-linearly with increasing n, while the Si—F, Si—Cl, P—F, and P—Cl bond lengths all increase, P—F and P—Cl linearly and Si—F and Si—Cl very nearly so (Fig. 2). The absolute value $|\Delta$(X—F)| of the percentage variation of X—F relative to XF_4^{ϵ} is largest for $n = 3$ and X = P, and that of X—Cl relative to XCl_4^{ϵ} is largest for $n = 1$ and X = P.

The differences $(X—F)_3 - (X—F)_0$ are, respectively, −0.018, 0.013, and 0.039 Å for Al, Si, and P, corresponding to −1.06, 0.85, and 2.62% of $(X—F)_0$; the $(X—Cl)_1 - (X—Cl)_4$ values are 0.036, −0.022, and −0.053 Å, corresponding to 1.66, −1.09, and −2.72% of $(X—Cl)_4$, respectively. The bond-length changes on progressive replacement of F in XF_4^{ϵ} by Cl are thus not insignificant. Their order of magnitude must be close to reality, as comparison with experiment for $SiF_{4-n}Cl_n$ (Table 1) shows that the available experimental Si—F and Si—Cl values all differ by less than three times their stated σ's from the calculated values. The exception is $SiFCl_3$, where the difference in Si—F is 0.051(5) Å.

Since XF_4^{ϵ} and XCl_4^{ϵ} are balanced configurations (T_d), the X—F and X—Cl bond lengths in them are not indicative of the "true" strength of the X—F and X—Cl bonds. The shortening of the Al—F bond with increasing n shows that this bond in AlF_4^- is capable of being strengthened (∂(Al—F)/$\partial n \rightarrow 0$ as $n \rightarrow \sim 4$), whereas the Si—F and P—F bonds in corresponding circumstances are weakened in proportion to the number of F atoms replaced by Cl.

These changes are associated with the net charge on the halogen atom. Quadratic regression of the difference $(X—F)_n - (X—F)_0$ on ϵ(F) yields a very high degree of correlation for Al and P; for Si, linear regression leads to an equally satisfactory result. In addition, a plot of $(X—F)_n - (X—F)_0$ vs. ϵ(F) (Fig. 3) shows that the points of equal n define parabolas ($f = 0$) intersecting at a crossover point at ϵ(F) ~ −0.506. Although

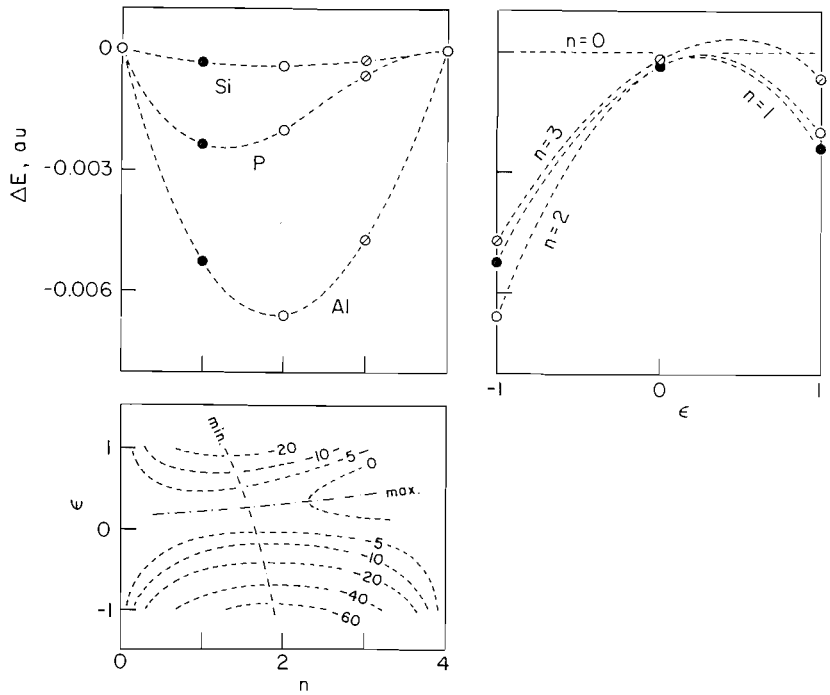

FIG. 1. Variation of the excess energy ΔE of $XF_{4-n}Cl_n^{\epsilon}$ (X = Al, Si, P) with n, ϵ, and ϵ, n. The ΔE contour values (au) have been multiplied by 10^4. The broken lines represent parabolic or visual fits.

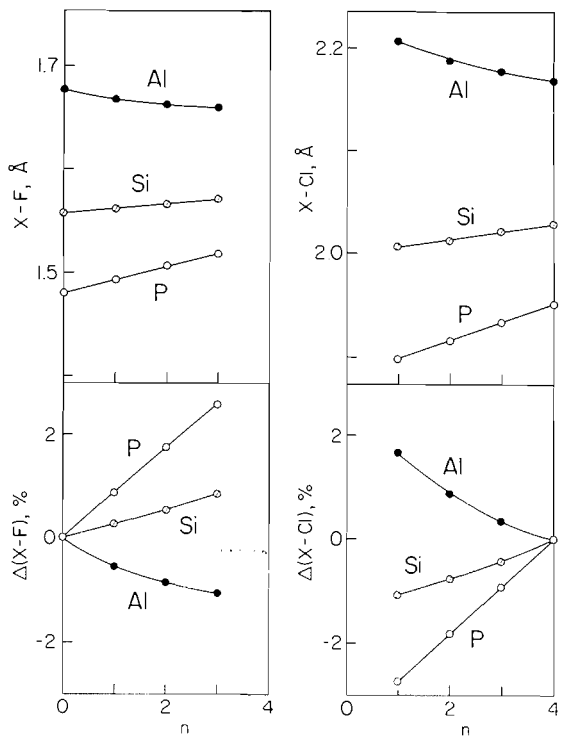

FIG. 2. Variation of the bond lengths and of the relative changes $\Delta(X—Hal)_n = 100[(X—Hal)_n - (X—Hal)_{0,4}]/(X—Hal)_{0,4}$ in $XF_{4-n}Cl_n^{\epsilon}$ with n.

there is no theoretical justification for a parabolic interpolation, the apparent existence of the crossover point is unlikely to be fortuitous, for an analogous behaviour is shown by the $(X—Cl)_n - (X—Cl)_4$ vs. $\epsilon(Cl)$ curves (Fig. 3), and similar points are present in other plots (see below). The crossover point for the X—Cl bonds lies at $\epsilon(Cl) \sim -0.408$.

For a more general idea of the dependence of the bond length on ϵ, the calculations were extended to include XF_4^{ϵ}, X = Na, Mg, S, and Cl (Tables 2 and 3). The $(X—F)_0$ values decrease with increasing m from Na to S, but unexpectedly at X = Cl there is a sudden upturn (Fig. 4). On the assumption that NeF_4^{4-} is unstable, i.e. $(X—F)_0 \rightarrow \infty$ as $m \rightarrow 0$, the $(X—F)_0$ vs. m variation for $m = 1$–5 can be represented with considerable fidelity ($\sigma = 0.002$ Å) by a power function, $(X—F)_0 = 2.01(m - 0.6)^{-0.2076}$, with the difference between the given and the fitted $(X—F)_0$ values increasing steadily as m approaches and then exceeds 5. This suggests that the variation for $m = 0$–7 can be represented as a sum of two power functions corresponding to opposing tendencies in the physical process of bond formation. To evaluate the contribution from the repulsive term adequately one needs to have an estimate of the bond length for the end member of the series, ArF_4^{4+}. However, numerous attempts to optimize the geometry of this species at the 6-31G* level failed to converge in the SCF procedure. Optimization using the minimal STO-3G basis set resulted in E values dropping steadily over the range $(Ar—F)_0 = 2$–4 Å, with no clear indication of a minimum beyond 4 Å. This was taken as evidence of instability of ArF_4^{4+}, i.e. $(Ar—F)_0 \rightarrow \infty$ as $m \rightarrow 8$. On this assumption the data points could be fitted to the composite power function $(X—F)_0 = 2.0073(m - 0.6)^{-0.2080} + 0.1145(8 - m)^{-2.4800}$, $\sigma = 0.0040$ Å $\sim 0.4\%$ of the $(X—F)_0$ range for $m = 1$–7.

Evaluation of the repulsive term is less certain than that of the attractive term, for a significant contribution to the former comes only from the $(X—F)_0$ values for $m = 5$–7, but it is clear that the repulsive term varies with m steeply as $m \rightarrow 8$ and in fact its rate of change begins to exceed, numerically, that of the attractive term at $m \sim 6.4$; the ratio (attractive term)/(repulsive term) from the above power function is 2645 for $m = 1$ but 11.9 for $m = 7$. If the assumption that $(Ar—F)_0 \rightarrow \infty$ as $m \rightarrow 8$ turns out not to be correct and $(Ar—F)_0$ is finite, the regression

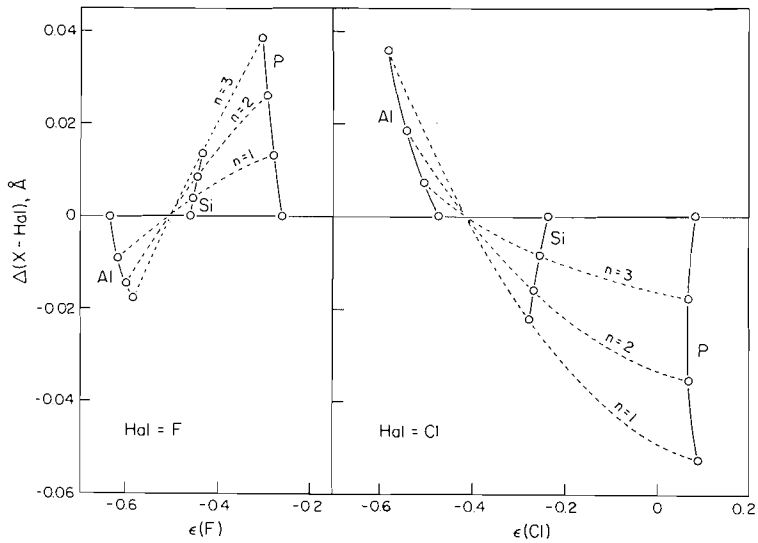

FIG. 3. Variation of the change in the bond length $\Delta(X—Hal)_n = (X—Hal)_n - (X—Hal)_{0,4}$ with ϵ(Hal).

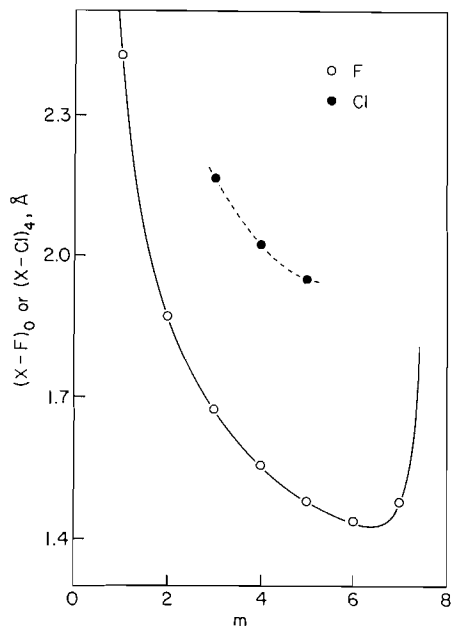

FIG. 4. Variation of the bond lengths $(X—F)_0$ and $(X—Cl)_4$ in $XF_{4-n}Cl_n^{\epsilon}$ with the oxidation state m of X. For the significance of the solid line see text. The broken line represents a visual fit.

function will have to be modified, but this will affect our analysis only numerically.

The three data points available for $(X—Cl)_4$ are insufficient for a similar treatment, but it would seem that the minimum in the $(X—Cl)_4$ vs. m curve occurs at a lower m than in the case of $(X—F)_0$ (Fig. 4); this would be consistent with the notion of lateral repulsion of the halogen atoms.

As would be expected, the bond length varies also with the critical radii of X and Hal (Fig. 5) and with ϵ(X) (Fig. 6). In the first case the decrease in X—Hal is monotonic and not far from linear from Na to S, with an upturn at X = Cl. The variation of X—Hal with ϵ(X) is, for XF_4^{ϵ}, also monotonic and decreasing from Na to S, though less regular, while for XCl_4^{ϵ} it is re-entrant, with the data points for the mixed species showing regular progressions both for n and X.

Bond angles

Analogous to the shortening of the bonds in $AlF_{4-n}Cl_n^-$ with increasing n and thus to increasing lateral repulsion of the halogen atoms, the bond angles also increase with n (Fig. 7). Conversely, in $SiF_{4-n}Cl_n$ and $PF_{4-n}Cl_n^+$ the angles decrease with increasing n. For X = Si and P the variation of FXF, FXCl, and ClXCl is linear or close to linear, while for Al it is non-linear and its rate decreases with increasing n. The ranges of FXF and ClXCl are quite substantial, about 105–111° and 109–115°, respectively; the ClXCl angle drops only slightly below τ for the m range considered here.

