dl-*Gephyrotoxin 223AB hydrobromide*: A solution of the free base in methanol was acidified with hydrogen bromide in methanol, the solvent removed *in vacuo*, and the salt recrystallized from acetone. It formed flat needles with mp 147–150°C. Good-sized crystals grown slowly from acetone were used for X-ray crystallography (13). Its mass spectrum gave peaks at *m/z* 223 (2.8) (M^+), 222 (2.7), 180 (93), and 166 (100).

[9]This stereochemical designation gives the relation (*Z* = *syn*, *E* = *anti*) of the 5- and 9-hydrogens to the 3-hydrogen.

MARK TISCHLER, STEPHEN W. AYER, RAYMOND J. ANDERSEN, JOHN F. MITCHELL, and JON CLARDY. Can. J. Chem. **66**, 1173 (1988).

Four new steroids, anthosterone A (**5**), anthosterone B (**6**), and the Δ^4-3,6-diketo steroids **7** and **8**, have been isolated from the sponge *Anthoarcuata graceae*. The structures of anthosterones A (**5**) and B (**6**) were deduced from their spectral data and verified via single crystal X-ray diffraction analysis on **5**. The proposed structures for steroids **7** and **8** were based on spectral analysis and confirmed by synthesis of a model compound **12**. Anthosterones A and B represent the first examples of a new type of ring A contraction in a steroid nucleus.

MARK TISCHLER, STEPHEN W. AYER, RAYMOND J. ANDERSEN, JOHN F. MITCHELL et JON CLARDY. Can. J. Chem. **66**, 1173 (1988).

À partir de l'éponge *Anthoarcuata graceae*, on a isolé quatre nouveaux stéroïdes, l'anthostérone A (**5**), l'anthostérone B (**6**) et les Δ^4 dicéto-3,6 stéroïdes **7** and **8**. On a déterminé les structures des anthostérones A (**5**) et B (**6**) en se basant sur leurs données spectrales et on les a vérifiées à l'aide d'une analyse par diffraction de rayons-X sur un cristal unique du composé **5**. On a proposé les structures des stéroïdes **7** et **8** en se basant sur des analyses spectrales et on les a confirmées en procédant à la synthèse du composé modèle **12**. Les anthostérones A et B sont les premiers exemples de stéroïdes comportant un nouveau type de contraction du cycle A.

Marine sponges continue to be a prolific source of interesting new steroids (1). Commonly encountered features in these compounds include: (*i*) A-nor skeletons of general structures **1** (2) and **2** (3), (*ii*) additional oxygenation of both the nucleus and the side chain (4), and (*iii*) side chains that have been extensively modified by alkylation and (or) degradation (5).

Several years ago we reported the isolation of the two cholestenone derivatives **3** and **4** from skin extracts of the dorid nudibranch *Aldisa sanguinea cooperi* (6). Specimens of *A. cooperi* are normally found deeply embedded in the sponge *Anthoarcuata graceae* from which they obtain nutrition and cryptic pigmentation. As part of an ongoing investigation of the origins of nudibranch skin chemistry (7), we undertook a careful examination of the steroids present in extracts of *A. graceae* to determine if compounds **3** and **4** were being sequestered by the nudibranchs directly from their sponge diet. As previously reported (6), we failed to find any evidence for the presence of either **3** or **4** in *A. graceae* extracts; however, we have found four new steroids, compounds **5–8**, whose structures are presented in this manuscript.

Anthoarcuata graceae was collected by hand using SCUBA on shallow rocky reefs (−2 to −15 m) along the shoreline of the Deer Group of Islands in Barkley Sound, British Columbia. Freshly collected sponge was homogenized in a Waring blender with methanol and extracted at room temperature for periods of up to a week. The methanol was removed via vacuum filtration, concentrated *in vacuo* to an aqueous suspension, and the suspension was partitioned between water and dichloromethane. The resulting sponge solids were extracted three additional times with dichloromethane at 1-day intervals. Combination and reduction of all the dichloromethane solutions gave a dark red oil. Fractionation of the red oil by sequential application of silica-gel flash, Sephadex LH-20, reverse phase hplc, and preparative thin-layer silica-gel chromatographies gave pure samples of anthosterones A (**5**) and B (**6**) and the Δ^4-3,6-diketosteroids **7** and **8**.

Anthosterone A (**5**), obtained as white needles (mp 142–143°C) from acetonitrile, gave a parent ion in the EI hrms at m/z 442.3083 daltons that was consistent with a molecular formula of $C_{28}H_{42}O_4$ (ΔM + 0.4 mmu). The ultraviolet spectrum of **5** showed a single absorption with λ_{max} 250 nm (ε 12 500), and its infrared spectrum had absorption bands at 3532, 1744, and 1717 cm^{-1} that were assigned to alcohol, ester carbonyl, and α,β-unsaturated cyclopentenone carbonyl functionalities respectively. A methyl resonance at δ 3.79 (s) ppm in the ^1H nmr spectrum of **5**, in conjunction with a mass spectral fragment at m/z 383 daltons ($M^+ - 59$; CO_2CH_3) and the ester carbonyl stretch in the infrared spectrum, indicated that anthosterone A was a methyl ester. The remainder of the ^1H nmr spectrum of **5** was typical of a steroid. Resonances at δ 0.73 (s), 0.96 (d, J = 6.7 Hz), and 1.21 (s) ppm were assigned to the C18, C21, and C19 methyl protons respectively. A pair of resonances at δ 1.69 (s) and 1.62 (s) ppm assigned to the protons on olefinic methyl groups at C26 and C27, and an olefinic resonance at δ 5.10 (t, J = 8 Hz) ppm assigned to H24, revealed that anthosterone A had a standard Δ^{24} steroid side chain. An intense fragment ion at m/z 329 daltons (rel. int. 41%, $M^+ - (C_8H_{15} + H_2)$) in the mass spectrum of **5** (8), and a close agreement between the chemical shifts of ^{13}C nmr resonances assigned to the side-chain carbons of **5** (Table 2) and values for model compounds (9) confirmed the nature of the side chain.

Subtracting the methoxy carbon of the ester functionality from the 28 carbons in the molecular formula of anthosterone A (**5**) left the 27 carbons of a standard steroid skeleton. All of the

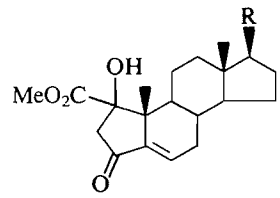
one-carbon appendages of the standard skeleton (carbons 18, 19, 21, 26, and 27) could be accounted for in the ^{1}H nmr spectrum of **5** as indicated above, and it was apparent that there were no additional alkyl substituents in the side chain. We concluded, therefore, that the primary carbon represented by the methyl ester carbonyl had been exposed by a contraction of one of the rings of the nucleus.

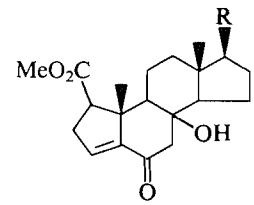
A number of additional fragments of **5** could be identified from spectral data. The ^{1}H nmr resonances at δ 2.10 (d, J = 13.3 Hz) and 2.19 (d, J = 13.3 Hz) ppm were assigned to a pair of spin-isolated geminal protons. The ^{13}C nmr resonances at δ 200.9 (s), 145.1 (s), and 136.3 (d) ppm, an ^{1}H nmr resonance at δ 6.73 (t, J = 3.3 Hz) ppm, the ir band at 1717 cm^{-1}, and the uv chromophore were assigned to an α,β-disubstituted-α,β-unsaturated ketone. Finally, a ^{13}C nmr resonance at δ 79.9 (s) ppm and the OH stretching band in the ir spectrum were assigned to a tertiary alcohol.

We were able to construct only the three candidate structures **5, 9**, and **10** that could accommodate all the identified fragments of anthosterone A. Nuclear magnetic resonance experiments allowed us to eliminate two of the possible structures. Application of a soft pulse to the geminal proton at δ 2.19 ppm in a SINEPT experiment, optimized for polarization transfer through 2- and 3-bond ^{1}H,^{13}C couplings (J = 7 Hz), showed transfer to the ester carbonyl (δ 173.4), the ketone carbonyl (δ 200.9), the tertiary carbinol (δ 79.9), and the fully substituted olefinic (δ 145.1) carbon resonances. The observed polarization transfer to the ester carbonyl carbon would require a highly improbable six-bond ^{1}H,^{13}C coupling in structure **10**. An ^{1}H COSY spectrum of anthosterone A showed a correlation between the downfield doublet of the isolated geminal spin system at δ 2.19 ppm and the methyl resonance at δ 1.21 ppm assigned to the protons on the C19 methyl group. The observed correlation could only be attributed to a W coupling between the C19 methyl protons and an α proton on Cl of structure **5**. With the constitution of anthosterone A (**5**) in hand, all that remained was to determine the relative stereochemistry at C2. This was accomplished by carrying out an acetylation reaction on anthosterone B (**6**).

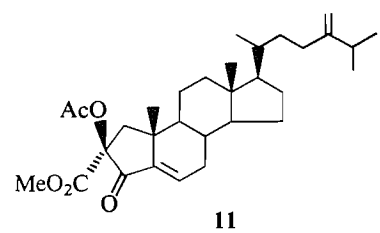
Anthosterone B (**6**), obtained as white needles (mp 155–157°C, acetonitrile), gave a parent ion at m/z 456.3236 daltons in the EI ms appropriate for a molecular formula of $C_{29}H_{44}O_4$ (ΔM + 0.5 mmu). It was apparent from the ^{1}H (Table 1) and ^{13}C nmr (Table 2) spectra of **6** that it contained the same ring A contracted nucleus as anthosterone A (**5**). The ^{1}H nmr resonances at δ 1.04 (d, J = 6.5 Hz, 6H), 4.67 (s), and 4.73 (s) ppm could be assigned to isopropyl and olefinic methylene fragments in the side chain of anthosterone B (**6**). Mass spectral fragments at m/z 382 ($M^+ - (CO_2CH_3 + CH_3)$) and 298 (382 − C_6H_{12} via a McLafferty rearrangement) daltons indicated that the olefinic methylene was at C24 of the side chain. Comparison of the chemical shifts of the ^{13}C nmr resonances assigned to the side chain carbons of **6** (Table 2) with the chemical shifts of the corresponding carbons in model compounds confirmed this assignment (10). Acetylation of anthosterone B (**6**) with acetic



9



10



11

anhydride and pyridine gave the mono acetate **11**. The ^{1}H nmr resonance assigned to the C19 methyl protons showed an upfield shift (δ 1.20 in **6**; δ 1.10 in **11**) and the resonances assigned to the Cl methylene protons showed a downfield shift (δ 2.10 and 2.18 in **6**; δ 2.47 and 2.65 in **11**) in the spectrum of acetate **11**. These acetylation shifts confirmed the spatial proximity of the tertiary alcohol, isolated methylene, and C19 methyl groups in **6**, and they required that the tertiary alcohol and the C19 methyl group be *cis* to each other. The complete structures of anthosterones A and B could therefore be represented as **5** and **6**.

To verify that our structural assignments for **5** and **6** were correct, we subjected anthosterone A (**5**) to single crystal X-ray diffraction analysis.

Crystal data:

reflections (0,0,10; 4,0,0; 0,0,2) were monitored at every 100 reflections during the data collection. No decrease of the intensities of the check reflections was observed and their variation was less than 10%. Of the 2061 reflections measured, only 929 (45%) were judged observed ($|F_o| > 3\sigma(F_o)$) due to the poor quality of the crystal.[2]

A phasing model was found using direct methods, and recycling of a plausible molecular fragment revealed the entire heavy atom structure. Isotropic block diagonal least squares for the non-hydrogen atoms were terminated at R = 0.105. Block diagonal least-squares refinements with anisotropic non-hydrogen atoms and isotropic hydrogens have converged to a conventional crystallographic residual of 0.075, R_w = 0.098, S = 1.151. The function minimized was $\Phi = \Sigma\, w\Delta F^2$, where $w = 1/\sigma(F)^2$. The hydroxyl hydrogen atom was located in a difference map, all other hydrogen atomic positions were generated from assumed geometries, and the isotropic temperature factors for the hydrogen atoms were calculated from the B(eq) value of the atom to which they were bonded (B(H) = 1.1B(eq), Å^2). The highest peak in the final difference electron density map was 0.48 e Å^{-3}. No hydrogen atomic parameters were refined and no absorption correction was applied. The X-ray experiment did not define the absolute configuration. A computer generated perspective drawing of the final X-ray model is given in Fig. 1, the positional parameters and B(eq) values for the non-hydrogen atoms are given in Table 3, bond distances and angles are shown in Table 4. Additional crystallographic information is available.[3]

Two additional steroids, **7** and **8**, which had Δ^4-3,6-diketo nuclei and side chains identical to those found in anthosterones A (**5**) and B (**6**) respectively, were also isolated from *A. graceae* extracts. Steroid **7**, obtained as needles from acetonitrile (mp 92–93°C), gave a parent ion in the EI ms at m/z 396.3034 daltons that was consistent with a molecular formula of $C_{27}H_{40}O_2$ (ΔM − 0.4 mmu). An olefinic proton resonance at δ 6.19 (s) ppm in the ^{1}H nmr, carbonyl and olefinic carbon resonances at δ 202.4 (s), 199.6 (s), 161.1 (s), and 125.5 (d)

[2]All crystallographic calculations were done on a PRIME 9950 computer operated by the Cornell Chemistry Computing Facility. Principal programs employed are given in ref. 11.

[3]Atomic coordinates for this structure have been deposited and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

ppm in the ^{13}C nmr, carbonyl and olefinic double bond stretching bands at 1686 and 1643 cm^{-1} in the ir, and a uv chromophore with a λ_{max} at 249 nm were assigned to the Δ^4-3,6-diketo functionality in **7**. Compound **12**, prepared by Jones oxidation of cholesterol (12), served as a model for the Δ^4-3,6-diketo nucleus of **7**. The nmr, ir, and uv data collected on **12** were in excellent agreement with those assigned to the ene dione functionality of **7**. The ^1H nmr resonances at δ 1.61 (s, 3H), 1.69 (s, 3H), and 5.09 (t, J = 6 Hz, 1H) in the spectrum of **7** were assigned to the protons on C26, C27, and C24 of a Δ^{24} steroid

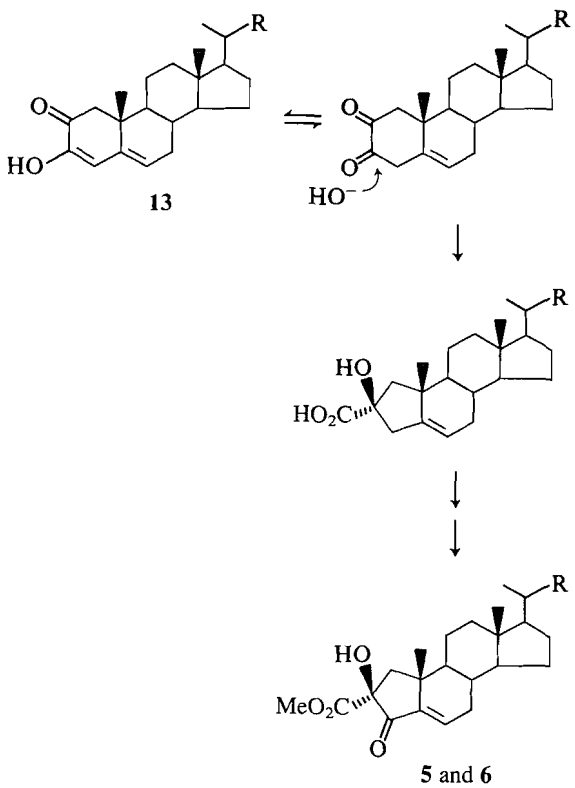

SCHEME 1

side chain. An intense mass spectral fragment at m/z 283 daltons ($M^+ - C_8H_{17}$ (side chain)) confirmed the nature of the side chain in **7** (8).

Steroid **8**, also obtained as needles from acetonitrile (mp 111–112°C), gave a parent ion in the EI ms at m/z 410.3182 daltons consistent with a molecular formula of $C_{28}H_{42}O_2$(ΔM − 0.5 mmu). It was immediately apparent from the ^1H and ^{13}C nmr spectra of **8** that it shared the Δ^4-3,6-diketo steroid nucleus with **7** and the $\Delta^{24,28}$ olefinic methylene side-chain functionality with **6** (Tables 1 and 2). The ms and uv data for this steroid were also consistent with structure **8**.

Anthosterones A (**5**) and B (**6**) apparently represent the first examples of ring A contracted steroids in which there is a one-carbon appendage at C2 of the cyclopentane ring. All previously reported examples have a one-carbon appendage at C3 (i.e., general structure **1**). A benzilic acid rearrangement on an α diketone such as **13** represents a possible ring contraction step in the biosynthesis of the anthosterone nucleus (Scheme 1). The Δ^4-3,6-diketone nucleus in steroids **7** and **8** has not been previously reported from a natural source.

Experimental

The nmr spectra were recorded on Varian XL 300 and Bruker WH-400 spectrometers. Me_4Si was used as an internal standard. Low resolution mass spectra were recorded on an AEI MS902 spectrometer and high resolution mass spectra on an AEI MS50 spectrometer. The ir spectra were recorded on a Perkin Elmer 1710 Fourier transform spectrometer. The uv spectra were recorded on a Bausch and Lomb Spectronic 2000 instrument. Optical rotation measurements were recorded on a Perkin Elmer 141 polarimeter.

Merck silica gel (230–400 mesh) was used for flash chromatography and a Whatman Magnum 9 Partisil 10 ODS-3 column was used for preparative hplc. Sephadex LH 20 was used for molecular exclusion chromatography.

Anthoarcuata graceae (1.2 kg dry wt.) was collected with the aid of SCUBA on shallow rocky reefs (−2 to −15 m) in the Deer Group of Islands in Barkley Sound, British Columbia. Freshly collected sponge was immediately immersed in methanol (8L) and homogenized in a Waring blender. After extraction at room temperature for 1 week, the methanol was removed via vacuum filtration, concentrated *in vacuo* to an aqueous suspension (250 mL), and the suspension was partitioned between brine (750 mL) and dichloromethane (4 × 300 mL). The resulting sponge solids were extracted three additional times with dichloromethane (1.5 L) at 1-day intervals. The combined dichloromethane solutions were dried over Na_2SO_4, filtered, and concentrated *in vacuo* to give a dark red oil (46.9 g, 3.9% dry wt.).

Flash chromatography (step gradient from 100% hexane to 30% ethyl acetate/ 70% hexane) on the red oil gave a fraction containing a mixture of steroids, fats, and pigments. Sephadex LH20 chromatography (eluent 55% methanol/ 45% chloroform) largely removed the fats and pigments from the steroid mixture. Reverse phase hplc (eluent 10% water/90% aectonitrile) separated the steroid fraction, obtained from LH20, into two major fractions that each contained a mixture of two steroids. The fast running hplc fraction contained steroids **6** and **8**, while the slow running hplc fraction contained steroids **5** and **7**. Preparative tlc (silica gel, eluent: 5% methanol/95% dichloromethane) separated anthosterone B (**6**) from steroid **8**, and anthosterone A (**5**) from steroid **7**.

Anthosterone A (**5**): 7 mg, 6 × 10^{-4}% dry wt; mp 142–143°C (CH_3CN); uv (CH_3CN) λ_{max}: 250 nm (ε 12 500); ir ($CHCl_3$, cast): 3532, 3021, 2951, 2869, 1744, 1717, 1648 cm^{-1}; ^1H nmr (Table 1); ^{13}C nmr (Table 2) δ: 200.9, 173.4, 145.1, 136.3, 131.1, 125.1, 79.9, 56.3, 56.0, 55.9, 53.4, 49.7, 46.7, 42.9, 39.9, 36.1, 35.6, 32.3, 32.2, 28.1, 25.8, 24.7, 24.4, 22.1, 21.8, 18.7, 17.7, 12.0 ppm; EI hrms M^+: 442.3083 ($C_{28}H_{42}O_4$, ΔM + 0.4 mmu); EI lrms m/z: 442, 427, 383, 358, 329, 298, 283, 95, 81, 69(100%), 55.

Anthosterone B (**6**): 5 × 10^{-4}% dry wt; mp 155–157°C (CH_3CN); uv (CH_3CN) λ_{max}: 249 nm (ε 12 030); ir ($CHCl_3$, cast): 3022, 2929, 2856, 1744, 1717, 1643, cm^{-1}; ^1H nmr (Table 1); ^{13}C nmr (Table 2) δ: 200.9, 173.4, 156.8, 145.1, 136.3, 106.0, 79.9, 56.3, 55.9, 53.4, 49.6, 46.7, 42.9, 39.9, 39.3, 35.7, 34.6, 33.8, 32.3, 32.2, 31.0, 28.1, 24.3, 22.1, 22.0, 21.9, 21.8, 18.7, 12.0 ppm; EI hrms M^+: 456.3236 ($C_{29}H_{44}O_4$, ΔM + 0.5 mmu); EI lrms m/z: 456, 382, 367, 298, 269.

Acetylation of anthosterone B

Anthosterone B (**6**) (2.8 mg) was stirred overnight at room temperature in a mixture of pyridine (0.4 mL) and acetic anhydride (0.2 mL). The pyridine/acetic anhydride mixture was removed *in vacuo* to give anthosterone B acetate (**11**) in quantitative yield as a white solid. *Acetate* (**11**): ^1H nmr ($CDCl_3$) δ: 0.72(s, 3H), 0.97(d, J = 8 Hz, 3H), 1.03(d, J = 8 Hz, 6H), 1.10(s, 3H), 2.16(s, 3H), 2.47(d, J = 14 Hz, 1H), 2.65(d, J = 14 Hz, 1H), 3.76 (s, 3H), 4.67(bs, 1H), 4.73(s, 1H), 6.81(t, J = 4 Hz, 1H); EI hrms M^+: 498.3347 ($C_{31}H_{46}O_5$, ΔM 0.0 mmu).

Ene dione **7**: 3 × 10^{-4}% dry wt; mp 92–93°C; uv (CH_3CN) λ_{max}: 249 nm (ε 11 600); ir ($CHCl_3$, cast): 3031, 2956, 1686, 1643, 1606 cm^{-1}; ^1H nmr (Table 1); ^{13}C nmr (Table 2); EI hrms M^+: 396.3034 ($C_{27}H_{40}O_2$, ΔM + 0.4 mmu); EI lrms m/z 396, 326, 283, 243.

Ene dione **8**: 3 × 10^{-4}% dry wt; mp 111–112°C (CH_3CN); uv (CH_3CN) λ_{max}: 249 nm (ε 12 500); ^1H nmr (Table 1); ^{13}C nmr (Table 2); EI hrms M^+: 410.3182 ($C_{28}H_{42}O_2$, ΔM − 0.5 mmu); EI lrms m/z 410,327, 326, 312, 311, 283, 257.

Ene dione **12**: Prepared according to the literature (12); mp 132–134°C (CH_3CN); ir ($CHCl_3$, cast): 2953, 2871, 1685, 1606 cm^{-1}; ^1H nmr (Table 1); ^{13}C nmr (Table 2); EI hrms M^+: 398.3186 ($C_{27}H_{42}O_2$, ΔM − 0.1 mmu).

Excess molar volumes, V^E, and excess molar heat capacities at constant pressure, C_p^E, have been obtained for some *n*-alkanoate + *n*-alkane mixtures at 298.15 K from density and volumetric heat capacity measurements using liquid-flow techniques. The alkanoates selected were *n*-propyl methanoate, methyl ethanoate, ethyl ethanoate, methyl propanoate, methyl butanoate, methyl pentanoate, and methyl octanoate. V^E are positive for all systems and rather symmetric. The composition dependence of C_p^E is typically of the ω-shaped type with two minima, more or less pronounced, which are separated by a positive part in the case of the more polar esters, i.e. *n*-propyl methanoate and methyl ethanoate. These results are discussed in terms of possible changes in conformation of both the ester and the *n*-alkane.

MERCEDES PINTOS, RAMON BRAVO, MARIA CARMEN BALUJA, MARIA INMACULADA PAZ ANDRADE, GENEVIÈVE ROUX-DESGRANGES et JEAN-PIERRE E. GROLIER. Can. J. Chem. **66**, 1179 (1988).

Les volumes d'excès, V^E, et les capacités calorifiques d'excès, C_p^E, ont été obtenus pour quelques mélanges *n*-alcanoate + *n*-alcane à 298.15 K à partir de mesures des densités et des capacités calorifiques volumiques, à l'aide de techniques à écoulement de liquide. Les alcanoates choisis ont été le méthanoate de *n*-propyle, l'éthanoate de méthyle, l'éthanoate d'éthyle, le propanoate de méthyle, le butanoate de méthyle, le pentanoate de méthyle et l'octanoate de méthyle. Les volumes d'excès sont positifs et plutôt symétriques pour tous les systèmes. La variation avec la concentration des capacités calorifiques d'excès est représentée par des courbes avec deux minima plus ou moins marqués qui sont séparés par une partie positive dans le cas des esters les plus polaires tels que le méthanoate de propyle et l'éthanoate de méthyle. Ces résultats sont interprétés en terme de changements de conformations possibles, à la fois dans l'ester et l'alcane.

Binary mixtures of the type (an alkanoate + an *n*-alkane) have been investigated fairly extensively from a thermodynamic point of view. For our part, we have measured a number of heats of mixing and excess volumes (1), and recently we published a review paper (2) analysing the information available in the literature about the thermodynamic properties of this class of mixtures in terms of a quasi-chemical group contribution model. Ten years ago Dusart *et al.* (3) measured the excess volumes of binary mixtures with *n*-heptane of a series of methylalkanoates to investigate a possible cyclization of alkanoates in an aliphatic medium. With the availability of calorimetric techniques for precise measurements of heat capacities such mixtures are good candidates for a systematic study of these properties which are rather sensitive to molecular motions and interactions. Surprisingly, no data could be found for the heat capacities of such mixtures and this lack of information prevented us to extend the correlation of thermodynamic properties in a range of temperatures (2).

However, the main reason for the present investigation has to be found in our interest in binary liquid mixtures having an alkane as one component and a simple organic compound, Y, as the other. Indeed quite interesting mixing behavior has been observed with mixtures of the type (Y + an alkane) depending on the nature of second component Y. We have experimentally established that mixtures of this type usually exhibit a strong concentration dependence of excess heat capacities, C_p^E, (i.e. with mole fraction x of component Y). For example, if Y is a α,ω-dichloroalkane (4–6), a cyclic ether (7), or an alkanone (8) the $C_p^E(x)$ curves in the case of an *n*-alkane as second component are more or less ω-shaped (curves with two minima). Such behavior was also found by Benson and co-workers (9, 10) for Y being an aliphatic ether. Patterson and Saint-Victor (11) confirmed these results in the case of an alkanone. A similar concentration dependence has been observed in case of the more polar nitrobenzene and benzonitrile by Lainez *et al.* (12). Interestingly enough Patterson and co-workers (11) have shown that this type of concentration dependence also exists when the alkane is a branched alkane, what we indeed confirm with the binary mixtures (an alkanoate + a branched alkane) (13).

We have discussed this general behavior of thermodynamic properties in terms of destruction or creation of "order" and/or whenever possible, induced conformational changes in liquid *n*-alkanes, with respect to the situation existing in the pure liquid, and in terms of the change in the population of *gauche/trans* conformations (14). When Y is a "flexible" molecule which itself exhibits conformational equilibria, we suggested that cooperative induced conformational molecular "arrangements" may take place between Y and the aliphatic chains of the *n*-alkane (8). Therefore of particular interest were the studies of binary mixtures of a flexible molecule Y with a flexible cycloalkane such as cyclohexane. Indeed similar behavior (ω-shaped $C_p^E(x)$ curves) was also observed for 1,2-dichloroethane + cyclohexane and + methylcyclohexane (15),

[o]Values from Fortier *et al.* (22) adopted for the *n*-heptane used as the ultimate reference liquid in all our density and heat capacity measurements.

even more pronounced for 1,4-dioxane + cyclohexane (16) and, just recently, for a series of alkanoates with cyclohexane (17). On the ground of the results observed with branched alkanes Patterson and co-workers (11) have been advocating a more general explanation in terms of non-randomness which in our view most likely involves the conformational changes. Furthermore we agree with these authors that the closeness of the upper critical solution temperature (UCST) is an extreme case of non-randomness which would explain the marked concentration dependence observed when component Y is strongly polar (11–13).

Against this background of experimental studies and possible explanations we have determined the excess volumes, V^E, and the C_p^E of binary mixtures of some alkanoates with an *n*-alkane. As previously (17) the aliphatic esters were selected in order to make a comparative study between different isomers, namely in the $C_4H_8O_2$ series, *n*-propyl methanoate, ethyl ethanoate, and methyl propanoate. We also selected a polar 3-carbon alkanoate, methyl ethanoate, to compare with the more polar *n*-propyl methanoate. In addition, three methyl alkanoates of increasing chain length, methyl butanoate, methyl pentanoate, and methyl octanoate were chosen to investigate the influence of chain length on the concentration dependence of V^E and C_p^E.

The present paper reports C_p^E at 298.15 K for eleven binary mixtures: *n*-propyl methanoate ($HCOOC_3H_7$) with *n*-heptane and *n*-decane, ethyl ethanoate ($CH_3COOC_2H_5$) with *n*-heptane, *n*-decane, and *n*-tetradecane, methyl propanoate ($C_2H_5COOCH_3$) with *n*-heptane and *n*-decane, and with *n*-heptane only, methyl ethanoate (CH_3COOCH_3), methyl butanoate ($C_3H_7COOCH_3$), methyl pentanoate ($C_4H_9COOCH_3$), and methyl octanoate ($C_7H_{15}COOCH_3$). In addition, V^E are reported at the same temperature for the same systems but *n*-propyl methonate with *n*-decane which has been published elsewhere (18).

Experimental

Component liquids

Sources of the primary materials were as follows: ethyl ethanoate (puriss. p.a., with purity > 99.5 mol%), methyl propanoate (purum, with purity > 99 mol%), *n*-heptane (puriss. p.a. with purity > 99.5 mol%), *n*-decane (purum, with purity > 99 mol%), and *n*-tetradecane (puriss p.a., with purity > 99 mol%) from Fluka, propyl methanoate (synth., with purity > 98 mol%) and methyl ethanoate (synth., with purity > 99 mol%) from Merck. All these component liquids were used without further purification. The three methyl alkanoates, (butanoate, pentanoate, and octanoate) were prepared by direct esterification of the corresponding carboxylic acids, double distilled and purified chromatographically. Prior to the experimental measurements, the component liquids were carefully dried with molecular sieve beads (Union Carbide Type 4 A) from Fluka.

Density and heat capacity measurements

Mixtures were prepared by mass. The possible error in the mole fractions is estimated to be less than 10^{-4}. Densities, ρ, of the pure liquids and their mixtures were determined with a vibrating-tube densimeter (Sodev, model 02 D) operated in the flow mode. Before each series of measurements, the instrument was calibrated using a vacuum and doubly distilled and degassed water for which we used the density ρ(298.15 K) = 997.047 kg m^{-3} (19).

Excess molar volumes of a mixture with mole fraction x of the alkanoate

$$[1] \quad V^E = V - xV_1 - (1 - x)V_2$$

were obtained from the density ρ of the mixture according to the relation

$$[2] \quad V^E = xM_1(\rho^{-1} - \rho_1^{-1}) + (1 - x)M_2(\rho^{-1} - \rho_2^{-1})$$

where V_i, M_i, and ρ_i denote respectively the molar volume, molar mass, and density of pure component i (1 for alkanoate, 2 for *n*-alkane). Isobaric heat capacities per unit volume C_p/V were measured with a Picker flow calorimeter (from Setaram) equipped with gold cells, using the stepwise procedure. They were converted to isobaric molar heat capacities C_p using our densities. Isobaric excess molar heat capacities were then calculated from

$$[3] \quad C_p^E = C_p - xC_{p1} - (1 - x)C_{p2}$$

where C_{pi} is the molar heat capacity of pure component i.

For the vibrating-tube densimeter and the flow calorimeter, temperature control was better than ±0.003 K. Details of the experimental techniques and of the accuracy attainable for non-electrolyte mixtures may be found in previous publications; see, for example, refs. 20 and 21.

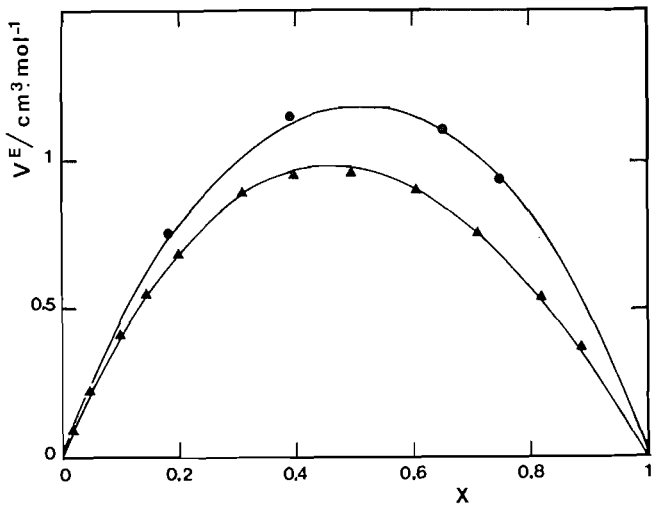

FIG. 1. Experimental excess molar volumes, V^E, at 298.15 K for xHCOOC$_3$H$_7$ + $(1-x)$C$_n$H$_{2n+2}$; ▲, n = 7; the curve was calculated from eq. [4] with coefficients from Table 3. ●, n = 10; the curve represents the smoothing function given by Sarmiento *et al.* (18).

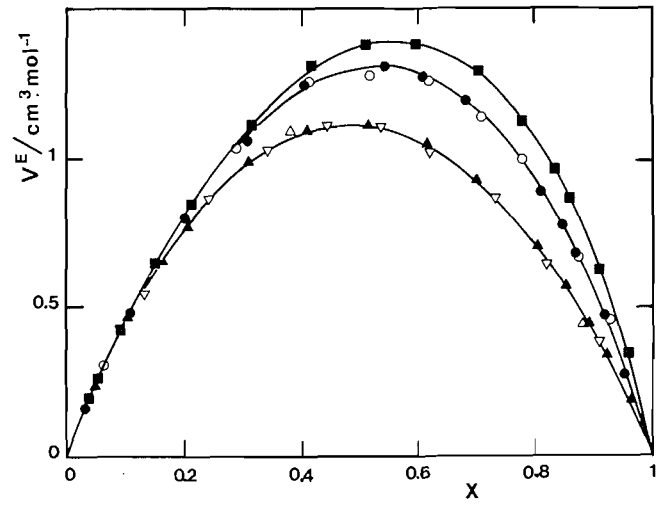

FIG. 2. Experimental excess molar volumes, V^E, at 298.15 K for xCH$_3$COOC$_2$H$_5$ + $(1-x)$C$_n$H$_{2n+2}$. With n = 7: ▲, present results; ▽, Grolier *et al.* (1); △, Dusart *et al.* (3). With n = 10: ●, present results; ○, Grolier *et al.* (1). With n = 14: ■, present results. The curves were calculated from eq. [4] with coefficients from Table 3.

Results and discussion

Experimental densities and heat capacities of the pure liquids are given in Table 1, where some literature values are given for comparison. Small discrepancies can be observed between the results from different sources but the overall agreement is satisfactory and we believe that our present results, particularly for the heat capacities of pure alkanoates, constitute reliable new data for these class of component liquids.

Experimental results for the excess molar volumes and the excess molar heat capacities at constant pressure are given in Table 2, while graphical representations are provided by Figs. 1–9. For each mixture, the excess quantities are fitted with a smoothing function of the form

$$[4]\quad Q^E = x(1-x)\sum_{i=0}^{n-1} A_i(2x-i)^i$$

where either $Q^E = V^E/(\text{cm}^3\ \text{mol}^{-1})$, or $Q^E = C_p^E/(\text{J K}^{-1}\ \text{mol}^{-1})$

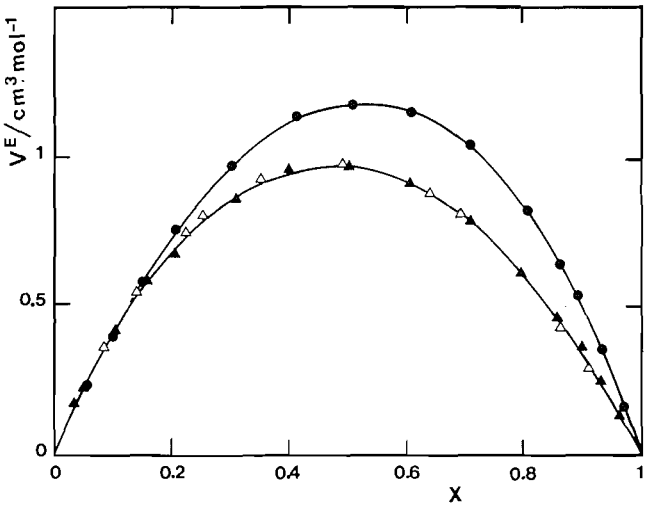

FIG. 3. Experimental excess molar volumes, V^E, at 298.15 K for xC$_2$H$_5$COOCH$_3$ + $(1-x)$C$_n$H$_{2n+2}$. With n = 7: ▲, present results; △, Dusart *et al.* (8). With n = 10: ●, present results. The curves were calculated from eq. [4] with coefficients from Table 3.

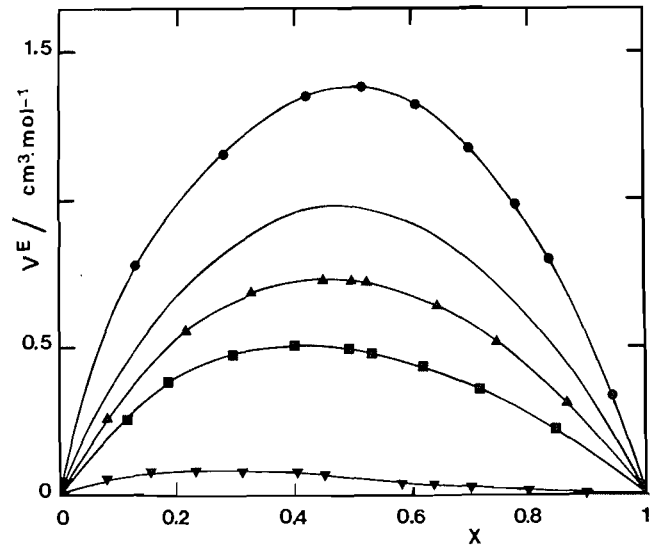

FIG. 4. Experimental excess molar volumes, V^E, at 298.15 K for methyl alkanoates with n-heptane: xC$_m$H$_{2m+1}$COOCH$_3$ + $(1-x)$-C$_7$H$_{16}$: ●, m = 1; ▲, m = 3; ■, m = 4; ▼, m = 7. Full curve without experimental points is for m = 2 (see Fig. 3). All the curves were calculated from eq. [4] with coefficients from Table 3.

The coefficients A_i, and the corresponding standard deviations $s(Q^E)$ are given in Table 3. These coefficients were used to obtain the calculated curves in the figures.

The excess molar volumes are positive for all the systems and show the usual concentration dependence of mixtures of alkanoates with n-alkanes (1, 3), as well as the familiar decrease of V^E when the alkylated part of the alkanoate increases (see Figs. 1 to 4). This decrease, in a given series of alkanoates, corresponds to a dilution of the ester group. Of particular interest is the different behavior of C$_4$H$_8$O$_2$ alkanoates with the same n-alkane. For example, propyl methanoate and methyl propanoate exhibit practically identical V^E with n-haptane (Figs. 1 and 3) in contrast ethyl ethanoate leads to more positive V^E. This is an indication that V^E results from the competition of different effects, e.g., size, polarity, chemical structure, which cancel out in the same way in the case of the propyl methanoate and methyl propano-

*Units for V^E, cm^3 mol^{-1}; C_p^E, J K^{-1} mol^{-1}.

ate. Also as expected, for a given alkanoate, the excess molar volumes become more positive as the length of the *n*-alkane increases (Figs. 1–3).

The present V^E data at 298.15 K agree well with our previous results (1) in the case of ethyl ethanoate and methyl propanoate, as well as with the results of Dusart *et al.* (3) (see Figs. 2 and 3). These latter authors have also measured V^E for the two systems methyl butanoate and methyl pentanoate with *n*-heptane (3). Their results (not shown in Fig. 4) agree also well with ours. These three sets of data have been obtained with similar vibrating-tube densimeters and the overall agreement between these results is normal.

No direct measurements of excess molar heat capacities could be found for any of the systems investigated here and the most remarkable aspect of this work relates to the composition dependence of these properties. For all esters the $C_p^E(x)$ curves show the now well-known ω-shaped concentration dependence with a more or less marked double minimum (Figs. 5 to 9).

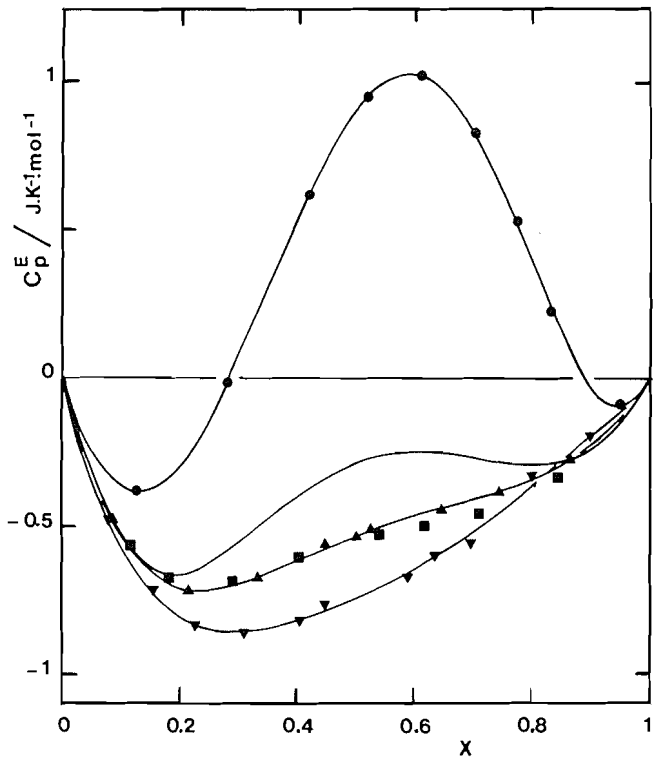

FIG. 9. Experimental excess molar isobaric heat capacities, C_p^E, at 298.15 K for methyl alkanoates with *n*-heptane: $xC_mH_{2m} + {}_1COOCH_3 + (1-x)C_7H_{16}$: ●, $m = 1$; ▲, $m = 3$; ■, $m = 4$; ▼, $m = 7$. Full curve without experimental points is for $m = 2$ (see Fig. 6). All the curves were calculated from eq. [4] with coefficients from Table 3.

The present behavior, even more pronounced, is similar to the observation made for mixtures of alkanoates with cyclohexane (17). In particular, a positive part in the $C_p^E(x)$ curves appears in the central range of concentration in the case of the smaller, more polar, esters: namely, propyl methanoate, methyl ethanoate and, to a less extent, ethyl ethanoate. This would be typical of the non-randomness advocated by Patterson and co-workers (11) to explain the large positive C_p^E values observed for mixtures containing a polar alkanone, like acetone. This positive part can be a pronounced sharp maximum, almost a peak, as observed with very polar substances like benzonitrile or nitrobenzene (12) in *n*-alkanes near the UCST. This strong concentration dependence almost vanishes when the anisotropy of the polar group (here the ester group) is "diluted" and thus becomes less effective on the aliphatic environment. This is indeed observed with either a given alkanoate in alkanes of increasing chain length, see Figs. 5, 6, and 7, or with alkanoates of increasing alkyl chain length in a given *n*-alkane (Fig. 9). Typically the ω-shape is no more present in the case of methyl octanoate in *n*-heptane (Fig. 9).

As indicated in the Introduction we tentatively interpret the present results as a possible consequence of the modification of the percentage of the *gauche/trans* conformations in *n*-alkanes upon addition of a solute which itself can exhibit conformers of different polarity, depending on its concentration in the mixture. For alkanoates, these possible conformers (or rotamers) correspond to molecular internal rotation around the C—O bond. A large body of studies supports this contention (33–36) and, as expected, propyl methanoate which has the highest dipole moment ($\mu = 1.91$ D) leads to the strongest concentration dependence. This is clearly shown in Fig. 8 where the three $C_4H_8O_2$ isomers are compared in admixture to *n*-decane: the C_p^E curve becomes more negative, and therefore less ω-shpaed, the smaller the dipole moment.

In conclusion our present results seem to confirm the effect on C_p^E of cooperative induced conformational arrangements already observed with mixtures containing alkanones (in alkanes) (8) or alkanoates (in cyclohexane (17).

Acknowledgments

This work was performed within the frame of the Spanish–French treaty on scientific and technical cooperation. Three of us (M.P., R.B., and M.C.B.) gratefully acknowledge the financial support by the French Embassy in Madrid and the University of Santiago de Compostela. We also are indebted to Mrs. Piekarski (University of Limoges) for carrying out some density measurements.

Excess partial molar enthalpies of *tert*-butanol in water–*tert*-butanol mixtures

YOSHIKATA KOGA

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received September 9, 1987

This paper is dedicated to the late Professor J. A. Morrison

YOSHIKATA KOGA. Can. J. Chem. **66**, 1187 (1988).

Excess partial molar enthalpies of *tert*-butanol (TBA) in water–*tert*-butanol mixtures were measured at 20.00, 26.90, 45.17, and 59.49°C in the water-rich region, and at 30.00°C for the entire range. The results together with those of the previous work, (Y. Koga. Can. J. Chem. **64**, 206 (1986)), appear to support the following views: At $X_{TBA} \approx 0$, TBA molecules form hydrogen bonds with H_2O molecules, and they enhance the structure of the hydrogen bond network of H_2O. The latter effect is of very long range; the enthalpic repulsion between solutes is already operative via enhancement of hydrogen bond network when two TBA molecules are separated by 12 H_2O molecules. This enthalpic repulsion becomes stronger as the concentration of TBA increases. At a certain threshold, $X_{TBA} \approx 0.03$ at 30.00°C for example, the new scheme in which solutes tend to associate sets in, and for $X_{TBA} > 0.06$ this scheme becomes predominant. The effect of higher temperature is to shift this threshold to the lower values of X_{TBA}. Therefore, it is probable that a lower critical solution temperature may exist at a temperature higher than the boiling points of the solution. It was also shown that if species of $TBA(H_2O)_k$ type persist, they exhibit a hard-sphere nature in terms of enthalpic interaction among themselves.

YOSHIKATA KOGA. Can. J. Chem. **66**, 1187 (1988).

Opérant à 20,00, 26,90, 45,17 et 59,49°C et à des concentrations riches en eau ainsi qu'à 30,00°C à toutes les concentrations, on a mesuré les enthalpies molaires partielles en excès du *tert*-butanol (ATB) dans des mélanges eau/*tert*-butanol. Il semble que les résultats obtenus, pris de concert avec ceux de notre travail antérieur (Y. Koga, Can. J. Chem. **64**, 206 (1986)), sont en accord avec les conclusions suivantes: à une $X_{ATB} \approx 0$, les molécules d'ATB forment des liaisons hydrogènes avec les molécules de H_2O et elles augmentent ainsi la structure du réseau de liaisons hydrogènes de H_2O. Ce dernier effet agit à une très grande distance; la répulsion entre les solutés qui dûe à l'entropie se fait déjà sentir, par le biais d'une augmentation du réseau de liaisons hydrogènes, lorsque deux molécules d'ATB sont séparées par 12 molécules de H_2O. Lorsque la concentration en ATB augmente, cette répulsion dûe à l'enthalpie augmente aussi. A un nouveau seuil, par exemple, à une $X_{ATB} \approx 0.03$ et à 30,00°C, il s'établit un nouveau schéma d'association entre les solutés et à une $X_{ATB} > 0{,}06$, ce schéma devient prédominant. Lorsqu'on augmente la température, ce seuil se déplace vers des valeurs plus faibles de X_{ATB}. Il est donc probable qu'une température de solution critique plus faible puisse exister lorsque les températures d'ébullition de la solution sont plus élevées. On a aussi démontré que, si les espèces du type $ATB(H_2O)_k$ persistent, elles présentent une nature de sphère dure en termes d'interaction enthalpiques entre elles.

[Traduit par la revue]

Introduction

In a previous article in this journal (1) (called paper I hereinafter) excess partial molar enthalpies[1] of *tert*-butanol (TBA) in water–*tert*-butanol mixtures, H_m^E(TBA), at 26.90°C were reported. It was shown that in terms of excess partial molar enthalpies and their temperature dependence there were two regions bound at about $X_{TBA} = 0.06$, X_{TBA} being the mole fraction of *tert*-butanol. In the water-rich region, $X_{TBA} < 0.06$, H_m^E(TBA) depends sharply on X_{TBA} and C_p^E(TBA) ($= \partial H_m^E(TBA)/\partial T$) is large and positive ($\sim$250 J K^{-1} mol^{-1}). In the region, $X_{TBA} > 0.06$, H_m^E(TBA) is small and nearly constant ($\pm$1 kJ mol^{-1}) and C_p^E(TBA) is also nearly constant at ~ -30 J K^{-1} mol^{-1}. The peculiarity of TBA–H_2O mixtures is thus promient in the water-rich region, while in the rest of the X_{TBA} regions the TBA molecules in the mixture find themselves in the situation not very different from that in pure TBA.

In the present work are reported the additional results of H_m^E(TBA) at 30.00°C and also at 20.00, 26.90, 45.17, and 59.49°C in the water-rich region. While the system of TBA–H_2O has been subjected to numerous investigations for a long time, recent measurements (2, 3) on thermodynamic quantities that are proportional to a second derivative of the free energy with respect to appropriate variables, appear to add some new insights. Indeed, Sakurai has presented an alternative explanation to the classical "iceberg" formation using accurate values of partial molar volumes of TBA and H_2O in the entire range of mole fraction (3). The excess partial molar enthalpy, H_m^E(TBA), is one of such quantities and provides direct information on the solute–solvent and the solute–solute interaction potentials, which no doubt is important in gaining an additional insight.

In theory, the excess partial molar enthalpy can be obtained graphically by the Bakhuis–Rooseboom (21) method from the data of excess (integral) molar enthalpies of the mixture. However, existing data for the TBA–H_2O mixtures (4) are not so closely netted in terms of the mole fraction that an accurate graphical differentiation is not possible, particularly in the water-rich region. For the very close proximity to $X_{TBA} = 0$, the apparent molar enthalpies were fitted to a virial expansion (5, 6) from which excess partial molar enthalpies can be calculated. However, the applicability of such expression is limited to the very water-rich region only. Thus, it was elected to measure the excess partial molar enthalpies directly for the entire range of mole fraction in paper I (1). The present paper is an extention thereof. In the event that excess partial molar enthalpies of H_2O in the mixtures become available, the excess (integral) molar enthalpies and the apparent molar enthalpies are calculated from the measured excess partial molar enthalpies of H_2O and those

[1]In paper I, a conventional term, the differential heat of dilution, and a notation, Δh, were used. In this paper, however, in accordance with the recommendations by the IUPAC Commissions on Thermodynamics, use will be made of the term, the excess partial molar enthalpy with the notation, H_m^E(TBA) instead. Thus H_m^E(TBA) in this paper is the same as Δh in paper I. By the same token, ΔC_p ($= \partial \Delta h/\partial T$) in paper I is the same as $C_P^E(TBA)$ ($= \partial H_m^{EE}(TBA)/\partial T$) in this paper.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

of TBA, and can then be compared directly with the existing data (4–6).

Experimental

The excess partial molar enthalpies were measured by means of an LKB Bromma 8700 precision calorimetry system. Two separate sets of measurements were made. For the runs at 20.00, 26.90, and 30.00°C, the same procedure as described elsewhere was employed (1, 18). Briefly, a glass ampoule containing about 1 mL of purified TBA was broken in about 90 g of the mixture. For the runs at 45.17 and 59.49°C about 1 mL of TBA (BDH assured, analytical reagent) was introduced from a 5 mL buret, through a heat exchanger immersed in the bath and into the so-called titration cell (~100 mL) provided with the apparatus. In the series of addition of TBA from the buret, the accurate amount of TBA for the first one is always uncertain, although correction was made to account for a small amount of additional TBA introduced due to the thermal expansion of TBA in the heat exchanger. The data of the first run in each series was therefore discarded. This uncertainty about the amount of the first dose of TBA causes uncertainties in the values of X_{TBA} in the subsequenty runs. However, it was estimated to be at most 0.5% at the lowest mole fraction studied.

The excess partial molar enthalpies were calculated as $H_m^E(TBA) = \Delta H/\Delta n_{TBA}$, where ΔH is the enthalpy change of the mixture due to the addition of a small amount Δn_{TBA} (~0.01 mol) of TBA. Since the increment, Δn_{TBA} is very small in comparison with the total amount of the mixture, typically about 4 mol, the above relation, $H_m^E(TBA) = \Delta H/\Delta n_{TBA}$, should hold. This was checked by reducing Δn_{TBA} to 0.007 mol for the two runs at 26.90°C of this work. As shown later, the data points with the two different sets of increments appear to lie on the smooth curve within the experimental error. The error limit in H_m^E(TBA) obtained by the ampoule method was estimated to be 0.5% of the resulting value with the upper bound ±0.05 kJ mol^{-1} for the results, the absolute value of which are larger than 10 kJ mol^{-1} and with the lower bound ±0.015 kJ mol^{-1} for those smaller than 3 kJ mol^{-1}. The buret method was found to be not as accurate, with an estimate of error ±0.2 kJ mol^{-1}. To test the consistency between the two methods, three runs by the buret method were conducted at 30.00°C. As shown below, the results appeared consistent within the stated error limits.

Results and discussion

The excess partial molar enthalpies of TBA in TBA–H_2O mixtures are tabulated in Table 1, together with the data of paper I (1) in which only graphical presentation was made. The values of H_m^E(TBA) were plotted against X_{TBA} in the water-rich region in Fig. 1. Figure 2 is an enlarged view at close proximity of the origin for the ampoule runs at 26.90 and 30.00°C. In the figure the two data points at 26.90°C of this work in which Δn_{TBA} was reduced to 0.007 mol seem to lie on the smooth curve drawn through the data points of paper I (1) within experimental error. In paper I (1), Δn_{TBA} was 0.01 mol. Hence it was concluded that the relation $H_m^E(TBA) = \Delta H/\Delta n_{TBA}$ holds with $\Delta n_{TBA} = 0.01$ mol. Scatter of the data for 20.00°C is due to the fact that TBA solidifies in ampoules and there appears to be an additional work done on solid TBA when the ampoule is broken by the saphire needle. Such effect depends on the way the solid is formed and it is not controllable. Other than the data at 20.00°C, all the points appeared to be on smoothly drawn curves within the respective error limits. In Fig. 3 are shown the values of H_m^E(TBA) read off the smooth curves at various values of X_{TBA}, including those extrapolated to $X_{TBA} = 0$, against temperature.

As mentioned above, there are no data for the excess partial molar enthalpies for this mixture available in literature to compare directly with the present results. For $X_{TBA} < 0.05$ at 25°C, however, the apparent relative molar enthalpies, ϕ_L, are fitted to a virial expansion with respect to molality, m (6). Since

[1] $$H_m^E(TBA) - H_m^E(TBA, X_{TBA} = 0) = \partial(m\phi_L)/\partial m$$

an indirect comparison is possible. For $X_{TBA} > 0.05$, on the other hand, the excess molar (integral) enthalpies, H_m^E are compiled at various temperatures (4), but the data are not netted closely enough for an accurate graphical differentiation. When the excess partial molar enthalpies of H_2O in the mixture, $H_m^E(H_2O)$, become available, the values of H_m^E are calculated and a direct comparison will be possible. At present, however, the present data at 30.00°C were compared in an approximate manner with those obtained from the excess molar enthalpies compiled by Westmeier (4). Namely, the data of the excess molar enthalpies at 30°C (4) were plotted, through which a smooth curve was drawn using a flexible ruler, and H_m^E were estimated by the Bakhuis–Rooseboom method (21).

Such comparisons are summarized in Table 2. In column 2 are listed the values of H_m^E(TBA) of this work at 25°C, which were read off from Fig. 3. Column 3 contains the values of H_m^E(TBA) calculated as, by virtue of eq. [1],

[2] $$H_m^E(TBA) - H_m^E(TBA, X_{TBA} = 0) = 2mh_{xx} + 3m^2h_{xxx} + 4m^3h_{xxxx}$$

for $m < 3$ mol kg^{-1}, or $X_{TBA} < 0.05$, with the virial coefficients determined by Desnoyers *et al.* (6). For the value of H_m^E(TBA, $X_{TBA} = 0$) at 25°C, that by Desnoyers *et al.* at 26.0°C (6) was corrected by the value of C_p^E(TBA) at 25°C calculated using the apparent molar heat capacity of deVisser *et al.* (22). See Table 3, below. In column 4 are given the values of H_m^E(TBA) read off the smooth curve drawn through the present data points at 30.00°C, Fig. 1 showing a portion $X_{TBA} < 0.06$. In column 5 are listed the values of H_m^E(TBA) calculated from Westmeier's excess molar enthalpies (4) as mentioned above. In spite of the crudeness, the comparison between columns 2 and 3 and that between columns 4 and 5 are reasonable. While the virial expansion obtained by Desnoyers *et al.* (6), i.e. eq. [2], is applicable only in the range $X_{TBA} < 0.05$, the value calculated at $X_{TBA} = 0.06$ in column 2, 0.43 kJ mol^{-1}, and its difference from the observed value in column 1, −2.0 kJ mol^{-1}, serve to suggest the limitation of the virial expansion in understanding the nature of the mixture in the entire concentration range.

The value of the excess partial molar enthalpy at the infinite dilution, $H_m^E(TBA, X_{TBA} = 0)$, −17.4 kJ mol^{-1} at 25°C, should include the energetic gain for a TBA molecule to break hydrogen bondings to TBA molecules in the pure TBA liquid and to form hydrogen bondings to surrounding H_2O molecules in the mixture. There should also be an additional effect that a solute TBA makes on the solvent H_2O. Theoretical estimates (8, 9) indicate that the TBA–H_2O potential is −25.6 kJ mol^{-1} when TBA acts as the proton donor and H_2O the acceptor and is −21.7 kJ mol^{-1} in the opposite case, while the TBA–TBA potentials are −20 kJ mol^{-1} in both cases regardless of which acts as the proton donor or the acceptor. Thus, the energetic gain in exchange of hydrogen bondings amounts to −7.3 kJ mol^{-1}. The remaining −10.1 kJ mol^{-1} in H_m^E(TBA, $X_{TBA} = 0$) should therefore be attributed to some structural enhancement, i.e. formation of extra hydrogen bonds, in the solvent H_2O caused by a TBA molecule (2, 20). The temperature dependence of the energies of hydrogen bonds is small. Therefore, the values of $C_p^E(TBA) (= \partial H_m^E(TBA)/\partial T)$ in the water-rich region should be due mainly to the temperature dependence of the latter effect, which is likely to be high.

In passing, the heat of fusion of TBA at 20.0°C is estimated as

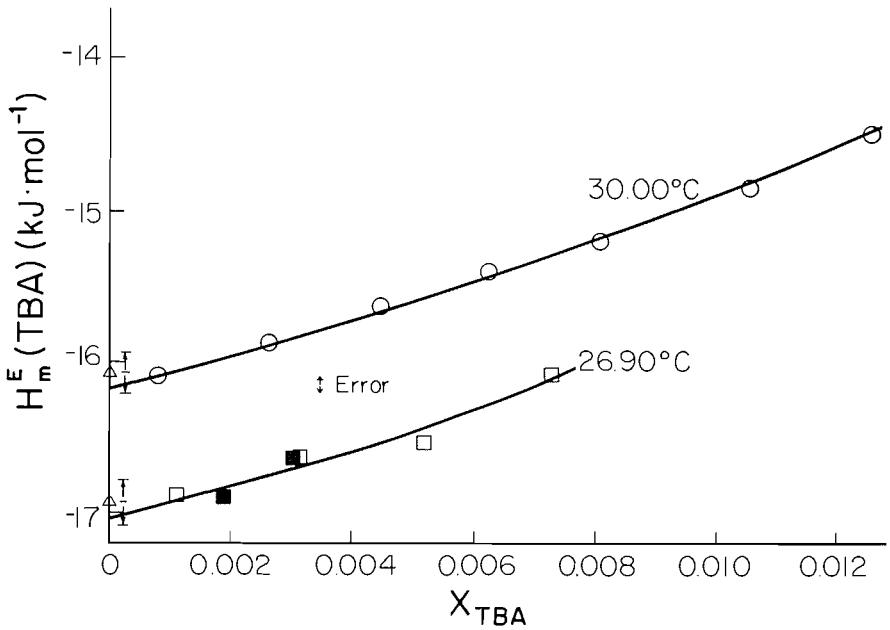

FIG. 2. The excess partial molar enthalpies of *tert*-butanol (TBA) in H_2O–TBA mixtures, H_m^E(TBA), against the mole fraction, X_{TBA}. The enlarged view of ampoule runs at 26.90 and 30.00°C. ○, ■, this work; □, previous work (1); △, ref. 7.

3.8 kJ mol^{-1} from the difference between the actual value and the extrapolated value of H_m^E(TBA, X_{TBA} = 0) to 20.0°C, as shown in Fig. 3.

As pointed out above, X_{TBA} = 0.06 is the boundary at 26.90°C which separates the two regions (1); for $X_{TBA} < 0.06$, H_m^E(TBA) depends sharply on X_{TBA} and C_p^E(TBA) (= $\partial H_m^E(\text{TBA})/\partial T$) is large, while for $X_{TBA} > 0.06$ they both become small and nearly constant. Figure 1 shows that such a boundary shifts towards a smaller value in X_{TBA} as the temperature is raised. Indeed, Fig. 3 suggests at about 100°C the boundary becomes very close to X_{TBA} = 0. Namely, the second scheme, in which TBA molecules in the mixture find themselves in a not very different environment than that in the pure TBA, dominates in almost the entire range of X_{TBA}. This suggests association of TBA molecules and hence the possible existence of a lower critical solution temperature above the boiling point (10). This is a very probable explanation on the abnormal enhancement in the concentration fluctuations (11–14) and the maxima in the correlation lengths (2, 10, 14) in the middle range of X_{TBA}.

Estimates of C_p^E(TBA) as $\Delta H_m^E(\text{TBA})/\Delta T$ were made from the two smooth curves of H_m^E(TBA) drawn through the points measured at 26.90°C (1) and 30.00°C. They are listed in column 4 of Table 3, which complements the data in paper I (1). The

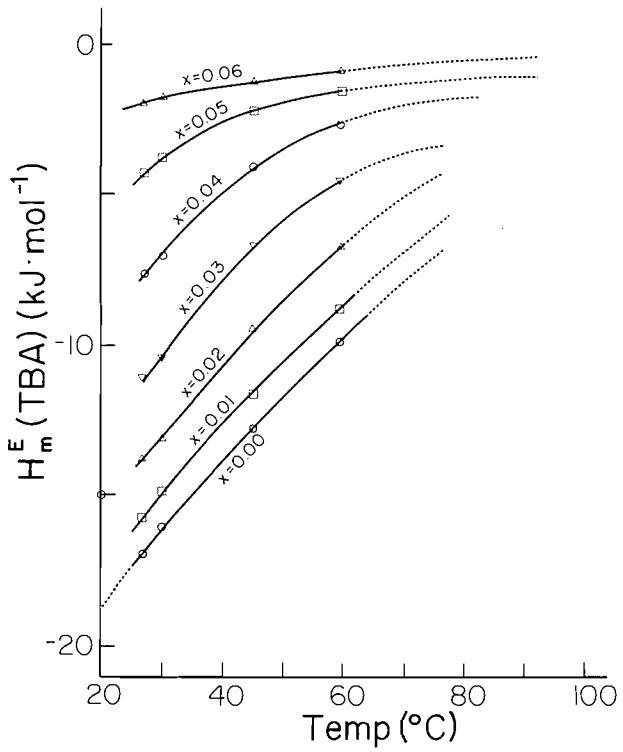

FIG. 3. The excess partial molar enthalpies of *tert*-butanol (TBA) in H_2O–TBA mixtures, H_m^E(TBA), against temperature at various values of X_{TBA}.

values of X_{TBA} in the table were so chosen that at a close proximity of X_{TBA} the actually measured values of H_m^E(TBA) for both temperatures are available. This is to minimize errors introduced in drawing a smooth curve. This method of obtaining C_p^E(TBA) inevitably causes a large error, an estimate of which is also given in column 4 of Table 3. While the data for the apparent molar heat capacities of the mixture, ϕ_c, are available in literature (22), there are no data for the partial molar heat capacities to compare directly with the present results. Thus an attempt was made to make an approximate comparison as follows: The data of ϕ_c at 25°C and 40°C (22) obtained from the Depository of Unpublished Data, CISTI, NRC, were plotted against X_{TBA}, and slopes at appropriate values of X_{TBA} were obtained graphically. C_p^E(TBA) was then calculated as,

$$[3]\quad C_p^E(\text{TBA}) = \phi_c + X_{TBA}(1 - X_{TBA})(\partial\phi_c/\partial X_{TBA}) - \phi_c(X_{TBA} = 1)$$

The resulting values are listed in columns 5 and 6 for 25°C and 40°C, respectively. The latter method of obtaining C_p^E(TBA) is superior if the data points for ϕ_c are closely netted, which is the case for $X_{TBA} < 0.04$ at 25°C and for $X_{TBA} < 0.055$ at 40°C (22). Thus, the fact that the present data do not show a maximum in the range $X_{TBA} < 0.05$ may be attributed to the large error involved in the method. However, the data in columns 4, 5, and 6 agree in the general trend of C_p^E(TBA) that $X_{TBA} \approx 0.06$ marks a sharp boundary above which C_p^E(TBA) is small, negative, and virtually constant.

The solute–solute interaction in the mixture in comparison with that in pure TBA is expressed as $(\delta H_m^E(\text{TBA})/\delta n_{TBA})$, which in the water-rich region is approximately equal to $(\delta H_m^E(\text{TBA})/\partial X_{TBA})$. Thus, the slopes of the smooth curves in Fig. 1 were obtained graphically as $(\partial H_m^E(\text{TBA})/\partial X_{TBA})$ with $\partial X_{TBA} = 0.002$ and shown in Fig. 4. The slopes do not appear to approach zero smoothly towards $X_{TBA} = 0$ though they may do so at much smaller value of X_{TBA} than the range covered in the present work. Arnett, Kover, and Carter (7) claimed that at 25°C the values of H_m^E(TBA) were constant within the error limit ±0.06 kJ mol^{-1} for $X_{TBA} < 2 \times 10^{-4}$. The present data clearly

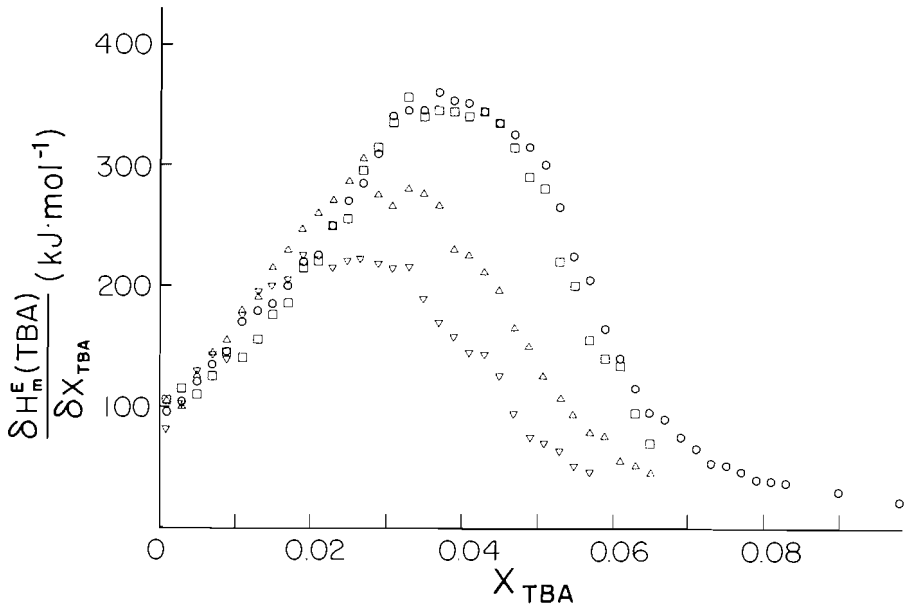

FIG. 4. The slopes of the curves of H_m^E(TBA) vs. X_{TBA}, i.e. $\delta H_m^E(TBA)/\delta X_{TBA}$, against the mole fraction, X_{TBA}. ○, 26.90°C; □, 30.00°C; △, 45.17°C; ▽, 59.49°C.

show as in Figs. 2 and 4, that at least at about $X_{TBA} = 0.001$ the slopes are non-zero and positive. This implies that the solute–solute interaction is repulsive in terms of enthalpy and is operating already at $X_{TBA} = 0.001$, i.e. the solute–solute interaction is effectively of very long range.

If TBA molecules are randomly distributed among H_2O molecules without any preferential association, a given TBA molecule is surrounded by $(1 - X_{TBA})/X_{TBA}$ H_2O molecules on average. Assuming that such H_2O molecules surround a TBA molecule in a spherical fashion, the radius, n_r, in terms of number of H_2O molecules may then be defined as

$$[4] \quad (4/3)\pi n_r^3 = (1 - X_{TBA})/X_{TBA}$$

In Fig. 5 are plotted the values of $\delta H_m^E(TBA)/\delta X_{TBA}$ against n_r. $n_r \approx 1.6$ marks a strikingly sharp rise in the solute–solute interaction, indicating a hard-sphere behaviour of the species of a TBA molecule surrounded by H_2O molecules with $n_r \approx 1.6$. Such hard-sphere radii, n_r*, were estimated from Fig. 5 to be 1.55, 1.68, and 1.77 at 26.90, 45.17, and 59.49°C, respectively. In terms of the number, k, in the species of TBA$(H_2)_k$ type, these values of n_r* correspond to 16, 20, and 23 at the respective temperatures. These values compare favourably with those obtained by Iwasaki *et al.* (13) by light scattering technique, i.e. $k = 15 \sim 19$ at 17.5°C and $k = 21 \sim 25$ at 63°C (13). Note, however, that this alone does not support the persistence of such species in the entire concentration range.

As can also be seen in Fig. 5, the value of $\delta H_m^E(TBA)/\delta X_{TBA}$ is ~100 kJ mol^{-1} at $n_r = 6$. Namely, the solute–solute repulsive interaction is already operative when two solutes are separated by about 12 H_2O molecules on average. Such a long range interaction is only possible via the hydrogen bond network of water (15–17). That the hydrogen bond network in pure H_2O extents to the entire bulk is well documented (15–17). Additional evidence has been given recently in the excess partial molar enthalpies of H_2O and D_2O in H_2O–D_2O mixtures (18). In spite of the fact that the strength of the hydrogen bonds and the probability of those intact are higher in D_2O, the measured excess partial molar enthalpies of H_2O and those of D_2O are

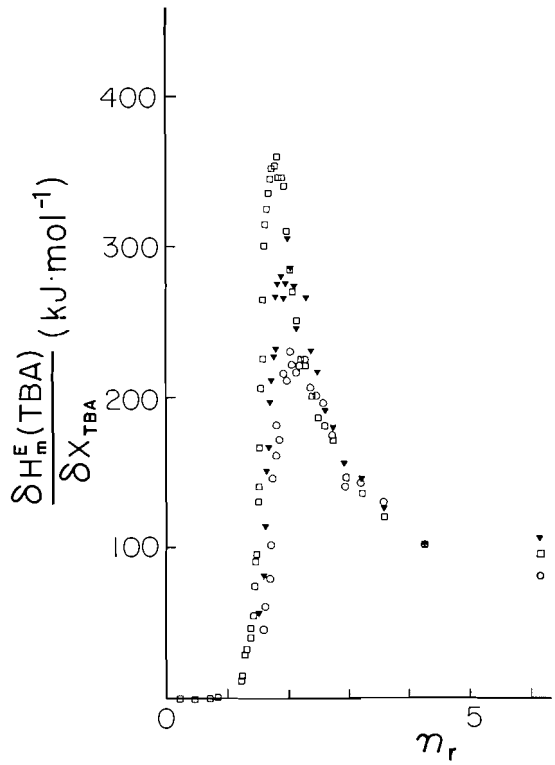

FIG. 5. The slopes of the curves of H_m^E(TBA) vs, X_{TBA}, i.e., δH_m^E(TBA/δX_{TBA}, against n_r defined by eq. [4]. □, 26.90°C; ▼, 45.17°C; ○, 59.49°C.

perfectly symmetric with respect to interchange of H_2O and D_2O. The resulting excess molar enthalpies of H_2O–D_2O, $H_m^E\{xH_2O + (1 - x)D_2O\}$, were expressed as,

$$[5] \quad H_m^E = A_1 x(1 - x)$$

with $A_1 = 132.3$ J mol^{-1} at 25.00°C (18). Namely, the intermolecular interactions in H_2O–D_2O mixture can be described by the mean-field type expression, which is rigorously correct

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

when the interaction is weak and infinite in range (19). Thus a TBA molecule causes structure enhancement (2, 8, 9, 20) in the surrounding H_2O molecules and this effect entails at least six H_2O molecules away via the hydrogen bond network.

Both Figs. 4 and 5 show the effect of temperature on the solute–solute interaction energy. Namely, at the low end of X_{TBA} or at large values of n_r, the effect of temperature is not apparent. However, the increase of the solute–solute interaction as X_{TBA} increases is cut short at higher temperatures and it appears that the second scheme in which H_m^E(TBA) as well as $\delta H_m^E(TBA)/\delta X_{TBA}$ becomes small sets in, i.e. TBA molecules tend to associate. From Fig. 5, these thresholds appear to be 0.02 at 59.49, 0.025 at 45.17, and 0.03 at 30.00°C. Indeed, a recent molecular dynamics calculation (9) showed a tendency that TBA molecules associate already at $X_{TBA} = 0.03$.

Thus a probable scenario for mixing TBA into H_2O may be as follows: AT $X_{TBA} \approx 0$, a TBA molecule forms hydrogen bonds with H_2O molecules and rearranges the surrounding H_2O molecules to enhance the network structure of H_2O. The latter exothermic effect is as significant as the hydrogen bond formation. At least at $X_{TBA} = 0.001$, the structure enhancement extend the entire bulk of the solution and an additional TBA molecule has an enthalpic difficulty to settle into an already somewhat enhanced structure of the solution. Thus H_m^E(TBA) increases and $\delta H_m^E(TBA)/\delta X_{TBA}$ also increases. Then at a certain threshold, $X_{TBA} = 0.02$ at 59.49, 0.025 at 45.17, and 0.03 at 30.00°C, this first scheme becomes unfavourable as compared to the second scheme whereby TBA molecule tend to associate. Beyond the threshold the second scheme starts to set in. Above a boundary somewhat higher than the threshold, 0.06 at 30.00°C, the second scheme dominates and the solution consists of clustered TBA molecules.

While the scenario presented here is not entirely new (23), the partial molar enthalpies and their derivatives with respect to X_{TBA}, Figs. 4 and 5, provide for the first time the threshold of X_{TBA} above which the solute–solute enthalpic repulsion start to die down, and the temperature dependence of such threshold value. Figure 5 also shows clearly a hard-sphere nature of the species of $TBA(H_2O)_k$ type, if such species persist. Thus, although much has been known about this mixture, it is still worthwhile to measure accurately the quantities that are proportional to the higher order derivatives of the free energy in the entire concentration range.

Acknowledgement

I wish to thank Professors D. H. Dolphin and L. G. Harrison for allowing me to use their facilities and many colleagues in Department of Chemistry, U.B.C., for kindly lending chemicals and incidentals. However, it is Professor James A. Morrison that has provided me with constant support and encouragement that have kept my research program somehow going since my lucky encounter with him 15 years ago. I do not have enough vocabulary to express my gratitude to him propertly. So, in the simplest possible way:

Thank you for everything, Jim!

Metal ion catalysis of the decomposition of transient 2-carboxy-2,5-cyclohexadienones in aqueous solution

OSWALD S. TEE[1] AND N. RANI IYENGAR

Department of Chemistry, Sir George Williams Campus, Concordia University, Montréal, P.Q., Canada H3G 1M8

Received September 10, 1987

OSWALD S. TEE and N. RANI IYENGAR. Can. J. Chem. **66**, 1194 (1988).

Bromide ion induced debromination of the anion of 4-bromo-4-methyl-2,5-cyclohexadienone-2-carboxylic acid (**1**) is catalyzed by cupric ions and ferric ions. Similarly, the enolization of the anion of the benzocyclohexadienone **3**, which is formed during the bromination of 1-naphthol-2-carboxylic acid, is catalyzed by some metal ions. The origin of the catalysis in these reactions is strong metal ion binding to the incipient dianion products that are of the salicylate type. Evidence for this is that the efficiency of the metal (and hydrogen) ion catalysis parallels the stability of the analogous complexes with the salicylate dianion.

OSWALD S. TEE et N. RANI IYENGAR. Can. J. Chem. **66**, 1194 (1988).

La débromation, induite par l'ion bromure, de l'anion de l'acide bromo-4 méthyl-4 cyclohexadiène-2,5 one-2 carboxylique (**1**) est catalysée par les ions cuivrique et ferrique. De la même manière, l'énolisation de l'anion de la benzacyclohexadiènone **3**, qui se forme lors de la bromation de l'acide naphtol-1 carboxylique-2, est catalysée par quelques ions métalliques. La catalyse dans ces réactions est due à la forte liaison des ions métalliques avec les produits dianioniques qui se forment et qui sont du type salicylate. Le fait que l'efficacité de la catalyse par les ions métalliques (ou l'hydrogène) soit parallèle à la stabilité des complexes analogues avec le dianion salicylate est en accord avec la conclusion précédente.

Labile cyclohexadienones can be observed during the aqueous bromination of phenols lacking electron-withdrawing groups (1–4). Two types of dienone are formed and they decompose by different reactions, depending on the phenol. Where the starting phenol has no *para* substituent a transient 4-bromo-2,5-cyclo-hexadienone is formed, which enolizes to the 4-bromo product (1–3). On the other hand, with *p*-alkylphenols, part of the initial fast bromine attack occurs *ipso* to the alkyl group, leading to a 4-alkyl-4-bromo-2,5-cyclohexadienone, an "ipso-dienone" (4, 5), which cannot enolize and which decomposes by debromination (1, 4).

Two particularly interesting examples of the above types of intermediates that we have found are the cyclohexadienones **1** and **3**, derived from bromine attack on certain salicylic acids. The bromide ion induced debromination of the ipso-dienone **1** (→ $\mathbf{2}^-$, eq. [1]) is greatly facilitated by the 2-carboxyl group (4, 6). Similarly, the enolization of the benzocyclohexadienone **3** (→ $\mathbf{4}^-$, eq. [2]) is catalyzed by its internal carboxyl group and by

[1] 
1 **2⁻**

[2] 
3 **4⁻**

external bases (3). We hereby report that the debromination of **1** and the enolization of **3** are also catalyzed by some metal ions.

We were prompted to look for such behaviour by the ongoing interest in enzymic and non-enzymic metal ion catalyzed reactions (7, 8) and by the knowledge that salicylate dianions form weak to strong complexes with various metal ions (9). It was anticipated that the binding of metal ions to the anions of **1** and **3** ($\mathbf{1}^-$ and $\mathbf{3}^-$) would be relatively weak whereas binding to the dianions of the products ($\mathbf{2}^{2-}$ and $\mathbf{4}^{2-}$) should be considerably stronger (9). Therefore, assuming that metal ion binding to the transition states of the reactions $\mathbf{1}^- \rightarrow \mathbf{2}^{2-}$ and $\mathbf{3}^- \rightarrow \mathbf{4}^{2-}$ is intermediate in strength, catalysis of these reactions by metal ions should occur, in favourable cases.

Since the early work of Pedersen (10) on the enolization of β-keto esters, various workers have shown that enolization (and closely related reactions such as the decarboxylation of β-keto acids) can be catalyzed by metal ions (11–14). The early studies tended to emphasize the binding abilities of the substrates but it is now clear that metal ion binding to the incipient products is of more importance (11–14). The present work provides further evidence that this is the case but the novel aspect of the work arises because the reactants **1** and **3** are labile intermediates.

The decomposition reactions [1] and [2] are energetically favourable and inherently fast (1–4, 6). Therefore, reactant-like transition states are to be expected and it is by no means clear that they will have sufficient product character that an increase in metal ion binding will lower their energies significantly.

Results

Our results for the effect of metal ions on the rate of debromination of the ipso-dienone **1** are summarized in Table 1. For ease of comparison, the observed first-order rate constants (k^{obs}) are presented together with the values (k^{calc}) expected in the absence of metal ions, calculated from the kinetic parameters obtained in our earlier study of **1** (6). Significant enhancements of rate were found with cupric ions and ferric ions but little or no effect[2] was observed with Zn^{2+}, Ni^{2+}, Mg^{2+}, and Co^{2+} ions.[3]

[1]Author to whom correspondence may be addressed.

[2]With nickel and zinc ions the rates are somewhat lower than expected. This may be due to a small effect on the partitioning of bromine attack (see later).

[3]With added Al^{3+} ions complex behaviour was observed, which was not pursued.

TABLE 1. The effect of metal ions on the rate of decomposition of 4-bromo-4-methyl-2,5-cyclohexadienone-2-carboxylic acid (**1**)[a]

[a]At 25°C, I = 0.11 M, in aqueous solution containing 0.1 M KBr.[2,3] The values of k^{calc} (for reaction in the absence of metal ions) are calculated from constants obtained earlier (6).

[b]Experiments at higher pH or [metal ion] were precluded by the unfavorable optical properties of the solutions.

[c]The dependence of k^{obs} on [ion] is linear.[4,5]

For both Cu^{2+} and Fe^{3+} the dependence of k^{obs} on the metal ion concentration at fixed pH is reasonably linear.[4, 5]

The extent of catalysis by metal ions varies with pH, as shown in Fig. 1. Presented there are appropriate rate data from Table 1, superimposed on the rate profile for the decomposition of the ipso-dienone **1** in the absence of metal ions. This profile (curve a, Fig. 1) corresponds to reaction of the undissociated form of **1** (pK_a = 3.06); reaction of the anion $\mathbf{1}^-$ is not important at the acidities studied (6). However, as seen in Fig. 1, this is no longer the case when the reaction medium contains either cupric ions (0.5 mM) or ferric ions (0.1 mM). For these ions there is a significant amount of catalysis only at acidities where the ipso-dienone **1** largely exists as its anion, $\mathbf{1}^-$. Thus, the rate data are consistent with the simple reaction of the metal ion with the anion of the substrate.

The catalysis by ferric ions decreases above pH 4.5. This is probably due to the presence of an equilibrium of the hydrated

[4]For cupric ions at pH 4.69 (Table 1): intercept = 0.0121 (sd = 0.0396); slope = 568 (sd = 6); r = 0.984.

[5]For ferric ions at pH 4.67 (Table 1): intercept = 0.0654 (sd = 0.0300); slope = 3040 (sd = 440); r = 0.979.

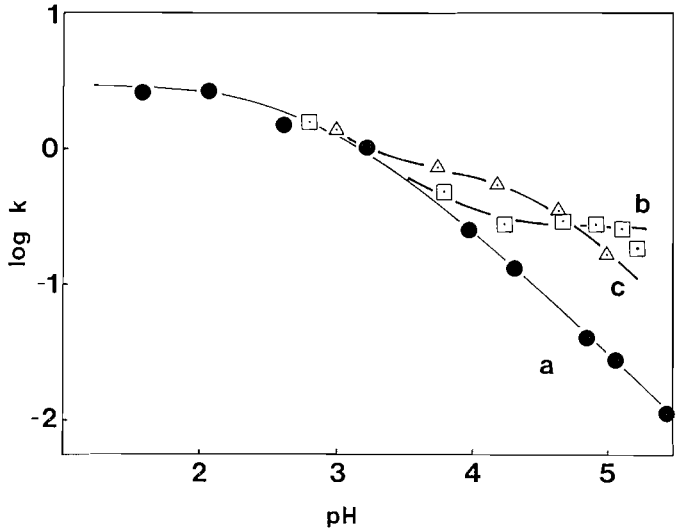

FIG. 1. pH dependence of the debromination of the dienone **1**: (a) in the absence of added metal ions (data from ref. 6); (b) in the presence of 0.5 mM cupric ions; (c) in the presence of 0.1 mM ferric ions.

ferric ion, which undergoes deprotonation in the pH range studied:

[3] $Fe(H_2O)_6^{3+} \rightleftharpoons Fe(H_2O)_5(OH)^{2+} + H^+$; pK_1 = 2.46 (9)

[4] $Fe(H_2O)_5(OH)^{2+} \rightleftharpoons Fe(H_2O)_4(OH)_2^{+} + H^+$; pK_2 = 4.70 (9)

At the acidities where the catalysis is most evident the dominant form of the ferric ion is $Fe(H_2O)_5(OH)^{2+}$ and this appears to be the form involved in the catalysis since the rate drops off with pH above pK_2, as discussed below.

In the absence of added metal ions and at fixed [Br^-] the pH dependence of the rate constant for the decomposition of **1** may be described by eq. [5], where k_1 is the rate constant for reaction of undissociated **1** and K_a is its acid dissociation constant.

$$[5] \quad (k^{obs})_0 = k_1[H^+]/(K_a + [H^+])$$

When ferric ions are present an additional term must be added to take account of the metal ion catalysis and the equilibria in eqs. [3] and [4] so that:

$$[6] \quad k^{obs} = (k^{obs})_0 + \frac{k_{cat}[Fe^{3+}]_t f_A K_1[H^+]}{([H^+]^2 + K_1[H^+] + K_1K_2)}$$

where $f_A = K_a/(K_a + [H^+])$ is the fraction of **1** existing at its anion. The derivation of eq. [6][6] assumes that the reactive form of the iron is $Fe(H_2O)_5(OH)^{2+}$. This assumption is necessary to reproduce the decrease in ferric ion catalysis that occurs when pH > pK_2. No catalysis by $Fe(H_2O)_6^{3+}$ is evident, presumably because of an unfavourable combination of the equilibria [3], [4], and the dissociation of **1**. The data in Fig. 1 correspond to a value of $k_{cat} \sim 5000\ M^{-1}\ s^{-1}$ for catalysis by $Fe(H_2O)_5(OH)^{2+}$.

The catalysis of the decomposition of **1** by cupric ions shows a plateau (k_{cat} = 570 $M^{-1}\ s^{-1}$) between pH 4 and 5 but the rate decreases slightly at higher pH. This decrease may be due to the

[6]In eq. [6] the quantity $[Fe^{3+}]_t$ is the total concentration of added iron (which is in large excess over [**1**]). For convenience we ignore the presence of the excess of 5-methylsalicylic acid (see Experimental). Any complexation involving this species will reduce the effective value of $[Fe^{3+}]_t$ but since the effect should be constant it should not affect our interpretation.

TABLE 2. The effect of cupric ions on the rate of bromination of 5-methylsalicylic acid (**2**)[a]

pH	k_2^{obs} (M^{-1} s^{-1})	k_2^{calc} (M^{-1} s^{-1})
0.13	3310	2350
1.09	2.53×10^4	2.13×10^4
2.09	1.74×10^5	1.95×10^5
2.76	1.25×10^6	6.80×10^5
3.85	2.21×10^6	1.80×10^6

[a]At 25°C, I = 0.11 M (KBr). Values of k_2^{obs} were determined in the presence of 0.1 mM cupric ions. The values of k_2^{calc} were calculated from the parameters of the rate profile for **2** in the absence of added metal ions, given earlier (6).

onset of the first ionization of the hydrated cupric ion:

[7] $Cu(H_2O)_6^{2+} \rightleftharpoons Cu(H_2O)_5(OH)^+ + H^+$; $pK_1 = 7.34$ (9)

In contrast to the behaviour of **1**, no catalysis by cupric ions (0.5 mM) was found for the decay of the analogous ipso-dienone lacking the 2-carboxyl group, formed during the reaction of *p*-methylphenol with bromine (1, 4). Thus, the 2-carboxyl group seems to be necessary for the occurrence of metal ion catalysis of the debromination of **1**.

The decomposition of **1** is a more complex reaction than is implied by eq. [1]. This arises because the debromination step produces 5-methylsalicylic acid (**2**) and bromine, which then react again, and the bromine attack is partitioned between *ortho* attack (~90%) and *para* (*ipso*) attack (~10%). Ultimately, all of the bromine is converted to the *o*-substituted product, 3-bromo-5-methylsalicylic acid (eq. [8]).

[8] $\mathbf{1} + Br^- \underset{k_p}{\overset{k_d}{\rightleftarrows}} \mathbf{2}^- + Br_2 \xrightarrow{k_0}$ product

This mechanism, which is amply supported by a variety of evidence (1, 4, 6), means that the rate constant for the decomposition of **1** (eq. [9]) contains the term: $k_o/(k_o + k_p)$, which represents the

[9] $k^{obs} = k_d k_o[Br^-]/(k_o + k_p)$

fraction of *ortho* bromine attack. This fraction, which is about 0.9 (4, 6), will be insensitive to the presence of metal ions as long as k_o and k_p do not vary markedly. As far as we can tell, this is the case.

Experiments carried out over a range of acidities (Table 2) showed that the second-order rate constants for the attack of bromine on 5-methylsalicylic acid **2** in the presence of 0.1 mM cupric ions are very close to those observed in their absence. Fitting to the data gives $k_2 = 2.9 \times 10^6$ M^{-1} s^{-1} for reaction of the anion $\mathbf{2}^-$ and $pK_a = 3.12$, compared to the values of $k_2 = 2.1 \times 10^6$ M^{-1} s^{-1} and $pK_a = 3.08$ that were found previously (6); this means that $k_2 = (k_o + k_p)$ is little changed by the cupric ions. Therefore, assuming that k_o and k_p are affected to a similar extent, the effect of the metal ions on k^{obs} for the decay of **1** (eq. [9]) is almost solely due to their effect on the rate constant of the debromination step, k_d.

The effects of added metal ions on the rate of enolization of the benzocyclohexadienone **3** were also studied and the results are presented in Table 3. Only in the pH region 4–6 were modest amounts of catalysis observed for Cu^{2+}, Fe^{3+}, and possibly Al^{3+}; outside this region the normal reaction (3) is dominant.

TABLE 3. The effect of metal ions on the rate of enolization of the benzocyclohexadienone **3**[a]

[a]At 25°C, I = 0.11 M, in 0.1 M aqueous KBr. The values of k^{calc} (for reaction in the absence of metal ions) are calculated from constants presented earlier (3).
[b]For $[Cu^{2+}] > 0.1$ mm the absorbance traces became increasingly noisy due to the large background absorbance.
[c]The dependence of k^{obs} on [ion] is linear.[7]
[d]At higher $[Al^{3+}]$ complex behaviour was observed.

For cupric ions the catalysis is maximal around pH 5.5 and the dependence of the rate on the [ion] is linear.[7] Above pH 6 this catalysis diminishes, probably due to the approach to the equilibrium [7], and the rate constants approach those observed in the absence of added metal ions (3). Likewise, the catalysis by Fe^{3+} and Al^{3+} ions, which is only apparent in a limited range of pH, is probably attenuated by the equilibria [3] and [4], and their analogues for Al^{3+} (9).

The enolizations of **3** and of its anion $\mathbf{3}^-$ are catalyzed by general bases (3). As seen by the results of experiments carried out in acetate buffers (Table 4) this also *seems* to be the case when cupric ions are present. However, the slopes of the buffer plots and the variation of these slopes with pH are virtually the same as those observed previously for reaction in the absence of added cupric ions (3).[8] Therefore, we conclude that increasing the buffer concentration simply increased the rate of the normal

[7]For cupric ions at pH 5.62 (Table 2): intercept = 0.0246 (sd = 0.2225); slope = 12400 (sd = 700); r = 0.9967.

[8]As previously, the data obtained in buffers are consistent with reaction of either acetate ion on the undissociated form of **3** or acetic acid on the anion of **3**. Of these two interpretations, the former is preferred, for reasons given previously (3).

TABLE 4. Dependence of the rate of the enolization of **3** on the acetate buffer concentration in the presence of cupric ions[a]

		k^{obs} (s^{-1})

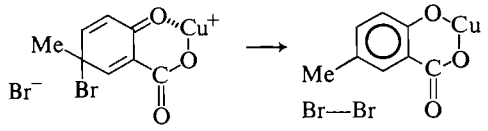
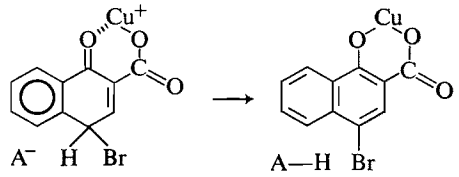
[a]At 25°C, I = 1.0 M (NaCl), $[Cu^{2+}]$ = 0.1 mM. The intercepts, slopes, and correlation coefficients are from the least-squares analysis of k^{obs} vs. [buffer].



SCHEME 1



SCHEME 2

TABLE 5. Constants for metal ion complexation and for the catalysis of the debromination of the anion of the dienone **1**[a]

Ion	pK_M	k_{cat} (M^{-1} s^{-1})
Fe^{3+}	16.35	~5000
Al^{3+}	14.11	—[b]
H^+	13.61	3010
Cu^{2+}	10.60	570
Ni^{2+}	6.95	—[c]
Zn^{2+}	6.85	—[c]
Co^{2+}	6.72	—[d]
Mg^{2+}	Small	—[d]

[a]Values of pK_M (20°C) for the complexation of ions with the dianion of salicylic acid[10] in aqueous solution are taken from the literature (9). The catalytic constants (k_{cat}) are for reaction in 0.1 M aqueous KBr at 25°C.
[b]Complex behaviour observed.
[c]No catalysis observed.
[d]There may be weak catalysis (see Table 1).

reaction relative to that of the metal ion catalyzed reaction. This should be the case if the third-order rate constant for catalysis by acetate ions and protons is greater than the analogous rate constant for acetate and cupric ions. Such is almost certainly the case since the catalytic constant for the proton (k_{cat} = 1.1 × 10^5 M^{-1} s^{-1} (3)) at low buffer concentration is almost 10 times that for Cu^{2+} (k_{cat} = 1.2 × 10^4 M^{-1} s^{-1}).[7] Therefore, even though the cupric ion catalyzed enolization of the anion $\mathbf{3}^-$ is probably susceptible to catalysis by buffer bases, it is difficult to observe such with only 0.1 mM of cupric ions at pH 4–5 because of the competition from proton catalysis.

Discussion

The results presented above indicate that the debromination of $\mathbf{1}^-$ and the enolization of $\mathbf{3}^-$ are catalyzed by some metal ions. However, the effects are relatively modest as the metal ions can barely compete with catalysis by protons under the conditions used.[9] The rate data are consistent with electrophilic catalysis (7) occurring through mechanisms analogous to those shown in eqs. [1] and [2] but in which the place of the carboxyl proton is taken by a metal ion. These mechanisms are shown in Schemes 1 and 2, using the cupric ion for illustrative purposes.

The dependences of the catalyzed rates on [metal ion] are linear over the concentration ranges studied and they show no downward curvature, which would be indicative of the onset of saturation.[4,5,7] Thus, the binding of the substrate anions ($\mathbf{1}^-$ and $\mathbf{3}^-$) to both Cu^{2+} and Fe^{3+} must be relatively weak with dissociation constants ≫1 mM. In contrast, the binding of these cations to the product dianions ($\mathbf{2}^{2-}$ and $\mathbf{4}^{2-}$) must be very much stronger, judging by stability constants in the literature (9). As shown by the constants[10] in Table 5, the binding of Fe^{3+}, Al^{3+}, and Cu^{2+} to the salicylate dianion ($\mathbf{S}^{2-}$) is very strong and comparable in strength to the binding of the proton. In contrast, the binding of the other metal ions, which do not show catalysis, is several orders of magnitude weaker.

Table 5 also lists the catalytic constants for Fe^{3+}, Cu^{2+}, and the proton in the debromination of $\mathbf{1}^-$. These values increase in a regular manner with the ability of the ion to form complexes with $\mathbf{S}^{2-}$ and so they provide good evidence that binding of the cation to the incipient product dianion $\mathbf{2}^{2-}$ is the primary factor that determines catalytic ability. The slope of log k_{cat} versus pK_M is about 0.2,[11] which implies that only a small part of the potential binding energy to $\mathbf{2}^{2-}$ is available at the transition state of the reaction. Nevertheless, this can be a significant amount of energy, as shown below.

The proton catalyzed debromination of the anion $\mathbf{1}^-$ actually involves the conversion of **1** into $\mathbf{2}^-$ (eq. [1]) (6). This reaction is accompanied by a *large* change in pK_a of about 13.61 − 3.06 = 10.55,[12] which is equivalent to an increase in the binding energy of the proton of 14.4 kcal/mol at 25°C. Even if only 20% of this energy is available for stabilization of the transition state of the debromination, a rate increase of 130 may accrue. In fact, the actual rate increase is 2300 times, relative to the proton catalyzed debromination of 4-bromo-4-methyl-2,5-cyclohexadienone (6). The difference between these two factors is probably due to an additional effect of the carboxyl group of **1**, since electron withdrawal by this group should facilitate the abstraction of Br^+ from **1** by bromide ion (eq. [1]).

Enolization of the anion $\mathbf{3}^-$ is catalyzed by Cu^{2+} ions and probably be Fe^{3+} and Al^{3+} ions, also. However, at acidities

[9]Higher concentrations of cupric or ferric ions gave solutions with unfavorable optical properties (due to turbidity or high background absorbance), which precluded the measurements of rates.

[10]The stability constants in Table 5 are $pK_M = -\log(K_M)$, where $K_M = [M^{n+}][S^{2-}]/[MS^{(n-2)+}]$ is the dissociation constant of the metal ion – salicylate dianion complex (9).

[11]We note that this slope is quite close to the Brønsted α of 0.27 for the general acid catalyzed debromination of 4-bromo-4-methyl-2,5-cyclohexadienone (4).

where such catalysis might compete with proton catalysis, the amounts of these ions are limited by unfavourable equilibria (eg., eqs. [3], [4], and [7]). Only in the case of Cu^{2+} was a reasonable amount of catalysis detected and its k_{cat} is about 10 times smaller than that for the proton (see Results). Thus, as found for the debromination of the dienone anion $\mathbf{1}^-$, the catalytic efficiency of an ion parallels its ability to bind salicylate dianions.

The energy considerations that apply to the ion catalyzed enolization of the anion $\mathbf{3}^-$ are similar to those discussed above for the debromination of $\mathbf{1}^-$. From the k_{cat} values for the proton and Cu^{2+} catalyzed enolization of $\mathbf{3}^-$, the slope of log k_{cat} vs. pK_M is 0.32. Assuming the same pK_a change of 10.55,[12] in going from **3** to $\mathbf{4}^-$, 32% of the increase in the binding energy of the proton corresponds to a rate increase of 2400 times. The actual increase for the proton catalyzed reaction of $\mathbf{3}^-$ is much larger, being 2×10^5 (3). Again, the difference betwen these two values may arise because of electron withdrawal by the 2-carboxyl group of **3**.

Our results have broad similarities to various earlier studies of electrophilic catalysis by metal ions. For example, the enolizations of β-keto esters (10), 2-acetylpyridine (11), and of acetonyl phosphonates (12) can be catalyzed by metal ions. Similarly, the decarboxylation of β-keto carboxylate anions can be promoted with metal ions (7*c*, 13, 14) and we note that the catalytic constants show a reasonable correlation with the stability constants for the metal ion complexes of the incipient product anions (7*c*). In suitable cases, divalent metal ions may also afford *electrophilic* catalysis of ester hydrolysis (15), as distinct from cases where the catalysts function by delivering a metal-bound OH^- to the ester (or amide) carbonyl (7*c*, 16) or in some other way (17).[13]

The present results emphasize that any reaction that produces a salicylate-type dianion in its rate-limiting step has the potentiality for electrophilic catalysis by metal ions, as well as by the proton. However, the extent to which a significant amount of metal ion catalysis actually occurs depends primarily on whether it can compete with proton catalysis. This, in turn, depends on various binding constants, the substrate pK_a, and the pHs at which the reaction can be studied. Only under favourable circumstances can ions such as Cu^{2+} or Fe^{3+}, which strongly bind to the product dianion, compete with the proton as the electrophilic catalyst.

It is also noteworthy that for the ions H^+, Cu^{2+}, and Fe^{3+} the strength of binding to the product dianions is so great that its partial expression in the transition states is significant, even though the transition states in question are "early" and reactant-like.

Experimental

The basic approach used was as in our previous studies of the dienones **1** and **3** (3, 6). Rate measurements were made at 25°C, using the same stopped-flow apparatus and data acquisition system as in other recent work (1–4, 6). One of the drive syringes of the stopped-flow apparatus contained a solution of bromine in the desired aqueous medium while the other contained the substrate necessary to generate the dienone (see below) in the same medium, containing the metal ion. The metal ions were introduced into solution as their chloride salts except for the use of ferric nitrate and aluminium sulphate.

The ipso-dienone was generated *in situ* in the stopped-flow apparatus from bromine (0.1 mM) and 5-methylsalicylic acid (**2**) (0.5 mM) in aqueous buffer containing 0.1 M KBr (total $I = 0.11$ M). Since only about 10% of the attack of bromine on **2** is *ipso*, the initial concentration of **1** was about 0.01 mM, much less than the concentration of the added metal ions. The disappearance of **1** was monitored at 250 nm (6)

Similarly, the benzocyclohexadienone **3** was generated *in situ* from 1-naphthol-2-carboxylic acid (0.1 mM) and bromine (0.05 mM) in the desired medium and its enolization was monitored as a decay at 270 nm (3). For the pH and metal ion dependence studies the total ionic strength $I = 0.11$ M (0.01 M buffer salt + 0.1 M KBr), whereas for the buffer catalysis studies $I = 1.0$ M ([buffer salt] + [NaCl]). Because of the very low solubility of 1-naphthol-2-carboxylic acid in water, experiments could not be carried out at pHs below 3.5, where it is not appreciably ionized (3).

In DMSO (TEAP), phenylbutazone, oxyphenbutazone, and kebuzone, pyrazolidine-3,5-dione species are irreversibly reduced in two steps at the mercury electrode. The total reduction process is monoelectronic with production of the enolate carbanion. A chemical–electrochemical mechanism is proposed, each step is attributed to one of the tautomeric forms, ketoenol (E) and diketone (D). The tautomeric equilibrium constants (K = [E]/[D]) are reached both by linear sweep voltammetry at 30 V s^{-1} and by FT ^{1}H NMR and the global apparent acidity constants are determined by potentiometry.

CHRISTINE HERRENKNECHT, ELISABETH GUERNET-NIVAUD, OLIVIER LAFONT, MICHEL GUERNET et CLAIRE GUEUTIN. Can. J. Chem. **66**, 1199 (1988).

Phénylbutazone, oxyphenbutazone et kébuzone, dérivés de la pyrazolidinedione-3,5 se réduisent à une électrode de mercure en deux étapes dans le DMSO (TEAP). Le transfert irréversible, globalement monoélectronique conduit à la forme carbanion énolate. Un mécanisme c.e. est proposé, chaque étape correspond à une des formes tautomères, cétoénol (E) ou dicétone (D). Les constantes de l'équilibre cétoénolique (K = [E]/[D]) sont atteintes aussi bien par voltamétrie linéaire à 30 V s^{-1} que par FT ^{1}H RMN, les constantes d'acidité globales apparentes sont déterminées par potentiométrie.

Introduction

Continuing our study on pyrazolidine-3,5-diones of pharmaceutical interest, we report some new results of electroreduction at the mercury electrode and ^{1}H NMR spectroscopy of phenylbutazone **1**, oxyphenbutazone **2**, and kebuzone **3**, in a dipolar aprotic medium such as dimethylsulfoxide (DMSO). These compounds present a hydrogen atom in α-position of two carbonyl groups. The lability of this hydrogen induces weak acidity and prototropic tautomerism of keto–enol type (see Scheme A).

Electrochemical behaviors of β-diketones are largely described in protic media, but the authors were mainly interested by protonation or hydration reaction of tautomeric forms (1, 2). In DMSO, in the case of diphenylpropanediones, a 0.5 electron process yielding the conjugated base and pinacol was reported (3).

In a previous investigation of title compounds in ethanol ($LiClO_4$), we noted the influence of tautomerism on electron transfer (4). The difference occurring in the limiting currents was related to the apparent pK_a values and suggested the attribution of the single cathodic wave to the keto–enol form; the diketone form was masked by the background discharge.

In the present article, linear voltammetry at the hanging drop mercury electrode in DMSO was used in order to elucidate the redox mechanism and reach the tautomeric equilibrium constants (Scheme A), FT ^{1}H NMR confirmed voltammetric values.

Results and discussion

The reduction of **1**, **2**, and **3** at the dropping mercury electrode in DMSO exhibited two well-defined waves (Fig. 1). The half-wave potentials ($E_{1/2}$) of the former (ca. −1.4 V) and the latter (ca. −1.9 V) were very similar for these three compounds, but a big discrepancy was observed in the intensities of the limiting currents (i_l) for equimolecular concentrations, although it was assumed that all the species had identical diffusion coefficients; i_{l1} assignable to the first step increased from oxyphenbutazone to phenylbutazone and kebuzone while the second step i_{l2} decreased. The total intensity ($i_{l1} + i_{l2}$) remained constant. The slopes of the linear plot of log $(i_l - i)/i$ versus E for these monoelectronic waves varied from 116 to 140 mv per unit of logarithm, thus proving a non nernstian transfer.

Exhaustive coulometry needed one Faraday per mole, the potential being applied upon the first (−1.5 V) or the second step (−2.2 V): the decrease of the more easily reducible form brought about the disappearance of the less reducible one.

These data could be interpreted as a chemical–electrochemical reduction process, each step being attributed to one of the tautomeric forms. In such mechanisms different variations of i_l with mercury column height (H) were expected according to the possible participation of the thermodynamic (K) and/or kinetic (k_f and k_b) constants in the overall values of current intensities (5). Two characteristic types of behavior are described; if K is the only constant involved, the plot of i_l versus $H^{1/2}$ is linear, whereas i_l is independent of H when only k_f and k_b are involved.

Pyrazolidine-3,5-diones showed an intermediate dependency of i_{l1} on H: a linear function with $H^{1/3}$ indicated a non diffusion-

$$K_a = \frac{[H^+]\,[\text{anion}]}{[\text{Keto–enol}] + [\text{Diketone}]}$$

$$K = \frac{[\text{Keto–enol}]}{[\text{Diketone}]} = \frac{K_f}{K_b}$$

1 : $R_1 = -\underset{b}{CH_2}-\underset{c}{CH_2}-\underset{d}{CH_2}-\underset{e}{CH_3}$, $R_2 = H$

2 : $R_1 = -\underset{b}{CH_2}-\underset{c}{CH_2}-\underset{d}{CH_2}-\underset{e}{CH_3}$, $R_2 = OH$

3 : $R_1 = -\underset{b}{CH_2}-\underset{c}{CH_2}-CO-\underset{e}{CH_3}$, $R_2 = H$

SCHEME A

controlled first step and supported the notion that the initial transfer is governed by the tautomeric equilibrium K as well as by kinetic constants k_f and k_b.

These results were compared with those provided by linear sweep voltammetry. Current–potential curves were recorded over a range of scan rates (v) from 0.1 to 30 V s^{-1}: current intensities were rather scan-rate independent when v is lower than 10 V s^{-1}, indicating a kinetic behavior; when increasing v (>10 V s^{-1}), they became a linear function of $v^{1/2}$, a pure diffusion-controlled process was then obtained and peak currents (i_{p1} and i_{p2}) were directly related to the concentration of each tautomeric form in solution (6).

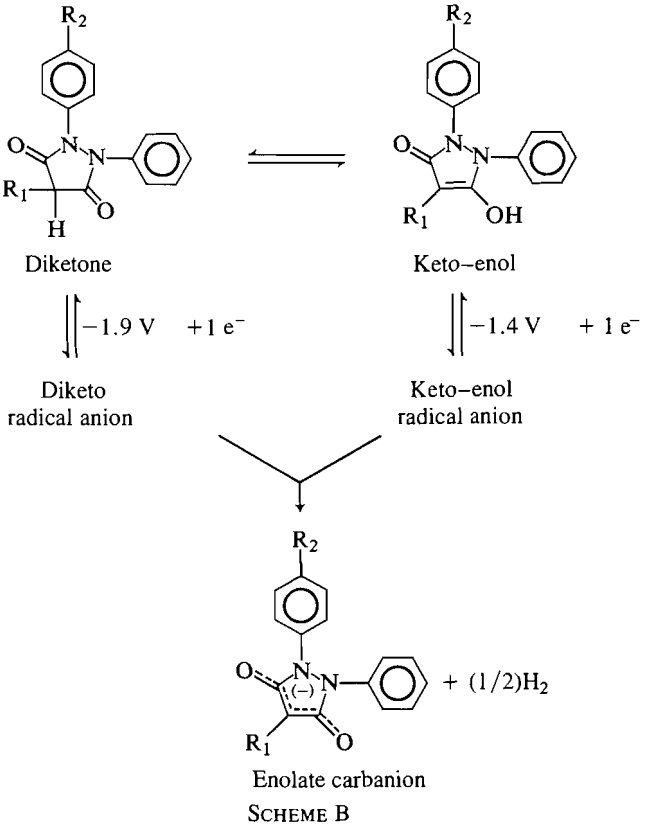
In order to attribute each reduction step to the convenient tautomeric form we undertook a spectroscopic study. When the usual concentrations were used for ^1H NMR study (i.e. 3×10^{-1} mol L^{-1}), ketoenolic forms of these derivatives could not be observed (7). FT ^1H NMR spectroscopy performed in the same concentration range as voltammetry (i.e. 2×10^{-3} mol L^{-1}, in DMSO-d_6) allowed us to identify the two tautomeric forms in solution. Chemical shifts, spin–spin couplings, relative integration intensities, and assignments of the side chains protons are listed in Table 2. For kebuzone homonuclear double irradiation unambiguously permitted the attribution of H_b and H_c signals (Table 3). The populations of the keto and enol tautomers were determined from the intensity of the H_b signals in both forms,

TABLE 1. Limiting currents (i_l) and half-wave potentials ($E_{1/2}$) of the first and the second cathodic steps (vs. Ag/AgCl)

	1st step		2nd step	
Compounds	i_l (μA)	$E_{1/2}$ (V)	i_l (μA)	$E_{1/2}$ (V)
Oxyphenbutazone	0.100	−1.38	0.645	−2.00
Phenylbutazone	0.285	−1.37	0.460	−1.94
Kebuzone	0.465	−1.36	0.280	−1.91

except for kebuzone where the H_c resonance was used (Table 3). The shielding effect of 0.1 ppm observed on the H_c, signal of ketoenol **3** was consistent with the formation of hydrogen bonding involving the C=O group of the side chain. Taking into account the accuracy of the measurements, a satisfactory correlation appeared between the ^1H NMR estimations of the relative ratios of ketoenol and diketo forms for the three compounds and the linear voltammetry ratios i_{p1}/i_{p2} measured at a sweep rate of 30 V s^{-1} (Table 4). It follows that this ratio intensity represents a good estimate of ketoenol and diketone relative concentrations.

Consequently, one may assume that the two polarographic waves correspond respectively to the ketoenol (−1.4 V) and diketone reduction (−1.9 V). The following chemical–electrochemical mechanism is proposed:



SCHEME B

The quantitative generation of the enolate carbanion by rapid elimination of half a molecule of hydrogen per mole of radical anion was proved by ultraviolet experiments. The same evolution of uv spectra appeared either during exhaustive coulometry or by adding an alkaline agent. Before electrolysis or in neutral solution the wavelength of the maximum of absorption of pyrazolidine-3,5-dione derivatives was less than 250 nm and therefore their absorption was masked by the solvent cut-off. Either

*t = triplet; d = doublet; s = singlet; dt = doublet of triplet.

after electrolysis or in an alkaline medium, a bathochromic shift appeared, consistent with the enolate carbanion formation (λ_m = 270 nm, $\epsilon_M = 2.1 \times 10^5$ for phenylbutazone). The irreversibility of the cathodic process was proved because no complementary anodic peak was observed even at potential scan rate as high as 30 V s^{-1}. This observation confirmed the high-rate irreversible evolution of the radical anion to the enolate carbanion which is not oxidizable in the solvent limits.

On the other hand, in a previous report (4), we assumed that in an ethanolic medium an increase of K was related to a decrease of pK_a' (Scheme A). In order to strengthen this assumption, we evaluated in DMSO the apparent pK_a' values for the three

TABLE 4. i_{p1}/i_{p2} ratios (linear sweep voltammetry at 30 V s^{-1}). K values (^1H FT NMR) and pK_a' (potentiometry)

Compounds	i_{p1}/i_{p2}	K	pKa′

Oxyphenbutazone	0.15	0.15	7.6
Kebuzone	0.59	0.52	6.3

compounds by potentiometry. If one considers the results listed in Table 4, pK_a' values decrease from oxyphenbutazone to phenylbutazone and kebuzone while corresponding K values increase. In this series, as it was expected, the acidic dissociation of —O—H enol bond is easier than that of the corresponding —C—H bond. The relative increase of K in kebuzone may be attributed to hydrogen bondings which would stabilize the ketoenol form.

Experimental

Solvents, electrolytes, and reagents

Phenylbutazone, oxyphenbutazone (Ciba-Geigy), and kebuzone (Beytout) were employed without further purification. Their identities were checked by IR and NMR spectra and their purity by TLC on glass plates coated with fluorescent silicagel (Merck) (solvent of migration: cyclohexane/methylisobutylketone/anhydrous acetic acid 80/35/5 — Rf:phenylbutazone 0.77, oxyphenbutazone 0.40, kebuzone 0.25).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

Salicylic acid (Fluka), sodium salicylate (Merck), benzoic acid (Prolabo), sodium benzoate (Merck) were employed without further purification.

Dimethylsulfoxide (DMSO): (*i*) spectroscopic grade (Merck) for voltammetric determinations; (*ii*) DMSO-d_6 (CEA, 99.99% purity) for NMR.

Tetraethylammonium perchlorate (TEAP) (Fluka) was purified according to the method described by Kolthoff and Coetzee (8). Tetrabutylammonium hydroxide (TBAH) (Merck) was used without further purification.

Apparatus

Polarographic measurements were made on a PRG5 Tacussel potentiostat coupled with an EPL1 Tacussel recorder. The three-electrode jacketed cell used was of conventional design and was thermostated at 25 ± 0.1°C. For polarography, the working electrode consisted of an MPO Tacussel dropping mercury electrode with an adjustable drop time. A platinum wire served as auxilliary electrode. An Ag/AgCl reference electrode and sample compartment were separated by a TEAP/solvent bridge.

Cyclic voltammetric triangular wave forms were obtained from a GSTP3 Tacussel function generator. A hanging drop mercury electrode (Kemula type) was used as the working electrode while reference and counter electrodes were identical to those described above. Data were recorded on an R 5103M Tektronik oscilloscope.

For controlled potential electrolysis, a mercury pool ca. 1 cm deep and 12 cm^2 in area was placed in the cell, a large surface platinum auxilliary electrode was used in the anodic compartment separated by a solvent bridge containing the background electrolyte. The reference electrode was the same as that described above. Potentials were imposed by a PRT 202X Tacussel potentiostat. The quantity of electricity used was measured using an IG5 Tacussel integrator.

Potentiometric pK_a' measurements were carried out at a hydrogen platinum electrode Pt151 Tacussel, using an Ag/AgCl reference electrode. The potentials were measured at 25 ± 0.1°C using a Tacussel S70 As/N millivoltmeter.

The ultraviolet technique was carried out with a Pye-Unicam SP 800 spectrometer.

The ^1H NMR technique was carried out with a BRUCKER FT 500 MHz spectrometer.

Procedures

For all the electrochemical experiments, the pyrazolidine-3,5-diones solutions, in which the background electrolyte was 2×10^{-1} mol L^{-1} TEAP, were about 2×10^{-3} mol L^{-1}. The solutions were purged with nitrogen and kept under a blanket of nitrogen during the recording. Cyclic voltammograms were recorded at different potential scan rates (0.1 to 30 V s^{-1}). For controlled potential electrolysis, nitrogen was continuously bubbled through the solution during electrolysis and a magnetic stirrer was used.

The potentiometric pK_a' determinations were carried out in DMSO 10^{-2} mol L^{-1} solutions after addition of half an equivalent of TBAH. The electrode was calibrated with DMSO solutions of salicylate and benzoate buffers (9).

The ultraviolet measurements were carried out on electrochemical solutions with 0.1 mm optical path cells.

The NMR spectra were recorded at 30°C using DMSO-d_6 2×10^{-3} mol L^{-1} solutions.

Received October 7, 1987

GEORGE I. BIRNBAUM, MILOŠ BUDĚŠÍNSKÝ, and JIŘÍ BERÁNEK. Can. J. Chem. **66**, 1203 (1988).

Crystals of 5′-chloroarabinosylcytosine, an inhibitor of nucleic acid synthesis, belong to the orthorhombic space group $P2_12_12_1$, and the cell dimensions are $a = 6.801(1)$, $b = 9.698(2)$ and $c = 16.497(3)$ Å. X-ray intensity data were measured on a diffractometer and the structure was determined by direct methods. Least-squares refinement, which included all hydrogen atoms, converged at $R = 0.032$ for 1251 observed reflections. The conformation about the glycosyl bond is *anti*, the furanose ring adopts a C3′ *endo*/C4′ *exo* pucker and the conformation of the side chain is *gauche*$^+$, stabilized by an intramolecular C6—H···Cl5′ hydrogen bond. ^{1}H and ^{13}C nmr spectra confirm the *anti* conformation about the glycosyl bond. In D_2O solution there is an approximately equal population of *N*- and *S*-type conformers of the furanose ring and a *trans* > *gauche*$^+$ > *gauche*$^-$ distribution of the 5′-CH_2Cl side chain rotamers.

GEORGE I. BIRNBAUM, MILOŠ BUDĚŠÍNSKÝ et JIŘÍ BERÁNEK. Can. J. Chem. **66**, 1203 (1988).

Les cristaux de la chloro-5′ arabinosylcytosine, un inhibiteur de la synthèse de l'acide nucléique, appartiennent au groupe d'espace orthorhombique $P2_12_12_1$, avec $a = 6{,}801(1)$, $b = 9{,}698(2)$ et $c = 16{,}497(3)$ Å. On a mesuré les intensités de diffraction par les rayons-X et on a déterminé la structure par des méthodes directes. L'affinement par le méthode des moindres carrés, incluant tous les atomes d'hydrogène, converge vers $R = 0{,}032$ pour 1251 réflexions observées. La conformation autour de la liaison glycosyle est *anti*, le cycle furannose adopte une conformation C3′ *endo*/C4′ *exo* et la chaîne latérale, qui est stabilisée par une liaison hydrogène intramoléculaire C6—H···C15′, est *gauche*$^+$. Les spectres rmn du ^{1}H et du ^{13}C confirment la présence d'une conformation *anti* autour de la liaison glycosyle. En solution dans le D_2O, les proportions des conformères des types N et S du cycle furannose sont approximativement égales alors que la distribution des rotamères de la chaîne latérale 5′-CH_2Cl est la suivante: *trans* > *gauche*$^+$ > *gauche*$^-$.

[Traduit par la revue]

Introduction

Having recently carried out X-ray and nmr analyses of 2′,5′-anhydroarabinosylcytosine (1), we turned our attention to 5′-chloroarabinosylcytosine (2), another analog of the antileukemic agent arabinosylcytosine (ara-C). Of all biologically active nucleoside analogs we studied (3), this compound is the most potent and specific inhibitor of DNA synthesis in L1210 cells. Also, its penetration through the intestinal wall is faster and it is metabolically more stable (4, 5) than the parent ara-C. This could be its fundamental advantage, particularly for oral applications. It was recently found that 5′-chloroarabinosylcytosine (5′-Cl-ara-C) could be directly phosphorylated to ara-C-5′-trihosphate (6), the biologically active form of ara-C (7, 8). Unusual properties, both chemical and/or biological, were also observed in some other 5′-chloro derivatives of nucleoside analogs, eg. 5′-chloro-5-fluorouridine (9) and 5′-chloro-6-azauridine (10). It appeared of interest, therefore, to carry out a detailed physico-chemical study of 5′-Cl-ara-C, a representative member of such a group of nucleoside analogs. In contrast to the rigid molecule of 2′,5′-anhydroarabinosylcytosine (1), one would not expect a large measure of agreement between the solid-state and solution conformations of the flexible 5′-Cl-ara-C molecule.

Experimental

5′-Chloroarabinosylcytosine was prepared as previously described (2) and crystallized from water to give colorless prisms. Precession photographs indicated the orthorhombic space group $P2_12_12_1$. A crystal measuring 0.3 × 0.5 × 0.6 mm was mounted on an Enraf-Nonius CAD-4 diffractometer; the crystal data are as follows:

$C_9H_{12}N_3O_4Cl$ mw = 261.67

Orthorhombic, $a = 6.801(1)$, $b = 9.698(2)$, $c = 16.497(3)$ Å, $V = 1088.0(4)$ Å^3, $\rho_c = 1.60$ g cm^{-1}, $Z = 4$ (20°C, MoKα_1, $\lambda = 0.70930$ Å), $F(000) = 544$, μ(MoKα) = 3.56 cm^{-1}.

Unit cell dimensions were determined from a least-squares refinement of the angular settings of 25 reflections with $20 < \theta < 26°$. Intensities were measured at room temperature (20°C) with Nb-filtered MoKα radiation, using $\omega/2\theta$ scans with variable scan ranges and speeds. Two standard reflections were measured at regular intervals; their intensities fluctuated by ±1%. Both *hkl* and *hkl̄* reflections with $\theta \leq 27.5°$ were measured and averaged. Of the 1464 unique reflections in the dataset there were 1252 (85.5%) with $I \geq 3\sigma(I)$ which were considered observed. The intensities were corrected for Lorentz and polarization factors; absorption corrections were unnecessary.

The structure was determined by direct methods with the aid of the computer program MULTAN78 (11). Atomic parameters of non-hydrogen atoms were refined by block-diagonal least squares with anisotropic temperature parameters. All hydrogen atoms were located on difference Fourier maps and their parameters refined with isotropic temperature factors. The scattering factors were taken from the International tables for X-ray crystallography (12) and the chlorine and oxygen curves were corrected for anomalous dispersion. Throughout the refinement the function $\Sigma w(|F_o| - |F_c|)^2$ was minimized and a factor of 0.8 applied to all shifts. The following weighting scheme was used during the final stages: $w = w_1 \cdot w_2$, where $w_1 = 1$ for $|F_o| \leq 15$, $w_1 = 15/|F_o|$ for $|F_o| > 15$; and $w_2 = \sin^2\theta/0.14$ for $\sin^2\theta < 0.14$, w_2, = 1 for $\sin^2\theta \geq 0.14$. This scheme made the average values of $w(\Delta F^2)$ independent of $|F_o|$ and $\sin^2\theta$. The strongest reflection (004) suffered from secondary extinction effects and was given zero weight. After the

final cycle the average parameter shift equalled 0.15σ and the largest 0.45σ. The final conventional residual index R is 0.032 and the weighted index R_w is 0.036 for 1251 observed reflections. A final difference Fourier map showed no significant features. Atomic coordinates are listed in Table 1. Anisotropic temperature parameters and a list of observed and calculated structure factors are available from the Depository of Unpublished Data.[2]

^{1}H and ^{13}C nmr spectra were measured on a Varian XL-200 FT-NMR spectrometer at frequencies of 200 and 50.3 MHz, respectively. Solutions of ~ 5 mg (for ^{1}H nmr) and 50 mg (for ^{13}C nmr) of 5′-Cl-ara-C in 0.4 mL of DMSO-d_6 were used. DMSO was used as an internal reference and the signals were recalculated to a δ-scale, using δ_H(DMSO) = 2.50 and δ_C(DMSO) = 39.7 ppm. In addition, the 400-MHz ^{1}H nmr spectrum of a saturated solution of 5′-Cl-ara-C (≤2 mg) in D_2O (0.4 mL) was measured on a Bruker AM 400 FT-NMR instrument, using HDO as internal reference (δ_H = 4.80 ppm). Selective decoupling on proton H1′ was used for the determination of its coupling constants in both ^{1}H and ^{13}C nmr spectra. The proton chemical shifts and coupling constants were checked using a spectrum-simulation procedure (standard program SPIN on Varian XL-200 instrument). Carbon-13 chemical shifts and the number of directly bonded protons were determined from the "attached proton test" ^{13}C nmr spectrum (13). The coupling constants J(C,H) were extracted from the proton-coupled ^{13}C nmr spectrum with nOe enhancement

Results and discussion

Solid-state structure

A stereoscopic view of the molecule is shown in Fig. 1. Figure 2 shows the bond lengths and bond angles while the Newman projections (Fig. 3) display the torsion angles. The pyrimidine ring is not exactly planar; the largest deviations from the mean plane (χ^2 = 1110.8) are 0.040(2) and −0.041(2) Å for N1 and C2, respectively. The bond lengths and bond angles of the cytosine base are in excellent agreement with previously found values (14). The conformation about the glycosyl bond is, as usual, *anti* with χ_{CN} [C6—N1—C1′—O4′] = 30.7(3)°. This is in good agreement with the average value of χ_{CN} in arabinonucleosides (15). The furanose ring adopts the C3′ *endo*/C4′ *exo* ($^3T_4$) pucker with a phase angle of pseudorotation (P) of 33.5° and a maximum amplitude of puckering (τ_m) of 36.8°. Again we note that, in contrast to ribonucleosides, there is no correlation betwen the ring pucker and χ_{CN} (15). The conformation about C4′—C5′ is *gauche*$^+$, possibly stabilized by an intramolecular hydrogen bond (15). Bond lengths and bond angles in the arabinose moiety have commonly observed values and require no comments.

As mentioned above, there is an intramolecular hydrogen bond in which H6 is donated to C15′. While C6—H···O5′ hydrogen bonds have been found in many crystal structures (16), the observation of an C6—H···C15′ bond apears to be

[a]The x and U_{eq} parameters of the non-hydrogen atoms were multiplied by 10^4, the y and z coordinates by 10^5; all hydrogen atom parameters were multiplied by 10^3.

[b]In Å^2; U_{eq} is $(1/3)(U_{11} + U_{22} + U_{33})$.

novel. In their review of C—H···X bonds in crystal structures determined by neutron diffraction Taylor and Kennard (16*a*) listed 13 C—H···Cl bonds with H···Cl distances in the range 2.569–2.944 Å. The corrected H···*A* distances listed in Table 2 were calculated following the normalization of C—H, N—H, and O—H bonds to their nominal values of 1.09, 1.04, and 0.97 Å, respectively (17). It can be seen that the H6···C15′ distance is well within this range. The C6—H6···C15′ angle (174°) lends futher support to the existence of this hydrogen bond. C15′ is also involved in a fairly strong intermolecular hydrogen bond, accepting a proton from N4. This hydrogen bond could stabilize the C4-amino group and thus slow down the deamination, and the resulting deactivation, of 5′-Cl-ara-C. We can now explain our earlier observation (4–6) that 5′-Cl-ara-C is more stable than ara-C.

The hydrogen bonding network can be represented schematically as follows:

C—H···Cl5′···H41—N4 O3′—H···O2′—H···N3

O2···H42

The molecular packing in the crystal is shown in Fig. 4. Apart from hydrogen bonds, there are no abnormally short intermolecular distances and there is no base stacking.

Solution conformation

^{1}H and ^{13}C nmr spectra were studied to determine the solution conformation of 5′-Cl-ara-C. The proton spectrum in DMSO-

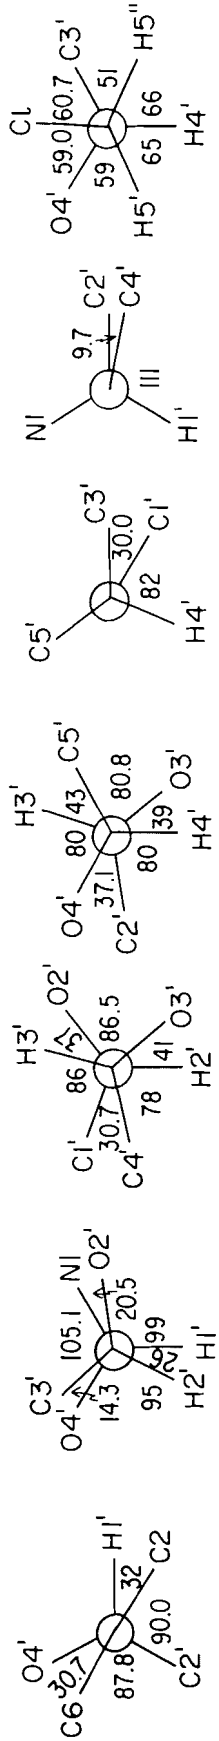

FIG. 3. Newman projections along N1—C1′, C1′—C2′, C2′—C3′, C3′—C4′, C4′—O4′, O4′—C1′, and C4′—C5′; the esd's are 0.2–0.3° for torsion angles which do not involve hydrogen atoms and 2–3° for those which do.

d_6 showed a strongly coupled spin system of H3′, H4′, H5′, and H5″ protons at δ 3.72–3.96 which made the analysis of related parameters very difficult. Much better resolution of signals was achieved in D_2O solution. Proton chemical shifts and coupling constants used for a conformational analysis (see Table 3) were therefore obtained from a 400 MHz spectrum in D_2O. Carbon-13 nmr spectra were mesured only in DMSO-d_6 because of the very low solubility of 5′-Cl-ara-C in D_2O.

Pentose ring

We followed the method of de Leeuw and Altona (18) for determining the relative population of *N*- and *S*-type puckers in th conformational equilibrium. Using $P_N = 16.6°$, $P_S = 159.6°$, $\tau_N = \tau_S = 36°$ (recommended for arabinosides (18)), we estimated an *N*/*S* conformer ratio of 0.45/0.55. The r.m.s. deviation between calculated (18) and observed *J*(1′2′), *J*(2′3′) and *J*(3′4′) values (Table 3) amounts to 0.21 Hz. Subsequently, we repeated the calculation with the parameters for the *N*-conformer corresponding to those found in the crystal structure ($P_N = 33.5°$, $\tau_N = 36.8°$). Assuming $\tau_S = \tau_N$, we optimized P_S and the *N*/*S* ratio for the best fit with the experimental *J* values. The results thus obtained ($P_S = 159°$, *N*/*S* ratio 0.46/0.54) are not much different from the original ones, but the r.m.s. deviation between observed and calculated coupling constants decreased to 0.07 Hz, a value which is comparable to the experimental error of *J*'s. This means that in D_2O solution 5′-Cl-ara-C exists as a nearly equally populated mixture of *N* (C3′ *endo*, ^3E) and *S* (C2′ *endo*, ^2E) conformers. This result agrees with the general conformational behaviour of arabinosides in which no distinct preference for either conformer has been found in solution (18) or in the solid state (15). Our *J* values and *N*/*S* ratio are very similar to those reported for 3′-Me-ara-A and 3′,5′-diMe-ara-A (18, 19).

Exocyclic 5′-CH_2Cl

The conformation about the C4′—C5′ bond in nucleosides can be interpreted in terms of rapid rotational averaging among three staggered rotamers, viz. *gauche*$^+$ (g^+), *trans* (*t*) and *gauche*$^-$ (g^-) (20). The rotamer populations can be calculated (21) from the observed couplings *J*(4′5′) and *J*(4′5″), and values of 11.5 and 1.5 Hz (for J_t and J_g, respectively) are generally used for 5′-OH nucleosides (21). In our case of a 5′-Cl derivative, we have to correct the *J* values for the effect of different substituent electronegativity. Using Bystrov's (22) equation $J_{corr} = J(1 - 0.1\Delta E)$ with $\Delta E = E_{Cl} - E_O = -0.35$, we obtained corrected values $J_t = 11.9$ and $J_g = 1.55$ Hz. From these values and the experimental values *J*(4′5′) = 4.35 and *J*(4′5″) = 5.9 Hz, we calculated the approximate rotamer populations given in Table 4. The values for the *gauche*$^-$ and *trans* rotamers were obtained by assigning the H5′ and H5″ protons according to the published convention (23). The population of the *gauche*$^+$ rotamer is slightly lower than in ara-C, presumably because the relatively weak C—H···Cl hydrogen bond would not play a significant role in D_2O solution. On the other hand, the population of the *gauche*$^-$ rotamer, energetically unfavourable in normal nucleosides (15), is somewhat higher owing to the decreased electronegativity of the substituent at C5′.

trum in DMSO-d_6 afforded nine signals. Their structural assignment (Table 3) was done on the basis of numbers of directly bonded protons, chemical shift arguments, and a comparison with ^{13}C nmr data of cytosine nucleosides and arabinofuranose derivatives. All one-bond couplings J(C,H) were determined from the proton-coupled ^{13}C nmr spectrum. Long-range couplings J(C,H) were established only for cytosine carbons because sugar carbons gave poorly resolved multiplets. The orientation about the glycosyl bond can be estimated from ^3J(C6, H1′) and ^3J(C2, H1′) couplings. As in our preceding work on 2′5′-anhydro-ara-C (1), we found a significantly higher value of the former (5.5 vs. 1.3 Hz). This indicates a preference for the *trans* orientation of the fragment C6—N1—C1′—H1′. The approximate values calculated (24) for the torsion angles C6—N1—C1′—H1′ and C2—N1—C1′—H1′ (140 and 40°, respectively) are in good agreement with the values 150(2) and 32(2)° obtained from the X-ray analysis (Table 4).

Photochemistry of cyclic α-hydroxy ketones. III. The nature of the photoproducts from 5-hydroxy-5β-cholest-3-en-6-one and the relationship of these to the photoproducts from analogous saturated 5-hydroxycholestan-6-ones[1]

PETER YATES AND SHIRLEY STIVER
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received October 29, 1987

PETER YATES and SHIRLEY STIVER. Can. J. Chem. **66**, 1209 (1988).

Photolysis of 5-hydroxy-5β-cholest-3-en-6-one (**2**) in hexanes gave 5-oxo-5,6-seco-cholest-3-en-6-al (**13**) and [(1*R*, 4*R*, 7a*R*)-1-(1*S*,5-dimethylhexyl)-7a-methyl-2,3,3a,4,7,7a-hexahydro-1*H*-inden-4-yllacetaldehyde (**14**). Similar irradiation of **13** gave **14** and a small amount of 5-hydroxy-*B*-nor-5β-cholest-3-ene-6α-carbaldehyde (**15**). The structures of **13** and **15** were confirmed by independent synthesis: the former from cholesteryl acetate via 3β-acetoxy-6,6-dimethoxy-5,6-seco-cholestan-5-one and the latter from **13** by treatment with methanolic sodium methoxide. Photolysis of 5-deuteroxy-5β-cholest-3-en-6-one (**26**) in hexanes gave the -CDO analogues of the aldehydes **13**, **14**, and **15**. These observations are interpreted in terms of α-cleavage of the C-5 — C-6 bond of **2** to give an acyl allyl diradical, which undergoes O—H hydrogen abstraction to give **13**. The occurrence of α-cleavage as the major reaction pathway is attributed to the increased stabilization of the alkyl radical center by the hydroxyl substituent. The preference for O—H rather than C—H abstraction in the diradical is attributed to the planar nature of the allyl radical center. The indenylacetaldehyde **14** is considered to arise via a Norrish type II reaction of **13**, while the formation of *B*-nor aldehyde **15** is ascribed to a "dark" aldol reaction of **13**.

PETER YATES et SHIRLEY STIVER. Can. J. Chem. **66**, 1209 (1988).

La photolyse de l'hydroxy-5 5β-cholestène-3 one-6 (**2**) dans des hexanes conduit à l'oxo-5 séco-5,6 cholestène-3 al-6 (**13**) et au [(1*R*, 4*R*, 7a*R*) (diméthyl-1*S*,5 hexyl)-1 méthyl-7a hexahydro-2,3,3a,4,7,7a 1*H*-indènyl-4] acétaldéhyde (**14**). En procédant à une irradiation semblable du composé **13**, on obtient le produit **14** ainsi qu'une faible quantité d'hydroxy-5 *B*-nor 5β-cholestène-3 carbaldéhyde-6α (**15**). On a confirmé les structures des composés **13** et **15** en procédant à leurs synthèses; le premier a été préparé à partir de l'acétate de cholestéryle, via l'acétoxy-3β diméthoxy-6,6 séco-5,6 cholestanone-5, alors que pour le deuxième on a soumis le composé **13** à un traitement par du méthanolate de potasssium en milieu méthanolique. La photolyse de la deutéroxy-5 5β-cholestène-3 one-6 (**26**) dans des hexanes conduit aux analogues -CDO des aldéhydes **13**, **14** et **15**. On interprète ces observations en fonction d'un clivage-α, de la liaison C-5/C-6 du composé **2**, qui conduirait à un diradical acyle allyle qui subirait un enlèvement d'hydrogène du O—H pour donner le composé **13**. Pour expliquer le fait que la voie principale de la réaction implique un clivage-α, on suggère qu'elle est due à une augmentation de la stabilisation du centre radicalaire alkyle par le substituant hydroxyle. Le fait que, dans le diradical, l'hydrogène du O—H est enlevé plutôt que celui du C—H est attribué à la nature planaire du centre radicalaire allylique. On considère que l'indènylacétaldéhyde **14** provient d'une réaction Norrish type II du composé **13** alors que la formation du *B*-nor aldéhyde **15** serait le résultat d'une réaction aldolique "à la noirceur" du composé **13**.

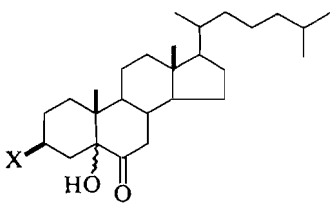
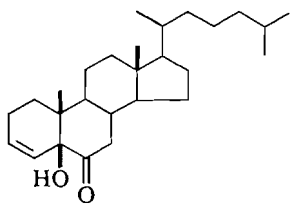
Introduction

As an extension of our studies of the photochemistry of α-hydroxy ketones of type **1** (1, 3) we have investigated the photochemistry of the β,γ-unsaturated α-hydroxy ketone, 5-hydroxy-5β-cholest-3-en-6-one (**2**), whose synthesis we have



1

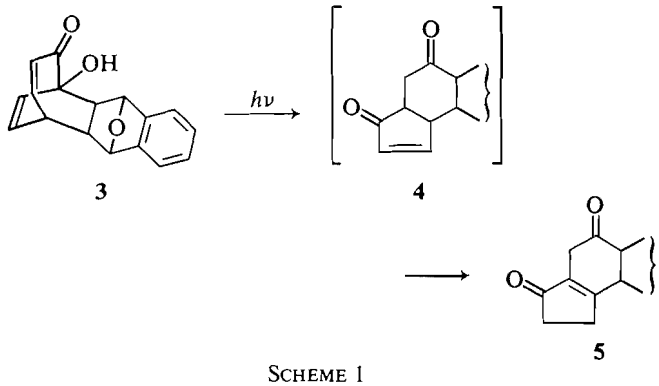
X = OAc, H, or OBn



2

recently reported (4). There have been few previous reports on the photochemistry of such ketones. Sasaki *et al.* (5) observed that direct irradiation of 1-hydroxy-bicyclo[3.2.2]nona-3,5-dien-2-ones of type **3** gave products of type **5** that were considered to be formed via intermediates of type **4**, themselves formed from **1** by 1,3-acyl shifts (Scheme 1). Carlson and

[1]For paper II, see ref. 1; for a preliminary communication concerning part of this work, see ref. 2.

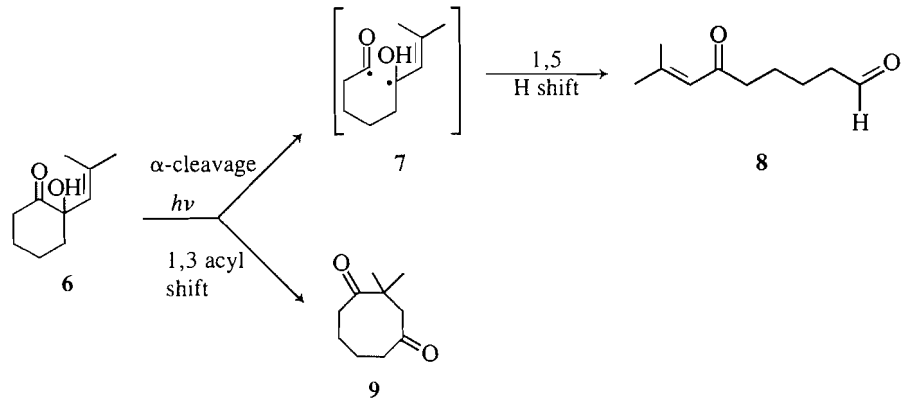


3 **4** **5**

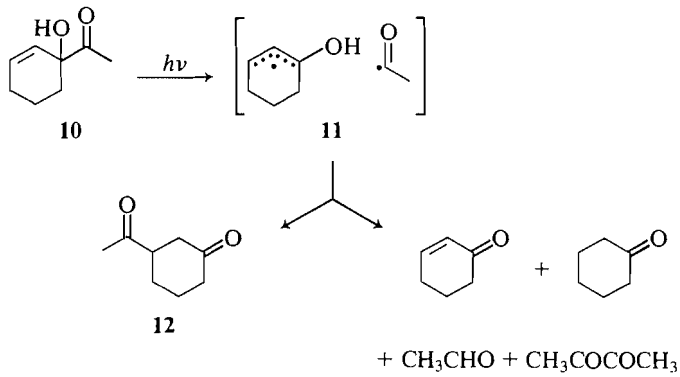
SCHEME 1

Prabhu (6) found that direct irradiation of 2-hydroxy-2-(2-methyl-1-propenyl)cyclohexanone (**6**) gave the aldehyde **8** as the major product and the cyclo-octane-1,4-dione **9** as a minor product. The latter was again considered to be formed via a 1,3 acyl shift, while the major product was thought to arise via α-cleavage of **6** to give the diradical **7**, followed by a 1,5 hydrogen shift (Scheme 2).

Hancock *et al.* (7) have carried out the most detailed mechanistic investigation of the photochemistry of β-γ-unsaturated α-hydroxy ketones. They observed that direct irradiation of 1-acetyl-2-cyclohexen-1-ol (**10**) gave 3-acetylcyclohexanone



SCHEME 2



SCHEME 3

(**12**) as the major product. The presence of cyclohexanone, 2-cyclohexen-1-one, acetaldehyde, and biacetyl among the minor products led them to propose that the 1,3 acyl shift involved in the conversion of **10** to **12** proceeded stepwise via α-cleavage to the acyl allyl radical pair **11**, followed by recombination to give **12** (Scheme 3).

Results

Photolysis of 5-hydroxy-5β-cholest-3-en-6-one (2)

Photolysis of **2** in alcoholic solvents led to intractable product mixtures. However, when the irradiation was carried out in hexanes two photoproducts could be isolated, the 5,6-seco-aldehyde **13** and the indenylacetaldehyde **14**, in 40 and 10% yield, respectively. The indenylacetaldehyde **14** was a secondary product, since it was formed from photolysis of the seco-aldehyde **13** in hexanes, which also gave a small amount of the β-nor aldehyde **15** (Scheme 4). In both irradiations the mass balance of isolated products was poor.

The structural assignment for the indenylacetaldehyde **14** was based on its ir and ^{1}H nmr spectra, in conjunction with its molecular composition, $C_{20}H_{34}O$. At 200 MHz, the signals of the two vinyl protons in the ^{1}H nmr spectrum of **14** were resolved into two multiplets at δ 5.45–5.52 (width = 16 Hz) and 5.58–5.68 (width = 19 Hz). In its mass spectrum the base peak with *m/z* 133 is attributed to the ion **17**, derived from McLafferty rearrangement of the molecular ion and further cleavage of the resultant ion **16** as depicted in Scheme 5.

The structural assignment for the seco-aldehyde **13** is based on its spectra and is confirmed by an independent synthesis. In its ir spectrum carbonyl-stretching bands at 5.80 and 5.97 μm witness the presence of both aldehyde and α,β-unsaturated ketone functions. Vinyl proton signals at δ 5.83 (br d, J = 10 Hz) and 6.80 (br m, width = 22 Hz) in its ^{1}H nmr spectrum are characteristic of the α,β-unsaturated ketone system. Two conformations, **13***A* and **13***B*, are available to the cyclohexenone ring of **13**. Models show that in conformer **13***A*, the C-19 methyl group resides in the deshielding region of the C-5 carbonyl group and the relatively low-field chemical shift observed for the C-19 methyl resonance of **13** (δ 1.10) suggests that **13** prefers to exist as conformer **13***A*. This places the more bulky substituent at C-10 in an axial orientation, as observed to result from the "2-alkyl ketone effect" in cyclohexanones (8). Compound **13** exhibits a base peak at *m/z* 110 in its mass spectrum; this peak is attributed to the very stable ion **18** derived from a McLafferty rearrangement of the molecular ion.

A monosemicarbazone **19** of **13** was prepared and its mixture melting point with an authentic sample (*vide infra*) was undepressed. The molecular composition of **19**, $C_{28}H_{47}O_2N_3$, verifies the presence of a single semicarbazone group. Although the enone and semicarbazone carbonyl-stretching bands in the ir spectrum of **19** are not resolved, the absence of an aldehydic carbonyl-stretching band at ~5.80 μm and the presence of an *H*—C=N signal at δ 6.90 (t, J = 6Hz) in its ^{1}H nmr spectrum establishes that it is the aldehydic carbonyl group of **13** that has been derivatized.

The structural assignment for the *B*-nor aldehyde **15** is based on its spectra and confirmed by independent synthesis (*vide infra*). In its ^{1}H nmr spectrum, the appearance of an aldehydic proton signal at δ 9.70 as a doublet (J = 3.5 Hz) suggested the ring-contracted *B*-nor structure. Assignment of the stereochemistry at C-5 and C-6 in **15** proved a difficult task. Irradiation at δ 9.70 collapsed a doublet of doublets at δ 2.41 (J = 9.5, 3.5 Hz), ascribed to the C-6 methine proton, to a doublet (J = 9.5 Hz); however, the 9.5-Hz coupling constant between the C-6 and C-8 methine protons is compatible with the dihedral angles measured from Dreiding models of all four diastereomers of **15**, and thus does not provide a basis for stereochemical assignment at either C-5 or C-6.

Assignment of the stereochemistry at C-5 in **15** was arrived at as follows. Hydrogenation over Adams catalyst in ethyl acetate gave the saturated *B*-nor aldehyde **20**, whose spectra are in accord with expectation. Examination of the chemical shifts of the C-19 methyl protons in the ^{1}H nmr spectra of a variety of Δ^3-unsaturated and analogous saturated steroids indicates that in 5α-steroids, hydrogenation of a Δ^3 double bond leads to a downfield shift of the C-19 methyl signal (9) whereas an upfield shift of this signal accompanies similar hydrogenation in the 5β series (9, 10). On this basis the C-19 methyl signals at δ 0.96 and 0.87 in the ^{1}H nmr spectra of the unsaturated and saturated

aldehydes **15** and **20**, respectively, signify the β stereochemistry of the hydroxyl groups at C-5 in these compounds.

With the 5β configuration for the C-5 hydroxyl group assigned, the α and β configurations of the C-6 formyl group can be distinguished, for in the β configuration, but not the α, the aldehyde would be expected to be strongly hydrogen bonded. The presence of both sharp and broad hydroxyl-stretching bands in the ir spectra and the appearance of the hydroxyl signals as broad multiplets in the ^{1}H nmr spectra suggest that the hydroxyl groups in **15** and **20** are not strongly hydrogen bonded; thus the C-6 formyl group in each is tentatively assigned the α configuration.

20

This assignment is supported by the lanthanide-induced shifts (LIS) in the ^{1}H nmr spectrum of **20**. Upon addition of a small amount of Sievers' reagent ($Eu(fod)_3$) the C-6 methine proton signal underwent a large downfield shift (Δδ 0.6) while only a negligible downfield shift (Δδ 0.03) was observed for the aldehydic proton signal. These differential shifts indicate that the europium complex is coordinated to the hydroxyl group at C-5 and not to the carbonyl group of the aldehyde (11, 12), since a substantial deshielding of the aldehydic proton via a contact shift would have been expected from coordination of the shift reagent to the latter (12, 13). Bidentate coordination of the shift reagent to both the 5β-hydroxyl and 6-formyl groups is expected for the β, but not the α, stereochemistry of the formyl group. Thus, the negligible LIS shift observed for the aldehydic proton further suggests the α configuration for the 6-formyl group.

The structural assignment for the seco-aldehyde **13** was confirmed by an independent synthesis as outlined in Scheme 6. Ozonolysis of cholesteryl acetate (**21**) with reductive work-up with dimethyl sulfide gave the acetoxy keto aldehyde **22**, which was converted to its dimethyl acetal **23** with triethyl orthoformate and a catalytic quantity of *p*-toluenesulfonic acid (14). Alternatively, addition of these reagents in the reductive work-up of the ozonolysis product gave the dimethyl acetal **23** directly in quantitative yield. In the ^{1}H nmr spectra of both **22** and **23** the appearance of the C-3 methine proton signals as narrow multiplets ($W_{1/2}$ = 8 Hz) evidenced the preference of these 5,6-seco-cholestan-5-ones for the conformations **22***A* and **23***A*, respectively. In this conformation the bulkier substituent at C-10 adopts the axial orientation in accord with the 2-alkyl ketone effect (*vide supra*).

β-Elimination of the acetoxyl group from **23** to give the acetal enone **24** was effected with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), and the aldehyde functionality was regenerated by the procedure of Conia and co-workers (15), using aqueous oxalic acid in a slurry of silica gel in dichloromethane. The aldehyde **13** thus obtained was identical with the major photoproduct isolated from irradiation of **2**.

An attempt to prepare the Δ^3-unsaturated *B*-nor aldehyde **15** by an alumina-induced aldol condensation (16) of **13** yielded instead the diene-6-carboxaldehyde **25** (Scheme 7). This was identified by the presence of well-separated vinyl proton signals at δ 6.18 and 6.93 and an aldehydic proton signal as a singlet at δ 10.03 in its ^{1}H nmr spectrum.

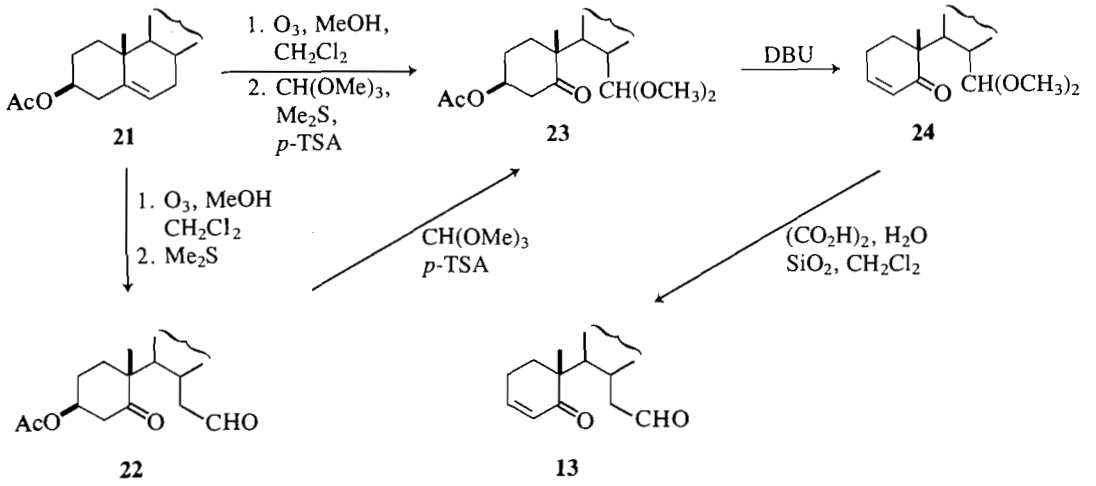
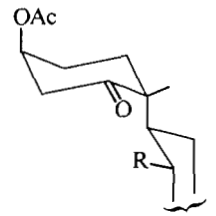


SCHEME 6

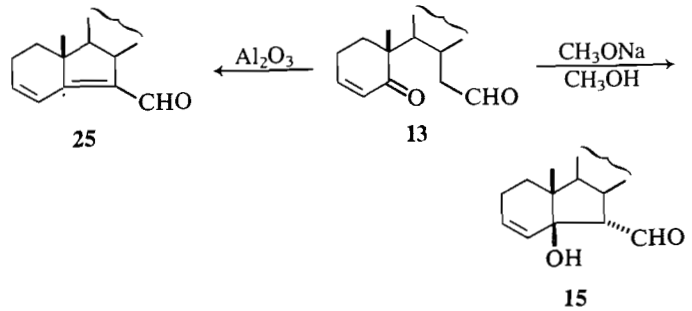


22A R = CHO
23A R = $CH(OCH_3)_2$

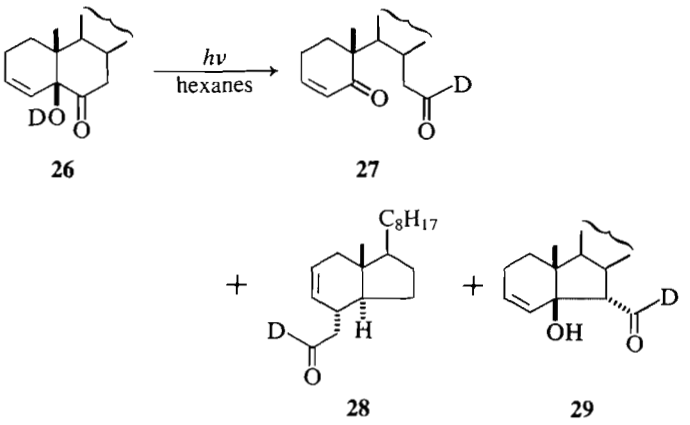
Aldol condensation of **13** without concomitant dehydration was achieved by brief treatment with methanolic sodium methoxide (Scheme 7). The *B*-nor aldehyde **15** thus obtained was identical with that isolated as a minor product from the irradiation of **13**.

Photolysis of 5-deuteroxy-5β-cholest-3-en-6-one (26)

To explore further the photoconversion of 5-hydroxy-5β-cholest-3-en-6-one (**2**) to the seco-aldehyde **13** and the indenylacetaldehyde **14**, the photolysis of **26**, the *O*-deuterated derivative of **2**, was investigated. Irradiation of an anhydrous solution of **26** in hexanes was found to give the deuterated seco-aldehyde **27** together with the deuterated indenylacetaldehyde **28** and the deuterated *B*-nor aldehyde **29** (Scheme 8). Weak aldehydic C–D stretching bands at 4.82 μm in the ir spectrum of each evidenced the presence of deuterium at the aldehydic site. The ^1H nmr spectra of **27**, **28**, and **29** were identical to the spectra of their undeuterated analogues **13**, **14**, and **15**, respectively, with the exception that the aldehydic proton signal in each was substantially diminished. Comparison



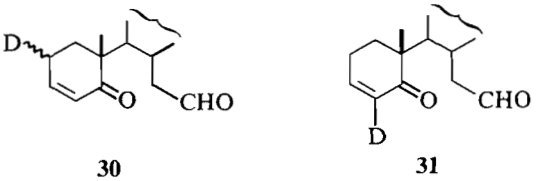
SCHEME 7



SCHEME 8

of the extent of deuterium incorporation into the aldehydic sites in **27** and **28**, as determined from their ^1H nmr spectra, with the total deuterium content calculated from their mass spectra established that the deuterium label in these aldehydes resided completely in the aldehydic site and indicated that the starting **26** was deuterated to the extent of 75–80%. There was no evidence for the formation of any of the ring A deuterated aldehydes **30** and **31**, whose formation could be envisaged to occur by other pathways.

However, since the deuterated aldehydes were isolated by silica gel column chromatography, we could not exclude the possibility that if deuterium label had been introduced into ring A, yielding aldehyde **30** or **31**, it might have been lost via



enolization and exchange during chromatography. We therefore sought to obtain higher deuterium incorporation by the addition of a small amount of deuterium oxide to the solvent hexanes used in the irradiation of **26**. These conditions could have led to additional deuterium incorporation at C-2, C-4, and C-7 in **27**,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

but, in the event, no such further deuteration was observed and **27** and **28** were obtained with 89% and 96% d_1 incorporation, as evidenced by their mass spectra. Their ^{1}H nmr spectra showed no trace of aldehydic proton signals. Thus it can be concluded that the deuterium label in **27** and **28** resides only in the aldehydic sites, and that the former is formed to the exclusion of the ring A deuterated analogues **30** and **31**.

Discussion

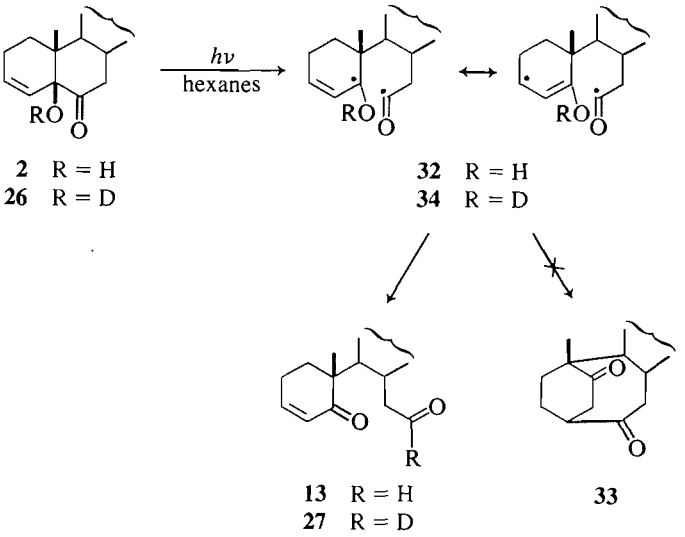
As noted in the Introduction, direct irradiation of certain β,γ-unsaturated α-ketols has been observed to lead to reactions that proceed via [1,3] acyl migration, a process typical of the singlet excited states of β,γ-unsaturated ketones (17). Debate regarding the role of discrete diradicals arising from α-cleavage in these [1,3] acyl migrations has not yet been resolved (17), although many features of the photochemical behavior of β,γ-unsaturated ketones can be most simply explained by this model.

The propensity of excited β,γ-unsaturated carbonyl chromophores to react via the [1,3] acyl shift mode has been correlated with the relative rate constants for α-cleavage and intersystem crossing from the singlet $n\pi^*$ state (18). α-Cleavage is in turn assisted when the angle between the two planes formed by the carbonyl and olefinic groups is decreased from 180°C, since the incipient unfilled orbital formed in the transition state for α-cleavage can overlap better with the ethylenic π system (18). This arrangement of the π systems is manifested by a hyperchromic effect of the $n\pi^*$ band in the ultraviolet spectrum. From a quantitative perspective, Beugelmans and co-workers (19) have noted that β,γ-unsaturated ketones with $n\pi^*$ molecular extinction coefficients greater than 100 react via [1,3] acyl migration, whereas those with coefficients less than 50 undergo photoreaction by alternative pathways.

We have shown that irradiation of the Δ^3-unsaturated ketol **2** affords, as the major product, the seco-aldehyde **13** (Scheme 9). Deuterium labelling studies (*vide infra*) are in accord with the formation of **13** via an α-cleavage mechanism giving the diradical **32**. The $n\pi^*$ ultraviolet maximum of ketol **2** (λ_{max} 283 (ε = 83)) has an extinction coefficient slightly smaller than that suggested by Beugelmans and co-workers as indicative of α-cleavage. However, in the Δ^3-unsaturated ketol **2**, α-cleavage is considered to be further favored by the radical-stabilizing effect of the α-hydroxyl group. This suggestion is not without precedent for, although the effects of α-substitution in β,γ-unsaturated ketone photolyses are relatively unexplored, Engel *et al.* (20) have noted that increasing α-substitution in β,γ-unsaturated ketones promotes a [1,3] acyl migration at the expense of a [1,2] acyl shift, an observation that they attributed to an increase in the rate of α-cleavage with α-methyl substitution.

In the case of the photolysis of 1-acetylcyclohex-2-en-1-ol (**10**) (Scheme 3), Hancock *et al.* (7) concluded that the predominant photoreaction involves α-cleavage followed by 1,3-recombination of the radical pair thus formed, while O—H abstraction by the acyl radical represents a minor pathway.

In contrast, abstraction of the O—H hydrogen to give aldehyde **13** represents the major disproportionation reaction of diradical **32** formed in the irradiation of **2**. The formation of diketone **33**, the expected product of 1,3-diradical recombination (Scheme 9), was not observed in the photolysis of **2**, although it cannot be excluded that some **33** was formed and underwent further photolysis to unisolated products.



SCHEME 9

Our deuterium labelling studies showed that irradiation of **26**, the *O*-deuteroxy analogue of **2**, gives the α-deutero aldehyde **27**. This establishes that the aldehyde **13** is formed from **2** via α-cleavage to the diradical **32** (Scheme 9). Three pathways can be envisaged for the conversion of **32** to **13**: (*i*) hydroxyl hydrogen abstraction by the acyl radical, (*ii*) C-2 hydrogen abstraction by this radical, and (*iii*) tautomerization of the enol function to the corresponding ketonic function, followed by C-4 hydrogen abstraction by the acyl radical. For the *O*-deutero ketol **26** these imply the product labeling patterns shown in Scheme 10. The fact that the deutero aldehyde **27** was the only product observed and that the deuterated ring A products **35** and **36** could not be detected provides strong evidence that pathway *i* is predominant by far.[2] Several factors are considered to contribute to the selective abstraction of the hydroxyl hydrogen. While each abstraction involves an eight-membered ring transition state, the close proximity of the hydroxyl hydrogen to the acyl radical immediately following α-cleavage is considered to favor this abstraction. Abstraction of the hydroxyl hydrogen, unlike the alternative C—H abstractions, leads directly to the formation of a thermodynamically favored carbonyl bond. It may be noted that an analogous pathway may be involved in the conversion of **7** and **8**, rather than that earlier proposed (Scheme 2) (6).

Interestingly, the disproportionation reactions of the diradicals formed from α-cleavage of the Δ^3-unsaturated 5β-steroidal ketol **2** and of the saturated 5α and 5β steroidal ketols **1** are different, the former involving O—H abstraction leading to the keto aldehyde **13** and the latter C—H abstraction to give a ketene **38** (Scheme 11) (3). This difference in behavior is attributed to the planar geometry, imposed by delocalization, of the allylic radical moeity of **32**. This projects the O—H group towards the acyl radical favoring abstraction of this hydrogen. In contrast, the nonplanar geometry of the hydroxyl substituted alkyl radical

[2]The ratio of **27** to **36** that would result from pathway *iii* would depend on the stereoselectivity associated with the ketonization and abstraction steps. Each step would have to be completely stereospecific for only **27** or **36** to be formed. Although we cannot exclude absolutely the formation of solely product **27** by this route, such complete stereoselectivity seems exceedingly unlikely.

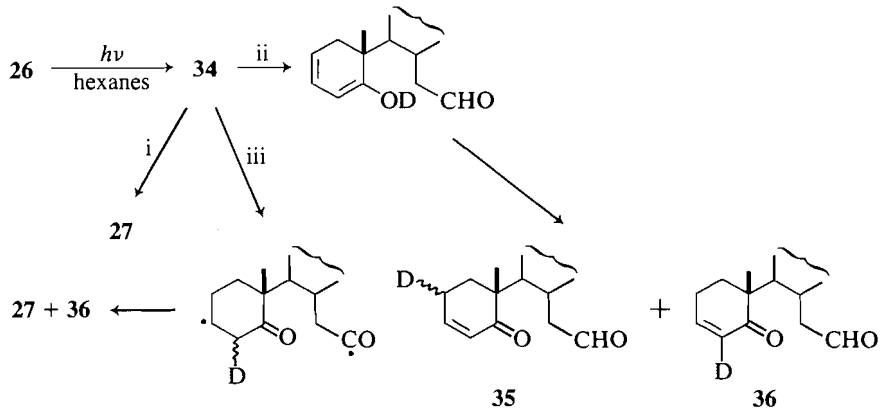
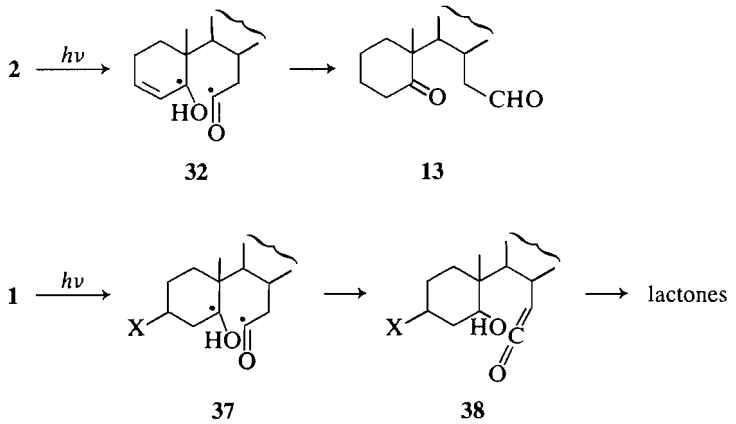
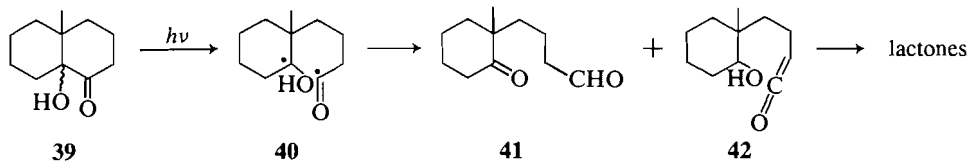
For personal use only.



SCHEME 10

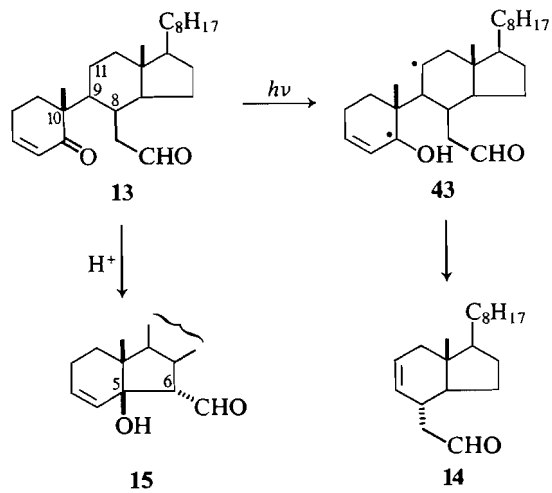




SCHEME 11

center in the saturated steroidal ketol diradicals **37** holds the O—H bond away from the acyl radical (3), inhibiting this mode of disproportionation,[3, 4]

The indenylacetaldehyde **14**, a secondary photoproduct from the irradiation of **2**, is considered to arise from a Norrish II reaction of **13** (Scheme 12). Models indicate that there are three γ-hydrogens that satisfy the geometric requirements for abstraction by the excited α,β-unsaturated enone carbonyl group: the C-11α, and C-11β hydrogens and the hydrogen at C-8 (23). Formation of **14**, resulting from abstraction of a secondary,



SCHEME 12

[3]In our examination of molecular models, a bent rather than a linear acyl radical was used, for this has been calculated and experimentally shown to be the preferred geometry of the acyl radical (21, 22).

[4]Other possible factors are contraindicated by the observation that the diradicals **40** produced from α-cleavage during irradiation of the bicyclic α-ketols **39** reacted partially by O—H abstraction giving the keto aldehyde **41** as well as by C—H abstraction giving the ketene **42** (Scheme 11).

For personal use only.

C-11, hydrogen atom rather than the tertiary, C-8, hydrogen atom, is attributed to the ability of the resulting diradical **43** to assume a favorable conformation for cleavage of the C-9—C-10 bond, which is not attainable by the corresponding diradical formed by C-8 hydrogen abstraction. The photoconversion of **13** and **14** is of considerable intrinsic interest since it involves a Norrish Type II reaction of a 6-substituted 2-cyclohexenone, a reaction without precedent insofar as we are aware.

The *B*-nor aldehyde **15** is considered to arise from a "dark" aldol reaction of the primary photoproduct **13** (Scheme 12). The pH of the photolysate following irradiation of **2** was found to be acidic, and the aldol condensation is considered to proceed by addition of the protonated enone carbonyl group of **13** to the enol of the aldehyde moiety. Such a route accounts for the observed stereochemistry of **15** at C-5 and C-6.

Conclusions

We have shown that the photolysis of the β,γ-unsaturated α-hydroxy ketone **2** proceeds via α-cleavage to an acyl allyl diradical, which undergoes hydrogen transfer from the hydroxyl group to the acyl radical center to give the keto aldehyde **13**. Two features of this reaction pathway are noteworthy: (*i*) the occurrence of α-cleavage as the major reaction pathway rather than a 1,3 acyl shift, the most frequently observed photochemical reaction pathway for β,γ-unsaturated ketones, and (*ii*) the occurrence of OH hydrogen abstraction in the diradical intermediate to the exclusion of CH hydrogen abstraction. The first feature is attributable to the additional stabilization of the allyl radical center by interaction with the oxygen atom of the hydroxyl group, thus favoring α-cleavage. The second feature is attributed to the planarity of the allyl radical center, which favors transfer of the hydroxyl hydrogen atom to the nearby acyl radical center, rather than transfer of hydrogen from the more distant C-2, C-4, or C-7 sites. The maintenance of the propinquity of the hydroxyl hydrogen and the acyl radical center is ascribable to restriction of rotation about the C-9—C-10 bond in the diradical intermediate as postulated in the cases of the saturated steroidal analogues of **2** (3). The formation of hydroxy ketenes rather than keto aldehydes in the saturated cases is attributable to the nonplanar nature of the alkyl radical center in the alkyl acyl diradicals formed as intermediates.

The secondary photochemical reaction of **13** to give **14** is considered to be a Norrish type II reaction. Formation of **14** results from abstraction of a secondary C-11 hydrogen atom; tertiary C-8 hydrogen abstraction, which would lead to an olefinic isomer of **14**, was not observed. Preferential abstraction from C-11 is attributed to the ability of the diradical intermediate thus formed to adopt a conformation that is favorable for cleavage of the C-9—C-10 bond.

The formation of the *B*-nor aldehyde **15** from **13** is attributable to a dark aldol reaction, catalyzed by an acidic species formed during the photolysis. Its formation could presumably be supressed by carrying out the photolysis in the presence of sodium bicarbonate (24).

Returning to the primary photochemical reaction of **2**, the formation of **13**, we conclude that in general α-cleavage will be favored over the 1,3-diacyl shift reaction in related cyclic β,γ-unsaturated α-hydroxy ketone systems, but that the exclusive formation of a keto aldehyde rather than a ketene-derived product may depend on the specific nature of the ring system into which the three functionalities are incorporated.

Experimental[5]

Irradiation of 5-hydroxy-5β-cholest-3-en-6-one (2) in hexanes. Formation of 5-oxo-5,6-seco-cholest-3-en-6-al (13) and [1R, 4R, 7aR)-1-(1S,5-dimethylhexyl)-7a-methyl-2,3,3a,4,7,7a-hexahydro-1H-inden-4-yl]acetaldehyde (14)

A solution (3 × 14 cm) of **2** (189 mg, 0.47 mmol) in hexanes (65 mL) was irradiated in a Pyrex tube under argon at 300 nm for 4 h. The colorless photolysate was washed with saturated aqueous sodium bicarbonate (10 mL) and saturated aqueous sodium chloride (3 × 5 mL), dried over anhydrous magnesium sulfate, and concentrated to give a colorless oil (175 mg). The oil was flash chromatographed on silica gel (2 × 16 cm) with hexanes – ethyl acetate (9:1 v/v) as eluent. Compound **14** (13.5 mg, 10%) was eluted first, as a colorless oil that resisted crystallization; ir λ_{max}: 3.70 (w), 5.81 μm; ^{1}H nmr δ: 0.70 (s, 3H, C-7a Me), 0.88 (d, J = 6 Hz), 2.40 (m), 5.20–5.83 (m, width = 40 Hz, 2H), 9.80 (nar m, $W_{1/2}$ = 4 Hz, 1H); ^{1}H nmr (200 MHz) δ: 0.71 (s, 3H, C-7a Me), 0.87 (d, J = 6 Hz, 6H), 0.92 (d, J = 6 Hz, 3H), 1.00–2.58 (m, 19H), 5.45–5.52 (m, width = 16 Hz, 1H), 5.58–5.68 (m, width = 19 Hz, 1H), 9.80 (nar m, $W_{1/2}$ = 5 Hz, 1H), ms m/z: 290 (42), 133 (100). *Exact Mass* calcd. for $C_{20}H_{34}O$: 290.2610; found: 290.2613.

A small amount of unconsumed starting ketol **2** (15 mg, 8%) was eluted next. This was followed by **13** (75 mg, 40%), obtained as a colorless oil that resisted crystallization; ir λ_{max}: 3.69 (w), 5.80, 5.97 μm; ^{1}H nmr δ: 0.70 (s, C-18 Me), 1.10 (s, C-19 Me), 5.83 (br d, J = 10 Hz, 1H), 6.80 (br m, width = 22 Hz, 1H), 9.60 (m, $W_{1/2}$ = 3 Hz, 1H); ms m/z: 400 (4), 110 (100). *Exact Mass* calcd. for $C_{27}H_{44}O_2$: 400.3341; found: 400.3343. The ir, ^{1}H nmr, ^{13}C nmr, and mass spectra of the seco-aldehyde **13** isolated from photolysis of the ketol **2** were identical to those of **13** prepared by an independent route (*vide infra*).

*Irradiation of 13. Formation of 14 and 5-hydroxy-*B*-nor-5β-cholest-3-ene-6α-carbaldehyde (15)*

A solution (4 × 19 cm) of **13** (547 mg, 1.37 mmol) in hexanes (180 mL) was degassed with argon for 1.5 h, and the solution was irradiated in Pyrex at 300 nm for 22 h. The colorless photolysate was washed with saturated aqueous sodium bicarbonate (1 × 15 mL) and saturated aqueous sodium chloride (4 × 20 mL), dried over anhydrous sodium sulfate, and concentrated to give a yellow oil (460 mg). Thin-layer chromatography of the oil with hexanes – ethyl acetate (4:1 v/v) evidenced two predominant spots and a host of smaller spots. The oil was flash chromatographed under nitrogen pressure on a silica gel column (2 × 12 cm) with hexanes – ethyl acetate (95:5 v/v) as eluent. Compound **14** (71 mg, 18%) was eluted first as a colorless oil. Further elution gave an impure 1:1 mixture of unconsumed seco-aldehyde **13** and *B*-nor aldehyde **15** (153 mg). The mixture of **13** and **15** was purified by flash chromatography under nitrogen pressure on silica gel (1.5 × 16 cm) with chloroform–methanol (99.5:0.5 v/v) as eluent. The oil obtained (70 mg) was flash chromatographed again under nitrogen pressure on a silica gel column (1.5 × 18 cm) with chloroform – diethyl ether (97:3 v/v) as eluent to give **15** (38 mg, 7%) as a colorless oil that resisted crystallization; ir λ_{max}: 2.78 (sh, w), 2.88 (br, w), 5.82 μm; ^{1}H nmr δ: 0.70 (s, C-18 Me), 0.97 (s, C-19 Me), 1.90 (m, OH), 2.42 (dd, J = 10, 4 Hz), 5.70 (nar m, $W_{1/2}$ = 2 Hz, 2H), 9.72 (d, J = 3 Hz, 1H); ^{1}H nmr (200 MHz) δ: 0.71 (s, C-18 Me), 0.86 (d, J = 7 Hz, C-26,27 Me), 0.91 (d, J = 6 Hz, C-21 Me), 0.96 (s, C-19 Me), 2.41 (dd, J = 9.5, 3.5 Hz, 1H), 5.64–5.79 (m, width = 31 Hz, 2H), 9.70 (d, J = 3.5 Hz, 1H); ms m/z: 400 (6), 110 (100). *Exact Mass* calcd. for $C_{27}H_{44}O_2$: 400.3341; found: 400.3340.

The indenylacetaldehyde **14** (49 mg, 0.17 mmol) was treated with a solution of semicarbazide hydrochloride (100 mg, 0.90 mmol) and sodium acetate trihydrate (150 mg, 1.10 mmol) in water (1 mL). Diethyl ether (1 mL) and 95% ethanol (1 mL) were added, and the solution was allowed to stand at room temperature for 24 h. Diethyl ether (20 mL) and saturated aqueous sodium bicarbonate (5 mL) were added to the resulting white suspension. The aqueous phase was ex-

tracted with diethyl ether (2 × 10 mL, 1 × 5 mL), and the combined ethereal solutions were washed with water (3 × 5 mL), dried over anhydrous sodium sulfate, and concentrated to give a white solid (58 mg). Crystallization from hexanes–ethanol gave the *semicarbazone of* ***14*** as white crystals, mp 167–170°C; ir λ_{max}: 2.96 (sh, w), 3.07 (br, w), 5.92, 6.40 μm; ^{1}H nmr δ: 0.67 (s, C-7a Me), 0.87 (d, J = 6 Hz, 6H), 5.52 (m, 4H, H—C=C—H and $CONH_2$, signal corresponding to 2H moves upfield on dilution), 7.05 (t, J = 6 Hz, 1H, H—C=N), 9.33 (nar m, $W_{1/2}$ = 4 Hz, 1H, C=N—NH, moves upfield on dilution); ms *m/z*: 347 (17), 101 (100). *Exact Mass* calcd. for $C_{21}H_{37}ON_3$: 347.2936; found: 347.2920.

*Ozonolysis of cholesteryl acetate (**21**). Formation of 3β-acetoxy-5-oxo-5,6-seco-cholestan-6-al (**22**)*

A stirred solution of **21** (500 mg, 1.17 mmol) in dichloromethane–methanol (95:5 v/v; 150 mL) cooled in an absolute ethanol – Dry Ice bath to −35 to −40°C was treated with an unstandardized stream of ozone for 1.5 h, at which point a starch – potassium iodide test of the effluent from the reaction flask became positive. The flask was flushed with argon, and the reaction mixture was treated with dimethyl sulfide (2.0 mL, 27 mmol). The solution was allowed to warm gradually to room temperature overnight under a slow stream of argon. The reaction mixture was washed with saturated aqueous sodium chloride (1 × 50 mL) and water (4 × 25 mL), dried over anhydrous sodium sulfate, and concentrated to give **22** (546 mg) as a pale yellow oil in quantitative yield; ir λ_{max}: 3.67 (w), 5.78, 5.85 μm; ^{1}H nmr δ: 0.70 (s, C-18 Me), 1.03 (s, C-19 Me), 2.02 (s), 5.33 (nar m, $W_{1/2}$ = 8 Hz, 1H), 9.62 (br s, 1H); ms *m/z*: 460 (3), 110 (100).

*3β-Acetoxy-6,6-dimethoxy-5,6-seco-cholestan-5-one (**23**)*

*(i) Ozonolysis of **21** with a dimethyl sulfide/p-toluenesulfonic acid/trimethyl orthoformate work-up*

A stirred solution of **21** (3.00 g, 7.00 mmol) in dichloromethane–methanol (95:5 v/v; 200 mL) cooled in an absolute ethanol – Dry Ice bath to −40°C was treated with an unstandardized stream of ozone. After 6 h, a starch – potassium iodide test of the effluent gas from the reaction mixture became positive. The flask was flushed with argon, and dimethyl sulfide (6.0 mL, 82 mmol), trimethyl orthoformate (3.6 mL, 33 mmol), and *p*-toluenesulfonic acid monohydrate (58 mg, 0.31 mmol) were added. The reaction mixture was allowed to warm gradually to room temperature overnight under a flow of argon and poured into saturated aqueous sodium bicarbonate (25 mL). The organic phase was washed with water (7 × 50 mL), dried over anhydrous sodium sulfate, and concentrated to give **23** (3.66 g) as a yellow oil in quantitative yield; ir λ_{max}: 5.77, 5.86, 7.29 (m) μm; ^{1}H nmr δ: 0.67 (s, C-18 Me), 1.05 (s, C-19 Me), 2.00 (s), 3.20 (s, 6H), 4.43 (t, J = 6 Hz, 1H), 5.37 (nar m, $W_{1/2}$ = 8 Hz, 1H); ms *m/z*: 506 (1), 75 (100). *Exact Mass* calcd. for $C_{31}H_{54}O_5$: 506.3971; found: 506.3947.

*(ii) From the seco-aldehyde **22***

A stirred solution of **22** (3.29 g, 7.15 mmol) and *p*-toluenesulfonic acid monohydrate (44 mg, 0.23 mmol) in anhydrous methanol (30 mL) under an argon atmosphere and cooled to −23°C in a carbon tetrachloride – Dry Ice bath was treated with trimethyl orthoformate (3.5 mL, 32 mmol). The reaction mixture was stirred in the cold bath for 4 h and poured into saturated aqueous sodium bicarbonate (10 mL). The methanol was removed on a rotary evaporator under water aspirator pressure. Water (50 mL) was added to the residue, and the mixture was extracted with diethyl ether (1 × 50 mL, 3 × 25 mL). The combined ethereal extracts were washed with water, dried over anhydrous sodium sulfate, and concentrated to give a colorless oil (3.35 g) comprising **23** contaminated with approximately 15% of **22**. This material gave satisfactory results in its reaction with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (*vide infra*).

*6,6-Dimethoxy-5,6-seco-cholest-3-en-5-one (**24**)*

A solution of **23** (3.66 g, 7.23 mmol) and 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) (4.5 mL, 30 mmol) in heanes (100 mL) was stirred at room temperature under an argon atmosphere for 19 h. The reaction mixture was poured into 2 *N* hydrochloric acid (25 mL), and the aqueous phase was extracted with hexanes (2 × 25 mL). The combined organic phases were washed with 2 *N* hydrochloric acid (5 mL), saturated aqueous sodium bicarbonate (25 mL), and water (4 × 15 mL), dried over anhydrous sodium sulfate, and concentrated to give a yellow oil (3.30 g). High performance liquid chromatography of the oil on a PrepPak-500 silica gel column (Waters Scientific; 5.7 × 30 cm) with dichloromethane – ethyl acetate (98:2 v/v) as eluent gave **24** (2.39 g, 74%) as a colorless oil that resisted crystallization; ir λ_{max}: 5.97, 7.28 (m), 8.99 (br) μm; ^{1}H nmr δ: 0.67 (s, C-18 Me), 1.15 (s, C-19 Me), 3.28 (s) and 3.32 (s) (6H), 4.40 (t, J = 5 Hz, 1H), 5.90 (br d, J = 10 Hz, 1H), 6.73 (br m, width = 20 Hz, 1H); ms *m/z*: 446 (1), 75 (100). *Exact Mass* calcd. for $C_{29}H_{50}O_3$: 446.3760; found: 446.3789.

*5-Oxo-5,6-seco-cholest-3-en-6-al (**13**)*

A slurry of 70–230 mesh silica gel (Brinkmann; 9.0 g) in dichloromethane (15 mL) was treated dropwise with aqueous 7% oxalic acid (890 μL). The acid-treated silica gel was stirred for 15 min, and a solution of **24** (734 mg, 1.65 mmol) in dichloromethane (15 mL) was added. The reaction mixture was stirred at room temperature under an argon atmosphere for 2 h and neutralized by the addition of solid sodium bicarbonate (2.5 g). The mixture was filtered, and the collected solids were washed with dichloromethane (4 × 15 mL). The combined filtrate and washings were washed with water (10 mL), dried over anhydrous sodium sulfate, and concentrated to give **13** (547 mg, 83%) as a colorless oil that resisted crystallization. The ir, ^{1}H nmr, ^{13}C nmr, and mass spectra were identical to those of **13** isolated from photolysis of 5-hydroxy-5β-cholest-3-en-6-one (**2**) (*vide supra*).

*5-Oxo-5,6-seco-cholest-3-en-6-al 6-semicarbazone (**19**)*

Compound **13** (200 mg, 0.05 mmol) was treated with a solution of semicarbazide hydrochloride (400 mg, 3.59 mmol) and sodium acetate trihydrate (600 mg, 4.41 mmol) in water (4 mL). Diethyl ether (5 mL) and 95% ethanol (5 mL) were added, and the resulting solution was stirred at room temperature for 2.5 h. The diethyl ether was removed on the rotary evaporator under reduced pressure, and the resulting white suspension was allowed to stand at 0°C overnight. The precipitate was filtered and washed with methanol–water (1:1 v/v; 40 mL) to give **19** as a white solid. Crystallization from 95% ethanol gave **19** (47 mg, 21%) as white needles, mp 189–194°C (dec. slowly); ir λ_{max}: 2.87 (sh, w), 3.01 (sh, w), 5.92, 6.39 (m) μm; ^{1}H nmr δ: 0.68 (s, C-18 Me), 1.12 (s, C-19 Me), 5.50 (m, 2H, $CONH_2$, moves upfield on dilution), 5.85 (br d, J = 10 Hz, 1H), 6.77 (m) and 6.90 (t, J = 6 Hz, H—C=N) (2H), 8.70 (m, 1H, C=N—NH, moves upfield on dilution); ms *m/z*: 457 (4), 81 (100). *Exact Mass* calcd. for $C_{28}H_{47}O_2N_3$: 457.3668; found: 457.3680. *Anal.* calcd for $C_{28}H_{47}O_2N_3$: C 73.47, H 10.35, N 9.18; found: C 73.43, H 10.40, N 9.18.