The variation with ϵ at constant n is, at least for the present m range, linear (Fig. 8). Assuming that the linearity persists, for $\epsilon < -1$ and $\epsilon > 1$, even more substantial departures from τ can be expected for $\epsilon < -1$ and $\epsilon > 1$. The estimated range for $-3 \leq \epsilon \leq 3$ is 98–116° for FXF and 104–122° for ClXCl.

For the molecular symmetries under consideration here, the bond angles are related by $(n-4)(n-3)(FXF)_n + 2n(4-n)(FXCl)_n + n(n-1)(ClXCl)_n = 12\tau$, so that, for $n = 1$ and 3, $\delta = (FXF)_n - \tau$ (or $(ClXCl)_n - \tau$) must be offset by $(FXCl)_n - \tau = -\delta$. For $n = 2$ the angles have an additional interesting property: $(ClXCl)_2 = 219.74(315) - 0.998(3)(FXF)_2$ ($r^2 = 1.000$, $\sigma = 0.02°$) (Fig. 9), i.e. $(ClXCl)_2 + (FXF)_2 \sim 219.7°$, and because of $\delta(FXCl)_2 = -\frac{1}{4}[(FXF)_2 + (ClXCl)_2 - 2\tau]$, $(FXCl)_2 = \tau - 0.200 - 0.0005(FXF)_2$, which explains the constancy of the $(FXCl)_2$ angle (Table 2).

Bond angle vs. bond length

An unexpected correlation results when the FXF angle is plotted against X—F and the ClXCl angle against X—Cl (Fig. 10). The bond length vs. bond angle variation for each X is linear, with the exception of Al—Cl vs. ClAlCl. The σ of the regressions of bond angle on bond length at constant X, with $(X—F)_\tau, \tau$ and $(X—Cl)_\tau, \tau$ as the respective pivot points, amount to only 2–3% of the observed $|FXF - \tau|$ and $|ClXCl - \tau|$ ranges; for Si/F the value is somewhat higher, ~7%, but in absolute terms still small.

The variation of X—F with FXF and of X—Cl with ClXCl at constant n is non-linear, except of course for $n = 0$ and 4. Parabolic fit to the data points ($f = 0$) yields a family of curves that intersect (or very nearly so) at a crossover point; this point

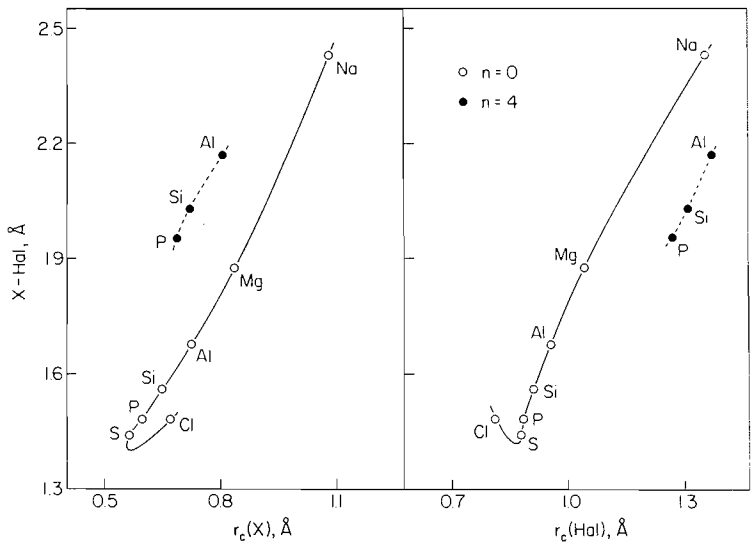

FIG. 5. Variation of $(X—Hal)_{0,4}$ in $XF_{4-n}Cl_n^{\epsilon}$ with the critical radii $r_c(X)_{0,4}$ and $r_c(Hal)_{0,4}$.

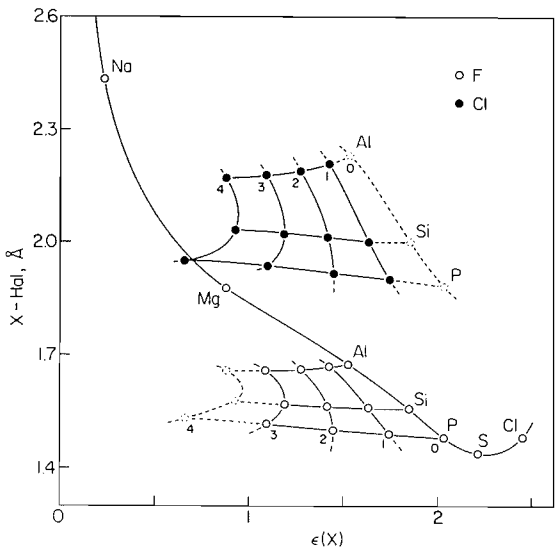

FIG. 6. Variation of $(X—Hal)_n$ in $XF_{4-n}Cl_n^{\epsilon}$ with $\epsilon(X)$.

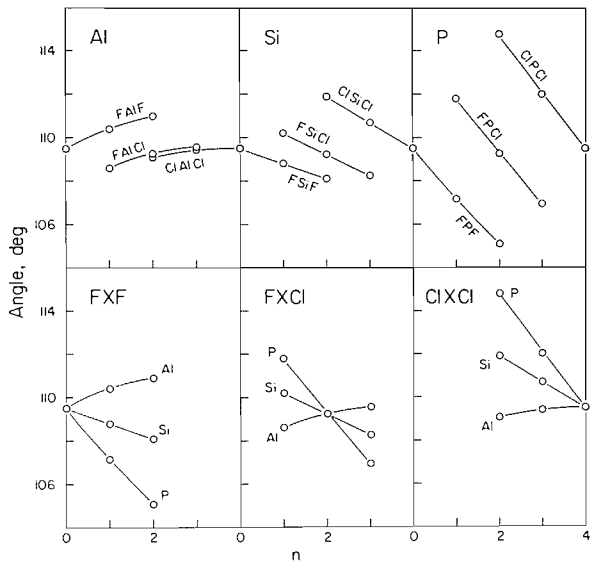

FIG. 7. Variation of the bond angles FXF, FXCl, and ClXCl in $XF_{4-n}Cl_n^{\epsilon}$ with n.

for ClXCl is much closer to Al than that for FXF. When the FXF vs. n and ClXCl vs. n curves on Fig. 7 are represented by parabolas ($f = 0$) passing through τ at $n = 0$ and 4, respectively, the fictitious extrapolated FXF angles for $n = 3$ and the corresponding ClXCl angles for $n = 1$ are such that the $|FXF_{extrapol} - \tau|$ values differ from the $|FXF_{calc} - \tau|$ values obtained from the linear FXF vs. X—F regressions by only 15% for Al, 14% for Si, and 7% for P. All these differences are less than 0.5°. For ClXCl the corresponding differences are 7% for both Si and P; for Al the extrapolation is less certain because of the pronounced curvature of the ClXCl vs. Al—Cl variation. When the three fictitious FXF,X—F points for $n = 3$ are represented by a parabola, the bond-length value at τ is ~1.61 Å, i.e. the curve again passes through the crossover point. Furthermore, when the constant-n curves are represented by exponential curves instead of parabolas, the respective positions of the crossover points for F and Cl remain practically unchanged. The FXF,X—F set thus shows a remarkable internal consistency.

The plot of Fig. 10 reveals at a glance the expectations for X not included in the present investigation. It would seem that significant non-linearity of the angle–distance correlation may develop for $|\epsilon| > 1$; for Mg/Cl and Na/Cl strong non-linearity may be taken for granted. Estimates, from consideration of Figs. 7–10, of the bond angle ranges for X = Na to Cl are 98–116° for FXF and 104–122° for ClXCl. The sensitivity of the bond angle to variation in bond length increases rapidly with $|\epsilon|$ on either side of the respective crossover point, although the magnitude of this rate of change is less easy to predict for $\epsilon < 0$ than for $\epsilon > 0$.

Whether by chance or for an unknown specific reason, the positions of the crossover points in Fig. 10 correspond quite closely to the positions of the points of intersection of the $(ClXCl)_2$ vs. $(FXF)_2$ straight line with the FXF = τ and ClXCl = τ lines (Fig. 9).

The correlation of the change in the bond length, $(X—F)_n - (X—F)_0$, with the change in the bond angle, FXF − τ, is displayed in yet another way in Fig. 11. This plot shows that

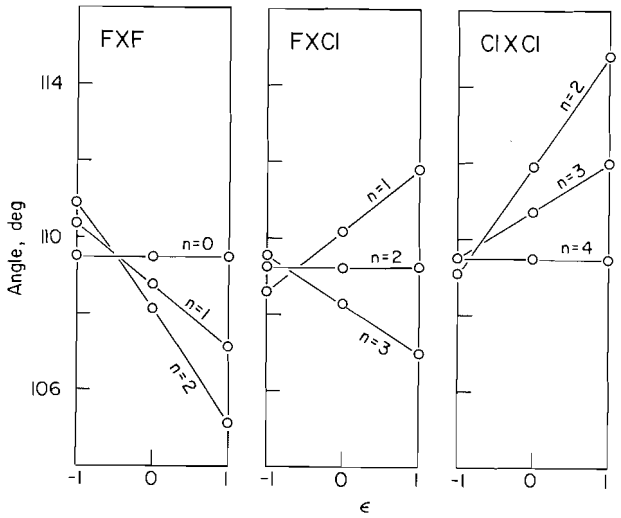

FIG. 8. Variation of the bond angles FXF, FXCl, and ClXCl in $XF_{4-n}Cl_n^{\epsilon}$ with ϵ.

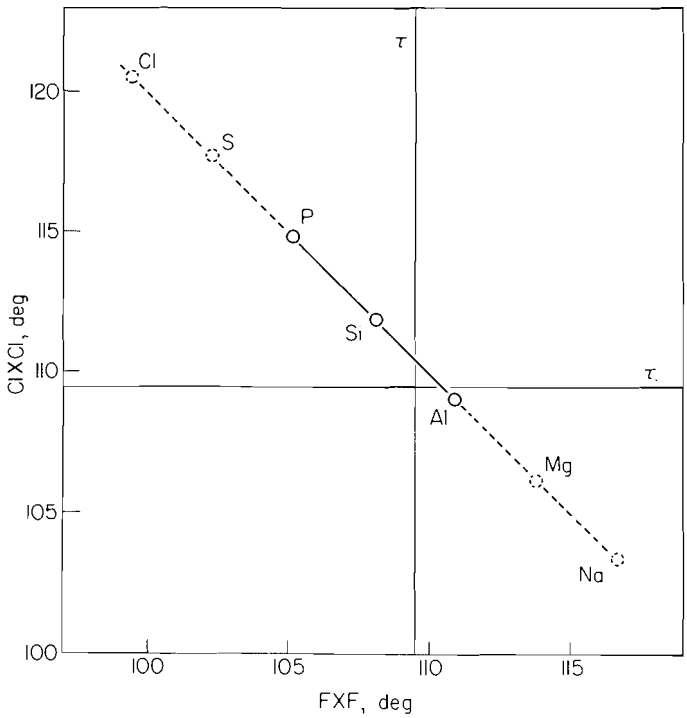

FIG. 9. Variation of the ClXCl with the FXF bond angle in $XF_2Cl_2^{\epsilon}$. Broken circles: data points obtained from extrapolations of FXF vs. ϵ and ClXCl vs. ϵ.

the variation is linear, but the rate of change is different for Al and for Si and P, −0.00590(6) and −0.0104(2) Å/deg, respectively. The correlation is thus decomposed into two branches, one for $\epsilon < 0$ and another for $\epsilon > 0$, intersecting at 0,0. Since the separate regressions for Si and P are statistically indistinguishable from the regression for Si and P combined, one may anticipate that the plot of Fig. 11 represents a correlation of $(X—F)_n - (X—F)_0$ and FXF − τ valid even for $-1 > \epsilon > 1$, with points for $\epsilon < -1$ falling on the Al branch and those for $\epsilon > 1$ on the Si,P branch. A similar behaviour is observed for $(X—Cl)_n - (X—Cl)_4$ vs. ClXCl − τ (Fig. 11), but here the Al branch is not linear. The slopes of the Si,P branches for F and Cl are −0.00590(6) and −0.00678(7) Å/deg,

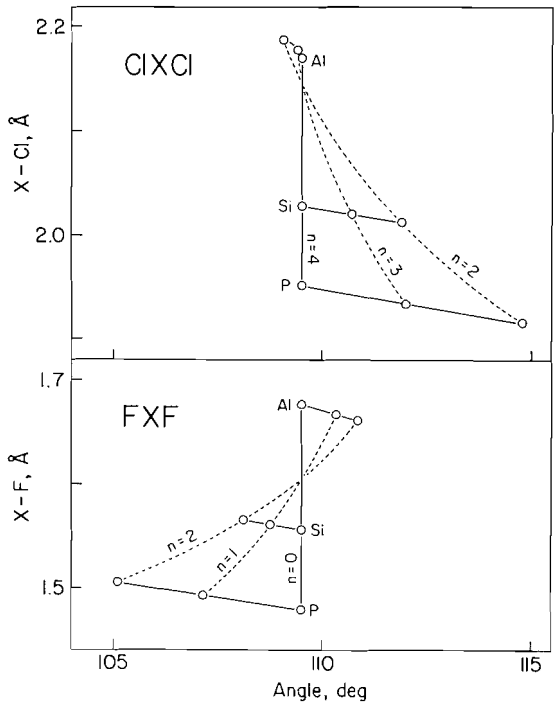

FIG. 10. Variation of the bond angle FXF with X—F and of ClXCl with X—Cl (parabolic interpolation for fixed n).

respectively. Statistical comparison of the two regressions shows that the difference between the two slopes is significant, i.e. the rate of change of the bond-length difference with the difference in the bond angle is ca. 15% larger for Cl.

Net charges $\epsilon(X)$, $\epsilon(F)$, and $\epsilon(Cl)$

Variation of $\epsilon(X)$

The charge on X in XF_4^{ϵ}, $\epsilon(X)_0$, is positive and increases monotonically though irregularly with m (Fig. 12). A polynomial probably of a degree at least four would be required to fit the curve, with the constraint $\epsilon(X)_0 \rightarrow 0$ as $m \rightarrow 0$. The $\epsilon(X)_0$ values, which range from 0.230 for X = Na to 2.456 for X = Cl, indicate that there is considerable transfer of electronic charge from F to X. In ClF_4^{3+} more than one unit of charge is transferred from F to Cl (Fig. 13). Beginning at $m = 3$ the amount of charge transferred from an F atom, $\frac{1}{4}[m - \epsilon(X)_0]$, increases at an almost constant rate.

In XCl_4^{ϵ}, on the other hand, $\epsilon(X)_4$ reaches a maximum at X = Si and then decreases, a change of sign for X = Cl being a distinct possibility (Fig. 12). For a given X the amount of charge transferred to X from a Cl atom in XCl_4^{ϵ} is significantly larger than from an F atom in XF_4^{ϵ} (Fig. 13), a little more than one unit of charge being transferred already at X = P. The greater readiness of Cl to give up charge is illustrated in Fig. 14*A*, where $\epsilon(Cl)_4$ is plotted against $\epsilon(F)_0$. The three available points can be accommodated on a straight line passing through $\epsilon(F)_0 = \epsilon(Cl)_4 = -1$ ($r^2 = 0.999$, see below), with $\partial\epsilon(Cl)_4/\partial\epsilon(F)_0 \sim 1.45$.

The $\epsilon(X)_n$ vs. m curves for the mixed species fall between those for $n = 0$ and $n = 4$ (Fig. 12). The shapes of these curves suggest the existence of $\epsilon(X)_n$ maxima at $m = 5$, $n = 2$ and at $m = 4$, $n = 3$; the direction of the continuation of the $n = 1$ curve beyond $m = 5$ is not self-evident.

The m,n combinations at which the net charge on X equals the charge on the complex are defined by the $\epsilon(X) = \epsilon$ line in Fig. 12. In the species located farthest to the left of this line the

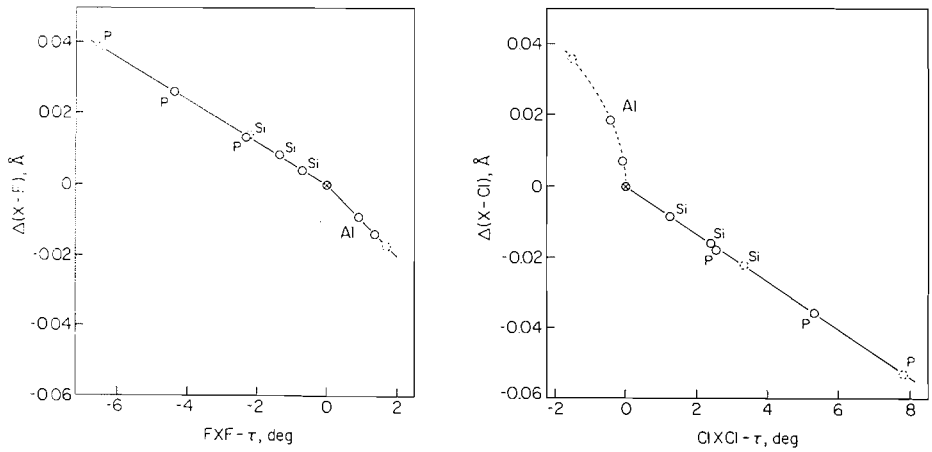

FIG. 11. *A* (*left*), variation of $\Delta(X—F)_n = (X—F)_n - (X—F)_0$ with the bond-angle difference FXF − τ. *B* (*right*), variation of $(X—Cl)_n - (X—Cl)_4$ with the bond-angle difference ClXCl − τ. Broken circles: values obtained by linear extrapolation of the X—F vs. FXF lines (Fig. 10) to $n = 3$, or of the X—Cl vs. ClXCl lines to $n = 1$.

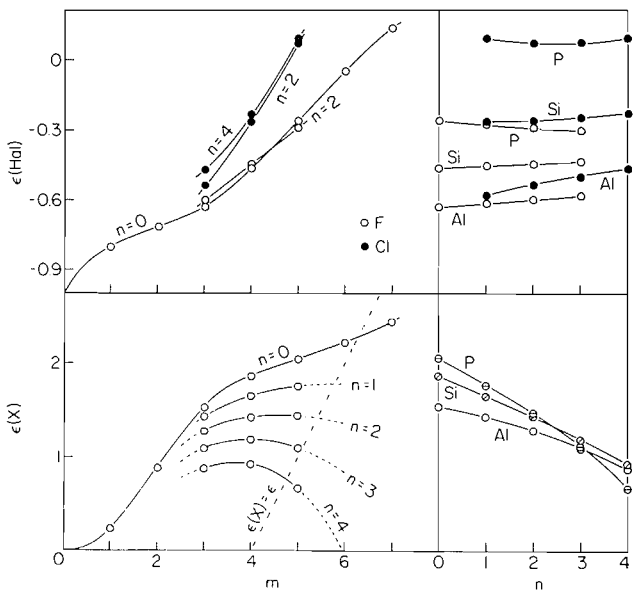

FIG. 12. Variation of ε(X) and ε(Hal) with *m* and *n*. The curves in the ε(X) and ε(Hal) vs. *m* plots represent visual fits, as the appropriate functional relationships are not known and the number of data points in general is insufficient to define the polynomials (of degree four or higher) that would be required for analytic representation.

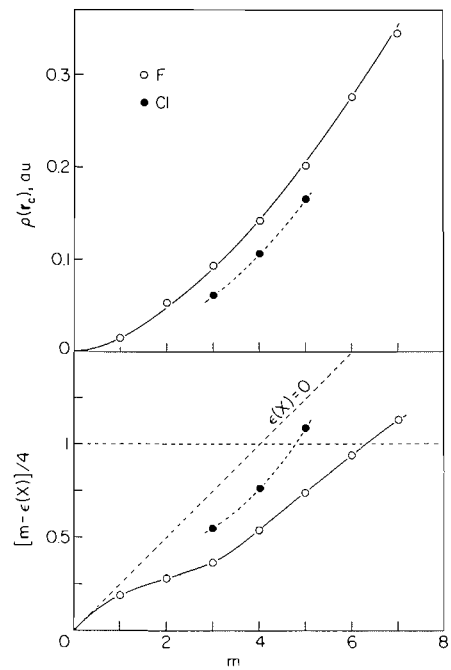

FIG. 13. Variation, with the oxidation state *m* of X, of the electron density at the critical point $\rho(r_c)$ (*A*, *top*) and of the amount of negative charge $\frac{1}{4}[m - \epsilon(X)]$ transferred from a F^- atom in XF_4^{ϵ}, or from a Cl^- atom in XCl_4^{ϵ}, to X (*B*, *bottom*). The points for $n = 1$–3 fall between the curves for $n = 0$ and 4.

total charge on the complex resides essentially on the halogens, whereas in the species to the right it resides essentially on X.[2] In SF_4^{2+}, where ε(F) is, numerically, about 40 times smaller than ε(S), the F atoms carry very little net charge and ε is located almost entirely on the S atom.

The steady variation of ε(X) with *n* is non-linear for all three elements studied, even though for X = Si the departure from linearity is slight (Fig. 12). In all three cases ε(X) decreases with increasing *n*, which again indicates that Cl loses charge to X more readily than does F. The rate of the decrease accelerates from Al to P; in $PF_{4-n}Cl_n^+$ it overtakes Al and Si at $n = 3$ and causes the order of ε(X) to change from P—Si—Al for $n = 0$ to Si—Al—P for $n = 4$.

Variation of ε(Hal)

In the balanced species, $4\epsilon(Hal) = \epsilon - \epsilon(X)$ and so the ε(Hal) vs. *m* curves for $n = 0$ and 4 of Fig. 12 are the same as the corresponding curves in Fig. 13 if allowance is made for $m = \epsilon + 4$. For $n = 2$ the $\epsilon(F)_2$ and $\epsilon(Cl)_2$ curves are quite close to those for $\epsilon(F)_0$ and $\epsilon(Cl)_4$, respectively. This is not surprising in view of the relatively small variation of $\epsilon(Hal)_n$ with *n* (Fig. 12). For F this variation is almost linear, but the slopes for Al and Si are positive while that for Si is negative. The curvatures for $\epsilon(Cl)_n$ are more pronounced, and the curve for P

[2]Removal of an electron from AlF_4^- produces relatively small changes in the net charges: for AlF_4^0 (6-31G*, D_{2d}; unpublished results), ε(Al) = 1.650, ε(F) = −0.412, ε(F) − ε(Cl) = −2.062 (−2.179 for AlF_4^-).

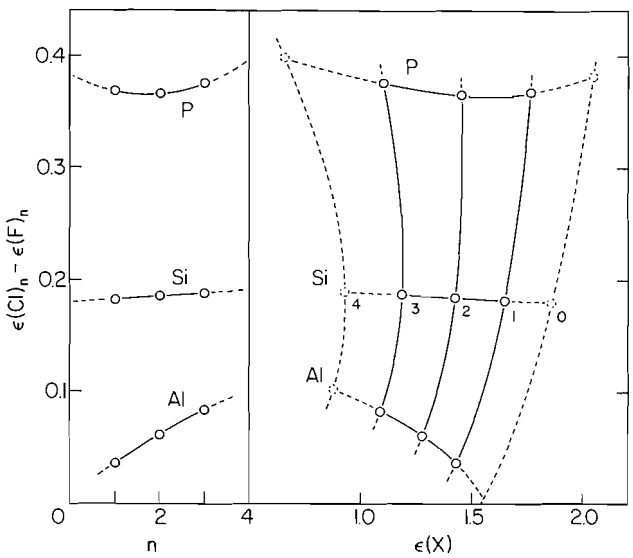

FIG. 15. Variation of the difference $\epsilon(Cl)_n - \epsilon(F)_n$ with n (*A*, *left*) and $\epsilon(X)$ (*B*, *right*). Broken circles: data points obtained by extrapolation.

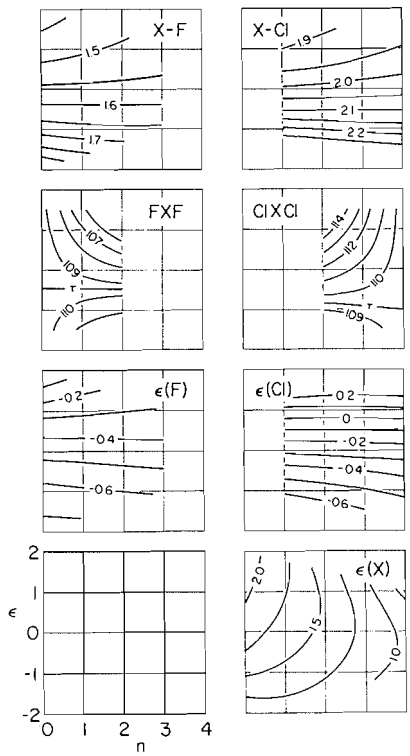

FIG. 16. Variation, with n and ϵ, of the bond lengths X—F and X—Cl, the bond angles FXF and ClXCl, and the net charges $\epsilon(X)$, $\epsilon(F)$, and $\epsilon(Cl)$ in $XF_{4-n}Cl_n^{\epsilon}$.

has an $\epsilon(Cl)_n$ minimum between $n = 2$ and 3, whereas that for Al is convex with respect to the n axis.