*Treatment of 5-oxo-5,6-seco-cholest-3-en-6-al (**13**) with alumina. Formation of B-nor-cholesta-3,5-diene-6-carbaldehyde (**25**)*

A mixture of **13** (340 mg, 0.85 mmol) and neutral, activity I, 70–230 mesh alumina (Merck; 3.4 g) in benzene (10 mL) was stirred at room temperature under an argon atmosphere for 7 h. The resulting yellow suspension was filtered, and the alumina was washed with chloroform. The filtrate and washings were concentrated to give **25** (251 mg, 77%) as a yellow solid; ir λ_{max}: 6.03, 6.23 (m) μm; ^{1}H nmr δ: 0.77 (s, C-18 Me), 0.93 (s, C-19 Me), 6.18 (dt, J = 10, 4 Hz, 1H), 6.93 (br d, J = 10 Hz, 1H), 10.03 (s, 1H).

A solution of **25** (29 mg, 0.08 mmol) in diethyl ether (2 mL) was added to a filtered solution of 2,4-dinitrophenylhydrazine (250 mg, 1.26 mmol) in methanol (5 mL) and concentrated sulfuric acid (0.4 mL). After 45 min the orange-red crystals that had formed were filtered and washed with aqueous methanol and water (30 mL) until the washings were no longer acidic to pH paper. Flash chromatography of the solid (41 mg) on silica gel with chloroform as eluent gave the *(2,4-dintrophenyl)hydrazone of **25*** (19 mg, 44%). Crystallization from hexanes – ethyl acetate gave orange crystals, mp 273–275°C (dec.; the crystals became red at 265–271°C and melted to give a dark red liquid) (lit. (25) mp 262–264°C (dec.) (benzene)).

*Reaction of 5-oxo-5,6-seco-cholest-3-en-6-al (**13**) with sodium methoxide. Formation of 5-hydroxy-*B*-nor-5β-cholest-3-ene-6α-carbaldehyde (**15**)*

Under an argon atmosphere, a solution of sodium methoxide in methanol, prepared by the addition of sodium (28 mg, 1.2 mmol) to anhydrous methanol (15 mL), was treated dropwise with a solution of **13** (373 mg, 0.93 mmol) in anhydrous methanol (10 mL). The solution was allowed to stand at room temperature for 35 min and poured into water (10 mL). The methanol was removed on a rotary evaporator under water aspirator pressure, and saturated aqueous sodium chloride (10 mL) was added to the residue. The mixture was extracted with diethyl ether (1 × 50 mL, 3 × 15 mL), and the combined ethereal extracts were washed with saturated aqueous sodium chloride (10 × 5 mL) and water (2 × 10 mL), dried over anhydrous sodium sulfate, and concentrated to give **15** (347 mg, 94%) as a yellow-orange oil. The ir, ^{1}H nmr, and ^{13}C nmr spectra were identical to those of **15** isolated from photolysis of **13** (*vide supra*).

Compound **15** (43 mg, 0.11 mmol) was treated with a solution of semicarbazide hydrochloride (100 mg, 0.90 mmol) and sodium acetate trihydrate (150 mg, 1.10 mmol) in water (1 mL). Diethyl ether (1 mL) and 95% ethanol (1 mL) were added to give a homogeneous solution, which was allowed to stand, unstoppered, at room temperature for 30 min. A white precipitate formed, and the reaction mixture was stoppered and allowed to stand at room temperature overnight. Saturated aqueous sodium bicarbonate (5 mL) was added to the white suspension, and the mixture was extracted with diethyl ether (4 × 15 mL). The combined ethereal phases were washed with water (3 × 5 mL), dried over anhydrous sodium sulfate, and concentrated to give the *semicarbazone of **15*** (41 mg, 87%) as a white solid. Crystallization from methanol–water gave white crystals, mp 208–210°C (dec.); ir λ_{max}: 3.05 (br, w), 5.90, 6.38 (m) μm; ms *m/z*: 457 (1), 55 (100). *Exact Mass* calcd. for $C_{28}H_{47}O_2N_3$: 457.3668; found: 457.3662. *Anal.* calcd. for $C_{28}H_{47}O_2N_3 \cdot 0.5$ MeOH: C 72.25, H 10.43, N 8.87; found: C 72.32, H 10.34, N 8.73.

*Hydrogenation of **15**. Formation of 5-hydroxy-*B*-nor-5β-cholestane-6α-carbaldehyde (**20**)*

A solution of **15** (249 mg, 0.62 mmol) in ethyl acetate (30 mL) was stirred with platinum oxide monohydrate (Alfa; 34 mg) at room temperature under 1 atmosphere (101.3 kPa) of hydrogen for 7 h. The reaction mixture was filtered through anhydrous magnesium sulfate, and the magnesium sulfate was washed with ethyl acetate (8 × 10 mL). The combined filtrate and washings were concentrated to give **20** (234 mg, 94%) as a colorless oil. The oil was flash chromatographed under nitrogen pressure on a silica gel column (2 × 16 cm) with hexanes – ethyl acetate (9:1 v/v) as eluent to give **20** (137 mg, 55%) as a colorless oil that resisted crystallization; ir λ_{max}: 2.76 (sh, w), 2.85 (br, w), 3.64 (w), 5.84 μm; ^{1}H nmr δ: 0.70 (s, C-18 Me), 0.87 (s, C-19 Me), 2.10 (m, OH), 9.80 (nar m, $W_{1/2}$ = 4 Hz, 1H); ^{1}H nmr (benzene-d_6, 200 MHz) δ: 0.62 (s, C-18 Me), 0.86 (s, C-19 Me), 0.94 (d, *J* = 7 Hz, C-26,27 Me), 0.98 (d, *J* = 7 Hz, C-21 Me), 1.95 (br d, *J* = 12 Hz), 2.04 (dd, *J* = 9, 3 Hz superimposed on a br s), 2.10 (dd, *J* = 9, 9Hz), 9.68 (d, *J* = 3 Hz); ^{1}H nmr (benzene-d_6 with added Eu(fod)$_3$, 200 MHz) δ: 0.69 (s, C-18 Me), 0.95 (d, *J* = 7 Hz, C-26,27 Me), 1.01 (d, *J* = 6 Hz, C-21 Me), 1.18 (s, C-19 Me), 2.02 (br d, *J* = 13 Hz), 2.46 (dd, *J* = 9.5, 10 Hz), 2.63 (dd, *J* = 8.5, 3 Hz), 9.70 (d, *J* = 3 Hz); ms *m/z*: 402 (9), 112 (100). *Exact Mass* calcd. for $C_{27}H_{46}O_2$: 402.3498; found: 402.3468.

A solution of semicarbazide hydrochloride (300 mg, 2.69 mmol) and sodium acetate trihydrate (450 mg, 3.31 mmol) in water (3 mL) was added to **20** (120 mg, 0.30 mmol). The homogeneous solution, obtained by the addition of diethyl ether (2 mL) and 95% ethanol (2 mL), was allowed to stand at room temperature overnight. The reaction mixture was poured into saturated aqueous sodium bicarbonate (10 mL) and extracted with chloroform (1 × 50 ml, 4 × 15 mL) and diethyl ether (1 × 100 mL). The combined organic phases were washed with saturated aqueous sodium chloride, dried over anhydrous sodium sulfate, and concentrated to give the *semicarbazone of **20*** (124 mg, 91%) as a white solid. Crystallization from methanol gave the semicarbazone as white needles, mp 213–215°C (dec.); ms *m/z*: 459 (41), 263 (100). *Exact Mass* calcd. for $C_{28}H_{49}O_2N_3$: 459.3825; found: 459.3832. *Anal.* calcd. for $C_{28}H_{49}O_2N_3$: C 73.15, H 10.74, N 9.14; found: C 72.91, H 10.85, N 9.09.

*Irradiation of 5-deuteroxy-5β-cholest-3-en-6-one (**26**) in anhydrous hexanes. Formation of [(1R,4R,7aR)-1-(1S,5-dimethylhexyl)-7a-methyl-2,3,3a,4,7,7a-hexahydro-1H-inden-4-yl]-(1-deutero)-acetaldehyde (**28**), 5-oxo-5,6-seco-cholest-3-en-(6-deutero)-6-al (**27**), and 5-hydroxy-B-nor-5β-cholest-3-ene-6α-(deutero)carbaldehyde (**29**)*

In a separatory funnel, a solution of **2** (189 mg, 0.47 mmol) in hexanes (200 mL) was treated successively with a solution of anhydrous potassium carbonate in deuterium oxide (99.8%, Aldrich; 1 × 100 mg K_2CO_3 in 1.5 mL D_2O, 1 × 100 mg K_2CO_3 in 3 mL D_2O, 1 × 100 mg K_2CO_3 in 5 mL D_2O) and deuterium oxide (2 × 5 mL). The organic phase was added to a flask pretreated with deuterium oxide, a short path distillation apparatus was fitted, and the hexanes – deuterium oxide azeotrope (bp ~ 64°C; ~1 mL) and hexanes (125 mL) were distilled at atmospheric pressure under an argon atmosphere. The residue (75 mL) was added via cannula under argon to a Pyrex photolysis tube pretreated with deuterium oxide. The solution (3 × 14 cm) was degassed with argon for 30 min and irradiated at 300 nm for 5.5 h. The colorless photolysate was washed with water (10 mL), saturated aqueous sodium bicarbonate (5 mL), and saturated aqueous sodium chloride (3 × 10 mL), dried over anhydrous sodium sulfate, and concentrated to give a colorless oil (203 mg). The oil was flash chromatographed on a silica gel column (2 × 16 cm) under argon pressure. Elution with chloroform – diethyl ether (99.5: 0.5 v/v) gave **28** (19 mg, 14%) as a colorless oil; ir λ_{max}: 4.82 (w), 5.84 μm; ^{1}H nmr δ: 0.72 (s, 3H, C-7a Me), 0.87 (d, *J* = 6 Hz), 2.42 (m), 5.53 (m, 2H), 9.88 (m, 0.19H); ms *m/z*: 291 (31), 133 (100); d_0 17%, d_1 81%, d_2 1%. *Exact Mass* calcd. for $C_{20}H_{33}DO$: 291.2672; found: 291.2657.

Further elution gave unconsumed **2** (65 mg, 34%) as a white solid followed by a mixture of **2** and the deuterated seco-aldehyde **27** (90 mg). Still further elution gave a mixture of the deuterated seco-aldehyde **27** and the deuterated *B*-nor aldehyde **29** (32 mg). The mixture of **2** and **27** was flash chromatographed again under argon pressure with chloroform – diethyl ether (99.5:0.5 v/v) as eluent to give another 4 mg of **2** (2%; total 36%) and **27** (46 mg, 24%) as a colorless oil; ir λ_{max}: 4.83 (w), 5.84, 5.97 μm; ^{1}H nmr (200 MHz) δ: 0.69 (s, C-18 Me), 0.85 (d, *J* = 6 Hz, C-26,27 Me), 0.89 (d, *J* = 7 Hz, C-21 Me), 1.08 (s, C-19 Me), 2.25 (dd, *J* = 18, 3.5 Hz), 2.53 (dd, *J* = 18, 5 Hz, 1H), 5.83 (ddd, *J* = 10, 3, 1 Hz, 1H), 6.78 (br d, *J* = 10 Hz, 1H), 9.58 (m, 0.17H); ms *m/z*: 401 (4), 110 (100); d_0 25%, d_1 72%, d_2 3%. *Exact Mass* calcd. for $C_{27}H_{43}DO_2$: 401.3404; found: 401.3422.

The mixture of **27** and **29** was flash chromatographed under argon pressure on a silica gel column (2 × 16 cm) with chloroform – diethyl ether (99:1 v/v) to give a further 9 mg of **27** (5%; total 29%) and **29** (10 mg, 5%); ir λ_{max}: 2.79 (sh, w), 2.91 (br, w), 4.82 (w), 5.89 μm; ^{1}H nmr δ: 0.72 (s, C-18 Me), 0.97 (s, C-19 Me), 5.73 (nar m, $W_{1/2}$ = 2 Hz, 2H), no aldehyde signal detected at δ 9.72; ms *m/z*: 401 (4), 110 (100); d_0 20%, d_1 77%, d_2 3%. *Exact Mass* calcd. for $C_{27}H_{43}DO_2$: 401.3404; found: 401.3408.

*Irradiation of 5-deuteroxy-5β-cholest-3-en-6-one (**26**) in hexanes in the presence of deuterium oxide. Formation of **27**, **28**, and **29***

In a separatory funnel, a solution of **2** (47 mg, 0.12 mmol) in hexanes (20 mL) was treated with a solution of anhydrous potassium carbonate in deuterium oxide (99.8%, Aldrich; 3 × 35 mg K_2CO_3 in 5 mL D_2O, 1 × 50 mg K_2CO_3 in 3 mL D_2O) and deuterium oxide (2 × 1 mL). Deuterium oxide (2 mL) was added, and the two-phase mixture was added via cannula under argon to a Pyrex photolysis tube pretreated with deuterium oxide. The solution (3 × 6 cm) was degassed with argon for 30 min and irradiated with stirring at 300 nm for 6 h. The photolysate was diluted with hexanes (25 mL), and the solution was washed with water (10 mL), saturated aqueous sodium bicarbonate (1 × 5 mL), and saturated aqueous sodium chloride (5 × 5 mL), dried

over anhydrous sodium sulfate, and concentrated to give a colorless oil (47 mg) that partially solidified. Flash chromatography under argon pressure on a silica gel column (1.5 × 15 cm) with chloroform – diethyl ether (99.5:0.5 v/v) as eluent gave **28** (11 mg, 32%) as a colorless oil; ^{1}H nmr δ: 0.72 (s, 3H, C-7a Me), 0.87 (d, J = 6 Hz), 2.42 (m), 5.53 (m, 2H), no aldehyde signal observed at δ 9.88; ms: d_0 2%, d_1 96%, d_2 2%. Further elution gave **27** (7 mg, 15%); ^{1}H nmr (200 MHz) δ: 0.69 (s, C-18 Me), 0.86 (d, J = 7 Hz, C-26,27 Me), 0.89 (d, J = 7 Hz, C-21 Me), 1.08 (s, C-19 Me), 2.25 (dd, J = 18, 3.5 Hz), 2.53 (dd, J = 18, 5 Hz, 1H), 5.83 (ddd, J = 10, 3, 1 Hz, 1H), 6.78 (br d, J = 10 Hz, 1H), no aldehyde signal observed at δ 9.58 even when the spectrum was amplified by a factor of 15; ms: d_0 5%, d_1 89%, d_2 4%. Still further elution gave a mixture of **27** and **29**, which was rechromatographed under the same conditions to give **29** (11 mg, 24%) as a colorless oil.

Enzyme catalysed hydrolysis of chlorophenoxypropionates

ROBERT CHÊNEVERT[1] AND LINDA D'ASTOUS

Département de chimie, Faculté des sciences et de génie, Université Laval, Québec (Québec), Canada G1K 7P4

Received September 16, 1987

ROBERT CHÊNEVERT and LINDA D'ASTOUS. Can. J. Chem. **66**, 1219 (1988).

We report on the enzymatic hydrolysis of methyl 2-phenoxypropionate and of the following chlorinated derivatives: methyl *o*-chloro-, *m*-chloro-, *p*-chloro-, and *o,p*-dichloro-2-phenoxypropionates. α-Chymotrypsin, lipase, and pig liver esterase have an *R* enantioselectivity whereas subtilisin has an *S* enantioselectivity. Enantiomeric excesses (e.e.) cover a wide range (from 5 to 100%).

ROBERT CHÊNEVERT et LINDA D'ASTOUS. Can. J. Chem. **66**, 1219 (1988).

Nous décrivons l'hydrolyse enzymatique du phénoxy-2 propionate de méthyle et de ses dérivés chlorés suivants : *o*-chloro, *m*-chloro, *p*-chloro et *o,p*-dichloro phénoxy-2 propionates de méthyle. La lipase, l'estérase et la α-chymotrypsine hydrolysent sélectivement l'isomère *R* alors que la subtilisine montre une sélectivité inverse. Les excès énantiomériques (e.e.) sont très variables (de 5 à 100%).

Introduction

The use of enzymes as catalysts in synthetic organic chemistry is being increasingly exploited by chemists (1). Hydrolases that are readily available and do not require cofactor regeneration are particularly valuable in asymmetric synthesis. In recent years, several hydrolytic enzymes have been used for the resolution of racemates (2) or the enantiotopic group differentiation in meso compounds (3). We report here a study on the resolution of chlorophenoxypropionates by hydrolases. Chlorophenoxyalkanoic acids and derivatives are plant growth regulators (herbicides) (4). They have an influence on lipid metabolism and are hypolipidemic and hypocholesterolemic agents (5). They also have a morphogenic activity on insects (6). Their structure has been incorporated in synthetic or semisynthetic penicillins (7). There is always a more or less pronounced difference in biological activity between the D and L forms. For instance, the D-(+)-4-chlorophenoxypropionic acid is an auxin 100 times more active than the L-(−) isomer (8).

Results and discussion

The racemic ester substrates (+)-(**1**–**5**) were prepared by esterification of the commercially available corresponding acids with methanol in the presence of 2,2-dimethoxy propane and *p*-toluenesulfonic acid. Preparative-scale (5–6 mmol) enzyme catalysed hydrolyses were performed in buffered aqueous solutions at pH 7–8. The enzymatic saponification was indicated by the decrease of pH, which was maintained at its initial value by the addition of a dilute sodium hydroxide solution. The reactions were monitored from the consumption of the base and terminated at the 50%-of-hydrolysis point. The unreacted esters were recovered from the reaction mixtures by extraction with ether at pH 7–8. The product acids that are present in the aqueous phase as sodium salts were isolated after acidification to pH 2 and extraction with ether. Acids were converted to their methyl esters before the determination of their optical purity. Enantiomeric excess (e.e.) values were determined by ^{1}H nmr analysis using tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato]europium(III) as a chiral shift reagent. In every case, well-resolved signals were obtained for the ester methyl protons. Absolute configurations were assigned by comparison with the optical rotation signs reported in the literature (8*b*, 9). The results are summarized in Tables 1 and 3 (experimental part). Recovery yields ranged from 70 to 99% of the amount estimated to be present based on acid released. α-Chymotrypsin, subtilisin, lipase, and esterase are enantioselective, and enantiomeric excesses cover a wide range from 5 to 100%. Esterase is the most active enzyme but its enantioselectivity is much lower than other enzymes. The dichlorophenoxyester **5** is more resistant to hydrolysis and poor enantioselectivities were found with all enzymes. Klibanov and co-workers (2*b*, 10) reported the resolution of 2-(*p*-chlorophenoxy)propionic acid by asymmetric hydrolysis and by esterification or transesterification with immobilized lipase or free lipase in dry organic media. Table 1 reports the e.e.'s that are consistently achievable under the usual reaction conditions. These reactions have not been optimized and Table 2 shows how manipulation of reaction conditions can sometimes be used to improve enantiomeric purities if the enantioselectivity of the enzyme under the usual conditions is inadequate. To avoid non-enzymatic hydrolysis, we kept the pH constant (pH 7–8) and changed the ionic strength and the nature of the electrolytes. Both sodium and calcium ions are activators of lipases (11). Sodium ions suppress enzyme inhibition by interfacial charge effects. The role of calcium ions is more complex. Calcium ions bind to the enzyme and affect the enzyme–substrate association. Calcium ions can also remove the unionized fatty acids from the interface where the reaction occurs, through the formation of insoluble calcium carboxylates. Since the values of enantiomeric excess increase with the extent of conversion (12), it is possible to improve the optical purity of the unreacted ester by extending reaction times, but at the expense of decreased yield. For example, α-chymotrypsin catalysed hydrolysis of methyl 2-phenoxypropionate gave a 66% e.e. at 50% conversion and a >90% e.e. at 70% conversion. Acids can be prepared with higher values of e.e. by carrying hydrolyses to low conversions. Whichever the desirable isomer, the other one can be readily racemized and recycled. Methyl esters were racemized by a

brief treatment with sodium methoxide in methanol. The corresponding acids can be recycled by esterification prior to racemization by using the same procedure.

The *R* enantiomers are better substrates for α-chymotrypsin and this stereoselectivity can be rationalized in terms of Cohen's active site model (13) as shown in Fig. 1. When the α-NHR group of an amino acid ester substrate is replaced by a new group like a methyl group, the L-enantiomers (*R*) bind as shown with the usual ar-aryl group and n-ester interactions unchanged. The methyl group is too large to fit the restricted h-site and only the L-isomer (*R*) is readily hydrolyzed. Although the methyl group can be accommodated at the am-site, it does not bind there because there is no formation of hydrogen bond, as occurs when the substituent is an amino group. It is noteworthy that the selectivity of subtilisin is different from that of chymotrypsin. Both serine proteases have a similar active center and often have the same stereoselectivity, the substrate specificity of subtilisin being broader than that of chymotrypsin. Lipase and esterase have an *R* stereoselectivity like chymotrypsin. No well-defined active site models are available for these enzymes. However, several studies have shown that a better enantioselectivity is obtained when the acid component of the ester is larger than an *n*-propyl group or when the alcohol component of the ester is a methyl or a small group (2*d*, 14). We found that the enantioselectivity decreases when the methyl group in chlorophenoxypropionates is replaced by an ethyl or an *n*-propyl group.

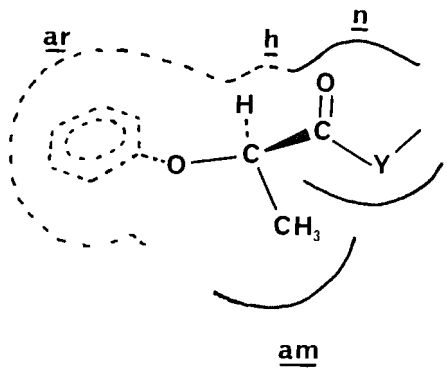

FIG. 1. Schematic representation of the binding of an L-phenoxypropionate in the active site of α-chymotrypsin.

Experimental

α-Chymotrypsin (E.C. 3.4.21.1, type II), subtilisin (E.C. 3.4.21.14, Carlsberg, protease type VIII), lipase (E.C. 3.1.1.13, type VII), and esterase (E.C. 3.1.1.1, porcine liver) were purchased from Sigma. Phenoxypropionic acids and $Eu(hfc)_3$ were purchased from Aldrich. The nmr studies were performed on a Varian XL-200 spectrometer. Optical rotations were measured with a Jasco DIP-360 digital polarimeter. Elemental analyses were carried out in a Carlo Erba Strumentazione-1106 apparatus.

Esterification of phenoxypropionic acids, general procedure

The acid (0.125 mol), 2,2-dimethoxypropane (0.185 mol), and a catalytic amount of *p*-toluenesulfonic acid (15 mg) were dissolved in dry methanol (0.185 mol). The solution was stirred magnetically for 4 h at 55°C under a dry atmosphere. Acetone and methanol were evaporated and the crude ester was distilled under reduced pressure (~1 Torr; 1 Torr = 133.3 Pa). The yields were in the range 70–100%. *Methyl 2-phenoxypropionate* (**1**): bp 75–76°C (0.65 Torr); ir (neat) ν_{max}: 3100–3000, 2960, 1765, 1740, 1300–1055 cm^{-1}; ^1H nmr δ: 1.62 (3H, d, J = 7 Hz), 3.74 (3H, s), 4.77 (1H, q, J = 7 Hz), 6.84–6.91 (2H, m), 6.93–7.01 (1H, m), 7.22–7.32 (2H, m); ^{13}C nmr δ: 18.54, 52.19, 72.36, 114.85, 121.40, 129.35, 157.27, 172.44; ms *m/e* (rel. intensity): 180 (39, M^+), 121 (100), 77(39). *Anal.* calcd. for $C_{10}H_{12}O_3$: C 66.65, H 6.71; found: C 66.37, H 6.62%. *Methyl 2-(2-chlorophenoxy)propionate* (**2**): bp 97–98°C (0.70 Torr); ir (neat) ν_{max}: 3070, 3000, 2960, 1760, 1295–1045, 750 cm^{-1}; ^1H nmr δ: 1.67 (3H, d, J = 7 Hz), 3.74 (3H, s), 4.77 (1H, q, J = 7 Hz), 6.84 (1H, dd, J_o = 8 Hz, J_m = 2 Hz), 6.92 (1H, td, J_o = 8 Hz, J_m = 2 Hz), 7.16 (1H, td, J_o = 8 Hz, J_m = 2 Hz), 7.36 (1H, dd, J_o = 8 Hz, J_m = 2 Hz); ^{13}C nmr δ: 19.08, 52.90, 74.56, 115.71, 123.08, 124.26, 128.08, 131.01, 153.76, 172.44; ms *m/e* (rel. intensity): 214 (60, M^+), 155 (100), 128 (72). *Anal.* calcd. for $C_{10}H_{11}O_3Cl$: C 55.96, H 5.17; found: C 55.72, H 5.01%. *Methyl 2-(3-chlorophenoxy)propionate* (**3**): bp 89–90°C (0.65 Torr); ir (neat) ν_{max}: 3080, 3000, 2960, 1760, 1740, 1280–1050 cm^{-1}; ^1H nmr δ: 1.61 (3H, d, J = 7 Hz), 3.75 (3H, s), 4.74 (1H, q, J = 7 Hz),

The physical properties and spectroscopic data of compound **5** were compared to those in the literature (15).

This esterification procedure has been used for the preparation of the substrates and esterification of product acids prior to the determination of their optical purities by nmr spectroscopy.

Enzyme-catalysed hydrolyses of phenoxyesters, general procedure

The ester (5 or 6 mmol) was suspended in a buffered aqueous solution (50 mL) at room temperature (20°C). The enzyme was added and the pH was maintained at its initial value by addition of 0.1 M aqueous NaOH from a burette. The reaction was stopped at the 50%-of-hydrolysis point. The mixture was first extracted at initial pH with ether (3 × 50 mL) to remove the unchanged ester. The aqueous mixture was then acidified to pH 2.0 with 2 M hydrochloric acid and was again extracted with ether (3 × 50 mL) to remove the product acid. The ether extracts were dried on magnesium sulfate and evaporated. Details pertaining to each enzyme are the following: α-chymotrypsin: substrate (5 mmol), enzyme (200 mg), solvent (phosphate buffer, pH 7.00); subtilisin: substrate (6 mmol), enzyme (15 mg), solvent (phosphate buffer, pH 7.70); lipase: substrate (5 mmol), enzyme (70 mg), solvent (phosphate buffer, pH 8.00, 10 mmol NaCl, 0.15 mmol $CaCl_2$); esterase: substrate (5 mmol), enzyme (200 units), solvent (borate buffer, pH 8.00, 10 mmol NaCl, 0.15 mmol $CaCl_2$). Reaction times and yields are reported in Table 3.

Racemization of methyl esters

A small amount of sodium (23 mg, 1 mmol) was added to 25 mL of dry methanol. When all the sodium had reacted, the optically active ester (5 mmol) was added and the solution was stirred under reflux for 30 min. After cooling to room temperature, most of the methanol was evaporated and water was added. The aqueous phase was extracted with ether and the ethereal solution was dried over magnesium sulfate and evaporated. The remainder was optically inactive (checked by nmr analysis in the presence of Eu(hfc)$_3$) and the yields were higher than 90%.

Conductivity and ionic association of tetraalkylammonium halides in *tert*-butanol–water mixture at 25°C

AIJAZ AHMAD ANSARI[1] AND M. R. ISLAM[2]
Department of Chemistry, Aligarh Muslim University, Aligarh-202001, India

Received July 23, 1987[3]

AIJAZ AHMAD ANSARI and M. R. ISLAM. Can. J. Chem. **66**, 1223 (1988).

The molar conductivities of Pr_4NBr, Bu_4NBr, Pr_4NI, and Bu_4NI have been measured in *tert*-butanol–water (*t*-BuOH–H_2O) mixtures ($61.30 \geq D \geq 16.50$) over the maximum concentration range ($2 \times D^3 \times 10^{-7}$ mol dm^{-3}) along with the densities and viscosities of the solvent mixtures at 25°C. The conductance data have been analysed by using the Fuoss-1978 (F78) conductance equation and the results compared with the values obtained from the Justice (J), Pitt's (P), and Fuoss–Onsager–Skinner (FOS) equations. Molar conductivities at infinite dilution (Λ_0), the thermodynamic ion association constants (K_A) and the distance or ion-size parameters (R^0 or a^0) are evaluated from these data. The F78 equation fitted the data better and yielded K_A and R values which are in accord with the ion-association theories. The interpretation of these parameters is discussed to provide some insight on the magnitude of the ionic association and the ion–solvent interaction.

AIJAZ AHMAD ANSARI et M. R. ISLAM. Can. J. Chem. **66**, 1223 (1988).

Opérant à 25°C et dans des mélanges de *tert*-butanol/eau (*tert*-BuOH/H_2O), ($61.30 \geq D \geq 16.50$), on a mesuré les conductivités molaires du Pr_4NBr, du Bu_4NBr, du Pr_4NI et du Bu_4NI sur un éventail maximal de concentrations ($2 \times D^3 \times 10^{-7}$ mol dm^{-3}); on a aussi déterminé les densités et les viscosités des mélanges de solvant. On a analysé les données de conductance à l'aide de l'équation de conductance de Fuoss-1978 (F78) et on a comparé les résultats aux valeurs obtenues à l'aide des équations de Justice (J), de Pitt (P) et de Fuoss–Onsager–Skinner (FOS). Utilisant ces données, on a évalué les conductivités molaires à dilution infinie (Λ_0), les constantes thermodynamiques d'association ionique (K_A) ainsi que les paramètres de distance ou de grosseur ionique (R^0 ou a^0). La meilleure corrélation est obtenue à l'aide de l'équation F78 et elle fournit des valeurs de K_A et de R qui sont en accord avec les théories d'association ionique. Dans le but de comprendre l'amplitude de l'association ionique et de l'interaction ion–solvant, on discute de l'interprétation de ces paramètres.

[Traduit par la revue]

Introduction

In investigating the electrical conductances of dilute electrolytic solutions in various pure and mixed solvents (1–3) the concentration–conductance data have been adequately explained by the Fuoss–Onsager equation (4) using ion–ion and ion–solvent interactions. The magnitude and nature of such interactions have been interpreted in terms of the limiting molar conductance, the ion-size parameter, and the ionic-association constant. The solvent properties like viscosity and dielectric constant have also been taken into account in determining the extent of such interactions. However, the implication of precise conductance data to the above has revealed the discrepancy between the parameters calculated using experimental data and those derived theoretically. Consequently, the Fuoss–Hsia equation (5) emerged as one of the equations which succeeded in explaining the conductance behaviour. Although Justice (6) extended this equation for long-range interactions by including the higher order concentration terms, its unique solution does not give reasonable values for the ion-size parameter in higher dielectric constant medium. While Fuoss primitive model (7) based on the formation of contact-ion-pair has been applied to 1:1 electrolytes, which are either unassociated or associated in dilute solutions, but discarded later on as the short-range interactions were counted twice. Finally, Fuoss (8, 9) proposed the theory of diffusion-controlled steady state which has two main features: (*a*) the unpaired ions surrounded by only solvent molecules within their Gurney cosphere diameter and (*b*) the paired ions within their cosphere, which are of two catagories, viz., those whose next neighbours are solvent molecules behave as a dipole while those whose next neighbours are ions of opposite charge give rise to the formation of contact ion-pairs contributing only to charging current.

The anomalous physical properties of *t*-BuOH–H_2O mixtures have attracted much attention, and there are numerous thermodynamic data available in the literature (10–13) in comparison with other alcohol–water mixtures. Of these, the differential heats of dilution could provide direct information about the energetics of the solute–solute interaction, or the hydrophobic interaction. It would, therefore, be worthwhile to undertake the measurement of electrical conductance of tetraalkylammonium halides in *t*-BuOH–H_2O mixtures in order to examine the suitability of F78 conductance equation over those of the Justice (14), Pitt's (15, 16), and FOS (17) conductance equations to provide a better understanding of the mechanism of the observed conductivity behaviour of associated and unassociated electrolytes.

Experimental

Reagent grade *t*-BuOH (E. Merck) was purified (18) until the measured density, 0.7808 g cm^{-3} viscosity, 4.462 cP, and specific conductance ($0.5–2 \times 10^{-8}$ ohm^{-1} cm^{-1} at 25°C were found to be comparable with those of the corresponding literature values (19). This freshly purified solvent was used for the preparation of the solvent mixtures with triply distilled water (sp. conductance, 2.3×10^{-6} ohm^{-1} cm^{-1}). The density and viscosity measurements of solvent mixtures were made with an accuracy of ±0.002% and ±0.13%, respectively, as reported earlier (20). Pr_4NBr (Fluka, AG), Pr_4NI, Bu_4NBr, and Bu_4NI (Estman, AG) were used as solute.

Conductance measurements were carried out by Impedence Bridge, 1608-A (General Radio & Co., U.S.A.) at a constant frequency of 1 kHz with a stated accuracy of ±0.05–0.005%. Other apparatus and procedure used for conductance measurements have been described elsewhere (21, 22). The overall reproducibility of the conductance measurement was found to be ±0.025%.

The solvent mixtures and solutions were prepared under pure and dry

nitrogen atmosphere in a dry box. The dielectric constants of the solvent mixtures used for analysis were taken from the literature (23).

Results and discussion

The physical properties of the solvents used are listed in Table 1. The molar conductivities, Λ (Ω^{-1} cm^2 mol^{-1}) of Pr_4NBr, Bu_4NBr, Pr_4NI, and Bu_4NI in t-BuOH–H_2O mixtures of different compositions are given in Table 2 as a function of concentration, C (mol dm^{-3}) at 25°C.

The concentration dependence of conductance data for all salts have been first analysed in terms of F78 conductance equation (8, 9) which gives three adjustable parameters Λ_0, K_A, and R by the following set of equations:

$$[1] \quad \Lambda = [1 - \alpha(1 - \gamma)][\Lambda_0(1 + RX) + EL]$$

$$[2] \quad K_R = (1 - \alpha)(1 - \gamma)/C\gamma^2 f^2 = (4\pi NR^3/3000)\exp(\beta/R)$$

$$[3] \quad K_S = \alpha/(1 - \alpha)$$

$$[4] \quad K_A = 1 - \gamma/C\gamma^2 f^2 = K_R/(1 - \alpha)$$

and the activity coefficient, f, is given by

$$[5] \quad -\ln f = \beta\kappa/2(1 + \kappa R)$$

Here R is the Gurney cosphere diameter (24) and RX and EL are the relaxation and hydrodynamic terms, respectively. Other terms have their usual significance. Details of computational methods are given elsewhere (21, 22).

Similarly, each set of conductance data has been analysed using Justice's modification (14) of the Fuoss–Hsia equation (5), and constants derived by Fernandez–Prini (25). The Fuoss–Hsia equation is given by

$$[6] \quad \Lambda = \Lambda_0 - S(\alpha C)^{1/2} + E\alpha C \ln(\alpha C) + J_1\alpha C - J_2(\alpha C)^{3/2} - \Lambda\alpha C f_\pm^2 K_A$$

where α is the degree of dissociation, $f_\pm$ is the mean molar activity coefficient, and all other terms have their usual significance. The thermodynamic association constant is defined by

$$[7] \quad K_A = (1 - \alpha)/\alpha^2 C f_\pm^2$$

where the activity coefficient for the neutral ion pair is taken as unity. Activity coefficients were calculated from the Debye–Hückel equation

$$[8] \quad \ln f_\pm^2 = -A(\alpha C)^{1/2}/\{1 + BR_j(\alpha C)^{1/2}\}$$

As proposed by Justice (14), the distance parameter, R_j in eq. [8] has been taken as the Bjerrum distance, q. The calculation of eq. [6] has been carried out by a pit-mapping method (26) in which Λ_0, R_j, and K_A are varied until a minimum is located for the standard error of estimate. This latter quantity, σ_Λ is defined by

$$[9] \quad \sigma_\Lambda = \{\Sigma(\Lambda_{obs} - \Lambda_{calc})^2/(N - 3)\}^{1/2}$$

The set of conductance data analysed using F78 and J equations has also been analysed using Pitt's (P) equation (15, 16),

$$[10] \quad \Lambda = \left[\Lambda_0 - \frac{Z^2e^2\kappa}{(1 + \kappa a)}\left(\frac{N\,10^9}{3\pi\eta_0 C^2}\right)\right] \times \left[1 - \frac{Z^2e^2\kappa}{3DkT(1 + \sqrt{2})(1 + \kappa a)(\sqrt{2} + \kappa a)}\right] - \frac{Z^4e^4\kappa^2}{3D^2k^2T^2}\left[\Lambda_0 S_1 - \frac{T_i}{(1 + \kappa a)}\left(\frac{NDkT\,10^9}{3\pi\eta_0 C^2}\right)\right]$$

where $q = Z^2e^2\kappa/DkT$, $\kappa^2 = 8\pi nZ^2e^2/DkT$, and n = number of positive and negative charges, N is Avogadro's Number, η_0 is the solvent viscosity, C is the velocity of light, a is the ion-size parameter, and other symbols have their usual meaning.

In the same way, each set of conductance data was then analysed by using FOS equation (17).

$$[11] \quad \Lambda = \Lambda_0 - S(C\gamma)^{1/2} + EC\gamma\log(6E'_1C\gamma) + LC\gamma - K_AC\gamma f_\pm^2\Lambda$$

for associated electrolytes. The symbols used have their usual meaning. The least-squares method have been used for calculation as proposed by Kay (27, 28).

The values of the best-fit parameters of the limiting molar conductance, Λ_0, association constant, K_A, and the distance parameter, R, or ion-size parameter, a^0, along with σ_Λ% thus computed which correspond to minimum standard deviation from F78, J, P and FOS conductance equations are recorded in Table 3(*a*) to (*d*) respectively. All calculations have been carried out on a VAX-11/780 computer.

A comparison of different available conductance equations has been made here with respect to their applicability to the measured conductances. The values of Λ_0 obtained for all the salts through the F78 and J methods of treatment of conductance data are found to be almost close to each other with an average deviation of $\sim\pm0.02$% while those obtained by using the P and the FOS conductance equations have an average deviation of $\sim\pm0.06$% and $\sim\pm0.11$%, respectively. An inspection of Table 3 reveals an apparently normal behaviour of tetraalkylammonium salts in the various solvent mixtures, i.e., Λ_0 decreases with increasing size of the tetraalkylammonium ions in the order $Pr_4\overset{+}{N} > Bu_4\overset{+}{N}$ and with decreasing dielectric constant of the solvent mixtures. This is in agreement with the earlier findings (1, 2, 21, 22, 26–30) in several pure and mixed solvents and can be attributed to the size and hydrophobic solvation of cations which increase in the order $Me_4\overset{+}{N} < Et_4\overset{+}{N} < Pr_4\overset{+}{N} < Bu_4\overset{+}{N}$, so that the mobility should be in the reverse order.

The computed values of association constant, K_A, obtained for all the salts under study through F78 equation (Table 3*a*) are 30%, 43.2%, and 48.8% higher than those obtained from J (Table 3*b*), P (Table 3*c*), and FOS (Table 3*d*) equations, respec-

tively. This uncertainty stems purely from the ambiguities in the theories and at present it is not possible to suggest the superiority of one equation over that of the other. An inspection of Table 3 shows that the K_A values for Pr_4NBr, Bu_4NBr, Pr_4NI, and Bu_4NI are found to increase with decrease in the dielectric constant of the medium (21, 22). However, the association constants obtained for Pr_4NBr and Bu_4NBr from F78 and J equations and to those of Pr_4NI and Bu_4NI from F78, J, P, and FOS conductance equations in t-BuOH–H_2O mixtures are an exponential function of the dielectric constant of the medium as is evident from the linear plots of log K_A vs. $1/D$ (Fig. 1). But, on the other hand, we get a concave curve for Pr_4NBr and Bu_4NBr when K_A obtained from P and FOS equations which is beyond explanation and also is contrary to the Justice–Bjerrum theory.

Furthermore, a perusal of Table 3 reveals that the K_A values

for all the salts in a given dielectric constant increase with increasing size of the ions and follow the order $Pr_4\overset{+}{N} < Bu_4\overset{+}{N}$ as expected (19, 31–34). Moreover, an increase in ionic-association with increasing the proportion of t-BuOH may be ascribed to the predominant solvation of cations with one of the solvent molecules which control the extent of ion-pairing in t-BuOH–H_2O mixtures.

The distance parameter or Gurney cosphere diameter, R (Table 3*a*) obtained from the F78 equation for Pr_4NBr, Bu_4NBr, Pr_4NI, and Bu_4NI are found to be larger compared to those of the distance of closest approach, R_j (Table 3*b*) and the ion-size parameter, α^0 (Table 3*c* and *d*) calculated from J, P, and FOS conductance equations, respectively. The values of distance or ion-size parameters obtained in the case of 20 wt% t-BuOH from J, 20 and 40 wt% t-BuOH from P, and 20, 40, and 60 wt% t-BuOH from FOS equations are smaller than the crystallographic radius of the ion pair which explain the inadequacy of the theories. However, the R values computed through the F78 equation are reasonable and higher than the Bjerrum distance, q, whereas $R_j \leq q$ and a^0 are less than q. Consequently, it is evident from Table 3 that the values of R or a^0 do not show any significant variation with the size of the cations or the anions but are found to increase with decrease in the dielectric constant of the medium which, in turn, indicates that the increase in ionic association (35, 36).

Thus, in the light of the above discussion it can be concluded that the F78 conductance equation seems to be better suited in explaining the behaviour of electrolytic solutions in all respects because it includes the solvated radii of ions present in the solution in diffuse steady state and gives significantly better fit parameters as compared to the other conductance equations.

Acknowledgements

The authors are indebted to Professors R. M. Fuoss, R. L. Kay, and J. C. Justice for sending the details of their equations and computer programs. I thank Professor A. D. Pethybridge, University of Reading (U.K.), for the personal communication and his invaluable suggestions on the distance parameters. We would also like to thank Professor N. Islam for his helpful discussion, Professor M. T. Ahmad, Z. H. Engg. College, AMU Aligarh, for the use of an impedence bridge and C.S.I.R., Government of India, for granting a Senior Research Fellowship.

Mechanisms of long-range $^{13}C,^{13}C$ spin–spin coupling in thioanisole and its derivatives. Conformational applications

TED SCHAEFER AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received September 8, 1987

TED SCHAEFER and GLENN H. PENNER. Can. J. Chem. **66**, 1229 (1988).

The ^{13}C nuclear magnetic resonance chemical shifts and the long-range $^{13}C,^{13}C$ spin–spin coupling constants are reported for 23 thioanisole derivatives enriched in ^{13}C at the methyl position. For *para* and *meta* substituted thioanisole derivatives, $^nJ(C,C)$ (n being the formal number of bonds intervening between the coupled nuclei) can be related to functions of the angle by which the thiomethyl group twists out of the aromatic plane. For $n = 3, 4, 5$, the ensuing relationships yield estimates of the twofold barriers to rotation about the C(1)—S bond. The barrier is lower in ethyl phenyl sulfide than in thioanisole derivatives. Complications arise for *ortho* substituted thioanisole derivatives but estimates of the torsional motion about the C(1)—S bond can be obtained from the observed $^nJ(C,C)$. Among the complications is the expected fact that $^3J(C,C)$, which is shown to be larger in the *cis* than the *trans* orientation of the intervening bonds ("anti-Karplus" behaviour), is perturbed by the substituent attached to the coupled nucleus. It is confirmed that in 2-hydroxythioanisole the thiomethyl group is oriented effectively perpendicular to the benzene plane, attributable to a stereospecific hydrogen bond between the hydroxyl group and the 3*p* lone-pair on the sulfur atom. In acetone-d_6 solution, an equilibrium exists between this conformation and one in which an intermolecular hydrogen bond exists with solvent molecules. In the latter, the thiomethyl group prefers a coplanar orientation. In 2-aminothioanisole, the thiomethyl group twists out of the plane by about 60° so as to optimize the N—H. . .3*p* interaction. This twist angle is changed very little in acetone-d_6 solution because the second N—H bond can hydrogen bond to the solvent molecules without disrupting the intramolecular N—H. . .3*p* interaction. It is also shown that the chemical shift of the ^{13}C nucleus in the methyl group is a good conformational indicator in *meta* and *para* substituted thioanisoles. Therefore it can be used as such for molecules in which $^nJ(C,C)$ is difficult to find, in 1,4-dithiomethylbenzene, for example.

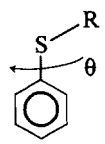
TED SCHAEFER et GLENN H. PENNER. Can. J. Chem. **66**, 1229 (1988).

On a mesuré les déplacements chimiques en résonance magnétique nucléaire du ^{13}C ainsi que les constantes de couplage spin–spin à longue distance $^{13}C,^{13}C$ pour 23 dérivés du thioanisole enrichis en ^{13}C dans la position du méthyle. Pour les dérivés du thioanisole substitués en positions *para* ainsi que *méta*, les constantes $^nJ(C,C)$, pour lesquelles n correspond au nombre de liaisons formelles intervenant entre les noyaux qui sont couplés, peuvent être reliées aux fonctions de l'angle de torsion du groupement thiométhyle par rapport au plan aromatique. Pour $n = 3, 4$ ou 5, les relations qui en dérivent permettent d'évaluer les barrières binaires à la rotation autour de la liaison C(1)—S. La barrière est plus faible dans le cas du sulfure d'éthyle et de phényle que dans les cas des dérivés du thioanisole. On fait face à des complications avec les dérivés du thioanisole substitués en *ortho*; toutefois, les évaluations du mouvement de torsion autour de la liaison C(1)—S peuvent être obtenues à partir des constantes $^nJ(C,C)$ observées. Parmi les complications rencontrées, mentionnons le fait attendu que la constante $^3J(C,C)$, qui est plus grande dans l'orientation *cis* des liaisons intermédiaires que dans l'orientation *trans* (comportement anti-Karplus), est perturbée par la présence du substituant attaché au noyau couplé. Il est confirmé que, dans l'hydroxy-2 thioanisole, le groupement thiométhyle est effectivement orienté d'une façon perpendiculaire au plan du benzène et que ce fait est attribuable à une liaison hydrogène stéréospécifique entre le groupement hydroxyle et la paire d'électrons 3*p* libre de l'atome de soufre. En solution dans l'acétone-d_6, il existe un équilibre entre cette conformation et celle dans laquelle il existe une liaison hydrogène intermoléculaire avec les molécules du solvant. Dans cette dernière, le groupement thiométhyle existe d'une façon préférentielle dans l'orientation coplanaire. Dans l'amino-2 thioanisole, l'angle de torsion du groupement thiométhyle par rapport au plan du benzène est de 60° et, dans cette conformation, l'interaction N—H. . .3*p* est optimale. En solution dans l'acétone-d_6, cet angle de torsion ne subit pas beaucoup de changement; ce résultat est dû au fait que la deuxième liaison N—H peut former une liaison hydrogène avec les molécules de solvant sans déranger l'interaction N—H. . .3*p* intramoléculaire. On a aussi démontré que le déplacement chimique du noyau ^{13}C du groupement méthyle est un bon indicateur conformationnel pour les dérivés du thioanisole substitués en positions *méta* ainsi que *para*. On peut donc en conclure qu'il peut être utilisé tel quel pour des molécules dans lesquelles la constante $^nJ(C,C)$ est difficile à déterminer comme, par exemple, dans le cas du dithiométhyl-1,4-benzène.

[Traduit par la revue]

Introduction

Long-range spin–spin coupling constants between ^1H and ^{13}C nuclei in the side chain and ^1H and ^{13}C nuclei in the ring provide conformational information about thiophenol and thioanisole derivatives (1–3). For example, in derivatives of **1** (R = H) the predominantly twofold barrier to rotation about the C(1)—S bond is sensitive to the nature of the *para* substituent. Thus, in thiophenol V_2 is 3.4 kJ mol^{-1} (4) with a planar, $\theta = 0°$, conformation as the most stable, while in *p*-nitrothiophenol V_2 increases to 9 kJ mol^{-1}. This increase in V_2 may be attributed to a larger mobile bond order of the C(1)—S bond in the nitro derivative. In *p*-aminothiophenol this mobile bond order decreases so much that the most stable conformer has θ as 90° (3).



$\theta = 0°$

1

These conclusions are based on $^4J(H,H)$, the coupling constant over four formal bonds between the *ortho* and sulfhydryl protons. It is assumed (1, 3) that $^4J(H,H)$ is proportional to $\sin^2\theta$ and a hindered rotor model is used to relate the expectation value of $\sin^2\theta$ to V_2. The value of $^4J(H,H)$ at $\theta = 90°$ is obtained from 2-hydroxythiophenol, **2** (R = H), in which a stereospecific intra-

2

molecular hydrogen bond between the hydroxyl group and the 3*p* orbital on the sulfur atom forces the S—H bond into a plane perpendicular to the molecular plane (5).

V_2 in thiophenol derivatives is also sensitive to *meta* substituents and the observed changes are qualitatively understandable (1) in terms of perturbation molecular orbital theory (6). For these molecules both ^4J(H,H) and ^6J(H,H) are employed as indicators of V_2.

In thioanisole and its derivatives, the indicator in the side chain is the ^{13}C nucleus in the methyl group. The value of $^6J_{90}$ in the equation, $^6J(H,C) = {}^6J_{90} \sin^2 \theta$, is estimated from the observed coupling constants between the ^{13}C nucleus of the methyl group and the *para* proton in molecules like 2,6-dichloro- or 2,6-dibromothioanisole (2). In derivatives of 4-fluorothioanisole, the *para* proton is replaced by the ^{19}F nucleus in the coupling scheme (2). ^6J(H,C) or ^6J(C,F) are measurable with the INEPT pulse sequence (7) or in the presence of ^{1}H broadband decoupling.

In the presence of *para* substituents other than hydrogen or fluorine, other indicator nuclei are required. These might be the remaining ring protons or ^{13}C nuclei in the benzene ring. Enrichment with ^{13}C in the methyl group allows a relatively facile measurement of ^nJ(C,C) if the ring protons are decoupled during the measurement. The use of model compounds may establish the θ dependence of ^nJ(C,C), and expectation values of the appropriate functions of θ may then give information about the internal rotational potential in the thioanisole derivatives of interest.

In this paper, such measurements are reported for 15 symmetrically substituted thioanisole derivatives, and for some 2-substituted thioanisole derivates. It turns out that ^5J(C,C) is a good conformational indicator. When the resonance peaks of the 4-^{13}C nucleus is broad (nitro or amino groups), other ^nJ(C,C) values provide conformational conclusions. It is also shown that the *ortho* hydroxyl and amino substituents differ significantly in the changes they cause in θ of the thiomethyl group on formation of O—H. . .S and N—H. . .S intramolecular hydrogen bonds.

Experimental

All ^{13}C enriched precursors came from MSD Isotopes and had a minimum isotopic purity of 95 at.%. The ^{13}C enriched thioanisoles were easily prepared as follows. About 0.1 g of sodium metal was added to 10 mL of absolute methanol, followed by addition of 2 mmol of the thiophenol derivative. Then 2.3 mmol (0.33 g) of $^{13}CH_3I$ was added while stirring the solution and the latter was continued for 15 min. Addition of water gave a cloudy suspension. Extraction with ether, drying over anhydrous $MgSO_4$, and filtration was followed by rotary evaporation. Ethylation of thiophenols used 2.3 mmol (0.36 g) of $CH_3{}^{13}CH_2I$.

Samples for nmr analysis, at concentrations in the solvents as given in the tables, were transferred to 10 mm od nmr tubes for ^{13}C nmr and to 5 mm od tubes for ^{1}H nmr. All solutions contained small amounts of tetramethylsilane as a reference. The sample tubes were degassed by the freeze–pump–thaw procedure and were then flame-sealed.

All nmr spectra were accumulated on an AM300 Bruker spectrometer at a probe temperature of 300 K. In proton-decoupled ^{13}C nmr, 128–256 free induction decays were additively stored, while 400–2800 decays were needed for proton-coupled ^{13}C nmr experiments. The actual number of added decays depended on the concentration of the ^{13}C enriched material. For reasons of cost, the concentration was sometimes too low to accumulate acceptable spectra of ^{13}C nuclei not bonded to hydrogen atoms in a reasonable time span. Acquisition times varied between 20 and 30 s; for example, a spectral width of 100 Hz was assigned to a 4K data region to give an acquisition time of 20.5 s. Some free induction decays were zero-filled to twice the original data region before Fourier transformation, using a small amount of Gaussian multiplication. The ^{1}H nmr spectra were the result of 8–32 accumulated decays with acquisition times as long as 40 s. The linewidths at half height of the ^{1}H and ^{13}C nmr spectra typically fell between 0.05 and 0.25 Hz. Relative signs of some coupling constants were determined by partial decoupling (8) experiments. The ^{13}C and ^{1}H excitation frequencies were 75.486 and 300.135 MHz, respectively.

Spectral analyses were performed with a locally modified version of the computer program NUMARIT (9). INDO MO FPT computations (10, 11) of coupling constants employed Amdahl 470/V8, 580/5850, or 5870 systems, as did the spectral analytical procedures.

Results and discussion

Tables 1–5 present chemical shift and coupling constant data relevant to the discussion below. In these tables, signs in parentheses are assumed while those not in parentheses are obtained from double resonance experiments. Figure 1 demonstrates the sign determination for $^3J(^{13}CH_3, {}^{13}C\text{-}2) \equiv {}^3J$(C,C) in 3,5-dichlorothioanisole-α-^{13}C.

$^nJ(C,C)$ *as a function of* θ

INDO MO FPT computations of long-range coupling constants in benzene derivatives are very useful as semiquantitative indicators of their θ dependence (2, 12–14). Quantitative agreement with experiment is relatively rare because of the parameterization of this semiempirical method and because the geometry assumed in the computations may well be different from the true geometry.

The computations for thioanisole, at 15° intervals of θ, yield numbers that can be fit by the expressions, $^5J(C,C)/Hz = 0.05(2) + 1.67(4) \sin^2 \theta$, $^4J(C,C)/Hz = -0.32(2) - 1.46(2) \sin^2 \theta + 0.17(2) \sin^2 (\theta/2)$, and $^3J(C,C)/Hz = 2.25(4) - 0.63(5) \sin^2 \theta + 0.50(5) \sin^2 (\theta/2)$. The equation for ^5J(C,C) indicates a σ–π mechanism for this coupling constant, just as for ^6J(H,C) to the *para* proton (2). The coefficient of $\sin^2 \theta$ is much too large, however, and, as argued previously for other coupling constants (12, 14, 15), the term independent of θ may well be an artifact of the calculation. The equation for ^4J(C,C) implies a large and negative σ–π component and a small σ electron component (16, 17), proportional to $\sin^2 (\theta/2)$. For an evenfold barrier, the expectation value of $\sin^2 (\theta/2)$ is 0.5, so that a distinction between a term in $\sin^2 (\theta/2)$ and a term independent of θ is impossible to establish for the compounds in Table 1. The equation ^3J(C,C) is an alternative representation of the Karplus equation (18), usually written in terms of cos θ, cos 2θ, and a constant term (trigonometric identities). With these hints about the conformational behaviour of ^nJ(C,C), the experimental values in Tables 1–3 can be discussed as follows.

Consider ^5J(C,C). The largest number in Table 1, 0.91 Hz, is that for 2,6-dimethylthioanisole. In the 2,6-dichloro derivative ^5J(C,C) drops to 0.77 Hz. The chloro and methyl substituents are often (19) taken to have very similar steric requirements. The two ^5J(C,C) values here indicate, on the face of it, that the

[p] 17 mol% in acetone-d_6; δ(2-CH_3) is 21.75, $^4J(CH_3,CH_3)$ is less than 0.1 Hz.

methyl groups cause $\langle\theta\rangle$ to be nearer 90° than do the two *ortho* chlorine atoms. There are some experiments, for example, on *ortho* disubstituted isopropyl benzene derivatives (19, 20), that agree that a methyl has larger steric requirements than a chlorine substituent. Yet, a methyl group is a better π electron donor than a chlorine substituent, therefore possibly causing a larger θ for the SCH_3 group (compare ^5J(C,C) for 4-methyl and 4-chlorothioanisole in Table 1). Hence the larger apparent $\langle\theta\rangle$ value in the 2,6-dimethyl derivative might arise for electronic instead of steric reasons. Furthermore, it is possible that the relatively electronegative chlorine substituents have an intrinsic effect on ^5J(C,C), as distinct from a conformational one (see below).

In 2-hydroxythioanisole ^5J(C,C) is also 0.91 Hz for a CCl_4 solution (Table 3). For reasons given in the introduction, this molecule is expected to have the perpendicular ($\theta \sim 90°$) conformation (see **2**). Note that ^4J(C,C) in **2** (R = CH_3) is the same for C-3 and C-5 (Table 3), as expected for such a conformation, as is $^5J(H,^{13}CH_3)$ for H-3 and H-5 (Table 4). Also $^6J(H\text{-}4,^{13}CH_3)$, a coupling proportional to $\sin^2\theta$, is −0.56 Hz in **2** (R = CH_3), to be compared with −0.54 Hz in 2,6-dibromothioanisole (2).

None of these molecules is rigid, of course, that is with $\langle\theta\rangle$ as 90°. Geometry-optimized STO-3G MO computations for 2,6-dichlorothioanisole give an energy difference of 31.3 kJ mol^{-1} between the planar and perpendicular forms, corresponding to a $\langle\sin^2\theta\rangle$ of 0.957. This number implies a $^5J_{90}$(C,C) of 0.80 Hz, much smaller than the observed ^5J(C,C) in 2-hydroxythioanisole or 2,6-dimethylanisole. If a substantial fourfold component of the barrier exists in the 2,6-dichloro derivative, with a sign opposite to the twofold component, as computed for 2,6-difluorothioanisole (2), then $\langle\sin^2\theta\rangle$ will be larger for a given V_2 than if V_4 is zero (this is easily seen pictorially by adding curves for V_2 and V_4 to yield a potential curve that clearly drives $\langle\theta\rangle$ towards 90°). If such a situation also exists in the 2,6-dimethyl derivative, any barrier derived from $\langle\sin^2\theta\rangle$, as indicated by ^5J(C,C), will be quite uncertain. Because of these ambiguities concerning the form of the internal rotational potential in the diortho-substituted molecules, and because of the further ambiguity connected with intrinsic substituent perturbations of ^5J(C,C), it is most likely best to write eq. [1] in which $^5J_{90}$(C,C) is taken as the maximum observed value of ^5J(C,C). The use of eq. [1] to obtain V_2 values in *meta* or *para* substituted derivatives of the thioanisole will therefore yield lower limits to

V_2 (see below).

[1] $$^5J(C,C)/Hz = 0.91 \langle \sin^2 \theta \rangle$$

Both $^5J(C,C)$ and $^6J(H,^{13}CH_3)$ are assumed to be pure $\sigma-\pi$ coupling constants (dependent only on $\sin^2 \theta$). In Table 5 numbers for these coupling constants are given for a variety of compounds. A linear relationship, with a correlation coefficient of 0.9995, exists between these coupling constants and is given by eq. [2]. This proportionality implies that, for neutral molecules, the hyperfine coupling parameters, Q^C_{CH} and Q^H_{CH}, which represent transmission of unpaired spin density from the aromatic π orbitals to the sites of the ring ^{13}C or ^1H nuclei, respectively, are of opposite sign. In aromatic free radicals Q^C_{CH} and Q^H_{CH} are positive and negative, respectively (23, 24).

[2] $$^5J(C,C) = -1.50\, ^6J(H,^{13}CH_3) + 0.02$$

Equation [2] implies that $^5J(C,C)$ and $^6J(H,^{13}CH_3)$ undergo proportional intrinsic substituent perturbations but, of course, cannot yield a value of $^5J(C,C)$ at a θ of 90° in thioanisole. Nor does eq. [2] prove that the form of eq. [1] is correct. The undetectable $^5J(C,C)$ and $^6J(H,^{13}CH_3)$ in anisole (Table 5) are consistent with a very small, if any, angle-independent term in eq. [1]).

Turning to $^4J(C,C)$ and reiterating that $\langle \sin^2 (\theta/2) \rangle$ is 0.5 for an evenfold barrier (symmetrically substituted molecules), the theoretical calculations above imply a proportionality between $^4J(C,C)$ and $\sin^2 \theta$ for the molecules in Table 1. Consequently, a linear regression between $^4J(C,C)$ and $^5J(C,C)$ is in order, yielding eq. [3] for 13 points ($r = 0.992$). It should be noted that $^4J(C,C)$ is measured as negative in 2,6-dichlorothioanisole and that the other signs of $^4J(C,C)$ in Table 1 are assumed; the INDO MO FPT computations agree that the $\sigma-\pi$ component of $^4J(C,C)$, proportional to $\sin^2 \theta$, is negative. In view of eq. [1], it follows that $^4J(C,C)$ is given by eq. [4]. The way in which the constant term in eq. [3] breaks into a term in $\sin^2 (\theta/2)$ and, possibly, an angle-independent term, cannot be determined from this approach.

[3] $$^4J(C,C)/Hz = -1.66\, ^5J(C,C) + 0.62$$

[4] $$^4J(C,C)/Hz = 1.51 \langle \sin^2 \theta \rangle + 0.62$$

Again, from the theoretical numbers for ^3J, a linear relationship between it and ^5J is expected and found, as in eq. [5].

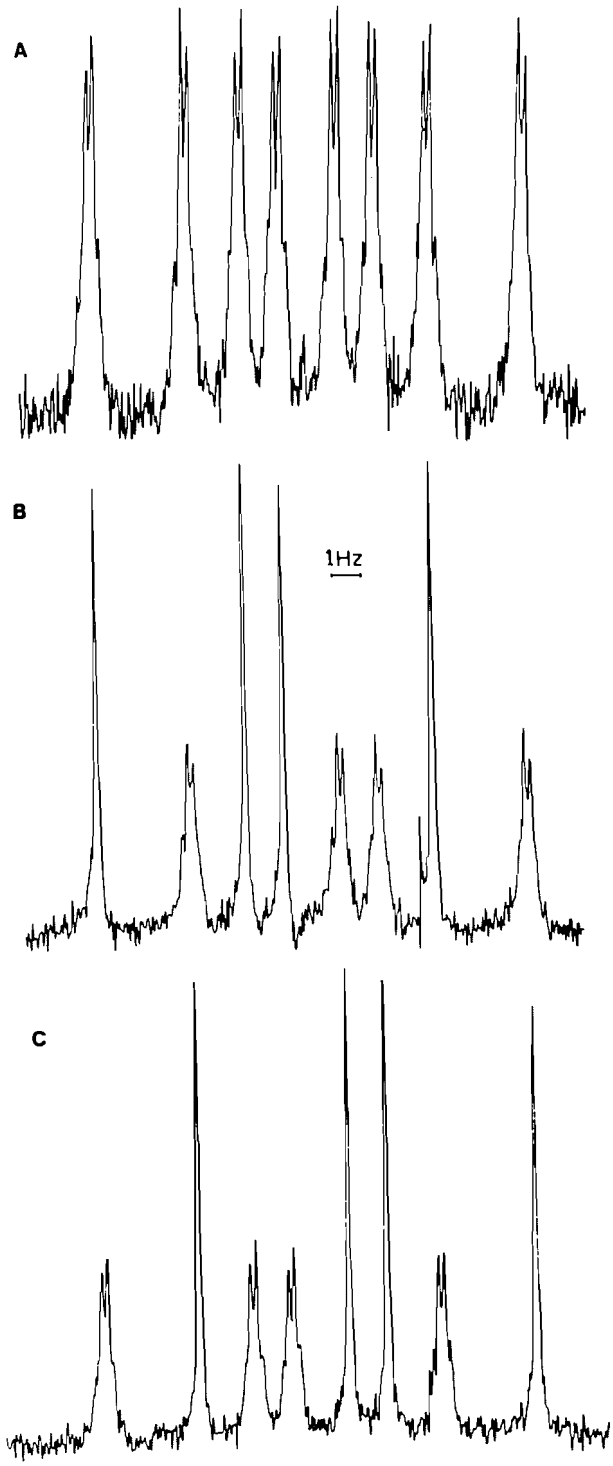

FIG. 1. Part A displays half of the ^{13}C nmr spectrum of C-2 in 3,5-dichlorothioanisole-α-^{13}C as a 3.4 mol% solution in acetone-d_6 at 300 K and 75.486 MHz. No attempt at peak width optimization is present here. The eight quartets arise from large, ca. 8 Hz, couplings to H-4 and H-6 and a 3-Hz coupling to the α ^{13}C nucleus. The quartet structure is caused by a coupling interaction with the methyl protons. In B the methyl proton peaks at high frequency are being irradiated (partial decoupling). The collapse of quartets of C-2 occurs in the high-frequency band of the doublets arising from coupling to the α ^{13}C nucleus. In C the methyl proton peaks at low frequency, corresponding to a spin state of the α ^{13}C nucleus opposite to that in B, are being irradiated. These experiments demonstrate that $^1J(^1H,\alpha\text{-}^{13}C)/^3J(^{13}CH_3,^{13}C\text{-}2)$ is positive, which yields the absolute value of ^3J given that ^1J is positive.

[5] $^3J(C,C)/Hz = -2.74\,^5J(C,C) + 3.55$

Here $r = 0.995$, but 2,6-difluorothioanisole is omitted from the analysis because it deviates strongly (0.15 Hz in 1.29 Hz) from the regression line. The probability of an intrinsic substituent perturbation is apparent. It follows that $^3J(C,C)$ is related to $\sin^2\theta$ by eq. [6]. The constant term is a composite of a term in $\sin^2(\theta/2)$ and an *apparent* angle-independent term (for free rotation both $\langle\sin^2\theta\rangle$ and $\langle\sin^2(\theta/2)\rangle$ become 0.5 and $^3J(C,C)$ would be 2.31 Hz).

[6] $^3J(C,C)/Hz = -2.49\langle\sin^2\theta\rangle + 3.55$

Rotational barriers from $^nJ(C,C)$

Equations [1], [4], and [6] yield $\langle\sin^2\theta\rangle$ for the molecules in Table 1. For thioanisole the available evidence suggests an almost purely twofold barrier to rotation about the C(1)—S bond (2). A hindered rotor model (25, 26) relates V_2 to $\langle\sin^2\theta\rangle$. In the present instance 31 free rotor basis functions were employed, the population distributions were computed at 300 K, and tables of $\langle\sin^2\theta\rangle$ and V_2 were constructed at intervals of 0.42 kJ mol^{-1} in V_2 for a range of reduced moments of inertia. For values of the latter appropriate to the compounds in Tables 1 and 2, $\langle\sin^2\theta\rangle$ is insensitive to their precise value relative to other errors involved in the deduction of the barrier heights.

In Table 6 the barriers are presented as deduced from $^nJ(C,C)$. The lower limit of the twofold barrier in thioanisole itself is 6.3 ± 0.2 kJ mol^{-1} if the simple average of the three numbers is taken. The true error in these numbers is difficult to assess reliably. Between a V_2 of 0 and about 12 kJ mol^{-1}, the hindered rotor model has a reasonably steep dependence of V_2 on $\langle\sin^2\theta\rangle$ at 300 K and is in principle quite accurate (±0.1 kJ mol^{-1}). Therefore the uncertainty in $^nJ_{90}(C,C)$ and the experimental

[a]In kJ mol^{-1}.
[b]Based on $\langle \sin^2 \theta \rangle$ derived from $^{3,4,5}J(C,C)$ and eqs. [1], [4], and [6].
[c]Too small a ^4J to observe accurately (Tables 1 and 2).
[d]These are upper limits to the barrier, the stable conformation having θ as 90°.
[e]V_2 values for 1,4-dithiomethyl benzene, 3,5-ditrifluoromethylthioanisole, 4-thiomethylbenzaldehyde, and 4-hydroxymethylthioanisole are derived in the text from the chemical shift of the ^{13}C nucleus of the methyl group. In the order above, they are 4.6, 8.7, 12.6, and 5.6 kJ mol^{-1}.

error in $^nJ(C,C)$ would appear to be a major source of inaccuracy. The $^nJ(C,C)$ were in general reproducible to within 0.01 Hz in repeated measurements. $^5J(C,C)$ in thioanisole is therefore the same in CS_2 and acetone-d_6 solutions to within experimental error. Clearly, the uncertainties in the $^nJ_{90}(C,C)$ numbers will introduce some relatively major errors in V_2. Thus, if $^5J_{90}(C,C)$ is as large as 1.00 Hz, V_2 in thioanisole rises to 7.2 kJ mol^{-1}. Such a value of $^5J_{90}(C,C)$ corresponds to an apparent V_2 of 15.9 kJ mol^{-1} in 2,6-dimethylthioanisole and of only 6.4 kJ mol^{-1} in the 2,6-dichloro derivative. Intuitively, these latter numbers appear as unreasonably small. Perhaps, therefore, the individual V_2 values in Table 6 will be only about 10% too low from this source of error, the error in $^nJ_{90}(C,C)$ introducing an error roughly proportional to V_2 in the range from zero to about 12 kJ mol^{-1}.

Another major source of error in the V_2 numbers in Table 6 may well be the intrinsic substituent perturbations of $^nJ(C,C)$, particularly of those in which the substituent is bonded to the atom containing a coupled nucleus. For example, in 4-chlorothioanisole the value of V_2 based on $^5J(C,C)$ is 1.4 kJ mol^{-1} lower than those based on $^{3,4}J(C,C)$, whereas in 4-*tert*-butylthioanisole the V_2 values from the three coupling constants agree much more closely among themselves. However, the data in Table 6 in general do not support an attribution of intrinsic substituent perturbations of $^nJ(C,C)$ to a unique substituent parameter such as electronegativity, for example. Nevertheless, such perturbations are present; see the V_2 values for the 3,5-dichloro-4-methoxy derivative, for example.

The geometry-optimized STO-3G MO calculations (2) have V_2 as 6.2 kJ mol^{-1} for thioanisole, but their reliability has not been assessed by computations with sufficiently large basis sets. The V_2 based on $^6J(H,^{13}CH_3)$ was given previously as 5.4 ± 0.4 kJ mol^{-1} (2). It must be revised because eq. [2] implies a minimum magnitude for $^6J_{90}(H,^{13}CH_3)$ of 0.59 Hz, instead of the 0.56 Hz assumed before (2). The revised V_2 is then 6.0 kJ mol^{-1}. The present set of numbers for V_2 may be compared with earlier theoretical and experimental approaches to the barrier in thioanisole, yielding values (27, 28) between 1 and 26 kJ mol^{-1} (see also references cited in ref. 2).

The barriers in the *para* substituted derivatives in Table 6 follow the expectations based on the notion that π electron donors decrease the mobile bond order of the C(1)—S bond (the S—CH_3 group is itself a weak π electron donor) and therefore reduce the magnitude of V_2; π electron acceptors therefore increase V_2. According to the data in Table 6, the *tert*-butyl group is a weaker π donor than a methyl group. The nitro

For personal use only.

substituent causes a large increase in V_2, the true value of this increase being somewhat uncertain because V_2 now lies in a range in which $\langle \sin^2 \theta \rangle$ changes less rapidly with V_2 (at a V_2 of 17 kJ mol^{-1}, $\langle \sin^2 \theta \rangle$ decreases by only 0.005 for an increase in V_2 of 0.84 kJ mol^{-1}). It is noteworthy, however, that the V_2 in *p*-nitrothioanisole is derived from ^3J(C,C) and ^4J(C,C) because ^5J(C,C) is obscured by broad C-4 peaks (quadrupolar relaxation of the ^{14}N nucleus causing a decrease in T_2 by scalar relaxation of the second kind). Broad C-4 peaks also occur in *p*-aminothioanisole, in which the strongly π-electron donating amino substituent stabilizes the perpendicular conformation of the thiomethyl moiety ($\theta = 90°$ for the ground state). This result follows from ^3J(C,C), whose value implies a ^4J(C,C) of +0.09 Hz, in agreement with observation. It follows that the planar ground state of thioanisole is a consequence of $3p \ldots \pi$ conjugation, which overcomes repulsion between the methyl group and the *ortho* C—H bonds.

The large V_2 in 3,5-dichlorothioanisole (2) found from $^6J(H,^{13}CH_3)$ is confirmed by the numbers in Table 6, although the error is relatively large. This result has been discussed (2) in terms of perturbation molecular orbital theory. If a 4-hydroxy substituent is added to this compound, then it is this substituent which dominates V_2. The same conclusion was reached for the thiophenol derivative (1). Phenomenologically, the *para* substituent is a first-order perturber and dominates the *meta* substituent, a second-order perturber. It would be useful to have an independent confirmation of this conclusion.

A hydroxy group flanked by two chlorine substituents remains in the aromatic plane, allowing full conjugation. A methoxy group in the same position lies predominantly perpendicular to that plane (21) and hence will not conjugate as strongly with the aromatic π system. Consequently, V_2 in 3,5-dichloro-4-methoxythioanisole rises to about 7 kJ mol^{-1} from the 3 kJ mol^{-1} in 3,5-dichloro-4-hydroxythioanisole.

Because of the probable presence of significant fourfold components of the internal barriers in the 2,6-di-X derivatives, various ratios of V_2 to V_4 being compatible with a given $\langle \sin^2 \theta \rangle$, it is best to conclude only that the perpendicular conformation of the thiomethyl group is most stable for X = F, Cl, CH_3; the ^nJ(C,C) imply that this stability increases in the indicated order. The ^3J(C,C) values are apparently decreased by electronegative substituents at the *ortho* positions, just as expected from the behaviour of other vicinal coupling constants, those between ^{13}C and ^{1}H nuclei, for instance (29). Such a decrease is also noticeable in 2-hydroxythioanisole in which ^3J(C,C-3) is 0.1 Hz smaller than ^3J(C,C-6) in Table 3. A decrease in ^3J(C,C) is therefore also expected on substitution of a methyl group for hydrogen on the side chain, as in 2-hydroxy-α-methylthioanisole; this decrease does occur (Table 3).

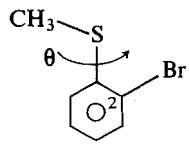
In this compound, ^5J(C,C) is 0.86 Hz. Then, if this number is taken as an approximation to $^5J_{90}$(C,C), lower limits to V_2 for the compounds in Table 2 are obtainable: 2.2, 0.0, and −2.7 kJ mol^{-1}, respectively, for ethyl phenyl sulfide and its 4-methyl and 4-methoxy derivatives. The conclusion seems inescapable that the barriers to rotation about the C(1)—S bonds in these compounds are about 3 kJ mol^{-1} lower than in the corresponding thioanisoles (Table 6). Furthermore, the stable conformer in 4-methoxyphenyl ethyl sulfide is almost certainly the one in which the *S*-ethyl group lies in a plane perpendicular to that of benzene ($^5J_{90}$(C,C) would have to be greater than 1.08 Hz for a coplanar stable form).

^4J(C,C) is calculated as 0.05, −0.09, and −0.28 Hz for the three compounds in the order given above, in rough agreement with the values in Table 2. To calculate ^4J(C,C) the coefficient of $\langle \sin^2 \theta \rangle$ in eq. [4] must be reduced by a factor of 0.86/0.91. The observed ^4J(C,C) of 0.23 Hz in the 4-methoxy derivative suggests a barrier of −2.0 kJ mol^{-1}, that is, in agreement with a perpendicular conformer indicated by ^5J(C,C).

A plot of ^3J(C,C) versus ^5J(C,C) for these ethyl phenyl sulfides fits ^3J/Hz = −3.01 ^5J(C,C) + 3.32 with a correlation coefficient of 0.997, significant at the 95% confidence level. Conversion to an equation in $\langle \sin^2 \theta \rangle$ has it that ^3J(C,C)/Hz = −2.59 $\langle \sin^2 \theta \rangle$ + 3.32. V_2 values follow as 1.4, 0.2, and −2.8 kJ mol^{-1} in the order 4-H, 4-CH_3, and 4-OCH_3. Note that these are lower limits for 4-H and 4-CH_3; for 4-OCH_3 the number implies an upper limit to the extent of stabilization of the perpendicular conformer.

2-X-Thioanisole derivatives

The internal rotational potentials about the C(1)—S bond in 2-X-thioanisole derivatives have onefold as well as twofold components; there may also be higher odd and evenfold harmonics. Equations [4] and [6] for ^4J and ^3J are then no longer valid. For ^3J(C,C) the constant term of 3.55 Hz in eq. [6] also contains the term $0.5J_{180}$. A crude approach to the problem assumes that 2-bromothioanisole takes on the planar conformation **3**, in which θ is zero from the aspect of C-4, C-5, and C-6 and is 180° for C-2 and C-3. A further approximation assumes that 2-hydroxythioanisole (CCl_4 solution) has conformation **2** with θ as 90°. ^5J(C,C) in the bromine compound is less than 0.05 Hz, implying a $\langle \sin^2 \theta \rangle$ probably less than 0.05, so that only small amplitude oscillations occur about the C(1)—S bond (the dipole moment of **3** has been interpreted in terms of θ being 45° (*29a*)).



3

From ^3J(C,C) in these two compounds, but ignoring that for C-2 in 2-bromothioanisole, one may write

$$^3J(C,C)/\text{Hz} = 4.3 - 2.4 \langle \sin^2 \theta \rangle - 1.4 \langle \sin^2 (\theta/2) \rangle$$

in reasonable agreement with eq. [6] for which $\langle \sin^2 (\theta/2) \rangle$ is 0.5. The new relationship has ^3J(C,C) for C-2 in 2-bromothioanisole as 2.9 Hz, compared to the measured value of 2.2 Hz. The reason for the discrepancy lies in the following facts. Computations of ^3J(H,C) for the methyl protons in 2-fluorotoluene, for example (29), yield smaller couplings to C-2 than for C-6 and may be attributed to the presence of the directly bonded fluorine substituent; compared to similar computations on toluene, the substituent perturbations at C-6 are much smaller than at C-2. Furthermore, the substituent effect on ^3J(H,C) is dependent on θ, being a minimum near 90°. Presumably a similar situation holds for the thioanisole derivatives.

An INDO MO FPT computation on 2-fluorothioanisole, for a geometry very similar to that given by STO-3G MO optimized calculations (2), gives a reduction of over 0.4 Hz at C-2 for θ = 180° relative to thioanisole, whereas at θ = 90° the two ^3J(C,C) values differ by 0.1 Hz at most (see below for further complications). Thus, the very similar values of ^3J(C,C) in 2-hydroxythioanisole, that for C-2 being about 0.1 Hz smaller than that for C-6, are a consequence of a θ very near 90°. In the 2-bromo derivative, the large discrepancy of 0.7 Hz in ^3J(C,C) for C-2 is connected with the nearly planar conformation.

In 2-fluorothioanisole, ^5J(C,C) suggests relatively large librations about the C(1)—S bond, $\langle \sin^2 \theta \rangle$ being 0.32 and arcsin $\langle \sin^2 \theta \rangle^{1/2}$ is 34°. A true $\langle \sin^2 \theta/2 \rangle$ is not available; yet, if the obvious approximation is made, then ^3J(C,C) is calculated as 3.4 Hz for C-6. The observed value is 3.5 Hz. For C-2, ^3J becomes 2.3 Hz and the observed 1.6 Hz yields a discrepancy of 0.7 Hz. That this difference is the same as that for the less electronegative bromine substituent may well have to do with the larger average θ in the fluorine compound. Similar remarks apply to the 2-methoxy derivative, although the calculated ^3J(C,C) values are in much poorer agreement with experiment.

The experimental relationship above has ^3J(C,C) as smaller at θ = 180° than at θ = 0°, the opposite behaviour from the usual Karplus equation. Indeed, the INDO MO FPT calculations agree with the normal form, the coefficient of the term in $\sin^2(\theta/2)$ being positive. It may be noted that these computations were performed on the STO-3G geometries (2) and that a standard geometry (30) gave ^3J(C,C) larger at θ = 0° than at θ = 180°C. Because the true geometry is not known and because the computed ^3J(C,C) are really quite sensitive to the C(1)—S bond length and the C(2)—C(1)—S angle, it is best to rely on the unequivocal experimental indications of the "anti-Karplus" behaviour of ^3J(C,C) in thioanisole. A recent discussion (31) of the coupling mechanisms of ^3J(C,C) should be consulted for the intricacies that are involved.

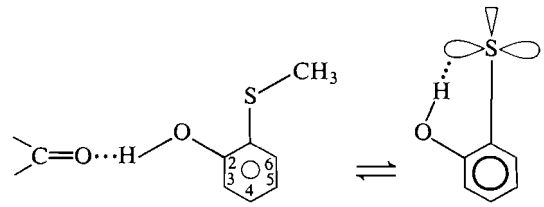
Again, ^4J(C,C) displays a larger magnitude at θ = 0° than at θ = 180° (see 2-bromothioanisole in Table 3). Further, ^4J(C,C) is very nearly zero at θ = 180°, possibly just the opposite of expectations based on intuition (see the 2-methoxy and 2-bromo derivatives in Table 3). It does appear, however, that the substituent at C-2 has a large influence on this result. Note that ^4J(C,C) for 2-hydroxythioanisole in CCl_4 solution, where θ ~ 90° and a substituent effect is expected to be minimal (see ^3J(C,C) above), is the same for C-3 and C-5. The INDO MO FPT calculations do imply a very small, negative ^4J(C,C) at θ = 180°, −0.15 Hz, and −0.32 Hz at θ = 0°. Equation [4], based on the symmetrically substituted molecules, could be written as

$$^4J(\mathrm{C,C})/\mathrm{Hz} = 1.51 \langle \sin^2 \theta \rangle + a + b \langle \sin^2 (\theta/2) \quad [4]$$

where $a + b \langle \sin^2 (\theta/2) \rangle = a + 0.5b = 0.6$ Hz. In 2-bromothioanisole, of course, $\langle \sin^2 (\theta/2) \rangle$ and $\langle \sin^2 \theta \rangle$ are near zero for C-5 and ^4J(C,C) is ±0.6 Hz. The positive sign is consistent with the treatment of ^4J(C,C) in the previous section. In that event, the coefficient of $\langle \sin^2 (\theta/2) \rangle$ must be very near zero, yielding eq. [4] as an approximation for C-5 in the *ortho* substituted thioanisoles. However, the very small or vanishing ^4J(C,C) for C-3 is not reproduced by this relationship. It is therefore best to conclude that, for near-planar conformations at least, an electronegative substituent at C-2 reduces ^4J(C,C) drastically, that is, for θ ~ 180°.

2-Hydroxythioanisole

In CCl_4 solution, the ^nJ(H,C) and ^nJ(C,C) numbers for the 2-hydroxy derivative (Tables 3 and 4) are consistent with a perpendicular conformation of the thiomethyl group, that is, with θ very near 90°. In acetone-d_6 solution, the solvent molecules compete with the 3*p* lone-pair on sulfur for hydrogen bonding to the hydroxyl group. If an equilibrium exists between **4***a* and **4***b*, then ^nJ(C,C) should lie between the values observed for 2-methoxythioanisole, in which the SCH_3 group is favored to lie in the aromatic plane, and those for 2-hydroxythioanisole in CCl_4 solution. This is confirmed by the data in Table 3. The lifetime of an intermolecular hydrogen bond in solution at



4*a* **4***b*

ambient temperatures is apparently less than 10^{-7} s (32, 33). δ(C-6) is 130.0, while (Table 3) it is 134.9 in CCl_4 solution and is 126.3 for 2-methoxythioanisole, which will roughly mimic the chemical shift of C-6 in **4***a* (C-6 is *meta* to the hydroxyl group and will be least influenced by the orientational behaviour of the latter). In other words, the rate process involved in the **4***a* ⇌ **4***b* equilibrium must be characterized by a rate constant of at least 2500 s^{-1} at 300 K (34). The barrier to internal rotation about the C—O bond in phenol is about 14.5 kJ mol^{-1} (4). The intermolecular hydrogen bond between phenol and cyclohexanone or acetone in CCl_4 solution has a free energy of formation of about −6.5 kJ mol^{-1} (35, 36). In the present situation the medium is acetone-d_6, however, and the two forms, **4***a* and **4***b*, may be stabilized by different amounts than in CCl_4 solution. An empirical relationship (37) has been used previously (38–40) to estimate the energy of hydrogen bond formation for hydroxyl groups in phenol derivatives: $\Delta\delta(\mathrm{OH}) = (-0.4 \pm 0.2) + E/\mathrm{kcal\ mol^{-1}}$, where Δδ(OH) is the chemical shift relative to the δ(OH) of 4.3 in phenol at infinite dilution in CCl_4 near 300 K (41). δ(OH) for 2-hydroxythioanisole in acetone-d_6 solution is 8.35 at 300 K; in CCl_4 solution it is 6.49. The population of **4***a* is assessed below at 0.64 ± 0.04. Hence δ(OH) of **4***a* is implied as 9.4 ± 0.2, ignoring any solvent effect on the shift of the proton in the hydrogen bond. Consequently, a *very rough* estimate of the enthalpy of formation of **4***a* is −23 ± 2 kJ mol^{-1}, to be compared with −20 ± 1 kJ mol^{-1} derived from calorimetric and vibrational information (35, 36). The entropy of formation of the intermolecular hydrogen bond in **4***a* is roughly −45 J mol^{-1} K^{-1} (35, 36). A free energy of activation of (6.5 + 14.5) kJ/mol for the interconversion of **4***a* and **4***b* is therefore taken as reasonable. At 300 K, the rate constant is then enormous (34) relative to any chemical shift difference between corresponding ^{13}C nuclei at 75 MHz in **4***a* and **4***b*.

The equilibrium populations of **4***a* and **4***b* can be estimated from some of the ^{13}C nmr chemical shifts, as well as from some of the ^nJ(C,C) in Tables 1 and 3. Assume that the nmr parameters for 2-methoxythioanisole are a measure of those in **4***a* and that those for the CCl_4 solution of 2-hydroxythioanisole characterize **4***b*. Then ^5J(C,C) and ^3J(C,C) yield the fractional population of **4***b* as 0.32 and 0.37, respectively. δ(C-4) and δ(C-6), least affected by the hydroxyl group, gave 0.37 and 0.42, respectively. $\delta(CH_3)$ yields 0.34. The ^{13}C chemical shifts that are subject to larger substituent effects from the hydroxyl group, namely, those of C-1, C-2, C-3, and C-5, are contraindicated as a measure of the populations of **4***a* and **4***b*. Of course, the thiomethyl group is changing its orientation drastically between **4***a* and **4***b* and that is what predominantly causes the alterations in the selected nmr indicators above. The average of the five estimates is 0.36 ± 0.04 (standard deviation) for the fractional population of **4***b*. The free energy difference at 300 K is therefore 1.4^{-3}_{+5} kJ mol^{-1}, **4***a* more stable. The free energy of interconversion estimated above would necessitate extremely low temperatures, about 100 K, to characterize **4***a* and **4***b* by their individual nmr spectra.

For personal use only.

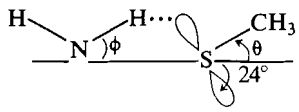
On the questionable assumption that δ(OH) of **4***b* in CCl_4 solution is a measure of the enthalpy of the O—H. . . .S intramolecular hydrogen bond, one has -10.9 kJ mol^{-1}. However, this estimate should presumably be corrected for the energy necessary to twist the thiomethyl group out of the molecular plane by roughly 90°, δ(OH) itself not being a measure of this energy. In thioanisole, V_2 is at least 6.1 kJ mol^{-1} (Table 6) but, of course, the hydroxy group will lower the $3p\ldots\pi$ conjugation in 2-hydroxythioanisole. The energy of twist is difficult to estimate, so that the O—H. . .3*p* bond may have an energy of at least 11 kJ mol^{-1}. This is higher than the energy of the O—H. . .O bond in 2-hydroxyanisole (42), in agreement with Schroeder–Lippencott potential functions (43) and with δ(OH) in the anisole derivative (44).

If the chemical shift difference between the hydroxyl protons in **4***a* and **4***b* is taken as a measure of their enthalpy difference, then the latter follows from the empirical relationship as 12.1 ± 0.8 kJ mol^{-1}. The free energy difference of **4***a* and **4***b*, being 1.4 ± 0.5 kJ mol^{-1}, implies an entropy difference at 300 K of 35.7 ± 4.5 J mol^{-1} K^{-1}. This estimate is somewhat lower in magnitude than the 45.2 ± 4.2 J mol^{-1} K^{-1} for free phenol and its complex with acetone in CCl_4 solution (36). As pointed out by Jaffé (45), the entropy change on formation of the intramolecular hydrogen bond in 2-halophenols is very small. Actually, **4***b* is favored by an entropy term of R ln 2 relative to a conformer with a coplanar thiomethyl group, so that firmer conclusions must be left in abeyance.

Finally, if there were no change in entropy on formation of **4***b*, then the present considerations would suggest a free energy barrier to conversion of **4***b* to a free, coplanar form (in which the hydroxyl group points away from the thiomethyl group) of 14.5 + 11 or about 25 kJ mol^{-1}. This is compatible with the discussion above concerning the rate processes leading to broadening of the ^{13}C nmr peaks.

2-Aminothioanisole

In 2-aminothioanisole in CCl_4 solution (Table 3) a stereospecific intramolecular hydrogen bond to the 3*p* lone-pair need not twist the thiomethyl group into a perpendicular conformation because the amino group has a pyramidal geometry. From the most recent structural data on aniline and derivatives (46, 47), the angle φ in **5** can be calculated (48) as 25°. The barrier to rotation about the C—N bond in aniline is near 21 kJ mol^{-1} (49). The thiomethyl group is not a strong electron donor; donation of π electron density would lower the C—N rotational barrier.



5

The barrier about the C(1)—S bond will be lowered by the amino group, however (see Table 6), so that the thiomethyl group can easily twist out of the benzene plane to optimize the intramolecular hydrogen bond indicated in **5**. The twist angle, θ, can be approximated from ^5J(C,C), being 0.76 Hz. Then arc sin $\langle\sin^2\theta\rangle^{1/2}$ is 66°, so that the 3*p* lone-pair would twist out of plane by about 24°, that is by about 66° away from its perpendicular orientation in a planar thioanisole molecule. In aniline, the barrier to inversion is only about 6 kJ mol^{-1} (50). Therefore an inversion at nitrogen is no doubt also occurring in **5**, which would entail oscillatory motion about the C(1)—S bond.

The estimate of 66° for θ based on ^5J(C,C) can be checked with, for example, ^3J(C,C) for C-6. The two relationships used in this paper yield an average of 1.67 ± 0.20 Hz for an angle of 66°, to be compared with the value in Table 3 of 1.68 Hz. ^4J(C,C) for C-5 yields an arc sin $\langle\sin^2\theta\rangle^{1/2}$ of 64°.

When dissolved in acetone-d_6, the second N—H bond, not involved in the intramolecular hydrogen bond in 2-aminothioanisole, can bond to solvent molecules. Therefore, unlike 2-hydroxythioanisole, the intramolecular hydrogen bond in the amino derivative need not be broken. Indeed, $^6J(H,CH_3)$ in such a situation is -0.42 Hz (Table 4) and arc sin $\langle\sin^2\theta\rangle^{1/2}$ is 60°. Further, assume that $^5J(H,CH_3)$ behaves like $^5J(H,CH_3)$ in toluene (16,17) and can be written as $^5J(H,CH_3) = A\langle\sin^2\theta\rangle + B\langle\sin^2(\theta/2)\rangle$. The data in Table 4 yield A as 0.116(4) and B as 0.136(4) Hz if $\langle\sin^2(\theta/2)\rangle$ is estimated on the assumption of two rigid molecules in Table 4, 90° and 60° for θ. Finally, on the assumption that $\delta(CH_3)$ is proportional to $\langle\sin^2\theta\rangle$, that its values in 2-methoxythioanisole, 14.23, and in 2-hydroxythioanisole, 19.70, correspond to $\langle\sin^2\theta\rangle$ values of 0.275 and unity, respectively (obtained from ^5J(C,C)), the equation in $\delta(CH_3)$ becomes $\delta = 12.2 + 7.54\langle\sin^2\theta\rangle$. The δ of 17.56 for 2-aminothioanisole then has arc sin $\langle\sin^2\theta\rangle^{1/2}$ as 58°. This result encourages the following approach to conformational deductions about thioanisole derivatives for which only $\delta(CH_3)$ is conveniently measurable.

δ(CH$_3$) as a conformational indicator

$\delta(CH_3)$ for the *para* substituted thioanisoles in Table 1, and including also the 3,5-dichloro derivative, is related to ^3J(C,C) by δ/ppm = $-3.46\ ^3J$(C,C)/Hz + 25.75 (nine points with a correlation coefficient of 0.991). Combined with eq. [6], this relationship should yield $\langle\sin^2\theta\rangle$ for the 4-thiomethyl, 3,5-ditrifluoromethyl, 4-carboxaldehyde, and 4-hydroxymethyl thioanisole derivatives; $\delta(CH_3)$ is 15.99, 14.99, 14.49, and 15.81, respectively, for dilute acetone-d_6 solutions. Consequently, $\langle\sin^2\theta\rangle$ is 0.293, 0.177, 0.119, and 0.272 for these compounds, corresponding to twofold barriers of 4.6, 8.7, 12.6, and 5.6 kJ mol^{-1}, respectively, for 4-SCH_3, 3,5-diCF_3, 4-CHO, and 4-CH_2OH derivatives of thioanisole. Comparison with the V_2 estimates in Table 6 suggests that the thiomethyl group is a weak π electron donor, as expected, that the CHO group is a somewhat weaker π electron acceptor than is the nitro group, and that the hydroxymethyl group is a weaker electron donor than is the methyl group; this is also reasonable. The CF_3 groups are not as effective as chlorine substituents at the *meta* position in raising the barrier to internal rotation about the C(1)—S bond. The present relationship between $\delta(CH_3)$ and ^3J(C,C) cannot be applied to most *ortho* substituted derivatives in Tables 1 and 3 because of proximity and other substituent perturbations of both parameters.

^{2}J(C,C) values

This coupling constant is not very sensitive to the average angle θ, as demonstrated by its near constancy in the *para* and *meta* substituted derivatives of thioanisole in Table 1. It increases in magnitude by 0.5 Hz in 2,6-dimethylthioanisole, but is also sensitive to proximate substituent perturbations, as can be seen by its magnitude in the 2-hydroxy derivative. ^2J(C,C) is negative in 3,5-dichlorothioanisole and most likely also negative for all the other molecules in Tables 1–3.

Ethyl cation transfer from diethylchloronium to alkyl aromatics studied by high pressure mass spectrometry

PEGGY JANE MATHEWS AND JOHN A. STONE
Chemistry Department, Queen's University, Kingston, Ont., Canada K7L 3N6

Received September 22, 1987

PEGGY JANE MATHEWS and JOHN A. STONE. Can. J. Chem. **66**, 1239 (1988).

Diethylchloronium ($(C_2H_5)_2Cl^+$) has been formed in a high pressure (2–4 Torr) ion source using a C_2H_5Cl/CH_4 mixture. $(C_2H_5)_2Cl^+$ reacts with C_2H_5Cl (E_a = 22 ± 2 kcal mol^{-1}) at temperatures above 500 K to give *t*-$C_4H_9^+$. The reaction of $(C_2H_5)_2Cl^+$ with B (B = benzene, toluene, isopropylbenzene, mesitylene) yields mainly $C_2H_5B^+$ at temperatures below 500 K but BH^+ is also formed at higher temperatures. The further reactions of $C_2H_5B^+$ include proton transfer to B yielding BH^+ (mesitylene), hydride transfer from B (isopropylbenzene), and reaction with C_2H_5Cl yielding $(C_2H_5)_2B^+$ (toluene and benzene) and $(C_2H_5)_3B^+$ (benzene). The rate constants for the reaction $(C_2H_5)_2Cl^+ + B \rightarrow C_2H_5B^+ + C_2H_5Cl$ increase in the order of increasing reaction exothermicity (mesitylene > isopropylbenzene > toluene > benzene). Mesitylene has a negative temperature coefficient, isopropylbenzene has no temperature coefficient, and toluene and benzene show positive temperature coefficients of reaction rate constants consistent with the double well potential theory for gas phase S_N2 reactions.

PEGGY JANE MATHEWS et JOHN A. STONE. Can. J. Chem. **66**, 1239 (1988).

Utilisant un mélange de C_2H_5Cl/CH_4 dans une source ionique à haute pression (2 à 4 Torr), on a formé l'ion diéthylchloronium ($(C_2H_5)_2Cl^+$). L'ion $(C_2H_5)_2Cl^+$ réagit avec le C_2H_5Cl (E_a = 22 ± 2 kcal mol^{-1}) à des températures supérieures à 500 K et il y a formation de *tert*-$C_4H_9^+$. A des températures allant jusqu'à 500 K, la réaction du $(C_2H_5)_2Cl^+$ avec les molécules B (B = benzène, toluène, isopropylbenzène et mésitylène) fournit principalement les ions $C_2H_5B^+$; toutefois, à des températures plus élevées, il y a formation des ions BH^+. Parmi les réactions subséquentes des ions $C_2H_5B^+$, on observe un transfert de protons à B conduisant à l'ion BH^+ (mésitylène), un transfert d'hydrure provenant de B (isopropylbenzène) et une réaction avec le C_2H_5Cl conduisant aux ions $(C_2H_5)_2B^+$ (toluène et benzène) et $(C_2H_5)_3B^+$ (benzène). Les constantes de vitesse pour la réaction $(C_2H_5)_2Cl^+ + B \rightarrow C_2H_5B^+ + C_2H_5Cl$ augmentent avec le rendement thermique positif de la réaction (mésityléne > isopropylbenzène > toluène > benzène). Pour ce qui est des coefficients de température des constantes des vitesses de réaction, celui du mésitylène est négatif alors que l'isopropylbenzène n'en a pas et que ceux du toluène et du benzène sont positifs; ces résultats sont en accord avec la théorie du potentiel à double puits pour les réactions S_N2 en phase gazeuse.

[Traduit par la revue]

Introduction

Dialkylhalonium ions have been shown to be excellent alkylating agent for aromatic hydrocarbons in both gas and liquid phases (1–4). Dimethylchloronium ($CH_3ClCH_3^+$) has been extensively studied in the gas phase because it is very readily prepared from methane/methyl chloride mixtures in a chemical ionization (CI) source (3, 4). It reacts with bases in the gas phase by methyl cation transfer.

[1] $CH_3ClCH_3^+ + B \rightarrow CH_3Cl + BCH_3^+$

Such reactions are bimolecular nucleophilic displacement (S_N2) reactions, the base B displacing methyl chloride from the chloronium ion. For example, reaction [1] is highly exothermic (>30 kcal mol^{-1}) for bases such as dimethyl ether and ammonia and reaction occurs at almost every collision (4). However, with the aromatic bases benzene, toluene, and isopropyl benzene, although the exothermicities of the reactions are still of the same magnitude the reaction efficiencies (the measured rate constant k divided by the collision rate constant k_c as calculated by the average dipole orientation (ADO) theory (5)) are far less than unity (4). For B = benzene the reaction efficiency increases with increasing temperature (positive temperature coefficient) while for B = toluene or isopropylbenzene the reaction efficiency decreases with increasing temperature (negative temperature coefficient). A series of relative rate determinations for B = benzene, toluene, and mesitylene for which reaction exothermicity increases in the order given suggested that the magnitude of the negative temperature dependence increases with increasing exothermicity (6).

The above observations are strong supporting evidence for the double well potential model first set out in some detail by Brauman and co-workers (7, 8) and well summarized by Magnera and Kerbale (9). In this model, reaction [1] is considered to occur in several steps as in reaction [2] and Fig. 1. There is initial formation of an ion–molecule complex $CH_3ClCH_3^+ \cdots B$ (rate constant k_c) which can either return to products (rate constant k_b) or pass over the central chemical barrier (rate constant k_p) to give the complex $CH_3Cl \cdots CH_3B^+$ which subsequently decomposes to products. In these highly exothermic reactions k_{-p} is considered to be negligibly small ($k_{-p} \ll k_p$) so that once the system passes over the barrier methyl cation transfer occurs irreversibly.

[2] $$CH_3ClCH_3^+ + B \underset{k_b}{\overset{k_c}{\rightleftharpoons}} CH_3ClCH_3^+ \cdots B \underset{k_{-p}}{\overset{k_p}{\rightleftharpoons}} CH_3Cl \cdots CH_3B^+ \overset{k_d}{\rightarrow} CH_3Cl + CH_3B^+$$

The steady-state assumption $d[CH_3^+ClCH_3 \cdots B]/dt = 0$ yields the overall rate constant k where $k = (k_c k_p)/(k_b + k_p)$ and reaction efficiency $k/k_c = k_p/(k_b + k_p)$. When the reaction exothermicity is sufficiently large the level of the top of the central barrier relative to the reactants energy level, ΔE^0, is large and negative, facilitating passage over the chemical barrier. When ΔE^0 is positive, return to reactants over the centrifugal barrier is favoured and the reaction has an activation energy $\approx \Delta E^0$. When ΔE^0 is small and negative the central barrier may still be rate controlling since entropic considerations favour return to reactants rather than formation of a constrained transition state at the top of the barrier in which the carbon being transferred to B is in a pentacoordinated state.

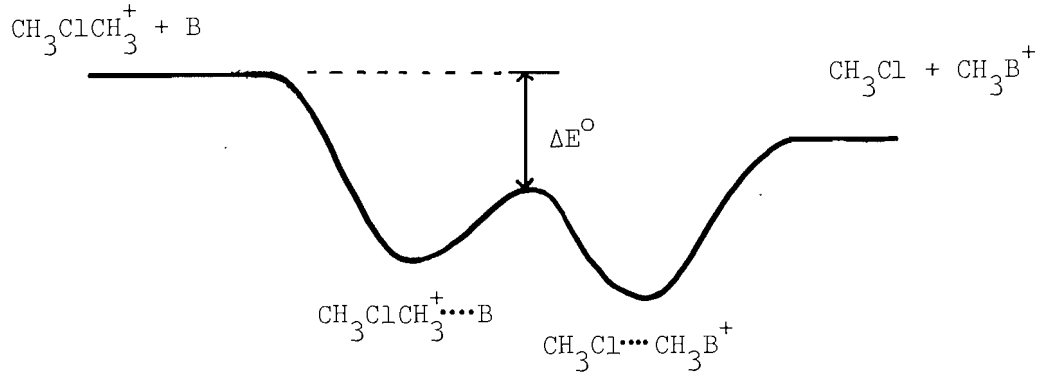

FIG. 1. The reaction coordinate for an ionic gas phase nucleophilic displacement reaction.

The use of different aromatic bases with a common chloronium ion enables the reaction exothermicity and hence ΔE^0 to be varied in a regular manner (3, 4). In this paper we seek additional evidence for the model by using the same series of bases but a different chloronium ion, namely diethylchloronium. S_N2 reactions with aromatic base B lead to the formation of $BC_2H_5^+$ in a reaction whose exothermicity will be different to that of the analogous reaction [1].

[3] $C_2H_5ClC_2H_5^+ + B \rightarrow C_2H_5Cl + C_2H_5B^+$

The order of reactivity of the different bases should be, according to the model, the same for $(C_2H_5)_2Cl^+$ and $(CH_3)_2Cl^+$ but the temperature coefficients should change with change of ΔE^0.

$(C_2H_5)_2Cl^+$ is the exclusive long-lived ion in C_2H_5Cl/CH_4 mixtures under most ion source conditions whereas CH_3Cl/CH_4 mixtures lead to both $(CH_3)_2Cl^+$ and $C_2H_5ClCH_3^+$, each of which reacts with aromatics, the latter ion forming $BC_2H_5^+$ (4, 6). The ion chemistry resulting from $C_2H_5^+$ addition may be followed using C_2H_5Cl/CH_4 mixtures without the complications resulting from a concurrent reaction.

Experimental

The mass spectrometer with pulsed electron beam and high pressure ion source (1–5 Torr, 300–600 K) has been described previously (10). Samples are prepared in a heated 5 L flask at a total pressure of ~700 Torr (1 Torr = 133 Pa) and are bled into the ion source via a heated leak valve and a heated glass line. A typical sample contained 6.6 mol% ethyl chloride, 1.4 mol% sulfurhexafluoride to capture thermalized electrons and hence increase ion residence time in the ion source, and 92 mol% methane. A small amount of an aromatic base was also added when required, ranging from 0.001–0.005 mol% in typical cases but for the very unreactive base, benzene, as much as 0.39% was used.

The aromatic bases were reagent grade and were used as received. Methane (99.99% pure) and ethyl chloride (99.7%) were from Matheson, Canada while the sulfur hexafluoride (Instrument Grade) was from Liquid Carbonic, Canada.

Results and discussion

The ion chemistry in methane/ethyl chloride mixtures

In mixtures containing only methane, ethyl chloride, and sulfur hexafluoride it is assumed that the major product, the diethylchloronium ion, is formed from the two methane reagent ions, CH_5^+ and $C_2H_5^+$, in a manner analogous to that for dimethylchloronium in a CH_4/CH_3Cl mixture (4).

[4] $CH_5^+ + C_2H_5Cl \rightarrow CH_4 + C_2H_5ClH^+$
$\Delta H^0 = -40$ kcal mol^{-1}

[5] $C_2H_5^+ + C_2H_5Cl \rightarrow C_2H_5ClH^+ + C_2H_4$
$\Delta H^0 = -9$ kcal mol^{-1}

[6] $C_2H_5ClH^+ + C_2H_5Cl \rightarrow C_2H_5ClC_2H_5^+ + HCl$

[7] $C_2H_5^+ + C_2H_5Cl \xrightarrow{M} C_2H_5ClC_2H_5^+$

In calculating the enthalpy changes for reactions [4] and [5] the proton affinity (PA) of C_2H_5Cl is taken as 172 kcal mol^{-1} (11) and other PA values are from ref. 12. Reactions [4] and [5] being typical, high exothermic proton transfer reactions involving ions with localized charges proceed at or near collision rates (13). The rate constant for reaction [6] has been reported as 5.5×10^{-10} cm^3 molecule^{-1} s^{-1} (14) which gives a half life for $C_2H_5ClH^+$ of $\sim 2 \times 10^{-7}$ s in a typical sample at 4 Torr and 300 K. This ion was not observed since $C_2H_5ClC_2H_5^+$ is generated well within 50 μs, the earliest observation time after the ionizing electron pulse. At low pressure under ion cyclotron resonance (ICR) conditions (< 10^{-4} Torr) $C_2H_5^+$ reacts with ethyl chloride mainly by proton transfer but isotopic experiments demonstrate the participation of an intermediate but unobserved complex in which hydrogen migration occurs (14). The stabilized complex was not observed under ICR conditions but the formation of the diethylchloronium ion by reaction [7] is probable at 1–4 Torr. The similar direct addition of $C_2H_5^+$ to methyl chloride has been suggested (4).

At 300 K $(C_2H_5)_2Cl^+$ is the only abundant ion in the mass spectrum of methane/ethyl chloride mixtures. A non-chlorine-containing ion of m/z 57 is also present but is of very low intensity (<1%). $(C_2H_5)_2Cl^+$ is the major ion present at all temperatures below 580 K. The relative intensity of m/z 57 shows little change with temperature up to 500 K but above this temperature its yield increases very rapidly and it becomes the major ion above 580 K. Luczynski and Wincel (15) reported the presence of m/z 57, which they identified as $C_4H_9^+$ but assigned no structure, in ethyl chloride at 403 K and 0.01–0.10 Torr. They proposed that it was formed by the unimolecular decomposition of excited $(C_2H_5)_2Cl^+$. No mode of excitation was suggested.

[8] $C_2H_5ClC_2H_5^+* \rightarrow C_4H_9^+ + HCl.$

If this were a thermal decomposition then the normalized intensity of m/z 57 might be expected to decrease as the total pressure is decreased which is contrary to what is observed. Figure 2 shows the normalized yields of ions at high temperature in a typical methane/ethyl chloride mixture. $(C_2H_5)_2Cl^+$ decays linearly with time to yield mainly m/z 57 and smaller amounts of m/z 55 and 69, none of which contains chlorine. The slope of

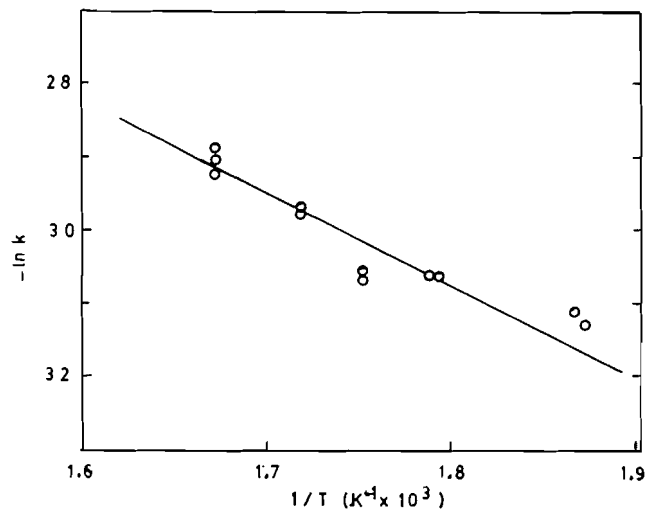

FIG. 3. Arrhenius plot for the reaction $(C_2H_5)_2Cl^+ + C_2H_5Cl \rightarrow C_4H_9^+ + C_2H_5Cl + HCl$.

the decay curve increases with increasing ethyl chloride concentration. The data fit a second order rate expression of the form

$$[9] \quad \frac{-d[(C_2H_5)_2Cl^+]}{dt} = k_{10}[(C_2H_5)_2Cl^+][C_2H_5Cl]$$

k_{10} is very small ($<10^{-13}$ cm^3 molecule^{-1} s^{-1}) and is independent of total pressure in the range 2.5 to 4.7 Torr but is strongly dependent on temperature. The Arrhenius plot of Fig. 3 yields an activation energy of 22 ± 2 kcal mol^{-1}. The overall reaction should therefore be written as [10] rather than [8].

[10] $(C_2H_5)_2Cl^+ + C_2H_5Cl \rightarrow C_2H_5Cl + C_4H_9^+ + HCl$

The standard enthalpy change for this reaction is of course the same as that for reaction [8]. This enthalpy change may be calculated provided that a value for $\Delta H_f^0((C_2H_5)_2Cl^+)$ is known. Reaction [7] was never observed as an equilibrium reaction so that a measurement of the binding energy of $C_2H_5^+$ to C_2H_5Cl which would lead to $\Delta H_f^0((C_2H_5)_2Cl^+)$ could not be made. An estimate of this enthalpy of formation may however be obtained. The standard enthalpy changes for reactions [11] and [12] are, respectively, −68 (16) and −30.7 kcal mol^{-1} (17)

[11] $CH_3^+ + CH_3Cl \rightleftharpoons (CH_3)_2Cl^+$

[12] $C_2H_5^+ + CH_3Cl \rightleftharpoons C_2H_5ClCH_3^+$

This leads to $\Delta H_f^0((CH_3)_2Cl^+) = 172$ kcal mol^{-1} and $\Delta H_f^0(C_2H_5ClCH_3^+) = 164$ kcal mol^{-1}. ΔH^0 for reaction [13] is then −71 kcal mol^{-1}.

[13] $CH_3^+ + C_2H_5Cl \rightleftharpoons C_2H_5ClCH_3^+$

This enthalpy of binding of CH_3^+ to C_2H_5Cl is 3 kcal mol^{-1} greater than that to CH_3Cl, which may be attributed to the slightly greater polarizability of the larger C_2H_5Cl. The difference in binding energies of $C_2H_5^+$ to CH_3Cl and C_2H_5Cl should be much the same as that for CH_3^+ so that a value of $\Delta H^0 = -34$ kcal mol^{-1} for reaction [7] is reasonable. This leads to $\Delta H_f^0((C_2H_5)_2Cl^+) = 155$ kcal mol^{-1}. The measured activation energy for reaction [10] of 22 kcal mol^{-1} is considerably less than $D(C_2H_5^+—ClC_2H_5)$ so that there are no conditions under which reaction [7] can be observed as an equilbrium and therefore $D(C_2H_5^+—ClC_2H_5)$ cannot be directly determined.

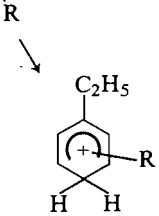
If $C_4H_9^+$ is the *t*-butyl cation then $\Delta H_{10}^0 = -11$ kcal mol^{-1} while if it is the *sec*-butyl cation then $\Delta H_{10}^0 = +6$ kcal mol^{-1}. The structure of $C_4H_9^+$ will be discussed later.

The ion chemistry in methane/ethyl chloride/aromatic mixtures

The primary reaction between aromatic B and $(C_2H_5)_2Cl^+$ is $C_2H_5^+$ transfer (reaction [3]). A typical mass spectrum is shown in Fig. 4*a* while Figs. 4*b* to 8 show time-resolved data. No adducts of formula $B\cdot(C_2H_5)_2Cl^+$ were observed under any conditions. Toluene$\cdot(CH_3)_2Cl^+$ has been observed in methane/methyl chloride/toluene mixtures at temperatures below 240 K (4), and equilibrium measurements yielded $D((CH_3)_2Cl^+—C_7H_8) = 12.3$ kcal mol^{-1}. There is no reason why the binding energies for the analogous $B\cdot(C_2H_5)_2Cl^+$ ion–neutral complexes would be significantly greater than this value and hence such complexes would not be observable in our available temperature range of 300–600 K.

The initial $B\cdot C_2H_5^+$ adduct is an *ipso*-protonated arenium ion. All the available evidence suggests that hydrogen migration occurs very rapidly to yield an ion with a tetrahedral or close to tetrahedral CH_2 group (2, 9).

[14] $(C_2H_5)_2Cl^+ +$  $\longrightarrow C_2H_5Cl +$ 



The structure of the final product may be described by the positions of the CH_2 and C_2H_5 groups relative to the site(s) of R. The preferred position of ethylation will be *para* to R in toluene and isopropylbenzene by analogy with other gas phase systems

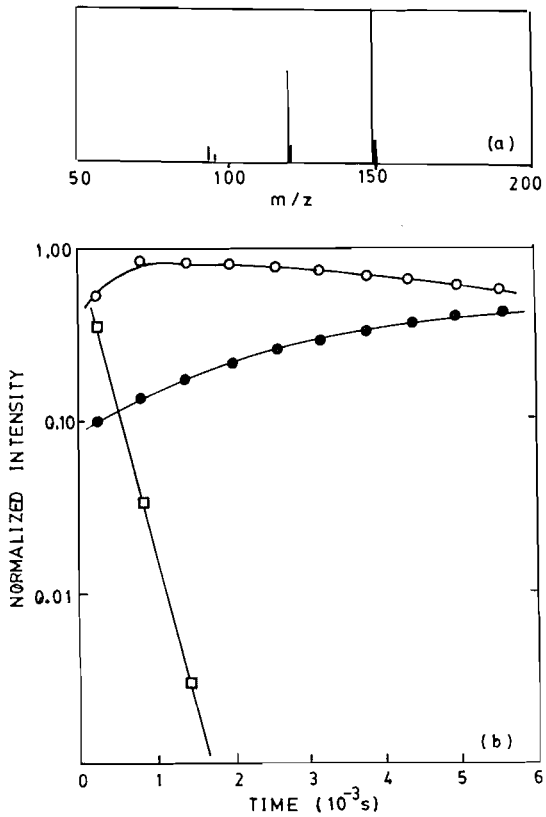

FIG. 4. (*a*) Mass spectrum of a mesitylene/$C_2H_5Cl/SF_6/CH_4$ (4×10^{-5}/0.072/0.014/0.914) mixture at 4.86 Torr and 306 K. (*b*) The normalized ion intensities after a 50 μs pulse of ionizing electrons for the same system. □, $(C_2H_5)_2Cl^+$; ○, $C_2H_5C_6H_3(CH_3)_3^+$ (*m/z* 149); ●, $C_6H_4(CH_3)_3^+$ (*m/z* 121).

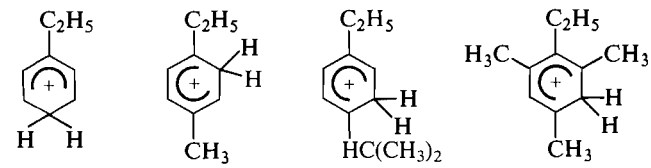
(18–20). The site of CH_2 giving the most stable structure is then determined by the positions of C_2H_5 and R and the nature of R. The final stable $B \cdot C_2H_5^+$ structures which are assumed to be formed and for which reaction enthalpies can be calculated are:



benzene toluene isopropylbenzene mesitylene

$C_2H_5^+$ transfer to initially yield the *ipso*-protonated species will be up to 7 kcal mol^{-1} less exothermic (18). The ion chemistries of the systems containing the individual aromatics are sufficiently different to warrant separate descriptions.

Mesitylene

This compound gives the simplest mass spectrum at any temperature (Fig. 4*a*). There are only two major product ions, $B \cdot C_2H_5^+$ (*m/z* 149) and BH^+ (*m/z* 121). The time-resolved, normalized ion yields in Fig. 4*b* show that $(C_2H_5)_2Cl^+$ disappears in a pseudo first order reaction giving *m/z* 149 which in turn disappears in a much slower pseudo first order proton transfer reaction to give *m/z* 121.

[15] $(C_2H_5)_2Cl^+ + (CH_3)_3C_6H_3 \rightarrow C_2H_5Cl + (CH_3)_3C_6H_3C_2H_5^+$ (*m/z* 149)
$\Delta H^0 = -33$ kcal mol^{-1}

FIG. 5. [16] $(CH_3)_3C_6H_3C_2H_5^+ + (CH_3)_3C_6H_3 \rightarrow (CH_3)_3C_6H_2C_2H_5 + (CH_3)_3C_6H_4^+$ (*m/z* 121)
$\Delta H^0 = +4$ kcal mol^{-1}

The enthalpy changes for these and subsequent reactions have been obtained using tabulated standard enthalpies of formation of neutrals from ref. 21 and of ions from ref. 12. For species with no tabulated data, standard enthalpies were calculated as described in Appendix 1.

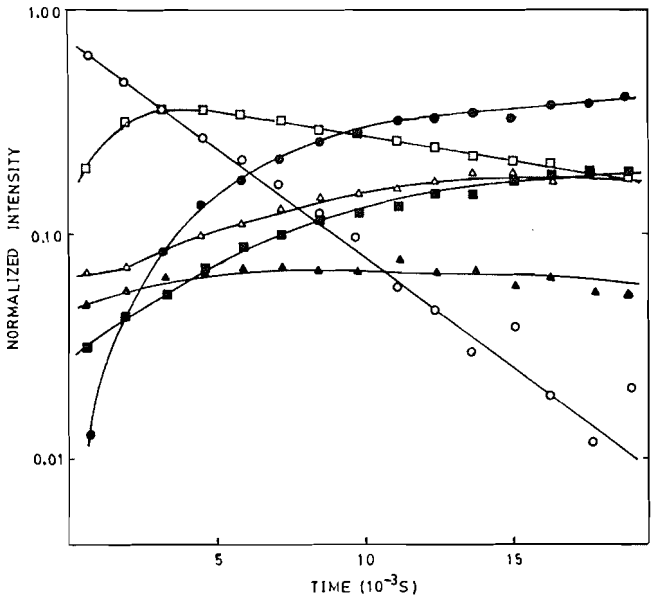

FIG. 7. The normalized ion intensities after a 50 μs pulse of ionizing electrons in a toluene/C_2H_5Cl/SF_6/CH_4 (3.6×10^{-4}/0.068/0.015/0.918) at 4.46 Torr and 303 K. ○, $(C_2H_5)_2Cl^+$; □, $C_2H_5C_6H_5CH_3^+$ (m/z 121); ●, $C_{12}H_{21}$ (m/z 177); △, m/z 184; ■, $C_{11}H_{17}^+$ (m/z 149); ▲, $C_6H_6CH_3^+$ (m/z 93).

FIG. 8. Reaction [16] is slightly endothermic and is consequently quite slow but the reverse reaction does not occur since there is essentially no $(CH_3)_3C_6H_3C_2H_5$ present in the system. The rate constant for this reaction was not measured but it was observed to proceed more slowly at high than at low temperature. Negative temperature coefficients for rate constants of slightly endothermic proton transfer reactions involving aromatic hydrocarbons have been previously observed (20). Such behaviour is a consequence of charge delocalization in the reactant ion.

At high temperature when $C_4H_9^+$ is also present proton transfer, reaction [17], also occurs and the yield of m/z 121 increases (Fig. 5).

[17] $C_4H_9^+ + (CH_3)_3C_6H_3 \rightarrow C_4H_8 + (CH_3)_3C_6H_4^+$

This reaction is exothermic by 5 kcal mol^{-1} if $C_4H_9^+$ is the *t*-butyl cation and by 21 kcal mol^{-1} if it is the *s*-butyl cation. In either case the reaction will occur at or near to the collision rate. The parallel decays of m/z 57 and 93 shows their interdependence via reaction [10]. At considerably lower mesitylene concentrations than that of Fig. 5 the build-up of the $C_4H_9^+$ fractional yield (via reaction [10]) is observed at short reaction times before its decay parallel with that of $(C_2H_5)_2Cl^+$

Isopropylbenzene

$B \cdot C_2H_5^+$ (m/z 149) is the major initial ion at low temperatures but at long reaction times it is replaced by m/z 119 (Fig. 6) which is the major ion at long reaction times at all temperatures. Since the yield of BH^+ (m/z 121), ring protonated *i*-propylbenzene, changes little with time at low temperature, the thermal decomposition of this ion can be ruled out as a source of m/z 119. This latter ion is formed either by the pyrolysis of m/z 149 or by the reaction of m/z 149 with isopropylbenzene. The latter is the case since the rate of decay of m/z 149 increases with increasing isopropylbenzene concentration, the reaction being pseudo first order with rate constant 6×10^{-12} cm^3 $molecule^{-1}$ s^{-1} at 300 K. The structure of m/z 119 is of course not directly determined in an experiment such as this; the ion was found not to react further. Two possibilities are ethyltropylium and the α,α-dimethylbenzyl cation. We favour the latter, formed by dissociative proton transfer.

[18] 
(m/z 149) (m/z 119)

$\Delta H° = 12$ kcal mol^{-1}

The reaction is significantly endothermic but is favoured by a large increase in entropy ($\Delta n = +1$). The possibility of the occurrence of such a process was tested using isopropylbenzene alone. Methane chemical ionization of this molecule forms mainly the ring protonated ion (m/z 121). This in turn slowly reacts with the neutral molecule to give m/z 119 ($k \sim 10^{-12}$ cm^3 $molecule^{-1}$ s^{-1} at 300 K) in a reaction which may be formulated.

[19] 
(m/z 121) (m/z 119)

$\Delta H° = 12$ kcal mol^{-1}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

m/z 119 again showed no further reaction. For comparison purposes m/z 119 was also formed by the protonation of α-methylstyrene using methane chemical ionization. This ion will have the same structure as that shown in reaction [18] since protonation of styrene is exclusively on the olefinic side chain (22). Once again m/z 119 did not react further but did react very slowly ($k < 10^{-12}$ cm^3 molecule^{-1} s^{-1} at 400 K) with cyclohexene. Ausloos and co-workers (23) found that the benzyl cation ($C_6H_5CH_2^+$) reacts very efficiently with cyclohexene ($k/k_c = 0.5$ at 320 K) and with about the same efficiency with alkyl benzenes. The two extra methyl groups in m/z 119 obviously confer considerably stability on the benzyl cation just as methyl substituents do on the methyl cation.

The occurrence of significantly endothermic entropy driven ionic reactions such as [18] and [19] has been debated (24). A likely explanation is that a proton is transferred in the initially formed ion–molecule complex yielding H_2 and m/z 119 which is solvated by the neutral product molecule. As long as this solvation energy is greater than the endothermicity, reaction with loss of H_2 can readily occur. Equilibration with the bath gas molecules leads to the break-up of the solvation complex. Under our ion source conditions we do not expect to observe such weakly bound (~12 kcal mol^{-1}) complexes.

m/z 135 which can be formulated $C_2H_5C_6H_5C_2H_5^+$ is formed at low temperature only. It could be the $C_2H_5^+$ adduct of a C_8H_{10} impurity or more probably the product of a displacement reaction involving m/z 149 and ethyl chloride.

[20] 
m/z 163 may be formulated as $C_6H_5(C_3H_7)_2^+$. The mechanism of its formation and that of m/z 135 ($C_{10}H_{15}$) are unknown.

At high temperature the system becomes very complex, major reaction channels involve the addition of $C_2H_5^+$ followed by the loss of either propylene yielding m/z 107 or propane yielding m/z 105. Such displacement reactions have been observed following protonation (13). The major ion at short reaction times is ring protonated isopropylbenzene which once again slowly reacts to give m/z 119.

Toluene

Protonated toluene ($C_7H_9^+$, m/z 93) is isobaric with $(C_2H_5)_2^{35}Cl$ and it was therefore necessary to obtain time-resolved information on the diethylchloronium ion by monitoring the smaller isotopic peak $(C_2H_5)_2^{37}Cl^+$ at m/z 95. The information from this ion was then also used to deconvolute m/z 93 and obtain the time-resolved contribution of $C_8H_9^+$. At low temperature $B \cdot C_2H_5^+$ (m/z 121) ultimately yields m/z 177 at long reaction time (Fig. 7). This latter ion could be formed in reactions similar to reaction [20] but since displacement of an olefin is not possible, only loss of HCl occurs.

[21] 
(m/z 121) (m/z 149)

[22] m/z 149 + C_2H_5Cl →  + HCl

(m/z 177)

Neither m/z 149 nor m/z 177 is observed at high temperature, presumably because the required collision complexes do not have a long enough lifetime for the elimination reactions to occur. As with isopropylbenzene a loss of alkane, in this case methane, leads at high temperature to the formation of a small amount of m/z 105 but BH^+ and $BC_2H_5^+$ are the major products.

Benzene

The reaction between benzene and $(C_2H_5)_2Cl^+$ is so slow that up to 0.39 mol% benzene was required in some of the experiments. This was considerably more than was required for the study of the other aromatics. At low temperature, Fig. 8*a*, $BC_2H_5^+$ (m/z 107) is the major product and there is a small yield of m/z 135 corresponding to $(C_2H_5)_2C_6H_5^+$ which could be formed by the reaction of the adduct with ethyl chloride.

[23] $C_2H_5C_6H_6^+ + C_2H_5Cl \rightarrow (C_2H_5)_2C_6H_5^+ + HCl$
$\Delta H^0 = -8$ kcal mol^{-1}

Some BH^+ (~ 4% total ionization) is formed presumably by reaction with precursors of $(C_2H_5)_2Cl^+$. At the highest temperatures the ion chemistry becomes more complex (Fig. 8*b*). As with the other alkylaromatics, the protonated molecule is a major product and indeed at very low benzene concentrations it is the major product.

The two stable forms of $C_4H_9^+$ are the *t*-butyl and *sec*-butyl cations (25). Proton transfer from *t*-$C_4H_9^+$ (PA(*i*-C_4H_8) = 196 kcal mol^{-1}) is endothermic with benzene (PA 181 kcal mol^{-1}), toluene (PA 190 kcal mol^{-1}), and isopropylbenzene (PA 192 kcal mol^{-1}) but is exothermic with mesitylene (PA 201 kcal mol^{-1}). Proton transfer from *sec*-$C_4H_9^+$ (PA(2-C_4H_8) = 179 kcal mol^{-1}) is exothermic to all of the aromatic hydrocarbons under study. We find that proton transfer from *t*-$C_4H_9^+$ to mesitylene occurs with high efficiency at a rate about one half the collision rate at 581 K, with toluene the reaction efficiency is about 1% while no proton transfer occurs with benzene. At high temperatures when $C_4H_9^+$ is formed by reaction [10], BH^+ is one of the two major products for all the aromatics. This ion is not formed by proton transfer from $C_4H_9^+$ in the case of benzene since the observed yields of $C_4H_9^+$ are those expected from reaction [10] alone. Toluene shows a very slow reaction with $C_4H_9^+$, isopropylbenzene reacts a little faster while mesitylene reacts fastest of all. This behaviour indentifies $C_4H_9^+$ as *t*-$C_4H_9^+$. This is consistent with extensive studies on the isomerization of *sec*-$C_4H_9^+$ to *t*-$C_4H_9^+$ (25). Even if the former ion were the immediate product of reaction [10], the high temperature and the presence of the dipolar ethyl chloride ($\mu_D = 2.1$ D) would cause very rapid isomerization (26).

The protonating agent at high temperatures must be the diethylchloronium ion itself. The rate constants for disappearance of $(C_2H_5)_2Cl^+$ by reaction with aromatic at high temperature are in the order benzene < toluene ≈ isopropyl benzene < mesitylene (*vide infra*) which will also be the order of rate constants for reaction to yield BH^+. The reaction mechanism is not known, a possible one being

[24] $(C_2H_5)_2Cl^+ + M \rightarrow C_2H_5Cl + C_2H_4 + MH^+$

The exothermicities for different B are (kcal mol^{-1}) benzene +15, toluene +7, isopropylbenzene +5, and mesitylene −4 which are consistent with the order of reaction rate constants. The use of these values in an expression for the rate constant of the form $k \approx k_c$ [exp $(-\Delta H^0/RT)$] gives rate constants of approximately the correct order of magnitude for toluene and isopropylbenzene but a value for benzene which is too small by several orders of magnitude. There is a large entropy change for this reaction which may, as discussed earlier, be described as an entropy driven reaction. The participation of product ion solvation may again be the explanation for the measurable, but low rate of reaction.

The kinetics of $C_2H_5^+$ transfer

The rate constants for the decay of $(C_2H_5)_2Cl^+$ in these systems was measured by two different methods. The most common method employed in high pressure mass spectrometry, which we call the normalization method, uses the slopes of the pseudo first order decays of $(C_2H_5)_2Cl^+$ from plots such as those in Figs. 4–8. The actual value of the slope for a given system depends on the precision with which all the different ions in the system are monitored. When there are many ions to monitor in a complex spectrum over an extended period of time there is the possibility of error which arises from a variation in ion source conditions. In addition, the rate constants obtained are for the overall disappearance of $(C_2H_5)_2Cl^+$ and not solely for the reaction of interest, namely, reaction with aromatic.

The second method, which we call the standard addition method and which has been described in detail (4), provides the rate constant for reaction with aromatic only. $(C_2H_5)_2Cl^+$ disappears by reactions [10] and [14] and also by diffusion to the walls with rate constant k_d

$$[25] \quad \frac{-d[(C_2H_5)_2Cl^+]}{dt} = (k_{10}[C_2H_5Cl] + k_{14}[B] + k_d)[(C_2H_5)_2Cl^+]$$

Under fixed ion source conditions $[C_2H_5Cl]$ and [B] are constant and taking the $(C_2H_5)_2Cl^+$ ion current i to be proportional to ion concentration, eq. [25] becomes pseudo first order.

$$[26] \quad -\frac{di}{dt} = k'i \text{ where } k' = k_{10}[C_2H_5Cl] + k_{14}[B] + k_d$$

Such behaviour is shown in Fig. 9 for a fixed C_2H_5Cl concentration and increasing concentration of aromatic. The experiment is performed by making up a $C_2H_5Cl/SF_6/CH_4$ mixture in the reservoir and monitoring the ion current due to $(C_2H_5)_2Cl^+$ as a function of time after the ionizing electron pulse. A known amount of aromatic is added and the current is monitored again. With increasing aromatic concentration the slope of the decay curve increases as described by eq. [25]. Under these conditions $k' = k'' + k_{14}[B]$ where $k'' = k_{10}[C_2H_5Cl] + k_d$. A plot of k' vs. [B] then yields a straight line with slope k_{14}. Plots for benzene at different temperatures are shown in Fig. 10. It is to be noted that both slope and intercept increase with increasing temperature. The increase in the size of the intercept is mainly due to an increase in k_d since the term $k_{10}[C_2H_5Cl]$ is of importance only at the highest temperatures.

The Arrhenius type plots shown in Fig. 11 for mesitylene, toluene, and benzene were obtained by the standard additions method while the plot for *i*-propylbenzene was obtained by the normalization method. Figure 12 compares the two methods of

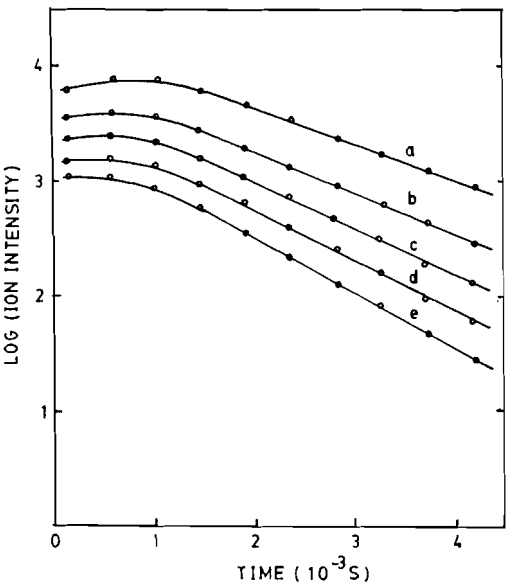

FIG. 9. The intensities of the $C_2H_5^+$ adduct of benzene ($C_6H_6C_2H_5^+$, m/z 107) after 60 μs ionizing pulses of electrons for $C_2H_5Cl/SF_6/CH_4$ (0.035/0.007/0.958) mixtures at 4.58 Torr and 512 K. The mole fractions of benzene are (*a*) 0, (*b*) 0.0005, (*c*) 0.0009, (*d*) 0.0014, and (*e*) 0.0019. The slope of the linear portion of each decay curve is equal to k', the pseudo first order rate constant for the disappearance of $(C_2H_5)_2Cl^+$.

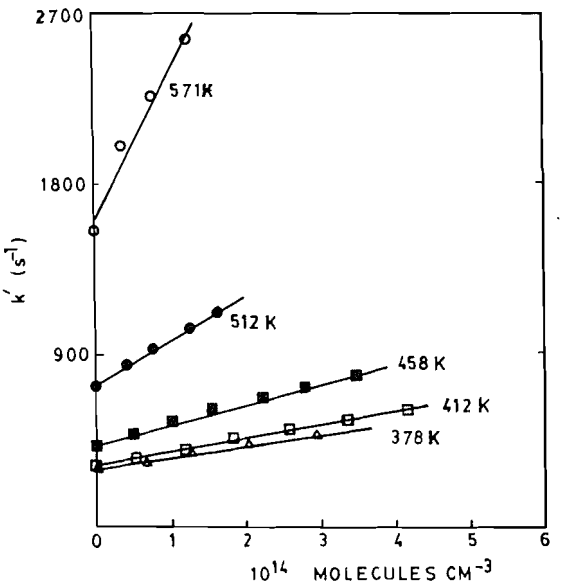

FIG. 10. Plots of $k' = k_{10}[C_2H_5Cl] + k_{14}[C_6H_6] + d_d$ versus benzene concentration at 4.58 Torr.

determining rate constants for mesitylene and benzene. It is evident that, except at the highest temperatures, there is good agreement between the two methods. There is a noticeable concentration dependence in the results obtained for benzene using the normalization method and a very slight dependence for mesitylene. The dependence for benzene increases with increasing temperature. Benzene has a much smaller rate constant for reaction with $(C_2H_5)_2Cl^+$ than does mesitylene and greater concentrations of benzene were therefore required for the same extent of reaction. In the standard addition method there is a noticeable non-linearity in the plot of k' versus ben-

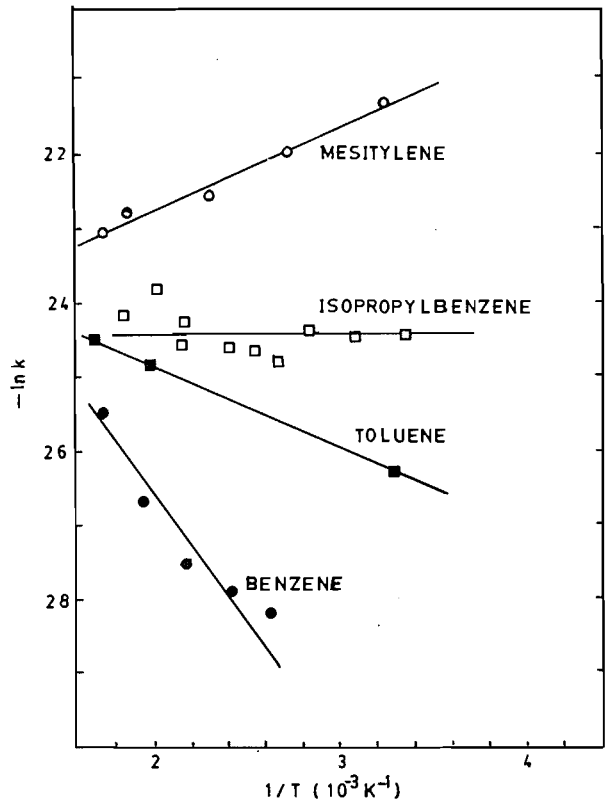

FIG. 11. Arrhenius plots for the reaction $(C_2H_5)_2Cl^+ + B \rightarrow BC_2H_5^+ + C_2H_5Cl$. Data for isopropylbenzene were obtained using the normalization method, the remainder were obtained using the standard addition method.

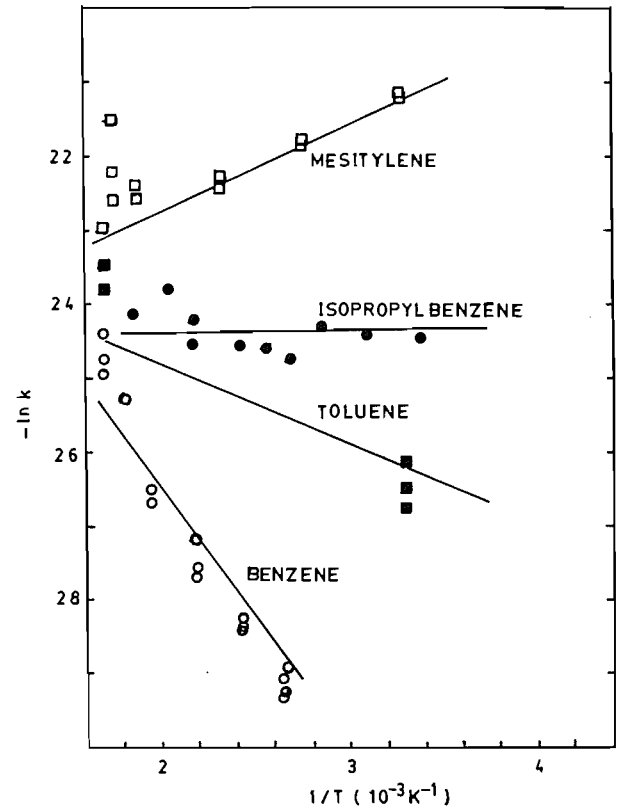

FIG. 12. Arrhenius plots for the reaction $(C_2H_5)_2Cl^+ + B \rightarrow BC_2H_5^+ + C_2H_5Cl$. Data for all aromatics were obtained by the normalization method (see text); the lines are those from Fig. 11. Comparison of the two sets of data illustrates the deviation of the normalized data at high temperatures due to the increased rate of disappearance of $(C_2H_5)_2Cl^+$ via reaction [10]. For benzene the value of k at a given temperature increases with increasing benzene concentration as shown, the lowest point at a given temperature is for the lowest benzene concentration.

zene concentration at the high concentration end which may be attributed to an increase in k_d since the diffusion coefficient of $(C_2H_5)_2Cl^+$ is reduced as the concentration of polarizable benzene molecules becomes significant. The error caused by this effect was minimized by limiting the benzene concentration range, especially at the high temperatures where k_d is large. The error due to this effect was, under these circumstances, less than the experimental errors inherent in measuring rate constants of value less than 10^{-12} cm^3 molecule^{-1} s^{-1}. The very marked deviation between the results for the two methods for all aromatics at the highest temperatures is because the normalization method measures the rate of disappearance of $(C_2H_5)_2Cl^+$ by both reactions [10] and [14]. For systems such as this involving competitive reactions the standard addition method of obtaining reaction rate constants is preferred. It does not, as does the normalization method, give information on product type and relative yields of products; the two methods are complementary when the full kinetic picture is required.

The rate of $C_2H_5^+$ addition at any temperature in the experimental range increases in the order benzene < toluene < isopropylbenzene < mesitylene. This is the order of increasing gas phase basicity of the aromatic substrate as measured by proton affinity. The same order was observed for the relative rates of CH_3^+ transfer from $(CH_3)_2Cl^+$ to aromatic hydrocarbons (6). Alkylation of toluene by $(C_2H_5)_2Cl^+$ in SO_2ClF solution at 195 K was found to be five times faster than alkylation of benzene (1) suggesting that there is a similar mechanism for alkylation in both gas and liquid phases.

The slowness of ethyl cation transfer from $(C_2H_5)_2Cl^+$ to an aromatic molecule is consistent with the mechanism discussed in the introduction for CH_3^+ transfer from $(CH_3)_2Cl^+$, i.e., the double well potential curve is appropriate as a description of the reaction path. The rate constants for transfer to benzene and toluene increase with increasing temperature while that for mesitylene decreases and the rate constant for transfer to isopropylbenzene is independent of temperature. All reactions are very exothermic (Table 1) and the analysis proposed by Sen Sharma and Kebarle (4) would have the energy level of the central maximum (chemical transition state) below the level of the reactants only for mesitylene. The positive activation energies for benzene and toluene show that the central maximum is above the reactant energy level; that for isopropylbenzene is at or close to the same level as the reactants.

It is at first somewhat surprising that the rate constants at 305 K for $C_2H_5^+$ transfer from $(C_2H_5)_2Cl^+$ to benzene, toluene, and isopropylbenzene are smaller than those for CH_3^+ transfer from $(CH_3)_2Cl^+$. This is in contrast to the observation of Sen Sharma and Kebarle (4) that $C_2H_5^+$ transfer from $CH_3ClC_2H_5^+$ to benzene, toluene, and isopropylbenzene is faster at 305 K than is CH_3^+ transfer from $(CH_3)_2Cl^+$. They suggested that the internal barrier will be smaller for transfer of the more weakly bound $C_2H_5^+$ ($D(C_2H_5^+—ClCH_3) = 30.7$ kcal mol^{-1} (27)) to a given aromatic. Sen Sharma and Kebarle could not measure the dependence of the rate constant for $C_2H_5^+$ transfer from $C_2H_5ClCH_3^+$ to aromatic molecules at higher temperatures because of problems engendered by its dissociation. Although

Isopropylbenzene	7	161	−27.1
Mesitylene	−4	145	−32.1

[a]Units, kcal mol^{-1}.

$(CH_3)_2Cl^+$ reacts more rapidly with a given aromatic at 305 K than does $(C_2H_5)_2Cl^+$, it does not necessarily do so at a higher temperature because of the different temperature dependences of the rate constants. Thus at 450 K transfer of $C_2H_5^+$ from $(C_2H_5)_2Cl^+$ to toluene and isopropylbenzene is faster than CH_3^+ transfer from $(CH_3)_2Cl^+$. CH_3^+ transfer to benzene still has the higher rate constant. All these CH_3^+ and $C_2H_5^+$ transfers are highly exothermic and the absolute value of the exothermicity is obviously not the sole criterion determining the relative rates with which they react with a given aromatic. In solution it is found that S_N2 displacements are more facile at a methyl than at a methylene group (28). This has been ascribed to a steric interaction (29), the chemical transition state for CH_3^+ transfer is less crowded than that for $C_2H_5^+$ transfer. Such a steric interaction in the gas phase would lead to a lower density of states at the central barrier for $C_2H_5^+$ transfer compared with CH_3^+ transfer for a given ΔE^0, ensuring a lower rate of ethylation. However, as argued earlier, the value of ΔE^0 is also different for $(CH_3)_2Cl^+$ and $(C_2H_5)_2Cl^+$ (and also presumably for $C_2H_5ClCH_3^+$) with the same aromatic; the change of electrophile therefore affects both the entropy and the energy of the transition state.

The trend of increasing rate constant with increasing exothermicity of reaction does, however, hold for each alkylating agent with the same series of aromatic bases over the temperature range 300–600 K.

Appendix I

Standard enthalpies of formation were not available for several of the neutral molecules and ions discussed in this paper. Estimates of such enthalpies were made as follows.

The following standard enthalpies of formation of alkyl aromatics are from ref. 21 (units kcal mol^{-1}): benzene 20, toluene 12, ethylbenzene 7, isopropylbenzene 1, and mesitylene −4. Single substituents decrease the enthalpy for formation of benzene by the following amounts: methyl 8, ethyl 13, *i*-propyl 19 kcal mol^{-1}. If substituent contributions are strictly additive then mesitylene (1,3,5-trimethylbenzene) with three methyl groups is calculated to have a standard enthalpy of formation of $20 - 3 \times 8 = -4$ cal mol^{-1}, which is identical with the experimental value. The other two trimethylbenzene isomers have only slightly different values viz. 1,2,3-trimethylbenzene −2 kcal mol^{-1} and 1,2,4-trimethylbenzene −3.3 kcal mol^{-1} i.e. geometrical isomerism has little effect on the standard enthalpy of formation. With the above values for the substituents, calculated standard enthalpies are usually within ±2 kcal mol^{-1} of known experimental values. For example the value calculated for ethyltoluene is −1 kcal mol^{-1} and the experimental values for *o*-, *m*-, and *p*-ethyltoluene are respectively, 0, 0, and −1 kcal mol^{-1}.

The standard enthalpies of formation of ions were obtained, where possible, from the literature (mainly ref. 12) and if not available they were estimated using estimated proton affinities as follows. An alkyl substituent increases the proton affinity of benzene, in general the larger the alkyl group the higher the proton affinity. Thus PA(benzene) = 181.3, PA(toluene) = 189.8, PA(ethylbenzene) = 191.6, and PA(isopropylbenzene) = 192.1 kcal mol^{-1}. Protonation is assumed to occur *para* to the alkyl group leading to the following stabilization energies for a *para* substituent: methyl 8.5, ethyl 10.3, and *i*-propyl 10.8 kcal mol^{-1}. Relative to stabilization by methyl (= 1.00) the stabilization efficiencies increase for ethyl by a factor of 1.21

and for *i*-propyl by 1.27. When more than one methyl substituent is present both their number and sites relative to the site of protonation determine the proton affinity (18, 20). The following stabilization enthalpies have been assigned for a methyl substituent: *ortho* 6.4, *meta* 2.6, and *para* 7.6 kcal mol^{-1} (20). This value for *p*-methyl is slightly lower than the value given above but the difference is within the spread of values of experimental proton affinities used in obtaining the evaluated proton affinity. For ethyl and isopropyl substituents, the stabilization enthalpy is assumed to be that for methyl multiplied by the stabilization efficiency eg for a *meta*-ethyl substituent it is $2.6 \times 1.21 = 3.1$ kcal mol^{-1}. The $C_2H_5^+$ is presumed to add *para* to the alkyl group on toluene and isopropylbenzene and at an unsubstituted site on mesitylene. The *ipso*-hydrogen then transfers to the nonsubstituted site on the aromatic ring that leads to the maximum stabilization enthalpy. For example, the addition of ethyl cation to isopropylbenzene is assumed to lead to protonated 1-ethyl-4-isopropylbenzene. The proton affinity of this molecule is calculated using the following stabilization enthalpies: *ortho*-propyl $6.4 \times 1.27 = 8.1$ kcal mol^{-1}, *meta*-ethyl $2.6 \times 1.21 = 3.1$ kcal mol^{-1}, i.e. PA(1-ethyl-4-isopropylbenzene) = 181.3 + 8.1 + 3.1 = 192.5 kcal mol^{-1}. For polymethylbenzenes such calculations agree with experimental values to better than ±2 kcal mol^{-1} (20). Similar error limits should hold for the ethyl and isopropylbenzenes but there is no experimental data to check this assumption. For aromatic B the following data have been estimated (kcal mol^{-1}).

B	PA(B)[a]	$\Delta H_f^0(B)$[a]	$\Delta H_f^0(BH^+)$[a]
4-Ethyltoluene	192	−1	173
1-Ethyl-4-isopropyl benzene	193	−12	161
1,3,5-Methyl-2-ethyl benzene	204	−17	145

A Raman and infrared spectroscopic study of triethylenediamine (DABCO) and its protonated forms

DAVID A. GUZONAS AND DONALD E. IRISH

Guelph–Waterloo Center for Graduate Work in Chemistry, Waterloo Campus, University of Waterloo, Department of Chemistry, Waterloo, Ont., Canada N2L 3G1

Received August 6, 1987

DAVID A. GUZONAS and DONALD E. IRISH. Can. J. Chem. **66**, 1249 (1988).

The Raman and infrared spectra of DABCO have been measured as a function of the pH, and the vibrational bands of the two protonated forms of DABCO have been tabulated and assigned. The frequencies of several of the Raman bands were found to exhibit substantial shifts upon protonation, and the appearance of the Raman spectrum in the region between 900 and 1100 cm^{-1} in particular shows differences which can be used to differentiate between the three forms of DABCO. The values of the two pK_a's were determined from the intensity versus pH plots for the three species.

DAVID A. GUZONAS et DONALD E. IRISH. Can. J. Chem. **66**, 1249 (1988).

On a mesuré les spectres Raman et infrarouges du DABCO en fonction du pH; on présente sous forme de tableaux les positions des bandes de vibration des deux formes protonées du DABCO et on en fait l'attribution. On a trouvé que, par protonation, les fréquences de plusieurs bandes observées dans le Raman subissent des déplacements importants; en particulier, les bandes qui apparaissent entre 900 et 1100 cm^{-1} du spectre Raman permettent de différencier les trois formes du DABCO. On a déterminé les deux pK_a à partir des courbes des intensités en fonction du pH des trois espèces.

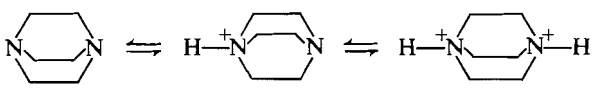
Introduction

As part of a detailed study of the surface enhanced Raman scattering (SERS) of the diamine, 1,4-diazabicyclo[2.2.2]-octane, abbreviated DABCO, at a silver electrode (1) the effect of the bulk solution pH on the SER spectrum has been investigated (2). This necessitated knowledge of the vibrational spectra of the protonated forms of DABCO, which is not available in the literature, and prompted this study of the infrared and unenhanced Raman spectra of this molecule as a function of pH.

DABCO can exist in three forms in aqueous solution, depending upon the pH, viz.:



Although the effect of protonation on the ^{13}C and ^{15}N nmr spectra of DABCO (3) and the effect of pH on the molecular motion of DABCO (4) have been studied, the Raman spectra of the two protonated forms have not been discussed in the literature. A very brief discussion of the infrared spectra of the salts of the diprotonated forms can be found in studies of the ligand properties of DABCO and $DABCOH_2^{2+}$ by Quagliano *et al.* (5) and Yokobayashi *et al.* (6).

The DABCO molecule has 54 ($3 \times 20 - 6$) vibrational degrees of freedom; the molecule is believed to be of D_{3h} symmetry (7, 8), and thus the irreducible representation is (activities given in parentheses, ia for inactive)

$$\Gamma_{vib} = 6a_1'(R) + 3a_2'(ia) + 4a_1''(ia) + 5a_2''(IR) + 9e'(R,IR) + 9e''(R)$$

There are therefore a total of 24 Raman-allowed modes and 14 infrared-allowed modes, including 9 coincidences, as well as seven modes inactive in both spectroscopies. Six of the Raman bands should be polarized. The Raman and/or infrared spectra of DABCO have been reported by a number of authors, the earliest study being of the infrared spectrum by Farkas *et al.* (9). The Raman spectra of DABCO in benzene and water, and the infrared spectrum of the solid were reported by Weiss *et al.* (7); at about the same time the infrared spectra of the gas phase, solution and solid state and Raman spectra of saturated solutions in chloroform and benzene were reported by Marzocchi *et al.* (10). A normal co-ordinate analysis of DABCO, azabicyclo[2.2.2]octane (ABCO), and bicyclo[2.2.2]octane (BCO) was performed by Bruesch (11), and an accompanying infrared and Raman study was reported by Bruesch and Gunthard (12). However, a substantial number of the expected Raman bands were not found by any of the above researchers. McDivett and Humphrey (13) also reported the infrared and Raman spectra of DABCO and some DABCO complexes; again, a large number of Raman bands were not observed, including most of the nine expected e'' modes. A more complete Raman study was reported by Ernstbrunner *et al.* (14), who also performed a new normal co-ordinate calculation in which the force constants were refined until the observed and calculated band frequencies were in good agreement. The normal coordinate analysis and band assignments for Ernstbrunner *et al.* were therefore used in this paper as a starting point for the assignments of the protonated DABCO species. Unfortunately, these authors do not report the calculated frequencies of the inactive modes or of the modes which were not observed, and do not report the observed Raman frequencies in the C—H stretching region. There are therefore a few unanswered questions concerning the band assignments of DABCO; as well, the infrared and Raman spectra of the two protonated forms need to be characterized.

The distribution diagram for a 1.0 *M* DABCO aqueous solution is shown in Fig. 1, calculated using the literature values of the pK_a's, $pK_{a_1} = 8.82$ and $pK_{a_2} = 2.97$ (15); see also Larson *et al.* (16). It can be seen that there exist pH values at which only one of the three species is present in the solution at concentrations greater than about 1%, which facilitates the analysis of the infrared and Raman spectra.

Experimental

Raman spectra were obtained using a digital drive, Jarrell-Ash, 25-100 spectrometer (1 meter double Czerny-Turner monochromator),

with an RCA 31034 photomultiplier tube and an SSR model 1105/1120 photon counting system. The 514.5 nm line of a Spectra Physics model 165-03 argon ion laser was used for excitation. The spectrometer was controlled by, and data collected on, a Commodore PET model 2001 computer. A DEC Pro 380 computer interfaced to a VAX 11/785 via ETHERNET was used to perform curve resolution and factor analysis, the latter being done using the TARGET™ factor analysis package obtained from Malinowski (17, 18).

Infrared spectra were obtained using a BOMEM DA 3.02 FTIR spectrometer, using a globar source, KCl beamsplitter, and a liquid nitrogen cooled Hg–Cd–Te detector.

Solutions were prepared from distilled water. DABCO was obtained from Aldrich and purified by recrystallization from low boiling petroleum ether before use. The solution pH was adjusted using 12 *M* HCl and 50% w/v NaOH, the pH being measured with a Fisher Accumet model 800 pH meter. The Raman samples were contained in 0.05 mm o.d. melting point tubes; the solutions were filtered using Millipore BD 0.06 μm polyvic filters before injection into the tubes. The infrared spectra were measured using a liquid cell with AgCl windows.

Results and discussion

Solvent shifts in the Raman spectrum of DABCO

In order to obtain information on the solute–solvent interactions of DABCO Raman spectra of DABCO dissolved in a number of solvents were obtained. Table 1 lists the positions of the strongest Raman bands in these solvents, arranged in order of solvent acceptor number (19). While most of the bands show only random one or two wavenumber shifts with changes in solvent, several bands, viz., ν_6, ν_4, and ν_3, show substantial shifts to higher wavenumber upon going from benzene (non-polar, non-hydrogen bonding, low acceptor number) to water (polar, hydrogen bonding, high acceptor number). As seen in Table 1, there is a clear relationship between the acceptor number and the band position of these three bands. Since DABCO is known to strongly hydrogen-bond, the observed shifts are undoubtedly caused in large part by the hydrogen-bonding of DABCO to the solvent. These bands have been previously assigned to the totally symmetric skeletal deformation (ν_6), the νCC/ωCH$_2$ (ν_4), and the ωCH$_2$/νCC (ν_3) (14). That the solvent–DABCO interaction is reflected most strongly in the frequency of ν_3, ν_4, and ν_6 can be understood in terms of the through-bond interactions of the lone-pair orbitals (20). Because of the favourable position of the two nitrogen atoms of DABCO, the lone pair orbitals interact via the carbon–carbon framework; molecular orbital calculations show that the lone pair electrons are 42% on the carbon–carbon framework (21). Any changes in the interactions of the lone pairs with the solvent will clearly alter the degree of mixing of the lone pair MO's with the C—C σ MO, and therefore alter the electron density on the C—C bonds as well as the N—C bonds. Since ν_3 and ν_4 both contain substantial amounts of the C—C stretching co-ordinate, these two bands will be particularly sensitive to changes in the environment of the lone-pairs. Similarly, since the anti-symmetric combination of the lone pair orbitals was shown (20) to be coupled to the NCC bond angle, and thus to ν_6, the sensitivity of ν_6 to solvent effects is also understandable. These observations suggest that the frequencies of these bands are good indicators of the extent of the interaction of the lone pairs, an upward shift in the frequency correlating with an increase in the strength of the interaction.

Infrared and Raman spectra of the protonated forms of DABCO

Raman spectra were obtained of solutions whose pH values differed by about 0.5 pH units, while infrared spectra were obtained only at pH values where each of the three forms could be studied in isolation. In both studies three distinct spectra were found, as seen in Figs. 2 and 3; the Raman spectra smoothly change from the DABCO spectra at high pH through the monoprotonated and then the diprotonated forms as the pH is lowered. The spectra of the three species are, not surprisingly, fairly similar in overall appearance, but do exhibit small band shifts, intensity changes, and some substantial changes in the spectral region from 900 to 1400 cm^{-1}, as indicated in Table 2. Because of the presence of a large number of bands in the C—H stretching region, some of which are overtones of the C—H wagging modes, no definitive assignment of a number of the Raman and infrared bands appearing in this region was possible.

Before turning to a discussion of the spectra, it is necessary to consider the effect of changes in the symmetry of DABCO upon protonation. The species DABCOH$^+$ is probably of C_{3v} symmetry while the diprotonated form is assumed to be of D_{3h} symmetry like the neutral DABCO. A correlation diagram summarizing the changes in activity to be expected based on these symmetries is presented in Fig. 4, and one can make some simple predictions from this figure concerning changes to be anticipated in the infrared and Raman spectra upon protonation.

Upon monoprotonation, the five a_2'', infrared-allowed, Raman-forbidden modes of DABCO become both infrared- and Raman-allowed; thus the Raman spectrum of the monoprotonated form could contain five new *polarized* bands, assuming

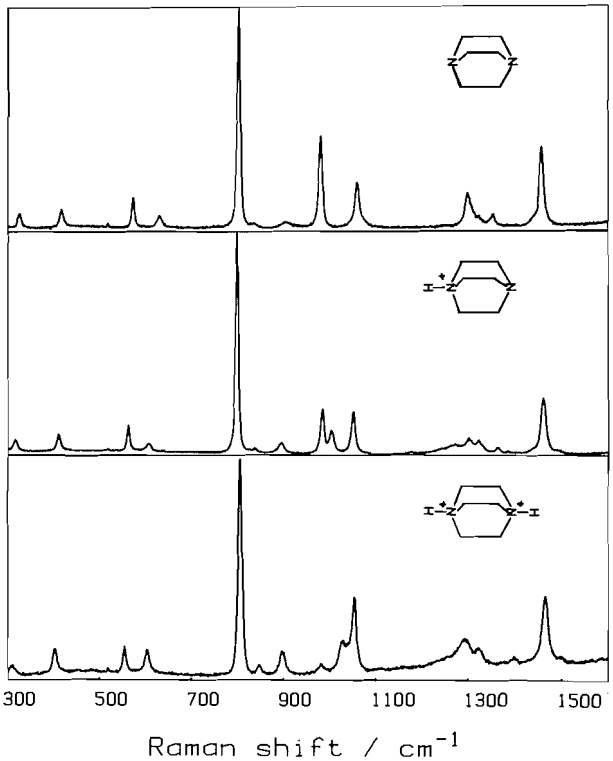

FIG. 2. Raman spectra from 300 to 1600 cm^{-1} of DABCO and its two protonated forms.

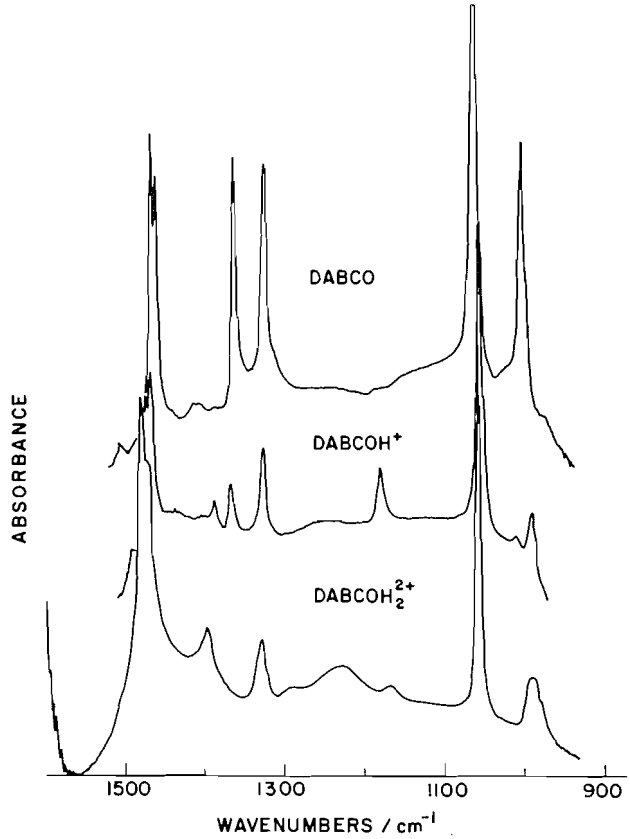

FIG. 3. Infrared spectra from 900 to 1600 cm^{-1} of DABCO and its two protonated forms.

observable intensity, as well as two new bands due to the N^+H group. The infrared spectrum is expected to become much more complex because the a_1' and e' modes (15 in total) become allowed in the monoprotonated species. Upon diprotonation, the infrared and Raman spectra are expected to resemble the spectra of the unprotonated DABCO species except for the addition of bands due to the N^+H groups, three bands being Raman active and two being infrared active.

There is a close structural similarity between the monoprotonated DABCO species and the monoamine azabicyclo-[2.2.2]octane (ABCO) that can be utilized to aid in the assignment of the former. As well, the similarity between the molecules bicyclo[2.2.2]octane (BCO), $ABCOH^+$, and the diprotonated DABCO has been exploited. The band assignments of Bruesch and Gunthard (12) for ABCO and BCO were thus useful in assigning the bands of the protonated DABCO species.

The 300 to 850 cm^{-1} region

The Raman bands ν_{36}, ν_{27}, ν_{35}, and ν_6 at 332, 424, 577, and 630 cm^{-1}, respectively, in the unprotonated DABCO spectrum shift to lower wavenumber in the sequence DABCO > $DABCOH^+$ > $DABCOH_2^{2+}$. These vibrations are associated with changes in the NC_3 bond angles; the addition of first one and then two protons affects both the mass at the nitrogen atoms and the bonding electron distribution. Note, however, ν_6, at 630 cm^{-1} in DABCO, which shows a shift to *higher* wavenumber when the strength of the solvent–DABCO interaction increases, shows the same downward shift in frequency as the other cage deformation (NCC bending) modes; the conversion of lone pair electron density to localized σ bond density must cause this change in force constant. The cage-breathing mode at 806 cm^{-1} in the unprotonated form undergoes a small shift to lower frequency (801 cm^{-1}) upon monoprotonation, due most likely to the increase of the mass at the nitrogen atom. On diprotonation, this band is observed to increase in frequency to 809 cm^{-1}, this shift possibly arising from a redistribution of electron density in the diprotonated species, not unexpected since there are now no lone-pair orbitals left for through-bond interaction. In the same spectral region, a new band is seen in the Raman spectrum as a weak shoulder at ≈760 cm^{-1}; this band is polarized and corresponds to $\nu_{18}(a_2'')$ of the unprotonated DABCO, now Raman-allowed and totally symmetric, as expected from the correlation diagram. Two weak bands, at 831 and 911 cm^{-1} in the unprotonated DABCO, are also seen in the Raman spectra of the monoprotonated form, at 841 and 896 cm^{-1}, and at 852 and 903 cm^{-1} in the diprotonated DABCO.

The 850 to 1200 cm^{-1} region

The spectral region from 950 to 1100 cm^{-1} exhibits perhaps the most distinctive and, as far as identification is concerned, useful changes upon protonation, as can be seen in Fig. 5. For the monoprotonated species, a new Raman band at 1005 cm^{-1} is seen, in addition to bands at 987 and 1053 cm^{-1} which occur at 1002 (IR), 983, and 1060 cm^{-1} for the unprotonated species. This new Raman band corresponds to $\nu_{10}(a_2'')$ which becomes Raman-allowed in $DABCOH^+$; at the same time ν_4 at 983 cm^{-1} in DABCO becomes allowed in the infrared spectrum of the monoprotonated species (987 (R), 991 (IR)). The Raman bands at 987 and 1005 cm^{-1} are both polarized as expected. These changes can all be understood in terms of a reduction of the symmetry of DABCO from D_{3h} to C_{3h} upon monoprotonation.

More puzzling are the spectral changes observed upon diprotonation. Raman bands are observed at 987, 1033, and

1061 cm^{-1} with only the band at 1033 cm^{-1} being polarized. Two bands, one at 1058 cm^{-1} and the other a broad band at 990 cm^{-1}, are observed in the infrared spectrum. If $DABCOH_2^{2+}$ is of D_{3h} symmetry as proposed, then only one polarized Raman band is expected, as observed; this means that the band at 1033 cm^{-1} must be ν_4 *shifted* by 46 cm^{-1} from its position in the unprotonated and monoprotonated species. The same behavior is observed upon protonation of ABCO, which rules out an explanation based on the interaction of two closely-spaced, positively-charged, nitrogen atoms. A plausible hypothesis is that diprotonation in DABCO and monoprotonation in ABCO removes the mixing of the lone-pair orbitals and the σ_{C-C} orbitals, thus radically altering the C—C bond length and/or strength and leading to the observed shift in the frequency of ν_4. Monoprotonation does not produce such an effect since one lone pair (or the equivalent thereof delocalized over the entire framework) is left unchanged; Cralk and George (3) have proposed that a rapid exchange

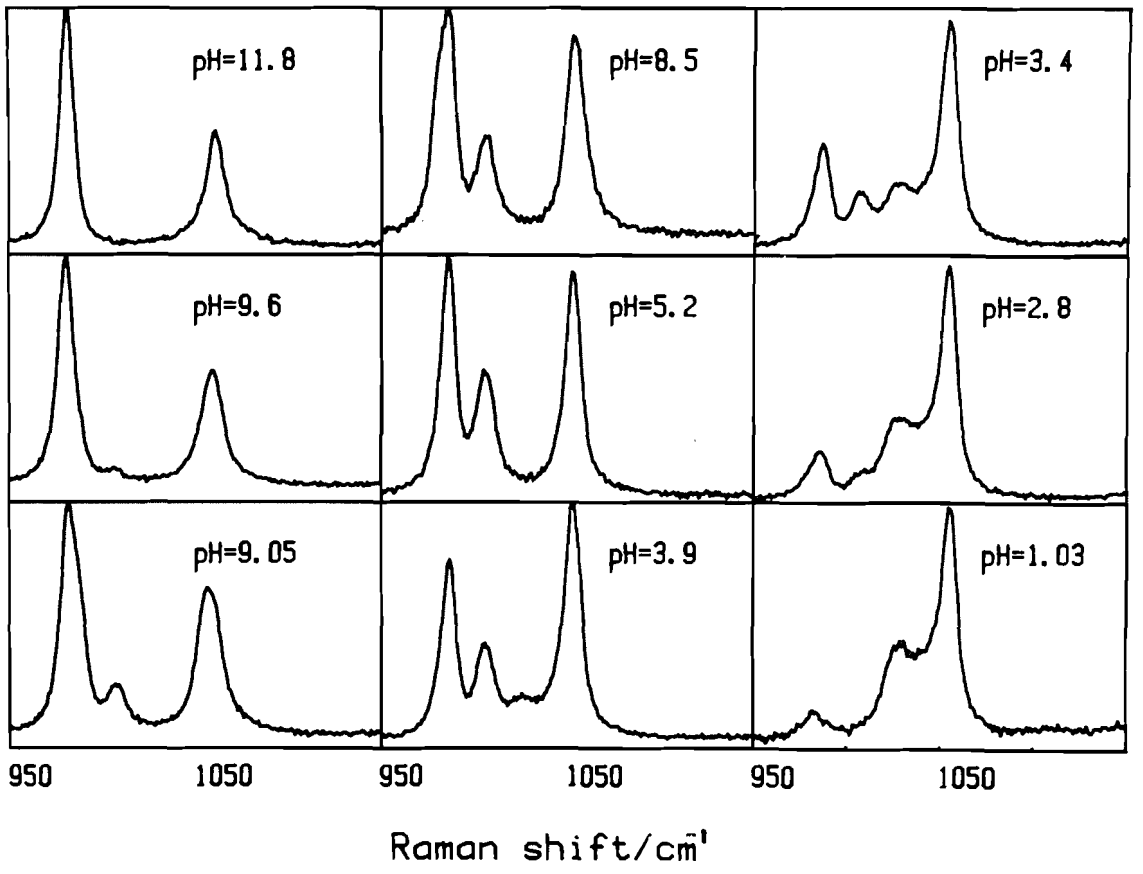

FIG. 5. Raman spectra from 950 to 1100 cm^{-1} of DABCO at the pH values specified.

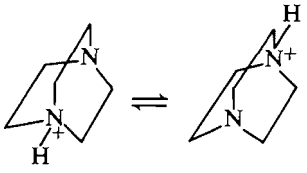

occurs in $DABCOH^+$ since the two nitrogens appear equivalent in NMR. Because the monoprotonated species conforms to the selection rules expected for C_{3v} symmetry in the Raman and infrared spectra, the exchange process above must be slow on a vibrational timescale; however, such an exchange would still leave the equivalent of one lone pair involved in the through-bond interaction, which could account for the unshifted value of ν_4 in the monoprotonated species compared to the unprotonated DABCO.

One anomaly still exists in the Raman spectrum of this region, namely, the appearance of a depolarized band at 987 cm^{-1}; this is the position at which ν_4 is found in the mono- and unprotonated DABCO's, and thus no band should be observed at this position if the band at 1033 cm^{-1} is correctly assigned as ν_4. Since the band observed at 987 cm^{-1} is not polarized, while the band at 1033 cm^{-1} is, the assignment of the latter to ν_4 is undoubtedly correct which leaves the assignment of the band at 987 cm^{-1} still open. The infrared band at this position is not Raman-allowed under D_{3h} symmetry. It is therefore suggested that this band be assigned to one of the missing e'' modes of DABCO; this band would be obscured in the unprotonated species by the much stronger ν_4 band at the same frequency. It is on this basis that the assignment of this band was made. This proposal can be verified by utilizing the sensitivity of ν_4 to solvent changes; the Raman spectrum of DABCO in carbon tetrachloride could not be obtained because of a photochemical process, previously reported by Weiss *et al.* (7); acetonitrile was therefore used as a solvent. In spite of the presence of interfering solvent bands in the 1000 cm^{-1} region, there does appear to be a weak band at about 995 cm^{-1} which could be the missing e'' mode. It is easier to see that this is the case by using ABCO instead of DABCO, as the former exhibits the same changes on monoprotonation as DABCO does on diprotonation, and a band is seen in the spectrum of the protonated ABCO at 987 cm^{-1}, similar to that observed in diprotonated DABCO. The C—C stretch of ABCO occurs at 987 cm^{-1} in water and is lowered to 967 cm^{-1} in carbon tetrachloride; in this solvent a weak band is observed at 991 cm^{-1}, as expected from the preceding argument. Thus the assignment of the band at 987 cm^{-1} to an e'' mode, previously unreported, appears reasonable.

Another unassigned band is found at 1178 cm^{-1} in the Raman spectrum of the monoprotonated DABCO and at 1169 cm^{-1} for the diprotonated form; it also appears with considerable intensity in the infrared spectrum of the monoprotonated species, and is weaker in the infrared spectrum of the diprotonated form. This band is tentatively assigned to another of the missing e'' modes.

N^+H vibrations

The spectral region between 1200 and 1600 cm^{-1} exhibits a number of changes on protonation, the most important of which is the appearance of a broad feature in both the infrared and

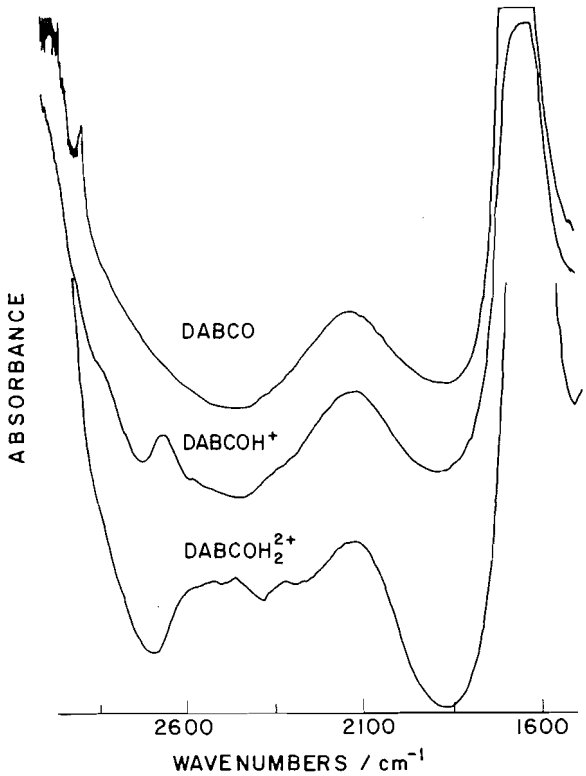

FIG. 6. Infrared spectra of the NH^+ stretching region of DABCO and its two protonated forms.

Raman spectra due to the N^+H group; at this point it is therefore useful to discuss the vibrational bands which arise from this group. The irreducible representations of the protonated species given in the correlation diagram show that upon monoprotonation, two bands due to the N^+H group arise, one of a_1 symmetry and the other of e species, and both should be present in the infrared and Raman spectra. Upon diprotonation, two further bands are expected thus giving rise to a total of four modes attributable to the vibration of the two N—H groups; the irreducible representation for the modes due to this group only is

$$\Gamma_{vib} = 1a_1'(R) + 1a_2''(IR) + 1e'(IR,R) + 1e''(R)$$

Ebsworth and Sheppard (22) discussed the infrared spectra of protonated amine salts, and gave the following frequencies for the stretching and deformation modes of trimethyl ammonium iodide:

$$\nu_s(N^+H) = 2725\ cm^{-1} \qquad \delta(N^+H) = 1418\ cm^{-1}$$

Brissette and Sandorfy (23) discussed the N^+H stretching vibration of several tertiary amines; in the solid state the centre of the broad band assigned to the N^+H stretch is found at about 2600 cm^{-1} for triethylamine and 2450 cm^{-1} for tri-*n*-butylamine hydrochloride, while in aqueous solution the same two bands are found at 2570 and 2640 cm^{-1}, respectively (Chenon and Sandorfy, ref. 24). Quagliano *et al.* (5) discussed the infrared spectrum of the diprotonated dabconium cation and assigned the N^+H stretching mode to a broad, intense infrared absorption between 1800 and 2800 cm^{-1}.

The infrared spectra of the N^+H stretching region of the three forms of DABCO in water are shown in Fig. 6. The analogous Raman spectra are shown in Fig. 7. It is apparent from the infrared spectra that the band at 2666 cm^{-1}, which appears upon monoprotonation, ought to be assigned to the N^+H stretching mode since it falls at about the same frequency as found for other protonated tertiary amines. Upon diprotonation this band becomes a broad, structured feature extending from below 2200 cm^{-1} to above 2700 cm^{-1}, evidence for considerable hydrogen bonding with the solvent water molecules, and it is assigned to the antisymmetric N^+H vibration. The Raman spectrum is less easily interpreted, since even the spectrum of the unprotonated species exhibits bands in this region. Upon monoprotonation several weak bands appear in this region, one at 2656 cm^{-1} which may correspond to the 2666 cm^{-1} band observed in the infrared spectrum. This leaves the identity of the band seen at 2761 cm^{-1} a mystery. Upon diprotonation a pair of Raman bands at 2761 and 2789 are observed and may represent the N^+H symmetric stretch. Because of the low intensity of these bands and the evidence of solvent interactions which causes them to become broad, it is safest to simply assign the N^+H stretch to bands between 2300 and 2800 cm^{-1} and leave the assignment of particular bands to particular modes unstated. To confirm that these bands do correspond to the N^+H stretches, the infrared and Raman spectra of $DABCOD_2^{2+}$ in D_2O

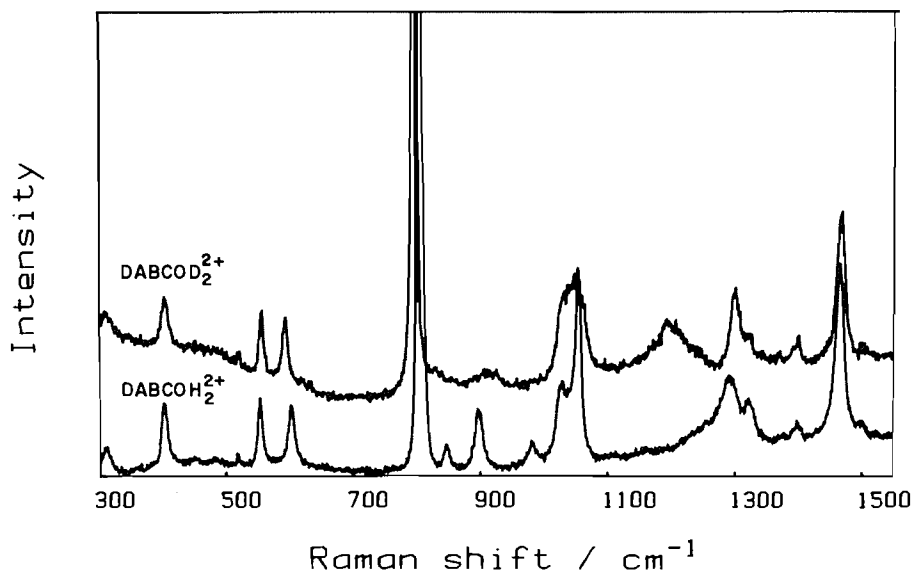

FIG. 9. Raman spectra of DABCO, protonated and deuteriated, at pH $\approx$ 0, in H_2O and D_2O.

were obtained. The N^+D stretches are expected to occur at $\approx 1970\ cm^{-1}$ if the above assignment is correct, and indeed the infrared and Raman spectra of the di-deuterated species show a number of bands between 1700 and 2100 cm^{-1} not seen in the spectrum of DABCO in D_2O. Thus the assignment of the N^+H stretching modes seems correct.

Turning now to the N^+H bending modes, Fig. 8 shows the Raman spectra of the region 1250 to 1450 cm^{-1}. One can see that a broad band appears in the spectra of both protonated species, centered around 1275 cm^{-1}; a similar band (or group of bands) appears in the infrared spectra, as seen in Fig. 3. That these bands are due to the N^+H bending modes can be verified by again turning to the spectra obtained in D_2O. Figure 9 shows the Raman spectra of $DABCOH_2^{2+}$ and $DABCOD_2^{2+}$, and as expected the broad band at $\approx 1275\ cm^{-1}$ is shifted in the deuteriated species, although its new location is not clear (the

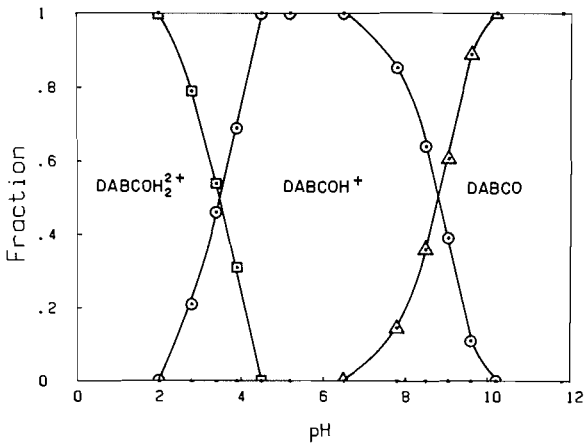

FIG. 10. Fractional composition of aqueous 2.0 *M* DABCO as a function of pH, obtained from Raman band areas.

broad band at about 1200 cm^{-1} arises from the D_2O bending mode). Interestingly, the Raman spectrum of $DABCOD_2^{2+}$ exhibits a number of intensity changes and band shifts compared to the spectrum of $DABCOH_2^{2+}$; their origins are not clear. For example, bands at 852, 903, and 987 cm^{-1} in the spectrum of the latter species become broad and weak in the spectrum of the former. As well, the infrared- and Raman-active band at 1061 cm^{-1} in the $DABCOH_2^{2+}$ spectrum shifts to 1043 cm^{-1} and merges with ν_4 to form a broad, poorly resolved feature in the Raman spectrum. At the same time the band at 852 cm^{-1} which is weak in the Raman is strong in the infrared spectrum, while weak bands appear in the infrared at 911 and 976 cm^{-1}.

No definitive explanation for these changes can be given at this time; it is suggested that coupling of the N^+D bending modes, which are of *e'* and *e''* species and which plausibly could lie between 900 and 1000 cm^{-1}, to modes of *e'* or *e''* species in this region occurs. The four modes which are observed to be affected are of these species. It is clear, however, that in spite of these unresolved changes, the spectra of the $DABCOD_2^{2+}$ confirm the assignment of the broad feature in both the Raman and infrared spectra of $DABCOH_2^{2+}$ at $\approx$1280 cm^{-1} to the N^+H bending modes.

Returning then to Fig. 8, most of the C—H wagging modes, which lie between 1300 and 1360 cm^{-1} and the C—H scissors modes between 1440 and 1470 cm^{-1} in DABCO exhibit shifts to higher wavenumber upon protonation, the shifts being of the order of up to 50 cm^{-1} for some of the bands. For example, ν_3 at 1352 cm^{-1} in DABCO shifts to 1364 cm^{-1} upon monoprotonation and to 1407 cm^{-1} upon diprotonation, while ν_{16} at 1364 cm^{-1} in DABCO shifts to 1383 cm^{-1} in the monoprotonated and 1397 cm^{-1} in the diprotonated form. The other C—H wagging modes do not show such large shifts. The C—H scissors modes all shift to higher wavenumber, the greatest shift being that of a polarized band which appears as a shoulder at 1488 cm^{-1} in the monoprotonated species and as a weak, polarized band at 1513 cm^{-1} in the diprotonated species; it can be assigned to ν_2 on the basis of its polarized Raman spectrum, the total band shift from DABCO to $DABCOH_2^{2+}$ being 56 cm^{-1}. Note that the bands which undergo the greatest shift with protonation appear to be the totally symmetric modes.

The results of the above discussions on the various spectral regions are summarized in Table 2, which lists the best assignments of all of the observed infrared and Raman bands of the three forms of DABCO. The mode numbering used in the

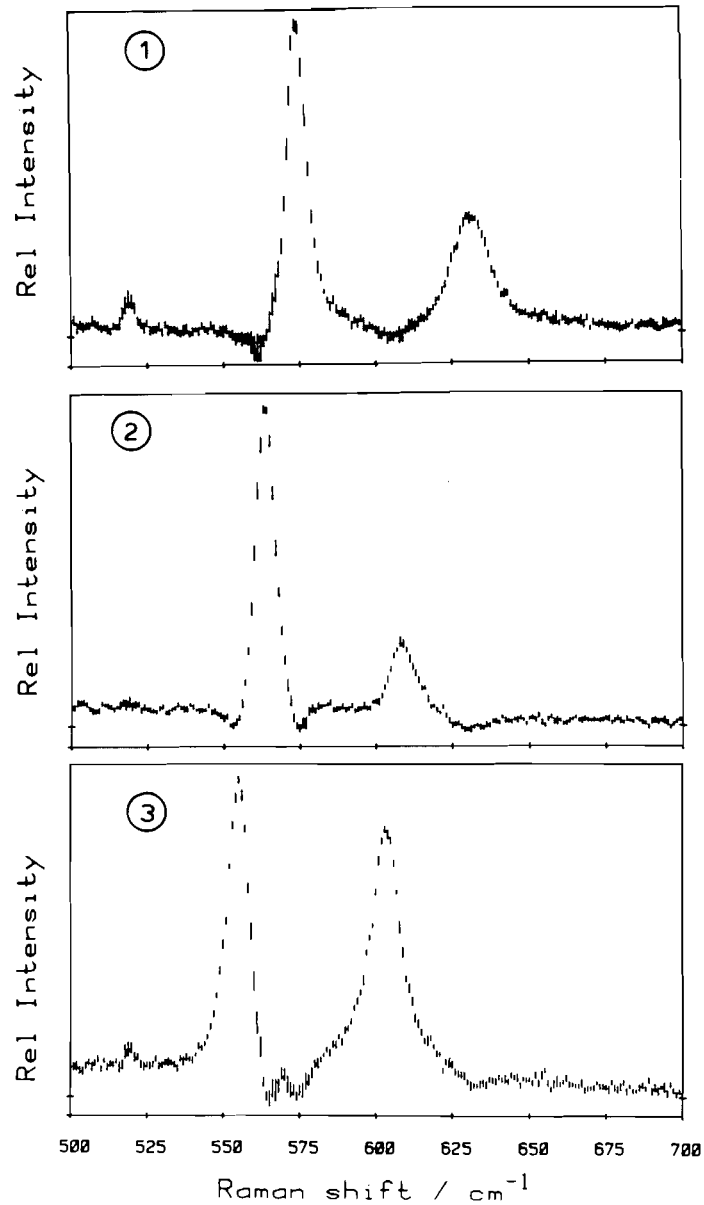

FIG. 11. Spectra of DABCO (*1*), $DABCOH^+$ (*2*), and $DABCOH_2^{2+}$ (*3*) isolated by key factor spectral isolation analysis.

table is that for unprotonated DABCO in order to provide a direct comparison of the band positions of the different species; the modes arising from the N^+H group(s) are listed at the end of the table, without any attempt to identify the species of the mode. Assignments are based on those of Ernstbrunner *et al.*; note, however the difference in the numbering of the modes between Table 2 and ref. 14.