The rate at which electronic charge is transferred, with varying n, from a halogen atom to X depends on m and is not the same for F and Cl. The difference $\Delta = \epsilon(Cl)_n - \epsilon(F)_n = [\epsilon - \epsilon(X) - 4\epsilon(F)]/n$, which may be taken as a measure of the relative strength of the X—Hal bond, is quite small for Al and increases rapidly with n; for X = Si it is nearly constant and about double that for Al, and for X = P it is about four times that for Al and goes through a minimum (Fig. 15*A*). These features are preserved when Δ is plotted against $\epsilon(X)$ (Fig. 15*B*). The extent of the charge transfer from an F atom relative to that from a Cl atom thus depends both on m and, for a given X, on $\epsilon(X)$.

The trend in the variation of Δ (Fig. 15*A*) and visual extrapolation in Fig. 15*B* both suggest that with decreasing m the difference Δ eventually will become negative, i.e. the transfer of charge from the halogen atom to X becomes progressively easier for F than for Cl as the anionic charge on the complex increases. This is also evident in Fig. 14*B*, where the $\epsilon(Cl)_n, \epsilon(F)_n$ data points approach the $\epsilon(Cl)_n = \epsilon(F)_n$ line with decreasing m. Although this seemingly paradoxical result

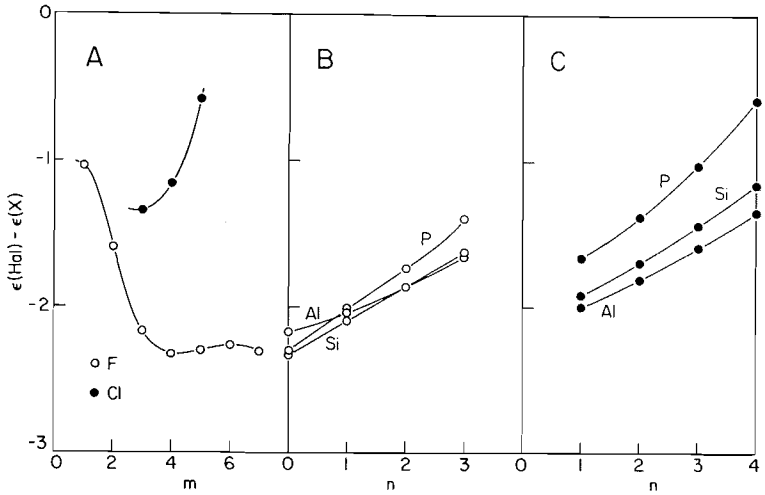

FIG. 17. Variation of the polarity of the X—Hal bond (as measured by $\epsilon(F)_0 - \epsilon(X)_0$ and $\epsilon(Cl)_4 - \epsilon(X)_4$, respectively) with m (*A*) and n (*B*, *C*).

may be an artefact of the 6-31G* chemistry, it is consistent with the experimental fact that the ionization potential of F^- (= the reverse of the electron affinity of F) is ca. 0.16 eV smaller than that of Cl^-, i.e. it is easier to remove an electron from a free F^- ion than from a free Cl^- ion. As the slopes of the lines for Al in Figs. 14*B* and 15*B* indicate, charge is withdrawn from Cl more rapidly with n than from F, and this would be expected to be even more the case for Mg and Na. The competition for charge is, however, reversed with increasing m, as shown by the n sequence for P in Fig. 14*B*.

The difference between F and Cl is displayed also by comparing $\epsilon(F)_0$ and $\epsilon(Cl)_4$ (Fig. 14*A*). Assuming that in $NeHal_4^{4-}$ $\epsilon(Hal)_{0,4} = -1$, the data points for X = Al, Si, and P can be accommodated quite well on the straight line $\epsilon(Cl)_4 = 0.4521 + 1.4521\epsilon(F)_0$ ($r^2 = 0.999$, $\sigma = 0.010$), i.e. the negative charge on Cl in XCl_4^ϵ decreases more rapidly with increasing m than the negative charge on F in XF_4^ϵ. To what extent this correlation is fortuitous will be determined when results for m = 1, 2, 6, and 7 have become available.

A conspectus of the simultaneous dependence of X—Hal, FXF, ClXCl, $\epsilon(X)$, $\epsilon(F)$, and $\epsilon(Cl)$ on n and ϵ is presented in Fig. 16.

Variation of $\epsilon(Hal) - \epsilon(X)$

This difference may be taken as an index of the polarity of the X—Hal bond. In XF_4^ϵ it varies steeply with m from Na to Al, after which it remains more or less constant, whereas in XCl_4^ϵ it rises appreciably from Al to P (Fig. 17*A*). In the mixed species it increases with n at comparable rates for all three X, the increase for X = P being somewhat steeper than for Al or Si (Figs. 17*B*,*C*).

Critical points, ionic radii, and deformation of the electron-density distribution

At a bond critical point r_c the electron density ρ satisfies $\nabla\rho(r_c) = 0$,[3] i.e. constitutes an electron-density minimum along the bond path between atoms A and B and a maximum with respect to a lateral displacement. The distance r_c^A from nucleus A to r_c and the distance r_c^B from nucleus B to r_c are the corresponding critical radii of A and B.

Critical radii of X^{m+}

The variation of $r_c(X)_0$ with m (Fig. 18*A*) strongly resembles

[3]These points are also known (31) as the (3, −1) critical points, since they are associated with three curvatures, one positive and two negative (+1 − 1 − 1 = −1).

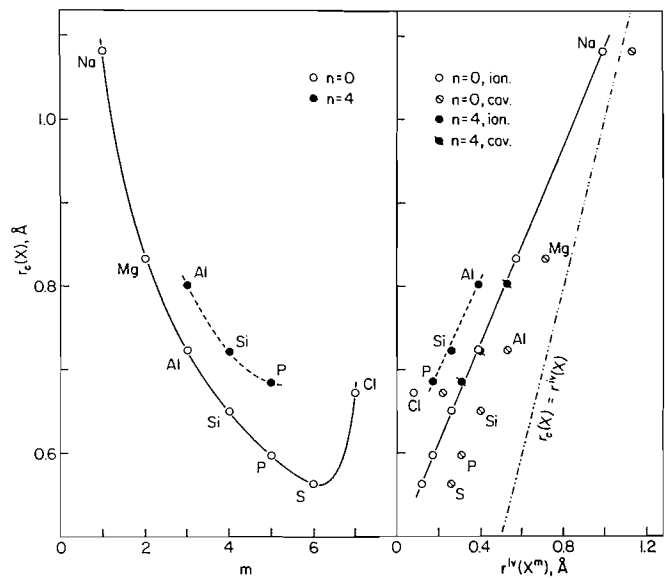

FIG. 18. *A* (*left*), variation of the critical radius $r_c(X)$ in XF_4^ϵ and XCl_4^ϵ with the oxidation state m of X. *B* (*right*), correlation of the critical radii $r_c(X)$ in XF_4^ϵ and XCl_4^ϵ with Shannon's effective ionic and covalent radii $r^{iv}(X^{m+})$ of X^{m+} in tetrahedral coordination.

that of X—Hal with m (Fig. 4). This would suggest that the variation of $r_c(X)_0$, too, could be resolved into an attractive and a repulsive component. The $r_c(X)_0$ values for m = 1–6 can be represented to a σ of 0.003 Å ($r^2 = 1.000$) by $r_c(X)_0 = 1.07923m^{-0.36554}$. This means that the effect of the repulsive forces does not become significant until m = 7, but after X = S the contribution of the repulsive component rises very steeply with m, similar to the X—Hal vs. m variation.

Since X—Hal = $r_c(X) + r_c(Hal)$, the $r_c(X)$ values may be expected to correlate with Shannon's effective ionic (or covalent) radii of X^{m+} in 4-coordination. Indeed, regressing $r^{iv}(X^{m+})$ on $r_c(X)_0$ for m = 1–6 yields $r^{iv}(X^{m+}$, ionic) = $-0.8314 + 1.6828r_c(X)_0$ ($r^2 = 1.000$, $\sigma = 0.003$ Å). The two radii would become equal only at ~1.22 Å, i.e. for $m < 1$ (Fig. 18*B*). Since Shannon's $r^{iv}(X^{m+}$, covalent) exceed his $r^{iv}(X^{m+}$, ionic) by the constant amount of 0.14 Å, $r^{iv}(X^{m+}$, covalent) would equal $r_c(X)_0$ at ~1.01 Å, i.e. roughly at m = 1.

For $r_c(X)_4$, the linear regression (three values only) yields $r^{iv}(X^{m+}$, ionic) = $-1.0689 + 1.8221r_c(X)_4$, $r^2 = 0.989$, σ =

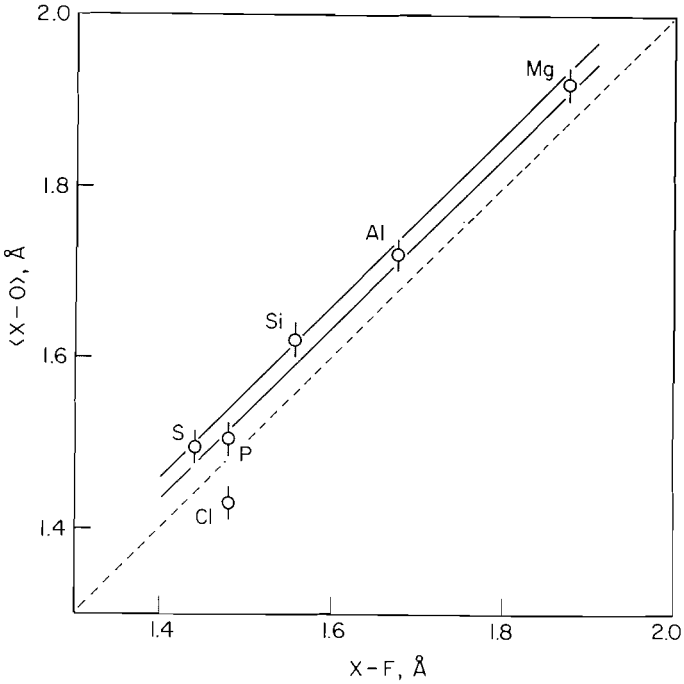

FIG. 19. Average X—O bond lengths in tetrahedral oxyanions $XO_4^{\epsilon-4}$ plotted against the calculated X—F distances in XF_4^{ϵ}. The width of the band is 2σ of the linear regression (excluding X = Cl). The estimated error bars on ⟨X—O⟩ represent ±0.02 Å.

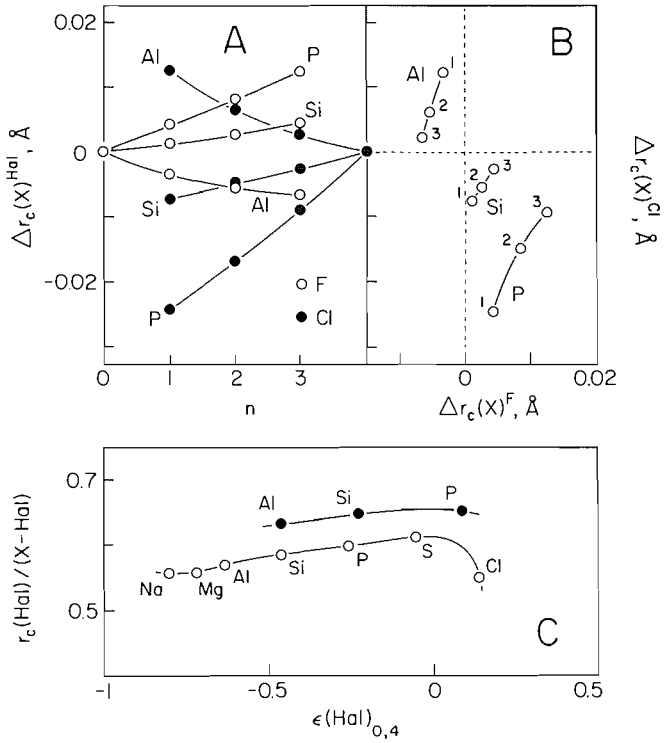

FIG. 20. (*A*) Variation of the critical radius of X with n; $\Delta r_c(X)^{Hal} = r_c(X)_n^{F} - r_c(X)_0$ or $r_c(X)_n^{Cl} - r_c(X)_4$. (*B*) Correlation of $r_c(X)_n^{Cl} - r_c(X)_4$ with $r_c(X)_n^{F} - r_c(X)_0$. (*C*) Variation of the relative position of the critical point in the X—Hal bond, $r_c(Hal)/(X—Hal)$, with $\epsilon(F)_0$ and $\epsilon(Cl)_4$.

0.012 Å. However, the line defined by $r^{iv}(X^{m+}$, covalent) = $0.14 - 1.0689 + 1.8221 r_c(X)_4$ practically coincides with the regression line for $r^{iv}(X^{m+}$, ionic) vs. $r_c(X)_0$, which would suggest that the $r^{iv}(X^{m+}$, covalent) set of radii is appropriate to the chlorides and the $r^{iv}(X^{m+}$, ionic) set to the fluorides. This is not unreasonable, considering that Shannon's set of ionic radii was devised primarily for use with oxides and to a lesser degree with fluorides. The breakdown of the $r^{iv}(X^{m+})$ vs. $r_c(X)_0$ correlation for X = Cl is thus not surprising, for the $r^{iv}(Cl^{7+})$ values have been derived exclusively from the experimental bond lengths in ClO_4^-. A plot of average experimental X—O bond lengths in the tetrahedral oxyanions $XO_4^{\epsilon-4}$ (ref. 17; Mg—O and Al—O from $MgAl_2O_4$) against the X—F in XF_4^{ϵ} (Fig. 19) in fact demonstrates that ClF_4^{3+} is a clear misfit in the X—O vs. X—F correlation for m = 2–6, ⟨X—O⟩ = 0.045(64) + 1.001(40)(X—F)$_0$ (r^2 = 0.995, σ = 0.014 Å), even when differences arising from experimental circumstances are taken into account, and that the parallellism of the two isoelectronic series does not extend beyond $m = 6$.[4]

The variation of $r_c(X)_n^{F}$ for m = 3–5 with n, relative to $r_c(X)_0$, does not exceed 0.015 Å, and that of $r_c(X)_n^{Cl}$ relative to $r_c(X)_4$ is within 0.025 Å (Fig. 20*A*), but here again the sign of the variation for Al is the opposite of that of Si and P, both for $r_c(X)_n^{F}$ and $r_c(X)_n^{Cl}$. The rate of change for $r_c(X)$ with n is highest for $r_c(P)_n^{Cl}$, ca. 0.008 Å/n. The differences $r_c(X)_n^{F} - r_c(X)_0$ and $r_c(X)_n^{Cl} - r_c(X)_4$ are correlated in Fig. 20*B*.

Critical radii of F and Cl

The variation of $r_c(F)_0$ and $r_c(Cl)_4$ with m is shown in Fig. 21*A*; the corresponding plots against $\epsilon(F)_0$ and $\epsilon(Cl)_4$, or against $m - \epsilon(X)_0$ and $m - \epsilon(X)_4$, have essentially the same features. Compared to $r_c(X)_0$ (Fig. 18*A*), the $r_c(F)_0$ values taper off more rapidly with m; unlike for $r_c(X)_0$, where $r_c(Cl)_0 > r_c(S)_0$, there is an additional sudden decrease in $r_c(F)_0$ on going from X = S to X = Cl. The range of $r_c(F)_0$ (m = 1–7), ~0.54 Å, is similar to the range of $r_c(X)_0$, ~0.52 Å; for $r_c(Cl)_4$ (m = 3–5) the ranges are ~0.10 and ~0.12 Å, respectively. The lengths of these intervals demonstrate the difficulty, in principle, of devising a "universal" effective radius of F^- or Cl^- even for a narrowly specified stereochemistry. However, the critical radius of F in NaF_4^{3-}, 1.35 Å, is close to Pauling's "crystal" radius of F^-, 1.36 Å, and to Shannon's $r^{iv}(F^-)$, 1.33 Å.

The effect of the polarity of the X—Hal bond is examined in Fig. 21*B*, where the $r_c(Hal)_{0,4}$ are plotted against $\epsilon(Hal) - \epsilon(X)$. While $r_c(F)_0$ is not a single-valued function of $\epsilon(F)_0 - \epsilon(X)_0$, similar values of this difference correspond to similar values of $r_c(F)_0$, the data point for X = Cl again being an exception. The corresponding curve for $r_c(Cl)_4$ (m = 3–5) is, to all appearances, analogous to the Si—P—S portion of the curve for $r_c(F)_0$.

Position of the critical point

The relative position of the critical point in the X—F bond, $r_c(F)_0/(X—F)_0$, in XF_4^{ϵ} is nearly the same for m = 1 and 2, after which the critical point begins to move gradually toward X only to shift again, appreciably, away from X at m = 7 (Fig. 20*C*). The variation in XCl_4^{ϵ} parallels that for XF_4^{ϵ} at least in the limited range m = 3–5.

In the mixed species the relative position of the critical point changes very slightly with n. The total change in $r_c(F)_n/(X—F)_n$ between n = 0 and n = 3 is 0.0005 for Al, −0.0008 for Si, and −0.0022 for P; the total change in $r_c(Cl)_n/(X—Cl)_n$ between n = 4 and n = 1 is −0.0005 for Al, 0.0003 for Si, and −0.0029 for P (note the change of sign).

[4]The compatibility but non-coincidence of an empirical set of radii with a corresponding set of critical radii is well known from simple ionic crystals, e.g. alkali halides (for a discussion of this problem see, for example, ref. 32).

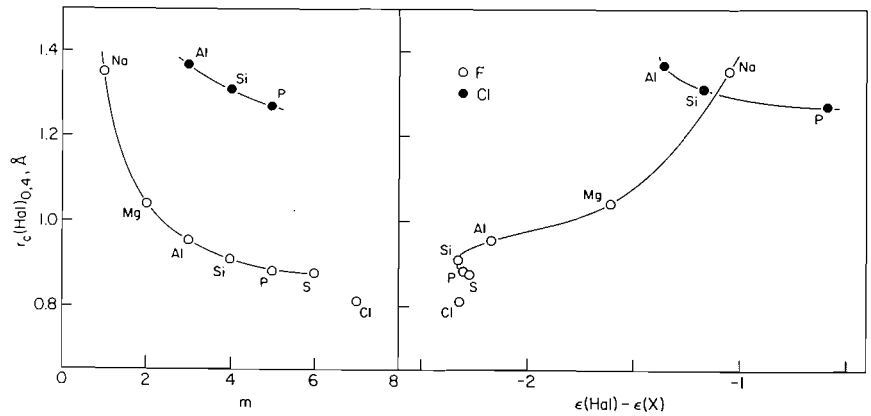

FIG. 21. *A* (*left*), variation of $r_c(F)_0$ and $r_c(Cl)_4$ with m. *B* (*right*), variation of $r_c(F)_0$ and $r_c(Cl)_4$ with the polarity of the X—Hal bond as measured by the difference $\epsilon(Hal) - \epsilon(X)$.

Electron density at the critical point

Assuming that $\rho(r_c) = 0$ for $m = 0$, the change in $\rho(r_c)_0$ with m can be approximated with reasonable accuracy by the power function $\rho(r_c) = 0.01584m^{1.59416}$ ($r^2 = 0.998$, $\sigma = 0.00423$ au $\sim 1.2\%$ of range) (Fig. 13*A*). The individual differences, which for $m = 1$ and 2 are $\sim 7\%$ and $\sim 10\%$, respectively, may be indicative of a weak fine structure in this variation. A power fit to the three points for $\rho(r_c)_4$ yields $0.007071m^{1.95638}$ ($r^2 = 1.000$, $\sigma = 0.00005$ au).

The increase in $\rho(r_c)$ with ϵ(Hal) is monotonic both for $\rho(r_c)_0$ and $\rho(r_c)_4$, for the latter at least for $m = 3$–5, but while the increase of $\rho(r_c)_0$ with $\epsilon(X)_0$ is monotonic and up to X = Al quasi-linear, the curve representing $\rho(r_c)_4$ vs. $\epsilon(X)_4$ is re-entrant (Fig. 22*A*). It appears possible, both for $\rho(r_c)_0$ vs. $\epsilon(F)_0$ and $\rho(r_c)_0$ vs. $\epsilon(X)_0$, to accommodate the point for X = Cl in a reasonable manner on a smooth extension of either curve. The course of such a continuation is, however, much less obvious for the variation of $\rho(r_c)_0$ with the critical radius of X or F (Fig. 22*B*), especially as the $\rho(r_c)_0$ vs. $r_c(X)_0$ curve can be approximated quite satisfactorily by a power function $\rho(r_c)_0 = 0.02195[r_c(X)_0]^{-4.38943}$ ($r^2 = 0.998$, $\sigma = 0.0054$ au $\sim 2\%$ of range) for $m = 1$–6, which renders the misfit of ClF_4^{3+} the more conspicuous.

The variation of $\rho(r_c)$ with n (Fig. 23*A*) again shows the difference between Al on the one hand and Si and P on the other. Because of its relative smallness this variation is better displayed as the difference $\Delta\rho(r_c)_n = \rho(r_c)_n - \rho(r_c)_{0,4}$. When $\Delta\rho(r_c)_n^{Cl}$ is plotted against $\Delta\rho(r_c)_n^{F}$ (Fig. 23*B*), interesting features reminiscent of Figs. 3 and 20*B* emerge, suggesting that the $\Delta\rho(r_c)_n$ points for Mg would fall in the Al quadrant and those for S in the Si,P quadrant. It remains to be seen whether the additional data points follow the tie-line relationships of Fig. 23*B*.

The $\rho(r_c)$ values being single numbers, the information they provide is valuable but limited. The electron-density contours (Fig. 24) give a more detailed insight into the deformation of the electron-density distribution in the X—F bond and a clearer understanding of what occurs when going from SF_4^{2+} to ClF_4^{3+}. Comparison of the shapes of the 0.2 au contour for the two species shows that the change which takes place here is qualitatively different from the progressive reduction of the separation of the individual electron-density distributions on the X and F atoms from X = Na to S. The bond in ClF_4^{3+} appears to be much more covalent, in spite of the lengthening of the internuclear X—F distance, and the change appears to affect even the 2 au contour.

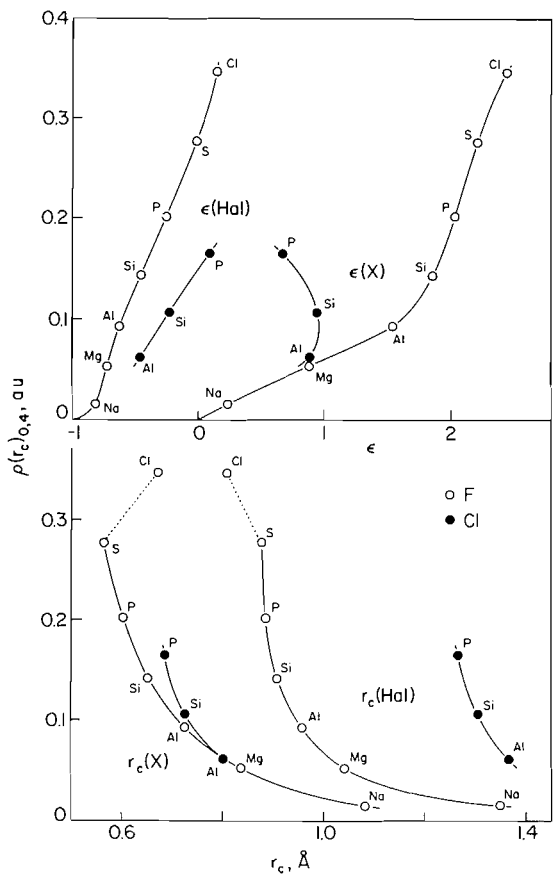

FIG. 22. Variation of the electron density at the critical point, $\rho(r_c)_{0,4}$, with ϵ(X) and ϵ(Hal) (*A*, *top*), and with r_c(X) and r_c(Hal) (*B*, *bottom*). Continuation of the visually fitted curves beyond X = S is uncertain. The label ϵ in *A* stands for ϵ(X) or ϵ(Hal).

Energy of formation

The energy of formation $E_f(0)$ of XF_4^{ϵ} decreases steadily from Na to Cl, and a similar trend is observed for $E_f(4)$ (Fig. 25). The functional form of the $E_f(0)$ vs. m variation is not known, but a cubic fit yields

$$[3] \quad E_f(0) = 0.79684 - 0.897527m - 0.04154661m^2 - 0.01436946m^3$$

($r^2 = 1.000$, $\sigma = 0.017$ au $\sim 0.14\%$ of the $m = 1$–7 range; zero at $m \sim 0.845$).