Intensity changes with solution pH

It was interesting to see if it was possible to estimate values for the pK_a's from the Raman spectral data. In order to do this, it was necessary to find a Raman band which could be used as a measure of the concentration of the species of interest; ideally the band chosen should exhibit a reasonably large frequency shift and little change in absolute intensity. The best candidates for this task are any one of the three lowest frequency cage deformation modes ν_{27}, ν_{35}, or ν_{36}; ν_{35} at 577 cm^{-1} was chosen, and the band areas of each of the components repre-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

senting the different DABCO protonated species was obtained. These areas were used to calculate the percentage of each of the three species DABCO, $DABCOH^+$, and $DABCOH_2^{2+}$, the results being plotted in Fig. 10. If one assumes that the molar scattering coefficients of the three species are identical, then the point at which the curves cross, which represents 50% abundance, should occur at the pH value equal to the pK_a for the equilibrium between the two species in question. In this manner, the following values were obtained:

$$pK_{a_1} = 3.2 \quad (2.97)$$

$$pK_{a_2} = 9.0 \quad (8.82)$$

These values are compared to the literature values in parentheses. The most obvious reason for the discrepancy is the change in the molar scattering coefficient upon protonation; there is no reason to expect the values of this factor to remain unchanged when DABCO is protonated. In fact, the data indicate that the molar scattering coefficients of these bands decrease successively on protonation. Also, for the large (2 *M*) concentration used in these experiments the activity coefficients should not be neglected.

An attempt was also made to use factor analysis to obtain the DABCO distribution diagram, using the same spectral region in the input data matrix. The principle component analysis correctly chose three as the number of components present, and the key factor spectral isolation program was able to reproduce the spectra of the three components (Fig. 11); these compare very well with the known spectra of the three protonated species. The relative concentrations obtained, however, did not produce a very sensible distribution curve above pH 6, and it appears that curve resolution was a superior method for obtaining the distribution diagram from the Raman data.

Received August 28, 1987

MORRIS J. ROBINS, DANUTA MADEJ, FRITZ HANSSKE, JOHN S. WILSON, GILLES GOSSELIN, MARIE-CHRISTINE BERGOGNE, JEAN-LOUIS IMBACH, JAN BALZARINI, and ERIK DE CLERCQ. Can. J. Chem. **66**, 1258 (1988).

Treatment of selectively 3′,5′-protected β-D-xylofuranosyl nucleosides (**4**) with phenyl chlorothionocarbonate and DMAP followed by hydrogenolysis of the resulting (2′-*O*-phenoxythiocarbonyl) phenyl thionocarbonate esters (**6**) with tributylstannane/AIBN, and deprotection, gave 2′-deoxy-β-D-*threo*-pentofuranosyl nucleosides (**7**). Formation of a by-product bis(nucleosid-2′-yl)thionocarbonate dimer (**8**) was detected in the uracil nucleoside reaction sequence. Its subsequent reduction provides one explanation for "reversion to starting alcohol" in Barton-type deoxygenation reactions. Only the guanine 2′-deoxynucleoside analogue (**7***b*) had (weak) antiviral activity (against herpes simplex virus type 1).

MORRIS J. ROBINS, DANUTA MADEJ, FRITZ HANSSKE, JOHN S. WILSON, GILLES GOSSELIN, MARIE-CHRISTINE BERGOGNE, JEAN-LOUIS IMBACH, JAN BALZARINI et ERIK DE CLERCQ. Can. J. Chem. **66**, 1258 (1988).

La réaction des nucléosides de β-D-xylofurannosyle protégés sélectivement en 3′,5′ (**4**) avec du chlorothionocarbonate de phényle et du DMAP, suivie d'une hydrogénolyse des esters thionocarbonates de (*O*-phénoxythiocarbonyl-2′) de phényle (**6**) avec le tributylstannane/AIBN et d'une déprotection, conduit aux nucléosides du désoxy-2′ β-D-*thréo*-pentofurannosyle (**7**). Dans la suite de réactions impliquant le nucléoside d'uracile, on a détecté la formation du dimère du thionocarbonate de bis-(nucléosidyl-2′) (**8**) comme sous-produit. Sa réduction subséquente permet d'expliquer la «réversion vers l'alcool de départ» qui est observée dans des réactions de désoxygénation du type de Barton. L'analogue désoxy-2′ nucléoside de la guanine (**7***b*) est le seul à présenter une activité antivirale (faible) (contre le virus herpès simplex de type 1).

[Traduit par la revue]

Methods for the synthesis of β-D-xylofuranosyl nucleosides via base-sugar coupling (ref. 1, and references therein) and for selective 2′-deoxygenation of nucleosides (2) have been developed by us previously. We now report combination of these approaches to give 2′-deoxy-β-D-*threo*-pentofuranosyl nucleosides (**7**) and their evaluation for antiviral activity in several cell systems.

In the pioneering studies of the Cambridge group, Michelson and Todd (3) reported preparation of the O2,C3′-cyclonucleoside of thymidine and its hydrolysis to give 1-(2-deoxy-β-D-*threo*-pentofuranosyl)thymine (**7***e*) in 1955. Fox and Miller (4) and Horwitz *et al.* (5) later described careful characterization of this product. An analogous procedure was employed (6) for the preparation of 1-(2-deoxy-β-D-*threo*-pentofuranosyl)uracil (**7***d*).

Goodman and co-workers (7) first prepared 9-(2-deoxy-β-D-*threo*-pentofuranosyl)adenine (**7***a*) (and its 3′-deoxy isomer) by nucleophilic ring opening (oxirane) of 9-(2,3-anhydro-β-D-lyxofuranosyl)adenine with benzylthiolate followed by desulfurization. Analogous (acid-catalyzed) ring opening with bromide followed by hydrogenolysis with tributylstannane gave alternative access to the isomeric adenine 2′-(**7***a*) and 3′-deoxy-*threo* nucleoside products (8). Ikehara's 8-mercaptoadenine-S8,C2′-cyclonucleoside desulfurization approach (9) has also provided the 2′-deoxy-*threo* compound (**7***a*). We (10) have more recently described a reductive rearrangement route to these analogues.

In the present study, condensation of 1,2-di-*O*-acetyl-3,5-di-*O*-benzoyl-α-D-xylofuranose (**1**) (11)[3] with the five major nucleic acid bases (**2***a–e*) under appropriate conditions (protection, catalyst, solvent, etc.) gave the 2′-*O*-acetyl-3′,5′-di-*O*-benzoyl-β-D-xylofuranosyl nucleoside derivatives (**3**) in moderate to good yields (1).[4]

Selective deacetylation of O2′ was effected by the Ishido procedure with hydrazine hydrate in buffered acetic acid/pyridine (11, 14) to give the 3′,5′-di-*O*-benzoyl derivatives (**4**). Direct treatment of **4***a,d,e* and the N^2-acetyl derivative of **4***b* with phenyl chlorothionocarbonate and 4-(dimethylamino)pyridine (DMAP) in acetonitrile (2) gave the corresponding 2′-*O*-(phenoxythiocarbonyl) derivatives **6***a,d,e* and N^2-acetyl-**6***b*. Barton-type deoxygenative hydrogenolysis of these thiono-

[1]For the previous paper in this series, see ref. 23.

[2]Author to whom inquiries may be addressed at the Department of Chemistry, Brigham Young University, Provo, Utah 84602, U.S.A.

[3]For condensations, alternative use of 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-α-D-xylofuranose (12) was equally effective. However, the noncrystalline preparation (13) of "tetra-*O*-acetyl-D-xylofuranose" contained significant quantities of pyranose and other contaminants (1*a*) and should be avoided.

[4]See the experimental section for compound **3***e*. Syntheses of **3***a,c,d* and the N^2-acetyl derivative of **3***b* are described in ref. 1.

[i]The keto tautomers of the indicated enol bases predominate almost exclusively in aqueous solutions.

SCHEME 1

carbonate esters[5] with tributylstannane (and AIBN, α,α′-azobisisobutyronitrile, initiator) in toluene at 80°C (2) followed by deprotection gave the desired 2′-deoxy-β-D-*threo*-pentofuranosyl products (**7***a*,*b*,*d*,*e*).

The cytosine nucleoside (**4***c*) underwent N^4 thionoacylation and subsequent side reactions as observed previously with cytidine (2*b*). Therefore, **3***c* was fully deprotected (1*a*) and the resulting 1-(β-D-xylofuranosyl)cytosine (**5***c*) was selectively N^4-acetylated with acetic anhydride in methanol at reflux (2*b*, 15) and then converted to its 3′,5′-*O*-(1,1,3,3-tetraisopropyldisiloxan-1,3-diyl) derivative (**4***c*; R = $[Si(iPr)_2]_2O$; B = N^4-acetyl-*c*) (1*b*, 2*b*, 16, 17). Thionoacylation at O2′, hydrogenolysis, and deprotection gave **7***c*.

In the original Barton deoxygenation of alcohols, "reversion" of thiono esters to starting alcohols was observed (18, 19). We did not detect this side reaction in our 2′-deoxygenations of 2′-*O*-(phenoxythiocarbonyl) ribonucleosides with AIBN initiated hydrogenolyses using tributylstannane (2). However, in the present work, formation of parent β-D-xylofuranosyl nucleosides (**5**) was observed after O2′-thionoacylation, hydrogenolysis, and deprotection of **4**.

Isolation of a dimeric nucleosid-2′-yl thionocarbonate ester (**8**) in the uracil series provided an explanation for this result. Apparently, the less hindered O2′ region of the α-face of β-D-xylofuranosyl nucleosides (relative to β-D-ribonucleosides with a bulky *cis*-vicinal O3′ function) allows transesterification of the free 2′-hydroxyl group of one nucleoside with the phenyl thionocarbonate moiety of a second 2′-*O*-(phenoxythiocarbonyl) nucleoside derivative (with expulsion of the less basic phenoxide) to give **8**. The ^{13}C nmr spectrum of this product had peaks corresponding to one thiocarbonyl carbon, two identically shifted pairs of benzoyl carbonyl carbons, and an identically shifted dimeric nucleoside carbon skeleton. This compound (**8**) had tlc migration slightly slower than the

[5]The N^2-acetyl-**6***b* compound was further solubilized by trimethylsilylation with *N*,*O*-bis(trimethylsilyl)trifluoroacetamide before the hydrogenolysis step.

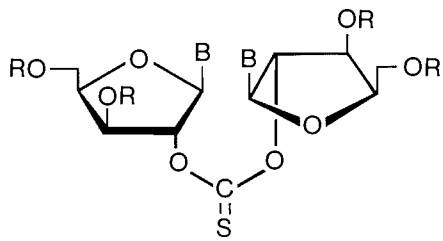
2′-*O*-(phenoxythiocarbonyl) monomer derivative (**6**), and could be separated by preparative tlc. Analytical tlc evidence for the formation of analogous dimeric thionocarbonates was observed in other cases also.

Barton first demonstrated that tributylstannane-mediated hydrogenolysis of a 2′,3′-*O*-thiocarbonyl derivative of adenosine gave a mixture of 2′- (major) and 3′-deoxy products (20). Analogous reduction of dimeric derivatives of **8** followed by



8

deprotection would produce one equivalent of 2′-deoxynucleoside (**7**) and one of the parent β-D-xylofuranosyl starting material (**5**).

Compounds **7***a–e* (Table 1) were evaluated against a variety of viruses: herpes simplex virus types 1 and 2, vaccinia virus, vesicular stomatitis virus, Coxsackie virus type B4, polio virus type 1, parainfluenza virus type 3, reovirus type 1, Sindbis virus, and Semliki forest virus in the appropriate (primary rabbit kidney, HeLa, and (or) Vero) host cell cultures (21*a*). Except for the 3′-epimer (**7***b*) of 2′-deoxyguanosine, which inhibited herpes simplex virus type 1 in primary rabbit kidney cells at a concentration of 70 μg/mL but was not cytotoxic at concentrations up to 400 μg/mL, no antiviral activity was noted with any compound in any system at a concentration lower than 200 μg/mL. Similarly, no significant protective activity was observed with any of the compounds when examined against the cytopathogenicity of human immunodeficiency virus (HIV) in ATH8 cells (21*b*) at a concentration of 100 μ*M* (~25 μg/mL).

Experimental

Biological assays in cell culture

The viruses, cell types, and methods have been described (21).

Chemical synthesis

General procedures and instrumentation used have been described (1*a*, 2*b*). See ref. 1*a* for syntheses of compounds **3***a*,*d* and **5***c*; ref. 1*b* for N^2-acetyl-**3***b* and **4***b* (R = Bz) and **3***c*; and ref. 11 for **4***a* (R = Bz). The nmr spectra were determined in Me_2SO-d_6 solutions with Me_4Si as internal reference unless otherwise noted.

*9-(2-Deoxy-β-D-*threo*-pentofuranosyl)adenine (7*a*)*

A solution of 951 mg (2 mmol) of **4***a* (R = Bz) (11), 400 μL (499 mg, 2.89 mmol) of PhOCSCl, and 500 mg (4.1 mmol) of DMAP in 40 mL of CH_3CN was stirred overnight at ambient temperature. Solvent was evaporated and the residue was partitioned between EtOAc/H_2O. The organic phase was washed with ice-cold 1 *N* HCl/H_2O, H_2O, saturated $NaHCO_3$/H_2O, saturated NaCl/H_2O, dried (Na_2SO_4), filtered, and evaporated to dryness. The resulting solid foam was dissolved in 10 mL of dry $PhCH_3$, evaporated *in vacuo*, and this process was repeated to give 9-(3,5-di-*O*-benzoyl-2-*O*-phenoxythiocarbonyl-β-D-xylofuranosyl)adenine as a crisp colorless tlc homogeneous solid foam.

This **6***a* (R = Bz) was dissolved in 20 mL of dry $PhCH_3$ and heated with 0.8 mL (866 mg, 2.97 mmol) of Bu_3SnH and 60 mg (0.37 mmol) of AIBN for 8 h at 80°C. The solution was evaporated and the tlc homogeneous residue was stirred with 5% NaOMe/MeOH at ambient temperature until deprotection was complete (tlc). The solution was evaporated and the residue was dissolved in a minimum volume of H_2O and applied to a column of Dowex 1X2(OH^-) resin (50 mL). Elution with H_2O and evaporation of appropriately pooled fractions gave 420 mg (84%) of crude **7***a*. Crystallization of this product from MeOH/Et_2O (diffusion) (22) gave 388 mg (77%) of **7***a*: mp 234–235°C (lit. (7) mp 218.9–219.5°C); uv (MeOH) max 260 nm (ε 15 000), min 227 nm (ε 3000); ^{1}H nmr δ: 2.25 (dd, $J_{1'-2'}$ = 2 Hz, $J_{2'-2''}$ = 14.5 Hz, 1, H2′), 2.77 ("sept", $J_{1'-2''}$ = 9.5 Hz, $J_{2''-3'}$ = 5 Hz, 1, H2″), 3.65 (m, 2, H5′, 5″), 3.90 (m, 1, H4′), 4.33 (m, 1, H3′), 4.68 (t, 1, OH5′), 5.97 (d, 1, OH3′), 6.25 (dd, 1, H1′), 7.33 (bs, 2, NH_2), 8.15 (s, 1, H8), 8.35 (s, 1, H2); ^{13}C nmr δ: 156.23 (C6), 152.76 (C2), 148.86 (C4), 140.83 (C8), 118.05 (C5), 85.53 (C4′), 83.29 (C1′), 69.69 (C3′), 60.39 (C5′), 41.11 (C2′); ms *m/z*: 251.1013 (M^+ 251.1018). *Anal.* calcd. for $C_{10}H_{13}N_5O_3$ (251.2): C 47.81, H 5.22, N 27.88; found: C 47.95, H 5.16, N 27.74.

*9-(2-Deoxy-β-D-*threo*-pentofuranosyl)guanine (7*b*)*

A mixture of 533.5 mg (1 mmol) of N^2-acetyl-**4***b* (R = Bz) (1*b*), 200 μL (250 mg, 1.45 mmol) of PhOCSCl, 366 mg (3 mmol) of DMAP, and 100 mL of CH_3CN was stirred for 6 h at ambient temperature. Thin-layer chromatography showed disappearance of starting material with formation of product N^2-acetyl-**6***b* (R = Bz) and ~20% of dimeric thionocarbonate (**8**; R = Bz, B = N^2-acetyl-*b*). This reaction mixture was evaporated and worked up as described above for the conversion **4***a* → **6***a* (R = Bz), except that ice-cold 10% HOAc in saturated NaCl/H_2O was substituted for the 1 *N* HCl/H_2O wash.

The crude N^2-acetyl-9-(3,5-di-*O*-benzoyl-2-*O*-phenoxythiocarbonyl-β-D-xylofuranosyl)guanine (**6***b*; R = Bz, B = N^2-acetyl-*b*) was dissolved in 24 mL of dry dimethylformamide (DMF) and treated with 2.4 mL (2.3 g, 9 mmol) of $CF_3C(=NSiMe_3)(OSiMe_3)$[5] for 30 min at 70°C. The residue obtained after evaporation *in vacuo* was dissolved in 10 mL of dry $PhCH_3$ and treated with 670 μL (725 mg, 2.49 mmol) of Bu_3SnH and 49 mg (0.3 mmol) of AIBN for 36 h at 80°C. The solution was evaporated and the residue was stirred with 20 mL of MeOH for 3 h. The mixture was evaporated and separated by preparative tlc

For personal use only.

(silica, MeOH/$CHCl_3$, 1:9). Elution of the appropriate band and deprotection with NH_3/MeOH gave the title compound, which was crystallized from H_2O to give 85 mg (31%) of **7***b*: mp >300°C; uv (MeOH) max 253 nm (ε 12 300), min 221 nm (ε 2900); ^{1}H nmr δ: 2.18 (dd, $J_{1'-2'}$ = 2 Hz, $J_{2'-2''}$ = 14.5 Hz, 1, H2′), 2.71 ("sept", $J_{1'-2''}$ = 8.5 Hz, $J_{2''-3'}$ = 5.3 Hz, 1, H2″), 3.68 (m, 2, H5′, 5″), 3.90 (m, 1, H4′), 4.35 (bs, 1, H3′), 4.69 (bs, 1, OH5′), 5.45 (bs, 1, OH3′), 6.06 (dd, 1, H1′), 6.50 (bs, 2, NH_2), 7.98 (s, 1, H8), 10.66 (bs, 1, NH); ^{13}C nmr δ: 156.62 (C6), 153.50 (C2), 150.50 (C4), 136.04 (C8), 116.37 (C5), 84.96 (C4′), 81.68 (C1′), 68.98 (C3′), 59.78 (C5′), 40.77 (C2′); ms (FAB) *m/z*: 268 (23%, *M* + 1). *Anal.* calcd. for $C_{10}H_{13}N_5O_4 \cdot 0.25\,H_2O$ (271.7): C 44.20, H 5.01, N 25.77; found: C 44.29, H 4.90, N 25.87.

*1-(2-Deoxy-β-D-*threo*-pentofuranosyl)cytosine (7*c*)*

A mixture of 243 mg (1 mmol) of **5***c* (1*a*), 0.24 mL of Ac_2O, and 25 mL of absolute MeOH was heated at reflux for 5 h (with further hourly additions of 0.24 mL of Ac_2O). The residual powder obtained after evaporation of the solution and drying was dissolved in 5 mL of pyridine and treated with 0.36 mL (360 mg, 1.14 mmol) of $(i\mathrm{Pr_2SiCl})_2O$ for 24 h at ambient temperature. The solution was evaporated and the residue was partitioned between EtOAc and H_2O. The organic phase was washed with saturated $NaHCO_3/H_2O$, saturated NaCl/H_2O, dried (Na_2SO_4), filtered, and evaporated. The vacuum-dried residual N^4-acetyl-1-[3,5-*O*-(1,1,3,3-tetraisopropyldisiloxan-1,3-diyl)-β-D-xylofuranosyl]cytosine (**4***c*; R = $(i\mathrm{Pr_2Si})_2O$, B = N^4-acetyl-*c*) was dissolved in 10 mL of CH_3CN and treated with 250 μL (312 mg, 1.81 mmol) of PhOCSCl and 978 mg (8 mmol) of DMAP for 3 h at ambient temperature. The solution was evaporated and the residue worked up as in the above procedure for conversion of **4***a* to **6***a* (R = Bz), except that ice-cold 1% HOAc in saturated NaCl/H_2O was substituted for the 1 *N* HCl/H_2O wash.

The crude dry foam containing N^4-acetyl-1-[2-*O*-phenoxythiocarbonyl-3,5-*O*-(1,1,3,3-tetraisopropyldisiloxan-1,3-diyl)-β-D-xylofuranosyl]cytosine (**6***c*; R = $(i\mathrm{Pr_2Si})_2O$, B = N^4-acetyl-*c*) was dissolved in 10 mL of dry $PhCH_3$ and heated with 620 μL (671 mg, 2.3 mmol) of Bu_3SnH and 49 mg (0.3 mmol) of AIBN for 24 h at 80°C. Successive deprotection (2*b*) with Bu_4NF/THF and NH_3/MeOH and evaporation gave a residue that was partitioned between Et_2O and H_2O. The aqueous phase was concentrated and applied to a column of Dowex 1X2(OH^-) resin. Elution with H_2O and evaporation of appropriately pooled fractions gave 113 mg (50%) of the title product, which was crystallized from MeOH/Et_2O (diffusion) (22) to give **7***c*: mp 153–155°C; uv (MeOH) max 272, 230 nm (ε 8500; 7600), min 251 nm (ε 6100); ^{1}H nmr δ: 1.80 (dd, $J_{1'-2'}$ = 2 Hz, $J_{2'-2''}$ = 14.5 Hz, 1, H2′), 2.50 ("sept", $J_{1'-2''}$ = 8.5 Hz, $J_{2''-3'}$ = 5.5 Hz, 1, H2″), 3.60–3.85 (m, 3, H4′, 5′, 5″), 4.20 (m, 1, H3′), 4.70 (bs, 1, OH5′), 5.15 (bs, 1, OH3′), 5.70 (d, J_{5-6} = 7.5 Hz, 1, H5), 6.00 (dd, 1, H1′), 7.06 (bs, 2, NH_2), 7.82 (d, 1, H6); ^{13}C nmr δ: 165.73 (C4), 155.49 (C2), 142.03 (C6), 93.48 (C5), 84.97 (C1′, C4′), 68.93 (C3′), 59.69 (C5′), 41.37 (C2′); ms *m/z*: 227.0906 (M^+ 227.0906). *Anal.* calcd. for $C_9H_{13}N_3O_4$ (227.2): C 47.57, H 5.77, N 18.49; found: C 47.27, H 5.54, N 18.72.

Further elution of the Dowex 1X2(OH^-) column with MeOH/H_2O gave 74 mg (30%) of starting **5***c* (presumably arising from hydrogenolysis of a derivative of dimeric **8**).

*1-(3,5-Di-O-benzoyl-β-D-xylofuranosyl)uracil (4*d*; R = Bz)*

To a solution of 6.00 g (12.1 mmol) of **3***d* (1*a*) in 105 mL of HOAc/C_5H_5N (1:4) was added 1.8 mL (1.86 g, 37.1 mmol) of $N_2H_4 \cdot H_2O$. The solution was stirred for 18 h at ambient temperature and 56 mL of Me_2CO was added. Stirring was continued for 2 h, the solution was evaporated, and the residue was partitioned between H_2O (200 mL) and EtOAc (2 × 250 mL). The combined organic phase was washed with saturated $NaHCO_3/H_2O$, H_2O, dried (Na_2SO_4), filtered, and evaporated. The resulting solid foam was chromatographed on a column of silica (EtOAc/CH_2Cl_2, 4:6). Evaporation of appropriate fractions gave 4.5 g (80%) of the title product, which was crystallized from PhH to give **4***d* (R = Bz): mp 94–97°C; uv (95% EtOH/H_2O) max 263, 230 nm (ε 8600, 25 000), min 251 nm (ε 7300); ^{1}H nmr ($CDCl_3$) δ: 4.6, 4.8, 5.0 (m, 4, H3′, 4′, 5′, 5″), 5.4–5.8 (m, 3, OH2′, H2′, H5; J_{5-6} = 8.4 Hz with D_2O exchange), 5.83 (s, 1, H1′), 7.2–8.1 (m, 11, Ph's and H6), 10.5 (bs, 1, H3); ms *m/z*: 452 (M^+). *Anal.* calcd. for $C_{23}H_{20}N_2O_8 \cdot 0.7H_2O$ (465.0): C 59.41, H 4.64, N 6.02; found: C 59.33, H 4.38, N 6.07.

*1-(2-Deoxy-β-D-*threo*-pentofuranosyl)uracil (7*d*)*

A mixture of 452.4 mg (0.97 mmol) of **4***d* (R = Bz) hydrate, 261 μL (326 mg, 1.89 mmol) of PhOCSCl, 427 mg (3.5 mmol) of DMAP, and 10 mL of CH_3CN was stirred for 6 h at ambient temperature. Evaporation was followed by work-up as described above for the conversion **4***a* → **6***a* (R = Bz), except ice-cold 1% HOAc in saturated NaCl/H_2O was substituted for the 1 *N* HCl/H_2O wash.

The resulting light-yellow solid foam containing **6***d* (R = Bz) was dissolved in 20 mL of dry $PhCH_3$ and heated with 620 μL (671 mg, 2.3 mmol) of Bu_3SnH and 49 mg (0.3 mmol) of AIBN for 24 h at 80°C. The solution was evaporated and the residue was deprotected by stirring with 540 mg (10 mmol) of NaOMe in 20 mL of MeOH overnight at ambient temperature. This solution was evaporated and the residue partitioned between Et_2O and H_2O. The aqueous phase was neutralized to pH 6.0 with Amberlite 120(H^+) resin, filtered, and evaporated. The residue was chromatographed on a column of silica (MeOH/$CHCl_3$, 1:1) and the product crystallized from absolute EtOH to give 157 mg (71%) of **7***d*: mp 170–171°C (lit. (6) mp 163–165°C); uv (MeOH) max 261 nm (ε 10 100), min 231 nm (ε 2200); ^{1}H nmr δ: 1.87 (dd, $J_{1'-2'}$ = 2.0 Hz, $J_{2'-2''}$ = 14.5 Hz, 1, H2′), 2.55 ("sept", $J_{1'-2''}$ = 8.5 Hz, $J_{2''-3'}$ = 5.2 Hz, 1, H2″), 3.56–3.87 (m, 3, H4′, 5′, 5″), 4.24 (m, 1, H3′), 4.70 ("t", $J_{OH5'-5',5''}$ = 5.5 Hz, 1, OH5′), 5.27 (d, $J_{OH3'-3'}$ = 3.3 Hz, 1, OH3′), 5.65 (d, J_{5-6} = 8 Hz, 1, H5), 6.05 (dd, 1, H1′), 7.92 (d, 1, H6), 11.26 (bs, 1, H3); ^{13}C nmr δ: 163.13 (C4), 150.46 (C2), 141.30 (C6), 101.06 (C5), 85.01 (C4′), 83.75 (C1′), 68.46 (C3′), 59.41 (C5′), 40.74 (C2′); ms *m/z*: 228.0746 (M^+ 228.0746). *Anal.* calcd. for $C_9H_{12}N_2O_5$ (228.2): C 47.37, H 5.30, N 12.28; found: C 47.27, H 5.34, N 11.90.

In the above thioacylation reaction of **4***d* → **6***d* (R = Bz), a second slightly slower migrating (tlc) product was formed in ≳10% yield. It was isolated in essentially pure form by preparative tlc and its ^{13}C nmr spectrum was taken and compared with that of **6***d* (R = Bz). This provides clear evidence for the formation of a dimeric thionocarbonate (**8***d*; R = Bz): δ: 191.11 (C=S), 165.24, 164.32 (2 × 2 C=O), 162.86 (C4), 150.21 (C2), 140.41 (C6), 133.84, 133.42, 129.48, 129.07, 128.99, 128.69, 128.60 (4 × Ph's), 102.15 (C5), 87.83 (C1′), 86.66 (C4′), 77.81 (C2′), 74.73 (C3′), 61.66 (C5′); ^{13}C nmr (**6***d*; R = Bz) δ: 193.11 (C=S), 165.26, 164.43 (2 × C=O), 162.83 (C4), 153.01 (C2), 140.30 (C6), 133.88, 133.44, 127.78, 129.46, 129.08, 129.01, 128.72, 128.62, 128.37, 126.88, 121.49 (3 × Ph's), 102.29 (C5), 87.39 (C1′), 86.67 (C4′), 77.45 (C2′), 74.77 (C3′), 61.80 (C5′).

*1-(2-O-Acetyl-3,5-di-O-benzoyl-β-D-xylofuranosyl)thymine (3*e*)*

To a mixture of 17.96 g (40.6 mmol) of **1** (11) and 5.12 g (40.6 mmol) of thymine (**2***e*) in 650 mL of dry CH_3CN were added 6.92 mL (5.29 g, 32.8 mmol) of $(Me_3Si)_2NH$ and 4.04 mL (3.46 g, 31.8 mmol) of Me_3SiCl, followed by 5.69 mL (12.7 g, 48.6 mmol) of $SnCl_4$. The resulting clear solution was heated for 45 min at reflux while protected from moisture and then cooled to ambient temperature and filtered. The filtrate was evaporated *in vacuo* and 500 mL of $CHCl_3$ was added. This solution was shaken with 350 mL of saturated $NaHCO_3/H_2O$ and the resulting emulsion was filtered using Celite. The filter aid was washed with hot $CHCl_3$ (2 × 200 mL) and the combined organic phase was washed with H_2O (3 × 200 mL), dried (Na_2SO_4), and evaporated. The resulting solid foam (20.6 g) was chromatographed on a column of silica (EtOAc/CH_2Cl_2, 18:82) and appropriate fractions were pooled and evaporated to give 9.5 g (46%) of the title compound, which crystallized from PhH/$i\mathrm{Pr_2O}$ to give **3***e*: mp 87–88°C; uv (95% EtOH/H_2O) max 266, 230 nm (ε 8400; 21 100), min 252 nm (ε 7100); ^{1}H nmr ($CDCl_3$) δ: 1.77 (s, 3, CH_3), 2.16 (s, 3, Ac), 4.7 (m, 3, H4′, 5′, 5″), 5.4 (m, 1, H3′), 5.7 (m, 1, H2′), 6.15 (d, $J_{1'-2'}$ = 2.9 Hz, 1, H1′), 7.2–7.7 and 7.9–8.1 (m, 11, 2 × Bz and H6), 9.48 (bs, 1, H3); ms *m/z*: 508 (M^+). *Anal.* calcd. for

$C_{26}H_{24}N_2O_9 \cdot C_6H_6$ (586.6): C 65.52, H 5.16, N 4.78; found: C 65.38, H 5.05, N 4.85.

*1-(3,5-Di-O-benzoyl-β-D-xylofuranosyl)thymine (**4**e; R = Bz)*

A solution of 5.6 g (9.5 mmol) of **3***e* solvate in 95 mL of $HOAc/C_5H_5N$ (1:4) was treated with 1.63 mL (1.68 g, 33.6 mmol) of $N_2H_4 \cdot H_2O$ and worked up as described above for the conversion of **3***d* → **4***d* (R = Bz). Addition of $CHCl_3$ to the resulting solid foam resulted in crystallization of 4.1 g of the title product. Column chromatography (silica, $EtOAc/CH_2Cl_2$, 4:6) afforded an additional 0.6 g (total 4.7 g, 84%) of **4***e* (R = Bz): mp 97–99°C; uv (95% $EtOH/H_2O$) max 268, 229 nm (ε 6900; 10 100), min 252 nm (ε 6000); ^1H nmr (Me_2SO-$d_6/CDCl_3$) δ: 1.76 (s, 3, CH_3), 4.4 (m, 1, H4′), 4.8 (m, 3, H2′, 5′, 5″), 5.5 (m, 1, H3′), 5.94 (d, $J_{1'-2'}$ = 1.9 Hz, 1, H1′), 6.3 (bs, 1, OH2′), 7.3–7.7 and 7.8–8.1 (m, 11, 2 × Bz and H6), 11.2 (bs, 1, H3); ms *m/z*: 466 (M^+). *Anal.* calcd. for $C_{24}H_{22}N_2O_8 \cdot CHCl_3$ (585.8): C 51.26, H 3.96, N 4.78; found: C 50.93, H 3.92, N 4.55.

*1-(2-Deoxy-β-D-*threo*-pentofuranosyl)thymine (7*e*)*

A mixture of 466 mg (1 mmol) of **4***e* (R = Bz), 250 μL (312 mg, 1.81 mmol) of PhOCSCl, 488 mg (4 mmol) of DMAP, and 10 mL of CH_3CN was stirred for ~20 min at ambient temperature and then worked up as described above for the conversion **4***d* → **6***d* (R = Bz).

The resulting solid foam was subjected to hydrogenolysis as described above for **6***d* (R = Bz) and the resulting oily residue was deprotected by stirring with 20 mL of NH_3/MeOH overnight at ambient temperature. Evaporation and partitioning of the residue between Et_2O and H_2O was followed by evaporation of the aqueous phase and column chromatography of the residue (silica, $MeOH/CHCl_3$, 2:8). Evaporation of appropriately pooled fractions and crystallization of the residue from $MeOH/Et_2O$ (diffusion) (22) gave 190 mg (78%) of **7***e*: mp 174–175°C (lit. (5) mp 170–171°C); uv (MeOH) max 266, 208 nm (ε 9600; 9500), min 233 nm (ε 2200); ^1H nmr δ: 1.77 (s, 3, CH_3), 1.85 (dd, $J_{1'-2'}$ = 2.2 Hz, $J_{2'-2''}$ = 14.5 Hz, 1, H2′), 2.60 ("sept", $J_{1'-2''}$ = 8.5 Hz, $J_{2''-3'}$ = 5.5 Hz, 1, H2″), 3.60–3.85 (m, 3, H4′, 5′, 5″), 4.25 (m, 1, H3′), 4.70 ("t", $J_{OH5'-5',5''}$ = 5.5 Hz, 1, OH5′), 5.26 (d, $J_{OH3'-3'}$ = 3.5 Hz, 1, OH3′), 6.07 (dd, 1, H1′), 7.82 (d, $J_{allylic}$ = 1.2 Hz, 1, H6), 11.24 (bs, 1, H3); ^{13}C nmr δ: 163.99 (C4), 150.77 (C2), 137.35 (C6), 108.83 (C5), 84.95 (C4′), 83.65 (C1′), 68.88 (C3′), 59.79 (C5′), 40.89 (C2′), 12.63 (CH_3); ms *m/z*: 242.0905 (M^+ 242.0903). *Anal.* calcd. for $C_{10}H_{14}N_2O_5$ (242.2): C 49.58, H 5.83, N 11.56; found: C 49.29, H 5.88, N 11.37.

Isotope effects in nucleophilic substitution reactions. VI. The effect of ion pairing on the transition state structure of S_N2 reactions

KENNETH CHARLES WESTAWAY[1] AND ZHU-GEN LAI
Chemistry Department, Laurentian University, Sudbury, Ont., Canada P3E 2C6

Received September 10, 1987

KENNETH CHARLES WESTAWAY and ZHU-GEN LAI. Can. J. Chem. **66**, 1263 (1988).

Spectroscopic and conductivity studies of sodium thiophenoxide solutions in four different solvents and the secondary α-deuterium kinetic isotope effects found in the presence of 15-crown-5 ether demonstrate that the secondary α-deuterium kinetic isotope effect and transition state structure for the S_N2 reaction between sodium thiophenoxide and *n*-butyl chloride are significantly different, depending on whether the ionic reactant is a solvent-separated ion-pair complex or a free ion. In all three solvents in which the form of the ionic reactant changes, a smaller isotope effect and tighter transition state are found for the reaction with the ion-pair complex.

KENNETH CHARLES WESTAWAY et ZHU-GEN LAI. Can. J. Chem. **66**, 1263 (1988).

On a réalisé des études basées sur la spectroscopie ou sur la conductivité de solutions de thiophénolate de sodium dans quatre solvants différents et on a mesuré des effets isotopiques cinétiques secondaires des deutérium en α en présence d'éther 15-couronne-5; l'ensemble de ces résultats démontre que l'effet isotopique cinétique secondaire du deutérium en α ainsi que la structure de l'état de transition de la réaction S_N2 du thiophénolate de sodium avec le chlorure de *n*-butyle sont assez différentes suivant qu'il s'agit d'une paire ionique complexe séparée par un solvant ou d'un ion libre. Dans les trois solvants où il se produit des changements dans la forme des réactifs ioniques, la paire ionique complexe conduit à un plus petit effet isotopique et à un état de transition plus compact.

Introduction

Westaway, Waszczylo, Smith, and Rangappa (1) recently reported that the magnitude of the secondary α-deuterium kinetic isotope effect for an S_N2 or E2 reaction can be concentration dependent, i.e., can change markedly when the concentration of an ionic reactant is altered. For example, the secondary α-deuterium kinetic isotope effect in the S_N2 reaction between *n*-butyl chloride and sodium thiophenoxide in DMF, eq. [1], changes from 1.129 ± 0.010 when the sodium thiophenoxide concentration is 4.0×10^{-3} M to 1.085 ± 0.011 when the sodium thiophenoxide concentration is increased to 8.6×10^{-3} M.

[1] $Na^+ {}^-SC_6H_5 + CH_3CH_2CH_2CL_2Cl \rightarrow CH_3CH_2CH_2CL_2SC_6H_5 + Na^+ {}^-Cl$ (L = H, D)

The authors suggested that the change in the kinetic isotope effect (transition state structure) was the result of a change in the state of the reacting anion from a free thiophenoxide ion to a sodium thiophenoxide ion pair. The work in this paper demonstrates that the change in the magnitude of the secondary α-deuterium kinetic isotope effect for the S_N2 nucleophilic substitution reaction between *n*-butyl chloride and thiophenoxide ion is, indeed, due to a change in the form of the reacting nucleophile from a free thiophenoxide ion to a solvent-separated sodium thiophenoxide ion-pair complex.

Results and discussion

Proof of an ion pair and a free ion reaction

The concentration dependence found for the secondary α-deuterium kinetic isotope effect in the S_N2 (2) reaction between sodium thiophenoxide and *n*-butyl chloride was tentatively attributed to a change in the form of the reacting ion from a sodium thiophenoxide ion pair to a free thiophenoxide ion (1). Conductivity measurements (3), nmr spectroscopy (4, 5), and uv spectroscopy (6, 7) have been used to study the phenomenon of ion pairing. Two of these techniques, uv spectroscopy and conductivity measurements, have been used to determine the concentration ranges where sodium thiophenoxide exists as an ion-pair complex and as a free ion in four different solvents.

Conductivity measurements

The conductance of sodium thiophenoxide solutions of different concentrations was measured in four different solvents, DMSO, DMF, methanol, and diglyme. At low sodium thiophenoxide concentrations, the conductance versus concentration plot was linear. However, at higher concentrations, the plot changed to a concave curve, Fig. 1. The concentration where the slope of the conductance versus concentration plot begins to decrease was taken as the concentration where the form of the sodium thiophenoxide changed from a pair of free ions to an ion-pair complex. The downward curve is found because the conductance resulting from the ion-pair complex is much lower than that caused by the two free ions. The approximate[2] concentrations where the sodium thiophenoxide changes from free ions to an ion-pair complex in each solvent are given in Table 1. The change in the state of the salt occurred at reasonably high concentrations, i.e., at approximately 2.1×10^{-2} M and 6.8×10^{-3} M, in the highly polar aprotic solvents DMSO and DMF, respectively. The change in the form of the salt occurred at significantly lower concentrations, i.e., at approximately 2.3×10^{-4} M, in the less polar methanol. No change in the form of the salt was detected in diglyme and it appears that the sodium thiophenoxide exists as an ion-pair complex in diglyme at all of the concentrations used in this study.

Ultraviolet spectroscopy

The changes that occurred in the uv spectrum when the concentration of the sodium thiophenoxide was varied were also used to determine (confirm) the concentrations where the sodium thiophenoxide changed from a free ion to an ion-pair

[1]Author to whom correspondence may be addressed.

[2]The concentrations are approximate because it is difficult to tell exactly where the curvature begins.

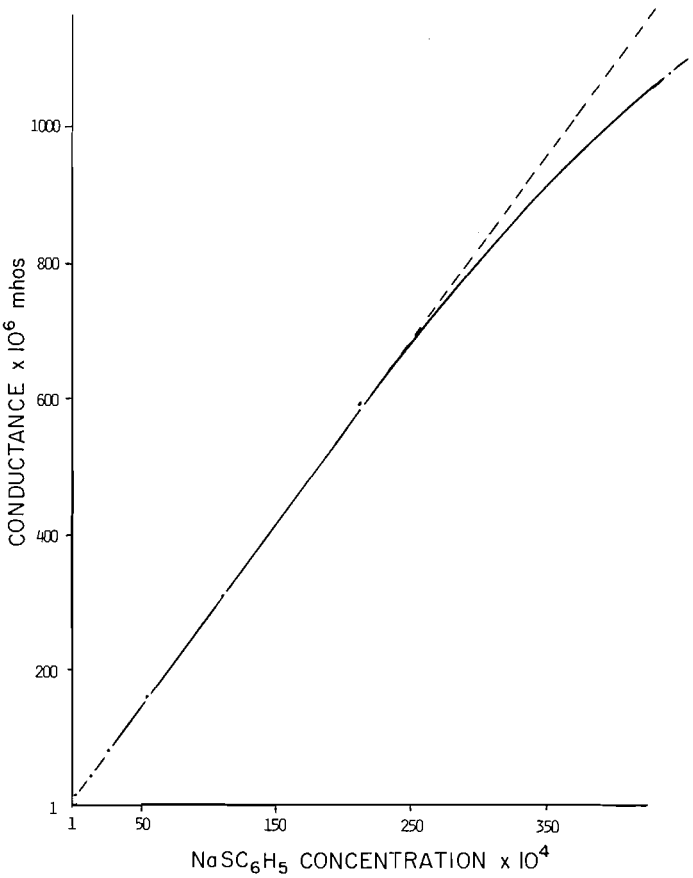

FIG. 1. The conductance versus the sodium thiophenoxide concentration in DMSO at 20°C. Similar curves at different sodium thiophenoxide concentrations were found in methanol and DMF.

TABLE 1. The approximate concentrations where conductivity measurements indicate that sodium thiophenoxide changes from a free ion to an ion-pair complex in DMSO, DMF, methanol, and diglyme at 20°C

Solvent	Concentration where conductivity measurements indicate sodium thiophenoxide changes from free ions to an ion-pair complex (mol/L)
DMSO	2.1×10^{-2}
DMF	6.8×10^{-3}
CH_3OH	2.3×10^{-4}
Diglyme	None

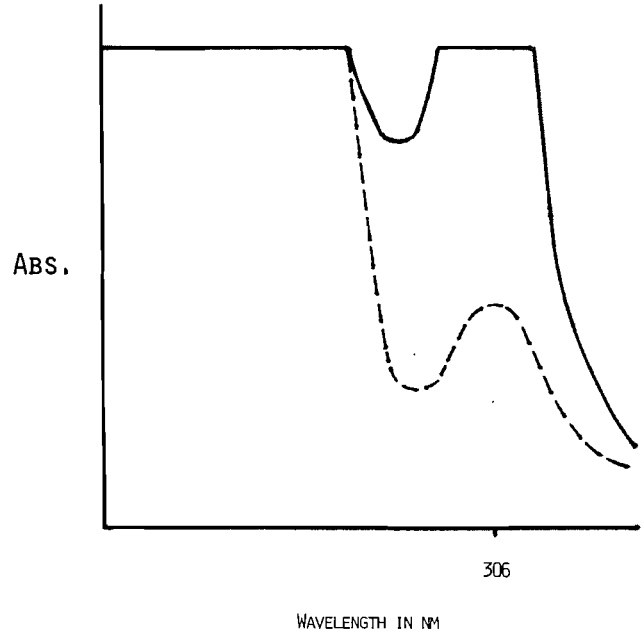

FIG. 2. The ultraviolet spectrum of a 1.2×10^{-2} M solution of the sodium thiophenoxide ion-pair complex on the 0–2 scale (—) and a 6.0×10^{-3} M solution of the free thiophenoxide ion on the 0–1 scale (– – –) in DMF. The same spectral maxima were observed in DMSO at different concentrations.

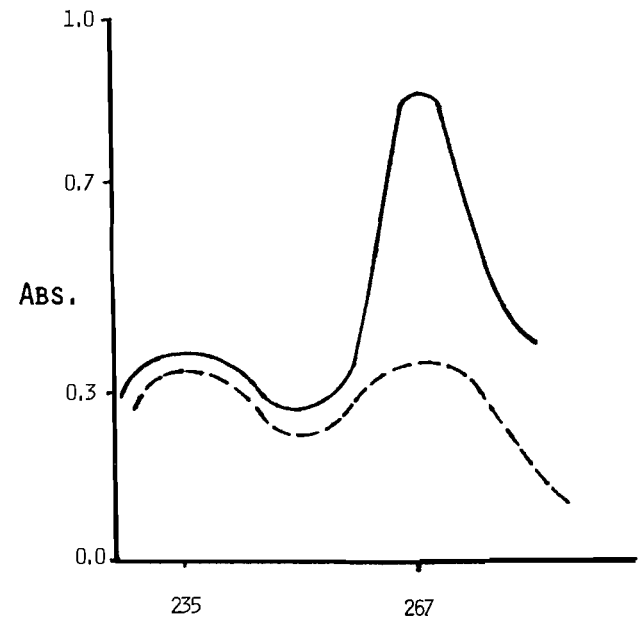

FIG. 3. The ultraviolet spectrum of a 1.2×10^{-4} M solution of the sodium thiophenoxide ion-pair complex (—) and a 6.0×10^{-5} M solution of the free thiophenoxide ion (– – –) in methanol at 20°C.

complex. Two different types of behaviour were observed in these experiments. In DMSO and DMF, the maximum absorbance changed from 306 nm at high concentrations, where the sodium thiophenoxide exists as an ion-pair complex, to a lower wavelength at lower concentrations, where the sodium thiophenoxide exists as free ions, Fig. 2. For example, the change in the form of the ion is demonstrated by the large change in the absorbance (molar extinction coefficient) at 306 nm, i.e., the very large peak found on the 0–2 absorbance scale when the sodium thiophenoxide concentration is 2.5×10^{-2} M is small on the 0–1 scale when the concentration of the sodium thiophenoxide is reduced by a factor of two. Since the molar extinction coefficient is not concentration dependent, the ion-pair complex that causes the absorbance at 306 nm must have been converted to free ions that absorb at a lower wavelength. The maximum absorbance for the free ion, which is hidden by the solvent absorbance, Fig. 2, appears to be near 260 nm. The λ_{max} for the free thiophenoxide ion was found by measuring the ultraviolet spectrum of the salt in 1-mm cells with a DMF–methanol or DMSO–methanol solution in the reference cell. The change in the uv spectrum (the form) of the sodium thiophenoxide occurs between 1.2×10^{-2} M and $6 \times$

TABLE 2. The concentration where the sodium thiophenoxide changes from an ion-pair complex to free ions in DMSO, DMF, methanol, and diglyme at 20°C

Solvent	Concentration where the sodium thiophenoxide changes[a]	
	From an ion-pair complex to free ions using uv spectroscopy	From fee ions to an ion-pair complex using conductivity
DMSO	1.9×10^{-2}	2.1×10^{-2}
DMF	9.0×10^{-3}	6.8×10^{-3}
CH_3OH	9.8×10^{-5}	2.3×10^{-4}
Diglyme	None	None

[a]Since the form of the thiophenoxide ion changes with concentration very rapidly (*vide infra*) these concentrations should be almost identical.

10^{-3} M in DMF and between 2.5×10^{-2} M and 1.2×10^{-2} M in DMSO.

In methanol, the uv spectrum of the sodium thiophenoxide ion-pair complex has a small absorbance at 235 nm and a strong absorbance at 267 nm, Fig. 3. The free ion, on the other hand, has a single absorbance at 235 nm. Thus, the shift from an ion-pair complex to a free ion occurs when the maximum absorbance changes from 267 nm at a sodium thiophenoxide concentration of $>1.3 \times 10^{-4}$ M, where the sodium thiophenoxide is present as an ion-pair complex, to 235 nm, when the sodium thiophenoxide concentration is 6.5×10^{-5} M. The sodium thiophenoxide exists as free ions at concentrations of $<6.5 \times 10^{-5}$ M.

The concentration ranges where uv spectroscopy indicates the sodium thiophenoxide changes from free ions to an ion-pair complex are given in Table 2. Again, the change from an ion-pair complex to free ions occurred at the highest concentrations in DMSO and DMF. The change in the form of the salt occurred at much lower concentrations in methanol and was not observed at any of the concentrations used in diglyme. Finally, a comparison of the concentrations where the conductivity and the uv results indicate sodium thiophenoxide changes from an ion-pair complex to free ions, Table 2, shows that the agreement between the two methods is excellent.

An interesting observation is the higher energy absorbance found in the uv spectra of the free ion. Although this relationship was not expected, CNDO/2 calculations of the energies of the highest occupied and lowest unoccupied π molecular orbitals of the free thiophenoxide ion and the sodium thiophenoxide ion pair in methanol suggest that the observed uv absorbances are correct. In fact, the calculated difference between the excitation wavelengths of the free ion and ion pair are almost equal to the observed differences in the wavelengths. This also supports the assignment of the ion pair and the free ion in the uv spectra.

Ion pairing and the secondary α-deuterium kinetic isotope effect

Once the concentration ranges in which the different forms of the nucleophilic species existed in the different solvents were known, the secondary α-deuterium kinetic isotope effects for the S_N2 reaction between *n*-butyl chloride and sodium thiophenoxide were determined at sodium thiophenoxide concentrations where the uv and conductivity studies indicated that the nucleophile existed as a free ion and as a solvent-separated ion-pair complex. The results in Table 3 indicate that the magnitude of the isotope effect changes in every solvent when the form of the thiophenoxide ion changes. It is important to note that there is no change in the kinetic isotope effect in diglyme even though the changes in concentration of the sodium thiophenoxide were larger than those made in the other solvents. This obviously is because the sodium thiophenoxide reacts as an ion pair at all concentrations in diglyme.

The isotope effects measured in the different solvents are interesting for another reason. A plot of the sodium thiophenoxide concentration where the secondary α-deuterium kinetic isotope effect (the form of the ionic reactant changes from an ion-pair complex to free ions) changes in DMSO, DMF, and methanol versus the dielectric constant of the solvent, Fig. 4, has a correlation coefficient of 0.9986 for the least-squares straight line. Although the data for this plot have only been obtained from three solvents, the very high correlation coefficient suggests that the concentrations where ion pairing becomes important can be estimated for a particular salt from the dielectric constant of the solvent. This relationship is to be expected, because the association constant for a salt in organic solvents is linearly related to the dielectric constant of the solvent (8).

The hypothesis that the magnitude of the secondary α-deuterium kinetic isotope effect is dependent on the form of the reacting anion was further confirmed by measuring the secondary α-deuterium kinetic isotope effects for the S_N2 *n*-butyl chloride – sodium thiophenoxide reaction in the presence of 15-crown-5 ether. The 15-crown-5 ether solvates sodium ions extremely well (9) and ensures that the sodium thiophenoxide exists as free ions even at concentrations where it usually exists as an ion-pair complex. When the 15-crown-5 ether was added to a reaction in which the sodium thiophenoxide was normally present as the ion-pair complex in DMF, Table 4, the secondary α-deuterium kinetic isotope effect changed markedly. In fact, the isotope effect of 1.127 ± 0.016 found in the presence of 15-crown-5 ether at high sodium thiophenoxide concentrations, where the sodium thiophenoxide usually reacts as an ion-pair complex, is identical to the $k_H/k_D = 1.129 \pm 0.010$ found when the thiophenoxide reacts as a free ion. An experiment was also done to ensure that the 15-crown-5 ether does not affect the isotope effect in the free ion reaction, Table 4. The secondary α-deuterium kinetic isotope effect of 1.128 ± 0.013 in the crown ether reaction, at concentrations where the sodium thiophenoxide usually reacts as a free ion, demonstrates that the change in the isotope effect is, indeed, the result of the change in the form of the reacting ion and not due to the 15-crown-5 ether.

Finally, the secondary α-deuterium kinetic isotope effects were measured at several different sodium thiophenoxide concentrations to ensure that the isotope effect only changed when the form of the reacting anion was altered and not when the sodium thiophenoxide concentrations were changed. The α-deuterium kinetic isotope effects found for a wide range of sodium thiophenoxide concentrations in DMF, Table 5, Fig. 5, show that the isotope effect changes very rapidly at a specific concentration (where the conductivity and uv spectroscopy indicate that the form of the reacting anion changes) and then remains constant when the concentration of the salt is either increased or decreased. Thus, the change in the secondary α-deuterium kinetic isotope effect (transition state structure) only occurs over a very narrow range of concentrations when the form of the nucleophile changes. It is important to note that the changes in the secondary α-deuterium kinetic isotope effects occur at the concentrations where the conductivity and

[a]Each isotope effect was determined with a different batch of solvent and often by a different worker.
[b]The errors are the standard deviation of at least three different kinetic runs.
[c]The error is $1/k_D[(\Delta k_H)^2 + (k_H/k_D)^2 \times (\Delta k_D)^2]^{1/2}$ where Δk_H and Δk_D are the standard deviations for the rate constants for the undeuterated and deuterated substrates, respectively (1).

uv spectroscopy indicate that the form of the reacting sodium thiophenoxide changes, Tables 2 and 4. What is surprising is how sharply the form of the nucleophile changes, i.e., the isotope effects and uv spectra suggest that the reacting nucleophile is completely different when the concentration of the salt changes by a factor of two.

Since the secondary α-deuterium kinetic isotope effect changes when, and only when, the form of the reacting nucleophile changes, the change in the secondary α-deuterium kinetic isotope effect must be due to a change in the form of the reacting ion (nucleophile) from a free ion to a solvent-separated ion-pair complex.

Type of ion pair

If one is to understand the effect of ion pairing on the secondary α-deuterium kinetic isotope effect and transition state structure of an S_N2 reaction, it is important to know the form of the ion pair. One way of determining the type of ion pair is to determine how a change in the cation affects the uv spectrum of the ion pair (6, 7). If a contact ion pair is present, a change in cation, e.g., from lithium to cesium, will cause a large shift in the λ_{max} of the ion pair. With a solvent-separated ion pair, on the other hand, the cation and the chromophore are separated and a change in cation has little or no effect on the λ_{max}. Accordingly, the uv spectra of lithium, sodium, and cesium thiophenoxides were measured in DMSO, DMF, methanol, and diglyme, at concentrations where the salts were known to exist as the ion-pair complex. The λ_{max} for these salts, Table 6, was independent of the cation in DMSO, DMF, and methanol. Thus, the ion-pair reactant in these three solvents is the solvent-separated ion pair.

Although the situation is different in diglyme, it appears that the solvent-separated ion pair is also the reacting species when sodium thiophenoxide is used in this solvent. The uv spectrum of the lithium thiophenoxide ion-pair complex, with a λ_{max} at 325 nm, is significantly different from that for the sodium and cesium thiophenoxide ion-pair complexes, which have a weak λ_{max} at 304 ± 2 nm. This suggests that the lithium salt exists as a contact ion pair in diglyme. However, sodium and cesium thiophenoxide, which have almost identical uv spectra, appear to exist as solvent-separated ion-pair complexes in diglyme. Thus, the sodium thiophenoxide appears to exist as a solvent-separated ion-pair complex in all of the solvents used in this study.

Although the uv spectra of the alkali metal thiophenoxides show that the sulfur end of the ion-pair reactant is a solvent-separated ion pair, the extremely sharp change in the uv spectrum and in the secondary α-deuterium kinetic isotope

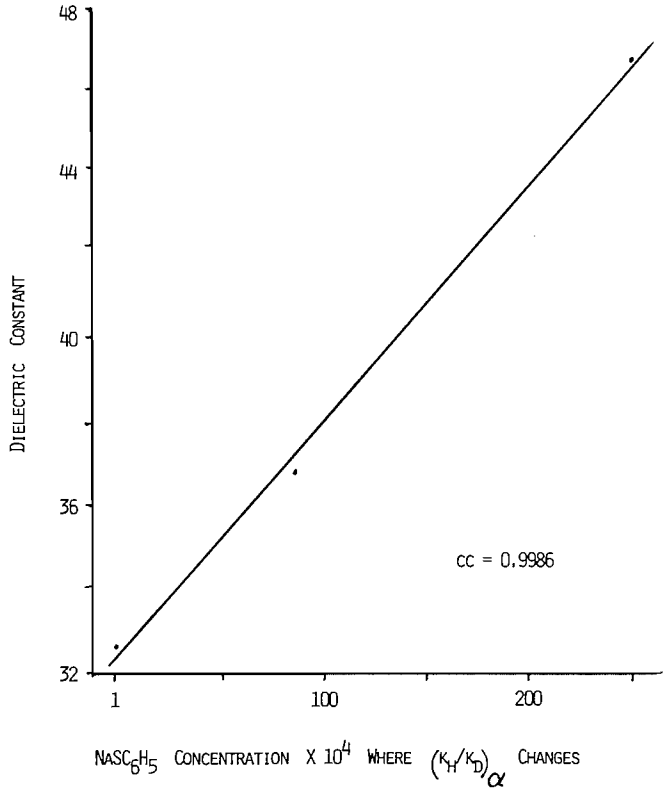

FIG. 4. A plot of the dielectric constant of the solvent versus the sodium thiophenoxide concentration where the secondary α-deuterium kinetic isotope effect changes.

effects with concentration indicates that the solvent-separated ion pair is not simple. In fact, if the ion pair consisted of a pair of ions, one would have to change the concentration of the salt by nearly 1000 times to convert most of the free ion into the ion pair. The extremely rapid change in the form of the reacting anion suggests that the solvent-separated ion pair must exist as a complex consisting of several solvent-separated sodium thiophenoxide ion pairs, eq. [2].

[2] $m\,Na^+ + m\,SC_6H_5^- \rightleftarrows (Na^+(solvent)_n\,(SC_6H_5^-))_m$

All of the experimental findings are consistent with such an equilibrium. First, the form of the reacting anion would change rapidly with concentration if this equilibrium existed. Thus, the rapid change that is observed in the uv spectra and in the secondary α-deuterium kinetic isotope effects, is expected. The conductivity data are also consistent with the formation of the ion-pair complex because the conductance of a complex ion is lower than that of the free ions (10). Finally, the ion-pair complex cannot form in the presence of 15-crown-5 ether because the sodium ions are complexed by the crown ether. Thus, the secondary α-deuterium kinetic isotope effects in the reactions containing 15-crown-5 ether should be identical to those found in the free ion reactions. This is observed.

Effect of a change in the form of the nucleophile on transition state structure

In each solvent where the reacting nucleophile changes, the secondary α-deuterium kinetic isotope effect is smaller in the reaction involving the ion-pair complex, i.e., the isotope effect is reduced from 1.12 for the free ion reaction to 1.03 in the ion-pair complex reaction in DMSO, from 1.13 to 1.08 in DMF,

[a]These isotope effects were calculated from single rate constants measured for the deuterated and undeuterated substrates. The average isotope effect over this range of concentrations is 1.084 ± 0.023.

[b]The error is $1/k_D[(\Delta k_H)^2 + (k_H/k_D)^2 \times (\Delta k_D)^2]^{1/2}$ where Δk_H and Δk_D are the standard deviations for the rate constants for the undeuterated and deuterated substrates, respectively (1).

and from 1.13 to 1.10 in methanol. The C_α—H(D) out-of-plane bending vibrations, which are primarily responsible for determining the magnitude of a secondary α-deuterium kinetic isotope effect (11), will be the same in the initial state of every reaction. As a result, the different secondary α-deuterium kinetic isotope effects for the free ion and ion-pair complex reactions reflect differences in the energy of the C_α—H(D) out-of-plane bending vibrations in the S_N2 transition states (transition state structure). Since a smaller secondary α-deuterium kinetic isotope effect is observed when the C_α—H(D) out-of-plane bending vibrations are sterically hindered (higher energy) in the transition state, it appears that the S_N2 transition states for the solvent-separated ion-pair complex reactions are more sterically crowded than those for the free ion reactions. Although the sodium atom of the ion-pair complex could

TABLE 6. The absorption wavelength for the lithium, sodium, and cesium thiophenoxide ion pairs in DMSO, DMF, methanol, and diglyme at 20°C

	λ_{max} (nm)			
Salt	DMSO	DMF	CH_3OH	Diglyme
$C_6H_5S^-\ Li^+$	305	308	266	325

increase the steric crowding around the C_α—H(D) bonds (the energy of the out-of-plane bending vibrations) in the S_N2 transition state of the ion-pair reaction, these isotope effects are more likely the result of a tighter transition state with shorter α-carbon–nucleophile and (or) α-carbon – leaving group bonds. This rationale is preferred because the sodium atom of the solvent-separated ion-pair complex is some distance away from the α carbon in the transition state. This separation between the sodium ion of the solvent-separated ion-pair complex and the C_α—H(D) transition state bonds is required because (*i*) the secondary α-deuterium kinetic isotope effects are large and normal, indicating that the transition states are loose with reasonably long α-carbon–nucleophile and α-carbon – leaving group bonds; (*ii*) the sodium atom of the solvent-separated ion pair is separated from the sulfur by at least one solvent molecule, and is far from the large, tetrahedral sulfur atom and, therefore, from the smaller α carbon; and (*iii*) the sodium ion will be associated with a nonreacting lone pair of electrons on the sulfur atom and will not be near the bonding electrons in the transition state. Since the sodium ion will not be near the lone pair of sulfur electrons that are forming the bond or to the very short C_α—H(D) bonds on the S----Cα----Cl axis of the S_N2 transition state, it should not affect the C_α—H(D) out-of-plane bending vibrations in the transition state. As a

Correlation coefficient	0.998	0.998

result, the smaller isotope effects in the ion-pair complex reactions must indicate that the transition states for these reactions are tighter than those for the free ion reactions. This is, in fact, expected because the negative charge on the nucleophilic atom of the ion pair is less than that of a free thiophenoxide ion[3] and the sulfur atom should have to be closer to the α carbon before it distorts the α-carbon–chlorine bond and displaces the leaving group. Thus, these results suggest that the S_N2 transition states for the ion-pair complex reactions are tighter, with shorter nucleophile–α-carbon and (or) α-carbon–leaving group bonds, than those in the free ion reactions.

It is important to note, however, that the secondary α-deuterium kinetic isotope effect for the reaction of the ion-pair complex in diglyme appears to be slightly larger (k_H/k_D = 1.14) than that for the free ion reactions (k_H/k_D = 1.126 ± 0.007). Thus, the ion-pair transition state in diglyme appears to be looser than that for the free ion reactions. This may arise because the sodium thiophenoxide ion pair is very weakly solvated in the slightly polar diglyme and the influence of the nucleophilic sulfur is felt at larger distances from the α-carbon.

The Hammett ρ values, obtained by changing the *para* substituent on the nucleophile, were determined for both the ion-pair complex and the free ion reactions, Table 7, in an effort to learn more about the relative lengths of the α-carbon–nucleophile bonds in the S_N2 transition states of these reactions. Although the Hammett ρ value for the free ion reaction is slightly larger, the free ion and ion-pair complex ρ values are statistically the same. Thus, this technique does not appear to be useful in distinguishing between the lengths of the α-carbon–nucleophile bonds in the free ion and ion-pair transition states.

Finally, it is interesting to investigate the magnitude of the change in the isotope effects for the ion-pair complex and the free ion reactions in the different solvents. The change in the secondary α-deuterium kinetic isotope effect when the form of the reacting ion changes is large in the dipolar aprotic solvents, DMSO and DMF, and much smaller in the protic solvent, methanol. The change in the magnitude of the isotope effect might be smaller in methanol because hydrogen bonding to the thiophenoxide ion in methanol lowers the electron density on the sulfur atom of the free ion in the same way the sodium ion does in the ion-pair complex. If this is so, the negative charge on the sulfur of the thiophenoxide ion in the free ion reaction in methanol will be lower than that on the free ions in DMSO and DMF where the anion is only weakly solvated. As a result, one would expect the change in charge on the nucleophilic sulfur atom (the change in the magnitude of the secondary α-deuterium kinetic isotope effect) to be smaller in going from the free "solvated" ion reaction to the ion-pair complex reaction in methanol than in the dipolar aprotic solvents, DMSO and DMF.

[3]Z.-g. Lai and K. C. Westaway. Submitted to Can. J. Chem.

Conclusions

The results obtained from spectroscopic and conductivity measurements of sodium thiophenoxide solutions in four different solvents, as well as the secondary α-deuterium kinetic isotope effects found with 15-crown-5 ether, demonstrate that the secondary α-deuterium kinetic isotope effects in the S_N2 reaction between sodium thiophenoxide and *n*-butyl chloride are significantly different when the ionic reactant is a solvent-separated ion-pair complex than when this reactant is a free ion. In all three solvents in which the form of the ionic reactant changes, a smaller isotope effect and tighter transition state are found for the reaction involving the ion pair complex.

Experimental

Preparation of reagents

Solvents

Oxygen, which reacts with the thiophenoxide ion, was removed from each solvent by bubbling extra-dry nitrogen through the solvent for 1 h. The DMSO and DMF were dried, and distilled in glass grade solvents purchased from Caledon Laboratories. Diglyme was purchased from Eastman. The DMSO was used directly. The diglyme and the DMF were further purified by distillation from sodium thiophenoxide in an extra-dry nitrogen atmosphere. Analar methanol was distilled in an extra-dry nitrogen atmosphere before use. The 15-crown-5 ether purchased from Parrish Chemical Co. was used without further purification.

para-*Substituted sodium thiophenoxides*

The preparation of these salts is described elsewhere (13).

n-*Butyl chloride*

Reagent grade *n*-butyl chloride was distilled and stored under extra-dry nitrogen.

n-*Butyl-1,1*-d_2 *chloride*

Methyl butyrate: 20 g (0.62 mol) of methanol was added dropwise to a cold mixture of 92 g (1.04 mol) of butyric acid and 15 mL of concentrated sulfuric acid. When the addition was complete, the mixture was refluxed overnight and then poured into 150 mL of a 4.0 M solution of sodium hydroxide. The organic layer was separated and washed twice with 100 mL of water, once with 100 mL of a 5% sodium bicarbonate solution, and twice with 100-mL portions of water. After drying over anhydrous magnesium sulfate, the organic layer was distilled to give 26.4 g (41.4%) of methyl butyrate, bp 100–101°C (lit.(14) bp 102.3°C).

n-*Butyl-1-1*d_2 *alcohol*: 1.2 L of dry (freshly distilled from lithium aluminum hydride) ether was placed in a 2-L three-necked flask fitted with a condenser and a dropping funnel, which were both sealed with a drying tube. Lithium aluminum deuteride (Merck) (10 g, 0.238 mol) was added to the dry ether and a solution comprised of 41.4 g (0.402 mol) of methyl butyrate and 200 mL dry ether was added, dropwise, from the dropping funnel. When all of the ester had been added, the mixture was refluxed overnight. Then the mixture was cooled and the excess lithium aluminum deuteride decomposed by adding a 10% solution of sulfuric acid in water, dropwise, until the mixture was homogeneous. The ether layer was separated and the aqueous layer was extracted twice with 200 mL of ether. The ether layers were combined, washed twice with 50 mL of water, once with 50 mL of 5% sodium bicarbonate, and again with 50 mL of water. After most of the ether had been removed on a rotary evaporator, distillation of the alcohol gave two fractions, bp 80–114°C and 114–116°C. The 80–114°C fraction was redistilled and the 114–116°C fraction collected. This gave 19.3 g (53%) of *n*-butyl-1,1-d_2 alcohol, bp 114–116°C (lit.(14) bp 117°C).

An nmr analysis indicated that the alcohol was more than 98.5% deuterated at the one position.

n-*Butyl-1,1*-d_2 *chloride*: 30 g (0.25 mol) of thionyl chloride was cooled to 5°C and 18.8 g (0.25 mol) of *n*-butyl-1,1-d_2 alcohol was added dropwise. When the addition was complete, 15 drops of pyridine were added and the mixture was heated at 70°C for 5 h. Three condensers were used to keep losses to a minimum. The reaction mixture was poured into 40 mL of water and the organic layer was separated, washed twice with 50 mL of water, twice with 50 mL of 10% sodium hydroxide, and twice with 50 mL of water. After the product had been dried over anhydrous magnesium sulfate, a distillation gave 18.7 g (79%) of *n*-butyl-1,1-d_2 chloride, bp 76–77°C (lit. (14) bp 78.4°C). An nmr analysis indicated that the sample was at least 99% deuterated at the α-carbon.

Conductivity and ultraviolet measurements

The solutions used for the conductivity and uv spectroscopy studies were prepared in a nitrogen atmosphere to prevent oxidation of the thiophenoxide ion. A 50-mL volumetric flask was filled with extra-dry nitrogen and weighed accurately. Then the sodium thiophenoxide and the 50 mL volumetric flask were placed in a IR^2 glove bag, which was filled, evacuated, and refilled with extra-dry nitrogen. Between 10 and 170 mg (7.6×10^{-5} and 1.3×10^{-3} mol depending on the solvent) of sodium thiophenoxide was placed in the volumetric flask. The flask was resealed, removed from the glove bag, and reweighed accurately.

The flask containing the sodium thiophenoxide, 10 50-mL volumetric flasks, three 50-mL glass-stoppered Erlenmeyer flasks, 10 25-mL pipettes, a 1-mL pipette, and the appropriate oxygen-free solvent were placed in the glove bag under a nitrogen atmosphere (*vide supra*). The solvent was added to the volumetric flask containing the sodium thiophenoxide and 1-mL samples of this solution were pipetted into the three 50-mL Erlenmeyer flasks. Then, 25 mL of this solution was pipetted into a new volumetric flask and diluted to 50 mL. This procedure was repeated until 11 solutions of varying concentration had been made. When all 10 dilutions were made, the glove bag was opened, the concentration of the thiophenoxide ion in the original solution was determined by titrating with standard mercury II nitrate (15), and the uv spectrum and the conductance of each solution were determined.

The uv spectra were recorded on Hitachi Perkin–Elmer 124 double beam and Beckman DU-65 spectrophotometers. The uv spectra in DMSO and DMF were recorded in 1-mm quartz cells to reduce the absorbance from the solvent. The spectra in methanol were recorded in 10-mm quartz cells. Methanol was used in the reference cell throughout the study.

The conductance of the sodium thiophenoxide solutions was determined by two methods. One method involved using a conductivity bridge that was capable of measuring resistances between 0.1 and 110 000 ohms to within 0.1% (16). The second method was used to measure very high resistances, i.e., up to several million ohms. This was done by measuring the current, I, in microamps, which passed through a conductivity cell when a known voltage, V, was placed across the cell. The conductance of the solution (1/R) is equal to I/V. The conductivity bridge method was used for the solutions in DMSO and DMF. The second method was used for the methanol solutions.

Kinetic measurements

All of the apparatus was cleaned with cleaning solution and distilled water and then dried at 140°C. To ensure a water-free environment, the apparatus was either sealed while hot or was cooled in a desiccator.

A stoppered 250-mL Erlenmeyer was filled with extra-dry nitrogen and weighed accurately. This flask, a bottle of sodium thiophenoxide, a spatula, a crude balance, and some Kimwipes were placed in an IR^2 glove bag. The bag was sealed and the tops removed from the Erlenmeyer and the sodium thiophenoxide. Then the bag was filled with extra-dry nitrogen, evacuated, and refilled. The appropriate amount (between 2 and 730 mg, depending on the solvent) of sodium thiophenoxide was placed in the Erlenmeyer flask, which was sealed, removed from the glove bag, and weighed accurately.

The Erlenmeyer containing the sodium thiophenoxide, an adapter fitted with a serum cap, a bottle of purified (*vide supra*) solvent, and a 250-mL graduated cylinder were placed in a glove bag, which was filled, evacuated, and refilled with extra-dry nitrogen. Approximately 220 mL of solvent was added to the Erlenmeyer and the flask was stoppered with the adapter and the serum cap. This solution was stored in a nitrogen atmosphere overnight.

The sodium thiophenoxide solution, two 125-mL Erlenmeyer flasks fitted with adapters and serum caps, three stoppered, 50-mL Erlenmeyer flasks, a 75-mL and a 5-mL pipette, and a rubber bulb were placed in the glove bag under a nitrogen atmosphere (*vide supra*). Then 75 mL of the sodium thiophenoxide solution was pipetted into each 125-mL Erlenmeyer flask and 5 mL of the sodium thiophenoxide solution was placed in each 50-mL Erlenmeyer flask.

The reaction vessels were temperature equilibrated for at least 0.75 h at 20.00 ± 0.02°C. The purity of the sodium thiophenoxide solution was determined by titrating the 5-mL samples with standard mercury II nitrate (15). Finally, the kinetic run was begun by injecting the appropriate amount of *n*-butyl chloride through the serum cap with an airtight syringe. The end of the syringe containing the *n*-butyl chloride was sealed with a rubber serum cap and weighed accurately before and after the addition of the *n*-butyl chloride.

The same general procedure was used in the kinetic runs with 15-crown-5 ether. The only difference was that approximately 1.1 equivalents (relative to the sodium thiophenoxide) of the 15-crown-5 ether was added to the reaction flask with a gastight syringe a few minutes before the *n*-butyl chloride was added.

The kinetic data were obtained by withdrawing aliquots of the reaction mixture at various times throughout the run. These samples were analyzed in two different ways. Ultraviolet spectroscopy was used for the fast reactions in DMSO, DMF, and diglyme. An electrochemical titration (17) was used for the extremely slow reactions with relatively high concentrations of sodium thiophenoxide in methanol.

In the uv method, 1-mL aliquots of the reaction mixture were withdrawn with a 1-mL gastight syringe fitted with a 6-in. needle. Each sample was quenched by diluting it to 50 mL with a 0.13% mixture (v/v) of sulfuric acid in methanol. The absorbance was followed at 262 nm using the 0.13% solution of sulfuric acid in methanol in the reference cell. The procedure used for determining the rate constants has been described previously (11).

In the electrochemical method, 5-mL aliquots were withdrawn with a 5-mL gastight syringe fitted with a 6-in. needle and quenched by diluting them to 25 mL with methanol. Both the chloride ion and the thiophenoxide ion were titrated with standard 0.1 M silver nitrate. The endpoint for the chloride titration was at 250 mV, whereas the endpoint for the thiophenoxide ion was at −100 mV. The rate constant was calculated using the chloride ion concentrations and the normal equation for a second-order reaction that is first order in each reactant (12).

Reactions of the bisphosphine monochalcogenides, $[Ph_2PCH_2P(Y)R_2]$, Y = O, S, or Se, R = Ph, Pr^i, or Bu^t, with the chloro-bridged dimers $[M_2Cl_4(PR'_3)_2]$, M = Pd or Pt, R′ = Et or Bu^n, in the presence of either $NaClO_4$ or $NaBF_4$ yield perchlorate and fluoroborate salts of the complex cations *cis*- and *trans*-$[PtCl(PR'_3)\{Ph_2PCH_2P(Y)R_2\}]^+$. In many cases both *cis* and *trans* isomers (defined by the relative orientation of the two M—P bonds) are obtained and the precise isomer distribution is a sensitive function of the substituents. Corresponding neutral complexes, *cis*- and *trans*-$[PtCl(PR'_3)\{Ph_2PCHP(Y)R_2\}]$, can be synthesized either by deprotonation of the cations using NaH or by use of the salts $Li[Ph_2PCHP(Y)R_2]$ in the initial bridge cleavage reactions. These and related complexes are characterized by complete ^{13}C, ^{31}P, ^{77}Se, and ^{195}Pt NMR studies and by two crystal structure determinations. The complexes **I**, *trans*-$[PtCl(PEt_3)\{Bu'_2PCH_2P(O)Me_2\}][ClO_4]$, and **II**, *trans*-$[PtCl(PEt_3)\{Ph_2PCH_2P(S)Bu'_2\}][ClO_4]$, crystallize in the monoclinic space group $P2_1/c$, respective cell dimensions: a = 15.579(2), b = 13.590(3), c = 13.578(1) Å; β = 105.96(1)°; and a = 14.002(4), b = 16.366(5), c = 15.524(5) Å; β = 106.01(3)°. Complete X-ray diffraction studies show that both complexes contain closely square planar platinum centres with the $R_2PCH_2P(Y)R'_2$ ligands coordinated via phosphorus and the Y atom so as to form five-membered chelate rings. The molecular dimensions suggest that the bond to sulphur is stronger than that to oxygen and exerts a larger *trans* influence.

DAVID ERIC BERRY, JANE BROWNING, KEITH ROGER DIXON, et ROBERT WAYNE HILTS. Can. J. Chem. **66**, 1272 (1988).

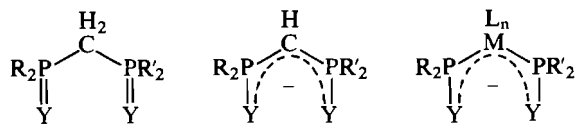
En présence soit de $NaClO_4$ ou de $NaBF_4$, les chalcogénures de bisphosphines, $[Ph_2PCH_2P(Y)R_2]$ dans lesquels Y = O, S ou Se et R = Ph, *i*-Pr ou *tert*-Bu, réagissent avec les dimères pontés par le chlore, $[M_2Cl_4(PR'_3)_2]$ dans lesquels M = Pd ou Pt et R′ = Et ou *n*-Bu, pour donner les perchlorates et les fluoroborates des cations complexes *cis*- et *trans*-$[PtCl(PR'_3)\{Ph_2PCH_2P(Y)R_2\}]^+$. Dans plusieurs cas, on obtient les deux isomères *cis* et *trans* (définis par rapport à l'orientation des deux liaisons M—P) et la distribution précise des isomères est très sensible à la nature des substitutants. On peut synthétiser les complexes neutres correspondants, *cis*- et *trans*-$[PtCl(PR'_3)\{Ph_2PCHP(Y)R_2\}]$, soit par une déprotonation des cations à l'aide de NaH soit en utilisant les sels de $Li[Ph_2PCHP(Y)R_2]$ lors des réactions initiales de clivage des ponts. On a caractérisé ces complexes ainsi que d'autres à l'aide d'études rmn complètes du ^{13}C, du ^{31}P, du ^{77}Se et du ^{195}Pt ainsi que par deux déterminations de structures cristallines. Les complexes **I**, *trans*-$[PtCl(PEt_3)\{tert\text{-}Bu_2PCH_2P(O)Me_2\}][ClO_4]$, et **II**, *trans*-$[PtCl(PEt_3)\{Ph_2PCH_2P(S)tert\text{-}Bu_2\}][ClO_4]$,cristallisent dans le groupe d'espace monoclinique $P2_1/c$ avec les dimensions respectives suivantes: a = 15,579(2), b = 13,590(3) et c = 13,578(1) Å et β = 105,96(1)° et a = 14,002(4), b = 16,366(5) et c = 15,524(5) Å et β = 106,01°. Les études complètes de diffraction des rayons-X démontrent que les deux complexes contiennent des centres de platine qui sont assez près du plan carré et que les ligands $R_2PCH_2P(Y)R'_2$ sont coordonnés au phosphore et à l'atome Y pour former des cycles de chélates à cinq chaînons. Les dimensions des molécules suggèrent que le liaison avec le soufre est beaucoup plus forte que celle avec l'oxygène et qu'elle exerce une influence trans beaucoup plus forte.

[Traduit par la revue]

Introduction

The potentially bidentate ligands, $[R_2PCH_2P(Y)R'_2]$, Y = O, S, or Se, were first synthesised and studied by Grim and co-workers approximately ten years ago (1–5). These authors reported extensive ^{31}P nuclear magnetic resonance (NMR) data including coordination complexes of the ligands with chromium, molybdenum and tungsten carbonyls. Subsequent to these studies very few coordination complexes of these ligands have been described in the literature, except for very recent reports of the reaction of $[Ph_2PCH_2P(O)Ph_2]$ with $[PtCl_2(COD)]$ (6), and of formation of $[Ph_2PCH_2P(Se)Ph_2]$ platinum complexes by selenium extrusion from complexes of the diselenide (7). Moreover, no X-ray structural studies of $[R_2PCH_2P(Y)R'_2]$ complexes have been reported.

We became interested in these ligands as part of a wide-ranging study of platinum group metal complexes involving ligands such as **1**, **2**, or **3**, which are loosely analogous to acetylacetone or acetylacetonate (8, 9). Some of this work had shown particularly interesting dynamic stereochemistry in cases



1 **2** **3**

where the ligands were bound by one strong, relatively inert, bond and one weaker, relatively labile, bond (9, 10). For example, **2** can be bound to a metal via a strong bond to carbon and a relatively weak bond to a Y atom. The $[R_2PCH_2P(Y)R'_2]$ ligands are further examples of this possibility since the most likely mode of coordination is a five-membered chelate ring with a strong bond to the PR_2 group and a weaker bond to the Y atom.

The present paper describes studies of a wide range of platinum and palladium complexes of $[R_2PCH_2P(Y)R'_2]$ and $[R_2PCHP(Y)R'_2]^-$ ligands. These appear to be the first examples of platinum group complexes of the anionic ligands, although mercury complexes of $[Ph_2PCHP(Y)Ph_2]^-$, Y = S or Se, have been described recently (11, 12). Characterization is primarily by detailed NMR studies but we also report the crystal and molecular structures of two of the complexes, **I**, *trans*-

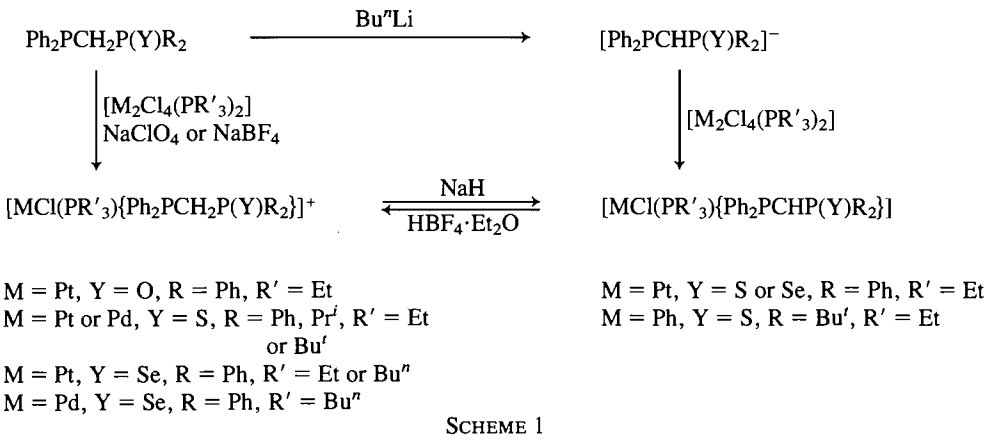


SCHEME 1

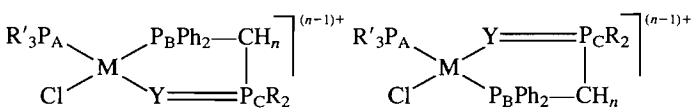
$[PtCl(PEt_3)\{Bu^t_2PCH_2P(O)Me_2\}][ClO_4]$ and, **II**, *trans*-$[PtCl(PEt_3)\{Ph_2PCH_2P(S)Bu^t_2\}][ClO_4]$. Future publications will deal with complexes of the same ligands with other platinum group metals and with the platinum group coordination chemistry of the related $[R_2P(Y)CH_2P(Y)R'_2]$ and $[R_2P(Y)CHP(Y)R'_2]^-$ ligands.

Results and discussion

(A) Synthesis

The ligands, $[Ph_2PCH_2P(Y)Ph_2]$ were prepared as previously described (1–3). For Y = O or S, $P(Y)Ph_3$ was reacted with methyl lithium to yield $[Ph_2P(Y)CH_2]Li$, followed by combination of the lithium salt with Ph_2PCl, and for Y = Se, $[Ph_2PCH_2PPH_2]$ was oxidized by elemental selenium (3). Previous preparations of the alkyl derivatives, $[Ph_2PCH_2P(S)R_2]$, R = Pr^i or Bu^t, have utilised similar procedures with $[Ph_2P(S)CH_2]Li$ and R_2PCl followed by sulphur transfer reactions (4). However, we have found it more satisfactory to obtain these ligands by reaction of $[Ph_2PCH_2]Li$ with R_2PCl followed by oxidation of the resulting $[Ph_2PCH_2PR_2]$ under reflux in benzene with one mole of elemental sulphur. The much higher reactivity of the dialkylphosphino group relative to the diphenylphosphino group ensures exclusive formation of the desired product.

Cleavage reactions of the chloro-bridged dimers, $[M_2Cl_4(PR'_3)_2]$, proceed in high yield under mild conditions with the above ligands or the derived anions, $[Ph_2PCHP(Y)R_2]^-$, to yield the extensive series of platinum and palladium complexes detailed in Scheme 1. The resulting square planar complexes have been fully characterized, primarily by the ^{31}P NMR data and the two crystal structure determinations discussed below. Comments on ^{13}C, ^{77}Se, and ^{195}Pt data are also given below. All of the complexes contain five-membered chelate rings in which the ligand is bound via one phosphorus atom and the chalcogen, but the distribution of isomers varies widely with the substituents. We have chosen to designate structures such as **5** and **6** as *cis* or *trans* respectively, depending on the relative orientation of the two M—P bonds.



5 (*cis*)

6 (*trans*)

In our work, the actual distribution of *cis* and *trans* isomers was a very sensitive function of the metal and of the substituents. For example, $[PtCl(PEt_3)\{Ph_2PCH_2P(S)Bu^t_2\}]^+$ was obtained exclusively as the *trans* isomer whereas the analogous Pr^i and palladium complexes were exclusively *cis*. In many other cases isomer mixtures were obtained and we were not able to discern any general patterns. Details of the isomers obtained are presented in the ^{31}P NMR and experimental sections.

As outlined in Scheme 1, the synthesis of complexes containing $[Ph_2PCH_2P(S)R_2]^-$ ligands was accomplished either by cleavage of a metal dimer by the lithium salt of the ligand, or by sodium hydride deprotonation of the corresponding $Ph_2PCH_2P(S)R_2$ complex. The latter route demonstrates the enhanced acidity of the coordinated ligand since sodium hydride does not deprotonate the free ligands. Moreover, the reversal of these deprotonations by $HBF_4.Et_2O$ provides an important confirmation of the assigned structures. Our previous studies using $Ph_2P(S)CH_2P(S)Ph_2$ and related ligands showed that deprotonation of the ligand sometimes led to a change from S,S to S,C coordination (9). Thus, it is also important, and somewhat disappointing, to note that none of the present complexes showed any evidence of this effect.

Successful synthesis of complexes of the anionic ligands was limited to platinum, since the greater lability of palladium gave complex mixtures of products under similar conditions. Selenium analogs of the sulphur complexes were accessible only by the sodium hydride route because the salt, $Li[Ph_2PCHP(Se)Ph_2]$, proved highly unstable.

During the course of the work, we obtained several other complexes which, while not strictly within the format of Scheme 1, are closely related. Thus, *trans*-$[PtCl(PEt_3)\{Ph_2P(S)CH_2PPr^i_2\}]^+$ resulted from cleavage of $[Pt_2Cl_4(PEt_3)_2]$ by the appropriate ligand, and *trans*-$[PtCl(PEt_3)\{Bu^t_2PCH_2P(O)Me_2\}]^+$ was obtained by inadvertent oxidation during an attempted preparation of $[PtCl(PEt_3)\{Bu^t_2PCH_2PMe_2\}]^+$. More interesting were a series of reactions using $[Ph_2PCH_2P(O)Ph_2]$, since the weaker coordinating ability of oxygen for platinum gave a more complex reaction pattern than that observed for the sulphur analogs. The initial product of reaction of $[Ph_2PCH_2P(O)Ph_2]$ with $[Pt_2Cl_4(PEt_3)_2]$, either alone or in the presence of $NaClO_4$, was *trans*-$[PtCl_2(PEt_3)\{Ph_2PCH_2P(O)Ph_2\}]$ in which the ligand is coordinated only via phosphorus and has a "dangling" P(O) group. ^{31}P NMR studies showed that during purification procedures this complex tends to convert to the corresponding *cis* isomer. The ^{31}P NMR spectrum of this *cis* isomer is broad at ambient temperature but sharp at −35°C. This suggests that a chloride ligand is labilized by the *trans* effect of phosphorus and exchanges rapidly with the dangling P(O) group, leading to broadening of the phosphorus resonances. Further, in the presence of $NaClO_4$, the chloride is completely displaced by

the P(O) group and the ultimate product is *cis*-[PtCl(PEt$_3$){$Ph_2PCH_2P(O)Ph_2$}][ClO_4] as indicated in Scheme 1. Chloride displacement by the P(O) group of the [Ph_2PCH_2-$P(O)Ph_2$] ligand also occurs in its reaction with the chloro-bridged complex, [$Pt_2Cl_2(PEt_3)_4$][ClO_4]$_2$, which yields the chelate complex, [$Pt(PEt_3)_2$\{$Ph_2PCH_2P(O)Ph_2$\}][ClO_4]$_2$, under ambient conditions. Comparable behaviour has been reported recently in reactions of [$Ph_2PCH_2P(O)Ph_2$] with [$PtCl_2$(COD)] where the initial product *cis*-[$PtCl_2$\{$Ph_2PCH_2P(O)Ph_2$\}] can be converted to [Pt\{$Ph_2PCH_2P(O)Ph_2$\}$_2$] by chloride abstraction using silver nitrate (6).

(B) Nuclear Magnetic Resonance

1. General

Data derived from ^{31}P, ^{13}C, ^{77}Se, and ^{195}Pt NMR spectra are collected in Tables 1–3. The most extensive set is for ^{31}P since the high sensitivity of this nucleus enabled us to obtain spectra even for isomers available only as small percentage of reaction mixtures. For ^{13}C the only significant data are for the carbon of the P—CH_n—P groups and only these parameters have been included in the tables. The following discussion deals first with some general trends and then with the detail of individual assignments. The labelling scheme used is shown in structures **5** and **6**. Those assignments which are not specifically discussed rest upon similar arguments and upon the internal consistency of the various series of complexes shown in Table 1.

The assignments shown in Tables 1–3 lead to several useful generalisations: (*i*) Coordination of the [$Ph_2PCH_2P(Y)R_2$] ligands results, as expected (13), in extensive deshielding of the directly coordinated phosphorus with coordination shifts ranging from 42–50 ppm in *cis* platinum complexes and 58–68 ppm in *cis* palladium complexes. The *trans* complexes of the two metals experience a common range of coordination shifts from 58–68 ppm. The indirectly coordinated phosphorus of the $P_C(Y)$ group is less strongly affected, with coordination shifts ranging from 1–16 ppm in *cis* complexes of both metals and 16–37 ppm in *trans* complexes. The phosphine oxide complex, *cis*-[PtCl(PEt$_3$){$Ph_2PCH_2P(O)Ph_2$}]$^+$, is an exception here with a coordination shift for the P(O) phosphorus of +36.4 ppm. Coordination also causes deshielding of the carbon of the P_B—C—P_C group, especially in *cis* complexes where the range is 10–13 ppm compared with only 2–3 ppm in *trans* complexes. When the Y atom is selenium (Table 3), it also is deshielded by coordination. The last major effect of coordination is a sharp decrease in the magnitude of the two bond P_B—C—P_C coupling, for example changing from 76.2 Hz in [Ph_2PCH_2-$P(S)Ph_2$] to 25.2 Hz in *cis*-[PtCl(PEt$_3$){$Ph_2PCH_2P(S)Ph_2$}]$^+$. This change could be a normal result of the change in coordination number at phosphorus, since we note that in [$Ph_2P(O)CH_2$-$P(S)Ph_2$] the coupling is only 15.6 Hz (3) and it is also generally known that P^V—C—P^V couplings are smaller than P^{III}—C—P^{III} (14*a*). However, in the case of the metal complex there is also the possibility of a contribution of opposite sign from the P—Y—M—P pathway.

*The labelling scheme is shown in structures **5** and **6**. Chemical shifts (δ) are quoted in ppm relative to $Se(CH_3)_2$ at 19.071523 MHz. Coupling constants (*J*) are in Hz.

†*a*, $CDCl_3$ solution; *b*, C_6D_6 solution; *c*, BF_4^- salt; *d*, not resolved.

The data also enable us to establish a *trans* influence order for the P(Y) groups. Thus in *cis*-$[PtCl(PEt_3)\{Ph_2PCH_2P(Y)Ph_2\}]^+$ complexes, the ^1J(Pt—P$_A$) couplings *trans* to the coordinated Y atom are Y = O, 3959; Y = S, 3061; Y = Se, 3035 Hz; indicating that the *trans* influence order is Se > S ≫ O.

(*ii*) Deprotonation of the initial complexes results in several effects. The couplings, ^2J(P$_B$—C—P$_C$), ^1J(P$_C$(Y)—C), and ^2J(Pt—Y—P$_C$) all increase and the carbon of the P$_B$—C—P$_C$ group becomes more shielded. For example these parameters change from 25.4, 49.8, <10 Hz, and 45.03 ppm, respectively, in *cis*-$[PtCl(PEt_3)\{Ph_2PCH_2P(S)Ph_2\}]^+$ to 80.5, 114.5, 41.9 Hz, and 31.75 ppm, in the corresponding neutral complex, *cis*-$[PtCl(PEt_3)\{Ph_2PCHP(S)Ph_2\}]$. These changes are consistent with the increased electron density being located primarily in the C—P$_C$—Y region of the molecule and indicate contributions from both resonance forms of the ligand: Ph_2P—C$^-$(H)—P(=S)R$_2$ and Ph_2P—C(H)=P(—S$^-$)R$_2$.

(*iii*) Variation of the substitution pattern of the $[Ph_2PCH_2P(Y)R_2]$ ligand affects mainly δ(P$_C$) and ^2J(P$_B$—C—P$_C$) with other parameters being little changed. Increased shielding of P$_C$(Y) is accompanied by increased coupling in the sequences O ≪ S < Se and Bu^t < Pr^i ≪ Ph.

2. Phosphorus-31 NMR spectra

(i) cis *complexes*

These spectra basically consist of three doublets of doublets,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

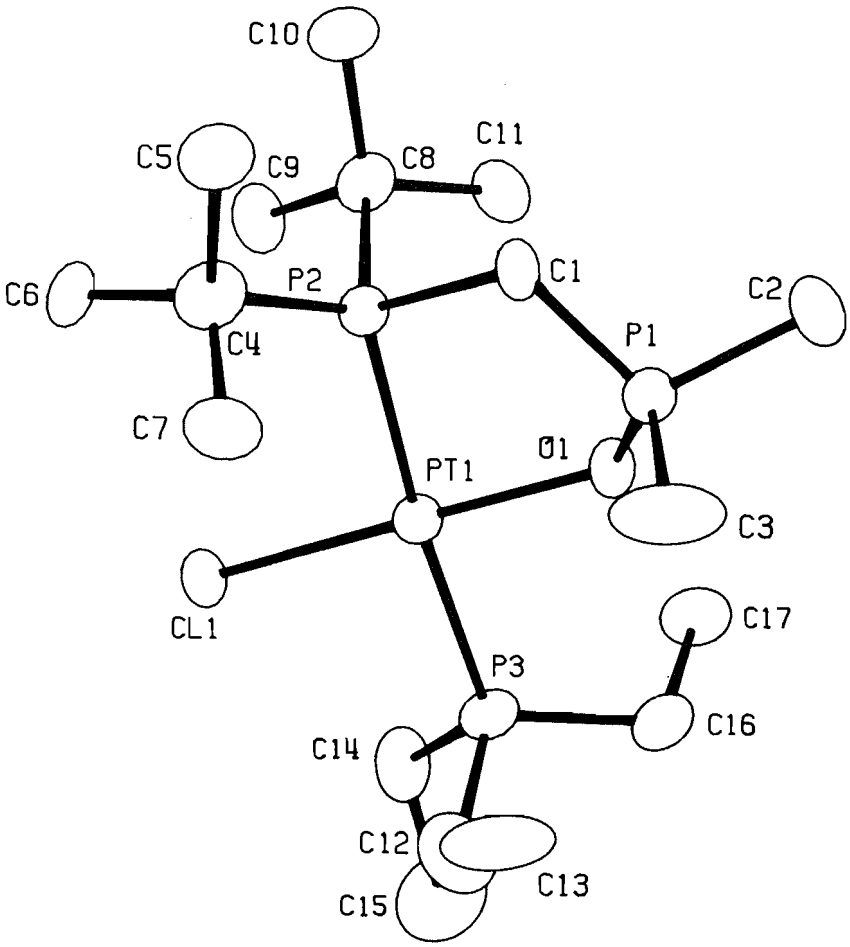

FIG. 1. ORTEP plot of compound **I**, *trans*-[PtCl(PEt$_3$){Bu$^t_2$PCH$_2$P(O)Me$_2$}][ClO$_4$].

easily analyzed as first order AMX spin systems but somewhat more difficult to assign to the appropriate phosphorus atoms in the molecules. For example, in *cis*-[PtCl(PEt$_3$){Ph$_2$PCH$_2$P(S)Ph$_2$}]$^+$ the three doublets of doublets occur at 12.67, 17.30, and 49.86 ppm relative to H_3PO_4. Using the labelling shown in structure **5** the resonance at 49.86 ppm is unambiguously assigned to P_C by the absence of any large (one-bond) coupling to ^{195}Pt, but the problem is to distinguish P_A and P_B. A PPh$_2$ group coordinated in a five-membered ring is expected to undergo a large deshielding coordination shift (up to 60 ppm) (13). Since the PPh$_2$ group in the uncoordinated ligand occurs at −27.87 ppm, this suggests that the more deshielded resonance (17.30 ppm) is the PPh$_2$ group (P_B). This assignment then gives 12.67 ppm for the PEt$_3$ ligand (P_A), consistent with values in similar complexes (e.g. [Pt$_2$Cl$_4$(PEt$_3$)$_2$] at 11.85 ppm). We also obtain $^2J(P_B—P_C) > {}^3J(P_A—P_C)$, as expected for a two bond relative to a three bond coupling and consistent with the large value (76.2 Hz) of $^2J(P_B—P_C)$ in the uncoordinated ligand. Finally, when the complex is deprotonated to form *cis*-[PtCl(PEt$_3$){Ph$_2$PCHP(S)Ph$_2$}] the only really significant change in NMR parameters is an increase in the value of $^2J(P_B—P_C)$ from 25.4 to 80.5 Hz, thus confirming the complete assignment.

For the *cis* palladium complexes the assignments are made slightly more difficult by the absence of a suitable magnetically active metal isotope, but the normal expectation (14*b*) is that palladium phosphorus complexes are deshielded relative to their platinum analogs (e.g. in our work [Pd$_2$Cl$_4$(PEt$_3$)$_2$] is at 48.42 ppm relative to its Pt analog at 11.85 ppm). Thus for *cis*-[PdCl(PEt$_3$){Ph$_2$PCH$_2$P(S)Ph$_2$}]$^+$, assignment of P_A and P_B at 32.18 and 37.73 ppm, respectively, is consistent with deshielding from the above platinum analog. Moreover, when the substituent at the P(S) group is changed from Ph to Pr^i to Bu^t the most significant NMR changes are in $\delta(P_C)$, 48.52 to 80.07 to 90.95 ppm, and $^2J(P_B—P_C)$, 31.6 to 16.1 to 10.0 Hz, thus confirming the assignments of P_B and P_C.

(ii) trans *complexes*

These spectra are basically similar to those of the *cis* complexes except that, using the labelling of structure **6**, P_A and P_B are now closely coupled because of the large two-bond *trans* coupling, and the spectra appear as ABX spin systems. These were fully analyzed by computer simulation in all cases and the large $^2J(P_A—P_B)$ values in these *trans* complexes form the major basis of our stereochemical assignments. The problem of distinguishing between P_A and P_B is similar to that in the *cis* complexes and the arguments are similar to those above. Most importantly in, for example *trans*-[PtCl(PEt$_3$){Ph$_2$PCH$_2$P(S)Ph$_2$}]$^+$, it is the resonance at 20.75 ppm whose coupling to P_C changes dramatically (from 54.6 to 117.0 Hz) on deprotonation, thus establishing this coupling as $^2J(P_B—P_C)$ and $\delta(P_B)$ as 20.75 ppm.

(iii) [Pt(PEt$_3$)$_2${*Ph$_2$CH$_2$P(O)Ph$_2$*}*]*

Relatively little information can be obtained from the ^{31}P NMR spectrum of this complex because the large *trans* ^2J(P—Pt—P) coupling produces a deceptively simple pattern even at 101.3 MHz. The phosphorus of the PEt$_3$ group *trans* to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

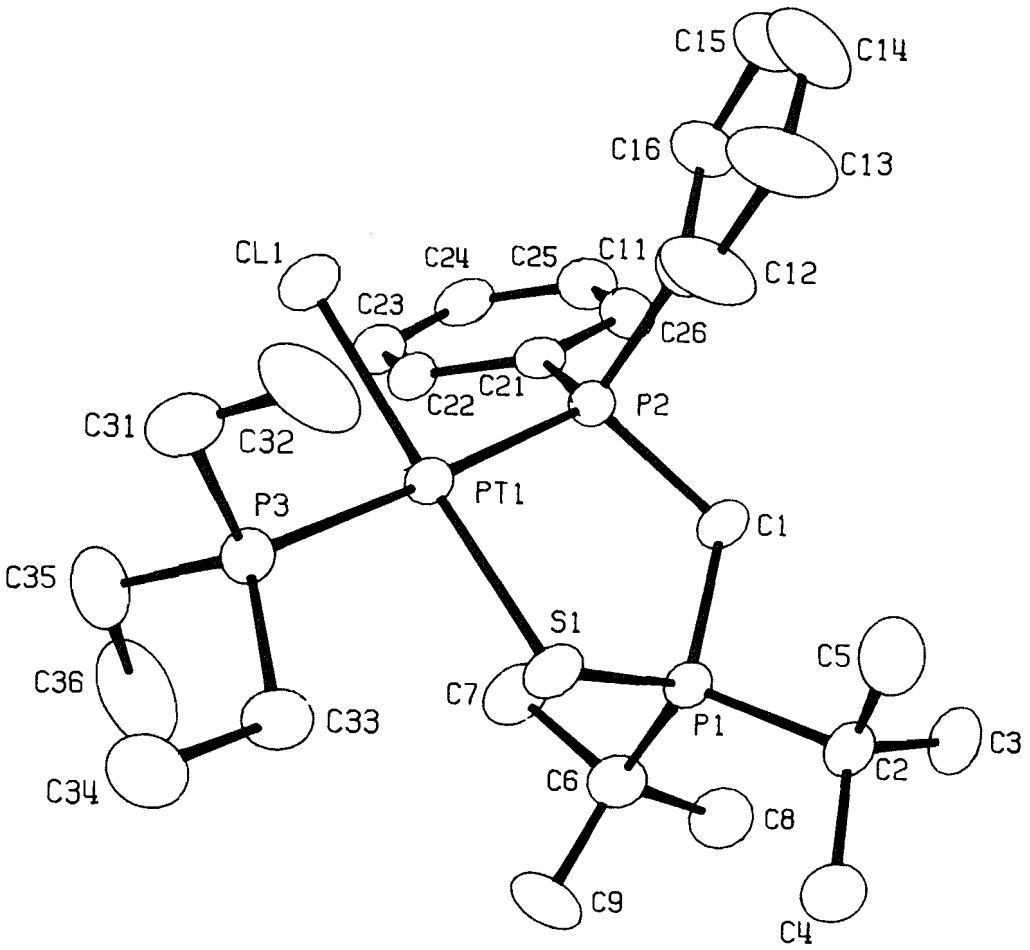

FIG. 2. ORTEP plot of compound **II**, *trans*-[PtCl(PEt$_3$){Ph$_2$PCH$_2$P(S)Bu$^t_2$}][ClO$_4$].

oxygen appears at 0.88 ppm as a triplet (19.8 Hz) due to two averaged couplings, ^2J(P—M—P)$_{cis}$. The phosphorus of the P(O) group is a similarly averaged triplet (16.8 Hz) at 71.58 ppm, and the mutually *trans* phosphorus atoms of the PPh$_2$ group and the remaining PEt$_3$ appear centred at 25.55 ppm as two closely spaced triplets (18.3 Hz). These are probably the centre lines of a closely coupled AB spin system, with the triplet structure arising from averaged couplings to the other two phosphorus atoms. The weak outer lines of the AB system are not observed and hence the individual chemical shifts and the ^2J(P—M—P)$_{trans}$ coupling cannot be obtained. The spectrum also shows ^{195}Pt sidebands which yield ^1J(Pt—PEt$_3$)$_{trans\ to\ O}$, 3561 Hz; ^1J(Pt—PEt$_3$)$_{trans\ to\ P}$ and ^1J(Pt—PPh$_2$), 2350 and 2460 Hz. For the latter pair it is not possible to say which is which, and finally ^2J(Pt—P(O)) is not resolved.

3. ^{13}C, ^{77}Se, and ^{195}Pt NMR spectra

In general these were simple first order spectra and assignments presented no particular problems. In the ^{13}C spectra the larger of the two couplings to the P—CH$_n$—P(Y) carbon was assigned to the coupling to the P(Y) phosphorus on the basis of previous results (3). The electronegative chalcogenide substituent is expected to raise the effective nuclear charge at phosphorus and also to modify the phosphorus hybridization so as to raise *s* orbital participation in the C—P bond. The ^{195}Pt spectra showed the expected first order patterns from coupling to phosphorus and served mainly to confirm the ^{31}P assignments.

The ^{77}Se spectra (Table 3) were mostly simple patterns with doublet coupling due to ^1J(Se—P$_C$), doubled again by ^2J(Se—M—P$_A$) and with first order ^{195}Pt sidebands. The $^{2/3}J$(Se—P$_B$) couplings were not resolved. As expected ^2J(Se—M—P$_A$) is much larger when the two atoms are mutually *trans*. The only complication is in the spectrum of *cis*-[PtCl(PEt$_3$){Ph$_2$PCHP(Se)Ph$_2$}], where increased ^2J(P$_B$—C—P$_C$) coupling combined with a reduced value for ^1J(Pt—Se) results in a complex non-first order multiplet. Computer simulation of the spectrum was successful using the parameters given in Tables 1 and 3, with the addition of $^{2/3}J$(Se—P$_B$) = −4 Hz and with the use of negative signs for ^2J(P$_A$—P$_B$) and ^3J(P$_A$—P$_C$). However, considerable caution is necessary since this may not be a unique solution.

(C) X-Ray crystal structures

The atom labelling schemes and structures of single cations of compounds **I**, *trans*-[PtCl(PEt$_3$){Bu^{t}PCH$_2$P(O)Me$_2$}][ClO$_4$], and **II**, *trans*-[PtCl(PEt$_3$){Ph$_2$PCH$_2$P(S)Ph$_2$}][ClO$_4$], are shown in Figs. 1 and 2, respectively. Fractional atomic coordinates and isotropic temperature parameters, bond lengths and bond angles are collected in Tables 4–7, and further Tables have been deposited, including: structure factors, anisotropic temperature parameters, complete bond lengths and angles, and selected intermolecular distances.[2]

[2]Copies of these tables may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

*Estimated standard deviations are given in parentheses. Coordinates $\times 10^n$ where $n = 5$ for Pt and 4 otherwise; temperature parameters $\times 10^n$ where $n = 4$ for Pt and 3 otherwise.

†U_{eq} = the equivalent isotropic temperature parameter = $(1/3)\ \Sigma_i\Sigma_j U_{ij} a_i^* a_j^* (\boldsymbol{a}_i \cdot \boldsymbol{a}_j)$.

In both structures the $R_2PCH_2P(Y)R'_2$ ligand coordinates via phosphorus and the Y atom so as to form a five-membered chelate ring. The platinum coordination is closely square-planar with all five atoms of the coordination plane within −0.036 to +0.038 Å of the least squares plane for **I**, and within −0.10 to +0.02 Å for **II**. The chelate ligands lie in twisted conformations so that P(1) is above the coordination plane, 0.763 Å for **I** and 0.524 Å for **II**. The associated Pt(1)—Y—P(1) angles are 117.3(7) and 107.2(1)°, respectively, and the twist also raises C(1) above the coordination plane by 0.677 Å for **I** and by 0.174 Å for **II**. The chelate ligand geometries are closely similar with respective values of P(1)—C(1), 1.80(2) and 1.824(7) Å, P(2)–C(1), 1.87(2) and 1.860(7) Å, and P(1)—C(1)—P(2), 108.7(9) and 112.8(4)°. The bond lengths are within the normal ranges for P—C single bonds (ref. 15, p. 7). The precise character of the P—Y bonds is more problematical. Some lengthening of these bonds on coordination is expected (16) and previous authors have suggested that a P—S bond of 2.013(2) Å in a palladium complex of P(S)Et$_2$Ph is long enough to suggest extensive participation of the R_3P^+—S^- resonance form rather than $R_3P{=}S$ (17). Among simple phosphorus compounds, the lengths for P—O bonds in P_4O_{10}, 1.604 (single) and 1.439 (double), and for P—S bonds in P_4S_{10}, 2.097 (single) and 1.908 (double), appear to be fairly typical (ref. 15, pp. 7, 65, 74). Thus, the distances observed in the present complexes, P—O 1.536(13), and P—S 2.045(2) Å, are rather closer to single bond rather than double bond lengths. The most closely comparable complex in the literature is probably, [CuCl{Ph$_2$P(S)CH$_2$P(S)Ph$_2$}], in which the P—S lengths are 1.970(2) and 1.974(3) Å (18).

Within the coordination sphere, the relative strengths of the Pt—S and Pt—O bonds are of interest in that platinum is expected to be more strongly bound by the soft sulphur base than by the harder oxygen base. Comparison of the P—O and P—S lengths (1.536(13) and 2.045(2) Å, respectively) suggests that the covalent radius of S is greater than that of O by about 0.5Å. However, the Pt—S bond (2.282(2) Å) is only 0.24 Å longer than the Pt—O bond (2.044(11) Å), consistent with a relatively greater strength for the Pt—S bond. This greater strength for the Pt—S bond is also reflected in the trans influence sequence S ≫ O, which has been demonstrated above by the ^{31}P coupling constants. In the structural data the trans influence is shown by the Pt—Cl lengths 2.304(2) Å (*trans* to O) and 2.326(2) Å (*trans* to S).

Experimental section

(A) Synthetic and spectroscopic studies

Data relating to the characterization of the complexes are given in the Tables, the Results section and in the preparative descriptions below. Microanalysis was by the Canadian Microanalytical Service, Vancouver, B.C., Canada. ^{31}P nuclear magnetic resonance spectra were recorded in appropriate solvents (Table 1) at either 24.3 MHz using a Nicolet TT14 Fourier transform spectrometer with a Varian HA60 magnet and an external C_6D_6 lock signal or at 101.3 MHz using a Bruker WM250 Fourier transform spectrometer locked to the solvent deuterium resonance. ^{13}C, ^{77}Se, and ^{195}Pt spectra were recorded at 62.9, 47.7, and 53.5 MHz, respectively, in $CDCl_3$ solution using the Bruker instrument. For all nuclei protons were decoupled by broad band ("noise") irradiation at appropriate frequencies. ^{31}P chemical shifts were measured relative to external P(OMe)$_3$ and are reported in parts per million relative to 85% H_3PO_4 using a conversion factor of +141 ppm. ^{13}C, ^{77}Se, and ^{195}Pt chemical shifts are reported in ppm relative to Si(CH$_3$)$_4$, Se(CH$_3$)$_2$ (19.071523 MHz (19),[3] and $\Xi(^{195}Pt)$ = 21.4 MHz (20), respectively. Positive values are deshielded relative to the references. Simulated NMR spectra were calculated on an IBM 3031 computer and plotted on a Calcomp 1039 plotter. The programs used were a locally constructed package based on the UEAITR and NMRPLOT programs from the literature (21, 22).

All operations were carried out at ambient temperature (ca. 25°C) under an atmosphere of dry nitrogen using standard Schlenk tube techniques. Solvents were dried by reflux over appropriate reagents (calcium hydride for dichloromethane, molecular sieves or K_2CO_3 for acetone, and potassium/benzophenone for diethyl ether, tetrahydrofuran, toluene, benzene, and hexane) and were distilled under nitrogen prior to use. Recrystallizations from solvent pairs were by dissolution of the complex in the first solvent (using about double the volume required for complete solution) followed by dropwise addition of sufficient second solvent to cause turbidity at ambient temperature. Crystallization was then completed either by continued very slow dropwise addition of the second solvent or, in those cases where a temperature is indicated in the detailed descriptions below, by setting the mixture aside at a reduced temperature.

The complexes, [M$_2$Cl$_4$(PR$_3$)$_2$], M = Pt, R = Et or Bu^n, or M = Pd, R = Et (23) and the ligands [Ph$_2$PCH$_2$P(Y)Ph$_2$], Y = O, S, or Se, and [Ph$_2$P(S)CH$_2$PPr$^i_2$] were prepared as previously described (1–3). The ligands [Ph$_2$PCH$_2$P(S)R$_2$], R = Pr^i or Bu^t, were obtained by reaction of the known diphosphines, [Ph$_2$PCH$_2$PR$_2$] (24), with one mole equivalent of elemental sulphur under reflux in benzene for 2 h.

[3]This value is misquoted as 19.091523 MHz in the widely used secondary reference, C. Mcfarlane and W. McFarlane. *In* NMR and the Periodic Table. *Edited by* R. K. Harris and B. E. Mann. Academic Press, London. 1978. p. 402.

Colourless crystals of the monosulphide ligands were obtained in yields ranging from 60–80% by recrystallization from ethanol.

The lithium salts Li[Ph$_2$PCHP(Y)R$_2$], Y = S, R = Ph, Pr^i, Bu^t, Y = O, R = Ph, were prepared by dropwise addition of a slight excess (ca. 1.1–1.2 molar equivalents) of *n*-butyl lithium (1.5 *M* in hexane) to stirred solutions of [Ph$_2$PCH$_2$P(Y)R$_2$] in tetrahydrofuran. ^{31}P and ^{13}C NMR spectra confirmed that the required anions were the sole phosphorus containing products.

^{31}P NMR data for the metal complexes used as starting materials were recorded in CH_2Cl_2 solution: [Pd$_2$Cl$_4$(PEt$_3$)$_2$], δ(P) +49.52 ppm, [Pt$_2$Cl$_4$(PEt$_3$)$_2$], δ(P) +11.85 ppm, *J*(Pt—P) 3832 Hz, [Pt$_2$Cl$_2$(PEt$_3$)$_4$][BF$_4$]$_2$, δ(P) +19.62 ppm, *J*(Pt—P) 3585 Hz. For the neutral ligands ^{31}P data were recorded in chloroform and for the anionic ligands in tetrahydrofuran. The following data are given in the order, δ(P)R$_2$ (ppm), δ(P(Y))R$_2$ (ppm), ^{2}*J*(PP) (Hz): [Ph$_2$PCH$_2$P(O)Ph$_2$], −28.12, +29.00, 51.3; [Ph$_2$PCHP(O)Ph$_2$]$^-$, −18.77, +38.99, 148.8; [Ph$_2$PCH$_2$P(S)Ph$_2$], −27.87, +40.38, 76.2; [Ph$_2$PCHP(S)Ph$_2$]$^-$, −10.22, +51.04, 162.7; [Ph$_2$PCH$_2$P(Se)Ph$_2$], −27.04, +30.76, 83.2; [Ph$_2$PCH$_2$P(S)Pr$^i_2$], −27.63, +66.20, 52.9; [Ph$_2$PCHP(S)Pr$^i_2$]$^-$, −13.04, +73.25, 139.7; [Ph$_2$PCH$_2$P(S)Bu$^t_2$], −24.64, +75.89, 52.8; [Ph$_2$PCHP(S)Bu$^t_2$]$^-$, −5.74, +89.37, 132.3. Many of these species have been reported previously and where ^{31}P data are available (1–3, 25), or data are in good agreement.

(1) [MCl(PR$_3$){R$'_2$PCH$_2$P(Y)PR$''_2$}][Z], M = Pt or Pd, R = Et or Bu^n, R$'$, R$''$ = Ph, Pr^i, or Bu^t, Y = S or Se, Z = BF$_4^-$ or ClO$_4^-$

These complexes were obtained by reaction of the appropriate ligand with a dinuclear metal complex, [M$_2$Cl$_4$(PR$_3$)$_2$], in the presence of NaClO$_4$.H$_2$O or NaBF$_4$. The procedures were all similar to the following representative example and yields were in the range 70–90% based on conversion of the metal dimers.

A solution of [Ph$_2$PCH$_2$P(S)Bu$'_2$] (0.171 g, 0.454 mmol) in acetone (10 mL) was added dropwise to a stirred solution of [Pt$_2$Cl$_4$(PEt$_3$)$_2$] (0.175 g, 0.227 mmol) and NaClO$_4$.H$_2$O (0.064 g, 0.457 mmol) in acetone (25 mL). After 2 h the mixture was filtered to remove precipitated NaCl and the solvent removed *in vacuo*. The residue was washed with diethyl ether and recrystallized from dichloromethane/diethyl ether to give *trans*-[PtCl(PEt$_3$){Ph$_2$PCH$_2$P(S)Bu$'_2$}][ClO$_4$] as pale yellow crystals (0.279 g, 0.338 mmol). *Anal.* calcd. for C$_{27}$H$_{45}$Cl$_2$O$_4$P$_3$PtS: C 39.3, H 5.50; found: C 39.2, H 5.45.

The representative example described above was obtained exclusively as the *trans* isomer, which we have designated as the isomer in which the two metal–phosphorus bonds are mutually *trans*. The other related complexes showed considerable variation in the isomer mixture obtained. Usually ^{31}P NMR spectra of the initial reaction products showed the presence of both possible isomers whereas the final crystals were often single isomers. In the characterization details given below the isomers are indicated as in the following example, Isomers: reaction mixture, *c*20/*t*80; crystals, *c*0/*t*100, where the numbers indicate percentages of *cis* and *trans* isomers.

(2) [Ph$_2$PCH$_2$P(O)Ph$_2$] complexes

(*i*) A preparation of [PtCl(PEt$_3$){Ph$_2$PCH$_2$P(O)Ph$_2$}][ClO$_4$] was attempted by reacting the ligand with [Pt$_2$Cl$_4$(PEt$_3$)$_2$] in a procedure similar to (*1*) above for the sulphur analog. In this case, however, the products were more complex. The initial product in all reactions, both in the presence of NaClO$_4$ and with no added salts, was shown by ^{31}P NMR to be *trans*-[PtCl$_2$(PEt$_3$){Ph$_2$PCH$_2$P(O)Ph$_2$}]. A crystalline sample of this yellow product was obtained as the first precipitate in a fractional crystallization from acetone/pentane in the presence of NaClO$_4$. The second (colourless) precipitate in this procedure was *cis*-[PtCl(PEt$_3$){Ph$_2$PCH$_2$P(O)Ph$_2$}][ClO$_4$].

During work-up procedures, but before the fractional crystallization, the solutions also showed ^{31}P NMR evidence for a third product, *cis*-[PtCl$_2$(PEt$_3$){Ph$_2$PCH$_2$P(O)Ph$_2$}], which could not be isolated in crystalline form.

trans-*[PtCl$_2$(PEt$_3$){Ph$_2$PCH$_2$P(O)Ph$_2$}]*

Anal. cald. for $C_{31}H_{37}Cl_2OP_3Pt$: C 47.5, H 4.75; found: C 47.8, H 4.84%. Melting point 146–148°C.

cis-*[PtCl(PEt$_3$){Ph$_2$PCH$_2$P(O)Ph$_2$}][ClO$_4$]*

Anal. calcd. for $C_{31}H_{37}Cl_2O_5P_3Pt$: C 43.9, H 4.40, Cl 8.4; found: C 44.3, H 4.50, Cl 8.8. Melting point 250–252°C.

(ii) [Pt(PEt$_3$)$_2${Ph$_2$PCH$_2$P(O)Ph$_2$}][ClO$_4$]$_2$

A solution of [Ph$_2$PCH$_2$P(O)Ph$_2$] (0.25 g, 0.62 mmol) in CH$_2$Cl$_2$/acetone (10 mL) was added dropwise to a stirred solution of [Pt$_2$Cl$_2$(PEt$_3$)$_4$][ClO$_4$]$_2$ (0.35 g, 0.31 mmol) and NaClO$_4$.H$_2$O (0.20 g, 1.4 mmol) in CH$_2$Cl$_2$/acetone (25 mL). After 15 h the mixture was filtered to remove precipitated NaCl and the solvent removed *in vacuo*. The residue was extracted into dichloromethane and crystallized by addition of diethyl ether to give [Pt(PEt$_3$)$_2${Ph$_2$PCH$_2$P(O)Ph$_2$}]-[ClO$_4$]$_2$.CH$_2$Cl$_2$. Recrystallization: dichloromethane/diethyl ether. *Anal.* calcd. for $C_{38}H_{54}Cl_4O_9P_4Pt$: C 40.9, H 4.88; found: C 40.8, H 5.00. Melting point 252–253°C.

(3) trans-*[PtCl(PEt$_3$){Bu$^t_2$PCH$_2$P(O)Me$_2$}][ClO$_4$]*

This complex was prepared by inadvertent oxidation of the ligand during some related work with [Bu$^t_2$PCH$_2$PMe$_2$] complexes.

A solution of [Bu$^t_2$PCH$_2$PMe$_2$] (0.33 g, 1.5 mmol) in acetone (15 mL) with NaClO$_4$.H$_2$O (0.18 g, 1.3 mmol) was added dropwise to a stirred solution of [Pt$_2$Cl$_4$(PEt$_3$)$_2$] (0.28 g, 0.36 mmol) in acetone (25 mL). After 6 h the solvent was removed *in vacuo* and the residue extracted with dichloromethane. Dropwise addition of hexane to the extract yielded an oily first precipitate which was discarded and a crystalline second precipitate. The second precipitate was extracted into benzene, the solvent removed *in vacuo* and the resulting residue recrystallized from dichloromethane/hexane to give *trans*-[PtCl(PEt$_3$){Bu$^t_2$PCH$_2$P(O)Me$_2$}][ClO$_4$] as pale yellow crystals. *Anal.* calcd. for $C_{17}H_{41}Cl_2O_5P_3Pt$: C 29.8, H 6.04; found: C 29.1, H 5.86.

(4) [Ph$_2$PCHP(Y)R$_2$]$^-$ complexes

(i) [PtCl(PEt$_3$){Ph$_2$PCHP(S)Ph$_2$}]

This complex was prepared by two different routes:

(*a*) Sodium hydride (0.100 g, 3.33 mmol, 80% in oil) and *cis*-[PtCl(PEt$_3$){Ph$_2$PCH$_2$P(S)Ph$_2$}][BF$_4$] (0.180 g, 0.211 mmol) were stirred in tetrahydrofuran for 3 h. After filtration to remove unreacted sodium hydride, the solvent was removed *in vacuo* and the resulting yellow residue extracted with benzene (20 mL). Evaporation of the extract under reduced pressure gave a yellow oil which was converted to a free flowing yellow solid, [PtCl(PEt$_3$){Ph$_2$PCHP(S)Ph$_2$}] (0.113 g, 0.148 mmol), by washing with hexane (3 × 10 mL). Recrystallization: tetrahydrofuran/diethyl ether. Isomers: reaction mixture, *c*80/*t*20; crystals, *c*80/*t*20 *Anal.* calcd. for $C_{31}H_{36}ClP_3PtS$: C 48.7, H 4.75; found: C 49.4, H 4.80.

(*b*) *n*-Butyl lithium (1.5 *M* in hexane, 0.87 mL, 1.30 mmol) was added dropwise to a stirred solution of [Ph$_2$PCH$_2$P(S)Ph$_2$] (0.541 g, 1.30 mmol) in tetrahydrofuran (5 mL) and the resulting yellow solution was added to a solution of [Pt$_2$Cl$_4$(PEt$_3$)$_2$] (0.500 g, 0.648 mmol) in tetrahydrofuran (10 mL). After 2 h, the solvent was removed *in vacuo* and the residue washed with hexane (3 × 10 mL) to leave [PtCl(PEt$_3$){Ph$_2$PCHP(S)Ph$_2$}] (0.874 g, 1.144 mmol).

TABLE 7. Selected interatomic distances (Å) and bond angles (deg) for compound **II**, *trans*-[PtCl(PEt$_3$){Ph$_2$CH$_2$P(S)Bu$^t_2$}][ClO$_4$]*

*Estimated standard deviations are given in parentheses.

(ii) [PtCl(PEt$_3$){Ph$_2$PCHP(Se)Ph$_2$}]

This complex was prepared in 85% yield by reaction of sodium hydride with [PtCl(PEt$_3$){Ph$_2$PCH$_2$P(Se)Ph$_2$}][BF$_4$] in a procedure identical with method *i(a)* above for the sulphur analogue. Recrystallization: tetrahydrofuran/diethyl ether. Isomers: reaction mixture, *c*100/*t*0; crystals, *c*100/*t*0 *Anal.* calcd. for C$_{31}$H$_{36}$ClP$_3$PtSe: C 45.9, H 4.47; found: C 46.2, H 4.74.

(iii) trans-*[PtCl(PEt$_3$){Ph$_2$PCHP(S)Bu$^t_2$}]*

This complex was prepared by reaction of sodium hydride with *trans*-[PtCl(PEt$_3$){Ph$_2$PCH$_2$P(S)Bu$^t_2$}][ClO$_4$] in a procedure identical with method *i(a)* above for the phenyl analogue. The product was identified by ^{31}P NMR.

(iv) Reactions with fluoroboric acid

Approximately two-fold molar excesses of HBF$_4$.Et$_2$O were added dropwise to stirred solutions of *cis*(85%)/*trans*(15%)-[PtCl(PEt$_3$){Ph$_2$PCHP(S)Ph$_2$}] and *cis*-[PtCl(PEt$_3$){Ph$_2$PCHP(Se)Ph$_2$}], respectively, in diethyl ether (5 mL). The resulting immediate yellow precipitates were identified by ^{31}P NMR as essentially quantitative yields of the corresponding *cis*-[PtCl(PEt$_3$){Ph$_2$PCH$_2$P(Y)Ph$_2$}][BF$_4$] complexes.

(B) X-ray data collection

Compounds **I**, *trans*-[PtCl(PEt$_3$){Bu$^t_2$PCH$_2$P(O)Me$_2$}][ClO$_4$], and **II**, *trans*-[PtCl(PEt$_3$){Ph$_2$PCH$_2$P(S)Bu$^t_2$}][ClO$_4$], were prepared as described above and crystals suitable for study by X-ray diffraction were grown for **I** by recrystallization from dichloromethane/hexane, and for **II** by vapour diffusion of diethyl ether into a solution of the complex in dichoromethane. Preliminary photographic work was carried out with Weissenberg and precession cameras using Cu K$_\alpha$ radiation. After establishment of symmetry and approximate unit cells the crystals were transferred to diffractometers (see below). The unit cells were refined by least-squares methods employing respectively 25 and 23 pairs of centering measurements at $\pm 2\theta$ in the ranges $|2\theta|$ = 35–40° and $|2\theta|$ = 18–47°. The crystals were mounted approximately along the *a* and *c* axes respectively. The crystal data at approximately 24°C were as follows:

Compound **I**

Monoclinic, space group $P2_1/c$; a = 15.579(2), b = 13.590(3), c = 13.578(1) Å; β = 105.96(1)°; V(cell) = 2764(2) Å^3; D_m = 1.644 g cm^{-3} (flotation in CCl$_4$/CHBr$_3$), D_c = 1.647 g cm^{-3}; formula C$_{17}$H$_{41}$Cl$_2$O$_5$P$_3$Pt; M_r = 684.43; Z = 4; asymmetric unit = one molecule.

Compound **II**

Monoclinic, space group $P2_1/c$; a = 14..002(4), b = 16.366(5), c = 15.524(5) Å; β = 106.01(3)°; V(cell) = 3419(2) Å^3; D_m = 1.58 g cm^{-3} (flotation in CCl$_4$/CHBr$_3$), D_c = 1.60 g cm^{-3}; formula C$_{27}$H$_{45}$Cl$_2$O$_4$P$_3$PtS; M_r = 824.63; Z = 4; asymmetric unit = one molecule. For both crystals intensity measurements were collected for two reciprocal space octants (h unrestricted, $k \geq 0$, $l \geq 0$) up to 2θ = 50°.

For compound **I** the diffractometer was an Enraf-Nonius CAD4 instrument using graphite monochromated Mo K$_\alpha$ radiation and the NRCCAD modification of the ENRAF-NONIUS program (26). Measurements used the "Profile" $\omega/2\theta$ scan developed by Grant and Gabe (27), with scan rate 2.06° min^{-1} over a range of (0.80 + 0.34 tan θ) degrees in ω. Three standard reflections (−2, 3, 4; −2, −4, 0; and −6, −3, 1) were measured every hour to check crystal stability and three others (−8, 0, 4; 0, −10, 0; and −2, 6, 2) were measured every 500 reflections to check crystal orientation. There was no evidence of deterioration in either set of measurements. Approximate dimensions of the crystal were 0.83 × 0.12 × 0.09 mm. Lorentz and polarization factors were applied and the data were corrected for absorption using an empirical method based on a scan of ϕ Eulerian. Reflections with intensity less than 4.0$\sigma(I)$ were removed from the data set to give a final file containing 2523 reflections.

For compound **II** the diffractometer was a Picker 4-circle instrument automated with a PDP11/10 computer and using Zr filtered Mo K$_\alpha$

For personal use only.

radiation ($\lambda = 0.71069$ Å). A $\theta/2\theta$ step scan was used with 160 steps of 0.01° in 2θ, counting for 0.25 s per step. Background measurements were for 20 s at each end of the scan. Each batch of 50 reflections was preceded by the measurement of three standard reflections (0, 0, 4; 5, 0, 0; and 0, −8, 0;). The Lorentz and polarization factors were applied and each batch was scaled to maintain the sum of the standards constant. There was no evidence of sample decomposition during the data collection. Absorption corrections were applied with a numerical integration procedure utilizing an 8 × 8 × 16 Gaussian grid. The crystal shape was defined by perpendicular distances to crystal faces from a central origin as follows: ±{1$\bar{1}$0}, 0.1144 mm; ±{110}, 0.1144 mm; ±{001}, 0.5013 mm. The absorption coefficient was 43.36 cm^{-1} and the range of transmission factors 0.33–0.43. Reflections with intensity less than $2.0\sigma(I)$ were removed from the data set to give a final file containing 5279 reflections.

(C) Structure solution and refinement

The structures were found and refined using the SHELX-76 program package (28), and illustrations were drawn using ORTEP (29). The atomic scattering factors used were for neutral atoms, with corrections for anomalous dispersion (30). The structures were solved by direct methods, developed by standard Fourier synthesis procedures using difference maps, and refined by the method of least squares minimising $\Sigma w\Delta^2$ where $\Delta = ||F_o| - |F_c||$. The weights were obtained from counting statistics using $w = 1/(\sigma^2(F) + 0.001F^2)$. For compound **I** there were 253 parameters to be determined from 2523 independent observations, and for compound **II**, 343 parameters from 5279 independent observations. Hydrogen atoms were not located. All non-hydrogen atoms were treated anisotropically and convergence was obtained with maximum shift/esd ratios of 0.060 and 0.249 for **I** and **II**, respectively. The respective residuals were $R = 0.0650$ and 0.0444, and $R_w = (\Sigma w\Delta^2/\Sigma wF_o^2)^{1/2} = 0.0632$ and 0.0463. The final difference maps had maxima of +1.4 and +0.79 e $Å^{-3}$ and minima of −1.2 and −0.32 e $Å^{-3}$ and gave no indication that any material had been overlooked.

Excess molar enthalpies of binary mixtures containing esters of fatty acids

SANTOS OTIN, IGNACIO SENAR, MA JOSÉ SORIANO, AND CELSO GUTIERREZ LOSA
Departamento de Química Física, Facultad de Ciencias, Universidad de Zaragoza, 50009 Zaragoza, Spain

Received September 15, 1987

SANTOS OTIN, IGNACIO SENAR, MA JOSÉ SORIANO, and CELSO GUTIERREZ LOSA. Can. J. Chem. **66**, 1283 (1988).

Excess molar enthalpies H_m^E, at 310.15 K and 101.32 kPa, have been determined for the binary mixtures: lauric acid ethyl ester +, stearic acid ethyl ester +, oleic acid ethyl ester +, linoleic acid ethyl ester + *n*-hexadecane, + toluene, or + ethyl alcohol, and elaidic acid ethyl ester + *n*-hexadecane or + toluene.

The results show that H^E of ester + *n*-hexadecane mixtures increases with decreasing chain length and with increasing unsaturation of the ester molecule. Ester + toluene mixtures are slightly exothermic and ester + alcohol are strongly endothermic, with H_m^E values ranging from 1535 to 1740 J mol^{-1} at the maximum.

SANTOS OTIN, IGNACIO SENAR, MA JOSÉ SORIANO et CELSO GUTIERREZ LOSA. Can. J. Chem. **66**, 1283 (1988).

Opérant à 310,15 K et 101,32 kPa, on a déterminé les enthalpies molaires en excès, H_m^E, des mélanges binaires : ester éthylique de l'acide laurique +, ester éthylique de l'acide stéarique +, ester éthylique de l'acide oléique + et ester éthylique de l'acide linoléique + *n*-hexadécane, + toluène ou + alcool éthylique ainsi que de l'ester éthylique de l'acide élaidique + *n*-hexadécane ou + toluène.

Les résultats indiquent que le H^E des mélanges d'esters + *n*-hexadécane augmentent avec une diminution de la longueur de la chaîne et avec l'augmentation du degré d'insaturation de la molécule d'ester. Les mélanges d'esters + toluène sont légèrement exothermiques alors que les mélanges d'esters + alcool sont fortement endothermiques; les valeurs de H_m^E varient de 1535 à un maximum de 1740 J mol^{-1}.

Introduction

In recent years, the application of thermodynamics of liquid mixtures has been often extended to systems of biological interest. These "biothermodynamic" studies refer specially to the behaviour of aminoacids and peptides, and their terminal derivatives, but, in general, include biological macromolecules and the components of cellular membranes, too.

The present paper is a contribution to the study of some interactions in the apolar zone of the membranes, which basically are those existing between the side chains of aminoacids and the hydrocarbon chain of lipids in the double layer. In such interactions, hydrophobicity of the aminoacid will play a fundamental role, but other factors, such as chain length in lipids, the number and location of unsaturations (if they exist) and their geometric isomerism, are also important.

We report here on the calorimetric behaviour of mixtures containing ethyl ester derivatives of some aliphatic acids which differ either in their chain length (lauric and stearic acids), or in the number of unsaturations (oleic and linoleic acids), or in their geometric isomerism (oleic and elaidic acids). The apolar zone in the esters lies in the hydrocarbon chain, and the carboxylate group can be located between both the polar and the apolar zones. As second component of the mixtures we have first used *n*-hexadecane and then, toluene and ethyl alcohol, as they represent, respectively, the side chain (RH) of the aminoacids $H_2N(R)CHCOOH$ phenylalanine (strongly hydrophobic) and treonine (moderately hydrophobic).

We measured the excess molar enthalpy H^E of the mixtures at 310.15 K and 101.32 kPa.

As far as we know, there exist no previous measurements on these mixtures.

Experimental

The esters used were Sigma products (better than 99 mol% purity). *n*-Hexadecane, toluene, and ethyl alcohol were Merck-Schuchardt (better than 99.5% purity). No purification was attempted, because of the difficulty of handling the esters.

Refractive index measurements for the sodium D-line were carried out to ±0.00002 with an Abbe refractometer, and the experimental values of static dielectric constants at 2 MHz, were obtained using a DM01 Dipolometer (Kahl Scientific Inst. Corp.) using the heterodyne beat method (accuracy of ±1%). Refractive indices and static dielectric constants of the pure liquids are given in Table 1.

Excess molar enthalpies were obtained using an isobaric and quasi-isothermic calorimeter (1). Electric energy was measured to better than 0.5%, and the temperature of the water thermostat was controlled to within ±0.002 K. The calorimeter was checked with *n*-hexane + cyclohexane, the agreement with the reported data (2) being better than 0.5% over the central range of concentration.

Results

Table 2 contains the experimental values of H^E for each mixture at 310.15 K. The results for ester + *n*-hexadecane, or + toluene were fitted by least squares to a Redlich–Kister type polynomial

$$[1] \quad H^E = x(1-x)\sum_{i=0}^{i} A_i(1-2x)^i$$

and, in the case of ester + ethyl alcohol mixtures, H^E values were fitted to a Mrazek and van Ness (4) type polynomial

$$[2] \quad H^E = x(1-x)\sum_{i=0}^{i} A_i(1-x)^{i/2}$$

where x is, in both cases, the mole fraction of ester. The values of the coefficients A_i and the standard deviations $\sigma(H^E)$ given by

$$[3] \quad \sigma(H^E) = [\Sigma(H^E - H^E_{exp})^2/(N-n)]^{1/2}$$

where N is the number of experimental points and n the number of coefficients A_i, are reported in Table 3.

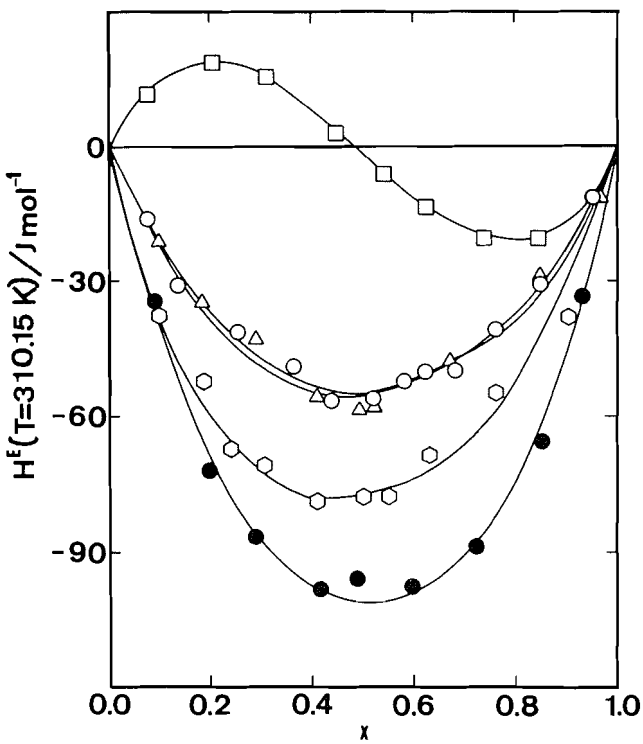

FIG. 2. Excess molar enthalpies H^E(310.15 K) of toluene + (○) lauric acid ethyl ester; + (□) stearic acid ethyl ester; + (△) oleic acid ethyl ester; + (●) elaidic acid ethyl ester; + (⬡) linoleic acid ethyl ester.

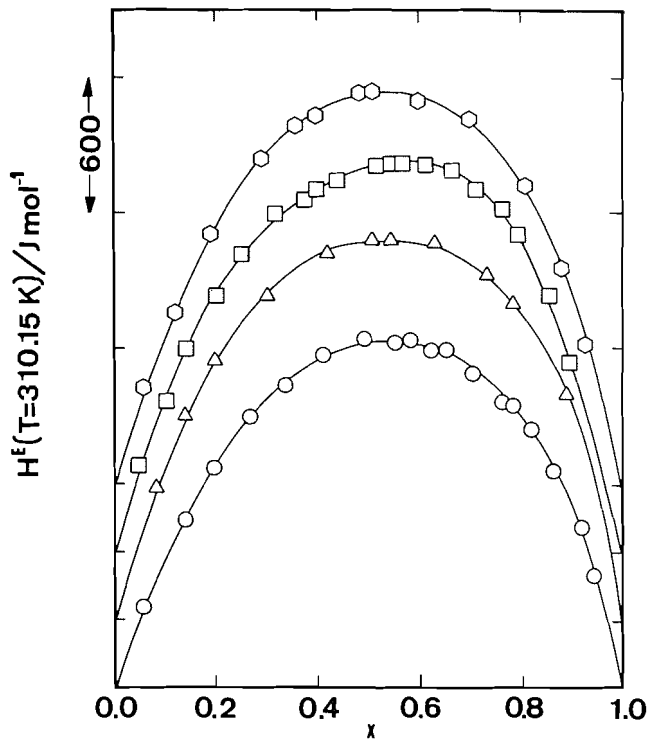

FIG. 3. Excess molar enthalpies H^E(310.15 K) of ethyl alcohol + (○) lauric acid ethyl ester; + (□) stearic acid ethyl ester; + (△) oleic acid ethyl ester; + (⬡) linoleic acid ethyl ester.

All the results are plotted in Figs. 1–3 where the solid lines are those calculated from smoothing equations.

Discussion

As Fig. 1 shows, H^E of a saturated ester + *n*-hexadecane increases when the chain length of the ester decreases, in accord with a "dilution" effect of the carboxylate group ("size effect").

When a double bond is introduced into an ethyl stearate molecule, a new positive contribution to H^E of the corresponding mixtures (ethyl *cis*- or *trans*-oleate + *n*-hexadecane) appears. Since comparison of the H^E values of (*n*-alkane + *n*-alkane) and (*n*-alkane + *n*-alkene) reveals an increase in H^E_{max} ranging from 10 to 100 J mol^{-1} (by short chains) (5), it is explainable that *cis*- or *trans*-oleate + *n*-hexadecane to be more entothermic than ethyl stearate + *n*-hexadecane (about 150 and 90 J mol^{-1} at the maximum, respectively). With the present data it is, however, not so easy to explain why ethyl *cis*-oleate + *n*-hexadecane is a little more endothermic than ethyl *trans*-oleate + *n*-hexadecane. The greater electrical asymmetry of the *cis* isomer might probably play a role as the other component of the mixture is a non polar one. It is to be expected that the aliphatic – double bond interaction in ethyl *cis*-oleate + *n*-hexadecane will be stronger than that in ethyl elaidate + *n*-hexadecane as the elaidate molecules will show a more compact packing.

Ester + toluene mixtures show a remarkable exothermic effect relative to *n*-hexadecane (ranging from 350 to 780 J mol^{-1}, at $x = 0.5$), which can be put down to the possibility of formation of n–π complexes between free electrons of carboxylate group and the aromatic π system; with unsaturated esters, an additional effect exists coming from the π(double bond)–π′(aromatic) interaction.

The behaviour of ethyl alcohol + ester mixtures is clearly the most difficult to explain (Fig. 3). In the mixing process two opposite effects take place: (*i*) an endothermic effect owing to the disappearance of both hydrogen bonds in the alcohol and dipole–dipole interactions in the ester, and (*ii*) an exothermic effect mainly coming from the formation of new hydrogen bonds between the carboxylate group and alcohol molecules. Molar enthalpy of formation of hydrogen bonds in normal alcohols is estimated to be $-23.5\ \text{kJ mol}^{-1}$ (6) and Nagata *et al.* (7) give the value of $-18.4\ \text{kJ mol}^{-1}$ for the molar energy of the ester–alcohol hydrogen bonds. Besides, it was shown (8) that in the absence of any other effects (as "orientational order" effect), the energy of alcohol–alcohol and ester–alcohol hydrogen bonds is almost independent of the aliphatic chain length. We do not know any reference about the calorimetric value for ethyl alcohol + *n*-hexadecane; however, it is known that ethyl alcohol + *n*-nonane is strongly endothermic ($H^{E}_{x=0.5} = 1000\ \text{J mol}^{-1}$) (9) and that the value of H^{E} increases with increasing length of the hydrocarbon chain. This information together with our results on the *n*-hexadecane + ester mixtures, points to a weak exothermic effect of the OH(alcohol)–COOR(ester) interaction and also to a rather small influence of a double bond in the ester (OH–π interaction). In fact, ethyl alcohol + ethyl stearate, + ethyl oleate, or + ethyl linoleate show quite similar values of H^{E}_{max}, ranging from 1680 to $1750\ \text{J mol}^{-1}$.

The proton affinity of triethylsilanol obtained by proton transfer equilibrium measurements using a high pressure mass spectrometer

XIAOPING LI AND JOHN A. STONE
Chemistry Department, Queen's University, Kingston, Ont., Canada K7L 3N6

Received July 8, 1987

XIAOPING LI and JOHN A. STONE. Can. J. Chem. **66**, 1288 (1988).

The proton affinity (PA) of triethylsilanol has been determined by equilibrium proton transfer measurements using a high pressure mass spectrometer. The reference bases were naphthalene and *m*-xylene which have the required low affinities for trialkylsilylium. van't Hoff plots were used to obtain PA($(C_2H_5)_3SiOH$) = 197.9 ± 0.4 kcal mol^{-1}. This value is used to recommend that PA($(CH_3)_3SiOH$) ≈ 192 kcal mol^{-1}. $(C_2H_5)_3Si^+$ has been produced by the protonation of $(C_2H_5)_4Si$ and the enthalpy change for the reaction $(C_2H_5)_3SiOH_2^+ \rightleftharpoons (C_2H_5)_3Si^+ + H_2O$ has been determined to be 32 ± 1 kcal mol^{-1} which gives $\Delta H_f^0((C_2H_5)_3Si^+)$ = 135 kcal mol^{-1}. A value of ~141 kcal mol^{-1} is recommended for $\Delta H_f^0((CH_3)_3Si^+)$.

XIAOPING LI et JOHN A. STONE. Can. J. Chem. **66**, 1288 (1988).

Utilisant un spectromètre de masse à haute pression et des mesures d'équilibre de transfert protonique, on a déterminé l'affinité protonique (AP) du triéthylsilanol. Comme bases de référence, on a utilisé le naphtalène et le *m*-xylène dont les affinités pour l'ion trialkylsilylium sont suffisamment basses. On a utilisé des courbes de van't Hoff pour déterminer l'AP($(C_2H_5)_3SiOH$) = 197,9 ± 0,4 kcal mol^{-1}. On utilise cette valeur pour recommander que l'AP($(CH_3)_3SiOH$) ≈ 192 kcal mol^{-1}. On a produit l'ion $(C_2H_5)_3Si^+$ par protonation du $(C_2H_5)_4Si$ et on a déterminé que le changement d'enthalpie pour la réaction $(C_2H_5)_3SiOH_2^+ \rightleftharpoons (C_2H_5)_3Si^+ + H_2O$ est égal à 32 ± 1 kcal mol^{-1}; on peut en déduire que le $\Delta H_f^0((C_2H_5)_3Si^+)$ = 135 kcal mol^{-1}. On recommande une valeur de ~141 kcal mol^{-1} pour le $\Delta H_f^0((CH_3)_3Si^+)$.

[Traduit par la revue]

Introduction

The gas phase proton affinity of a molecule is determined with best accuracy by measuring the equilibrium constant for proton transfer to a reference base of similar proton affinity. In this manner the proton affinities of a large number of organic molecules have been determined and these data are compiled in several publications (1–3). A few proton affinity values for organosilicon compounds are present in the most comprehensive and consistent compilation (3) but all the data were obtained by other than the equilibrium method and the values listed are approximate ones. A major problem in using the equilibrium method is that due to the electropositive nature of silicon, protonated organosilicon compounds tend to transfer a silicon-containing cation rather than the proton, thus preventing the setting up of proton transfer equilibria. In order for the equilibrium method to be feasible the reference base must have a proton affinity in the correct range and also have a relatively low affinity for the silicon-containing cation. We have previously shown that alkyl aromatics, with proton affinities in the range 183–205 kcal mol^{-1}, have relatively low affinities for $(CH_3)_3Si^+$ (4) and have used them to determine the proton affinity of hexamethyldisiloxane by the equilibrium method (5). In this paper we report the first determination of the proton affinity of a silanol, triethylsilanol, by the same method.

Theoretical calculations suggest that an α-silyl group, except at oxygen, is a destabilizing species which lowers the proton affinity of a molecule (6). There was no difference between the calculated proton affinities of methanol and silanol but significant differences for nitrogen- and phosphorus-containing molecules. There is no reported experimental proton affinity measurement for silanol but there are two quite different values for the proton affinity of trimethylsilanol. Clemens and Munson (7) estimated the value as 197 ± 2 kcal mol^{-1}. They used methane/tetramethylsilane/water mixtures in a chemical ionization (CI) source. Protonated trimethylsilanol is formed by the following reactions:

[1] $CH_5^+ + (CH_3)_4Si \dashrightarrow 2CH_4 + (CH_3)_3Si^+$

[2] $(CH_3)_3Si^+ + H_2O \rightleftharpoons (CH_3)_3SiOH_2^+$

With excess water, equilibrium [2] is far to the right. Bases (B) of increasing proton affinity were introduced into the ion source via a gas chromatograph and significant amounts of BH^+ were observed for bases with proton affinities greater than 199 kcal mol^{-1}. This value was taken to be the upper limit of PA($(CH_3)_3SiOH$). The authors point out that their results could be ambiguous since competing reactions might have obscured proton transfer to bases of lower proton affinity.

We obtained ΔH_2^0 = −30.1 kcal mol^{-1} by direct measurement (8) and used $\Delta H_f^0((CH_3)_3Si^+)$ = 150.5 kcal mol (9) and $\Delta H_f^0((CH_3)_3SiOH)$ = −119.4 kcal mol^{-1} (10) to obtain PA($(CH_3)_3SiOH$) = 183.7 kcal mol^{-1}. This value is substantially lower than the upper limit suggested by Clemens and Munson but depends not only on the accuracy of the experimental value of ΔH_2^0 but also on the accuracy of the standard enthalpies of formation of $(CH_3)_3Si^+$ and $(CH_3)_3SiOH$. The former has been discussed by Walsh (11) who suggests a value of 145 ± 6 kcal mol^{-1}, the lower bound of which would raise PA($(CH_3)_3SiOH$) to 195 kcal mol^{-1}.

A direct determination of the proton affinity of trimethylsilanol would be appropriate to settle both the above experimental discrepancy and to check the validity of the theoretical calculation. Unfortunately, trimethylsilanol is not commercially available and is also relatively unstable with respect to our experimental conditions but triethylsilanol is more stable, is commercially available, and was, therefore, used in this study. In addition tetraethylsilane is also commercially available, allowing the determination of the binding energy of $(C_2H_5)_3Si^+$ to water and hence providing a check on the value we previously obtained for $(CH_3)_3Si^+$.

Experimental

The high pressure mass spectrometer equipped with pulsed electron beam has been described previously as has the method of sample

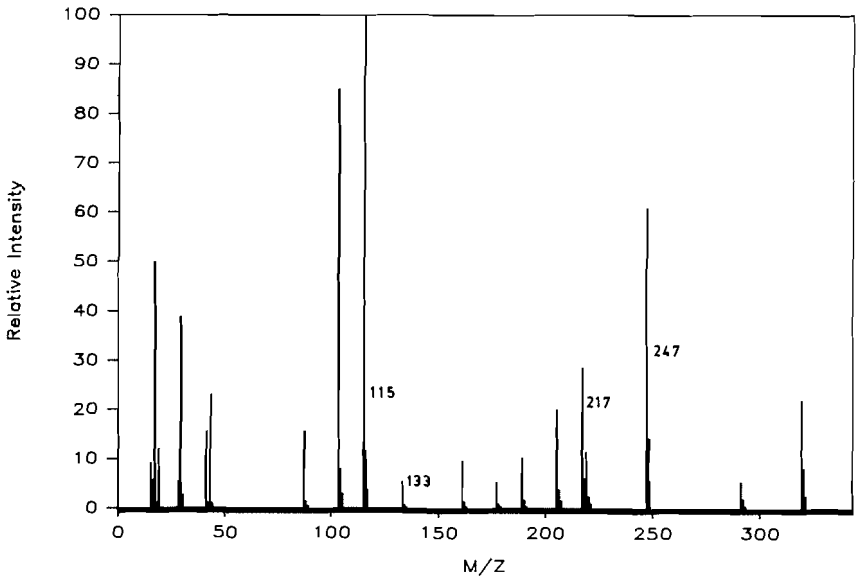

FIG. 1. Mass spectrum of $(C_2H_5)_3SiOH$ (6×10^{-3} mol%) in CH_4 at 4.1 Torr and 585 K.

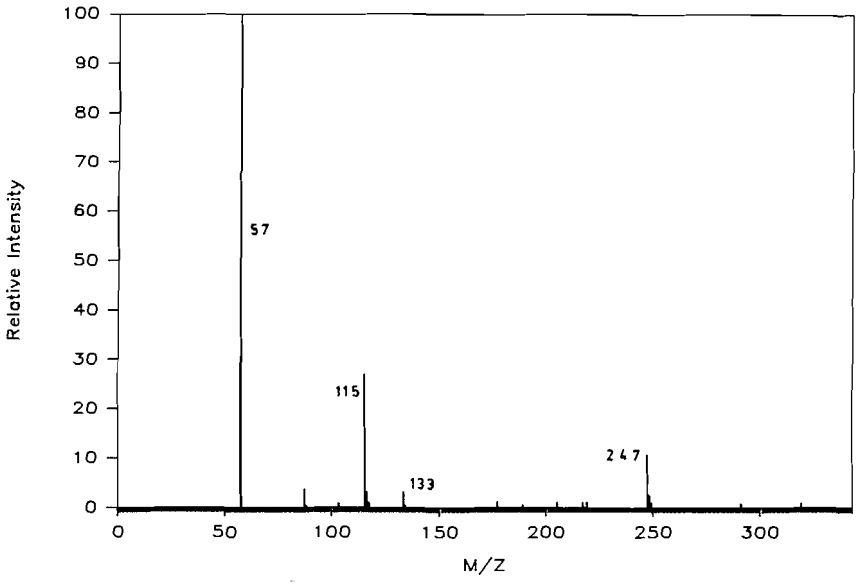

FIG. 2. Mass spectrum of $CH_4/i\text{-}C_4H_{10}/(C_2H_5)_3SiOH$ (92:8:1.5 $\times$ 10^{-3}) at 4.0 Torr and 585 K.

preparation and data collection (12). The pumping of the ion source housing has been improved by the addition of a second 4 in. diffusion pump.

Pre-mixed samples are flowed from a heated reservoir via a heated metering valve into the ion source. Time-resolved spectra are obtained by pulsing the electron beam on for ~50 μs and off for ~10 ms. The ions of each m/z value leaving the ion exit slit are collected as functions of time after the electron pulse using ion counting equipment and a multi-channel analyzer. Data are processed using a personal computer.

Triethylsilanol and tetraethylsilane from Petrarch Systems, Inc., were used without further purification. The *m*-xylene and naphthalene were from the Aldrich Chemical Company, Inc. No ions attributable to impurities in these chemicals were observed in this work. The methane (99.99%) and isobutane (99.5%) which were used as buffer gases were from Matheson Gas Products Canada.

Results and discussion

The CI spectrum of triethylsilanol is dependent on both the type and pressure of the protonating reagent gas and the ion source temperature. Figures 1, 2, and 3 show the effects of reagent gas at a temperature near the experimental maximum of 600 K. In methane as buffer gas the major ions from triethylsilanol result from protonation by the reagent ions CH_5^+ and $C_2H_5^+$ at either ethyl or oxygen, while in methane/isobutane protonation by $t\text{-}C_4H_9^+$ is predominantly at oxygen. Time-resolved spectra show the following reactions leading to the major ions seen in the spectrum (BH^+ is a reagent ion)

[3a] $(C_2H_5)_3SiOH + BH^+ \dashrightarrow (C_2H_5)_3SiOH_2^+ * + B$

[3b] $\dashrightarrow (C_2H_5)_2SiOH^+ + C_2H_6 + B$ (m/z 103)

[4a] $(C_2H_5)_3SiOH_2^+ * \dashrightarrow (C_2H_5)_3Si^+ + H_2O$ (m/z 115)

[4b] $\overset{M}{\dashrightarrow} (C_2H_5)_3SiOH_2^+$ (m/z 133)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12

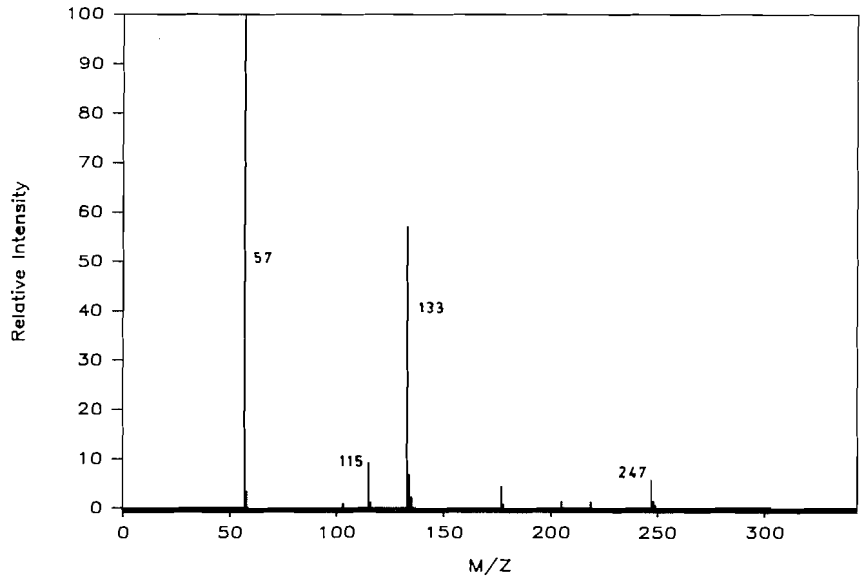

FIG. 3. Mass spectrum of $CH_4/i\text{-}C_4H_{10}/(C_2H_5)_3SiOH/H_2O$ (87:8:1.5 × 10^{-3}:5) at 4.1 Torr and 586 K.

[5] $(C_2H_5)_2SiOH^+ + (C_2H_5)_3SiOH \rightarrow (C_2H_5)_2SiOSi(C_2H_5)_3^+ + H_2O$ (m/z 217)

[6] $(C_2H_5)_3Si^+ + (C_2H_5)_3SiOH \xrightarrow{M} (C_2H_5)_3SiO(H)Si(C_2H_5)_3^+$ (m/z 247)

Using PA($(C_2H_5)_3SiOH$) = −197.9 kcal mol^{-1} (*vide infra*) the enthalpies of proton transfer from the reagent ions B to $(C_2H_5)_3SiOH$ (reaction [3a]) are: CH_5^+ −66 kcal mol^{-1}, $C_2H_5^+$ −35 kcal mol^{-1}, and $t\text{-}C_4H_9^+$ −2 kcal mol^{-1}. The increasing site selectivity for protonation noted above is, as expected, correlated with the exothermicity of the reactions, the more basic site, oxygen being preferred when $t\text{-}C_4H_9^+$ is the protonating agent. A similar behaviour was observed with hexamethyldisiloxane, protonation on both methyl and oxygen occurring in methane but only oxygen protonation in methane/isobutane mixtures (5).

There is only a small yield of m/z 133 ($(C_2H_5)_3SiOH_2^+$) in methane when highly exothermic proton transfer to oxygen leads to m/z 115 and 247 via reactions [4a] and [6] (Fig. 1). In methane/isobutane the relative yield of m/z 133 increases but at 585 K (Fig. 2) m/z 115 and 247 still predominate. This is due to the thermal dehydration of $(C_2H_5)_3SiOH_2^+$ as discussed later. At temperatures lower than 500 K, this dissociation is negligible and proton transfer from $t\text{-}C_4H_9^+$ to triethylsilanol leads to m/z 133 alone. The presence of water in the reagent gas reduces the intensity of m/z 115 and therefore of m/z 247 by reversing the thermal dehydration. Figure 3 shows that a methane/isobutane/water mixture gives the high fractional yield of protonated triethylsilanol which is necessary for proton transfer equilibrium studies.

At low temperatures in a methane/isobutane buffer gas, triethylsilanol (M) yields mainly MH^+ which is further solvated to M_2H^+ and M_3H^+. As with the analogous alcohols this behaviour places a lower limit on the temperature range over which proton transfer equilibria may be studied. Since the yields of M_2H^+ and M_3H^+ increase with increasing concentration of M the equilibrium measurements were made with the minimum amount of M present. This was assured by having reference bases of lower proton affinity then triethylsilanol. The chosen bases, which must be aromatic, were *m*-xylene and naphthalene. Equilibria were studied over the temperature range 360–560 K for triethylsilanol/*m*-xylene and 440–580 K for triethylsilanol/naphthalene. The proton transfer equilibrium between *m*-xylene and naphthalene could be studied over the full range of temperature accessible to the instrument, i.e. 300–600 K.

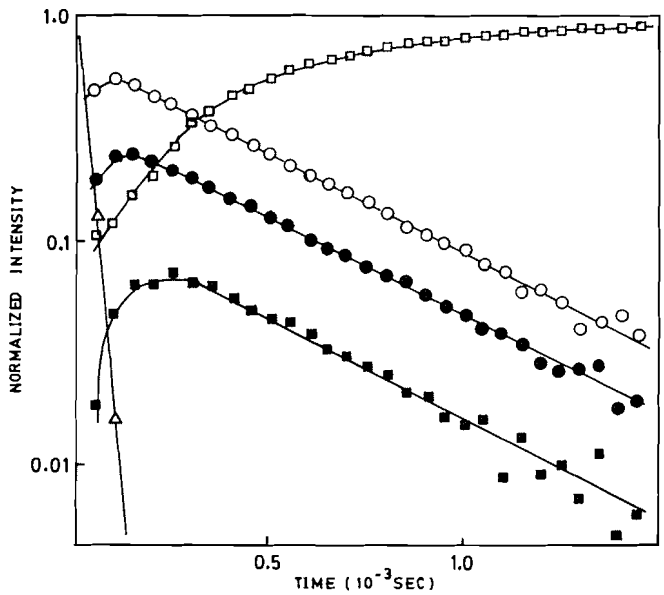

FIG. 4. Normalized ion intensities as functions of time after a 50 μs pulse of ionizing electrons in $CH_4/i\text{-}C_4H_{10}/m\text{-xylene}/(C_2H_5)_3SiOH$ (92:8:1.3 × 10^{-1}:5.8 × 10^{-3}), 3.5 Torr, 453 K. △ $t\text{-}C_4H_9^+$ (m/z 57), ○ $C_8H_{11}^+$ (m/z 107), ● $(C_2H_5)_3SiOH_2^+$ (m/z 133), ■ $((C_2H_5)_3SiOH)_2H^+$ (m/z 265), □ $(C_2H_5)_3SiO(H)Si(C_2H_5)_3^+$ (m/z 247).

A typical temporal profile of normalized ion intensities after a short ionizing electron pulse is shown in Fig. 4. Although m/z 247 is the dominant ion at long reaction time, the rate of its

production is sufficiently small compared with the rate of proton exchange (reaction [7]) that the equilibrium is not disturbed.

[7] $(C_2H_5)_3SiOH_2^+ + C_8H_{10} \rightleftharpoons (C_2H_5)_3SiOH + C_8H_{11}^+$

The calculated equilibrium constant at a given temperature is independent of both ion source pressure (2–4 Torr) and ratio of neutral molecules (varied by a factor of five). The standard enthalpy and standard entropy changes for the three equilibria are obtained from the van't Hoff plots of Fig. 5. The results, which are presented in Table 1, show acceptable internal consistency although not as good as is usually obtained with organic compounds. We attribute this to the smaller than usual temperature range that was used for the two equilibria involving triethylsilanol.

The slow formation of m/z 247 at 453 K, the temperature at which the data in Fig. 4 were taken, could be by reaction [6]. However, $(C_2H_5)_3Si^+$ was not observed in the mass spectrum and its steady state concentration must therefore have been extremely low and would be even lower at lower temperatures when m/z 247 is still present. The probable mechanism of formation of m/z 247 in this mixed system is the dehydration of the nascent proton bound dimer.

[8] $(C_2H_5)_3SiOH_2^+ + (C_2H_5)_3SiOH \dashrightarrow ((C_2H_5)_3SiOH)_2H^+ *$

[9a] $((C_2H_5)_3SiOH)_2H^+ * \dashrightarrow (C_2H_5)_3SiO(H)Si(C_2H_5)_3^+ + H_2O$ (m/z 247)

[9b] $\xrightarrow{M} ((C_2H_5)_3SiOH)_2H^+$ (m/z 265)

The analogous reaction is well known in alcohols (13). Figure 4 shows that the proton bound dimer (m/z 265) decays in parallel with protonated triethylsilanol (m/z 133) and therefore these two ions are in equilibrium with each other; the formation of m/z 247 is so slow as not to disturb this equilibrium.

To fix the proton affinity of triethylsilanol, an acceptable value for the proton affinity of either *m*-xylene or naphthalene is required. The gas phase basicity of *m*-xylene has been measured by the equilibrium method using ion cyclotron resonance but only the value is quoted, no details of the reference bases etc. are given (14). The evaluated proton affinity is 195.9 kcal mol^{-1} which is 1.2 kcal mol^{-1} greater than the evaluated proton affinity of naphthalene (3), a difference which is in fair agreement with the 1.55 kcal mol^{-1} of Table 1. There are problems, however, in accepting the absolute values quoted for *m*-xylene and naphthalene since, for example, a value from each of two different laboratories is used in obtaining the evaluated proton affinity of naphthalene, and one of these finds a difference between the proton affinities of naphthalene and toluene of only 1.7 kcal mol^{-1} (15). The evaluated difference is 4.9 kcal mol^{-1} (3). We recently measured the proton affinity of *m*-xylene as 194.9 kcal mol^{-1} relative to PA(mesitylene) = 201 kcal mol^{-1} (5). We have reconfirmed this value which is 1.0 kcal mol^{-1} below that quoted above. Using our value, the proton affinity of triethylsilanol is 197.9 ± 0.4 kcal mol^{-1} and that of naphthalene is 193.3 ± 0.6 kcal mol^{-1}.

The proton affinity of trimethylsilanol may be estimated from that of triethylsilanol. An ethyl group is more polarizable than a methyl group and is therefore better able to stabilize a positive charge on an adjacent site as shown by the following pairs of proton affinities (units kcal mol^{-1}) $(CH_3)_3N$ (225.1), $(C_2H_5)_3N$ (232.2); $(CH_3)_3P$ (227.1), $(C_2H_5)_3P$ (231.7); C_2H_5OH (188.3), n-C_3H_7OH (191.2) (3). Replacing one methyl by one ethyl increases the proton affinity by roughly 2 kcal mol^{-1}. With PA($(C_2H_5)_3SiOH$) = 198 kcal mol^{-1}, an estimated value of PA($(CH_3)_3SiOH$) is 192 kcal mol^{-1} leading to $\Delta H_f^0((CH_3)_3Si^+)$ = 142 kcal mol^{-1}, which is in the range of values, 146 ± 5 kcal mol^{-1}, suggested by Walsh (11). This estimated value for PA($(CH_3)_3SiOH$) is preferable to our earlier value of 183.7 kcal mol^{-1} which was based on the enthalpy change for reaction [2] and Szepes and Baer's indirect measurement of $\Delta H_f^0((CH_3)_3Si^+)$ = 150.5 kcal mol (9). Walsh (11) has discussed the uncertainties involved in the interpretation of the latter data and notes that slightly different values are obtained for $\Delta H_f^0((CH_3)_3Si^+)$ when data for its production from different compounds are used. It is readily apparent that many more direct determinations of the thermochemical properties of

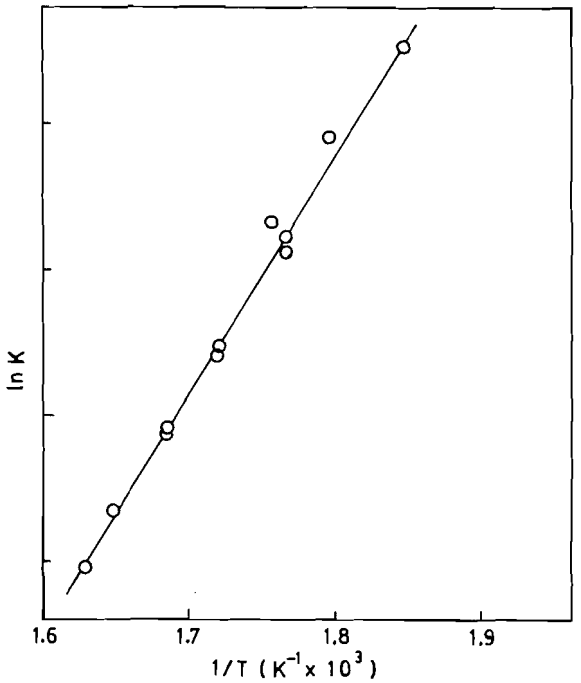

FIG. 6. van't Hoff plot for the equilibrium $(C_2H_5)_3Si^+ + H_2O \rightleftharpoons (C_2H_5)_3SiOH_2^+$.

silicon compounds, both ionic and neutral, are required in order to provide a firm base for organosilicon chemistry.

The condensation of triethylsilylium with water

Upon methane chemical ionization, tetraethylsilane, like tetramethylsilane, loses an alkyl group to yield the trialkylsilylium cation.

[10] $(C_2H_5)_4Si + CH_5^+ \dashrightarrow (C_2H_5)_3Si^+ + C_2H_6 + CH_4$

In the presence of water triethylsilylium is in equilibrium with protonated triethylsilanol

[11] $(C_2H_5)_3Si^+ + H_2O \rightleftharpoons (C_2H_5)_3SiOH_2^+$

The equilibrium constant, K, was measured over a range of temperatures to yield the van't Hoff plot in Fig. 6. K is defined in terms of the ratio of ion currents at long reaction time when equilibrium has been attained, and the pressure P_{H_2O} of water vapour in the ion source. The standard pressure P^0 is one atmosphere.

$$[12] \quad k = \frac{i_{(C_2H_5)_3SiOH_2^+}}{i_{(C_2H_5)_3Si^+}(P_{H_2O}/P^0)}$$

From the plot the standard enthalpy of binding of water to triethylsilylium is -32 ± 1 kcal mol^{-1} and the standard entropy change is -35 ± 3 cal K^{-1} mol^{-1}. These values are consistent with the designation of the adduct as protonated triethylsilanol. In particular, the large entropy change shows the formation of a "tight" structure with Si—O bonding rather than a "looser" structure which would be associated with a water/triethylsilylium complex (16). The numbers are very close to the 31 ± 2 kcal mol^{-1} and 27 ± 3 cal K^{-1} mol^{-1} observed for the association of water with trimethylsilylium. A slightly lower binding energy was expected for triethylsilylium compared with trimethylsilylium because of the greater stabilizing effect on a charge centre of an ethyl compared with a methyl. For example, we found that the binding energies of water to $(CH_3)_3Ge^+$ and $(C_2H_5)_3Ge^+$ were 28.6 ± 0.5 and 24.9 ± 0.5 kcal mol^{-1}, respectively (17). The wider error limits for $(CH_3)_3Si^+$ (30.1 ± 1.9 kcal mol^{-1}) and $(C_2H_5)_3Si^+$ (32 ± 1 kcal mol^{-1}) are due to the smaller temperature range encompassed by the van't Hoff plot and are such that the true order could be the reverse of the stated one. The difference between the values for the trimethyl- and triethylsilicon-containing ions appears to be considerably less than for the germanium-containing ions.

The above data may be used to estimate the standard enthalpy of formation of the triethylsilylium ion. The standard enthalpy of formation of triethylsilanol is not known but with $\Delta H_f^0((CH_3)_3SiOH) = -119.4$ kcal mol^{-1} and assuming that substitution of an ethyl for a methyl on silicon decreases the enthalpy of formation by 1.2 kcal mol^{-1} ($\Delta H_f^0((CH_3)_4Si = -58.7$ kcal mol^{-1} and $\Delta H_f^0((C_2H_5)_4Si) = -63.5$ kcal mol^{-1} (10)) then $\Delta H_f^0((C_2H_5)_3SiOH) \approx -123$ kcal mol^{-1}. This value, combined with $PA((C_2H_5)_3SiOH) = 198$ kcal mol^{-1}, gives $\Delta H_f^0((C_2H_5)_3Si^+) = 135$ kcal mol^{-1}. The error limits in this calculation are difficult to assess, but the value is probably good to better than ± 5 kcal mol^{-1}. This value of 135 kcal mol^{-1} supports a value of 140–145 kcal mol^{-1} for $\Delta H_f^0((CH_3)_3Si^+)$ if, as discussed earlier, 2 kcal mol^{-1} is assigned as the stabilization energy of an ethyl compared with a methyl substituent on a siliconium centre.

The photochemistry of the rhodizonate dianion in aqueous solution

G. IRACI AND M. H. BACK

Ottawa–Carleton Chemistry Institute, University of Ottawa Campus, Ottawa, Ont., Canada K1N 6N5

Received August 12, 1987

G. IRACI and M. H. BACK. Can. J. Chem. **66**, 1293 (1988).

The photochemistry of the rhodizonate dianion at 483 nm has been studied in aqueous solution at pH 8.3. In the absence of oxygen no reaction was observed. In the presence of oxygen, 6.2×10^{-5} *M*, the dianion was consumed with a quantum yield of 0.044. The oxidation apparently did not involve the formation of $O_2(^1\Delta_g)$. Electron transfer from the excited dianion was observed with methyl viologen.

G. IRACI et M. H. BACK. Can. J. Chem. **66**, 1293 (1988).

Opérant en solution aqueuse, à un pH de 8,3 et à une longueur d'onde de 482 nm, on a étudié la photochimie du dianion rhodizonate. En l'absence d'oxygène, on n'a pas observé de réaction. En présence d'oxygène, $6{,}2 \times 10^{-5}$ *M*, le dianion est consommé avec un rendement quantique de 0,044. Il ne semble pas que l'oxydation implique la formation d'$O_2(^1\Delta_g)$. Avec le viologène de méthyle, on a observé un transfert d'électrons.

Introduction

Rhodizonic acid, $H_2C_6O_6$, is one of the series of cyclic oxocarbons whose dianions are stabilized by electron delocalization to the extent of possessing aromatic properties (1, 2). The dianions all show strong π–π^* absorption giving an absorption band with a characteristic double maximum. In rhodizonic dianion the strongest absorption is at 483 nm ($\epsilon = 3.3 \times 10^4$ L mol^{-1} cm^{-1}) (3) which makes it of interest for solar energy conversion. It is known that aerated aqueous solutions of rhodizonic acid are unstable and in basic solution conversion to croconic acid takes place (1). The disappearance of rhodizonic dianion is accelerated by exposure to visible light (4, 5) but it appears that no systematic study of the photolysis of rhodizonic, or of any of the oxocarbons, has been reported. The present paper describes a brief investigation of the behaviour of the rhodizonic dianion in aqueous solution following absorption of light at 483 nm.

Experimental

Solutions of sodium rhodizonate (Aldrich Chemical Co.) were degassed and photolyzed in a 1-cm quartz spectrophotometer cell, using a tungsten lamp and monochromator. Dissolved oxygen was analyzed by the Winkler method (6). Fluorescence was measured using a SLM 8000 Fluorescence Spectrophotometer.

Flash photolysis experiments were performed with a model 858 Flash Kinetic Spectrometer from Applied Photophysics Ltd., supplied by Photochemical Research Associates. London, Ont. The transient absorption was measured with a Tektronix 2235 100 MHz oscilloscope and photographed with Polaroid Type 667 film. The flash duration to half maximum was 150 μs.

Results

Both acidic and basic solutions of rhodizonic acid were unstable. In basic solution, pH > 10, croconic acid was formed in the presence of oxygen, while in the absence of oxygen the tetrahydroxyquinone tetra-anion, identified by its maxima at 380 and 270 nm, was formed (Fig. 1). This product had previously been observed only in an electrochemical reduction reaction (7).

De-oxygenated solutions (5×10^{-5} *M*, pH 8.3) were stable for several days and irradiation at 483 nm caused no measurable disappearance of the dianion. In the presence of oxygen, however, the rhodizonic dianion disappeared upon irradiation but the only product identified was croconic acid, which accounted for < 10% of the decomposition. An unstable product was tentatively identified from its absorption maximum (280 nm) (4) as cyclohexanehexone.

The light intensity at 483 incident on the reaction cell was measured using the potassium ferrioxalate actinometer (8) and the average value, from five experiments, was $6.2 \pm 0.3 \times 10^{14}$ quanta s^{-1}. Quantum yields for the disappearance of rhodizonate dianion were measured at two concentrations of oxygen and are shown in Table 1.

Photolyses were also performed in partially de-oxygenated solutions in the presence of two compounds, maleic acid and 3-methyl-1,3-pentadiene, which are expected to react efficiently with any $O_2(^1\Delta_g)$ generated in the system (9, 10). The rate of reaction of rhodizonate was unaffected by the presence of either compound. Unless the rate of reaction of $O_2(^1\Delta_g)$ with rhodizonic dianion is much faster than with either of these reactants, it appears that the photooxidation of the rhodizonic dianion occurs by a direct reaction rather than through the intermediate formation of $O_2(^1\Delta_g)$.

De-oxygenated solutions of rhodizonate excited at 483 nm showed only a very weak fluorescence with a maximum intensity at 584 nm. As a rough estimate, less than 1% of the excited ions formed by absorption at 483 nm decayed by emission of fluorescence.

De-oxygenated solutions of rhodizonate in a Pyrex cell at concentrations in the range 5×10^{-4} to 15×10^{-4} *M* were subjected to flash photolysis using a broad spectrum of visible light, and a broad transient absorption band was observed with a maximum at 640 nm. The lifetime of the transient was, however, scarcely longer than the duration of the flash (~150 μs) and further investigation was not practical with this apparatus.

Solutions of rhodizonate ($1.5 - 3.0 \times 10^{-4}$ *M*) and methyl viologen ($1.3 \times 10^{-3} - 1.3 \times 10^{-2}$ *M*) were flash-photolyzed in the Pyrex cell and a transient absorption was observed in the region of 610 nm. This absorption was not present after flash photolysis of the rhodizonate alone at these concentrations and suggests that the methyl viologen monocation was formed following flash photolysis by electron transfer from an excited $C_6O_6^{2-}$ species.

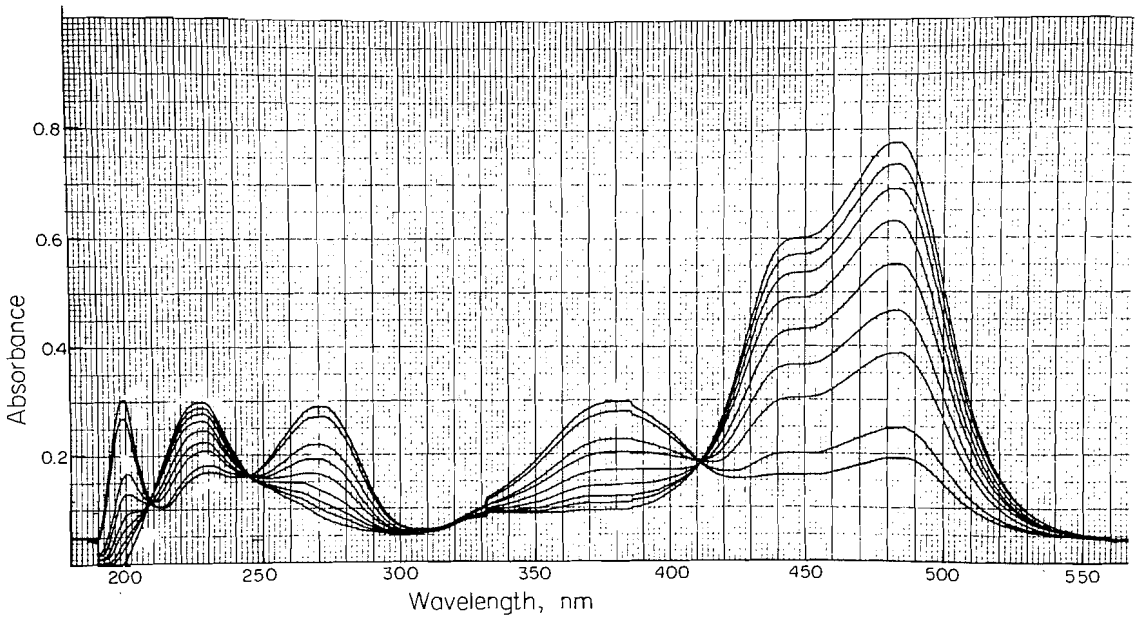

FIG. 1. Absorption spectra of a de-aerated solution of sodium rhodizonate (2.3×10^{-5} *M*) at pH 10.9. Decreasing absorptions at 483 and 227 nm are due to rhodizonate dianion while increasing absorptions at 380 and 270 nm are due to tetrahydroxy quinone. The spectra record reaction times of 0, 5, 10, 20, 35, 55, 75, 150, and 180 min.

TABLE 1. Quantum yields for the disappearance of rhodizonate dianion

$[Rh^{2-}]$ (*M*)	$[0_2]$ (*M*)	$-d[Rh^{2-}]/dt$ ($M\ s^{-1}$)	ϕ
2.5×10^{-5}	6.2×10^{-5}	1.2×10^{-8}	0.044 ± 0.005
2.5×10^{-5}	9.5×10^{-6}	9.0×10^{-9}	0.031 ± 0.006

Conclusions

No photodecomposition of rhodizonic dianion at 483 nm and at pH 8.3 occurs in the absence of oxygen and the quantum yield of fluorescence is less than 1%. Irradiation of the dianion in the presence of oxygen leads to its disappearance, and the croconate ion is a minor product. The photooxidation probably does not proceed through formation of $O_2(^1\Delta_g)$. If the excited rhodizonate reacts with oxygen at a diffusion-controlled rate, ($\sim 10^9\ M^{-1}\ s^{-1}$) the quantum yield for its disappearance indicates a lifetime of the order of 10^{-6} s, which, together with the lack of fluorescence, suggests involvement of the triplet state.

Excess molar volumes, speeds of sound, and isentropic compressibilities of binary mixtures of furfural with some aromatic hydrocarbons

HOMENDRA NAOREM AND S. K. SURI[1]

Department of Chemistry, Indian Institute of Technology, Hauz Khas, New Delhi – 110 016, India

Received September 16, 1987

HOMENDRA NAOREM and S. K. SURI. Can. J. Chem. **66**, 1295 (1988).

Molar excess volumes of mixing and isentropic compressibilities for the binary mixtures of furfural with benzene, toluene, ethylbenzene, and *o*-, *m*-, and *p*-xylenes at 308.15 K have been measured. The results reveal that geometric factors are predominant in determining the solution behaviour of the binary mixtures under investigation.

HOMENDRA NAOREM et S. K. SURI. Can. J. Chem. **66**, 1295 (1988).

Opérant à 308,15 K, on a mesuré les volumes molaires en excès de mélange et les compressibilités isentropiques des mélanges binaires du furfural avec le benzène, le toluène, l'éthylbenzène et les *o*-, *m*- et *p*-xylènes. Les résultats révèlent que les facteurs géométriques prédominent dans la détermination du comportement en solution des mélanges binaires étudiés.

Introduction

In earlier communications from this laboratory (1–3) we reported the excess molar volumes of binary mixtures of different hydrocarbons with tetrahydrofuran, cyclohexanone, dioxane, etc. A perusal of literature reveals that studies on hydrocarbon–furfural mixtures are scanty. As a part of our investigation, it was, therefore, considered worthwhile to study the mixture behaviour of furfural with some hydrocarbons. In this manuscript, we report the results of our studies on the excess molar volumes and isentropic compressibilities of binary mixtures of furfural with benzene, toluene, ethylbenzene, *o*-xylene, *m*-xylene, and *p*-xylene at 308.15 K over the entire composition range. The present study aims to provide some information on binary mixtures containing furfural with a view to understanding the nature of interaction present in these mixtures.

Experimental

The aromatic hydrocarbons (Fluka, AG Grade) were purified by established procedures (4). Commercial grade furfural was distilled under vacuum and the middle fraction boiling at constant temperature was collected. The solvents were stored in brown glass bottles and fractionally distilled using a column of 15 theoretical plates immediately before use. The purities of the liquids were checked by comparing the measured densities and refractive indexes with those reported in the literature (4, 5); agreement was within 5×10^{-5} g cm^{-3} and 4×10^{-4} respectively.

The excess molar volumes, V^E, were computed from the experimental density data. The densities of liquids and liquid mixtures were measured using a vibrating tube digital densimeter model DMA 60/602 (Anton Paar, Austria). The temperature of the liquid under investigation was maintained at 308.15 ± 0.01 K with the help of a closed-loop circulating ultra-thermostat. Duplicate densities were reproducible to within 5×10^{-5} g cm^{-3}, which propagates an uncertainty of ±0.005 cm^3 mol^{-1} in the V^E values.

The isentropic compressibility, k_s, was computed from the ultrasonic speed of sound, u, of the solution, which in turn was measured with a single crystal interferometer (model F-81, Mittal Enterprise, India) operating at a frequency of 2 MHz. The error in the measurement of u was estimated to be around 0.15%. This generates an uncertainty of ±2 TPa^{-1} in the k_s values reported in this paper.

Results and discussion

The excess molar volumes of the aforesaid systems are recorded in Table 1 and graphically represented in Fig. 1. The

experimental V^E values were fitted into the smoothing equation:

$$[1]\quad V^E/x(1-x) = A_0 + A_1(2x-1) + A_2(2x-1)^2 + A_3(2x-1)^3$$

where x is the mole fraction of furfural in the mixture. The values of the parameters A_0, A_1, A_2, and A_3 were evaluated by the method of least squares and are given in Table 2, along with the standard deviation $\sigma(V^E)$. Since the $\sigma(V^E)$ values for all the mixtures studied are less than the experimental uncertainty involved, eq. [1] may be taken to represent the experimental results.

The k_s values reported in Table 3 were computed using the relation

$$[2]\quad k_s = (u^2 \cdot \rho)^{-1}$$

where u is the speed of sound and ρ is the density of the solution. In the last column of Table 3 are recorded the values of K_s, the deviation in isentropic compressibility, given by the expression

$$[3]\quad K_s = k_s - \phi_1 k_{s,1} - \phi_2 k_{s,2}$$

where the subscripts 1 and 2 represent the component molecules of the binary mixtures and ϕ_i is the volume fraction of the component i in the mixture. The K_s values were fitted into the polynomial:

$$[4]\quad K_s/\phi_1 \cdot \phi_2 = B_0 + B_1(\phi_1 - \phi_2) + B_2(\phi_1 - \phi_2)^2 + B_3(\phi_1 - \phi_2)^3$$

The values of the adjustable parameters B_0, B_1, B_2, and B_3 obtained by the method of least squares are included in Table 4 along with the standard deviation $\sigma(K_s)$. Figure 2 shows the graphical representation of the variation of K_s with the volume fraction of furfural, ϕ_1.

It is observed from Table 1 that the V^E values for all the mixtures studied (except those containing *o*-xylene) are negative over the entire composition range. For mixtures containing *o*-xylene, a plot of V^E vs. x yields an S-shaped curve and V^E becomes negative only at the furfural end. Further, the substitution of an alkyl group in the benzene ring influences $V^E_{0.5}$, the excess molar volume at equimolar concentration, in

the following order: toluene < benzene < ethylbenzene. The methyl substitution in toluene influences $V^E_{0.5}$ in the order toluene < *p*-xylene < *m*-xylene < *o*-xylene. To the best of our knowledge, no data have been reported in the literature for the excess volumes and isentropic compressibilities of any of the binary mixtures under investigation, to compare with our results.

The overall volumetric effects in a binary mixture may be attributed to geometric and interaction factors. These arise from the differences in size and shape and cohesive energy of the component molecules (6, 7). The excess volumes, unlike the excess enthalpies, H^E, are more sensitive to geometrical effects (8), and a significant contribution of these geometric factors to the volumetric behaviour of these mixtures is also reflected in the V^E values of xylene solutions. The results of H^E studies on these systems will be published elsewhere.

Isentropic copressibilities presented in Table 3 show that K_s values for all the mixtures studied are negative over the entire composition range. The values suggest that "intermolecular spaces" in the mixtures, as defined by Jacobson (9), might decrease from benzene to a xylene.

Received December 2, 1987

K. F. PRESTON, J.-P. CHARLAND, and L. H. SUTCLIFFE. Can. J. Chem. **66**, 1299 (1988).

An anisotropic ESR signal detected in single crystals of 5-methyl-1,3,2,4-dithiazolylium hexafluoroarsenate ($CH_3\overline{CNSNS}^+AsF_6^-$) is shown to be that of 1,2,4,3,5-trithiadiazolyl, $S_3N_2^{+\bullet}$. The **g**- and ^{14}**N**-hyperfine tensors for this radical were established in the monoclinic *abc** crystal-axis system from spectral measurements at room temperature on aligned single crystals. Agreement of the principal values of the tensors with those obtained in our earlier studies by simulation of powder spectra is excellent. The **g**-tensor (2.0021, 2.0072, 2.0248) and the two ^{14}**N**-tensors (25.4, 0.8, 0.8 MHz) are collinear within experimental error and lie with minimum *g* and maximum hyperfine perpendicular to the plane of the host cation. The electronic structure of the radical deduced from our earlier studies ($^2A_2$ in C_{2v}) is confirmed, and the impurity is shown to substitute for the host cation in the anticipated manner.

K. F. PRESTON, J.-P. CHARLAND et L. H. SUTCLIFFE. Can. J. Chem. **66**, 1299 (1988).

On démontre que le signal rpe anisotrope qui est détecté dans les cristaux uniques de l'hexafluoroarsenate de méthyl-5 dithiazolylium-1,3,2,4 ($CH_3\overline{CNSNS}^+AsF_6^-$) est dû au trithiadiazolyl-1,2,4,3,5, $S_3N_2^{+\bullet}$. Utilisant des mesures spectrales effectuées à la température ambiante, sur des monocristaux alignés, on a déterminé les tenseurs **g** et hyperfins du ^{14}**N** de ce radical dans l'axe cristallin du système monoclinique *abc**. Il existe un accord excellent entre les valeurs principales des tenseurs et celles qui ont été obtenues au cours de nos études antérieures effectuées par simulation des spectres de poudre. A l'intérieur des erreurs expérimentales, le tenseur **g** (2,0021, 2,0072 et 2,0248) et les deux tenseurs du ^{14}**N** (25,4, 0,8 et 0,8 MHz) sont colinéaires et se trouvent à la valeur minimale de g et à la valeur maximale du tenseur hyperfin perpendiculaire au plan du cation hôte. On a confirmé la structure électronique du radical qui avait été déduite à partir de nos études antérieures ($^2A_2$ dans C_{2v}) et on démontre que l'impureté se substitue au cation hôte de la manière anticipée.

[Traduit par la revue]

Introduction

The vast majority of free-radical structures have been determined from spectroscopic measurements made on samples of liquid or solid solutions, or of both types of sample. Rarely is it possible to carry out the ultimate spectroscopic measurement on an aligned single crystal containing the free radical as an impurity. Such single-crystal determinations by ESR spectroscopy provide additional and invaluable information in the principal directions of tensors, which cannot be extracted from powder data (1*a*, 2, 3). Structural similarities between the free radical and the host often predetermine the location of the radical within the crystal structure, so that the experimental principal directions in the crystal axis system may be transformed into an axis system of the free radical itself (1*a*, 2–4). Armed with both principal values and directions of the **g**- and hyperfine tensors in a molecular axis system, the spectroscopist can usually unequivocally establish the ground-state geometry and electronic wavefunction of the free radical. An added advantage of measurements on a single crystal, of course, is the lack of ambiguity associated with the spectral analysis of powder samples.

Much of the early literature on the chemical applications of ESR spectroscopy was concerned with the class of radicals commonly referred to as cyclic π radicals (1*b*). Although almost exclusively populated by carbocyclics, one of the simplest members of this class of free radicals is, in fact, inorganic, viz. the cyclic sulphur nitride $S_3N_2^{+\bullet}$ (5–10). This free radical is remarkably persistent and is a common by-product of the reactions of sulphur–nitrogen compounds in polar solvents (9). Liquid-phase and powder spectra of this species suitably enriched in ^{33}S and ^{15}N have been interpreted (8–11) in terms of a planar π radical (Fig. 1) in which the unpaired electron occupies an orbital of the A_2 representation in C_{2v} symmetry.

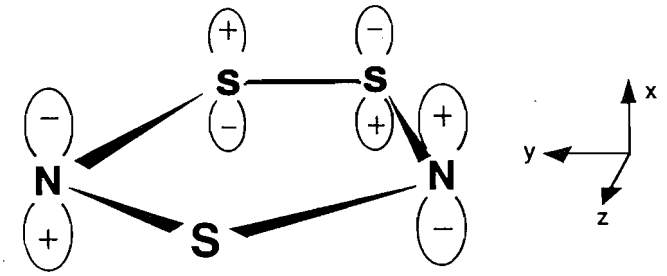

FIG. 1. The $^2A_2$ SOMO of $S_3N_2^+$.

Experimental

5-Methyl-1,3,2,4-dithiadiazolylium hexafluoroarsenate (V) was prepared according to a literature method (12) from acetonitrile (May and Baker, HPLC grade) and S_2N^+ AsF_6^-, kindly provided by Dr. A. G. Kendrick of Durham University. The dithionitronium salt is very reactive and can produce the $S_3N_2^{+\bullet}$ radical in high concentrations with, for example, tetrahydrofuran (11). Hence by using a slight excess of this salt in the preparation of $CH_3\overline{CNSNS}^+AsF_6^-$ some $S_3N_2^+$ radical (its identity being proved by ESR — see below) was introduced

into the crystal: crystals were obtained by recrystallisation from liquid sulphur dioxide (BDH).

Good single crystals (needle axis ≈2–3 mm) were selected with the aid of a polarizing microscope. One of these was attached with epoxy resin to the gear wheel of a two-circle goniometer (4, 13). Other crystals were aligned on a Nonius diffractometer according to the established crystal structure (12). Such crystals were sealed in the ends of 4 mm quartz tubes so that the tube axis was one of the orthogonal axes abc^* of the monoclinic ($P2_1/c$) crystal (12), and a second crystal axis lay in a known direction in the plane perpendicular to the tube. Contact of the crystals with air was minimized by carrying out most of the manipulations under an atmosphere of very dry nitrogen in a dry box.

The single crystal, either mounted on the two-circle goniometer or sealed into the end of a quartz tube, was placed at the centre of the rectangular resonant cavity of a Varian E-12 spectrometer. Dry nitrogen was passed through the cavity during the course of the measurements to limit deterioration of the crystal. Magnetic field intensity was determined with a Cyclotron Corporation gaussmeter and microwave frequency with a Systron–Donner digital counter. Since the linewidth of the signal increased at sub-ambient temperatures, measurements were confined to room temperature.

Results

Examination of single crystals of 5-methyl-1,3,2,4-dithiadiazolylium hexafluoroarsenate prepared as described above revealed the presence of an intense ESR spectrum. For an arbitrary orientation of the d.c. magnetic field, the spectrum consisted of two sets of quintets each having the 1:2:3:2:1 intensity ratio characteristic of interaction of a single unpaired electron with two equivalent ^{14}N ($I = 1$) nuclei. Certain orientations (Fig. 2) of the crystal resulted in a coalescence of the spectrum to that of a single quintet, and others in the collapse of the nuclear hyperfine in one or both of the quintets to a single broad resonance. No orientation could be found for which the ESR spectrum either consisted of more than two sets or indicated inequivalence of the two ^{14}N nuclei. This behaviour conformed with that anticipated for the two magnetically inequivalent sites of a monoclinic crystal, and showed furthermore that the two ^{14}N hyperfine tensors of the radical are parallel (4).

The method of spectral coalescences (4) was used successfully to locate the b axis of the monoclinic ($P2_1/c$) crystal: a particularly narrow coalescence showing no resolved hyperfine structure was chosen as a tentative y axis (4), and it was found that the spectrum remained coalesced (i.e. only one site observed) throughout the plane (xz) perpendicular to that axis. Axes x and z were chosen corresponding to the minimum and maximum in the least-squares best fit (3, 4) to the g^2 data (Fig. 3) for the xz plane. The ESR spectra from crystallographically-aligned samples were then examined and it was found that to within the experimental error in measured g (one standard deviation ±0.0002), the initially chosen axes x,y,z corresponded to the orthogonal crystal axes a,b,c^*. Subsequent measurements made with the two-circle goniometer were then referred to the crystal axis system. Spectra were recorded as a function of angular departure from a crystal axis in each of the three crystal planes, and were analyzed to yield values of g^2 and g^2a^2 for each site. Exact analysis for the ^{14}N hyperfine coupling was not possible for the bc^* plane since the hyperfine was not resolved for any direction in that plane. Crude estimates of the ^{14}N coupling constants for that plane were obtained by spectral simulation using the linewidth (3.0 G) determined for the spectrum of a single site showing a well-resolved hyperfine manifold. The values of g^2 and g^2a^2 exhibited the usual sinusoidal behaviour (Fig. 3) within a plane; least-squares fitting procedures were used (3, 4) to determine the best-fit diagonal and off-diagonal tensor components in the abc^* basis (Table 1). Relative signs of the off-diagonal elements of the two matrices were established in the approved manner by the comparison of measured and predicted values of g^2 and g^2a^2 for the skew direction (1,1,1) in the abc^* basis (4).

Following diagonalization of the $\mathbf{g}^2$ matrix, which yielded the principal values and directions of $\mathbf{g}$ (Table 1), the $\mathbf{g}$-matrix was assembled in the crystal axis system. The $\mathbf{a}^2$ matrix was generated by pre- and post-multiplication of $\mathbf{g}^2\mathbf{a}^2$ by $\mathbf{g}^{-1}$ (4), and was diagonalized to give principal values and directions of the ^{14}N tensor (Table 1).

In order to ascertain the origin of the paramagnetic "impurity", the reagents used in the preparation of the host material were examined by ESR spectroscopy. It was quickly established that the reagent $NS_2^+AsF_6^-$, as expected, contained a free-radical impurity. When dissolved in liquid SO_2, it exhibited an isotropic spectrum of two equivalent ^{14}N nuclei with (at 0°C) $g = 2.0115$, $a_{14}(2) = 8.98$ MHz. An identical spectrum was obtained from a solution of a host crystal in SO_2. Evidently the radical can easily be incorporated into the host during the crystallization process.

Discussion

A comparison of the principal values and of the isotropic values of $\mathbf{g}$ and $\mathbf{a}_{14}$ with those reported (8–10) for the cyclic inorganic radical $S_3N_2^{+\bullet}$ (Table 2) leaves no doubt whatsoever as to the identity of the radical detected in this single-crystal study. The added directional information obtained from the single crystal substantiates the structural and electronic symmetry assignments made for trithiadiazolylium on the basis of powder and solution spectra alone.

Dealing firstly with the principal values, we note the excellent agreement between the three components of the $\mathbf{g}$-tensor determined here and the values deduced from powder spectra of $S_3N_2^{+\bullet}$ (9, 10). The maximum principal value of the ^{14}N

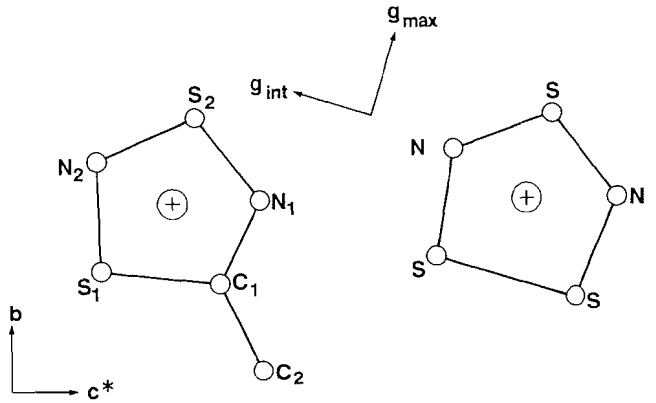

FIG. 4. Projection along *a* of the host cation structure, and the presumed orientation of the impurity cation radical $S_3N_2^{+\bullet}$.

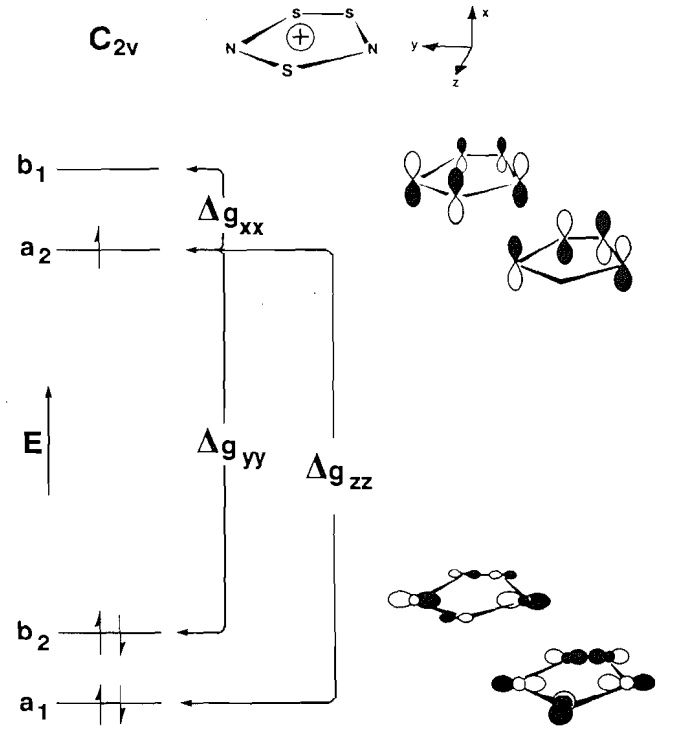

FIG. 5. Hückel molecular orbitals and symmetry-allowed *g* shifts for $S_3N_2^{+\bullet}$.

hyperfine interaction, a_{xx}, is also in good accord with the powder value, but the remaining two values seem to be larger than the limits imposed by the line-widths of the powder spectrum (Table 2). Hyperfine coupling to the ^{14}N nuclei was not resolved in the *yz* (*bc**) plane (Figs. 2, 3), and only crude estimates of its value were made (Fig. 3) from line-width measurements and simulations. Furthermore, with such small couplings the contribution from the ^{14}N nuclear Zeeman interaction (≈1 MHz) to the "observed" splittings cannot be ignored (3). A better estimate of the very small hyperfine interactions, a_{yy} and a_{zz}, can be obtained from a comparison of the isotropic value, measured in SO_2 or D_2SO_4 near room temperature (Table 2), and the value of a_{xx}. In this manner we obtain a $^{14}\mathbf{N}$ tensor of (25.4, 0.8, 0.8) MHz with standard errors of 0.1 MHz in each component, providing the tensor is perfectly axial.

Considering next the principal directions of the **g**- and $^{14}\mathbf{N}$ hyperfine tensors, we note that since **g** is distinctly rhombic, all three principal directions are well defined. In the case of the $^{14}\mathbf{N}$ tensors, the proximity, the uncertainty and the small magnitudes of a_{yy} and a_{zz} result in ill-defined directions for those two components. Nevertheless, they are found to lie 12° from g_{yy} and g_{zz}, respectively. The direction of unique and maximum hyperfine is, of course, very well defined; it lies only 1° from g_{xx}. We conclude, therefore, that to within the experimental error (±2°) all three tensors are collinear.

In Table 3 we have assembled some directions in the *abc** basis of the host crystal (12) which are germane to the present discussion. The perpendicular to the host cation plane lies 6.5° from g_{xx} and 7.4° from a_{xx}. g_{xx} (maximum *g*) lies 4.0° from the bisector of $N_1S_2N_2$, and g_{yy} lies 11.9° from C_1S_1. If we accept the π-radical description (Fig. 1) of $S_3N_2^+$ in which g_{min} and a_{max} lie perpendicular to the radical plane and g_{max} lies along the (*z*) two-fold axis (9, 10) we see (Fig. 4) that the impurity radical cation has substituted for the host cation in the manner most expected. Since this particular orientation accounts for both powder and single-crystal data and corresponds to the predictions (see below) of simple molecular orbital calculations, we feel that the assignment of $^2A_2$ in C_{2v} for the electronic ground-state wavefunction of $S_3N_2^{+\bullet}$ can be accepted with a high degree of confidence.

The assignment of the in-plane *g* values, given without justification in our earlier work (9, 10), is corroborated by the present data if the orientation of Fig. 4 is in fact correct. Molecular orbital calculations at the Hückel and INDO levels give some support for the assignment of g_{max} to the two-fold axis. Figure 5 shows the upper filled and the lowest unoccupied molecular orbitals predicted by an energy optimized Hückel calculation, and indicates the symmetry-allowed *g* shifts which may arise through spin–orbit interactions of the half-filled a_2 level with neighbouring levels. (INDO predictions are similar and do not alter the conclusions reached here regarding *g* shifts.) The Stone formula (14) tells us that the *g* shift is proportional to the spin–orbit interaction and inversely proportional to the difference in energy between ground and excited states. Since the spin–orbit coupling constant for sulphur is roughly 5 times that for nitrogen (15), the *g* shifts in $S_3N_2^{+\bullet}$ are essentially determined by sulphur orbital components in the ground and excited states. At first glance, the proximity of the b_1 level suggests a significant *negative* shift for $H_0//x$, but the orbital compositions of a_2 and b_1 are inappropriate: *both* are made up

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

of p_x atomic orbitals, so that spin–orbit interaction is zero to first approximation. Similarly, energy considerations alone (Fig. 5) would suggest that the (positive) g shift along y should exceed that along z. However, the b_2 orbital has very little contribution from p_z atomic orbitals which generate the spin–orbit interaction about y. In contrast, the a_1 orbital has important S $3p_y$ components which are responsible for the considerable positive g shift when $H_0 // z$. Qualitatively, therefore, the molecular orbital predictions match the experimental **g** tensor extremely well: maximum g is predicted to lie along the two-fold axis (z); g_{xx} and g_{yy} are predicted to lie very near to the free-spin value with small negative and positive departures therefrom, respectively.

Ideally, it would be desirable to study the ESR spectrum of $S_3N_2^{+\bullet}$ in a single crystal of its dimer $S_6N_4^{2+}$, whose crystal structure is well-established (16). The dimer is known to contain small amounts of the radical (16) but unfortunately, it has not proven possible to grow a crystal of sufficient size for our purposes. However, it may be feasible to use a host more symmetrical than $CH_3\overline{CNSNS}^+$ such as the salts of $R\overline{CSNSC}R^+$, where R = H, CH_3 etc. Unfortunately, in spite of our successes (10) in labelling $S_3N_2^+$ with sulphur-33 and nitrogen-15, there does not appear to be a practicable way of introducing the labelled radical into a single crystal.

Acknowledgements

We would like to express our gratitude to Dr. A. G. Kendrick of Durham University for the gift of a sample $S_2N^+AsF_6^-$: K.F.P. and L.H.S. are also indebted to NATO for a travel award.

Electron thermalization distance distribution in liquid carbon monoxide: electron capture

G. RAMANAN AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 13, 1987

G. RAMANAN and GORDON R. FREEMAN. Can. J. Chem. **66**, 1304 (1988).

Electron thermalization in X irradiated liquid CO is truncated by electron capture to form an anion, as it is in liquid N_2. The thermalization distance distribution in these two liquids is a modified exponential, rather than the modified Gaussian obtained in liquid hydrocarbons where electron capture does not occur. The density normalized distance parameter $b_{EP}d$ in CO was constant, 2.8×10^{-6} kg/m^2, at densities $2.7 \gtrsim d/d_c > 2.0$, but increased somewhat at lower densities, reaching 3.3×10^{-6} kg/m^2 at $d/d_c = 1.4$. The thermalization distances in CO are about two thirds those in N_2 at the same density. Electrons are captured more readily by CO than by N_2.

G. RAMANAN et GORDON R. FREEMAN. Can. J. Chem. **66**, 1304 (1988).

Comme il a été observé antérieurement dans le N_2 liquide, la thermalisation des électrons dans le CO liquide irradié par des rayons-X est tronquée par une capture d'électron qui forme un anion. Dans ces deux liquides, la distribution de la distance de thermalisation est une exponentielle modifiée plutôt que la distribution de Gauss modifiée observée dans les hydrocarbures liquides dans lesquels la capture d'électron ne se produit pas. Dans le CO, à des densités $2{,}7 \gtrsim d/d_c > 2{,}0$, le paramètre de distance normalisé pour la densité, $b_{EP}d$, est constant à $2{,}8 \times 10^{-6}$ kg/m^2; toutefois, à des densités plus faibles, cette valeur augmente pour atteindre $3{,}3 \times 10^{-6}$ kg/m^2 à $d/d_c = 1{,}4$. A la même densité, la distance de thermalisation dans le CO est environ les deux tiers de celle dans le N_2. Il se produit une capture plus rapide des électrons dans le CO que dans le N_2.
[Traduit par la revue]

Introduction

The distribution of electron thermalization distances in X irradiated liquid nitrogen has been found to be non Gaussian (1), which is different from those in hydrocarbons (2). The distribution is mainly a one-dimensional exponential, attributed to truncation of the electron thermalization process by electron capture (3). Carbon monoxide is isoelectronic with nitrogen, and both form transient anions with low energy electrons, carbon monoxide at 0.27 aJ (1.7 eV) and nitrogen at 0.37 aJ (2.3 eV) (4). We therefore chose carbon monoxide for a comparative study.

The rotational constants for CO and N_2 are $B = 3.9 \times 10^{-23}$ J and 3.6×10^{-23} J, respectively, and the vibrational quanta are also similar, respectively 4.4×10^{-20} and 4.3×10^{-20} J (5). The electric moments are more different: dipole 3.7×10^{-31} C m (6) and zero; quadrupole 6.0×10^{-40} C m^2 (7) and 5.1×10^{-40} C m^2 (8) for CO and N_2, respectively. Thus rotational and vibrational excitation by low energy electrons are more efficient for CO (4*b*, 9) than for N_2 (10) in the gas phase, and presumably also in the liquid phase. One might therefore expect shorter thermalization distances in liquid carbon monoxide than in liquid nitrogen at the same density.

Experimental

Materials

Matheson Research Grade CO (99.99%) with sub ppm levels of oxygen, methane, ethane, and hydrogen, and other impurities like carbon dioxide (<5 ppm), nitrogen (~35 ppm), propane (~35 ppm), and dimethyl ether (~15 ppm), was used after purification. The CO from the cylinder was passed through a column of KOH pellets previously degassed in the high vacuum line at an elevated temperature (heated with a brush flame while watching the pressure gauge). This CO was then passed through cold traps kept in liquid oxygen (~90 K), to reduce the condensable impurities. The standard technique of reducing sub ppm levels of oxygen by keeping over a potassium mirror was not possible due to the rapid reaction of this metal with CO (11–13) to give a sequence of colored substances ending in a black solid. The indication that our method of purification reduced the impurity to acceptable levels was indicated by the linear electron current transient (ECT) signal obtained in a low pressure sample.

Sample preparation, irradiation, and dosimetry

The CO was transferred in the vacuum line by distillation with liquid nitrogen as coolant.

The amount of material transferred into the cell was measured in a calibrated burette at a known temperature (77.3 K). From the volume and density, the mass of the material put into the cell was known (6.08 ± 0.04 g).

The conductance cell was of the high pressure type (14). Its internal volume including the tip of the capillary that had been sealed after filling was 21.6 ± 0.1 cm^3. The volume was measured by filling with distilled water using calibrated syringes. The distance between the electrodes was 3.3×10^{-3} m and the cell constant was 12.9 m^{-1} (measured by a four wire capacitance bridge, Electro Scientific Industries model 273, calibrated by a General Radio precision capacitance model 1422-CD).

The cell was accurately positioned in a cylindrical Dewar covered with a styrofoam top, all in a Faraday cage. The method of temperature control was described earlier (15) with one essential difference. The electrical connection through the 1 cm thick glass cell wall to the collector electrode was a 2 mm OD Kovar tube, sealed at the electrode end, which took a 30 gauge copper–constantan thermocouple (calibrated) inside the cell to within ~2 mm of the electrode surface. The recorded temperatures are those at the electrode. The temperature differences between different places on the outside surface of the cell were up to ±0.4 K due to inhomogeneities in the flow of thermostating gas. The temperature registered inside the Kovar tube was usually 0.1 K higher than the average of the three temperatures measured at the top, middle and bottom of the outside surface of the cell.

The irradiations were with 300 ns pulses of 1.7 MeV (270 fJ) X rays which delivered 1.0×10^{11} eV/g (1.6×10^{-5} J/kg) to the sample. Dosimetry was done with lithium fluoride thermoluminescent crystals between the electrodes of a dummy cell that had the same geometry as the conductance cell. The crystals were calibrated against the Fricke dosimeter (16). Energy absorption in liquid CO was calculated from that in the Fricke solution by multiplying by the ratio of the electron densities. The numbers of moles of electrons per gram are CO, 0.500; Fricke solution, 0.554.

[b]Critical fluid: T_c, d_c, and assume η_c equals that of nitrogen.

Free ion yields and ion mobilities

The free ions produced in the liquid by each pulse of radiation were measured by sweeping them from the sensitive volume by an electric field and integrating the charges. A low drift integrator (17) and a Nicolet 1170 waveform digitizer were used. Separate measurements were made with positive and negative applied voltages. For a given magnitude of voltage, the amount of charge collected was the same for the positive and negative applied voltages within 5%; the average was used at each voltage to calculate the yield.

The ion mobilities were measured by a time of flight method (18, 19).

Physical properties

Values of the density, d, of liquid CO under its vapor pressure at various temperatures were obtained from ref. 20.

Values of the dielectric constant, ϵ, were calculated from the Mosotti–Clausius relation and the densities using $\epsilon = 1.572$ and $d = 805$ kg/m^3 at 77.3 K as the basis. This value of the ϵ was obtained by measuring the capacitance of the cell filled with liquid N_2 and then with liquid CO at 77.3 K; $\epsilon(N_2) = 1.431$ (1). Our value of $\epsilon = 1.539$ for liquid CO at 84.9 K compares with 1.55 reported earlier (21).

Values of the viscosity of liquid CO are not available in the literature. We have approximated them by using values for N_2 at the same T/T_c (Table 1).

Results

Free ion yields

Yields were measured in the liquid under its vapor pressure at temperatures from 77.3 to 131.2 K (Figs. 1 and 2). The data at 77.3 K were taken with the cell immersed in liquid nitrogen, whereas the rest were taken with the thermoregulated nitrogen gas flowing through the Dewar vessel. The attenuation of the X ray beam by the liquid nitrogen bath was estimated by putting methanol in the Dewar during dosimetry (density 790 kg/m^3 at 295 K), because the LiF crystals had to be irradiated at room temperature. The attenuation factor was 1.15, after adjusting for the different electron densities of nitrogen (0.500 mol/g) and methanol (0.562 mol/g).

Measurements in the liquid nitrogen bath were used as a monitor from day to day. The four sets of free ion yield values agreed within 2%.

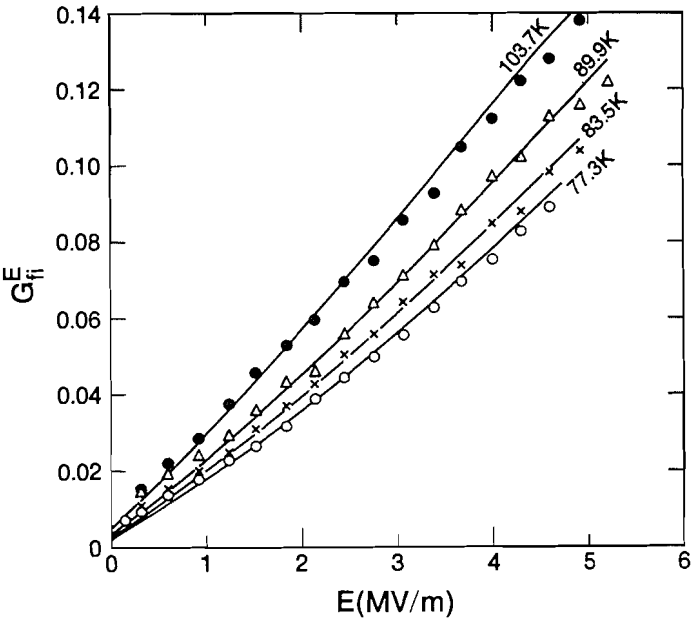

FIG. 1. Free ion yields in liquid CO at the temperatures indicated. The lines were calculated from eqs. [1]–[5], using parameter values from Table 1.

Ion mobilities

The ion mobilities in liquid carbon monoxide were measured at temperatures ranging from 77.3 to 131.2 K. The variation of ion current with time showed a single slope even at high fields, indicating little difference between anion and cation mobilities. The mobilities are independent of applied field strength over the range 0.3–5.2 MV/m, and are listed in Table 1.

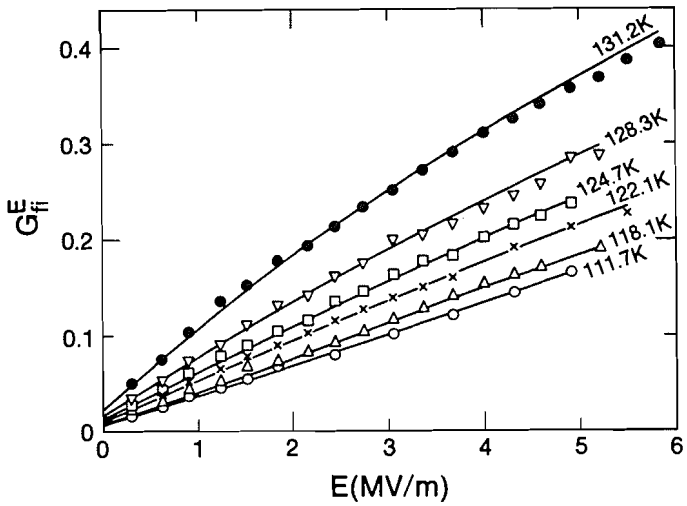

FIG. 2. Free ion yields in liquid CO at the temperatures indicated. Lines calculated as in Fig. 1.

Discussion

Free ion yields and electron thermalization distances

Information about the distribution function $F(y)$ of electron thermalization distances y in irradiated liquids can be obtained from the field and temperature dependences of the free ion yields (1, 22–24). The relevant equations relate the measured yield G^E_{fi} at applied field strength E to the total ionization yield G_{tot} and the probability $\phi^E_{fi}(y)$ that an electron with thermalization distance y escapes geminate neutralization and becomes a free ion.

$$[1] \quad G^E_{fi} = G_{tot} \int_0^\infty F(y)\phi^E_{fi}(y)dy$$

where

$$[2] \quad \phi^E_{fi}(y) = \phi^0_{fi}(y)[1 + f(E,y,T)]$$

where $\phi^0_{fi}(y)$ is the escape probability at zero applied field,

$$[3] \quad \phi^0_{fi}(y) = \exp(-r_c/y)$$

where $r_c = \xi^2/4\pi\epsilon_0\epsilon k_B T$ is the distance (value of y) at which the coulombic attraction between the ion and electron in a pair equals the average thermal energy $k_B T(J)$, ξ is the protonic charge (C), ϵ_0 is the permittivity of vacuum, and ϵ is the relative permittivity of the medium between the two charges. The function $f(E,y,T)$ describes the fractional increase of G^E_{fi} with increasing E,

$$[4] \quad f(E,y,T) = e^{-\beta y} \sum_{n=1}^{\infty} \frac{(\beta y)^n}{(n+1)!} \sum_{j=0}^{n-1} (n-j) \frac{(r_c/y)^{j+1}}{(j+1)!}$$

where $\beta = \xi E/k_B T$.

Equation [4] is based on an assumption that each ion–electron pair is sufficiently far from other pairs that each electron is coulombically influenced only by its sibling ion, although for a fraction of the electrons this is not true. Furthermore, the value of G_{tot} in eq. [1] is taken equal to that in the gas phase, although the value in the liquid phase is probably a fraction larger. The errors caused by these two assumptions tend to cancel each other (25).

The distribution function $F(y)$ is chosen by fitting eqs. [1] to [4] to measured ion yields. Our recent paper on liquid N_2 (1) describes several Gaussian and exponential forms of $F(y)$, designated YG, YGP, YEC, YE, and YEP. The free ion yields

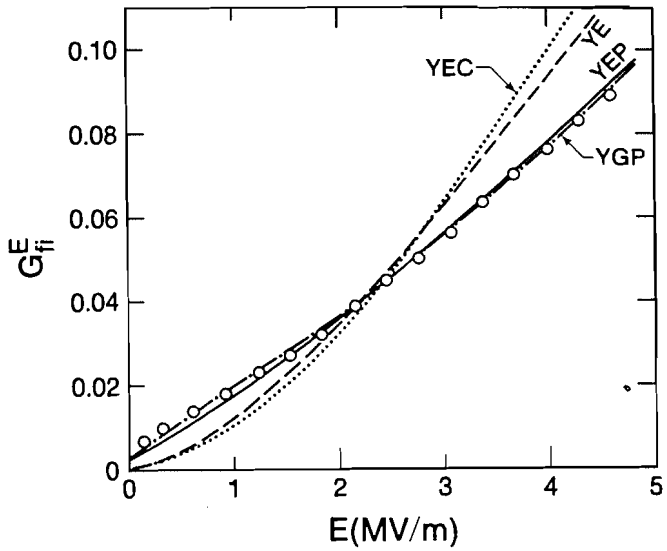

FIG. 3. Effect of distribution of electron thermalization distances on field dependence of calculated free ion yields in liquid CO at 77.3 K. ○, experimental. Lines calculated from eqs. [1]–[4] and the $F(y)$ distributions indicated (1): —, YEP; ----, YE; ...., YEC: -·-·, YGP. Parameter values are in Table 2.

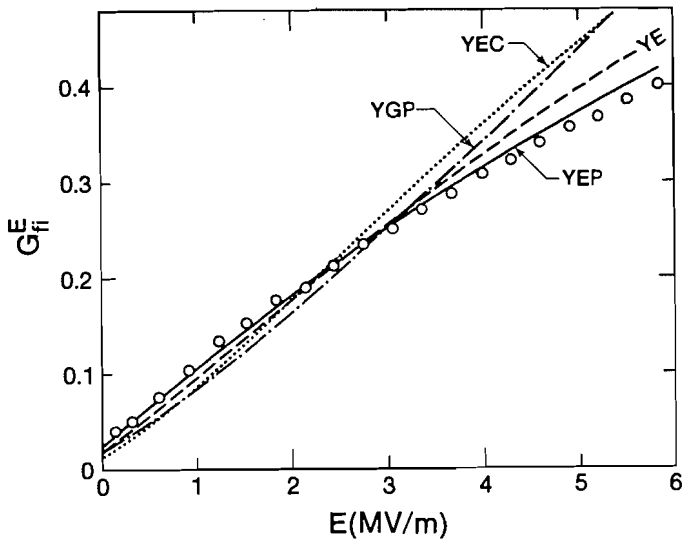

FIG. 4. Experimental (○) and calculated free ion yields in liquid CO at 131.2 K. Symbols as in Fig. 3.

in liquid nitrogen could not be fitted with Gaussian or simple exponential distributions. A similar disagreement occurs for liquid CO (Figs. 3 and 4).

The function YEP that fits the N_2 data (1) also provides the best fit to the CO data over the range of temperatures (Figs. 3 and 4). The distribution YEP is

$$[5] \quad F(y) = \begin{cases} \text{YE} & , 0 < (y - y_0) < 3.5b_{EP} \\ \text{YE} + 0.74\, b^2_{EP}/(y - y_0)^3, & (y - y_0) > 3.5b_{EP} \end{cases}$$

where YE is

$$[6] \quad F(y) = \begin{cases} 0 & , y < y_0 \\ b^{-1}_{EP} \exp[(y_0 - y)/b_{EP}], & y > y_0 \end{cases}$$

where y_0 is taken as 1 nm.

Values of the dispersion parameters of the four functions used

[c]Assume $y_0 = 1$ nm.

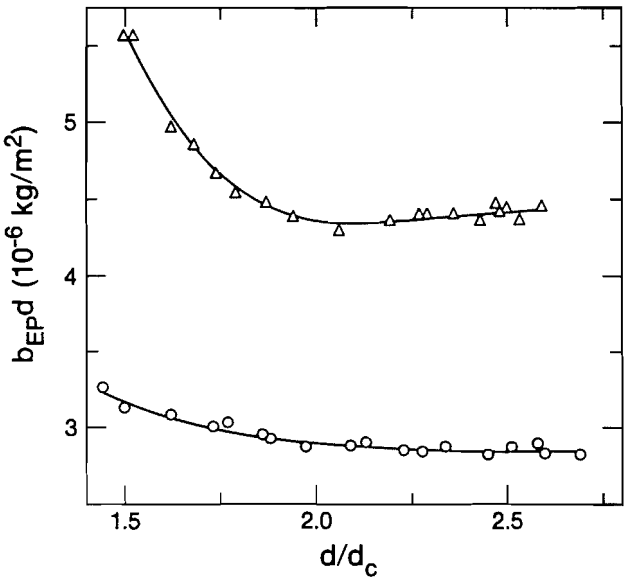

FIG. 5. Electron thermalization distances normalized for liquid density, $b_{EP}d$, as functions of d/d_c, where d_c refers to the critical fluid. △, N_2, d_c = 312 kg/m^3 (1); ○, CO, d_c = 300 kg/m^3.

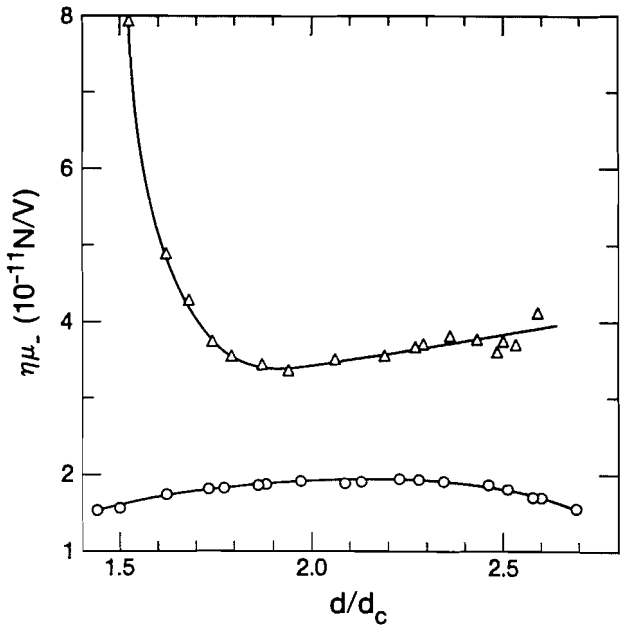

FIG. 6. Anion mobility normalized for liquid viscosity, $\eta\mu_-$, as a function of d/d_c. Symbols as in Fig. 5.

to calculate the curves in Figs. 3 and 4 are listed in Table 2. The values of b_{EP} are also listed in Table 1.

Density dependence of electron thermalization distances

The liquid was under its vapor pressure, so as the temperature was increased from 77.3 to 131.2 K the density decreased from 805 to 433 kg/m^3 (d/d_c from 2.69 to 1.44). The density normalized thermalization distance $b_{EP}d$ decreases with increasing density in the low density liquid, but is constant at $d/d_c > 2.0$ (Fig. 5). The values of $b_{EP}d$ in dense CO are about 1.5 times smaller than those in N_2, and the variation at $d/d_c < 2.0$ is less (Fig. 5). Thus electron thermalization occurs more rapidly in liquid CO than in liquid N_2, as expected.

We conclude that the electron thermalization process in liquid CO is truncated by electron capture to form an anion, as it is in liquid N_2.

The viscosity normalized mobility of the anions in liquid N_2 increased rapidly at $d/d_c < 1.7$, whereas it remained low in that density region of liquid CO (Fig. 6). This confirms that electron capture occurs more readily in liquid CO than in N_2.

Received November 17, 1987

ALEXANDER F. JANZEN, KOHRSHED ALAM, MEEHAE JANG, BARRY J. BLACKBURN, and ANTHONY S. SECCO. Can. J. Chem. **66**, 1308 (1988).

The hydrolysis of $PhTeF_5$, *trans*-Ph_2TeF_4, and *mer*-Ph_3TeF_3 is described. The hydrolysis products $PhTeF_4OH$, Ph_2TeF_3OH, and Ph_3TeF_2OH were identified by ^{19}F nmr and mass spectrometry and, in the case of Ph_3TeF_2OH, by X-ray crystallographic analysis. Ph_3TeF_2OH has non-equivalent fluorines and the conditions under which stereoselective fluorine exchange occurs are described.

Crystals of Ph_3TeF_2OH are triclinic, $P\bar{1}$, $a = 8.791(2)$, $b = 9.832(2)$, $c = 11.147(2)$ Å, $\alpha = 95.51(2)$, $\beta = 102.01(2)$, $\gamma = 112.56(2)°$, and $Z = 2$. The structure was determined from a Patterson map and refined to an R value of 0.026 for 2562 observed data. The coordination about Te is described as octahedral with two phenyl groups *trans* to each other and the third phenyl *trans* to a fluorine. The molecule exhibits the longest Te(VI)—F bond known, 2.011(2) Å. This same F which undergoes the more rapid exchange in solution is involved in H-bonding in the crystal, linking centrosymmetrically related molecules into dimers where OH...F is 1.90(3) Å and O—H...F is 177(4)°. However, H-bonding is not responsible for the stereoselective fluorine exchange in solution.

ALEXANDER F. JANZEN, KOHRSHED ALAM, MEEHAE JANG, BARRY J. BLACKBURN et ANTHONY S. SECCO. Can. J. Chem. **66**, 1308 (1988).

On décrit l'hydrolyse du $PhTeF_5$, du *trans*-Ph_2TeF_4 et du *mer*-Ph_3TeF_3. Pour identifier les produits d'hydrolyse, le $PhTeF_4OH$, le Ph_2TeF_3OH et le Ph_3TeF_2OH, on a fait appel à la rmn du ^{19}F et à la spectrométrie de masse et, dans le cas du Ph_3TeF_2OH, à la diffraction des rayons-X. Le Ph_3TeF_2OH comporte des fluors qui ne sont pas équivalents et on décrit les conditions dans lesquelles il se produit un échange stéréosélectif du fluor.

Les cristaux du Ph_3TeF_2OH sont tricliniques, groupe d'espace $P\bar{1}$ avec $a = 8{,}791(2)$, $b = 9{,}832(2)$ et $c = 11{,}147(2)$ Å, $\alpha = 95{,}51(2)$, $\beta = 102{,}01(2)$, $\gamma = 112{,}56(2)°$ et $Z = 2$. On a déterminé la structure à partir d'une carte de Paterson et on l'a affinée jusqu'à une valeur de R de 0,026 pour 2562 réflexions observées. On décrit la coordination autour du Te comme octaédrique avec deux groupements phényles *trans* l'un par rapport à l'autre et le troisième phényle *trans* par rapport à un fluor. Dans cette molécule, on a observé la plus longue liaison Te(VI)—F connue, 2,011(2) Å. Dans le cristal, l'atome de fluor qui subit un échange rapide en solution est impliqué dans une liaison hydrogène; cette liaison associe des molécules liées d'une façon centrosymétrique et conduit à des dimères dans lesquels la liaison OH...F est égale à 1,90(3) Å et l'angle O—H...F est de 177(4)°. Toutefois, la liaison hydrogène n'est pas responsable de l'échange stéréosélectif de fluor qui se produit en solution.

[Traduit par la revue]

Introduction

The synthesis of organotellurium(VI) compounds (1–3), including a series of phenyltellurium(VI) fluorides prepared in our laboratory (4), has made these compounds available for chemical and structural study. We have carried out an investigation of the hydrolysis of $PhTeF_5$, *trans*-Ph_2TeF_4, and *mer*-Ph_3TeF_3 and determined the X-ray structure of one of the hydrolysis products, Ph_3TeF_2OH. The fluorine ligands in Ph_3TeF_2OH are non-equivalent and stereoselective Te—F bond cleavage may be studied by ^{19}F nmr and compared with the nmr and structural studies reported for the *mer*-Ph_3TeF_3–$Ph_3TeF_2^+$ system (5).

Experimental

Synthesis

^{19}F nmr spectra were recorded on a Bruker WH90 spectrometer at 84.66 MHz with C_6F_6 (−162.9 ppm) as an internal reference. ^{125}Te nmr spectra were recorded on a Bruker AM300 spectrometer at 94.76 MHz using Ph_2Te (692 ppm with respect to Me_2Te) as an external reference. Mass spectra were obtained on a Finnegan 1015 quadrupole instrument. XeF_2 was obtained from PCR Research Chemicals Inc. $PhTeF_5$, Ph_2TeF_4, and Ph_3TeF_3 were prepared from XeF_2 and PhTeTePh, Ph_2TeF_2, and Ph_3TeF, respectively, as described previously (4, 5).

cis- *and* trans-*$PhTeF_4OH$*

H_2O (0.20 mmol) was added to a solution of $PhTeF_5$ (0.19 mmol) in acetonitrile (0.3 mL) in an nmr tube fitted with a Teflon insert and closed with a plastic cap. The mixture was kept at room temperature for 1 h with occasional gentle shaking. ^{19}F nmr examination of the reaction mixture shows the formation of *cis*- and *trans*-$PhTeF_4OH$. The *cis*-to-*trans* ratio was approximately 1:3 and the combined yield was about 70%, as determined by nmr peak integration.

Nuclear magnetic resonance data are shown in Table 1. Mass spectrum of 1:3 mixture of *cis*- and *trans*-$PhTeF_4OH$, m/z: 300 (M^+), 281 ($M^+ - F$), 223 ($M^+ - Ph$).

Ph_2TeF_3OH

H_2O (0.10 mmol) was added to *trans*-Ph_2TeF_4 (0.08 mmol) in CD_3CN (2 mL) in a Teflon-lined nmr tube. After 5 days at 25°C, Ph_2TeF_3OH (20%) and unreacted Ph_2TeF_4 (80%) were present. Nuclear magnetic resonance data in Table 1; ms m/z: 358 (M^+).

Ph_3TeF_2OH

Ph_3TeF_2OH was often observed as a minor component in samples of Ph_3TeF_3, Ph_3TeF_2Cl, $Ph_3TeF_2{}^+PF_6{}^-$, and Ph_4TeF_2. It was crystallized from dichloromethane solution and identified by X-ray crystallography, ^{19}F nmr (Table 1) and ms, m/z: 416 (M^+), 399 ($M^+ - OH$), 339 ($M^+ - Ph$).

X-ray crystallographic analysis of Ph_3TeF_2OH

$C_{18}H_{16}OF_2Te$ fw = 413.92

Triclinic, $P\bar{1}$, a = 8.791(2), b = 9.382(2), c = 11.147(2) Å, α = 95.51(2), β = 102.01(2), γ = 112.56(2), V = 814.6(4) Å^3, Z = 2, ρ_c = 1.687 g cm^{-3}, ρ_0 not measured, μ = 18.5 cm^{-1}, (21°C; MoKα, λ = 0.71073 Å).

Reflection data from a single crystal of Ph_3TeF_2OH grown from dichloromethane were collected on a Nicolet $R3m$ automated diffractometer. Data were collected with the ω–2θ mode in the range $3° \leq 2 \leq 50°$, exploring the $\pm h$, $\pm k$, $\pm l$ region of reciprocal space. Of the 3042 reflections measured 2879 were considered unique after symmetry equivalents were averaged, R_{sym} = 0.013. The 2564 observed reflections had $I \geq 1.5\sigma(I)$, where $\sigma(I) = R[S + B_L + B_R]$, R = scan rate, S = total scan count, and B_L, B_R = left and right background counts. Data were corrected for Lorentz and polarization effects. An empirical absorption correction based on the reflection intensity measurements at 36 different azimuthal angles for 10 reflections was also applied. Other aspects of data collection were as reported in an earlier publication (5).

A Patterson map revealed the positions of the Te and both F atoms. Refinement of these atoms, followed by difference Fourier syntheses yielded the remaining atoms. The complete list of atoms was refined by full-matrix least-squares procedures[1] with the Te corrected for anomalous dispersion (6). Non-hydrogens were refined with anisotropic temperature parameters, whereas, hydrogens were assumed to undergo isotropic thermal motion. Convergence was reached at R = 0.027 and R_w = 0.020 where $R = \Sigma||F_o| - k|F_c||/\Sigma|F_o|$ and $R_w = [\Sigma w(|F_o| - k|F_c|)^2/\Sigma w|F_o|^2]^{1/2}$. A weighting analysis confirmed the use of the weights $w = 1/\sigma^2(F_o)$ in the function $\Sigma w(|F_o| - k|F_c|)^2$ which was minimized throughout the refinement. It was apparent at this stage that the two reflections for which the attenuator was required during data collection were in poor agreement with their calculated, F_c, values. Because of uncertainty in the operation of the attenuator it was decided that the two low angle reflections $\bar{2}01$ and $\bar{1}21$ should be eliminated from the data set. The final cycle of refinement yielded values of R = 0.026 and R_w = 0.020 for 2562 observed data and R = 0.032 and R_w = 0.020 when the 2877 observed and unobserved data were included. Mean and maximum shifts were 0.072 and 0.492σ, respectively, and the goodness of fit, S = 1.570. A final difference map showed a maximum peak of 0.484 e$^-$/Å^3 located between Te and C(13), and three troughs −1.06 e$^-$/Å^3 (0.239, 0.276, 0.209), −1.02 e$^-$/Å^3 (0.110, 0.222, 0.247), and −0.645 e$^-$/Å^3 (0.102, 0.199, 0.166) symmetrically positioned and forming a triangle about, and in a plane with the Te atom. The mean plane through the three troughs and the Te atom lies approximately 34° away from the mean plane through Te, F(1), O, C(1), and C(13) with the $\bar{T}e$...trough(3) vector pointing towards H(O). These troughs may be due to the inadequacy of ellipsoids in describing the anisotropic thermal motion of the Te atom and that higher order functions may be required for a more detailed description of the motion. Scattering factors for Te, C, and O were from ref. 7 while those for hydrogen were from ref. 8. Final atomic positional parameters are given in Table 2.[2] Thermal

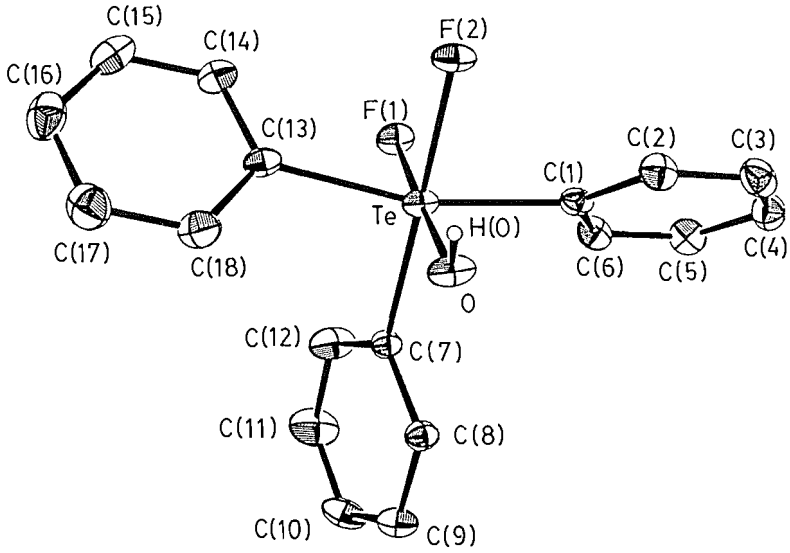

FIG. 1. ORTEP drawing of the Ph_3TeF_2OH molecule. Atoms are represented by thermal ellipsoids at the 50% probability level.

motion analysis (9) in terms of rigid-body modes of translation, libration, and screw motion indicated some independent motion of the PhTe groups and the C_3TeF_2O moiety.

Discussion

The hydrolysis of $PhTeF_5$ was carried out in acetonitrile solution at 25°C in the presence of 1 equiv. of H_2O,

[1] $$PhTeF_5 + H_2O \xrightarrow[CH_3CN]{} PhTeF_4OH + HF$$

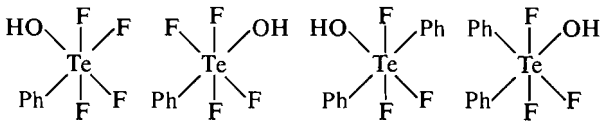
and the product $PhTeF_4OH$ consisted of a 1:3 mixture of *cis* **1***a* and *trans* **1***b* isomers in a combined yield of 70%. The ABC_2 and A_4 ^{19}F nmr spectra (Table 1) establish the geometry of *cis* **1***a* and *trans* **1***b* isomers.

trans-Ph_2TeF_4 hydrolysed more slowly than $PhTeF_5$ and the

[2] $$trans\text{-}Ph_2TeF_4 + H_2O \xrightarrow[CH_3CN]{} Ph_2TeF_3OH + HF$$

product Ph_2TeF_3OH, **2**, was formed in 20% yield after 5 days at 25°C. Only one AB_2 ^{19}F nmr spectrum (Table 1) was observed but three isomeric structures are possible for Ph_2TeF_3OH. Since each of the three isomers is expected to have an AB_2 spin system, therefore, we cannot establish which isomer is the hydrolysis product.

The hydrolysis product Ph_3TeF_2OH, **3**, was present as a minor contaminant in samples of *mer*-Ph_3TeF_3, Ph_3TeF_2Cl, $Ph_3TeF_2^+PF_6^-$, and Ph_4TeF_2 and its AB ^{19}F nmr spectrum is consistent with structure **3**.



1*a* **1***b* **2***a* **2***b*

F(2)—Te—C(1)	83.74(11)	C(7)—Te—C(13)	96.35(13)

TABLE 4. Selected bond lengths (Å) with estimated standard deviations in parentheses

	Length			Length	
Bond	Uncorr.	Corr.	Bond	Uncorr.	Corr.
Te—F(1)	1.951(2)	1.958	Te—C(1)	2.119(4)	2.124
Te—F(2)	2.011(2)	2.016	Te—C(7)	2.123(3)	2.129
Te—O	1.929(2)	1.937	Te—C(13)	2.110(4)	2.115

Ph_3TeF_2OH molecules (Fig. 1) exist in a conformation similar to molecules of *mer*-Ph_3TeF_3 (5) which is best described by the distorted octahedral bonding about the central Te atom with the phenyls oriented so as to minimize the intramolecular steric strain. The *trans* phenyl groups adopt a bent propeller arrangement. They form a dihedral angle of 92° between the mean planes of the rings and form a C—Te—C angle of 165.37(12)° (Table 3) compared to the corresponding angles of 109° and 167.98(11)° in Ph_3TeF_3. Despite the increased twist of the phenyls and the closing of the C—Te—C angle, intramolecular contacts between these phenyls and the equatorial F are very similar to those in the trifluoride structure. The contacts are able to be maintained as a result of the long Te—F(2) bond of 2.011(2) Å (Table 4).

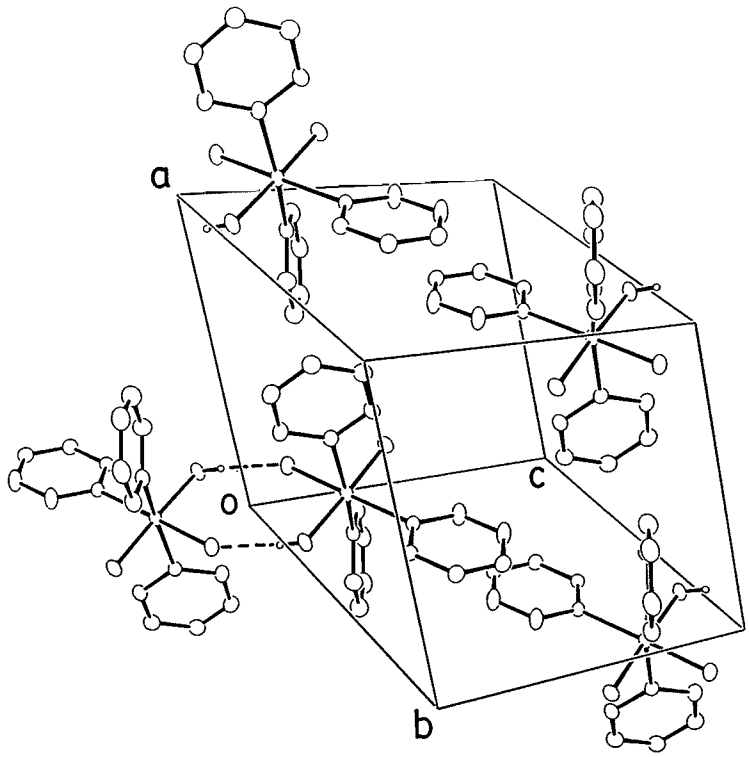

FIG. 2. ORTEP packing diagram of Ph_3TeF_2OH molecules with dashed lines indicating H bonding.

Both Te—F bond lengths (2.011(2) Å, 1.951(2) Å) are significantly longer than their counterparts (1.954(2) Å, 1.915(2) Å), respectively) in Ph_3TeF_3 (5) but there is no accompanying increase in Te—C bond lengths. Since it is unlikely that packing forces would affect bond lengths to this extent, it is reasonable to suggest that the 2–3% difference in Te—F bond lengths is due to the replacement of F by OH but how the OH decreases the electron density in the Te—F bonds is unclear. One explanation may be a $(d–p)\pi$ interaction between the Te and O as suggested for $Te(OTeF_5)_4$ (10). It is of interest to note that the Te(VI)—F bond length of 1.954 Å in Ph_3TeF_3 was the longest known and is now superseded by the 2.011 Å Te(VI)—F bond in the present compound.

An additional minor difference between the conformations of Ph_3TeF_2OH and Ph_3TeF_3 is manifested in the amount of twist of the C(7)—phenyl ring about the Te—C(7) bond. The twist is defined by the torsion angles O—Te—C(7)—C(8) (−21.6°) and F(1)—Te—C(13)—C(18) (−10.5°) in the respective compounds. The extra 11° twist in the hydroxide molecule is required to reduce the steric interaction between H(C8) and the OH group which is bulkier, and protrudes further over the phenyl than the corresponding fluoride ligand in Ph_3TeF_3.

The Te(VI)—O(H) bond length of 1.929(3) Å can be compared to the only other known Te(VI)—O(H) distances of 1.904(5) Å and 1.937(5) Å found in $H_2Te_2O_6$ (11). While the former is considerably shorter, the latter is not significantly different from that in the present structure. Lindqvist *et al.* (11) have suggested that the variation in Te(VI)—O(H) bond lengths in $H_2Te_2O_6$ results from a difference in π bonding between Te and each of the hydroxy groups. If the bond length can be used as an indicator for π bonding, it appears that such bonding does not occur to a large extent in Ph_3TeF_2OH.

Crystal packing (Fig. 2) is dictated by hydrogen bonding linking centrosymmetrically related molecules into dimers via O—$H(x,y,z)\ldots F(2)(\bar{x},\bar{y},\bar{z})$ (and by symmetry $F(2)(x,y,z)\ldots H$—$O(\bar{x},\bar{y},\bar{z})$) and by π–π interactions resulting from [C(1)]-phenyl$(x,y,z)\ldots$[C(1)]phenyl$(1-x, 1-y, \bar{z})$ overlap. The hydrogen bonded dimers have H...F distances of 1.90(3) Å and O—H...F angles of 177(4)° compared with tetravalent $H_2Te_2O_3F_4$ where H bonds link the molecules in a diamond network and the respective values are 1.6 Å and 164° (12).

The phenyl...phenyl stacking, where the interplanar spacing is 3.46 Å, links H-bonded dimers into a chain along the [110] direction. Similar stacking is observed in Ph_3TeF_3 (5) and Ph_2TeCl_2 (13).

The AB ^{19}F nmr spectrum of **3** is consistent with the solid state structure as determined by X-ray crystallography. Since the fluorines are non-equivalent, the relative rate of Te—F^a versus Te—F^b bond cleavage may be studied by ^{19}F nmr and the results compared with the stereoselective exchange observed in the *mer*-Ph_3TeF_3–$Ph_3TeF_2^+$ system (5).

Under certain conditions, no intra- or intermolecular fluorine exchange can be observed by ^{19}F nmr and **3** is thus a "rigid" molecule in solution. For example, re-crystallizing **3** from CH_2Cl_2 or treating solutions of **3** with NaF stops all fluorine exchange. As found previously, treatment with NaF or R_4NCl also stopped fluorine exchange in the *mer*-Ph_3TeF_3–$Ph_3TeF_2^+$ system (5) because any five-coordinate Te(VI) cation was converted to a six-coordinate Te(VI) compound.

On standing for several days in glass nmr tubes, intermolecular fluorine exchange in **3** was observed by ^{19}F nmr. This exchange leads to loss of F^a—F^b and Te—F^a coupling but retention of Te—F^b coupling, as shown in Fig. 3, and these results demonstrate that Te—F^a bonds are cleaved more rapidly than Te—F^b bonds in the exchange process. This behaviour resembles that observed in the *mer*-Ph_3TeF_3–$Ph_3TeF_2^+$ system

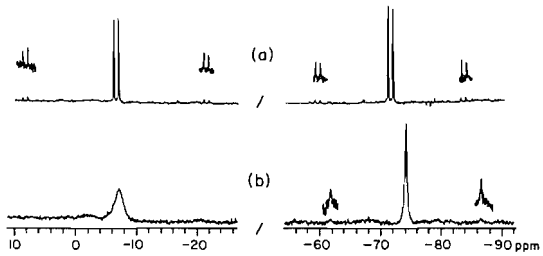

FIG. 3. ^{19}F nmr spectrum of Ph_3TeF_2OH, **3**: (*a*) in the absence of fluorine exchange. Fluorine–tellurium couplings given in Table 1. (*b*) with exchange, showing loss of F^a—F^b and Te—F^a coupling but retention of Te—F^b coupling.

and we propose a similar mechanism, namely, initial formation of cation **4**, followed by a rapid equilibrium involving a fluorine-bridged intermediate **5** in which F^a occupies the bridging position.

[3] $$Ph_3TeF_2OH \xrightarrow[\text{e.g. HF}]{\text{Lewis acid}} Ph_3TeFOH^+AF^-$$

[4] 
3 **4** **5**

We assume that a Lewis acid such as HF, or Si or B fluorides which are produced by the reaction of HF with glass, reacts with **3** to give cation **4**; although **4** could not be observed directly, it was found that treatment of an exchanging sample of **3** with NaF stopped exchange and regenerated "rigid" **3**, presumably because any cation **4** was converted to **3**. Reactions of phenyltellurium(VI) fluorides with PF_5 can generate cations such as $Ph_3TeF_2^+$ (5) or Ph_3TeFCl^+,[3] but the use of PF_5 would be inappropriate for the synthesis of Ph_3TeFOH^+ because of the presence of the hydroxy group.

Those features in the Ph_3TeF_3–$Ph_3TeF_2^+$ system (5) which were assumed to be important for the observation of stereoselective fluorine exchange are also present in the Ph_3TeF_2OH–Ph_3TeFOH^+ system, namely, the presence of three phenyl substituents which prevents the scrambling of F^a and F^b ligands, significantly longer Te—F^a bonds (2.011 Å in **3**) than Te—F^b bonds (1.951 Å in **3**), and a F^a-bridged intermediate **3** which minimizes the steric interactions among six phenyl substituents.

Although hydrogen-bonding leads to dimerized Ph_3TeF_2OH molecules in the solid state, such hydrogen-bonding cannot be responsible for stereoselective fluorine exchange because re-crystallized samples of **3** show no fluorine exchange in solution.

The conformational behavior of aromatic α-diimines has been analyzed by means of *ab initio* computations making use of the standard STO-3G minimal basis set. The absolute minimum of the potential energy curve always corresponds to the planar *trans* conformation and a secondary minimum is also found for a non planar cisoid conformation. An alternate analysis, rooted in bond energy calculations explicitly involving the charges of the bond-forming atoms, indicates that bonded rather than nonbonded interactions are responsible for the observed conformational preferences.

VINCENZO BARONE, CAMILLA MINICHINO, SÁNDOR FLISZÁR, et NINO RUSSO. Can. J. Chem. **66**, 1313 (1988).

Une étude conformationelle *ab initio*, conduite en base minimale STO-3G, est présentée pour une série d' α-diimines aromatiques. La conformation planaire trans correspond dans tous les cas au minimum absolu de la courbe de potentiel, un minimum secondaire étant observé pour la forme cisoïde non planaire. Une analyse complémentaire, basée sur des calculs d'énergies de liens en termes de charges électroniques, montre que ce sont les interactions liées (par opposition a celles entre atomes non liés) qui sont responsables pour les préférences conformationelles observées.

Introduction

Transition metal complexes of aromatic α-diimine ligands such as 2,2′-bipyridine (bpy) have found extensive applications in preparative and analytical chemistry for almost a century (1–3) and are currently receiving further attention in view of solar energy conversion and storage (4, 5) and of modelling intermediates in transition metal catalyzed reactions (6, 7). In this connection, since the replacement of CH groups by N atoms leads to more electron-deficient compounds, attention has turned to coupled diazines, such as 4,4′-bipyrimidine (bpm), 2,2′-bipyrazine (bpz), or 3,3′–bipyridazine (bpd). Although the complexing ability of these ligands is essentially related to their ionization potentials and electron affinities (8, 9), for such flexible molecules the conformation assumed upon complexation often does not correspond to the equilibrium conformation of the free ligand. This consideration stimulated several experimental investigations about the conformational behavior of heteroaromatic systems consisting of two rings linked together by essentially single bonds (10–13). Only the neighborhood of potential energy minima can be well characterized by these techniques, the rest of the potential energy curve remaining ill defined. Theoretical computations do not suffer from this problem and the only limitation to their systematic use is the definition of the best compromise between reliability of the results and computational costs. There is now a general consensus on the use of non empirical computations employing minimal or split valence basis sets (13–18) in the rigid rotor approximation (14–16).

Ab initio studies at these levels have been recently performed in a systematic and comprehensive way for biphenyl (14, 17, 18), bipyridines (13, 19, 20), bipyrimidines (21, 22), phenylpyridines (19), phenylpyrimidines (23), bipyrroles (24, 25), bifurans (15, 26), furylpyrroles (26), phenylpyrroles (27), and bithienyls (28). These studies have shown that the complete torsional potential of nonfused biheterocycles is transferable with a high degree of accuracy among molecules with the same *ortho* substituents, irrespective of the nature of *meta* and *para* groups. On these grounds all the bihexaheterocyclic systems have been grouped into five classes (14), whose serial number corresponds to the number (0 to 4) of *ortho* nitrogen atoms. Two situations are actually possible when there are two nitrogen atoms in *ortho* positions, and the corresponding classes are labelled 2 (when the two nitrogen atoms are on the same ring) or 2′ (when the two nitrogen atoms belong to different rings). Only molecules belonging to class 2′ (i.e. α-diimines) are characterized by a torsional potential which is intrinsically not symmetric around $\theta = 90°$, irrespective of possible asymmetries at *meta* positions. This characteristic implies a doubling of the number of points to be computed for a comparable fitting of the potential and has prevented till now a systematic study of this class. The main object of the present paper is to present a systematic study of this kind and to analyze the results in terms of simple interpretative models. As we shall see, the significant electron redistribution, which accompanies conformational changes, requires the use of a refined model explicitly accounting for the variations of bond energies.

Computational procedure

The torsional potentials of the title molecules were computed by the internal STO-3G basis set (29) of the GAUSSIAN/82 package (30) using structures of the different rings optimized at the STO-3G level (9) and a CC inter-ring distance of 1.50 Å.

The torsional angle θ between the planes of the two rings was spanned in steps of 30°. The different sets of conformational

energies $V(\theta)$ (expressed as the total energies $E(\theta)$ minus the energy $E(0°)$ of the planar *cis* conformation) have been fitted by a truncated Fourier expansion

$$V(\theta) = \Sigma \tfrac{1}{2}V_j[1 - \cos(j\theta)]$$

This fitting allows a quantitative comparison of different molecules and the analytical location of the extreme points on the potential energy curve (10, 14, 25, 26). Furthermore, the physical origin of the low-order potential constants is well recognized (14).

Results

The structures, labelling, and atom numbering of the ligands studied in this work are shown in Figs. 1 and 2. The conformational energies and their six-term Fourier expansions are collected in Table 1 together with the location and relative energies of the critical points of the torsional curves obtained from these expansions. From these data it is apparent that the V_5 and V_6 potential constants play only a negligible role, so that four potential constants are sufficient for an accurate description of the conformational behavior of the title molecules. As a matter of fact, the relative weights of the odd and even potential constants are very similar in these molecules.

From a general point of view, the most striking feature of the results of Table 2 is the very similar torsional potential computed for all the title molecules. Closer inspection of the results, however, reveals a decrease of the *cis–trans* energy difference in going from bpy to the various diazines. Furthermore the value of this barrier is particularly low for bpz.

In agreement with the experimental data for 2,2′-bipyridine (14,31–36) the planar *trans* arrangement always corresponds to the absolute energy minimum. With respect to biphenyl, the loss of steric interactions between the *ortho* hydrogens (at $\theta = 180°$) now favors the planar structure. A second minimum at $\theta = 43 \pm 2°$ is revealed by STO-3G computations. The energy difference and the barrier between the two minima amount to 6 ± 1 and 1.5 ± 0.5 kcal mol^{-1}, respectively, and the position of the second minimum is similar to the minimum conformation of

*The molecules are labelled as in Fig. 1. Energy differences with respect to planar *cis* conformations ($V(\theta)$) and potential terms (V_i) are in kcal mol^{-1} and angles in degrees. For all the molecules the absolute energy minimum corresponds to the planar *trans* conformation ($\theta = 180°$), so that only values for the secondary minimum are reported.

biphenyl. Visibly, the nitrogen lone pair interaction in the planar *cis* conformation of these molecules causes a destabilization similar in nature to that occurring between the *ortho* hydrogens in the planar form of the molecules belonging to class 0. In fact, the energy differences between the second minimum at $\theta \approx 43°$ and the *cis* conformation from one side ($E_1 = 3 \pm 1$ kcal mol^{-1}), or the maximum conformation at $\theta = 90°$ from the other side ($E_2 = 1.5 \pm 0.5$ kcal mol^{-1}), are similar to those found for molecules of class 0 ($E_1 = 3.5$, $E_2 = 2.3$ kcal mol^{-1} for eight molecules (14)).

In agreement with electron diffraction data for 2,2′-bipyridine (36), the planar *cis* form represents the absolute maximum of the potential energy curve. The energy difference between the two planar forms is particularly significant (9 ± 1 kcal mol^{-1}) and can be expressed in terms of variations of (*i*) bond energies and (*ii*) nonbonded interactions between atoms belonging to different rings.

The data of Table 2 show a significant electron redistribution between *cis* and *trans* conformations, which, however, essentially involves the N and H *ortho* atoms. In particular there is a net N → H charge transfer in each *cis* conformation, while the contrary occurs in the corresponding *trans* form. This transfer reduces N ... N and H ... H repulsions in the *cis* conformation, and increases N ... N attractions in the *trans* form. Although the involvement of the sole *ortho* groups explains the similarity of conformational behavior for the molecules belonging to the same class (i.e., with the same *ortho* substituents) the differences in electrostatic interactions between the *cis* and *trans* conformations are reasonably expected to be of minor import (37–39).

Let us now examine how the relative energies of *cis* and *trans* conformations can be affected by electron redistributions. Several studies (37, 40) indicate that the individual bond energies of ground-state molecules are (to a good approximation) linearly dependent on the charges of the bond-forming atoms, i.e.,

$$\epsilon_{ij} = \epsilon_{ij}^0 + a_{ij}\Delta q_i + a_{ji}\Delta q_j$$

*The labelling of the molecules and the numbering of the atoms are defined in Figs. 1 and 2. The values of the a_{ij}'s in kcal mol^{-1} me^{-1} are −0.083 (C—H), −0.358 (C—C), −0.480 (C—N), −0.587 (N—N), −0.632 (H—C), and −0.497 (N—C).

where ϵ_{ij}^0 is for a reference bond with net charges q_i^0 and q_j^0 at atoms i and j, respectively, whereas ϵ_{ij} corresponds to modified charges, $q_i = q_i^0 + \Delta q_i$ and $q_j = q_j^0 + \Delta q_j$. The a_{ij} and a_{ji} parameters (Table 2, Appendix 1) measure the effect of unit charge variations at atom i (bonded to j) and j (bonded to i), respectively.

The derivation of the ϵ_{ij}^0's can be avoided in the present context. Indeed, if only bonded terms are important, the energy difference $V(180)$ between the *cis* and *trans* conformations of the same molecule is

$$V(180) = \left(\sum_{i<j} \epsilon_{ij}\right)^{cis} - \left(\sum_{i<j} \epsilon_{ij}\right)^{trans}$$

$$= \sum_i \sum_j a_{ij} (\Delta q_i^{cis} - \Delta q_i^{trans})$$

$$= \sum_i \sum_j a_{ij} (q_i^{cis} - q_i^{trans})$$

i.e.,

$$[1] \quad V(180) = \sum_i (\Delta' q_i \sum_j a_{ij})$$

where $\Delta' q_i = q_i^{cis} - q_i^{trans}$. The use of eq. [1] involves the computation of reliable net charges. Mulliken's approximation is appropriate because[2] $\Delta' q_i = \Delta' q_i^{\text{Mulliken}}$. The required level of sophistication, using correlated wave functions constructed from extended and carefully optimized basis sets (41, 42), is out of computational reach for the molecules at hand for which we only know Mulliken populations obtained from the STO-3G basis set with standard orbital exponents. On the other hand, past experience (37, 40–42) indicates that the Δq_i's obtained in this manner correlate with their corrected counterparts satisfying charge–energy relationships with great accuracy. On these grounds, we tentatively scale our STO-3G results as follows

$$\Delta' q_i \simeq \frac{1}{2} \Delta' q_i^{\text{STO-3G}}$$

and subsequently show that this approximation suffices to bring the present results in line with the vast body of evidence gathered so far concerning the role of electronic charges in determining molecular energies (37, 40–42).

[2]In a Mulliken-type charge analysis not involving the classical equipartitioning of overlap populations between dissimilar atoms, the net charge of each individual atom must be corrected depending on what is bonded to it (37). These corrections cancel in the differences between net charges of homologous atoms in *cis* and *trans* conformers.

TABLE 3. The calculation of the *cis–trans* energy difference of bipyridazine (bpd)*

Atom	$\Delta' q_i$, me	$\Sigma_j a_{ij}$	$\Sigma_j a_{ij} \Delta' q_i$

C5	−0.2	−0.80	0.2
H5	0.7	−0.63	−0.4
C6	0.3	−0.92	−0.3
H6	−0.4	−0.63	0.2

*The sum of the $\Sigma_j a_{ij} \Delta' q_i$ terms, 6.0 kcal/mol, is taken twice in order to account for the changes occurring in both cycles. The atom numbering is that of Fig. 2.

The energy differences between the *cis* and *trans* forms of the title molecules were now computed from eq. [1], using the appropriate a_{ij} and $\Delta' q_i$ results. An example is given in Table 3. The final energy calculations indicated in Table 2 are, indeed, similar to those derived from straightforward conventional STO-3G computations. The general trends are satisfactorily reproduced with the exception of bpd. This can be possibly traced back to the notorious weakness of STO-3G calculations using standard orbital exponents in situations dealing with adjacent atoms carrying lone pairs (43).

This result offers new insight into the origin of the energy differences between the conformers considered in our study.

Discussion

Ab initio computations have led to a comprehensive picture describing the conformational behavior of aromatic α-diimines. The *trans* forms are significantly favored over their *cis* counterparts, with a relatively shallow local minimum for a torsional angle of $\theta \approx 43°$. The conformational behavior of nonfused heterocycles appears to be adequately represented by three or four term Fourier expansions. Similar two-term expansions which are often used in experimental studies provide much poorer (and sometimes incorrect) results.

In an assessment of the reason why the *trans* form should be preferred over the *cis* conformer in the molecules considered here, one can easily be drawn to interpretations invoking steric repulsions, namely those involving the nitrogen lone pairs. As a corollary, this type of argument contracts to a consideration of nonbonded interactions between the atoms of one cycle with those of the other cycle. Our results are not there to dispute the involvement of "nonbonded interactions," but rather to examine their physical nature and the energetic effect accompanying them.

In the first place, it is clear that the molecular wave function differs depending upon what conformer is considered and, hence, also its square, and, therefore, the distribution of electronic charge. This is, indeeed, what is observed in our SCF charge analyses.

A school of thought could now suggest to interpret the conformational behavior in terms of electrostatic interactions between nonbonded atoms. The general failure of this type of approach, and its reasons, are well known from numerical analyses: with the use of realistic atomic charges, it simply turns out that electrostatic effects would usually be far too small to provide satisfactory explanations and, occasionally, even lead to wrong predictions (39). On the other hand, it also seems to reflect a lack of logics to consider variations of electronic charges at the individual atoms and their rôle in conformational effects solely in terms of nonbonded interactions and, at the same time, treat the problem as if any interaction between bonded atom pairs was to remain unaffected by the charges carried by these atoms.

This is precisely where our alternate energy analysis steps in. The effects on the bonded terms resulting from changes of electron populations were explicitly taken into account. It now appears, though our rough charge analyses cannot provide great precision, that the differences in bond energies do, indeed, discriminate between the *cis* and *trans* conformers. They do account for at least the major part of the energy differences revealed by conventional SCF calculations. Briefly, the *trans* forms are more stable than their *cis* counterparts primarily because the bond energies of the former are larger than those of the latter.

The direct comparison between planar forms offers no difficulty because the conjugation between the two rings should remain essentially the same in each planar form. This would no longer hold true for nonplanar forms, largely because the link between the two cycles would suffer from a partial suppression of conjugative stabilization, as in biphenyl (44). Thus restricting our considerations to the planar forms, it suffices, for an off-hand rough diagnosis, to observe the directions of the partial charge transfers. When the atom whose Σa_{ij} value is most negative gains electronic charge at the expense of atoms with less negative Σa_{ij} sums, the final result is one of a thermochemical stabilization. Accordingly the most stable *trans* conformer has more negative nitrogen atoms than its *cis* counterpart, a result satisfying common chemical intuition. The prime sources from which nitrogen gains electronic charge are the hydrogen atoms.

Our account of the electronic origin of energy changes associated with conformational preferences illustrates the prevailing weight of bonded over nonbonded energy contributions. This insight complements the information which can be derived from conventional SCF energy analyses.

Appendix

The a_{ij} parameter is deduced from the formula (37, 40)

$$a_{ij} = \frac{3}{7}\left[\frac{(\partial E_i^{vs}/\partial N_i)^0 - (1/2)(\partial^2 E_i^{vs}/\partial N_i^2)^0 \Delta q_i}{v_i K_i^{mol}} - Z_j^{eff} < r_{ij}^{-1} >^0\right]$$

where Z^{eff} are effective nuclear charges ($Z^{eff} = 1, 4, 5$ for H, C, and N, respectively), v_i is the number of atoms attached to i, and $<r_{ij}^{-1>0}$ is the average inverse distance between the N_i electrons of atom i and the nucleus of atom j. K_i^{mol} is 1/2 for H, 0.4287 for C, and 0.4260 for N (37, 40, 45). The factor 3/7 translates nuclear–electronic into total (potential + kinetic) energy changes. Since the second-order term is negligible for H, C, and N, all the a_{ij}'s used in this work can be treated as constants.

The derivatives of the valence state energies for hydrogen and carbon are taken from ref. 44, whereas those of nitrogen are taken from ref. 46, namely, $\partial E^{\sigma}{}_N/\partial N_N = -0.29$ and $\partial E^{\pi}{}_N/\partial N_N = -0.26$ a.u. When the charges vary at both the σ and π levels, we have (37)

$$a_{ij}\,\Delta q_i = a^{\sigma}{}_{ij}\,\Delta q^{\sigma}{}_i + a^{\pi}{}_{ij}\,\Delta q^{\pi}{}_i$$

Taking advantage of the relationship (47)

$$\Delta q^{\sigma}{}_i = m_i \Delta q^{\pi}{}_i$$

it follows that

$$a_{ij} = (m_i a^{\sigma}{}_{ij} + a^{\pi}{}_{ij})/(1 + m_i)$$

The value of m_C was taken from ref. 44 and the value for nitrogen was computed from the STO-3G charges of pyridine derivatives given in ref. 48. Although the m_N values obtained using standard or optimized orbital exponents differ significantly from one another (−0.418 vs. −0.234) it is noteworthy that the values computed for a_{NC} and a_{NN} are virtually unaffected by the value selected for m. Similarly, any uncertainty concerning our selection of the $(\partial E/\partial N)$ derivatives for nitrogen has only a marginal effect on the final a_{NC} and a_{NN} values, not exceeding ~0.05 kcal mol^{-1} me^{-1}. This comes from the fact that the leading term in the expression of a_{ij} is represented by $(3/7)\,Z_j^{eff} < r_{ij}^{-1} >^0$. The set of a_{ij} values used in the present study is indicated in Table 2.

Received August 13, 1987

R. ANTHONY SHAW, CHARLES URSENBACH, ARVI RAUK, and HAL WIESER. Can. J. Chem. **66**, 1318 (1988).

Ab initio harmonic force fields were calculated for ethane, propane, dimethyl ether, and cyclobutane at the STO-3G and 3-21G levels. The calculated frequencies, displacement eigenvectors, and calculated infrared absorption intensities were compared as they derive from force constants that were (*i*) unscaled; (*ii*) scaled to fit observed vibrational frequencies reported in the literature; (*iii*) evaluated at the optimized geometries; and (*iv*) evaluated at structures for which the bond lengths were corrected from the optimized geometries according to published procedures. A total of nine combinations of *ab initio* force field/reference geometry/**G**-matrix geometry were investigated for each of the four molecules. The ability of scaling factors as the only variables to predict vibrational parameters from STO-3G and 3-21G force fields was explored. Conditions were examined for which the scaling factors are satisfactorily transferable among different molecules.

R. ANTHONY SHAW, CHARLES URSENBACH, ARVI RAUK et HAL WIESER. Can. J. Chem. **66**, 1318 (1988).

On a calculé les champs de force harmonique *ab initio* de l'éthane, du propane, de l'éther diméthylique et du cyclobutane à des niveaux STO-3G et 3-21G. Les fréquences calculées, les déplacements des vecteurs fondamentaux ainsi que les intensités calculées des absorptions infrarouges sont comparées à celles obtenues à l'aide de constantes de forces : (*i*) qui ne sont pas graduées; (*ii*) qui sont graduées de façon à s'ajuster aux fréquences de vibration rapportées dans la littérature; (*iii*) qui ont été évaluées à l'aide de géométries optimisées et (*iv*) qui ont été évaluées à l'aide de structures pour lesquelles les longueurs des liaisons avaient été corrigées à partir de géométries optimisées en fonction de procédures publiées. Pour chacune des molécules, on a examiné un total de neuf combinaisons de champs de force *ab initio*/géométrie de référence/géométrie de matrice **G**. On a exploré la possibilité d'utiliser uniquement les facteurs scalaires pour prédire les paramètres vibrationnels à partir des champs de force de niveaux STO-3G et 3-21G. On a examiné les conditions pour lesquelles les facteurs scalaires sont transférés d'une façon satisfaisante entre les différentes molécules.

[Traduit par la revue]

Introduction

Over the past 15 years a number of *ab initio* harmonic vibrational force fields have been published (for reviews, see ref. 1). A general procedure for their evaluation has evolved, which involves the following steps: (*i*) selection of a basis set for the force constant evaluation; (*ii*) specification of a reference geometry about which the force constants are to be calculated; (*iii*) evaluation of the force constants via a second differentiation of the energy with respect to either Cartesian or suitable internal (local symmetry) coordinates, and subsequent calculation of vibrational frequencies. Frequently, it is necessary to proceed further by (*iv*) scaling of the *ab initio* force constants in local symmetry coordinates; and (*v*) optimizing the scaling factors to provide agreement between observed and calculated vibrational frequencies. For the purpose of scaling, the force constants are grouped according to type (e.g., CC stretch, CH stretch, CH_2 deformation, etc.) and are then scaled within each group following previous experience with similar types of coordinates.

The most difficult aspect of developing empirical force fields is the assignment of interaction constants (i.e., off-diagonal elements of the force constant matrix). From early theoretical work, it is evident that even basis sets of moderate size are sufficient to calculate the interaction constants with high accuracy (2–4). However, the diagonal force constants are overestimated even near the Hartree–Fock limit (5, 6) and as a consequence the *ab initio* force field must be scaled to reproduce experimentally observed frequencies. The final scaled force field is generally insensitive to improvements in the basis set beyond the simplest "split valence" (3-21G or 4-21G) level (7). Results obtained with the minimal STO-3G basis set have been criticized on the grounds that the diagonal force constants, and hence the vibrational frequencies, are overestimated to a significantly greater extent than for split valence basis sets, and its use in this regard has been limited (3, 4, 8–16). The majority of these reports present only unscaled STO-3G frequencies, with just three attempting to scale the STO-3G force field (10, 14, 16).

With respect to the choice of reference geometry, it has been argued on theoretical grounds that the experimental r_e structure is the most appropriate (17). In practice, such experimental data are rarely available. An alternative and more straightforward choice is the optimized structure for the chosen basis set. Extensive comparisons between optimized 4-21G and experimental geometries show that the *ab initio* bond lengths generally differ systematically from the experimental ones (4, 8, 19). It has become common practice to apply systematic "corrections" to the bond lengths, as first suggested by Blom and Altona (4). However, the actual benefits of such corrections for the purpose of vibrational analysis are not obvious in view of other approximations involved. These include the use of limited basis sets, invocation of the harmonic approximation, and the necessity of scaling the force field in any case to match observed frequencies.

Scaling of the calculated force field is intended to compensate for systematic errors that ensue from the practical necessity to use approximate uncorrelated wavefunctions (Hartree–Fock with limited basis set), and must be accomplished in such a manner as to retain the physical information available from the theory. For example, one procedure uniformly scales the entire force constant matrix by a constant, bringing the calculated frequencies in closer agreement with those observed while leaving unchanged the descriptions of the nuclear vibrational

displacements. Calculated intensities in this case are not affected. If the force fields are expressed in internal coordinates, the scale factors are generally different for bond stretching, angle bending, and torsional deformations. A body of experience based on combined theoretical and experimental investigations on small molecules already exists from which initial scaling factors may be chosen and transferred to new molecules of interest. To interpret congested spectra for which the majority of assignments are impossible to determine with any confidence from experimental data alone, it is desirable that the initial set of scale factors be sufficiently accurate to calculate most frequencies to within $10\,cm^{-1}$.

In the following we describe extensive comparisons of *ab initio* harmonic force fields calculated at the STO-3G and 3-21G levels for ethane, propane, dimethyl ether, and cyclobutane, for all of which the vibrational spectra are well documented in the literature. Our objective was to examine systematically the effects on the calculated frequencies, displacement eigenvectors, and absorption intensities, of scaling the force constants to reproduce the observed vibrational data, and of varying the reference geometry at which the **F** and **G** matrices are evaluated. For practical applications the results indicate: (*i*) for what purposes scaling is advisable and (or) necessary; (*ii*) whether optimized or corrected geometries are to be preferred; (*iii*) to what extent scaling factors optimized for one molecule are transferable to structurally similar or different molecules; and (*iv*) whether and with what compromise STO-3G force fields could be substituted when necessary for practical considerations.

Calculations

Force constants and geometry optimizations

The procedures adopted here for evaluating the various force fields were guided by our aim to quantify the influence of various choices for determining the force constants. Accordingly, for each molecule the force fields differ in terms of: (*i*) the basis set used to calculate the force constants; (*ii*) the reference geometry adopted for calculating the force constants, optimized for the basis set used or employing the "corrected" 3-21G structures; and (*iii*) the reference geometry adopted for calculating the **G** matrix. The "corrected" 3-21G structures were derived by adjusting the optimized bond lengths, a procedure intended to compensate for systematic deviations between optimized and experimental structures (4, 8, 19). The C—H and C—O bond lengths were adjusted by +0.005 and −0.023 Å, respectively. For the C—C bond length we used the procedure recommended by Pulay *et al.* for the 4-21G basis (19), according to which $\Delta R_{C-C} = 0.16(R^{calc}_{C-C} - 1.45\,Å)$.

The structures used for steps (*ii*) and (*iii*) need not be identical. We have examined two alternatives for each of the 3-21G and STO-3G basis sets. With one, both the **F** matrix (i.e., the force constants) and the **G** matrix are evaluated at the same (optimized) structure, while with the second the **F** matrix, evaluated at the optimized geometry, is used with **G** calculated with the "corrected" geometry. Our aim for this comparison was to assess the effect of changing the reference geometry for either the **F** or the **G** matrix separately.

In this manner we examined three alternative procedures for each basis set (Table 1). Systematic comparisons of individual elements of STO-3G force fields with corresponding 3-21G values further suggested that a uniform correction, as described in a following section, should be applied to certain of the STO-3G force constants. We designated this kind of a force field as STOcorr in Table 1.

All *ab initio* Cartesian force constants and optimized geometries were evaluated using the Gaussian 82 program (20). The force constants were transformed to a non-redundant set of local symmetry coordinates via the method prescribed by Fogarasi and Pulay (1*a*). The optimized geometries are summarized in Tables 2–4, and the local symmetry coordinate definitions in Tables 5–8. The vibrational secular equation was then solved using the standard Wilson **GF** formalism, and finally the local symmetry force constants were adjusted via least-squares refinement of a number of scaling factors to fit the observed frequencies. The scaling procedure adopted is that of Pulay *et al.* (19) according to which

$$[1] \quad F_{ij} = (C_i C_j)^{1/2} K_{ij}$$

where K_{ij} and F_{ij} denote the unscaled and scaled *ab initio* force constants, respectively, and C_i is the scaling factor for the local symmetry coordinate i. Least-squares optimization of the scaling factors was accomplished using a program that minimizes the rms deviation between observed and calculated frequency parameters, $\lambda_i = 4\pi^2 c^2 \nu_i^2$, with the observed parameters weighted by $1/(\lambda_i^{obs})^2$. Molecules included in the

refinements were propane-h_8, -d_2, and -d_6, ethane-h_6 and -d_6, dimethyl ether-h_6 and -d_6, and cyclobutane-h_8 and -d_8. The vibrational frequencies and assignments were taken from the literature (4, 21, 22). The optimized scaling factors are summarized in Table 9.

Absorption intensities

The charge flow model, as formulated by Abbate *et al.* for calculating dipole and vibrational rotatory strengths (23), was used for evaluating the theoretical infrared absorption intensities. This theory is formally equivalent to the electro-optical parameter (EOP) method (see, for example, ref. 24) employed by Gussoni *et al.* (25) for interpreting and reproducing the experimental intensities of both ethane and propane. The EOPs of ref. 25 were converted to the charge flow formalism,[2] and were then used to calculate the dipole strengths, D_j, and integrated infrared absorption intensities, A_j, for propane and ethane via:

$$[2]\quad D_j = \frac{e^2 h}{4\pi c \nu_j}\left[\sum_A Z_A^0 \boldsymbol{t}_{A,j} + \sum_{\alpha,k} \boldsymbol{r}_{AB}\frac{\partial \xi_\alpha}{\partial R_k} L_{kj}\right]^2$$

$$[3]\quad A_j = 8\pi^3 N D_j \nu_j / 3hc$$

where Z_A^0 = equilibrium net charge of atom A; $\boldsymbol{t}_{A,j} = \partial \boldsymbol{r}_A / \partial Q_j$ is the Cartesian displacement vector of atom A accompanying unit displacement in normal coordinate Q_j, i.e., the appropriate element of the Cartesian eigenvector matrix; $\boldsymbol{r}_{AB}$ = a vector joining atoms A and B in the direction BA, defining bond α; $\partial \xi_\alpha / \partial R_k$ = the flow of positive charge from atom B to atom A in response to unit increase in coordinate R_k; L_{kj} = the appropriate element in the conventional **L** matrix ($= \partial R_k / \partial Q_j$). The expression for D_j is equivalent to that given by Abbate *et al.* (23).

Analogous charge flow parameters have not been derived for either dimethyl ether or cyclobutane, so that the intensities in

[2]The parameters so derived have been deposited as supplementary material, and may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[b]All coordinates were normalized. Normalization constants are not shown.

these cases were evaluated assuming fixed partial charges Z^0 (STO-3G Mulliken population analysis) on each atom, i.e., no terms of the type $\partial\xi_\alpha/\partial R_k$ were included. While the intensities calculated in this fashion generally do not agree well with the experimental values, they are considered adequate for the present purpose.

Comparison of calculated quantities

It is impossible to list all the relevant calculated eigenvectors, intensities, etc. for all force fields. Their accuracy was therefore assessed by comparing with the same quantities obtained with the scaled 321/321c/321c force field (see Table 1 for definitions used to designate the various force fields). While this choice may appear to be arbitrary, we concur with the opinion expressed by Pulay *et al.* (26) that properly scaled quantum mechanical force fields derived using medium sized split-valence basis sets "probably represent the limiting accuracy that can be achieved within the harmonic approximation". Their chosen method, which in our notation would be designated 421/421c/421c, is virtually equivalent to our 321/321c/321c combination. Accordingly the eigenvectors, calculated intensities, and force constants for a given force field n are assessed in terms of their average percent deviations from the scaled 321/321c/321c parameters (i.e., the reference set) as follows:

intensities:

$$[4]\quad \Delta A_n/\% = \frac{\sum_i |A_{i,n} - A_{i,\mathrm{ref}}|}{\sum_i A_{i,\mathrm{ref}}} \times 100$$

including only infrared active transitions;

eigenvectors:

$$[5]\quad \Delta L_n/\% = \frac{\sum_{i,j} |L_{i,j,n} - L_{i,j,\mathrm{ref}}|}{\sum_{i,j} |L_{i,j,\mathrm{ref}}|} \times 100$$

excluding all $L_{i,j} = 0$;

force constants:

$$[6]\quad \Delta F_n/\% = \frac{\sum_{i,j} |F_{i,j,n} - F_{i,j,\mathrm{ref}}|}{\sum_{i,j} |F_{i,j,\mathrm{ref}}|} \times 100$$

including only unique symmetry allowed force constants. The frequencies calculated with each combination were compared with experimental numbers, and the accuracy assessed in a similar fashion:

$$[7]\quad \Delta \nu_n/\% = \frac{\sum_i |\nu_{i,\mathrm{obs}} - \nu_{i,n}|}{\sum_i \nu_{i,\mathrm{obs}}} \times 100$$

including only the k_ν observed frequencies.

Tables 10–13 summarize the results for both the scaled and unscaled force fields listed in Table 1, while Table 14 summarizes separately an analogous comparison for the four symmetry blocks of propane.

Scaled STO-3G and 3-21G force constants

Since in all scaled force fields corresponding diagonal force constants are generally within 2% or better (see ΔF_n (diag.) of Tables 10–13), the interaction constants may be compared directly. Such a comparison is provided in Table 15. The interaction constants listed in the first two columns were obtained by scaling (eq. [1]) to fit the frequencies separately for the four molecules using either the 3-21G or STO-3G basis sets evaluated at the same corrected 3-21G reference geometry. It is seen that while the STO-3G stretch/stretch interactions are unreliable, often differing in sign as well as magnitude, the bend/bend constants adopt comparable values. The stretch/bend interactions, which are of significant magnitude (i.e., greater than 0.05 mdyn/Å), are underestimated by a nearly constant factor. This last observation suggests the possibility of first correcting the STO-3G constants as they are obtained from the *ab initio* calculations, and then optimizing the force field by scaling using eq. [1]. A multiplicative correction factor of 1.48 was derived on the basis of the comparisons presented here as well as with the appropriate force constants for oxetan.[3] The "corrected" force constants derived in this fashion are listed under STOcorr in Table 15, and are identified as such throughout this report.

[a]See Fig. 1 for atom numbering.
[b]All coordinates were normalized. Normalization constants are not shown.

For propane, the calculation of infrared absorption intensities first required transformation of the force constants, reported by Snyder (27) and adopted by Gussoni *et al.* (25) for the evaluation of the electro-optical parameters, from internal valence coordinates to the local symmetry coordinates used in the *ab initio* force field. The symmetrized empirical force constants are listed in Table 16, together with the corresponding optimized scaled 3-21G and STOcorr values. The agreement between the diagonal force constants is evident and with certain minor discrepancies, particularly for the CH_2 rock, the corresponding empirical values are in good accord with the *ab initio* results. Among the interaction force constants, with the exception of the STOcorr stretch/stretch interactions, the general agreement between the *ab initio* results is excellent. There are a number of empirical interaction constants, most notably the C–C stretch/CH_2 scissor, C–C stretch/CH_3 symmetric deformation, and CH_2 scissor/CH_3 symmetric deformation, that are in poor accord with the *ab initio* results. It seems unlikely that the scaled *ab initio* force fields should be in error for these particular cases, especially in view of the otherwise good agreement between empirical and *ab initio* results, and so it is likely that in these instances the empirically derived force constants are in error.

[a]See Fig. 1 for atom numbering.
[b]All coordinates were normalized. Normalization constants are not shown.

Such discrepancies are reflected in the calculated absorption intensities (Table 17) for the A_1 scissor (ν_4), CH_3 symmetric deformation (ν_6), and C–C stretching (ν_8) modes, which are increased by 70%, 20%, and 140%, respectively, when the scaled 3-21G force field is substituted for the empirical one. The B_2 CH_3 symmetric deformation mode, ν_{24}, is similarly affected. These observations suggest that even the most carefully derived empirical force fields, although satisfactory in reproducing observed vibrational frequencies, are considerably less reliable than scaled *ab initio* force fields for the purpose of calculating infrared absorption intensities.

Reference geometry effects

The most objective measure of the accuracy of a force field is the fit of observed to calculated frequencies. Only minor variations occur among the three scaled 3-21G force fields, amounting to 0.5 ± 0.1% (Tables 10–13). Most importantly, the eigenvectors and calculated intensities are reproducible with an average percent deviation of 4.3% at worst. Since this is well below the usual uncertainty inherent in infrared intensity calculations, we conclude that for practical purposes when a force field is scaled to fit observed spectra it is not necessary to adjust the optimized 3-21G structure prior to evaluating the force constants except as noted below. The compromise approach, namely evaluating the force constants about the optimized geometry and then using the corrected structure for calculating the **G** matrix (321/321/321c), generally yields results comparable to the 321/321/321 combination.

Exceptions to this generalization are molecules for which the chosen basis set yields an optimized structure that is different from the r_e geometry in some significant aspect. For example, this is the case for cyclobutane for which STO-3G appreciably underestimates the ring dihedral angle compared to 3-21G (see Table 4). As demonstrated in Table 15 the scaled STO-3G force constants are decidedly more accurate when calculated at the corrected 3-21G reference geometry (STOcorr/321c/321c) than when evaluated at the optimized STO-3G structure (STOcorr/STO/STO). The most convincing evidence favoring the use of the more reliable reference geometry of the two is the resulting improvement in the fit of observed to calculated frequencies. The eigenvectors and calculated intensities are similarly brought into better agreement with the reference values (i.e., 321/321c/321c), with their average deviations being reduced by factors of about 2.5 and 4, respectively (24.4 to 10.7%, and 23.0 to 5.6%, respectively; see Table 13).

3-21G scaling factors

The scaling process serves to correct for the overestimation of the *ab initio* diagonal force constants. A simpler alternative is to scale the *ab initio* frequencies. It is well documented, however, that some types of force constants are systematically overestimated to a greater extent than others. The scaling of the force constants using different factors for different types of

local symmetry coordinates can therefore change not only the absolute magnitudes of the frequencies but also their relative positions.

Scaling also has the effect of altering the eigenvectors relative to those derived with unscaled constants, as is illustrated by comparing the scaled vs. unscaled 321/321c/321c force fields of Tables 10–13. The difference in the average deviation (ΔL_n) between the two varies from less than 1% in ethane, for which the high symmetry is the dominant factor determining the nature of the normal modes, to 7% in propane, for which the largest discrepancies arise in the A_1 and B_2 symmetry species with average deviations of 11 and 9.5% respectively (see Table 14). Calculated absorption intensities for A_1 and B_2 modes are therefore influenced to a greater extent by scaling than the B_1 modes. As illustrated in Table 17, the calculated intensities for ν_8 (symmetric C–C stretch), ν_{26} (asymmetric C–C stretch), and ν_{27} (CH_3 rock) are doubled, halved, and tripled, respectively, upon scaling. The reason that these modes are particularly affected can be attributed to the need for scaling the C–C stretching force constants by a relatively larger factor (i.e., less

[a]See Table 10.

scaling) than the bending vibrations (~0.96 vs. 0.8, respectively). In general, the extent to which the calculated intensity of a particular vibration will be changed by scaling will depend on the relative magnitudes of the scaling factors for the coordinates that are involved in that vibration.

It is desirable that the scaling factors employed in the initial prediction be sufficiently reliable to enable one to assign the observed absorptions at the outset with confidence. That required level of accuracy is attainable only when the factors are optimized for specific coordinates, implying that they should be refined independently for all coordinates that are not symmetry equivalent. For example, although the scissoring, rocking, wagging, and twisting modes of a methylene group all consist of angle bending motions, four separate scaling factors should be refined independently. Indeed, as the calculations reveal, the refined 321/321/321 factors for three of these (i.e., scissor, wag, and twist in Table 9) are similar in magnitude (0.78–0.79), independent of the mode and compound, while the rocking factor is larger for both propane and cyclobutane. The significance of such differences may be demonstrated by observing that if 0.79 were used instead of 0.84 for a hypothetical "pure" rocking mode, the latter's position would be predicted to occur at 970 rather than 1000 cm^{-1}. If this region of the spectrum were congested, the result would likely be a misassignment of the relevant mode to an observed band at lower frequency.

In addition, it is reasonable to expect that the scaling factors may be sensitive to the chemical environment of a particular moiety. For the molecules investigated here, the methyl groups in propane and dimethyl ether provide the opportunity for such a comparison. As seen in Table 9, of the three methyl deformations, the rocking mode requires a larger scaling factor for the ether, indicating that the adjacent oxygen atom does have an effect.

One particularly desirable feature of scaling factors would be their transferability. This is perhaps the most important aspect to consider in deciding among the various options. If scaling factors refine to virtually identical values when fit individually and independently to the observed frequencies of a set of molecules, it may be safely assumed that the vibrational spectra of other species encompassing the same coordinates may be predicted with the same level of accuracy.

The optimized scaling factors of Table 9 indicate that from the point of view of their transferability, there is little to choose among the three alternative procedures. For each of the four CH_2 deformation modes, the analogous refined scaling factors are within 0.02 of one another at worst. The same applies to the CH_3 deformations of ethane and propane. A wider range is evident among the C–C stretch scaling factors optimized for ethane, propane, and cyclobutane; however, the range of values is the same in all three cases and hence from the point of view of transferability none of the three procedures emerges as being preferable to the other two.

STO-3G force fields

As anticipated, the unscaled STO-3G frequencies are markedly higher, and the eigenvectors and calculated infrared absorption intensities uniformly less accurate than the corresponding unscaled 3-21G values. While scaling of the force constants in the same manner as for 3-21G improves the calculated frequencies, the eigenvectors and intensities remain unacceptable (Tables 12–15). Inclusion of the stretch/bend correction factor (STOcorr) serves to bring the scaled STO-3G eigenvectors and intensities into much better accord with the 3-21G results. For each molecule, excepting only cyclobutane for the reasons given earlier, ΔA_n and (or) ΔL_n (eqs. [3] and [4]) are reduced by a factor of two or better for the STOcorr/STO/STO force field as compared to the uncorrected STO/STO/STO. The apparently marginal improvement in ΔA_n of propane is due to the damping effect of the large C–H stretching intensities, which are poorly reproduced by the uncorrected force field and are virtually unaffected by the adjusted stretch/bend interaction constants that distinguish the STOcorr from the STO force field.

[a]See Table 10.

The marked improvement in ΔL_n thus reflects, not only for propane but for all four molecules, alterations in the nature of lower frequency mid-infrared modes.

The modes most affected by the stretch/bend correction should be those involving simultaneous displacement of both bending and skeletal stretching coordinates. For propane, the in-phase and out-of-phase C–C stretching coordinates transform as A_1 and B_2 respectively, and so it is within these symmetry species that the STOcorr force fields should be more accurate than the uncorrected STO-3G. Table 14 confirms this to be the case. Modes comprising the A_2 and B_1 symmetry species, i.e., virtually pure bending modes, are adequately described by the uncorrected STO-3G force field and a affected little by the stretch/bend correction. Although not presented explicitly here, analogous behaviour is found for each of the other three molecules. For ethane the species A_{1g} (C–C stretch), for dimethyl ether A_1 and B_2 (C–O in-phase and out-of-phase stretch), and for cyclobutane A_1, B_1, and E (ring C–C stretching) are all substantially better described by the STOcorr than the uncorrected STO-3G force field.

As for the 3-21G case, the frequencies, eigenvectors, and intensities for the scaled STOcorr force fields are little affected by changing the reference geometry from the optimized (STO-3G) to corrected 3-21G structure for ethane, propane, and

dimethyl ether. In each of these cases the ΔL_n and ΔA_n for the scaled STOcorr/321c/321c combination are only marginally better than the corresponding STOcorr/STO/STO parameters (see Tables 10–12). In general, the refined STOcorr scaling factors (Table 9) exhibit a reasonably good degree of reproducibility, with similar trends as previously noted in the context of 3-21G. Among the methyl deformation modes, the three scaling factors refine to similar values for both propane and ethane, with the magnitudes of the scaling factors increasing reproducibly in the order asymmetric deformation < symmetric deformation < rocking. As for 3-21G, the last mentioned is higher for dimethyl ether, reflecting the presence of the neighboring oxygen atom.

Some major discrepancies occur for the refined STOcorr/STO/STO scaling factors of cyclobutane as compared to those of ethane and propane, particularly for the C–C stretching, CCC bending, and CH_2 rocking and wagging vibrations. As noted earlier in the context of reference geometry effects, the STO-3G ring dihedral angle in cyclobutane is significantly in error (Table 4), and the scaled STOcorr/STO/STO force constants and derived quantities do not compare well with the corresponding 3-21G results. It is of interest to note in this connection, the CH_2 rocking, CH_2 wagging, and CCC bending scaling factors refine to very similar values for both cyclobutane and propane when the force constants are reevaluated at the more accurate, corrected 3-21G structure (STOcorr/321c/321c). The C–C stretching factor remains appreciably lower for cyclobutane than for ethane and propane, probably reflecting the inaccuracy of the C–C/C–C interaction force constants. These observations indicate that while relatively small corrections of bond lengths are generally not necessary, large errors in molecular angles should be corrected empirically prior to evaluating the force constants. Analogous behaviour has been noted by Schlegel *et al.* (3) when they calculated the force field of ammonia using the 4-31G basis set. In that case the calculated H—N—H angle is much larger than the experimental value (113.7 vs. 107.3°). The corresponding diagonal bending force constant, which is appreciably lower when evaluated at the theoretical structure, reproduces the "experimental" constant with the level of accuracy expected for the 4-31G basis (i.e., marginally overestimated) when calculated at the experimental geometry.

Conclusions

While it is well known that *ab initio* force constants calculated at the 3-21G level can be scaled to reproduce observed vibrational frequencies, the results presented here indicate that a reasonably flexible scaling procedure is required. Such a properly devised procedure then provides a level of accuracy for the vibrational eigenvectors sufficient for calculating infrared absorption intensities. The choice of reference geometry at which the force constants are evaluated is less critical in this regard. Small corrections to the optimized bond lengths lead to negligible changes in the scaled force constants, and in other vibrational parameters derived from them. However, if the optimized structure is known to be in significant

error in some aspect, such as dihedral angles of cyclic molecules for example, force constants are better evaluated at a more accurate reference structure.

Another criterion that might be anticipated to favor one choice of reference geometry over the other is the transferability of scaling factors. We note that the C–C stretching force constants are calculated less accurately at the corrected structure than at the optimized one, as reflected by the optimized scaling factors averaging 0.90 (0.89, 0.92, 0.87 for PR, ET, and CB, respectively, in Table 9) and 0.97 (0.96, 0.99, 0.95), respectively, for the two alternatives. For the three relevant molecules these scaling factors are lowered by the same amount, their relative magnitudes remaining the same, when the geometry is adjusted. The uncertainty in vibrational frequencies calculated by transferring the average of the optimized factors hence appears to be the same for both instances. However, the values chosen empirically for adjusting the bond lengths in many cases may be subject to appreciable uncertainties, particularly for unusual structures (18, 28). Such uncertainties would then be reflected as noticeable variations in the refined scaling factors. For this reason, we prefer to use consistently optimized structures. The scaling factors derived in this manner should then reflect mainly the systematic deficiencies of the basis set (and Hartree–Fock wavefunctions in general).

It has become clear that the scaling factor for any particular type of coordinate is not a universally transferable parameter, but may be influenced by the chemical and (or) geometrical environment surrounding a particular moiety. This has been demonstrated in the present work by the discrepancy between the refined CH_3 rocking factors for propane and dimethyl ether, as well as in our previous determination of a scaled 3-21G force field for oxetan.[4] In the latter case, for example, scaling factors refined for analogous CH_2 bending modes in the α and β positions assume significantly different values. These examples illustrate that assuming a single factor to be appropriate for all CH_2 or CH_3 bending modes may lead to significant differences in certain scaled force constants and hence to appreciable errors in calculated frequencies. Retrospectively, useful relationships among individually refined scaling factors may emerge. One persistent observation that we have made in this and other studies using the 3-21G basis, is that the refined CH_2 twisting and wagging factors are generally within 0.01 of one another for

[4]R. A. Shaw, N. Ibrahim, and H. Wieser, unpublished results.

any individual methylene group. This suggests that these two modes could be scaled with a common factor. Although for the molecules discussed here this factor is equivalent to that for CH_2 scissoring, we have encountered instances where they differ. The CH_2 rocking vibration generally needs a factor higher than the other methylene deformations.

The STO-3G basis set is deficient in that the stretch/stretch interaction force constants are inaccurate, often differing in sign from 3-21G, and the stretch/bend interaction force constants are significantly underestimated. We suggest that the scaling of the STO-3G force constants, using the same procedure as for 3-21G, should be preceded by multiplying all stretch/bend constants by a factor of about 1.48. The calculated frequencies, eigenvectors, and absorption intensities obtained in this manner approach the accuracy of scaled 3-21G force fields throughout the mid- and far-infrared regions. The inaccuracy of the stretch/stretch interactions is noticeable primarily in the C–H stretching region, where the STO-3G frequencies and particularly the vibrational eigenvectors are completely unreliable.

We conclude by suggesting that the potential accuracy of scaled *ab initio* force fields for predicting vibrational frequencies may be fully realized by defining and optimizing scaling factors individually for each type of vibrational coordinate, for a number of small molecules containing diverse structural and chemical features. Significant differences among the optimized factors should be recognized and correlated with structural and (or) chemical influences. For the reasons outlined above, the consistent use of the optimized geometry for force field calculations should facilitate such correlations, and hence emerge as the preferred procedure. An alternative presented by Pulay *et al.* (28), namely to use high quality calculations for determining the equilibrium geometry and then a basis set of more moderate size for evaluating the force constants, is equally consistent but is impractical at this time for any but the smallest molecules.

Finally, it should be stressed that we have concerned ourselves primarily with ascertaining the role of force field uncertainties when evaluating vibrational frequencies and intensities. We have not addressed the separate problem of using *ab initio* methods for calculating molecular dipole moment derivatives, i.e., terms of the type $\partial\mu/\partial X$ or $\partial\mu/\partial R$. It is well known that split valence basis sets of medium size can be expected to provide order of magnitude estimates for these quantities (19, 26), while the STO-3G basis appears to be much less accurate (29).

Measurements of steady-state currents in thin-layer cells provide an opportunity to apply a stringent test of theories of electrochemical transport by simultaneous diffusion and migration. We have applied such a test and find the theory to be vindicated.

CHRISTA L. COLYER, PAUL J. J. CONNELLY, HEATHER L. GORDON et KEITH B. OLDHAM. Can. J. Chem. **66**, 1333 (1988).

Les mesures de courants à l'état stationnaire effectuées sur des cellules en couche mince fournissent une occasion d'appliquer un test rigoureux aux théories du transport électrochimique par diffusion et migration simultanées. On a appliqué un tel test et on a trouvé que la théorie est justifiée.

Introduction

Apart from studies employing rotating disc electrodes, voltammetry is generally carried out under transient conditions with diffusion being the sole transport mode. There are good reasons for these choices. Transient, rather than steady-state, conditions are selected because the latter are not usually attained experimentally without the participation of (deliberate or natural) convective transport. Two considerations persuade electrochemists to use excess supporting electrolyte and thereby inhibit migratory transport: first, the mathematical problem of predicting the voltammetric current is lessened when diffusion is the only transport mode; second, unwelcome ohmic polarization is alleviated when migration is minimized.

The present interest in microelectrodes has changed the picture somewhat. Small electrodes permit a steady state to be reached in times small enough that natural convection is not a problem (1). Moreover, ohmic polarization is held not to be as serious at microelectrodes and therefore studies with such electrodes have sometimes been carried out in the presence of little or no supporting electrolyte (2, 3). Thus the time seems opportune for an examination of voltammetry under steady-state conditions with both diffusion and migration contributing to the transport process. For experimental convenience, however, we do not use microelectrodes in the present study. Instead, the early attainment of a steady state is ensured by a small interelectrode separation.

The laws of transport by combined diffusion–migration have been tested under voltammetric conditions only rarely (4–6). Such a test is the object of the present study. The charge numbers of the participating ions, both electroactive and electroinactive, are important parameters in studies involving migration, but here we shall treat theoretically only the case that is employed experimentally: a dipositive electroactive cation and univalent supporting ions. To achieve a steady state in a thin-layer cell requires that the anode and cathode reactions be mutual converses, and we have chosen the reactions

[1] $\mathrm{M} \rightarrow \mathrm{M}^{2+}(\mathrm{aq}) + 2e$

and

[2] $\mathrm{M}^{2+}(\mathrm{aq}) + 2e \rightarrow \mathrm{M}$

to ensure this, with both electrodes being of metal M. To prevent electrolysis altering the surface geometry of the electrodes it is desirable that the electrode metal be a liquid and for this reason we have selected mercury as the electrode metal. Liquid electrodes cause difficulty with the gravitational stability of the thin-layer cell but this has been overcome by the tactic described in the experimental section of the article.

Theory

Our object here is to derive the steady-state voltammetric relationship, i.e., the equation that interrelates the potential ΔE of the two-electrode thin-layer cell to the steady-state current i that flows through it. This equation will contain the initial concentrations of the electroactive and supporting cations as parameters. The same steady state is achieved by applying a known ΔE and observing the resultant current i as by applying a known i and observing the resultant ΔE. The former is the more appropriate description of our experimental procedure but the appreciation of this theoretical section is aided by regarding the current as being imposed on the cell and treating potential as the dependent variable.

Of course, in practice, the steady state is preceded by a transient phase in which local concentrations, fluxes, and potentials are functions of time. The present treatment will ignore this transient phase entirely, because our interest is confined to the time-independent final state.

Cell geometry

Figure 1 diagrams the cell, which consists of two electrodes of metal M, each of area A and separated by a uniform distance L, the intervening space being filled by electrolyte solution. Meters monitor the cell current i and the interelectrode potential ΔE. A distance coordinate x is erected normal to the electrode surfaces, with its origin at the cell centre such that $x = -L/2$ corresponds to the anode and $x = L/2$ to the cathode.

Solution composition

The electrolyes MA_2 and BA are strong and therefore the solution contains the ions B^+, M^{2+}, and A^- as the only solutes; we shall use the subscripts 1, 2, and 3 to denote these three ions. The superscript "b" will denote conditions before electrolysis, while "a" and "c" will refer to conditions at the anode and cathode respectively once the steady state is attained. Because of the electroneutrality requirement, initial ion concentrations are interrelated by

[3] $$0 = \sum_j z_j c_j^{\mathrm{b}} = c_1^{\mathrm{b}} + 2c_2^{\mathrm{b}} - c_3^{\mathrm{b}}$$

where z_j denotes the charge number of ion j. The absence of a subscript will refer to the total ion content, thus:

[4] $$c^{\mathrm{b}} = \sum_j c_j^{\mathrm{b}} = c_1^{\mathrm{b}} + c_2^{\mathrm{b}} + c_3^{\mathrm{b}} = 2c_1^{\mathrm{b}} + 3c_2^{\mathrm{b}}$$

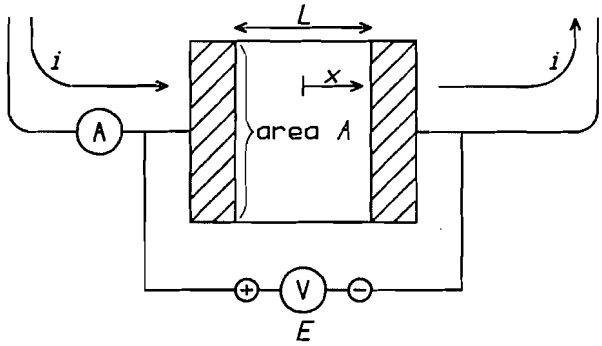

FIG. 1. Geometry of the steady-state cell.

In the steady state, the concentrations of B^+, M^{2+}, and A^-, as well as the total ion concentration, vary with distance and we shall emphasize this functional dependence by writing $c_1(x)$, $c_2(x)$, and $c_3(x)$, as well as $c(x)$. Since the total amount of each ion is conserved during electrolysis, the relationship

$$[5] \quad \int_{-\frac{1}{2}L}^{\frac{1}{2}L} c_j(x)\,dx = Lc_j^b \qquad j = 1,2,3$$

must be obeyed. Moreover, electroneutrality will hold locally, as well as globally, so that

$$[6] \quad 0 = \sum_j z_j c_j(x) = c_1(x) + 2c_2(x) - c_3(x)$$

We shall have occasion to refer to the local total ion concentration and the local ionic strength. These are

$$[7] \quad c(x) = \sum_j c_j(x) = c_1(x) + c_2(x) + c_3(x)$$

and

$$[8] \quad \mu(x) = \tfrac{1}{2}\sum_j z_j^2 c_j(x) = \tfrac{1}{2}c_1(x) + 2c_2(x) + \tfrac{1}{2}c_3(x)$$

respectively.

Ion fluxes

Each ion is subjected to a diffusive flux and a migratory flux. The diffusive flux is given by Fick's first law and equals $-D_j dc_j(x)/dx$ where D_j is the diffusion coefficient of ion j and the negative sign indicates that diffusion occurs down the concentration gradient $dc_j(x)/dx$. The migratory flux is proportional to the local concentration $c_j(x)$ of the ion, to its mobility u_j, and to the local electric field $-d\phi(x)/dx$ where $\phi(x)$ is the electric potential in the solution at distance x from the cell's midplane. The direction of the electrostatic force acting on each ion depends on the sign of its charge and this is taken into account by including the factor $|z_j|/z_j$ in the expression for the migratory flux. Hence the total flux experienced by each ion is

$$[9] \quad J_j = -D_j \frac{d}{dx}c_j(x) - \frac{|z_j|}{z_j}u_j c_j(x)\frac{d}{dx}\phi(x)$$

Recognize that, in the steady state, each ion flux is independent not only of time but also of position in the cell, so that we have written J_j rather than $J_j(x)$.

The Nernst–Einstein relationship (7) links the diffusion coefficient of an ion to its mobility by the identity $RTu_j = F|z_j|D_j$. When this is used to eliminate u_j from eq. [9], one arrives at

$$[10] \quad \frac{J_j}{D_j} = -\frac{d}{dx}c_j(x) - z_j c_j(x)\frac{F}{RT}\frac{d}{dx}\phi(x)$$

after division by D_j.

Because the ions B^+ and A^- are not involved in electrode reactions, their steady-state fluxes J_1 and J_3 must be zero. The flux of M^{2+}, however, is proportional to the current density i/A and is given by application of Faraday's law to reaction [1] or [2] as $J_2 = i/(2AF)$. Hence, the forms adopted by eq. [10] on application to each of the three ions are

$$[11] \quad 0 = -\frac{d}{dx}c_1(x) - c_1(x)\frac{F}{RT}\frac{d}{dx}\phi(x)$$

$$[12] \quad \frac{i}{2AFD_2} = -\frac{d}{dx}c_2(x) - 2c_2(x)\frac{F}{RT}\frac{d}{dx}\phi(x)$$

and

$$[13] \quad 0 = -\frac{d}{dx}c_3(x) + c_3(x)\frac{F}{RT}\frac{d}{dx}\phi(x)$$

respectively. These equations will later enable us to determine the ways in which $\phi(x)$ and each $c_j(x)$ depend on distance and will ultimately lead to an expression for the interelectrode potential difference ΔE.

Concentration interrelationships

Elimination of the field-dependent term between eqs. [11] and [13] leads to

$$[14] \quad \frac{dc_1(x)}{c_1(x)} + \frac{dc_3(x)}{c_3(x)} = 0$$

which implies that $\ln\{c_1(x)\} + \ln\{c_3(x)\}$ is invariant, so that

$$[15] \quad c_1(x)c_3(x) = \text{constant}$$

The constant in this last result is independent not only of x but also of the current i. It must, therefore, equal the product $c_1^b c_3^b$ of the concentrations of B^+ and A^- prior to electrolysis. Hence

$$[16] \quad c_1(x)c_3(x) = c_1^b c_3^b$$

This latest equation interrelates two of the three local ion concentrations. Equation [7] provides another relationship linking the $c_j(x)$ values to the total concentration $c(x)$. A third interrelationship is provided by the electroneutrality condition, eq. [6]. Using these three interrelationships one can, for example, eliminate $c_2(x)$ and $c_3(x)$, and generate the quadratic equation $c_1^2(x) - 2c(x)c_1(x) + 3c_1^b c_3^b = 0$, which solves to give the local concentration of B^+ to be

$$[17] \quad c_1(x) = c(x) - [c^2(x) - 3c_1^b c_3^b]^{1/2}$$

Similarly one may derive expressions for the local concentrations of M^{2+}

$$[18] \quad c_2(x) = \tfrac{2}{3}[c^2(x) - 3c_1^b c_3^b]^{1/2} - \tfrac{1}{3}c(x)$$

or of A^-

$$[19] \quad c_3(x) = \tfrac{1}{3}[c^2(x) - 3c_1^b c_3^b]^{1/2} + \tfrac{1}{3}c(x)$$

in terms of the local total concentration $c(x)$.

The surd that occurs in eqs. [17]–[19] has a simple interpretation: it equals the local ionic strength. That this is so follows by making the weighted sum of the three equations, with weights as specified by eq. [8]:

$$[20] \quad \mu(x) = \tfrac{1}{2}c_1(x) + 2c_2(x) + \tfrac{1}{2}c(x) = [c^2(x) - 3c_1^b c_3^b]^{1/2}$$

Total concentration

The condition of local electroneutrality, eq. [6], leads to the cancellation of all terms that involve the field when eqs. [11],

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

[12], and [13] are straightforwardly summed. The simple result

$$[21] \quad \frac{i}{2AFD_2} = -\frac{d}{dx}[c_1(x) + c_2(x) + c_3(x)] = -\frac{d}{dx}c(x)$$

shows that the gradient of the local total concentration is a constant. One integration leads to

$$[22] \quad c(x) = \sum_j c_j(x) = \text{constant} - \frac{ix}{2AFD_2}$$

and a second, between $x = -L/2$ and $x = L/2$, produces

$$[23] \quad \sum_j \int_{-\frac{1}{2}L}^{\frac{1}{2}L} c_j(x)\, dx = L(\text{constant})$$

Each of the integrals in eq. [23] may be evaluated as Lc_j^b by recourse to eq. [5], so that the constant term turns out to be simply c^b. The profile of the total concentration thus emerges from eq. [22] as

$$[24] \quad c(x) = c^b - \frac{ix}{2AFD_2}$$

Ion concentration profiles

The profiles of individual ion concentrations follow by substitution of expression [24] into each of eqs. [17]–[19]. For example

$$[25] \quad c_2(x) = \frac{2}{3}\left[\left(c^b - \frac{ix}{2AFD_2}\right)^2 - 3c_1^b c_3^b\right]^{1/2} - \frac{c^b}{3} + \frac{ix}{6AFD_2}$$

Unlike the profile of the total ion concentration, none of the profiles of individual ion concentrations is linear. An example of the shapes encountered is found in Figure 2.

A surprising result is discovered when $x = 0$ is substituted into eq. [25] and its $c_1(x)$ and $c_3(x)$ cohorts. In each case one finds, after considerable algebra, that $c_j(0) = c_j^b$. In other words, this means that the ion concentrations at the cell midplane in the steady state are unchanged from their values prior to electrolysis.

Limiting current

As i is increased, concentration polarization of M^{2+} at the cathode increases; that is, $c_2(L/2)$ diminishes. At some critical value of i, the limiting current i_l, $c_2(L/2)$ or c_2^c becomes zero. The cell cannot sustain a steady-state current exceeding this critical value.

To determine i_l, we set $c_2(L/2)$ equal to zero in eq. [25]. This leads to the expression

$$[26] \quad i_l = \frac{4AFD_2}{L}[c^b - 2(c_1^b c_3^b)^{1/2}]$$

If we regard the solution as composed of a concentration c_1^b of the electrolyte BA and a concentration c_2^b of the salt MA_2, then the limiting current is more usefully written as

$$[27] \quad i_l = \frac{4AFD_2}{L}(2c_1^b + 3c_2^b - 2[c_1^b(c_1^b + 2c_2^b)]^{1/2})$$

Two limiting cases of eq. [27] are of interest. The "unsupported" case corresponds to the virtual absence of supporting electrolyte so that c_1^b is negligible; eq. [27] reduces to

$$[28] \quad i_l \simeq \frac{12AFD_2c_2^b}{L} \qquad c_2^b \gg c_1^b$$

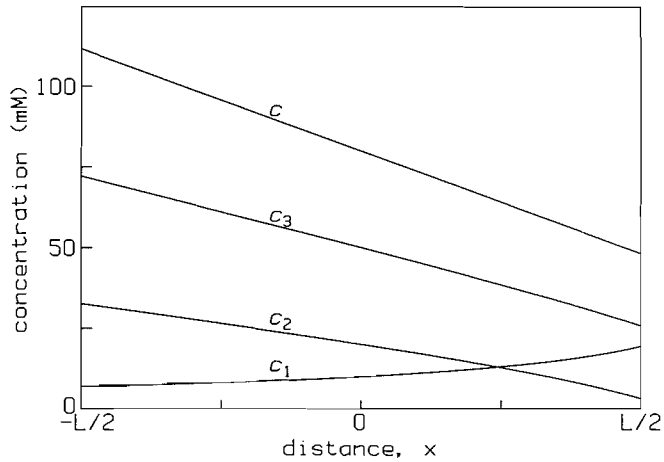

FIG. 2. The total concentration profile and the individual concentration profiles of the NO_3^-, Hg_2^{2+}, and H^+ ions for initial concentrations $c_3^b = 50$ mM, $c_2^b = 20$ mM, and $c_1^b = 10$ mM. The current is 90% of the limiting current.

in this case. The other limit, corresponding to the "fully supported" case when supporting electrolyte is in excess, may be deduced from eq. [27] by binomially expanding $[c_1^b(c_1^b + 2c_2^b)]^{1/2} = c_1^b[1 + (2c_2^b/c_1^b)]^{1/2}$ as $c_1^b[1 + (c_2^b/c_1^b) - (c_2^b/c_1^b)^2/8 + \ldots]$. Thence

$$[29] \quad i_l \simeq \frac{4AFD_2c_2^b}{L} = i_d \qquad c_2^b \ll c_1^b$$

Here we use the i_d symbol to denote the diffusion-limited current, because only diffusion is important in transporting M^{2+} when the concentration of supporting electrolyte massively exceeds that of the electroactive ion.

Comparison of eqs. [28] and [29] shows that, in the totally unsupported case, the limiting current is three times as large as the diffusion current. To discuss intermediate cases, it is useful to define the "support ratio" (8)

$$[30] \quad \text{support ratio} = \rho = \frac{\text{concentration of electroinactive ions excluding counter ions}}{\text{concentration of electroactive ions plus counter ions}} = \frac{c_1^b + (c_3^b - 2c_2^b)}{c_2^b + 2c_2^b} = \frac{2c_1^b}{3c_2^b}$$

As the support ratio increases from zero to infinity, the i_l/i_d ratio ranges from 3 down to 1. Table 1 shows some intermediate values calculated from the relationship

$$[31] \quad i_l = 3\{1 + \rho - [\rho(\rho + 4/3)]^{1/2}\}i_d$$

Notice that i_l is exactly twice i_d for a support ratio of one sixth.

Concentration polarization

The concentration of M^{2+} at the anode exceeds that at the cathode when the cell is undergoing steady-state electrolysis. Nernst's law reveals that this gives rise to a potential difference

$$[32] \quad \Delta E_{conc} = \frac{RT}{2F} \ln \{c_2^a/c_2^c\}$$

between the electrodes, the anode being positive. In writing this result we ignore any discrepancy between activity coefficients at the two electrodes. Steady-state values of the concentrations c_2^a and c_2^c can be found by substituting $x = -L/2$ and $x = L/2$, respectively, into eq. [25]. This gives

$$[33]\quad \frac{2}{3}\left[\left(c^b \pm \frac{iL}{4AFD_2}\right)^2 - 3c_1^b c_3^b\right]^{1/2} - \frac{c^b}{3} \mp \frac{iL}{12AFD_2}$$

where upper signs refer to c_2^a, lower signs to c_2^c. Notational economies result from using the expression $i_d = 4AFD_2c_2^b$ for the diffusion current to replace the denominators of the terms that involve the current. After factoring $c_2^b/3$, expressions [33] then become

$$[34]\quad c_2^a \text{ or } c_2^c = \frac{c_2^b}{3}\left(2\left[\left(\frac{c^b}{c_2^b} \pm \frac{i}{i_d}\right)^2 - \frac{3c_1^b c_3^b}{(c_2^b)^2}\right]^{1/2} - \frac{c^b}{c_2^b} \mp \frac{i}{i_d}\right)$$

The c^b/c_2^b terms may be replaced by $3(1 + \rho)$, where ρ is the support ratio $2c_1^b/3c_2^b$, and similarly $3c_1^b c_3^b/(c_2^b)^2$ may be replaced by $9\rho(4 + 3\rho)/4$. After making these replacements, substitution into eq. [32] of the expressions for c_2^a and c_2^c leads to

$$[35]\quad \Delta E_{conc} = \frac{RT}{2F}(\ln[\{4(1 + \rho + i/3i_d)^2 - 4\rho - 3\rho^2\}^{1/2} - 1 - \rho - i/3i_d] - \ln[\{4(1 + \rho - i/3i_d)^2 - 4\rho - 3\rho^2\}^{1/2} - 1 - \rho + i/3i_d])$$

This complicated expression cannot be further simplified. Moreover, attempts to invert eq. [35] to give an explicit formula for i/i_d lead only to a quartic equation $(i/i_d)^4 + \alpha_3(i/i_d)^3 + \alpha_2(i/i_d)^2 + \alpha_1(i/i_d) + \alpha_0 = 0$ in which the α coefficients are elaborate functions of ρ and $\exp(2F\Delta E_{conc}/RT)$. The solution of this equation to give an explicit expression for i/i_d would be extremely complicated and was not pursued.

Potential profile

We have yet to address the question of how the local potential $\phi(x)$ varies across the cell. Because only differences in ϕ are significant, we are free to choose any particular plane as the location of zero potential; we select the midplane, so that $\phi(0) = 0$.

Equation [13] may be rewritten

$$[36]\quad \frac{F}{RT}d\phi(x) = d\ln\{c_3(x)\}$$

and integrated to

$$[37]\quad \frac{F\phi(x)}{RT} = \frac{F}{RT}[\phi(x) - \phi(0)] = \ln\{c_3(x)\} - \ln\{c_3(0)\} = \ln\{c_3(x)/c_3^b\}$$

Analogous to eq. [25], the concentration profile of A^- is

$$[38]\quad c_3(x) = \frac{1}{3}\left[\left(c^b - \frac{ix}{2AFD_2}\right)^2 - 3c_1^b c_3^b\right]^{1/2} + \frac{c^b}{3} - \frac{ix}{6AFD_2}$$

which may be combined with eq. [37] to give

$$[39]\quad \phi(x) = \frac{RT}{F}\left(\ln\left\{\left[\left(c^b - \frac{ix}{2AFD_2}\right)^2 - 3c_1^b c_3^b\right]^{1/2} + c^b - \frac{ix}{2AFD_2}\right\} - \ln[3c_3^b]\right)$$

for the potential profile. This may be expressed somewhat more concisely in terms of an inverse hyperbolic cosine (9)

$$[40]\quad \phi(x) = \frac{RT}{F}\left(\text{arcosh}\left[\left(c^b - \frac{ix}{2AFD_2}\right)\Big/(3c_1^b c_3^b)^{1/2}\right] - \frac{1}{2}\ln(3c_3^b/c_1^b)\right)$$

Figure 3 provides an example of the potential profile.

Ohmic polarization

The difference $\phi^a - \phi^c$ represents the potential between the solution layers immediately adjacent to the anode and the cathode. This is the ohmic polarization or "iR drop" experienced by the cell. To determine the magnitude of ϕ^a or ϕ^c, one need only substitute $x = -L/2$ or $x = L/2$ into eq. [40]. Thereby one finds

$$[41]\quad \Delta E_{ohm} = \phi^a - \phi^c = \frac{RT}{F}\left(\text{arcosh}\left[\left(c^b + \frac{iL}{4AFD_2}\right)\Big/(3c_1^b c_3^b)^{1/2}\right] - \text{arcosh}\left[\left(c^b - \frac{iL}{4AFD_2}\right)\Big/(3c_1^b c_3^b)^{1/2}\right]\right)$$

Some simplification results from introducing the expression for the diffusion current $i_d = 4AFD_2c_2^b/L$, namely

$$[42]\quad \Delta E_{ohm} = \frac{RT}{F}\left(\text{arcosh}\left[\left(\frac{c^b}{c_2^b} + \frac{i}{i_d}\right)\Big/\frac{(3c_1^b c_3^b)^{1/2}}{c_2^b}\right] - \text{arcosh}\left[\left(\frac{c^b}{c_2^b} - \frac{i}{i_d}\right)\Big/\frac{(3c_1^b c_3^b)^{1/2}}{c_2^b}\right]\right)$$

There are terms in this equation similar to those found in eq. [34] and once more we may replace c^b/c_2^b by $3(1 + \rho)$ and $(3c_1^b c_3^b)^{1/2}/c_2^b$ by $3[\rho(1 + 3\rho/4)]^{1/2}$. Using the formula (9) for the difference of two inverse hyperbolic cosines, one may then invert eq. [42] to yield

$$[43]\quad \frac{i}{3i_d} = \left[(1 + \rho)^2 \tanh^2\left(\frac{F}{2RT}\Delta E_{ohm}\right) - \rho\left(1 + \frac{3\rho}{4}\right)\sinh^2\left(\frac{F}{2RT}\Delta E_{ohm}\right)\right]^{1/2}$$

The relationship between the potential difference ΔE_{ohm} and the current i is distinctly nonlinear, as illustrated in Fig. 4.

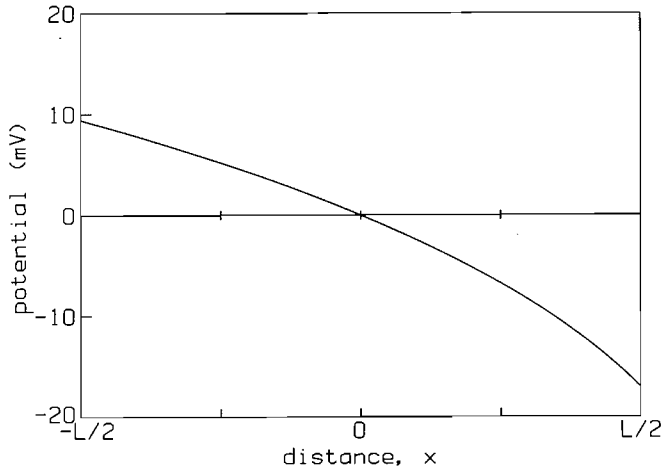

FIG. 3. The potential profile under the conditions of Fig. 2.

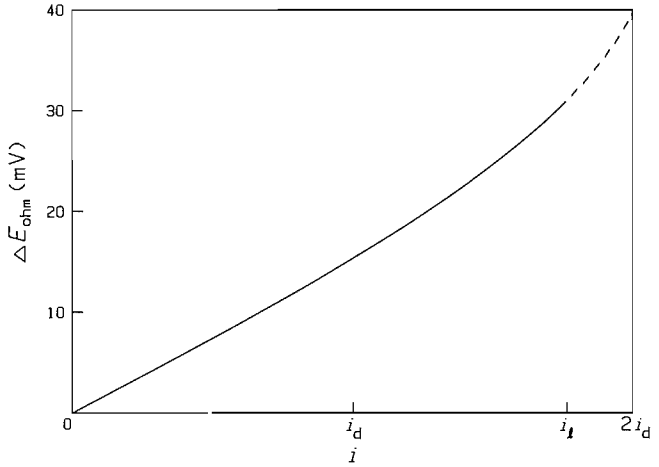

FIG. 4. The ohmic overpotential as a function of current for the solution composition described under Fig. 2. The dashed portion is inaccessible because the current cannot exceed i_l.

Thus the phrase "ohmic polarization" must not be interpreted as implying that Ohm's Law is obeyed.

Cell potential

Because the equilibrium interelectrode potential difference of the cell is zero, any potential difference existing in the steady state may be ascribed to polarizations. Of the three polarizations, ohmic, concentration, and activation, that afflict electrochemical cells, the choice of the Hg_2^{2+}/Hg electrode, for which reactions [1] and [2] are known to be very fast (10), permits us to ignore activation polarization. Thus the total cell potential ΔE contains only two terms, ΔE_{conc} and ΔE_{ohm}, due to concentration and ohmic polarizations, respectively.

After replacement of the terms c^b/c_2^b and $3c_1^bc_3^b/(c_2^b)^2$ by their $3(1 + \rho)$ and $9\rho[1 + (3\rho/4)]$ equivalents, addition of eqs. [35] and [42] produces, after some rearrangements

$$[44]\quad \Delta E = \frac{RT}{F}\left(\ln\left[\frac{[4(1+\rho+i/3i_d)^2 - \rho(4+3\rho)]^{1/2} - 1 - \rho - i/3i_d}{[4(1+\rho-i/3i_d)^2 - \rho(4+3\rho)]^{1/2} - 1 - \rho + i/3i_d}\right]^{1/2} + \operatorname{arcosh}\left[\frac{1+\rho+i/3i_d}{[\rho+(3\rho^2/4)]^{1/2}}\right] - \operatorname{arcosh}\left[\frac{1+\rho-i/3i_d}{[\rho+(3\rho^2/4)]^{1/2}}\right]\right)$$

as the final expression for the cell potential. Recall that we use the abbreviations $i_d = 4AFD_2c_2^b/L$ for the diffusion current and $\rho = 2c_1^b/3c_2^b$ for the support ratio, c_1^b and c_2^b being the initial concentrations of the supporting cation B^+ and the electroactive cation M^{2+}, respectively.

Though it is complicated, eq. [44] does provide an analytical solution to the problem that we posed. It permits us to calculate the cell potential for any applied current i and for any chosen values of the concentration parameters c_1^b and c_2^b. An example is shown as Fig. 5.

Unsupported limit

It is of interest to determine the forms acquired by eqs. [35] and [42], and thence by [44], as the support ratio $2c_1^b/3c_2^b$ approaches zero. One finds

$$[45]\quad \Delta E_{conc} \rightarrow \frac{RT}{2F}\ln\left[\frac{3i_d + i}{3i_d - i}\right] = \frac{RT}{F}\operatorname{artanh}\left[\frac{i}{3i_d}\right]$$

and (unless i approaches $3i_d$)

$$[46]\quad \Delta E_{ohm} \rightarrow \frac{RT}{F}\ln\left[\frac{3i_d + i}{3i_d - i}\right] = \frac{2RT}{F}\operatorname{artanh}\left[\frac{i}{3i_d}\right]$$

so that, in this limit, the ohmic polarization is exactly twice the concentration polarization.

Hence the equation of the totally unsupported steady-state voltammogram is

$$[47]\quad \Delta E = \Delta E_{conc} + \Delta E_{ohm} = \frac{3RT}{F}\operatorname{artanh}\left[\frac{i}{3i_d}\right] = \frac{3RT}{F}\operatorname{artanh}\left[\frac{iL}{12AFD_2c_2^b}\right]$$

or equivalently

$$[48]\quad \frac{iL}{12AFD_2c_2^b} = \frac{i}{3i_d} = \tanh\left[\frac{F\Delta E}{3RT}\right] = 1 - \frac{2}{1+\exp(2F\Delta E/3RT)}$$

Fully supported limit

Here we seek the limiting form of eq. [44] as $\rho \rightarrow \infty$, that is, as the concentration of electroinactive ions overwhelms the M^{2+} concentration. One finds that, in this limit

$$[49]\quad \Delta E_{conc} \rightarrow \frac{RT}{2F}\ln\left[\frac{i_d + i}{i_d - i}\right] = \frac{RT}{F}\operatorname{artanh}\left[\frac{i}{i_d}\right]$$

whereas

$$[50]\quad \Delta E_{ohm} \rightarrow \frac{4RTi}{3F\rho i_d} \rightarrow 0$$

Hence the equation of the fully supported voltammogram is

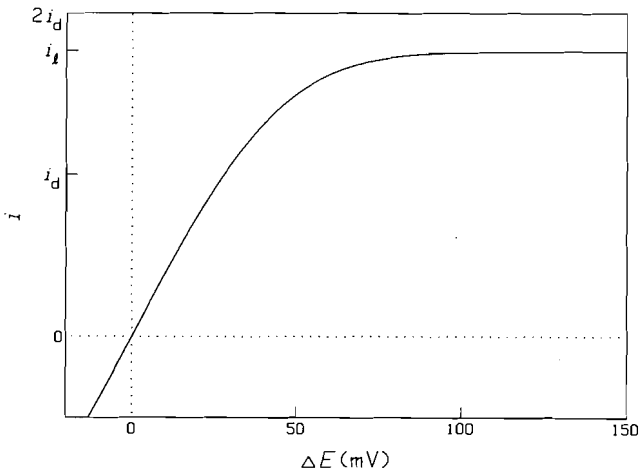

FIG. 5. Current as a function of the cell potential for the solution composition described under Fig. 2.

$$[51]\quad \Delta E = \Delta E_{conc} + \Delta E_{ohm} = \frac{RT}{F}\,\text{artanh}\left[\frac{i}{i_d}\right] = \frac{RT}{F}\,\text{artanh}\left[\frac{iL}{4AFD_2c_2^b}\right]$$

or equivalently

$$[52]\quad \frac{iL}{4AFD_2c_2^b} = \frac{i}{i_d} = \tanh\left[\frac{F\Delta E}{RT}\right] = 1 - \frac{2}{1 + \exp(2F\Delta E/RT)}$$

which agrees with established theory (11, 12).

Experimental

The theory we have just presented presupposes parallel pools of the liquid metal mercury separated by a thin layer of electrolyte solution. Of course, three liquid phases cannot be maintained in this configuration. To overcome this difficulty we absorbed the electrolyte in an inert porous disc, which was then sandwiched between the mercury pools. The effect of the porous medium on the steady-state theory can be interpreted in terms of a "uniform tortuosity" model (11). This simple, but surprisingly successful, model envisages the pore structure as a bundle of non-intersecting tubules, all of length λL, which penetrate the porous matrix from one surface to the other. Thus each L in our theory is to be replaced by λL, where λ is the "tortuosity factor" of the medium, a number somewhat larger than unity. A second effect arises from the space-filling aspect of the porous matrix: the effective area for interelectrode transport is diminished from A to $A\theta/\lambda$, where θ is the porosity of the medium, equal to the fraction of the total volume that is void. Hence, according to the uniform tortuosity model, eq. [43] remains valid provided that the definition of the diffusion current is modified to

$$[53]\quad i_d = 4AFD_2c_2^b\theta/\lambda^2 L$$

Cell

Details of the thin-layer cell have been described previously (12). The soaked porous disc was clamped between two abutting plastic annuli, so as to create three chambers, as illustrated in Fig. 6. The anode and cathode chambers contain mercury pools that serve as opposing electrodes, each with an area of 1134 mm^2. The peripheral chamber encloses the protruding edge of the porous disc. Careful measurements (12) gave 272 ± 14 μm as the thickness L of the porous matrix under the conditions of the experiments.

Solutions

Stock solutions of $Hg_2(NO_3)_2/HNO_3$ and HNO_3 were prepared

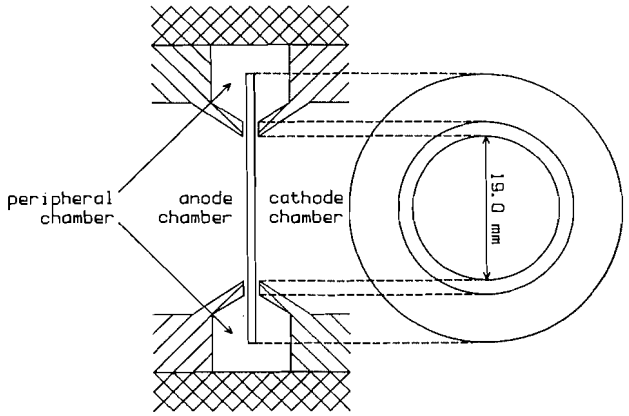

FIG. 6. Diagram illustrating the construction of the cell.

volumetrically from concentrated HNO_3 and gravimetrically from $Hg_2(NO_3)_2 \cdot 2H_2O$: they were deaerated by the passage of argon and stored under argon and over mercury. Soaking solutions were prepared by appropriate dilution of mixed stock solutions. Generally Hg_2^{2+} concentrations ranged between 10 and 30 mM; supporting electrolyte concentrations ranged from 112 mM down to a lower limit dictated by the hydrolysis of Hg(II) as discussed below.

In a few experiments NO_3^- was replaced by ClO_4^-: no discernable difference resulted.

To avoid high acidity, some diffusion current measurements were made in solutions containing excess KNO_3, in addition to $Hg_2(NO_3)_2$ and HNO_3. The theory suggests that the identity of the supporting monovalent cation is unimportant, so that substitution of some H^+ by K^+ should be without effect. Experiments confirmed this prediction.

Procedure

Whatman No. 5 filter paper circles were used as the porous discs. To remove soluble impurities, the papers were soaked in repeatedly renewed deionized water and then air dried. As described in ref. 12, the papers were soaked in electrolyte solution using a technique that avoided air pockets being trapped within the pores.

The soaked disc was mounted in the cell prior to assembly. After cell assembly, all three chambers were flushed with argon and the two electrode chambers were then filled with mercury using the careful technique described elsewhere (12).

In some preliminary experiments, erratic currents were obtained that we believe have an origin in common with polarographic maxima (13). Large electroosmotic forces must operate in our cell, and it appears that their sign is such as to push the solution towards the cathode. Normally these forces do not result in any movement of the electrolyte solution because mercury from the anode cannot enter the pores to replace the migrating solution. However, it appears that the standard soaking and wiping procedure leaves sufficient solution adhering to the surface of the matrix that small pockets, sustained by electroosmosis, can develop between the mercury cathode and the matrix itself. Motion within these pockets is, we believe, responsible for the anomalous currents. To obviate this effect, dry argon was circulated through the peripheral chamber for a sufficient time: water evaporated into the argon and the excess solution was thereby wicked away from the electrode interface. If the drying was continued for too long, a precipitous fall in current ensued; a "sufficient" length of time was one that just failed to cause this condition.

In principle it makes no difference to the steady state how one proceeds from the initial unpolarized cell to the final condition of a constant interelectrode potential ΔE. The simplest route—a single potential step—was, however, considered unsuitable because the large initial currents that flow with this technique might "stress" the system. Accordingly, we imposed a "capped ramp" signal in which the potential rose from an initial zero value to the final ΔE value at a rate of 2.0 mV s^{-1}, and was thereafter held constant. The eventual steady-state current, i, was read from a chart recording of the chronoamperogram. A PARC model 170 electrochemistry system was employed

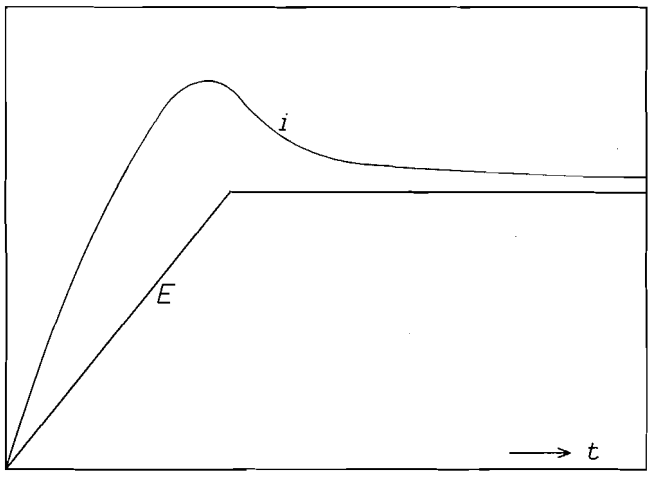

FIG. 7. Illustrating the capped ramp signal and the current response. The pertinent potential and current are the constant values at long times.

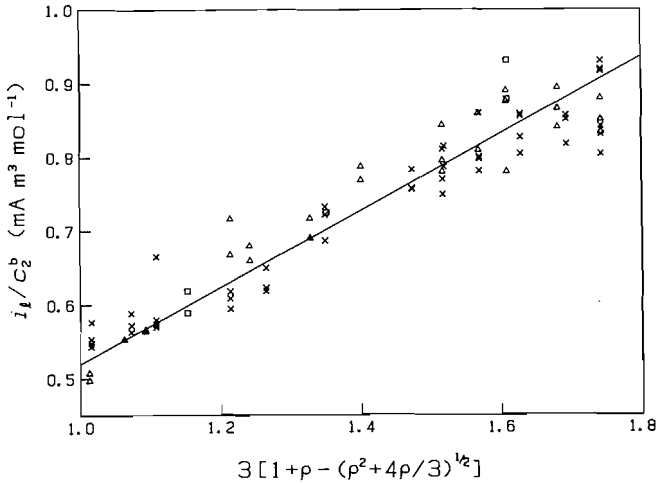

FIG. 8. Results of experiments in Classes III and IV. Mercurous ion concentrations are as follows: □, c_2^b = 10 mM; ×, c_2^b = 18 mM; △, c_2^b = 30 mM. The straight line is the linear regression through the origin.

both to apply the capped ramp signal and to monitor the cell response, as exemplified in Fig. 7.

The cell was not thermostated. Experiments were conducted at an ambient temperature close to 294 K.

Hydrolysis

From literature values (14) of the equilibrium constant for the $Hg_2^{2+}(aq) \rightleftarrows Hg^{2+}(aq) + Hg(l)$ disproportionation, the solubility product of the $HgO(s) + H_2O(l) \rightleftarrows Hg^{2+}(aq) + 2OH^-(aq)$ dissolution, and the ionic product of the $H_2O(l) \rightleftarrows H^+(aq) + OH^-(aq)$ dissociation, one calculates an equilibrium constant

$$[54] \quad K = \frac{[H^+]^2}{[Hg_2^{2+}]} = 3.1 \times 10^{-5} \text{ mol L}^{-1}$$

for the hydrolysis reaction

$$[55] \quad Hg_2^{2+}(aq) + H_2O(l) \rightleftarrows HgO(s) + Hg(l) + 2H^+(aq)$$

This implies that hydrolysis will occur at small support ratios. Quantitatively, eq. [54] predicts that one needs

$$[56] \quad \rho > \frac{3.7 \times 10^{-3} \text{ mol}^{1/2} \text{ L}^{-1/2}}{(c_2^b)^{1/2}}$$

to ensure that hydrolysis does not occur in the bulk solution.

However, the situation is worse than eq. [56] suggests because, as Fig. 2 demonstrates, the Hg_2^{2+} concentration at the anode is greater than its bulk value, while the H^+ concentration there is less than c_1^b. Both these factors encourage hydrolysis and, in fact, we observed a yellow precipitate at the anode for solutions of borderline composition. Of course, results are invalid when hydrolysis occurs.

This unfortunate circumstance places a lower limit on the support ratios that can be studied. The smallest value of ρ that we employed successfully was 0.355.

Results

Our experiments have three independent variables: the imposed interelectrode potential ΔE, the support ratio ρ, and the concentration c_2^b of the electroactive Hg_2^{2+} species. There is one dependent variable, the steady-state current i. Because there is no reason to believe that i will not be proportional to c_2^b, at constant values of ΔE and ρ, we will express our results in terms of the ratio i/c_2^b as a function of the two independent variables ΔE and ρ. In fact, the experimental i/c_2^b ratios were independent of c_2^b.

Limiting cases are approached at high values of ΔE and at both high and low values of ρ. Thus, one can delineate six possible classes of experiment, as shown in Table 2, of which two are inaccessible. The nomenclature of the remaining four classes is established in the table. Of the 143 experiments conducted in this study, 49 were in Class I, 14 in Class II, 74 in Class III and 6 in Class IV.

Analysis of experiments in Classes III and IV

In these classes we have total concentration polarization and therefore the measured steady-state currents are limiting currents. Accordingly, eq. [31] should apply, so that we expect

$$[57] \quad \frac{i_l}{c_2^b} = 3[1 + \rho - (\rho^2 + 4\rho/3)^{1/2}]\frac{i_d}{c_2^b}$$

A plot of i_l/c_2^b versus $3[1 + \rho - (\rho^2 + 4\rho/3)^{1/2}]$ is shown as Fig. 8. There is considerable scatter but a clear linear relationship emerges. A regression through the origin yields a correlation coefficient of 0.9988 and a gradient of

$$[58] \quad \frac{i_d}{c_2^b} = (5.20 \pm 0.26) \times 10^{-4} \text{ A m}^3 \text{ mol}^{-1}$$

Analysis of experiments in Classes II and IV

In these classes supporting electrolyte is in large excess and therefore eq. [51] should hold. This may be rewritten as

$$[59] \quad \frac{i}{c_2^b} = \frac{i_d}{c_2^b} \tanh \frac{F\Delta E}{RT}$$

Figure 9 is a plot of i/c_2^b versus $\tanh(F\Delta E/RT)$ for the 20 data from Classes II and IV. The regression line has a slope (with standard error) of

$$[60] \quad \frac{i_d}{c_2^b} = (5.44 \pm 0.20) \times 10^{-4} \text{ A m}^3 \text{ mol}^{-1}$$

the correlation coefficient being 0.9993.

Analysis of experiments in Class I

In this class we have neither excess supporting electrolyte nor concentration polarization, so that the full equation [44] applies without simplification. Thus it is this class that affords the most stringent test of the theory.

Because it is impossible to invert eq. [44] to obtain an explicit formula for i_d, a more circuitous analysis was adopted. Starting from a guessed value of $i/3i_d$, an estimate of ΔE_{conc} was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

TABLE 2. Classification of experiments

	Unsupported (small ρ)	Modest support (intermediate ρ)	Fully supported (ρ ≥ 41)
Not concentration polarized (modest ΔE)	Inaccessible because of hydrolysis	Class I $i/c_2^b = f(\rho,\Delta E)$	Class II $i/c_2^b = f(\Delta E)$
Concentration polarized ($\Delta E \geq 500$ mV)	Inaccessible because of hydrolysis	Class III $i/c_2^b = i_l/c_2^b = f(\rho)$	Class IV $i/c_2^b = i_l/c_2^b = i_d/c_2^b =$ constant

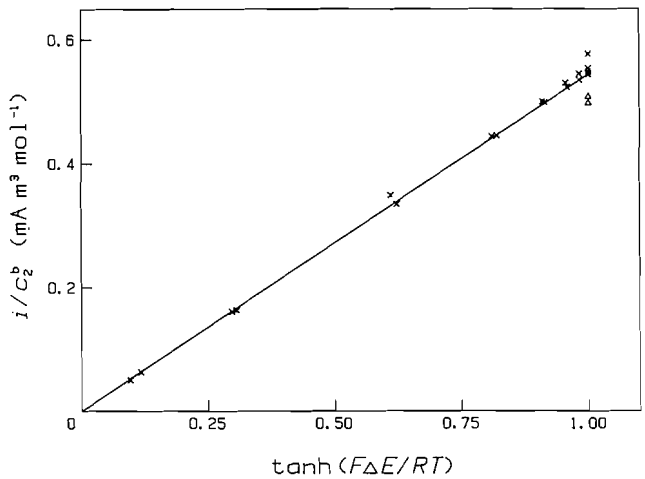

FIG. 9. Results of experiments in Classes II and IV. Symbols and line have the same significance as in Fig. 8.

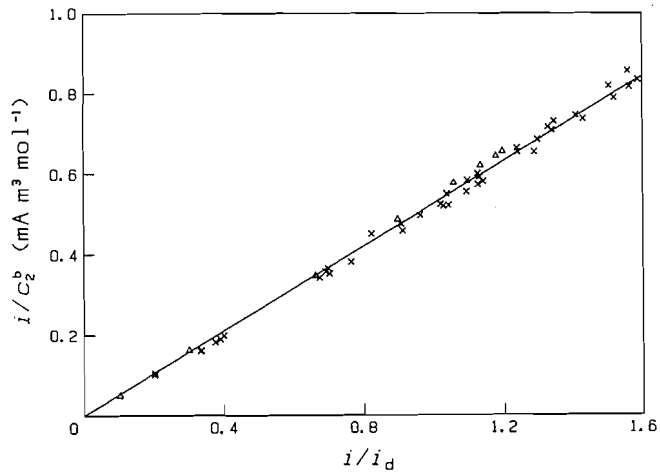

FIG. 10. Results of experiments in Class I. Symbols and line have the same significance as in Fig. 8.

calculated via eq. [35]. This was then subtracted from the measured ΔE to obtain an estimate of ΔE_{ohm}. This, in turn, was substituted into eq. [43] to yield a second value of $i/3i_d$, as illustrated in scheme [61]

$$[61]\quad \frac{i}{3i_d} \xrightarrow{\text{eq. [35]}} \Delta E_{conc} \xrightarrow[\text{from } \Delta E]{\text{subtract}} \Delta E_{ohm} \xrightarrow{\text{eq. [43]}} \frac{i}{3i_d}$$

On this basis a revised estimate of $i/3i_d$ was arrived at and the procedure was iterated until the input and output of scheme [61] were identical. Values of i/c_2^b were then plotted versus i/i_d, producing the graph shown as Fig. 10. A linear regression through the origin leads to the slope

$$[62]\quad \frac{i_d}{c_2^b} = (5.28 \pm 0.15) \times 10^{-4}\ \text{A m}^3\ \text{mol}^{-1}$$

with a correlation coefficient of 0.9996.

Comparison of values

The values of i_d/c_2^b summarized in eqs. [58], [60], and [62] are in total agreement with each other, the compromise value

$$[63]\quad \frac{i_d}{c_2^b} = (5.3 \pm 0.1) \times 10^{-4}\ \text{A m}^3\ \text{mol}^{-1}$$

applying to all. The agreement between the three values represents a successful outcome of this study.

According to eq. [53], the experimental value of $(5.3 \pm 0.1) \times 10^{-4}$ A m^3 mol^{-1} is to be associated with the constant $4AFD_2\theta/(\lambda^2 L)$. Using measured values of A and L, as reported in the experimental section, and a literature value (12, 15) of $(9.5 \pm 0.1) \times 10^{-10}$ m^2 s^{-1} for D_2, we calculate $\theta/\lambda^2 = 0.35 \pm 0.03$, which agrees perfectly with the porosity value $\theta = 0.748 \pm 0.008$ and a tortuosity factor of about 1.45, as determined previously (12) for similar porous media.

Discussion

Experiments performed with porous media do not have a high degree of reproducibility, as the scatter in Figs. 8, 9, and 10 will attest. Nevertheless, it is evident that the linear relationships that are predicted for these three diagrams are obeyed. Moreover, it is clear from the lack of any dependance in the figures on the concentration symbols that the same linear relationship holds irrespective of the mercurous ion concentration.

We believe that the fact that, to within experimental error, all three graphs have an identical slope and that this slope is precisely what theory would predict is a convincing proof that the theory is correct. Recall the steady-state data were collected over wide ranges of mercurous ion concentration, hydrogen ion concentrations, and applied potential, so that we have exercised the theory as strenuously as possible.

Conclusion

We conclude that existing electrochemical theory is capable of predicting the results of steady-state voltammetry, whether or not supporting electrolyte is in excess. The theory must take into account concentration and ohmic polarizations, as well as activation polarization where this is encountered.

A quantitative examination of the photoisomerization of some protonated phenols

RONALD F. CHILDS[1] AND BAHA E. GEORGE
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1
Received August 5, 1987

RONALD F. CHILDS and BAHA E. GEORGE. Can. J. Chem. **66**, 1343 (1988).

The photoisomerization of a series of protonated, methyl substituted phenols to protonated bicyclo[3.1.0]hexenones has been examined. These reactions, which were carried out in CF_3SO_3H as a strong acid solvent at ambient temperatures, provide a convenient route to a variety of bicyclo[3.1.0]hexenones. The quantum yields for these photoisomerizations vary from 0.018 for protonated 3,5-dimethylphenol to 0.65 for protonated 2,6-dimethylphenol. This variation in efficiency can be understood in terms of a competition between ring opening, to regenerate the starting phenol, or cyclopropyl migration, to give product, of an initially formed intermediate.

RONALD F. CHILDS et BAHA E. GEORGE. Can. J. Chem. **66**, 1343 (1988).

On a étudié les photo-isomérisations d'une série de méthyl-phénols protonés qui conduisent aux formes protonées de bicyclo[3.1.0]hexènones. Ces réactions qu'on a effectuées à la température ambiante, dans le CF_3SO_3H qui agit comme solvant acide fort, offrent une voie d'accès intéressante à une variété de bicyclo[3.1.0]hexènones. Les rendements quantiques de ces photo-isomérisations varient de 0,018, dans le cas du diméthyl-3,5 phénol, à 0.65, dans le cas du diméthyl-2,6 phénol. On peut interpréter cette variation en fonction d'une compétition entre une ouverture de cycle qui regénère le phénol de départ et une réaction qui conduit au produit et qui implique la migration du cyclopropyle d'un intermédiaire qui se formerait initialement.

Most often on dissolution of a phenol in a strong acid medium, proton attachment occurs on the carbon *para* to the oxygen atom of the phenol to give what can be considered to be an *O*-protonated cyclohexa-2,5-dienone, eq. [1] (1). These

[1] 
protonated phenols are stable in solution provided the strong acid solvent is a non-oxidizing and non-sulphonating medium. Triflic acid, CF_3SO_3H, meets these criteria and is an excellent medium for these cations, with solutions being stable for long periods even at elevated temperatures (2). The only limitation on the use of triflic acid would seem to be its lower acidity compared to the other commonly used super-acid solvents (3) and the requirement for a more acidic medium to ensure ring protonation of some of the least basic phenols.

Ring protonated phenols have been shown to photoisomerize to give protonated bicyclo[3.1.0]hexenones on irradiation, eq. [2] (4, 5). This transformation parallels the analogous photo-

[2] 
rearrangements of neutral (6) and protonated cyclohexa-2,5-dienones (7) and provides a convenient preparative route to a wide variety of bicyclohexenones that have one or no substituents at C6.

An important feature of these photoisomerizations of protonated phenols is that the products of the reactions are also photochemically active and are converted back to a protonated phenol on irradiation. This overall process can lead to the production of an isomer of the original starting protonated phenol.

Protonated bicyclohexenones, the initial photoproducts of the isomerization of these protonated phenols, can also be converted back to a protonated phenol thermally. In many instances the activation energies for these isomerizations are large and the acid solutions have to be heated to relatively high temperatures for the thermal isomerizations to proceed. Indeed, the thermal stability and highly exothermic nature of these rearrangements (8) have led us to suggest that the photochemical and reverse thermal isomerizations of protonated phenols are potential candidates for a solar energy, photochemical/latent heat storage system (9). To evaluate the potential use of protonated phenols for solar energy storage it is important to know considerably more about the photoreactions themselves. For this purpose we have undertaken a quantitative examination of the photoisomerization of a series of methyl substituted protonated phenols. The results of this study are reported here.

Results and discussion

Characterization of the protonated phenols

The methyl substituted phenols **1–10** were protonated by dissolving them in CF_3SO_3H at 25°C. The resulting cations, **1*H*–10*H***, were characterized by comparison of their ^1H nmr spectra with those reported previously for the same cations in

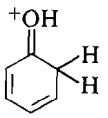
FSO_3H at low temperature (1). Apart from **7**, in every case the spectra were entirely consistent with the formation of the C4 protonated cations **1***H*–**6***H*, and **8***H*–**10***H*. With **7**, in addition to **7***H*, the C6 protonated material **7***H′* was shown to be present in small amounts (5%).



7*H′*

One difference that was observed between the room temperature ^1H nmr spectra of these cations in CF_3SO_3H at room temperature, as compared to those obtained in FSO_3H at low temperatures, was the line shapes of some of the resonances associated with ring protons. In most cases no coupling was detected between the H4 protons and adjacent protons on the C3, C5, or C4 methyl groups in these cations in CF_3SO_3H, in contrast to that found when FSO_3H was used as the solvent. The absence of this coupling suggests that relatively rapid exchange of the H4 proton with solvent is occurring in triflic acid (10). This exchange can be sufficiently rapid on the nmr time scale to lead in certain cases to a very significant degree of line broadening of the H4 resonances. As the temperature of the samples is lowered there is a reduction in the half-width of the resonances associated with H4. These effects are most pronounced in the ^1H nmr spectra of **1***H* and **8***H*. For example, the nmr spectrum of **8***H* at room temperature shows the resonances of both H4 and H5 to be very broad and the C4 methyl resonance to be a singlet, Fig. 1, suggesting at this temperature the occurrence of an intermolecular exchange of H4 with the acid medium and either an intramolecular exchange of H4 with H5 or direct exchange of H5 with the solvent. It is not known whether the difference in behaviour between the rates of exchange of H4 in the two acid media results from the difference in their acidities (3) or is associated with the difference in temperature under which the spectra were obtained. The freezing point of CF_3SO_3H and the reactivity of FSO_3H towards these cations at temperatures above −20°C make a direct experimental test of these factors difficult.

A further point to note with respect to the ^1H nmr spectra of these protonated phenols is the position of the resonances associated with the H4 protons. In those cases where there is a methylene group at C4 resonance is typically found at ca. 4.0 ppm. In the three cases where there is a methyl group at C4, the methine proton is found upfield of this position at ca. 3.6 ppm. Normally it is expected that a methine proton would be found at lower chemical shift than a comparably situated methylene proton. A likely reason for this unusual reversal is that the cations with a methyl group at C4 (**7***H*, **8***H*, and **10***H*) are not planar but rather adopt a conformation to which the C4 carbon is tilted out of the plane of the ring carbons so as to minimize interaction of the C4 methyl with the groups at C3 and C5. This twisting effect would move the C4 methine proton into the plane of the other ring carbons, Fig. 2, and as such it would be in a different magnetic environment relative to the methylene protons of the other cations. A comparable twisting of the six-membered ring has been suggested to take place with protonated hexamethylbenzenium cation (11). It is interesting to note that the chemical shift discrepancy noted above is also found in the parent benzenium ions, which have a single methyl substituent at the saturated ring carbon (10).

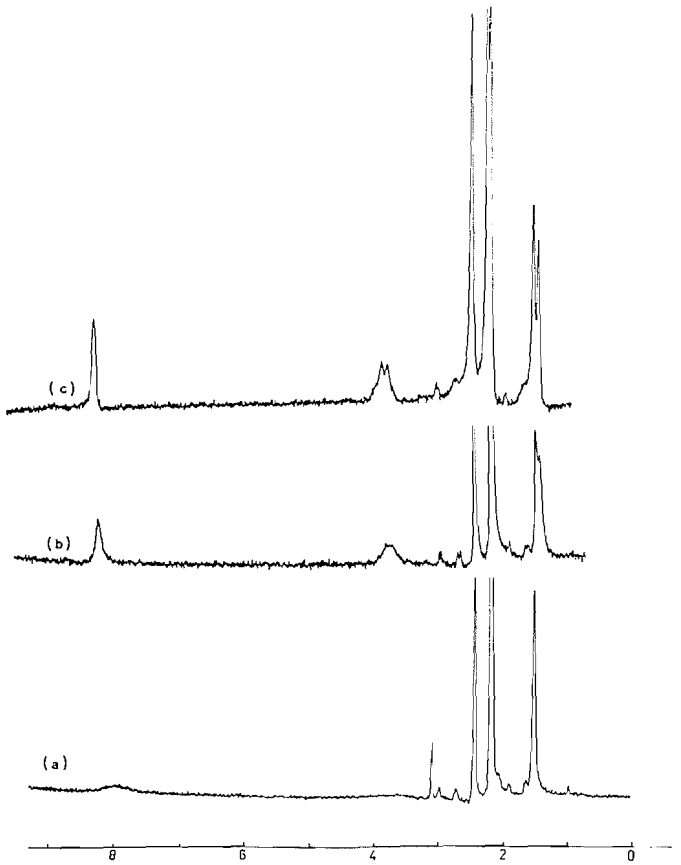


FIG. 1. The ^1H nmr spectra of **8***H*. (a) Room temperature: (b) 0°C; (c) −20°C.

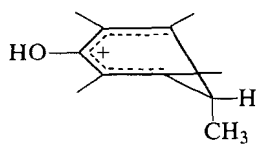

FIG. 2. Conformation of a protonated phenol with a methyl group at C4.

The uv spectra of the acid solutions of the protonated phenols are summarized in Table 1. In all cases a strong absorption band was observed between 300 and 330 nm. The position of this band is characteristic of oxygen protonated cyclohexa-2,5-dienones (11). In the case of solutions of **7**, a further weak absorption band was observed at 385 nm (log ε 2.63). Protonated cyclohexa-2,4-dienones exhibit absorption spectra in this region and the presence of this second band in the spectrum of **7** in CF_3SO_3H is consistent with the presence of **7***H′* in addition to **7***H*.

Photoisomerization of protonated phenols. Qualitative aspects

Irradiation of solutions of the protonated methyl substituted phenols at room temperature in triflic acid led to the formation of isomeric protonated bicyclo[3.1.0]hexenones and, in certain instances, isomeric phenols, Table 2. The products were identified on the basis of the ^1H nmr spectra of the protonated species and the subsequent isolation and characterization of the bicyclic ketones, see Tables 3, 4, and 6 and the experimental section. Some of these bicyclic ketones have been previously characterized and where this is the case it is noted in the tables.

In the case of the photoisomerization of **8***H*, two primary products, **17***H* and **18***H*, were obtained in which the stereochemistry of the C6 methyl group was the only difference. These two cations were distinguished by the positions of the resonances of these methyl substituents on C6 in comparison with other protonated and neutral bicyclohexenones (12). As has been noted before, with this type of photoisomerization of protonated phenols or benzenium ions themselves, the major isomer formed has the methyl group in the C6 *endo* position (13). Such a preference is consistent with the nonplanar conformation of the starting cations as was discussed above.

The reversible nature of these reactions is well exemplified in the photoisomerizations of the tetramethyl phenols **8***H* and **9***H*. The change in composition versus length of irradiation of **9***H* is shown in Fig. 3. Initially, the decrease of **9***H* is matched by the formation of **19***H*. The proportion of this bicyclic product rises to little over 50% and then drops to what appears to be a limiting value of 46%. As the reaction proceeds, protonated bicyclic ketones, **17***H* and **18***H*, are produced as well as **8***H*.

At longer irradiation times it would appear that a photostationary state involving all five cations is being reached. This can be seen from the data presented in Fig. 4. Ultimately a solution with the same composition was reached, upon irradiation of **8***H*, as was obtained starting with **9***H*. These interconversions of the tetramethyl substituted cations can be understood in terms of the processes depicted in Scheme 1. That the protonated bicyclic ketones will absorb light under the conditions used is seen on examination of their uv spectra given in Table 1.

The photoisomerization of protonated durenol, **9***H*, has also been investigated by Baeckstrom *et al.* (5). In addition to the formation, after quenching, of **19** and two unidentified ketones, presumably **17** and **18**, they also reported the formation of a trimethylphenol (2%) and 2,3,4,5-tetramethylphenol (7%). Under the conditions used in this work, neither of these latter two products was present in the reaction mixture. It should be noted that in our earlier work on the irradiation of **9***H*, using a super-pressure mercury lamp and a longer wavelength cut-off filter, only **8***H* was detected as a product (3). These photoisomerizations with a variety of absorbing and potentially photoreactive species present can be particularly sensitive to the wavelength of the light used for the isomerizations.

In the case of protonated 3,5-dimethylphenol, **4***H*, no characterizable photoproducts could be detected even after prolonged irradiations of the acid solutions. The photoisomerization of **5***H* yielded several minor products and these were not characterized.

In addition to the stereoselectivity exhibited at C6 of the product cations, the unsymmetrical arrangement of methyl groups at carbons 2, 3, 5, and 6 of **2***H*, **3***H*, **6***H*, and **8***H* means that products may result from the formation of the cyclopropyl ring between either C2,3 or C5,6. With triflic acid as a solvent, the product detected at room temperature was in each case that in which the number of methyl groups on the double bond of the bicyclic ketone product was maximized. However, with **3***H* and **6***H*, the protonated phenols **21***H* and **22***H*, respectively, were also formed in low amounts during the photoisomerizations. These two protonated phenols cannot arise from a further photoisomerization of **13***H* or **16***H* and suggest that **23***H* and

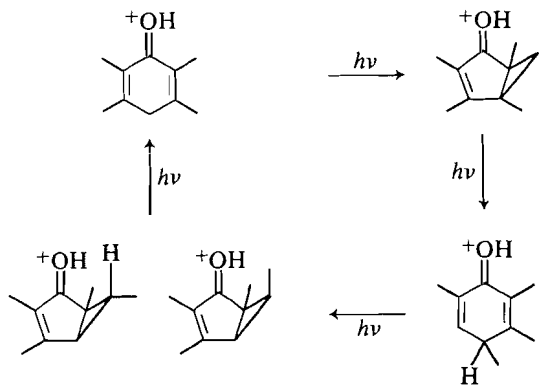

SCHEME 1

24*H* could be formed during the photoreactions but not survive the reaction conditions. Indeed, previous work on the photoisomerization of **6***H* at low temperature using FSO_3H as a solvent has shown that **24***H* is formed as a minor product of the reaction. In this work it was shown that triflic acid solutions of **24***H* were stable up to −10°C but at higher temperatures it rearranged thermally to form **22***H* (3). Irradiations of **3***H* and **8***H* in FSO_3H at low temperature also led to the formation of minor amounts of the less stable isomers **23***H* and **25***H* respectively.

Photoisomerization of protonated phenols. Quantitative aspects

The quantum efficiencies for the photoisomerizations of a number of protonated phenols and the reverse ring opening of

protonated bicyclic ketones were measured, Table 5. In each case the composition of the solutions was determined by quenching the acid solutions and carrying out quantitative analyses by glpc. In all cases the degree of conversion was kept below 10% and no correction was made for any back reaction.

The effect of dissolved oxygen on the reactions was determined by comparing reactions in which the oxygen had been removed by purging with argon with those using aerated samples. As can be seen from the results in Table 5, oxygen has no detectable effect on these reactions, consistent with the earlier suggestions that these reactions involve singlet or short-lived triplet excited states.

As can be seen on examination of the data in Table 5, at least over the range of systems studied here the quantum efficiency of the ring opening of the protonated bicyclic ketones is insensitive to the positions and number of methyl substituents. In each case

[a]Measured relative to the photodecomposition of potassium ferrioxalate at 313 nm.

the measured quantum efficiency is close to 0.2. The seeming insensitivity of the efficiency of this ring-opening reaction stands in marked contrast to the relatively large changes that are observed with the photoisomerizations of the protonated phenols, which in the systems studied here range from a low of 0.018 to a high of 0.65, a factor over nearly 40.

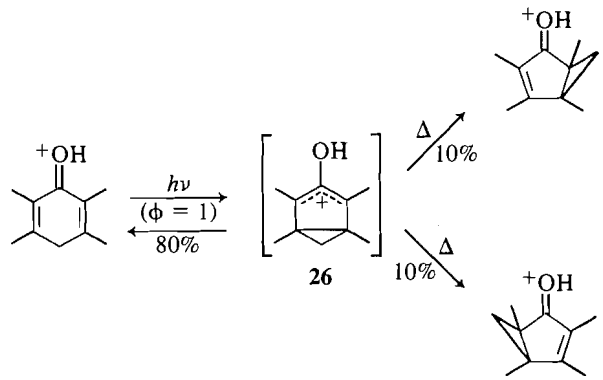
In examining the changes of the efficiencies of the photoisomerizations of the protonated phenols it is clear that there are some definite trends present. It is clear that the isomerization reaction is favoured by the presence of methyl groups at carbons 2 and 6 and hindered by methyls at carbons 3 and 5. Thus, comparing the series **1***H* (0.65), **6***H* (0.50), and **9***H* (0.24), there is a consistent drop in the efficiency of conversion to the corresponding protonated bicyclic ketone as methyl groups are successively added to the *meta* positions. The reverse effect is seen in comparing the effect of the addition of a methyl group to the *ortho* position(s), for example comparing **3***H* (0.38) with **1***H* (0.65) or **4***H* (0.018) with **9***H* (0.24). These effects are large and well beyond the experimental uncertainty of the measurements. In contrast, the quantum efficiencies for the isomerizations of **9***H* and **10***H* or **6***H* and **8***H* are essentially the same, indicating that groups at C4 are relatively unimportant.

Why are such large effects observed? In seeking to answer such a question it is necessary to know the mechanism of the reaction. In the case of the directly comparable photoisomerizations of cross-conjugated cyclohexadienones there is very strong evidence to indicate that the reactions proceed via an initial bonding between C3 and C5 followed by a ground state cyclopropyl migration to give the bicyclohexenone (6). It is particularly interesting that the effect of methyl substituents on the efficiencies of the photoisomerization of cross-conjugated cyclohexadienones is exactly the same as found here with the protonated systems and it would seem most likely that a similar two-step isomerization pathway holds in these latter systems (14).

If it is assumed that the photoisomerization of the protonated phenols discussed here proceeds as shown in Scheme 2, then it is possible to account for the observed variations in quantum efficiency on the basis of a competition between ring opening of the ground state intermediate formed in the reaction and cyclopropyl migration to give the protonated bicyclic product.

From the work described in the accompanying paper on the thermal isomerization of deuterated **19***H* it is clear that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.



SCHEME 2

relative rates of ring opening and cyclopropyl migration in the intermediate **26** are very closely matched, with ring opening being favoured by a factor of 4 as compared to migration. Such a ratio between these rate constants should also hold in the photochemical reaction if **26** is formed as a ground state intermediate. This means that if the first photochemical step of the reaction is assumed to have an efficiency of 1.00, then the maximum efficiency observed for the formation of **19***H* should be 0.2 with the remainder of **26** reverting to starting material. The observed quantum efficiency for the conversion of **9***H* to **19***H* is 0.24 + 0.02. The agreement between these two numbers suggests that this analysis is correct.

On the basis of this result with **9***H*, if we further assume that the efficiencies of the first photochemical step in these isomerizations of protonated phenols are high and approach 1 in each case, then the effect of the placement of methyl substituents can be understood. The work described in the accompanying paper suggested that when an intermediate such as **26** has methyl substituents at C3 and C5, the bridgehead positions, then ring opening will be facile. Conversely, the presence of methyls at the vinylic positions C2 and C6 will retard ring opening. If the barriers to ring opening and cyclopropyl migration in these photochemically generated intermediates are close, then the effect of *ortho* and *meta* substituents on the overall quantum efficiencies can be accounted for. It is interesting that Schuster and Liu (14) have provided evidence for a similar competition between ring opening and cyclopropyl migration of the corresponding zwitterion involved in the photoisomerization of neutral 2,5-cyclohexadienones.

Conclusion

In conclusion, it should be noted that the combination of relatively high quantum efficiencies and overall freedom of these photoisomerizations from side reactions make these photoisomerizations attractive from a synthetic perspective. In general, bicyclo[3.1.0]hexenones are not easy materials to prepare and this room temperature photoisomerization provides convenient access to a variety of methyl substituted derivatives of these bicyclic ketones. In using these reactions for synthetic purposes it is important to stress that the bicyclo[3.1.0]hexenones are very volatile materials and that great care should be taken not to lose material during the evaporation of solvent during work-up manipulations. It is also advisable, for maximum yields of the bicyclic materials, that the reactions be monitored and stopped at the appropriate point, to minimize subsequent photoreactions that can complicate the purification steps.

Experimental

General

The ^1H nmr spectra were recorded in Varian EM 390 and Bruker WM-250 spectrometers. The absorption spectra were obtained on Tracor Northern DA RSS system or Hewlett Packard 8451A spectrometers. The gc analyses were carried out on Varian 3700 and Hewlett Packard 5790A gas chromatographs. A 1/8 in. × 8 ft copper column packed with 2% OV17 on Chromosorb W (Column A) and a 1/8 in. × 10 ft stainless steel column packed with 10% Flourad FC 431 on Chromosorb W (Column B) were used in the gc analyses. An Aerograph model A-90-P3 gas chromatograph with a 1/4 in. × 5 ft copper column packed with 10% OV17 on Chromosorb W (Column C) column was used for preparative separation.

FSO_3H and CF_3SO_3H were obtained commercially and the former acid distilled prior to use. Cyclohexane was distilled over $LiAlH_4$ and pyridine was refluxed over solid KOH and distilled. Phenols **1**–**6** and **9** were obtained commercially and purified by sublimation before use. 2,3,4,6-Tetramethylphenol (15), 2,3,4,5-tetramethylphenol (16), and pentamethylphenol (15) were prepared by published procedures.

Protonation

Samples were protonated by the addition of cooled FSO_3H (−78°C) or CF_3SO_3H (0°C) to weighed amounts of phenols in nmr tubes cooled in a Dry Ice – acetone bath (FSO_3H) or an ice bath (CF_3SO_3H). Solution was achieved by mixing the contents of the tubes with a thin glass rod.

Photoisomerizations

These were carried out using a Rayonet photoreactor (Southern New England Ultraviolet Co.) equipped with 253.7-nm or 300-nm lamps. For low temperature irradiations the samples contained in 5-mm quartz nmr tubes were cooled in a partially silvered quartz Dewar held at −70°C with a FTS Flexicool FC2084P1 refrigeration unit.

Preparative scale irradiations were carried out using the appropriate phenol (2 g) dissolved in CF_3SO_3H (10 mL). The reaction mixtures were stirred during irradiation. Aliquots were withdrawn periodically to check the progress of the reaction using ^1H nmr spectroscopy. The reaction mixtures were quenched by pouring into $NaHCO_3$/ether at −78°C (FSO_3H) or at 0°C (CF_3SO_3H). Organic products were extracted into ether and careful removal of ether gave the products. Care should be taken during ether removal to prevent loss of volatile products.