From the definition of $E_f(0)$, and using the analytical

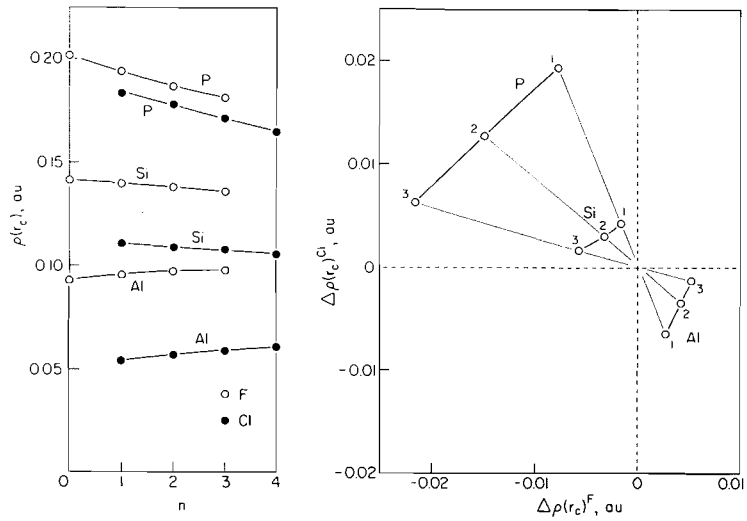

FIG. 23. *A* (*left*), variation of the electron density at the critical point, $\rho(\boldsymbol{r}_c)$, with n. *B* (*right*), correlation of $\Delta\rho(\boldsymbol{r}_c)^{Cl} = \rho(\boldsymbol{r}_c)_n{}^{Cl} - \rho(\boldsymbol{r}_c)_4$ with $\Delta\rho(\boldsymbol{r}_c)^{F} = \rho(\boldsymbol{r}_c)_n{}^{F} - \rho(\boldsymbol{r}_c)_0$.

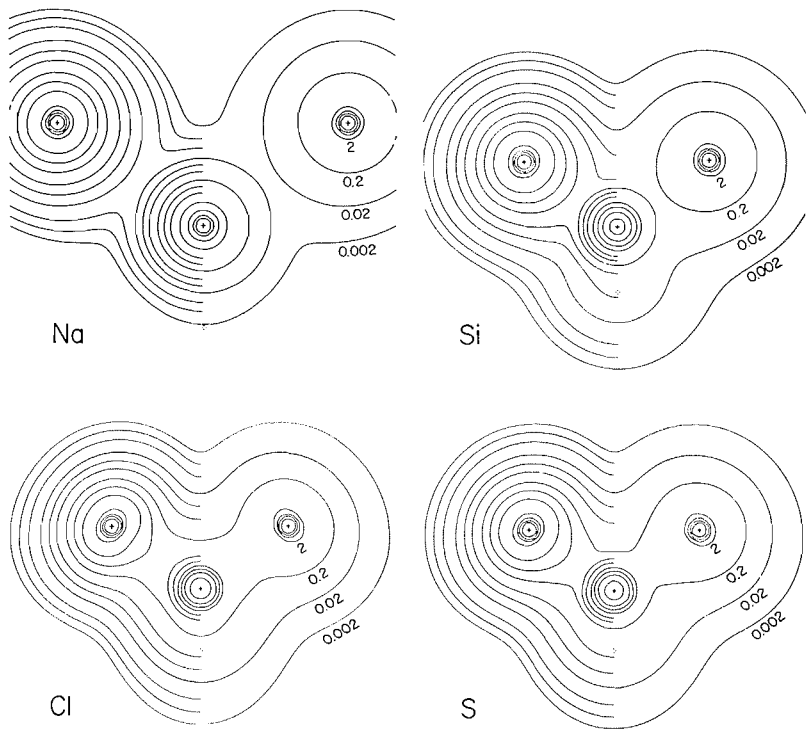

FIG. 24. Electron-density contours for NaF_4^{3-}, SiF_4, SF_4^{2+}, and ClF_4^{3+} in planes defined by the X and two of the F nuclei. The other two F nuclei project onto a position indicated by a small cross. The contours are in ten-multiples of 0.002, 0.004, and 0.008 au up to 8 au followed by 16 au.

representations of $E(0)$ (eq. [2]) and $E(X^{m+})$ (eq. [1]) together with $E(F^-)$, one obtains

$$[4]\quad E_f(0) = 0.79533 - 0.895638m - 0.0421527m^2 - 0.0143148m^3$$

($r^2 = 1.000$, $\sigma = 0.017$ au; zero at $m \sim 0.845$), from which $E_f(0)$ is 0.79533 for NeF_4^{4-} and -16.39674 au for ArF_4^{4+}. This confirms that for NeF_4^{4-} $E_f(0) > 0$, in accord with expectation. At the same time the large negative $E_f(0)$ calculated from eq. [4] for ArF_4^{4+} indicates that this species ought to be stable; the difference between $E(0)$ of ArF_4^{4+} calculated from eq. [2] and $E(Ar^{8+}) + 4E(F^-)$ is -16.39635 au, i.e. indistinguishable from the corresponding $E_f(0)$ value from eq. [3]. This conflicts with the result of the STO-3G optimization process (see above), which suggested instability of ArF_4^{4+}.

Conclusions[5]

1. Where verification is possible, the X—Hal bond lengths obtained from calculations at the 6-31G* level for the series of isoelectronic tetrahedral $XF_{4-n}Cl_n^{\epsilon}$ ($n = 0$, X = Na to Cl; $n =$ 1–4, X = Al, Si, P) species are in reasonable agreement with

[5]ADDED IN THE PROOF. The suggestion of one of the referees that we consider the results of Cremer and Kraka (33, 34) and S. Bachrach (to be published) in our discussion of the bond critical points came too late to be acted upon here. We intend to take it into account in a sequel to the present paper.

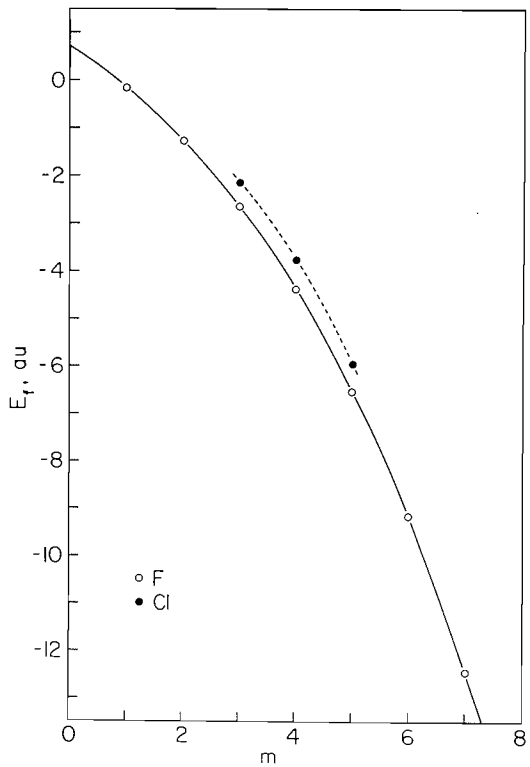

FIG. 25. Variation of the energy of formation E_f of XF_4^{ϵ} and XCl_4^{ϵ} with the oxidation state m of X.

experiment. This lends, at least qualitatively, credibility to the trends observed in the calculated molecular parameters.

2. The SCF procedure failed to converge for ArF_4^{4+}, even though the trend in the electronic energy of formation E_f suggests that this species should be more stable than any of the other XF_4^{ϵ} species in the series. On the other hand, the species SF_4^{2+} and ClF_4^{3+}, for which equilibrium geometries have been obtained, do not seem to have been reported to date, in spite of vigorous activity in fluorine chemistry in recent years. One cannot therefore conclude with certainty on the physical existence of a particular $XF_{4-n}Cl_n^{\epsilon}$ species from the result of an SCF calculation alone.

3. In general, correlations between the calculated molecular parameters for the series are not simple, but occasionally quasi-linear relationships between parameters or their changes emerge.

4. The direction in which the bond lengths, bond angles and other molecular parameters change on progressive replacement of F in XF_4^{ϵ} by Cl depends on the ionic charge ϵ. On existing indications the dividing line falls between $\epsilon < 0$ and $\epsilon > 0$.

A more detailed analysis of the results will be presented when the calculations for the mixed species $XF_{4-n}Cl_n^{\epsilon}$ (X = Na, Mg, S, Cl) and the corresponding calculations for elements of the first row (now in progress) have been completed. Comparison of the second-row with the first-row series cannot fail to be interesting, as effects of composition on the molecular parameters are always more pronounced for the first-row elements.

Received October 21, 1986

This paper is dedicated to Professor Douglas E. Ryan on the occasion of his 65th birthday

H. DASARATHA GUNAWARDHANA and S. AMARASIRI FERNANDO. Can. J. Chem. **65**, 1124 (1987).

N-Phenylbenzohydroxamic acid reacts with molybdenum(VI) in 3.5–6.0 *M* hydrochloric acid to give a complex that is extractable into chloroform. The chloroform extract of the molybdenum complex, on second extraction from a dilute hydrochloric acid medium (0.2–0.3 *M*) in the presence of phenylfluorone and ethanol, forms an intensely coloured complex possessing an absorption maximum at 518 nm. Job's method of continuous variation reveals that the complex is Mo(VI)—2NPBHA—PF. The molar absorptivity under optimum conditions is 7.4×10^4 dm^3 mol^{-1} cm^{-1}. The system obeys Beer's law up to 0.6 ppm of molybdenum(VI). Considerable amounts of many cations and anions can be tolerated. The interference from vanadium(IV) and vanadium(V) can be eliminated by the addition of sodium metabisulphite, whereas the interference from titanium(IV) is mitigated by oxalate ions. The method has been successfully applied for the determination of molybdenum in a standard steel sample.

H. DASARATHA GUNAWARDHANA et S. AMARASIRI FERNANDO. Can. J. Chem. **65**, 1124 (1987).

L'acide *N*-phénylbenzohydroxamique réagit avec le molybdène(VI), dans des solutions contenant de 3,5 à 6,0 *M* d'acide chlorhydrique, pour donner un complexe que l'on peut extraire par le chloroforme. La solution chloroformique du complexe de molybdène, soumise à une seconde extraction avec une solution diluée (0,2 à 0,3 *M*) d'acide chlorhydrique, en présence de phénylfluorone et d'éthanol, forme un complexe extrèmement coloré qui possède un maximum d'absorption à 518 nm. La méthode de Job de variation continue permet de mettre en évidence que le complexe est Mo(VI)—2 ANPBH—PF. L'absorption molaire, dans des conditions optimales, est égale à $7,4 \times 10^4$ dm^3 mol^{-1} cm^{-1}. Le système obéit à la loi de Lambert-Beer jusqu'à une concentration de 0,6 ppm de molybdène(VI). Des quantités considérables de plusieurs cations ou anions peuvent être tolérées. On peut éliminer les interférences dues au vanadium(IV) et (V) en additionnant du métabisulfite de sodium et l'on peut mitiger les interférences dues au titane(IV) en ajoutant des ions oxalates. On a appliqué la méthode avec succès à la détermination du molybdène dans un échantillon standard d'acier.

Introduction

In the determination of molybdenum using atomic absorption spectrometry, it is difficult to obtain high sensitivity, owing to the formation of stable oxides in the flame and sometimes stable carbides in non-flame atomizers. Therefore, it is useful to develop highly sensitive and selective spectrophotometric methods for the determination of molybdenum.

Pilipenko and co-workers (1, 2) reported the use of phenylfluorone(9-phenyl-2,6,7-trihydroxy-3*H*-xanthen-3-one) (PF) and an alcohol in conjunction with *N*-phenylbenzohydroxamic acid (NPBHA) to achieve an enhanced intensity of colour in the determination of titanium. *N*-Phenylfurohydroxamic acid (3) and *N*-phenyllaurohydroxamic acid (4) have also been used in place of NPBHA. The method consists of first extraction of metal from a strong mineral acid medium into a chloroformic solution of NPBHA, followed by a second extraction of the resulting chloroform extract with an alcoholic solution of PF and very dilute hydrochloric acid. The first extraction provides a certain amount of selectivity for molydbenum and gives a colourless chloroform extract (5), and the second extraction imparts a coloured organic layer possessing a maximum absorption at 518 nm.

Experimental

Apparatus

A Cecil model 373 visible spectrophotometer was used for absorptiometric measurements. A Varian DMS 90 UV/Visible spectrophotometer was used for the spectra.

Reagents

Analytical grade reagents were used wherever possible. All solvents were purified and distilled prior to use. NPBHA was prepared using a procedure described by MAJUMDAR (5), and the purity of the recrystallised product was checked by melting point determination. Analytical reagent grade phenylfluorone (Eastman) was used without further purification.

A stock solution of molybdenum(VI) was prepared by dissolving ammonium molybdate in water. The final solution of approximately 1000 ppm was standardised by using a Jones reductor (6).