The products were analysed (quantitative) by analytical gc and the components of the mixtures were separated by preparative gc. The ir and mass spectral data for the bicyclic ketones are given in Table 6.

Analysis of tetramethyl phenols

Acid solutions resulting from irradiations of **8***H* and **9***H* were quenched and the products isolated as outlined above. Following the removal of volatile ketones, the residue (10 mg) was dissolved in dry pyridine (1 mL). To 10 μL of this solution in a screw cap septum reacti-vial 100 μL of bis(trimethylsilyl)trifluoroacetamide was added, and the mixture was allowed to stand at room temperature for 1/2 h. Gas chromatographic analysis of the products (Column B) showed the presence of two components. These were identified as silyl derivatives

of durenol and isodurenol by comparison with authentic samples. Detector response was checked using mixtures of known composition.

Quantum yield measurements

The light source used in this work was an Osram HBO 200-W super-pressure mercury lamp with a Kratos LPS 25T power supply. Wavelength selection (313 nm) was achieved using a Kratos GM100 grating monochromator with entrance and exit slits set for a 24-nm bandwidth. The filter used was an Optikon filter no. 313FS10-25 with a high wavelength cutoff at 325-nm. The parallel beam from the monochromator was split by a quartz plate (7.5 cm square, 1.5 mm thick) fixed at 45° to the beam inside a light-tight box. Samples were contained in quartz "Lollipop cells". The samples were prepared by weighing the phenol or ketone (5–10 mg) into the sample container and dissolving in CF_3SO_3H (0.5 mL).

The quantum yields were measured at 313 nm with potassium ferrioxalate actinometry. The percent conversion, in all cases, was less than 10% and the quantum yields were not corrected for back reaction. After irradiation the neutral photoproducts were recovered by the procedure described above. The degree of conversion of the starting material was determined by analytical gc using Column B.

The quantum yield for the conversion of each protonated phenol to the corresponding protonated bicyclo[3.1.0]hexenones was measured at least three times and the mean values and the errors (standard deviation from the mean) are given in Table 5. The quantum yields for the conversion of protonated bicyclo[3.1.0]hexenones to protonated phenols were measured twice and the two values averaged to give the quantity given in Table 5. The error was estimated at 10%.

Thermal isomerizations of protonated bicyclo[3.1.0]hexenones

RONALD F. CHILDS[1] AND BAHA E. GEORGE
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 5, 1987

RONALD F. CHILDS and BAHA E. GEORGE. Can. J. Chem. **66**, 1350 (1988).

The thermal isomerization of a wide range of protonated methyl substituted bicyclo[3.1.0]hex-3-en-2-ones to protonated phenols has been examined using triflic acid as a strong acid solvent. The rate constants and activation energies of these isomerizations have been determined. The barriers to the isomerizations were shown to be dependent on the number and position of the methyl substituents. The results show that three different mechanisms are needed to account for these isomerizations, two of which involve a preliminary circumambulatory rearrangement prior to ring opening and the other process involving a direct ring opening of the initial protonated bicyclohexenone to give an intermediate *meta*-protonated phenol.

RONALD F. CHILDS et BAHA E. GEORGE. Can. J. Chem. **66**, 1350 (1988).

Opérant dans l'acide triflique qui agit comme solvant fortement acide, on a étudié l'isomérisation thermique d'un grand nombre de bicyclo[3.1.0]hexène-3 ones-2 substituées par des groupements méthyles en phénols protonés. On a déterminé les constantes de vitesse ainsi que les énergies d'activation de ces isomérisations. On a démontré que les barrières à ces isomérisations dépendent du nombre et de la position des substituants méthyles. Les résultats démontrent que trois mécanismes différents sont nécessaires pour expliquer ces isomérisations : deux impliquent une transposition circumambulatoire préliminaire précédant l'ouverture du cycle alors que l'autre processus implique une ouverture directe du cycle de la bicyclohexènone protonée initiale conduisant à un phénol intermédiaire protoné en *méta*.

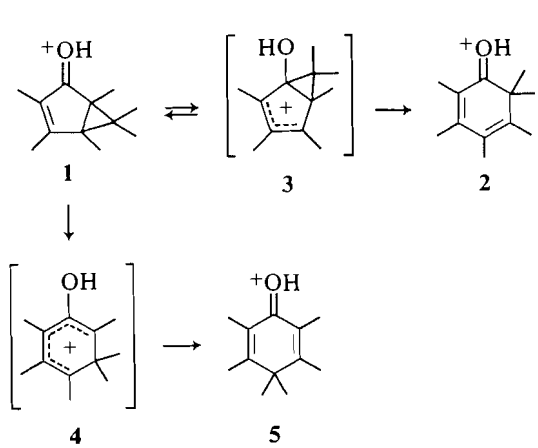
The thermal isomerization of bicyclo[3.1.0]hexenyl cations to the isomeric benzenium ions is a well-known reaction (1–4). This $4e^-$ disrotatory electrocyclic reaction is formally forbidden in the ground state and as a consequence these reactions, despite their strongly exothermic nature, involve relatively high activation energies (5).

When these bicyclic cations bear a hydroxy substituent, the corresponding thermal isomerization to hydroxybenzenium cations appears to be more complicated than that of the parent benzenium ions. The isomerization of the hexamethyl substituted cation, **1**, has been studied in detail (1, 6). Careful studies with deuterium labeled derivatives showed that this reaction proceeds by a circumambulation of the cyclopropyl ring around the five-membered ring followed by a higher energy ring-opening reaction of the unobserved intermediate **3**. There have been no further reports of studies of the ring-opening reactions of other protonated bicyclo[3.1.0]hexenones and it is not clear whether the isomerization pathway observed with **1** is a general feature of these systems.

In the isomerization of **1** the direct ring-opening reaction to give **4** and thence **5** is of higher energy than the observed pathway involving **3**. The indirect route involving the intermediacy of **3** does not eliminate the need for the disrotatory electrocyclic ring opening and questions arise as to why this is the preferred isomerization pathway and how much higher in energy is the direct pathway involving **4**. As the barriers to circumambulation in these types of cation are dependent on the substituents at C6 (1, 7), it seems likely that the pathway for this type of isomerization could be altered by changes in the substitution pattern of the protonated bicyclic ketones.



SCHEME 1

In this present work we report the results of an examination of the isomerization of a wide range of different methyl substituted protonated bicyclo[3.1.0]hexenones and show that ring opening to yield a protonated phenol is a common reaction. However, it is also clear that there are a range of mechanisms at play and that subtle changes in the substitution pattern of the starting bicyclic ketone can dramatically alter the direction of the ring-opening reaction.

Results

The bicyclic ketones **6–14** were prepared by irradiation of the corresponding protonated phenols in triflic acid as previously described (8). Dissolution of the ketones in triflic acid yielded solutions of the corresponding protonated materials **6*H*–14*H***. Except in the cases of **10*H*** and **12*H***, the acid solutions of these protonated ketones were stable at room temperature.

The thermal isomerizations of these protonated ketones in triflic acid were examined by nmr spectroscopy. The products of isomerization were identified by comparison of the nmr spectra of the products with those of authentic protonated phenols, and in several cases these assignments were confirmed by isolation of the phenol following neutralization of the acid solution. The rate of isomerization was measured by heating the samples in a constant temperature bath and monitoring the changes in the ^1H nmr spectra as a function of time. No side products were detected during the course of these isomerizations and in each case good first-order kinetics were observed. The results of these studies are summarized in Table 1.

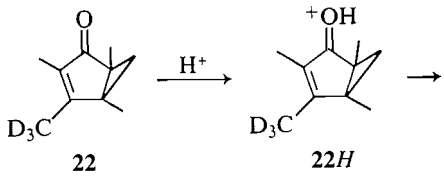
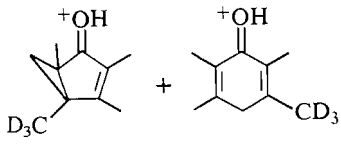
[a]Reference 1.

To check for the occurrence of circumambulation in **7*H***, the deuterated cation **22*H*** was prepared. Treatment of **7** with CD_3O^-/CD_3OD led to the formation of **22**, which on protonation in triflic acid gave **22*H***. This solution was heated at 60°C until some 40% of **22*H*** had isomerized to **23*H***. Careful analysis of the ^1H nmr spectra of the resulting solution showed that there was a small increase in the relative intensity of the resonance due to the residual undeuterated C4 methyl group of **22*H*** at δ 1.40, which could be attributed to the formation of **22*H'***. As it is possible that some of the growth of this signal results from a slow exchange of deuterium in **22*H*** with solvent, it can only be stated with certainty that the rate of circumambulation of **22*H*** to give **22*H'*** cannot be faster than the growth in this resonance. Thus the maximum rate constant for this scrambling process is $7.8 \pm 0.8 \times 10^{-6}\ s^{-1}$ at 60°C.

The stability of the various protonated phenols in CF_3SO_3H was determined by heating the acid solutions to the temperatures used to study the isomerizations of the protonated bicyclic ketones. Only one phenol, **17*H***, was observed to rearrange under these conditions. In the case of **17*H*** it isomerized to **16*H*** at 60°C with a first-order rate constant of $3.2 \times 10^{-6}\ s^{-1}$. This isomerization is slower than that of the conversion of **8*H*** to **16*H*** ($k = 1.7 \times 10^{-5}\ s^{-1}$ at 60°C) meaning that **17*H*** could have



22 **22*H***



22*H'* **23*H***

been detected if it had been produced as an initial product of the rearrangement of the protonated bicyclic ketone.

Discussion

It is clear from the results presented above that all of the protonated bicyclohexenones studied isomerize on heating to give protonated phenols. The barriers to these isomerizations are relatively high and elevated temperatures are required for most of the reactions. From the data given in Table 1 it can be seen that there is a wide spread of free energies of activation

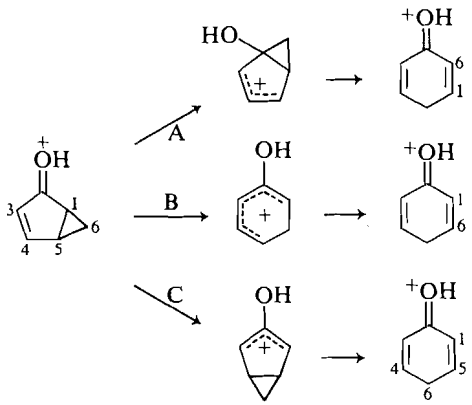


SCHEME 2

associated with these reactions. Only one product is observed in each case and the reactions occur with no detectable loss of material. This is remarkable in terms of the rather extreme conditions of acid and temperature that were employed and the results point to the usefulness of triflic acid as a non-oxidizing strong acid medium for high temperature carbocation rearrangements.

In principle there are three ways in which the ring opening of a protonated bicyclo[3.1.0]hexenone can take place. As is shown in Scheme 2, the cyclopropyl carbon C6 can potentially end up in the *ortho*, *meta*, or *para* positions of the protonated phenol. The first of these reactions, path A, involves insertion of C6 into the *ortho* position. This corresponds to the reaction seen by Hart and co-workers with **1** (6). Path B involves an initial ring opening of the bicyclohexenone followed by a subsequent rearrangement of the initially formed *meta*-protonated phenol to give the more stable isomer. The last example, path C, is a reaction comparable to that described by Hart; however, in this instance, the cyclopropane carbon has migrated to the ring position opposite to the hydroxy function.

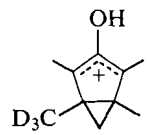
The control experiments show that solutions of the protonated phenols in triflic acid are stable when heated to the same temperatures under which the thermal isomerizations of the bicyclic cations were conducted. This means that while there can be proton reorganization on the phenolic rings, the positions of the methyl groups remain unchanged once the ring opening of the bicyclic ketones has occurred. Thus the positions of the methyl groups in the products as compared to the starting bicyclic ketones indicate the location of C6, the cyclopropane carbon.

The methyl substitution pattern present in some systems does not enable a clear differentiation between the three isomerization pathways to be made. However, in the reactions of **7***H*, **9***H*, **12***H*, and **14***H* the results are unambiguous. The isomerization of **14***H* to **21***H* corresponds to the involvement of path A. The conversion of **12***H* to **19***H* is a direct ring-opening process, path B, while the formation of **16***H* and **17***H* from **7***H* and **9***H*, respectively, provides clear-cut examples of the intervention of path C.

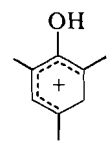
While the overall course of these ring-opening reactions would seem clear, questions arise as to how these reactions take place and what factors determine the relative activation energies of each pathway in a particular case. The occurrence of cyclopropyl circumambulations in bicyclo[3.1.0]hexenyl cations and protonated bicyclo[3.1.0]hexenones is a well-established isomerization process. Furthermore, while the intermediate **3** has not been directly observed in the isomerization of **1**, there is excellent evidence for its existence in the very careful work of Hart and colleagues. Similarly, in this work the detection of scrambling of deuterium in the isomerization of **22***H* would again indicate the presence of a circumambulatory rearrangement and it is highly suggestive that the intermediate **24** is involved in this ring-opening process. It would thus seem likely that the ring openings by paths A and C, as shown in Scheme 2, take place by an initial circumambulatory step followed by an electrocyclic ring opening.

It is possible to account for the products obtained in pathways A and C on the basis of single-step mechanisms. While such mechanisms cannot be ruled out on the basis of the existing results, it would seem very unlikely that they are involved in these rearrangements, particularly as it has been shown that they do not occur in the isomerization of alkyl substituted bicyclo[3.1.0]hexenyl cations nor indeed with the analogous isomerizations of the isoelectronic bicyclo[2.1.0]pentenes to cyclopentadienes (9).

In examining the factors determining the preference for isomerization by the various pathways shown in Scheme 2, it is useful to consider first the direct ring-opening reaction, path B. The one clear-cut example of the operation of this pathway is the conversion of **12***H* to **19***H*. The rate-determining step in this isomerization will be the initial electrocyclic ring opening to yield **25**. The subsequent hydride shift, whether it be an inter- or intramolecular process, will be fast.



24



25

Previous work on the isomerization of bicyclo[3.1.0]hexenyl cations has shown that the addition of an *endo* methyl group to C6 has a small rate-accelerating effect on the ring-opening reaction (1). In this present work, the addition of an *endo* methyl group to C6 of **12***H* gives **10***H*. The positions of the methyl groups in **10***H* do not permit an unequivocal identification of which isomerization path is followed. However, as the isomerization of **10***H* proceeds with the same rate constant as that of **12***H* but at a temperature 10° lower than the latter system, it would seem likely that **10***H* also isomerizes by path B.

In contrast to the straightforward reaction path for the isomerization of **12***H*, both **7***H* and **14***H* undergo a different type of ring opening. Protonated ketone **7***H* only differs from **12***H* by the presence of a methyl group at C4 of the latter cation. The effect of this methyl group is to cause **7***H* to isomerize by path C. On the other hand, the formal removal of the the C5 methyl group from **12***H* gives **14***H*, and this cation isomerizes by path A. The addition of a methyl group to C4 or removal from C5 of **12***H* must raise the barrier of the direct ring-opening reaction by at least 3.8 or 4.8 kcal/mol, respectively. These are very large effects for the introduction or removal of a methyl group on the barrier in an electrocyclic reaction.

The effect of a methyl group at C4 would seem to result from changes in the relative stabilities of the starting bicyclic cations. A C4 methyl group in **7***H* would stabilize this cation and presumably raise the barrier to isomerization with respect to **12***H*. A comparable effect of a methyl group on the barriers to the electrocyclic ring opening with the penta- and 1,2,3,5-tetramethyl-bicyclo[3.1.0]hexenyl cations has been reported (2). It is interesting that similar but smaller effects have been

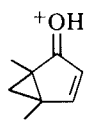
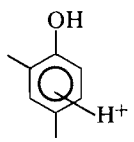
noted by Klärner and Adamsky on the barrier to the ring opening of substituted bicyclo[2.1.0]pentenes by the introduction of a methyl group at the 2 position (10, 11).

Related studies on the ring openings of bicyclo[2.1.0]pentenes and cyclobutenes show that methyl substituents at the bridgehead positions lower the barrier to the ring-opening reactions (12–15). In the present case, methyl groups at C1 or C5 of the bicyclic cations will have relatively little effect on the stability of the starting cations. However, they are ideally placed to stabilize the initially formed intermediate in Path B of these reactions and so lower the barrier to isomerization by this route. The absence of a C5 methyl group in the case of **14***H* causes the energy barrier for the direct electrocyclic ring opening to be greater than 27.2 kcal/mol, as compared to 22.4 kcal/mol for **12***H*.

The importance of the two methyl groups on the bridgehead carbons for the direct ring-opening reaction can also be seen in the photoisomerization of **20***H*. Irradiation of a solution of **20***H* in FSO_3H at −70°C leads to the formation of a mixture of **13***H* (95%) and **26** (5%). When this same photoisomerization is carried out in triflic acid at room temperature, **13***H* and **27** are formed in the same ratio. As there was no change in the light source or in any other conditions in the irradiation other than temperature, it is clear that **26** is thermally unstable at room temperature and isomerizes to **27** via path B.



26



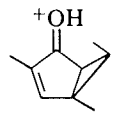
27

In examining the effect of substituents on the barriers to isomerization by paths A and C, it is important to know which is the rate-determining step in the two reactions. In the case of **1** the work of Hart (8) clearly establishes that the circumambulatory step is a relatively low energy process and that the ring opening of the intermediate is the rate-determining step. The effect of C6 methyl substituents on the circumambulatory reactions of bicyclo[3.1.0]hexenyl cations is well established (1). In general, an *exo* methyl substituent at C6 greatly accelerates the circumabulatory process in a bicyclo[3.1.0]hexenyl cation while an *endo* methyl group has a much smaller effect. These effects have been previously discussed in terms of both the steric requirements for these concerted reactions and the need for charge-stabilizing substituents at C6.

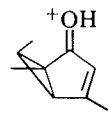
The effect of substituents at C6 in the ions studied here is clearly seen in the various isomerizations summarized in Table 1. In the case of the isomerization of **7***H*, it is clear that the barriers for circumambulation and ring opening via path C are now very comparable. The increase in the barrier to circumambulation of **7***H* (26.2 kcal/mol) as compared to that of **1** (17.4 kcal/mol) is not unexpected in view of the difference in substitution at C6 in the two cations.

While the substituent patterns in **8***H* and **11***H* do not allow an unambiguous definition of the isomerization pathways, comparison of the effect of the C6 substituents on the rate of isomerization of these ions as compared to **9***H* supports the suggestion that they isomerize via a two-step process in which the barrier to circumambulation determines the overall rate of the reaction. In particular, it should be noted that **9***H*, which isomerizes by path C, has the lowest isomerization barrier. This is consistent with the presence of an C6 *exo* methyl substituent in this ion. It is also interesting that the barrier to isomerization of **6***H* is the same as that of **7***H*. In the former case the pathway by which isomerization occurs is not known; however, in view of the behavior of both **1** and **7***H* it would seem likely that **6***H* also isomerizes by either pathway A or C. If this is the case then the *endo* C6 substituent on **6***H* is not having much effect on the barrier to circumambulation, as would be expected from the previous results.

Previous work has shown that **28** rearranges to **29** at 10°C,



28



29

indicating that in this case circumambulation is a lower energy process than any of the ring-opening pathways (8). However, in this present work neither **10***H* nor **12***H* undergoes circumambulatory rearrangements in preference to direct ring opening. It is interesting that **28** lacks the second methyl substituent at the bridgehead positions that would seem to be a requirement for the operation of path B.

One further feature of these ring openings that deserves mention is the choice of ring opening between paths A and C. Once the barrier to ring opening by a direct reaction, path B, becomes of higher energy than the circumambulatory routes, then there formally is a choice between two related paths, A and C. One thing that is clear from the results presented above is that the stability of the intermediates involved in paths A and C is not of major importance in determining the course of the reactions. This is clearly shown in comparing the isomerization of **1**, **14***H*, and **7***H*. Indeed the contrasting behavior of **1** and **7***H* is difficult to understand from a single perspective and points to the subtle blend of factors that are at play in these ions in determining the course of the ring-opening reactions.

Experimental

The nmr spectra were obtained using Varian EM390 and Bruker WM-250 instruments. The bicyclic ketones were prepared as described in the accompanying paper (16). Product identification was made by comparison with authentic samples of the various phenols.

Preparation of carbocations

The cation precursor, ca. 10 mg, in an nmr tube was cooled in an ice bath (0°C). CF_3SO_3H (0.5 mL), cooled previously to 0°C, was added dropwise. Dissolution of the base was achieved as the solution was slowly brought to ambient temperature.

Quenching acid solutions

The CF_3SO_3H solution containing the cation was added to a rapidly stirred aqueous solution of $NaHCO_3$. The organic material was extracted into ether (3 × 5 mL) and the combined extracts washed with water (2 × 5 mL) and dried over $MgSO_4$. The solvent was removed carefully by evaporation through a 7-cm Vigreux column using a steam bath. The products were analysed by gc using a 10% Flourad FC 431 on a Chromosorb W column as described in the accompanying paper (16).

Synthesis of 1,3,5-trimethyl-4-methyl-d_3-bicyclo[3.1.0]hexenone, 22

This compound was prepared from **7** using a procedure similar to that outlined by Hart *et al.* (17). The bicyclic ketone **7** (50 mg) was dissolved in $NaOCD_3$ (0.5 mL CD_3OD/50 mg Na). The solution was left at 25°C and its ^1H nmr spectrum examined periodically. After 1 h the methyl signal at δ 1.96 had disappeared and no further change in the nmr spectrum was observed after several hours. The trideuterio ketone was isolated by pouring the solution into 5 mL of CH_2Cl_2 and washing with ice water (3 × 5 mL). After drying ($MgSO_4$) the solvent was

evaporated slowly through a 7-cm Vigreux column to give **22** as an oil; ^{1}H nmr ($CDCl_3$) δ: 1.47 (s, 3H, CH_3), 1.33 (s, 3H, CH_3), 1.20 (s, 3H, CH_3), 1.16 (d, 1H, J = 3 Hz), 0.83 (d, 1H, J = 3 Hz).

Thermal stability of bicyclo[3.1.0]hexenones in CF_3SO_3H

Each ketone (ca. 10 mg) was dissolved in CF_3SO_3H according to the above method. The resultant solutions were examined by ^{1}H nmr at various temperatures between 34 (probe temperature) and 100°C for cations **6***H*, **7***H*/**8***H*, **9***H*, **11***H*, **13***H*, and **14***H* and between 0 and 30°C for cations **10***H* and **12***H*. Normally, the bath or probe temperature was increased from the lowest value by increments of 10°C until an isomerization was observed. The isomerization was followed by ^{1}H nmr spectroscopy. Products were identified by ^{1}H nmr and by gc after quenching the acid solution.

Isomerization rate constants

The rate constants for the conversion of the protonated bicyclic ketones **6***H*, **7***H*, **8***H*, **9***H*, **11***H*, and **14***H* to their isomeric phenols at 60°C were determined by dissolving the ketone (ca. 10 mg) in CF_3SO_3H (0.40 mL) and adding a small amount of $(CH_3)_4N^+BF_4^-$ as an internal standard. This mixture was placed into a medium-walled nmr tube. The sample was heated in a Haake A81 constant temperature bath and at various time intervals the sample was cooled quickly to 25°C and its ^{1}H nmr spectrum obtained. The relative concentration of the starting material was determined by comparison with the signal due to the internal standard and the first-order rate constant calculated. Each determination was repeated at least in duplicate.

The importance of ground state conformation in the photoisomerizations of protonated enones

RONALD F. CHILDS,[1] MAILVAGANAM MAHENDRAN, CHRISTOPHER BLACKBURN, AND GREGORY ANTONIADIS
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1
Received October 21, 1987

RONALD F. CHILDS, MAILVAGANAM MAHENDRAN, CHRISTOPHER BLACKBURN, and GREGORY ANTONIADIS. Can. J. Chem. **66**, 1355 (1988).

The conformations of several protonated enones have been determined by low temperature ^{13}C nuclear magnetic resonance spectroscopy. Information on the ground state conformation has been used to understand the differences in the photochemistry of these systems. Photoisomerizations of **4** and **5** have been examined. In the case of **4**, irradiation leads only to the formation of the *Z* isomer **16**; protonated dihydrofuran **13** was not observed. In the case of **5**, both the *Z* isomer **17** and protonated dihydrofuran **14** were observed. The protonated dihydrofuran **14** was produced from the start of the reaction. It is concluded from these and previous results that for the photocyclization to occur the starting cation must exist in an *s-cis* conformation in the ground state.

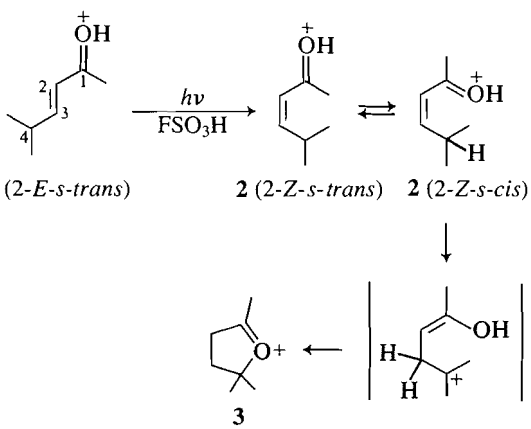
RONALD F. CHILDS, MAILVAGANAM MAHENDRAN, CHRISTOPHER BLACKBURN et GREGORY ANTONIADIS. Can. J. Chem. **66**, 1355 (1988).

Faisant appel à la résonance magnétique nucléaire du ^{13}C, à basse température, on a déterminé les conformations de plusieurs ènones protonées. On a utilisé les informations relatives aux conformations dans l'état fondamental pour comprendre les différences observées lors de la photochimie de ces systèmes. On a étudié les photo-isomérisations des composés **4** et **5**. Dans le cas du composé **4**, l'irradiation ne conduit qu'à la formation de l'isomère-*Z* (**16**); on n'observe pas de formation du dihydrofuranne protoné **13**. Dans le cas du composé **5**, on observe la formation de l'isomère-*Z* **17** ainsi que celle du dihydrofuranne protoné **14**. La formation du dihydrofuranne **14** commence dès le début de la réaction. Sur la base de ces résultats et d'autres obtenus antérieurement, on en conclut que la photo-isomérisation ne peut se produire que si le cation de départ existe dans la conformation *s-cis*, à l'état fondamental.

[Traduit par la revue]

Protonated enones and their oxygen alkylated analogues undergo a variety of photoisomerizations upon irradiation (1). The primary photoreactions of the acyclic cations are *E*/*Z* isomerizations about their C=C and C=O partial double bonds (2). A second type of reaction, occurring with systems containing an isopropyl group at the β-position, is cyclization to form a protonated dihydrofuran (3). These reactions are illustrated in Scheme 1. All of these photoisomerizations of protonated enones involve π,π* excited states.

One feature of the cyclization reaction of **1** is that ring closure has been shown to take place only from the 2-*Z* isomer,[2] **2**. A mechanism that could account for this observation would involve hydrogen abstraction by oxygen from the γ position. Such a 1,5-hydrogen abstraction reaction would parallel that commonly found in the photoreactions of unprotonated enones (4). However, deuterium labelling experiments showed that such a process did not occur with these protonated systems but instead that the C4 isopropyl hydrogen migrates exclusively to C3 of the starting enone (5). This hydrogen migration can be considered to involve a photochemically initiated 1,2 hydride shift from C4 to C3.



1 (2-*E*-*s*-*trans*) **2** (2-*Z*-*s*-*trans*) **2** (2-*Z*-*s*-*cis*)

3

SCHEME 1

The photochemical interconversion of **1** and **2** will involve a common, twisted excited state. It is likely that the hydride shift from C4 to C3 also occurs from this twisted excited state or a closely related ground state species. As such it is difficult to see why the ground state conformation about the 2–3 bonds of these cations can determine that **2** but not **1** undergoes photochemically induced ring closure to give **3**. Rather it would seem most likely that the critical feature is the ground state conformation about the C1—C2 bonds of these protonated ketones.

Calculations on acrolein indicate that the barriers to rotation about the C2—C3 bond are increased in the π,π* excited states as compared to the ground state (6). This means that in the case of the cyclization reaction shown in Scheme 1, which involves π,π* excited states, ring closure can only occur upon excitation of cations that have an *s-cis* conformation in the ground state. As a result, one possible reason for the photochemical cyclization of **2** as compared to **1** is that the relative proportions of the *s-cis* and *s-trans* conformations of these protonated enones might depend on the configuration of the C2—C3 bond.

In this paper we describe a series of experiments that, in the first place, determine the conformation about the C1—C2 bonds of several of these cations using low temperature nmr methods. Second, the photochemistry of these cations has been shown to correlate with the known conformational preferences.

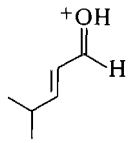
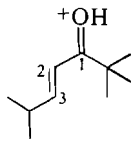
Results and discussion

Preparation of protonated enones

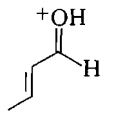
The protonated enones studied were **1**, **2** and **4**–**7**. These cations were chosen because the groups attached to the carbonyl group, hydrogen, methyl, and *tert*-butyl, provide a wide range of steric requirements (7). Of these, cations **1** and **6** have been reported previously and **2** generated as a mixture with **1** and **3**.



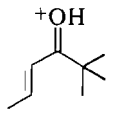
4



5

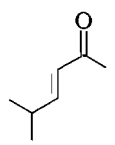


6

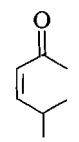


7

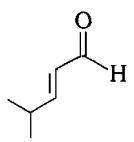
Dissolution of the enones **8**–**12** in FSO_3H at low temperature led to the formation of cations **1**, **2**, **4**, **5**, and **7**. The low temperature ^1H nmr spectra of these cations were consistent with the indicated structures, Table 1 (8). In the case of **1**, **2**, and **6** the spectra obtained were identical to those previously reported (3, 14).



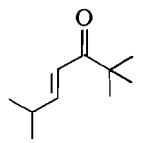
8



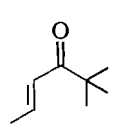
9



10

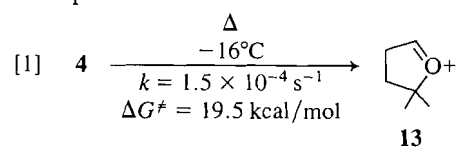


11

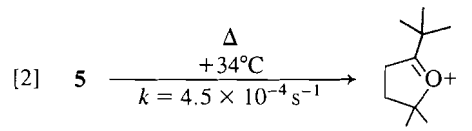


12

As was expected from the behaviour of **1**, cations **4** and **5** rearrange on heating the acid solutions to yield the corresponding protonated dihydrofurans **13** and **14**, respectively. The identity of the products was established by comparison of their ^1H nmr spectra with those of other protonated dihydrofurans (3, 9). These isomerizations proceeded in high yield with no other products being detected. The first-order rate constants for these isomerizations were determined by monitoring changes in the nmr spectra as a function of time.



[1] **4** $\xrightarrow[k = 1.5 \times 10^{-4}\ s^{-1}]{\Delta \quad -16°C}$ **13**
$\Delta G^{\neq} = 19.5$ kcal/mol

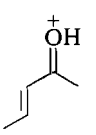


[2] **5** $\xrightarrow[k = 4.5 \times 10^{-4}\ s^{-1}]{\Delta \quad +34°C}$ **14**

Heating solutions of **6** and **7** to 25°C did not lead to the formation of any rearranged products. A darkening of solutions of **6** was noted under these conditions.

Conformational studies

It has been shown by Mullen *et al.* that rotation about the C1—C2 bond of protonated enones is slowed sufficiently at −80°C that it is possible to observe non-averaged ^{13}C nmr spectra of both conformations (10). At even lower temperatures interconversion of the two conformers about the C=O partial double bond is almost stopped on the nmr time scale (10, 12). Thus these workers showed that protonated enone, **15**, which



15

serves as a good model for **1**, exists predominantly in the *s-trans* conformation (75%) in equilibrium with the *s-cis* conformer (25%) (11).

The critical features determining the conformational preferences of protonated enones are the groups attached to the carbonyl carbon and the *Z* substituent in the β-carbon. The *E* substituent on the β-carbon is unimportant (11) and, rather than **4** and **5**, for the purposes of these conformational studies cations

2, **6**, and **7** were used, as their thermal stability permitted studies to be made over a wide range of temperatures.

The low temperature ^{13}C nmr spectra of FSO_3H/SO_2ClF solutions of **2**, **6**, and **7**, are given in Table 2. Cooling solutions of **7** led to changes in its ^{13}C nmr spectra that were qualitatively similar to those observed for **15**. However, they differed in the proportion of the C1—C2 conformations present. Analysis of the changes observed showed that at −85°C, **7** exists as a mixture containing 80% of the *s-cis* and 20% *s-trans* conformers. As was found by Mullen *et al.*, further broadening and splitting of the resonances associated with the *s-trans* conformer occurred as the temperature of the sample was lowered to −105°C.

Similar changes were observed in the low temperature nmr spectra of **2**. This cation was shown to consist of 88% of the *s-cis* and 12% of the *s-trans* conformers.

No change was observed in the nmr spectra of **6** on cooling to −105°C, indicating that this cation exists predominantly in one conformation. In the absence of two signals for the different conformations it is difficult to make an absolute identification. However, it would be expected that the *s-trans* conformation would be the most stable. In the case of a protonated aldehyde an *E* conformation about the C=O bond would be greatly preferred, and no broadening or splitting of any of the carbon resonances would be expected as the temperature is lowered (13).

It is clear from these observations that a substantial difference in the ground state conformations of cations **1** and **2** would be expected. The *s-trans* conformation will be preferred with **1** whereas the *s-cis* conformation will dominate for **2**.

Underlying this conclusion, however, is the question of what is the determining factor lying behind these changes in conformation of the C1—C2 bond of these cations. The steric requirement of the substituents is clearly important. This is shown by comparison of the series of cations **6**, **15**, and **7** in which, as the substituent attached to the carbonyl carbon is varied from H to methyl to *tert*-butyl, the proportion of the *s-cis* conformer is increased relative to the *s-trans*. This pattern follows the results found for the related allyl cations in which the key determinant in deciding the conformational preference of these systems is the 1,3 interaction of the *Z* groups on the terminal carbons (14).

In the case of **7**, where the carbonyl substituent is a *tert*-butyl group, it is interesting to note that while the *s-cis* conformer predominates there is still some 20% of the *s-trans* form present. This contrasts with the situation found with the corresponding neutral ketone **12**. Examination of the ir spectrum of **12** shows that it exhibits only a single carbonyl absorption at 1695 cm^{-1}, indicating that the molecule exists essentially completely in the *s-cis* conformation (11). It would seem that an "OH" group in a protonated carbonyl compound has an effective steric requirement that is somewhat comparable to a *tert*-butyl group. Examination of the crystal structures that have been reported for protonated carbonyl compounds shows that in each case an exceptionally strong hydrogen bond is formed between the OH proton and an electronegative atom in the counterion (15). In general, there is little difference in the ^{13}C nmr spectra of protonated carbonyl compounds in the solid state and highly polar solvents such as FSO_3H, and it would seem that this specific hydrogen bonding situation is maintained in solution. In other words, in terms of its three-dimensional shape, a more appropriate model for the OH group of a protonated carbonyl compound would be $-OHOSO_2F$.

A group such as $-OHOSO_2F$ would have a rather unusual steric requirement in that it would be large at a relatively long distance from the carbon to which it is attached. As such it would have quite different properties than a group such as methyl, and this could account for the switch in the preferred conformation of **1** as compared to **2**.

Photoisomerizations

The photoisomerizations of **4** and **5** were examined at low temperatures in FSO_3H. In the case of **4**, λ_{max} 260 nm, irradiation at 254 nm led to the formation of a new cation, which was identified by its low temperature ^1H nmr spectrum as **16**, Table 1. The proton/proton coupling constant between H(2) and H(3) was 11.7 Hz, a value typical of a *Z* configuration about the C2—C3 bond of a protonated enone. A photostationary state was set up between **4** and **16**, consisting of 35% of the former and 65% of the latter ion. No evidence could be found for the formation of **13** as a product of these photoisomerizations, even on prolonged irradiations.

Irradiation of **5**, λ_{max} 279 nm, gave two additional cations. One of these was identified as **14** by comparison of the ^1H nmr spectra of the mixture with those obtained from the thermal rearrangement of **5**. The second product was shown to be the

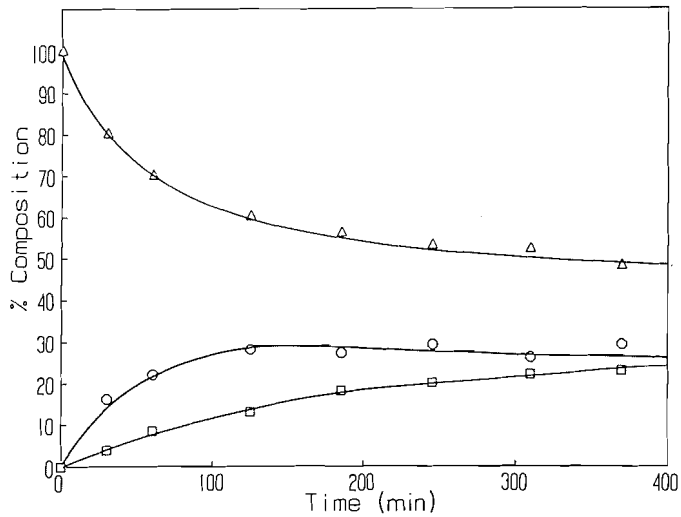

FIG. 1. Photoisomerization of **5** as a function of irradiation time (**5**, △; **17**, ○; **14**, □.)

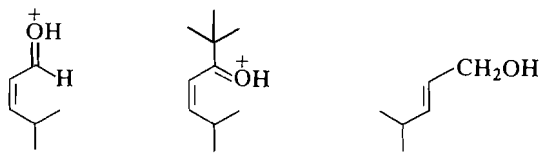
2-*Z* isomer **17** by its characteristic nmr spectrum, Table 1. As can be seen from the data given in Fig. 1, **14** is produced from the start of the irradiation. This indicates that **14** is produced from both **5** and **17**.



16 **17** **18**

The formation of the cyclic product from both **5** and **17**, but not from **4** or **16**, is entirely consistent with ground state conformational control of these photoreactions and the results fully substantiate the suggestion made earlier to account for the photo-induced cyclization of **2**, but not **1**, to **3** (2). It is quite clear with these protonated enones that photochemically induced ring closure by the bonding of the oxygen atom to the cation center at C4 requires an *s-cis* conformation in the ground state.

Experimental

General

The ^1H nmr spectra were obtained on Varian EM390 and Bruker WM-250 spectrometers. The ^{13}C nmr spectra were recorded on a Bruker WM-250 spectrometer. Samples were protonated by adding cooled FSO_3H to weighed amounts of compounds in nmr tubes cooled in a Dry Ice – acetone bath.

Syntheses

Aldehyde **10** (16), the precursor to **4**, was obtained by oxidation of 4-methyl-pent-2-en-1-ol **18** with pyridinium dichromate.

Condensation of 1-bromopinacolone with isobutryaldehyde in the presence of zinc, followed by dehydration of the initially formed alcohol with iodine, led to the formation of **11** (17).

A similar series of reactions using the bromoketone and acetaldehyde yielded **12** (17). The crude product was purified by distillation; ir(neat): 1695 and 1630 cm^{-1}.

3-Z-5-Methyl-hex-3-en-2-one

A pentane solution (50 mL) of **8** (500 mg) was irradiated (254 nm) for 12 h at −60°C. The solvent was removed under reduced pressure to yield a mixture of *Z* and *E* isomers. The *Z* compound was separated by preparative layer chromatography (silica; 20% ether/petroleum ether). The *Z* isomer obtained was further purified by distillation to yield pure *Z*-enone **9** (150 mg); ir(liquid film); 1700, 1625 cm^{-1}; M^+ calcd. for $C_7H_{12}O$: 112.0888; found: 112.0879.

Photoisomerizations were carried out using a Rayonet photoreactor and 253.7-nm lamps. The samples, contained in 5-mm quartz nmr tubes, were cooled in a partially silvered quartz Dewar held at −70°C. The reaction was followed by low temperature ^1H nmr spectroscopy.

Synthesis of a β-diketone from a dithioacetal. A model study for the synthesis of an ionomycin fragment

KEVIN P. SHELLY AND LARRY WEILER[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received December 2, 1987

KEVIN P. SHELLY and LARRY WEILER. Can. J. Chem. **66**, 1359 (1988).

The anions of dithioacetals react with epoxides to give β-hydroxydithioketals, which can be oxidized and hydrolyzed to β-diketones. This sequence is applied to a model study of the synthesis of the C-5 to C-15 fragment of the antibiotic ionomycin.

KEVIN P. SHELLY et LARRY WEILER. Can. J. Chem. **66**, 1359 (1988).

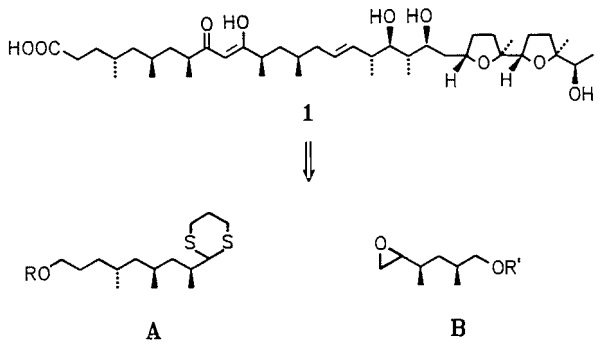
Les anions des dithioacétals réagissent avec les époxydes; cette réaction fournit des β-hydroxydithiocétals qui peuvent être oxydés et finalement hydrolysées en β-dicétones. Cette série de réactions a été appliquée à une étude modèle de la synthèse du fragment C-5 à C-15 de l'antibiotique ionomycine.

[Traduit par la revue]

Introduction

In 1978, Liu *et al.* reported the production and isolation of the antibiotic ionomycin from *Streptomyces conglobatus* (1*a*; see also 1*b*). The antibiotic was isolated as its calcium salt from a broth concentrate that had been adjusted to pH 12 with sodium hydroxide. This illustrated the high affinity of ionomycin for calcium ions, which was verified by subsequent studies (2). Ionomycin chelates dipositive ions as a dibasic acid, whereas the few other known ionophores that chelate divalent cations do so as monobasic acids. The structure of ionomycin (**1**) was determined from spectroscopic data and an X-ray structure analysis of the calcium salt (3). Ionomycin (**1**) was found to be a polyether compound with a β-diketone and a carboxyl group. These latter two functional groups are ionized in the calcium salt and together with three other oxygen atoms encapsulate the calcium cation in an octahedral coordination site.

Several reports of the synthesis of ionomycin fragments have already occurred (4–8). None of these reports deals with the generation of the β-diketone moiety. At this time we would like to report our model studies on the preparation of two fragments corresponding to carbons 5–9 and 10–15 of ionomycin (**1**), the fusion of these two fragments, and the generation of the requisite β-diketone unit.[2]

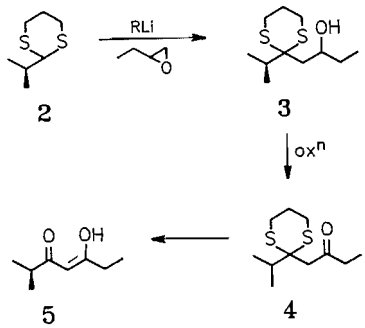


Our retrosynthetic analysis of the left-hand side of ionomycin (**1**) led us to consider the use of a dithiane to link subunits A and B together with the expectation that subsequent transformations would yield the desired β-diketone. Dithianes have been used extensively in organic synthesis (10) following the discovery of their metallation and subsequent reaction with electrophiles by Seebach and Corey (11). These authors noted that epoxides "are opened very slowly" by dithiane anions and they suggested storage of the reaction mixture at low temperature for up to 1 week. In spite of that warning of their sluggish reactivity, the opening of epoxides by dithiane anions has been used in the synthesis of natural products (12). These two examples involved either a simple epoxide or a simple dithiane moiety. We planned to employ both a complex dithiane and complex epoxide in the key alkylation.

Results and discussion

The dithiane **2** was prepared from isobutyraldehyde following the procedure of Seebach and Corey (11). By careful control of the concentration and time for the metallation reaction, we were able to obtain high isolated yields of product **3** from the reaction with 1,2-epoxybutane after a few hours. The ease of this reaction was encouraging, although it was achieved employing both a very simple dithiane and epoxide as models.

Initially we studied the oxidation of **3** with pyridinium chlorochromate. However, the isolated yields of keto dithiane **4** were disappointing (ca. 40%). We then turned our attention to pyridinium dichromate, which previously had been used to oxidize a hydroxy dithiane (13). Using similar conditions to Corey and Schmidt we could obtain yields of **4** in the 80% range. The β-keto dithiane **4** was hydrolyzed using mercury(II) (14) to give the β-diketone **5** in about 50% yield. Since there are



numerous techniques available to hydrolyse dithianes, we did not invest any time in trying to improve the yield in this simple model.

meso-2,4-Dimethylglutaric anhydride (**6**) was prepared according to the method of Allinger (15). Methanolysis (16) of **6** gave poor yields of the monomethyl ester **7**. Elemental analysis

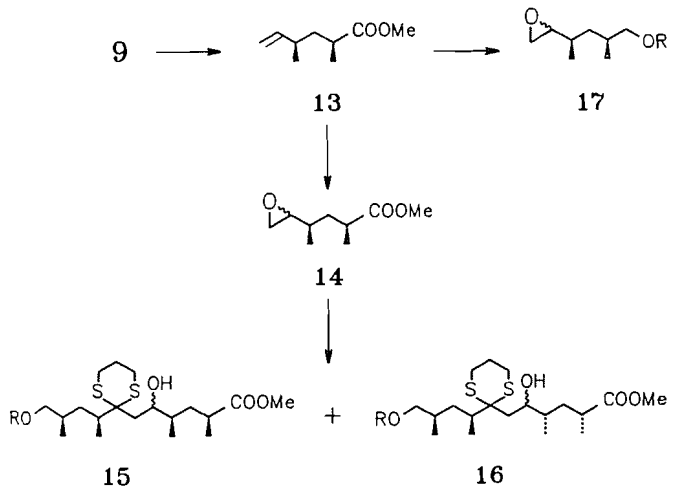
of **6** showed that under our experimental conditions one mole of water had crystallized with the anhydride. This problem was overcome by Kugelrohr distillation of the hydrated anhydride. Subsequent methanolysis of the distilled anhydride afforded the desired monoester **7** in over 90% yield. The acid chloride **8** was readily prepared and was stable and easy to handle. Rosenmund reduction of **8** to **9** had to be carried out under controlled conditions (17). Because of the instability of the aldehyde **9**, it was not isolated but was used immediately after preparation. Treatment of **9** with 1,3-dithiolpropane gave the dithiane **10** in over 60% yield from **8**. Reduction of the ester in **10** and protection gave the silyl ether **11**.

The dithiane **11** was metallated and reacted with 1,2-epoxybutane as above in the preparation of **3**. We were unable to isolate any product under these conditions, but we did recover **11** in high yield. A deuterium oxide quench of the attempted metallation of **11** showed that the carbanion formation using *n*-butyllithium as base was unsuccessful. At this stage we embarked on an extensive study of the effect of base, solvent, time, ligand addition, and temperature on the metallation of **11**. Using *tert*-butyllithium in *n*-heptane with the addition of at least one equivalent of tetramethylethylenediamine resulted in about 50% incorporation of deuterium in **11** on quenching. We were unable to increase the amount of deuterium incorporation by further refining the experimental conditions. This could be due to complete formation of the lithiated dithiane, which then forms an aggregate that on protonation gives a very stable 1:1 complex of the lithio dithiane anion and the neutral dithiane.

The incomplete incorporation of deuterium on quenching a carbanion has been known for several years (18) and is not good evidence for the lack of formation of such anions. Enolate carbanions are frequently only partially quenched by D^+ sources. It has been suggested that this is due to the formation of enolate amine complexes, which result in reprotonation of the carbanion rather than deuteration (19). These complexes are stable and crystalline, and X-ray studies have been carried out on a number of these compounds. The X-ray structure of the TMEDA complex of the lithium anion of the benzaldehyde dithiane shows that this carbanion forms similar complexes to the above enolates (20). We suggest a similar mechanism for the incomplete incorporation of deuterium into the dithane carbanions as for the enolate carbanions.

We returned to the use of *n*-butyllithium as base and found that addition of TMEDA in THF resulted in levels of deuterium incorporation approaching 75% when the metallated reaction mixture was quenched with deuterium oxide. Generation of the anion from **11** under these conditions and alkylation with 1,2-epoxybutane gave the product **12** in up to 75% yield by gc.

Methylenation of the aldehyde **9** with a Wittig reagent did not proceed efficiently. This problem was solved by carrying out the methylenation using the Lombardo modification (21) of the Nozaki reagent (22). In this way we were able to obtain the olefin **13** in about 40% yield from **8**. Epoxidation of **13** gave a diastereomeric mixture of epoxides **14**, which were not separated. Reaction of the epoxides **14** with the metallated dithiane **11** under the above conditions gave about 10% yield of the products **15** and **16**. Deuteration studies showed that generation of the dithiane carbanion was not the problem and we speculated that deprotonation of the ester in **14** might be competing with alkylation of the epoxide moiety. As a result, the epoxides **17** were prepared from **13** by reduction of the ester,



protection, and epoxidation. A gc analysis of **17** showed that the diastereomeric epoxides were formed in a ratio 65:35. Since the asymmetric centre at C-5 in **17** is destined to become an sp^2 carbon, the epimeric mixture was carried forward.

Generation of the anion from **11**, followed by reaction with **17**, gave the β-hydroxy dithianes **18** and **19** in 40% yield along with about 40% recovered dithiane **11**. We then experienced some difficulty in the oxidation of **18** and **19**. As a result we investigated the hydrolysis and subsequent oxidation to generate the β-diketone functionality. Hydrolysis of **18** and **19** with methyl iodide (23) followed by a Moffat oxidation gave the β-diketones **20** and **21** in 25% isolated yield, along with about 50% unreacted β-hydroxy ketones from the Moffat oxidation. The structure proof of **20** and **21** came from an analysis of their spectroscopic data. We were able to separate the diastereomers of the *tert*-butyldimethylsilyl enol ethers of **20** and **21** by capillary column gc. The ratio of the two diastereomers was 55:45. We have not been able to determine which diastereomer predominates. Nor could we detect any spectral differences between **20** and **21** even on a 400-MHz ^{1}H nmr spectrum.

Thus these model studies indicate that the coupling of a dithiane and an epoxide, followed by hydrolysis of the dithiane and oxidation, would appear to be a viable route to the β-diketone of ionomycin. The use of optically pure starting materials would avoid the formation of diastereomers such as **20** and **21**. The synthesis and coupling of such units is under active investigation. The two protecting groups in **20** and **21** are identical, to simplify the product identification. However, they would be different in the actual subunits corresponding to A and B.

Experimental

General

Melting points were determined on a Kofler micro heating stage and are uncorrected. Kugelrohr distillations were performed by means of a Büchi Kugelrohr thermostat. Infrared spectra were recorded on a Perkin–Elmer model 710B spectrophotometer. Solution spectra were performed using a sodium chloride solution cell of 0.2 mm thickness. Absorption positions are given in cm^{-1} and are calibrated by means of the 1601 cm^{-1} band of polystyrene. The proton nuclear magnetic resonance spectra were taken in deuterochloroform solution and recorded on a Bruker WP-80 (80 MHz) instrument unless otherwise specified. The 400-MHz spectra were recorded on a Bruker WH-400 instrument, the 270-MHz spectra were recorded on a home-built unit consisting of an Oxford instrument 63.4 KG superconducting magnet and a Nicolet 32K computer, and the 60-MHz spectra on an EM-360 instrument. Signal positions are given in parts per million downfield from tetramethylsilane using the δ scale. Signal multiplicity, coupling constants, and intgrated areas are indicated in parentheses. Low resolution mass spectra were determined on either a Varian MAT CH4B or Kratos MS50 mass spectrometer. Spectra are quoted as *m/z* values. The major ion fragmentations are reported as percentages of the base peak. High resolution mass measurements were determined using a Kratos MS50 mass spectrometer. Gas–liquid chromatography was performed on a Hewlett Packard model 5880A gas chromatograph using a 12 m × 0.2 mm column of OV-101 or Carbowax 20M. The flow rate was 1.0 mL/min or 2.4 mL/min and helium was used as the carrier gas. In all cases a flame ionization detector was used. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver.

Silica gel $PF_{254+366}$ supplied by E. Merck Co. was used for preparative tlc. The plates were ca. 1 mm in thickness. Analytical tlc was performed on commercial, precoated silica gel plates (silica gel 60 F_{254}) supplied by E. Merck Co. Visualization was effected by a combination of uv fluorescence, iodine vapour, or a 2 M sulfuric acid spray. Flash chromatography (24) was performed using silica gel 60, 230–400 mesh ASTM, supplied by E. Merck Co.

All reactions involving air or moisture sensitive reagents were performed under an atmosphere of dry nitrogen using either oven or flame-dried glassware. All reaction products were dried by allowing the solutions to stand over anhydrous magnesium sulfate. The petroleum ether used was of boiling range ca. 30–60°C. Dry solvents and reagents were prepared as follows: acetonitrile and methylene chloride by distillation from phosphorus pentoxide; benzene, boron trifluoride etherate, dimethylsulfoxide, 2,6-dimethylpyridine, diethyl methylmalonate, 1,2-epoxybutane, ethyl 2-bromoisobutyrate, *n*-heptane, and hexamethylphosphoramide by distillation from calcium hydride; dichloroacetic acid by storage over anhydrous magnesium sulfate followed by filtration and distillation; dimethylformamide by distillation from barium oxide followed by storage over 4A molecular sieves; dicyclohexylcarbodiimide and oxalyl chloride were distilled before use; ethanol by refluxing over magnesium ethoxide followed by distillation; ethyl ether and tetrahydrofuran by refluxing over lithium aluminum hydride followed by distillation; methanol by refluxing over magnesium methoxide followed by distillation; tetramethylethylenediamine by distillation from potassium hydroxide.

n-Butyllithium and *tert*-butyllithium were obtained from Aldrich Chemical Company, Inc. The alkyllithium solutions were standardized by titration against 1,3-dipheny1-2-propanone tosylhydrazone in THF (25).

1,1-(Propane-1',3'-dithio)-2-methyl propane (2)

A 1-L flask was charged with 36 mL isobutyraldehyde (0.4 mol), 800 mL chloroform, and 40 mL 1,3-dithiolpropane (0.4 mol). The solution was stirred for 1 h under an atmosphere of nitrogen, then cooled to −20°C. Boron trifluoride etherate (24.6 mL, 0.2 mol) was added, and the reaction was allowed to warm to room temperature overnight. The organic layer was washed three times each with water, potassium hydroxide solution, and water and was dried over anhydrous magnesium sulfate. Removal of the solvent under reduced pressure yielded a yellow oil. Distillation at reduced pressure (90°C/3 Torr; 1 Torr = 133.3 Pa) gave 51 g of compound **2** (71% yield) as a pale yellow oil; ir ($CHCl_3$): 1460, 1415, 1280, 1190, and 910 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.03 (d, *J* = Hz, 6H), 1.67–2.23 (m, 3H), 2.70–2.93 (m, 4H), 3.98 (d, *J* = 6 Hz, 1H); mass spectrum: (*a*) high resolution calcd. for $C_7H_{14}S_2$: 162.0537 amu; found: 162.0535; (*b*) low resolution *m/z* (rel. intensity): 162 (M^+, 41), 121 (12), 119 (100), 55 (14), 45 (18), and 41 (22).

5,5-(Propane-1',3'-dithio)-6-methyl heptan-3-ol (3)

A 50-mL flask was charged with 0.81 g of the dithiane (5.0 mmol) and 25 mL THF. The stirred solution was cooled to −20°C under a nitrogen atmosphere and 4.0 mL *n*-butyllithium (1.4 M in hexane, 5.6 mmol) was added dropwise. After stirring for 2.5 h at −20°C, the reaction flask was stored at −10°C for 16 h. The solution was then warmed to 0°C, and 0.43 mL of 1,2-epoxybutane (5.0 mmol) was added. After 5 h, the mixture was concentrated under reduced pressure. Water was added and the aqueous phase was extracted three times with ethyl ether. The combined organic extracts were washed with water, brine solution, and water, dried over anhydrous magnesium sulfate, and filtered. Removal of the solvent under reduced pressure afforded 1.06 g of the alcohol **3** (90% yield) as a white crystalline solid. Preparative tlc of a small amount of this material using petroleum ether:ethyl acetate (6:1) gave **3** as white powdery crystals, mp 65–66°C; ir ($CHCl_3$): 3425, 1460, 1420, 1385, 1130, 1060,and 990 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.03 (t, *J* = 7 Hz, 3H), 1.06 (d, *J* = 7 Hz, 3H), 1.24 (d, *J* = 7 Hz, 3H), 1.35–2.55 (m, 7H), 2.75–3.00 (m, 4H), 3.75 (bs, 1H, exchangeable with D_2O), 3.75–4.10 (m, 1H); mass spectrum: (*a*) high resolution calcd. for $C_{11}H_{22}OS_2$: 234.1112 amu; found: 234.1108; (*b*) low resolution *m/z* (rel. intensity): 234 (M^+, 24), 191 (79), 161 (18), 135 (12), 133 (100), 107 (13), 73 (13), 69 (20), 59 (25), 57 (29), and 41 (40).

5,5-(Propane-1',3'-dithio)-6-methylheptan-3-one (4)

A 100-mL flask was charged with 11.32 g pyridinium dichromate (30.0 mmol) and 25 mL DMF. The resulting solution was cooled to 0°C and the alcohol **20** (1.0 g, 4.3 mmol) was added to this solution. After 11 h at 0°C, the reaction mixture was poured into 150 mL water. The aqueous phase was extracted several times with ethyl ether. The combined organic phases were washed four times with water, dried over anhydrous magnesium sulfate, and the solvent was removed under reduced pressure giving 0.84 g of the crude ketone (85% yield). Preparative tlc of a small amount of this material using petroleum ether:ethyl acetate (8:1) gave **4** as a colourless oil; ir ($CHCl_3$): 1710, 1460, 1355, 1230, 1140, and 1110 cm^{-1}; ^1H nmr ($CDCl_3$) 270 MHz, δ: 1.04 (t, *J* = 7 Hz, 3H), 1.22 (d, *J* = 6.5 Hz, 6H), 1.79–2.12 (m, 2H), 2.41–2.56 (m, 1H), 2.59 (q, 2H), 2.73–3.01 (m, 4H), 3.16 (s, 2H); mass spectrum: (*a*) high resolution calcd. for $C_{11}H_{20}OS_2$: 232.0955 amu; found: 232.0942; (*b*) low resolution *m/z* (rel. intensity: 232 (M^+, 22), 189 (72), 175 (13), 133 (29), 107 (18), 69 (16), 57 (100), 41 (37), and 29 (66).

2-Methyl-3,5-heptanedione (5)

A 100-mL flask was charged with 2.61 g mercuric chloride (9.6 mmol), 1.05 g mercuric oxide (4.8 mmol), and 10 mL acetonitrile. To this suspension was added the dithiane **4** (1.0 g, 4.3 mmol) in 30 mL acetonitrile and 3 mL water. After heating to reflux for 2 h, ethyl ether was added and the mixture was filtered. The solvent was removed under reduced pressure until 50 mL remained. After cooling this solution in an ice bath, it was added to a mixture of 20 g ice and 6 mL concentrated hydrochloric acid. The organic layer was separated and the aqueous phase was washed three times with ethyl ether. The combined organic extracts were dried over anhydrous magnesium sulfate, filtered,and solvent was removed under reduced pressure to yield a brown oil. Kugelrohr distillation (80°C/20 Torr) yielded 0.32 g of the β-diketone **5** (52% yield) as a colourless oil; ir ($CHCl_3$): 1730, 1680, 1560, 1465, and 1155 cm^{-1}; ^1H nmr ($CDCl_3$) 60 MHz, δ: 0.90–1.33 (m, 9H), 2.07–2.70 (m, 3H), 3.50 (s, 0.26H), 5.40 (s, 0.74H).

meso-*2,4-Dimethylglutaric anhydride (6)*

2,4-Dimethylglutaric acid (26) (8.14 g, 0.05 mmol) was heated to 100°C with 10.8 mL acetic anhydride for 2 h. Removal of the volatile materials under reduced pressure, followed by Kugelrohr distillation of the resulting oil (80–140°C/0.1 Torr) afforded 7 g (97% yield) of a mixture of *meso-* and *dl*-anhydrides. This material was dissolved in 10 mL warm ethyl acetate and filtered. The filtrate was washed six times with 10-mL portions of ethyl acetate. The combined ethyl acetate washings were reduced to a volume of 50 mL. Crystallization by allowing the solution to stand afforded 2.76 g *meso*-anhydride **6** as a white crystalline solid, mp 93.5–94°C (lit. (26) mp 94–95°C); ir ($CHCl_3$): 1818, 1770, 1080, and 1020 cm^{-1}.

Methyl (2S,4R*)-2,4-dimethylglutarate (7)*

A 50-mL flask, fitted with a reflux condenser, was charged with 3.07 g (21.6 mmol) **6** and 15 mL dry methanol. The resulting solution was heated to reflux and stirred overnight, after which the methanol was removed under reduced pressure. Vacuum distillation (102°C/0.2 Torr) yielded 3.41 g of the monoacid **7** (91% yield), as a colourless oil; ir ($CHCl_3$): 2990, 1735, 1715, 1460, 1280, and 1175 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.18 (d, J = 6 Hz, 3H), 1.20 (d, J = 6 Hz, 3H), 1.53 (q, 1H), 2.10 (q, 1H), 2.38–2.78 (m, 2H), 3.67 (s, 3H), 11.33 (bs, 1H); mass spectrum: (*a*) high resolution calcd. for $C_8H_{12}O_3$ ($M^+ - H_2O$): 156.0787 amu; found: 156.0784; (*b*) low resolution m/z (rel. intensity): 156 ($M^+ - H_2O$, 7), 143 (32), 142 (21), 128 (47), 115 (33), 114 (45), 101 (39), 88 (49), 69 (100), 59 (50), 57 (36), 56 (71), 45 (62), and 41 (67).

Methyl (2R,4S*)-4-chloromethanoyl-2-methylpentanoate (8)*

The monoacid **7** (3.21 g, 18.5 mmol) was stirred in 15 mL of dry benzene in a 3-necked 100-mL flask fitted with an equal pressure addition funnel and a nitrogen inlet. A catalytic amount of DMF was added (15 μL), followed by 2.42 mL oxalyl chloride (27.7 mmol) in 5 mL benzene over 30 min. After 3 h, the benzene was removed by distillation. Vacuum distillation (52°C/0.2 Torr) afforded 3.26 g of the acid chloride (92% yield) as a colourless oil; ir (CCl_4): 1800, 1745, 1460, 1200, and 1180 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.21 (d, J = 6 Hz, 3H), 1.32 (d, J = 6 Hz, 3H), 1.58 (q, 1H), 2.21 (q, 1H), 2.94 (q, 1H), 3.70 (s, 3H); mass spectrum: (*a*) high resolution calcd. for $CH_{10}O_2Cl$ ($M^+ - OCH_3$): 161.0370 amu; found: 161.0361; (*b*) low resolution m/z (rel. intensity): 161 ($M^+ - OCH_3$, 10), 157 (35), 129 (31), 128 (32), 73 (25), 69 (100), 59 (41), 56 (48), and 41 (56).

Methyl (2S,4R*)-2,4-dimethyl-5,5-(propane-1',3'-dithio)-pentanoate (10)*

A 50-mL flask was charged with 80 mg 9% Pd/C catalyst (15 mg per mmol acid chloride), 18 mL THF, and 0.6 mL 2,6-dimethylpyridine (5 mmol). The acid chloride **8**, 0.985 g (5.1 mmol), in 7 mL THF was added and the system was hydrogenated for 8 h at atmospheric pressure. The reaction was filtered through Celite, and the solid was washed with ethyl ether. The filtrate was reduced to a volume of 10–15 mL. Then 50 mL ethyl ether was added and the organic layer was washed three times with cold 0.2 N hydrochloric acid, three times with sodium bicarbonate solution, ammonium chloride solution twice, brine, and water. The organic phase was dried over anhydrous magnesium sulfate, filtered, and the solvent removed under reduced pressure to a volume of 5–10 mL. This solution was transferred to a 50-mL flask fitted with a nitrogen inlet. Chloroform (15 mL) was added, followed by 0.51 mL 1,3-dithiolpropane (5.1 mmol). After 1 h stirring at room temperature the solution was cooled to −20°C. Boron trifluoride etherate (0.315 mL, 2.56 mmol) was added and the reaction was allowed to warm to room temperature overnight, after which chloroform was added. The organic layer was washed with water, then three times each with potassium hydroxide solution and water. The organic layer was dried over anhydrous magnesium sulfate, filtered, and the solvent was removed under reduced pressure to give a yellow oil. Flash chromatography (3:1, petroleum ether:ethyl acetate) provided 787 mg of the dithiane **10** (62% yield) as a pale yellow oil; ir ($CHCl_3$): 1735, 1460, 1390, 1280, 1180, and 1150 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.15 (t, 6H), 1.33–1.60 (m, 1H), 1.68–2.23 (m, 4H), 2.34–2.70 (m, 1H), 2.78–3.03 (m, 4H), 3.68 (s, 3H), 4.13 (d, J = 3 Hz, 1H); mass spectrum: (*a*) high resolution calcd. for $C_{11}H_{20}O_2S_2$: 248.0905 amu; found: 248.0905; (*b*) low resolution m/z (rel. intensity): 248 (M^+, 26), 121 (17), 119 (100), 106 (10), 73 (15), 59 (15), 45 (21), and 41 (32).

(2S,4R*)-2,4-Dimethyl-5,5-(propane-1',3'-dithio)-pentan-1-ol*

A 50-mL 2-necked flask was charged with 191 mg lithium aluminum hydride (5 mmol) and 8 mL ethyl ether, under a nitrogen atmosphere. The suspension was cooled to 0°C, and then 635 mg of the ester **10** (2.56 mmol) in 7 mL ethyl ether was added. After 30 min at 0°C and 90 min at room temperature, the reaction was carefully quenched with dilute hydrochloric acid. Ethyl ether was added and the organic layer was separated. The aqueous phase was washed three times with ethyl ether. The combined ether extracts were dried over anhydrous magnesium sulfate, filtered, and the solvent was removed under reduced pressure to give a yellow oil. Flash chromatography (1:1, petroleum ether:ethyl acetate) provided 492 mg of the alcohol (87% yield) as a pale yellow oil; ir ($CHCl_3$): 3475, 1460, 1420, 1380, 1275,and 1015 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.00 (d, J = 9 Hz, 3H), 1.05 (d, J = 9 Hz, 3H), 1.58–2.33 (m, 6H), 2.15 (bs, 1H, exchangeable with D_2O), 2.73–3.05 (m, 4H), 3.28–3.68 (m, 2H), 4.15 (d, J = 3 Hz, 1H); mass spectrum: (*a*) high resolution calcd. for $C_{11}H_{20}OS_2$: 220.0956 amu; found: 220.0957; (*b*) low resolution m/z (rel. intensity): 220 (M^+, 23), 121 (15), 120 (10), 119 (100), 73 (14), 55 (13), 45 (22),and 41 (35).

(2S,4R*)-2,4-Dimethyl-5,5-(propane-1',3'-dithio)-1-[(*tert*-butyldimethylsilyl)oxy]-pentane (11)*

To a solution of the above alcohol (0.48 g, 2.2 mmol) in 3 mL methylene chloride was added 2,6-dimethylpyridine (0.51 mL, 4.4 mmol) at 0°C under nitrogen. After 5 min, *tert*-butyldimethylsilyl trifluoromethane sulfonate (0.75 mL, 3.3 mmol) was added and the reaction was stirred for 30 min at 0°C and 2.5 h at room temperature. The reaction was diluted with ethyl ether, washed with 0.2 N hydrochloric acid twice, sodium bicarbonate solution twice, ammonium chloride solution, and water. The organic layer was dried over anhydrous magnesium sulfate, filtered, and the solvent was removed under reduced pressure giving a yellow oil. Kugelrohr distillation (140°C/0.2 Torr) afforded 0.708 g **11** as a colourless oil (97% yield); ir ($CHCl_3$): 1465, 1455, 1240, 920, and 825 cm^{-1}; ^1H nmr ($CDCl_3$) 270 MHz, δ: 0.07 (s, 6H), 0.95 (s, d, 12H), 1.13 (d, J = 6 Hz, 3H), 1.63–2.22 (m, 6H), 2.84–3.05 (m, 4H), 3.35–3.59 (ddd, 2H), 4.20 (d, J = 4 Hz, 1H); mass spectrum: (*a*) high resolution calcd. for $C_{16}H_{34}OS_2Si$: 334.1820 amu; found: 334.1825; (*b*) low resolution m/z (rel. intensity): 334 (M^+, 2), 319 (2), 279 (12), 278 (19), 277 (91), 171 (22), 165 (25), 149 (11), 129 (10), 119 (77), 113 (37), 95 (23), 91 (11), 75 (100), 73 (46), and 41 (20).

For personal use only.

(6S,8R*)-6,8-Dimethyl-9-[(*tert*-butyldimethylsilyl)oxy]-5,5-(propane-1',3'-dithio)-nonan-3-ol (**12**)*

The dithiane **11** (137 mg, 0.41 mmol) was stirred in 1 mL THF at −35°C. *n*-Butyllithium (0.34 mL, 1.45 M in hexane, 0.49 mmol) was added, followed by tetramethylethylenediamine (0.074 mL, 0.49 mmol). After 1 h, hexamethylphosphoramide (0.107 mL, 0.62 mmol) was added and a deep yellow coloured solution was observed. This colour faded upon addition of 1,2-epoxybutane (0.106 mL, 1.23 mmol). The solution was stirred at −35°C for 1 h, then stored at −20°C for 48 h. The reaction was diluted with water and ethyl ether. The organic layer was washed with copper sulfate solution, sodium chloride solution, and ammonium chloride solution, dried over anhydrous magnesium sulfate, and filtered. Removal of the solvent under reduced pressure afforded 93 mg of an oil, which by gc analysis was 75% product **12** and 20% starting dithane **11**. Flash chromatography using methylene chloride gave a pure sample of **12**; ir ($CHCl_3$): 3400, 1465, 1260, 1090, and 840 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.04 (s, 6H), 0.77–2.24 (m, 19H), 0.87 (s, 9H), 2.72–3.04 (m, 4H), 3.32–4.19 (m, 4H); mass spectrum: (*a*) high resolution calcd. for $C_{20}H_{42}O_2S_2S_1$: 406.2398 amu; found: 406.2391 amu; (*b*) low resolution *m/z* (rel. intensity): 406 (M^+, 32), 349 (19), 291 (21), 193 (60), 192 (68), 191 (100), 165 (41), 133 (81), 109 (65), 75 (79), 73 (88), 59 (82), and 55(60).

Methylenation reagent

The active methylene complex was prepared by a slight modification of Lombardo's method (21). A 500-mL 2-necked flask, fitted with an equal pressure addition funnel, was charged with 11.5 g zinc dust, 100 mL THF, and 4.04 mL methylene bromide under nitrogen. The slurry was cooled to −40°C. Titanium tetrachloride (4.6 mL) was poured into the addition funnel and, over 30 min, was added dropwise to the slurry. As the addition of the titanium tetrachloride is very vigorous, it is recommended to leave the addition funnel stopperless. After 2 h stirring at −40°C, the grey slurry was warmed to 0°C, and stirred for 24 h. The active methylene complex can be stored between 0 and 5°C for up to 2 weeks.

Methyl (2R,4S*)-2,4-dimethyl-5-hexenoate (**13**)*

A 100-mL 3-necked flask was charged with 0.18 g 9% Pd/C catalyst (15 mg per mmol acid chloride), 40 mL THF, and 1.35 mL 2,6-dimethylpyridine (11.6 mmol). The acid chloride **8**, 2.25 g (11.7 mmol), in 15 mL THF was added and the system was hydrogenated for 8 h at atmospheric pressure. The reaction was filtered through Celite and the solid was washed with methylene chloride. The filtrate was reduced to a volume of 10–15 mL. Then 50 mL methylene chloride was added and the organic layer was washed three times with cold 0.2 N hydrochloric acid, three times with sodium bicarbonate solution, ammonium chloride solution twice, brine, and water. The organic phase was dried over anhydrous magnesium sulfate, filtered, and the solvent removed under reduced pressure to a volume of 50 mL. The methylene complex stirred at 0°C was added portionwise, using a pipette, to this methylene chloride solution of the aldehyde **9**. Conversion to the alkene **13** is instantaneous and can be monitored by gc or tlc analysis. After complete conversion, the black solution was poured into 150 mL saturated solution of sodium bicarbonate and 300 mL ethyl ether. The mixture was stirred for 2 h until the solution was white with a black solid evident. The organic layer was separated and the aqueous layer was washed a few times with ethyl ether. The combined organic extracts were dried over anhydrous magnesium sulfate, filtered, and the solvent was removed under reduced pressure to give a yellow oil. Flash chromatography using methylene chloride provided 729 mg of the alkene **13** as a pale yellow oil (40% yield); ir ($CHCl_3$): 135, 1650, 1460, 110, and 920 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.03 (d, J = 7 Hz, 3H), 1.11 (d, J = 7 Hz, 3H), 1.28–2.65 (m, 4H), 3.65 (s, 3H), 4.83–5.13 (m, 2H), 5.38–5.88 (m, 1H); mass spectrum: (*a*) high resolution calcd. for $C_8H_{13}O$ ($M^+ - OCH_3$): 125.0966 amu; found: 125.0974; (*b*) low resolution *m/z* (rel. intensity): 156 (M^+, 5), 125 (10), 124 (8), 101 (12), 97 (20), 96 (13), 88 (100), 81 (12), 69 (26), 57 (27), 55 (63), 41 (36), and 29 (24).

Methyl (2S,4R*)-2,4-dimethyl-5,6-epoxyhexanoate (**14**)*

To a stirred solution of the alkene **13** (593 mg, 3.80 mmol) in 20 mL methylene chloride at 0°C, was added 1.18 g (6.84 mmol) metachloroperoxybenzoic acid. The reaction was allowed to warm to room temperature slowly and was left stirring overnight. The reaction was diluted with methylene chloride and washed once with sodium bicarbonate solution, sodium thiosulfate solution, three times with sodium bicarbonate solution, and finally water. The organic layer was dried over anhydrous magnesium sulfate, filtered, and the solvent removed under reduced pressure giving an oil. Flash chromatrography using methylene chloride provided 492 mg of the epoxide **14** (75% yield) as a pale yellow oil; ir ($CHCl_3$): 1735, 1460, and 1170 cm^{-1}; ^1H nmr ($CDCl_3$) 60 MHz, δ: 0.86–1.79 (m, 9H), 2.39–2.86 (m, 4H), 3.66 (s, 3H).

Methyl (2S,4R*,8S*,10R*)-2,4,8,10-tetramethyl-5-hydroxy-7,7-(propane-1',3'-dithio)-11-[(*tert*-butyldimethylsilyl)oxy]-undecanoate (**15**) and its diastereomer **16***

The dithiane **11** (160 mg, 0.48 mmol) was stirred in 2 mL THF at −35°C. *n*-Butyllithium was added (0.41 mL, 1.45 M in hexane, 0.60 mmol), followed by tetramethylethylenediamine (0.09 mL, 0.60 mmol). After 1 h, hexamethylphosphoramide (0.125 mL, 0.72 mmol) was added and a deep yellow colour was observed. After 1 h, the epoxide **14** (93 mg, 0.54 mmol) in 0.125 mL hexamethylphosphoramide and 1 mL THF were added to the reaction. After 4 h, the reaction was worked up as for **12** to give 164 mg of an oil, which by tlc analysis was predominantly the starting dithiane **11**. Preparative tlc using petroleum ether:ethyl acetate (3:1) gave 30 mg of products **15** and **16** (12% yield); ^1H nmr δ: 0.04 (s, 6H), 0.69–2.94 (m, 28H), 0.87 (s, 9H), 3.29–4.09 (m, 4H), 3.64 (s, 3H); mass spectrum: low resolution *m/z* (rel. intensity): 506 (M^+, 6), 417 (20), 291 (49), 259 (45), 185 (14), 159 (100), 133 (34), 127 (63), 75 (59), 74 (48), 73 (50), and 55 (46).

(2R,4S*)-2,4-Dimethyl-5-hexen-1-ol*

Lithium aluminum hydride (0.185 g, 4.9 mmol) was stirred in 8 mL ethyl ether at 0°C. The alkene **13** (0.38 g, 2.4 mmol) in 7 mL ethyl ether was added. After 30 min at 0°C and 90 min at room temperature, the reaction was carefully quenched with dilute hydrochloric acid. Ethyl ether was added and the organic layer was separated. The aqueous phase was washed three times with ethyl ether. The combined ether extracts were dried over anhydrous magnesium sulfate, filtered, and the solvent was removed under reduced pressure to give a yellow oil. Flash chromatography using methylene chloride afforded 0.174 g of the desired alcohol (56% yield) as a yellow oil; ir ($CHCl_3$): 3480, 1650, 1460, 1380, 1020, and 920 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.90 (d, J = 6 Hz, 3H), 0.98 (d, J = 6 Hz, 3H), 1.13–1.88 (m, 2H), 2.03–2.49 (m, 2H), 2.45 (bs, 1H, exchangeable with D_2O), 3.30–3.63 (m, 2H), 4.80–5.15 (m, 2H), 5.40–5.90 (m, 1H); mass spectrum: (*a*) high resolution calcd. for C_7H_{13} ($M^+ - CH_2OH$): 97.1017 amu; found: 97.1021; (*b*) low resolution *m/z* (rel. intensity): 128 (M^+, 1), 97 (18), 95 (41), 71 (47), 70 (29), 69 (22), 68 (42), 58 (43), 57 (21), 56 (35), 55 (100), 43 (33), 41 (54), 39 (22), 31 (30), and 29 (36).

(2R,4S*)-2,4-Dimethyl-1-[(*tert*-butyldimethylsilyl)oxy]-hex-5-ene*

To a solution of the above alcohol (159 mg, 1.24 mmol) in 1.5 mL methylene chloride was added 2,6-dimethylpyridine (0.29 mL, 2.55 mmol) at 0°C under nitrogen. After 5 min *tert*-butyldimethylsilyl trifluoromethane sulfonate (0.43 mL, 1.9 mmol) was added, and the reaction was stirred for 30 min at 0°C and 2.5 h at room temperature. The reaction was diluted with ethyl ether, washed with 0.2 N hydrochloric acid twice, sodium bicarbonate solution twice, ammonium chloride solution, and water. The organic layer was dried over anhydrous magnesium sulfate, filtered, and the solvent was removed under reduced pressure giving a yellow oil. Flash chromatography (10:1, petroleum ether:ethyl acetate) afforded 270 mg of the silyl ether (90% yield) as a colourless oil; ir ($CHCl_3$): 1650, 1480, 1260, 950, and 840 cm^{-1}; ^1H nmr ($CDCl_3$) 400 MHz, δ: 0.09 (s, 6H), 0.92 (d, J = 6 Hz, 3H), 0.95 (s, 9H), 1.02–1.11 (m, 1H), 1.05 (d, J = 6 Hz, 3H),

1.39–1.48 (m, 1H), 1.63–1.75 (m, 1H), 2.23–2.34 (m, 1H), 3.37–3.51 (ddd, 2H), 4.92–5.05 (m, 2H), 5.61–5.72 (m, 1H); mass spectrum: (*a*) high resolution calcd. for $C_{10}H_{21}OSi$ ($M^+ - t$Bu): 185.1376 amu; found: 185.1369; (*b*) low resolution *m/z* (rel. intensity): 185 ($M^+ - t$Bu, 57), 115 (14), 76 (12), 75 (100), 73 (27), 55 (11), and 41 (11).

(2R,4S*)-2,4-Dimethyl-1-[(*tert*-butyldimethylsilyl)oxy]-5,6-epoxy hexane (**17**)*

To a stirred solution of the above alkene (253 mg, 1.04 mmol) in 6 mL methylene chloride at O°C, was added 543 mg (3.14 mmol) metachloroperoxybenzoic acid. The reaction was allowed to warm to room temperature slowly and was left stirring overnight. The reaction was diluted with methylene chloride and washed once with sodium bicarbonate solution, sodium thiosulfate solution, three times with sodium bicarbonate solution, and finally, with water. The organic layer was dried over anhydrous magnesium sulfate, filtered, and the solvent was removed under reduced pressure, giving a yellow oil. Flash chromatography (3:1, petroleum ether:ethyl ether) provided 231 mg of the epoxide **17** (86% yield) as a pale yellow oil; ir ($CHCl_3$): 1460, 1255, 1090, 830, and 770 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.05 (s, 6H), 0.83–1.13 (m, 8H), 0.93 (s, 9H), 1.38–1.93 (m, 2H), 2.40–2.85 (m, 3H), 3.33–3.48 (m, 2H); mass spectrum: (*a*) high resolution calcd. for $C_{10}H_{21}O_2Si$ ($M^+ - t$Bu): 201.1335 amu; found: 201.1323; (*b*) low resolution *m/z* (rel. intensity): 201 ($M^+ - t$Bu, 16), 171 (30), 145 (22), 129 (13), 115 (28), 109 (22), 105 (12), 89 (20), 75 (100), and 73 (26).

(2S,4R*,8S*,10R*)-2,4,8,10-Tetramethyl-1,11-[di(*tert*-butyldimethylsilyl)oxy]-7,7-(propane-1′,3′-dithio)-undec-5-ol (**18**) and its diastereomer **19***

The dithiane **11** (114 mg, 0.34 mmol) was stirred in 1 mL THF at −40°C. *n*-Butyllithium (0.17 mL, 2.2 M in hexane, 0.37 mmol) was added, followed by tetramethylethylenediamine (TMEDA, 0.06 mL, 0.41 mmol), producing a faint yellow coloured solution. After 1 h, hexamethylphosphoramide (HMPA, 0.09 mL, 0.51 mmol) was added and a deep yellow coloured solution was observed. After 15 min, the reaction was cooled to −78°C. The epoxide **17** (96 mg, 0.37 mmol) in 1 mL THF was added dropwise. The reaction was stirred for 30 min at −78°C, 30 min at −40°C, 2 h at −10°C, and was stored at −2°C for 40 h. The reaction was diluted with water and ethyl ether. The organic layer was washed with sodium chloride solution, ammonium chloride solution, dried over anhydrous magnesium sulfate, and filtered. Removal of the solvent under reduced pressure afforded an orange oil. Flash chromatography (methylene chloride) gave the following compounds, in order of elution: (*a*) dithiane **11** (49 mg, 43%); (*b*) β-hydroxy dithianes **18** and **19** as a pale yellow oil (79 mg, 39% yield, 69% based on recovered starting dithiane); ir ($CHCl_3$): 3450, 1470, 1260, 1050, 910, and 820 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.05 (s, 12H), 0.80–1.27 (m, 16H), 0.93 (s, 18H), 1.30–2.33 (m, 8H), 2.60–2.95 (m, 4H), 3.20–3.65 (m, 5H), 3.73–4.05 (m, 1H); mass spectrum: (*a*) high resolution calcd. for $C_{30}H_{64}O_3S_2Si_2$: 592.3834 amu; found: 592.3834; (*b*) low resolution *m/z* (rel. intensity): 592 (M^+, 3), 535 (10), 377 (20), 359 (15), 246 (19), 245 (100), 187 (29), 185 (26), 165 (16), 145 (11), 133 (19), 115 (15), 113 (99), 109 (22), 107 (13), 95 (27), 75 (58), 73 (41), and 55 (15).

(2R,4S*,8R*,10S*)-2,4,8,10-Tetramethyl-1,11-[di(*tert*-butyldimethylsilyl)oxy]-7-hydroxy-undec-5-one and its diastereomer*

The β-hydroxy dithianes **18** and **19** (39 mg, 0.07 mmol) and 18 mg calcium carbonate (0.4 mmol) were stirred in 5 mL acetonitrile and 2 mL water. Methyl iodide (1 mL) was added and the reaction was heated to reflux for 17 h. The solvents were removed under reduced pressure and water was added to the residual material. The aqueous phase was washed three times with ethyl ether. The combined organic extracts were dried over anhydrous magnesium sulfate, filtered, and the solvent was removed under reduced pressure to give a yellow oil. Flash chromatography (4:1, petroleum ether:ethyl ether) provided 18 mg of the β-hydroxy ketones (54% yield); ir ($CHCl_3$): 1710, 1460, 1390, 1260, 1110, and 840 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.05 (s, 12H), 0.80–2.15 (m, 20H), 0.93 (s, 18H), 2.48–2.70 (m, 2H), 3.33–3.53 (m, 5H), 3.80–4.05 (m, 1H); mass spectrum: (*a*) high resolution calcd. for $C_{23}H_{49}O_4Si_2$ ($M^+ - t$Bu); 445.3170 amu; found: 445.3170; (*b*) low resolution *m/z* (rel. intensity): 445 ($M^+ - t$Bu, 11), 427 (9), 313 (5), 295 (6), 287 (7), 246 (10), 245 (57), 243 (12), 221 (15), 203 (17), 201 (24), 188 (12), 187 (94), 185 (30), 113 (100), 109 (37), 95 (49), 85 (43), 83 (31), 75 (86), 73 (59), and 57 (47).

(2R,4S*,8R*,10S*)-2,4,8,10-Tetramethyl-1,11-[di(*tert*-butyldimethylsilyl)oxy]-undec-5,7-dione (**20**) and its diastereomer **21***

The above β-hydroxy ketones (10 mg, 0.02 mmol) were stirred in 0.2 mL dimethylsulfoxide and 0.2 mL methylene chloride. Dicyclohexylcarbodiimide (DCC, 25 mg, 0.12 mmol) was added and after it dissolved, 0.8 μL (0.01 mmol) dichloroacetic acid was added. Petroleum ether was added, and the organic layer was washed with water and aqueous oxalic acid. The combined aqueous layers were washed once with petroleum ether. All the organic extracts were dried over anhydrous magnesium sulfate, filtered, and concentrated affording a pasty solid. Flash chromatography (40:1, petroleum ether:ethyl ether) provided, in order of elution: (*a*) product β-diketones **20** and **21** (2.5 mg, 25% yield, 75% based on recovered starting material); (*b*) starting β-hydroxy ketone (5 mg, 50%). The β-diketones **20** and **21** were characterized by the following spectral data: ir ($CHCl_3$): 1600, 1460, 1260, 1060, and 1020 cm^{-1}; ^1H nmr ($CDCl_3$) 400 MHz, δ: 0.03 (s, 12H), 0.90 (d, s, 24H), 1.08–1.18 (m, 2H), 1.14 (d, J = 8 Hz, 6H), 1.56–1.66 (m, 2H), 1.72–1.81 (m, 2H), 2.40–2.50 (m, 2H), 3.34–3.46 (m, 4H), 5.47 (s, 1H); mass spectrum: (*a*) high resolution calcd. for $C_2H_{56}O_4Si_2$: 500.3719 amu; found: 500.3718; (*b*) low resolution *m/z* (rel. intensity): 500 (M^+, 2), 485 (4), 445 (12), 444 (33), 443 (100), 311 (40), 244 (14), 243 (71), 185 (49), 115 (11), 109 (11), 95 (11), 85 (30), 75 (74), 73 (57), 69 (21), and 55 (16).

Products and reaction paths in the liquid phase oxidation of trans-1,2-dichloroethene with oxygen

KARL GRIESBAUM,[1] MICHAEL P. HAYES, AND VERA WERLI

Engler-Bunte-Institut, Bereich Petrochemie, Universität Karlsruhe (TH), D-7500 Karlsruhe, Germany

Received September 21, 1987

KARL GRIESBAUM, MICHAEL P. HAYES, and VERA WERLI. Can. J. Chem. **66**, 1366 (1988).

Ultraviolet initiated liquid phase oxidation of neat *trans*-1,2-dichloroethene (**1***a*) with oxygen at 30°C afforded ca. 45% of the combined C1-products CO, CO_2, and phosgene as well as nine oxygenated and nine non-oxygenated chlorinated organic products. Major oxygenated products were *cis*- and *trans*-2,3-dichlorooxirane (**6***a*, *b*) and 1,2,2-trichloroethyl formate (**13**); minor products were e.g., *meso* and *rac* bis(1,2,2-trichloroethyl) ether (**11***c*, *d*) and dichloromethyl 1,2,2-trichloroethyl ether (**12**). The mode of formation of all products is rationalized by a unified reaction scheme.

KARL GRIESBAUM, MICHAEL P. HAYES et VERA WERLI. Can. J. Chem. **66**, 1366 (1988).

Le dichloro-1,2 éthène *trans* (**1***a*) à l'état pur, à 30°C, soumis à une oxydation par l'oxygène, catalysée par la lumière ultraviolette, fournit des produits en C1 (comme le CO, le CO_2 et le phosgène) avec un rendement global d'environ 45% ainsi que neuf produits organiques chlorés qui sont oxygénés et neuf qui ne sont pas oxygénés. Les produits oxygénés principaux sont les dichloro-2,3 oxiranes *cis* et *trans* (**6***a* et **6***b*) et le formiate de trichloro-1,2,2 éthyle (**13**); parmi les produits mineurs, on note les isomères *méso* et *rac* de l'éther bis(trichloro-1,2,2 ethylique) (**11***c* et **11***d*) et l'éther dichlorométhoxy-1 trichloro-1,2,2 éthane (**12**). On rationalise le mode de formation de tous les produits à l'aide d'un schéma réactionnel unifié.

Introduction

Oxidation reactions of the chloriated ethenes vinyl chloride (1–4), 1,1-dichloroethene (5–7), 1,2-dichloroethene (8–11), trichloroethene (12–15), and tetrachloroethene (16, 17) with oxygen have been examined under a variety of conditions and aspects. While earlier studies were concerned with industrial aspects such as the production of chlorinated acetaldehydes (1, 6) or chlorinated acetyl chlorides (14), recent work has been focused on health (15) and environmental (4, 10, 18) aspects. Thus, it has been claimed that chloroethenes may be metabolized via potentially carcinogenic chlorinated epoxides (15) on the one hand, and that they may be a significant cause for the phenomenon called forest decline (18).

From the information that is currently available, it appears that photosensitized oxidations of chloroethenes with oxygen in the gas phase result predominantly in the cleavage of the carbon skeleton to give C1-products such as carbon monoxide and phosgene, whereas bulk phase liquid oxidations give the corresponding chlorooxiranes and (or) chlorinated oxo compounds by ring-opening isomerizations of the former.

In connection with a program concerned with the chemistry of halogenated epoxides (19), we tried to make use of the liquid phase oxidation of *trans*-1,2-dichloroethene (**1***a*) to prepare larger amounts of the stereoisomeric 2,3-dichlorooxiranes (**6***a*, *b*) that had been reported (8, 9) as products of this reaction. This led us to the observations reported below.

Results and discussion

trans-1,2,-Dichloroethene (**1***a*) was treated with oxygen at pressures of 1.4 bar (1 bar = 100 kPa) at 30°C. In the dark, no reaction products could be detected after 46 h of exposure, whereas under uv irradiation **1***a* was gradually consumed (Fig. 1, curve 1), in line with previous experience (8, 9). The reaction could be accelerated by the admixture of chlorine to the oxygen feed (Fig. 1, curves 2 and 3).

Oxidation of **1***a* with oxygen in the absence of added chlorine afforded the volatile inorganic products HCl, CO, CO_2, and phosgene, along with a liquid that contained the organic products **2** – **13** in the proportions shown in Table 1. Furthermore, small amounts of formic acid, mono- and dichloroacetic acid, and, in cases of incomplete conversions of **1***a*, variable amounts of **1***b* were formed. Oxidation of **1***a* with oxygen in the presence of equimolar amounts of chlorine afforded the same products, albeit in considerably different proportions, along with compounds **14** – **17** (Table 1). In addition to the above mentioned products, small amounts of a solid precipitated during the oxidation reaction and ca. 25 – 30% of a viscous residue remained after distillation of the liquid reaction products, neither of which have been characterized.

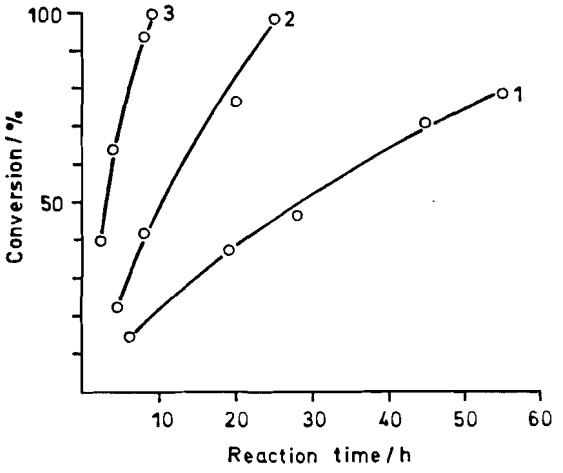

FIG. 1. Conversion vs. reaction conditions in the uv initiated liquid phase oxidation of *trans*-1,2-dichloroethene with oxygen at 30°C. O_2 flow rate, 6 mL/min. (1) O_2; (2) $O_2/Cl_2 = 6$; (3) $O_2/Cl_2 = 1$.

The organic products **1***b* and **2** – **17** were identified by glc and gc/ms analyses of the liquid product mixtures. In addition, compounds **1***b*, **2**, **4** – **7**, **10** – **13**, **16**, and **17** were isolated and characterized by their ^1H nmr and ir spectra. Formic acid as well as mono- and dichloroacetic acid were identified as the corresponding methyl esters after treatment of the product mixtures with diazomethane and subsequent glc and gc/ms

17

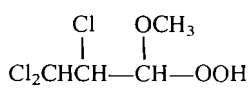
analyses; in addition, mono- and dichloromethyl acetate were isolated from such mixtures.

The structure assignment of the hitherto unknown trichloroethyl formate (**13**) was supported by its facile solvolysis with ethanol to give ethyl formate, as well as the hemiketal (**18***a*) and the ketal (**18***b*) of dichloroacetaldehyde. The structures of **4***a* and **4***b* were substantiated by ozonolysis in methanol, which—in line with the results of the ozonolysis of other substrates containing chloro-substituted double bonds (20)—yielded **20**, probably by HCl-catalyzed dehydration of **19** (21).

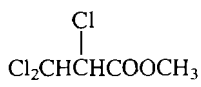
It is evident from the foregoing results that the liquid phase oxidation of **1***a* provides a considerably larger variety of products than had been recognized in previous investigations concerned with the oxidation of this or other chloroethenes. In particular, the oxygenated products **11** – **13**, but also the non-oxygenated product **10**, had not been reported before in the oxidation of **1***a*. All of the products obtained in this investigation can be logically explained by applying and extending a reaction scheme that had been proposed by Mayo for liquid phase oxidations of both chlorinated (13) and non-chlorinated (22) olefins. According to this proposal (Scheme 1) the reaction starts with the addition of chlorine atoms to substrate **1***a* to give radical **A** as the first and key intermediate for all products.

18

a: R = H; *b*: R = C_2H_5



19



20

The oxygenated products are explained by the following reaction steps: Alternating reactions of **A** with oxygen and **1** afford radicals of type **B**, which in turn are cleaved to give **6***a*, **6***b*, **7** (by isomerization of **6**), and radical **C** for $n=0$, and **6***a*, **6***b*, **7**, **C**, CO, and HCl for $n \geq 1$. Radical **C** could provide additional **7** by loss of chlorine. On the basis of the low proportion of **7** in the reaction mixture (Table 1) we assume, however, that the major reaction path of **C** in the bulk phase proceeds via **D** to give radicals of type **E**, which in turn are cleaved to give additional CO, HCl, **6***a*, **6***b*, and **7**, as well as radical **F**. Finally, alternating reactions of **F** with oxygen and **1** give radicals of type **G**. Cleavage of the latter provides still more CO, HCl, **6***a*, **6***b*, and **7**, along with radical **H**, which by loss of chlorine affords **13**. Radicals **D** and **F** can also be intercepted by chlorine to give products **11** and **12**, respectively.

The non-oxygenated products are explained by the following reactions: Radical **A** can react by loss of chlorine to give **1***b* in addition to the starting material **1***a*. Furthermore, **A** can react with chlorine to give **2** and **3**, or with **1** via radical **I** to give structures **4** and **5**. Radical **C** can undergo cleavage to give CO, HCl, and radical **J** (10), which in turn leads to **8** + **9** by reaction with chlorine and to **10** by addition to **1**, followed by reaction of the ensuing radical with chlorine.

Of the additional products that were obtained when **1***a* was oxidized in the presence of added chlorine, **14** is formed by chlorination of **6**, as we have shown independently, and **16** is

For personal use only.

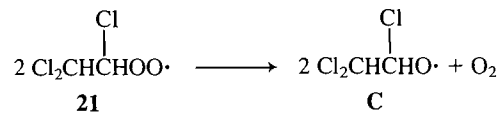
assumed to be formed by chlorination of **11**. Compound **15** can arise both from the isomerization of **14** (15) and from oxidation of **2**, which was the single major product from the reaction of **1***a* with oxygen and chlorine (Table 1). We have shown that the conversion of **2** into **15** occurs not only in the gas phase (23), but also in the liquid phase oxidation under the conditions that were applied for the oxidation of **1***a*. Finally, compound **17** could possibly be formed by reaction of **6** with **15**.

The reaction sequence proposed in Scheme 1 draws support from the fact that the proportion of **11** + **12** + **16** in relation to that of the combined other oxidation products **6** + **7** + **13** + **14** + **15** is increased from ca. 1:20 in the oxidation of **1***a* with oxygen alone to ca. 1:2 in the joint reaction of **1***a* with oxygen and chlorine. This result is indicative of a competition between chlorine and oxygen for the intermediate radicals **D** and **F**.

A material balance of the products obtained from the oxidation with oxygen alone showed that the carbon contained in **1***a* was converted into CO with 37.8% and into CO_2 with 5.1% selectivity. This means that ca. 43% of **1***a* has suffered cleavage of the double bond. Furthermore, the relative amounts of CO + CO_2 on the one hand, and of **6** + **7** + **13** + **15** on the other hand, indicate that in radicals **B** and **E** the number *n* of the respective repeating units is, on the average, between one and two. This means that the incipient peroxy radical **21**, which is



derived from the reaction of **A** with oxygen, is effectively trapped by the excess substrate **1***a*. By contrast, in the gas phase oxidation of **1** (10), radicals of type **21** have been reported to react with themselves by loss of oxygen to give, among other products, radical **C**, which in turn is cleaved to give CO, HCl, and radical **J**.

The assumed initiation of the oxidation of **1***a* by chlorine atoms (Scheme 1) has been well documented in the literature. These chlorine atoms probably arise from light-induced decomposition of **1***a* by direct C—Cl cleavage and (or) via the intermediate formation of HCl. In line with this assumption is the fact that the oxidation of **1***a* is inhibited in the absence of light (see above) and also in the presence of an added base. Thus, treatment of **1***a* with oxygen at 30°C under uv irradiation gave no detectable amounts of products in the presence of ca. 2 molar equivalents of 1,4-diazabicyclo[2.2.2]octane (DABCO).

Experimental

General methods

The ^{1}H nmr spectra were recorded on a Bruker WP 60, ir spectra on a Beckman Acculab 1, and gc/ms spectra on a Varian MAT 111 instrument. The glc analyses were carried out on a Varian model 1400 instrument (column 0.35 × 300 cm; 2.5% Nitrilesiliconoil XE on Chromosorb G; 60–160°C at 4°C/min). The pgc separations were performed on a Perkin Elmer F 21 instrument. Conditions: (*a*) column 0.8 × 500 cm; 5% Nitrilesiliconoil XE on Chromosorb G; 90–180°C at 3°C/min; (*b*) column 0.8 × 350 cm; 2.5% Nitrilesiliconoil XE 60 on Chromosorb G; 140–180°C at 1.5°C/min; (*c*) column 0.8 × 500 cm; 2.5% Nitrilesiliconoil XE 60 on Chromosorb G; 100°C; (*d*) column 0.8 × 500 cm; 2.5% Nitrilesiliconoil XE 60 on Chromosorb G; 90–180°C at 3°C/min.

Oxidation procedure

The oxidations were carried out in cylindrical glass reactors of appropriate (20, 55, 110, 300 mL) capacity. Each reactor was equipped with a surrounding cooling mantle, a coaxially arranged water-cooled 125-W medium pressure uv immersion lamp (Philips HPK 125) having a quartz mantle, a frit for the dispersion of oxygen, and a sampling device. The oxygen was dried over silica gel and molecular sieve and then passed through the reactor at a pressure of ca. 1.4 atmospheres (1 atm = 101.3 kPa) and at a flow rate of 6 mL/min, in one case also at 18 mL/min (Fig. 1). The exit gases from the reactor were sequentially passed through a condenser kept at −50°C, two cold traps, each kept at −78°C, for the condensation of remaining organic material, a solution of 1 N aqueous potassium hydroxide for the removal of HCl, CO_2, and phosgene, a fixed bed reactor of copper oxide kept at 600°C for the conversion of CO into CO_2, and, finally, a solution of 1 N aqueous potassium hydroxide for the absorption of CO_2. The proportions of HCl and CO_2 in the exit gases were determined by titration of the first KOH solution by an established procedure (24); the proportion of CO resulted from titration of the second KOH solution.

Commercial **1***a* (Fluka) was, for each experiment, washed 3 times with water to remove added stabilizer, sequentially dried over sodium sulfate and phosphorus pentoxide, and distilled through a 100-cm packed column; the fraction boiling at 47.5°C was collected.

Oxidation of **1**a *with oxygen*

(*a*) *Identification of products*

In a 55-mL reactor, 70.0 g of **1***a* was treated with oxygen at 30°C for 56 h, while the progress of the reaction was monitored by glc analysis at regular intervals (Fig. 1). The reaction reached a conversion of 79% and produced 17.8 g (42.9% based on the amount of **1***a* converted) of HCl, 12.2 g (37.8%) of CO, 3.1 g (5.1%) of CO_2, 10.8 g of a liquid condensate in the traps kept at −78°C, and 34.5 g of a liquid material in the reactor. The glc and gc/ms analyses of the latter product showed the presence of **1***a* and **1***b* as well as **2** – **13** in the proportions reported in Table 1. A sample of the liquid condensate reacted spontaneously with methanol. The glc and gc/ms analyses of the product after the reaction had ceased showed the presence of **1***a* and of **1***b* as major, and of methyl formate (*m*/*e* = 60; 32; 31; 29), chloromethyl carbonate (*m*/*e* = 96, 94; 65, 63; 59), and dimethyl carbonate (*m*/*e* = 90; 59; 45) as minor components. The latter two components are derived from phosgene.

(*b*) *Isolation of* **1**b, **2**, **6**a, **6**b, **7**, *and* **13** *and identification of chloro-, dichloroacetic, and formic acid*

A sample of 29.5 g of the liquid material in the reactor was distilled through a 10-cm Vigreux column by gradually lowering the pressure and increasing the bath temperature. By pgc (condition *a*), **1***b*, **2**, **6***a*, **6***b*, and **7** were isolated from a fraction of 8.6 g boiling at 24°C/33 Torr (1 Torr = 133.3 Pa), and **13** was isolated from a fraction of 2.0 g boiling at 30–31°C/4 Torr. A fraction of 1.7 g boiling at 31–39°C/0.25 Torr was treated with a solution of diazomethane in ether. When gas evolution had ceased, the ether was removed in a rotary evaporator. The glc and gc/ms analyses of the residue showed the presence of methyl formate, and methylchloro and methyldichloro acetate. From this residue methylchloro and methyldichloro acetate were isolated by pgc (conditions *a*).

The isolated products **1***a*, **2**, **6***a* (25), **6***b* (25), **7**, and methylchloro and methyldichloro acetate have been identified based on the identity of their ^{1}H nmr spectra with those of authentic samples.

1,2,2-Trichloroethyl formate (**13**): Colorless liquid; ir (film): 1755 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$, Me_4Si) δ: 5.92 (dd, *J* = 3.9 and 0.4 Hz, 1H), 6.76 (dd, *J* = 3.9 and 0.9 Hz, 1H), 8.20 (dd, *J* = 0.9 and 0.4 Hz 1H); ms, see Table 1. *Anal.* calcd. for $C_3H_3OCl_3$: C 20.31, H 1.70, O 18.04, Cl 59.95; found: C 20.44, H 1.72, O 17.98, Cl 59.85.

(*c*) *Isolation of* **4**a, **4**b, **5**c, **5**d, ***10***, *and* **12**

In a 300-mL reactor 300 g of **1***a* was oxidized for 60 h under the conditions reported above to give 165 g of liquid product, which was submitted to a vacuum distillation. From a fraction of 3.7 g boiling at 42–45°C/4–5 Torr compounds **4***a*, **4***b*, **10**, and **12** were isolated by pgc (condition *a*). From a fraction of 3.2 g boiling at 82°C/5 Torr, compound **5***c* was isolated by crystallization at room temperature, and **5***d* by pgc separation (condition *a*) of the mother liquor.

The isolated products **4***a* (26), **4***b* (26), **5***c* (27), and **10** (28) were

identified by comparison of their ^{1}H nmr spectra with those of published data.

Dichloromethyl 1,2,2-trichloroethyl ether (**12**): Colorless liquid; ir (CCl_4): 1375, 1305, 1290, 1215, 1095, 1060, 985, 835, 705 cm^{-1}; ^{1}H nmr ($CDCl_3$, Me_4Si) AB system with δ_A 5.85, δ_B 6.04, J_{AB} = 3.29 Hz (2H), 7.22 (s, 1H); ms data, see Table 1. *Anal.* calcd. for $C_3H_3OCl_5$: C 15.51, H 1.30, O 6.89, Cl 76.30; found: C 15.64, H 1.25, O 6.66, Cl 76.45.

Oxidation of **1**a *with oxygen in the presence of chlorine*

(*a*) *Identification of products*

In a 110-mL reactor, 122 g of **1***a* was treated with an equimolar mixture of oxygen and chlorine at 30°C for 10 h; glc and gc/ms analyses showed the presence of compounds **2**–**17** in the proportions reported in Table 1.

(*b*) *Isolation of* **11**c, **11**d, **16**, *and* **17**

From the combined liquid material of two reactions, 117 g was submitted to a vacuum distillation. From a fraction of 5.9 g, gained at 3 Torr and bath temperatures of 80–160°C and which was collected at −5°C, compounds **11***c*, **11***d*, **16**, and **17** were isolated by pgc (condition *b*).

meso-*Bis(1,2,2-trichloroethyl) ether* (**11**c): ^{1}H nmr ($CDCl_3$, Me_4Si) AB system with δ_A 5.88, δ_B 5.99, J_{AB} = 3.5 Hz; (C_6D_6, Me_4Si) δ_A 4.99, δ_B 5.39, J_{AB} = 3.2 Hz). *Anal.* calcd. for $C_4H_4OCl_6$: C 17.11, H 1.44, O 5.70, Cl 75.75; found: C 17.46, H 1.40, O 6.69, Cl 74.32.

rac-*Bis(1,2,2-trichloroethyl) ether* (**11**d): ^{1}H nmr ($CDCl_3$, Me_4Si) δ: 5.85 (s); (C_6D_6, Me_4Si) AB system with δ_A 4.87, δ_B 5.01, J_{AB} = 4.0 Hz. *Anal.* calcd. for $C_4H_4OCl_6$: C 17.11, H 1.44, Cl 75.75; found: C 17.56, H 1.38, Cl 74.12.

The stereochemical assignments of **11***c* and **11***d* are only made by analogy with **5***c* and **5***d*, in which the isomer with the larger coupling constant was assigned the racemic structure.

1,2,2,2-Tetrachloroethyl 1,2,2-trichloroethyl ether (**16**): ^{1}H nmr ($CDCl_3$, Me_4Si) AB system with δ_A 5.88, δ_B 6.33, J_{AB} = 3.4 Hz (2H), 6.01 (s, 1H).

1,2,2-Trichloroethyl dichloroacetate (**17**): AB system with δ_A 5.91, δ_B 6.64, J_{AB} = 4.2 Hz (2H), 6.06 (s, 1H).

Solvolysis of **13** *with ethanol*

A solution of 0.88 g (5 mmol) of **13** in 0.92 g (20 mmol) of ethanol was kept stirring in a closed vessel for 6 h. Preparative gc separation (condition *c*) provided ethyl formate, **18***a* and **18***b*. These were identified by comparison of their ^{1}H nmr spectra with known data in the case of ethyl formate (29*a*) and **18***b* (29*b*), and with that of authentic **18***a* (δ 1.26, t; 3.74, q; 4.81, d; 5.66, d).

Ozonolysis of **4**a *and* **4**b *in methanol*

A mixture of 0.91 g (5 mmol) of **4***a* and **4***b* (1:2) and 5.5 mL of a 1 N solution of anhydrous hydrogen chloride in methanol was ozonized at −78°C until the solution turned blue, and then warmed up to room temperature. Methanol was largely removed by distillation at normal pressure to give a residue consisting of two phases. From the lower phase, 0.4 g (42%) of **20** was isolated by pgc (condition *d*).

Methyl 2,3,3-trichloropropionate (**20**): ir (film): 1760 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$, Me_4Si) δ: 3.86 (s, 3H), 4.61 (d, J = 7.5 Hz, 1H), 6.02 (d, 1H).

Chlorination of **6**

In a 20-mL reactor, 5.6 g of a mixture of **6***a* and **6***b* was treated with a stream of chlorine in nitrogen under uv irradiation at 30°C. After 23 h glc analysis showed the presence of **14** and of tetrachlorooxirane, as shown by coinjection with authentic samples.

Oxidation of **2**

In a 20-mL reactor, 18.2 g of **2** was treated with oxygen under the conditions that were applied for the oxidation of **1***a*. After 6 h, glc and ^{1}H nmr analyses of the product mixture (15.9 g) showed the presence of unreacted **2** (81%) and of the products **3** (6%), **8** (1%), and **15** (12%). The assignment of **15** was confirmed by the formation of methyl dichloroacetate upon addition of methanol to the mixture.

Inhibition of the oxidation of **1**a *by base*

A solution of 1.4 g (12.5 mmol) of 1,4-diazabicyclo[2.2.2]octane (DABCO) in 60 g (625 mmol) of **1***a* was treated with oxygen under the usual oxidation conditions. The solution turned yellow and small amounts of solid material precipitated on the reactor walls. After 84 h of continuous oxygenation, glc analysis showed only the peak of **1***a* to the exclusion of any oxidation products.

On the role of partition and surface reactions in the adsorption of binary liquid mixtures on silica gel

PREM P. SINGH[1] AND KRISHAN K. SHARMA
Department of Chemistry, Maharshi Dayanand University, Rohtak – 124001, India

Received June 4, 1987[2]

PREM P. SINGH and KRISHAN K. SHARMA. Can. J. Chem. **66**, 1371 (1988).

The adsorption behaviour of benzene (A), toluene (A), *p*-xylene (A), and *o*-xylene (A) in their binary mixtures with *o*-chlorotoluene (B) on silica gel has been studied at 308.15 K. The data have been analysed in terms of a model that assumes that partition and surface reactions play an important role in the adsorption process, and have revealed that while both partition and surface reactions dictate the adsorption (U-shaped isotherms) of *o*-chlorotoluene (OCTE) (B) from benzene (A) or toluene (A) + OCTE (B) mixtures, the adsorption of A and B entities of *p*-xylene (A) or *o*-xylene (A) + OCTE (B) mixtures (S-shaped isotherms) onto the silica gel surface is governed primarily by the distribution process and secondarily by the surface reaction.

PREM P. SINGH et KRISHAN K. SHARMA. Can. J. Chem. **66**, 1371 (1988).

Opérant à 308,15 K, on a étudié le comportement du benzène (A), du toluène (A), du *p*-xylène (A) et de l'*o*-xylène (A) dans leurs mélanges binaires avec l'*o*-chlorotoluène (B) lors de leur adsorption sur le gel de silice. On a analysé les données en fonction d'un modèle qui fait l'hypothèse que la partition ainsi que les réactions de surface jouent un rôle important dans le processus d'adsorption. Les données démontrent que la partition ainsi que les réactions de surface déterminent l'adsorption (isothermes en U) de l'*o*-chlorotoluène (OCTE) (B) à partir de mélanges de benzène (A) ou toluène (A) + OCTE (B); toutefois, l'adsorption des entités A et B à partir de mélanges de *p*-xylène (A) ou d'*o*-xylène (A) + OCTE (B) (isothermes en S) sur la surface de gel de silice est principalement déterminée par un processus de distribution et d'une façon secondaire par la réaction de surface.
[Traduit par la revue]

Introduction

The analysis of the adsorbed phase when binary liquid mixtures are equilibrated with inert solids has invoked considerable theoretical interest (1–6). While some (1, 2) of these approaches assume that the non-ideality of the bulk liquid phase is responsible for the imperfection of the surface phase, others (3–6) maintain that the heterogeneity of the solid phase also plays an important role in solution adsorption. None of these approaches (1–6), however, take into consideration the role of partition (7) and surface reactions (7) in the adsorption process, and the failure of the present approaches (1–6) to explain the S-shaped adsorption isotherms may be traced to the neglect of these important factors. The present work was undertaken to highlight the role of (*i*) partition and (*ii*) surface reactions in the solution adsorption process.

Experimental

Analytical grade benzene (E. Merck), toluene (E. Merck), *o*-xylene (E. Merck), *p*-xylene (E. Merck), and *o*-chlorotoluene (J. T. Baker Chemicals Co., U.S.A.) were purified as suggested elsewhere (8). The purity of the final samples was checked by measuring their densities at 298.15 ± 0.01 K, which agreed to within ±0.00005 g cm^{-3} with the literature values (9–12). Since the surface properties of these reagents were involved in the present work, we also determined their surface tension at 293.15 ± 0.01 K before and after adsorption (for 72 h at 308.15 ± 0.2 K) on silica gel (0.3 g in 10 mL of the pure liquid) by a modified double capillary rise method (13). The radii of the two capillaries (r_1 = 0.0151 cm and r_2 = 0.0801 cm) were determined from the lengths and weights of mercury threads. The lengths of the mercury threads were read by a cathetometer (M/s OSAW, India) that could read to ±0.001 cm. The uncertainty in the measured surface tension values is about 0.27% at the worst. The surface tension values of benzene, toluene, *p*-xylene, and OCTE before and after adsorption, along with the corresponding literature values (12, 14, 15), are recorded in Table 1.

The adsorbent used was silica gel (without binder) (100–120 mesh) supplied by M/s Glaxo Laboratories, India. It was dried at 393.15 K for 72 h. Portions of known weight (0.15–0.3 g) of silica gel were placed in glass ampoules and degassed for 24 h under 10^{-5} Torr pressure (1 Torr = 133.3 Pa). These ampoules were then filled with 5.0 mL of binary solutions of known composition (by weight), sealed, and then placed (for 72 h) in an air thermostat maintained at 308.15 ± 0.2 K. The liquid phase was subsequently separated from the solid and the change in composition of the solution due to adsorption was determined by a Carl Zeiss interferometer maintained at 308.15 K. For this purpose preliminary composition of the solution, after adsorption, was first determined from plots of composition vs. refractive indices (determined by an Abbé refractometer maintained at 308.15 ± 0.01 K). (The refractometer readings were reproducible to better than ±0.0002 and the compositions were accurate to ±0.1 mol% at the worst.) The final composition of this solution was determined by comparing it with a solution of known composition (by weight) using the Carl Zeiss interferometer and the calibration curves that were first drawn (using this interferometer). The interferometer readings were reproducible to ±1 unit and the changes in composition (on the mole fraction scale) are believed to be accurate to better than 3 × 10^{-4}.

TABLE 1. Comparison of the measured surface tension of the reagents before and after adsorption on silica gel at 293.15 ± 0.01 K, with their corresponding literature values

	Surface tension (dynes cm^{-1})			
Reagent	Before adsorption	After adsorption	Lit. value	Ref.
Benzene	28.86	28.85	28.88	14
Toluene	28.53	28.54	28.52	14
p-Xylene	28.48	28.48	28.50	15
OCTE	33.42	33.42	33.44	12

Results and discussion

The experimental results are recorded in Table 2. It is apparent from Table 1 that while *o*-chlorotoluene (OCTE) is adsorbed preferentially from benzene (A) or toluene (A) +

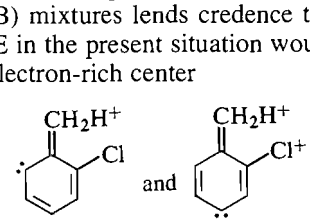
[a] In mol for 5 mL of solution.
[b] $\Delta x_{A(l)} = x_{A(l)initial} - x_{A(l)final}$.

OCTE (B) mixtures, *o*-xylene (A) or *p*-xylene (A) is adsorbed preferentially in the range $x_A^l \leq 0.5$ and OCTE is adsorbed preferentially in the rest of the composition range from *o*-xylene (A) or *p*-xylene (A) + OCTE (B) mixtures. Again, while the extent of OCTE (B) adsorption is greater from toluene (A) + OCTE (B) mixtures than that from benzene (A) + OCTE (B) mixtures, OCTE (B) is adsorbed (in the range $x_A^l > 0.5$) to a greater extent from its binary mixtures with *p*-xylene (A) than from those with *o*-xylene (A). The transition from the U-shaped isotherms in benzene (A) or toluene (A) + OCTE (B) mixtures to S-shaped isotherms for *o*-xylene (A) or *p*-xylene (A) + OCTE (B) mixtures when these mixtures are equilibrated with silica gel highlights the influence of $-CH_3$ substituents in the benzene ring on their adsorption on silica gel in the presence of OCTE (B).

Since specific molecular adsorption and chemical reactions with the surface of silica gel are determined (16) by surface hydroxyl groups and as these groups are the most accessible (ref. 16, p. 131) for interaction, we first recorded the infrared spectrum (in KBr pellets) of the present silica gel (Fig. 1) to understand the state of the surface -OH groups. The infrared spectrum of the present silica gel (Fig. 1) showed four characteristic absorption bands at 3420, 1625, 1100, and 800 cm^{-1}. While the very strong absorption band at 1100 cm^{-1} is due (17) to the asymmetric stretching vibrations of the Si—O—Si moiety, the weak absorption band at 800 cm^{-1} is due (18) to the Si—O—Si bending mode and the weak absorption at 1625 cm^{-1} is due (19) to the in-plane deformation of the -OH group. The band at 3420 cm^{-1} has been attributed (20) to -OH stretching vibration of molecular water. The position of the band at 1625 cm^{-1} also compares (20) favourably (at 1627 cm^{-1}) with the H—O—H bending vibrations in liquid water. Further, since the band at 3500 cm^{-1} observed in the spectra of some silica surfaces has been assigned (21) to the H—O—Si(^)—O—H moiety, we assume that the band at 3420 cm^{-1} in the infrared spectrum of the present silica gel is also due to this entity.

Further, aromatic hydrocarbons with their π-electron clouds have weak hydrogen-bond base characteristics (22). If specific interactions can occur (23–27) between the surface -OH groups and the π-electron clouds of the constituents of the present (A + B) mixtures, it is apparent that the adsorption of A and (or) B on the surface of silica gel must involve (ref. 20, p. 132) an acid–base type of interaction between the surface $-\bar{O}—H^+$ groups of the H—O—Si(^)—O—H moiety and the π-electron clouds of the basic adsorbate(s).

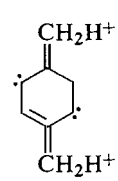
The presence of a $-CH_3$ substituent in *o*-chlorotoluene (OCTE) (B) would then require (28) (due to hyperconjugation) that there be an excess of charge at its *o* and *p* positions. Evidently the extent to which this happens in an (A + B) mixture would be dictated by the molecular entity A. Since the accumulation of charge at the *o* and *p* positions of OCTE (B) would be greater in the presence of toluene (A) than in the presence of benzene (A), and as B would now be more basic than the normal forms of benzene or toluene (A), it follows that compared to benzene (A) or toluene (A), OCTE (B) should be adsorbed preferentially on the silica gel surface and that the extent to which this happens should be greater in the presence of toluene (A) than in the presence of benzene (A). The experimental excess adsorption data of benzene (A) or toluene (A) + OCTE (B) mixtures lends credence to this conjecture. Again, as OCTE in the present situation would be expected to have only one electron-rich center



I

it follows that in the adsorption of OCTE (B) from benzene (A) or toluene (A) + OCTE (B) mixtures on silica gel only one -O—H of the H—O—Si(^)—O—H moiety is involved.

On the other hand, the presence of two $-CH_3$ substituents *para* to each other, as in *p*-xylene, would cause the creation of two electron-rich centres,



II

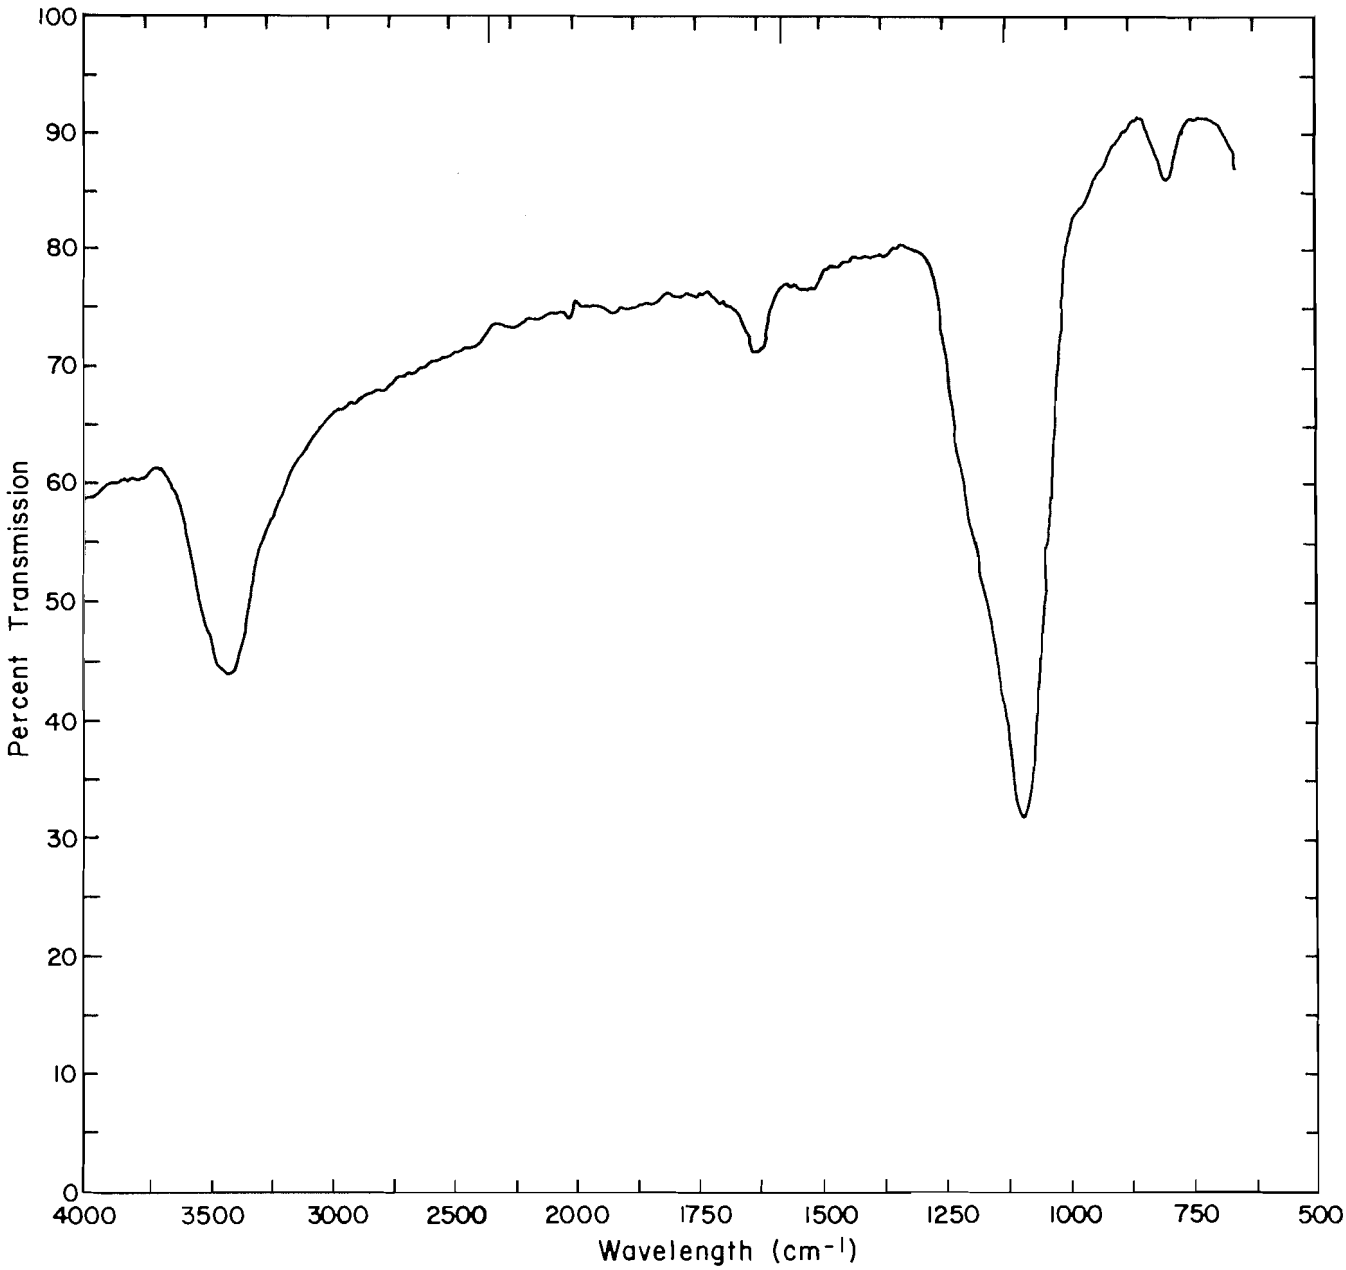


FIG. 1. Infrared spectrum (in KBr pellets) of silica gel.

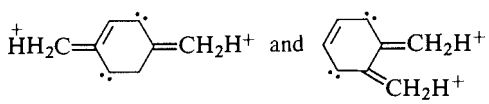
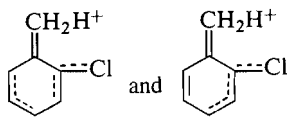
The weak absorption band at 1700 cm^{-1} observed in the infrared spectrum (in KBr pellets) of pure *p*-xylene or *o*-xylene adsorbed on silica gel (Fig. 2) may be due to species like



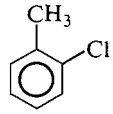
III

The extent to which this happens should evidently be greater in *p*-xylene than in *o*-xylene and should be dictated by the concentration of OCTE (B). Thus while the large excess of OCTE would cause *p*-xylene in the *p*-xylene (A) + OCTE (B) mixture to exist, in increasing proportion, in the **II** form, the increasing proportion of *p*-xylene would also cause OCTE to exist in increasing proportions, in the forms:



IV

Since the **II** form of *p*-xylene would be expected to be a stronger base than the



V

form of OCTE, it follows that at low mole fractions of *p*-xylene, *p*-xylene should be adsorbed preferentially and that this should decrease as the mole fraction of x_A in the *p*-xylene (A) + OCTE

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

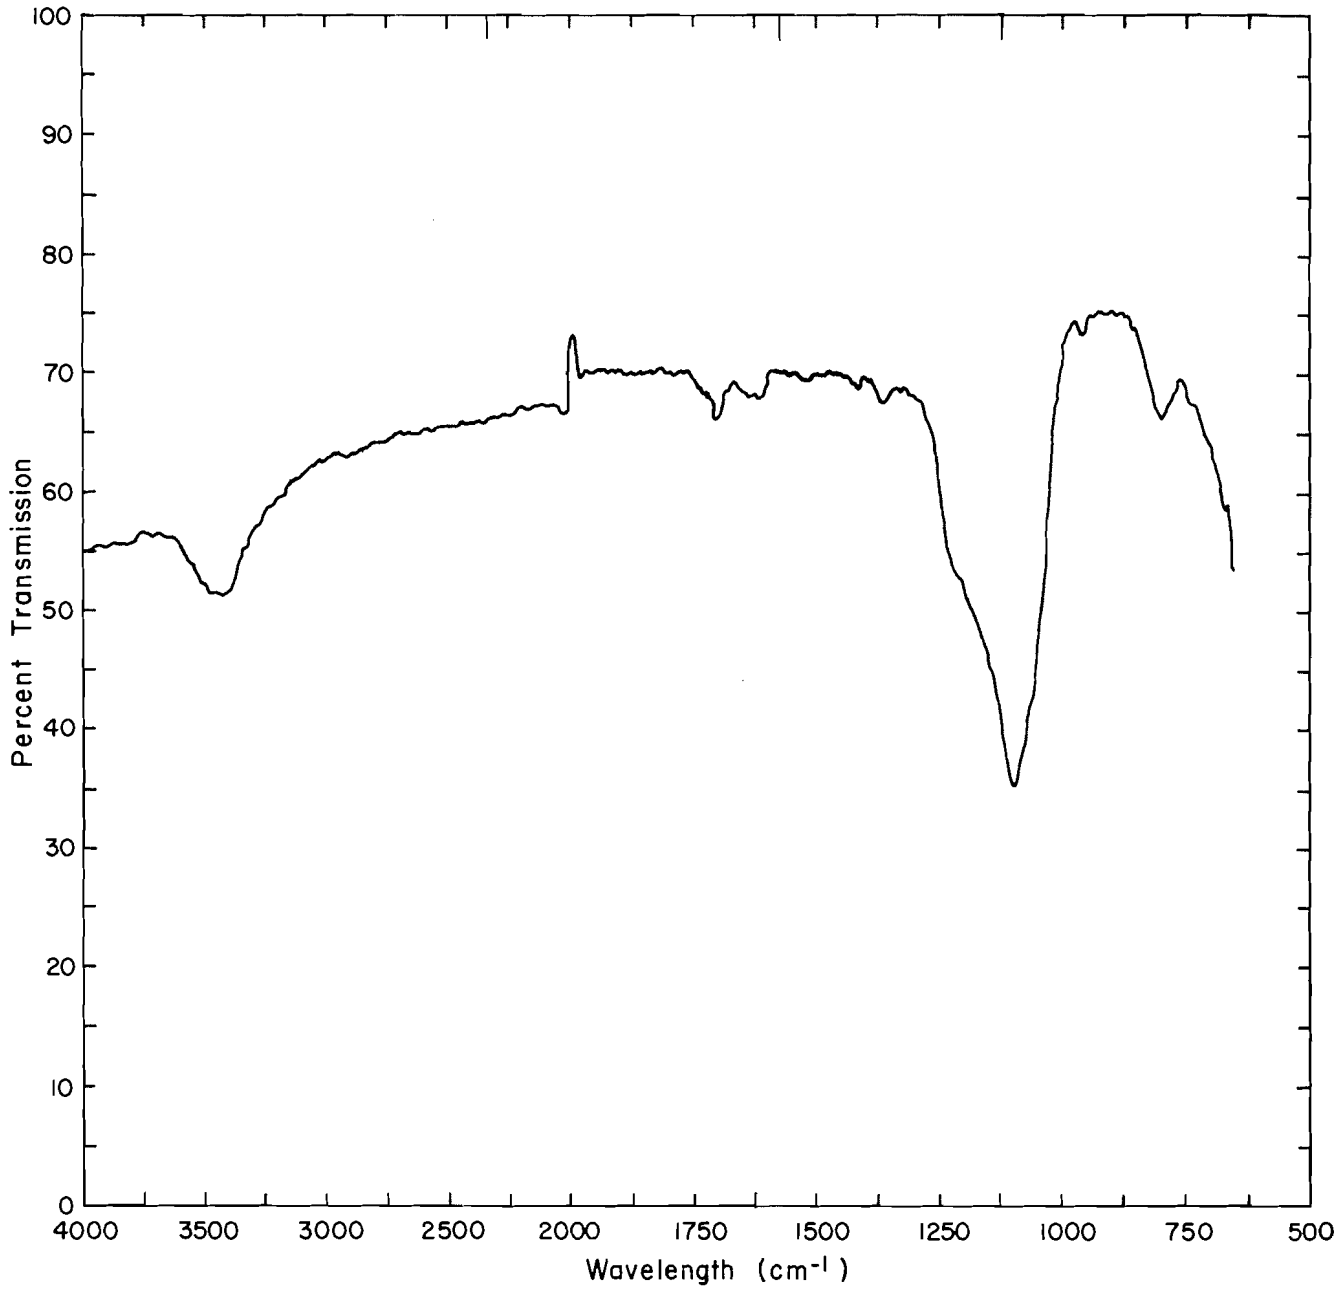


FIG. 2. Infrared spectrum (in KBr pellets) of *p*-xylene (after adsorption on silica gel).

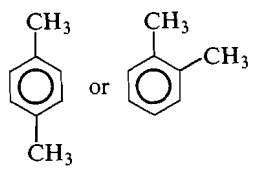
(B) mixture increases. Again as the **IV** forms of OCTE, in the presence of large x_A, would be more basic than the



VI

forms of *p*-xylene or *o*-xylene, it follows that at high x_A, OCTE should be adsorbed preferentially and that this effect should be greater in the *p*-xylene (A) + OCTE (B) mixture than in the *o*-xylene (A) + OCTE (B) mixture, as has indeed been observed. If the postulated formation of increased proportions of the **IV** forms of OCTE as the concentration of *p*-xylene is increased is valid, then one would envisage that the Cl center of these species should also interact with the O-H entity (or entities) of the H—O—Si—OH moiety. The fact that a new weak band has been observed at 2300 cm^{-1} in the infrared spectrum (in KBr pellets) of the *p*-xylene (A) + OCTE (B) mixture adsorbed on silica gel (Fig. 3) at $x_A = 0.8935$, and a band at 2300 cm^{-1} can be assigned (29) to hydrogen-bonded hydrogen chloride molecules, lends credence to such a type of interaction. Again, because the infrared spectrum of the *p*-xylene (A) + OCTE (B) mixture adsorbed on silica gel exhibits a reasonably intense band at 1700 cm^{-1} (with no new band at 2300 cm^{-1}) corresponding to $x_A = 0.1939$ (Fig. 4), and because the intensity of the band at 1700 cm^{-1} decreases while a new weak band appears at 2300 cm^{-1} corresponding to $x_A = 0.8935$, it appears that while at low x_A *p*-xylene is adsorbed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

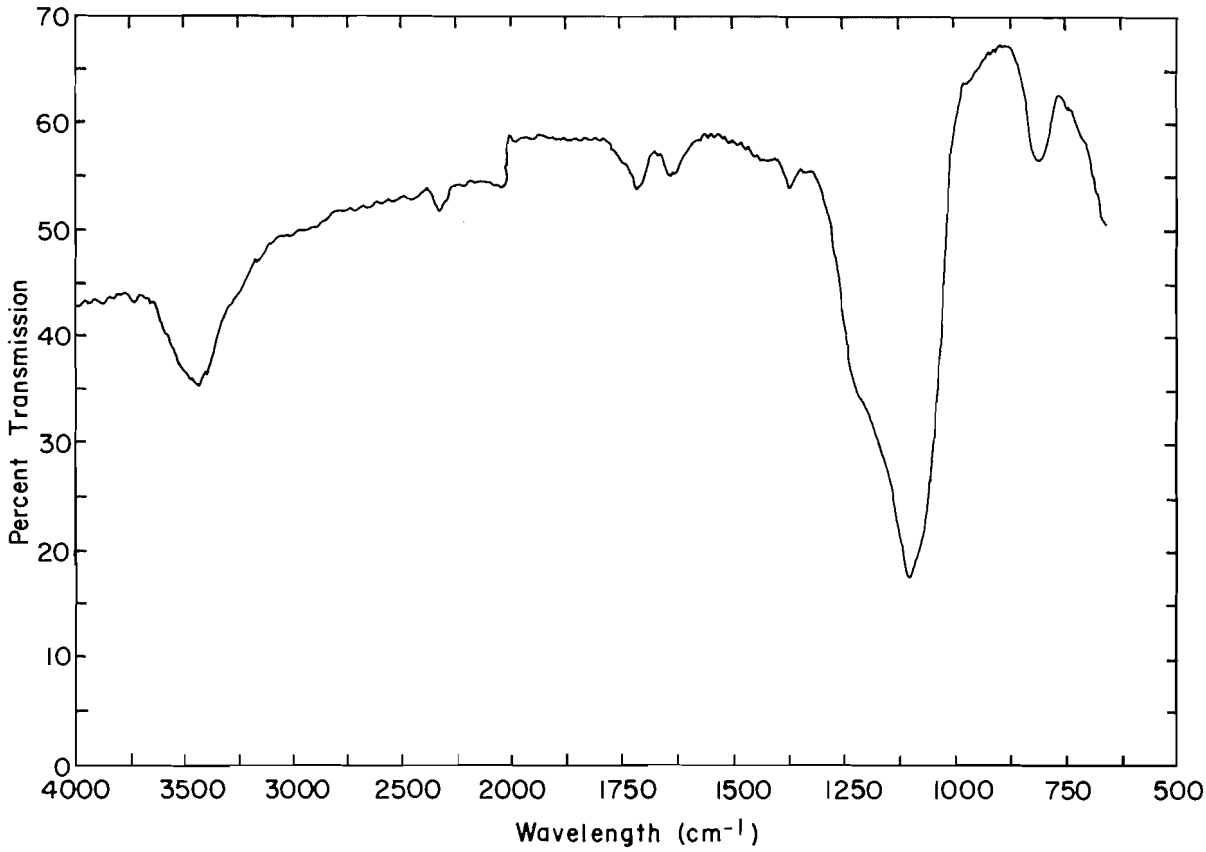


FIG. 3. Infrared spectrum (in KBr) pellets) of *p*-xylene + OCTE ($x_{p\text{-xylene}} = 0.8935$) mixture adsorbed on silica gel).

preferentially, at high x_A it is the OCTE that is preferentially adsorbed. Further, as *p*-xylene (A) or *o*-xylene (A) and OCTE (B) in *p*-xylene (A) or *o*-xylene (A) + OCTE (B) mixtures has been postulated to have two electron-rich centers, it follows that both -OH groups of the O—H—Si—O—H moiety should be involved in the adsorption process characterizing the *p*-xylene (A) + OCTE (B) mixtures.

If the preferential adsorption of B from an (A + B) mixture on a solid (S) surface causes no appreciable changes in the composition of A, and if the addition of a degassed solid S to an (A + B) liquid mixture causes absorption of B, which subsequently undergoes surface reaction on S, then the preferential adsorption of B on the silica gel (S) may involve (*i*) the distribution of B(l) between two immiscible phases, A(l) and S, and (*ii*) the interaction of a part of the absorbed B(l) molecules with the surface -OH groups. Consequently if $(N_{B(l)})_S$ represents the total number of moles of B(l) per gram of the S phase, then

$$[1] \quad (N_{B(l)})_S = \begin{array}{l}\text{number of moles of B(l) per gram of S that are}\\ \text{free in the body of S + number of moles of B(l)}\\ \text{per gram of S due to the surface reaction}\end{array}$$

The "equilibrium constant", K, of the surface reaction

$$[2] \quad x(B(l))_S \rightleftharpoons y(B^\sigma)_S$$

would then be given by

$$[3] \quad K = (n_B^g)_S^y (\gamma^\sigma{}_{B(l)})_S^y / (n_{B(l)})_S^x (\gamma_{B(l)})_S^x$$

where $(\gamma^\sigma{}_{B(l)})_S$ and $(n_B^g)_S$ represent, respectively, the activity coefficient and the number of moles of B(l) per gram of S that are adsorbed on the surface of S; $(\gamma_{B(l)})_S$ and $(n_{B(l)})_S$ are the corresponding quantities of B(l) entity that exist free in the body of S. Since no method is available to evaluate $(\nu^\sigma{}_{B(l)})_S$ and $(\gamma_{B(l)})_S$ we assume that $(\gamma_B^g)_S/(\gamma_{B(l)})_S \approx 1$, so that eq. [3] reduces to

$$[4] \quad K = (n_B^g)_S^y / (n_{B(l)})_S^x$$

If ξ is the extent of the surface reaction, then the number of moles of B(l) per gram of S due to the surface reaction would be $x\xi$, so that eq. [1] yields

$$[5] \quad (N_{B(l)})_S = (n_{B(l)})_S + x\xi$$

But as $(n_B^g)_S = y\xi$, eq. [4] yields

$$[6] \quad K = (y\xi)^y / (n_{B(l)})_S^x$$

so that

$$[7] \quad \xi = K^{1/y} (n_{B(l)})_S^{x/y} / y$$

Equation [5] then yields

$$[8] \quad (N_{B(l)})_S = (n_{B(l)})_S + \frac{x}{y} \cdot K^{1/y} (n_{B(l)})_S^{x/y}$$

Again, as no reaction is assumed to occur between A and B in the liquid phase, and as B(l) distributes itself between the A(l) and S phases, we define a "distribution coefficient", K_d, as

$$[9] \quad K_d = \frac{(n_{B(l)})_S}{(n_{B(l)})_{\equiv \text{m in A(l)}}}$$

where $(n_{B(l)})_{\equiv \text{m in A(l)}}$ refers to the number of moles of B(l) per mL of the total liquid phase in the equilibrium state. Consequently

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

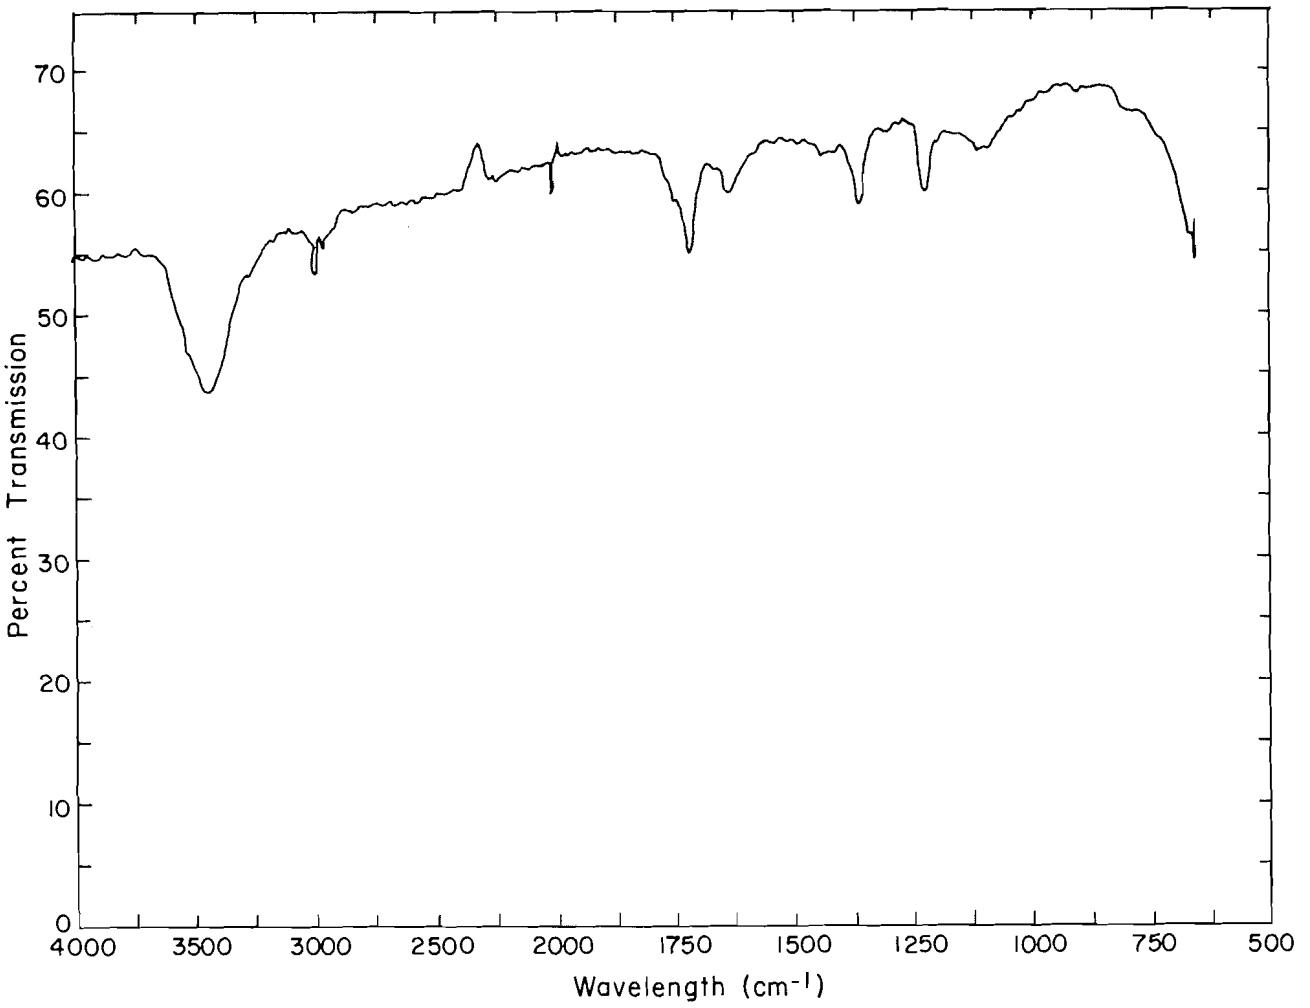

FIG. 4. Infrared spectrum (in KBr pellets) of *p*-xylene + OCTE ($x_{p\text{-xylene}} = 0.1939$) mixture adsorbed on silica gel.

[10] $(n_{B(l)})_S = K_d \cdot (n_{B(l)})_{\equiv \text{m in A(l)}}$

Hence expression [8] yields

[11] $$(N_{B(l)})_S = [K_d(n_{B(l)})_{\equiv \text{m in A(l)}})] + \frac{x}{y} \cdot K^{1/y}(K_d)^{x/y}(n_{B(l)})^{x/y}_{\equiv \text{m in A(l)}}$$

or

[12] $$\frac{(N_{B(l)})_S}{(n_{B(l)})_{\equiv \text{m in A(l)}}} = K_d + \frac{x}{y} \cdot K^{1/y}(K_d)^{x/y}(n_{B(l)})^{(x/y)-1}_{\equiv \text{m in A(l)}}$$

Evaluation of K_d and K from eq. [12] thus requires a knowledge of $(N_{B(l)})_S$ and $(n_{B(l)})_{\equiv \text{m in A(l)}}$. Since the equilibrium mole fraction $x_{B(l)_m}$ in the A(l) is known and if $n_{A(l)}$ is the number of moles of A(l) per mL of the liquid phase, then

[13] $$x_{B(l)_m} = \frac{(n_{B(l)})_{\equiv \text{m in A(l)}}}{(n_{A(l)} + (n_{B(l)})_{\equiv \text{m in A(l)}}}$$

or

[14] $$(n_{B(l)})_{\equiv \text{m in A(l)}} = \frac{x_{B(l)_m} \cdot n_{A(l)}}{1 - x_{B(l)_m}}$$

Hence

[15] $(N_{B(l)})_S = (n_{B(l)})_{\text{initial in A(l)}} - (n_{B(l)})_{\equiv \text{m in A(l)}}$

Since all the relevant quantities in eq. [12] can be deduced from the experimental adsorption data, it should be possible to evaluate the K_d and K parameters of the adsorption process.

We now consider two cases:

Case (*i*): $x = 1$, $y = \frac{1}{2}$ so that eq. [12] reduces to

[16] $$\frac{(N_{B(l)})_S}{(n_{B(l)})_{\equiv \text{m in A(l)}}} = K_d + 2K^2K_d^2(n_{B(l)})_{\equiv \text{m in A(l)}}$$

Case (*ii*): $x = 1$, $y = 2$, so that eq. [12] yields

[17] $$\frac{(N_{B(l)})_S}{(n_{B(l)})_{\equiv \text{m in A(l)}}} = K_d + 0.5K^{0.5}(K_d)^{0.5}(n_{B(l)})^{-0.5}_{\equiv \text{m in A(l)}}$$

Since, in the adsorption of OCTE (B) from benzene (A) or toluene (A) + OCTE (B) mixtures onto the silica surface, one -OH group of the H—O—Si—O—H moiety of the silica gel is assumed to be involved per molecule of OCTE, and if the basic arguments in deriving eq. [12] are valid, then according to eq. [16] a plot of Q $(=(N_{B(l)})_S/(n_{B(l)})_{\equiv \text{m in A(l)}}$ vs. Z $(=(n_{B(l)})_{\equiv \text{m in A(l)}})$ should be a straight line of slope $2K^2K_d^2$ and intercept K_d. This was indeed found to be true of the adsorption of OCTE (B) on silica gel from its binary mixtures with benzene (A) or toluene (A) (Fig. 5); the relevant K_d and K values are recorded in Table 3.

On the other hand, as the adsorption of OCTE (B) or *p*-xylene (A) or *o*-xylene (A) into the silica gel surface from the *p*-xylene (A) or *o*-xylene (A) + OCTE (B) mixtures is assumed to involve the interaction of both -OH groups of the

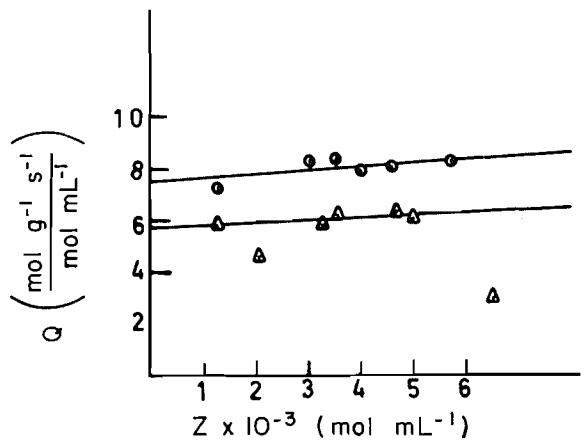

FIG. 5. Plot of Q vs. Z for benzene + OCTE (⊙) and toluene + OCTE (△) adsorbed on silica gel at 308.15 K.

TABLE 3. The distribution coefficient, K_d, and the equilibrium constant, K, of the surface reaction, for the B and (or) A entity of the various (A + B) mixtures adsorbed on silica gel at 308.15 K

System	K_d (mL g^{-1})	K
Benzene (A) + OCTE (B)	7.54	1.075
Toluene (A) + OCTE (B)	5.70	1.24
o-Xylene (A) + OCTE (B)	0.7 (for B) 1.8 (for A)	0.132 (for B) 0.01655 (for A)
p-Xylene (A) + OCTE (B)	0.4 (for B) 1.0 (for A)	0.2152 (for B) 0.01145 (for A)

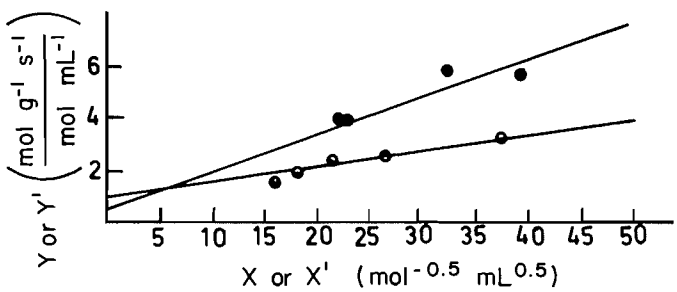

FIG. 6. Plot of Y or Y' vs. X or X' for *p*-xylene + OCTE mixture adsorbed on silica gel at 308.15 K.

H—O—Si—O—H moiety, then according to eq. [17], a plot of $Y\,(=(N_{B(l)})_S/(n_{B(l)})_{\equiv m \text{ in } A(l)})$ vs. $X\,(=(n_{B(l)})^{-0.5}_{\equiv m \text{ in } A(l)})$ and a plot of $Y^1\,(=(N_{A(l)})_S/n_{A(l)})_{\equiv m \text{ in } B(l)})$ vs. $X^1\,(=(n_{A(l)})^{-0.5}_{\equiv m \text{ in } B(l)})$ (utilizing the necessary relevant data) should be straight lines. This was found to indeed be true of the adsorption of A and B entities of the *p*-xylene (A) or *o*-xylene(A) + OCTE (B) mixtures on the silica gel surface (Figs. 6, 7); the relevant K_d and K values are recorded in Table 3.

Examination of Table 3 thus clearly reveals that while the adsorption of OCTE on the silica gel surface from benzene (A) or toluene (A) + OCTE (B) mixtures is dictated by both the distribution and the surface complexation reaction processes, the adsorption of A and B entities of the *p*-xylene (A) or

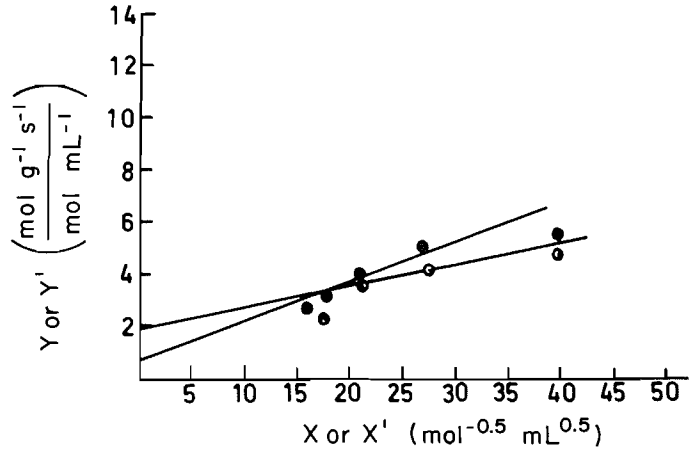

FIG. 7. Plot of Y or Y' vs. X or X' for *o*-xylene + OCTE mixture adsorbed on silica gel at 308.15 K.

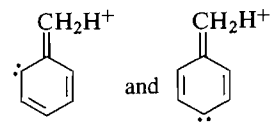
o-xylene (A) + OCTE (B) mixtures onto the silica gel surface is governed primarily by the distribution process and secondarily by surface reaction processes. Further, the variation of the distribution coefficient K_d of OCTE (B) between A(l) and the solid phase (S) for benzene (A) or toluene (A) or the *o*-xylene (A) or *p*-xylene (A) + OCTE (B) mixtures in the order benzene > toluene > *o*-xylene > *p*-xylene suggests that the partitioning of OCTE (B) between the A(l) and S phases is dictated by $-CH_3$ substituents in the benzene ring. This is understandable. The adsorption of OCTE (B) from benzene (A) or toluene (A) or *o*-xylene (A) or *p*-xylene (A) + OCTE (B) mixtures onto the silica gel has been postulated to involve the **IV** species of OCTE, and because toluene (A), *p*-xylene (A), and *o*-xylene (A) can exist (due to hyperconjugation) in the



VII

and **III** forms respectively and these species also have electron-deficient centers, the relative strengths of which vary in the order *p*-xylene > *o*-xylene > toluene, it is apparent that the partitioning of OCTE (B) between the A(l) and S phases in the present study should vary in the order benzene > toluene > *o*-xylene > *p*-xylene. This would of necessity require that A(l) and B(l) be characterized by some sort of mutual interaction. A recent study (30) on the molar excess volumes and excess enthalpies of benzene (A) or toluene (A) or *p*-xylene (A) or *o*-xylene (A) + OCTE (B) liquid mixtures indeed has suggested that weak specific interactions (probably contact charge-transfer type) do take place between the components of these mixtures. Since the interactions between the A and B components of the present (A + B) mixtures in the liquid phase are very weak (activity coefficients of A and B in the bulk phase of the (A + B) mixtures are all close to unity (30)), it is reasonable to assume that their presence does not seriously jeopardize the mathematical arguments of the present analysis. The K_d and K values for the adsorption of A and B entities of the *p*-xylene or *o*-xylene (A) + OCTE (B) mixtures on the silica gel surface further suggest that the S-shaped adsorption isotherms characterizing these mixtures are dependent on the relative partitioning abilities of the A and B entities and that the surface reaction plays a relatively minor part.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

The present study has thus revealed that any comprehensive theory of adsorption must take into consideration not only the partitioning abilities of the A and or B components of the (A + B) mixtures but also their ability to undergo surface reactions on the solid surface. Perhaps the non-ideality of the bulk liquid phase may also be an important factor.

Conformational changes in serine on methylmercury complexation

MARIE-CLAUDE CORBEIL AND ANDRÉ L. BEAUCHAMP

Département de Chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Qué.) Canada H3C 3J7

Received October 19, 1987

MARIE-CLAUDE CORBEIL and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **66**, 1379 (1988).

The CH_3Hg^+ cation forms a zwitterionic complex $CH_3Hg[HOCH_2CH(NH_2)CO_2$—N,O,O] with serine in aqueous solution. X-ray diffraction ($P2_12_12_1$, $a = 5.821$, $b = 8.052$, $c = 14.307$ Å, $R = 0.021$) shows that mercury is linearly bonded to the NH_2 end of the amino acid, whereas one carboxylate oxygen and the side-chain hydroxyl group establish secondary Hg—O bonds. Coordination leads to characteristic changes in the infrared and Raman spectra of serine. From the ^1H and ^{13}C nmr spectra, N-coordination is found to be retained in aqueous solution, whereas the ligand conformation observed in the solid accounts for 76% of the conformer distribution.

MARIE-CLAUDE CORBEIL and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **66**, 1379 (1988).

Le cation CH_3Hg^+ forme un complexe zwiterionique $CH_3Hg[HOCH_2CH(NH_2)CO_2$—N,O,O] avec la sérine en solution aqueuse. La diffraction des rayons X ($P2_12_12_1$, $a = 5{,}821$, $b = 8{,}052$, $c = 14{,}307$ Å, $R = 0{,}021$) montre que le mercure est lié de façon linéaire à l'extrémité NH_2 de l'acide aminé, alors que l'un des oxygènes carboxylates et la fonction hydroxyle de la chaîne latérale établissent des liaisons secondaires Hg—O. La coordination introduit des changements caractéristiques dans les spectres infrarouge et Raman de la sérine. Les spectres rmn ^1H et ^{13}C indiquent que la coordination du métal à l'azote persiste en solution aqueuse et que le complexe adopte à 76% la conformation observée à l'état solide.

Introduction

When bonded to flexible ligands containing extra free donor groups, the methylmercury(II) cation is expected to have an influence on the ligand conformation, since the linearly-coordinated Hg atom tends to satisfy its residual Lewis acidity by forming secondary bonds near the equatorial plane perpendicular to the CH_3—Hg—L direction. We are currently examining the effect of CH_3Hg^+ coordination on the conformation of protein components. Conditions and sites for primary coordination have been studied by using ligands like glycine, alanine (1), and glycylglycine (2), which are devoid of functionalized side chains. In the present paper, complexation with serine, which contains a —CH_2OH side chain, is being examined.

Experimental section

Reagents

L-Serine (from Nutritional Biochemicals Corporation) was used without further purification. The source of CH_3Hg^+ ions was the hydroxide CH_3HgOH (1 *M* aqueous solution from Alfa Inorganics).

Vibrational spectroscopy

The Raman spectra, excited by the 514.5 nm line from a Spectra Physics Model 165 argon ion laser, were recorded at Université Laval on a Spex Model 1400 microcomputer-controlled spectrometer. The samples were contained in capillary tubes which were mounted on a motor shaft and rotated at high speed in the laser beam. The laser power at the sample was 200 mW for free serine and 25 mW for the complex to prevent decomposition. The spectra were recorded at 5 cm^{-1} spectral slit width, with a 2 s integration time at each 2 cm^{-1} frequency increment.

The infrared spectra were recorded as KBr pellets on a FTIR Nicolet 7199 instrument equipped with a HeNe class II laser with a resolution of 1 cm^{-1} and 200 scans per spectra.

Nuclear magnetic resonance spectroscopy

The ^1H and ^{13}C nmr spectra were obtained with the Bruker WH-400 spectrometer of the Centre Régional de RMN à Haut Champ located at the Université de Montréal. The samples were dissolved in D_2O (Cambridge Isotope Lab., 99.83% isotopic purity). DSS and 1,4-dioxane were used as external references for the ^1H and ^{13}C spectra, respectively. The concentration of the solutions was ~0.15 *M*.

Preparations

CH_3Hg(L-ser): 1 mmol (105 mg) of L-serine was dissolved in 1.0 mL of 1 *M* aqueous CH_3HgOH. Absolute ethanol (10 mL) was added. After a few hours at room temperature and in open air (hood), colorless needles precipitated. Yield: 150 mg (48%). *Anal.* calcd. for $C_4H_9HgNO_3$: C 15.03, H 2.84, Hg 62.74; N, 4.38; found (Schwarzkopf Lab.): C 15.28, H 2.89, Hg 62.33, N 4.20.

O,N-Deuterated L-serine-d_4 and CH_3Hg(L-ser-d_3) were obtained by exchange with heavy water.

Crystal data

$C_4H_9HgNO_3$ fw = 319.71

Orthorhombic, $P2_12_12_1$, $a = 5.821(2)$, $b = 8.052(1)$, $c = 14.307(3)$ Å, $V = 670.6$ Å^3, $Z = 4$, $D_c = 3.166$ g cm^{-3}, λ(MoK$\bar{\alpha}$) = 0.71069 Å, μ(MoKα) = 228.8 cm^{-1}, $T = 293$ K.

Crystallographic measurements and structure determination

A crystal of dimensions (mm) 0.05 (between 011 and 011) × 0.05 (011–011) × 0.11 (100–100) was used for X-ray work. The space group and cell parameters were initially determined from precession and cone-axis photographs. Accurate cell parameters and intensity data were obtained with an Enraf-Nonius CAD4 diffractometer, as described elsewhere (3). The six standard reflections monitored during the experiment showed random fluctuations within ±1.7%. A total of 713 *hkl* reflections was measured ($2\theta \leq 50°$). Inspection of the full data set confirmed the systematic absences noted on the films ($h00$, $h \neq 2n$; $0k0$, $k \neq 2n$; $00l$; $l \neq 2n$), unambiguously identifying $P2_12_12_1$ as the space group. After removal of the 16 systematic absences, the data set consisted of 697 independent reflections, of which 675 were used to solve the structure ($I \geq 3\,(\sigma(I))$. The data were corrected for the Lorentz effect, polarization, and absorption (Gaussian integration, grid 8×8×8, transmission range: 0.24–0.44).

The structure was solved by the heavy-atom method and refined on $|F_o|$. The mercury atom was located from a Patterson map and the non-hydrogen atoms were found on the difference Fourier (ΔF) map phased on Hg. Isotropic refinement by full-matrix least squares converged to $R = \Sigma\|F_o| - |F_c\|/\Sigma|F_o| = 0.052$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.069$. At this stage, it was checked that the absolute configuration was that of the L enantiomer of serine. Refinement was completed by block-diagonal least squares. The hydrogen atoms on the amino, methine, and methylene groups were fixed at idealized positions (C—H = 0.95 Å, N—H = 0.87 Å, $B_{iso} = 4.0$ Å^2). The methyl and hydroxyl hydrogens were not visible in the ΔF map. The hydrogen parameters were not refined, but their

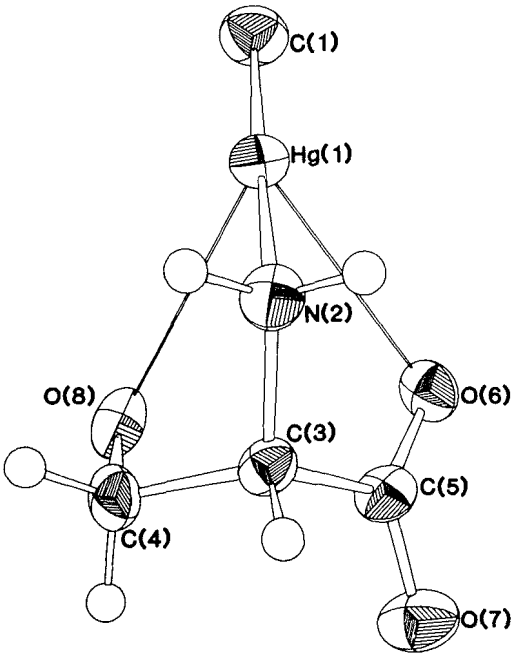

FIG. 1. Numbering scheme and structure of $CH_3Hg[HOCH_2CH(NH_2)(CO_2—N,O,O]$ complex with L-serine. The thin bonds correspond to Hg...O contacts. The thermal ellipsoids for the non-hydrogen atoms correspond to 50% probability. The methylene and methine hydrogens are represented by open spheres of arbitrary size. The methyl and hydroxyl hydrogens were not located.

coordinates were recalculated after each least-square cycle. Anisotropic refinement of all non-hydrogen atoms converged to $R = 0.021$, $R_w = 0.026$, and a goodness-of-fit ratio of 1.15. The final ΔF map was featureless, and the general background was below ± 0.55 e/Å^3.

The scattering curves were from standard sources. The f' and f'' contributions of Hg to anomalous dispersion were included in structure-factor calculation (4). The refined coordinates and equivalent isotropic temperature factors are listed in Table 1.

Results and discussion

Description of the structure

The CH_3Hg(L-ser) complex is represented in Fig. 1, with the numbering scheme used. Interatomic distances and bond angles are listed in Table 2.

The CH_3Hg^+ ion has replaced an ammonium proton of serine. The metal shows a linear coordination (C(1)—Hg—N(2) = 174.0(4)°), with a Hg—N(2) distance (2.128)(7) Å) similar to those reported for this type of complexes (1, 2). Mercury also makes two intramolecular contacts with oxygen

TABLE 2. Interatomic distances and bond angles

Atoms	Distance (Å)

O(6)—C(5)—O(7)	125.5(9)

atoms. The first one with the O(6) carboxylate oxygen at 2.726(6) Å (Table 3) is common for methylmercury — amino acid complexes, since it has been observed in complexes with alanine (1), methionine (5), and tyrosine (6). A second contact involves the hydroxylic oxygen O(8) at 2.890(8) Å. This appears to be the first example of intramolecular tridentate coordination for serine. Some very weak Zn...OH interaction may be present for one of the ligands in the Zn(L-ser)$_2$ chelate (7), but with an adjacent molecule in the polymeric structure. The present complex also appears to be only the second example of a CH_3Hg^+ hydroxylic oxygen interaction, the previous example being a Hg...OH contact of 2.680(6) Å $[CH_3Hg(L—N, 0)]NO_3$, where L is tris(*N*-methylimidazol-2-yl)methanol (8).

In presence of mercury, light-atom positions cannot be determined with high accuracy. Considering the esd's, the bond lengths and angles of L-serine (9–11) are not significantly affected by complexation.

A stereo view of the unit cell is given in Fig. 2. Two molecules related by a 2_1 axis parallel to *a* are connected via hydroxyl groups forming moderately strong O(8)—H...O(6) hydrogen bonds (O...O = 2.769(9) Å) and a normal Hg—O(8) contact of 3.000(7) Å (Table 3). This pair is anchored to four similar pairs in the unit cell by symmetry equivalent N(2)—H(21)...O(7) hydrogen bonds (N...O = 2.88(1) Å). The pairs of molecules are repeated by the *a* translation, generating an infinite chain in which propagation is mainly achieved by weak N(2)—H(22)...O(7) interactions (N...O = 3.18(1) Å).

In the crystal structures of serine (9–11) and most of its complexes (7, 12–17), the role of the —OH group is restricted to intermolecular hydrogen bonding. Hence, the orientation of the CH_2—OH bond is not controlled by coordinative interactions, but by hydrogen bonding. The three low-energy conformations of serine are shown in structures **I**–**III**. Conformation **III** is found in the crystals of L-serine (9, 10), DL-serine (9, 11, and L-serine monohydrate (11), and for chelate rings in various metal complexes (7, 14, 16). In this conformation, the —OH group is *gauche* to the $—CO_2^-$ and NH_2 groups. The other common conformation **I** (OH *anti* to CO_2^-) has been observed

[a] $-x,\frac{1}{2}+y,-\frac{1}{2}-z$.
[b] $1+x,y,z$.
[c] $\frac{1}{2}+x,-\frac{1}{2}-y,-z$.

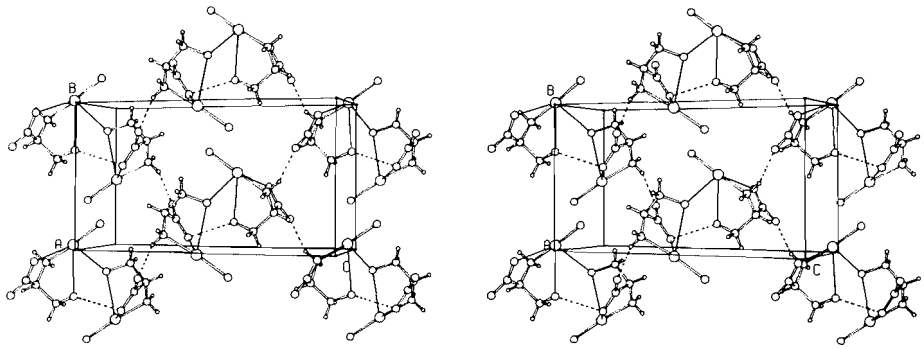

FIG. 2. Stereo view of the unit cell of CH_3Hg(L-serine) down the *a* axis. Atoms can be identified from Fig. 1. Full lines correspond to Hg...O contacts and dottted lines to hydrogen bonds.

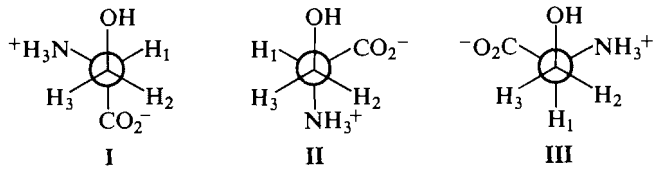

in several chelates (12, 13, 15–17), sometimes in the presence of a second chelate ring with conformation **III**. The only example of conformation **II** is found in Zn(L-ser)$_2$ (7) for the ligand providing chain propagation in the polymeric structure: this serine forms an O/N chelate with one Zn atom and uses the other carboxylate oxygen to strongly coordinate to a nearby Zn atom, whereas the —OH group is weakly interacting with the latter Zn atom, as mentioned above. These constraints probably force an atypical conformation in the amino acid.

The present CH_3Hg(L-ser) complex adopts conformation **III**, with N(2)—C(3)—C(4)—O(8) and C(5)—C(3)—C(4)—O(8) angles of 70.0(9)° and −49.9(9)°, respectively. However, this time, the preference for conformation **III** probably originates mainly from intramolecular Hg...O interactions.

Deviation from planarity in the N—C—CO_2 backbone remains within 2° in uncoordinated serine (9–11). In chelates, coordination introduces a twist about the C—C bond, generally increasing the N—C—C=O torsion angle to the 19–24° range (7, 14–17), although extreme values of 7° (12) and 42° (13) have been noted. The CH_3Hg(L-ser) complex lies in the normal region, with a N(2)—C(3)—C(5)—O(6) angle of −21(1)°.

Vibrational spectroscopy

The spectra of DL-serine and five deuterated derivatives have been empirically assigned by Madec, Lauransan, and Garrigou-Lagrange (18). Those of L-serine and its ND_3/OD derivative have also been reported by the same group, who briefly commented on the differences compared to the racemic material (19). Our results for L-serine and L-serine-d_4 are in good agreement with those reported by these authors.[1] On the basis of a normal coordinate analysis, Machida, Izumi, and Kagayama (20) have proposed for DL-serine assignments which have been recently reexamined and generally confirmed by Susi and co-workers (21). The approximate assignments used for the L-isomer have been directly transferred from the interpretation of Machida *et al.* for the DL-isomer (20), with only a few changes. These authors assigned a band at 1249 cm^{-1} to the δ(OH) mode for DL-serine. However, since this band for

[a]Abbreviations: v,very; s, strong; m, medium; w, weak; b, broad; sh, shoulder. Vibration types: ν, stretching; ∂, bending; ρ, rocking; ω, wagging; τ, twisting, t, torsion; s, symmetric; a, antisymmetric.

L-serine is not removed, but simply shifted from 1246 to 1265 cm^{-1} on deuteration, we assigned it to the $\omega(CH_2)$ vibration, which was assumed to coincide with the a $\rho(NH_3^+)$ vibration at 1176 cm^{-1} for DL-serine. The broad feature at 1216 cm^{-1} for L-serine , removed by deuteration, would then correspond to the δ(OH) mode, as proposed by Madec *et al.* (19). The δ(OD) vibration could correspond to one of the components, probably the first, of the pair of weak infrared bands at 875 and 838 cm^{-1}, the other component being due to a $\rho(ND_3^+)$ motion.

The wavenumbers for the (CH_3Hg)(L-ser) complex are listed in Table 4. Figures of the spectra are part of the supplementary material.[1] The assignments are largely based on the normal coordinate analysis carried out on the Cu(II) and Zn(II) complexes of DL-serine by Machida *et al.* (22).

The presence of the CH_3Hg^+ group in the compound is evidenced from the characteristic bands at 2928 (ir,R,υ), 1210 (ir,R,δ), and 790 cm^{-1} (ir,ρ) of the Hg-bonded methyl group (1, 2). The υ(Hg—CH_3) and υ(Hg—N) modes produce very strong Raman bands at 560 and 476 cm^{-1}, respectively, that is the

same positions as for CH_3Hg(gly) and CH_3Hg(L-ala) in solution (1). It is noteworthy that the υ(Hg—N) mode undergoes a $-20\,cm^{-1}$ shift upon deuteration. A similar effect has been noted for the CH_3Hg^+ complexes with methionine (5).

In the CH_3Hg(L-ser) complex, one of the NH_3^+ protons is replaced by a CH_3Hg^+ group. Accordingly, the high frequency υ(N—H) massif of L-serine is shifted upward by complexation as usual (22, 23). The NH_3^+ deformation modes at 1639, 1620, 1500 (δ), 1181, and 1130 (ρ) cm^{-1} are replaced by vibrations of the coordinated NH_2 group. The $\delta(NH_2)$ and $\upsilon_a(CO_2^-)$ modes both contribute to the strong infrared peak at $1600\,cm^{-1}$. The $\delta(ND_2)$ counterpart probably gives rise to the weaker infrared feature at $1193\,cm^{-1}$ in the spectrum of the N,O–d_3 derivative. The $\omega(NH_2)$ band is observed at $1164\,cm^{-1}$ and shifted to $829\,cm^{-1}$ by deuteration. This mode occurs at the same position for various serine chelates (22, 23).

No individual band can be assigned to the $\tau(NH_2)$ mode, but it likely contributes to the strong bands in the $1250–1390\,cm^{-1}$ region by coupling with the $\delta(CH_2)$ and δ(CH) motions, as indicated by Machida *et al.* (22). Evidence for this comes from the disappearance of one of the strong bands in this region upon deuteration, and from the presence of a broad low-wavenumber shoulder at ca. $930\,cm^{-1}$, assigned to $\tau(ND_2)$ mode, which would correspond to an ideally uncoupled $\tau(NH_2)$ mode at $1300\,cm^{-1}$. The $\rho(NH_2)$ band could not be identified with certainty, but it could contribute to the very broad infrared absorption between 600 and $700\,cm^{-1}$, which is removed by deuteration.

The crystal structure shows that the coordinated ligand adopts a conformation favoring the formation of a moderately strong secondary Hg—O bond with the hydroxylic oxygen. This does not appreciably affect the δ(OH) vibration, but the low-frequency torsion mode of the free ligand has become a genuine γ(OH) deformation mode, which should now occur at a much higher wavenumber. For instance, in solid ethanol, it is observed at $\sim 660\,cm^{-1}$ (24). It is likely that the γ(OH) mode of the complex contributes to the broad infrared absorption at $600–700\,cm^{-1}$ mentioned above.

The υ_a and υ_s carboxylate vibrations are not appreciably shifted from their positions in the free ligand, which was anticipated since this group is not involved in the primary coordination of mercury. The ρ, ω, and δ modes, which are usually more sensitive to hydrogen bonding and Hg...carboxyl contacts, are affected to a greater extent.

Nuclear magnetic resonance spectroscopy

Figure 3*a* shows the ^{1}H nmr spectrum of L-serine. Inequivalence of the methylene protons (H_2 and H_3) produces an ABX multiplet for the CH_2—CH fragment. The coupling constants and chemical shifts were refined by spectral simulation using the spectrum analysis program PANIC (25). The refined data given in Table 5 are similar to those reported earlier (26).

The ^{1}H nmr spectrum of the methylmercury complex (Fig. 3*b*) shows a CH_3Hg^+ signals at 0.87 ppm, accompanied by a pair of satellites resulting from coupling with ^{199}Hg (17% natural abundance). the $^2J(^{199}Hg—^1H)$ coupling constant of 216 Hz is common for complexation to nitrogen in amino acids (27). Displacement of an amino hydrogen by the less electron-attracting mercury produces a downfield shift of 0.31 ppm for the methine (H_1) signal, while protons H_2 and H_3 are not greatly affected. However, the slight upfield shift (−0.09 ppm) of one of these two protons increases the signal separation which turns the L-serine ABX spectrum into an AMX pattern. With glycine and alanine, methylmercury complexation gave similar shifts:

TABLE 6. Populations of the rotational isomers for serine and its methylmercury complex

Compound	P_I	P_{II}	P_{III}
L-ser	0.28	0.16	0.56
CH_3Hg(L-ser)	0.07	0.17	0.76

the methylene protons of glycine were downfield shifted by 0.14 ppm, the methine proton of alanine by 0.41 ppm, while its methyl protons were not affected (1).

The vicinal coupling constants $^3J(H_1—H_2)$ and $^3J(H_1—H_3)$ provide information on the conformation of the molecule (28, 29). Serine has three possible rotational isomers whose Newman projection down the CH—CH_2 bond are shown in structures **I** to **III**.

To each rotamer corresponds a set of $^3J(H_1—H_2)$ and $^3J(H_1—H_3)$ coupling constants reflecting its conformation. However, rotation about the CH—CH_2OH bond is fast on the nmr time scale, so that the observed coupling constants are averaged over the three rotamers. The weighted average values are given by eq. [1] and [2],

$$[1] \quad {}^3J(H_1—H_2) = P_I J_g + P_{II} J_t + P_{III} J_g$$

$$[2] \quad {}^3J(H_1—H_3) = P_I J_t + P_{II} J_g + P_{III} J_g$$

where $^3J(H_1—H_2)$ and $^3J(H_1—H_3)$ are the observed coupling constants, J_g and J_t are the coupling constants corresponding to *gauche* and *trans* interactions, respectively, and P_i is the fractional population of rotamer i.

With $(P_I + P_{II} + P_{III})$ normalized to unity, eq. [1] and [2] become:

$$[3] \quad P_I = [{}^3J(H_1—H_3) - J_g] \,/\, (J_t - J_g)$$

$$[4] \quad P_{II} = [{}^3J(H_1—H_2) - J_g] \,/\, (J_t - J_g)$$

$$[5] \quad P_{III} = 1 - P_I - P_{II}$$

However, to use these equations, unambiguous assignment of the H_2 and H_3 signals is a prerequisite. This can be achieved by using the ^3J(C—H) vicinal coupling constants between the carboxylate carbon and the CH_2 protons. These coupling constants are also weighted averages over the three conformations:

$$[6] \quad {}^3J(C—H_2) = P_I J_g + P_{II} J_g + P_{III} J_t$$

$$[7] \quad {}^3J(C—H_3) = P_I J_g + P_{II} J_t + P_{III} J_g$$

The following set of equations, where J_g and J_t now represent ^3J(C—H) constants, can be deduced as above:

$$[8] \quad P_{II} = [{}^3J(C—H_3) - J_g]/(J_t - J_g)$$

$$[9] \quad P_{III} = [{}^3J(C—H_2) - J_g]/(J_t - J_g)$$

$$[10] \quad P_I = 1 - P_{II} - P_{III}$$

From the experimental ^3J(H—H) coupling constants and eqs [3] and [4], two sets of P_I, P_{II}, and P_{III} values can be calculated, depending on the assignments for H_2 and H_3. In a same way, the ^3J(C—H) coupling constants and eqs [8] and [9] give two sets of populations, one of which must coincide with one of those obtained from ^{1}H spectrum. From this common set, ambiguity is removed. This method has been applied to several amino acids, including serine (30).

From the observed values of $^3J(H_1—H_2)$ and $^3J(H_1—H_3)$ of Table 5, the populations of Table 6 were calculated, assuming the J_t and J_g values (13.3 and 2.4 Hz for H—H, 10.0 and 1.2 Hz for C—H) proposed by Martin (11).

According to Ogura *et al.* (32), **III** is the major conformation of serine over the whole pH range. Interestingly, this is also the conformation observed in the solid state by X-ray diffraction (9–11). From our results (Table 5), we calculate that **III** accounts for 56% of free serine in solution. For CH_3Hg(L-ser), the population of **III** raises to 76% at the expense of rotamer **I**, whose population decreases from 28% to 7%. Therefore, the conformer observed in the crystal structure described above remains by far the most important contributor in solution.

Concluding remarks

The CH_3Hg^+ cation binds to the NH_2 group of serine as it generally does with amino acids. The Hg...O secondary bond with a carboxylate oxygen observed in the crystal structure also occurs commonly. In this serine complex, the —OH group is suitably oriented to form an extra intramolecular Hg...O secondary bond, thereby leading to tridentate binding. In order for the three coordinating interactions to take place simultaneously, serine must adopt conformation **III**, in which the three donor atoms occupy the same region of space and can cluster around Hg.

Conformation **III** is already the most populated (56%) in aqueous solutions of free serine. Its contribution is raised to 76% for the CH_3Hg(L-ser) complex. Stabilization of this conformer probably originates mainly in the Hg...O contacts. Besides the contribution to cohesion due to the contacts themselves, the chelate effect provides a favorable contribution to the tridentate coordination. However, the Hg...O contacts are not strong to the point that the molecule is frozen in conformation **III** exclusively. Disruption of the Hg...O contacts can probably be balanced to some extent by hydration: Hg...OH_2 contacts could be acceptable alternatives to those formed with serine, whereas hydrogen bonding with water could satisfy the residual basicity of the —OH and —CO_2^- groups. Nevertheless, the overall effect observed in this work is a definite enrichment in the conformer **III** observed in the crystal, and it is clear that the orientation of the —CH_2OH side chain is affected by the presence of coordinated mercury.

Received September 24, 1987

HAMDI M. HASSANEEN, HIYAM A. H. MOUSA, SALEH T. EZMIRLY, and AHMAD S. SHAWALI. Can. J. Chem. **66**, 1386 (1988).

The cycloaddition of nitrilimines **1***a–e* to ethyl α-cyanocinnamate **6***a* furnished the 2-pyrazoline derivatives **11***a–e* respectively. Similar reactions of **1***a–e* with ethyl α-cyano-*p*-nitrocinnamate **6***b* yielded 1,3-disubstituted 4-(*p*-nitrophenyl)-5-ethoxycarbonylpyrazoles **14***a–e*, via elimination of hydrogen cyanide from their precursors, the 2-pyrazoline derivatives **13***a–e*, respectively. The structures of the cycloadducts **11** and **14** were supported by spectral (^{13}C and ^{1}H nuclear magnetic resonance and infrared) and analytical data.

HAMDI M. HASSANEEN, HIYAM A. H. MOUSA, SALEH T. EZMIRLY et AHMAD S. SHAWALI. Can. J. Chem. **66**, 1386 (1988).

Le cycloaddition des nitrilimines **1***a–e* sur l'α-cyanocinnamate d'éthyle (**6***a*) conduit aux divers dérivés **11***a–e* de la pyrazoline-2. Des réactions semblables entre les composés **1***a–e* et l'α-cyano *p*-nitrocinnamate d'éthyle (**6***b*) conduisent aux (*p*-nitrophényl)-4 éthoxycarbonyl-5 pyrazoles disubstitués **14***a–e*, par le biais de l'élimination de cyanure d'hydrogène à partir des dérivés pyrazolines-2 (**13***a–e*) qui sont leurs précurseurs. On a déduit les structures des cycloadduits **11** et **14** en se basant sur leurs spectres (résonance magnétique nucléaire du ^{13}C et du ^{1}H ainsi que infrarouge) et sur des données analytiques.

[Traduit par la revue]

Introduction

Nitrilimines **1***a–f* are well-known 1,3-dipoles and their reactions with a variety of mono- and di-substituted ethylenes **2–4** have been extensively investigated (1). However, reactions of **1** with trisubstituted ethylenes **5** have received little if any attention (2, 3). Here we wish to report the results of the study of the cycloadditions of ethyl α-cyanocinnamate **6***a* and its *p*-nitro derivative **6***b* with nitrilimines **1***a–e* (Scheme 1). Our aim in studying the dipolarophilicity of **6** was to explore the effect of the α-cyano group on the regiochemistry of the cycloaddition of ethyl cinnamate **7**. The reactions of the latter ester with diphenylnitrilimine **1***a* (3) and with *N*-phenyltrifluoroacetonitrilimine **1***f* (4) yielded, in each case, a mixture of the two possible isomers **9** and **10** (Scheme 2).