Recommended procedure for the spectrophotometric determination of molybdenum(VI)

First extraction

Transfer an aliquot of sample solution containing up to 6 μg of molybdenum(VI) into a separating funnel. Add 3.0 cm^3 of concentrated hydrochloric acid and dilute to 10 cm^3. Add 10 cm^3 of 0.005% m/V NPBHA in chloroform and equilibrate for 3–5 min.

Second extraction

Withdraw 5.0 cm^3 of the organic phase from the first extraction and transfer it into a separating funnel. Add 2.0 cm^3 of 0.025% m/V PF in ethanol. Then add 5.0 cm^3 of a solution which is 0.25 *M* with respect to hydrochloric acid and 0.64 *M* with respect to sodium chloride. Equilibrate for 1 min. After 20 min, measure the absorbance of the organic phase at 518 nm against a reagent blank.

The solution of PF in ethanol was prepared by mixing 1.0 cm^3 of 0.3% m/V PF in dimethylformamide with 10.0 cm^3 of ethanol. In this way, it is possible to achieve a greater solubility of PF in ethanol. This preparation was done daily.

Results and discussion

Absorption spectra and the composition of the extracted species Mo(VI)—NPBHA—PF

Molybdenum(VI) forms a colourless complex with NPBHA. This complex on the second extraction with phenylfluorone forms an intensely coloured complex possessing a prominent

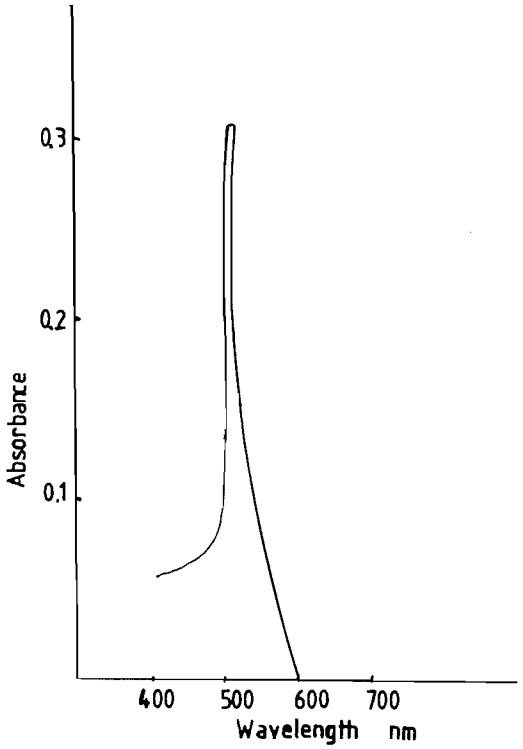

FIG. 1. Absorption spectra of Mo(VI)—NPBHA—PF complex in chloroform against a reagent blank. Mo(VI) = 0.5 ppm, NPBHA = 0.005% m/V in chloroform, PF = 0.025% m/V in ethanol.

absorption maximum at 518 nm against a reagent blank (Fig. 1). Job's method of continuous variation was applied to Mo(VI)—NPBHA by keeping the concentration of PF in excess. The Job's plot (Fig. 2(*A*)) obtained in this manner suggests the formation of a 1:2 complex between molybdenum(VI) and NPBHA. The second Job's plot (Fig. 2(*B*)) was obtained by keeping the stoichiometric ratio of molybdenum(VI) to NPBHA at 1:2, which reveals the stoichiometry of the complex Mo(VI):NPBHA:PF as 1:2:1. Greater curvature of graph *A* compared with graph *B* reveals a strong bonding between molybdenum(VI) and PF.

The absorbance at 518 nm increases with time and reaches a maximum about 20 min after the second extraction. This remains constant even 2 h after the second extraction if the organic phase is separated from the aqueous phase soon after the extraction.

Effect of concentration of hydrochloric acid and chloride ions

The concentration of hydrochloric acid in the first extraction was varied from 1.0 to 11.0 *M* and the concentration was determined by titrating with a standard solution of sodium carbonate (0.05 *M*) using methyl orange as the indicator. The optimum concentration of hydrochloric acid that could be used for the first extraction of molybdenum with NPBHA was found to be in the range 3.0–5.5 *M*.

In the second extraction, the concentration of hydrochloric acid was varied from 0.06 to 0.5 *M* maintaining the chloride ion concentration at 0.5 *M*. The results indicate that the optimum concentration of hydrochloric acid is 0.25 *M* (Table 1), which is equivalent to a calculated pH of 0.6. Variation of the concentration of chloride ions at optimum concentration of hydrochloric acid reveals (Table 2) that absorbance is highest at 0.64 *M* chloride ion concentration.

At low acidities (high pH) the Mo(VI)—NPBHA—PF complex breaks down due to hydrolysis of molybdenum(VI) and also due to the formation of an insoluble red complex of Mo(VI)—PF (Table 1). With increasing concentration of hydrochloric acid, beyond 0.25 *M*, the organic phase became more yellow in appearance, and was accompanied by a decrease in absorbance at 518 nm against a reagent blank. The protona-

TABLE 4. Tolerance limits for diverse ions in the determination molybdenum(IV) by the proposed method

Foreign ion	Tolerance limit (ppm)	Molar ratio Mo(V):ion
Vanadium(V) and vanadium(IV)*	—	—
Titanium(IV)†	12.5	50
Zirconium(IV)	20.0	42
Fluoride	100.0	1010
Oxalate	800.0	1744
Phosphate	300.0	606

*In the presence of sodium metabisulphite.
†In the presence of 800 ppm of oxalate.

tion of PF at high acidities (low pH) may lead to a break down of the Mo(VI)—NPBHA—PF complex. The variation of the chloride ion concentration also reveals a somewhat similar effect (Table 2), indicating that chloride ions are involved in complex formation. However, concentrations of chloride ions above 0.64 *M* lead to a break down of the mixed ligand complex.

Effect of concentrations of the reagents (NPBHA and PF)

The absorbance of the Mo(VI)—NPBHA—PF complex at 518 nm increases with increasing concentration of NPBHA and reaches a maximum when the concentration of NPBHA in chloroform is maintained around 0.005% m/V. This corresponds to a 59-fold molar excess of NPBHA. The observed decrease in absorbance at low NPBHA concentrations may be due to incomplete extraction of molybdenum(VI). Higher NPBHA concentrations are undesirable, probably owing to increased interaction between NPBHA and PF, resulting in a decrease in interaction with molybdenum(VI), thus giving lower absorbance values.

The absorbance at 518 nm reaches a maximum when the concentration of PF is in 60-fold molar excess. A decrease in absorbance at lower and higher concentrations has been observed. At higher concentrations of PF, a practical difficulty arose as a result of precipitation. This can be accounted for by the formation of a Mo(VI)—PF complex, which in general is not soluble in the organic phase and also not extracted by the chloroform–ethanol organic phase (4).

Effect of different alcohols

Table 3 shows that ethanol gives the highest absorbance values among the five alcohols investigated. The results in the Table 3 were obtained while keeping the chloroform:alcohol ratio at 5:2 by volume.

Verification of Beer's law

The verification of Beer's law was carried out under optimum conditions. They were NPBHA = 0.005% m/V in chloroform, HCl = 4.0 *M* (first extraction), PF = 0.025% m/V in ethanol, HCl = 0.25 *M* (second extraction) and shaking time of 4 min. The system obeys Beer's law at 518 nm up to 0.6 ppm of molybdenum(VI). A negative deviation has been observed at higher concentrations. The molar absorptivity at 518 nm was $7.4 \times 10^4\ dm^3\ mol^{-1}\ cm^{-1}$. A plot of Beer's law gave a highly precise, reproducible straight line calibration graph that passed through the origin.

Effect of diverse ions

The system was found to tolerate a large excess of cobalt(II), chromium(III), copper(II), aluminium, manganese, zinc, nickel, iron, thorium, and lanthanum(III). The tolerance limit was considered as the amount of foreign ion causing a deviation of more than 0.02 absorbance. There is interference from titanium(IV), tungsten(VI), vanadium(V) and vanadium(IV). The interference from vanadium(V) and vanadium(IV) can be completely eliminated by the addition of sodium metabisulphite. As the system can tolerate a 1700-fold molar excess of oxalate (Table 4), the ability of titanium to form stable complexes with oxalate more readily than molybdenum was taken into consideration. It was observed that in the presence of a 1700-fold molar excess of oxalate (approximately 800 ppm) the system was capable of tolerating a 50-fold molar excess of titanium without affecting the overall sensitivity appreciably.

Application of the method

The proposed spectrophotometric method was applied to the determination of molybdenum in standard low alloy steel samples. Steel sample number 401 (B.C.S.), containing 1.03% molybdenum, was analysed and was found to contain 1.03% molybdenum. Similarly, sample 406 (B.C.S. certified value 0.53% molybdenum) was found to contain 0.52%. A sample containing an apatite matrix was also analysed for molybdenum using the proposed method. The results obtained were comparable to those obtained by inductively coupled plasma emission spectroscopy (ICP). The ICP analyses reported the following elements in the sample were molybdenum = 0.54 ppm, iron = 22.05 ppm, aluminium = 11.50 ppm, vanadium = 0.13 ppm, calcium = 214.00 ppm, manganese = 1.46 ppm, zinc = 0.13 ppm, cadmium = 0.01 ppm, copper = 0.11 ppm, and strontium = 2.16 ppm. The concentration of molybdenum in the sample obtained by the proposed method was 0.50 ± 0.016 ppm.

Highly sensitive and selective spectrophotometric methods of this nature will find many advantages in the determination of unbound or "free" concentrations of molybdenum (7), provided that the concentration of the bound species of molybdenum is unaffected by 3–5 *M* hydrochloric acid NPBHA in chloroform.

Illumination of aqueous or organic solutions of nitrofurazone, **1**, with fluorescent or tungsten light caused the appearance of two new compounds, **2** and **3**. Compound **2**, which eluted just before nitrofurazone on a reverse phase hplc column, had a mass spectrum identical to that of **1** and converted back to **1** at a rate proportional to the temperature and the polarity of the solvent when allowed to sit in the dark. High resolution proton nmr spectroscopy provided conclusive evidence that compound **2** is the *syn* isomer of **1**. Compound **3** had a retention time, ultraviolet spectrum, and mass spectrum that were indistinguishable from those of synthetic 5-nitrofuraldehyde azine. The toxicity of **3** to *E. coli* was determined to be the same as **1** while its mutagenicity was over 10-fold lower. No detectable cross-links were formed in the DNA of *E. coli* in the presence of compound **3**. Thus, it is unlikely that the relatively small amounts of the azine **3** formed have much influence on the antibacterial potency or mutagenicity of nitrofurazone solutions. However, these results do confirm the desirability of conducting experiments with these agents in the dark or under yellow light. Photochemical formation of *syn* isomers was also observed with two other Schiff's base nitrofuran derivatives, nitrofurantoin and furazolidone.

L'irradiation de solutions aqueuses ou organiques de nitrofurazone (**1**) par de la lumière fluorescente ou au tungstène conduit à l'apparition des deux nouveaux composés, **2** et **3**. Le spectre de masse du composé **2**, qui est élué juste avant la nitrofurazone par clhp en phase inverse, est identique à celui du composé **1** et, lorsqu'on le laisse reposé dans un solvant à l'abri de la lumière, il se retransforme dans le composé **1** à une vitesse qui est proportionnelle à la température et à la polarité du solvant. La rmn ^1H à haute résolution a permis de démontrer sans ambiguïté que le composé **2** est l'isomère *syn* du composé **1**. Les temps de rétention et les spectres de masse et ultraviolet du composé **3** ne peuvent être différenciés de ceux de l'azine synthétique du nitro-5 furaldéhyde. On a déterminé que la toxicité du composé **3** pour l'*E. coli* est la même que celle du composé **1** et que sa mutagénicité est dix fois moindre. On n'a pas pu détecter de réticulation de l'ADN du *E. coli* en présence du composé **3**. Il semble donc peu probable que les petites quantités de l'azine **3** qui se forment puissent influencer le pouvoir antibactérien ou la mutagénicité de solutions de nitrofurazone. Toutefois, nos résultats confirment qu'il est désirable d'effectuer, avec ces agents, des expériences à l'abri de la lumière ou en présence de lumière jaune. On a aussi observé la formation photochimique des isomères *syn* avec deux autres bases de Schiff dérivées du nitrofuranne, soit la nitrofurantoïne et la furazolidone.

[Traduit par la revue]

Introduction

Nitrofurans are used as antibacterial agents in clinical and veterinary medicine and as additives to feed for livestock (see review in ref. 1). In the course of examining the bacterial metabolism of one of these agents, nitrofurazone, **1**, using reverse phase high performance liquid chromatography (hplc) we observed two new compounds which retained the strong absorption band near 370 nm. These compounds were not observed in the absence of nitrofurazone but were formed even in the absence of bacteria. Further analysis showed that both of these compounds are photoproducts formed from nitrofurazone by laboratory illumination. We show here that one of these compounds is the *syn* isomer of nitrofurazone, **2**, and that the other is the 5-nitro-2-furaldehyde azine, **3**. We also show that the azine is a considerably weaker mutagen than nitrofurazone and that it does not induce the formation of cross-links in DNA in *E. coli*.

Experimental

Materials

Hydrazine hydrate, semicarbazine hydrochloride, and 5-nitro-2-furaldehyde diacetate were purchased from Aldrich Chemical. Nitrofurantoin and furazolidone were purchased from Sigma Chemical. HPLC-grade methanol and acetonitrile were purchased from Caledon Chemicals and HPLC-grade water was produced with a Millipore Milli-Q purification unit.

Synthesis

5-Nitro-2-furaldehyde, **4**, was prepared by hydrolysis of the

5-nitro-2-furaldehyde diacetate (3). Nitrofurazone (**1**, 2-[[5-nitro-2-furanyl]methylene]-hydrazinecarboxamide) was prepared by condensing 5-nitro-2-furaldehyde, **4**, with semicarbazide (2) and was purified by recrystallization and silica gel column chromatography. The 5-nitro-2-furaldehyde azine, **3**, was prepared by condensation of 3.0 g (0.02 mol) of **4** with 0.5 g (0.01 mol) of hydrazine hydrate (4). The hydrazone of 5-nitro-2-furaldehyde, **5**, was prepared from 5-nitro-2-furaldehyde diacetate and hydrazine hydrate (5).

Photolysis by fluorescent illumination

Nitrofurazone (0.05 mg/mL) in 200 mL Davis Mingioli culture medium (6) was exposed for 1 h at 37°C to light from standard cool white fluorescent laboratory illumination or incubated under the same conditions in the dark. Aliquots of these solutions (10 mL) were extracted with equal volumes of ethyl acetate, the organic extracts were evaporated and the residues dissolved in 0.5 mL methanol for analysis. The samples were protected from light during these steps.

Photolysis by tungsten illumination

Solutions of nitrofurazone (0.1 mg/mL) in water, methanol, or tetrahydrofuran were illuminated for 5 min with a Sylvania tungsten photographic lamp (type ECT, 500 W) at a distance of 7 cm while immersed in an ice bath. Analyses were performed directly on these solutions before and after illumination.

A solution of nitrofurazone (1.0 mg/mL) in methanol-d_4 was similarly illuminated for 50 min. High performance liquid chromatographic and nmr analyses were performed on this solution before and after illumination.

Chromatography and ultraviolet spectroscopy

High performance liquid chromatographic analyses were performed using a Hewlett-Packard model HP1090 liquid chromatograph with detection and ultraviolet spectrum scanning provided by a built-in HP1040A photodiode array detector (set to scan 200 to 400 nm every 2 s). A Beckman reverse phase hplc column (5 μm Ultrasphere-ODS, 25 cm × 4.6 mm id) was operated with 1 mL/min flow rate and a gradient elution that started at 10% aqueous methanol and was programmed linearly first to 50% methanol in 13 min and then to 100% methanol in a further 3 min. Samples were injected with a 20 μL Rheodyne injector. Separated compounds were isolated for further analysis by collecting eluent at the detector outlet into glass tubes protected from light.

Mass spectrometry

Electron ionization mass spectra were acquired on a VG7070F mass spectrometer with an electron energy of 70 eV and a source temperature of 200°C. Samples were introduced either via the solid probe inlet or via the hplc and the VG moving belt lc/ms interface. Only 20% of the hplc eluent was taken to the lc/ms interface and an infrared evaporator was used to evaporate the solvent prior to the vacuum lock system.

Nuclear magnetic resonance spectroscopy

Proton nmr spectra were obtained at 500 MHz on a Brucker AM-500 spectrometer.

Mutagenicity assays

With *Escherichia coli* WP2 and WP2 *uvr A* the "treat and plate" protocol described by Green and Muriel (7) was followed. Assays with *Salmonella typhimurium* were carried out as described by Ames *et al.* (8). Bacteria were exposed to the azine, **3**, for 20 min before plating.

Crosslinking assay

E. coli B/r of WP2 *uvr A* (8×10^{10} bacteria in 200 mL) were exposed to 1 μg/mL mitomycin C and 1 or 5 μg/mL of **3** in a 37°C water bath for 60 min. DNA was isolated as described by Marmur (9).

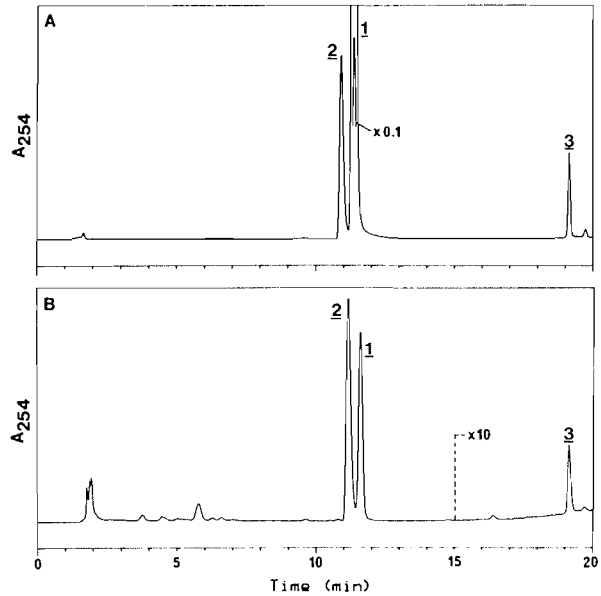

FIG. 1. Reverse phase hplc chromatograms with detection at 254 nm of: (*A*) nitrofurazone in Davis Mingioli culture medium exposed for 1 h to light from fluorescent laboratory illumination; (*B*) nitrofurazone in methanol exposed for 5 min to high intensity tungsten illumination.

The percentage reversibility of DNA denaturation was estimated using the general procedure described by Rutman *et al.* (10).

Results

Figure 1*a* shows the chromatogram resulting from the reverse phase hplc analysis of a solution of nitrofurazone in Davis Mingioli culture medium that had been incubated at 37°C and exposed to laboratory fluorescent illumination for 1 h. An identical solution that had been kept in the dark under the same conditions showed only nitrofurazone, **1**, to be present. Thus, compounds **2** and **3** are formed as a result of a photochemical reaction of nitrofurazone. High performance liquid chromatographic analysis of a methanolic solution of nitrofurazone that had been exposed to intense tungsten illumination for 10 min at 0°C gave the chromatogram shown in Fig. 1*b*. A maximum yield of **2**, approximately equal to that of **1**, was achieved within 5 min of exposure. In addition to a small amount of compound **3**, a number of polar products with short retention times were also observed. Through the use of a combination of hplc with a scanning photodiode array detector and with a mass spectrometer (equipped with a moving belt lc/ms interface), the ultraviolet and mass spectra were acquired for compounds **2** and **3** (see Figs. 2 to 4).

The mass spectrum of compound **2** (see Fig. 3) is identical to that of nitrofurazone, showing a molecular ion at m/z 198 and fragment ions due to loss of OH from the nitro group (m/z 181) and HNCO from the amide group (m/z 155). The facts that compounds **1** and **2** have the same molecular weight and very similar ultraviolet spectra (see Fig. 2) suggested that the two compounds are geometrical isomers. This was supported by the observation that, as the exposed solutions sat in the dark, the concentration of compound **2** decreased while that of **1** increased proportionately. The rate of the dark reaction was proportional to temperature, supporting a thermally induced *syn/anti* isomerization. When compound **2** was isolated by hplc and then re-chromatographed, both compounds **1** and **2** were again observed due to isomerization during the time between peak collection and re-injection.

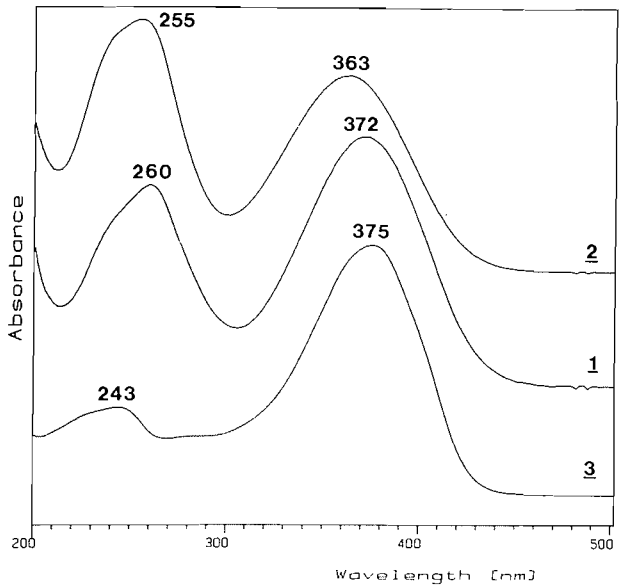

FIG. 2. Ultraviolet spectra for compounds **1** to **3**.

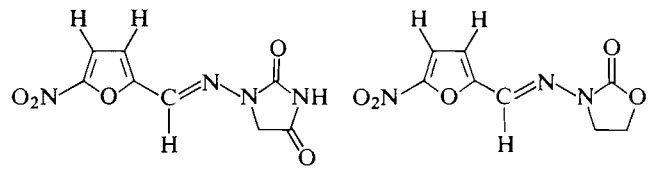
A nitrofurazone solution in methanol-d_4 was examined by high resolution proton nuclear magnetic resonance spectroscopy before and after exposure to tungsten illumination; the nmr spectra are shown in Fig. 5. Before irradiation nitrofurazone showed three resonances at 7.025 (doublet), 7.509 (doublet), and 7.777 (singlet) ppm; after irradiation, in addition to these resonances, three new ones appeared at 7.102 (doublet), 7.243 (singlet), and 7.578 (doublet) ppm. The greatest change in chemical shift was observed for the imino C—H proton which underwent an upfield shift of 0.534 ppm. Similar upfield shifts have been observed in the *syn* isomers of a wide range of hydrazones, oximes, and related compounds (11). Thus, the unstable product from irradiation of compound **1** is the *syn* isomer of nitrofurazone, compound **2**.

When different solvents were used for the photolysis experiments, it was observed that the rate of thermal isomerization of the *syn* to *anti* isomer depended on the polarity of the solvent. The $t_{1/2}$ values for water, methanol, and tetrahydrofuran were very roughly estimated to be in the order of 1 min, 1 h, and 10 h, respectively. Since the mobile phase used in the hplc experiments is aqueous methanol, we should expect some conversion of **2** to **1** during the time period of the chromatographic experiment. Evidence for this isomerization is apparent from the chromatograms in Fig. 1, where the peak for compound **2** is wider and more asymmetric than that for compound **1**. To provide further evidence for on-column isomerization, isocratic elutions were conducted at elevated column temperatures. Unfortunately, an increased column temperature resulted in a decreased separation factor. At 50°C the peaks were fused together so that any increased tailing could not be observed. Using acetonitrile in place of methanol gave poorer resolution of **1** and **2** at any temperature. The polarity of the solvent used in the photolysis did not appear to substantially affect the yield of **3**.

Chromatographic analysis of the illuminated solutions of two other Schiff's base nitrofuran derivatives, **6** (nitrofurantoin) and **7** (furazolidone), revealed in each case a new peak which eluted



6 **7**

just before the original nitrofuran. Re-chromatography of these products gave the original as well as the more rapidly eluting material. Therefore, we conclude that these compounds also undergo a light induced *anti*/*syn* isomerization.

Compound **3** was much less polar than the nitrofurazone but retained the absorption maximum near 370 nm (see Fig. 2) suggesting that it contained one or more intact nitrofuran groups attached to a side chain having conjugated double bonds. The mass spectrum of **3** revealed a molecular weight of 278. The azine of 5-nitro-2-furaldehyde was synthesized and compared with the compound produced in the photolysis mixtures; the mass spectrum, ultraviolet spectrum and retention time of the synthetic azine were identical to compound **3**.

It was of interest to determine whether the azine would have an appreciable influence on the antibacterial potency or mutagenicity of nitrofurazone solutions. Tests with *E. coli* showed that the azine is toxic to the WP2 strain and its *uvr A* derivative and mutagenic to the *uvr A* strain. However, in comparison with nitrofurazone the azine was a rather weak mutagen giving 14-fold fewer mutations at 180 μM than nitrofurazone. Somewhat unusual results were obtained when the azine was tested with *S. typhimurium* TA98 in the standard plate assay. Without added S-9 extract, the azine gave a weakly positive result at 2.5 μg/plate. At higher concentrations the chemical precipitated out and no colonies were seen on the plates. However, in the presence of S-9 preparation from the livers of Arochlor-1254