Results and discussion

The reactions of nitrilimines **1***a–e*, generated *in situ* by treatment of the corresponding hydrazidoyl halides **8***a–e* with triethylamine, with **6***a* were carried out in refluxing chloroform. Thin-layer chromatographic analysis of the reaction mixture on silica gel with a mixture of carbon tetrachloride and chloroform (5:1.5 v/v) as eluent showed the formation of only one product. This was confirmed by ^{1}H nmr analysis of the crude reaction product, in which only one methine singlet signal was observed. These findings indicate that the reactions studied are regiospecific, yielding one of the two possible regioisomers **11** or **12** (Scheme 3). The structures of the cycloadducts were assigned on the basis of their spectral (ir, ^{13}C nmr, and ^{1}H nmr) and elemental analyses (Tables 1–3). The distinction between the two structures **11** and **12** was made on the basis of the nitrile absorption in the infrared spectra. Aliphatic nitriles activated by a nitrogen or an oxygen atom in the α-position (4, 10), such as the 5-cyano-2-pyrazoline derivatives, exhibit no nitrile absorption in their infrared spectra (11). On the other hand, the nitrile group in the 4-cyano-substituted 2-pyrazoline and pyrazole derivatives is ir active, showing a strong band in the 2100–2400 cm^{-1} region (12). In the infrared spectra of the products isolated from the reaction of **1***a–e* with **6***a* the nitrile absorption was absent. Therefore they were assigned the 5-cyano-5-ethoxycarbonyl-substituted 2-pyrazoline structure **11**. This assignment is supported by ^{13}C nmr spectra (5). For example, compounds **11***a–e* showed four characteristic lines assignable to C-3(s, δ141.1–142.6), C-4 (d, δ62.1–64.5), C-5 (s, δ71.1–74.0), and CN (s, δ211.6) ppm (Table 2). The ^{1}H nmr spectra of the cycloadducts showed, in each case, one characteristic singlet near δ5.0 ppm assignable to the methine proton at the 4-position in **11**. The methine chemical shift at the 5-position in **12** is expected to appear at lower field (13). Attempts to prepare an authentic sample of **12** for comparison purposes failed, however.

The reaction of ethyl α-cyano-*p*-nitrocinnamate **6***b* with **1***a–e* under the same conditions proceeded to give 4-(*p*-nitrophenyl)-5-ethoxycarbonyl-1,3-disubstituted pyrazoles **14***a–e* respectively (Table 3). The latter products undoubtedly resulted via thermal elimination of hydrogen cyanide from the corresponding cycloadducts **13***a–e* (Scheme 4). The assigned structures **14***a–e* were supported by analytical and spectral data (Tables 1–3). In the ^{1}H nmr spectra, the products **14***a–e* showed no signals due to 4-H or 5-H characteristic of 2-pyrazoline derivatives (6). In the ir spectra, the products **14***a–e* revealed in each case a strong absorption band near 1720 cm^{-1} due to an α,β-unsaturated ester carbonyl group (Table 1). The ^{13}C nmr spectra of **14***a–e*, while revealing the absence of nitrile carbon, had three characteristic lines near δ 140.2–147.0 (s), 131.3–131.7 (s), 138.7–140.0 (s) ppm assignable to C-3, C-4, and C-5 atoms of the pyrazole ring, respectively (Table 2) (5).

These results indicate that ethyl α-cyanocinnamates **6***a–b*, unlike ethyl cinnamate **12**, react with nitrilimines **1***a–e* regiospecifically in each case. These results may be interpreted by HOMO–LUMO interaction of **1** and dipolarophile **6** (7). The α-cyano group, being electron withdrawing, tends to lower the HOMO and LUMO energies, particularly the LUMO energy in this case, thus causing greater dipole (HOMO) – dipolarophile

(LUMO) control of orientation (8). Furthermore, the α-cyano group decreases the LUMO coefficient at the site of attachment (8) so that the difference between the LUMO coefficients of the α- and β-carbon atoms becomes larger in **6** than in **7**. Consequently, the largest bonding interaction in the transition state arises between the carbon atom of the nitrilimine **1** and the β-carbon atom of **6**, thereby leading exclusively to the formation of the cycloadducts **11** and **13**.

Regarding the mechanism of elimination of hydrogen cyanide from **13** to give **14**, it is difficult to say anything conclusively except that it is similar to thermal elimination of hydrazoic acid from 1,3,4-triphenyl-5-benzoyl-5-azido-2-pyrazoline (2). The observation that such elimination occurs easily from **13** and not from **11** seems to be due to the higher acidity of the 4-H in **13**.

[a]All compounds exhibited aromatic proton multiplet signals in the region 7.0 – 8.4 ppm.
[b]The value of coupling constant *J* for the triplet (t) and the quartet (q) signals is 7 Hz.

Experimental

All melting points were measured on a Bockmonoscop hot-stage type melting point apparatus and are uncorrected. The infrared spectra were recorded in potassium bromide on a Zeiss infrared spectrophotometer model IMT16. The ^{1}H nmr spectra were obtained in deuterated chloroform with a Varian EM-390 90-MHz spectrometer. The ^{13}C nmr spectra were obtained from 1 M deuterated chloroform solutions on a JEOL JNM FX 100 spectrometer using tetramethylsilane as internal reference. Microanalyses were performed on a Perkin Elmer elemental analyzer model 240-B at the microanalytical laboratory of King Abdulaziz University. The hydrazidoyl halides **1***a–e* (1) and the dipolarophiles **6***a–b* (9) were prepared as described in the literature.

*1-Aryl-3-*R*-4-phenyl-5-cyano-5-ethoxycarbonyl-2-pyrazolines***11***a–e. General method*

To a stirred solution of the appropriate hydrazidoyl halide **1** (5 mmol) and ethyl α-cyanocinnamate **6***a* (5 mmol) in chloroform (40 mL) was added triethylamine (0.7 mL, 5 mmol) at room temperature. The mixture was then refluxed for 10–12 h and cooled. The reaction mixture was washed three times with water, and the organic layer was collected, dried over anhydrous sodium sulfate, and then filtered. The solvent was evaporated under reduced pressure and the residue was triturated with a little methanol, whereupon it solidified. The crude

Nuclear analogs of β-lactam antibiotics. Synthesis of 6,6-disubstituted acylaminopenems[1]

JACQUES BANVILLE,[2] PHILIPPE LAPOINTE, BERNARD BELLEAU,[3] AND MARCEL MENARD

Antiinfective Chemistry Department, Pharmaceutical Research and Development Division, Bristol–Myers Co., 100 Industrial Blvd., Candiac, P.Q., Canada J5R 1J1

Received October 2, 1987

JACQUES BANVILLE, PHILIPPE LAPOINTE, BERNARD BELLEAU, and MARCEL MENARD. Can. J. Chem. **66**, 1390 (1988).

The preparation of 6α-methyl-2-methyl-6β-phenoxyacetamidopenem-3-carboxylate, 6α-methoxy-2-methyl-6β-phenoxyacetamidopenem-3-carboxylate, and 6α-methoxy-2-methyl-6β-phenylmalonylamidopenem-3-carboxylate from penicillin V and 6-aminopenicillanic acid is described. These penems have been isolated and characterized as their sodium or potassium salt. The chemical stability of the above compounds was determined as their half-life in aqueous buffer. In this way, it was found that the 6α-methyl analog was more stable than the parent 6-monosubstituted acylaminopenem while the remaining analogs were of comparable stability.

JACQUES BANVILLE, PHILIPPE LAPOINTE, BERNARD BELLEAU et MARCEL MENARD. Can. J. Chem. **66**, 1390 (1988).

On décrit la préparation du méthyl-6α méthyl-2 phénoxyacétamido-6β pénemcarboxylate-3, du méthoxy-6α méthyl-2 phénoxyacétamido-6β pénemcarboxylate-3 et du méthoxy-6α méthyl-2 phénylmalonylamido-6β carboxylate-3 à partir de la pénicilline V et de l'acide amino-6 pénicillanique. Ces pénems ont été isolés et caractérisés sous forme de sels de sodium ou de potassium. La demi-vie de ces produits dans un tampon aqueux indique leur stabilité chimique. On a trouvé, de cette façon, que l'analogue méthyl-6α est plus stable que l'acylaminopénem monosubstitué en position 6 tandis que les deux autres analogues ont une stabilité comparable.

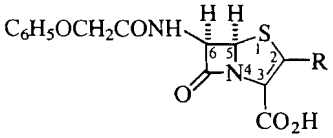
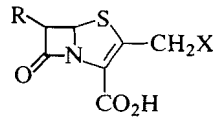
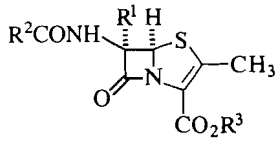
The first penems to be synthesized by Woodward and co-workers (1) were acylaminopenem-3-carboxylic acids of the type **1** (R = H, Me, Ph). These compounds were found to be quite unstable and had little antibacterial activity. Since the 6-unsubstituted penems **2***a* (2) and especially the penems **2***b* (3) having the 6-hydroxyethyl substitution of thienamicin (4) were chemically more stable and had a more interesting spectrum of biological activity, little attention has been given to the preparation of 6-acylamino penems. It has been shown that the introduction of a substituent, especially a methoxyl group, at the 6 or 7 position of, respectively, a penicillin or a cephalosporin results in an improvement in the chemical and enzymatic stability (3*b*). To see what effect a 6-substituent would have on the stability and activity of a 6-acylamino penem, we undertook the synthesis of penems **3***a* and **3***b*. As well, the effects of different acyl groups in the 6-acylamino side chain (**3***c*) were examined. When we initiated this study, none of these products had been reported in the literature. Recently, though, the preparation of the protected 6α-methoxy-2-methyl-6β-phenoxyacetamido penem-3-carboxylate **16** has been described (5). However, in this case, the corresponding deprotected penem could not be obtained. We were able to prepare and characterize the deprotected 6,6-disubstituted penems **3***a*, **3***b*, and **3***c*, using Woodward's approach (1) for the preparation of 6-acylamino penems from penicillin V.



1



2 *a*, R = H
b, R = CH_3CHOH (*trans R*)



3 *a*, $R^1 = CH_3$, $R^2 = C_6H_5OCH_2$, R^3 = Na or K
b, $R^1 = OCH_3$, $R^2 = C_6H_5OCH_2$, R^3 = Na
c, $R^1 = OCH_3$, $R^2 = C_6H_5CHCO_2Na$, R^3 = Na

The first compound to be prepared by the above mentioned approach was the 6α-methyl-2-methyl-6β-phenoxyacetamido-penem-3-carboxylate **3***a*. In the case of penicillin, the introduction of an α-methyl group had a marked effect on the chemical stability of the β-lactam ring (6). The rate of the basic hydrolysis of 6-methyl-penicillin V methyl ester is four times slower than the unsubstituted compound.

The presence of the α-methyl group did not introduce a major problem, since the configuration at positions 5 and 6 of the penicillin nucleus is the same in the penem. The introduction of a 6α-alkyl substituent via a Schiff base is a well-documented process in penicillin chemistry (6, 7) and we used this approach. First, *N*-benzylidene-6-aminopenicillanic acid **4***a* (7*a*) was protected as its methyl ester **4***b* by treatment with diazomethane. Then, to introduce the 6-methyl group, we found Bohme's procedure (6) (potassium *tert*-butoxide, methyl iodide) to be the most satisfactory. Removal of the benzylidene group from **4***c* by exchange with 2,4-DNPH·TSOH in ethanol (7*c*) followed by acylation with phenoxyacetyl chloride gave the acylated compound **5***a* in a 59% yield from **5***c*. This compares favorably with the results of Dolfini and co-workers (6) who reported a 23% yield of acylated material by direct acylation of the Schiff base. The next step required oxidation of the sulfur of the thiazolidine ring and subsequent opening of this ring. Oxidation of **5***a* with *m*-chloroperbenzoic acid gave in high yield (90%) the two isomeric sulfoxides **5***b* and **5***c* (ratio 76:24 respectively) and these were separated by chromatography. Based on previous proton nmr studies (8) of penicillin "*R*" and "*S*" sulfoxides, the major isomer **5***b* was assigned the *S* stereochemistry and

the minor, more polar, isomer **5***c* the *R* stereochemistry. Specifically, a downfield shift for the proton at position 3 due to a "*syn*-axial" effect (8*c*) is observed in the case of *S* isomer **5***b* (Table 1). Also, as has been noted by Barton for the 6-monosubstituted sulfoxides, the H-5 proton in both 6-disubstituted sulfoxides shows an upfield shift that is greater in the case of the *R* isomer. The latter upfield shift was attributed to shielding brought about by a *trans* orientation of the H-5 proton with respect to the lone pair of the sulfur atom.

We found that the two isomeric sulfoxides, **5***b* and **5***c*, behaved differently when subjected to ring-opening conditions (acetic anhydride, trimethylphosphite (9)). The major *S* isomer **5***b* reacted more slowly (105°C, 10 h) than the *R* isomer **5***c* and gave, after isomerization of the butenoate double bond with triethylamine, the thioester **6***a* in less than 30% yield. The main product isolated from this reaction was the thiazoline **7**. However, when the *R* sulfoxide **5***c* was subjected to the same conditions, the rearrangement was complete in 2 h and **6***a* was obtained in a 45% yield after isomerization. In this case, the thiazoline **7** was formed in trace amounts only.

To increase the proportion of the *R* sulfoxide **5***c* in the oxidation of **5***a*, different oxidizing agents were examined (Table 2). When sodium periodate was used, the ratio of *R* to *S* was lowered to 17:83. However, when the oxidation was conducted with ozone in a mixture of acetone and water (10), the *R* sulfoxide **5***c* predominated (ratio *R*:*S* > 95:5 by ^{1}Hmr). Steric effects direct the approach of the ozone molecule, and the α-methyl group seems to enhance this effect.

The butenoate **6***a* was then cleaved with ozone and the resulting alkoxalyl derivative **6***b* treated with methanol to give the azetidinone **8** in a 50% yield from **6***a*. The phosphorane **6***c* was obtained using Woodward's original procedure. Reaction of **8** with *p*-nitrobenzyl glyoxylate afforded a diastereomeric mixture of hemiaminals **9***a*, which, upon successive treatment with thionyl chloride and triphenyl phosphine, gave the phosphorane **6***c* in a 45% overall yield from **8**. Upon being heated in toluene at 100°C for 48 h, the phosphorane **6***c* was smoothly converted to the penem **10** in a 72% yield after chromatography.

penems at 297 nm, and the absorption of 1770 cm^{-1} in the infrared spectrum is characteristic of a strained β-lactam.

The 6-methoxy penem **3***b* was obtained by a route similar to that described for the 6-methyl penem. Numerous methods for the introduction of a 6β or a 7β methoxy substituent into, respectively, a penicillin or a cephalosporin have been described (11). In this case, the 6-methoxy penicillins **11***a* and **11***c* were chosen as starting materials. The two 6β-methoxy sulfoxides **11***b* (42%) and **11***d* (12) (71%), were readily obtained via the procedure of Koppel and Koehler (13). Opening of the thiazoline ring of **11***b* and **11***d* followed by isomerization under basic conditions gave the two azetidinones **12***a* (60%) and **12***b* (55%). These were then treated with ozone to give the respective alkoxalyl derivatives, **12***c*, (97%) and **12***d* (85%). Methanolysis of the alkoxalyl derivative **12***c* under neutral conditions gave only traces of the desired azetidinone **13**. The major product that was obtained was the ring-opened product **14**. Even methanolysis at −20°C in the presence of a catalytic amount of triethylamine resulted in opening of the β-lactam ring. However, in the presence of aqueous acid (THF, 1 N HCl), **12***c* was slowly converted to the azetidinone **13** (40% completion after 8 h; evaluated by ^{1}Hmr) and the latter could be isolated in a 36% yield.

A more convenient route to the hemiaminal **15***a* was by the direct reduction of the alkoxalyl **12***c* with diborane (1). Treatment of **15***a* with thionyl chloride and pyridine followed by triphenylphosphine and 2,6-lutidine gave the phosphorane **12***e* in 12% overall yield from **12***b*. Cyclization of **12***e* was effected by heating in toluene to give the crystalline penem **16** in a 55% yield. Hydrogenolysis of the *p*-nitrobenzyl ester **16** was conducted as before to give the deprotected penem **3***b* (61%). This material was purified by chromatography on reversed phase silica gel and the lyophilized, amorphous product showed reasonable stability at room temperature. Its ultraviolet (297 nm) and infrared (1759 cm^{-1}) spectra are consistent with the proposed structure.

We were also interested in the effect produced by varying the acylamino substituents of those penems. The combination of a methoxyl group with an α-carboxythienyl-acetamido group (as in temocillin) or various arylmalonylamino groups at position 6 of penicillins results in compounds that have very interesting antibacterial activity (11*a*, pp. 326–364; 14). However, because the thienyl moiety was not compatible with the ozonolysis step in our synthetic scheme, we undertook the preparation of the 6α-methoxy-6-phenylmalonylamidopenem **3***c*.

Our first approach to the preparation of **3***c* was to take advantage of the various intermediates that had been generated in the synthesis of the phenoxyacetamido penem **3***b*. Direct cleavage of the acylamino side chain followed by introduction of the desired acyl group was not examined because racemization problems at position 7 were encountered when this was attempted in the case of the cephamycins (15). The possibility of trans-acylation was examined. However, attempts to convert **12***b* into its diacylated derivative by treatment of this material with an acid chloride in presence of an acid scavenger (16) were not successful. Accordingly, introduction of the phenylmalonyl group at an earlier stage of the synthesis was examined.

The possible introduction of the desired acyl side chain via a sulfenimine intermediate as described by Gordon *et al.* (17) was then examined. Indeed, reaction of the sulfenimine **17** with triphenylphosphine and mercuric acetate in methanol followed by acylation with phenylmalonyl chloride mono-*p*-nitrobenzyl ester gave **18** (63%). Oxidation of **18** with *m*-chloroperbenzoic acid gave the two isomeric sulfoxides **19***a* and **19***b* in a 19:9 ratio (93%). The two sulfoxides were also a mixture of epimers at the malonyl center.

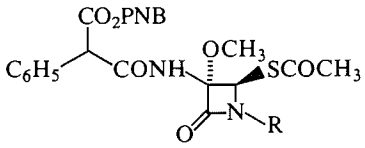
b, $n = 1$, β-sulfoxide



20 *a*, R = $COCO_2PNB$
b, R = H
c, R = $CHOHCO_2PNB$

The oxalimide **20***a* and the azetidinone **20***b* could be obtained in a similar manner to that described for the preparation of the phenoxyacetamido derivative **13**. However, all subsequent attempts to obtain the phosphorane analog of **12***e* were unsuccessful. That is, reduction of the oxalimide **20***a* to **20***c* ($NaBH_4$–AcOH (18), since diborane reduction did not work in this case), followed by reaction with thionyl chloride and triphenylphosphine, only resulted in the formation of decomposition products no longer containing a β-lactam ring. Furthermore, the hemiaminal **20***c* could not be obtained by reaction of **20***b* with *p*-nitrobenzyl glyoxylate due to the instability of the β-lactam ring under the reaction conditions.

We then turned to examining alternative methods for the preparation of the penem nucleus. After considering the available methods (19), Betty's procedure involving 1,5 ring closure (20) of the penem by nucleophilic attack of sulfur at C-4 of an azetidinone was considered most promising. This method required the specific formation of the 4α-chloroazetidinone **24**, which should then be closed to the penem having the correct stereochemistry at position 5.

Heating the mixture of sulfoxides **19***a* and **19***b* with 2-mercaptobenzothiazole gave the disulfide **21** (Scheme 1). Ozonolysis of the terminal olefin gave the enol **22**, which was then treated with triphenylphosphine to form the oxazoline **23***a*. This product was more easily purified as the mesylate **23***b*, which was obtained in a 39% overall yield from **19**. Ring opening of the oxazoline with hydrochloric acid gave only one product, the α-chloroazetidinone **24** in 48% yield. Attack by the chloride ion on the less encumbered α face of the oxazoline results in the formation of the α-chloro isomer.

Reaction of this chloroazetidinone **24** with hydrogen sulfide and triethylamine gave the penem **25** in a low yield (25%). This penem, like most of the intermediates in this sequence, was relatively unstable on silica gel and was obtained contaminated with the degradation product, the thiazole **26***a*. Simultaneous deprotection of both ester groups by hydrogenolysis gave the penem **3***c* as its sodium salt (30% yield after chromatography on reversed phase silica gel). This product was also contaminated by the thiazole **26***b* (ratio of penem to thiazole, 75:25 by ^{1}Hmr). The malonyl penem was more unstable than the two that had been previously prepared and, even as a dry powder, underwent decomposition over the period of a few days. The carbonyl frequency of the β-lactam is at 1765 cm^{-1} and the proton nmr indicated a 1:1 mixture of epimers at the malonyl side chain.

The half-life in a pH 7.4 buffer solution at 37°C of the penems prepared above is a good indication of their chemical stability (3*a*). The parent 6-monosubstituted acylaminopenem **1** (R = CH_3) prepared by Woodward has a half-life of 1.5 h under these conditions. The 6α-methoxypenems **3***b* and **3***c* were comparable, having half-lives of 1.2 and 1.6 h respectively. Introduction of a 6α-methoxy group did not seem to have much of an effect on the stability of the penem. However, the 6α-methyl group did, since the 6α-methylpenem **3***a* had a half-life of 12 h under these conditions. This greater stability is also reflected in the ease with which this compound could be synthesized relative to the α-methoxy analogs. In vivo, all three penems **3***a*, **3***b*, and **3***c* showed only weak activity against Gram-positive and Gram-negative strains of bacteria.

on a Pye Unicam SP8-100 uv/vis spectrophotometer. The infrared spectra were recorded on a Perkin–Elmer 267 grating infrared spectrophotometer. Optical rotations were measured with a Perkin–Elmer model 141 polarimeter. The ^{1}H nuclear magnetic resonance spectra were taken with either a Varian EM-360 (60 MHz) or a Varian CFT-20 (80 MHz) nmr spectrometer. Tetramethylsilane was employed as the internal standard and chemical shifts were reported in parts per million (δ) relative to the internal standard. Tetrahydrofuran was freshly distilled from lithium aluminum hydride. Solvents were reagent grade and had been stored over molecular sieves (4Å) before use. *p*-Nitrobenzyl glyoxylate (21) was prepared from di-*p*-nitrobenzyl fumarate by ozonolysis (CH_2Cl_2, −78°C) followed by reduction with dimethyl sulfide (22). *p*-Nitrobenzyl 6-phenoxyacetamidopenicillanate-1-β-oxide **11***c* was obtained by esterification of the potassium salt of penicillin V with *p*-nitrobenzyl bromide followed by oxidation with *m*-chloroperbenzoic acid by a method similar to the one described by Baldwin and Abraham and co-workers (27). Column chromatography was carried out on silica gel (230–400 mesh, Merck) or on reversed phase silica gel (μ-Bondapak C_{18}, 55–105 μm, Waters) for the penem salts **3***a*, **3***b*, and **3***c*. Microanalyses were performed by Micro-Tech Laboratories, Skokie, Illinois, U.S.A. The half-lives of the penems **3***a*, **3***b*, and **3***c* were determined by uv at 37°C for 10^{-4} M solutions using the method of Woodward (3*a*).

Methyl N-*benzylidene-6-aminopenicillanate* (**4**b) (7*b*)

A suspension of *N*-benzylidene-6-aminopenicillanic acid (**4***a*) (7*a*) (108.0 g, 0.375 mol) in ether (2.1 L) was cooled to 5°C and treated dropwise with a cold solution of diazomethane (18 g, 0.43 mol, prepared from Diazald, Aldrich Chemical Co.) in ether (1.5 L). The solution obtained was then concentrated under vacuum and the residual solid was triturated with cold hexanes to give 102.7 g (86%) of the title material **4***b* as a white solid; ir (Nujol) ν_{max}: 1760 (C=O β-lactam), 1740 (CO ester), and 1635 (C=N) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 1.51 and 1.68 (2s, 2 × 3H, CH_3-2), 3.85 (s, 2H, CO_2CH_3-3), 4.43 (s, 1H, H-3), 5.37 (dd, J = 2 Hz, J = 4 Hz, 1H, H-6), 5.63 (d, J = 4 Hz, H-5), 7.3–7.9 (m, 5H, aromatic), and 8.65 (d, J = 2 Hz, 1H, CH=N) ppm.

Methyl N-*benzylidene-6-amino-6α-methylpenicillanate* (**4**c) (6)

A solution of methyl *N*-benzylidene-6-aminopenicillanate (**4***b*) (102.5 g, 0.32 mol) in dry 1,2-dimethoxyethane (1.4 L) was cooled to −40°C and treated with iodomethane (320 mL). Potassium *tert*-butoxide (36.3 g, 0.32 mol) was then added in portions over 5 min and the mixture was stirred at −40°C for 2 h. The red solution was then diluted with CH_2Cl_2 (2 L) and washed several times with water and brine. The organic phase was dried ($MgSO_4$) and evaporated to give 106 g (100%) of an oil, which solidified upon standing. This material was used as such for the next step: ir (Nujol) ν_{max}: 1765 (C=O β-lactam), 1750 (C=O ester), and 1635 (C=N) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 1.43 and 1.52 (2s, 2 × 3H, CH_3-2), 1.78 (s, 3H, CH_3-6), 3.77 (s, 3H, CO_2CH_3-3), 4.30 (s, 1H, H-3), 5.3 (s, 1H, H-5), 7.2–7.8 (m, 5H, aromatic), and 8.63 (s, 1H, CH=N) ppm.

Methyl 6α-methyl-6-phenoxyacetamidopenicillanate (**5**a)

A mixture of *p*-toluenesulfonic acid monohydrate (61.4 g, 0.32 mol) and finely ground 2,4-dinitrophenylhydrazine (75.8 g, containing 20% water) in anhydrous EtOH (1.4 L) was stirred at 22°C for 30 min. Then a solution of **4***c* (106.0 g, 0.32 mol) in EtOH (1 L) was added and the heterogenous mixture was stirred for 50 min. The solid formed was filtered and washed with EtOH. The filtrate and the washings were concentrated under vacuum to give a solid. Trituration with ether and filtration gave 127.7 g of the intermediate methyl 6α-methyl-6β-aminopenicillanate *p*-toluenesulfonate salt. The salt was dissolved in CH_2Cl_2 (1.4 L), cooled to 0°C, and treated successively with a solution of phenoxyacetyl chloride (60.5 g, 0.355 mol) in CH_2Cl_2 (0.5 L) and a solution of KH_2PO_4 (155 g) in cold water (1.4 L). The mixture was stirred vigorously for 30 min at 5°C, treated with pyridine (29 mL), and stirred for another 15 min. The organic phase was separated and the aqueous phase was extracted with CH_2Cl_2. The combined organic phases were washed with cold HCl (0.1 N), saturated $NaHCO_3$, and then brine. After drying (Na_2SO_4), evaporation of the solvent gave an oil, which was purified by filtration through a short pad of silica gel (500 g) followed by high-pressure liquid chromatography (hplc, Waters Associates Prep LC/system 500 using PrepPak-500/silica cartridges, elution CH_2Cl_2:EtOAc, 9:1). The title compound **5***a* was obtained as a pale yellow foam: 71.6 g (59%) (lit. (6) 23% by direct acylation of the Schiff base). The spectral data were in accordance with those already described.

Methyl 6α-methyl-6-phenoxyacetamidopenicillanate-1β- and -1α-oxide (**5**b *and* **5**c)

Method A: Oxidation with m-*chloroperbenzoic acid*

A solution of methyl 6α-methyl-6-phenoxyacetamidopenicillanate **5***a* (2.30 g, 6.1 mmol) in CH_2Cl_2 (30 mL) was cooled in an ice–water bath and treated dropwise with a solution of *m*-chloroperbenzoic acid (1.23 g of 85%, 6.1 mmol) in CH_2Cl_2 (15 mL). After 30 min at 5°C, the mixture was washed successively with cold 5% $NaHCO_3$, brine, and then dried ($MgSO_4$). The oil obtained after evaporation of the solvent was chromatographed on silica gel (100 g) using a mixture of toluene and ethyl acetate (gradient 8:2 to ethyl acetate). The β-sulfoxide **5***b* eluted first and was obtained as a white foam: 1.60 g (68%); $[\alpha]_D^{25}$ +284° (*c* 1.0, $CHCl_3$); ir (film) ν_{max}: 3300 (NH), 1780 (C=O β-lactam), 1750 (C=O ester), 1665 and 1520 (amide), and 1050 (S—O) cm^{-1}.

The more polar α-sulfoxide **5***c* was obtained as a solid, which was recrystallized from a mixture of ethyl acetate and hexanes to give 0.50 g (21%) of a white solid: mp 109–110°C; $[\alpha]_D^{25}$ +155° (*c* 1.0, $CHCl_3$); ir (KBr) ν_{max}: 3400 (NH), 1790 (C=O β-lactam), 1750 (C=O ester), 1670 and 1520 (amide), and 1050 (S—O) cm^{-1}. *Anal.* calcd. for $C_{18}H_{22}N_2O_6S$: C 54.81, H 5.62, N 7.10, S 8.13; found: C 54.63, H 5.57, N 7.55, S 8.10.

Method B: Oxidation with sodium metaperiodate

A solution of **5***a* (0.115 g, 0.3 mmol) in MeOH (1 mL) was cooled in an ice–water bath and treated with a solution of $NaIO_4$ (0.064 g, 0.30 mmol) in water (0.2 mL). The resulting mixture was slowly warmed up to 22°C and stirred for 18 h. The precipitate that formed was filtered and washed with MeOH. Evaporation of the filtrate gave the sulfoxide as a foam. The ^{1}Hmr of the crude product indicated that an 83:17 mixture of β- and α-sulfoxides had been obtained.

Method C: Oxidation with ozone

A solution of **5***a* (71.6 g, 0.189 mol) in a mixture of acetone–water (1:1, 1 L) was cooled to 0–5°C and treated with a stream of ozone until the starting material disappeared (tlc). The solution was then flushed with N_2 and extracted with CH_2Cl_2 (1 L). The aqueous phase was extracted twice with CH_2Cl_2 (100 mL) and then the combined organic phases washed successively with 3% aqueous sodium thiosulfate and brine. After drying (Na_2SO_4), evaporation of the solvent gave a solid that was triturated with hexanes to give 61.0 g (82%) of the α-sulfoxide **5***c*. The β-sulfoxide was not detected by ^{1}Hmr (60 MHz).

*Methyl α-(4*R*-acetylthio-3*R*-methyl-3-phenoxyacetamido-2-azetidinon-1-yl)-β-methylcrotonate* **6**a)

A. By rearrangement of the α-sulfoxide **5**c

A solution of methyl 6α-methyl-6-phenoxyacetamidopenicillanate 1α-oxide **5***c* (10.0 g, 25.4 mmol) in toluene (250 mL) was treated with acetic anhydride (20 mL, 0.21 mol) and trimethyl phosphite (9.25 g, 74.5 mmol) and then heated at 85°C for 3 h. The solvent and excess reagents were evaporated *in vacuo* and the last traces of reagents removed by coevaporation with toluene. The residual oil was diluted with ethyl acetate (100 mL), washed with water, cold 5% $NaHCO_3$, and brine, and dried ($MgSO_4$). The solution was concentrated to approximately 20 mL, cooled in an ice–water bath, and then treated with triethylamine (0.8 mL, 5.7 mmol). After 4 h at 0–5°C, the reaction mixture was diluted with ethyl acetate (100 mL), washed with cold 5% aqueous AcOH, 5% $NaHCO_3$, and brine, and dried ($MgSO_4$). The solvent was evaporated and the residue chromatographed on silica gel (400 g) using a mixture of CH_2Cl_2 and ethyl acetate (4:1) as eluent. The title material **6***a* was obtained as a clear oil: 4.80 g (45%); ir (film) ν_{max}: 1775 (C=O β-lactam), 1720 (sh C=O ester), 1690 (C=O amide and thioester), and 1520 (amide) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 1.76 (s, 3H, CH_3-3 of azetidinone), 2.16, 2.23, and 2.26

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

(3s, 3 × 3H, CH_3 of crotonate and $SCOCH_3$-4 of azetidinone), 3.81 (s, 3H, CO_2CH_3), 4.5 (s, 2H, CH_2 of phenoxyacetyl), 5.66 (s, 1H, H-4 of azetidinone), and 6.7–7.5 (m, 6H, aromatic and NH) ppm.

B. By rearrangement of the β-sulfoxide **5**b

A solution of the β-sulfoxide **5***b* (0.175 g, 0.44 mmol) in toluene (1.5 mL) was treated with trimethyl phosphite (0.15 mL) and acetic anhydride (0.27 mL) and heated at 105°C for 10 h. After work-up and isomerization as above, chromatography on silica gel gave 0.080 g (43%) of thiazoline **7** as an oil and 0.055 g (30%) of the thioester **6***a*. Thiazoline **7**: ir (film) ν_{max}: 1700 (C=O β-lactam), 1715 (C=O ester), 1650 and 1595 cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 1.56, 1.73, and 2.16 (3s, 3 × 3H, CH_3 of crotonate and CH_3-3 of azetidinone), 3.70 (s, 3H, CO_2CH_3), 4.7 (s, 2H, CH_2 of phenoxyacetyl), 5.70 (s, 1H, H-4 of azetidinone), and 6.8–7.3 (m, 5H, aromatic) ppm.

N-*Methoxalyl-4*R-*acetylthio-3*R-*methyl-3-phenoxyacetamido-2-azetidinone* **6**b

A solution of methyl α-(4*R*-acetylthio-3*R*-methyl-3-phenoxyacetamido-2-azetidinon-1-yl)-β-methylcrotonate **6***a* (4.20 g, 10.0 mmol) in a mixture of CH_2Cl_2 (100 mL) and MeOH (25 mL) was cooled to −25°C and treated with ozone until a light blue color persisted. The reaction mixture was then flushed with N_2, treated with methyl sulfide (2.5 mL), and allowed to warm up to 22°C. The mixture was diluted with CH_2Cl_2 (100 mL), washed successively with 3% aqueous sodium bisulfite and brine, and dried ($MgSO_4$). Evaporation of the solvent gave 4.0 g of the crude *N*-methoxalylazetidinone **6***b* as white foam. This product was used as such for the next step: ir (film) ν_{max}: 1815 and 1750 (C=O), 1700 (br, C=O ester, amide and thioester), and 1520 (C=O amide) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 1.80 (s, 3H, CH_3-3), 2.33 (s, 3H, $SCOCH_3$-4), 3.93 (s, 3H, CO_2CH_3), 4.56 (s, 2H, CH_2 of phenoxyacetyl), 5.80 (s, 1H, H-4), and 6.8–7.4 (m, 6H, NH and aromatic) ppm.

*4*R-*Acetylthio-3*R-*methyl-3-phenoxyacetamido-2-azetidinone* **8**

A solution of the crude *N*-methoxalyl azetidinone **6***b* (4.0 g) in a mixture of MeOH (300 mL), EtOAc (30 mL), and water (6 mL) was stirred at 22°C for 18 h. The solvent was then concentrated *in vacuo* and the residue was partitioned between EtOAc (150 mL) and water. The organic phase was dried ($MgSO_4$) and concentrated *in vacuo* to give a crude product that was chromatographed on silica gel (75 g). Elution with toluene–EtOAc (1:2) gave 1.53 g (50%) of the azetidinone **8** as a white solid. Recrystallization from EtOAc gave white needles: mp 118–119°C; $[\alpha]_D^{22}$ −20° (*c* 1.0, $CHCl_3$); ir (KBr) ν_{max}: 3320 (NH), 1780 (C=O β-lactam), 1680 and 1660 (C=O amide and thioester), and 1520 (C=O amide) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 1.77 (s, 3H, CH_3-3), 2.32 (s, 3H, $SCOCH_3$-4), 4.54 (s, 2H, CH_2 of phenoxyacetyl), 5.41 (s, 1H, H-4), 6.1 and 6.7 (bs, 2 × 1H, NH), and 6.8–7.5 (m, 5H, aromatic) ppm. *Anal.* calcd. for $C_{14}H_{16}N_2O_4S$: C 54.53, H 5.23, N 9.08, S 10.40; found: C 54.64, H 5.21, N 9.04, S 10.11.

p-*Nitrobenzyl (4*R-*acetylthio-3*R-*methyl-3-phenoxyacetamido-2-azetidinon-1-yl)triphenylphosphoranylidene acetate* **6**c

A suspension of azetidinone **8** (1.53 g, 4.96 mmol) and *p*-nitrobenzyl glyoxylate monohydrate (1.25 g, 5.46 mmol) in CH_2Cl_2 (30 mL) was cooled to 0–5°C and treated with triethylamine (35 μL, 0.25 mmol). After 1 h, the resulting solution was diluted with CH_2Cl_2, and washed with cold 0.1 N HCl and brine. After drying ($MgSO_4$), evaporation gave 2.7 g of the crude hemiaminal **9***a* as an oil; ir (film) ν_{max}: 3300 (br), 1770 (C=O β-lactam), 1690 (C=O), and 1520 (C=O amide) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) (mixture of two diastereoisomers in a 1:1 ratio) δ: 1.69 and 1.73 (2s, 3H, CH_3-3 of azetidinone), 2.22 and 2.32 (2s, 3H, $SCOCH_3$), 4.54 (s, 2H, CH_2 of phenoxyacetyl), 5.35 (m, 2H, CH_2 of *p*-nitrobenzyl), 5.52 and 5.55 (2s, 1H, H-4 of azetidinone), 6.7 (br s, 1H, NH), and 6.9–8.3 (m, 9H, aromatic) ppm.

Thionyl chloride (0.38 mL, 5.26 mmol) was added dropwise over 5 min to a cooled (−20°C) solution of the crude hemiaminal **9***a* (2.7 g) and pyridine (0.45 mL, 5.56 mmol) in dry tetrahydrofuran (60 mL). After 15 min, the white precipitate that formed was filtered on a Celite pad and washed with benzene. The filtrate and washings were combined and concentrated *in vacuo*. The residue was rapidly purified on a silica gel pad (40 g) using a mixture of CH_2Cl_2:EtOAc, 3:1, as eluent. Evaporation gave 2.39 g (85% from **8**) of *p*-nitrobenzyl (4*R*-acetylthio-3*R*-methyl-3-phenoxyacetamido-2-azetidinon-1-yl) chloro acetate **9***b* (4:3 mixture of diastereoisomers by ^{1}Hmr) as a clear oil: ir (film) ν_{max}: 1790, 1770 (C=O), 1690 (C=O amide and thioester), and 1520 (amide) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 1.72 (s, 3H, CH_3-3 of azetidinone), 2.21 and 2.31 (2s, 3H, $SCOCH_3$), 4.55 (s, 2H, CH_2 of phenoxyacetyl), 5.32 and 5.38 (2s, 2H, CH_2 of *p*-nitrobenzyl), 5.66 and 5.77 (2s, 1H, H-4 of azetidinone), 6.16 and 6.26 (2s, 1H, H-2 of acetate), 6.6 (br s, 1H, NH), and 6.8–8.2 (br s, 1H, NH) ppm.

A solution of the epimeric chloro compounds **9***b* (0.95 g, 1.77 mmol) in dry tetrahydrofuran (50 mL) was treated with triphenylphosphine (1.0 g, 3.81 mmol) and 2,6-lutidine (0.25 mL, 2.14 mmol) and the resulting mixture was heated at 50°C under N_2 for 66 h. The solvent was then evaporated and the residue dissolved in EtOAc (200 mL). The solution was washed successively with cold 0.1 N HCl, cold 1% $NaHCO_3$, and brine, and dried ($MgSO_4$). Evaporation and chromatography of the residue on silica gel (40 g, elution with toluene:EtOAc 1:1–1:3) gave 1.20 g (88%) of the title phosphorane **6***c* as an oil: ir (film) ν_{max}: 1770 (C=O β-lactam), 1690 (br), 1620 (br), and 1520 (amide) cm^{-1}.

p-*Nitrobenzyl (5*R*) 6*R-*methyl-2-methyl-6-phenoxyacetamidopenem-3-carboxylate* ***10***

A solution of the phosphorane **6***c* (1.20 g, 1.57 mmol) in toluene (800 mL) was heated under N_2 and in the presence of a small crystal of hydroquinone, at 100°C for 48 h. The solvent was then concentrated *in vacuo* and the residue was chromatographed on silica gel (60 g). Elution with a mixture of toluene and EtOAc (85:15) gave 0.550 g (72%) of the penem **10** as a white foam: $[\alpha]_D^{25}$ +302° (*c* 1.06, $CHCl_3$); uv (EtOH) λ_{max} (ε): 307 (10 700), 274 (sh), 268 (15 000), and 262 (15 000) nm; ir (film) ν_{max}: 1787 (C=O β-lactam), 1707 (C=O ester), 1668 and 1517 (amide), and 1325 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 1.83 (s, 3H, CH_3-6), 2.35 (s, 3H, CH_3-2), 4.51 (s, 2H, CH_2 of phenoxyacetyl), 5.33 (ABq, J_{AB} = 13.6, $\Delta\nu$ = 17.8, CH_2 of *p*-nitrobenzyl), 5.74 (s, 1H, H-5), 6.8–7.4 (m, 5H, aromatic), 7.59 (d, *J* = 8.8 Hz, 2H, H-2 of *p*-nitrobenzyl), and 8.23 ppm (d, *J* = 8.8 Hz, 2H, H-3 of *p*-nitrobenzyl). *Anal.* calcd. for $C_{23}H_{21}N_3O_7S$: C 57.14, H 4.38, N 8.69, S 6.63; found: C 56.94, H 4.60, N 8.69, S 6.50.

*(5*R*) 6*R-*Methyl-2-methyl-6-phenoxyacetamidopenem-3-carboxylic acid, sodium–potassium salt* **3**a

A solution of *p*-nitrobenzyl (5*R*) 6*R*-methyl-2-methyl-6-phenoxyacetamidopenem-3-carboxylate **10** (0.150 g, 0.31 mmol) in a mixture of tetrahydrofuran (15 mL), ether (30 mL), water (15 mL), and pH 7 phosphate buffer (20 mL of a 0.05 M solution, KH_2PO_4–NaOH) was hydrogenated over 0.3 g of 10% Pd on activated carbon in a Parr apparatus under a pressure of 45 psi (1 psi = 6.9 kPa) at room temperature for 1.5 h. The mixture was then filtered through a Celite pad, and the aqueous phase, after evaporation of traces of organic solvent *in vacuo*, was chromatographed at 0–5°C on reversed phase silica gel (2 × 18 cm). Elution with water and then a mixture of water–CH_3CN, 9:1, gave 0.053 g (48%) of the penem **3***a* as a white powder after lyophilization: $[\alpha]_D^{22}$ +321° (*c* 0.88, H_2O); uv (H_2O, pH 7.4 phosphate buffer) λ_{max} (ε based on K salt): 297 (7850), 274 (7200), 267 (7700), and 260 (7500) nm; ir (KBr) ν_{max}: 1770 (C=O β-lactam), 1675 and 1520 (amide), and 1600 (br, carboxylate) cm^{-1}; ^{1}Hmr (D_2O, 80 MHz) δ: 1.69 (s, 3H, CH_3-6), 2.19 (s, 3H, CH_3-2), 4.69 (CH_2 of phenoxyacetyl overlapping with HDO), 5.67 (s, 1H, H-5), and 6.9–7.4 ppm (m, 5H, aromatic). By uv, at 37°C, the half-life of this penem was determined to be 12 h at pH 7.4.

p-*Nitrobenzyl 6α-methoxy-6β-phenoxyacetamidopenicillanate-1-β-oxide* ***11*** d (12)

This product was obtained via a slight modification (23) of the Koppel and Koehler's method (13).

A solution of *p*-nitrobenzyl 6-phenoxyacetamidopenicillanate-1-β-oxide (**11***c*) (20.0 g, 39.8 mmol) in dry CH_2Cl_2 (300 mL) was cooled to −30°C and treated with freshly prepared *tert*-butyl hypochlorite (24).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

Then lithium methoxide (43.8 mmol, prepared by dissolving lithium, 0.30 g, in MeOH, 35 mL) was added dropwise over 1 h. After another hour at −30°C, acetic acid (2.5 mL) was added and the solution was washed with 5% cold aqueous $NaHCO_3$, 5% $Na_2S_2O_3$, and brine, and dried (Na_2SO_4). Evaporation left an oil, which was chromatographed on silica gel (200 g). Elution with a mixture of toluene and EtOAc (7:3) gave 15.1 g (71%) of **11***d* as an oil: ir (film) ν_{max}: 1788 (C=O β-lactam), 1753 (C=O ester), 1688 and 1521 (amide), and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 1.13 and 1.6 (2s, 2 × 3H, CH_3-2), 3.46 (s, 3H, OCH_3-6), 4.53 (s, 2H, CH_2 of phenoxyacetyl), 4.63 (s, 1H, H-3), 5.0 (s, 1H, H-5), 5.3 (s, 2H, CH_2 of *p*-nitrobenzyl), 6.8–7.4 (m, 6H, NH and aromatic), 7.53 (d, J = 9.0 Hz, 2H, H-2 of *p*-nitrobenzyl), and 8.23 (d, J = 9.0 Hz, 2H, H-3 of *p*-nitrobenzyl) ppm.

Methyl 6α-methoxy-6β-phenoxyacetamidopenicillanate-1β-oxide ***11***b (12)

Starting with methyl 6-phenoxyacetamidopenicillanate **11***a* (25) (3.80 g, 10.0 mmol) and using the same procedure as was used to prepare **11***d*, we obtained 1.73 g (42%) of **11***b* as an oil: ir (film) ν_{max}: 1788 (C=O β-lactam), 1755 (C=O ester), 1690 and 1510 (amide) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 1.23 and 1.66 (2s, 2 × 3H, CH_3-2), 3.5 (s, 3H, OCH_3-6), 3.83 (s, 3H, CO_2CH_3-3), 4.58 (s, 2H, CH_2 of phenoxyacetyl), 4.60 (s, 1H, H-3), 5.0 (s, 1H, H-5), and 6.7–7.6 (m, 6H, NH and aromatic) ppm.

p-*Nitrobenzyl α-(4*R*-acetylthio-3*S*-methoxy-3-phenoxyacetamido-2-azetidinon-1-yl)-β-methylcrotonate* ***12***b

A solution of sulfoxide **11***d* (15.0 g, 28.0 mmol) in toluene (250 mL) was treated with trimethyl phosphite (12.4 g, 0.1 mol) and acetic anhydride (26.7 mL, 0.28 mol) at 96°C for 24 h. Work-up as for **6***a* followed by isomerization (EtOAc 50 mL, Et_3N 0.8 mL, 3 h) and chromatography gave 8.69 g (55%) of **12***b* as a syrup: $[\alpha]_D^{22}$ +20° (*c* 1.14, $CHCl_3$); ir (film) ν_{max}: 1780 (C=O β-lactam), 1715 (sh, C=O ester), 1695 and 1520 (amide), and 1345 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 2.16 and 2.3 (2s, 3H and 6H, CH_3 of crotonate and $SCOCH_3$), 3.5 (s, 3H, OCH_3-3), 4.53 (s, 2H, CH_2 of phenoxyacetyl), 5.30 (s, 2H, CH_2 of *p*-nitrobenzyl), 5.93 (s, 1H, H-4), 6.8–7.4 (m, 6H, NH and aromatic), 7.56 (d, J = 9.0 Hz, 2H, H-2 and *p*-nitrobenzyl), and 8.20 (d, J = 9.0 Hz, 2H, H-3 of *p*-nitrobenzyl) ppm.

*Methyl α-(4*R*-acetylthio-3*S*-methoxy-3-phenoxyacetamido-2-azetidinon-1-yl)-β-methylcrotonate* ***12***a

Using the same procedure described above for **12***b*, 10.3 g (72.1 mmol) of **11***b* gave 6.59 g (60%) of **12***a* as an oil: $[\alpha]_D^{20}$ +55° (*c* 1.08, $CHCl_3$); ir (film) ν_{max}: 1772 (C=O β-lactam), 1715 (sh C=O ester), 1700 and 1520 (amide) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 2.15, 2.26 and 2.3 (3s, 3 × 3H, CH_3 of crotonate and $SCOCH_3$), 3.6 and 3.76 (2s, 2 × 3H, OCH_3-3 and CO_2CH_3), 4.53 (s, 2H, CH_2 of *p*-nitrobenzyl), 6.0 (s, 1H, H-4), and 6.8–7.5 (6H, NH and aromatic) ppm. *Anal.* calcd. for $C_{20}H_{24}N_2O_7S$: C 55.03, H 5.54, N 6.42, S 7.34; found: C 54.85, H 5.47, N 6.25, S 6.86.

N-p-*Nitrobenzoxalyl 4*R*-acetylthio-3*S*-methoxy-3-phenoxyacetamido-2-azetidinone* ***12***d

Ozonolysis of 2.60 g (4.66 mmol) of **12***h* in a mixture of CH_2Cl_2 (80 mL) and MeOH (10 mL) at −20°C and work-up as described above for **6***b* gave 2.40 g (97%) of **12***d* as a clear oil; $[\alpha]_D^{23}$ +17° (*c* 0.98, $CHCl_3$); ir (film) ν_{max}: 1822 and 1760 (C=O β-lactam, oxalyl), 1710 (br, C=O ester, amide), 1525 (amide), and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 2.36 (s, 3H, $SCOCH_3$), 3.6 (s, 3H, OCH_3-3), 4.60 (s, 2H, CH_2 of phenoxyacetyl), 5.40 (s, 2H, CH_2 of *p*-nitrobenzyl), 6.0 (1H, s, H-4), 7.0–7.6 (m, 6H, NH and aromatic), 7.56 (d, J = 8.8 Hz, 2H, H-2 of *p*-nitrobenzyl), and 8.4 (d, J = 8.8 Hz, H-3 of *p*-nitrobenzyl) ppm.

N-*Methoxalyl 4*R*-acetylthio-3*S*-methoxy-3-phenoxyacetamido-2-azetidinone* ***12***c

Ozonolysis of 0.736 g (1.68 mmol) of the crotonate **12***a* at −20°C in methanol (25 mL) and work-up as described above for **6***b* gave 0.602 g (85%) of **12***c as a clear oil: ir (film)* ν_{max}: 1820 and 1755 (C=O β-lactam and oxalyl), 1710 (br, C=O ester, amide, and thioester), and 1510 (sh, amide) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 2.37 (s, 3H, $SCOCH_3$), 3.63 (s, 3H, OCH_3-3), 3.96 (s, 3H, CO_2CH_3), 4.63 (s, 2H, CH_2 of phenoxyacetyl), 6.03 (s, 1H, H-4), and 6.8–7.6 (m, 6H, NH and aromatic) ppm.

*4*R*-Acetylthio-3*S*-methoxy-3-phenoxyacetamido-2-azetidinone* ***13***

A solution of *N*-methoxalyl 4*R*-acetylthio-3*S*-methoxy-3-phenoxyacetamido-2-azetidinone **12***c* (0.677 g, 1.85 mmol) in tetrahydrofuran (10 mL) was treated with 1 M aqueous HCl (2 mL) and stirred at 22°C for 8 h. The reaction mixture was diluted with EtOAc, washed with brine, and dried (Na_2SO_4). Evaporation of the solvent and chromatography of the residue on silica gel (20 g, elution toluene–EtOAc 1:1) gave 0.180 g (36%) of the title azetidinone **13** as a solid. Recrystallization from a mixture of ether and hexanes gave white needles: mp 123–124°C (lit. (*5a*) mp 136–139°C); ir (KBr) ν_{max}: 3260 (NH), 1778 (C=O β-lactam), and 1681 (amide) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.34 (s, 3H, $SCOCH_3$), 3.58 (s, 3H, OCH_3-3), 4.58 (s, 2H, CH_2 of phenoxyacetyl), 5.58 (s, 1H, H-4), 6.3 (br, 1H, NH), and 6.8–7.4 (m, 5H, aromatic) ppm. *Anal.* calcd. for $C_{14}H_{16}N_2O_5S$: C 51.84, H 4.97, N 8.63, S 9.88; found: C 51.44, H 4.96, N 8.39, S 9.58.

p-*Nitrobenzyl (4*R*-acetylthio-3*S*-methoxy-3-phenoxyacetamido-2-azetidinon-1-yl)triphenylphosphoranylidene acetate* ***12***e

A solution of *N*-*p*-nitrobenzoxalyl 4*R*-acetylthio-3*S*-methoxy-3-phenoxyacetamido-2-azetidinone **12***d* (2.40 g, 4.52 mmol) in tetrahydrofuran (40 mL) was cooled to 0–5°C and treated with 6.8 mL (6.8 mmol) of a 1 M solution of B_2H_6 in tetrahydrofuran (Aldrich Chemical Co.). After 1 h, the reaction mixture was quenched by addition of aqueous NH_4Cl solution (20 mL) and extracted with CH_2Cl_2. After drying (Na_2SO_4), evaporation gave 2.09 g of crude hemiaminal **15***a* as an oil. This product was unstable on silica gel and was used as is for the next step: ir (film) ν_{max}: 1760 (C=O β-lactam), 1700 (C=O) and 1520 (amide) cm^{-1}.

Thionyl chloride (0.27 mL, 3.74 mmol) was added dropwise over 5 min to a cooled (−27°C) solution of the crude hemiaminal **15***a* and pyridine (0.30 mL, 3.74 mL) in dry tetrahydrofuran (40 mL). After 15 min, the solid that formed was filtered through a Celite pad and washed with tetrahydrofuran (20 mL). The combined filtrates were concentrated *in vacuo* and chromatographed on silica gel (30 g). Elution with a mixture of CH_2Cl_2 and ethyl acetate (8:2) gave 0.71 g (34% from **12***d*) of *p*-nitrobenzyl (*4R*-acetylthio-3*S*-methoxy-3-phenoxyacetamido-2-azetidinon-1-yl) chloro acetate **15***b* as a clear oil. The ^{1}Hmr indicated a 2:1 mixture of diastereoisomers: ir (film) ν_{max}: 1794 (C=O β-lactam), 1766 (C=O ester), 1700 (C=O thioester and amide), and 1526 (amide) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 2.23 and 2.3 (2s, 3H, $SCOCH_3$), 3.56 (s, 3H, OCH_3-3), 4.56 (s, 2H, CH_2 of phenoxyacetyl), 5.33 and 5.36 (2s, 2H, CH_2 of *p*-nitrobenzyl), 5.86 and 5.93 (2s, 1H, H-4 of azetidinone), 6.13 and 6.16 (2s, 1H, H-2 of acetate), 6.7–7.3 (m, 6H, aromatic and NH), 7.52 (d, J = 8.5 Hz, 2H, H-2 of *p*-nitrobenzyl), and 8.20 (d, J = 8.5 Hz, 2H, H-3 of *p*-nitrobenzyl) ppm.

A solution of the chloro acetate **15***b* (0.70 g, 1.27 mmol) in tetrahydrofuran (45 mL) was treated with triphenylphosphine (1.04 g, 3.96 mmol) and 2,6-lutidine (0.112 g, 1.04 mmol) and heated under N_2 at 53°C for 48 h. The solvent was evaporated *in vacuo*, the residue dissolved in CH_2Cl_2, washed with cold 0.1 N aqueous HCl, cold 1% aqueous $NaHCO_3$, and brine. After drying (Na_2SO_4), evaporation of the solvent gave a residue that was chromatographed on silica gel (2 × 14 cm). Elution with a mixture of CH_2Cl_2 and EtOAc (7:3) gave 0.361 g (36% from **15***b*) of the title phosphorane **12***e* as a gum: ir (film) ν_{max}: 1770 (C=O β-lactam), 1700 (C=O), 1625 and 1600, 1520 (amide), and 1350 (NO_2) cm^{-1}.

p-*Nitrobenzyl (5*R*) 6*S*-methoxy-2-methyl-6-phenoxyacetamidopenem-3-carboxylate* ***16***

A solution of the phosphorane **12***e* (0.360 g, 0.46 mmol) in dry toluene (200 mL) was maintained at 98°C under N_2 for 24 h. The solvent was then concentrated to ~10 mL and this was chromato-

For personal use only.

graphed on silica gel (20 g). Elution with a mixture of toluene and EtOAc (8:23) gave 0.129 g (55%) of the title penem **16** as a white solid. Recrystallization from a mixture of CH_2Cl_2 and ether gave white cubes: mp 152–153°C (lit. (5*a*) mp 152–153°C); $[\alpha]_D^{22}$ +235° (*c* 0.44, $CHCl_3$); uv (EtOH) λ_{max} (ε): 308 (8300), 274 (sh), 268 (12 200), and 262 (sh) nm; ir (KBr) ν_{max}: 1785 (C=O β-lactam), 1704 (C=O ester), 1670 and 1513 (C=O amide), 1585, 1493, and 1323 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.33 (s, 3H, CH_3-2), 3.51 (s, 3H, OCH_3-6), 4.56 (s, 2H, CH_2 of phenoxyacetyl), 5.34 (ABq, J_{AB} = 13.6 Hz, $\Delta\nu$ = 17 Hz, CH_2 of *p*-nitrobenzyl), 5.92 (s, 1H, H-5), 6.7–7.4 (m, 5H, aromatic), 7.60 (d, *J* = 8.8 Hz, 2H, H-2 of *p*-nitrobenzyl), 7.78 (br s, 1H, NH), and 8.20 (d, *J* = 8.8 Hz, 2H, H-3 of *p*-nitrobenzyl) ppm. *Anal.* calcd. for $C_{23}H_{21}N_3O_8S$: C 55.30, H 4.24, N 8.41, S 6.42; found: C 55.36, H 4.28, N 8.36, S 6.49.

Sodium (5R) 6S-methoxy-2-methyl-6-phenoxyacetamidopenem-3-carboxylate ***3b***

A solution of *p*-nitrobenzyl (5*R*) 6*S*-methoxy-2-methyl-6-phenoxyacetamidopenem-3-carboxylate **16** (0.095 g, 0.19 mmol) in a mixture of tetrahydrofuran (5 mL), ether (15 mL), water (15 mL), pH 7.0 phosphate buffer (4 mL of a 0.5 M solution), and sodium bicarbonate (0.015 g, 0.19 mmol) was hydrogenated over 0.15 g of 10% Pd on activated carbon under 45 psi of H_2 at ~15°C for 3 h. The catalyst was removed by filtration through a Celite pad and the aqueous phase was chromatographed at 0–5°C on reversed phase silica gel (2 × 8 cm). Elution with a mixture of H_2O and CH_3CN (9:1) gave 0.045 g (61%) of the penem **3***b* as a white amorphous powder after lyophilization: $[\alpha]_D^{22}$ +150° (*c* 0.44, H_2O); uv (H_2O, pH 7.4 phosphate buffer) λ_{max} (ε): 297 (4900), 272 (5200), 265 (5700), and 259 (5700) nm; ir (KBr) ν_{max}: 1759 (C=O β-lactam), 1688 (C=O of amide), and 1620 (br, carboxylate) cm^{-1}; ^{1}Hmr (D_2O, 80 MHz) δ: 2.16 (s, 3H, CH_3-2), 3.44 (s, 3H, OCH_3-6), 4.67 (s, 2H, CH_2 of phenoxyacetyl), 5.86 (s, 1H, H-5), and 6.8–7.4 (m, 5H, aromatic) ppm. By uv, at 37°C the half-life of this penem was determined to be 1.2 h in a pH 7.4 phosphate buffer.

p-*Nitrobenzyl 6α-methoxy-6β-[α-(*p*-nitrobenzyloxycarbonyl)phenylacetamido]penicillanate* ***18***

A solution of *p*-nitrobenzyl 6-*p*-toluenesulfenimidopenicillanate (**17**) (13.7 g, 29.1 mmol) (17) in dry CH_2Cl_2 (500 mL) was treated at 24°C with triphenylphosphine (22.8 g, 87.0 mmol) and a solution of mercuric acetate (9.23 g, 29.0 mmol) in methanol (100 mL). After 3.5 h, the solvent was evaporaed and the residue dissolved in CH_2Cl_2 (300 mL). Propylene oxide (180 mL) and pyridine (9 mL) were added and the mixture cooled to −10°C. Then a solution of phenylmalonyl chloride mono-*p*-nitrobenzyl ester (87.6 mmol) in CH_2Cl_2 (70 mL) (prepared by mono-esterification of the commercial phenylmalonic acid with *p*-nitrobenzyl alcohol (26) to give the phenylmalonic acid mono-*p*-nitrobenzyl ester (mp 128–129°C), followed by reaction of the mono-ester (27.6 g, 87.6 mmol) in CH_2Cl_2 (70 mL) with oxalyl chloride (7.7 mL) and a drop of *N*,*N*-dimethylformamide at 22°C for 2 h and evaporation) was added dropwise over 10 min and the resulting mixture was stirred for 3 h at −10°C. The reaction mixture was filtered through a Celite pad, which was then washed with CH_2Cl_2. The filtrate and the washings were washed with cold saturated aqueous $NaHCO_3$, brine, and dried (Na_2SO_4). Evaporation of the solvent gave an oil, which was chromatographed on silica gel (200 g). Elution with a mixture of toluene and EtOAc (9:1–7:3) gave 12.6 g (63%) of the title material **18** as a clear oil. The ^{1}Hmr indicated a 1:1 mixture of diastereoisomers: ir (film) ν_{max}: 1778 (C=O β-lactam), 1750 (C=O ester), 1695 and 1520 (amide), and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 1.24, 1.28, and 1.23 (3s, 2 × 3H and 6H, CH_3-2), 3.36 and 3.38 (2s, 2 × 3H, OCH_3-6), 4.41 and 4.46 (2s, 1H, CH of malonyl), 4.67 and 4.69 (2s, 1H, H-3), 5.28 (s, 4H, CH_2 of *p*-nitrobenzyl), 5.52 and 5.54 (s, 1H, H-5), and 7.2–8.3 (m, 14H, NH and aromatic) ppm. *Anal.* calcd. for $C_{32}H_{30}N_4O_{11}S$: C 56.63, H 4.46, N 8.26, S 4.72; found: C 56.63, H 4.48, N 8.05, S 4.73.

p-*Nitrobenzyl 6α-methoxy-6β-[α-(*p*-nitrobenzyloxycarbonyl)phenylacetamido]penicillanate-1β- and -1α-oxide (****19****b and* ***19****a)*

m-Chloroperbenzoic acid (3.09 g, 17.9 mmol) was added in small portions over 30 min to a solution of 6α-methoxy penicillanate **18** (12.2 g, 17.9 mmol) in CH_2Cl_2 (250 mL) at −20°C. After 1 h at −20°C, the mixture was washed with cold aqueous saturated $NaHCO_3$, brine, and dried (Na_2SO_4). Evaporation of the solvent gave an oil, which was chromatographed on silica gel (300 g). Elution with a mixture of toluene and EtOAc (7:3) gave 10.65 g (85%) of the major β-oxide **19***b* as an oil: ir (film) ν_{max}: 1785 (C=O β-lactam), 1750 (C=O ester), 1680 and 1515 (amide), and 1345 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) (mixture of epimers at the malonyl side chain in 1:1 ratio) δ: 1.12 and 1.59 (2s, 2 × 3H, CH_3-2), 3.38 (s, 3H, OCH_3-6), 4.6, 4.62, 4.65, 4.75, 4.90, and 4.93 (6s, total 3H, H-3, H-5 and CH of malonyl), 5.27 and 5.32 (br s, 4H, CH_2 of *p*-nitrobenzyl), and 7.1–8.3 (m, 13H, aromatic) ppm. *Anal.* calcd. for $C_{32}H_{30}N_4O_{12}S$: C 55.33, H 4.35, N 8.05, S 4.61; found: C 55.0, H 4.24, N 7.97, S 4.61. Further elution with the same solvent system gave 1.01 g (8%) of the minor α-sulfoxide **19***a* as a solid, which was crystallized from a mixture of toluene and CH_2Cl_2: mp 160–165°C (dec); ir (KBr) ν_{max}: 1788 (C=O β-lactam), 1750 and 1740 (sh) (C=O ester), 1690 and 1520 (amide), and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) (mixture of epimers at the malonyl side chain in 1:1 ratio) δ: 1.12, 1.17, 1.20, and 1.22 (4s, 6H, CH_3-2), 3.45 and 3.50 (2s, 3H, OCH_3-6), 4.50, 4.53, 4.66, 4.71, 4.84, and 4.92 (6s, 3H, H-3, H-5 and CH of malonyl), 5.29 (br s, 4H, CH_2 of *p*-nitrobenzyl), and 7.2–8.3 (m, 13H, aromatic) ppm. *Anal.* calcd. for $C_{32}H_{30}N_4O_{12}S$: C 55.33, H 4.35, N 8.05, S 4.61; found: C 55.39, H 4.39, N 8.03, S 4.63.

Disulfide ***21***

A mixture of *p*-nitrobenzyl 6α-methoxy-6β-[α-(*p*-nitrobenzyloxycarbonyl)phenylacetamido]penicillanate-1β-oxide (**19***b*) (5.50 g, 7.99 mmol) and 2-mercaptobenzothiazole (1.34 g, 8.0 mmol) in toluene (160 mL) was heated under reflux for 5 h. The solvent was evaporated and the residual oil (6.60 g) was used as such for the next step. Attempted purification on silica gel led to isomerization of the β double bond; ir (film) ν_{max}: 1775 (C=O β-lactam), 1740 (C=O ester), 1680 and 1520 (amide), and 1345 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 60 MHz) δ: 1.90 (br s, 3H, CH_3 of 3-butenoate), 3.50 (br s, 3H, OCH_3), and 7.1–8.3 (m, aromatic) ppm.

Enol ***22***

A solution of the disulfide **21** (6.60 g, 7.83 mmol) in CH_2Cl_2 (120 mL) was cooled to −78°C and treated with a stream of ozone until a yellow-green solution was obtained. The mixture was then stirred at −78°C for 15 min, flushed with N_2, and treated with methyl sulfide (2 mL). The solution was allowed to warm up to 22°C and washed successively with 10% aqueous solution bisulfite (100 mL) and brine. After drying (Na_2SO_4), evaporation gave 6.0 g of the title material **22** as an oil. Since the product was strongly absorbed on silica gel, the crude material was used as such for the next step. Chromatography of a sample on silica gel (elution toluene:EtOAc 6:4) gave the title enol **22** as an oil; ir (film) ν_{max}: 3300 (OH), 1780 (C=O β-lactam), 1755 (C=O ester), 1675 and 1520 (amide), and 1345 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) (mixture of epimers ratio 1:1 at the malonyl side chain) δ: 2.32 (br s, 3H, CH_3 acetoacetate), 3.45 and 3.50 (2s, 3H, OCH_3), 4.7 and 4.75 (2s, 1H, H of malonyl), 5.1 and 5.3 (br s, CH_2 of *p*-nitrobenzyl and H-4), and 7.2–8.3 (m, aromatic) ppm.

Oxazoline ***23***b

Triphenylphosphine (1.02 g, 3.90 mmol) was added over 15 min to a solution of the crude enol **22** (3.30 g, 3.90 mmol) in ethyl acetate (30 mL) that had been cooled to 0°C. The resulting mixture was stirred at 0°C for 30 min. Mesyl chloride (0.60 mL, 7.8 mmol) and triethylamine (1.08 mL, 7.8 mmol) were then added over 5 min. After 1.5 h at 0°C, the reaction mixture was diluted with EtOAc (300 mL), washed with brine, and dried (Na_2SO_4). Evaporation of the solvent gave a dark violet gum, which was rapidly chromatographed on silica gel (2.5 × 20 cm; this product was relatively unstable on silica gel). Elution with a mixture of CH_2Cl_2 and EtOAc 9:1 gave 1.10 g (39% from the enol **22**) of the oxazoline **23***b* as a light yellow oil: ir (film) ν_{max}: 1790 (C=O β-lactam), 1730 (C=O ester), 1675, 1605, 1520, and 1345 cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) δ: 2.63 (s, 3H, CH_3 of

crotonate), 3.1 and 3.16 (2s, 3H, CH_3 of mesylate), 3.58 (s, 3H, OCH_3), 5.3 (br, CH_2 of *p*-nitrobenzyl), 6.06 and 6.1 (2s, 1H, H-4), and 7.2–8.4 (m, aromatic) ppm.

Chloro azetidinone 24

A solution of the oxazoline **23***b* (1.10 g, 1.52 mmol) in dry CH_2Cl_2 (40 mL) was treated with a stream of dry HCl for 2.5 h. The reaction mixture was then concentrated *in vacuo* and chromatographed on silica gel (2 × 18 cm). Elution with a mixture of CH_2Cl_2 and EtOAc (9:1) gave 0.55 g (48%) of the chloro azetidinone **24** as a clear oil; $[\alpha]_D^{22}$ +30° (*c* 2.5, $CHCl_3$); ir (film) ν_{max}: 1788 (C=O β-lactam), 1730 (C=O ester), 1690 and 1520 (amide), and 1350 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) (mixture of epimers at the malonyl side chain, ratio 1:1) δ: 2.68 (s, 3H, CH_3 of crotonate), 3.15 and 3.17 (2s, 3H, CH_3 of mesylate), 3.48 and 3.51 (2s, 3H, OCH_3), 4.61 and 4.63 (2s, 1H, H of malonate), 5.27 (s, 4H, CH_2 of *p*-nitrobenzyl), 6.11 and 6.15 (2s, 1H, H-4 of azetidinone), and 7.1–8.2 (m, 14H, aromatic) ppm.

p-*Nitrobenzyl (5*R*) 6*S*-methoxy-2-methyl-6-[α-(*p*-nitrobenzyloxycarbonyl)phenylacetamido]penem-3-carboxylate 25*

A solution of triethylamine (0.106 mL, 0.76 mmol) in dry THF (5 mL) was cooled to −20°C and hydrogen sulfide was bubbled through the solution for 5 min. Then *N*,*N*-dimethylformamide (1 mL) and the chloroazetidinone **24** (0.290 g, 0.38 mmol) in THF (2 mL) were added and the mixture was stirred at −20°C for 30 min. The reaction mixture was then diluted with EtOAc (25 mL), washed with cold brine, and dried (Na_2SO_4). Evaporation of the solvent gave an oil, which was rapidly chromatographed on silica gel (2 × 10 cm, elution with toluene–EtOAc 85:15) to give 0.070 g (~25%) of the title penem **25** as an oil. This product was relatively unstable on silica gel and was contaminated by the thiazole **26***a* (ratio penem:thiazole = 7:3 by ^{1}Hmr); ir (film) ν_{max}: 1785 (C=O β-lactam), 1740 (C=O ester), 1700 (broad), 1520 and 1445 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz) penem **25** (mixture of epimers ratio 1:1 at the malonyl side chain) δ: 2.22 and 2.29 (2s, 3H, CH_3-2), 3.39 and 3.43 (2s, 3H, OCH_3-6), 4.68 (s, 1H, H of malonyl), 5.29 (br s, CH_2 of *p*-nitrobenzyl), 5.81 and 5.83 (2s, 1H, H-5), and 7.2–8.2 (m, aromatic) ppm; thiazole **26***a* δ: 2.8 (s, CH_3), 5.47 (s, CH_2 of *p*-nitrobenzyl), and 8.8 (br s, H-2) ppm.

*Disodium (5*R*) 6*S*-2-methyl-6-(α-carboxyphenylacetamido)penem-3-carboxylate 3*c

A solution of the crude penem ester **25** (0.070 g, mixture of penem **25** and thiazole **26***a* in a 7:3 ratio) in a mixture of tetrahydrofuran (8 mL), ether (15 mL), pH 7.0 phosphate buffer (5 mL of a 0.05 M solution), ice (15 g), and 0.017 g (0.2 mmol) of $NaHCO_3$ was hydrogenated over 0.2 g of 10% Pd on activated carbon under 45 psi of H_2 at 15°C for 1.5 h. The reaction mixture was then filtered through a Celite pad and the aqueous phase was chromatographed on reversed phase silica gel (1.5 × 11 cm) using cold water (0–5°C) as eluent. Freeze-drying of the uv active fractions gave 0.015 g (~30%) of the title material as a white amorphous powder. By ^{1}Hmr this product contained 25% (mole ratio) of the thiazole **26***b*; uv (H_2O pH 7.4 phosphate buffer) λ_{max}: 299 (4100) and 250 (4700) nm; ir (KBr) ν_{max}: 1765 (C=O β-lactam), 1670 (amide), and 1600 (br, carboxylate) cm^{-1}; ^{1}Hmr (D_2O, 80 MHz) penem **3***c* (mixture of epimers at the malonyl side chain in a 1:1 ratio) δ: 2.13 and 2.17 (2s, 3H, CH_3-2), 3.40 and 3.54 (2s, 3H, OCH_3-6), 4.51 and 4.61 (2s, 1H, H of malonyl), 5.80 and 5.82 (2s, 1H, H-5) ppm; thiazole **26***b* δ: 2.60 (s, CH_3) and 8.61 (s, H-2) ppm.

By uv at 37°C, the half-life of this penem was determined to be 1.6 h in a pH 7.4 phosphate buffer. At 22°C the half-life increased to 6.6 h. This penem was unstable even in the dry form and decomposed at 0°C after a few days.

Acknowledgements

We would like to thank Drs. H. Mastalerz and A. Martel for helpful discussions in the course of this work and also during the preparation of this manuscript. We also thank Mr. G. Lacasse for running the 80-MHz ^{1}Hmr spectra.

Received October 13, 1987

MASAKI ENDO and ROBERT DROGHINI. Can. J. Chem. **66**, 1400 (1988).

A chiral intermediate bearing the 1-β-methyl moiety (**14***a*) for 1-β-methylcarbapenem antibiotics (**1**) was prepared by stereoselective aldol-type reaction between 4-acetoxyazetidinone **3***a* and the dianion (or corresponding bissilyl enol ether) of a 3-oxopentanoate **12** or **13** in the presence of a metal salt. A major side reaction has also been elucidated.

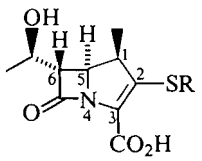
MASAKI ENDO et ROBERT DROGHINI. Can. J. Chem. **66**, 1400 (1988).

On a préparé un intermédiaire chiral portant la portion méthyl-1β (**14***a*) des antibiotiques méthyl-1β carbapénème (**1**) en faisant appel à une réaction stéréosélective de type aldol entre l'acétoxy-4 azétidinone (**3***a*) et le dianion (ou l'éther énolique bissylilé correspondant) d'un oxo-3 pentanoate (**12** ou **13**), en présence d'un sel métallique. On a aussi expliqué une réaction secondaire importante.

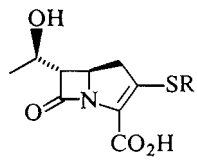
[Traduit par la revue]

Introduction

The 1-β-methylcarbapenems (**1**) are chemically and metabolically more stable than their carbapenem progenitors (**2**)



1



2

while still retaining high antimicrobial activity (1). This discovery has led to intense efforts to stereoselectively introduce the β-methyl function onto carbapenem precursors (1–8, 10).

Two general approaches to this problem account for most of successful syntheses to date (Scheme 1). The more popular is the aldol-type reaction between the chiral 4-acetoxyazetidinone **3***a* (9) or the 4-chloroazetidinone **3***b* (6) and metal enolates or silyl enol ethers **4** (R = auxiliary group) affording compound **5** (2–6). The other is stereoselective reduction of olefinic esters **6** and propargyl alcohols **8** to give **7** (7, 8) and **9** (10) respectively. These approaches then require several transformations of the 4-substituent of the azetidinone to produce the key intermediate **10***a* (1*a*), which, after diazo-transfer and intramolecular cyclization, yields the important carbapenem precursor **11** (1*a*).

It appeared to us that an aldol-type reaction between **3***a* and the dianion (or corresponding bissilyl enol ether) of a 3-oxopentanoate **12** or **13** would afford **10***a* directly. Therefore, we investigated the stereochemical outcome of these reactions (Scheme 2).

Results and discussion

Huckin and Weiler (11) demonstrated that the dianions of β-ketoesters generated by using one equivalent of sodium

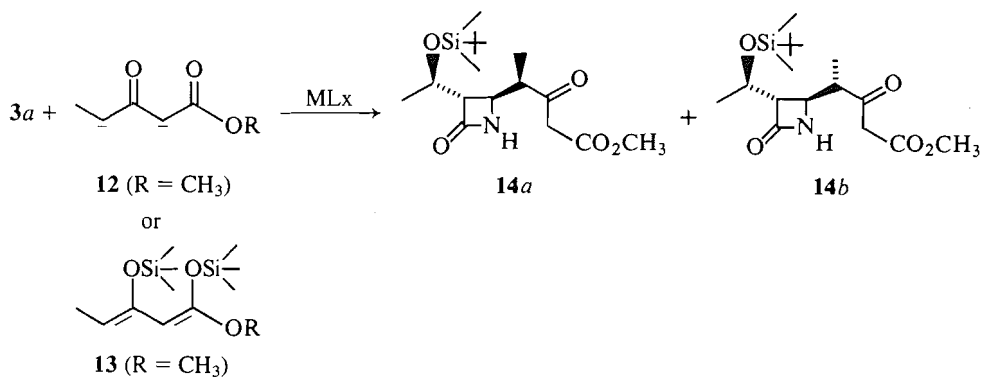
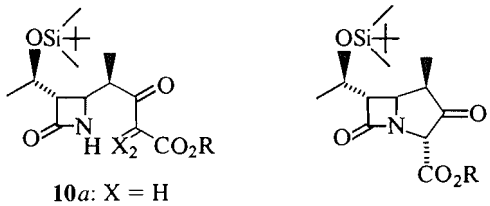


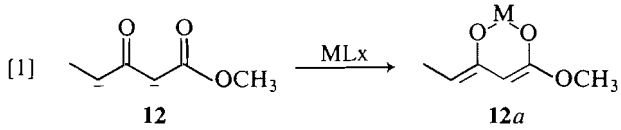
SCHEME 2

hydride and one equivalent of *n*-butyllithium react with alkylating agents to produce only γ-alkylated products in good yields. Based on the above report, we carried out a series of coupling reactions of 4-acetoxyazetidinone **3***a* with the dianion



12 of methyl 3-oxopentanoate in the presence of Lewis acid (Scheme 2).

The dianion **12** generated by following Weiler's procedure (11) was cooled to −30 to −40°C and was quenched with Lewis acid, presumably to form the metal enolate **12***a* (eq. [1]).



The enolate **12***a* formed at −30 to −40°C reacted with 4-acetoxyazetidinone **3***a* to give a mixture of **14***a* and **14***b*.

According to the results shown in Table 1, all reactions went in favor of the β-isomer **14***a*. In particular, zinc chloride, tri-*n*-butylborane, and tin(II) chloride were found to be good reagents.

It should be noted that exclusion of Lewis acid gave only decomposition products at the usual reaction temperatures, but at −70°C, β-rich product was nevertheless obtained.

The generally low yields could largely be explained by the formation of a stable, crystalline by-product identified as the 2-pyridone **15**. Also observed in these reactions was a compound that converted to **15** on attempts to isolate it in pure form. This precursor was tentatively identified as the amide **16** by ^{1}H nmr.[3] It seemed likely that **16** derived from the 2-azetidinone **17**, product of alkylation at the α-site of dianion **12**.

To confirm this sequence, an independent synthesis of **17** was attempted. Lewis acid-mediated coupling of **3***a* with silyl enol

[3]Data for ^{1}H nmr (200 MHz, $CDCl_3$), δ: 0.83, 0.90 (2s, 6H, CH_3Si), 0.86 (s, 9H, CH_3CSi), 1.10 (t, J = 7.2 Hz, 3H, CH_2CH_3), 1.18 (d, J = 6.2 Hz, 3H, CH_3CHOSi), 2.68 (m, 2H, CH_2CH_3), 3.47 (dd, J = 5.6 and 10.4 Hz, 1H, CHC=), 3.83 (s, 3H, CO_2CH_3), 4.26 (m, 1H, CH_3CHOSi), 5.38, 6.50 (2s, 1H, NH_2), 6.94 (d, J = 10.4 Hz, 1H, CH=).

ether **18** (12) gave only traces of desired product. However, **17** was obtained in good yield under the essentially neutral conditions of the Reformatsky-type reaction shown in Scheme 3. Thus the enol ether **18** (12), prepared *in situ* at 0°C from the reaction of methyl 3-oxopentanoate with trimethylsilyl triflate, was reacted with one equivalent of bromine to yield α-bromopentanoate **19** in quantitative yield. Compound **19** was then treated with activated zinc dust at −15°C to form the zinc enolate **20** (13), which immediately reacted with 4-acetoxyazetidinone **3***a* to produce the α-alkylated product **17** (*R*/*S*) in 83% yield (after recrystallization).

It was then possible to show that base treatment of **17** (TEA, 23°C, 24 h) gave 94% of a crystalline compound identical to the major by-product identified as **15**. Furthermore, nmr analysis of the reaction after 30 min clearly showed the presence of compound **16**.

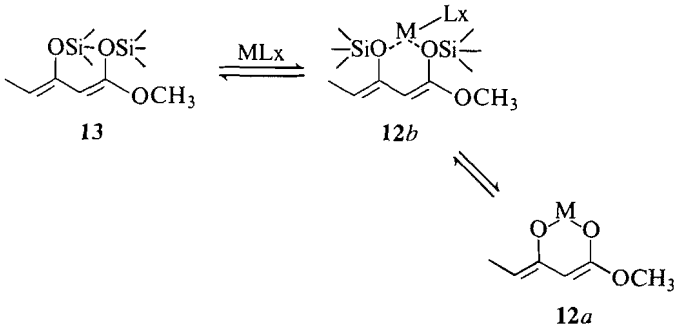
SCHEME 3

The dianion **12** is a very strong base and is considered a hard nucleophile, while the bissilyl enol ether **13** is a soft nucleophile (12). The silyl enol ether **13** would therefore be expected to give a better controlled reaction. Indeed, the reaction of 4-acetoxyazetidinone **3***a* with **13** in the presence of metal salt was much cleaner compared to that of the dianion **12**, and good β-selectivity was also obtained. Furthermore, no α-alkylation was observed.



13 **12***b* **12***a*

The reaction probably first involves metal exchange and (or) interaction between **13** and a metal salt MLx. The mixture of **13** and **12***a*,*b* then reacts with 4-acetoxyazetidinone **3***a* to give the coupled products **14***a* and **14***b* (Scheme 2). The results are shown in Table 2.

There was a clear difference in the stereoselectivity when tin(II) and tin(IV) salts were employed (entries 1–4). Tin(II) chloride and triflate favored the β isomer, particularly with THF as solvent, while tin(IV) chloride (a stronger Lewis acid) completely reversed the β/α ratio. Similar results were obtained using zinc compounds (entries 5, 6). Diethyl zinc gave good β-selectivity, while zinc chloride, a Lewis acid, favored the α isomer. Thus far, Lewis acids would seem to disfavor β-selectivity. However, boron trichloride, a Lewis acid, showed β-selectivity, as did boron trifluoride (entries 8, 9). On the other hand trialkylboranes such as tri-*n*-butylborane were α-selective (entry 7). Titanium(IV) and silicon compounds were also found to favor slightly the β isomer.

The β-ketoester diastereomers **14***a* and **14***b*, separated by chromatography, were shown to exist as keto/enol tautomers in solution (Scheme 4). The ^{1}H nmr spectra indicated 17% of the enol form for the 1-β-methyl isomer **14***a* and 52% enol for the α-methyl isomer. The ir spectrum in $CHCl_3$ clearly showed the enol form (ν_{OH} = 3410 cm^{-1}).

In carbapenem or penem syntheses it is desirable to protect the carboxylic acid with groups such as allyl or *p*-nitrobenzyl, which may be removed under mild conditions at or near the end of the reaction sequence (1*a*, 14). Therefore the methyl ester of the 1-β-methylcarbapenem intermediate **14***a* was transformed into its allyl ester **23** by simple ester exchange in 50% yield. The allyl ester **23** was then diazotized to give the key 1-β-methylcarbapenem intermediate **24** in 97% yield (1*a*) (Scheme 5). When the diazotization of **14***a* was carried out first, it proceeded well. However, the following transesterification did not work at all.

In summary, a useful chiral intermediate **14***a* for 1-β-methylcarbapenem antibiotics **1** has been prepared directly and stereoselectively by coupling 4-acetoxyazetidinone with the dianion or a bissilyl enol ether of methyl 3-oxopentanoate.

Experimental

*(3S,4R)-3-[(1R)-1-*tert*-Butyldimethylsilyloxyethyl]-4-[(1R)-3-methoxycarbonyl-1-methyl-2-oxopropyl]azetidin-2-one (**14**a + **14**b)*

Some typical procedures for both the dianion and the bissilyl enolate processes are described.

Via the dianion process

Example 1, using tin(II) chloride

To a suspension of sodium hydride (0.192 g, 4 mmol, 50% in mineral oil) in dry THF (10 mL) at −10 to −5°C under nitrogen atmosphere was added dropwise a solution of methyl 3-oxopentanoate (0.52 g, 4 mmol) in dry THF (1 mL), maintaining the temperature at −5 to 0°C. The resulting slurry was stirred at −5 to 0°C for 15 min, giving a colorless solution in 5–10 min. Then *n*-butyllithium (2.58 mL, 4 mmol, 1.55 M solution in hexane) was added dropwise, maintaining the temperature at −5 to 0°C. It was stirred for 15 min. The yellow dianion solution (**12**) was then cooled to −45°C and anhydrous tin(II) chloride (0.76 g, 4 mmol) was added all at once. As soon as the tin(II) chloride was added, a precipitation took place as the temperature started rising to −35°C, and it gradually dissolved back into the solution. The cloudy solution was stirred at −45 to −35°C for 0.5 h and a solution of 4-acetoxyazetidinone **3***a* (9) (0.574 g, 2 mmol) in dry THF (1 mL) was added. The resulting solution was allowed to warm up to room temperature and stirred for 1.5 h. Thin-layer chromatography (tlc) (silica gel, petroleum ether – ether 3:2 as solvent, uv and molybdate solution for visualization) showed completion of reaction. The reaction mixture was diluted with ether (70 mL), washed successively with 1 N hydrochloric acid (30 mL), saturated sodium bicarbonate (30 mL), and brine (30 mL), dried over anhydrous magnesium sulfate, and concentrated to give an oil (0.87 g), which was chromatographed on silica gel (ether – petroleum ether 1:1), yielding 0.22 g (30%) of the title compound with a β/α ratio of 88:12 and the pyridone **15** (0.19 g, 28%).

Both pure isomers **14***a* and **14***b* were isolated by further chromatography for characterization.

*β-Isomer **14**a*: mp 67–68°C (recrystallized from hexane); $[\alpha]_D^{23}$ −2.4° (*c* 0.46, $CHCl_3$); ir ($CHCl_3$): 3415 (OH, enol), 1755 (β-lactam), 1735 (CO_2CH_3, keto), 1712 (CO, keto), 1655 (CO_2CH_3, enol), and 1625 (C=C, enol) cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 0.04, 0.05 (2s, 6H, CH_3Si keto + enol), 0.85 (s, 9H, CH_3CSi keto + enol), 1.11–1.21 (4 overlapping d, *J* = 6.3 and 7.1 Hz for keto form, 6H, CH_3CHOSi keto + enol and $CH_3CH{=}O$, $CH_3CHC(OH){=}$), 2.40 (m, 0.17H, $CH_3CHC(OH){=}$), 2.89, 2.95 (overlapping dd and m, *J* = 2.3 and 4.7 Hz, 1.83H, H-3 keto + enol and $CH_3CHC{=}O$), 3.52 (q, *J* = 15.8 Hz, 1.66 Hz, $COCH_2CO_2$), 3.72 (overlapping s and m, 3.17H, CO_2CH_3 keto + enol and H-4 enol), 3.92 (dd, *J* = 2.3 and 4.5 Hz, 0.83H, H-4 keto), 4.16 (m, 1H, CH_3CHOSi keto + enol), 5.02 (s, 0.17H, =CH), 5.80 (br s, 0.83H, NH keto), 5.93 (br s, 0.17H, NH enol); mass spectrum (C.I.) *m/e*: 358 $(M + H)^+$. *Anal.* calcd. for $C_{17}H_{31}NO_5Si$ (357.492): C 57.12, H 8.74, N 3.92; found: C 57.10, H 8.86, N 3.86.

*α-Isomer **14**b*: mp 82–83°C (recrystallized from hexane); $[\alpha]_D^{23}$ +6.1° (*c* 0.49, $CHCl_3$); ir ($CHCl_3$): 3415 (OH, enol), 1755 (β-lactam), 1735 (CO_2CH_3, keto), 1712 (CO, keto), 1650 (CO_2CH_3, enol), and 1625 (C=C, enol) cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 0.05, 0.06 (2s, 6H, CH_3Si keto + enol), 0.85, 0.86 (2s, 9H, CH_3CSi keto + enol), 1.20 (m, 6H, CH_3CHOSi keto + enol and $CH_3CHC{=}O$, $CH_3CHC(OH){=}$), 2.31 (m, 0.52H, $CH_3CHC(OH){=}$), 2.65–2.80 (overlapping m and dd, 1.42H, $CH_3CHC{=}O$ and H-3 keto + enol), 3.52 (s, 0.84H, $COCH_2CO_2$), 3.68 (2 overlapping dd, 1H, H-4 keto + enol), 3.73 (s, 3H, CO_2CH_3 keto + enol), 4.15 (m, 1H, CH_3CHOSi keto + enol), 5.40 (s, 0.52H, =CH), 5.84 (br s, 0.52H, NH enol), 5.92 (br s, 0.48H, NH keto); mass spectrum (C.I.) *m/e*: 358 $(M + H)^+$. *Anal.* calcd. for $C_{17}H_{31}NO_5Si$ (357.492): C 57.12, H 8.74, N 3.92; found: C 56.66, H 8.95, N 3.99.

*Pyridone **15***: mp 104–105°C (recrystallized from *i*-PrOH–H_2O 2:3); ir ($CHCl_3$): 1712, 1645 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 0.03, 0.08 (2s, 6H, CH_3Si), 0.92 (s, 9H, CH_3CSi), 1.30 (t, *J* = 7.5 Hz, 3H, CH_2CH_3), 1.37 (d, *J* = 6.2 Hz, 3H, CH_3CHO), 3.07 (m, 2H, CH_2CH_3), 3.83 (s, 3H, CO_2CH_3), 4.94 (d of q, *J* = 1.0 and 6.2 Hz, 1H, CH_3CHO), 8.18 (d, *J* = 1 Hz, =CH), 11.18 (br s, 1H, NH); mass spectrum (C.I.) *m/e*: 340 $(M + H)^+$. *Anal.* calcd. for $C_{17}H_{29}NO_4Si$ (339.484): C 60.14, H 8.69, N 4.12; found: C 59.73, H 8.58, N 3.95.

Example 2, using zinc chloride

The dianion solution of **12** (4 mmol, produced as described in Example 1) was cooled to −40°C, to which was added zinc chloride (0.68 g, 5 mmol, fused-dry). The mixture was stirred at −40 to −10°C for 15 min to give a cloudy solution. Then, a solution of 4-acetoxyazetidinone **3***a* (0.574 g, 2 mmol) in dry THF (1 mL) was added. The resulting solution was stirred at room temperature for 1 h. Disappearance of the starting 4-acetoxyazetidinone was shown by tlc. The reaction mixture was worked up as described in Example 1, yielding 0.54 g (75%) of the title compound with a β/α ratio of 78:22.

*Example 3, using tri-*n*-butylborane*

The dianion solution of **12** (4 mmol, produced as described in Example 1) was cooled to −70°C. To this was added dropwise a solution of 4-acetoxyazetidinone **3***a* (0.574 g, 2 mmol) and $(n\text{-Bu})_3B$ (1 mL, 1 M solution in THF) in dry THF (5 mL) over 10 min, and the resulting yellow solution was stirred at −70 to −65°C for 2 h. The reaction mixture was treated with a mixture of pH 7 buffer (4 mL), methanol (5 mL), and 30% H_2O_2 (1 mL) at room temperature for 1 h, then extracted with ether. The ether extract was washed with brine, 10% $NaHSO_3$, and brine, respectively, dried over anhydrous magnesium sulfate, and concentrated *in vacuo* to give an oil (0.58 g), which was chromatographed on silica gel (ether – petroleum ether 1:1), yielding the title compound (0.21 g, 28%); hplc showed β:α = 93:7.

Example 4, without Lewis acid

The dianion solution of **12** (4 mmol, produced as described in Example 1) was cooled to −70°C. To this was added a solution of 4-acetoxyazetidinone **3***a* (0.574 g, 2 mmol) in dry THF (2 mL). The resulting solution was stirred at −70°C for 1 h. Thin-layer chromatography (silica gel, ether – petroleum ether 3:2, uv and a molybdate solution for visualization) showed no starting 4-acetoxyazetidinone **3***a*. The reaction was then quenched with 6 N hydrochloric acid (10 mL) and the reaction mixture was worked up in the same manner as described in Example 1, yielding the title compound (0.27 g, 38%, β:α 77:23).

Via the bissilyl enolate process

Example 5, using tin(II) chloride

To a solution of 1,3-bis(trimethylsilyloxy)-1-methoxypenta-1,3-diene (**13**) (12) (0.466 g, 1.7 mmol) in dry THF (10 mL) at −40°C under N_2 was added anhydrous tin(II) chloride (0.323 g, 1.7 mmol). The slurry was stirred at −40 to −10°C for 25 min, and then a solution of 4-acetoxyazetidinone **3***a* (0.287 g, 1 mmol) in dry THF (1 mL) was added. The resulting solution was stirred at room temperature for 3 h. The reaction mixture was diluted with ether (70 mL), washed with brine (5×), dried over anhydrous magnesium sulfate, and concentrated to give a colorless oil (0.57 g), which was chromatographed on silica gel eluting with ether – petroleum ether 1:1, then ether alone, giving the title compound (0.25 g, 70%, β:α 69:31).

*Example 6, using tri-*n*-butylborane*

To a solution of 1,3-bis(trimethylsilyloxy)-1-methoxypenta-1,3-diene (**13**) (12) (0.274 g, 1 mmol) in dry THF (5 mL) at −70°C under N_2 was added $(n\text{-Bu})_3B$ (1 mL, 1 M solution in THF) and it was stirred at −70°C for 0.5 h. 4-Acetoxyazetidinone **3***a* (0.17 g, 0.59 mmol) was then added. The resulting solution was allowed to warm up and stirred at room temperature for 18 h. The reaction mixture was worked up as described in Example 3, affording the title compound (0.22 g, 100%, β:α 20:80).

*(3S,4R)-3-[(1R)-1-*tert*-Butyldimethylsilyloxyethyl]-4-(1-methoxycarbonyl-2-oxo-butan-1-yl]azetidin-2-one (**17**)*

Zinc dust (0.65 g, 10 mmol) was activated by washing with 1 N hydrochloric acid and dry THF (5×). The activated zinc dust was stirred in dry THF (10 mL) at −20°C under N_2 atmosphere. To this was added dropwise a solution of 4-acetoxyazetidinone **3***a* (0.574 g, 2 mmol) and methyl 2-bromo-3-oxopentanoate (**19**) (1.254 g, 6 mmol) in dry THF (5 mL) over 10 min. The slurry was stirred at −15 to 0°C for 3 h. The reaction mixture was filtered on Celite. The filtrate was diluted with ether (70 mL), washed successively with 1 N hydrochloric acid and brine (4×), dried over anhydrous magnesium sulfate, and concentrated to give an oil, which was chromatographed on silica gel eluting with ether–petroleum ether 1:1, then ether alone, affording the title compound as a diastereomeric mixture (55:44, 0.46 g, 83%); mp 81–83°C (recrystallized from hexane); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 0.05 (s, 6H, CH_3Si), 0.85, 0.86 (2s, 9H, CH_3CSi), 1.03–1.11 (overlapping 2d and 2t, 6H, CH_3CHOSi and CH_3CH_2), 2.49, 2.55 (2q, J = 7.2 Hz, 2H, CH_2CH_3), 2.88, 2.92 (2dd, J = 2.7, 3.3 and 2.5, 5.0 Hz, 1H, H-3), 3.56, 3.74 (2d, J = 9.6 and 8.2 Hz, 1H, $CHCO_2CH_3$), 3.74, 3.75 (2s, 3H, CO_2CH_3), 4.12–4.24 (overlapping m and 2dd, 2H, CH_3CHOSi and H-4), 5.91, 5.96 (br s, 1H, NH); mass spectrum (C.I.) m/e: 358 $(M + H)^+$. *Anal.* calcd. for $C_{17}H_{31}NO_5Si$ (357.198): C 57.12, H 8.74, N 3.92; found: C 57.52, H 8.88, N 4.02.

*Methyl 2-bromo-oxopentanoate (**19**)*

To a solution of methyl 3-oxopentanoate (13.0 g, 0.1 mol) and triethylamine (12.12 g, 0.12 mol) in dry dichloromethane (150 mL) at −5°C under nitrogen atmosphere was added dropwise trimethylsilyltriflate (26.66 g, 0.12 mol). The resulting yellow solution was stirred at 0–5°C for 1.5 h. To this solution (containing enol ether **18** (12)) was added dropwise a solution of bromine (16.0 g, 0.1 mol) in dichloromethane (60 mL). The resulting solution was stirred at 0°C for 1 h. The reaction mixture was washed with water (4×), dried over anhydrous magnesium sulfate, and concentrated to give an oil (21.0 g). The crude oil was distilled under reduced pressure, yielding **19** (14.32 g, 68%); bp 51–54°C/0.5 Torr (1 Torr = 133.3 Pa); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 1.12 (t, J = 7.2 Hz, 3H, CH_3CH_2), 2.79 (q, J = 7.2 Hz, 2H, CH_3CH_2), 3.82 (s, 3H, CO_2CH_3), 4.81 (s, 1H, CHBr).

*(3S,4R)-3-[(1R)-1-*tert*-Butyldimethylsilyloxyethyl]-4-[(1R)-3-allyloxycarbonyl-1-methyl-2-oxopropyl]azetidin-2-one (**23**)*

A solution of methyl ketoester **14***a* (223 mg, 0.625 mmol) in allyl alcohol (25 mL) was heated in oil bath at 100–110°C for 17 h with removal of methanol/allyl alcohol. The remaining solution was concentrated under reduced pressure to give an oil (260 mg), which was chromatographed on silica gel (30% ethyl acetate in heptane), giving the title compound (120 mg, 50%); mp 75–76°C (recrystallized from hexane); $[\alpha]_D^{23}$ −21.9° (*c* 0.63, $CHCl_3$); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 0.05, 0.06 (2s, 6H, CH_3Si keto + enol), 0.86 (s, 9H, CH_3CSi keto + enol), 1.11–1.22 (4 overlapping d, 6H, CH_3CHOSi keto + enol and $CH_3CHC{=}O$, $CH_3CHC(OH){=}$), 2.41 (m, 0.24H, $CH_3CHC(OH){=}$), 2.90, 2.96 (overlapping dd and m, J = 2.6 and 4.5 Hz, 1.76H, H-3 keto + enol and $CH_3CHC{=}O$), 3.55 (q, J = 15.8 Hz, 1.52H, $COCH_2CO_2$), 3.81 (dd, J = 2.2 and 6.4 Hz, 0.24H, H-4 enol), 3.94 (dd, J = 2.3 and 4.5 Hz, 0.76H, H-4 keto), 4.17 (m, 1H, CH_3CHOSi keto + enol), 4.63 (m, 2H, $CO_2CH_2CH{=}$), 5.06 (s, 0.24H, $C(OH){=}CHCO_2$), 5.23–5.38 (m, 2H, $CH{=}CH_2$), 5.80–6.00 (m, 2H, $CH{=}CH_2$ and NH); mass spectrum (C.I.) m/e: 384 $(M + H)^+$. *Anal.* calcd. for $C_{19}H_{33}NO_5Si$ (383.565): C 59.50, H 8.67, N 3.65; found: C 59.51, H 8.94, N 3.70.

*(3S,4R)-3-[(1R)-1-*tert*-Butyldimethylsilyloxyethyl]-4-[(1R)-3-allyloxycarbonyl-3-diazo-1-methyl-2-oxopropyl]azetidin-2-one (**24**)*

To a solution of β-ketoester **23** (0.19 g, 0.5 mmol) in dry acetonitrile (3 mL) at room temperature were added *p*-toluenesulfonyl azide (0.127 g, 0.65 mmol) and triethylamine (0.051 g, 0.5 mmol). The resulting solution was stirred for 18 h. The reaction mixture was diluted with ether (50 mL), then washed successively with 1 N hydrochloric acid, and brine (2×), dried over anhydrous magnesium sulfate, and concentrated to give the white crystalline title compound (0.20 g, 97%); mp 102–104°C (recrystallized from hexane); $[\alpha]_D^{23}$ −19.3° (*c* 0.62, $CHCl_3$); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 0.04, 0.05 (2s, 6H, CH_3Si), 0.85 (s, 9H, CH_3CSi), 1.16, 1.18 (2 overlapping d, J = 6.3 and 6.7 Hz, 6H, CH_3CHOSi and $CH_3CHC{=}O$), 2.96 (dd, J = 1.3 and 4.1 Hz, 1H, H-3), 3.84–3.96 (overlapping m and dd, 2H, $CH_3CHC{=}O$ and H-4), 4.17 (m, 1H, CH_3CHOSi), 4.71 (m, 2H, $CO_2CH_2CH{=}$), 5.27–5.39 (m, 2H, $CH{=}CH_2$), 5.86–5.95 (m, 2H, $CH{=}CH_2$ and NH); mass spectrum (C.I.) m/e: 410 $(M + H)^+$. *Anal.* calcd. for $C_{19}H_{31}N_3O_5Si$ (409.562): C 55.72, H 7.63, N 10.25; found: C 55.67, H 7.77, N 10.13.

*(3S,4R)-3-[(1R)-1-*tert*-Butyldimethylsilyloxyethyl]-4-[(1R)-3-methoxycarbonyl-3-diazo-1-methyl-2-oxopropyl]azetidin-2-one (**25**)*

The title compound was prepared in the same manner as described in the preparation of compound **24** in quantitative yield; mp 105–106°C (recrystallized from hexane); ^{1}H nmr (200 MHz, $CDCl_3$) δ: 0.04, 0.05 (2s, 6H, CH_3Si), 0.84 (s, 9H, CH_3CSi), 1.15 (d, J = 4.5 Hz, 3H, $CH_3CHC{=}O$), 1.17 (d, J = 4.1 Hz, 3H, CH_3CHOSi), 2.95 (dd, J = 1.3 and 4.1 Hz, 1H, H-3), 3.82 (s, 3H, CO_2CH_3), 3.89 (overlapping m and dd, 2H, $CH_3CHC{=}O$ and H-4), 4.17 (m, 1H, CH_3CHOSi), 5.86 (br s, 1H, NH); mass spectrum (C.I.) m/e: 384 $(M + H)^+$. *Anal.* calcd. for $C_{17}H_{29}N_3O_5Si$ (383.316): C 53.27, H 7.57, N 10.96; found: C 53.24, H 7.74, N 10.95.

*Base-catalyzed rearrangement of **17** to pyridone **15***

A solution of compound **17** (50 mg, 0.14 mmol) and triethylamine (0.02 mL, 0.14 mmol) in dichloromethane (2 mL) was stirred at room temperature for 24 h. The reaction mixture was diluted with dichloromethane (20 mL), washed successively with 1 N hydrochloric acid (10 mL), saturated sodium bicarbonate (10 mL), and water (2 × 10 mL), dried over anhydrous magnesium sulfate, and concentrated to give a white crystalline solid whose ^{1}H nmr spectrum and physical properties were identical to that of pyridone **15**. Yield 43 mg (94%).

Fused heterocycles from *o*-acylbenzenethiol derivatives

DAVID M. MCKINNON AND KINGSLEY R. LEE
Chemistry Department, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received November 18, 1987

DAVID M. MCKINNON and KINGSLEY R. LEE. Can. J. Chem. **66**, 1405 (1988).

The oximes of 2-acylthioanisole derivatives may be conveniently converted into 1,2-benzisothiazoles by acetic anhydride in pyridine. 3-(2-Methylthiophenyl)-1,2-benzisothiazole, prepared by this method, has been further converted into the 1,2-benzisothiazolo[2,3-*b*]-1,2-benzisothiazolium system. The phenylhydrazones of certain 2-acylthioanisoles are also cyclized by polyphosphoric acid to 2-(2-methylthio)phenylindoles, which are further converted into benzo[*b*]thieno[3,2-*b*]indoles by demethylation and oxidation.

DAVID M. MCKINNON et KINGSLEY R. LEE. Can. J. Chem. **66**, 1405 (1988).

Sous l'influence de l'anhydride acétique dans la pyridine, on peut facilement transformer les oximes de dérivés de l'acyl-2 thioanisole en benzisothiazoles-1,2. Utilisant cette méthode, on a préparé le (méthyl-2 thiophényl)-3 benzisothiazole-1,2 qu'on a utilisé pour préparer le système benzisothiazolo-1,2 [2,3-*b*]benzisothiazole-1,2 ium. Sous l'influence de l'acide polyphosphorique, on peut cycliser un certain nombre de phénylhydrazones d'acyl-2 thioanisoles en (méthyl-2 thio)-2 phénylindoles qui, par déméthylation et oxydation, peuvent être transformés en benzo[*b*] thiéno[3,2-*b*] indoles.

Introduction

In connection with our interest in isothiazoles, we wished to examine certain fused systems where the nitrogen atom forms a bridgehead to another heterocyclic ring. One of the most synthetically appealing methods to certain 1,2-benzisothiazole precursors **1** appeared to be from the readily accessible oximes of 2-(methylthiophenyl) ketones **2**.

Results and discussion

A number of variations of this method have been reported, involving heating the aromatic esters (1, 2), *p*-toluenesulfonate esters (1), or thionocarbamate esters (2) of the oximes. The conversions may also be effected in polyphosphoric acid (3). However, these methods suffer some disadvantages in that either products may be inconvenient to separate, there could be realkylation on nitrogen, or conditions are too drastic for certain compounds. What is required is that the hydroxy group of the oxime be converted into a suitable leaving group by esterification, and that the eliminated ester be volatile and nonreactive.

These conditions are supplied by the use of the acetate ester of the oxime, and we have found that heating the oximes **3***a–f* of the ketones **2***a–f* in an acetic anhydride/pyridine mixture converts them into 1,2-benzisothiazoles **1***a–f* in good to excellent yields. The intermediate oxime acetates may be isolated, but on longer heating the elimination is completed. Reaction mixtures become dark, but yields of 1,2-benzisothiazoles are not seriously compromised.

The method appears to be of fairly wide scope, allowing the synthesis of a number of aryl- and alkyl-1,2-benzisothiazoles, but failed for the oxime **3***g* of methyl 2-(2-methylthiophenyl)-2-oxoacetate **2***g*. Instead, 2-methylthiobenzonitrile was formed by elimination.

Starting ketones were available by Friedel–Crafts acylation of aryl methyl sulfides, or from 2-methylthiobenzoyl chloride. For the oxime **3***g*, benzo[*b*]thiophene-2,3-dione was converted by treatment with dimethyl sulfate in base to 2-(2-methylthiophenyl)-2-oxoacetic acid. This esterified in methanol with sulfuric acid to the ketoester **2***g*, which was converted to **3***g* by treatment with hydroxylamine. While the use of *tert*-butyl sulfides might give even better yields of 1,2-benzisothiazoles (2), many suitable methyl sulfides are available or more readily prepared.

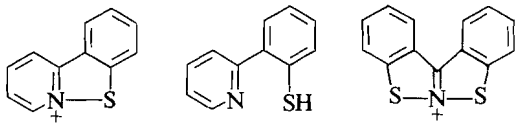
It was also of interest, since the related system **4** may be made (4) by oxidation of 2-(2-mercaptophenyl)pyridine (5), to use this method to prepare the novel 1,2-benzisothiazolo[2,3-*b*]-1,2-benzisothiazolium system **6**, via the 1,2-benzisothiazole **7***a*. A suitable starting ketone was not available by Friedel–Crafts procedures, but 2,2′-dichlorobenzophenone reacted with sodium methanethiolate to form 2,2′-bis(methylthio)benzophenone **8***a*. Under more severe conditions only thioxanthenone was obtained. The ketone reacted slowly with hydroxylamine to give the oxime **3***i*, which was also contaminated with the isothiazole **7***b*. However, the latter was more efficiently made by the acetic anhydride/pyridine procedure on the oxime **3***i*. Attempted direct demethylation and oxidation of the 1,2-benzisothiazole **7***b* to the system **5** did not succeed. It was recovered from perchloric acid. Accordingly demethylation was achieved via a Pummerer rearrangement of the sulfoxide **7***c* to the acetoxy sulfide **7***d*. This hydrolysed in acid to the mercaptan **7***a*. Probably dealkylation of a *tert*-butylthio sulfide **7***e* might have been easier (3) but 2,2′-bis(*tert*-butylthio)benzophenone (**3***b*), prepared from 2,2′-dichlorobenzophenone and 1,1-dimethylethanethiolate, could not be converted to an oxime. Reaction of 2,2′-dichlorobenzophenone with less *tert*-butylmercaptan gave the chloro *tert*-butylthioketone **8***c*.

When the mercaptan **7***a* was treated with iodine, a dark red solid was obtained, which crystallized from nitromethane



4 5 6

as fine red prisms. While the analysis of this material was consistent with the triiodide **6**, X = I_3, and the mass spectrum showed an intense ion at $M^+ = 242$, the ^{1}H nmr spectrum in acetone was not consistent with a symmetrical structure, i.e., eight different protons were evident. In view of its solubility properties, this material does appear to be a salt, although it could not be converted to a perchlorate. The methylthio precursor **7***b* also demonstrated a large ion at $M^+ = 242$, by demethylation.

These ketones **2***a,b,c* also permitted the synthesis of three 2-(2-methylthiophenyl)indoles **9***a,b,c*, via their phenylhydrazones **10***a,b,c* respectively. Previous attempts to synthesize these types by Fischer indolization procedures failed (5), but we found that cyclization to the indoles was readily effected in polyphosphoric acid, as suggested in ref. 6. These dealkylated by treatment with sodium in liquid ammonia to the mercaptans **9***d,e,f* respectively. While oxidation of suitable mercapto- or thio-amines to isothiazoles is a versatile method of synthesis (7), treatment of **9***d,e* with iodine gave, not the indolo[1,2-*b*]-

1,2-benzisothiazoles **11***a,b*, but the benzo[*b*]thieno[3,2-*b*]indoles **12***a,b* respectively. These cyclizations therefore correspond to various sulfenylation reactions of indoles (8). Even the sterically hindered mercaptan **9***f* failed to produce an isothiazole, and what appear to be decomposition products were obtained. If electrophilic attack of a sulfur cation at carbon-3 had occurred, then reaction intermediates could not aromatize and decomposition would be expected. This method represents a new approach to the system **12**. A previous method (9) involved indole formation as a last stage in the reaction sequence.

The benzothienoindole **12***b* was also made by acid treatment of the sulfoxide **9***g*. We saw no evidence of the formation of a

benzothiopyranoindole, which might have been produced by cyclization of an intermediate in a Pummerer rearrangement of **9***g*. These results are similar to some observed for 1-(2-alkylsulfinylaryl)pyrroles (10).

Experimental

Unless otherwise stated, ^{1}H nmr spectra were obtained in deuteriochloroform solution using tetramethylsilane as an internal standard, on Varian model EM360 or AM 300 spectrometers. Mass spectra were obtained on a V.G. 707E spectrometer. Infrared spectra were recorded on a Perkin Elmer model 881 spectrophotometer. Thick layer chromatography was performed on Merck type 60 PF 254 silica gel. Where necessary, solutions were dried over anhydrous magnesium sulfate.

Preparation of ketones **2**a–f

The ketones **2***a,b,c* were prepared by reported methods (1, 11, 12) respectively. Others were prepared by the methods described herein.

*Preparation of 1-(5-methyl-2-methylthiophenyl)propanone (***2**c*)*

To methyl 4-methylphenyl sulfide (27.6 g, 0.2 mol) in dichloromethane (100 mL), at −20°C, was added propanoyl chloride (18.5 g, 0.2 mol), followed by portionwise addition of anhydrous aluminum chloride (26.8 g, 0.2 mol) over 5 min. The mixture was allowed to attain room temperature and left for 48 h. The dark red mixture was poured over dilute hydrochloric acid in ice, and extracted with methylene chloride. The evaporated dried extract gave a yellow oil, which was distilled at 0.5 Torr (1 Torr = 133.3 Pa). The fraction of boiling range 115–120°C was collected. It crystallized on cooling and was recrystallized from cyclohexane as colorless prisms, mp 40–41°C (58%). The ir spectrum of **2***c*: 1666 (C=O str) cm^{-1}; ^{1}H nmr, δ: 1.25, 2.92 (3H, t, 2H, q, resp. the ethyl group), 2.39, 2.42 (two 3H, s, the S- and C-methyls), 7.20–7.62 (3H, bands, the aromatic protons) ppm; mass spectrum, *M* calcd.: 194; found, M^+: 194. *Anal.* calcd. for $C_{11}H_{14}SO$: C 68.06, H 7.22, S 16.49; found: C 68.12, H 7.25, S 16.29.

*Preparation of 2-methylthiobenzophenone (***2** d*)*

To 2-methylthiobenzoyl chloride (18.6 g, 0.1 mol) in dry benzene (200 mL) was added anhydrous aluminum chloride (13.4 g, 0.1 mol), and the mixture allowed to stand 16 h. The mixture was poured over dilute hydrochloric acid in ice, and the organic layer separated, dried, and evaporated to a yellow oil that was distilled at 0.35 Torr. The fraction of boiling range 162–167°C was collected. On cooling, this deposited a small amount (50 mg) of thioxanthenone, which was removed by filtration. Otherwise the ketone was fairly pure (81%).

The ir spectrum: 1667 (C=O) cm^{-1}; ^{1}H nmr, δ: 2.38 (3H, s, the S-methyl), 7.20–7.95 (9H, bands, the aromatic protons) ppm; mass spectrum, *M* calcd.: 228; found, M^+: 228.

This compound was identical (R_f, spectroscopic properties) with a sample prepared from 2-mercaptobenzophenone (13) for which different nmr spectral data have been reported.

Preparation of 4-(5-methyl-2-methylthiophenyl)-4-oxobutanoic acid (2b)

To a solution of methyl 4-methylphenyl sulfide (27.4 g, 0.2 mol) and succinic anhydride (20.04 g, 0.2 mol) in methylene chloride (150 mL) was added anhydrous aluminum chloride (29.3 g, 0.22 mol). The mixture was let stand 48 h, then poured over dilute hydrochloric acid in ice. The organic layer was separated and extracted with 20% sodium hydroxide solution. On acidification this gave the desired acid, which crystallized from benzene as colorless prisms, mp 132°C (48%); ^{1}H nmr, δ: 2.41 (two 3H, s, the S- and C-methyls), 2.78, 3.33 (two 2H, t, the methylene protons), 7.33–7.80 (3H, bonds, the aromatic protons) ppm; mass spectrum, *M* calcd.: 238; found, M^+: 238. *Anal.* calcd. for $C_{12}H_{14}SO_3$: C 60.50, H 5.88, S 13.45; found: C 60.53, H 6.02, S 13.33.

Preparation of methyl 4-(5-methyl-2-methylthiophenyl)-4-oxobutanoate (2f)

The acid **2***h* (9.52 g, 0.04 mol) prepared above, in methanol (60 mL) and concentrated sulfuric acid (1 drop), was heated under reflux 4 h. The solution was evaporated to 20 mL volume, and allowed to stand. The desired ester crystallized as pale yellow prisms. These were collected and recrystallized from cyclohexane as pale yellow prisms, mp 73–74°C (80%); ^{1}H nmr of **2***f*, δ: 2.41, 2.42 (two 3H, s, the S- and C-methyl protons), 3.73 (3H, s, the O-methyl protons), 2.78, 3.33 (two 2H, t, the methylene protons), 7.32–7.80 (3H, bands, the aromatic protons) ppm; mass spectrum, *M* calcd.: 252; found, M^+: 252. *Anal.* calcd. for $C_{13}H_{16}SO_3$: C 61.90, H 5.56, S 12.70; found: C 61.81, H 5.38, S 12.71.

Preparation of methyl 2-(2-methylthiophenyl)-2-oxoethanoate (2g)

Benzo[*b*]thiophene-2,3-dione (16.4 g, 0.1 mol) (14) was dissolved with stirring in 20% aqueous sodium hydroxide solution (100 mL) and treated with dimethyl sulfate (19.2 g, 0.15 mol). After 30 min the solution was acidified with concentrated hydrochloric acid. The crude acid precipitated as a viscous, dark yellow oil. It was dissolved in methanol (100 mL), concentrated sulfuric acid (2 drops) was added, and it was allowed to stand for 4 weeks. The mixture was poured into water and extracted with chloroform. This was washed with base and water, and dried. Evaporation gave a yellow-brown oil, which was purified by chromatography in benzene giving **2***g* as a dark yellow oil (89%); ^{1}H nmr of **2***g*, δ: 2.57 (3H, s, the S-methyl group), 3.97 (3H, s, the O-methyl group), 7.10–7.91 (4H, bands, the aromatic protons) ppm; mass spectrum, *M* calcd.: 210; found, M^+: 210. *Anal.* calcd. for $C_{10}H_{10}SO_3$: C 57.14, H 4.76, S 15.24; found: C 57.08, H 4.83, S 15.50.

Preparation of 2,2′-bis(methylthio)benzophenone (8a)

To a solution of sodium methoxide in methanol (from sodium (1 g) in methanol (20 mL)) was added excess methanethiol, and the mixture evaporated to dryness. The solid was dissolved in bis(2-methoxyethyl) ether (25 mL) in a pressure bottle, and to it added liquid methanethiol (10 mL) and 2,2′-dichlorobenzophenone (5.02 g, 0.02 mol). The mixture was heated at 100°C for 24 h, then poured into water. A yellow oil precipitated and crystallized on standing. It was collected and recrystallized from a toluene:cyclohexane 1:1 mixture as yellow prisms, mp 100–101°C (86%); ^{1}H nmr of **8***a*, δ: 2.47 (6H, s, the S-methyl protons), 7.05–7.60 (8H, bands, the aromatic protons) ppm; mass spectrum, *M* calcd.: 274; found, M^+: 274. *Anal.* calcd. for $C_{15}H_{14}S_2O$: C 65.69, H 5.11, S 23.36; found: C 65.65, H 5.02, S 23.51.

At 150°C, without excess methanethiol, only thioxanthenone was isolated.

*Preparation of 2,2′-bis(*tert*-Butylthio)benzophenone (8b)*

This was performed as for **8***a*. The product was recrystallized from cyclohexane as yellow prisms, mp 110°C (96%); ^{1}H nmr of **8***b*, δ: 1.30 (18H, s, the *tert*-butyl protons), 7.18–7.58 (8H, bands, the aromatic protons) ppm; mass spectrum, *M* calcd.: 358; found, M^+: 358. *Anal.* calcd. for $C_{21}H_{26}S_2O$: C 70.39, H 7.26, S 17.88; found: C 70.22, H 7.13, S 18.05.

When equivalent quantities of 2,2′-dichlorobenzophenone and sodium 1,1-dimethylethanethiolate were used in the above procedure, work-up gave **8***c* as a yellow oil. This was purified by chromatography using benzene as an eluent (81%). The ^{1}H nmr spectrum of **8***c*, δ: 1.21 (9H, s, the *tert*-butyl protons), 7.17–7.59 (8H, bands, the aromatic protons) ppm; mass spectrum, calcd. for two isotopes, *M*: 306, 304; found, M^+: 306, 304. *Anal.* calcd. for $C_{17}H_{17}ClSO$: C 66.78, H 5.58, Cl 11.16, S 10.51; found: C 66.83, H 5.49, Cl 11.32, S 10.29.

Preparation of ketoximes 3a–g

The ketones prepared above, dissolved in an approximately 20-fold weight of a pyridine:ethanol 1:1 mixture, with an equal weight of hydroxylamine hydrochloride, were heated under reflux for 24 h for benzophenones, and 4 h for the other compounds. Mixtures were worked up by addition to ice-cold 20% hydrochloric acid. Solids were collected and liquids isolated by chloroform extraction. No analyses were taken but in all cases mass spectral and nmr data were consistent with pure oximes or mixtures of their geometrical isomers. Yields were usually high (90–95%).

Melting points (oximes) are as follows: **3***a* (106–108°C); **3***b* (103°C); **3***d* (130°C); **3***e* (133–136°C); **3***g* (102–104°C). Other oximes were either oils or melting ranges were too broad to be diagnostic.

Preparation of 2,2′-bis-methylthiobenzophenone oxime (3i)

The ketone **2***h* (5.48 g, 0.02 mol) in pyridine (20 mL) and hydroxylamine hydrochloride (6 g) was heated under gentle reflux for 1 week. The mixture was added to concentrated hydrochloric acid (20 mL) in ice (100 g), and a sticky solid precipitated. This was collected and crystallized from methanol giving **3***i* as pale yellow prisms, mp 136–137°C (56%). Chromatography of the mother liquor using a benzene:chloroform 10:1 mixture as an eluent gave, in reverse order of elution, more oxime (20%), starting ketone (8%), and a fast running material that crystallized on standing. It was recrystallized from cyclohexane, giving **7***b* as pale yellow prisms, mp 80°C (15%).

The ^{1}H nmr spectrum of **3***i*, δ: 2.43, 2.48 (two 3H, s, the S-methyl protons), 3.70 (1H, br, the oxime proton), 7.05–7.50 (8H, bands, the aromatic protons) ppm; mass spectrum, *M* calcd.: 289; found, M^+: 289. *Anal.* calcd. for $C_{15}H_{15}NS_2O$: C 62.28, H 5.19, N 4.84, S 22.15; found: C 62.21, H 5.30, N 4.62, S 22.04.

The ^{1}H nmr spectrum of **7***b*, δ: 2.35 (3H, s, the S-methyl protons), 7.20–8.04 (8H, bands, the aromatic protons) ppm; mass spectrum, *M* calcd.: 257; found, M^+: 257. In addition, a large ion at M^+ 242 (M^+ − 15) was evident. *Anal.* calcd. for $C_{14}H_{11}NS_2$: C 65.37, H 4.28, N 5.45, S 24.90; found: C 65.42, H 4.31, N 5.28, S 24.79.

Preparation of 1,2-benzisothiazoles 1a–f, 7b

The ketoximes **3** (1 g) in pyridine (20 mL) and acetic anhydride (2 g) were heated under reflux 24 h. Mixtures were diluted with 50% concentrated hydrochloric acid in water and extracted with chloroform. Where necessary this was treated with charcoal. Drying and evaporation gave the desired 1,2-benzisothiazoles. 3-Aryl-1,2-benzisothiazoles crystallized on standing and were recrystallized from methanol. Others were purified by chromatography or distillation. The results are summarized in Table 1. All compounds gave mass spectra consistent with their formulae.

If mixtures are heated for 1 h, the oxime acetates may be isolated.

Reaction of methyl 2-(2-methylthiophenyl)-2-oxoacetate oxime (3g) with acetic anhydride to form 2-methylthiobenzonitrile

The ketoester oxime (4.46 g, 0.02 mol) was heated with pyridine and acetic anhydride by the general procedure above. Work-up gave a colorless oil that crystallized on standing. It was recrystallized from cyclohexane as colorless needles, mp 36°C (83%). The compound was identical (mixture mp, spectroscopic properties) with an authentic specimen (16).

Preparation of 3-(2-methylsulfinylphenyl)-1,2-benzisothiazole (7c)

3-(2-Methylthiophenyl)-1,2-benzisothiazole (1.028 g, 4.0 mmol) in acetone (20 mL) was treated with the equivalent quantity of *m*-chloroperoxybenzoic acid in acetone (20 mL) and warmed 5 min. The solution was evaporated to dryness and partitioned between chloroform and saturated sodium carbonate solution. The former was

‡For further data see this work (above).
§This was purified by chromatography and isolated as an oil.

dried and evaporated to an oil, which was purified by chromatography in methylene chloride, giving **7***c* as a colorless oil (83%); ^{1}H nmr of **7***c*, δ: 3.01 (3H, s, the S-methyl protons), 7.30–8.53 (8H, bands, the aromatic protons) ppm; mass spectrum, *M* calcd. 273; found, M^+: 273. *Anal.* calcd. for $C_{14}H_{11}NS_2O$: C 61.54, H 4.03, N 5.13, S 23.44; found: C 61.66, H 4.07, N 5.01, S 23.29.

*Preparation of 3-(2-acetoxymethylthiophenyl)-1,2-benzisothiazole (**7**d)*

A solution of the sulfoxide **7***c* (1.09 g, 4.0 mmol) in acetic anhydride (10 mL) and *p*-toluenesulfonic acid (50 mg) was heated under reflux 1 h, then added to a stirred solution of sodium bicarbonate and left for 1 h. The dried chloroform extract of this mixture was evaporated, giving **7***d* as a pink oil, further purified by chromatography in a benzene:chloroform 1:1 mixture (93%). The ^{1}H nmr spectrum of **7***d*, δ: 2.07 (3H, s, the acetoxy protons), 5.37 (2H, s, the methylene protons), 7.13–8.16 (8H, bands, the aromatic protons) ppm; mass spectrum, *M* calcd.: 315; found, M^+: 315. In addition, a large ion at M^+ 242 was evident. *Anal.* calcd. for $C_{16}H_{13}NS_2O_2$: C 60.95, H 4.13, N 4.44, S 20.32; found: C 61.08, H 4.40, N 4.41, S 20.18.

*Preparation of 3-(2-mercaptophenyl)-1,2-benzisothiazole (**7**a)*

The acetate **7***d* (0.63 g, 2.0 mmol) in methanol (10 mL) and concentrated hydrochloric acid (1 mL) was heated under reflux in a nitrogen atmosphere for 3 h. The solution was decanted from a tarry precipitate and evaporated *in vacuo*. The product was then dissolved in chloroform, washed with aqueous sodium bicarbonate solution, and dried. Evaporation gave a smelly reddish oil. No further purification of this was attempted, but the nmr spectrum indicated only peaks in the mercaptan and aromatic ranges (73%).

Iodine oxidation of 3-(2-mercaptophenyl)-1,2-benzisothiazole

The crude product from above (0.283 g, 1 mmol) in ethanol (5 mL) was treated dropwise with a saturated solution of iodine in ethanol until precipitation was complete. The dark red precipitate was collected and recrystallized from nitromethane as fine, dark red prisms, mp 162°C (61%). This material, tentatively **6**, X = I_3, was insoluble in ether, benzene, and chloroform. It was slightly soluble in acetone.

The nmr spectrum of **6** (X = I_3) in acetone indicated a series of bands, δ 7.43–8.46 ppm, consistent with eight different aromatic protons. The mass spectrum, M^+ calcd.: 242; found, M^+: 242. *Anal.* calcd. for $C_{13}H_8NS_2I_3$: C 25.04, H 1.28, N 2.25, S 10.27, I 61.16; found: C 24.98, H 1.30, N 2.20, S 10.32, I 60.98. An attempt to convert this material to a perchlorate in acetic acid failed.

*Preparation of phenylhydrazones of ketones **2**a–c*

Equivalent quantities of ketones, phenylhydrazine hydrochloride, and sodium acetate in ethanol were heated under reflux for 1 h. Mixtures were poured over ice and products collected or extracted with chloroform. Solid products were recrystallized from ethanol. They were not analysed.

Compounds (mp), yields are as follows: **10***a* (118°C; lit. (5) mp 86°C) 86%; **10***b* (115°C) 80%; **10***c* (oil) 70%.

*Cyclization of phenylhydrazones **10**a–c to indoles **9**a–c*

General procedure

The phenylhydrazones (2 g) in polyphosphoric acid (40 mL) were heated at 100°C for 2 h, with occasional stirring. Mixtures were diluted with water and products extracted with ethyl acetate. These extracts were washed with sodium bicarbonate solution, dried, and evaporated to give crude indoles, which were recrystallized from ethanol. Data are summarized below.

*2-(2-Methylthiophenyl)indole (**9**a)*

This was obtained as colorless prisms, mp 124–125°C (65%); ^{1}H nmr, δ: 2.40 (3H, s, the S-methyl protons), 6.89 (1H, s, the indole proton), 7.14–7.90 (8H, bands, the aromatic protons), 9.15 (1H, br s, the N-H proton) ppm; mass spectrum, *M* calcd.: 239; found, M^+: 239. *Anal.* calcd. for $C_{15}H_{13}NS$: C 75.31, H 5.44, N 5.86, S 13.39; found: C 75.36, H 5.40, N 5.99, S 13.42.

*2-(5-Methyl-2-methylthiophenyl)indole (**9**b)*

This was obtained as colorless prisms, mp 107–108°C (71%); ^{1}H nmr, δ: 2.33 (3H, s, the C-methyl protons), 2.38 (3H, s, the

S-methyl protons), 6.85 (1H, s, the indole proton), 7.01–7.78 (7H, bands, the aromatic protons), 9.15 (1H, br s, the N-H proton) ppm; mass spectrum, *M* calcd.: 253; found, M^+: 253. *Anal.* calcd. for $C_{16}H_{15}NS$: C 75.89, H 5.93, N 5.53, S 12.65; found: C 75.83, H 6.09, N 5.46, S 12.62.

*3-Methyl-2-(2-methylthio-5-methylphenyl)indole (**9**c)*

This was obtained as colorless prisms, mp 96–98°C (78%); ^{1}H nmr, δ: 2.25, 2.28, 2.34 (three 3H, s, the C and S methyl groups), 7.05–7.70 (7H bands, the aromatic protons), 8.17 (1H, br s, the N-H proton) ppm; mass spectrum, *M* calcd.: 267; found, M^+: 267. *Anal.* calcd. for $C_{17}H_{17}NS$: C 76.40, H 6.37, N 5.24, S 11.99; found: C 76.41, H 6.29, N 5.18, S 11.82.

*Preparation of benzo[b]thieno[3,2-b]indole (**12**a)*

The indole **9***a* (0.478 g, 2.0 mmol) in ether (10 mL) was added to liquid ammonia (50 mL), and sodium (60 mg) was added in small pieces until a permanent blue color appeared. After 1 h ethanol (5 mL) was added, and the ammonia allowed to evaporate. The mixture was acidified with dilute hydrochloric acid and extracted with ether. The dried solvent gave, on evaporation, 2-(2-mercaptophenylindole) (**10***d*) as an oil. This was not further characterized. It was dissolved in acetic acid (2 mL), treated with a saturated solution of iodine in ethanol (2 mL), and let stand 16 h. The mixture was added to a solution of sodium bisulfite and sodium bicarbonate in water and extracted with ether. The dried extract gave the crude indole **12***a* on evaporation. It was recrystallized from cyclohexane as small colorless prisms, mp 250–252°C (lit. (9) mp 250–252°C) (46%).

*Preparation of 8-methylbenzo[b]thieno[3,2-b]indole (**12**b)*

This was prepared as above, using the indole **9***b*. The product **12***b* was obtained as colorless prisms, mp 220–222°C (lit. (9) mp 222–224°C (62%).

*Cleavage and oxidation of 3-methyl-2-(2-methylthio-5-methylphenyl)-indole (**9**c)*

Performed as above, the iodine oxidation gave only a complex mixture, which was not further examined.

*2-(2-Methylsulfinyl-5-methylphenyl)indole (**9**g)*

To the indole **9***b* (5.06 g, 2.0 mmol) in acetone (10 mL) was added a solution of the equivalent quantity of *m*-chloroperbenzoic acid in acetone (10 mL), and the solution refluxed gently 30 min. The mixture was poured into saturated sodium bicarbonate solution and extracted with chloroform. The dried extract gave **9***g* on evaporation, which was recrystallized from ethanol as colorless prisms, mp 184–185°C (55%); ^{1}H nmr, δ: 2.45 (6H, two superimposed singlets, the S- and C-methyl protons), 6.75–7.95 (8H, bands, the indole and aromatic protons), 10.67 (1H, br s, the N-H proton) ppm; mass spectrum, *M* calcd.: 269; found, M^+: 269. *Anal.* calcd. for $C_{16}H_{15}NSO$: C 71.38, H 5.58, N 5.20, S 11.90; found: C 71.22, H 5.46, N 5.31, S 12.08.

*Conversion of 2-(2-methylsulfinyl-5-methylphenyl)indole into 8-methylbenzo[b]thieno[3,2-b]indole (**12**b)*

The sulfoxide **9***g*, (100 mg, 0.37 mmol) in acetic acid (10 mL), saturated with hydrogen chloride, was heated under reflux 1 h, neutralized with aqueous sodium bicarbonate solution, and extracted with chloroform. The dried extract gave the benzothienoindole **12***b* on evaporation, identical (mixture mp, mass spectrum, nmr) to a sample prepared above (56%).

J. ALONSO, L. BAÑARES, M. MENÉNDEZ, and A. GONZÁLEZ UREÑA. Can. J. Chem. **66**, 1410 (1988).

A variational transition state theory has been developed to account for the kinetic energy dependence of the reaction cross-section which is valid for the case where experiments are carried out at different, but fixed, collision energies. One of the main aspects of the present work is the inclusion of non-collinear configurations for the transition state.

Analytical expressions for $\sigma_R(E_T)$ averaged over the angle of attack are presented and several model calculations where carried out for the M + RX → MX + R reaction family with an orientational dependence of the energy barrier. The relative success of the present model calculations has been rationalized considering the possibility that long range interactions, via alignment forces, would favour the collinear approach regardless of the initial angle of attack.

J. ALONSO, L. BAÑARES, M. MENÉNDEZ et A. GONZÁLEZ UREÑA. Can. J. Chem. **66**, 1410 (1988).

On a mis au point une théorie variationnelle de l'état de transition pour expliquer le fait que la réaction de section droite dépend de l'énergie cinétique; cette théorie est valide dans les cas où les expériences sont faites à des énergies de collision différentes, mais fixes. Un des principaux aspects de ce travail est l'inclusion de configurations qui ne sont pas colinéaires pour l'état de transition.

On présente des expressions analytiques pour les valeurs de $\sigma_R(E_T)$ moyennes suivant l'angle d'attaque et on a effectué plusieurs calculs modèles pour la famille de réactions M + RX → MX + R, suivant l'orientation de la barrière d'énergie. On rationalise le succès relatif de nos calculs modèles en suggérant que des interactions à longue distance, par le biais d'alignement de forces, favorisent l'approche colinéaire quel que soit l'angle initial d'attaque.

I. Introduction

In a previous study (1) a microcanonical transition state theory was developed to account for the kinetic energy dependence of the reaction cross-section, that is the excitation function, $\sigma_R(E_T)$, of atom–diatom exchange reactions. Essentially a variational transition state theory model was considered valid for quasi-collinear configurations on LEPS energy surfaces. A test was performed to the excitation function for Cl + CH_3I → ClI + CH_3 (2), which yields satisfactory results in the interpretation of its collision energy dependence.

The present paper is an extension of that treatment for non-collinear configurations of the transition state. Analytical expressions for the excitation function averaged over the angle of attack are presented and several model calculations were carried out with an orientational dependence of the reaction barrier of the linear form $E = E_0 + E_0'(1 - \cos\gamma)$. Applications were made to the M + RX → MX + R family of reactions for which an extensive body of data is available from molecular beam experiments (3–10). Therefore we have an excellent opportunity to test the present treatment.

We anticipate that the present theory is useful to predict the collision energy dependence of the reaction cross-section with no or small negative energy dependence, i.e. those systems without sharp maximum in their excitation functions. In these latter cases the theory is not good enough to predict such post-maximum decline in $\sigma_R(E_T)$ as a result, perhaps, of some dynamic effect absent in our statistical treatment even though the location of the transition state varied (see, for example, ref. 11) on the reaction coordinate.

One interesting result is that the quasi-collinear configuration seems to be more capable of reproducing the observed behaviour of $\sigma_R(E_T)$ in the near post-threshold range. This has been rationalized by the possibility that, over this low energy range, long range interaction via alignment forces, it would favour the collinear approach regardless of the initial angle of attack.

II. Theory

Microcanonical variational transition state theory (μVTST)

Our starting point is the variational TST rate constant $k(E)$ for the microcanonical ensemble of A, BC pairs at total energy E, given by (11)

$$[1] \qquad k_{\mu VTST}(E) = \kappa(E)\frac{N^+(E - V^+(s^*))}{h\rho(E)}$$

where h is Planck's constant, $\rho(E)$ is the density of states of reactants per unit energy and volume, $N^+(E - V^+(s^*))$ is the minimum in the total number of internal states of the transition state, within the active modes, excluding the reaction coordinate, and energy less than or equal to $E - V^+$, where V^+ is the potential energy of transition state, along the reaction coordinate s and s^* is the location of this minimum in the energy path. $\kappa(E)$ is the transmission coefficient, which is traditionally assumed to be independent of energy and equal to unity.

To obtain analytical expressions for $N^+(E - V^+(s^*))$ and $k_{\mu VTST}(E,s^*)$ two cases were considered: the quasi-collinear model (1), where only collinear configurations of the ABC system were included and the bent, non-collinear model, where allowance was made for bent transition states, including an orientational dependence of the reaction barrier as a result of the bending potential for the A..B..C triatomic system.

A. Quasi-collinear model (1)

This model considers a configuration on the triatomic ABC system whose minimum energy (or reaction path) is the collinear one at transition state configuration. For a strictly collinear configuration only symmetric and asymmetric stretching modes ν_S and ν_A are relevant, but in the realistic three-dimensional situation, when slight deviations from collinearity contribute, the doubly degenerate bending mode ν_B is also active.

TABLE 1. Microcanonical reaction cross-section expressions for triatomic quasi-collinear configurations (see text for details)

Case	Stretch: Harmonic	Stretch: Morse	Bending	β	$F(z)$
A0		0	0	$\pi I^{\ddagger} D_e$	z
A1		0	1	$\frac{\pi I^{\ddagger} D_e^2}{2(h\nu_B)}$	z^2
A2		0	2	$\frac{\pi I^{\ddagger} D_e^3}{6(h\nu_B)^2}$	z^3
A3	1		0	$\frac{\pi I^{\ddagger} D_e^2}{2(h\nu_S)}$	z^2
A4	1		1	$\frac{\pi I^{\ddagger} D_e^3}{6(h\nu_S)(h\nu_B)}$	z^3
A5	1		2	$\frac{\pi I^{\ddagger} D_e^4}{24(h\nu_S)(h\nu_B)^2}$	z^4
B1		1	0	$\frac{\pi I^{\ddagger} D_e}{2x_e}$	$z - \frac{2}{3}(1 - (1 - z)^{3/2})$
B2		1	1	$\frac{\pi I^{\ddagger} D_e^2}{2x_e(h\nu_B)}$	$\frac{z^2}{2} - \frac{2}{3}z + \frac{4}{15}(1 - (1 - z)^{5/2})$
B3		1	2	$\frac{\pi I^{\ddagger} D_e^3}{12x_e(h\nu_B)^2}$	$\frac{z^3}{2} - \frac{4}{5}z(1 + (1 - z)^{5/2}) + \frac{16}{35}(1 - (1 - z)^{7/2})$

At the internal energy $E_{int}^{\ddagger}$ the density of internal states of the activated complex is (12, 13)

$$[2] \qquad \rho(E_{int}^{\ddagger}) = \frac{2I^{\ddagger}}{\hbar^2} N_{vib}(E_{int}^{\ddagger})$$

where $N_{vib}(E_{int}^{\ddagger})$ is the total number of vibrational states of the activated complex with energy $E_{int}^{\ddagger}$ and $I^{\ddagger}$ is the moment of inertia.

This density was obtained by compounding the number of vibrational states $N_{vib}(E_{int}^{\ddagger})$ with the density of rotational states $\rho_{rot} = 2I^{\ddagger}/\hbar^2$ for the transition state.

For the present case in which all vibrational modes (i.e. $(\nu_S + 2\nu_B)$) are considered active (13)

$$[3] \qquad \rho(E_{int}^{\ddagger}) = \frac{I^{\ddagger}}{3\hbar^2}\left(\frac{1}{h\nu_B}\right)^2 \frac{1}{h\nu_S} E_{int}^{\ddagger 3}$$

where the asymmetric stretch is taken as the reaction coordinate and the harmonic approximation is used for the symmetric stretch and bending modes.

If the more realistic Morse-oscillator approximation (1) is used for the symmetric stretch motion, the above density becomes (1, 13)

$$[4] \qquad \rho(E_{int}^{\ddagger}) = \frac{I^{\ddagger} D_e^2}{\hbar^2 (h\nu_B)^2 2x_e}\left\{\frac{1}{2}\left(\frac{E_{int}^{\ddagger}}{D_e}\right)^2 + \frac{2}{3}\frac{E_{int}^{\ddagger}}{D_e}\left(1 - \frac{E_{int}^{\ddagger}}{D_e}\right)^{3/2} - \frac{4}{15}\left(1 - \left(1 - \frac{E_{int}^{\ddagger}}{D_e}\right)^{5/2}\right)\right\}$$

where x_e is the anharmonicity constant (12), $x_e = h\nu_S/4D_e$ and ν_S, D_e are the vibrational frequency and dissociation energy of the oscillator, respectively.

The sum of states $N(E - V(s))$ is obtained by integrating [4] up to the total available energy, $E - V(s)$,

$$[5] \qquad N(E - V(s)) = \int_0^{E - V(s)} \rho(E_{int}^{\ddagger}) dE_{int}^{\ddagger} = \frac{I^{\ddagger} D_e^3}{6x_e \hbar^2 (h\nu_B)^2} F(z)$$

where

$$[6] \qquad F(z) = \frac{z^3}{2} - \frac{4}{5}z(1 + (1 - z)^{5/2}) + \frac{16}{35}(1 - (1 - z)^{7/2})$$

and

$$[7] \qquad z(s) = \frac{E - V(s)}{D_e}$$

is the reduced available energy.

The $F(z)$ functions for the cases where different subsets of the total number of modes are active are summarized in Table 1. In this table two cases are considered: case A where all the internal degrees of freedom of ABC complex are treated as harmonic oscillators; case B is the same but the stretching motion is described by the Morse-oscillator model.

Excitation function expressions

Since we are primarily interested in the collision energy dependence of the cross section, we restrict ourselves here to the case of a low and constant reactant internal energy E_{int} (e.g. as controlled by the nozzle conditions for a supersonic beam). In this case one can split $\rho(E)$ as follows:

$$[8a] \qquad \rho(E) = \rho_T(E_T) N_{int}(E_{int})$$

where

$$[8b] \qquad E = E_T + E_{int}$$

where $\rho_T(E_T)$ is the reactant translational density of states and $N_{int}(E_{int})$ the sum of states of the target molecules BC. They are given by (1)

$$[9] \quad \rho_T(E_T) = A_T E_T^{1/2} = (\mu^{3/2}/2^{1/2}\pi^2\hbar^3)E_T^{1/2}$$

and, within the rigid-rotor Morse-oscillator approximation for BC, by

$$[10] \quad N_{int}(E_{int}) = \left(\frac{1}{2x_e^R}\right)\left(1 - \left(\frac{D_e^R - E_V}{D_e^R}\right)^{1/2}\right)\left(\frac{E_R}{hcB_e}\right)$$

where the vibrational and rotational energies of BC, E_V and E_R, are taken fixed and x_e^R, D_e^R stand for the anharmonicity constant and dissociation energy of the (diatom) reactant, respectively.

In these cases where the reactants have different, but fixed collision energies, a corresponding cross-section $\sigma_R(E)$ can be defined given the μVTST rate (eqs. [1] and [5]) as follows

$$[11] \quad \sigma_R(E) = \frac{k^{\ddagger}(E,s^*)}{v} = \left(\frac{\mu}{2E_T}\right)^{1/2}\frac{N^{\ddagger}(E,s^*)}{h\rho(E)}$$

where μ is the reduced mass of the reactant.

Substituting eqs. [9] and [10] into eq. [11] yields a cross-section expression as a function of E_T, E_V, and E_R. In the idealized situation, which is approximated by many experiments, the target molecule is in the vibrational and rotational ground state (i.e. cold), in which case $N_{int}(E_{int}) \rightarrow 1$. In this case the excitation function reduces to

$$[12] \quad \sigma_R(E) = \sigma_R(E_T) = \beta F(z)/\mu E_T$$

where the expressions for β and $F(z)$ are given in Table 1 for the cases of fully and partially active internal modes. We are concerned with translational effects and so we employ the simplified version of eq. [12].

(B) Bending potential effect: dependence of reaction barrier on orientation angle

In the previous treatment no allowance was made for any orientation angle dependence of the reaction barrier. To include it let us consider a configuration of the triatomic ABC system specified by the angle γ as shown in Fig. 1. The total reaction cross-section can be obtained by

$$[13] \quad \sigma_R(E) = \frac{\int_{-1}^{+1}\sigma_R(E,\gamma)\,d(\cos\gamma)}{\int_{-1}^{+1}d(\cos\gamma)}$$

where

$$[14] \quad \sigma_R(E,\gamma) = \left(\frac{\mu}{2E_T}\right)^{1/2}\frac{N^{\ddagger}(E - V^{\ddagger}(s^*,\gamma))}{h\rho(E)}$$

Note that $N^{\ddagger}(E - V^{\ddagger}(s^*,\gamma))$ now measures the minimum number of energetically available internal states of the transition state at the molecular configuration specified by γ.

In the present work we have considered as valid the quasi-collinear approximation described above. Essentially it is equivalent to assume that the maximum angle of approach, γ_{max}, leading to reaction always occurs at molecular configurations where the normal vibrational modes of the triatomic molecule can be described by those of the linear triatomic molecule. So, the same cases as in the quasi-collinear model can be described here.

With respect to $V^{\ddagger}(s,\gamma)$, it can be approximated by a linear function of cosine (14), i.e.,

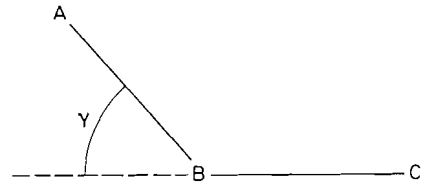

FIG. 1. Bent configuration for the ABC triatomic at the specified γ angle.

$$[15] \quad V(s,\gamma) = V(s) + V'(s)(1 - \cos\gamma)$$

This function has been used (14–16) successfully to fit experimental and calculated data on the orientation dependence of the reaction threshold.

With this assumption and using the harmonic approximation, with all modes considered active, one gets

$$[16a] \quad N(E - V(s,\gamma_{max})) = \int_{\cos\gamma_{max}}^{+1} C\cdot(E - V(s) - V'(s)(1 - \cos\gamma))^4 d(\cos\gamma)$$

where

$$[16b] \quad C = \frac{I^{\ddagger}}{12(h\nu_B)^2(h\nu_S)\hbar^2}$$

and so

$$[17] \quad N(E - V(s,\gamma_{max})) = \frac{I^{\ddagger}D_e^5}{240\,V'(s)(h\nu_B)^2(h\nu_S)}F(z,x)$$

where $z(s)$ is defined by eq. [7] and

$$[18] \quad x(s) = \frac{V'(s)(1 - \cos\gamma_{max})}{D_e}$$

being $z(s) - x(s)$ the reduced available energy at γ_{max}.

The functions $F(z,x)$ for the cases where different subsets of the total number of modes are active are summarized in Table 2. As in Table 1 two cases are considered: internal modes as harmonic oscillators (case A) and stretching motion described by the Morse-oscillator model (case B).

As in the quasi-collinear model, the corresponding cross-section $\sigma_R(E)$ results

$$[19] \quad \sigma_R(E) = \sigma_R(E_T) = \beta F(z,x)/\mu E_T$$

where the expressions for β and $F(z,x)$ are given in Table 2 for the cases of fully and partially active internal modes.

We should point out that section II.B does not include the angular terms of the transition state configurations again. Essentially what it does is to modify the potential energy barrier as a function of the bending angle, i.e. it takes into consideration an orientational dependence of the reaction barrier or, equivalently, the potential energy value as a function of the bending angle. If we use the harmonic approximation, the number of internal states is given by

$$N_{int} = \left(\frac{E - V^{\ddagger}(s)}{h\nu_B}\right)$$

where $E - V^{\ddagger}(s)$ is the total energy available for the transition state. For the results described in section I and Table 2, $V(s)$ has been taken as the collinear $V^{\ddagger}(s)$ value. In section II.B what we have done is to account for an orientational dependence of $V(s)$, i.e. $V(s,\gamma) = V(s) + V(s)'(1 - \cos\gamma)$. We have used

TABLE 2. Microcanonical reaction cross-section expressions for triatomic non-collinear configurations (see text for details)

Case	Stretch: Harmonic	Stretch: Morse	Bending	β	$F(z,x)$
A0	0		0	$\frac{\pi I^{\ddagger} D_e^2}{4V'}$	$z^2 - (z-x)^2$
A1	0		1	$\frac{\pi I^{\ddagger} D_e^3}{12V'(h\nu_B)}$	$z^3 - (z-x)^3$
A2	0		2	$\frac{\pi I^{\ddagger} D_e^4}{48V'(h\nu_B)^2}$	$z^4 - (z-x)^4$
A3	1		0	$\frac{\pi I^{\ddagger} D_e^3}{12V'(h\nu_S)}$	$z^3 - (z-x)^3$
A4	1		1	$\frac{\pi I^{\ddagger} D_e^4}{48V'(h\nu_S)(h\nu_B)^2}$	$z^4 - (z-x)^4$
A5	1		2	$\frac{\pi I^{\ddagger} D_e^5}{240V'(h\nu_S)(h\nu_B)^2}$	$z^5 - (z-x)^5$
B1		1	0	$\frac{\pi I^{\ddagger} D_e^2}{4x_e V'}$	$\frac{1}{2}(z^2 - (z-x)^2 - \frac{2}{3}x + \frac{4}{15}((1-z-x)^{5/2} - (1-z)^{5/2})$
B2		1	1	$\frac{\pi I^{\ddagger} D_e^3}{12x_e V'(h\nu_B)}$	$\frac{z^3-(z-x)^3}{2} - (z^2-(z-x)^2) + \frac{4}{5}x + \frac{8}{35}((1-z)^{7/2} - (1-z-x)^{7/2})$
B3		1	2	$\frac{\pi I^{\ddagger} D_e^4}{24x_e V'(h\nu_B)^2}$	$\frac{z^4-(z-x)^4}{8} - \frac{z^2-(z-x)^2}{10} + \frac{16}{35}x + \frac{8}{35}(z(1-z)^{7/2} - (z-x)(1-z-x)^{7/2}) + \frac{48}{315}((1-z)^{9/2} - (1-z-x)^{9/2})$

this procedure because the bending potential for these systems are not known.

In ordinary treatments, perhaps more rigorous than the present one, the orientational dependence of the potential energy is intrinsically considered by the calculation of $E - V^{\ddagger}(s)$ at different bending angles. On the other hand, potentials of the linear form in $\cos\gamma$ described above, are currently used in the literature. We realize that this procedure may be a grossly classical approximation, but it does imply repetition in counting the angular terms. It only introduces an orientational angle dependence of the reaction barrier rather than use the same collinear value for all the bent configurations of the activated complex. This can be proven as follows. Let us take, for example, the A0 case in both approximations, as described in Tables 1 and 2. The former considers the same collinear E_0 for all the bent configurations. The latter uses the angle dependence described by the linear terms in cosine of γ. If we adopt the limit $V' \to 0$, which physically means taking the same E_0 value for all the non-collinear configurations, Table 2 results reduce to those in Table 1. For example, in the case A0 one gets

$$\frac{\pi I^{\ddagger} D_e^2}{4V'(s)}(z^2 - (z-x)^2) \xrightarrow[(V'(s)\to 0)]{} \pi I^{\ddagger} D_e z$$

(Table 2 result) ⟶ (Table 1 result)

It is obvious that the same result could not be achieved if we would have incorporated twice the angular terms.

Potential energy surface (PES)

The potential energy surface (PES) was taken to be of the extended LEPS form

$$[20] \quad E = Q_1 + Q_2 + Q_3 - 2^{-1/2}|(J_1 - J_2)^2 + (J_2 - J_3)^2 + (J_3 - J_1)^2|^{1/2}$$

where

$$[21] \quad Q_i = \frac{1}{2}\left({}^1\Sigma_i + \frac{1 - S_i}{1 + S_i}{}^3\Sigma_i\right)$$

$$[22] \quad J_i = \frac{1}{2}\left({}^1\Sigma_i - \frac{1 - S_i}{1 + S_i}{}^3\Sigma_i\right)$$

and where diatomic singlet and triplet potential-energy curves are given by Morse and anti-Morse functions

$$[23] \quad {}^1\Sigma = D_e|\exp(-2\beta(R - R_e)) - 2\exp(-\beta(R - R_e))|$$

$$[24] \quad {}^3\Sigma = \tfrac{1}{2}D_e|\exp(-2\beta(R - R_e)) + 2\exp(-\beta(R - R_e))|$$

The diatomic parameters D_e, β, R_e were taken from the literature, and the Sato parameters S_i were adjusted to give a

†From ref. 17.

classical barrier height V_0 equal to the measured threshold energies. The LEPS parameters are listed in Table 3.

The minimum energy or reaction path was then found (1, 11) by using the gradient of the potential to calculate the paths of steepest descent from the saddle point to reactants ($s < 0$), and products ($s > 0$), where the distance from the saddle point along this path is s. Two new coordinates were defined at each s:x^s is the tangent to the reaction path at s, and u^s is perpendicular to x^s. Then a Morse potential $V(u^s)$ was fitted to the local vibrational potential $V(u^s; x^s = 0)$:

$$V(u^s) = D(s)|1 - \exp(-\beta(s)u^s)|^2$$

in terms of the Morse parameters $D(s) = V(A + B + C) - V^{\ddagger}(s)$ and $\beta(s)$. For a given action Ah, the local vibrational energy is

$$\epsilon(A,s) = h\nu_s(s)A(1 - A/\beta(s))$$

Further, the frequency of the bending motion was determined at each s as described elsewhere (1, 11).

We thus calculated $\nu_s(s)$, $\nu_B(s)$ and hence $N(E,s)$ for each value of E in intervals of s and found its minimum $N^{\ddagger}(E - V(s^*))$. The same search procedure was repeated at different E.

To account for the non-collinear configurations we have used the angle-averaged expressions of section II.B and particularly eq. [19] with the corresponding $F(z,x)$ from Table 2. To carry out such calculation an orientational angle dependence of the reaction barrier of the linear form described by eq. [15] was used.

III. Results and discussion

The present theoretical approach was applied to the collision energy dependence of the M + RX → MX + R family of reactions where M = alkali, R = radical, and X = halogen. A significant body of data is now available for this family from molecular beams experiments (10). The results are presented for each system separately.

(A) K + CH_3Br → KBr + CH_3 (6)

This reaction has been studied by Bernstein and co-workers (6) and its excitation function shows an Arrhenius behaviour with an energy threshold value of 0.24 eV.

Figure 2 shows the contour map of the collinear LEPS PES obtained by fitting the Sato parameters to obtain the experimental threshold. The minimum energy path is indicated by the dashed curve. Figure 3 shows the experimental versus theoretical excitation functions. The best fit was obtained with no vibrational degrees of freedom as active mode (hereafter the vibrationally adiabatic case), i.e. case A0 of Table 2. This is shown by the solid line. The dashed line represents the model calculation using the stretching degree of freedom as active, i.e. assuming energy transfer between the motion along the reaction coordinate and the stretching motion. It seems clear that this choice gives poorer results than in the previous case.

Figure 4 displays the same excitation function comparison but now the calculation have been carried out including non-collinear configurations. These were performed by using the angle-average cross-section described in section II.B with an orientational dependence of the reaction barrier. To carry out these calculations some value of the E_0' was required. Unfortunately no reliable threshold parameter has been reported so far. In the present work we have used $E_0' = 0.07$ eV which is close to the one reported for analogous systems, as for example, the Rb + CH_3I reaction (4, 15).

As can be seen in Fig. 4, once again the vibrationally adiabatic case describes much better the experimental behaviour than does the non-adiabatic one. Nevertheless a cross comparison of Figs. 3 and 4 indicates that the calculations using the collinear approach give a better representation of the experimental results than those obtained with non-collinear configurations.

(B) K + C_2H_5Br → KBr + C_2H_5 (7, 8)

This excitation function was measured in our laboratory (9)

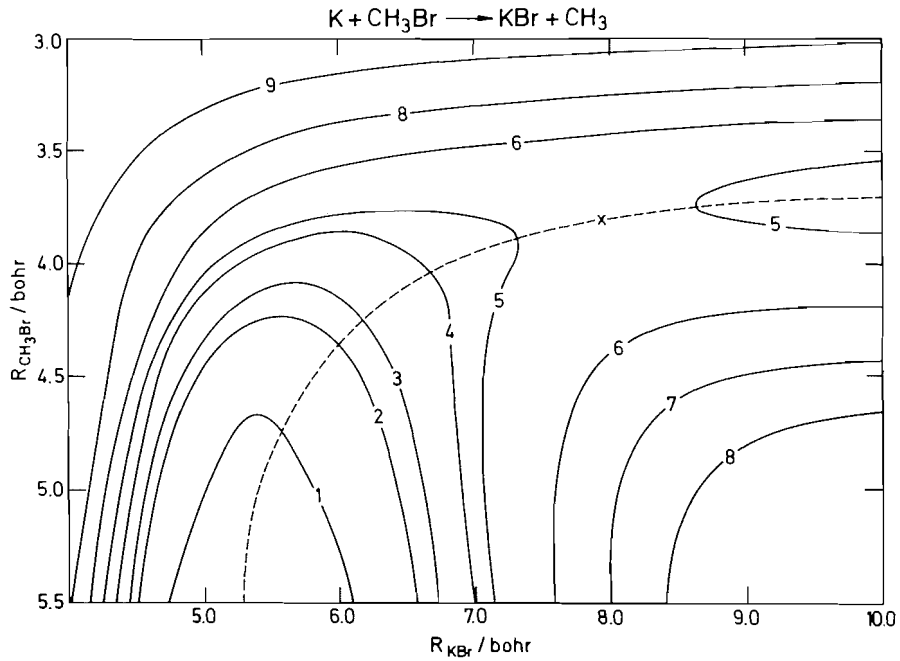

FIG. 2. Potential energy surface for the collinear reaction K + $CH_3Br \rightarrow KBr + CH_3$. The energy contours are as follows (in kJ mol^{-1}): (*1*) −50, (*2*) −20, (*3*) −10, (*4*) 10, (*5*) 20, (*6*) 50, (*7*) 75, (*8*) 100, (*9*) 200. The LEPS parameters used in the present calculation are described in Table 3. Dashed line corresponds to the reaction path.

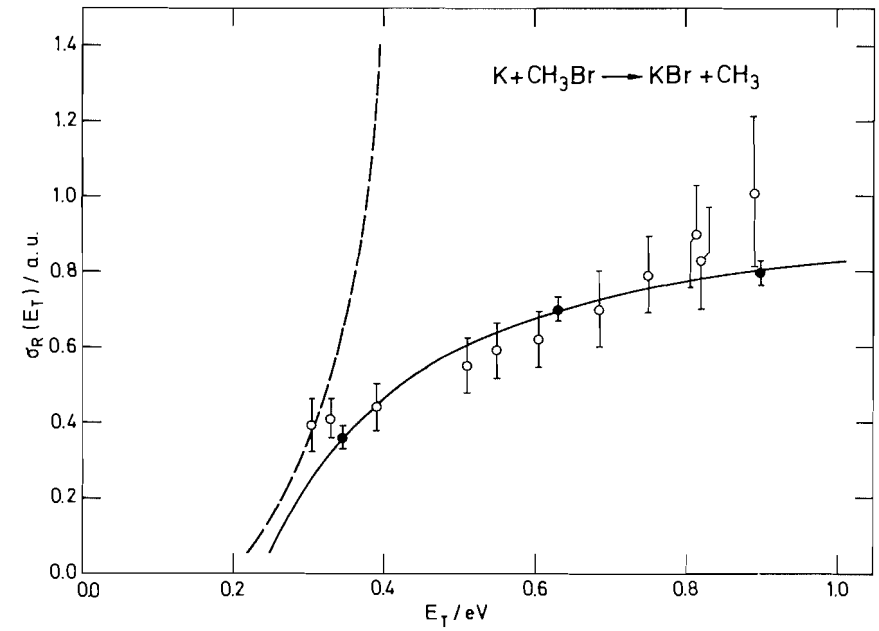

FIG. 3. Excitation function for the K + $CH_3Br \rightarrow KBr + CH_3$ reaction. Open circles: experimental points from ref. 6. Solid line: present model calculation, using the quasi-collinear model without vibrational excitation (case A0, Table 1). Dashed line: result of considering the stretching mode active (case A3, Table 1). Solid circles: present trajectory results scaled at E_T = 61 kJ mol^{-1}. The actual trajectory calculation value at this energy is σ_R = 26.4 $Å^2$. The μTST value is σ_R = 40.7 $Å^2$.

and it is displayed in Fig. 5 together with the same type of calculation described in Fig. 3, but now using the LEPS potential built with the same procedure as before and with the parameters listed in Table 3. Note how a better overall representation of the experimental excitation function is achieved in the vibrationally adiabatic case with the quasi-collinear model. Figure 6 shows the same comparison as Fig. 4, but now for the present system. An E_0' value of 0.07 eV was also used. A comparison between Figs. 5 and 6 furnishes analogous conclusions to the previous case with respect to the validity of the collinear approach in the present model calculation.

(C) Na(K) + $CH_3I \rightarrow$ Na(K)I + CH_3 (3, 9)

These two excitation functions have been measured by the

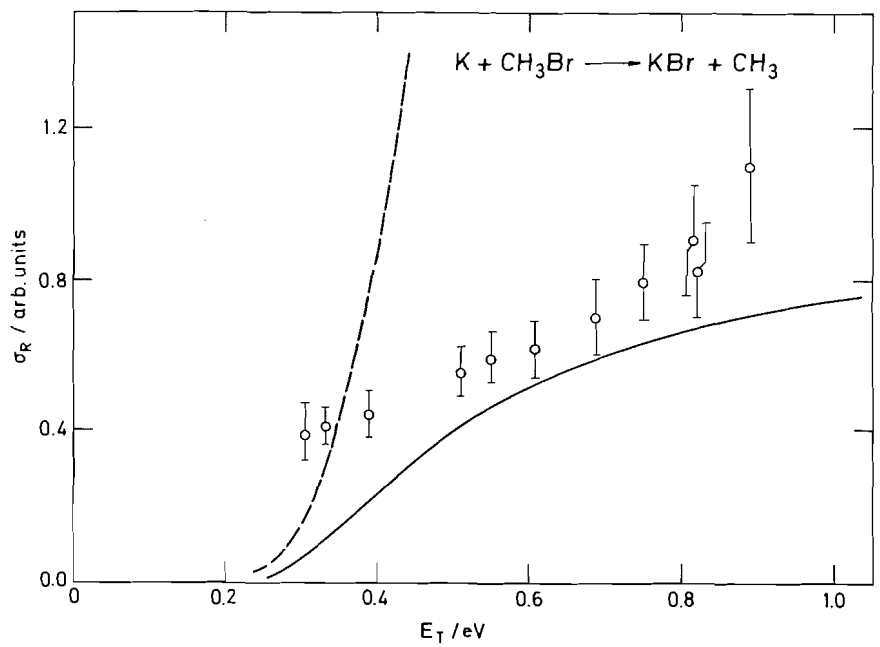

FIG. 4. Same presentation as in Fig. 3 but now using the angle average cross-section, with an orientational dependence of the reaction barrier. Solid line is the model prediction using case A0 of Table 2, i.e. no vibrational activation; dashed line is the result of using case A3 of Table 2.

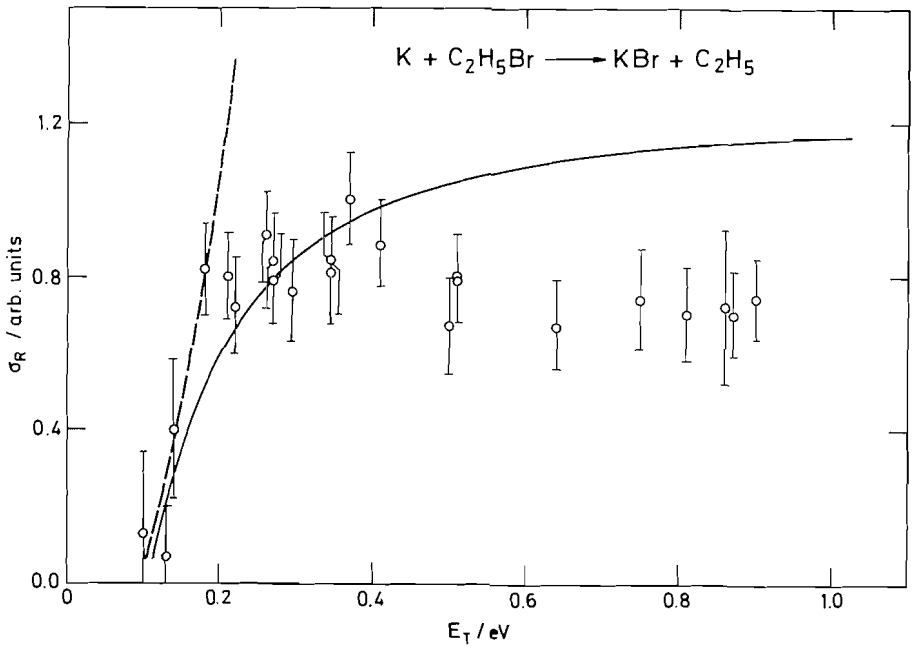

FIG. 5. Same presentation as in Fig. 3 but now for the $K + C_2H_5Br \rightarrow KBr + C_2H_5$ reaction. Open circles are experimental points from ref. 8. Solid line is the vibrationally adiabatic case (quasi-collinear configuration). Dashed line represents the result of the case A3 in Table 1, i.e. the model prediction when one considers the stretching mode as active one.

molecular beam method (3, 9). We have grouped them because they represent clear examples where a maximum in the collision energy dependence of the reaction cross-section was found. In fact the post-maximum decline in the excitation function has drawn considerable theoretical attention. Several mechanisms have been reported to account for this translational feature being the recrossing mechanism one of the most widely proposed (10, 17).

Figures 7 and 8 show the LEPS potential for these systems built using the parameters of Table 3. Theoretical and experimental data of these excitation functions are displayed in Figs. 9 and 10 for the Na and K reactions, respectively. From inspection of these two figures the following comments can be made:

(*a*) None of the cases used in the present model calculation are able to predict the maximum and post-maximum decline in the reaction cross-section. It seems clear that variational

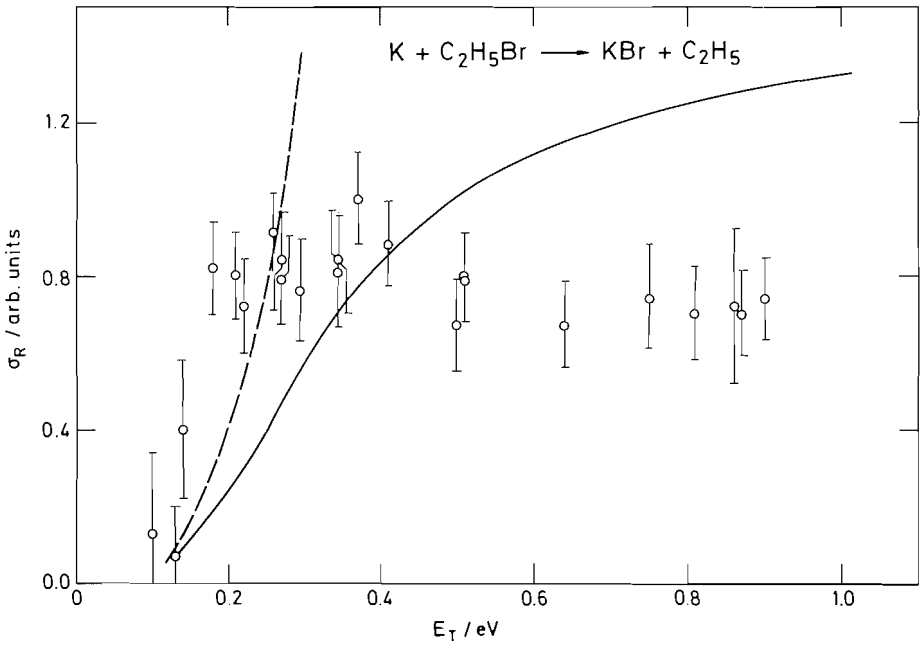

FIG. 6. Same presentation as in Fig. 4 but for the $K + C_2H_5Br \rightarrow KBr + C_2H_5$ reaction.

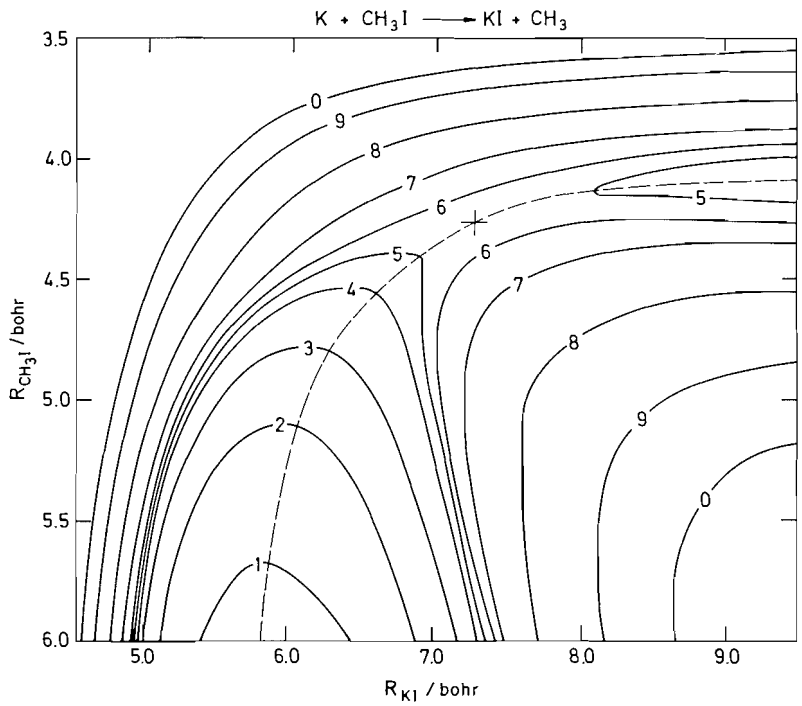

FIG. 7. Potential Energy Surface for the collinear reaction $K + CH_3I \rightarrow KI + CH_3$. The energy contours are as follows (in kJ mol^{-1}): (*1*) −50, (*2*) −25, (*3*) −10, (*4*) 0, (*5*) 3, (*6*) 5, (*7*) 10, (*8*) 25, (*9*) 50, (*0*) 75. The LEPS parameters used in the present calculation are described in Table 3. The dashed line corresponds to the reaction path.

transition state calculation at least within the approximation presently used is unable to account for this negative collision energy dependence. Even though one takes advantage of the variational location of the transition state, as in the present work, some dynamic effects seem to be still absent in our treatment to reproduce the observed behaviour of the excitation function.

(*b*) Once again the vibrationally adiabatic case seems to offer the better prediction of the experimental collision energy dependence of the reaction cross-section, at least before a maximum in $\sigma_R(E_T)$.

(*c*) Since for the K reaction absolute data on the reaction cross-section are available, a comparison of these absolute

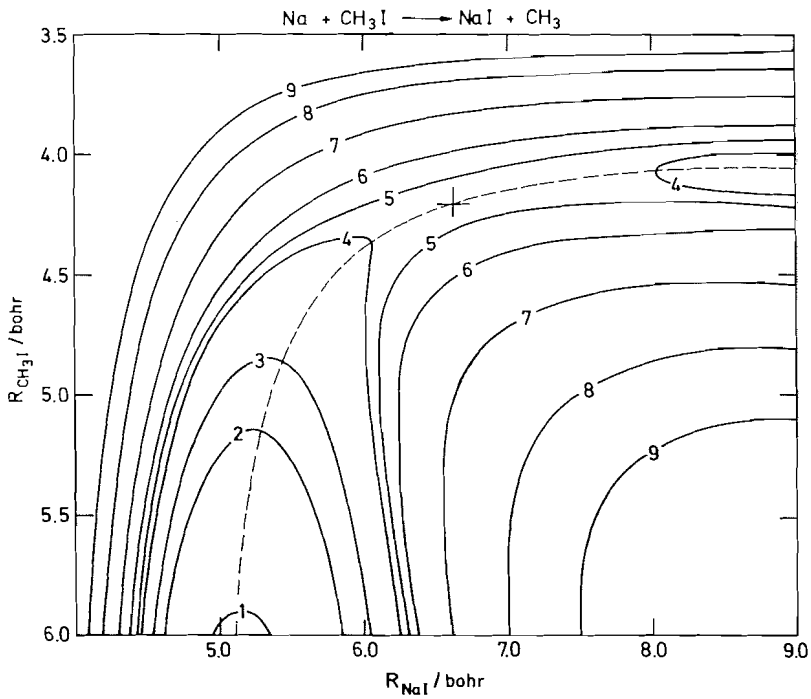

FIG. 8. Same presentation as in Fig. 7 but for the N + $CH_3I \rightarrow$ NaI + CH_3. The energy contours are as follows (in kJ mol^{-1}): (*1*) −40, (*2*) −20, (*3*) −10, (*4*) 3, (*5*) 5, (*6*) 10, (*7*) 25, (*8*) 50, (*9*) 75. The LEPS parameters used are described in Table 3. The dashed line corresponds to the reaction path.

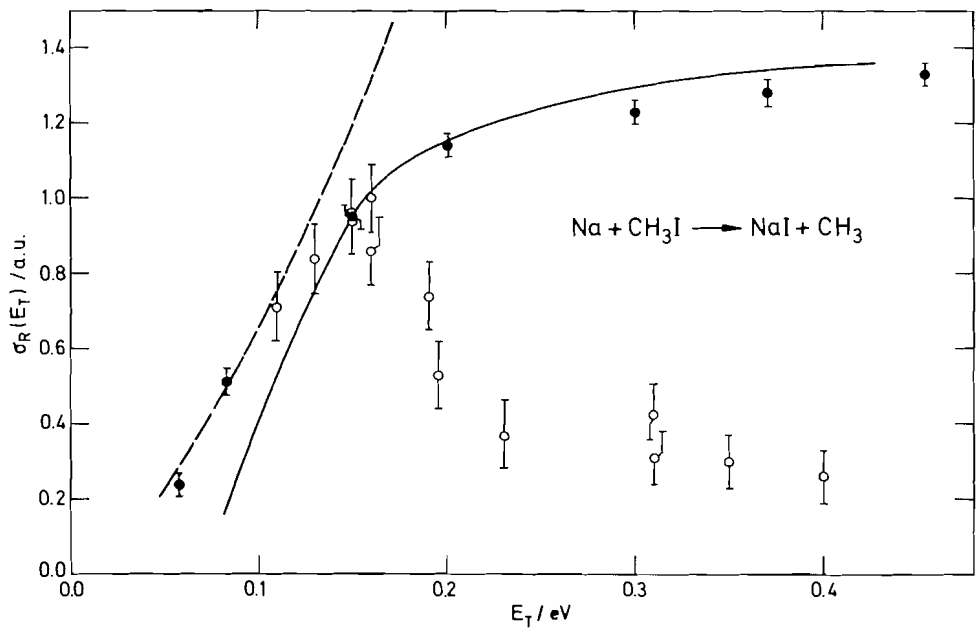

FIG. 9. Excitation Function for the Na + $CH_3I \rightarrow$ NaI + CH_3 reaction. Open symbols: experimental points from ref. 9. Solid and dashed line as in Fig. 3. Closed symbols: quasiclassical trajectory simulation scaled at E_T = 14.6 kJ mol^{-1}, being the calculated value σ_R (E_T = 14.6 kJ mol^{-1}) = 16.1 $Å^2$.

values is also possible. The best quantitative results are obtained for the quasi-collinear vibrationally adiabatic model, as long as one uses the two degrees of freedom associated with the linear transition state configuration as described by cases A3 or B1 of Table 2.

(D) Near threshold behaviour

Figures 11 and 12 show an interesting comparison of the four excitation functions already mentioned in the near threshold range. The representation is the quantity $\sigma_R(E_T).E_T$ versus E_T. Theoretical calculations include: (*a*) solid line: quasi-collinear model, where only the collinear reaction barrier was used. (*b*) Dashed line represents the same calculation but using the angle average cross-section with an orientation dependence for the reaction barrier of the type $E_{th} = E_0 + E_0'(1 - \cos \gamma)$. (*c*) Closed circles represent trajectory calculation results (see

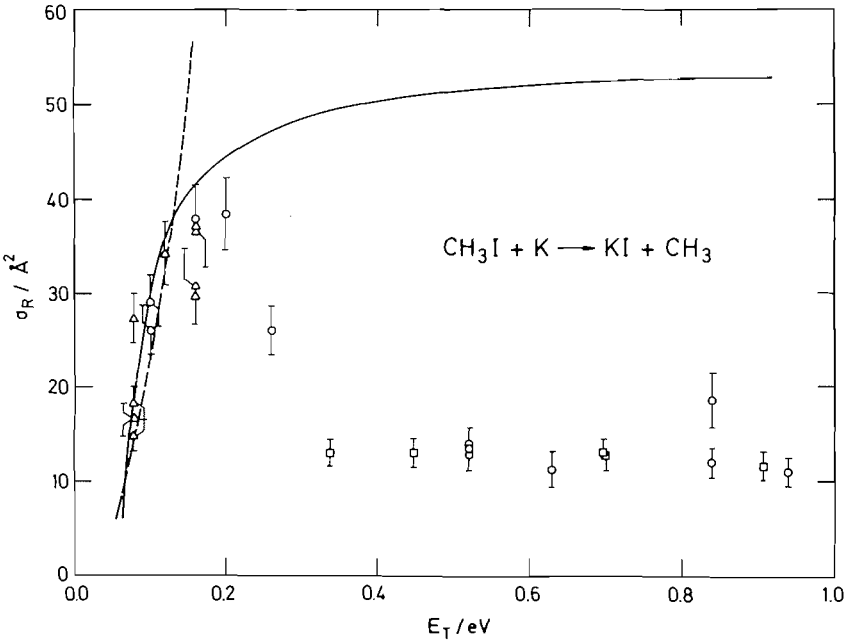

FIG. 10. Same presentation as in Fig. 9 but for the $K + CH_3I \rightarrow KI + CH_3$ reaction. Symbols: experimental data from ref. 3.

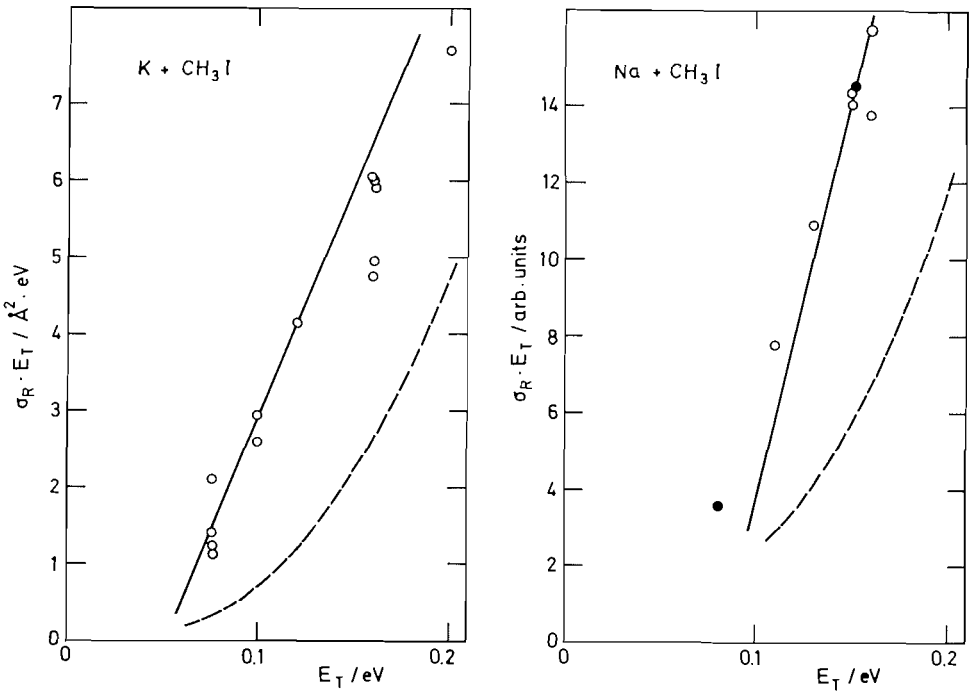

FIG. 11. Theoretical and experimental data on $\sigma(E_T)^* E_T$ versus E_T for the indicated reaction over the near threshold range. All the calculations have been carried out considering the spread of the collision energy reported in the experiments. Symbols are experimental data from the same references as in previous figures. Solid line is quasi-collinear calculation. Dashed line is the angle average cross-section with the orientational dependence of the reaction barrier. See text for comments. Solid circles are present trajectory calculation results, i.e. low energy results from Fig. 9.

below) that seem to be in good agreement with experimental data.

For a better illustration these functionalities are shown in Fig. 13. All the calculations were convoluted considering the spread of the collision energy as reported in the respective molecular beam experiment from where data were taken. It is known that (14) the post-threshold law should show a quadratic dependence on the energy excess $(E_T - E_0)$ if one uses a linear functionality with respect to $\cos\gamma$, as described earlier, as well as in the rotating rod model (18). From inspection of Figs. 11 and 12 one may conclude that the best fit of the data is always obtained by the calculation carried out with the collinear configuration (i.e. E_0 instead of $E_0 + E_0'(1 - \cos\gamma)$).

It seems as if over this post-threshold range where the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

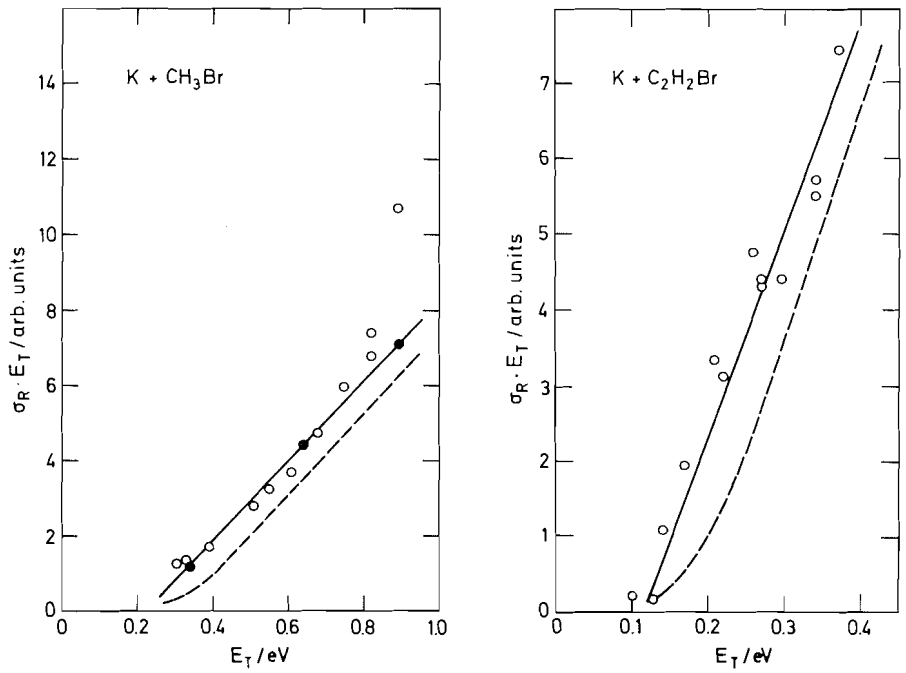

FIG. 12. Same presentation as in Fig. 11 for the indicated reactions. Solid circles are present trajectory calculation results.

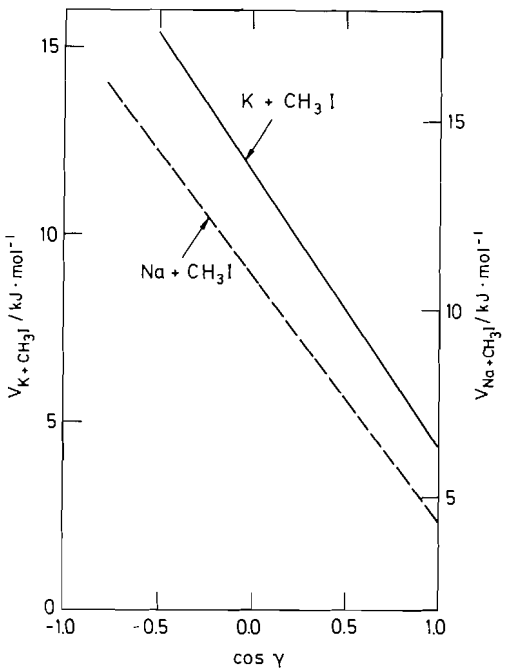

FIG. 13. Orientational dependence of the reaction barrier for the indicated reactions. Solid line: K reaction with $E_0' = 0.07$ eV. Dashed line: Na reaction with $E_0' = 0.067$ eV.

collision energy is low, and the reaction time correspondingly large, long range orientational interactions (via bending interactions, i.e. alignment forces) would select the collinear configuration for the transition state regardless of the initial angle of approach. Of course, excitation function with fixed reactants geometry as it is currently studied (19) will clarify this point, so care should be taken with this interpretation and the satisfactory fit of the excitation functions should not be over-interpreted. In fact trajectory calculations (20) have shown that only right above the threshold can one see the quadratic energy dependence of $\sigma_R(E_T)$.

(E) Comparison with quasi-classical trajectory calculations

Since, except for the CH_3Br case, the calculations using the variational transition state theory fail to reproduce the observed maxima in the cross-section, we think it is worthwhile to compare the present theoretical calculations with quasi-classical trajectory simulations on the same (assumed physical) potential energy surface. This comparison would provide a clear way to distinguish between the goodness of the μTST and that of the primitive LEPS surface used.

Two set of calculations using the quasi-classical trajectory method have been carried out for the K and Na plus CH_3I reactions. The potential energy surface used were of the LEPS extended form and their parameters are listed, as it was already mentioned, in Table 3. The program and method of calculation was the same as the one used in ref. 21, therefore we omit details for brevity.

Figure 3 shows trajectory calculation result for the reaction cross-section and three different collision energies (solid circles are used for a better display) for the $K + CH_3Br \rightarrow KBr + CH_3$ reaction. The theoretical values were reduced by a factor of 1.5 in order to normalize the quasi-classical trajectory results to those μTST. Except for this factor one can see the excellent agreement between both theories and the experimental results as far as the collision energy dependence of the reaction cross-section is concerned.

On the other hand, the fact that in the $Na + CH_3I$ case both calculations, as shown in Fig. 9, fail to reproduce the experimental excitation function values, is a clear indication that the disagreement is mainly due to the wrong (assumed) PES rather than to a failure of the μTST treatment here adopted. Work is in progress to build a more suitable potential energy surface from which one could reproduce the experimental cross sections by using both theoretical treatments.

Enzymes in organic synthesis. 44.[1] Stereoselective pig liver esterase-catalyzed hydrolyses of 3-substituted glutarate diesters of compactin-synthon interest[2]

LISTER K.-P. LAM AND J. BRYAN JONES
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received December 7, 1987

LISTER K.-P. LAM and J. BRYAN JONES. Can. J. Chem. **66**, 1422 (1988).

Pig liver esterase-catalyzed hydrolyses of dimethyl 3-hydroxy-, 3-methoxyethoxymethoxy-, and 3-benzyloxyglutarates occur with enantiotopic stereoselectivity to give the corresponding acid-ester products of 16–40% enantiomeric excess (ee). The results also provide another example of reversal of PLE-stereoselectivity.

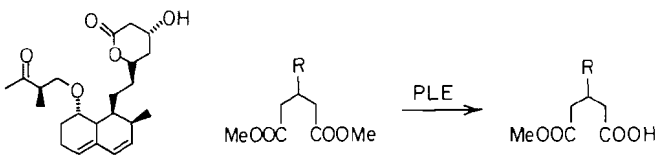
LISTER K.-P. LAM et J. BRYAN JONES. Can. J. Chem. **66**, 1422 (1988).

Les hydrolyses, catalysées par l'estérase du foie de porc, des hydroxy-3, méthoxyéthoxyméthoxy-3 et benzyloxy-3 glutarates de diméthyle se produisent avec une stéréosélectivité énantiotopique et elles fournissent les produits acide-esters correspondants avec un excès énantiomérique (eé) de 16–40%. Les résultats fournissent aussi un autre exemple de renversement de la stéréosélectivité de l'EFP.

[Traduit par la revue]

Compactin (**1**) and related compounds are potent inhibitors of HMG-CoA reductase, the rate-limiting enzyme in cholesterol biosyntheses (2*a*), and are consequently able to reduce plasma cholesterol levels in animals, including humans (2*b*). This property, combined with the very low toxicity (2), has elicited great interest in compactin and its analogues as hypocholesteremic drugs. As a result, the synthesis of compactins remains a very active field (3).

Chiral acid-esters such as **3***a* are potentially useful synthons for the therapeutically vital (4) lactone moiety of compactin. Our previous work on pig liver esterase (PLE)-catalyzed hydrolyses of 3-substituted glutarate diesters **2** had shown that enantiotopically selective hydrolyses could be effected to give acid-esters **3** of up to 97% enantiomeric excess (ee) (5). This encouraged us to evaluate the potential of PLE-catalyzed hydrolyses of the 3-oxygenated glutarate diesters **2***b–d* for the production of the potential compactin-lactone synthons **3***b–d*.



1 **2** **3**

a, R = Me
b, R = OH
c, R = OMEM
d, R = $OCH_2C_6H_5$

Results

Diesters **2***b–d* were prepared in good yields by unexceptional methods. Each proved to be a reasonable substrate for PLE, having rates of hydrolyses (relative to that of the reference standard ethyl butyrate = 100) of 17 for **2***b*, 2 for **2***c*, and 4 for **2***d*. The preparative-scale hydrolyses of **2***b–d* proceeded smoothly to give high yields of the corresponding acid-esters **3***b–d*. The results are summarized in Table 1.

The absolute configurations of **3***b–d* were established by their correlations with (−)-(*R*)- and (+)-(*S*)-**3***b* of known (6) stereochemistry. The ee's of Table 1 were determined on the acid-esters **3***b* derived from **3***b–d* during the absolute configuration assignments, via their conversions to their (*S*)-1-phenethanamide derivatives **4** by the method of Heathcock and co-workers (7), followed by ^1H nmr examinations of the *tert*-butyl and methoxyl resonances.

TABLE 1. PLE-catalyzed hydrolyses of **2***b–d*[a]

Substrate	Product (% yield, % ee)
2*b*	(+)-(3*S*)-**3***b* (87, 16)
2*c*	(+)-(3*R*)-**3***c* (92, 39)
2*d*	(−)-(3*S*)-**3***d* (87, 40)

[a]At pH 7, 20°C.

Discussion

The easily removable methoxyethoxymethyl (MEM) and benzyl functions were chosen as the hydroxyl-protecting groups for substrates **2***c,d* because of their stability during the acidic work-up involved in the enzyme-catalyzed reactions, and to avoid stereochemical complications introduced by the use of other common, but chiral, protecting groups. Substrates **2***b,c* were readily prepared by standard methods. However, due to the sensitivity of dimethyl 3-hydroxyglutarate (**2***b*) to base, benzylation attempts using sodium hydride – benzyl bromide conditions were unsuccessful in the preparation of **2***d*, and the acid-catalyzed procedure of Iversen and Bundle (8) was used instead. It was found that $BF_3 \cdot Et_2O$ was a more effective benzylation catalyst than the triflic acid used originally (8).

Although the relative rates of PLE-catalyzed hydrolyses of **2***b–d* were significantly slower than that of the ethyl butyrate

standard, each still remained a good candidate for preparative-scale reactions.[3]

The results of the preparative-scale experiments (Table 1) show that the ee levels are significantly increased by the conversion of the C3-OH group of **2***b* to the more bulky O-MEM and O-benzyl functions of **2***c* and **2***d* respectively. This ee increase on functionalization, and the reversal of stereoselectivity observed, parallel the observations recorded in the 3-amino- and 3-alkylglutarate series (5, 9). Rationalizing the many stereospecificity reversals within different series of substrates documented (5, 9, 10) for PLE now represents a formidable interpretative challenge.

There is interest (11, 12) in **3***b* as a chiral precursor of important target molecules other than compactin, with esterase-based methods complementing those involving reductions of β-ketoesters (13, 14).

While the current PLE-catalysis approach has not yet reached its goal of producing enantiomerically pure **3***b*,[4] further increases in ee levels should be attainable by control of reaction conditions (5, 15) and, by analogy with the 3-amino series (9), by different O-functionalization of **2***b*. Interestingly, when 3-methyl (16*a*) or 2,4-dimethyl (16*b*) substituents are present in **2***b* of 2,4-dimethyl (16*b*) substituents are present in **2***b*, PLE-catalyzed hydrolyses yield acid-esters of high ee's (16).

Experimental

The instrumentation and general purification and analytical methods used were as described previously (5). PLE (EC 3.1.1.1) was Sigma Chemical Company Type II (Lot 123F-0240). Unless noted otherwise, ir spectra were for films, and ^{1}H nmr and $[\alpha]_D^{25}$ measurements were taken on $CDCl_3$ and $CHCl_3$ solutions respectively.

Preparation of substrates

Dimethyl 3-hydroxyglutarate (**2***b*) was obtained in 80% yield by reduction (6) with $NaBH_4$ of dimethyl 3-ketoglutarate (Aldrich); **2***b* had bp 138–140°C (8 Torr; 1 Torr = 133.3 Pa); ir: 3430, 1740 cm^{-1}; ^{1}H nmr δ: 2.58 (4H, d, J = 6 Hz), 3.63 (1H, br s, OH), 3.75 (6H, s), and 4.48 (1H, quintet, J = 6.2 Hz) ppm.

*Dimethyl 3-methoxyethoxymethoxyglutarate (2*c*)*

Triethylamine (100 mL, 0.72 mol) was added dropwise with stirring at 20°C to a mixture of dimethyl 3-hydroxyglutarate (**2***b*, 5 g, 28.4 mmol) and methoxyethoxymethyl chloride (13.3 g, 107 mmol) at 25°C. The mixture was then refluxed for 1.5 days, filtered, and the solvent removed by rotoevaporation. The residual oil was taken up in diethyl ether (30 mL), and washed with saturated aqueous $NaHCO_3$ (10 mL) and then with brine (10 mL). The ether layer was dried ($MgSO_4$), filtered, and the solvent was removed by rotoevaporation. The crude oil was purified by flash chromatography (ether:hexanes (1:1) elution), followed by Kugelrohr distillation to afford dimethyl 3-methoxyethoxymethoxyglutarate (**2***c*, 6.9 g, 92% yield), bp 89–91°C (0.15 Torr); ir: 1736 cm^{-1}; ^{1}H nmr δ: 2.63 (4H, d, J = 6 Hz), 3.33 (3H, s), 3.37–3.77 (4H, m), 3.65 (6H, s), 4.38 (1H, quintet, J = 6 Hz), and 4.72 (2H, s) ppm. *Anal.* calcd. for $C_{11}H_{20}O_7$: C 49.99, H 7.63; found: C 49.97, H 7.61%.

*Dimethyl 3-benzyloxyglutarate (2*d*)*

Boron trifluoride – diethyl ether (catalytic amount, 0.05 mL) was added with stirring to a solution of dimethyl 3-hydroxyglutarate (**2***b*, 1.76 g, 10 mmol) and benzyl trichloroacetimidate (5.05 g, 20 mmol) in cyclohexane–CH_2Cl_2 (2:1; 100 mL). The reaction was kept for 3 h at 23°C prior to addition of more cyclohexane (100 mL). The organic layer was then filtered and washed with saturated aqueous $NaHCO_3$ (2 × 50 mL) and then with brine (50 mL). The dried ($MgSO_4$) solution was filtered, and the solvent was removed by rotoevaporation. The crude oil obtained was purified by flash chromatography (ethyl acetate:hexanes (1:10) elution) and then Kugelrohr-distilled to give dimethyl 3-benzyloxyglutarate (**2***d*, 1.87 g, 70% yield), bp 126–130°C (0.2 Torr); ir: 1739 cm^{-1}; ^{1}H nmr δ: 2.63 (4H, d, J = 6 Hz), 3.68 (6H, s), 4.32 (1H, quintet, J = 6 Hz), 4.58 (2H, s), and 7.32 (5H, s) ppm. *Anal.* calcd. for $C_{14}H_{18}O_5$: C 63.13, H 6.81; found: C 62.80, H 6.94%.

*PLE-catalyzed hydrolyses of 2*b–d

The relative rates of hydrolyses of **2***b–d* were determined as described previously (17).

The preparative-scale reactions were performed according to the standard procedure for symmetrical diester substrates (5). The results obtained (summarized in Table 1) were as follows:

Dimethyl 3-hydroxyglutarate (**2***b*, 1.0 g, 5.68 mmol) with PLE (400 units) for 80 min gave methyl hydrogen (3*S*)-3-hydroxyglutarate (**3***b*, 800 mg, 87% yield, 16% ee), bp 124–126°C (0.2 Torr); $[\alpha]_D^{25}$ +0.13° (*c* 15) (lit. (6) $[\alpha]_D^{22}$ −1.7° (*c* 12.5) for (3*R*)-**3***b*); ir: 3450–2610, 1734, 1715 cm^{-1}; ^{1}H nmr δ: 2.60 (4H, d, J = 6 Hz), 3.73 (3H, s), 4.45 (1H, quintet, J = 6 Hz), and 7.17 (2H, br s) ppm. *Anal.* calcd. for $C_6H_{10}O_5$: C 44.45, H 6.22; found: C 44.33, H 6.07%.

Dimethyl 3-methoxyethoxymethoxyglutarate (**2***c*, 750 mg, 2.84 mmol) with PLE (200 units) for 11 h yielded methyl hydrogen (3*R*)-3-methoxyethoxymethoxyglutarate (**3***c*, 655 mg, 92% yield, 39% ee), bp 140–145°C (0.25 Torr); $[\alpha]_D^{25}$ +1.0° (*c* 25); ir: 3430–2610, 1736, 1714 cm^{-1}; ^{1}H nmr δ: 2.68 (4H, d, J = 6 Hz), 3.37 (3H, s), 3.40–3.80 (4H, m), 3.68 (3H, s), 4.37 (1H, quintet, J = 6 Hz), 4.77 (2H, s), and 8.99 (1H, br s) ppm. *Anal.* calcd. for $C_{10}H_{18}O_7$: C 48.00, H 7.25; found: C 47.39, H 7.16%.

Dimethyl 3-benzyloxyglutarate (**2***d*, 500 mg, 1.88 mmol) with PLE (132 units) for 12 h afforded methyl hydrogen (3*S*)-3-benzyloxyglutarate (**3***d*, 410 mg, 87% yield, 40% ee), bp 145–147°C (0.2 Torr); $[\alpha]_D^{25}$ −0.3° (*c* 10); ir: 3440–2680, 1736, and 1714 cm^{-1}; ^{1}H nmr δ: 2.68 (2H, d, J = 6 Hz), 2.69 (2H, d, J = 6 Hz), 3.70 (3H, s), 4.32 (1H, quintet, J = 6 Hz), 4.60 (2H, s), 7.33 (5H, s), and 10.38 (1H, br s) ppm. *Anal.* calcd. for $C_{13}H_{16}O_5$: C 61.90, H 6.39; found: C 61.03, H 6.52%.

Absolute configuration determinations

Correlations were to the known (6) (−)-(3*R*)-**3***b*.

*Of (+)-3*c

The cleavage method of Boeckman and Potenza (18) was used. (+)-Methyl hydrogen methoxyethoxymethoxyglutarate (**3***c*, 635 mg, 2.54 mmol) in dry CH_2Cl_2 (10 mL) was treated dropwise with *o*-phenylene bromoboronate (19) in CH_2Cl_2 (0.2 M, 12.7 mL, 2.54 mmol) at 20°C. After stirring at 20°C for 30 min the mixture was treated with water (10 mL) and stirred for another 20 min. The reaction mixture was then extracted with ethyl acetate (4 × 50 mL), and the organic phase dried ($MgSO_4$), filtered, and rotoevaporated. The Kugelrohr distillation gave (−)-(3*R*)-**3***b* (339 mg, 82% yield), bp 123–128°C/0.2 Torr; $[\alpha]_D^{25}$ −0.43° (*c* 7.5, $CHCl_3$) (lit. (6) $[\alpha]_D^{22}$ −1.7° (*c* 12.5) for (3*R*)-**3***b*); ir and ^{1}H nmr identical to spectra obtained for (+)-(3*S*)-**3***b* above.

*Of (−)-3*d

A mixture of (−)-(3*S*)-monomethyl 3-benzyloxyglutarate ((−)-(3*S*)-**3***d*, 252 mg, 1.0 mmol) and pre-equilibrated 10% Pd/C (75 mg) in 95% ethanol (12 mL) was hydrogenated at 23°C and atmospheric pressure (20). Hydrogen uptake (1 equiv.) ceased after 12 h. The mixture was then filtered and rotoevaporated to give (+)-(3*S*)-**3***b* (146 mg, 90% yield), bp 122–125°C (0.2 Torr); $[\alpha]_D^{25}$ +0.78° (*c* 5.0); ir and ^{1}H nmr identical with those of (+)-(3*S*)-**3***b* above.

Enantiomeric excess determinations

The method of Rosen *et al.* (7) was used, using ^{1}H nmr measurements on the amides **4** obtained from (+)-(3*S*)- or (−)-(3*R*)-**3***c* above and (*S*)-1-phenylethanamine. The ee values obtained (accuracy: ±1%) are recorded in Table 1.

[3]Any ester with a rate of hydrolysis ≥ 0.02% of that of ethyl butyrate will work satisfactorily in synthetic-scale conversions.

[4]The 16% ee level of **2***b* attained in this study matches that reported by Tamm and co-workers (11). Under normal conditions, we do not observe higher ee levels (12) with any of our current PLE batches.

The properties of the reference amide diastereomers, separated by flash chromatography, are as follows:

(3*S*,1′*S*)-**4**: ^{1}H nmr (200 MHz) δ: 0.03 (3H, s), 0.07 (3H, s), 0.86[5] (9H, s, *t*-Bu), 1.47 (3H, d, J = 7.0 Hz), 2.39 (1H, d of d, J = 5.1, 14.8 Hz), 2.45 (1H, d, J = 1.6 Hz), 2.48 (1H, d, J = 0.8 Hz), 2.55 (1H, d of d, J = 5.1, 14.8 Hz), 3.65[5] (3H, s, -OMe), 4.50 (1H, m), 5.13 (1H, m), 6.60 (1H, br d, J = 7.6 Hz), and 7.32 (5H, m) ppm.

(3*R*,1′*S*)-**4**: ^{1}H nmr (200 MHz) δ: 0.03 (3H, s), 0.07 (3H, s), 0.80[5] (9H, s, *t*-Bu), 1.50 (3H, d, J = 7.0 Hz), 2.39 (1H, d of d, J = 5.3, 14.9 Hz), 2.59 (2H, d, J = 5.9 Hz), 3.68[5] (3H, s, -OMe), 4.52 (1H, m), 5.12 (1H, m), 6.60 (1H, br d, J = 7.6 Hz), and 7.31 (5H, m) ppm.

Reaction of $Me_3SnCu \cdot Me_2S$ with terminal alkynes. Preparation of 2-trimethylstannyl-1-alkenes

EDWARD PIERS AND J. MICHAEL CHONG

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received December 7, 1987

EDWARD PIERS and J. MICHAEL CHONG. Can. J. Chem. **66**, 1425 (1988).

Reaction of ω-substituted terminal alkynes **5** with (trimethylstannyl)copper(I)·dimethyl sulfide (**1**) under suitable reaction conditions provides good to excellent yields of the corresponding 2-trimethylstannyl-1-alkenes **6**.

EDWARD PIERS et J. MICHAEL CHONG. Can. J. Chem. **66**, 1425 (1988).

La réaction, dans des conditions appropriées, d'alcynes terminaux substitués en ω (**5**) avec du diméthylsulfure de (triméthylstannyl)cuivre (I) (**1**) fournit les triméthylstannyl-2 alcènes-1 correspondants (**6**) avec des rendements qui vont de bons à excellents.

Introduction

The reactions of various alkylcopper(I) reagents with terminal alkynes have been investigated in detail and have been applied to the synthesis of structurally diverse alkenes, dienes, and related substances (1, 2). In general, the alkylcopper(I) species add to the triple bond in a regioselective, *cis* fashion, with the alkyl group and the copper moiety being transferred to C-2 and C-1, respectively, of the 1-alkyne substrate.

Fleming *et al.* (3) have reported that lower order silylcuprates such as $(Me_2PhSi)_2CuLi$ or $(Me_2PhSiCuCN)Li$ add to terminal alkynes with *cis* stereochemistry but with low regioselectivity. In contrast, the higher order cuprate $[(Me_2PhSi)_2CuCN]Li_2$ adds to 1-alkynes stereo- (*cis*) and regioselectively to produce intermediates in which the dimethyl(phenyl)silyl group is attached exclusively to C-1 (3). Thus, interestingly, the regioselectivity of silylcupration of terminal alkynes with the higher order silylcuprate is opposite to that of carbocupration with a variety of alkylcopper(I) reagents (1, 2).

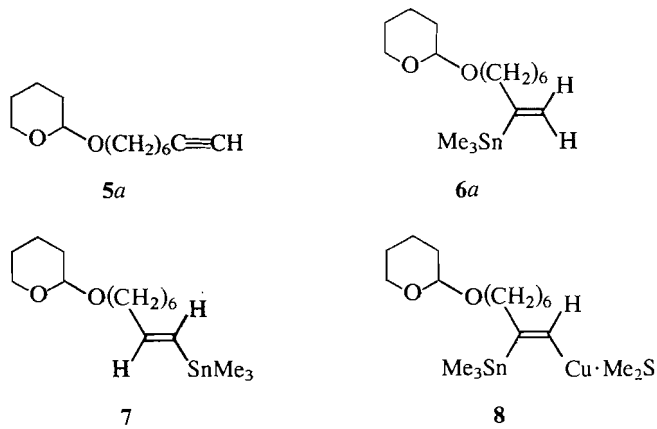
Recently we described the preparation of a number of (trimethylstannyl)copper(I) reagents (e.g., **1**–**4**) and reported

$Me_3SnCu \cdot Me_2S$	$[Me_3SnCuY]Li$
1	**2** Y = SPh
	3 Y = C≡CC(OMe)Me_2
	4 Y = CN

that these species transfer efficiently the trimethylstannyl group to the β carbon of a variety of α,β-unsaturated carbonyl compounds (4). Ongoing investigations into the chemical reactivity of **1**–**4**, along with our desire to prepare ω-substituted 2-trimethylstannyl-1-alkenes, led to a study of the reaction of (trimethylstannyl)copper(I)·dimethyl sulfide (**1**) with 1-alkynes. We report herein the results of this study.[1]

Results and discussion

For our initial experiments, we chose the substrate 8-tetrahydropyranyloxy-1-octyne (**5***a*)[2] (see Chart 1). This compound is a relatively high-boiling, nonvolatile substance and, therefore, any starting material remaining in a crude product mixture would be detected very readily.



5*a* **6***a* **7** **8**

CHART 1

Reaction of the 1-alkyne **5***a* with 1.5 equivalents of $Me_3SnCu \cdot Me_2S$ (**1**) in tetrahydrofuran (THF) at −78°C for 6 h, followed by suitable work-up, afforded an oil that contained (gas–liquid chromatographic analysis), in addition to hexamethylditin, a 31:65:4 mixture of the starting material **5***a* and two products, respectively. The major product, obtained by flash chromatography (7) of the mixture on silica gel, was shown to be the 2-trimethylstannyl-1-alkene **6***a*. On the basis of subsequent work (*vide infra*), the minor product was, presumably, the (*E*)-1-trimethylstannyl-1-alkene **7**, although this substance was not isolated.

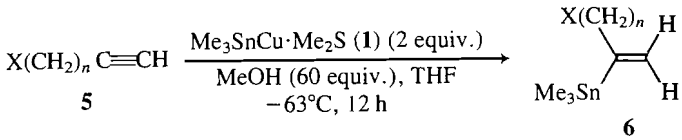
When the reaction of **5***a* with reagent **1** was allowed to proceed for 17 h (−78°C), the composition of the crude product mixture was very similar to that given above. On the other hand, much more starting material (crude product composition 74(**5***a*):25(**6***a*):1(**7**)) was recovered when the reaction mixture was quenched (NH_4Cl, H_2O) after only 2 h. When the reaction was carried out at a higher temperature (−63°C) for 6 h, the isolated material consisted of a 29:67:4 mixture of **5***a*, **6***a*, and **7**, respectively.

The fact that the reaction of reagent **1** with the terminal alkyne **5***a* did not go to completion even after extended reaction times seemed to indicate that the reaction is reversible and that the equilibrium favors only marginally the vinylcopper(I) intermediate **8**. Some evidence for a reversible process was obtained by treating the reaction mixture (after a reaction time of 6 h at −78°C) with iodine instead of a proton source. In this experiment, the starting material **5***a* was recovered in 94%

[1]For a preliminary account of this work, see ref. 5.

[2]This material is readily prepared by reaction of lithium acetylide – ethylenediamine complex with 1-bromo-6-tetrahydropyranyloxyhexane. We are very grateful to Professor L. Weiler and Ms. M. E. Alderdice for a generous gift of the latter compound (see also ref. 6).

TABLE 1. Conversion of 1-alkynes **5** into 2-trimethylstannyl-1-alkenes **6**



5 6

Entry	Substrate 5			Product 6 (yield, %)[a]	
		n	X		
1	*a*	6	OTHP[b]	*a*	(84)
2	*b*	4	OH	*b*	(85)
3	*c*	4	Cl	*c*	(80)
4	*d*	3	OSiBu^{t}Me$_2$	*d*	(82)
5	*e*	3	OH	*e*	(88)
6	*f*	3	Cl	*f*	(79)
7	*g*	2	OSiBu^{t}Me$_2$	*g*	(81)
8	*h*	2	OH	*h*	(82)[c]
9	*i*	2	Cl	*i*	(59)[d]
10[e]	*j*	1	OTHP[b]	*j*	(58)[f]
11[e]	*k*	1	OSiBu^{t}Me$_2$	*k*	(51)[g]

[a]Yields refer to isolated, purified product. The reactions were performed on a 0.2-mmol scale.

[b]THP = 2-tetrahydropyranyl.

[c]When the reaction was performed on a 1-mmol scale, **6***h* was obtained in 81% yield and (*E*)-4-trimethylstannyl-3-buten-1-ol (**9**) was isolated in 8% yield.

[d]Also isolated (preparative gas–liquid chromatography) was a small sample of (*E*)-4-chloro-1-trimethylstannyl-1-butene (**10**).

[e]This reaction was carried out at −78°C in the absence of methanol (see text).

[f]Also isolated (22%) was (*E*)-3-tetrahydropyranyloxy-1-trimethylstannylpropene (**11**).

[g]Also isolated (20%) was (*E*)-3-*tert*-butyldimethylsiloxy-1-trimethylstannylpropene (**12**).

yield. This result may be rationalized by postulating that the strong electrophile iodine pulls the equilibrium towards the starting material by destroying the (trimethylstannyl)copper(I) reagent **1** faster than it reacts with the intermediate vinylcopper(I) species **8**. We[3] and others (9) have made similar observations with the reactions of (trimethylstannyl)copper(I) reagents with α,β-acetylenic esters. The latter processes appear to be reversible since, although the initial equilibria probably lie far "to the right," treatment of the reaction mixtures with electrophiles such as bromine or iodine provides high yields of the starting materials (α,β-acetylenic esters). On the other hand, high yields of β-trimethylstannyl α,β-unsaturated esters are obtained if the reaction mixtures are treated with a proton source such as methanol (9–11).

It is known (4, 9–11) that (trimethylstannyl)copper(I) reagents are very weak bases in THF and react very slowly, if at all, with weak proton donors such as methanol. On the other hand, as noted above, vinylcopper(I) species formed by addition of (trimethylstannyl)copper(I) to α,β-acetylenic esters are readily protonated by methanol (9–11). Therefore, in the hope of "driving" the reaction of the 1-alkyne **5***a* with reagent **1** to completion, varying amounts of methanol were added to the reaction mixture. After some experimentation, it was found that **5***a* could be converted efficiently (84% yield) into the 2-trimethylstannyl-1-alkene **6***a* by reaction with 2 equivalents of reagent **1** (THF, −63°C, 12 h) in the presence of 60 equivalents of methanol. Subjection of other 1-alkynes **5** to the same reaction conditions gave good to excellent yields of the corresponding 2-trimethylstannyl-1-alkenes **6**. The appropriate data are summarized in Table 1.

A number of comments should be made regarding the chemical reactions summarized in Table 1. Some of the starting materials (**5***b*,*e*,*f*,*h*) are commercially available, while others were either known substances (**5***c*,*d*,*i*,*k*; references 12–15, respectively) or were prepared readily (**5***a*, see footnote 2; **5***g*, reaction of *tert*-butyldimethylsilyl chloride with **5***h* in the presence of imidazole in *N*,*N*-dimethylformamide; **5***j*, reaction of 2-propyn-1-ol with dihydropyran in the presence of *p*-toluenesulfonic acid in benzene) from known materials.

In the conversions involving substrates **5***a–h* (Entries 1–8), gas–liquid chromatographic analyses of the crude products showed that, in each case, a small amount (~2–10%) of a second product was present. However, when the product mixtures were subjected to (slow) column chromatography on silica gel, only the major products **6** were isolated. Apparently the minor products were rather unstable to chromatography and were destroyed on the column. Nevertheless, when the reaction summarized in Entry 8 was repeated on a larger scale (see footnote *c*, Table 1) and flash chromatography (7) was carried out on the resultant 9:1 mixture of products, the minor product was obtained in 8% yield. On the basis of its spectra, this material was identified as (*E*)-4-trimethylstannyl-3-buten-1-ol (**9**). Of particular note was the proton nuclear magnetic resonance (^{1}H nmr) spectrum of **9**, which exhibited signals due to two vicinal olefinic protons (H_A and H_B in **9**) with a mutual coupling constant of 18.5 Hz. Other excellent evidence for the constitution and stereochemistry of **9** was provided by the magnitude of the coupling constant ($^3J_{Sn-H} \sim 72$ Hz) between the ^{117}Sn and ^{119}Sn isotopes and H_B. This value is typical of alkenes having a trimethylstannyl group and a proton in a *cis* relationship (16).

On the basis of the isolation and characterization of the product **9** and analogous substances from reactions summarized in Entries 9–11 (*vide infra*), it is highly likely that the minor products formed from the reactions of **5***a–g* with $Me_3SnCu\cdot Me_2S$ (**1**) (Entries 1–7) are the corresponding (*E*)-1-trimethylstannyl-1-alkenes. Thus, in each case, there is a small amount of $Me_3SnCu\cdot Me_2S$ addition of the acetylenic linkage regioisomeric with that leading to the major product **6**. This addition evidently takes place with the expected (1–3) *cis* stereochemistry to give, after protonation of the vinylcopper(I) species, the corresponding (*E*)-1-alkene.

The additions of $Me_3SnCu\cdot Me_2S$ (**1**) to the 1-alkynes **5***i–k* (Entries 9–11) are significantly less regioselective than those involving substrates **5***a–h*. Reaction of **5***i* with **1** provides the 2-trimethylstannyl-1-alkene **6***i* and the (*E*)-1-trimethylstannyl-1-alkene **10** in a ratio of 4:1. A small sample of the latter substance, isolated by preparative gas–liquid chromatography, exhibited the expected spectral properties. In similar fashion, the reactions of $Me_3SnCu\cdot Me_2S$ (**1**) with the 2-propyn-1-ol derivatives **5***j* and **5***k* gave, in each case, a mixture of regioisomeric products (**6***j* and **11** (7:3) and **6***k* and **12** (72:28), respectively). The (*E*)-1-trimethylstannyl-1-alkenes **11** and **12** were obtained in yields of 22 and 20%, respectively, and were spectrally characterized. Thus, it is evident that placement of an electron-withdrawing group close to the triple bond reduces the regioselectivity of the addition of $Me_3SnCu\cdot Me_2S$ (**1**) to the alkyne function.

It should also be noted that the reactions of **1** with the substrates **5***j* and **5***k* proceed to completion at −78°C (6 h) in the *absence* of a proton source (methanol) (see footnote *e*, Table 1).

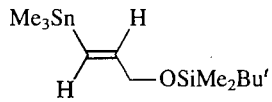
11



12

Thus, not only are these processes relatively nonregioselective, but they do not require the presence of a proton source for the efficient conversion of starting material to products.

The reaction characteristics summarized above may be rationalized qualitatively as follows. The addition of **1** to **5** is expected (1–3) to occur in a *cis* fashion and, if the reaction is reversible, the two possible regioisomeric intermediates **13** and **14** would be in equilibrium with one another. When the electronegative group X is separated from the triple bond by a number of carbon atoms, the intermediate **13** is appreciably more stable than **14**. Thus, not unexpectedly, it appears that the polar carbon–copper(I) bond prefers to be associated with the terminal carbon atom (C-1) rather than with C-2. However, when electronegative groups are placed near to the alkyne function (e.g., Cl in **5***i*, OR in **5***j* and **5***k*), the intermediate **14** is inductively stabilized to a greater extent than **13**.[4] Therefore, the energy difference between the two intermediates is reduced and the proportion of the (*E*)-1-trimethylstannyl-1-alkenes (**10**–**12**) in the product mixtures increases.

Finally, it may be noted that the electron-withdrawing effect of a propargylic OR group can also be invoked to rationalize the fact that the reactions of **1** with **5***j* and **5***k* (Table 1, Entries 10 and 11) proceed to completion even in the absence of a proton source. Thus, in these cases, the intermediates **13** and **14** (n = 1, X = OR) are, apparently, stabilized sufficiently to allow the (potentially) reversible reactions to lie very largely (or completely) to the right.

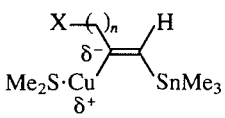
13



14

Conclusion

Reaction of (trimethylstannyl)copper(I)·dimethyl sulfide (**1**) with ω-substituted 1-alkynes **5** under suitable conditions provides good to excellent yields of the corresponding 2-trimethylstannyl-1-alkenes **6**. We have shown and reported in preliminary form (17) that some of the latter substances serve as excellent precursors of novel, synthetically useful bifunctional reagents. The details of these and other related studies will be reported in the near future.

[4]A referee suggested that coordination between the X and Cu atoms in **14** might assist in stabilizing the intermediate. This suggestion is entirely reasonable.

Experimental

General information

Distillation temperatures, which refer to short path (Kugelrohr) distillations, are uncorrected. Infrared (ir) spectra were recorded on Perkin Elmer models 710 or 710B spectrophotometers and were calibrated using the 1601 cm^{-1} band of a polystyrene film. Proton nuclear magnetic resonance (^1H nmr) spectra were taken on $CDCl_3$ solutions and were recorded at 80 MHz (Bruker WP-80 spectrometer) or at 400 MHz (Bruker WH-400 spectrometer). Signal positions are given in δ units and, for compounds containing Me_3Sn or *t*-$BuMe_2Si$ groups, were measured relative to the chloroform signal (δ 7.25). The tin–proton coupling constants (J_{Sn-H}) are given as an average of the ^{117}Sn and ^{119}Sn values. High resolution mass spectra were recorded with Kratos/AEI MS 50 or MS 902 spectrometers. For compounds containing the Me_3Sn group, molecular mass measurements are based on ^{120}Sn and were made on the (M^+ − Me) peak.

8-Tetrahydropyranyloxy-1-octyne (5a)

To a cool (10°C), stirred suspension of lithium acetylide – ethylenediamine complex (5.81 g, 60 mmol) in 40 mL of dry dimethyl sulfoxide (argon atmosphere) was added, dropwise, 13.25 g (50 mmol) of 1-bromo-6-tetrahydropyranyloxyhexane (see footnote 2). After the addition was complete, the dark brown slurry was warmed to room temperature and stirred for 2 h. Water (25 mL) was added dropwise. The mixture was diluted with water (100 mL) and then was extracted with ether (3 × 100 mL). The combined extracts were washed with water (3 × 50 mL), dried ($MgSO_4$), and concentrated. Distillation (air-bath temperature 105–110°C/0.9 Torr (1 Torr = 133.3 Pa)) of the residual yellow oil afforded 8.12 g (77%) of the 1-alkyne **5***a* as a colorless oil that exhibited ir (neat): 3290, 2100, 1140, 1120, 1080, 1035 cm^{-1}; ^1H nmr (80 MHz) δ: 1.2–1.9 (m, 14H), 1.93 (t, 1H, J = 2.5 Hz), 2.0–2.4 (m, 2H), 3.2–4.1 (m, 4H), 4.55 (br s, 1H). *Exact Mass* calcd. for $C_{13}H_{22}O_2$: 210.1620; found: 210.1607.

General procedure for the addition of $Me_3SnCu\cdot Me_2S$ (1) to 1-alkynes (5). Preparation of 2-trimethylstannyl-1-alkenes (6)

To a cold (−78°C), stirred solution of $Me_3SnCu\cdot Me_2S$ (**1**) (0.4 mmol) in 3 mL of dry THF (argon atmosphere) was added sequentially a dry THF solution (0.5 mL) of the 1-alkyne **5** (0.2 mmol) and dry methanol (0.5 mL, 12 mmol). The dark red reaction mixture was stirred at −78°C for 10 min and at −63°C for 12 h. Saturated aqueous ammonium chloride (pH 8) (5 mL) and ether (20 mL) were added and the mixture was allowed to warm to room temperature with vigorous stirring. Stirring was continued until the aqueous phase became deep blue. The layers were separated and the aqueous phase was extracted with ether (2 × 5 mL). The combined organic extracts were washed with saturated aqueous ammonium chloride (pH 8) (2 × 5 mL) and dried ($MgSO_4$). Removal of the solvent afforded a crude oil that, on the basis of gas–liquid chromatographic analysis, consisted of a mixture of hexamethylditin, a major product, and a minor (1–20%) product. Subjection of this oil to conventional or flash (7) column chromatography on silica gel, followed by concentration of the appropriate fractions and bulb-to-bulb distillation of the residual material, furnished the 2-trimethylstannyl-1-alkene **6**. In most cases, the minor product (the corresponding (*E*)-1-trimethylstannyl-1-alkene) was not isolated.

8-Tetrahydropyranyloxy-2-trimethylstannyl-1-octene (6a)

Following the general procedure, 8-tetrahydropyranyloxy-1-octyne (**5***a*) (39 mg, 0.2 mmol) was converted into a 95:5 mixture of two products. Subjection of the crude oil to flash chromatography on silica gel (2 × 15 cm column, elution with 1:20 ether – petroleum ether), followed by distillation (air-bath temperature 115–120°C/0.7 Torr) of the oil thus obtained gave 59 mg (84%) of the vinylstannane **6***a* as a colorless oil. This material exhibited ir (neat): 1140, 1120, 1080, 1040, 915, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.13 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 1.1–1.9 (m, 14H), 2.1–2.4 (m, 2H), 3.2–4.0 (m, 4H), 4.5–4.7 (m, 1H), 5.12 (br d, 1H, J = 3 Hz, $^3J_{Sn-H}$ = 70 Hz), 5.63 (dt, 1H, J = 3, 1.5 Hz, $^3J_{Sn-H}$ = 156 Hz). *Exact Mass* calcd. for $C_{15}H_{29}O_2Sn$ (M^+ − Me): 361.1190; found: 361.1203.

*5-Trimethylstannyl-5-hexen-1-ol (**6**b)*

Conversion of 5-hexyn-1-ol (**5***b*) (24 mg, 0.2 mmol) into a 97:3 mixture of two products was accomplished via the general procedure. Column chromatography of the crude mixture on silica gel (7 g, elution with 1:3 ether – petroleum ether) and distillation (air-bath temperature 80–83°C/12 Torr) of the oil obtained afforded 54 mg (85%) of the alcohol **6***b* as a colorless oil that exhibited ir (neat): 3300 (br), 1060, 920, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.17 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 1.25 (t, 1H, *J* = 5 Hz), 1.4–1.7 (m, 4H), 2.32 (br t, 2H, *J* = 7 Hz), 3.65 (dt, 2H, *J* = 5, 6 Hz), 5.14 (dt, 1H, *J* = 3, 1 Hz; $^3J_{Sn-H}$ = 70 Hz), 5.65 (dt, 1H, *J* = 3, 1.5 Hz; $^3J_{Sn-H}$ = 152 Hz). *Exact Mass* calcd. for $C_8H_{17}OSn$ (M^+ − Me): 249.0302; found: 249.0302.

*6-Chloro-2-trimethylstannyl-1-hexene (**6**c)*

By means of the general procedure, 6-chloro-1-hexyne (**5***c*) (12) (22.5 mg, 0.2 mmol) was converted into a 92:8 mixture of two products. Subjection of this material to column chromatography (4 g of silica gel, elution with petroleum ether) gave a colorless liquid that, upon distillation (air-bath temperature 55–58°C/12 Torr) afforded 44 mg (80%) of the chloro alkene **6***c*. This liquid exhibited ir (neat): 1440, 920, 775 cm^{-1}; ^1H nmr (80 MHz) δ: 0.17 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 1.4–2.0 (m, 4H), 2.32 (br t, 2H, *J* = 7 Hz, $^3J_{Sn-H}$ = 50 Hz), 3.55 (t, 2H, *J* = 6 Hz), 5.17 (dt, 1H, *J* = 2.5, 1 Hz; $^3J_{Sn-H}$ = 70 Hz), 5.67 (dt, 1H, *J* = 2.5, 1.2 Hz; $^3J_{Sn-H}$ = 150 Hz). *Exact Mass* calcd. for $C_8H_{16}{}^{35}ClSn$ (M^+ − Me): 264.9957; found: 264.9952.

*5-tert-Butyldimethylsiloxy-2-trimethylstannyl-1-pentene (**6**d)*

Following the general procedure, 5-*tert*-butyldimethylsiloxy-1-pentyne (**5***d*) (13) (45 mg, 0.2 mmol) was transformed into a 95:5 mixture of two products. Column chromatography (7 g silica gel, elution with petroleum ether) of this material provided a colorless oil that, upon distillation (air-bath temperature 98–103°C/12 Torr), yielded 68 mg (82%) of the ether alkene **6***d*; ir (neat): 1260, 1105, 840, 780 cm^{-1}; ^1H nmr (80 MHz) δ: 0.07 (s, 6H), 0.17 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.92 (s, 9H), 1.5–1.7 (m, 2H), 2.35 (br t, 2H, *J* = 7.5 Hz), 3.62 (t, 2H, *J* = 6 Hz), 5.16 (br d, 1H, *J* = 2.5 Hz, $^3J_{Sn-H}$ = 72 Hz), 5.68 (dt, 1H, *J* = 2.5, 1 Hz; $^3J_{Sn-H}$ = 152 Hz). *Exact Mass* calcd. for $C_{13}H_{29}OSiSn$ (M^+ − Me): 349.1010; found: 249.1011.

*4-Trimethylstannyl-4-penten-1-ol (**6**e)*

4-Pentyn-1-ol (**5***e*) (16 mg, 0.2 mmol) was converted, via the general procedure, into a 98:2 mixture of two products. The crude product was chromatographed on silica gel (7 g, elution with 1:3 ether–petroleum ether). Distillation (air-bath temperature 72–76°C/12 Torr) of the oil thus obtained produced 43 mg (88%) of the alcohol **6***e*, which exhibited ir (neat): 3300 (br), 1060, 920, 775 cm^{-1}; ^1H nmr (80 MHz) δ: 0.20 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 1.42 (t, 1H, *J* = 5.5 Hz), 1.5–1.9 (m, 2H), 2.40 (br t, 2H, *J* = 7 Hz), 3.68 (dt, 2H, *J* = 5.5, 6 Hz), 5.20 (dt, 1H, *J* = 2.5, 1 Hz; $^3J_{Sn-H}$ = 70 Hz), 5.72 (dt, 1H, *J* = 2.5, 1 Hz; $^3J_{Sn-H}$ = 150 Hz). *Exact Mass* calcd. for $C_7H_{15}OSn$ (M^+ − Me): 235.0145; found: 235.0134.

*5-Chloro-2-trimethylstannyl-1-pentene (**6**f)*

By means of the general procedure, 5-chloro-1-pentyne (**5***f*) (20 mg, 0.2 mmol) was converted into a 9:1 mixture of two products. Column chromatography (4 g of silica gel, elution with petroleum ether) of this material, followed by distillation (air-bath temperature 55–60°C/12 Torr) of the oil thus obtained, afforded 42 mg (79%) of the chloro alkene **6***f*; ir (neat): 1440, 920, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.16 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 1.7–2.1 (m, 2H), 2.19 (br t, 2H, *J* = 7 Hz), 3.52 (t, 2H, *J* = 6.5 Hz), 5.22 (dt, 1H, *J* = 2.5, 1 Hz; $^3J_{Sn-H}$ = 70 Hz), 5.72 (dt, 1H, *J* = 2.5, 1 Hz; $^3J_{Sn-H}$ = 148 Hz). *Exact Mass* calcd. for $C_7H_{14}{}^{35}ClSn$ (M^+ − Me): 252.9840; found: 252.9823.

*4-tert-Butyldimethylsiloxy-2-trimethylstannyl-1-butene (**6**g)*

Following the general procedure, 4-*tert*-butyldimethylsiloxy-1-butyne (**5***g*) (35 mg, 0.2 mmol) was converted into a 92:8 mixture of two products. Column chromatography (8 g of silica gel, elution with petroleum ether) of the crude product and distillation (air-bath temperature 97–105°C/12 Torr) of the oil thus obtained furnished 54 mg (81%) of the alkene ether **6***g*; ir (neat): 1250, 1100, 920, 840, 775 cm^{-1}; ^1H nmr (80 MHz) δ: 0.08 (s, 6H), 0.16 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.92 (s, 9H), 2.50 (br t, 2H, *J* = 7 Hz), 3.65 (t, 2H, *J* = 7 Hz), 5.22 (br d, 1H, *J* = 2.5 Hz, $^3J_{SnH}$ = 71 Hz), 5.70 (dt, 1H, *J* = 2.5, 1 Hz; $^3J_{Sn-H}$ = 150 Hz. *Exact Mass* calcd. for $C_{12}H_{27}OSiSn$ (M^+ − Me): 335.0854; found: 335.0856.

*3-Trimethylstannyl-3-buten-1-ol (**6**h)*

(a) "Small" scale

Following the general procedure, 3-butyn-1-ol (**5***h*) (15 mg, 0.2 mmol) was converted into a 92:8 mixture of two products. Subjection of the crude product mixture to flash chromatography (6 g of silica gel, elution with 1:3 ether – petroleum ether), followed by distillation (air-bath temperature 65–70°C/12 Torr) of the oil thus obtained, produced 42 mg (82%) of the alcohol **6***h*; ir (neat): 3300 (br), 920, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.18 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 1.46 (t, 1H, *J* = 6 Hz), 2.55 (br t, 2H, *J* = 6 Hz, $^3J_{Sn-H}$ = 51 Hz), 3.66 (dt, 2H, *J* = 6, 6 Hz), 5.32 (dt, 1H, *J* = 1.2, 1 Hz; $^3J_{Sn-H}$ = 70 Hz), 5.77 (dt, 1H, *J* = 1.2, 1 Hz; $^3J_{Sn-H}$ = 148 Hz). *Exact Mass* calcd. for $C_6H_{13}OSn$ (M^+ − Me): 220.9989; found: 220.9986.

(b) "Large" scale

To a cold (−78°C), stirred solution of $Me_3SnCu\cdot Me_2S$ (**1**) (2.0 mmol) in 15 mL of dry THF (argon atmosphere) was added sequentially a dry THF solution (1 mL) of 3-butyn-1-ol (**5***h*) (70 mg, 1.0 mmol) and methanol (2.5 mL, 62 mmol). The dark red reaction mixture was stirred at −78°C for 10 min and at −63°C for 12 h. Work-up as described in the general procedure produced a colorless oil that consisted of hexamethylditin and a 9:1 mixture of two products (gas–liquid chromatographic analysis). Flash chromatography (17 g of silica gel, elution with 1:3 ether – petroleum ether) gave 191 mg (81%) of the less polar, major product **6***h* (spectra identical with those summarized above) and 19 mg (8%) of the more polar, minor product **9** (distillation temperature 65–70°C/12 Torr). The latter oil exhibited ir (neat): 3350 (br), 1600, 1050, 990, 775 cm^{-1}; ^1H nmr (400 MHz) δ: 0.13 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.45 (t, 1H, *J* = 6 Hz), 2.42 (ddt, 2H, *J* = 6.2, 1.2, 6 Hz), 3.69 (dt, 2H, *J* = 6, 6 Hz), 5.96 (dt, 1H, *J* = 18.5, 6.2 Hz; $^3J_{Sn-H}$ = 72 Hz), 6.11 (dt, 1H, *J* = 18.5, 1.2 Hz; $^2J_{Sn-H}$ = 84 Hz). *Exact Mass* calcd. for $C_6H_{13}OSn$ (M^+ − Me): 220.9989; found: 220.9994.

*4-Chloro-2-trimethylstannyl-1-butene (**6**i) and (E)-4-chloro-1-trimethylstannyl-1-butene (**10**)*

Following the general procedure, 4-chloro-1-butyne (**5***i*) (14) (17 mg, 0.2 mmol) was transformed into a mixture of two products in a ratio of 4:1. Chromatography of the crude mixture on silica gel (8 g, elution with petroleum ether), followed by distillation (air-bath temperature 55–60°C/12 Torr) of the less polar oil gave 28 mg (59%) of the major product **6***i* as a colorless oil; ir (neat): 1615, 925, 775 cm^{-1}; ^1H nmr (80 MHz) δ: 0.24 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 2.50 (br t, 2H, *J* = 7 Hz, $^3J_{Sn-H}$ = 47 Hz), 3.58 (t, 2H, *J* = 7 Hz), 5.32 (dt, 1H, *J* = 2.2, 1 Hz; $^3J_{Sn-H}$ = 68 Hz), 5.78 (dt, 1H, *J* = 2.2, 1 Hz; $^3J_{Sn-H}$ = 144 Hz). *Exact Mass* calcd. for $C_6H_{12}{}^{35}ClSn$ (M^+ − Me): 238.9650; found: 238.9651.

A small sample of the minor, more polar product **10** was obtained from the appropriate chromatography fractions by preparative gas–liquid chromatography. This material exhibited ir ($CHCl_3$): 1600, 780 cm^{-1}; ^1H nmr (400 MHz) δ: 0.13 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 2.60 (ddt, 2H, *J* = 1.2, 6, 7 Hz), 3.57 (t, 2H, *J* = 7 Hz), 5.96 (dt, 1H, *J* = 18.5, 6 Hz; $^3J_{Sn-H}$ = 71 Hz), 6.11 (dt, 1H, *J* = 18.5, 1.2 Hz; $^2J_{Sn-H}$ = 82 Hz). *Exact Mass* calcd. for $C_6H_{12}{}^{35}ClSn$ (M^+ − Me): 238.9650; found: 238.9657.

*3-Tetrahydropyranyloxy-2-trimethylstannylpropene (**6**j) and (E)-3-tetrahydropyranyloxy-1-trimethylstannylpropene (**11**)*

To a cold (−78°C), stirred solution of $Me_3SnCu\cdot Me_2S$ (**1**) (1.5 mmol) in 12 mL of dry THF (argon atmosphere) was added a solution of 3-tetrahydropyranyloxypropyne (**5***j*) (140 mg, 1 mmol) in dry THF (1 mL) and the dark red mixture was stirred at −78°C for 6 h. Methanol

(0.5 mL), saturated aqueous ammonium chloride (pH 8) (5 mL), and ether (40 mL) were added and the vigorously stirred mixture was allowed to warm to room temperature. Stirring was continued until the aqueous phase became deep blue. The phases were separated and the organic phase was washed with saturated aqueous ammonium chloride (pH 8) (2 × 10 mL) and then was dried ($MgSO_4$). Removal of the solvent gave an oil that contained hexamethylditin and two products in a ratio of 7:3 (gas–liquid chromatographic analysis). Flash chromatography of this material on silica gel (2 × 15 cm column, elution with 1:15 ether – petroleum ether) provided 177 mg (58%) of the major, less polar product **6***j* (distillation temperature 103–110°C/12 Torr) and 67 mg (22%) of the minor, more polar product **11** (distillation temperature 105–115°C/12 Torr).

Compound **6***j* exhibited ir (neat): 1140, 1120, 1030, 775 cm^{-1}; ^1H nmr (80 MHz) δ: 0.20 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.4–2.0 (m, 6H), 3.70 (m, 2H), 4.28 (m, 2H), 4.67 (m, 1H), 5.30 (dt, 1H, J = 2.5, 1.5 Hz; $^3J_{Sn-H}$ = 71 Hz), 5.86 (dt, 1H, J = 2.5, 1 Hz; $^3J_{Sn-H}$ = 146 Hz). *Exact Mass* calcd. for $C_{10}H_{19}O_2Sn$ (M^+ − Me): 291.0407; found: 291.0408.

Compound **11** exhibited ir (neat): 1600, 1030, 910, 875, 775 cm^{-1}; ^1H nmr (400 MHz) δ: 0.14 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.50–1.68 (m, 4H), 1.70–1.79 (m, 1H), 1.82–1.93 (m, 1H), 3.48–3.54, 3.86–3.92 (m, m, 1H each), 4.01 (ddd, 1H, J = 13, 5.2, 1.2 Hz; $^4J_{Sn-H}$ = 11 Hz), 4.27 (ddd, 1H, J = 13, 4.8, 1.5 Hz; $^4J_{Sn-H}$ = 11 Hz), 4.65 (t, 1H, J = 7 Hz), 6.11 (ddd, 1H, J = 19, 5.2, 4.8 Hz; $^3J_{Sn-H}$ = 71 Hz), 6.29 (ddd, 1H, J = 19, 1.2, 1.5 Hz; $^2J_{Sn-H}$ = 82 Hz). *Exact Mass* calcd. for $C_{10}H_{19}O_2Sn$ (M^+ − Me): 291.0407; found: 291.0406.

*3-*tert*-Butyldimethylsiloxy-2-trimethylstannylpropene (**6**k) and (*E*)-3-*tert*-butyldimethylsiloxy-1-trimethylstannylpropene (**12**)*

To a cold (−78°C), stirred solution of $Me_3SnCu \cdot Me_2S$ (**1**) (1.3 mmol) in 10 mL of dry THF (argon atmosphere) was added a solution of 3-*tert*-butyldimethylsiloxypropyne (**5***k*) (15) (147 mg, 0.86 mmol) in 1 mL of dry THF and the dark red mixture was stirred at −78°C for 6 h. Saturated aqueous ammonium chloride (pH 8) (5 mL) and ether (40 mL) were added and further work-up proceeded as described above. Gas–liquid chromatographic analysis of the crude product showed that it consisted of a mixture of hexamethylditin and two products in a ratio of 72:28. Flash chromatography of this material on silica gel (2 × 15 cm column, elution with petroleum ether) provided 161 mg (51%) of the less polar major product (**6***k*) (distillation temperature 90–95°C/12 Torr) and 59 mg (20%) of the more polar minor product **12** (distillation temperature 93–98°C/12 Torr).

Compound **6***k* exhibited ir (neat): 1460, 1260, 1080, 860, 840, 780 cm^{-1}; ^1H nmr (80 MHz) δ: 0.07 (s, 6H), 0.15 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 0.92 (s, 9H), 4.32 (dd, 2H, J = 2, 1 Hz; $^3J_{Sn-H}$ = 33 Hz), 5.21 (dt, 1H, J = 2.5, 2 Hz; $^3J_{Sn-H}$ = 71 Hz), 5.81 (dt, 1H, J = 2.5, 1 Hz; $^3J_{Sn-H}$ = 148 Hz). *Exact Mass* calcd. for $C_{11}H_{25}OSiSn$ (M^+ − Me): 321.0697; found: 321.0686.

Compound **12** exhibited ir (neat): 1600, 1260, 1130, 1100, 850, 780 cm^{-1}; ^1H nmr (400 MHz) δ: 0.09 (s, 6H), 0.14 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 0.94 (s, 9H), 4.20 (dd, 2H, J = 4.1, 1.6 Hz; $^4J_{Sn-H}$ = 14 Hz), 6.08 (dt, 1H, J = 19, 4.1 Hz; $^3J_{Sn-H}$ = 73 Hz), 6.24 (dt, 1H, J = 19, 1.6 Hz, $^2J_{Sn-H}$ = 84 Hz). *Exact Mass* calcd. for $C_{11}H_{25}OSiSn$ (M^+ − Me): 321.0697; found: 321.0698.

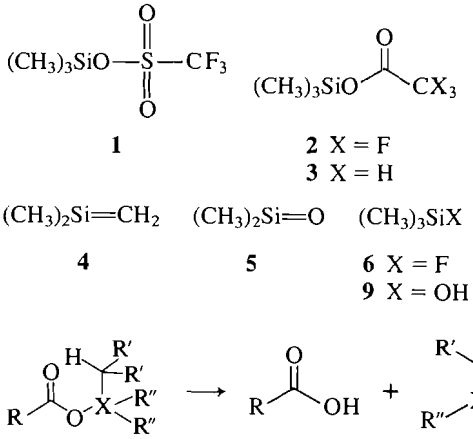
Thermolysis of trimethylsilyl esters: an ultraviolet photoelectron spectroscopy study

NICK HENRY WERSTIUK, MICHAEL A. BROOK, AND PETER HÜLSER
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 19, 1987

NICK HENRY WERSTIUK, MICHAEL A. BROOK, and PETER HÜLSER. Can. J. Chem. **66**, 1430 (1988).

The thermolytic behaviour of trimethylsilyl trifluoromethanesulfonate, **1**, trimethylsilyl trifluoroacetate, **2**, and trimethylsilyl acetate, **3**, has been investigated by ultraviolet photoelectron spectroscopy. Acetate **3** undergoes decomposition only to a small extent at 800°C via the mechanism shown in Scheme 1 (X = Si); only acetic acid and starting material are detected. In contrast



SCHEME 1

with this result, **1** and **2** decompose completely at 725–800°C and yield products which cannot be derived via the mechanism shown in Scheme 1. Evidence is presented to support our proposal that the thermolysis of **1** yields trimethylsilyl fluoride, **6**, and difluorooxathirane dioxide, **7**, as primary products. The photoelectron spectra of **1, 2, 3, 6** and trimethylsilanol, **9**, are presented. Molecular orbital eigenvalues of dimethylsilene, **4**, dimethylsilanone, **5** (calculated using AMPAC and Gaussian 82), **6** and **9** (AMPAC) are reported. Molecular orbital contour diagrams are given for selected MOs of **6** and **9**.

NICK HENRY WERSTIUK, MICHAEL A. BROOK et PETER HÜLSER. Can. J. Chem. **66**, 1430 (1988).

Faisant appel à la spectroscopie ultraviolette photoélectronique, on a étudié le comportement thermolytique des trifluorométhanesulfonate (**1**), trifluoroacétate (**2**) et acétate (**3**) de triméthylsilyle. A 800°C, l'acétate **3** ne subit qu'une faible décomposition qui se produit par le biais de départ. Par opposition à ce résultat, les composés **1** et **2** se décomposent complètement, à des températures allant de 725 à 800°C, et ils fournissent des produits dont on ne peut pas expliquer la formation en se basant sur le schéma 1. On présente des données qui supportent notre hypothèse selon laquelle la thermolyse du composé **1**

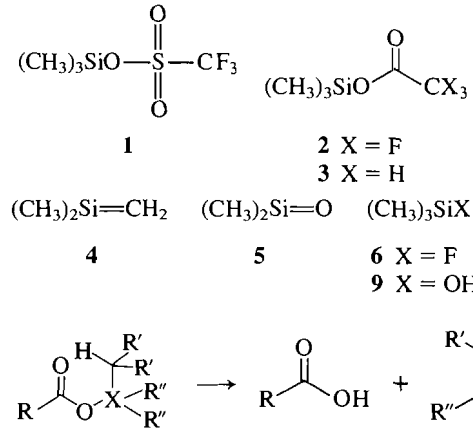


SCHÉMA 1

fournirit du fluorure de triméthylsilyle (**6**) ainsi que le dioxyde du difluorooxathirane (**7**) comme produits primaires. On rapporte les spectres photoélectroniques des composés **1, 2, 3, 6** ainsi qui du triméthylsilanol (**9**). On rapporte aussi les valeurs fondamentales des orbitales moléculaires du diméthylsilène (**4**), de la diméthylsilanone (**5**) (calculées à l'aide de l'AMPAC et de la Gaussienne 82), ainsi que des composés **6** et **9** (AMPAC). Introduction

The thermolysis of carboxylic acid esters has been the subject of extensive mechanistic studies (1, 2). In general, the reaction occurs via a six-membered ring transition state and yields an alkene and a carboxylic acid (Scheme 1, X = C). Although tetrakis (trifluoroacetates) of silicon, germanium, tin, lead, and titanium have been shown to decompose thermally via a different mechanism (3), there have been no reported studies of silyl esters such as trimethylsilyl trifluoromethanesulfonate **1** (TMSOTf), trimethylsilyl trifluoroacetate, **2** (TMSTFA), and trimethylsilyl acetate, **3** (TMSOAc).

In our continuing studies on transients (4) in the gas phase, the thermolyses of **1**, **2**, and **3** were investigated by ultraviolet photoelectron spectroscopy (UPS) to establish whether or not dimethylsilene, **4**, and/or dimethylsilanone, **5**, both highly reactive, elusive molecules, are formed by thermolysis of the esters. The former — only its lowest IE (7.98 eV) has been obtained experimentally (5) — would be expected to arise via a typical ester decomposition of **2** or **3** (Scheme 1, X = Si). The latter, not yet detected in the gas phase by UPS, could be formed via the mechanism shown in Scheme 2: cleavage of the relatively weak SiC bond (~318 kJ/mol) (6) of **2** or **3** would yield an oxygen stabilized silyl radical which by β-scission would give **5** and the acyl radical. If the same mechanism were to apply to the thermal decomposition of **1**, the corresponding sulfonyl radical and **5** would be formed.

In this paper we show that while acetate **3** decomposes thermally via the classical route, the thermolyses of **1** and **2**, driven by silicon–fluorine bond formation, proceed via a different mechanism.

Experimental

Preparation of silyl compounds

TMSOTf, **1**, obtained from Aldrich Chem. Co. was used without further purification upon freshly opening a vial.

TMSTFA, **2**, was prepared using a modified procedure of Sartori (3). Trimethylsilyl chloride (3.42 g, 32 mmol) and trifluoroacetic acid (3.22 g, 28 mmol) were heated at reflux for 2 h during which time the temperature of the vapor phase increased from 57 to 90°C. TMSTFA (4.28 g, 79.9%) was distilled from the reaction mixture. ^{1}H nmr ($CDCl_3$): δ 0.35 (s, 9H). **1** and **2** displayed a single peak in the ^{1}H nmr and on this basis were assumed to be >95% pure.

TMSOAc **3** was prepared as described by Schuyten *et al.* (7) and purified by preparative gas chromatography (GC).

TMSF, **6**, and TMSOH, **9**, were prepared according to the procedure of Sommer *et al.* (8); TMSOH was purified by preparative gas chromatography.

Thermolysis studies

The thermolysis apparatus and the photoelectron (p.e.) spectrometer used in this study are described in a previous publication (4). Thermolyses were carried out at a pressure of approximately 1×10^{-3} Torr. In each case, a p.e. spectrum of the total thermolysate was obtained initially. Subsequently, the thermolysate was condensed in a U-trap cooled with liquid nitrogen and the components separated by a low-temperature distillation (4) which was monitored by recording p.e. spectra.

Theoretical calculations

Calculations of the molecular orbital eigenvalues (MOEs) and molecular orbital contour plots (MOCs) were carried out on VAX 8600 and 11/780 computers. The initial geometries of TMSOH and dimethylsilanone were obtained using the molecular modelling packages CHEMGRAF (9) or MODEL (10). These provide an interactive graphics environment for performing molecular mechanics structural energy minimizations using MODEL generalized force constants or MM2/MMP2 force constants (11). This procedure greatly facilitated construction of input files for the AMPAC calculations (12). For TMSF the experimental geometry was used (13), and for dimethylsilene the DZ + d SCF structure (14) was used. The final geometries and MOEs of **1–9** were calculated using the MNDO hamiltonian of AMPAC. MOCs of TMSF and TMSOH were obtained using the programs DENSITY (density plots from MOPAC (QCPE 455) calculations, ref. 15) which uses an output file from AMPAC, and DRAW (molecular drawing program (QCPE 456), ref. 16) which generates a plot of the contours. The *ab initio* calculations on **4** and **5** were carried out using GAUSSIAN 82 (17) with a 6-31G* basis set. MOCs were displayed on an IBM XT compatible microcomputer, equipped with a Princeton HX-12E color monitor and a Genoa Spectra enhanced graphics card, running Grafpoint TGRAF-05 software (18). This system emulates a Tektronix 4105 color terminal. Plots of the MOCs were obtained by a screen dump to a dot-matrix printer.

Results

Thermolysis of TMSOTf, 1

The p.e. spectra of **1** and its thermolysate obtained at 725°C are given in Fig. 1 as 1(*A*) and 1(*B*), respectively. It is evident that conversion to products is essentially complete under these conditions. When the thermolysate was trapped by liquid nitrogen as 300 scans were accumulated over several hours, no discernible spectrum over background was obtained. When a low-temperature distilation was carried out, spectra 1(Cl) and 1(D) were obtained after only a slight warming of the trap. Subtraction of spectrum 1(D) from 1(Cl) yielded 1(C2) which corresponds closely to the spectrum of $CH_2{=}CF_2$ (19). Based on the number of scans accumulated during the distillation of the product giving rise to spectrum 1(Cl), however, it is a minor component. 1(D) is the spectrum of COF_2 (20). Further warming yielded spectrum 1(E1), then 1(F). Subtraction of spectrum 1(F) from 1(E1) yielded 1(E2), which is the spectrum of SO_2 (21). The identity of the component giving rise to spectrum 1(F), a major product of thermolysis, was initially unknown. Since the p.e. spectra of TMSF and TMSOH were also unknown prior to this study, the compounds were prepared from $(CH_3)_3SiCl$ and the molecular orbital eigenvalues (MOEs) calculated using AMPAC and are given in Tables 1 and 2, respectively. While the eigenvalues of these compounds correlated reasonably well with the experimentally determined IEs, the p.e. spectrum of TMSF, **6** was identical to spectrum 1(F) thereby identifying the fluoride as a major product of thermolysis. The p.e. spectrum of TMSOH is shown in Fig. 2.

Thermolysis of TMSTFA, 2

The p.e. spectra of **2** and its thermolysate, produced at 790°C, are shown in Fig. 3 as 3(A) and 3(B), respectively. As was the case in the thermolysis of **1**, TMSF, identified by the broad band at 11 eV and the general features of spectrum 3(B), is a major product; CO_2 (IEs 13.8, 17.5–18.0, 18.1), and what appears to be CO (IEs 14.0, 16.5–17.5) (21) are the other directly identifiable products. To obtain a more accurate analysis of the products, the thermolysate was trapped by liquid nitrogen as 200 scans were accumulated. Although a spectrum with a good signal-to-noise ratio was obtained, it did not correspond to CO, CHF_3, CF_4, $CH_3{-}CF_3$, or $CF_3{-}CF_3$, all possible products of thermolysis. As the trap was warmed slowly, spectrum 3(C) was obtained, followed by spectrum 3(D), 3(E1), 3(F), and 3(G). Spectra 3(C) and 3(D) are composed of CO_2, COF_2 (see 1(D)), and $CF_2{=}CF_2$, the latter identified by the broad peak with fine structure centered at approximately 10.5 eV and differentiated

from $CF_2{=}CH_2$ (see Fig. 1 (C2)) by the fact that the σ and fluorine lone pair bands appear at higher energies than the corresponding bands for $CF_2{=}CH_2$ (19). Spectra 3(E1) and 3(F) correspond to CO_2 (21) and 3(G) is the spectrum of TMSF. Subtraction of 3(F) from 3(E1) gave 3(E2) which is the spectrum of COF_2 (20). Although it appears that CO is one of the products (*vide supra*), it was not detected during the trapping or during the low-temperature distillation. The reason for this is not obvious. To establish whether or not the α-lactone, **8** (Scheme 4) — a potential intermediate — could be detected, TMSTFA was thermolyzed at 720°C and the products were trapped over a period of 3 h. Figure 4 is the spectrum of the thermolysate before the products were trapped. The small peak at 18.1 eV establishes that only a small amount of CO_2 is produced at this temperature. Low-temperature distillation of the thermolysate yielded no additional components other than those observed at 790°C.

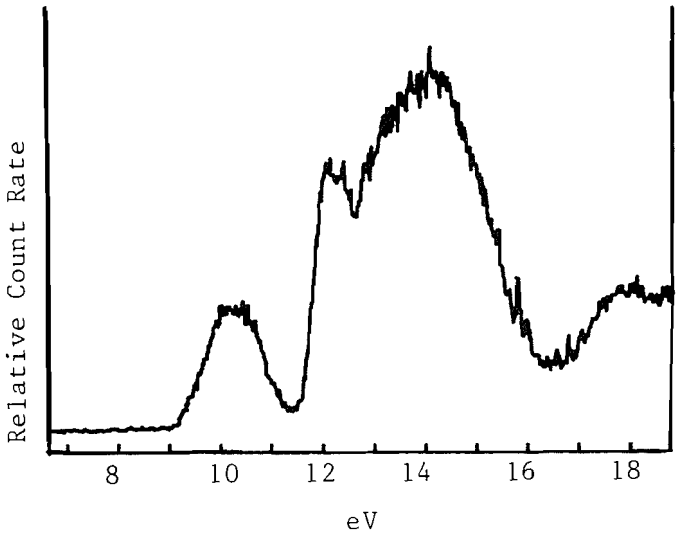

FIG. 2. Photoelection spectrum of TMSOH.

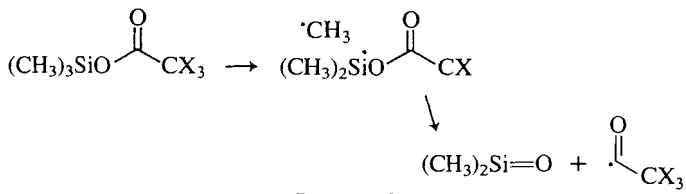
Thermolysis of TMSOAc, 3

Spectra 5(A) and 5(B) of Fig. 5 correspond to **3** and its thermolysate obtained at 800°C. It is evident from these spectra that TMSOAc decomposes only to a minor extent under the conditions employed in this study. Subtraction of 5(A) from 5(B) yielded a spectrum with a low signal-to-noise ratio (IEs 10.9, 12.1, 15.0, and 17.1) which identified acetic acid as a product (21).

Theoretical calculations

The MOEs calculated for TMSF, TMSOH, dimethylsilene **4**, and dimethylsilanone **5**, along with the experimentally obtained IEs for TMSF and TMSOH, are given in Tables 1–4. Figures 6 and 7 show selected MOCs for TMSF and TMSOH obtained using AMPAC, DENSITY and DRAW.



SCHEME 2

Discussion and conclusions

Thermolysis of TMSOTf

This study establishes clearly that the strong SiF bond (~807 kJ mol^{-1}) (6) determines the course of the thermolyses of TMSOTf and TMSTFA. Possible mechanisms for thermolysis of TMSOTf and TMSTFA are shown in Scheme 3 (pathways *a* and *b*) and Scheme 4 (pathways *a* and *b*), respectively. In the case of TMSOTf, it is significant that no SO_3 is observed in the spectrum of the thermolysate or during the low temperature distillation; SO_3 exhibits sharp bands at 12.8 and 17.9 eV indicated by the arrows in spectrum 1(B) as well as broad bands at 13.8 and 14.9 (22, 23). If TMSOTf decomposes via pathway *a* (Scheme 3), then COF_2 could be formed by singlet $:CF_2$ stripping oxygen from SO_3. The absence of SO_3 in the thermolysis mixture requires that the reaction be nearly quantitative, an unreasonable expectation based on the high reactivity and instability of $:CF_2$. That is, $:CF_2$ would also be expected to react via other channels such as dimerization, polymerization, and inser-

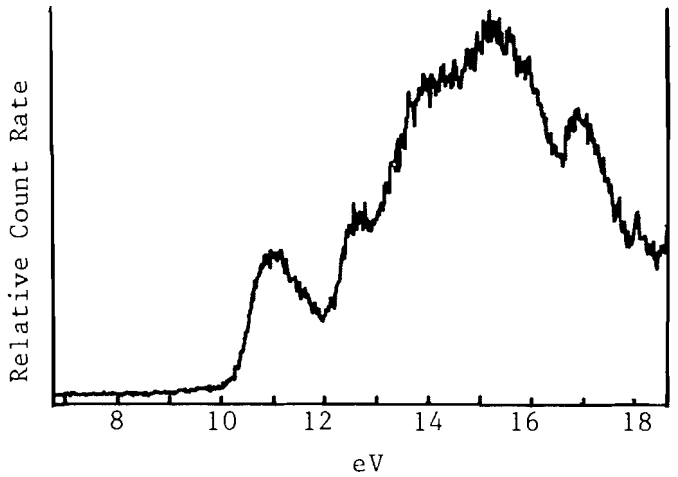

FIG. 4. Photoelectron spectrum of the thermolysate of **2** at low conversion.

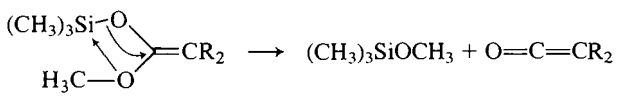
tion into SiC bonds of the starting ester. The only other route to SO_2 involves thermal extrusion of an oxygen atom from SO_3. This is possible, as indicated by studies of the high-temperature thermolyses of metal sulfates: SO_3 given off as a primary product along with the metal oxide and at 700°C, is almost completely converted to SO_2 and O_2 (24–28). However, O_2 was not detected either in the spectrum of the total thermolysate (spectrum (1B)) or during the trapping with liquid nitrogen; the lowest IE band of O_2 is a series of well-resolved vibrational components beginning at 12 eV. Furthermore, neither O_2 or SO_3 was detected even at 630°C when the thermolysate was passed through a dry-ice/acetone trap. Under these conditions, as was the case at 720°C, TMSF and SO_2 were clearly identified as the major products.

We take these observations as support for our view that TMSOTf decomposes predominantly via pathway *b* to form 3,3-difluoro-oxathiirane dioxide **7** which extrudes SO_2 to give COF_2 (Scheme 3). This is also supported by the fact that attempts to prepare oxathiirane dioxide have been unfruitful (29). Although the yield of COF_2 is substantially less than the yields of SO_2 and TMSF based on the number of scans collected for each substrate, this must be due to the instability of COF_2 at 720°C. That pathway *b* is the mechanism of decomposition of TMSOTf is further supported by the work of Ainsworth *et al.* (30). They showed by ^{18}O labelling that ketene alkyl trialkylsilyl acetals decompose thermally via a four-membered ring transition state (Scheme 5).



SCHEME 5

The formation of $CH_2{=}CF_2$ as a minor product rather than $CF_2{=}CF_2$ is unexpected; the compounds are easily distinguished by UPS. Since Bell and co-workers (31) have shown that β-trifluoroethylsilanes decompose thermally to yield $CH_2{=}CF_2$ and fluorosilane, it is conceivable that this product arises from a silane such as $R_2XSiCH_2CF_3$. While the exact

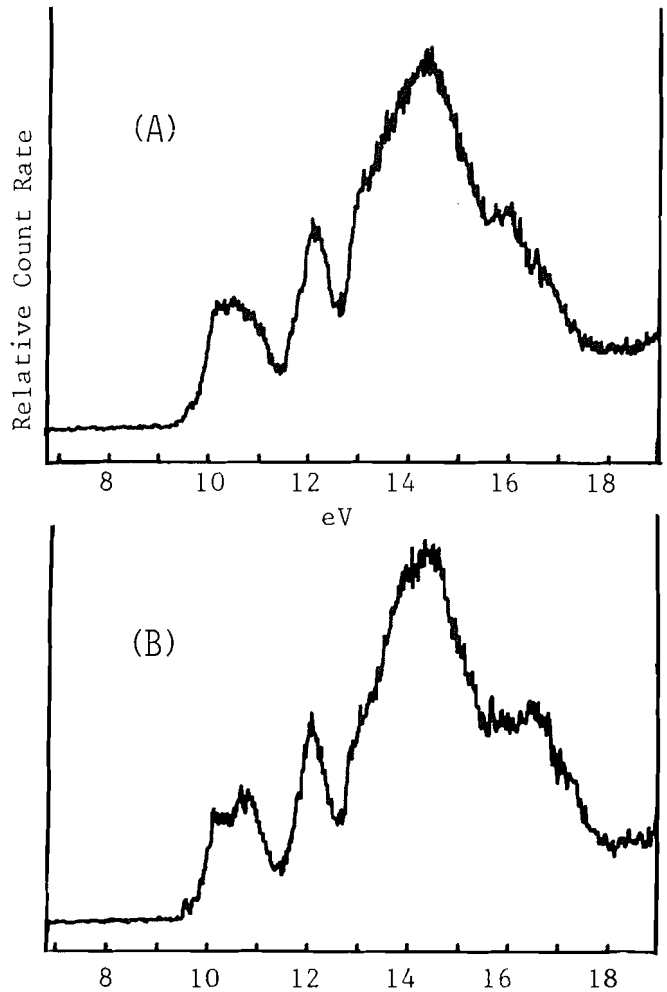

FIG. 5. 5(A), p.e. spectrum of **3**; 5(B) p.e. spectrum of the thermolysate of **3** at low conversion.

source of such a silane is unknown, the starting material is a potential source of $\cdot CF_3$ and dimethylsilene.

Our results contrast with the observations of Voronkov *et al.* on the thermolysis of bis(trimethylsilyl)sulfate ($(CH_3)_3SiO)_2SO_2$) at 200°C at room pressure (32). In that case, the major products were hexamethyldisiloxane, trimethylsilyl methanesulfonate ($(CH_3)_3SiOSO_2CH_3$), and tetramethyl-1,2-bis(mesyloxy)disiloxane ($(CH_3SO_2OSi(CH_3)_2)O$). It is clear that the absence of the driving force provided by the formation of the SiF bond results in a changeover in the mechanism of thermal decomposition of trimethylsilyl esters.

Thermolysis of TMSTFA

In keeping with the mechanism proposed for the thermolysis of TMSOTf, we propose that TMSTFA decomposes predominantly via pathway *b* (Scheme 4). The small amount of COF_2 that is observed could be formed via the reaction of $:CF_2$ with CO_2 or by extrusion of CO from α-lactone, **8**. However, unlike TMSOTf (*vide supra*), the decomposition of TMSTFA yields $CF_2{=}CF_2$, presumably by the dimerization of $:CF_2$. To determine whether or not TMSTFA decomposes via pathway *b*, an attempt was made to detect α-lactone, **8**, by thermolyzing TMSTFA at 720°C, a temperature at which only a small amount of CO_2 is formed (Fig. 4). However, no products other than those observed at 790°C were detected upon low temperature distillation of the thermolysate. If the lactone is a primary product of thermolysis, it decomposes at 720°C — not an unreasonable expectation considering that α-lactones are highly strained.

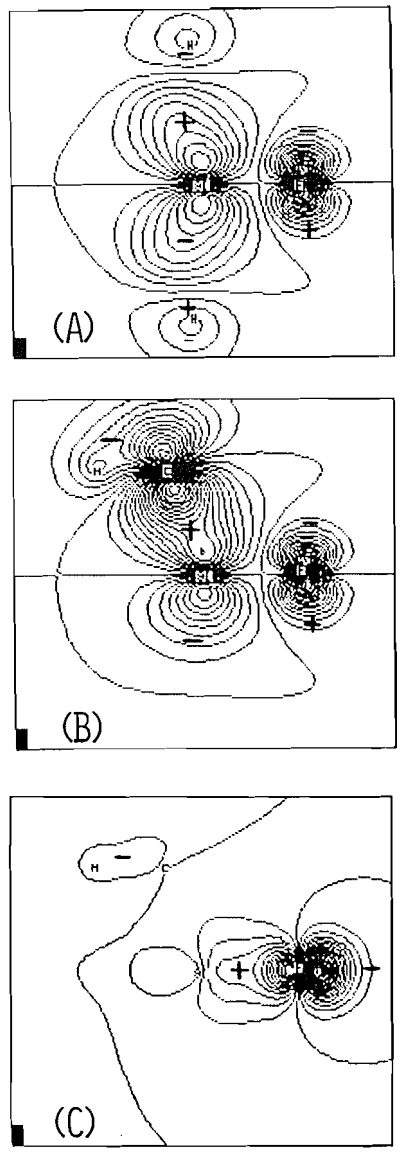

FIG. 6. Molecular orbital contours (MOCs); 6(A), MO 16 of TMSF in the *xz* plane, contour interval 0.05; 6(B), MO 15 of TMSF in the *xy* plane, contour interval 0.05; 6(C), MO 5 of TMSF in the *xy* plane, contour interval 0.125.

Thermolysis of TMSOAc

While TMSOTf and TMSTFA decompose completely at temperatures below at 790°C, TMSOAc undergoes only partial decomposition at 800°C yielding acetic acid as the only detectable product. Although the formation of acetic acid requires dimethylsilene, **4**, as a coproduct, no peak was observed at 7.9 eV where the lowest ionization energy of dimethylsilene is expected (5). That **4** is not detected is presumably due to the low conversion and its reactivity (5). The inertness of TMSOAc, probably a consequence of the high SiO bond energy, contrasts with the reactivity of *tert*-butyl acetate that decomposes readily to 2-methylpropene and acetic acid at 300°C at higher pressures (2).

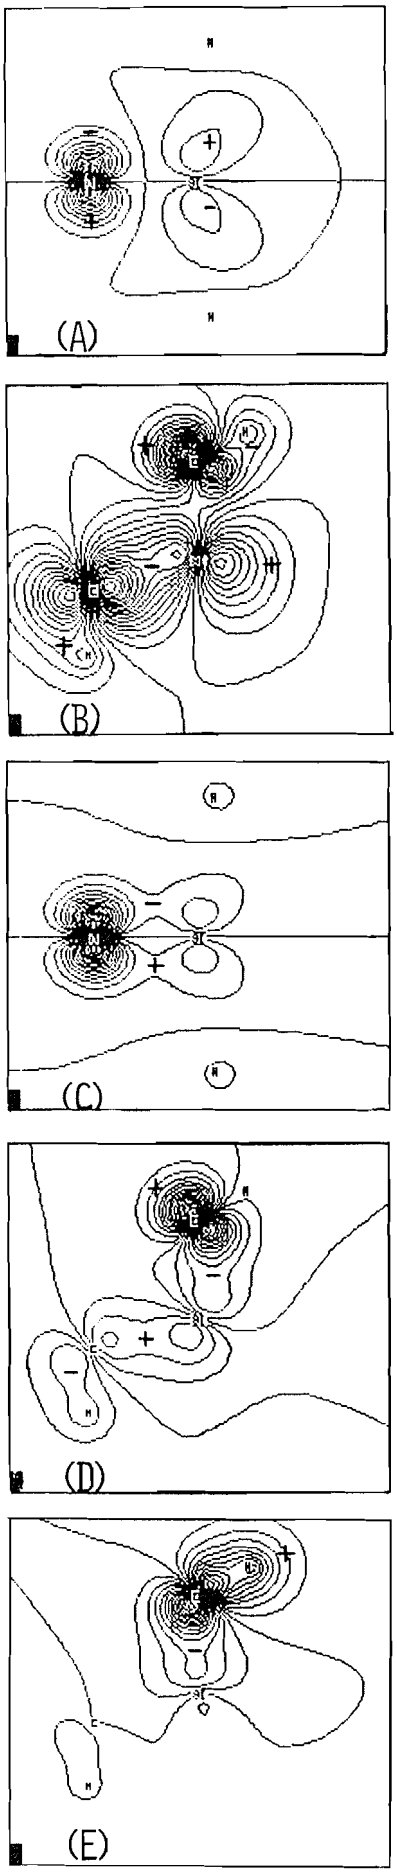

FIG. 7. MOCs; 7(A), MO 16 of TMSOH in the *xz* plane, contour interval 0.125; 7(B), MO 15 of TMSOH in the *xy* plane, contour interval 0.05; 7(C), MO 14 of TMSOH in the *xz* plane, contour interval 0.125; 7(D), MO 13 TMSOH in the *xy* plane, contour interval 0.125; 7(E), MO 5 of TMSOH in the *xy* plane, contour interval 0.125.

TMSF, the experimentally obtained geometry (13) was used. In the case of TMSOH, the MNDO optimized geometry given in Fig. 8 was used because an experimentally determined geometry was not available. As shown in Table 1, the correlation between the experimentally obtained IEs of TMSF and MOEs obtained by AMPAC and GAUSSIAN 82 is good, and, in fact, the MOEs were used to identify TMSF (*vide supra*) as a major product of thermolysis. The molecular orbital contours (MOCs) of MO 16 (HOMO) and MO 15 of TMSF which are degenerate and which are characterized by the broad peak at 11 eV of spectrum 1(F), are shown in Fig. 6 and 6(A) and 6(B), respectively. Both MOs have $\sigma_{SiC}n_F$ character. As shown by the MOC plot in Fig. 6(C), MO 5, characterized by the peak at 17.8 eV, has n_F character.

The MOEs of TMSOH, **9** obtained by AMPAC are given in Table 2. Again, as in the case of TMSF, the correlation between the MOEs and the IEs is good. The MOCs of MO 16 (HOMO) and MO 15 of TMSOH, characterized by the unsymmetrical broad band centered at 10.5 eV of spectrum 2, are shown in Fig. 7 as 7(A) and 7(B), respectively. The HOMO has n_O character while MO 15 is predominately σ_{SiC} in character. MOs 14 and 13, which are degenerate according to AMPAC (Table 2) and which are characterized by the peak at 12.2 eV in spectrum 2, are shown as in 7(C) and 7(D), respectively. MO 5 characterized by the peak at 17.7 eV has σ_{OH} character as shown by the MOC plot given in 7(E).

*Dimethylsilene, **4***

The MOEs of dimethylsilene calculated using AMPAC and GAUSSIAN 82 (6-31G*) from the geometry calculated at the DZ + d SCF level (14) are given in Table 3. Only the lowest IE (7.9 eV) of dimethylsilene has been observed because the photoelectron spectrum was recorded for a mixture obtained by thermolysis (5). At first glance, the MOE of the HOMO of **4** obtained at the 6-31G* level appears to correlate reasonably well with the experimental value (7.98 eV) of the lowest IE (5). However, when 92% of Koopman's theorem is taken, which usually yields better correlations (33), the MOE (7.26 eV) is considerably lower than the experimental value. Furthermore, the MOEs calculated by AMPAC are usually high by approximately 0.5 eV at low IEs, thereby placing the lowest MOE at approximately 7.5 eV, again considerably lower than the experimental value. The reason for the difference between the experimental and calculated values is not evident. The AMPAC calculation also provided support for the view of Schaefer and co-workers (14) that the geometry of dimethylsilene obtained by electron diffraction (34) is in error. The MOE of the HOMO obtained using this geometry is 7.58 eV, substantially lower than the experimental value. Taking into account the overestimation by AMPAC of MOEs at low binding energies (0.5 eV), the predicted value should be at approximately 7.1 eV, thereby establishing that the geometry obtained by electron diffraction, at least as far as the length of the SiC double bond is concerned, is in error.

Dimethylsilanone

The MOEs of dimethylsilanone calculated using AMPAC and GAUSSIAN 82 (6-31G*) are given in Table 4. For the

semi-empirical calculations, the geometry generated by CHEMGRAF was optimized using MNDO (AMPAC) and is given in Fig. 8. For the *ab initio* calculations the STO-3G optimized geometry was used. As in the case of acetone, MO 12 (HOMO) has n_O character and MO 11 is π_{SiO}. However, the separation is considerably less (0.9 eV, AMPAC; 0.4 eV, 6-31G*) than the separation in acetone. This is largely due to a shift of the π_{SiO} MO to higher energy.

Conclusions

Thermolysis studies show that, where possible, formation of a strong SiF bond provides a driving force for thermal decomposition of trimethylsilyl esters. We plan to exploit this to synthesize highly reactive silicon containing species in the gas phase and in solution.

The effect of the water–cation interaction on the polarisability and second hyperpolarisability of hydrated Li^+. A comparative study

J. WAITE AND M. G. PAPADOPOULOS

National Hellenic Research Foundation, 48, Vas. Constantinou Avenue, GR-116 35 Athens, Greece

Received September 18, 1987

J. WAITE and M. G. PAPADOPOULOS. Can. J. Chem. **66**, 1440 (1988).

The CHF-PT-EB-CNDO method has been used to compute the polarisability and second hyperpolarisability of the hydrated lithium cation with one and two hydration shells. The effect of the $Li^+ \ldots (H_2O)_n$ interaction on these properties is discussed and the main findings are confirmed in hydrated Na^+, Be^{2+}, and Al^{3+}.

J. WAITE et M. G. PAPADOPOULOS. Can. J. Chem. **66**, 1440 (1988).

On a utilisé la méthode CHF-PT-EB-CNDO pour calculer la polarisabilité et la seconde hyperpolarisabilité du cation du lithium hydraté avec une ainsi qu'avec deux couches d'hydratation. On discute de l'effet de l'interaction $Li^+ \ldots (H_2O)_n$ sur ces propriétés et on confirme les principales conclusions avec les ions Na^+, Be^{2+} et Al^{3+} hydratés.

[Traduit par la revue]

I. Introduction

The nature of short-range (5 Å or less) interactions between water and ions has been a matter of long-standing chemical interest (1, 2). One important problem which has attracted the attention of theorists is the change induced in the structure and properties of water and ion due to their interaction (3–5). The objective of this article is to report and analyse the effect of the water–cation interaction on the static electric polarisability (6), α, and hyperpolarisability (6), γ, of some hydrated cations.[1] These properties have been chosen because, first, they depend to a great extent on the outer regions of the charge cloud (e.g. the valence electrons generally account for at least 90% of the polarisability of an atom or molecule (7)), which are mainly affected by the intermolecular interaction and second, the change in the hyperpolarisability resulting from the above interaction has not been reported before.

This study has been performed by employing hydrated Li^+ with one and two hydration shells as a test model. Calculations of the properties (α and γ) of other hydrated cations (Na^+, Be^{2+}, Al^{3+}) have also been performed in order to check the validity of the findings in $Li^+(H_2O)_4$. The first hydration shell is formed from four water molecules tetrahedrally placed (8–10). The properties of this and $Li^+(H_2O)_{12}$, which contains the second hydration shell (11), have been calculated and the effect of the outer water sheath on the interaction hyperpolarisability has been demonstrated. In addition the interaction property values for various configurations of $Li^+(H_2O)_n$, where $n = 2$ and 4 are compared.

There have been several studies analysing other interesting aspects of the water–cation interactions (3, 4, 12, 13). For example, the charge transfer from the water cluster to the cation and the polarization of the electronic charge distribution of $(H_2O)_n$ by the positively charged atom (4). The present findings contribute to the formation of a more comprehensive view concerning the water–cation interaction.

[1]The average polarisability α and second hyperpolarisability γ are given by (6*a*):

$$\alpha = \tfrac{1}{3}(\alpha_{xx} + \alpha_{yy} + \alpha_{zz})$$

$$\gamma = \tfrac{1}{5}(\gamma_{xxxx} + \gamma_{yyyy} + \gamma_{zzzz} + 2\gamma_{xxyy} + 2\gamma_{xxzz} + 2\gamma_{yyzz})$$

where x, y, and z define Cartesian components. Expressions for the relevant tensor components, in terms of which α and γ are defined are given in ref. 6*b* and *c*.

The computations have been performed using the CHF-PT-EB-CNDO method (14–18). The basis set was optimized to the experimental α and γ values of H_2O (19) in order to reasonably reproduce the charge distribution of water and in particular its outer regions which are of importance for the proposed study.

II. Computational method

The computations have been performed using the CHF-PT-EB-CNDO method, which has been shown to give polarisability and hyperpolarisability results in satisfactory agreement with experimental values (14–16, 18a, 20).

The CHF-PT-EB-CNDO method relies on: (*a*) An extended basis CNDO/2 wave function (EB-CNDO) (21); (*b*) The coupled Hartree–Fock perturbation theory (CHF-PT) of McWeeny and co-workers (6*b*, *c*); (*c*) The optimisation of the basis set with respect to the hyperolarisability (and/or polarisability) of some judiciously chosen model compound(s). This basis set is subsequently used for the computation of the polarisability and the hyperpolarisability of compounds with similar structure.

The CHF-PT-EB-CNDO method, through the optimisation of the basis set, with respect to some experimental values, allows (at least to some extent) for the effect of electron correlation.

It is considered that CHF-PT-EB-CNDO provides the proper apparatus for the first approach to the considered problem since: (*a*) It is known that an accurate description of intermolecular interactions depends mainly on the outer regions of the molecules. However, ample evidence has been provided, for a wide variety of compounds, that these parts are satisfactorily described by CHF-PT-EB-CNDO (14–16, 18*a*, 20). (*b*) An essential part of our method is the optimisation of the basis set, in some model compound(s), so that the computed properties (α and γ) approach as closely as possible the experimental values. This optimisation procedure helps to ensure the physically correct description of the polarised charge cloud, at least of the isolated molecule (14–16, 18*a*, 20); (*c*) The analysis of the results utilises ratios and differences of property values and thus the effect of any systematic errors in their absolute values is reduced.

It is noted that the deficiency of standard CNDO/2 (21) to give accurate absolute values for properties like equilibrium geometries (22, 23) is not relevant to our objective as we are interested in differences in property (α, γ) values and ratios. Furthermore, while our method uses the CNDO (21) approx-

For personal use only.

imations it also employs the above stated optimisation principle, making a reasonably accurate determination of non-linearities possible.

Within the set of options and approximations which define the CHF-PT-EB-CNDO method, we have performed a considerable amount of computational experimentation employing the water molecule as a test model. Basis sets involving up to *d* orbitals for H and up to *f* for O have been used, a small but representative set of which is given in Table 1.

Detailed analysis on an extensive set of data, referring to several molecules, has shown that high l AOs like *d* and *f* orbitals are sufficient (they can lead to reasonable results) but not necessary within a semiempirical framework, in particular if one takes advantage of the flexibility and freedom allowed within such schemes (14–16, 18*a*, 20*b*). Analysis of the computations on H_2O has led to the following, optimised basis:

H: 1*s*(0.8), 2*s*(0.38), 2*p*(0.475)

O: 2*s*(1.975), 2*p*(1.975)

For the considered cations (Li^+, Na^+, Be^{2+}, and Al^{3+}) we have used Burns' exponents (24), which have been shown to give, in general, reasonable results for α and γ (16, 18*a*, 20*a*).

The geometric models (coordinates) were built by employing data from the literature (mainly from refs. 1 and 11). Detailed information is given in the footnotes of Table 2 and Figs. 1–4. The coordinates of all the studied hydrated ions are available on request.

The same geometric elements (bond lengths and angles) have been used for all the hydrated cations. This choice facilitates the comparison of trends found in hydrated Li^+ with those determined using the other hydrated cations (Na^+, Be^{2+}, and Al^{3+}).

The convergence criteria for the iterative computation of $R^{(0)}$, $R^{(1)}$, and $R^{(2)}$ (where these are the zeroth order density matrix and its first and second order corrections respectively) are given in refs. 17 and 18*a*.

III. Results and discussion

We have defined the index:

$$[1] \quad p'_{int} = \frac{p[M^{v+}(H_2O)_n] - p[(H_2O)_n]}{p[M^{v+}(H_2O)_n]} \times 100$$

where p'_{int} is either α'_{int} or γ'_{int} and *v* is 1, 2, or 3. This index gives the property arising from the interaction of the cation, M^{v+}, with the water cluster, $(H_2O)_n$, as percent of the property of $M^{v+}[(H_2O)_n]$. The above index helps to systematically analyse the interaction properties of the considered hydrated cations.

TABLE 2. The interaction polarisability, α'_{int}, and hyperpolarisability, γ'_{int}, of hydrated Li^+, Na^+, Be^{2+}, and Al^{3+}

Hydrated cation	Configuration			
	Linear		Tetrahedral or cluster	
	α'_{int}	γ'_{int}	α'_{int}	γ'_{int}
$Li^+(H_2O)_4$[a,c]	−1.72	7.42	−8.13	−11.0
$Na^+(H_2O)_4$[c]	−1.14	9.01	−5.33	−5.52
$Be^{2+}(H_2O)_4$[c]	−1.96	80.7	−19.2	−43.3
$Al^{3+}(H_2O)_4$[c]	—	—	−18.8	−52.2
$Li^+(H_2O)_{12}$[d]	—	—	−4.0	−5.64

[a]Tetrahedral configuration of $Li^+(H_2O)_4$ (Fig. 3) (8–10). The Li^+ is placed at the center of the tetrahedron. The Li^+ ... O line bisects the ∠HOH, with the hydrogens away from the Li^+. The planes of the water molecules are such that the hydrogen atoms are maximally separated. The O...O distance is 5. a.u. (1) and Li^+ ... O distance is 4 a.u.
[b]Linear configuration of $Li^+(H_2O)_4$ (**6** in Fig. 2). The Li^+, the first H_2O (that is the water which is nearest to the Li^+), and the third H_2O lie on the same plane. The second and the last H_2O (the one furthest from Li^+) lie on the plane which is perpendicular to the previous plane.
[c]The geometries of the hydrated Na^+, Be^{2+}, and Al^{3+} are the same as that used for $Li^+(H_2O)_4$, Fig. 3.
[d]The $Li^+(H_2O)_{12}$ cluster (Fig. 4) is built from the tetrahedral $Li^+(H_2O)_4$ by associating one water molecule with each hydrogen. The added water is in a plane perpendicular to that of the water to which it is bonded and the peripheral water's ∠HOH is bisected by the extension of H—O bond of the inner water.

The results of Table 2 show that the contribution of the property (polarisability or hyperpolarisability) which is due to the interaction between Li^+ or Na^+ and $(H_2O)_n$ to the property of $M^+(H_2O)_n$ is small.

Practically it seems that the properties of the hydrated monovalent cations Li^+ or Na^+ can be approximated by the properties of the hydration shell itself. It is also observed (Table 2) that the interaction properties which are due to interaction of Be^{2+} or Al^{3+} with $(H_2O)_4$, contribute to the property (α, γ) of $M^{v+}(H_2O)_4$, considerably more than the interaction properties associated with Li^+ or Na^+.

It is emphasized that the interaction hyperpolarisabilities are much greater than the property of the cation itself. For example, it has been found that:

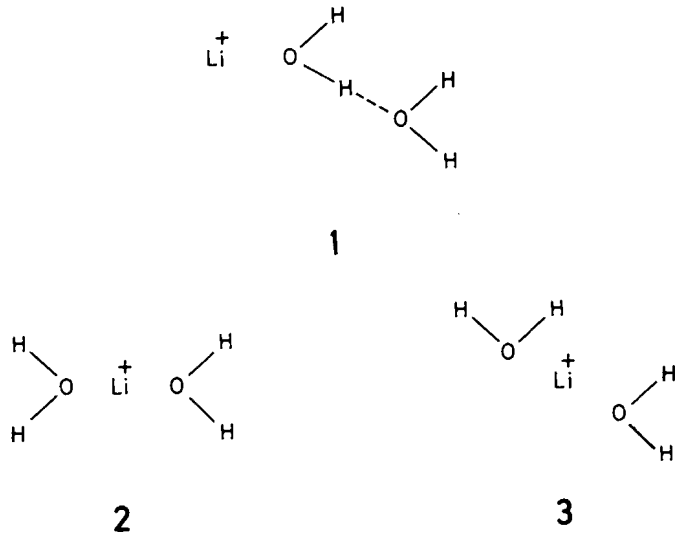

FIG. 1. Structure of three different configurations of $Li^+(H_2O)_2$. In **1** the outer water is perpendicular to the plane of Li^+ and the inner water molecule. The configuration **2** is planar. In **3** the two water molecules have the arrangement defined in the tetrahedral cluster (Table 2, footnote *a* and Fig. 3).

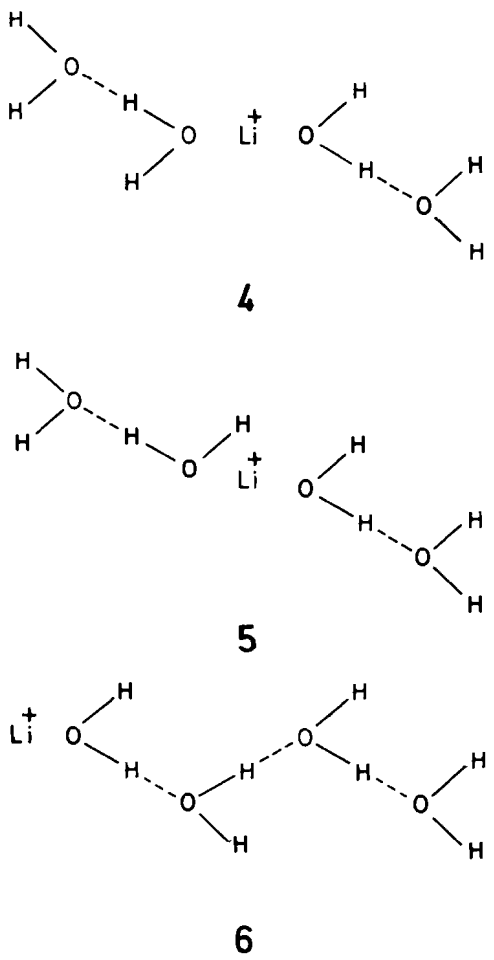

FIG. 2. Three configurations of $Li^+(H_2O)_4$. In **4**, Li^+ and the two adjacent water molecules are planar (as in **3** of Fig. 1). The planes of the two outer water molecules are perpendicular to this plane. In **5** the four water molecules and Li^+ have the geometry which corresponds to a segment of $Li^+(H_2O)_{12}$. In **6** the linear configuration of $Li^+(H_2O)_4$ is presented (geometric details are given in Table 2, footnote *b*).

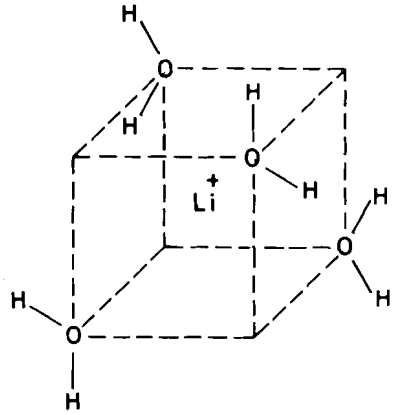

FIG. 3. Tetrahedral configuration of $Li^+(H_2O)_4$. Geometric details are given in Table 2, footnote *a*.

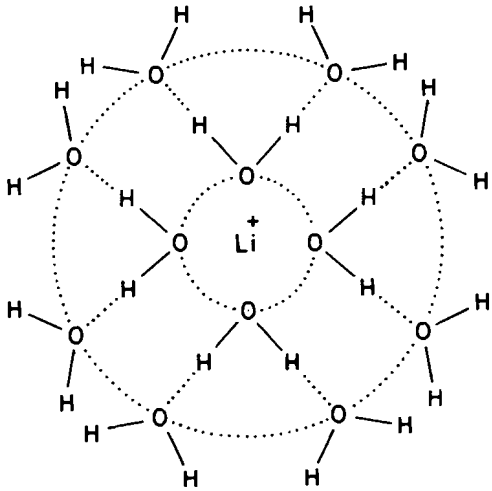

FIG. 4. Structure of $Li^+(H_2O)_{12}$ (11).

[2] $\gamma[Li^+(H_2O)_4]_{tet} - \gamma[(H_2O)_4]_{tet} = -1800$ a.u.

[3] $\gamma[Li^+(H_2O)_4]_{lin} - \gamma[(H_2O)_4]_{lin} = 1700$ a.u.

[4] $\gamma[Li^+(H_2O)_{12}] - \gamma[(H_2O)_{12}] = -5500$ a.u.

while γ of Li^+ is 0.24 a.u. (25*a*).

Thus the effect of environmental interactions on the nonlinear electric properties of hydrated cations is expected to be of fundamental importance for their understanding. The magnitude of the interaction polarisability is also large in comparison to that of the isolated cation. For example we have:

[5] $\alpha[Li^+(H_2O)_{12}] - \alpha[(H_2O)_{12}] = -11$ a.u.

while the polarisability of Li^+ is approximately 0.19 a.u. (25).

The results of Tables 2 and 3 show:

[6] $\alpha[M^{\nu}(H_2O)_4]_{lin} > \alpha[M^{\nu+}(H_2O)_4]_{tet}$

[7] $\alpha[(H_2O)_4] > \alpha[M^{\nu+}(H_2O)_4]$

[8] $\gamma[M^{\nu+}(H_2O)_4]_{lin} > \gamma[M^{\nu+}(H_2O)_4]_{tet}$

[9] $\gamma[M^{\nu+}(H_2O)_4]_{lin} > \gamma[(H_2O)_4]_{lin}$

[10] $\gamma[(H_2O)_4]_{tet} > \gamma[M^{\nu+}(H_2O)_4]_{tet}$

The results of Table 3 show the remarkable variation of α and γ of $M^{\nu+}(H_2O)_4$, where $M^{\nu+} = Li^+$, Na^+, or Be^{2+}, is depen-

	Fig. 2, **6**	−1.72	7.42
	Fig. 3	−8.13	−11.0

dent on the shape of the configuration. Furthermore, the results of Table 4 show that changes in the configuration of the hydrated cation may induce a considerable change in the contribution of the interaction properties to α or γ of the hydrated species.

It has been found that for the linear configuration the polarisability of $Li^+(H_2O)_4$ is less than that of $(H_2O)_4$ while the reverse is true for the hyperpolarisability (Table 2). The above trends are also shown in the results of the hydrated Na^+ and Be^{2+} (Table 2, linear configuration). The hyperpolarisability results are remarkable, since the formal addition of positive charge usually decreases the property values due to the contraction of the charge cloud (26). Presumably the polarisation of the waters' valence electrons overrides this effect for the hyperpolarisability.

It has been found that:

$$[11] \quad \frac{\gamma[(H_2O)_{12}]}{3 \times \gamma[(H_2O)_4]_{tet}} \simeq 2$$

This result demonstrates the important effect of the water–water interaction on the hyperpolarisability of the H-bonded cluster. It is added that the considerable effect of the environmental interactions, in strongly associating liquids, on the electric non-linearities has been experimentally demonstrated (27).

The intermolecular interactions in water clusters constitute a cooperative process (that is each interaction enhances the next one) (28). Apparently the addition of each water molecule acts to further polarise the electron distribution within the cluster (29). This cooperative effect has also been observed for hydrogen bond energies, dipole moments (29), and polarisabilities (28).

Clementi *et al.* found that for $Li^+(H_2O)_2$ the non-additivity correction to the total interaction energy is satisfactorily approximated by the induction energy (30). This approximation is completed by a short-range exponential repulsive term. The above model has also been successfully applied to larger hydration numbers (30). The long-range induction energy has been used to explain the main contribution to the non-additive part of the interaction energy in $(H_2O)_3$ (31).

IV. Conclusions

The effect of the water–Li^+ interaction on the polarisability and hyperpolarisability of the hydrated ion has been studied by employing various clusters, simulating the first and second hydration shells. For the computation of the properties (α and γ) the CHF-PT-EB-CNDO method has been used, which has been shown to give satisfactory results for the polarisability and hyperpolarisability of a large number of molecules belonging to several families (alkanes (14), polyenes (15), amides (28) etc.). Considering that the computation of accurate molecular hyperpolarisabilities is a very difficult task (elaborate *ab initio* treatments have only been used for atoms, diatomics, and triatomics), we have taken many precautions to safeguard the validity of the findings which are mainly trends and phenomena.

The computational work has been performed mainly on hydrated Li^+, but for confirmation (within the employed methodology) and generalisation of the observations, the properties of hydrated Na^+, Be^{2+}, and Al^{3+} have also been calculated.

In summary it is noted: (*a*) The first direct computational evidence has been presented for the magnitude of the effect which is due to the interaction $M^{v+} \ldots (H_2O)_n$, on the polarisability and hyperpolarisability of hydrated M^{v+}. It has been demonstrated in the case of $Li^+(H_2O)_n$ that the interaction property (α, γ) is much greater than the property of the cation itself in isolation. (*b*) Changes in the configuration of the hydrated cation may induce a remarkable variation in the interaction hyperpolarisability. We found that for the linear configuration the unexpected trend: $\gamma[M^{v+}(H_2O)_4] > \gamma[(H_2O)_4]$. (*c*) Comparing the changes induced in the electric properties due to the water–cation interaction, the greater sensitivity of the hyperpolarisability becomes clear. Thus one may define indices in terms of the hyperpolarisabilities (like γ'_{int} that has been employed in the present work) which may serve as powerful probes of solute-solvent interactions. (*d*) The cooperative character of the water–water interactions on the hyperpolarisability has been demonstrated.

The present results illustrate the importance of the solute–solvent interaction in the study of hyperpolarisabilities of positively charged species in solution and complement previous studies where the interacting systems were neutral (18*c*, 23). The reported findings are expected to be of importance in the rationalization of trends and phenomena in terms of polarisation theory.

Equilibrium and kinetic studies of a chemical model of active transport: Membrane transport of potassium salts by cryptand carriers driven by potassium ion complexation

THOMAS M. FYLES AND STEVEN P. HANSEN
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received October 6, 1987

THOMAS M. FYLES and STEVEN P. HANSEN. Can. J. Chem. **66**, 1445 (1988).

A theoretical framework of energy transduction in membranes was used as a point of departure for the design of a simple chemical model of primary active transport (reaction pumping). In the model, cryptand carriers transport potassium salts across a bulk liquid membrane, driven by the complexation of potassium by a dicarboxylate crown ether in one aqueous phase. Both the equilibrium position and kinetic behavior of the model system could be predicted from the theoretical framework. Experimental verification of the predictions confirms the fitness of the theoretical framework and provides a design tool for the formulation of new membrane transport systems.

THOMAS M. FYLES et STEVEN P. HANSEN. Can. J. Chem. **66**, 1445 (1988).

On a utilisé un cadre de référence théorique de l'énergie de transduction dans les membranes comme point de départ pour élaborer un modèle chimique simple du transport actif primaire (réaction de pompage). Dans ce modèle, le transport des sels de potassium à travers une membrane liquide globale est effectué par un cryptand qui y est entraîné par la complexation du potassium, à partir d'une phase aqueuse, par un éther couronne portant deux groupements carboxylates. On peut prédire la position de l'équilibre ainsi que le comportement cinétique du système modèle à partir du cadre de référence théorique. Une vérification expérimentale des prédictions permet de confirmer l'utilité du cadre théorique et fournit un outil pour élaborer la formulation de nouveaux systèmes de transport membranaire.

1. Introduction

Energy transduction achieved by the coupling of chemical reactions to membrane transport processes is a central concept in membrane bioenergetics (1, 2). The most prominent example is the "chemiosmotic" hypothesis of Mitchell (3), first applied to oxidative phosphorylation. The concept now includes all aspects of (primary) active transport, group translocation, and light driven processes (4, 5). Although the concept is simple, the molecular details of natural active transport systems are exquisitely complex (4, 5).[1] Molecular and mechanistic complexity, joined with the formidable mathematics of some theoretical treatments (4), provide little guidance for the elaboration of abiotic applications or, indeed, for biomimetic model studies.

In contrast, Goddard (7) has recently proposed a unified model that describes both the equilibrium and the kinetic behavior of transporter mediated energy transduction systems. The model is conceptually simple and provides the general case, applicable in specific cases to both natural (6) and abiotic (8) membrane transport systems. More importantly, the conceptual framework and derived kinetic and thermodynamic relationships can be used predictively in the design or evaluation of new membrane transport systems. The general case can be succinctly stated in a form that reveals the requirements for each chemical entity in the system, readily leading to the assignment of explicit chemical identities for each component of the new transport system. Our first venture in using this framework as a design tool for the elaboration of new transport systems is centered on a system exhibiting primary active transport. Our goals are to illustrate how the approach can work in a simple case and to examine the interplay between theory and experiment. It is important neither to be seduced by the simplicity of the theory, nor repelled by the complexities of the flux equations. A reasoned examination of simple predictions of the theory will serve to balance the two tendencies and will serve to buttress future development of more complex systems.

1.1 Conceptual model

The basic schematic mechanisms for secondary active transport (gradient pumping), for primary active transport (reaction pumping), and for reaction coupling are given in Fig. 1. These follow directly from Goddard (7). The carrier (or in general, the transporter) is confined to the membrane and serves as the sole means of transport of the species A and B either together (symport) or in opposite directions (antiport). Numerous examples of abiotic secondary active transport (gradient pumping) are known, especially those involving crown ether and cryptand carriers (8–10). The most common examples involve cation–anion symport mediated by lipophilic cation complexing agents (10) and cation–proton antiport mediated by ionizable cation complexing agents (9). Examination of Fig. 1 reveals the strong similarities between the three cases. Indeed the sole difference between gradient pumping and reaction pumping is that the species A is intercepted by some C in the right aqueous phase. For any A and C, a formal equilibrium with AC can be written, which embodies the free energy of the AC "bond". It is this reaction free energy that energizes the active transport. At the same time, however, the formation of AC is seen to be a device for controlling the free A concentation at some (low) level in the right aqueous phase. From the equilibrium viewpoint, reaction pumping is thus just a special case of gradient pumping (or vice versa) and the two systems can in principle be interconverted by addition, or deletion, of a suitable reactant C.

All three systems of Fig. 1 can be represented by a single generalized cycle involving composite solution species S and P on the left, S′ and P′ on the right, and the transporter Q(Q′) in the membrane. The flux across the membrane (J) is related to the solution concentrations, interfacial reaction rates, and transporter translocation rates by eq. [1] (7):[2]

$$[1] \quad \hat{C}(K - K') = \{2\hat{R} + (1/k + \hat{R})(K + K') + 2KK'/k + (R - R')(K - K')\}J$$

[1]The entire volume (ref. 6) is devoted to the sodium–potassium pump.

[2]Equation [1] is somewhat different from equation 3.17 of ref. 7; this version is correct (J. D. Goddard, personal communication).

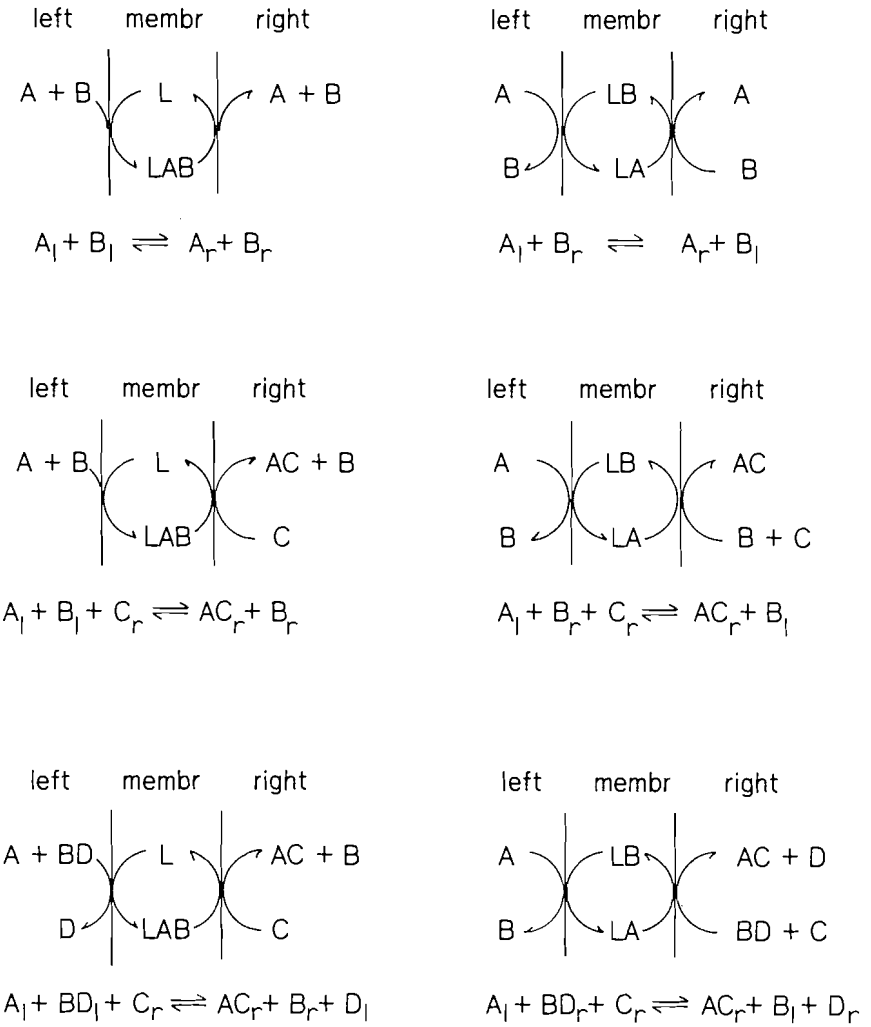

FIG. 1. Schematic mechanisms of gradient pumping (top), reaction pumping (middle), and reaction coupling (bottom). L is a membrane bound carrier that facilitates the transport of solutes A and B through the membrane. The symport case is on the left, the antiport is on the right. The equilibria denote the overall equilibrium condition of the transport.

where $\hat{C}$ is the total transporter concentration at any point in the membrane, $1/k$ (and $1/k'$) are the transport resistances for transporter translocation, R and R' are the equivalent resistances of the interfacial reactions away from equilibrium (thus $\hat{R} = R + R' + 1/k'$), and K and K' describe the equilibria at the left and right interfaces in terms of extraction constants and the solution concentrations (7).

Equation [1] is a completely general form, which should apply to the full range of natural and abiotic transport systems. It allows for, but does not compel, membrane asymmetry (1, 2) ($K \neq K'$, $R \neq R'$, $k \neq k'$). It allows for transport limited by reaction rate (R, R'), by diffusion or translocation (k, k'), or by a combination of the two rate limiting processes. It does not, however, allow for "leaky" transport. The membrane is impermeable to the species S, P in the absence of transporter, hence the coupling is predicted to be perfectly efficient with strict reversibility preserved. For the development of new abiotic transport systems, it serves as a fundamental point of departure.

2. Chemical model of active transport

We wish to examine a simple, reversible reaction pumping case at and near equilibrium. This will permit an assessment of both the overall equilibrium position as well as the kinetic predictions of eq. [1]. For experimental convenience, concentrations near 10^{-3} M are required for all species. This implies that the association constant of AC should be $\log K = 4$–6. If a weaker association were chosen then the unbound A would be significant. A stronger association drives the transport cycle strongly in one sense, requiring large opposing gradients to achieve equilibrium. In this context we note that the free energy of hydrolysis of ATP (AC) to ADP and inorganic phosphate (A + C) provides approximately 30 kJ of energy as the driving force for transport under physiological conditions (11). This corresponds to an association constant of $\log K = 5.3$. In general, a tenfold concentration gradient of an ionic solute correponds to a membrane potential of 59.2 mV (at 298 K) or to a free energy requirement of 5.7 kJ to create the gradient. The energy demands of active transport are modest, and easily accessible with common reagents.

Drawing on the close analogy between the sections of Fig. 1 and the large body of available work on artificial symport and antiport gradient pumping (9, 10), we chose to examine the symport transport system sketched in Fig. 2. Initially crown ether carriers were envisaged. However, the kinetic analysis (below) suggested that the values of the extraction constants

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

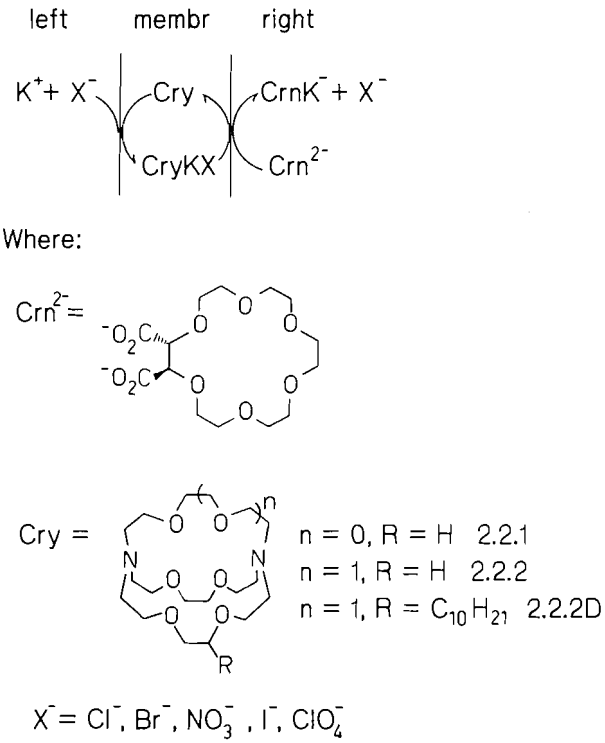

FIG. 2. Schematic mechanism of the chemical model of reaction pumping.

required would be higher than normally accessible with crown ethers and simple potassium salts (12). Consequently, cryptand carriers, with their greater extraction constants, were utilized. Commercially available carriers and a range of common potassium salts provide a distribution of values of extraction constant, controlled by the nature of the anion (12). The dicarboxylate crown ether (13) (Crn) shown in Fig. 2 was chosen as the species C; thus AC represents the potassium complex of this crown ether. The formation constant of the 1:1 complex is $\log K_{110} = 4.6$ in water at 5×10^{-3} M (14). Both aqueous phases must be buffered at a basic pH to prevent protonation of the cryptand carrier (Cry) (pK_a (2.2.2) = 9.6) (15). In such basic solutions, the complexation equilibria of Crn can be simply represented as the formation of the 1:1 complex without need to consider the ligand pK_a or the protonated complexes of the ligand (14).

The use of a polycarboxylate crown ether to control the internal potassium and sodium ion concentrations in an emulsion membrane experiment has been previously reported (40); this case and related cases will be discussed in the Conclusions.

2.1 Equilibrium position

The overall equilibrium state of the system of Fig. 2 can be represented by eq. [2],

[2] $K_l^+ + X_l^- + Crn_r^{2-} \rightleftharpoons CrnK_r^- + X_r^-$

which defines an equilibrium constant K_{eq} (eq. [3]) in terms of concentrations (strictly activities of the various species).

$$[3] \quad K_{eq} = \frac{[CrnK^-]_r[X^-]_r}{[K^+]_l[X^-]_l[Crn^{-2}]_r}$$

The complex $CrnK^-_r$ is in equilibrium with K_r^+ and Crn_r^{2-} (eq. [4]) with defined equilibrium constant K_{110}.

$$[4] \quad Crn_r^{2-} + K_r^+ \rightleftharpoons CrnK_r^- \quad K_{110} = \frac{[CrnK^-]_r}{[Crn^{2-}]_r[K^+]_r}$$

Substitution of $[CrnK^-]_r$ from eq. [4] into eq. [3] gives eq. [5].

$$[5] \quad K_{eq} = K_{110}\,\frac{[K^+]_r[X^-]_r}{[K^+]_l[X^-]_l}$$

The ratio of concentrations (activities) that appears in eq. [5] is the same as the "overall equilibrium constant" defined for the gradient pumping symport case of Fig. 1. In a simple gradient pumping system, the overall equilibrium constant is unity, by definition (7). Thus the value of K_{eq} (eq. [3]) is numerically equal to K_{110} (eq. [4]). At total concentrations of $[K^+]_{tot} = 2 \times 10^{-3}$ M and $[Crn^{2-}]_{tot} = 5 \times 10^{-3}$ M, the potassium is 99.2% complexed. Thus, to a good approximation, $[CrnK^-]_r \simeq [K^+]_{tot,r}$ and $[Crn^{2-}]_r = [Crn^{2-}]_{tot,r} - [K^+]_{tot,r}$. This provides a means to determine K_{eq} experimentally from the total measured concentrations of K^+ and X^- in each phase, according to eq. [6].

$$[6] \quad K_{eq} = \frac{[K^+]_{tot,r}[X^-]_r}{[K^+]_l[X^-]_l([Crn^{2-}]_{tot,r} - [K^-]_{tot,r})}$$

The experimental value of K_{eq} can then be compared to an independently measured value of K_{110}.

2.2 Flux behavior

For experimental simplicity we chose a U-tube bulk liquid membrane. We follow the analysis of Behr, Kirch, and Lehn (8) in defining the characteristics of the liquid membrane. We assume here, and demonstrate experimentally (see Experimental), that the transport is limited by diffusion. This means that the interfacial reactions are fast and $R = R' = 0$. For a simple diffusional process, k and k' are defined by Fick's law. We assume the membrane is symmetric, thus $k = k' = D/l$ where D is a general diffusion coefficient, equal for all species in the membrane, and l is the diffusion thickness of the unstirred boundary layers adjacent to the interfaces (8). Substitution of these constraints into eq. [1] yields eq. [7].

$$[7] \quad J\left(\frac{2l}{\hat{C}D}\right) = \frac{(K - K')}{(1 + K)(1 + K')}$$

We note that $\hat{C}$ is the total carrier concentration at every point (L_0 in ref. 8), hence the bracketed term on the left of eq. [7] is simply $1/J_{max}$, the reciprocal of the maximal flux the system can exhibit under the imposed experimental conditions (8). Equation [7] thus defines the term J/J_{max} in parallel with the analysis of Behr, Kirch, and Lehn (8).

Finally, chemical identities can be assigned to generate explicit forms for K and K'. Since membrane symmetry is assumed (8), K_{ex}, defined by eq. [8], applies at both interfaces:

[8] $K^+(aq) + X^-(aq) + Cry(org) \rightleftharpoons CryKX(org)$

$$K_{ex} = \frac{[CryKX(org)]}{[K^+(aq)][X^-(aq)][Cry(org)]}$$

and eq. [7] becomes eq. [9].

$$[9] \quad \frac{J}{J_{max}} = \frac{K_{ex}(F - G)}{(1 + K_{ex}F)(1 + K_{ex}G)}$$

where

$$[10] \quad F = [K^+]_l[X^-]_l$$

$$[11] \quad G = \frac{[CrnK^-]_r[X^-]_r}{K_{110}[Crn^{2-}]_r}$$

Equation [9] is a close relative of the equations independently

developed (8) for the symport and antiport cases of gradient pumping. Using K and K' as defined for gradient pumping, eq. [7] also yields eqs. (8) and (9) of ref. 8 for the symport and antiport respectively.

As previously derived (8, 12), eq. [9] is a quadratic in K_{ex} and may be solved as follows: 1. For a given fraction of transport (f), the total concentrations in both aqueous phases may be derived from the initial concentrations. Using these concentrations in the right compartment, the values for stability and acidity constants of Crn, the pH, and the mass balance equations, the equilibrium concentrations $[Crn^{2-}]_r$ and $[CrnK^-]_r$ can be calculated (16). 2. The terms F and G (eqs. [10] and [11]) are thus defined and the two roots (K_{ex}) of eq. [9] can be solved for a cycle of values of J/J_{max} (8, 12). 3. Finally, the results are plotted as a bell-shaped curve of J/J_{max} as a function of log K_{ex}. This procedure permits a computational survey of the flux behavior of the system expected for various initial conditions, values of K_{110}, or extents of transport.

The normalized flux, J/J_{max}, is a bell-shaped function of log K_{ex}. At low values of the extraction constant, the extraction of KX into the organic phase is poor and the flux is low. As K_{ex} increases, the flux increases up to a maximum at an optimal value of K_{ex} (K_{ex}(opt)). At this point the concentration gradients in the unstirred boundary layers are symmetric and equal, and the carrier is half saturated (8). A further increase in K_{ex} results in a decrease in flux as the carrier holds KX in the organic phase.

Figure 3 illustrates the influence of the concentrations in the left aqueous phase. Below K_{ex}(opt), the flux varies with the product $[K^+]_l[X^-]_l$ and a Michealis–Menton analysis will apply. (8). At values of K_{ex} greater than K_{ex}(opt) the flux is independent of the left aqueous phase composition, hence saturation kinetics do not apply. Similarly, the flux is a function of the concentration of the anion in the right aqueous phase as shown in Fig. 4. As $[X^-]_r$ increases there is a marked decrease in the flux for systems with log K_{ex} > log K_{ex}(opt). Behavior such as this is not found in gradient pumping cases and provides an additional experimental test. Figure 5 illustrates that the flux depends on the extent of transport, falling ultimately to zero in the equilibrium limit. The curves are symmetrical about K_{ex}(opt), in contrast to symport gradient pumping but similar to antiport gradient pumping (8). This suggests that initial rate methods should be used with some caution since the concentrations are nowhere strictly linear functions of time. Figure 6 shows the variation expected for a variation of carrier concentration. This set is similar to related gradient pumping cases. Note that J_{max} is a linear function of carrier concentration, hence the absolute transport rate is slower at the lower concentrations but the rate relative to a given amount of carrier is greater at lower concentration for systems above log K_{ex}(opt).

3. Experimental tests of the model

The equilibrium state of the experimental system is in principle easy to assess. In practice, however, these experiments were complicated by the very low rates of transport for near equilibrium conditions; the flux depends upon the concentration gradients, which are shallow near equilibrium. As a consequence, experiments take several weeks to reach equilibrium. Small amounts of evaporation or acidification by atmospheric CO_2 strongly perturb the calculation of K_{eq} by eq. [6]. In addition, although the Br^- and ClO^-_4 cases initially proceed more rapidly

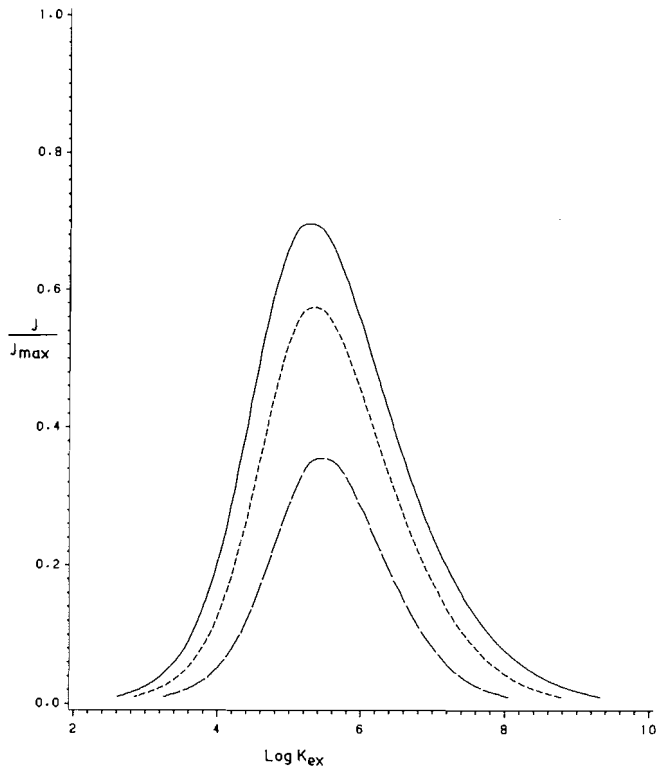

FIG. 5. J/J_{max} as a function of log K_{ex} showing the effect of the fraction of transport on the behavior of the system for the cell 5×10^{-3} M KX $\|$ 1×10^{-3} M Cry $\|$ 2×10^{-3} M KX, 5×10^{-3} Crn, pH 9.6. ——— $f = 1\%$; ----- $f = 25\%$; – – – $f = 50\%$.

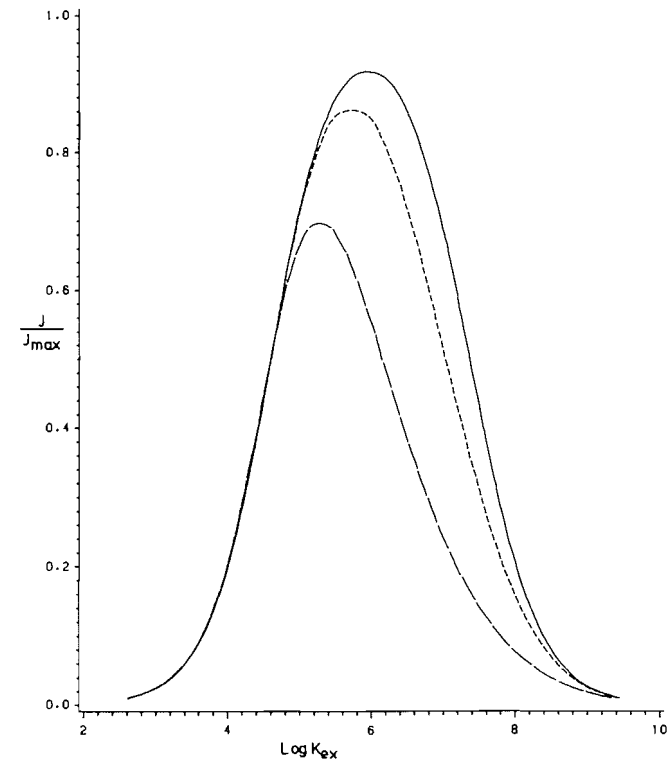

FIG. 6. J/J_{max} as a function of log K_{ex} showing the effect of variable carrier concentration on the cell: 5×10^{-3} M KX, pH 9.6 $\|$ vary [Cry] $\|$ 2×10^{-3} M KX, 5×10^{-3} Crn, pH 9.6. ———, [Cry] = 1×10^{-5} M; ---- [Cry] = 10^{-4} M; – – – [Cry] = 10^{-3} M.

than the Cl^- system (due to favorable log K_{ex}), an appreciable amount of potassium is held in the organic phase. This eventuality is ignored in the derivation of eq. [6]. The effect is minimized by use of Cl^- as anion, engendering even longer experimental times.

Nevertheless, the equilibrium of a KCl system was reached in 5–7 weeks using a sealed cell. The initial conditions were 2.0×10^{-3} M KCl, pH 9.60 $\|$ 1.0×10^{-3} M 2.2.2D in $CHCl_3$ $\|$ 2.0×10^{-3} M KCl, 5.0×10^{-3} M Crn, pH 9.6. The equilibrium state for these conditions is calculated to be $[KCl]_{l,eq} = 4.5 \times 10^{-4}$ M, $[KCl]_{r,eq} = 3.55 \times 10^{-3}$ M. The experimental values are: $[K^+]_l = (4.31 \pm 0.05) \times 10^{-4}$ M, $[Cl^-]_l = (4.5 \pm 0.1) \times 10^{-4}$ M, $[K^+]_{r,tot} = (3.51 \pm 0.05) \times 10^{-3}$ M, and $[Cl^-]_r = (3.57 \pm 0.1) \times 10^{-3}$ M. Substitution of these values into eq. [6] yields an experimental value of log $K_{eq} = 4.64 \pm 0.05$, in comparison to log $K_{110} = 4.6 \pm 0.2$ (14). Similar experiments using KBr or $KClO_4$ yield somewhat higher values of log K_{eq} (4.79, 4.84), complicated by potassium extraction as noted above. Nevertheless, the agreement of theory with experiment lies within or near the limit of the experimental uncertainties.

3.1 Determination of J_{max}

The term J_{max} contains the parameters D and l, neither of which is readily accessible. The value of J_{max} may be determined in the same way as in an enzyme kinetics experiment, from the variation in flux as a function of substrate concentration. In the present case the substrate is the left aqueous phase concentration $[K^+]_l[X^-]_l$ (12). The procedure is only valid if $K_{ex} < K_{ex}(opt)$ (8), but J_{max} should be a constant for all systems at equal carrier concentration and equal stirring behavior (18). The Eadie–Hofstee form of the Michealis–Menton equation was used (17) (eq. [12])

$$[12] \quad J = \frac{-1}{K_{ex}} \left(\frac{J}{[K^+]_l[X^-]_l} \right) + J_{max}$$

and J_{max} was determined as the intercept of a plot of J as a function of $J/([K^+]_l[X^-]_l)$. The systems examined are given in Table 1; six of the seven cases cluster around 3.4×10^{-6} mol m^{-2} s^{-1} but the seventh (2.2.2/KCl) is much lower. In this case, much higher salt concentrations were required to achieve useful rate variation. Further, the carrier 2.2.2 is water soluble and may be salted out into the aqueous solution. This would lower [Cry(org)] and thus lower J_{max}. Ignoring this one case, the average of the other six is $(3.40 \pm 0.17) \times 10^{-6}$ mol m^{-2} s^{-1}, taken to apply to all 12 systems examined.

3.2 Determination of K_{ex}

For systems where saturation kinetics apply, K_{ex}, defined by eq. [2], can be evaluated from the slope of the plot of eq. [12]. This method is inappropriate for systems with $K_{ex} > K_{ex}(opt)$ and extraction constants were determined directly. Two types of experiments were done for each carrier/salt pair. In one set a strongly basic (pH 11.7) aqueous phase was used. Under these conditions, protonation of the cryptand can be ignored and eq. [13] applies for equal phase volumes of organic and aqueous phases.

$$[13] \quad K_{ex} = \frac{(M - M_{eq})}{(L - M + M_{eq})(M_{eq})(M_{eq})}$$

where L is the total initial carrier concentration, M is the total initial potassium concentration, and M_{eq} is the equilibrium aqueous phase potassium ion concentration. In a second set of two-phase extraction experiments, the solution pH and carrier

concentration were identical to the transport experiment. Since the pH is close to the carrier pK_a, these values were corrected to account for partial protonation according to eq. [14],

$$[14] \quad K_{ex} = \frac{(M - M_{eq})}{(L - M + M_{eq})(M_{eq})^2}\left(1 + \frac{pH}{pK_a}\right)$$

where the pK_a is for the first protonation of the carrier. Further protonation and partitioning of partly protonated species were ignored. The values of log K_{ex} derived from the two sets of experiments agreed to ±0.1 in all cases. Values averaged between two initial potassium concentrations are given in Table 1.

3.3 Flux behavior of the model

The initial concentrations in the standard experiment were $[KX]_l = 5 \times 10^{-3}$ M, pH 9.6 ‖ 1.0×10^{-3} M Cry in $CHCl_3$ ‖ $[KX]_r = 2.0 \times 10^{-3}$ M, [Crn] = 5.0×10^{-3} M, pH 9.6. As noted above, the potassium on the right is 99.2% complexed; at 20% transport this only drops to 98.8%. The potassium on the right is virtually entirely complexed throughout the experiment. The observed fluxes for 12 directly comparable cases at 5% total transport are given in Table 1. Experimental pairs of J/J_{max} and log K_{ex} are compared with the theoretical curve in Fig. 7. The agreement is quite good, especially on the saturation kinetics side. The lack of suitable systems with log K_{ex} > log K_{ex}(opt) limits the number of independent points on the other side of the bell curve.

The anion dependence of flux predicted in Fig. 4 can be observed experimentally. However, as the transport proceeds, $[X^-]_r$ increases quite rapidly. Thus the flux decreases after a brief induction period. The net result is a sigmoidal curve of $[K^+]_r$ vs. time, which is difficult to reliably quantify. Attempts to buffer $[X^-]_l$ at some low value were messy and unreliable, but in qualitative agreement with Fig. 4. Alternatively, the flux can be markedly suppressed by addition of ClO_4^- or I^- to the right-hand aqueous phase, not only of systems containing these same counterions (entries 13, 15; 16, 17) but also in a Br^- system (entries 8, 9). In the latter case, ClO_4^- on the right inhibits Br^- transport from left to right even though no ClO_4^- can be detected

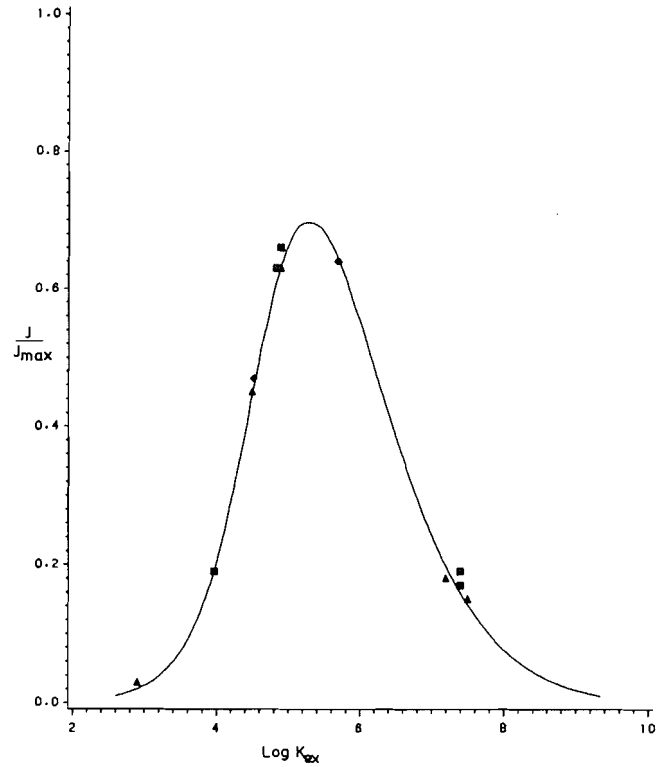

FIG. 7. J/J_{max} as a function of log K_{ex}. Experimental points from Table 1, condition C. Theoretical curve calculated for condition C at 5% total transport. ■ 2.2.2D as carrier; ▲ 2.2.2 as carrier; ◆ 2.2.1 as carrier.

in the left aqueous phase. This is entirely consistent with the model. That a saturable process occurs for $K_{ex} < K_{ex}(opt)$ is implicitly demonstrated by the determination of J_{max} and K_{ex} by eq. [12]. The converse case is demonstrated by the KI/2.2.2D system (entries 13, 14), consistent with the calculation presented in Fig. 3.

4. Conclusions

Taken together, the experimental results provide strong confirmation that the development from eq. [1] as outlined above is a reliable predictor of the kinetic and equilibrium behavior to be expected of systems derived from Fig 1. It is perhaps less clear that the experimental system examined is in fact an "active" transport system within the sense of a biochemical definition. Certainly no covalent bond lysis occurs, as the paradigm of ATP hydrolysis would require. Nonetheless, transport is clearly coupled to a reaction free energy change, that of the complexation of K^+ by Crn^{2-}, and the transport ceases when the equilibrium condition of eq. [3] is satisfied. The gradients present at equilibrium are balanced by the reaction free energy change as would occur in an isolated Na^+/K^+ pump energized by ATP hydrolysis. The distinction is to focus attention upon what the ΔG achieves rather than upon where it came from.

Within this context it is of interest to examine previous reports of active transport as well as other reports in which the question of active transport was not addressed. The most obvious of the latter are the reports of Izatt and co-workers on the transport of cations across emulsion membranes driven by suitable complexing anions in the internal phase (19–21). The system is formally identical to the one presented here; the authors discuss the role of the complexing anion and stability of the metal ion complexes formed in determining the extent of transport. From the viewpoint of active transport this is equivalent to varying the available reaction free energy, which controls varying the magnitude of the concentration gradient that can be achieved at equilibrium. The brief report involving polycarboxylate crown ethers as complexing agents (40) must also fall in this class. However, the pH of the internal phase of the system is not reported and it is unclear what the full driving force might be. Cation complexation in an unbuffered system would result in deprotonation (14) and acidification of the internal phase. The net result would be to diminish the ability of the crown ether to bind further potassium or sodium internally.

When one of the transported species is a proton, in cation–proton antiport systems for example, use of buffer solutions to maintain a target pH gradient results in formal similarities to primary active transport. In these cases AC is some acid in equilibrium with its conjugate base C. Extent of transport should then be determined by the pK_a of the acid. This has not been explicitly demonstrated, as the buffer components are usually regarded as uninteresting and are commonly used in excess with respect to the transported ions (17). An antiport reaction pumping scheme for ammonia, exploiting acid/base behavior, has been described by Selegny and Langevin (22). These authors focus on membrane asymmetry as the essential principle, but the system can equally well be represented according to Fig. 1 and eq. [1]. An earlier glucose transport system, also asymmetric, can similarly be cast in the form of Fig. 1 and eq. [1] (23).

Of the systems claiming to involve active transport, the majority of cases are examples of gradient pumping (9). Systems that are unambiguous examples of reaction pumping all involve electron transport coupled to cation symport (24) or anion antiport (25–27). One of the latter has been examined near equilibrium, where an anion gradient has been shown to drive a redox process (25), as anticipated by Fig. 1. This is akin to reaction coupling, as are other reports of electron transport (28, 29). The equilibrium and kinetic behavior of these systems probably also follows the predictions from eq. [1]; curves such as Figs. 3–6 would thus involve a composite electron transfer/extraction equilibrium constant. These electrochemically driven processes are in contrast to numerous electrochemically (30–33) or photochemically (34–37) switched transport processes. The distinction between redox or light *driven* transport and redox or light *switched* transport turns on the utilization of the input energy. In a driven transport process the energy is used for gradient creation. In switching, the carrier or substrate is prepared for efficient extraction or release; any "uphill" transport that occurs is a result of gradient pumping.

It is clear that some good examples of reaction pumping and reaction coupling have been demonstrated. However, examples involving transport of substrates other than electrons or protons, such as the model outlined in this report, have not been widely investigated. At the same time these are the cases that will yield useful separation and reaction coupling applications. The carriers required for numerous types of substrates are known (9). The procedure outlined in this report will assist in the design of systems incorporating these known carriers for new transport systems.

Experimental

The carriers utilized were commercially available (Merck) and were used as received. Potassium salts and other buffer components were of analytical grade. The crown ether, *R,R*-(+)-1,4,7,10,13,16-hexaoxacyclooctadecane-2,3-dicarboxylic acid (Crn) was prepared and purified as previously described (13, 14). The buffers utilized

methyl tris(hydroxyethyl)ammonium ($MTEA^+$) as a non-extractable cation and were prepared from $MTEA^+OH^-$, which was prepared as previously described (38). A stock buffer solution was prepared from glycine by addition of MTEAOH to reach a final pH of 9.6 and then made to volume to contain 2×10^{-2} M glycine. The stock solution was diluted by 1:2 for the solutions used for transport and extractions, which therefore contained 1×10^{-2} M glycine/$\sim 5 \times 10^{-3}$ M $MTEA^+$. Potassium analyses were done using atomic emission as previously described (17). Anion analyses were done by anion chromatography using the system previously described (39).

Equilibrium position of transport

These experiments used the U-tube cell described previously (17) sealed with serum caps on either arm. Only the organic phase in the base of the cell was stirred (magnetic stirrer); the aqueous solutions were slowly mixed by convection and viscous drag at the interfaces. The initial conditions were as follows: left aqueous phase, 8.0 mL, 2.0 $\times 10^{-3}$ M KX, glycine/MTEAOH (10^{-2} M gly), pH 9.6 ‖ 12.0 mL membrane phase ($CHCl_3$) containing 1.0×10^{-3} M carrier ‖ right aqueous phase, 8.0 mL, 2.0×10^{-3} M KX, 5.0×10^{-3} M Crn, glycine/MTEAOH (10^{-2} M gly), pH 9.6. The initial solutions were analysed for potassium and anion concentrations. The cell was sealed, and the pressure in both arms was equalized with needles through the serum caps, which were then withdrawn. The cell was thermostatted at 25.0 ± 0.5°C, and the organic phase was stirred at 400 ± 1 rpm for periods ranging up to 8 weeks. Samples (25 μL) were withdrawn periodically and checked for change in potassium ion concentration. When no further change was noted over a period of 7–10 days, the cell was opened, the pH was checked, and multiple samples were withdrawn for potassium and anion concentration determination. A sample of the organic phase was evaporated and analysed for potassium. The systems examined were (salt, carrier, length of experiment, log K_{eq} calculated by eq. [6], residual potassium in the membrane expressed as % carrier saturation): $KClO_4$, 2.2.2D, 3 weeks, 4.84, 65%; KBr, 2.2.2D, 3 weeks, 4.79, 35%; KCl, 2.2.2D, 7 weeks, 4.64, 7%.

Kinetic behavior

The transport experiments, analytical procedures and transport rate determinations followed procedures previously described (17). The initial conditions are given in the footnotes to Table 1; all solutions contained glycine/MTEAOH pH 9.6 (10^{-2} M glycine). Additional experimental tests included the following: 1. A repeat of entry 6 with no cryptand carrier, which gave no detectable transport. Thus the dicarboxylate crown cannot act as a carrier. 2. Multiple repeats of entry 6 at stirring rates of 100, 200, and 600 rpm; fluxes of 1.41, 1.81, and 2.43 $\times 10^{-6}$ mol m^{-2} s^{-1} show that the rate is a function of stirring, hence is controlled by diffusion (18) as assumed. 3. A repeat of entry 6 with carrier concentrations of 5×10^{-4} M and 2×10^{-3} M; fluxes of 1.21 and 3.87 $\times 10^{-6}$ mol m^{-2} s^{-1} indicate that the rate is a function of carrier concentration (approximately first order in carrier (17)) as required by the mechanism assumed. 4. Several repeats of entries 22–24 at different buffer concentrations; no detectable change in flux from the values reported.

Determination of log K_{ex}

In a small stoppered test tube, immersed in a constant temperature bath, was placed 0.500 mL of the carrier solution in $CHCl_3$ (5×10^{-4} M or 1×10^{-3} M) followed by 0.500 mL of an aqueous solution of potassium salt (5×10^{-4} M, 1×10^{-3} M, or 2×10^{-3} M KX in glycine/MTEAOH pH 9.6 (10^{-2} M gly) or 10^2 M MTEAOH pH 11.7). The mixture was stirred on a vortex mixer for 60 s, equilibrated in the constant temperature bath for 5 min, and the aqueous phase was sampled in triplicate (50–100 μL). The mixing/equilibration/sampling procedure was repeated. The six samples were diluted and analysed for potassium by atomic emission. Initial concentrations of potassium were determined by atomic emission from the stock solutions used. Values of K_{ex} were calculated for each sample using eq. [13] or [14] and averaged within each set of triplicates. In general the two sets agreed within log K_{ex} ± 0.05 and were averaged. This result suggests that 60 s of mixing is sufficient to reach equilibrium. The concentration range is best suited for log K_{ex} 5.5–7.5 and the calculations are most reliable for approximately 50% extraction; for lower values of log K_{ex} the pair of experimental values from 1×10^{-3} M and 2×10^{-3} M KX solutions were averaged and reported in Table 1; for higher values of log K_{ex} the results from 5.0×10^{-4} M and 1.0×10^{-3} M KX solutions were averaged. Agreement between eqs. [13] and [14] at a given concentration was good (log K_{ex} ± 0.1) but agreement between pairs of concentrations was less satisfactory (log K_{ex} ± 0.3). The values reported in Table 1 are reliable to log K_{ex} ± 0.5, as assessed from replicate experiments from separate solution preparations. The extraction stoichiometry was assumed to be 1:1 in all cases. This was confirmed by an nmr extraction experiment utilizing 2.2.2D in $CDCl_3$ and $KClO_4$ in D_2O. The ^1H nmr spectrum changed with added $KClO_4$ up to one equivalent but was constant thereafter, consistent with the formation of a 1:1 complex.

Calculations of theoretical curves

The general procedure follows those reported previously (8, 12) and the methods outlined in the text. The equilibrium concentrations for the right aqueous phase were calculated using the algorithm of COMPLEX (16), the total concentrations and the pH, and the values of cumulative association constants for Crn: log $\beta_{101} = 4.48$, log $\beta_{102} = 7.42$, log $\beta_{110} = 4.60$ (= log K_{110}), log $\beta_{111} = 8.07$. For a given fraction of transport f, the total concentrations can be calculated, followed by the equilibrium concentrations as required for eqs. [10] and [11]. A further correction for diffusion resistance in the aqueous unstirred layers must also be applied as in eq. [15] (8, 12).

$$[15] \quad G = \frac{[CrnK^-][X^-]_r}{K_{110}[Crn^{2-}]_r} + \frac{C}{2}\left(\frac{J}{J_{max}}\right)$$

With the terms defined, and $y = J/J_{max}$, eq. [9] can be cast as a quadratic in K_{ex} ($AK_{ex}^2 + BK_{ex} + C = 0$) where $A = yFG$, $B = ((F + G)y + G - F)$, and $C = y$. Repeated solutions for K_{ex} with an increment of 0.01 y yields points for the curves of Fig. 3–7. Interpolation used a cubic spline procedure.[3]

Proton transfer reactions between *ortho*-methyl substituted derivatives of 4-nitrophenylphenylcyanomethane and nitrogen bases in acetonitrile solvent

KENNETH T. LEFFEK AND PRZEMYSLAW PRUSZYNSKI[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4H6

Received January 4, 1988

KENNETH T. LEFFEK and PRZEMYSLAW PRUSZYNSKI. Can. J. Chem. **66**, 1454 (1988).

Equilibrium constants, rate constants, primary deuterium isotope effects, and activation parameters have been measured for the proton transfer reactions in acetonitrile solvent of 4-nitrophenylphenylcyanomethane and 2-methyl-4-nitrophenylphenylcyanomethane with tetramethylguanidine base and for the reactions of 2-methyl-4-nitrophenylphenylcyanomethane and 2,6-dimethyl-4-nitrophenylphenylcyanomethane with 1,5-diazabicyclo[5.4.0]undec-7-ene base. Introduction of the *ortho*-methyl groups in the substrate molecule caused significant reductions in the equilibrium and rate constants. The expected rise in the kinetic primary deuterium isotope effect was not observed when the first *ortho*-methyl group was introduced, but a 20% increase did accompany the introduction of the second *ortho*-methyl group. Enthalpy of activation measurements indicated that there was no increase in the proton tunnelling contribution to the isotope effect when the amount of steric hindrance is increased with *ortho*-methyl groups.

KENNETH T. LEFFEK et PRZEMYSLAW PRUSZYNSKI. Can. J. Chem. **66**, 1454 (1988).

Opérant dans l'acétonitrile comme solvant, on a mesuré les constantes d'équilibre, les constantes de vitesse, les effets isotopiques primaires du deutérium ainsi que les paramètres d'activation pour les réactions de transfert de proton des nitro-4 et méthyl-2 nitro-4 phénylphénylcyanométhanes avec la base tétraméthylguanidine ainsi que pour les réactions des méthyl-2 nitro-4 et diméthyl-2,6 nitro-4 phénylphénylcyanométhanes avec la base diaza-1,5 bicyclo[5.4.0]undécène-7. L'introduction des groupements méthyles en *ortho* des molécules de substrat provoque des diminutions importantes des constantes d'équilibre ainsi que de vitesse. Lorsqu'on a ajouté le premier groupement méthyle en *ortho*, on n'a pas observé l'augmentation prévue de l'effet isotopique cinétique primaire du deutérium; toutefois, l'introduction du second groupement méthyle en *ortho* provoque une augmentation de 20%. Des mesures d'enthalpie d'activation permettent de déduire qu'une augmentation de l'encombrement stérique, provoquée par la présence de groupements méthyles en *ortho*, ne conduit pas à une augmentation de la contribution de l'effet tunnel du proton.

[Traduit par la revue]

Introduction

Recent kinetic studies of proton transfer reactions from 4-nitrophenylphenylcyanomethane and its ring substituted derivatives in aprotic solvents have shown substantial primary deuterium isotope effects ($k_H/k_D > 10$ at 25°C) indicating a possible significant contribution to the rate constants from proton tunnelling (1). Changes in the rate constant for proton transfer accompanying *para* substitution of the second phenyl ring (2) and variation of the solvent (3) led to the conclusion that the transition state for the reaction came early on the reaction pathway and that the developing negative charge was localized on the central carbon atom. Thus, the carbanionic transition state retains most of the tetrahedral structure of the substrate molecule.

This work is now extended to a study of the steric effects of *ortho*-substituted methyl groups on the phenyl ring carrying the *para* nitro group. Consideration of enhanced primary deuterium isotope effects as a manifestation of steric effects was proposed by Lewis and Funderburk in 1967 (4), but no clear relationship has become apparent. Work done on secondary kinetic deuterium isotope effects in the 1960s and early 1970s, particularly on the configurational inversion of biphenyls, showed that effects arising from steric hindrance (5, 6) did not necessarily increase when very large amounts of steric hindrance were involved (7, 8).

Steric effects on proton transfer reactions from carbon acids have been observed (9, 10), particularly with the highly hindered base 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene, but no specific study of steric effects in these reactions has been carried out.

[1]Visiting Scientist 1986–1987.

Results and discussion

Three substrate molecules were used, 4-nitrophenylphenylcyanomethane (**1**), 2-methyl-4-nitrophenylphenylcyanomethane (**2**), and 2,6-dimethyl-4-nitrophenylphenylcyanomethane (**3**). The proton transfer reaction rate constants for **1** and **2** were measured with tetramethylguanidine base (TMG) but the reaction of **3** was too slow to be measured. Substrates **2** and **3** reacted at convenient rates with 1,5-diazabicyclo[5.4.0]undec-7-ene (DBU) but substrate **1** was too fast to be measured with this base. The three substrates can be compared using both of these nitrogen bases overlapping the series with substrate **2**.

The reactions were carried out in acetonitrile solvent and the substrates gave a product with a single broad strong absorption peak at 590 nm for **1**, 597 nm for **2**, and 671 nm for **3** characteristic of the carbanions of the acid substrates. The large absorption peak shift for the 2,6-dimethyl substituted product is probably due to steric inhibition of the tendency of the carbanion to assume a nearly planar structure. The absorbance measurements of the equilibrium mixtures were fitted to the Hildebrand–Benesi equation [1] for an ion-pair product, where a and b are the initial concentrations of the acid and base repectively and A is the equilibrium absorbance.

$$[1] \quad a/A = \frac{1}{Kb\epsilon} + \frac{1}{\epsilon}$$

The equilibrium constant K and the molar absorptivity ϵ were derived from a plot of a/A vs. $1/b$. The 2-methyl substrate **2** with TMG gave $K = 300 \pm 60$ dm^3 mol^{-1} at 25°C (ϵ 24 000), a considerably lower value than that previously reported (1) for the unsubstituted substrate **1** of 6000 dm^3 mol^{-1} (ϵ 40 000). This

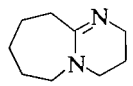
(TMG)



(DBU)

would be expected as a result of the steric inhibition to planarity in the carbanion by the 2-methyl group and also, as a minor contribution, the electron releasing character of that group.

The reaction of DBU with the 2-methyl substrate **2** gave $K = 3500 \pm 700$ dm^3 mol^{-1} at 25°C (ε 37 000) and the addition of the second *ortho*-methyl group in substrate **3** decreased the equilibrium constant to 100 ± 20 dm^3 mol^{-1} (ε 15 000). This change is again consistent with increased steric inhibition to planarity in the carbanion.

The pseudo-first-order rate constants were measured under conditions of a large excess of base using a stopped-flow spectrophotometer, by monitoring the increase of the product concentration at the wavelength corresponding to the product peak. The carbanion formed from the 2-methyl substrate **2** decompsed slowly but no decomposition was detectable at times less than 2 min, whereas the kinetic measurements (10 half-lives) were always complete in less than 2 s.

The pseudo-first-order rate constants, k_{obs}, were fitted to eq. [2] for an equilibrium of the type shown in eq. [3], by a least-squares calculation to yield k_2 and k_b, the rate constants for the forward and backward reactions.

$$[2] \quad k_{obs} = k_2[\text{Base}] + k_b$$

$$[3] \quad \geq C{-}H + N\!\!\leq \underset{k_b}{\overset{k_2}{\rightleftharpoons}} \geq C^- HN^+\!\!\leq$$

These results are shown in Table 1 for five different temperatures for the normal and deuterated analogues of substrates **2** and **3**. The results (1) for substrate **1** at 25°C are included for comparison. The ratio k_2/k_b gives the equilibrium constant K. For the 2-methyl substrate **2** with TMG, $k_2/k_b = 220 \pm 30$ dm^3 mol^{-1} at 25°C for the proton transfer reaction, in satisfactory agreement with the value of 300 ± 60 obtained from the equilibrium measurements. The slow decomposition of the carbanion from this substrate may introduce a slight error in the 300 value, but such an error would be in the direction to increase the value of K.

For the reactions with DBU base, the dimethyl substrate **3** gave $k_2/k_b = 86 \pm 6$ dm^2 mol^{-1} at 25°C, in good agreement with the value of 100 ± 20 from the equilibrium measurements. The methyl substrate **2** gave $k_2/k_b = 2000 \pm 200$ dm^3 mol^{-1} at 25°C, whereas the equilibrium measurements gave 3500 ± 700. However, the experimental error of the Hildebrand–Benesi method may be significantly larger than the statistical value quoted, since K is determined from the slope of the graph $(1/K\varepsilon)$. When $K = 3500$ dm^3 mol^{-1} and $\varepsilon = 37\,000$ the slope is 7.7×10^{-9}. In these circumstances the difference between k_2/k_b of 2000 and 3500 determined for K from the equilibrium measurements may not be significant.

Comparison of the second-order rate constants for the reaction with TMG base shows that the introduction of one *ortho*-methyl group reduces the rate, relative to the unsubstituted substrate, by a factor of 18 at 25°C. However, the primary deuterium isotope effect is essentially unchanged. The second *ortho*-methyl group causes another rate constant reduction in the reaction with DBU base of a factor of 18 at 25°C but in this case the primary deuterium isotope effect is increased by about 20%. The second *ortho*-methyl group decreases the acid strength of the carbon acid and therefore shifts the transition state so that it comes later along the reaction path. This transition state is more planar and more symmetrical, corresponding to greater loss of zero-point energy and larger primary isotope effect. This is not expected to be a large effect (11) and would be offset by some steric inhibition of C—H and C—D vibrational frequencies in the intial state, which would result in smaller isotopic rate ratio. The increased isotope effect is also qualitatively in agreement with an enhanced contribution from proton tunnelling to the rate of the reaction as a consequence of a narrower energy barrier to reaction in the presence of considerable steric hindrance. It is plausible that such an effect would have a threshold and not appear until the steric hindrance reached a particular level with the introduction of the second *ortho*-methyl group.

The activation parameters and the effect of deuterium substitution on them are shown in Table 2. These results show that the major part of the rate constant change for proton transfer when *ortho*-methyl groups are introduced into the substrate molecule is due to increases in the enthalpy of activation, confirming that the effect is predominantly steric in origin. The deuterium isotope effect on the enthalpy of activation is generally greater than the 1.1 kcal mol^{-1} that is expected from the complete loss of the C—H (C—D) stretching vibration in the transition state. However, the three measurements carried out on the methyl substituted substrates all show a slightly smaller enthalpy isotope effect than that obtained for the unsubstituted molecule (1). This demonstrates that there is no evidence for increased tunnelling in this system when the amount of steric hindrance is increased with *ortho*-methyl groups. Thus, although the rates of the reactions are changed by the increased steric hindrance and also the isotope effects to some extent, the width of the barrier to reaction, which controls the amount of proton tunnelling, does not seem to be altered.

Experimental

Materials

p-Nitrophenylphenylcyanomethane and its deuterated analogue were prepared as described previously (1).

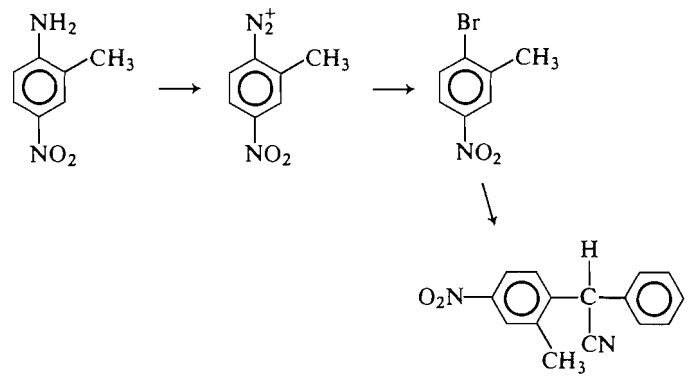
(2-Methyl-4-nitrophenyl)phenylcyanomethane was prepared by the following synthetic route: 2-methyl-4-nitroaniline (0.1 mol) was treated with a solution of 20 g of concentrated H_2SO_4 in 80 mL of water and cooled to 0–5°C. Then 7 g of $NaNO_2$ in 12–15 mL of water was added dropwise and the resulting diazonium salt kept in ice. Cuprous bromide solution was prepared by dissolving 6.3 g of $CuSO_4$, 2 g of clean copper turnings, 15.2 g of NaBr, and 3–4 g of concentrated H_2SO_4 in 100 mL of water. This mixture was heated for 3–4 h until the solution acquired a yellowish colour. The solution was placed in a flask fitted with a steam distillation head, and steam was passed. The cold solution of diazonium salt was then added dropwise. The crude product of 2-bromo-5-nitrotoluene obtained in the steam distillate was purified by washing its ether solution with NaOH solution (to remove phenol) and then by column chromatography on silica gel. Finally it was recrystallized from methanol; mp 78°C; ^{1}H nmr δ(ppm): 2.46 (s, 3H), 7.66–8.14 (m, 3H).



This material was reacted with phenylcyanomethane using the procedure of Davis and Pizzini (12). 2-Bromo-5-nitrotoluene (7.7 g) was dissolved in 56 g of pyridine and 24 g of a paste, obtained by grinding 12 g KOH with 12 g of pyridine, was added. This mixture was kept at 5°C and 4.6 g of phenylcyanomethane was added. The reaction mixture was stirred overnight and the temperature maintained below 0°C. Then 30 mL of benzene was added and the resulting precipitate was filtered, washed with ether, dissolved in water, and finally acidified by acetic acid. The dark colour disappeared and an oily product was formed. This product, after purification by column chromatography, was dissolved in a small amount of chloroform and poured slowly into excess pentane. Yellow crystals were formed, which were then recrystallized from methanol; mp 73–74.5°C; ^{1}H nmr δ(ppm): 2.38 (s, 3H), 5.40 (s, 1H), 7.33–8.17 (m, 8H).

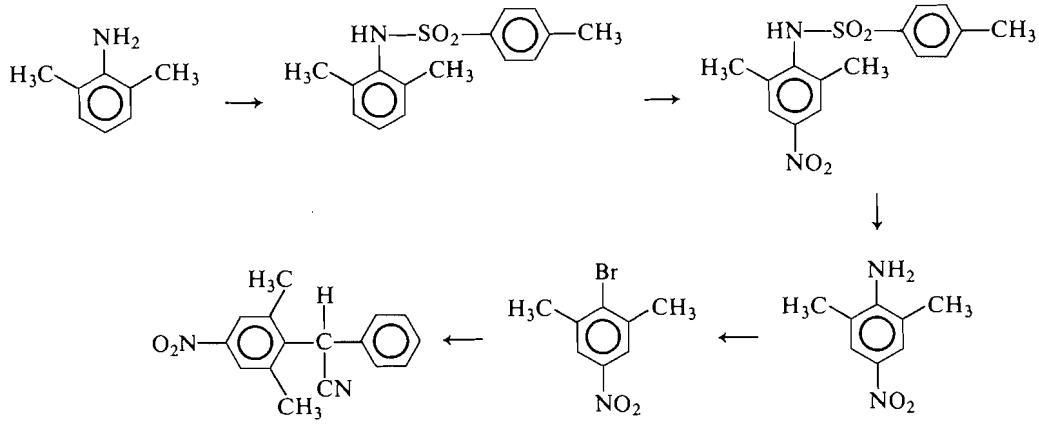
The deuterated analogue was obtained by exchanging 200 mg of the carbon acid with a solution of NaOD in a solution of 25% D_2O in dioxan. After about 2–3 min the reaction mixture was neutralized by several drops of DCl in D_2O. The solvents were then evaporated and the organic part was separated from the NaCl by washing with dry chloroform. The chloroform was then evaporated and the residue dissolved in dioxan. This procedure was repeated four times. A high degree of deuteration was indicated by the disappearance of the proton nmr signal at 5.40 ppm. The mass spectrum indicated 96% deuteration.

(2,6-Dimethyl-4-nitrophenyl)phenylcyanomethane was prepared by the following synthetic route: pure 2,6-dimethylaniline (17.4 g) was dissolved in 112 mL of pyridine (dried over NaOH and distilled) and 31 g of *p*-toluenesulfonylchloride was added. The reaction mixture was refluxed for 2 h and then poured into 700 mL of 2 N HCl; the precipitate was filtered and recrystallized twice from ethanol. Yield 82%, mp 137°C; ^{1}H nmr δ(ppm): 2.03 (s, 6H), 2.4 (s, 3H), 6.2 (s, 1H), 7.03–7.7 (m, 7H).

The nitration step was carried out using a modification of the method of Bambenek (13). A mixture of the sulfonamide (15.3 g), nitric acid, and glacial acetic acid was refluxed for 10 min, after which 5–7 mL of fuming nitric acid was added to initiate the nitration. After heating for a further 6 to 7 min the reaction mixture was cooled and diluted with water. The solid material was filtered and washed with cold water. The crude product was recrystallized from ethanol; yield 66.4%, mp 162–164°C (lit. (14) mp 167°C); ^{1}H nmr δ(ppm): 2.17 (s, 6H), 2.47 (s, 3H), 6.43 (s, 1H), 7.23–7.93 (m, 6H).

The nitrated sulfonamide (19.2 g) was dissolved in concentrated H_2SO_4 (190 mL) and heated at 50°C for 1 h, then cooled and poured into 500 g of ice. The precipitate was decolourized with charcoal in ethanol and recrystallized as yellow needles; yield 50%, mp 165.2°C; ^{1}H nmr δ(ppm): 2.17 (s, 6H), 4.03 (br s, 2H), 7.8 (s, 2H). This 2,6-dimethyl-4-nitroaniline (5 g) was dissolved in a solution of concentrated H_2SO_4 (4.1 mL) in water (30 mL). This solution was cooled to 0–5°C and $NaNO_2$ solution (2.7 g in 4.7 mL H_2O) was added slowly. The diazonium salt thus formed was then added to a CuBr solution, prepared as described above, and the mixture was steam distilled. The distillate was washed with NaOH and the residue filtered to yield about 3 g of crude 2,6-dimethyl-4-nitrobromobenzene; ^{1}H nmr δ(ppm): 2.53 (s, 6H), 7.97 (s, 2H).

This product (2.5 g) was dissolved in pyridine (20 mL) and a paste, obtained by grinding 4.2 g of KOH in 4.2 g pyridine, was added. The mixture was cooled to −5°C and 1.5 g of phenylcyanomethane was added with stirring. The stirring was continued for 10 h with the reaction flask cooled in ice, then 20 mL benzene was added. The resulting precipitate was filtered and the crude product washed with benzene and ether. This product was dissolved in about 100 mL water



and then precipitated by the addition of acetic acid. The yellow solid was washed with water and dried. Yield 1 g (35%), mp 116–117°C; ^{1}H nmr δ(ppm); 2.36 (s, 6H), 5.67 (s, 1H), 6.90–7.37 (m, 5H), 7.83 (s, 2H).

Deuteration of the 2,6-dimethyl-4-nitrophenylphenylcyanomethane was accomplished using a solution of 5 mg of metallic sodium in a mixture of 10 mL D_2O and 10 mL dioxane. About 200 mg of the carbon acid was dissolved in 2 mL of dioxane and 2 mL of the above solution. After 1 min the coloured solution was neutralized with several drops of DCl in D_2O. The solvents were evaporated and the carbon acid was separated from NaCl by extraction with chloroform. After evaporation of the chloroform, the procedure was repeated four times. The nmr signal at 5.67 ppm disappeared, and the mass spectrum indicated 98% deuteration.

Reagent grade acetonitrile was purified by the method of O'Donnell *et al.* (15) with a final fractional distillation from P_2O_5.

Tetramethylguanidine was dried with KOH and then fractionally distilled under reduced pressure. The middle fraction, about 25% of the total, was used.

1,8-Diazabicyclo[5.4.0]undec-7-ene was dried with KOH and fractionally distilled under reduced pressure.

Equilibrium measurements

The absorbance at equilibrium was measured for a series of reactions with a constant acid concentration of either 1×10^{-5} M or 4.7×10^{-5} M, and different base concentrations in excess of the acid concentration by factors ranging from 23 to 1000, using a Cary 219 spectrophotometer.

Kinetic measurements

The reaction rate constants were measured with a Durrum–Gibson stopped-flow spectrophotometer using acid concentrations of 1×10^{-5} or 2×10^{-5} M with base concentrations shown in Table 1. The pseudo-first-order rate constants were obtained as described previously (2).

Received November 12, 1987

C. N. N'SOUKPOÉ-KOSSI and R. M. LEBLANC. Can. J. Chem. **66**, 1459 (1988).

The molecular state of a single monolayer of lutein, zeaxanthin, and of a mixture of lutein and L-α-phosphatidylcholine-β-oleoyl-γ-stearoyl has been investigated using absorption and photoacoustic spectroscopies. Both methods, confirmatively, reveal that the two carotenoids are mostly in a monomer state coexisting with carotenoid crystals. We observe that the absorption as well as the photoacoustic bands are red-shifted relative to the bands in solution. The absorption bands are found to peak at mean values of 440.0, 464.8, and 503.8 ± 0.5 nm for lutein, and at 452.7, 475.9, and 513.7 ± 0.5 nm for zeaxanthin. The photoacoustic peaks are situated at 444.0, 467.2, and 502.4 ± 0.5 nm for lutein, and 455.4, 473.8, and 509.0 ± 0.5 nm for zeaxanthin. Diluting lutein monolayer with the phospholipid results into a blue-shift of the absorption bands compared with those of the pure carotenoid monolayer and the macular pigment spectra. The results are discussed in connection with the Haidinger's brushes. It is concluded that lutein molecules might not be mixed with membrane lipids in the macular tissue, but form a monolayer protruding from the Henle fiber membranes to form the Haidinger's brushes in the macula.

C. N. N'SOUKPOÉ-KOSSI et R. M. LEBLANC. Can. J. Chem. **66**, 1459 (1988).

Faisant appel à des méthodes spectroscopique d'absorption et photoacoustique, on a étudié l'état moléculaire d'une monocouche simple de lutéine, de zéaxanthine ainsi que d'un mélange de lutéine et de la L-α-phosphatidyl β-oléoyl γ-stéaroyl choline. Les deux méthodes confirment que les deux caroténoïdes existent principalement dans un état monomère qui coexiste avec des cristaux de caroténoïde. On a observé que, par rapport aux bandes en solution, l'absorption ainsi que les bandes photoacoustiques sont déplacées vers le rouge. On a trouvé que les bandes d'absorption ont une intensité maximale à des valeurs moyennes de 440,0, 464,8 et 503,8 ± 0,5 nm pour la lutéine et à 452,7, 475,9 et 513,7 ± 0,5 nm pour la zéaxanthine. Les pics photoacoustiques sont situés à 444,0, 467,2 et 502,4 ± 0,5 nm pour la lutéine et à 455,4, 473,8 et 509,0 ± 0,5 nm pour la zéaxanthine. Lors de la dilution de la monocouche de lutéine avec le phospholipide, les bandes observées sont déplacées vers le bleu par rapport à celles obtenues dans le spectre de la monocouche de caroténoïde pur ainsi dans celui du pigment maculeux. On discute des résultats en fonction des brosses de Haidinger. On en conclut que les molécules de lutéine ne sont peut être pas mélangées avec les lipides membranaires dans le tissu maculeux; toutefois, elles forment une monocouche faisant saillie par rapport aux fibres membranaires de Henle et elles conduisent à la formation des brosses de Haidinger dans la macule.

[Traduit par la revue]

Introduction

The presence of carotenoids has often been observed in biological membranes (1–4). They belong to the most widely distributed pigments in the animal kingdom (1, 5, 6). Particularly seen in photosynthetic units (1, 2), in vertebrate retina macula (3, 4, 7–9) and in cone oil droplets of some animals (10–14), they are linked with photoprotection of photosensitive pigments (15–20). Among them, lutein and zeaxanthin are the most widespread carotenoid alcohols in nature which are responsible for the yellow colour of human retina macula (9), the site of localization of the structures responsible for Haidinger's brushes (21). The brushes are attributed to the directional organization of the carotenoid molecules in the membranes of Henle's fibers (i.e. the inner segments of cone receptor cells (21)). Because of their great ability to absorb light quanta due to their polyenic chain, carotenoids can easily be studied by photometric methods. Yet, their spectroscopic properties are far from clear. It has been observed that carotenoids undergo changes in their molecular state which are associated with changes in their spectroscopic properties (21–27). Most of these studies have been performed in solution and liposomes, and it has been reported that carotenoids could be in some aggregate state (23, 25–27, 28–30) or crystalline state (21, 31) depending on the experimental conditions. The monolayer model has also been employed to study properties of carotenoid molecules (29, 31–38).

One important question to be answered would certainly be: what is the aggregation state of the carotenoids in the macular tissue? The monolayer model (Langmuir–Blodgett films) is known to match the packing pattern of molecules in biological membranes or similar structures. The comparison of the spectroscopic properties of the carotenoids in Langmuir–Blodgett films with those of the macular pigments can answer the above question and help us better understand the structural organization underlying the important role of protection against photooxidation ascribed to the macular pigments. To do this, two independent spectroscopic methods, i.e., absorption and photoacoustic spectroscopies have been used in conjunction with the monolayer methodology.

Materials

All the solvents used were distilled as follows: benzene (BDH Chemicals, Montréal, Québec, Canada) at 80°C in a glass bead column, and ethanol (Les Alcools de Commerce Ltée, Ville St-Laurent, Québec, Canada) at 78.5°C in a Vigreux column; the first 200 mL served to rinse the column. Water used for the monolayer work has been first filtered and deionized in a nanopure Barnstead column (Fisher Chem. Co., Montréal, Québec, Canada) to obtain specific resistivity of 16–18 MΩ cm and then bidistilled in a quartz distillation system (Heraeus Quarzschmelze BmbH Produktbereich Infrarot, Hanau 1, W. Germany): the surface tension was equal to or higher than 71 mN m^{-1}. Zeaxanthin was obtained from Hoffmann-La Roche Co. (Basle, Switzerland). Highly purified all-*trans*-lutein was supplied by Drs. Bone and Landrum of the International University of Florida (Miami, U.S.A.). The spectrophotometric measurements were per-

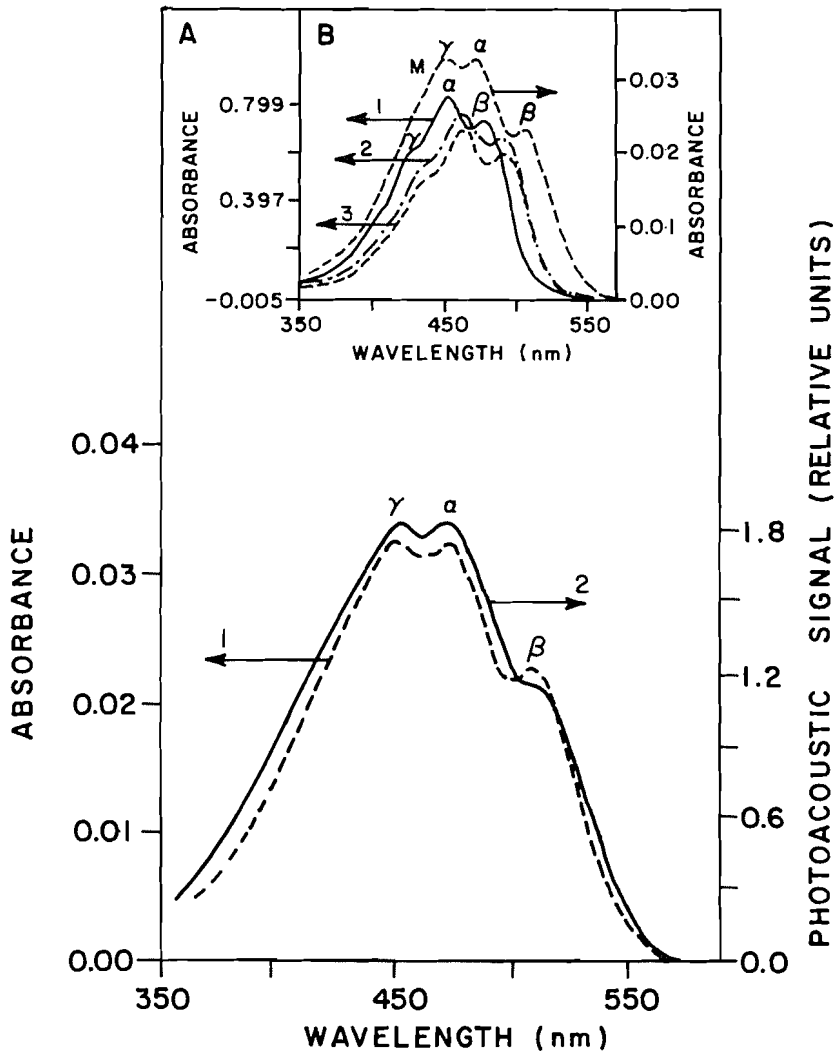

FIG. 1. (*A*) Absorption (curve 1) and photoacoustic (curve 2) spectra of a zeaxanthin single monolayer. (*B*) Absorption spectra of zeaxanthin solution in ethanol (curve 1), benzene (curve 2) and in benzene–ethanol (9:1, v:v) mixture (curve 3). Concentration: 6.40×10^{-5} mol dm^{-3}; pathlength: 1 mm. Curve M is the absorption spectrum for a single monolayer.

formed with a Perkin-Elmer 553 spectrophotometer. For the photoacoustic determinations, a home-made photoacoustic spectrometer (39–43) provided with Challenger II or Apple II computer was utilized. The power of the incident beam given by a xenon lamp (Conrad-Anovia, West Germany) was about 5 to 15 W m^{-2} in the spectral range used, i.e., from 350 to 600 nm.

Methods

Monolayer preparation

The carotenoid (lutein or zeaxanthin) were dissolved in a mixture of benzene: ethanol (9:1, v:v) which has been at first bubbled with argon. The solutions were stored in small vials (~3 mL) filled with argon and closed with mininert valves (Chromatographic Specialties Ltd., Brockville, Ont., Canada). The concentrations of the solutions were adjusted to $(2–4) \times 10^{-4}$ mol dm^{-3}. The fresh solution, protected against light by wrapping the vial with aluminium foil was used within 3 days under argon or nitrogen atmosphere to avoid oxidative damage. A Langmuir-type film balance provided with a vibration-free hydraulic deposition system (44) was used. As solid support for the monolayers, we used two quartz disks, 2.54 cm in diameter (Esco Product Inc., Oak Ridge, New Jersey, U.S.A.) joined face-to-face along their rims by paraffin wax. This arrangement allows for adsorption of a single monolayer on only one face of each slide when lifted from the subphase. The support was immersed into the aqueous subphase, the carotenoid solution (~150 μL) spread at the interface and after having waited for about 10 min, the molecules were compressed at a speed of $\sim 10^{17}$ Å^2 min^{-1} to the desired pressure (i.e., 5 and 25 mN m^{-1}). The support was then lifted without vibration with the hydraulic deposition device at a speed of 0.61 cm min^{-1} and constant surface pressure (5 or 25 mN m^{-1}). The reason for depositing the monolayer at these surface pressures comes from the interest to know about the state of the monolayers below and above a *plateau* observed at about 5 mN m^{-1} in the π–*A* isotherm (N'soukpoé-Kossi *et al.*, submitted for publication). After the deposition, the slides were separated carefully and mounted in a special holder which was placed in an aluminium foil-wrapped beaker in the presence of argon. The monolayers were immediately analyzed by two independent methods (absorption and photoacoustic spectroscopies) to avoid introduction of spurious instrumental signals in the results.

Spectroscopic measurements

All of the absorption measurements were performed under nitrogen atmosphere, at normal incidence, and at temperature between 23 and 25°C. The absorption spectra were recorded from 350 to 600 nm at a speed of 60 nm min^{-1}, bandwidth: 1 nm. The wavelength of peaks and subpeaks, and their intensity ratios (spectral ratios) were compared with those of spectra in solutions, in PVA, in liposomes and *in vivo* tissue. The absorption coefficients (α') and the optical absorption length ($\mu_{\alpha'}$) of the monolayers were also calculated.

The photoacoustic (PA) measurements were carried out at normal incidence and room temperature. The PA spectra were recorded from

350 to 600 nm at a speed of 50 nm min^{-1} at a modulation frequency of 100 Hz; the bandwidth was 10 nm and time constant of the lock-in amplifier was 1.25 s. Usually, the PA spectra were measured on the same monolayers as the ones used for absorption. However, sometimes one of the pair of slides bearing the monolayer was used for absorption and the other one for photoacoustic spectroscopy. The PA spectra for the carotenoids were normalized against that of carbon black under the same experimental conditions. Details of the theory and methods of photoacoustic spectroscopy are reviewed elsewhere (45, 46).

Results

The carotenoid monolayers were observed to be very unstable: when the compression was stopped, a drop in the surface pressure occurred. To prevent this drop in pressure we deposited the monolayer onto the support immediately after the desired pressure was reached and maintained the surface pressure constant by keeping the compression on. The deposition ratio was found to be usually greater than 1.2 indicating that some unidentified process responsible for reduction of surface pressure was in course. This instability was observed for pure monolayers of lutein and zeaxanthin. The addition of a phospholipid stabilized the films: this stabilizing effect was true for lutein mixed with L-α-phosphatidylcholine-β-oleoyl-γ-stearoyl for carotenoid molar ratio of 0.10 to 0.50. Zeaxanthin has not been tested for this stabilizing effect.

The absorption and photoacoustic spectra of a pure zeaxanthin monolayer are shown in Fig. 1*A* and the absorption spectra in solution in Fig. 1*B*. We notice that all spectra display three peaks and subpeaks in the visible that we name α, β, and γ in the decreasing order of their intensities in solution. The peaks are bathoshifted in the monolayer (Fig. 1*B*, curve M) compared with solution (Fig. 1*B*, curves 1, 2, 3), and excellent accordance is observed between absorption and PA spectra of the monolayer (Fig. 1*A*, curve 1 vs. curve 2). The absorption and PA bands have been characterized not only by their positions, but also by their respective spectral ratios (i.e., α/β and α/γ). The mean values were found to be 452.7, 475.9, and 513.7 ± 0.5 nm for the absorption bands, and 455.4, 473.8, and 509.0 ± 0.5 nm for PA bands. The spectral ratios are shown in Table 1.

The results obtained for a lutein monolayer are shown in Fig. 2. Figure 2*A* represents the absorption (curve 1) and PA (curve 2) spectra of a pure lutein monolayer with average values of 440.0, 464.8, and 503.8 ± 0.5 nm for the absorption bands, and 444.0, 467.2, and 502.4 ± 0.5 nm for the PA bands. Similar to zeaxanthin, we observed a bathoshift for the spectra of the

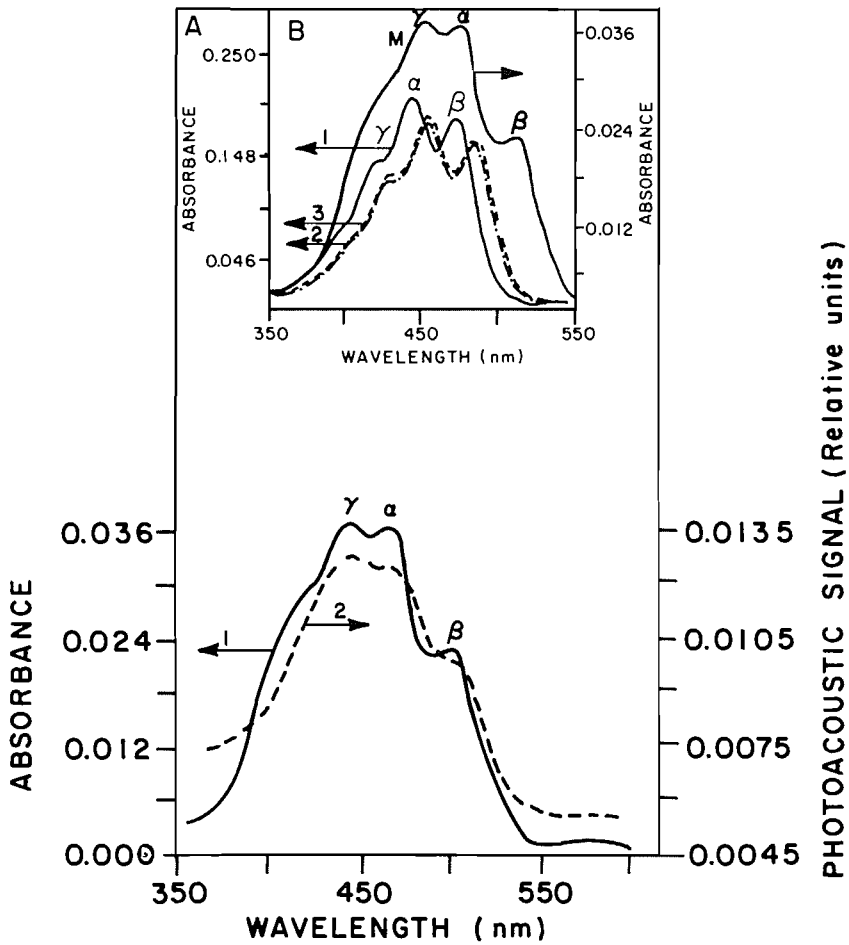

FIG. 2. (*A*) Absorption (curve 1) and photoacoustic (curve 2) spectra of a lutein single monolayer. (*B*) Absorption spectra of lutein solution in ethanol (curve 1), benzene (curve 2) and in benzene–ethanol (9:1, v:v) mixture (curve 3). Concentration: 1.85×10^{-5} mol dm^{-3}; pathlength: 1 mm. Curve M is the absorption spectrum of a single monolayer.

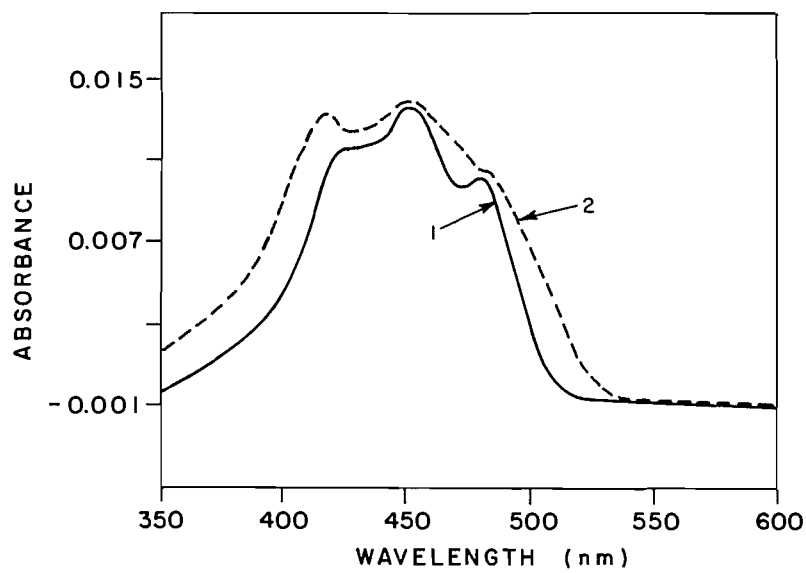

FIG. 3. Absorption spectra of two monolayers of lutein mixed with L-α-phosphatidylcholine-β-oleoyl-γ-stearoyl (1:1, mol:mol) deposited at a surface pressure of 5 mN m^{-1} (curve 1) and at 25 mN m^{-1} (curve 2).

monolayer in comparison with solution (Fig. 2*B*) resembling the absorption spectrum *in vivo* shown in Fig. 4, curve 4. Here also, a good agreement is observed between absorption and PA spectra of the monolayer (see positions of peaks and their relative intensities in Table 1).

Now, it appears interesting to investigate the packing pattern of carotenoid molecules in monolayer. To do this, we have measured the absorption spectra of mixtures of lutein and phosphatidylcholine. The molar ratios of lutein were 0.50, 0.40, 0.30, 0.25, 0.16, and 0.10. The deposition surface pressures

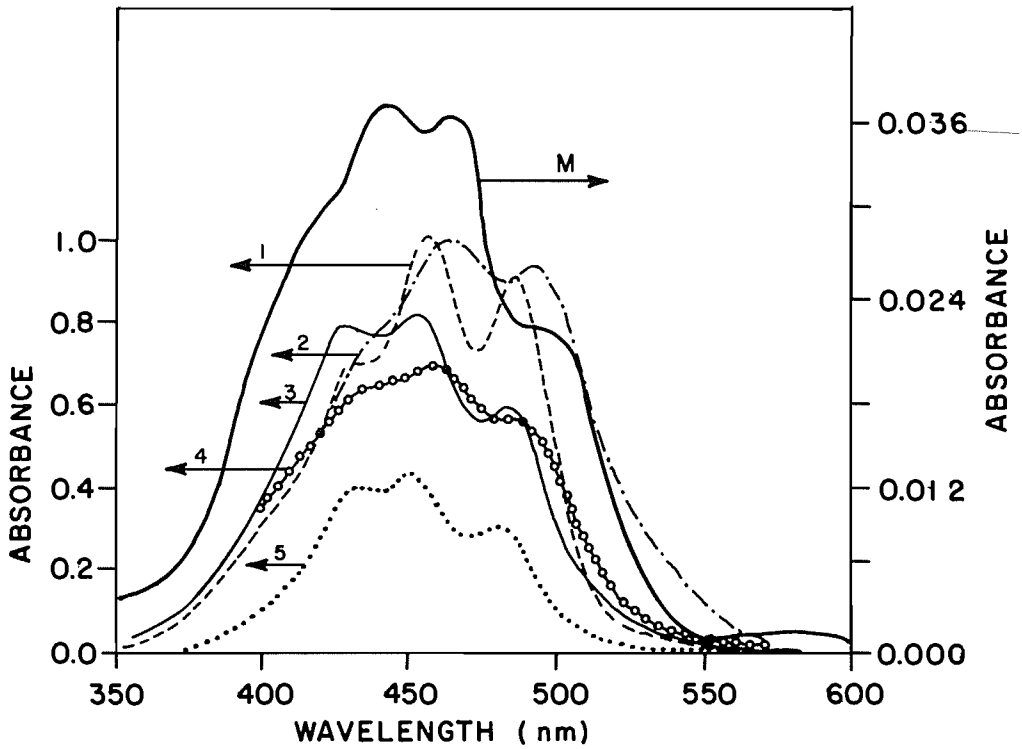

FIG. 4. Absorption spectra of lutein in different media: in benzene-ethanol (9:1, v:v) solution (curve 1), in polyvinyl alcohol (curve 2, taken from ref. 21), in mixed monolayer (lutein–PC, 1 mol:1 mol) at 5 mN m^{-1} (curve 3), *in vivo* (curve 4, taken from ref. 3), in phospholipid liposomes (curve 5, taken from ref. 21), and in a single monolayer (curve M).

were 5 and 25 mN m^{-1}. Among all the molar ratios tried, only two (0.50, 0.40) gave a measurable signal in absorption. The absorption spectra of monolayers deposited at 5 and 25 mN m^{-1} for lutein–PC (molar ratio of 0.50) mixture are shown in Fig. 3. There is no significant difference between the two curves (λ of peaks are 425.3, 450.0, and 479.2 ± 0.5 nm for 5 mN m^{-1}, and 418.0, 450.0, and 484.0 ± 0.5 nm for 25 mN m^{-1}). The absorption spectra have shifted to blue relative to pure lutein monolayer and fairly well reproduce the absorption bands in liposomes (Fig. 4; curve 3 vs. curve 5: curve 3 is the absorption spectrum of the mixed monolayers deposited at a surface pressure of 5 mN m^{-1} and curve 5 is that for lutein-containing liposomes (21)). The blue-shift amounts to 14.6 to 24.5 nm depending on the band, the largest shift occurring for β-bands. The spectral ratios are indicated in Table 1. Attempts to record the photoacoustic spectra of mixed lutein–phospholipid monolayer were unsuccessful, the signal being too weak and too noisy.

In some of our experiments we oberved deformation of the absorption spectra with a concomitant deformation of PA signals compared with what we usually obtained. Examples of this are given in Fig. 5. In Fig. 5*A*, we can see the appearance of a shoulder at about 425.0 nm for zeaxanthin (curve 1) and at about 410 nm for lutein monolayers (curve 2), or in a more pronounced form with a well-defined peak at 380.0 nm (Fig. 5*A*, curve 3). Curve 4 in Fig. 5*A* is another case of deformation of the absorption band (of lutein monolayer). In all these cases, when the monolayer is dissolved into benzene–ethanol (9:1, v:v) mixture, the absorption spectrum of fresh solution is restored as indicated in Fig. 5*C* where curve 1 is the spectrum of fresh lutein solution and curve 2 is that of the solubilized lutein monolayer. This clearly indicates that there was no chemical change in the molecules, but only a change in the state. In Fig. 5*B* we see the absorption and photoacoustic spectra of a typical monolayer displaying this peculiar blue-shift. As discussed later, the growth of these shorter-wavelength peaks is caused by the crystallization of the carotenoids.

To set a basis of comparison for further work, some photometric parameters have been derived. For instance, the extinction coefficient[1] of the carotenoid monolayer has been found to be 9.43×10^7 cm^2 mol^{-1} (or 1.57 $Å^2$ $molecule^{-1}$) for pure zeaxanthin and 8.27×10^7 cm^2 mol^{-1} (or 1.37 $Å^2$ $molecule^{-1}$) for pure lutein, using a molecular area at 25 mN m^{-1} of 37 $Å^2$/molecule for zeaxanthin and 41.5 $Å^2$/molecule for lutein. The mean absorbance (A) was 0.042 and 0.031 for zeaxanthin and lutein monolayers, respectively. The unexpectedly lower absorbance value obtained for lutein monolayer compared with that of zeaxanthin probably reveals the presence of much more pinholes in lutein than in zeaxanthin monolayers.

If we know the thickness of the monolayer, the coefficient of optical absorption ($\alpha' = 2.3A/l$), a useful photoacoustic parameter, can be easily calculated. According to Zsako *et al.* (37), the length of carotenoid molecule is 32.0 Å and the molecular diameter, D, is 7.82 Å. Considering that in the monolayer, zeaxanthin and lutein molecules form an angle, θ, of 47.1° and 48.6°, respectively, with the plane of the support (N'soukpoé-Kossi *et al.*, submitted for publication), the thickness of their monolayers comes to be 32 Å $\sin\theta + D\cos\theta$; that gives 28.7 Å for zeaxanthin monolayer and 29.2 Å for lutein monolayer. Therefore, $\alpha'_{Zea} = 3.3 \times 10^5$ cm^{-1} and $\alpha'_{Lut} = 2.4 \times 10^5$ cm^{-1}.

[1]The extinction coefficients in ethanol solution as deducted from the results of Strain (47) are 1.442×10^8 cm^2 mol^{-1} and 1.448×10^8 cm^2 mol^{-1} for zeaxanthin and lutein, respectively. The fact that the absorption coefficients we have found for the monolayers are lower than those in solution may be an indication of inhomogeneity, e.g. presence of empty spaces in the monolayer film, or/and the consequence of different interaction media.

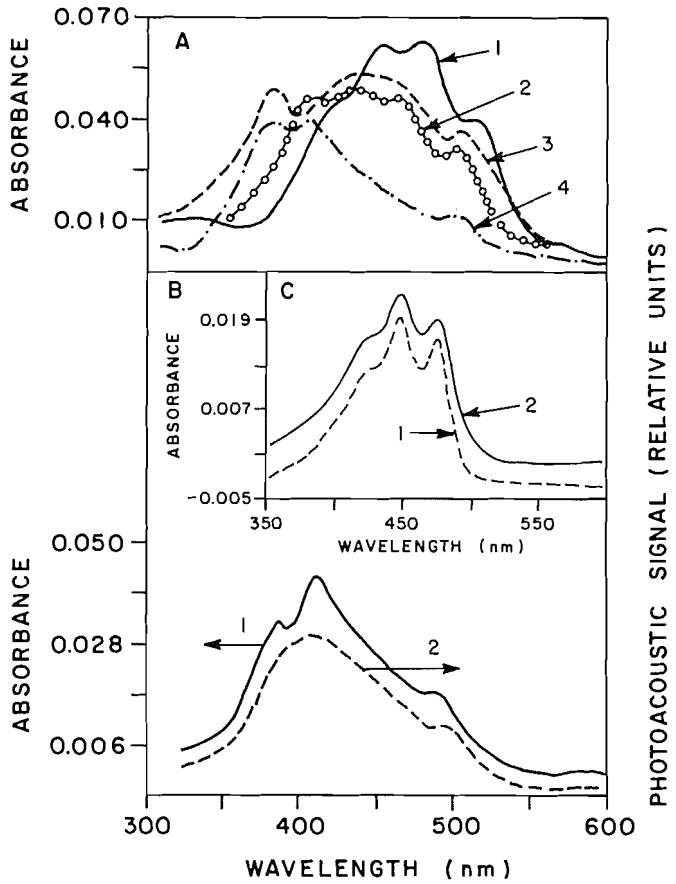

FIG. 5. (*A*) Absorption spectra showing different degrees of crystallization of a single zeaxanthin monolayer (curve 1) and of single lutein monolayers (curves 2 through 4). (*B*) Absorption (curve 1) and photoacoustic (curve 2) spectra of a typical crystallized lutein monolayer. (*C*) Absorption spectra of fresh lutein solution (curve 1) and of crystallized lutein monolayer dissolved in benzene–ethanol (9:1, v:v) mixture (curve 2).

The optical absorption length, $\mu_{\alpha'} = \alpha'^{-1}$ (45) is found to be 30.3 nm for zeaxanthin and 41.2 nm for lutein. The optical absorption length is much larger than the thickness. Under these circumstances, it is quite normal that electronic and PA spectra coincide as we observed, since the carotenoid monolayers are transparent from photoacoustic point of view. The small discrepancy observed between the absorption band maxima and the corresponding photoacoustic ones could simply be accounted for by the lesser resolution power for the PA spectrometer and bandwidth of which was set at 10 nm in order to obtain greater and noise-free signal while the bandwidth of the spectrophotometer was 1 nm.

Discussion

Stability of the carotenoid Langmuir–Blodgett films

One of the more striking features of carotene and carotenoid-monolayers is probably their instability reflected by rapid drop in the surface pressure as soon as the compression is stopped (32). But mixed with phospholipid, lutein forms stable monolayers as we point out in this paper in contrary to the observation reported by Lejeune and Tric (31) on β-carotene mixed with some fatty acid. The failure of the preparation of mixed monolayer of β-carotene and fatty acid has been explained by the absence of polar group in β-carotene that could interact with fatty acid polar groups (31). Two years later, Pincus *et al.* (33) succeeded in preparing stable monolayers of β-carotene mixed with arachidic acid which were easily transferred onto glass slides. In 1978, Ohnishi *et al.* (48) reported the work on monolayers of β-carotene mixed with barium stearate. In the case of lutein which possesses a polar group at each end, strong interactions with the polar head group of the lecithin are possible thereby favouring formation of stable monolayers.

Spectroscopic properties of the carotenoid Langmuir–Blodgett films

Of great importance are the spectroscopic properties of carotenoid monolayers in order to know their state and organization in the films. We begin by discussing about the shift of the absorption spectrum of the carotenoid monolayer relative to solution. As indicated in Figs. 1 and 2, the absorption and photoacoustic spectra of zeaxanthin (Fig. 1*A* vs. Fig. 1*B*) and of lutein (Fig. 2*A* vs. Fig. 2*B*) monolayers are shifted toward red relative to the spectra of solutions. Compared with ethanolic-solution spectra, the mean shift was 29.0 nm for zeaxanthin and 22.7 nm for lutein. The shift was smaller compared with benzene or benzene:ethanol (9:1, v:v) solutions, i.e., 17.3 nm for zeaxanthin and 11.4 nm for lutein monolayers. The largest shift was observed for β-band in all cases (Table 1). This bathochromicity of the monolayers can be explained by π–π electron interactions along the polyenic chains due to close packing of the molecules in a "head-to-tail" manner (49). If this is so, we should expect a decrease of the magnitude of the red-shift when the monolayer is diluted, with a concomitant change in the spectral ratios. In order to investigate the packing model of the carotenoid molecules in the monolayer, the absorption spectra of lutein when mixed with L-α-phosphatidylcholine-β-oleoyl-γ-stearoyl were measured. The results presented in Fig. 3 clearly support the "head-to-tail" model according to which reduction of the magnitude of the red-shift would be observed (49). Indeed, the absorption spectra of mixed monolayers of lutein and L-α-phosphatidylcholine-β-oleoyl-γ-stearoyl are blue-shifted relative to pure lutein monolayer and the macular tissue. The intermolecular interactions involved here resulted in changes in the spectral ratios of the absorption spectra compared with solutions (see Table 1). In the diluted monolayers (especially at 5 mN m^{-1}), the spectral ratios match fairly well those calculated for liposomes (Table 1) according to the results of Bone and Landrum (21). Since the fine structure of the absorption spectra is due to vibrational modes, it is worth noting how much the intermolecular interactions in monolayers affect the relative intensities of these vibrational peaks.

Similar results concerning the bathochromicity have been reported for PVA films incorporated with lutein (21) as depicted in Fig. 4, curve 2 and on mixed monolayers of β-carotene and barium stearate (48). Our results, which are in accordance with these two papers, do not support entirely those of Lejeune and Tric (31). Rather, they observed a blue-shift in the absorption spectra of carotenoid aldehydes (β-apo 2′ carotenal and apo 4′ carotenal) monolayers deposited on glass slides at surface pressure 6, 8, 11, and 14 mN m^{-1}. A gradual blue-shift was observed for the unique peak from 430 nm to 417 nm. We occasionally have observed this kind of blue-shift for zeaxanthin and lutein monolayers (Fig. 5) which we consider to be due to crystallization of the monolayer. As we have recently observed, some crystallization may occur in the carotenoid film (Fig. 5) and was most visible in the π–*A* isotherm. This phenomenon was also observed by many authors in solution especially in presence of water (22, 24–27, 30) and by Lejeune and Tric (31) in air–water

interfacial β-carotene. Such hypsochromicity assigned to crystalline state of the carotenoid (21) can be explained by the excitonic coupling theory of McRae and Kasha (49). We believe that this crystallization process is responsible for the instability of the monolayer that was reflected by the drop in surface pressure.

The spectral similarity is intriguing between the crystallized lutein that we observed and the P410 pigment reported by Snodderly *et al.* (3) from microspectrophotometric recordings in the retinal macula of macaque monkeys. Both have absorbance maximum at 410 nm. At this time we do not see any objection against the P410 pigment being lutein crystals in the macular tissue.

From these observations some general conclusions can be drawn: (*1*) pure carotenoid monolayers present absorption and photoacoustic spectra red-shifted compared with solution and resemble the *in vivo* situation; (*2*) the spectrum in liposome can be reproduced by diluting the carotenoid monolayers; (*3*) the lutein molecules are arranged in a "head-to-tail" manner in the monolayer; (*4*) the spectral ratios which are reversed in monolayer relative to solution are reversible upon dilution; (*5*) in presence of water, a number of carotenoids and particularly lutein crystallize.

Molecular organization of lutein in the macula

The results presented here raise a number of questions: how are the carotenoid molecules organized in the macular tissue? In what state are they present? Do they exist as pure compounds or mixed with other pigments or lipids? Based solely on its spectral characteristics, human macula pigment has been identified as lutein (7, 8). But, quite recently, it has been found that human macula is most probably composed of lutein and zeaxanthin in almost equal quantities (9). Surprisingly, the absorption spectrum that we recorded for pure lutein monolayer matches fairly well that of the macula of macaque monkeys (3). Could this imply that lutein is the only carotenoid of macaque macula or probably the predominant one? This hypothesis could be tenable considering that the absorption spectrum of macaque macula presents only three peaks like lutein. This point remains to be clarified by other independent methods.

Now, the similarity between the macular spectrum and that of the lutein monolayer strongly suggests that the macular carotenoids, whatever they be, are highly organized, and most probably, in a monomolecular layer, in a "head-to-tail" manner. This assertion is in accordance with the finding that the macular tissue is dichroic (4). It may reasonably be assumed that the carotenoid layer is embedded in a lipid bilayer (21, 24). But, the blue-shift that we observed in the absorption spectra of mixed lutein and phosphatidylcholine monolayers compared with that of the macular pigment seems inconsistent with this hypothesis. Besides, it is hard to figure out a lipid bilayer structure in which carotenoid molecules would be incorporated when they have to lie at an angle of about 48° (N'soukpoé-Kossi *et al.*, submitted for publication) relative to the plane of the bilayer.

One further point to be made with respect to the molecular arrangement of carotenoid in the native tissue is the relationship between the carotenoid molecules and the Henle fiber membranes. As already reported (50, 51) the carotenoid molecules should be aligned at an acute angle to the membrane plane. In the dichroic macula (4), the greatest absorption was observed when the plane of polarization of the incident light was perpendicular to the axes of the Henle fibers, thereby accounting for the formation of the Haidinger's brushes. It has been proposed (21) that a fraction of the carotenoid molecules are aligned perpendicular to the cylindrically shaped fiber membranes. The remainder was assumed to have random orientations. We have calculated that, for a fiber as a whole to absorb light more strongly which is polarized perpendicular to its axis, rather than parallel, this angle would have to exceed approximately 35°. Our measured angles (N'soukpoé-Kossi *et al.*, submitted for publication) are equal to or greater than 45°, in accordance with these calculations and macula dichroism measurements (4). Since the macular pigment appears to be highly organized and does not seem to be really mixed with lipids as reflected by our results, it can consequently be suggested that the pigment is arranged in a monolayer protruding from the Henle fiber membrane at a mean angle of 48° forming the Haidinger's brushes. This seems to be a reasonable conclusion based on the similarities between the spectroscopic properties of the Langmuir–Blodgett carotenoid films, on those of the macular pigments and on dichroic properties of the macula.

Conclusion

We have given a reasonable concept of the macular structure. While a definite characterization of this system should wait for additional work, we expect this hypothesis to stimulate further investigations. It is very interesting that carotenoid monolayers exhibit spectroscopic properties similar to those of the macular pigment. As characterized, carotenoid monolayers represent a useful tool for the study of macular carotenoids. The use of photoacoustic spectroscopy, apart from supporting the absorption data, adds an especially interesting advantage. Being a non-destructive probe, it can be conveniently applied to *in vivo* samples and any material for which conventional spectroscopic methods are not suitable.

Acknowledgments

The authors would like to thank Drs. R. A. Bone and J. T. Landrum of the International University of Florida for having supplied lutein samples for this study. We are also grateful to Miss Louise Leblanc for her help in the course of this research and to Drs. S. Hotchandani and J.-J. Max for commenting on this paper. This paper is dedicated to Dr. John T. Edward

CARMEN AVENDAÑO, MARÍA TERESA RAMOS, JOSÉ ELGUERO, MARÍA LUISA JIMENO, JUANA BELLANATO, and FELICIANA FLORENCIO. Can. J. Chem. **66**, 1467 (1988).

Tautomerism of dibenzothiazolylmethane (**1**) and its *C*-methyl derivative (**2**) has been studied by ^{1}H nuclear magnetic resonance, ultraviolet, and infrared spectroscopy using *C*,*C*-dimethyl (**3**) and *N*-methyl (**4**) derivatives as model compounds of the "CH" and "NH" forms, respectively. X-ray diffraction analysis of the "fixed" *N*-methyl derivative **4** shows that it corresponds to the *Z-sE* isomer **4***b*$_2$. The CH tautomers are unstable in solution and they slowly isomerize into a mixture of NH tautomers that depends on the solvent and on the *C*-substituent (H or CH_3).

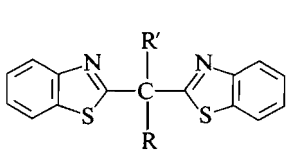
CARMEN AVENDAÑO, MARÍA TERESA RAMOS, JOSÉ ELGUERO, MARÍA LUISA JIMENO, JUANA BELLANATO et FELICIANA FLORENCIO. Can. J. Chem. **66**, 1467 (1988).

Faisant appel à la résonance magnétique nucléaire du ^{1}H ainsi qu'à la spectroscopie ultaviolette et infrarouge et utilisant les dérivés *C*,*C*-diméthylé (**3**) et *N*-méthylé (**4**) comme modèles, on a étudié la tautomérie du dibenzothiazolylméthane (**1**) et de son dérivé *C*-méthylé (**2**). Une étude par diffraction des rayons-X effectuée sur le dérivé *N*-méthyle «figé» (**4**) démontre qu'il correspond à l'isomère *Z-sE* (**4***b*$_2$). En solution, les tautomères CH sont instables et ils s'isomérisent lentement en un mélange des tautomères NH dont la composition dépend du solvant et du substituant porté par le carbone (H ou CH_3).

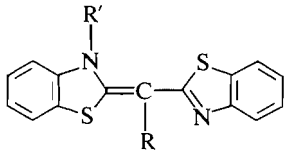
[Traduit par la revue]

Introduction

In a previous work on the synthesis of aryl(heteroaryl)dibenzothiazolylmethanes (**2**, R = aryl or heteroaryl, R′ = H) (1), we reported that their ^{1}H nmr spectra, even at 300 MHz, were extremely complex and time dependent. This is due to the superimposition of two phenomena: CH/NH tautomerism and air oxidation to carbinols or even to ketones (R = H). In this paper only the first problem will be examined. We report here a careful study of the tautomerism of dibenzothiazolylmethane **1** and its *C*-methyl derivative **2** as a preliminary and necessary step in understanding the more complex case of the aryl(heteroaryl) substituted compounds.



a



b

1 R = R′ = H
2 R′ = H; R = CH_3
3 R = R′ = CH_3 **4** R′ = CH_3; R = H

Although the tautomerism of diquinolylmethanes has been studied in detail (2), the question of whether unsubstituted dibenzothiazolylmethane (DBM, **1**) and its derivatives with one substituent attached to the methane carbon atom only exist in the CH form (*a*, R′ = H), or whether they are capable of tautomerizing to the enamine NH form (*b*, R′ = H), has given rise to some speculations, often based on insufficient experimental evidence (3–5). Because of conjugation, the *b* forms, which are heterocyclic analogues of enaminoketones, have barriers to rotation of comparable energy about both C—C bonds (6), justifying the possible existence of four isomers (b_1–b_4) when R′ ≠ H.

If R′ = H, prototropy must also be considered. In this case, tautomerism of b_1 and b_3 isomers yields the same compounds, b_1 and b_3, respectively (autotropic prototropy). The only difference is that in the *E-sE* structure, the activation energy of

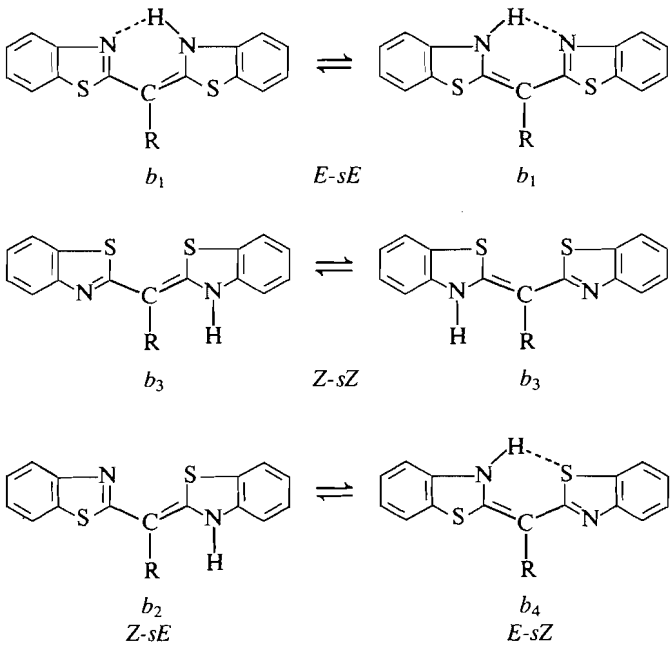

SCHEME 1

the intramolecular $b_1 \rightleftarrows b_1$ process should be very low (as in the enol form of β-diketones) and only averaged signals should be expected in nmr, whereas in the case of *Z-sZ* isomer the $b_3 \rightleftarrows b_3$ intermolecular interconversion would be relatively slow (Scheme 1). Finally, tautomerism interconverts b_2 and b_4 structures. In conclusion, when R′ = H, at most three different structures can be observed in ^{1}H nmr: *E-sE*, *Z-sZ*, and *Z-sE* (or *E-sZ*).

Compounds **3** and **4** have been chosen as fixed *a* and *b* tautomers respectively, **1** and **2** being representatives of compounds capable of tautomerism. Finally, compound **5** (R = CH_3), the cyanine dye obtained by methylation of **4**, is also included in this study.

The structural analysis was undertaken by ^{1}H nmr, uv, and ir spectroscopy in all cases and by X-ray diffraction analysis for compound **4**.

Experimental

Synthesis

Compounds **1**, **4**, and **5** were obtained following literature references (7, 8). Compound **2** was prepared by two different methods: by using *o*-aminothiophenol and diethyl methylmalonate in polyphosphoric acid (according to experimental conditions described for analogous compounds in ref. 1) and by the cross-coupling reaction of 2-chlorobenzothiazole with 2-ethylbenzothiazole in the presence of *n*-butyllithium.[3] Both methods afforded a syrup, identified as **2***a*, which solidified on standing. From this solid, chromatography over aluminium oxide (eluent: hexane/ethyl acetate, 9:1) yielded a compound, mp 165°C, identified as **2***b*.

Compound **3** was obtained as a minor product in the reaction of diethyl dimethylmalonate with *o*-aminothiophenol following the experimental conditions described in ref. 1 (the main product was 2-isopropylbenzothiazole as the result of a monocondensation–decarboxylation reaction). Its melting point was identical to that given for this compound in ref. 3 (132°C), in contrast to ref. 4, which gives 157°C.

X-ray crystallographic analysis of compound 4

A crystal of about 0.1 × 0.2 × 0.3 mm was mounted along the long axis. The cell dimensions were refined from 47 general reflections with the Bragg angle $\theta_{max} = 48°$ on an Enraf–Nonius CAD4 diffractometer. Crystal data are

$C_{16}H_{12}N_2S_2$ fw = 296.40

Monoclinic, $P2_1/a$, $a = 14.868(1)$, $b = 10.850(1)$, $c = 8.653(1)$ Å, $\beta = 104.65(1)°$, $V = 1350.5(3)$ Å^3, $Z = 4$, $\rho_c = 1.458$ g cm^{-3}, CuK_α, $\lambda = 1.5418$ Å (graphite monochromator), $\mu = 34.180$ cm^{-1}, $F(000) = 616$.

A total of 2371 independent reflections were measured in the range $2 < \theta < 65°$ (above this value, the reflections were very weak), of which 1973 were considered as observed with the criterion $I > 2\sigma(I)$. Two standard reflections were measured every 90 min. No decomposition was detected during processing; corrections were made for Lorentz and polarization effects, but not for extinction.

Structure was solved by direct and Fourier methods and refined by full-matrix, least-squares procedures, minimizing $\Sigma w(\Delta F)^2$ with isotropic temperature factors on all the atoms. An absorption correction following the DIFABS procedure (10) was applied to isotropically refined data, maximum and minimum absorption factors being 0.973 and 0.782 respectively. Refinement was continued by full-matrix least-squares with anisotropic temperature factors on all atoms including the hydrogen atoms (from difference synthesis) with isotropic temperature factors, and it converged with $R = 0.055$ and $R_w = 0.053$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$ with $w = k/\sigma_1^2\sigma_2^2$, $\sigma_1 = a_1 + b_1(F_o)$, $\sigma_2 = a_2 + b_2(\sin\theta/\lambda)$, and $k = 0.569$ (11); $(\Delta/\sigma)_{max} = 0.05$, residual electron density in final difference map 0.20 e Å^{-3}, $s = 1.48$.

The atomic scattering factors are taken from the literature (12). The computations were performed on a VAX 11/750 using MULTAN 80 (13) and XRAY 76 (14) programs.

^{1}H nuclear magnetic resonance study

The ^{1}H nmr spectra were obtained on a Varian XL-300 spectrometer operating at 300 MHz and on a Bruker AM-200 spectrometer operating at 200 MHz, using $CDCl_3$ and DMSO-d_6 as solvents and TMS as internal standard.

The typical instrumental parameters were as follows: sweep width, 3000 Hz; flip angle, 52°; acquisition time, 5 s; and data size, 32 K.

To assign and determine chemical shifts and coupling constants, computer assisted analyses of the four-, five-, and eight-spin systems were performed with the iterative program PANIC 81 on a Bruker Aspect 2000 computer. The eight-spin systems were treated like two subsystems of four spins, using an additional routine for obtaining the experimental envelope. The errors in the chemical shifts and coupling constants were estimated to be ±0.04 Hz and ±0.06 Hz respectively and the standard deviation between the observed and calculated line frequencies was 0.07 Hz.

Infrared spectra

Infrared spectra were recorded on a Perkin–Elmer 599B spectrophotometer. Indene and polystyrene were used for instrument calibration. All compounds were compressed into KBr pellets. Spectra in deuterated dimethylsulfoxide, deuterated chloroform, and carbon tetrachloride solutions at different dilutions were also recorded.

[3]A similar reaction using *n*-butylmagnesium bromide instead of butyllithium has been reported (3).

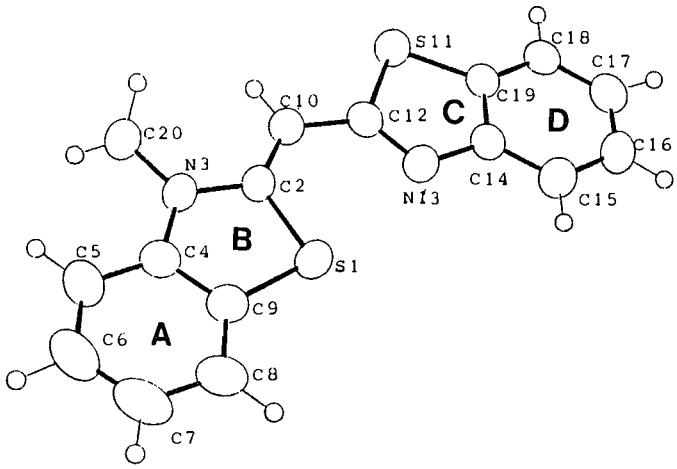

FIG. 1. A view of a molecule of compound $4b_2$ with atom numbering.

Raman spectra were measured for some samples on a Jobin Yvon U 1000 (5145 Å) spectrometer in the solid state and in $CDCl_3$ solutions.

Ultraviolet spectra

Ultraviolet spectra were recorded in ethanol (10^{-5}–10^{-6} M solutions) between 500 and 200 nm on a Bausch and Lomb Spectronic 2000 spectrophotometer.

Results and discussion

X-ray study

Crystallographic numbering (Fig. 1) has been used in this section and in Tables 1 and 2. Figure 1 shows a projection of compound **4** that corresponds to the *Z-sE* isomer b_2. Table 1 gives the final atomic coordinates while interatomic distances and interbond and torsion angles are given in Table 2.[4] The molecular rings are planar (mean torsion angles 0.7(7), 0.7(4), 1.3(5), and 1.2(7)° for A, B, C, and D rings respectively). The two fused rings that form each benzothiazolyl group are situated approximately in a plane (the dihedral angles between the two six- and five-membered rings are 0.8(1) and 1.6(1)° respectively). The two benzothiazolyl groups form a dihedral angle of 3.95(6)° and the C_2—C_{10}—C_{12}—S_{11} and N_3—C_2—C_{10}—C_{12} torsion angles are 177.1(4) and 179.2(4)° respectively, corresponding to a *Z-sE* structure. Stereogeometry of this molecule is consistent with that found in other benzothiazole rings (15, 16).

There is no intra- or intermolecular interaction between the molecular atoms, therefore the molecular packing is only realized by van der Waals forces.

^1H nuclear magnetic resonance study

One of the main problems of this study was to assign the H4 and H7 benzothiazole protons. This assignment has been tentatively reported for benzothiazole itself by comparison with its 4-nitro derivative as δ H4 (8.23 ppm) > δ H7 (8.12 ppm) in CCl_4 (17). Solvent effects for 2-methylbenzothiazole have shown that the polarity of the solvent has a greater influence on the H7 proton than on the H4 (18, 19). Our data support these results and also show a new criterion for assigning protons H4 and H7 in benzothiazoles: $J_{45} > J_{67}$. This question will be discussed at the end of this section. Tables 3 and 4 contain the

chemical shifts and coupling constants of model compounds **3** (as a CH fixed form *a*) and **4** (as an NH fixed form *b*) respectively.

Protons H4 and H7 of **3** were assigned according to the downfield shift of H7 in DMSO-d_6 (Table 3). In ref. 3 only the value for the methyl group was reported.

In compound **4**, the chemical shifts of protons H4′ and H7′ are very different in the $CDCl_3$ and DMSO-d_6 spectra (Table 4). The H4′ proton has a rather low chemical shift in $CDCl_3$ and appears as a broad singlet because of a long-distance coupling constant with the *N*-methyl protons. This coupling has been checked by double irradiation.

The spectra of **1** in DMSO-d_6 and in $CDCl_3$ are given in Table 3. In both solvents, only the CH tautomer (**1***a*) was observed for this compound. The methylene protons appeared at δ 4.96 and 5.10 ppm in $CDCl_3$ and DMSO-d_6 respectively. A δ value of 4.92 ppm has been reported for the $CDCl_3$ solution of compound **1** (20). The spectrum in $CDCl_3$, obtained after several days, is characterized by a singlet at 7.14 ppm, besides the methylene signal at 4.96 ppm. The 7.14-ppm signal was attributed to the vinyl hydrogen of a *b* form. A broad signal at 8.45 ppm could be assigned to the NH proton of this tautomer. Leaving aside oxidation products, it is easy to calculate the following populations by measuring the integrals at 4.96 and 7.14 ppm: 78% of NH and 22% of CH tautomers. However, the CH/NH tautomerization is so slow that the aforementioned proportions may not correspond to the equilibrium mixture.

The two forms isolated for compound **2** gave different ^{1}H nmr

spectra. The solid one gave the parameters shown in Table 5. This form was characterized as the NH or *b* tautomer, mainly because the methyl protons appeared as a singlet. The NH proton was not clearly visible since it is included in the aromatic region of the spectrum.

The spectrum of the syrup **2** is characteristic of the CH tautomer **2***a* with its methyl signals at 2.08 and 1.97 ppm (doublet) and its CH proton at 5.13 and 5.34 ppm (quartet) in $CDCl_3$ and DMSO-d_6, respectively (Table 3). The values in $CDCl_3$ solution were in agreement with ref. 3. On standing, the spectrum of the chloroform solution changes: the doublet (CH_3) and the quartet (CH) decrease until they disappear, while two methyl singlets of progressively increasing intensities (δ 2.63 and 2.82 ppm) appear. At the end of the process, these two singlets correspond to populations of 44 and 56%, respectively. The 2.63-ppm signal is due to the isolated NH tautomer (Table 5), the other one (2.82 ppm) must correspond to another NH tautomer. In DMSO-d_6 solution, tautomer **2***a* was indefinitely stable (2 weeks).

A comparison of the above results with literature reports on benzothiazole and 2-methylbenzothiazole (18) concerning the assignment criteria (see above) shows: (*i*) the chemical shifts criterion, δ H4 > δ H7 in chloroform and δ H7 > δ H4 in DMSO-d_6 is fulfilled by all compounds save the *N*-methyl derivative **4**; (*ii*) the coupling constants criterion, $J_{45} > J_{67}$, is always valid.

For the monomethinecyanine **5** (R = CH_3), three different isomers can be proposed. G. Scheibe *et al.* (21) have described the analogous compound **5** (R = C_2H_5) as the *Z-sZ* isomer on the basis of the calculated oscillator strength value *f*. Since only one signal corresponding to the methyl protons was observed in the ^1H nmr spectrum of **5** (Table 6), a symmetrical (which excludes **5***b*) and planar structure must be present in solution. Since **5***a* is sterically crowded, we agree with Scheibe's conclusion about the *Z-sZ* structure, **5***c*, of the cyanine here studied.

Infrared study

Table 7 shows the characteristic ir bands of compounds **1–5**, including some Raman data.

According to the literature, the benzothiazole ring in 2-methylbenzothiazole was characterized (22) by three absorption

bands in the 1600–1500 cm^{-1} infrared region at 1592 (w), 1560 (m), and 1534 (s) cm^{-1}, which were respectively attributed to "thiazole I", aromatic $\nu C{=}C$, and "thiazole II". However, coupling between $\nu C{=}N$ and $\nu C{=}C$ makes it difficult to distinguish individual vibrations. Several other ir spectroscopic studies on benzothiazoles have been published and the fundamental vibrations assigned (23).

The three "benzothiazole bands" for compound **3** appeared at 1585 (vw), 1554 (w), and 1491 (vs) cm^{-1} in the solid state and were slightly shifted to higher frequencies in chloroform solution (1594 (vw), 1560 (vw), and 1500 (m) cm^{-1}). The Raman pattern in this region was similar.

The ir spectrum of compound **4** in the solid state was characterized by a very strong broad band at 1555 cm^{-1} (weak in Raman), a weak double band with maxima at 1592 and 1585 cm^{-1}, and two strong bands at 1491 and 1473 cm^{-1}. The results in chloroform and carbon tetrachloride were similar. According to literature data for compound **5** (24), the strong ir band at 1555 cm^{-1} of **4** can be assigned to coupled vibrations in the planar N=C—C=C system while the strong band at 1491 cm^{-1}, which is the predominant band in Raman, may also be related with this vibrational mode.

Infrared data for compound **1** in the solid state and in chloroform solution pointed to the same *a* structure as compound **3** discussed above, this assignment being in accordance with the ^1H nmr study. However, important changes took place in the spectrum of the chloroform solution (0.05 M) after several days. The intensity of the band at ca. 1505 cm^{-1} decreased and a strong new band appeared at ca. 1555 cm^{-1}. Results suggest a tautomeric transformation $\mathbf{1}a \rightarrow \mathbf{1}b_1$ in chloroform solution, although it must be remarked that the νN—H absorption could not be unequivocally assigned here. (A weak broad absorption band at ca. 3270 cm^{-1} was observed in some experiments.) When compound **1** was studied as a very dilute CCl_4 solution (0.002 M) and also at a greater concentration (0.025 M), a new broad complex absorption between 3100 and 2400 cm^{-1} was observed after several hours. These results pointed to the formation of the b_4 form (Scheme 1) with an intramolecular N—H···S hydrogen bond. This type of hydrogen bonding has been described in the literature (25, 26). It must be remarked that this b_4 structure is not very stable in the solid state. In fact, on recovering the substance from solution to make a KBr pellet, a large proportion of the b_1 form was obtained.

The ir spectrum of compound **2** obtained as a syrup (see Experimental) was similar to that of compound **3**. In accord with this fact and with ^1H nmr data, this form was characterized as **2***a*.

Surprisingly enough, the NH form **2***b* gave an ir spectrum that, in the 1600–1400 cm^{-1} region, was similar to that of the CH form as a solid and in chloroform solutions, and no NH absorption could be clearly detected. However, according to ^1H nmr data, it must be a *b* form, probably a b_1 structure.

Ultraviolet study

The uv absorption data of compounds **1–5** in ethanolic solution are summarized in Table 8. Two different absorption patterns were observed for model compounds **3** and **4**. Compound **3**, a fixed *a* form, showed four bands with maxima at 292, 282, 258, and 219 nm, similar to those described for benzothiazole itself and other 2-substituted benzothiazoles in 95% ethanol (27). On the other hand, compound **4**, a fixed *b* form, exhibited, in addition to the absorptions in the above-mentioned region (slightly shifted), two new strong bands at the edge of the visible region of the spectrum, corresponding to a more conjugated structure.

TABLE 8. Ultraviolet data of compounds **1–5** in ethanolic solution

Compound	λ	ε	Compound	λ	ε
1	428	2574	**3**	292	3894
	404	2133		282	6018
	346	6670*		258	18307
	295	4953		219	46374
	283	5591	**4**	397	52807
	257	12923		380	51332
	217	41098		273	11407
2*a*	293	4778		265	12981
	283	6371		236	19766
	258	13804		222	33140
	218	34908	**5**	422	71036
				216	89089

*Not observable in fresh solutions.

The CH tautomer **2***a* (syrup) gave, as expected, the same absorption pattern as compound **3**. Due to the low solubility of compound **2***b* in ethanol, a saturated solution was recorded. The absorption bands found at 294, 282, 262, and 217 nm can be explained if the registered spectrum corresponds exclusively to the solubilized CH tautomer.

The data for compound **1** showed the presence of both isomers, the CH form being predominant. Finally, compound **5** (R = Me) showed two maxima, one of them in the visible region (24), in agreement with the greater conjugation of this cyanine dye.

Conclusions

The conclusive and circumstantial evidence concerning the tautomeric equilibrium data on compounds **1** and **2** is summarized below:

	Solvent		
Compound	$CDCl_3$	DMSO	Ethanol
1	22% **1***a* – 78% $\mathbf{1}b_1$	**1***a*	**1***a*
2	44% $\mathbf{2}b_1$ – 56% $\mathbf{2}b_4$	**2***a*	**2***a*

The stabilization of the CH tautomer *a* in polar solvents is similar to that observed for β-diketones (28). The effect of the *C*-methyl group, lowering the stability of the CH tautomer, is opposite to that reported for β-diketones (*C*-methylacetylacetone is less enolized than acetylacetone (9)). Since compound **2***a* tautomerized more quickly than compound **1***a* it is possible that the 22% of **1***a* that remains after several days could disappear after a longer period. However, oxidation problems in chloroform preclude carrying out the experiment under normal conditions.

The equilibrium between the conjugated tautomers *b* shows that intramolecularly hydrogen-bonded forms b_1 and b_4 are the most stable. The effect of the *C*-methyl group (stabilization of b_4) is difficult to rationalize. It may result from a steric effect between R and the sulfur atoms in b_1, but experiments with more bulky R groups would be necessary to assess this hypothesis.

Photochemistry of α-chloro- and α-bromoacetophenone. Determination of extinction coefficients for halogen–benzene complexes[1]

W. G. McGimpsey and J. C. Scaiano

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received November 26, 1987

W. G. McGimpsey and J. C. Scaiano. Can. J. Chem. **66**, 1474 (1988).

The photochemical dehalogenation of α-haloacetophenones (Cl, Br) in benzene solution has been examined under conditions of continuous and pulsed laser irradiation. Product and quantum yield studies indicate that carbon-halogen bond cleavage occurs with quantum yields of 0.88 and 0.41 for α-chloro- and α-bromoacetophenone, respectively. These values are based on trapping studies in which the $PhC(O)\dot{C}H_2$ radicals produced photochemically are scavenged by hydrogen donors such as benzenethiol. Laser flash photolysis studies lead to intense transient signals due to benzene–halogen complexes. Combination of transient data and quantum yields lead to extinction coefficients of 1 800 and 23 700 M^{-1} cm^{-1} for the chlorine (490 nm) and bromine (550 nm) complexes, respectively.

W. G. McGimpsey et J. C. Scaiano. Can. J. Chem. **66**, 1474 (1988).

Opérant dans des conditions continues ainsi que pulsées par irradiation au laser, on a étudié la déshalogénation photochimique des α-haloacétophénones (Cl et Br) en solution dans le benzène. Les résultats relatifs tant à la nature des produits qu'aux rendements quantiques indiquent que les clivages des liaisons carbone-halogène des α-chloro et α-bromoacétophénones se produisent avec des rendements quantiques respectifs de 0,88 et de 0,41. Ces valeurs sont basées sur des études de piégeage dans lesquelles les radicaux $PhC(O)CH_2\cdot$, qui sont produits d'une façon photochimique, sont piégés par des donneurs d'hydrogène comme le benzènethiol. Les études de photolyse éclair au laser conduisent à la production de signaux transitoires intenses qui sont dûs aux complexes benzène–halogène. Les données relatives à la combinaison des espèces transitoires ainsi qu'aux rendements quantiques permettent de déterminer que les coefficients d'extinction sont respectivement de 1 800 et 23 700 M^{-1} cm^{-1} pour les complexes du chlore (490 nm) et du brome (550 nm).

[Traduit par la revue]

Introduction

Aryl alkyl ketones are known to undergo efficient homolytic β-cleavage when substituted at the α-position with a suitable leaving group. A number of published studies have shown that α-phenoxy and α-thiophenoxyacetophenones as well as related systems undergo this process (1–3). It has also been established that excited carbonyl compounds can sensitize homolytic C—X cleavage in intermolecular as well as intramolecular systems. An example of the former is provided by the decomposition of carbon tetrachloride sensitized by aliphatic ketones (4). Intramolecular sensitization leading to C—Cl bond cleavage occurs in a variety of alkyl ketones (5) as well α-chloroacetophenone which is used as a photochemical source of chlorine atoms (6). However, in spite of this application, the photochemistry of α-haloacetophenones has not been examined in detail before.

The initial motivation for this work resulted from the need to establish reliable extinction coefficients for halogen–benzene complexes, as well as to identify reactions involving C—Cl and C—Br cleavage that could be used as reference processes in laser flash photolysis studies. In particular, our interests center on the cleavage of C—X bonds from upper triplet states.[2] While the details of these studies are beyond the scope of this paper, suffice to say that the results reported herein provide adequate quantitative data to allow the use of α-haloacetophenones as reference compounds or actinometers in the study of other transient processes leading to the generation of halogen atoms in solution.

The formation of complexes between halogen atoms (Cl, Br, and I) and aromatics in solution and in matrices has been well established in the literature (8). For benzene, the visible absorption maxima of these complexes are ~490 (Cl·) (8, 9), 540–550 (Br·) (8, 10), and 500 nm (I·) (8, 11). Also, it has recently been shown that at least the $[Cl\cdot,C_6H_6]$ complex has a strong absorption band in the uv region ($\lambda_{max} < 360$ nm) (6).

In this paper we report the results of a study of the photochemistry of α-chloroacetophenone and α-bromoacetophenone in benzene solution in which we combine laser flash photolysis data with product and quantum yield studies.

Experimental

Materials

Benzene (Aldrich Gold Label), cyclohexane (BDH Omnisolv), benzenethiol (Aldrich Gold Label), valerophenone (Aldrich), benzyl bromide (Aldrich), and dodecane (Aldrich) were used as received. α-Bromoacetophenone (BrACP) and α-chloroacetophenone (ClACP) (Aldrich) were recrystallized twice from hexane.

CW irradiations: product studies, quantum yield determinations

(i) Product studies

Typical samples contained either 1 *M* cyclohexane or 0.05 *M* benzenethiol as hydrogen donors. Samples were deaerated by passing a stream of dry nitrogen through the solution for several minutes. Irradiations were carried out using a photochemical reactor with Rayonet lamps supplying light in the 300 or 350 nm wavelength regions. Irradiations at 350 nm were performed with samples contained in quartz cells. Typical irradiation times were 5–10 min corresponding to ~10–20% conversion of starting material. Irradiations carried out at 300 nm were performed with samples contained in quartz cells which were in turn placed in Pyrex test tubes. This modification was necessary because the lamp profile indicated the presence of a considerable intensity in the 254 nm region; Pyrex effectively filters these wavelengths. Typical irradiation times at 300 nm were shorter than for the 350 nm lamps (2–3 min) reflecting the greater lamp intensity and the larger ground state extinction coefficient at 300 nm.

Gas chromatographic analysis was performed using a Perkin Elmer

[1]NRCC No. 28378.

[2]We have measured quantum yields for dehalogenation of naphthalenes following excitation of the triplet state in two-laser experiments (7).

8320 capillary instrument equipped with a 12 meter BP10 on vitreous silica column. Retention times for the product mixtures were compared with those of authentic samples. Further corroboration for the identity of products was given by GC–MS analysis.

(ii) Quantum yield determinations

Quantum yield determinations were carried out using valerophenone as a chemical actinometer: irradiation results in production of acetophenone by the Norrish Type II mechanism ($\Phi = 0.30$ in benzene (12)). Samples of BrACP, ClACP, and valerophenone were prepared and their absorption spectra were obtained in the range 280–400 nm. Attempts were made to match the optical density for all three samples at 350 or 300 nm. Corrections were made for band intensity and for band shape relative to the lamp profile, i.e., absorption bands were integrated and multiplied by the integral of the lamp profile. The resulting product was used as a correction factor.

The GC peak areas for acetophenone were quantified by use of an internal standard (dodecane) and the area ratios obtained for the BrACP and ClACP were compared with that of valerophenone in order to obtain $\Phi_{PhC(O)\dot{C}H_2}$, the quantum yield of carbon–halogen bond cleavage. For irradiations carried out in benzene containing 1 *M* cyclohexane the areas of the acetophenone and benzyl halide peaks were included in the calculation of $\Phi_{PhC(O)\dot{C}H_2}$ because both products are derived from the $PhC(O)\dot{C}H_2$ radical (*vide infra*). For irradiations carried out in the presence of benzenethiol, only the acetophenone peaks were used in the calculation of $\Phi_{PhC(O)\dot{C}H_2}$.

Laser flash photolysis studies

A full description of the experimental set up used is given elsewhere (13). Samples of ClACP and BrACP (7×10^{-3} *M*) in benzene were irradiated with the pulses from an excimer laser (308 nm, ~4 ns, <40 mJ/pulse). Solutions were flowed through a specially constructed 7×7 mm^2 quartz cell. The flow system was required to ensure that a fresh volume of solution was irradiated by each laser pulse. Transient absorption spectra were obtained point-by-point with conventional monochromator-photomultiplier detection as well as by using an EG & G optical multichannel analyzer (OMA) equipped with a gated image intensifier (20 ns gate) and controlled by an EG & G 1461 interface.

Extinction coefficient information for the π-complexes was obtained by comparing the optical density of the π-complex with that of the coloured form of Aberchrome-540 produced by 308 nm excitation (14) (monitored at 494 nm). Both the haloacetophenone and Aberchrome-540 measurements were carried out using the same flow cell in order to minimize the effect of changing the experimental geometry.

Phosphorescence

Phosphorescence spectra were obtained at 77 K in degassed glasses using a Perkin Elmer LS-5 spectrofluorimeter. Excitation wavelengths were 300 nm for both ClACP and BrACP. Samples were contained in 0.5 mm i.d. cylindrical quartz cells which were placed in a rectangular quartz Dewar containing liquid nitrogen.

Results and discussion

All studies reported in the various subsections have been carried out under oxygen-free conditions. Unless otherwise indicated the temperatures are 20–22°C for time-resolved studies and ~30°C for product and quantum yield determinations.

Phosphorescence

The phosphorescence spectra of ClACP and BrACP were examined in a methylcyclohexane glass at 77 K. The spectra are relatively well resolved (see Fig. 1) and lead to triplet energies of 69.8 ($\lambda_{0,0}$ = 409 nm) and 68 kcal/mol ($\lambda_{0,0}$ = 421 nm) for ClACP and BrACP, respectively. These triplet energies are somewhat lower than that of acetophenone (73.7 kcal/mol) (15). Well-resolved ketone phosphorescence is typically associated with nπ* character and on this basis we assign ClACP and BrACP triplets as nπ*. The spectrum obtained for BrACP is substantially weaker than that of ClACP. This observation is indicative of a reduced triplet population and may be the result of efficient singlet state dehalogenation. This observation is corroborated by the laser flash photolysis results (*vide infra*).

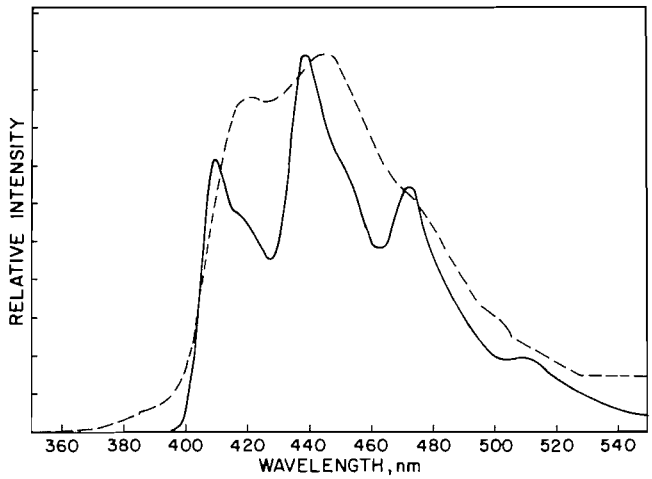

FIG. 1. Phosphorescence spectra from α-chloroacetophenone (—) and α-bromoacetophenone (- - -) in a methylcyclohexane glass at 77 K.

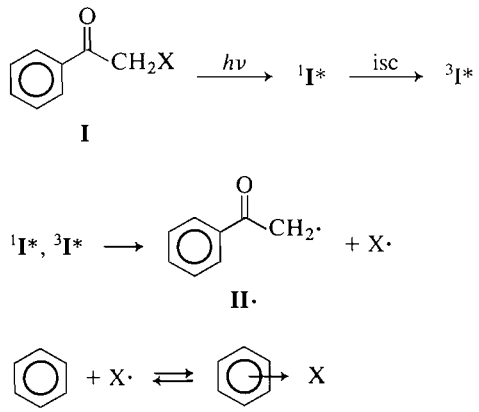
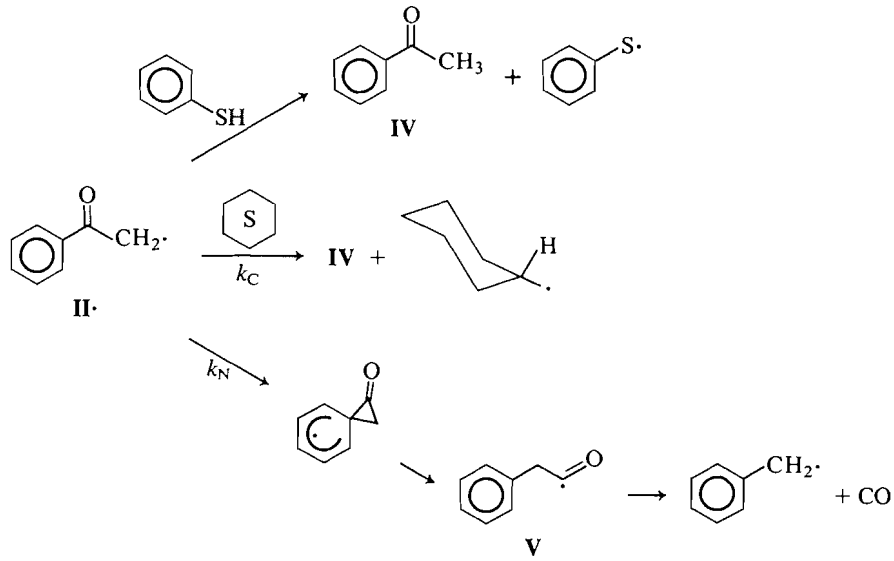


SCHEME 1

Product studies

These studies were carried out in benzene containing ~10^{-2} *M* α-haloacetophenone and either 0.05 *M* benzenethiol or 1 *M* cyclohexane which were used as hydrogen donors. Recent work by Wagner *et al.* (2) has shown that 0.05 *M* benzenethiol is sufficient to quantitatively trap all of the $PhC(O)\dot{C}H_2$ radicals produced during the β-cleavage of α-substituted acetophenones. The reactions which are expected to take place following initial excitation of α-haloacetophenone in the presence of these quenchers are given in Schemes 1 and 2. The initially produced excited singlet state may undergo intersystem crossing to the triplet manifold or β cleavage, yielding radical **II** ($PhC(O)\dot{C}H_2$) and the halogen atom $\dot{X}$. The triplet state may also undergo β cleavage to give **II** and thus, $\Phi_{PhC(O)\dot{C}H_2}$ represents the sum of all products resulting from reaction of **II**. The fate of **II** is given in Scheme 2 and involves hydrogen abstraction in the presence of hydrogen donors as well as a "neophyl-like" rearrangement suggested by the detection of other products (16, 17) (*vide infra*). It should be noted that the neophyl-like product was observed only in the benzene–cyclohexane experiments.

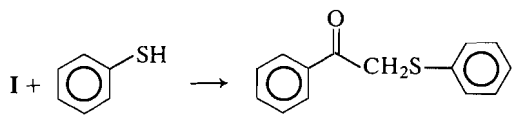


SCHEME 2

Hydrogen abstraction should be slower from cyclohexane than from benzenethiol, thus allowing the rearrangement reactions to compete more efficiently.

The major product of the photolysis using benzenethiol or cyclohexane as radical scavengers was found to be acetophenone (**IV**). When cyclohexane was used as the hydrogen donor the yield of benzyl halide (**VI**), the neophyl-derived product, was 25–30% relative to acetophenone. Thus, under our experimental conditions abstraction from cyclohexane is ca. twice as fast as the rearrangement of $PhC(O)\dot{C}H_2$. For the latter the rate constant k_N (see Scheme 2) been estimated as $10\ M^{-1}\ s^{-1}$ (16, 17). Since the cyclohexane concentration is $1\ M$, we obtain $k_c \sim 20\ M^{-1}\ s^{-1}$ for the abstraction by **II** from cyclohexane at room temperature. Toluene, the other major product of neophyl-like rearrangement is not detectable under our GC conditions.

On the other hand, reaction with benzenethiol is much cleaner with the only major product being acetophenone. It should be noted that another species observed by GC in the benzenethiol experiments initially believed to be a photochemical radical coupling product was shown to be produced thermally, possibly by a non-radical mechanism:



Following carbon–halogen bond cleavage, a certain percentage of $\dot{X}$ undergoes in cage recombination to regenerate the starting material. This process is not detectable by our time resolved methods and does not contribute to the quantum yield, $\Phi_{PhC(O)\dot{C}H_2}$. Following cage escape, $\dot{X}$ is scavenged by benzene resulting in the formation of the π-complex. Decay of this species may take place by reaction with the hydrogen donors present. Alternatively, the π-complex may dissociate yielding $\dot{X}$ which can also undergo hydrogen abstraction from hydrogen donors (chlorine atoms are much more reactive towards hydrogen donors than bromine atoms).[3] Free Cl· atoms abstract from 2,3-dimethylbutane at a nearly diffusion-controlled rate (6).

[3]The activation energy for hydrogen abstraction by Cl· is ~1 kcal/mol while for Br· it is $E_a \sim 14$ kcal/mol (5*c*).

TABLE 1. Quantum yield studies in benzene at 30°C

Substrate	Scavenger	Excitation (nm)	Φ_{ACP}	Φ_{PhCOCH_2}[a]
ClACP	PhSH (0.05 *M*)	350	0.88	0.88
ClACP	PhSH (0.05 *M*)	300	0.64	0.64
ClACP	C_6H_{12} (1 *M*)	350	0.50	0.65
BrACP	PhSH (0.05 *M*)	350	0.41	0.41
BrACP	PhSH (0.05 *M*)	300	0.38	0.38
BrACP	C_6H_{12} (1 *M*)	350	0.27	0.36

[a]This value is identical to Φ_{ACP} for experiments using benzenethiol as a hydrogen donor. For experiments with cyclohexane this value incorporates production of benzyl halide.

Quantum yield studies

Quantum yield determinations were carried out using the formation of acetophenone (ACP) from valerophenone as an actinometer and taking $\Phi_{ACP} = 0.30$ in benzene at room temperature (12). This particular actinometer has two advantages: first, the system of interest and the actinometer yield the same main product (i.e., acetophenone); and second, the absorption spectrum of valerophenone, although not identical to the spectra of ClACP or BrACP is in fact very similar to these spectra and hence, matching of absorbances at 350 nm was not difficult. Our quantum yields are summarized in Table 1, where Φ_{ACP} refers to the quantum yield for acetophenone production. The quantum yields for initial, out-of-cage production of $PhC(O)\dot{C}H_2$, $\Phi_{PhC(O)\dot{C}H_2}$ are also included. For the experiments using benzenethiol as hydrogen donor, this quantity is identical to Φ_{ACP} since acetophenone is the only detectable photochemical product. For experiments using cyclohexane, $\Phi_{PhC(O)\dot{C}H_2}$ includes contributions due to acetophenone production as well as benzyl halide production (neophyl). There is a larger error associated with this value since one cannot assume that all neophyl-derived benzyl radicals led to the formation of benzyl halide. Presumably these radicals may also react with hydrogen donors to yield toluene, which was not distinguishable under our GC conditions. We find the quantum yields at 300 and 350 nm for BrACP to be the same within experimental error. However, the yield at 300 nm for ClACP is lower (0.64 compared with 0.88). There may be more error associated with

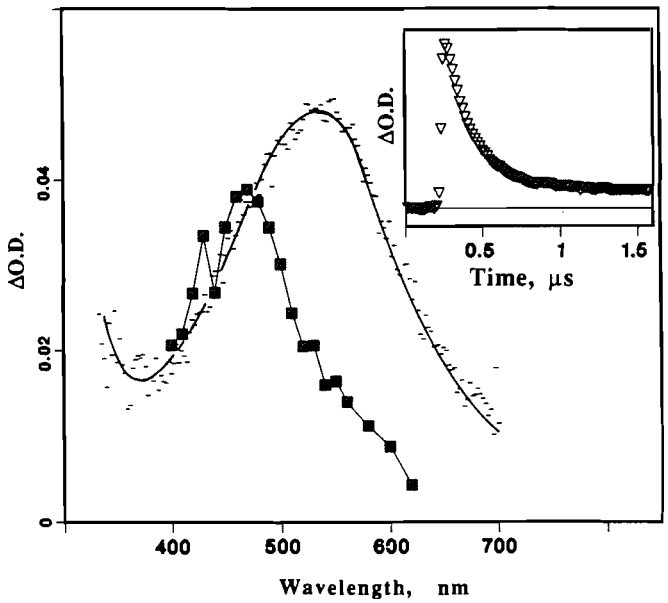

FIG. 2. Transient spectrum of the halogen–benzene complex monitored 1 μs after laser excitation of ClACP (λ_{max} 490 nm) and BrACP (λ_{max} 550 nm) in benzene. Insert: Decay of triplet ClACP monitored at 360 nm.

the 300 nm measurements, since matching of ClACP, BrACP, and valerophenone absorbances is more difficult at this wavelength. Furthermore, irradiations at 300 nm were carried out in Pyrex cells, which adds to the difficulty of compensating for the lamp profile. For these reasons we feel that the 350 nm results are more reliable.

In addition, the values of $\Phi_{PhC(O)\dot{C}H_2}$ obtained in the benzenethiol experiments are believed to be more reliable than those obtained in the cyclohexane experiments because in the latter our analysis does not measure the extent of neophyl-derived toluene under our experimental conditions.

Laser flash photolysis

Laser excitation of ClACP (typically 7×10^{-3} *M*) at 308 nm in benzene leads to its readily detectable triplet state which can be conveniently monitored at 360 nm (not λ_{max}). The triplet lifetime was 155 ± 15 ns and was concentration independent in the range examined (0.0028 to 0.014 *M*), indicating that self-quenching is unimportant in this concentration range. Figure 2 (see insert) illustrates a typical time profile for triplet decay. The formation of a new band centered at 490 nm accompanies triplet decay. This band can be readily characterized as that due to the benzene–chlorine complex on the basis of assignments made in the literature (6, 8). The transient spectrum obtained 1.0 μs after laser excitation is illustrated in Fig. 2.

When the same type of experiments are repeated with BrACP we also observe the formation of the corresponding halogen atom–benzene complex, now centered at 550 nm (see Fig. 2). However, in this case the formation of the complex is "instantaneous" within our time resolution and no signals that we could attribute to triplet BrACP were detected.

In an attempt to determine the triplet lifetimes using indirect techniques, we used 337 nm excitation and carried out quenching experiments using 1-methylnaphthalene (MeN) as a quencher. Under these conditions only the ketone is excited directly by the laser, provided that only moderate concentrations of MeN are used, and the formation of triplet MeN occurs as a result of triplet energy transfer, i.e.

$$[1] \quad XACP^* + MeN \xrightarrow{k_q} XACP + MeN^*$$

The formation of MeN* can be conveniently monitored at 420 nm. The absorbance due to MeN* (A_{420}) before significant triplet decay takes place is related to the rate constant for quenching, k_q, and the lifetime of the ketone triplet, τ_T, according to:

$$[2] \quad \frac{1}{A_{420}} = \alpha + \frac{\alpha}{k_q \tau_T [MeN]}$$

where α is a constant which includes experimental parameters and the quantum yield of intersystem crossing for XACP. This analysis led to $k_q\tau_T = 2090 \pm 430\, M^{-1}$ for ClACP, corresponding to $k_q = (1.34 \pm 0.36)\, 10^{10}\, M^{-1}\, s^{-1}$.

When the same type of experiments were repeated with BrACP we did not find any evidence for sensitized formation of MeN* at quencher concentrations of up to 0.3 *M*. Higher concentrations of MeN cannot be used because direct excitation of the quencher becomes a problem even at 337 nm. It is clear that either the triplet yield is extremely low (suggesting singlet state cleavage), or its lifetime is so short (i.e., $\tau_T \leq 0.1$ ns) that it cannot sensitize MeN before it decays. This observation is consistent with the phosphorescence results which also suggest a low triplet yield.

Another set of experiments was performed in order to verify the monophotonic nature of the $PhCOCH_2$—Cl cleavage under conditions of laser excitation. It is clear that a monophotonic process does take place, since lamp irradiation (*vide supra*) readily leads to photocleavage. The question addressed here is whether lamp and laser photocleavage involve the same process; this is a precondition if quantum yields derived from lamp experiments are to be combined with laser-derived data. In order to achieve this we measured the transient absorption due to the coloured form of Aberchrome-540 (at 494 nm) and the π-complex (at 490 nm after complete formation), as a function of the laser dose, which was adjusted with a calibrated set of neutral density filters. The laser dose was changed by a factor of 9. Plots of the Aberchrome-540 and π-complex absorbances versus the laser dose are shown in Fig. 3. The linearity of these plots indicates that Aberchrome-540 and the π-complex formation have the same dependence on excitation dose. Since Aberchrome-540 formation is known to be monophotonic (14) it can be safely assumed that the same applies to the chlorine–benzene complex.

Similar experiments have been performed in the BrACP system and the results are also shown in Fig. 3.

Determination of transient extinction coefficients

Aberchrome-540 has been developed for use as an actinometer by Heller and Langan (18). We have recently tested and extended this technique for laser applications (14). Aberchrome-540 involves the phototransformation shown in reaction [3] which occurs with $\Phi = 0.20$ in toluene at room temperature.

[3] 
This actinometer is ideally suited for these experiments, since the wavelength maximum for the coloured form (494 nm) is very close to the wavelength maxima for the halogen-benzene

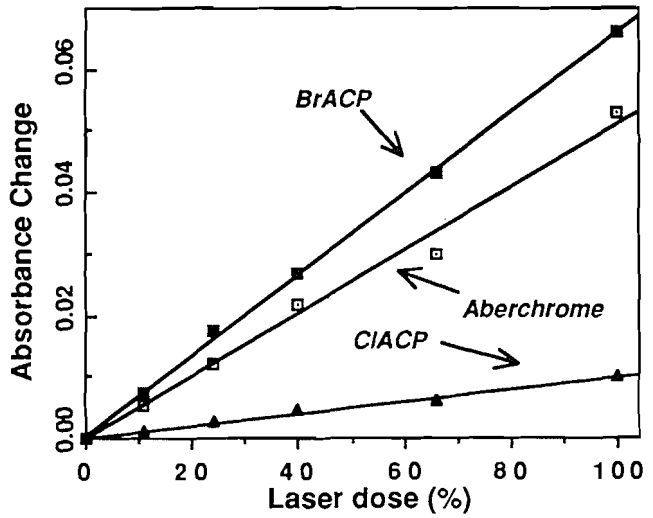

FIG. 3. Transient change in absorbance induced by 308 nm excitation of matched samples of ClACP (in benzene, monitored at 490 nm), BrACP (in benzene, monitored at 550 nm), and Aberchrome-540 (in toluene, monitored at 494 nm). The laser dose was adjusted with a calibrated set of neutral density filters.

complexes. This technique yields the product $\Phi_{complex}\epsilon_{complex}$; the values obtained were 9700 M^{-1} cm^{-1} (550 nm) and 1600 M^{-1} cm^{-1} (490 nm) for the bromine and chlorine complexes, respectively. We now assume that the quantum yield for complex formation, $\Phi_{complex}$, has the same value as $\Phi_{PhC(O)\dot{C}H_2}$, since in pure benzene all the halogen atoms that escape the geminate cage are expected to form a complex with the solvent. For example in the case of Cl· the rate of association with benzene has been measured as 6.0×10^9 M^{-1} s^{-1} (6). Thus, combining the values given above with the 350 nm data from Table 1 we obtain ϵ values of 23 700 and 1 800 M^{-1} cm^{-1} for bromine and chlorine complexes, respectively. All data in this section have been obtained by extrapolation to zero laser dose following the procedures described elsewhere (14). Errors are estimated as ±15%.

Conclusions

Our results indicate that C—X cleavage in α-haloacetophenones is a fast and efficient process which, in the case of ClACP occurs predominantly or exclusively from the triplet state, while for BrACP it may take place from an extremely short lived triplet and/or from the singlet state. The carbon centered radical, $PhC(O)\dot{C}H_2$ can be readily trapped by benzenethiol or by cyclohexane; in the latter case, trapping is competitive with a neophyl-like rearrangement leading to $PhCH_2\dot{C}O$ radicals which subsequently decarbonylate. The cleavage of the C—X bond has been shown to be a monophotonic process under both lamp and laser irradiation. The benzene–halogen complexes have extinction coefficients of 23 700 and 1 800 M^{-1} cm^{-1} for bromine and chlorine, respectively. These extinction coefficients provide needed data to allow the study of other dehalogenation processes using laser techniques.

Two facile methods for preparing 4-fluororesorcinol have been developed. In the first method, the direct fluorination of 1,3-dimethoxybenzene with trifluoromethyl hypofluorite carried out in Freon 11 at −78°C afforded 2,4-dimethoxyfluorobenzene. Demethylation by heating under reflux in 48% HBr in acetic acid gave 4-fluororesorcinol in an overall yield of 60%. The second method involved the fluorination of 2,6-dimethoxyacetophenone by trifluoromethyl hypofluorite in Freon 11 at −78°C, leading to 2,6-dimethoxy-3-fluoroacetophenone. On heating under reflux in 48% HBr in acetic acid, 4-fluororesorcinol was obtained in an overall yield of 74%. The latter is the method of choice for preparing 4-fluororesorcinol.

PATRICE C. BÉLANGER, C. K. LAU, HAYDN W. R. WILLIAMS, C. DUFRESNE et JOHN SCHEIGETZ. Can. J. Chem. **66**, 1479 (1988).

On a mis au point deux méthodes faciles de préparer le fluoro-4 résorcinol. Dans la première méthode, on a procédé à une fluoration directe du diméthoxy-1,3 benzène par l'hypofluorite de trifluorométhyle dans le Freon-11, à −78°C, et on a ainsi obtenu le diméthoxy-2,4 fluorobenzène. La déméthylation, par chauffage au reflux avec du HBr à 48% dans l'acide acétique, conduit au fluoro-4 résorcinol avec un rendement global de 60%. La deuxième méthode implique une fluoration de la diméthoxy-2,6 acétophénone par l'hypofluorite de trifluorométhyle dans le Freon-11, à −78°C, qui fournit la diméthoxy-2,6 fluoro-3 acétophénone. Par chauffage au reflux avec du HBr à 48% dans l'acide acétique, on obtient le fluoro-4 résorcinol avec un rendement global de 74%. Cette dernière méthode est la méthode de choix pour préparer le fluoro-4 résorcinol.
[Traduit par la revue]

Introduction

Fluorination of aromatic compounds is of great interest chemically and biochemically. Replacing hydrogen by the isosteric fluorine is commonly utilized in the design of new drugs (1, 2) to elevate hydrophilicity and to modify metabolism and bioavailability. In one of our projects, a method of preparing 4-fluororesorcinol was needed and it had to be rapid, efficient, and potentially applicable to large-scale preparation.

Aromatic fluorination by electrophilic sources of fluorine has been the subject of several recent reviews (3). It is normally achieved by performing the Balz–Schiemann reaction (4, 5) or via electrophilic fluorination with reagents such as trifluoromethyl hypofluorite (6), acetyl hypofluorite (7), or xenon difluoride (8).

A survey of literature revealed that there are only a few reported syntheses (8) of 4-fluororesorcinol **4** or of its corresponding dimethyl ether **2** (9) and that the use of the Balz–Schiemann reaction (4, 5), if attempted, has not been reported. Direct fluorination of resorcinol with xenon difluoride (8) gave a monofluoro product whose structure has yet to be confirmed. Fluorination of 1,3-dimethoxybenzene **5** with acetyl hypofluorite (7) gave a 40% yield of 2,4-dimethoxyfluorobenzene **2**, and also 1,5-difluoro-2,4-dimethoxybenzene **6**.

We wish to present two facile and different approaches to the preparation of 4-fluororesorcinol **4**, which have been successful in our hands and are amenable to large-scale preparations.

Discussion

The Balz–Shiemann reaction (4, 5) involves a controlled thermal decomposition of a diazonium fluoroborate and is the most commonly used method of preparing fluoroaromatic compounds.

The advantage of this reaction resides in the fact that the product is a monofluorinated species, unlike those electrophilic fluorination methods that usually give a mixture of mono and polyfluorinated products. With readily available 2,4-dimethoxyaniline, the Balz–Schiemann reaction (4, 5) was considered the logical route to prepare the desired 2,4-dimethoxyfluorobenzene **2**, and consequently 4-fluororesorcinol **4**. The diazonium fluoroborate **1***a* was prepared accordingly (4*a*), and its pyrolysis investigated under a wide variety of conditions.

On heating the fluoroborate **1***a* slowly from 150 to 200°C, less than a 10% yield of 2,4-dimethoxyfluorobenzene **2** was isolated, the residue being intractable tarry materials. In an attempt to control the heating evenly, **1***a* was mixed well with fine washed sand and the mixture was heated at 165°C, but, again, only tarry materials resulted. Pyrolysis of **1***a* under vacuum (20 Torr; 1 Torr = 133.3 Pa) at 200°C also failed to give any desired product. Interestingly, the pyrolysis of **1***a* in refluxing *N*,*N*-dimethylformamide or xylene gave 1,3-dimethoxybenzene **5**. Substitution of hydrogen for the diazonium group during pyrolysis occurred as reported in other cases by Niemann *et al.* (9). Pyrolysis in Dowtherm (10) at 150–200°C gave only tarry materials. Reaction of **1***a* with cuprous chloride as a catalyst in aqueous acetone at room temperature (11) gave instead small amounts of 2,4-dimethoxychlorobenzene. Pyrolysis of aryl diazonium hexafluorophosphate salts **1***b* has been reported (12) to give better yields of aryl fluorides, but in our hands only a small amount of 1,3-dimethoxybenzene **5** was

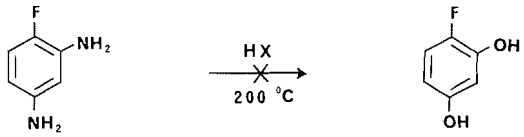
For personal use only.



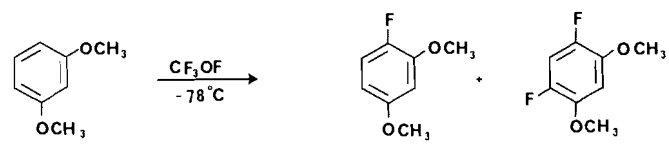
X = Cl, HSO_4, H_2PO_4

isolated when **1***b* was pyrolyzed at 140°C. The reaction of aryltriazenes with 70% hydrogen fluoride in pyridine (13) is another modification of the Balz–Schiemann reaction that was attempted, but again without success. Photolytic decomposition of aryl diazonium fluoroborates in fluoroboric acid at 0°C, although reported to be a more reliable process (14), gave also tarry materials.

Since the decomposition of diazonium salts **1***a* and **1***b* did not give the desired 2,4-dimethoxyfluorobenzene **2**, other approaches were investigated. One such alternative would utilize an aryl compound already substituted with a fluorine at the appropriate position. Thus, the Bucherer reaction (15) was tried on 2,4-diaminofluorobenzene **3**. Heating a solution of the latter in either hydrochloric, sulfuric, or phosphoric acid in a sealed tube at 200°C for 6 h resulted only in polymeric materials.

Direct fluorination of 1,3-dimethoxybenzene **5** with electrophilic fluorinating agents was then considered. Treatment of resorcinol with trifluoromethyl hypofluorite at −78°C did not afford any of the desired 4-fluororesorcinol **4** but reaction of 1,3-dimethoxybenzene **5** with this fluorinating reagent in Freon 11 at −78°C gave a 5:1 mixture of 2,4-dimethoxyfluorobenzene **2** and of 1,5-difluoro-2,4-dimethoxybenzene **6**, together with 15% of the starting material **5**. The two products were found to be easily separable by silica gel chromatography, making the reaction applicable to large-scale preparation.

After demethylating **2** by heating under reflux with 48% hydrobromic acid in acetic acid (16), 4-fluororesorcinol **4** was obtained in 87% yield.

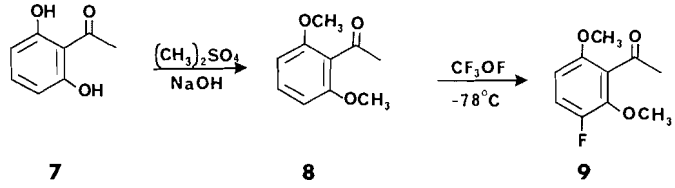


5 **2** **6**

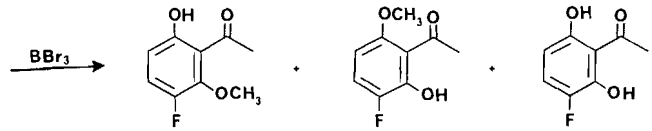
This approach is therefore an interesting alternative, as the overall yield is of the order of 60%. Although 1,3-dimethoxybenzene **5** appears to be somewhat too reactive towards an electrophilic reagent such as trifluoromethyl hypofluorite, careful monitoring of the reaction and careful addition of the reagent will ensure a good product ratio.

Deactivation of 1,3-dimethoxybenzene **5** would permit a better control of this electrophilic substitution reaction and minimize polyfluorination. The deactivation can be achieved by the use of the electron-withdrawing acetyl substituent, reported to be labile under acidic or basic conditions in dihydroxybenzene derivatives (17). Thus, 2,6-dimethoxyacetophenone **8**, readily prepared by methylation of 2,6-dihydroxyacetophenone **7**, reacted readily with trifluoromethyl hypofluorite in Freon 11 at −78°C to give 90% yield of 2,6-dimethoxy-3-fluoroacetophenone **9**.

It was also interesting to observe that in this case, contrary to 2,4-dimethoxyfluorobenzene **2**, the two methoxy groups are readily assignable since the 6-methoxy is a singlet at 3.80 ppm



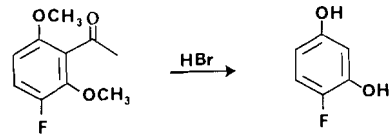
7 **8** **9**



10 **11** **12**

whereas the 2-methoxy is a doublet with a coupling constant of 2 Hz. Such coupling constants have been reported (18) in similar cases.

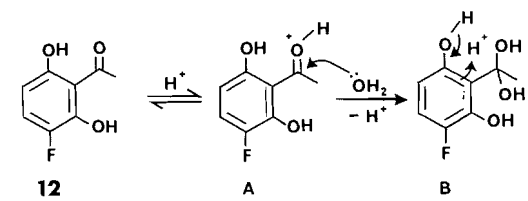
Removal of the methoxy and of the acetyl groups can be achieved readily by refluxing a solution of 2,6-dimethoxy-3-fluoroacetophenone **9** in a mixture of 48% hydrobromic acid and acetic acid for a period of 2–3 h.



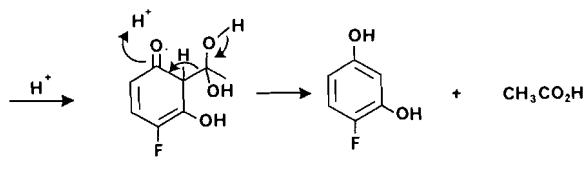
9 **4**

Under these conditions, the methyl groups are assumed to be removed to yield the corresponding 2,6-dihydroxy-3-fluoroacetophenone **12** and, in a subsequent step, a deacylation via a mechanism involving the keto–enol equilibrium of the 1,3-dihydroxy system takes place, leading to **4**.

It is of interest to note that treatment of 2,6-dimethoxy-3-fluoroacetophenone **9** with boron tribromide (19) in dichloromethane at 0°C for 2 h led to a mixture of 3 products readily separable by silica gel chromatography. The two isomeric monomethoxy derivatives **10** (minor) and **11** (major) were readily distinguished by the fluorine methyl coupling constant of 2 Hz when the methoxy is *ortho* to the fluoro group. The third product isolated was found to be 2,6-dihydroxy-3-fluoroacetophenone **12**.



12 **A** **B**



C **4**

Similar results were obtained when 2,4-dimethoxyfluorobenzene **2** was treated with boron tribromide, thus providing a method of preparing monomethoxy derivatives **13** and **14**.

Thus, by carrying out the fluorination on the 2,6-dimethoxyacetophenone **8**, aromatic fluorination with trifluoromethyl hypofluorite was easily controlled and, when combined with

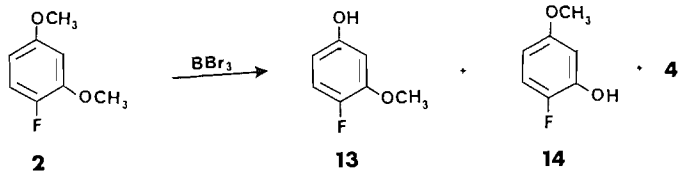
For personal use only.



2 13 14

the hydrolysis of the resulting 2,6-dimethoxy-3-fluoroacetophenone **9** by 48% hydrobromic acid in acetic acid, it gave a rapid, efficient preparation of 4-fluororesorcinol **4** that can easily be scaled up. This approach is the preferred route to 4-fluororesorcinol **4**.

Experimental

Melting points were taken on a Thomas Hoover apparatus in open capillary tubes and are uncorrected. A Varian EM-390 spectrometer was used to record nmr spectra in deuterochloroform, unless indicated otherwise. Proton chemical shifts are relative to tetramethylsilane (TMS) as internal standard. Elemental analyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario. Silica gel chromatographic separations were carried out in the flash chromatography mode following the indications of Clark Still (20) using British Drug House silica gel of 200 mesh size. All reactions as well as column chromatography were monitored routinely with the aid of thin-layer chromatography (tlc) using precoated 0.25-mm silica gel GF plates (Analtech), visualizing them by uv, and then charring with sulfuric acid.

Preparation of 2,4-dimethoxyfluorobenzene 2

In a Teflon reaction vessel, a solution of 1,3-dimethoxybenzene **5** (1.5 g; 10.9 mmol) in Freon 11 (50 mL) was cooled to −78°C and trifluoromethyl hypofluorite was bubbled through the solution slowly, monitoring the reaction by tlc. The mixture was poured onto a silica gel column and elution with 7% ethyl acetate in hexane gave 1.0 g (68%) of 2,4-dimethoxyfluorobenzene **2** as an oil and 0.2 g of unreacted 1,3-dimethoxybenzene **5**. For compound **2**, ^{1}H nmr: 3.77 (s, 3H, CH_3), 3.87 (s, 3H, CH_3), 6.37 (pair of triplets, $J_{H5,F}$ = 5 Hz, $J_{H3,H5}$ = 3 Hz, and $J_{H5,H6}$ = 9 Hz, 1H, H5), 6.57 (d of d, $J_{H3,F}$ = 7.2 Hz, $J_{H3,H5}$ = 3 Hz, H3), 7.00 (d of d, $J_{H6,F}$ = 11.2 Hz, $J_{H5,H6}$ = 9 Hz, 1H, H6). *Anal.* calcd. for $C_8H_9FO_2$: C 61.53, H 5.81, F 12.17; found: C 61.51, H 5.95, F 12.40.

1,5-Difluoro-2,4-dimethoxybenzene **6** (0.2 g) was also isolated, mp 98–99°C (lit. (7*d*) mp 99°C); ^{1}H nmr: 3.87 (s, 6H, $2CH_3$), 6.63 (t, $J_{H3,F}$ = 8 Hz, H3), 6.90 (t, $J_{H6,F}$ = 12 Hz, 1H, H6). *Anal.* calcd. for $C_8H_8F_2O_2$: C 55.17, H 4.63, F 21.82; found: C 55.24, H 4.86, F 21.97.

Preparation of 4-fluororesorcinol 4

To a solution of 2,4-dimethoxyfluorobenzene **2** (0.4 g, 2.6 mmol) in glacial acetic acid (2 mL) was added 48% hydrobromic acid (2 mL) and the mixture was refluxed for a period of 4 h. The resulting mixture was concentrated *in vacuo* and the residue was dissolved in a small volume of methylene chloride and chromatographed on silica gel. Elution with 15% ethyl acetate in hexane afforded 0.29 g (87%) of 4-fluororesorcinol **4**, mp 97–98°C; ^{1}H nmr: 6.32 (pair of triplets, $J_{H5,F}$ = 5 Hz, $J_{H3,H5}$ = 3 Hz, and $J_{H5,H6}$ = 9 Hz, 1H, H5), 6.55 (d of d, $J_{H3,F}$ = 7.2 Hz, $J_{H3,H5}$ = 3 Hz, 1H, H3), 7.00 (d of d, $J_{H6,F}$ = 11.2 Hz, $J_{H5,H6}$ = 9 Hz, 1H, H6). *Anal.* calcd. for $C_6H_5FO_2$: C 56.25, H 3.93, F 14.83; found: C 56.73, H 4.28, F 14.75.

Preparation of 2,6-dimethoxyacetophenone 8

To a solution of 2,6-dihydroxyacetophenone **7** (3.0 g, 20 mmol) in aqueous sodium hydroxide (7.5 N, 100 mL) maintained at 60°C was added dropwise over a period of 30 min dimethylsulfate (20 mL). The mixture was then cooled to room temperature; the solid was filtered, washed well with water, and air-dried to yield 2,6-dimethoxyacetophenone **8** (3 g, 82%), mp 58–59°C; ^{1}H nmr: 2.50 (s, 3H, CH_3), 3.83 (s, 6H, $2CH_3$), 6.60 (d, $J_{H3,H4}$ = 9 Hz, 2H, H3 and H5), 7.33 (t, $J_{H3,H4}$ = $J_{H4,F}$ = 9 Hz, 1H, H4). *Anal.* calcd. for $C_{10}H_{12}O_3$: C 66.65, H 6.71; found: C 66.31, H 6.99.

Preparation of 2,6-dimethoxy-3-fluoroacetophenone 9

In a Teflon reaction vessel, a solution of 2,6-dimethoxyacetophenone **8** (1.40 g, 7.7 mmol) in Freon 11 (50 mL) was cooled to −78°C and trifluoromethyl hypofluorite was bubbled through the solution slowly, while monitoring the reaction by tlc. The cold reaction mixture was poured onto a silica gel column and elution with 7% ethyl acetate in hexane gave 1.2 g (91%) of 2,6-dimethoxy-3-fluoroacetophenone **9** and 0.2 g of unreacted 2,6-dimethoxyacetophenone **8**. For compound **9**, ^{1}H nmr: 2.47 (s, 3H, CH_3), 3.80 (s, 3H, CH_3), 3.97 (d, J = 2 Hz, 3H, CH_3), 6.57 (d of d, $J_{H4,H5}$ = 9 Hz, $J_{H5,F}$ = 3 Hz, 1H, H5), 7.07 (d of d, $J_{H4,H5}$ = 9 Hz, $J_{H4,F}$ = 11 Hz, 1H, H4). *Anal.* calcd. for $C_{10}H_{11}FO_3$: C 60.60, H 5.59, F 9.59; found: C 60.40, H 5.70, F 9.20.

Demethylation of 9 with boron tribromide

To a solution of 2,6-dimethoxy-3-fluoroacetophenone **9** (0.5 g; 2.5 mmol) in methylene chloride (3 mL) cooled to −78°C, a 1 M solution of boron tribromide in methylene chloride (3 mL) was added. The mixture was allowed to warm to room temperature and was stirred at that temperature for 30 min. It was then cooled to −78°C and methanol (3 mL) was added. The resulting mixture was chromatographed on silica gel, and eluted with 15% ethyl acetate in hexane. It gave successively 3-fluoro-2-methoxy-6-hydroxyacetophenone **10** (28 mg) as an oil, 3-fluoro-2-hydroxy-6-methoxyacetophenone **11** (287 mg), mp 87–88°C, and 2,6-dihydroxy-3-fluoroacetophenone **12** (61 mg), mp 134–135°C.

3-Fluoro-6-hydroxy-2-methoxycetophenone 10: ^{1}H nmr: 2.70 (s, 3H, CH_3), 4.03 (d, J = 2 Hz, 3H, CH_3), 6.60 (d of d, $J_{H4,H5}$ = 9 Hz, $J_{H5,F}$ = 5 Hz, 1H, H5), 7.20 (d of d, $J_{H4,H5}$ = 9 Hz, $J_{H4,F}$ = 11 Hz, 1H, H4). *Anal.* calcd. for $C_9H_9FO_3$: C 58.69, H 4.92, F 10.32; found: C 58.84, H 4.92, F 10.12.

3-Fluoro-2-hydroxy-6-methoxyacetophenone 11: ^{1}H nmr: 2.70 (s, 3H, CH_3), 3.90 (d, J = 2 Hz, 3H, CH_3), 6.30 (d of d, $J_{H4,H5}$ = 9 Hz, $J_{H5,F}$ = 5 Hz, 1H, H5), 7.25 (d of d, $J_{H4,H5}$ = 9 Hz, $J_{H4,F}$ = 11 Hz, 1H, H4). *Anal.* calcd. for $C_9H_9FO_3$: C 58.69, H 4.92, F 10.32; found: C 58.83, H 4.98, F 10.20.

2,6-Dihydroxy-3-fluoroacetophenone 12: ^{1}H nmr: 2.77 (s, 3H, CH_3), 6.37 (d of d, $J_{H4,H5}$ = 9 Hz, $J_{H5,F}$ = 5 Hz, 1H, H5), 7.17 (d of d, $J_{H4,H5}$ = 9 Hz, $J_{H4,F}$ = 11 Hz, 1H, H4). *Anal.* calcd. for $C_8H_7FO_3$: C 56.42, H 4.14, F 11.16; found: C 56.31, H 4.22, F 11.40.

Preparation of 4-fluororesorcinol 4

To a solution of 2,6-dimethoxy-3-fluoroacetophenone **9** (0.4 g; 2.0 mmol) in glacial acetic acid (2 mL) was added 48% hydrobromic acid (2 mL) and the mixture was refluxed for a period of 4 h. The resulting mixture was concentrated *in vacuo* and the residue was dissolved in a small volume of methylene chloride and chromatographed on silica gel. Elution with 15% ethyl acetate in hexane afforded 0.21 g (81%) of 4-fluororesorcinol **4**, mp 97–98°C, found to be identical to that prepared above.

Demethylation of 2 with boron tribromide

To a solution of 2,4-dimethoxy-3-fluorobenzene **2** (0.5 g, 2.5 mmol) in methylene chloride (3 mL) cooled to −78°C, a 1 M solution of boron tribromide in methylene chloride (3 mL) was added. The mixture was allowed to warm to room temperature and was stirred at that temperature for 30 min. It was then cooled to −78°C and methanol (3 mL) was added. The resulting mixture was chromatographed on silica gel and eluted with 15% ethyl acetate in hexane. It gave successively **2** (19 mg), 4-hydroxy-2-methoxy-fluorobenzene **13** (31 mg) as an oil, 2-hydroxy-4-methoxy-fluorobenzene **14** (314 mg) as an oil, and 4-fluororesorcinol **4** (53 mg), mp 97–98°C.

4-Hydroxy-2-methoxy-fluorobenzene 13: ^{1}H nmr: 3.77 (s, 3H, CH_3), 6.32 (pair of triplets, $J_{H5,F}$ = 5 Hz, $J_{H3,H5}$ = 3 Hz, and $J_{H5,H6}$ = 9 Hz, 1H, H5), 6.60 (d of d, $J_{H3,F}$ = 7.2 Hz, $J_{H3,H5}$ = 3 Hz, 1H, H3), 7.00 (t, $J_{H6,F}$ = $J_{H5,H6}$ = 9 Hz, 1H, H6). *Anal.* calcd. for $C_7H_7FO_2$: C 59.15, H 4.96, F 13.37; found: C 59.46, H 5.59, F 13.00.

2-Hydroxy-4-methoxyfluorobenzene 14: ^{1}H nmr: 3.63 (s, 3H, CH_3), 6.30 (pair of triplets, $J_{H5,F}$ = 5 Hz, $J_{H3,H5}$ = 3 Hz, and $J_{H5,H6}$ = 9 Hz, 1H, H5), 6.63 (d of d, $J_{H3,F}$ = 7.2 Hz, $J_{H3,H5}$ = 3 Hz, 1H, H3),

Received September 1, 1987

DAVIDE ATZEI, PAOLA DEPLANO, EMANUELE F. TROGU, FRANCESCO BIGOLI, MARIA ANGELA PELLINGHELLI, and ALBERTO VACCA. Can. J. Chem. **66**, 1483 (1988).

The reaction of some tetra-substituted dithiooxamides $R_2NC(S)C(S)NR_2$ (R = CH_3:Me_4dto; R = C_2H_5:Et_4dto; R_2N = OC_4H_8N:Mo_2dto) with diiodine has been investigated by spectrophotometric methods in $CHCl_3$. The formation in solution of 1:1 and 1:2 charge-transfer (c.t.) complexes between the reagents has been observed. A new computer program, derived from "SUPERQUAD" (P. Gans, A. Sabatini, and A. Vacca. J. Chem. Soc. Dalton Trans. 1195 (1985)), has been applied to evaluate the formation constants. The 1:2 c.t. complexes have been isolated in the solid state, and an X-ray structure analysis of the $[OC_4H_8NC(S)C(S)NC_4H_8O]\cdot 2I_2$ compound indicated that the crystals are triclinic, space groups $P\bar{1}$, with a = 14.659(6), b = 15.111(6), c = 9.317(5) Å, α = 92.29(2), β = 99.71(2), γ = 99.48(2)° and Z = 4. In particular the torsion angle S—C—C—S (≈90°) shows that the conformation of the dithiooxamide is *not trans*.

DAVIDE ATZEI, PAOLA DEPLANO, EMANUELE F. TROGU, FRANCESCO BIGOLI, MARIA ANGELA PELLINGHELLI et ALBERTO VACCA. Can. J. Chem. **66**, 1483 (1988).

Opérant en solution chloroformique et utilisant des méthodes spectrophotométriques, on a étudié la réaction de quelques dithiooxamides tétrasubstituées ($R_2NC(S)C(S)NR_2$ (R = CH_3:Me_4dto; R = C_2H_5:Et_4dto; R_2N = OC_4H_8:Mo_2dto) avec l'iode. En solution, on a observé que les réactifs forment des complexes de transfert de charge (t.c.) 1:1 et 1:2. Dans le but d'évaluer les constantes de formation, on a appliqué un nouveau programme d'ordinateur dérivé du «SUPERQUAD» (P. Gans, A. Sabatini et A. Vacca. J. Chem. Soc. Dalton Trans. 1195 (1985)). On a isolé le complexe de t.c. 1:2 à l'état solide; une analyse par diffraction des rayons-X du composé $[OC_4H_8NC(S)C(S)NC_4H_8O].2I_2$ indique que les cristaux sont tricliniques, groupe d'espace $P\bar{1}$ avec a = 14,659(6), b = 15,111(6) et c = 9,317(5) Å, α = 92,29(2), β = 99,71(2) et γ = 99,48(2)° et Z = 4. On note, en particulier, que l'angle de torsion S—C—C—S (≈90°) démontre que la conformation du dithiooxamide n'est *pas* trans.

[Traduit par la revue]

Introduction

Diiodine (I_2) forms molecular compounds of the charge-transfer (c.t.) type, with a variety of molecules containing nitrogen, sulphur or selenium heteroatoms. Moreover, these c.t. complexes may be key intermediates in the oxidative mechanism of these molecules by means of I_2.

In recent studies about these reactions, in particular we have used molecules containing one or more thioamide groups: i.e. both the non-coordinated $[R_2NC(S)SSC(S)NR_2]$ = tetraalkyl-thiuram disulphide (1), and $[R_2NC(S)S^-]$ = dialkyl dithio-carbamato anion, which is coordinated to the transition metals Cr(III) (2), Co(III) (3), Fe(III) (4), Mn(III) (5).

The obtained results showed that (*i*) despite the several electron donor sites available in the molecule, the carbonyl sulphur is the site of interaction with I_2, and in solution no stoichiometries higher than 1:1 have been observed (in the explored concentration range); (*ii*) the carbonyl sulphur retains basic properties even though coordinated to transition metals; (*iii*) the c.t. complexes may evolve to give oxidation products, and it was possible to isolate them and determine their structures as cations having poly-iodides as counter ions.

As a progression, we are investigating the behaviour of dithiooxamides, and we here report on the results obtained with tetraalkyl dithiooxamides.

Experimental

Materials

Twice sublimed diiodine was purchased from Carlo Erba. $CHCl_3$ was Merck Reagent Grade and dried over 4 Å molecular sieves before use. Tetra-substituted dithiooxamides were prepared according to literature (6). The compound $[OC_4H_8NC(S)C(S)NC_4H_8O]\cdot 2I_2$ was obtained as red–brown lustrous crystals on slow evaporation of a $CHCl_3$ solution of $[OC_4H_8NC(S)C(S)NC_4H_8O]$ and I_2 in a 1:2.5 ratio. *Anal.* calcd. for $C_{10}H_{16}I_4N_2O_2S_2$: C 15.64, H 2.10, N 3.65; found: C 15.60, H 2.19, N 3.69.

The elemental analyses were performed by Istituto di Chimica Farmaceutica, Università di Cagliari.

The other adducts have been obtained analogously. Infrared data (KBr pellets) are as follows. $[Mo_2dto]\cdot 2I_2$: 2965m, 2920w, 2900w, 2855m, 1510s, 1500s, 1490s, 1457w, 1433vs, 1385m, 1357m, 1330vw, 1300m, 1285s, 1270vs, 1260vs, 1240vs, 1225s, 1200s, 1175m, 1125s, 1110vs, 1060s, 1025vs, 980s, 915w, 908w, 890w, 860s, 840m, 765s, 660w, 640s, 610m, 540s, 500m, 475w, 395wbr, 310w, 290w,br.

$[Et_4dto]\cdot 2I_2$: 2997w, 2975m, 2935m, 2875w, 1528 ÷ 1500vs broad, 1450sh, 1435vs, 1380s, 1355m, 1287s, 1273vs, 1227vs, 1198vs, 1163w, 1142m, 1113s, 1098sh, 1073m, 1060sh, 1010w, 968vs, 928vs, 905vs, 858s, 805w, 780m, 750vs, 640m, 623m, 545sh, 483sh, 405m, 340vw, 305vw.

$[Me_4dto]\cdot 2I_2$: 2963w, 2925mw, 2859w, 1561vs, 1553vs, 1526vs, 1443w, 1432w, 1397vs, 1273s, 1255sh, 1242s, 1184m, 1152s,

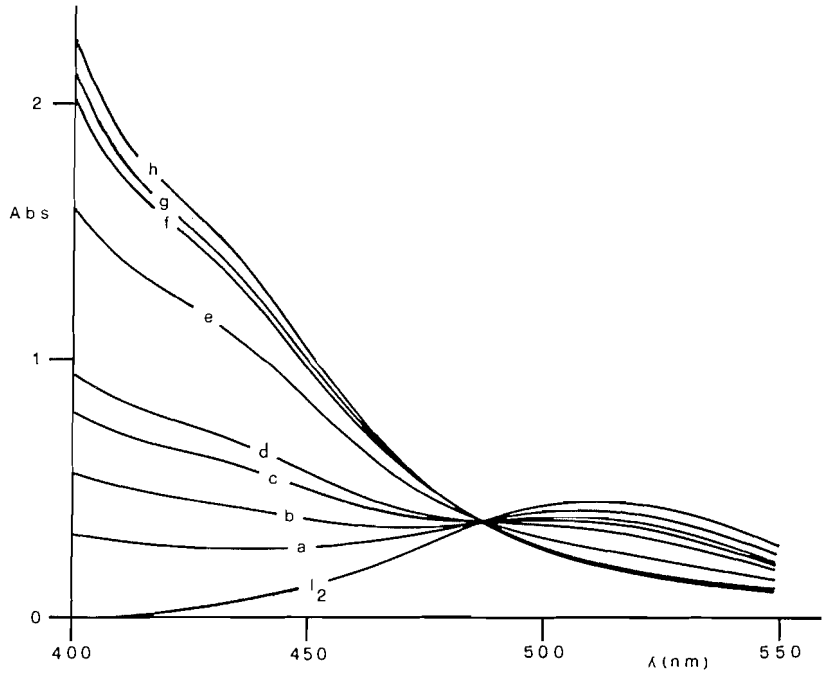

FIG. 1. Visible spectra at 283 K in 1 cm cell of $CHCl_3$ solutions containing constant amounts of I_2 (5×10^{-4} mol dm^{-3}) and variable Me_4dto concentrations in the ratios: *a* = 1:0.5; *b* = 1:1; *c* = 1:1.5; *d* = 1:2; *e* = 1:5; *f* = 1:10; *g* = 1:12; *h* = 1:15.

1112vs, 1046w, 972vs, 899w, 818vs, 621m, 568m, 514w, 437m, 375w, 313m.

Infrared spectra were recorded using a Perkin-Elmer model 983 spectrophotometer.

Spectrophotometric measurements

The electronic spectra were measured on $CHCl_3$ solutions with a Varian model Cary 2300 spectrophotometer equipped with an automatic system of data acquisition at different temperatures in the range 10 to 35°C.

A set of eight $CHCl_3$ solutions containing a constant diiodine concentration ($\approx 5 \times 10^{-4}$ mol dm^{-3}) and variable dithiooxamide concentrations (ranging from 2.5×10^{-4} to 1×10^{-2} mol dm^{-3}) (see Fig. 1) was prepared and the spectra recorded between 400 and 550 nm using 1 cm silica cells. Another set of twelve solutions was prepared with a constant concentration of dithiooxamide ($\approx 5 \times 10^{-4}$ mol dm^{-3}) and diiodine concentrations in the range $2.5 \times 10^{-4} - 2.5 \times 10^{-2}$ mol dm^{-3}; the relevant spectra were measured in the range 240–400 nm with 1 mm silica cells (see Fig. 2).

Calculations

The experimental points used in calculations have been taken from the recorded spectra at 10 nm intervals, the total number of the data being always greater than 95 for each system at each temperature.

A new computer program written in FORTRAN has been used to refine simultaneously equilibrium constants and molar extinction coefficients from the spectrophotometric measurements. The sum of the squared residuals of the optical densities is minimized by the Gauss–Newton least-squares method using unit weights, all the derivatives being obtained analytically. The program is designed to be as general and flexible as possible: the stoichiometry of the species formed can be varied by simple input information; the observed quantities may refer either to individual spectra (batch experiments) or points of spectrophotometric titrations; each spectrum may contain absorption data read at different wavelengths. The number of wavelengths per spectrum is not rigid and may change from one spectrum to another. A detailed description of the program will be the subject of a future publication (7). Calculations were carried out using a GOULD 32/27 computer at I.S.S.E.C.C., Firenze.

X-ray crystallography

Crystal data are as follows:

$C_{10}H_{16}I_4N_2O_2S_2$ mw = 767.987

Triclinic, a = 14.659(6), b = 15.111(6), c = 9.317(5) Å, α = 92.29(2); β = 99.71(2), γ = 99.48(2)° (by least-squares refinement from the θ values of 28 reflections accurately measured) U = 2002(2) Å^3, Z = 4, D_c = 2.549 g cm^{-3}, $F(000)$ = 1400, Mo-K_α radiation (λ = 0.71073 Å), μ(Mo-K_α) = 63.66 cm^{-1}, space group $P\bar{1}$. Crystal dimensions: 0.09 × 0.20 × 0.28 mm^3.

Data collection and processing

Siemens AED diffractometer, niobium-filtered Mo-K_α radiation, θ–2θ scan mode, 4829 unique reflections measured ($+h$, $\pm k$, $\pm l$), ($2.5 \leq \theta \leq 22°$), 2626 observed ($I \geq 2\sigma(I)$), data corrected for absorption (8) (maximum and minimum values 1.049664, 0.993898) and extinction (maximum and minimum values 1.005226, 0.977286).

Structure analysis and refinement

Patterson and heavy-atom methods were used, blocked full-matrix least-squares refinement was carried out with anisotropic thermal parameters for all the non hydrogen atoms excluding those of the morpholinic rings. Hydrogen atoms were placed in their geometrically calculated positions and their coordinates were introduced in the last cycle as fixed contributors. The weighting scheme used in the final cycles was $w = 0.6438/(\sigma^2(F_o) + 0.002250F_o^2)$. The final R and R' values were 0.0455 and 0.0545, respectively. The final electron-density difference synthesis showed no peaks >0.93 and <−0.90 e Å^{-3}. Scattering factors and corrections for anoma-

Results and discussion

The addition of diiodine to R_4dto is accompanied by a drastic change in the uv–visible spectrum of the solution, and a new c.t. maximum appears near 300 nm, while the characteristic band of the free diiodine is "blue shifted" (see Fig. 1, 2) and an isosbestic point is observed.

The spectrophotometric data obtained between 400 and 550 nm for the solutions with constant diiodine concentration and variable dithiooxamide concentration could be interpreted quite satisfactorily by assuming that the 1:1 species is the only adduct present. This was verified for all the dithiooxamides investigated at all the temperatures. The values of log K_1 are listed in Table 3. The interpolations of the plots of these quantities against $1/T$ (linear correlation coefficients greater than 0.99) allowed a sufficiently precise determination of the enthalpy of formation of the 1:1 adducts and consequently of the calculation of the entropy changes. The values of the thermodynamic functions shown in Table 3 are very close in the three examined dithiooxamides.

The spectral data measured in the range 240–400 nm on the solutions containing constant dithiooxamide concentrations and variable diiodine concentrations are clearly consistent with the stepwise addition of diiodine to the ligand. They have been used

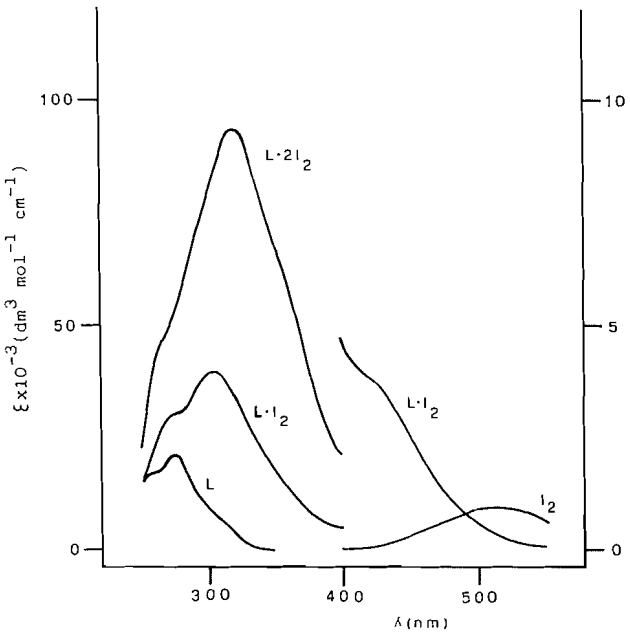

FIG. 3. Calculated uv–vis spectra of 1:1 and 1:2 adducts between Me_4dto and diiodine at 283 K in $CHCl_3$ solutions.

to calculate the formation constant of both of the 1:1 and 1:2 adducts together with the corresponding molar absorption coefficients of the adducts (see Fig. 3). Unfortunately the experimental errors in the observed data did not allow a precise determination of these quantities. However, the following overall values of log K_1 and log $K_1 \cdot K_2$ were obtained at 10°C: 2.87 ± 0.01 and 4.05 ± 0.06 for Me_4dto, 3.00 ± 0.01 and 4.39 ± 0.05 for Et_4dto, 2.45 ± 0.05 and 3.8 ± 0.2 for Mo_2dto.

The principal ir bands are listed in the Experimental part.

In Table 4 the thioamide (I) band with a major ν(CN) contribution, and (IV) band with a high ν(CS) contribution are assigned according to Desseyn and Herman (15).

Structural evidence shows that S atoms have the donor role in the molecule (see later), and that there is an extensive delocalization within the NCS moieties (but not along the carbon–carbon skeleton between them). Previously reported structural studies on some dithiooxamides have shown similar features (16–18).

The ir results reflect this situation. In fact, a significant positive shift is observed in the thioamide(I) ν(CN) band due to the coordination, while the thioamide(IV) ν(CS) band is less affected. The other bands do not undergo any significant shifts.

Because of the π-electron flow from the N atom to the S, the electronic delocalization through the system

allows to compensate the decrease of the bond order CS as a consequence of the coordination: therefore the ν(CS) is less affected by the coordination than expected.

As a consequence of the electron delocalization, the basicity of the parent amine should affect the association constants of the c.t. complexes. For the limited data so far available, a correlation between log K_1 and the pK_A of the parent amines in the protonated form seems to exist (pK_A = 8.492, 10.774, and 10.993 and 298 K for morpholine, dimethylamine, and

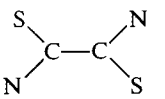
diethylamine, respectively) (19), while the ΔH^0 values are very close in the three dithiooxamides studied.

A more extensive investigation, using parent amines with pK_A varying in more extensive range, and *N,N'*-disubstituted dithiooxamides, to study the effect of the basicity of the parent amine and of hydrogen bonding is in project.

Crystal and molecular structure

The title compound, whose molecular structure is shown in Fig. 4 together with the atomic numbering scheme, is a neutral molecular compound belonging to the series with the two S as heteroatoms in the donor and with the two diiodine molecules as acceptors.

Excluding the S(1i)—I(1i)—I(2i) moieties (where i = 1,2 for molecule **1** and **2**, respectively), the two crystallographically independent molecules of the adduct are related by a pseudo-glide roughly parallel to (0 1 0) at (1/4)*b*. Moreover, they appear similar for several reasons. The bond distances and angles are in good agreement; in the



moieties the usual sp^2 hybridization is observed for the C and N atoms and the hybridization at S is essentially sp^3. In each molecule the S(1i)—I(1i) distance is greater than S(2i)—I(3i), and consequently the correlated I(1i)—I(2i) distance is shorter than I(3i)—I(4i). This is the result of the contacts involving the terminal iodine atoms; in fact the longest I—I bond distance is observed when the contacts are approximately in the I—I bond direction. Similar bond distances were observed in [benzyl sulphide]·I_2 (20), in [$Co(C_5H_5N)_4(NCS)_2$]·$2(I_2)$ (21), in [1,4-dithiane]$2(I_2)$ (22), in [2(merocyanine)]·I_2 (23), in dithia[3.3.1]propellane·$2I_2$, and in dithia[3.3.2]propellane·$2I_2$ (24). In addition, despite the large variation in S—I distance, a similar correlation (excluding only one couple of values in dithia[3.3.1]propellane·$2I_2$: S—I 2.852(2) and I—I 2.797(1) Å) and no appreciable change in the C=S distance were observed in the above mentioned and in several other compounds (Herbstein and Schwotzer (25) and references therein).

Besides the intermolecular contacts, the most significant differences between the two independent molecules regard the values of the C(1i)—S(1i)—I(1i) angles (107.7(7)° and 112.4(7)°, respectively) and of the torsion angles around S—C; 148(1)° is observed for I(12)—S(12)—C(12)—N(12) and −30(2)° for I(12)—S(12)—C(12)—C(22), while the values of all the other

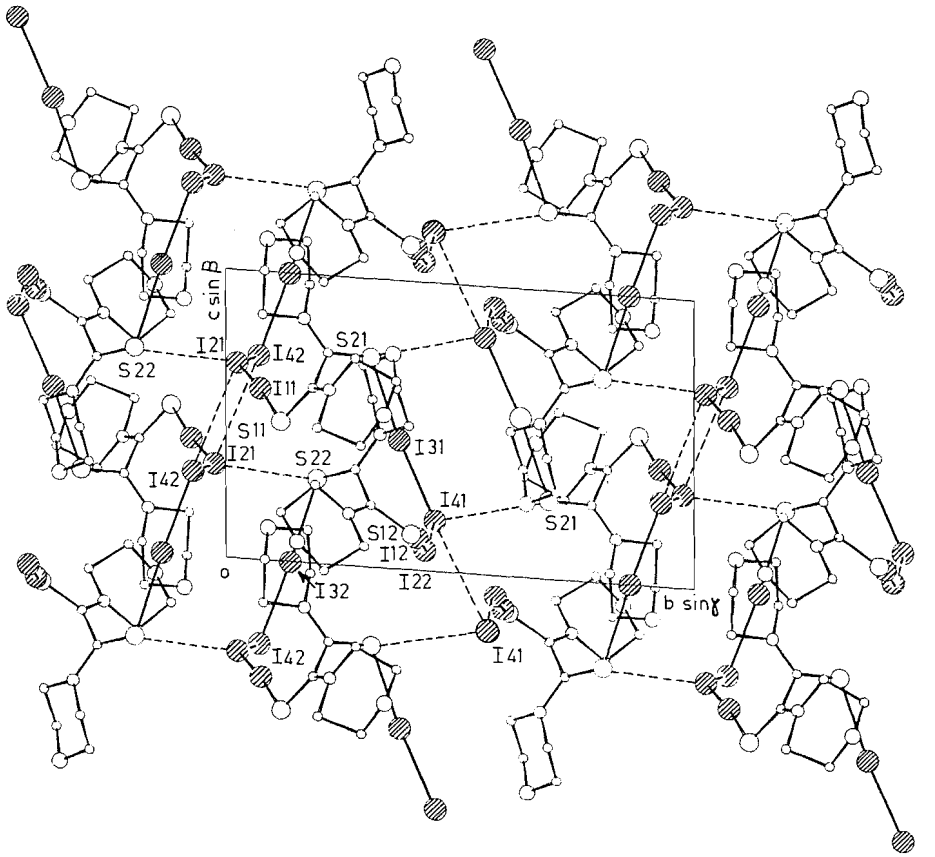

FIG. 5. Projection of the structure along [100].

corresponding angles are about 180° and 0°, respectively. This is determined by the contact I(22)···I(41) 3.705(3) Å.

The pseudo C_2 symmetry observed in molecule **1**, excluding the COC morpholinic moieties, lacks in molecule **2** owing to the above-mentioned I(22)···I(41) interaction. This contact is also responsible of the non-planarity of the C(22)C(12)S(12)I(12) fragment. In the other CCSI planar fragments interactions I(1i)···C(2i) and I(3i)···C(1i) less than the Van der Waals radii sum are observed (I(11)···C(21) 3.51(2), I(31)···C(11) 3.52(2), I(32)···C(12) 3.60(2) Å) while the contact I(12)···C(22) is 3.83(2) Å.

The conformation of these *N,N,N',N'*-tetrasubstituted molecules is the most favourable to yield the minimum hindrance: the values of the S—C—C—S torsion angles are −91(2) and 94(2)°, respectively.

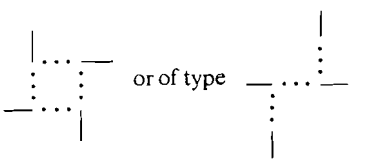
On the contrary, in the uncomplexed molecule and in some metal-complexes of dioxamides, dithiooxamides, and *N,N'*-disubstituted dioxamides and dithiooxamides, the *trans* conformation is determined by contacts which can be considered as intramolecular N—H···S hydrogen bonds.

Contacts of type I···I (as the menthioned I(22)···I(41), I(21)···I(42) $(-x, -y, -z)$ 3.758(3), I(21)···I(42) $(x-1, y, z+1)$ 3.931(3), I(41)···I(41) $(-x, 1-y, -z)$ 3.746(3) Å); I···S (I(21)···S(22) $(-x, -y, 1-z)$ 3.790(6), I(41)···S(21) $(-x, 1-y, 1-z)$ 3.755(5) Å); I···C_{morph} (I(41)···C(62) $(x-1, y, z)$ 3.83(2), I(22)···C(31) $(x, y, z-1)$ 3.99(2) Å); S···S (S(11)···S(11) $(-x, -y, 1-z)$ 3.54(7) Å); O···C_{morph} (O(12)···C(71) $(1+x, y, z-1)$ 3.23(3), O(22)···C(62) $(x, y, 1+z)$ 3.26(3) Å), and C_{morph}···C_{morph} (C(52)···C(82) $(x, y, z-1)$ 3.59(4), C(61)···C(81) $(x, y, z-1)$ 3.73(3) Å) are important in determining the molecular three-dimensional packing.

The first four values show that there are I_2···I_2 secondary interactions which are appreciably shorter than the sum of the Van der Walls radii. Similar unusual interactions were recently observed in dithia[3.3.1]propellane·$2I_2$ (3.720(1) Å) and in our tris(morpholinecarbodithioato-*S,S'*)manganese(IV)pentaiodide dichloromethane (2/1) (26) (3.795(3) and 3.877(3) Å), where however V-shaped I_5^- units of the type I_2···I^-···I_2 are present and where the interactions involve a terminal iodine of a unit and an internal iodine of another unit.

Excluding the I(22) atom, each of the other three terminal iodine interacts with the adjacent iodines in such a way to present a roughly planar T-shaped arrangement; moreover each of them is involved in a contact of type I···S or I···C_{morph} in a direction quite perpendicular to the corresponding T-shaped disposition.

The interactions between the T-shaped arrangements originate others of type



(— indicates the I_2 molecule) as well showed in Fig. 5. The values of the I—I···I angles (I(11)—I(21)···I(42) $(-x, -y, -z)$ 150.8(1)°, I(31)—I(41)···I(41) $(-x, 1-y, -z)$ 174.8(1)°, I(12)—I(22)···I(41) 156.7(1)°, I(32)—I(42)···I(21) $(1+x, y, z-1)$ 170.8(1)°) indicate that the interactions deviate

significantly from linearity and they are in good agreement with those observed in dithia[3.3.1]propellane·$2I_2$ (154.2(1)°) and in tris(morpholinecarbodithioato-*S*,*S*′)manganese(IV)pentaiodide dichloromethane (2/1) (155.9(1) and 176.7(1)°).

The conformational behaviour of ^5J_m(F,CH) in 3,5-difluoro derivatives of toluene, ethylbenzene, and cumene. Applications

TED SCHAEFER, CRAIG S. TAKEUCHI, AND STEVEN ERIC SVEINSON[1]
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received November 24, 1987

TED SCHAEFER, CRAIG S. TAKEUCHI, and STEVEN ERIC SVEINSON. Can. J. Chem. **66**, 1490 (1988).

The CNDO/2 and INDO MO FPT values for ^5J_m(F,CH$_3$) in 3-fluoro- and 3,5-difluorotoluene are exactly reproduced by $A\cos^2\theta + B\sin^2\theta + C\sin^2(\theta/2)$. Here θ is the angle by which the α C—H bond twists out of the benzene plane. Adjustment of A, B, and C to give an agreement with experiment for 3,5-difluorotoluene yields an equation, best considered empirical, which is tested by ^5J(F,CH) in 3,5-difluoroethylbenzene and 3,5-difluoroisopropylbenzene. The equation reproduces ^5J(F,CH) in these two compounds, the values of $\langle\sin^2\theta\rangle$ being derived from ^6J_p(H,CH), the spin–spin coupling constants over six bonds between the α and *para* ring protons. ^5J(F,CH) is obtained for the asymmetrical compounds, 2,3-difluorobenzylidene diacetate and 2-bromo-5-fluorobenzylidene diacetate. It is shown how ^5J(F,CH) in the latter can discriminate between two conformers, each of which, on the basis of ^6J(H,CH), will be characterized by a large degree of torsion about the C(1)—C_{sp^3} bond.

TED SCHAEFER, CRAIG S. TAKEUCHI et STEVEN ERIC SVEINSON. Can. J. Chem. **66**, 1490 (1988).

On peut reproduire exactement les valeurs calculées par CNDO/2 et INDO MO FPT pour les ^5J_m(F,CH$_3$) des fluoro-3 et difluoro-3,5 toluènes, grâce à l'équation $A\cos^2\theta + B\sin^2\theta + C\sin^2(\theta/2)$ dans laquelle θ correspond à l'angle qui existe entre la liaison C—H en α et le plan du benzène. L'ajustement des paramètres A, B, et C afin d'obtenir une concordance avec l'expérience effectuée sur le difluoro-3,5 toluène fournit une équation que l'on doit considérer comme empirique et que l'on a vérifiée à l'aide des ^5J(F,CH) des difluoro-3,5 éthyl (et isopropyl) benzènes. Pour ces deux composés, l'équation reproduit les valeurs des ^5J(F,CH); les valeurs de $\langle\sin^2\theta\rangle$ ont été obtenues à partir des valeurs de ^6J_p(H,CH), les constantes de couplage spin–spin à travers six liaisons entre les protons α et ceux présents en position *para* sur le cycle. On a déterminé les ^5J(F,CH) des composés asymétriques suivants : le diacétate du difluoro-2,3 benzylidène et le diacétate du bromo-2 fluoro-5 benzylidène. On a démontré que, dans ce dernier cas, les ^5J(F,CH) permettent de choisir entre deux conformères qui, sur la base des ^6J(H,CH), seront caractérisés par une torsion importante autour de la liaison (C1)—C_{sp^3}.

[Traduit par la revue]

Introduction

The mechanisms of the spin–spin coupling constants between the methyl and ring protons in toluene are understood in terms of σ–π and σ electron contributions (1–4). The coupling constants have been written as (in Hz)

$$[1]\quad {}^6J_p(\mathrm{H,CH_3}) = {}^6J^{\pi}_{90}\langle\sin^2\theta\rangle = -1.20\langle\sin^2\theta\rangle$$

$$[2]\quad {}^5J_m(\mathrm{H,CH_3}) = {}^5J^{\pi}_{90}\langle\sin^2\theta\rangle + {}^5J^{\sigma}_{180}\langle\sin^2(\theta/2)\rangle = 0.336\langle\sin^2\theta\rangle + 0.322\langle\sin^2(\theta/2)\rangle$$

$$[3]\quad {}^4J_o(\mathrm{H,CH_3}) = {}^4J^{\pi}_{90}\langle\sin^2\theta\rangle + {}^4J^{\sigma}\langle\cos^2\theta\rangle = -1.08\langle\sin^2\theta\rangle - 0.32\langle\cos^2\theta\rangle$$

In these equations the coefficients of the expectation values of $\sin^2\theta$ represent the σ–π components, while those of $\langle\cos^2\theta\rangle$ and $\langle\sin^2(\theta/2)\rangle$ are the σ components. The angle θ measures the out-of-plane twist of the α C—H bond. Relationships of this kind are useful in the description of the conformational behaviour of a variety of benzyl and benzal compounds (4, 5).

Replacement of hydrogen by a fluorine atom in the phenyl group of toluene leads to ^{1}H,^{19}F coupling constants analogous to the ^{1}H,^{1}H interactions in eqs. [1]–[3]. ^6J_p(F,CH$_3$) is thought to be dominated by a σ–π mechanism, i.e., it has a $\sin^2\theta$ dependence (1, 6). Unlike ^6J_p(H,CH$_3$), it is positive because the hyperfine interaction parameter, $Q^{\mathrm{F}}_{\mathrm{CF}}$, is of opposite sign to $Q^{\mathrm{H}}_{\mathrm{CH}}$. ^4J_o(F,CH$_3$) has a complex dependence on θ, part of the complexity arising from proximate interactions (7, 8) whose conformational dependence is still somewhat uncertain (8).

The substantial magnitudes of ^6J_p(F,CH$_3$) and ^4J_o(F,CH$_3$), being +1.15 Hz in 4-fluorotoluene and +2.0 Hz in 2-fluorotoluene, respectively, stand in sharp contrast to ^5J_m(F,CH$_3$) ≡ ^5J = −0.25 Hz in 3-fluorotoluene (9). It was argued that ^5J arises from a near cancellation of a positive, stereospecific, σ electron component by a negative σ–π contribution. INDO MO FPT computations do imply a large negative ^5J_m near θ = 90° (9) and a larger positive ^5J_m at θ = 180° (zigzag or all-*trans* bond arrangement). For a standard geometry the average ^5J_m is computed as +0.2 Hz (9). In a partially restricted molecular orbital calculation (10), designed to separate σ and σ–π contributions to ^5J_m, support for a negative σ–π component is adduced. Its contribution to ^5J_m is computed as −0.63 Hz, a reasonable magnitude when compared to the σ–π contribution to ^6J_p(F,CH$_3$). However, the net result then is that the σ contribution to ^5J_m has a θ dependence resembling that of a modified Karplus curve, with a slightly negative minimum near θ = 70°, and values near 0.6 and 2.3 Hz at θ = 0° and 180°, respectively. The following discussion takes an essentially empirical approach to ^5J_m, with a view to its use in conformational analysis.

TABLE 1. The CNDO/2 and INDO MO FPT values in Hz for ^5J(F,CH) in 3,5-difluorotoluene for a standard[a] geometry

θ/deg[b]	CNDO/2	INDO	θ/deg[b]	CNDO/2	INDO
0	0.60	0.388	105	0.23	−0.833

[a]Reference 21.
[b]See **1** for the angle θ.

Explicitly, and with reference to the compounds to be discussed in this work, the INDO MO FPT values for 3,5-difluorotoluene are given in Table 1. The angle θ is defined in **1**.

The INDO values in Table 1 are fit precisely by eq. [4], the

F(5): $\theta = 0°$ for H_a, 120° for H_b

1

maximum deviation being 0.02 Hz with an average deviation of 0.007 Hz. This relationship could be considered as arising from a $\sigma-\pi$ component, proportional to $\sin^2\theta$ and two σ components, one proportional to $\cos^2\theta$ and the other to $\sin^2(\theta/2)$. In other words, one would have eq. [5], in which ${}^5J_0^\sigma$

$$[4]\quad {}^5J_m(\mathrm{F,CH_3})/\mathrm{Hz} = 0.388 - 2.433\sin^2\theta + 1.685\sin^2(\theta/2)$$

$$[5]\quad {}^5J_m(\mathrm{F,CH_3})/\mathrm{Hz} = {}^5J_0^\sigma\cos^2\theta + {}^5J_{90}^\pi\sin^2\theta + {}^5J_{180}^\sigma\sin^2(\theta/2) = {}^5J_0^\sigma + ({}^5J_{90}^\pi - {}^5J_0^\sigma)\sin^2\theta + {}^5J_{180}^\sigma\sin^2(\theta/2)$$

is 0.388 Hz, ${}^5J_{90}^\pi = -2.045$ Hz, and ${}^5J_{180}^\sigma = 1.685$ Hz. The sixfold internal barrier to rotation in **1** is surely less than 200 J/mol (11, 12), so that $\langle\sin^2\theta\rangle$ and $\langle\sin^2(\theta/2)\rangle$ are both[2] 0.5. Equation [4] therefore yields 0.014 Hz for ${}^5J_m$. The observed value is −0.294 Hz (see below). Because there is no obvious reason to single out a given component in eq. [4], the observed number can be reproduced by a decrease of 0.308 Hz in each of the computed values in Table 1. This procedure yields eq. [6].

$$[6]\quad {}^5J_m(\mathrm{F,CH_3})/\mathrm{Hz} = 0.080 - 2.433\langle\sin^2\theta\rangle + 1.685\langle\sin^2(\theta/2)\rangle = A + B\langle\sin^2\theta\rangle + C\langle\sin^2(\theta/2)\rangle$$

This equation implies, but does not establish, a very small value of ${}^5J_m$ at $\theta = 0°$.

The CNDO/2 MO FPT results in Table 1 are accurately reproduced by eq. [7]. The form of eq. [7] is that of eq. [4]. It is

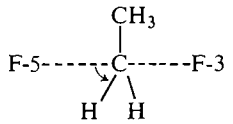
$$[7]\quad {}^5J_m(\mathrm{F,CH_3})/\mathrm{Hz} = 0.597 - 1.021\sin^2\theta + 0.940\sin^2(\theta/2)$$

sometimes assumed that CNDO/2 calculations yield σ electron contributions to coupling constants, whereas INDO includes the π electron contributions. The difference between eqs. [4] and [7] has a coefficient of −1.4 Hz in the $\sin^2\theta$ term. For fast internal rotation, therefore, the $\sigma-\pi$ contribution would be −0.7 Hz, in close agreement with the PRMO approach (10). Certainly, a ${}^5J_{90}^\pi$ of −2.3 Hz (see eqs. [5] and [6]) appears to be much too large in magnitude, so that the coefficients in eq. [6] should be treated as empirical.

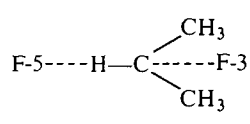
Now, for ${}^5J_m(\mathrm{H,CH_3})$ in toluene, all the experimental evidence is consistent with a zero value at $\theta = 0°$ (3, 4). Yet, both INDO and CNDO/2 compute significant values at this angle. Furthermore, the CNDO/2 numbers obey a curve analogous to that of eq. [6]. When it is noted that eq. [6], having a very small value at $\theta = 0°$, reproduces ${}^5J_m(\mathrm{F,CH_3})$ in **1**, the suspicion arises that the substantial computed numbers at this angle are artifacts. Equation [6] will be taken as an operational conformational equation.

One approach to a test of eq. [6] involves **2** and **3**, the 3,5-difluoro derivatives of ethylbenzene and isopropylbenzene.

[2]Because of the threefold symmetry of the methyl group, this statement is true as long as the barrier is small enough to yield an averaged chemical shift of the three protons.

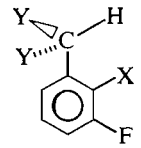


2, $\theta = 30°$



3, $\theta = 0°$

The most stable conformers are indicated in **2** and **3** and $\langle\sin^2\theta\rangle$ values are available from ${}^6J_p(\mathrm{H,CH})$. The internal barriers about the C_{sp^2}—C_{sp^3} bonds are predominantly twofold with some fourfold character. Therefore $\langle\sin^2(\theta/2)\rangle$ is 0.5. As a consequence, the presence of a ${}^5J_0^\sigma$ is not ascertainable from ${}^5J_m$ in **1**, **2**, and **3**. Ideally, a *rigid* molecule like **4** is needed for this purpose.



4

This paper gives the analyses of the ^{1}H and ^{19}F nmr spectra of **1**–**3** and of two molecules of type **4**, discusses the ensuing ${}^5J$ values in terms of the preceding equations, and illustrates how ${}^5J$ might be used in conformational analysis.

Experimental

Compounds

The starting materials, 3,5-difluorobenzyl bromide, 3,5-difluoroacetophenone, and 3,5-difluorobenzoic acid were obtained from Fluorochem Ltd. The 3,5-difluorotoluene, **1**, was prepared from the bromide via the Grignard, while 3,5-difluoroethyl benzene, **2**, came from the acetophenone precursor by a modification of the Wolf–Kishner method, exactly as described in ref. 13. The 3,5-difluoroisopropylbenzene, **3**, resulted from the benzoic acid derivative by a procedure described in detail for the corresponding 2,6-difluoro compounds (14, 15). The products gave unmistakable ^{1}H and ^{19}F nmr spectra.

Samples

Compounds **1**, **2**, and **3** were dissolved in CS_2/C_6D_{12}/TMS/C_6F_6 mixtures (see Table 1 for exact compositions) and transferred to 5 mm od nmr sample tubes by filtration through a wad of cotton wool. Degassing of the sample tubes by a number of freeze/thaw/pump cycles was followed by flame-sealing.

Spectral accumulations

The ^{1}H and ^{19}F nmr spectra were acquired on a Bruker AM300 nmr spectrometer at a probe temperature of 300 K. Wide sweepwidth survey spectra were used to reference them with respect to TMS and C_6F_6. Each spectral region was then examined in detail, with sweepwidth and data region adjusted to given acquisition times of approximately 41 s. As many as 32 scans were acquired. Zero filling to twice the original data region was done before transforming the FIDs using small amounts of Gaussian and Lorentzian multiplications. Intrinsic linewidths at half-height were often as small as 0.05 Hz (while decoupling methyl protons for **2** and **3**) after this resolution enhancement, but more typically were 0.07–0.08 Hz. Partial decoupling experiments (16) were used to determine the sign of ${}^5J_m(\mathrm{F,CH})$ in **1**–**3**.

CNDO/2 and INDO MO FPT computations of coupling constants (17, 18) were performed on an Amdahl 470 system.

Results and discussion

Spectral analyses

The ^{1}H and ^{19}F nmr spectra were analyzed with the local version of the computer program NUMARIT (19). The spectral parameters appear in Table 2. Although reasonably high precision was attained, as indicated by the standard deviations of the parameters, the particular AA′XX′B nature of the ring nuclei entailed relatively large correlations between two

coupling constants within the phenyl moiety (see Table 2). Fortunately, these coupling constants are not of immediate interest in the discussion below.

Figure 1 illustrates the sign determination of ^5J_m(F,CH) in **2** and **3**.

$^5J_m \equiv {}^5J_m$(F,CH) in 1, 2, and 3

In eq. [6] the terms A, B, and C have been adjusted to fit the ^5J of −0.294 Hz in **1**. For **2** and **3**, the expectation values of $\langle\sin^2(\theta/2)\rangle$ are both 0.5, the geometry-optimized STO-3G MO computations[3] yielding evenfold internal rotational barriers (20). The expectation values of $\langle\sin^2\theta\rangle$ are derived from ^6J_p(H,CH) via eq. [1]. In **1**, $^6J_p(H,CH_3)$ is −0.588(0) Hz, implying $^6J^{\pi}_{90}$ as −1.176 Hz. A recent discussion of $^6J^{\pi}_{90}$ in ethylbenzene (20) indicates a small reduction in $^6J^{\pi}_{90}$ in the presence of a methyl substituent on the α carbon atom, implying that $^6J^{\pi}_{90}$ is −1.137 Hz in **2**. Then $\langle\sin^2\theta\rangle$ in **2** follows as 0.463/1.137 or 0.407. If a second methyl substituent causes a further reduction in $^6J^{\pi}_{90}$, then $\langle\sin^2\theta\rangle$ in **3** becomes 0.245/1.098 or 0.223. Substitution of these estimates of $\langle\sin^2\theta\rangle$ into eq. [6] gives −0.068 Hz for ^5J_m in **2** and 0.380 Hz in **3**. The measurements give −0.067(1) and 0.362(2) Hz, respectively (Table 2). In our opinion, the model is therefore satisfactory.

[3]We thank Glenn Penner for the unpublished computations on isopropylbenzene. Because of the symmetry of **1**, **2**, and **3**, no odd components are expected for rotation about their C_{sp^2}—C_{sp^3} bonds; such components would cause $\langle\sin^2(\theta/2)\rangle$ to differ from 0.5.

Of course, if methyl substitution causes a reduction in the magnitude of $^6J^{\pi}_{90}$ in **2** and **3**, then a similar reduction in the $^5J^{\pi}_{90}$ component of ^5J_m is possible. However, the concomitant changes in the other components of ^5J_m are unknown. In ethylbenzene, $^5J_m(H,CH_2)$ is given by eq. [2], implying compensatory effects on $^5J^{\pi}_{90}$ and $^5J^{\sigma}_{180}$ (20) by the methyl group. It appears that eq. [6] is best treated as an empirical equation, with the possibility that the reasonably good agreement with the experimental data for **1**, **2**, and **3** is fortuitous.

Further examination of equation [6]

2,7-Difluorofluorene

An unpublished analysis in this laboratory of the ^1H nmr spectrum of the rigid 2,7-difluorofluorene in CS_2 solution gives $^5J_m(F,CH_2)$ as −1.06(1) Hz. An STO-3G MO structure of fluorene, with full geometry optimization, yields the HCH angle of the methylene group as 107.3° and the relevant angle θ as almost exactly 60°. An INDO MO FPT calculation on 2-fluorofluorene, assuming the STO-3G structure and a C—F bond length of 1.33 Å, gives $^5J_m(F,CH_2)$ as −0.76 Hz. The simplest approach to this number assumes that $^5J_m(F,CH_2)$ is again computed as too large, algebraically, by 0.31 Hz (compare eq. [4] with eq. [6]) and that the adjusted value should therefore be −1.07 Hz, as observed.

However, it is also noted that $^6J_{90}$(H,CH) for 2-fluorofluorene is −0.93 Hz, the measured value of ^6J(H,CH) being −0.72 Hz, whereas it is −1.20 Hz in toluene (4). Therefore it is unlikely that eq. [6] for toluene derivatives will apply quantitatively to $^5J(F,CH_2)$ in 2,7-difluorotoluene. It does not.

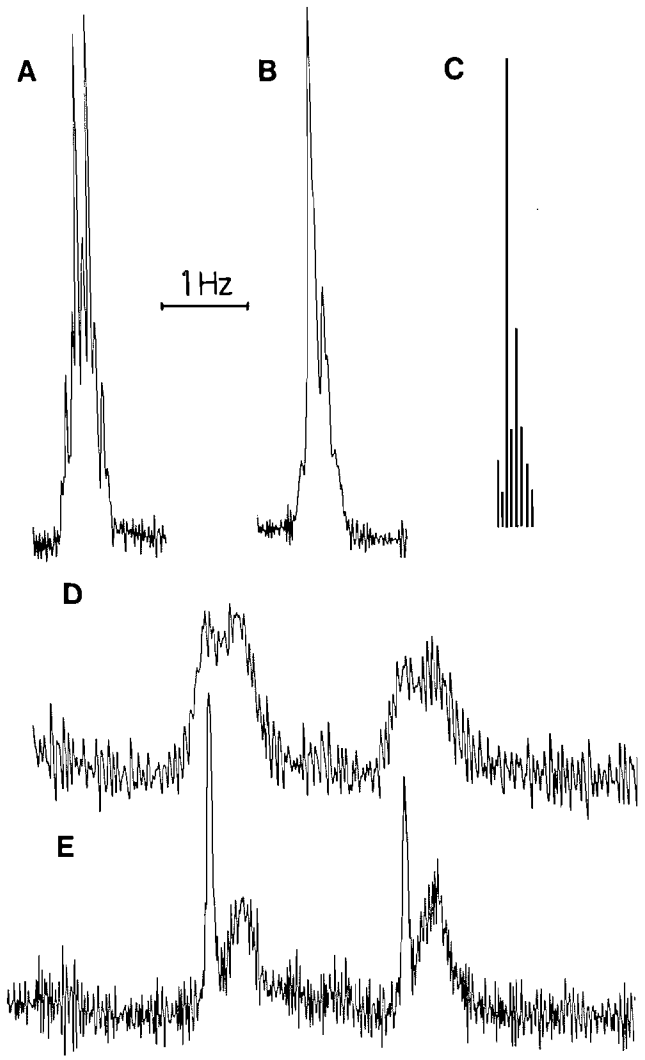

FIG. 1. A multiplet from the ^{19}F nmr spectrum of 3,5-difluoroethylbenzene is displayed in A. In the absence of coupling interactions with the ethyl protons this multipliet would be a single peak. $|^6J(F,CH_3)|$ is ca. 0.14 Hz and $|^5J(F,CH_2)|$ is ca. 0.07 Hz. In B the same multiplet appears under conditions where the high-field peak of the methyl proton resonance is irradiated. In other words, the methyl protons are undergoing classical (16) partial decoupling for a given spin state of the methylene protons, say $|-\frac{1}{2},-\frac{1}{2}|$. In C, a first-order reconstruction of the spectrum in B is presented in which it is assumed that $^5J(F,CH_2)/^3J(CH_2,CH_3) < 0$. The salient point is that the two most prominent peaks, having an intensity ratio of 7:3, appear in the correct sequence. If the coupling ratio above were positive, then the observed spectrum would appear as the mirror image of B. Because ^3J is positive, it follows that $^5J(F,CH_2)$ is negative. In D a pair of doublets is shown from the ^{19}F nmr spectrum of 3,5-difluoroisopropylbenzene. The peaks are broad due to unresolved coupling to six methyl protons. In E the same pair of doublets appears under conditions in which the low-field high-frequency methyl protons are being decoupled for one spin state of the methine proton. The spacing within a doublet, ca. 0.35 Hz, arises from $^5J(F,CH)$. It follows that $^5J(F,CH)/^3J(CH,CH_3) > 0$ and hence that $^5J(F,CH)$ is positive.

Nevertheless, the large negative $^5J(F,CH_2)$ in this molecule is reassuring qualitatively; in **1**, **2**, and **3** this coupling constant ranges from -0.3 to $+0.4$ Hz whereas eq. [6] implies rather large negative values for a large $\sin^2\theta$.

2,3-Difluorobenzylidene diacetate

The existence of a significant ^5J_m at $\theta = 0°$ is now tested as follows. Unfortunately, numerous attempts at the synthesis of **4** (Y = CH_3, X = Cl or F) ended in failure. However, 2,3-difluorobenzylidene diacetate (Y = $OC(O)CH_3$, X = F in **4**) could be prepared from the commercial benzaldehyde derivative in the usual way. The latter was also converted to 2,3-difluorotoluene in the manner described above for the preparation of 3,5-difluoroethylbenzene (13).

The full analysis of the ^1H and ^{19}F nmr spectra of a 3.9 mol% solution of 2,3-difluorotoluene in the CS_2/C_6D_{12} solvent mixture gave $^5J_m(H,CH)$ and $^6J_p(H,CH)$ as 0.328(2) and $-0.575(2)$ Hz, respectively. The threefold symmetry of the methyl group allows the conclusion (eq. [1]) that $^6J^{\pi}_{90}$ is -1.15 Hz in this molecule, whereas it is -1.20 Hz in toluene. Therefore $^5J^{\pi}_{90}$ in eq. [2] becomes 0.322 Hz and hence $^5J^{\sigma}_{180}$ is 0.334 Hz. $^5J_m(F,CH_3)$ is $-0.170(1)$ Hz in 2,3-difluorotoluene, algebraically larger than in 3-fluorotoluene (9). In accordance with the procedure used to arrive at eq. [6], its first term is to be changed to 0.204 Hz to reproduce the coupling in 2,3-difluorotoluene. With these calibration points, it is now possible to consider $^5J_m(F,CH)$ in 2,3-difluorobenzylidine diacetate. Values of $\langle\sin^2\theta\rangle$ and $\langle\sin^2(\theta/2)\rangle$ are found from $^6J(H,CH)$ and $^5J(H,CH)$.

In this molecule, $^6J_p(H,CH)$ is $-0.185(3)$ Hz for a 3.7 mol% solution in the CS_2/C_6D_{12} solvent mixture. The value of $^6J_{90}$ will be smaller in magnitude than for toluene. The electronegativity of the $OC(O)CH_3$ substituent is apparently (22) very near that of the OCH_3 group, the latter causing a reduction of -0.18 Hz in $^6J_{90}$ relative to toluene (see the discussion in a previous section). It appears unlikely that a second $OC(O)CH_3$ will reduce $^6J_{90}$ in an additive fashion. Choosing the reduction of $^6J_{90}$ by the second $OC(O)CH_3$ group to be half that caused by the first $OC(O)CH_3$ group, admittedly somewhat arbitrarily, yields $^6J_{90}$ as -0.930 (1.15/1.20) or -0.891 Hz. Then $\langle\sin^2\theta\rangle$ follows as 0.208. $^5J_m(H,CH)$ is 0.338(3) Hz and the requisite substitutions then imply $\langle\sin^2(\theta/2)\rangle$ as 0.857 and hence that $^5J_m(F,CH)$ is -0.06 Hz (remember that $\sin^2(\theta/2)$ in this connection becomes $1 - 0.857$, the C—H bond of the side chain lying mainly *cis* to the *ortho* C—F bond). In the ^{19}F nmr spectrum of 2,3-difluorobenzylidene diacetate, $^5J(F,CH)$ produces a doublet splitting of rather less than 10% of the peak height. Hence the observed splitting of 0.04(1) Hz is compatible with the existence of a ^5J_o, that is, with a small positive $^5J_m(F,CH)$ at $\theta = 0°$.

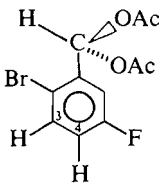
In acetone solution, $^5J_m(F,CH)$ is found as $-0.147(2)$ Hz for this compound. The above procedure yields a predicted value of -0.180 Hz, indicating a significant $^5J^{\sigma}_0$. In the acetone solution, $^5J_m(H,CH)$ and $^6J_p(H,CH)$ are 0.357(2) and $-0.202(2)$ Hz, respectively. The intricacies of the above procedure, although logical, may give rise to doubts about its validity. Suppose, therefore, that the spectral data for 2,3-difluorotoluene were unavailable and that eqs. [1] and [2], applicable to toluene, were used to obtain $\langle\sin^2\theta\rangle$ and $\langle\sin^2(\theta/2)\rangle$. Then $\langle\sin^2\theta\rangle$ for 2,3-difluorobenzylidene diacetate in acetone-d_6 solution would follow as $-0.202/-1.20$ or 0.168 and $\langle\sin^2(\theta/2)\rangle$ as 0.067, the latter from eq. [2] and the measured $^5J(H,CH)$ of 0.357 Hz in the diacetate. Hence eq. [6] would yield $^5J(F,CH)$ as -0.216 Hz, again compatible only with a significant positive value of $^5J(F,CH)$ at $\theta = 0°$.

It appears that empirical equations of type [6] are compatible with the conformational properties of **4** (Y = $OC(O)CH_3$, X = F) deduced from the long-range proton–proton coupling constants and that, therefore, they can be used in conformational analysis. However, as remarked in the introduction, the

identification of the coefficient of $\langle \sin^2 \theta \rangle$ as a pure $\sigma-\pi$ term is questionable.

A conformation application of $^5J(F,CH)$

For 2-bromo-5-fluorobenzylidene diacetate, ^5J(H,CH) is small, 0.04 Hz, and badly resolved. Furthermore, its spectral analytical value correlates strongly, by 0.51, with the chemical shift of H-3, 2238.675 Hz, and by 0.29 with ^3J(H-3,H-4). The magnitude of ^5J(H,CH) is therefore uncertain. However, ^5J(F,CH) is 1.037(0) Hz (CS_2 solution), implying as expected that a conformer predominates in which the methine C—H bond is situated near the bromine substituent. Equation [6] indicates 1.76 Hz for a rigid conformer of this kind, **5**, because θ is then



$\theta = 0°$ for H-3
$\theta = 180°$ for F

5

zero. Of course, the conformer is not rigid and the torsion about the C(1)—C_{sp^3} bond is also indicated by ^6J(H,CH), being −0.231(0) Hz.

If no reference molecule except toluene is available and no corrections are made to ^6J(H,CH), then $\langle \sin^2 \theta \rangle$ is 0.192 = −0.231/−1.20. Then arc sin $\langle \sin^2 \theta \rangle^{1/2}$ is 26°, indicating substantial torsion about the exocyclic bond. If $^6J_{90}$ is taken as −0.930(1.252/1.204) or −0.97 Hz (in 2-chloro-5-fluorotoluene, ^6J(H,CH) is −0.626(3) Hz (9) and the factor −0.930 is taken from the previous discussion), then $\langle \sin^2 \theta \rangle$ is 0.238; hence arc sin $\langle \sin^2 \theta \rangle^{1/2}$ is 29°. Further, if this value is taken as indicating θ as 151° for the term in $\sin^2(\theta/2)$ of eq. [6], then ^5J(F,CH) follows as 1.08 Hz, compared to the measured 1.04 Hz. Thus, although ^6J(H,CH) yields an estimate of the torsion it does not discriminate between **5** and a conformer obtained from **5** by rotation of 180° about the C(1)—C_{sp^3} bond. Equation [6] and ^5J(F,CH) do discriminate between these conformers and, apparently, provide a rough measure of the nonplanarity of the correct conformer. In some compounds, of course, ^6J(H,CH) would not be available because of substitution at the site in question.

Theoretical and experimental data on the internal rotational potential in isopropylbenzene

TED SCHAEFER, RUDY SEBASTIAN, AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received December 17, 1987

TED SCHAEFER, RUDY SEBASTIAN, and GLENN H. PENNER. Can. J. Chem. **66**, 1495 (1988).

Geometry-optimized STO-3G MO computations of the internal rotational potential about the C_{sp^2}—C_{sp^3} bond in isopropylbenzene yield V (kJ/mol) as $14.1(3)\sin^2\psi - 2.8(3)\sin^2 2\psi + 1.4(3)\sin^2 3\psi$; ψ is the angle by which the α C—H bond deviates from the benzene plane. This result provides no support for the very low internal barrier once hypothesized from microwave data for isopropylbenzene in the vapor phase, nor for the local minimum at $\psi = 90°$ inferred from hyperfine coupling constants in π electron radicals of isopropylbenzene derivatives. An alternative explanation in the literature for such microwave spectra is therefore a more likely one. Similar MO computations with the 6-31G basis at three values of ψ can be fit by $13.40\sin^2\psi - 2.61\sin^2\psi$ for the energies in kJ/mol. In CS_2 and acetone-d_6 solutions, the long-range proton–proton coupling constants imply the independence of the rotational potential of solvent polarity and also that the barrier is rather lower than that computed for the free molecule. An apparent twofold barrier of 6.5 kJ/mol is consistent with the coupling constants but so is a combination of twofold and fourfold barrier components amounting to 9.7, −3.5 and 7.2, −1.5 kJ/mol. The coupling constants do not allow discrimination among these possibilities. The internal rotational potential is not altered significantly in the presence of a 4-hydroxyl substituent in isopropylbenzene.

TED SCHAEFER, RUDY SEBASTIAN et GLENN H. PENNER. Can. J. Chem. **66**, 1495 (1988).

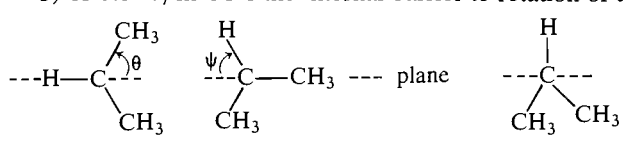
Des calculs d'OM STO-3G optimisés pour la géométrie ont été réalisés pour déterminer le potentiel de la rotation interne autour de la liaison C_{sp^2}—C_{sp^3} de l'isopropylbenzène et ils permettent d'établir que V (kJ/mol) = $14,1(3)\sin^2\psi - 2,8(3)\sin^2 2\psi + 1,4(3)\sin^2 3\psi$; ψ est l'angle par lequel la liaison C—H α dévie du plan du benzène. Ces résultats ne peuvent pas être utilisés pour confirmer la barrière interne très faible qui avait été suggérée sur la base de données de micro-onde obtenues à l'aide d'isopropylbenzène en phase vapeur ni le minimum local à $\psi = 90°$ qui avait été suggéré à partir de constantes de couplages hyperfins dans les radicaux d'électrons π de dérivés de l'isopropylbenzène. L'autre explication qui avait été proposée dans la littérature pour de tels spectres micro-ondes est donc plus probable. Des calculs semblables d'OM effectués au niveau 6-31G, à trois valeurs de ψ, conduisent à des énergies (en kJ/mol) qui peuvent être représentées par l'équation $13,40\sin^2\psi - 2,61\sin^2\psi$. En solutions dans le CS_2 ou dans l'acétone-d_6, les constantes de couplage proton–proton à longue distance impliquent que le potentiel à la rotation ne dépend pas de la polarité du solvant et que la barrière est vraisemblablement plus faible que celle calculée pour la molécule libre. Une barrière apparente binaire de 6,5 kJ/mol est en accord avec les constantes de couplage; toutefois, une combinaison de composantes de barrières binaire et quaternaire qui s'élèvent à 9,7, −3,5 et 7,2 et −1,5 kJ/mol fournit aussi un tel accord. Les constantes de couplage ne permettent pas de départager entre ces deux possibilités. La présence d'un substituant hydroxy-4 sur l'isopropylbenzène ne modifie pas le potentiel à la rotation interne d'une façon importante.

[Traduit par la revue]

Introduction

The recent literature contains some interesting and somewhat contradictory information on the potential function governing the internal rotation of the isopropyl group about the C_{sp^2}—C_{sp^3} bond linking it to the benzene ring. In a number of radicals containing the cumyl moiety (1), the temperature dependence of the hyperfine coupling interaction with the methine proton was interpreted to mean that **2** lies 5–7 kJ/mol above **1** in energy and that **3** lies at a local minimum in the potential energy, being 2.5–3.3 kJ/mol less stable than **1**. It was suggested that the rotational potential arises mainly from steric repulsion between the rotating methyl group and the neighbouring aromatic C—H bonds in the anion, cation, and neutral radicals. Apparently, the electronic structures of the radicals have only a small influence on the potential. A study of the isopropylbenzene anion radical (2) found the energy difference between **1** and **3** to be 1.6 kJ/mol.

The hyperfine coupling parameters for the ^{13}C nuclei in the methyl groups in the nickel acetylacetonate complexes of 4-isopropylaniline (3) yielded an (assumed) twofold potential (**1** → **3**) of 6.3 kJ/mol for the internal barrier to rotation of the isopropyl group. For the uncomplexed aniline derivative, the ^{13}C spin-lattice relaxation times indicated 11.7 ± 0.4 kJ/mol as the magnitude of the internal barrier.



1 **2** **3**

The long-range spin–spin coupling constant over six bonds between the methine and *para* ring protons in 3,5-dibromoisopropylbenzene was consistent with a twofold internal barrier of 8.4 ± 0.8 kJ/mol (4).

All these measurements were made on solutions. Although they differ as to the forms and magnitudes of the internal rotational potentials, the authors all agree that **1** is the most stable conformer. Furthermore, the electron diffraction patterns of isopropylbenzene (5) and of its 4-carboxaldehyde derivative (6) in the vapor phase unambiguously imply **1** as the conformation of the alkyl group.

On the other hand, low-resolution microwave spectra of 4-isopropylbenzaldehyde, also for the vapor, are consistent with a twofold internal barrier of 1.0 ± 0.6 kJ/mol, in strong contrast with the data for solutions and implying (7) a marked phase dependence of the rotational potential; but see below.

Now, *ab initio* molecular orbital computations have had some success in establishing the internal rotational potential in hydrocarbons like styrene (8, 9, 18) and ethylbenzene (10). For the latter, energies for geometry-optimized conformations at the STO-3G and 6-31G levels of theory gave twofold components to the internal barrier about the C_{sp^2}—C_{sp^3} bond as 6.6 and 6.0 kJ/mol, respectively, while the fourfold components were 0.8 and 1.2 kJ/mol, of opposite sign to the twofold magnitudes.

[a]In Hz at 300.135 MHz to high frequency of internal TMS.
[b]In CS_2, containing also 10 mol% of C_6D_{12} and 0.5 mol% TMS.
[c]In acetone-d_6, containing also 0.5 mol% TMS.
[d]Numbers in parentheses are standard deviations in the last significant figure.
[e]Transitions were assigned to all observed peaks; there are many degeneracies because of the methyl protons.

The long-range spin–spin coupling constants (10) for ethylbenzene indicated a barrier in solution in rough agreement with these computations for the isolated molecules.

Accordingly, it appears that STO-3G MO computations are useful in an attempt to establish the magnitude and shape of the internal rotational potential in isopropylbenzene, that is, whether it is indeed very low and whether **2** represents a local minimum. STO-3G MO computations were performed at 15° intervals of the angle ψ, allowing flexibility of the methyl group rotations about their local C—C bonds, among other geometrically optimizational motions. 6-31G computations were done at only three values of the angle ψ because of constraints on computing time.

In addition, the ^{1}H nmr spectra of isopropylbenzene in CS_2 and acetone solutions were analyzed precisely as 12-spin systems. The long-range proton coupling constants provide some information about the internal motion of the isopropyl group. The ^{1}H nmr spectrum of 4-isopropylphenol is also reported, to ascertain any perturbation of the internal barrier in the presence of a substituent that interacts significantly with the electrons in the benzene ring.

Experimental

A 2.5 mol% solution of isopropylbenzene in CS_2, containing 10 mol% of cyclohexane-d_{12} and 0.5 mol% of tetramethylsilane, was transferred to a 5 mm od nmr tube. The solution was degassed by the freeze–pump–thaw procedure and was then flame-sealed. A 2.5 mol% solution in acetone-d_6 was treated similarly. The ^{1}H nmr spectra were accumulated on an AM 300 spectrometer at a probe temperature of 300 K. The recording technique was identical to that described recently (11) and yielded linewidths at half-height of approximately 0.04 Hz for the *para* ring protons. The *ortho* and *meta* protons were slightly coupled to the methyl protons and the magnitudes of these coupling constants were estimated by spectral simulation (Table 1).

A 2.0 mol% of 4-isopropylphenol in CCl_4, containing ca. 5 mol% of tetramethylsilane, was subjected to ^{1}H nmr on an HA 100 spectrometer at a probe temperature of 305 K. The spectrum was calibrated in a manner described in detail previously (12).

The STO-3G MO computations were done with the program MONSTERGAUSS (13) on an Amdahl 470 system. The carbon atoms of the benzene ring were constrained to a planar hexagon during complete optimization of the side-chain geometries for seven conformations about the C_{sp^2}—C_{sp^3} bond (30 h of cpu time). The imposed constraint is unlikely to perturb significantly the computed internal potential (14). CNDO/2 and INDO MO computations (15*a*) on the STO-3G MO geometries were also performed with the Amdahl 470. Finally, 6-31G MO computations at ψ equal to 0°, 45°, and 90° employed the program GAUSSIAN 82 (15*b*,*c*) on an Amdahl 5870.

Results

Spectral analyses

These were performed with the computer program NUMARIT (16), extensively modified by R.S. Table 1 presents the ^{1}H nmr spectral parameters of isopropylbenzene, as obtained from analyses of the complete spectra arising from the 12-spin system. Figure 1 displays the calculated and observed spectra of most of the transitions arising from the *para* proton. The linewidth at half-height is very near 0.04 Hz.

For the 2.0 mol% solution of 4-isopropylphenol in CCl_4 solution, the germane coupling constants are −0.546(7) and 0.271(7) Hz, respectively, for ^4J(H,CH) and ^5J(H,CH). These long-range coupling constants are sensitive to the conformation of the isopropyl group.

The theoretical barrier

Table 2 presents the computed energies for seven conformations about the C_{sp^2}—C_{sp^3} bond. The STO-3G MO results can be fit by $V(\psi)/\text{kJ mol}^{-1} = (14.10 \pm 0.29)\sin^2\psi - (2.77 \pm 0.29)\sin^2 2\psi + (1.39 \pm 0.28)\sin^3 3\psi$. The quoted errors are given at the 95% confidence interval. There are significant fourfold and sixfold components in the computed internal barrier. Just as for ethylbenzene (10), the fourfold component is of opposite sign to the predominant twofold component. The computed barrier profile does not display a local minimum at $\psi = 60°$ (conformation **2**), suggesting that such a minimum, indicated by the hyperfine coupling constants of the radicals discussed above, either does not occur for the diamagnetic molecules or arises from solvent effects. Furthermore, the STO-3G results do not agree with the very small barrier once deduced from the microwave spectra at low resolution; but see the conclusions.

According to the 6-31G optimizations, the conformations at ψ equal 45° and 90° are 4.09 and 13.40 kJ/mol less stable than that at $\psi = 0°$. These energies are fit by $13.40\sin^2\psi - 2.61\sin^2 2\psi$, again yielding a fourfold component of the barrier

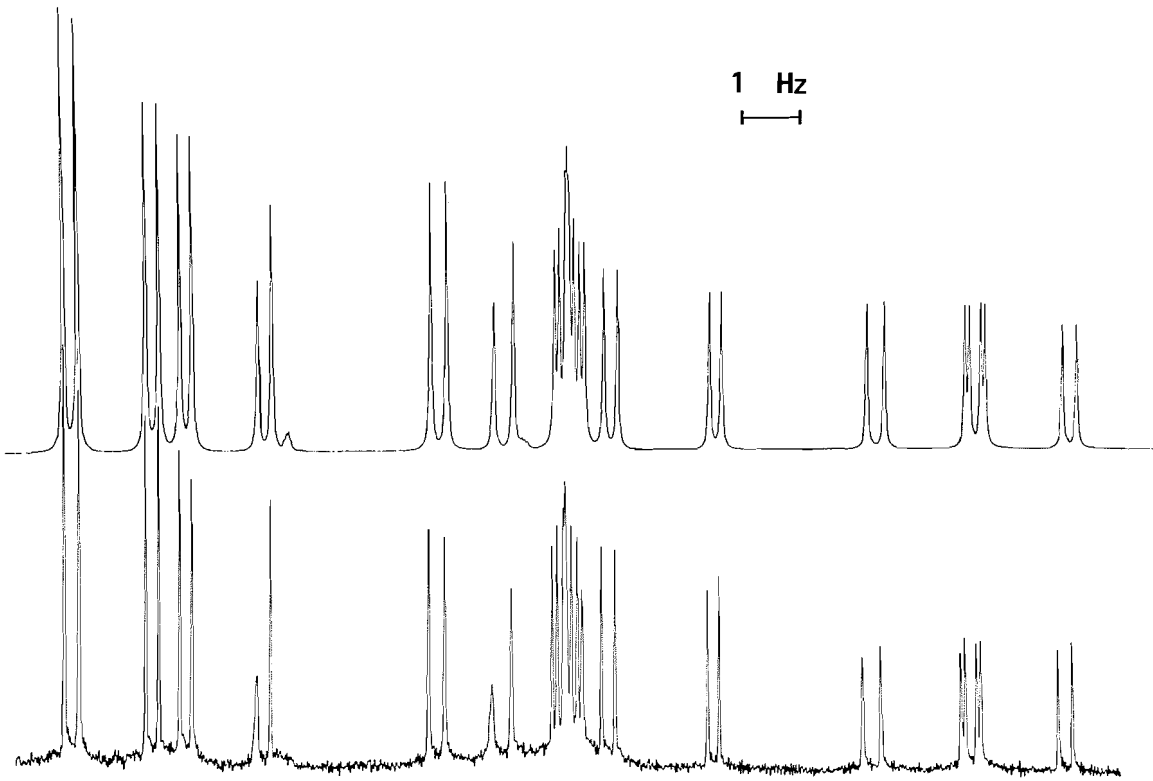

FIG. 1. The observed and computed ^{1}H nmr spectra of the *para* proton are displayed for a 2.5 mol% solution of isopropylbenzene in CS_2 solution (spectral parameters as in Table 1). The linewidths at half-height are near 0.04 Hz in the experimental spectrum.

of opposite sign to that of the twofold component. These components must have the same sign and, of course, different relative magnitudes if a local minimum is to exist at $\psi = 90°$.

The 6-31G structure is shown in Fig. 2 for $\psi = 0°$, the only constraint in the optimization procedure being a planar phenyl moiety; this was also the constraint at 45° and 60°. The computed geometry appears reasonable (see figure caption).

The long-range coupling constant, $^6J(H,CH)$

The coupling constant between the methine proton and the *para* ring proton, ^6J(H,CH), is independent of solvent and is −0.254(2) Hz in isopropylbenzene (Table 1). Such a coupling constant obeys the relationship, $^6J = {}^6J_{90}\langle\sin^2\psi\rangle$, where $^6J_{90}$ is the magnitude of ^6J when the methine C—H bond lies in a plane perpendicular to the aromatic ring (17). The expectation value of $\sin^2\psi$ can be computed as a function of the internal barrier, either quantum mechanically (17) or classically. For toluene, $^6J_{90}$ is −1.20 Hz (11). $^6J_{90}$ is reduced in magnitude by electronegative substituents attached to the α carbon atom. A methyl substituent, as in ethylbenzene (10), reduces the magnitude of $^6J_{90}$ to 1.16 Hz. On the assumption that two methyl substituents yield $^6J_{90}$ as −1.12 Hz (additivity assumption), $\langle\sin^2\psi\rangle$ follows as 0.229. For a hindered rotor model, the apparent twofold barrier is then 6.5 kJ/mol. If $^6J_{90}$ is −1.20 Hz, as in toluene, then the apparent twofold barrier is 7.1 kJ/mol.

Based on a classical averaging procedure, which also yields $\langle\sin^2\psi\rangle$ as 0.229 for a V_2 of 6.5 kJ/mol, the observed ^6J is compatible with twofold and fourfold components of 4.5 kJ/mol and −4.5 kJ/mol, respectively. In view of the MO computations, equal magnitudes of these barrier components seem unlikely. Other possible combinations of V_2 and V_4 are 9.7 and −3.5 kJ/mol, respectively, and 7.2 and −1.0 kJ/mol. These possibilities appear reasonable, although the coupling constant cannot be used to discriminate between them.

TABLE 2. Theoretical energies for various conformations of isopropylbenzene

	Relative energy/kJ mol^{-1}		
ψ/deg[a]	STO-3G MO[b]	STO-3G//CNDO[c]	STO-3G//INDO[c]
0	0.00[d]	0.00[e,g]	0.00[f,h]
15	1.05	0.89	0.92
30	2.98	2.88	2.96
45	4.71	3.29	4.01
60	8.63	8.89	8.68
75	13.29	13.90	13.52
90	15.23	17.14	16.62

[a]The angle by which the α C—H bond of the isopropyl group rotates out of the benzene plane.
[b]Full optimization of the side-chain geometry (see Experimental).
[c]Computed for the STO-3G geometries.
[d]Total energy of −343.634 297 au.
[e]Total energy of −73.155 342 au.
[f]Total energy of −70.875 791 au.
[g]The relative CNDO energies are fit by $V(\psi)$/kJ mol^{-1} = 15.3 $\sin^2\psi$ − 4.0 $\sin^2 2\psi$ + 1.7$_5$ $\sin^2 3\psi$ with errors of 0.5 kJ mol^{-1} at the 95% confidence level. See text for the definition of ψ.
[h]The INDO energies can be fit by $V(\psi)$/kJ mol^{-1} = 14.8 $\sin^2\psi$ − 3.8 $\sin^2 2\psi$ + 1.8 $\sin^2 3\psi$; errors as in footnote *g*.

The 6-31G MO potential above corresponds to a $\langle\sin^2\psi\rangle$ of 0.153, the expectation value of ψ being 20° at 300 K. ^6J very clearly indicates that this value of $\langle\sin^2\psi\rangle$ is too small. If the theory is correct, then the solvents *decrease* the internal barrier, whereas it has been suggested that the solvent would cause a dramatic increase in the barrier (7). It may be noted that the

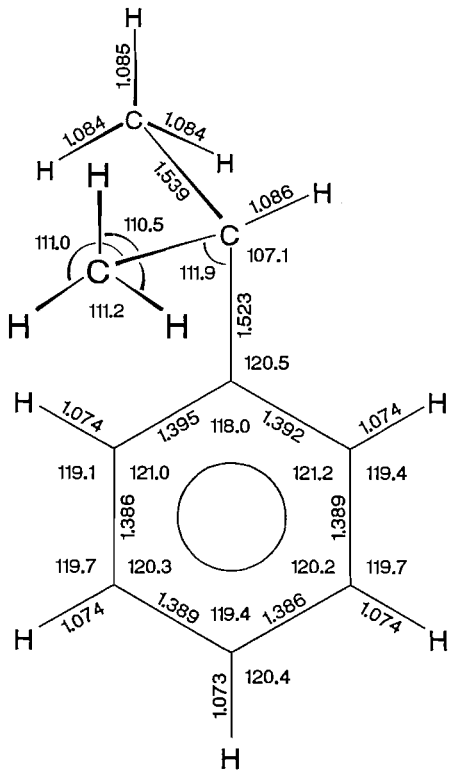

FIG. 2. The computed 6-31G geometry is displayed for the low-energy conformation of isopropylbenzene plane. The total energy is −347.681 397 au, reached during a geometry optimization procedure in which the phenyl nuclei are constrained to a plane. The C—H bonds of the methyl groups, as expected, take on staggered arrangements about neighbouring bonds and there are the usual parallel 1,3 arrangements between two pairs of C—H bonds on different methyl groups. The computed bond angles within the phenyl moiety are close to those (21–23) deduced from the substituent parameter for a methyl group as deduced from X-ray diffraction measurements. The *ortho* C—H bond nearest the methyl groups does not appear to move away significantly from the side chain but, of course, does so as rotation about the C_{sp^2}—C_{sp^3} bond brings the methyl groups nearer.

hyperfine splitting constant for the methine proton in the cation π radical of an isopropylbenzene derivative (1) corresponds to a $\langle\sin^2\psi\rangle$ of 0.222. Perhaps an MO calculation with a much larger basis set is warranted (the 6-31G computations needed 37.3 h of cpu time on the Amdahl 5870).

The other long-range coupling constants

For toluene, ^4J(H,CH) has been written as $-1.08\langle\sin^2\psi\rangle - 0.32\langle\cos^2\psi\rangle$, the first term representing the σ,π contribution and the second a σ component (19). Both expectation values are 0.5, so that ^4J becomes −0.70 Hz, as observed (11). The coefficient of $\langle\sin^2\psi\rangle$ should be multiplied by 1.12/1.20 if it is to apply to isopropylbenzene (see ^6J above). Consequently, ^4J in the latter becomes $-1.01(0.229) - 0.32(0.771)$ or −0.478 Hz, to be compared with the observed value of −0.559(1) Hz (Table 1). To obtain agreement with experiment, the coefficient of $\langle\cos^2\psi\rangle$ must be −0.43 Hz.

A similar discrepancy occurs for ^5J(H,CH). In toluene, ^5J(H,CH) is reproduced by $0.336\langle\sin^2\psi\rangle + 0.322\langle\sin^2(\psi/2)\rangle$, the second term representing the σ electron component (11, 20). This relationship yields 0.233 Hz for ^5J(H,CH) in isopropylbenzene when the coefficient of $\langle\sin^2\psi\rangle$ is reduced by 1.12/1.20 (note that $\langle\sin^2(\psi/2)\rangle$ is 0.5 for any combination of V_2 and V_4). To reproduce the observed value of 0.298(1) Hz in Table 1, the coefficient of $\langle\sin^2(\psi/2)\rangle$ is required to be 0.45 Hz. In other words, the magnitudes of the σ electron components of ^4J and ^5J increase by very nearly the same ratio relative to toluene.

Apparently, ^4J(H,CH) in isopropylbenzene is given by $-1.01\langle\sin^2\psi\rangle - 0.43\langle\cos^2\psi\rangle$ or $-0.43 - 0.58\langle\sin^2\psi\rangle$. In 4-isopropylphenol, ^4J is −0.546(7) Hz, corresponding to a $\langle\sin^2\psi\rangle$ of 0.20(2) if twice the standard deviation of ^4J is taken as a measure of accuracy.[1] It does not appear that the barrier to internal rotation about the C_{sp^2}—C_{sp^3} bond is significantly altered by the hydroxyl substituent. It therefore seems unlikely that the apparently very low barrier reported for 4-isopropylbenzaldehyde in the vapor phase (7) has its origin in a substituent effect.

Conclusion

Ab initio molecular orbital calculations at the STO-3G and 6-31G level do not support the suggestion of a very low internal barrier to rotation about the C_{sp^2}—C_{sp^3} bond in isopropylbenzene. It therefore appears, as pointed out by a referee, that an alternative explanation (24) for the microwave data (7) of isopropylbenzene is more likely. For molecules of this size, the relative intensities of low resolution microwave spectra are not easily related to internal rotational barriers and may well reflect the threshold energy for intramolecular vibrational redistribution. Hence the data (7) are not contradictory to the results of the present work. The long-range proton–proton coupling constants for isopropylbenzene in CS_2 and acetone solutions cannot discriminate between a purely twofold barrier and one containing an additional significant fourfold component. They are consistent with V_2 and V_4 combinations of 9.7 and −3.5 kJ/mol, respectively, as well as with 7.2 and −1.0 kJ/mol; the twofold components are rather smaller than those obtained from the geometry-optimized molecular orbital energies.

Received October 22, 1987

JOSEPH ARMAND, LINE BOULARES, CHRISTIAN BELLEC, and JEAN PINSON. Can. J. Chem. **66**, 1500 (1988).

The reaction of 2,3-diaminopyridine with the dimeric 4,5-dimethylcyclohexa-3,5-dien-1,2-dione gives 7,8-dimethylpyrido[2,3-*b*]quinoxaline, **1**, in good yields; in the same way 3,4-diaminopyridine gives the 7,8-dimethylpyrido[3,4-*b*]quinoxaline **2**. The electrochemical reduction of **1** and **2** in hydroorganic medium gives the 5,10-dihydro compounds **6** and **7**; **1** and **2** present a single $2e^-$ polarographic wave, in contrast to phenazine which shows two monoelectronic waves. The catalytic hydrogenation of **1** and **2** gives **6** and **7** and does not involve the pyridinic ring as in the case of pyridopyrazines. $AlLiH_4$ does not react with **2** but **1** is reduced into the 1,2-dihydro derivative **8**. The behavior of **1** and **2** is thus different from that of pyridopyrazines (which give the 1,2,3,4-tetrahydro compounds) and from that of phenazine (which gives the 5,10-dihydro derivative). $NaBH_4$ reacts with pyridopyrazines to give, according to the substituents, 1,2- or 5,6-dihydro or 1,2,3,4-tetrahydro derivatives. Methylmagnesium chloride reacts with **1** to give a mixture of 2-methyl-1,2-dihydro, 2,6,7-trimethyl, and 4,6,7-trimethylpyrido[2,3-*b*]quinoxaline. In the case of **2**, 4,6,7-trimethylpyrido[3,4-*b*]quinoxaline is obtained.

JOSEPH ARMAND, LINE BOULARES, CHRISTIAN BELLEC et JEAN PINSON. Can. J. Chem. **66**, 1500 (1988).

L'action de la diamino-2,3 pyridine sur la diméthyl-4,5 cyclohexadiène-3,5 dione-1,2 sous forme dimère fournit avec un bon rendement la diméthyl-7,8 pyrido[2,3-*b*]quinoxaline **1**. En utilisant la diamino-3,4 pyridine on obtient la diméthyl-7,8 pyrido[3,4-*b*]quinoxaline **2**. En milieu hydroorganique la réduction électrochimique de **1** et **2** fournit les dérivés dihydro-5,10 : **6** et **7**; **1** et **2** présentent une seule vague polarographique de $2e^-$ contrairement à la phénazine qui donne deux vagues monoélectroniques. L'hydrogénation catalytique de **1** et **2** fournit **6** et **7** et ne concerne donc pas le noyau pyridine comme dans le cas des pyridopyrazines. $AlLiH_4$ est sans action sur **2** alors que **1** fournit le dérivé dihydro-1,2 : **8**; le comportement de **1** et **2** diffère de celui des pyridopyrazines (qui donnent des dérivés tétrahydro-1,2,3,4) et de la phénazine (qui fournit le dérivé dihydro-5,10). Avec $NaBH_4$ **1** fournit un mélange de **6** et **8** tandis que **2** donne le dérivé tétrahydro-1,2,3,4. L'action de $NaBH_4$ sur les pyridopyrazines a été également étudiée : selon la nature du substituant des dérivés dihydro-1,2, tétrahydro-1,2,3,4 ou dihydro-5,6 sont obtenus. Le chlorure de méthylmagnésium conduit dans le cas de **1** à un mélange de dérivé dihydro-1,2 méthyl-2, de triméthyl-2,6,7 pyrido [2,3-*b*] quinoxaline et de triméthyl-4,6,7 pyrido [2,3-*b*] quinoxaline et dans le cas de **2** à la triméthyl-4,6,7 pyrido [3,4-*b*] quinoxaline.

N-Heterocyclic compounds present interesting electrochemical behaviour. Their electrochemical reduction allows one to obtain semi reduced compounds and permits the observation of rearrangements between these reduced compounds (1, 2). Combined with other means of reduction, it allows one to prepare selectively reduced compounds. Small structural changes may induce very different chemical behaviours. We now report the reactions of pyrido[2,3-*b*]quinoxalines and pyrido[3,4-*b*]-quinoxalines. The reduction and other chemical properties of these compounds have never been investigated, this may be related to their difficult preparation. We describe easier synthetic routes to these compounds. In the case of the chemical and electrochemical reduction of pyridoquinoxalines different behaviours could be forecasted: (*i*) reduction of the pyrazinic ring as in the case of phenazine, (*ii*) reduction of either the pyridinic or the pyrazinic ring as in the case of pyrido[2,3-*b*]-pyrazines, (*iii*) reduction following a mechanism not yet observed. The three types of reactions can be brought into play depending on which reagent is used. Thus the condensed benzene ring could exert an important influence on the reduction of pyridopyrazines.

Results and discussion

Preparation

Pyrido[2,3-*b*]quinoxalines have been prepared either by cyclization of 2-anilino-3-nitropyridine or of 2-toluidino-3-nitropyridine (3) or by condensation of ketones such as R—CO—CH_3 with 2-formyl-3-aminoquinoxaline (4). The few pyrido[3,4-*b*]quinoxalines which are known have been obtained by cyclization of 3-amino-4-(2-aminoanilino)pyridine (5) or of 3-amino-4-(2-aminotoluidino)pyridine (3). In view of the rather low yields and the complicated experiments, we looked for alternative routes to prepare these compounds. We reacted 2,3- and 3,4-diaminopyridine with a quinone: 4,5-dimethylcyclohexa-3,5-dien-1,2-dione. When the quinone is used as a monomer, only traces of pyridoquinoxalines are obtained, but when the quinone is present in a dimeric form, pyridoquinoxalines **1** and **2** are obtained in good yields.

Electrochemical reduction

We had previously investigated the electrochemical reduction of pyrido[2,3-*b*]pyrazines **3** and of pyrido[3,4-*b*]pyrazines **4** (6) and we were interested to see how the presence of a fused

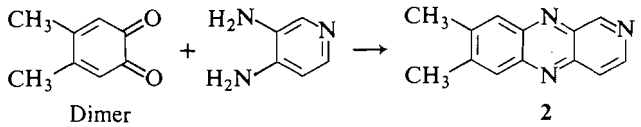
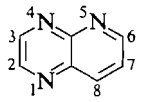
Dimer 1

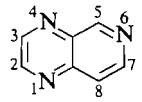


Dimer 2

benzene ring in the 2,3-positions would influence the reduction mechanism of **3** and **4**.

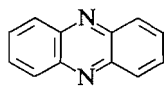


3



4

The comparison of the electrochemical behaviour of **1** and **2** with that of phenazine **5** is also of interest.



5

*7,8-Dimethylpyrido[2,3-*b*]quinoxaline 1*

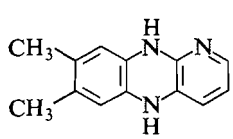
In aprotic medium (very dry acetonitrile or DMSO) **1** shows by cyclic voltammetry a first reversible monoelectronic peak: $E_1^0 = -1.10$ V/SCE in acetonitrile, which is followed by a second monoelectronic irreversible peak $E_{Pc_2} = -1.69$ V/SCE. The same voltammetric pattern is observed in the more basic solvent DMSO: $E_1^0 = -1.10$ V/SCE, $E_{Pc_2} = -1.85$ V/SCE. The voltammogram of phenazine in DMSO is similar: $E_1^0 = -1.10$ V/SCE and $E_{Pc_2} = -1.71$ V/SCE. In both cases, the transfer of a second electron leads to a very basic dianion which can abstract a proton from the solvent or from the supporting electrolyte (7) (one can note the small negative shift of the second peak when changing the solvent from acetonitrile to the more basic DMSO). The same potential is observed for both couples $\mathbf{1}/\mathbf{1}^{\cdot-}$ and $\mathbf{5}/\mathbf{5}^{\cdot-}$, the nitrogen atom on the pyridinic ring does not influence the reducibility of the system while pyridopyrazines are more easily reducible than quinoxalines.

In protic medium (H_2O–MeOH 50/50), **1** shows a two-electron wave between pH 1 and 13. Between pH 1 and 6.55, $E_{1/2}$ varies according to $E_{1/2} = 0.20 - 0.087$pH and according to $E_{1/2} = 0.01 - 0.058$pH between pH 6.55 and 13. A controlled potential electrolysis at pH 7.4 allows one to obtain the reduction product: 5,10-dihydropyrido[2,3-*b*]quinoxaline, **6**, which shows a $2e^-$ anodic wave the $E_{1/2}$ of which is near that of **1**. Thus the reduction scheme can be written as:

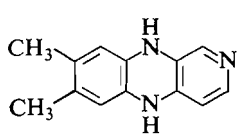
$$\mathbf{1} + 2e^- + 3H^+ \rightleftharpoons [\mathbf{6}]H^+ \qquad 1 < pH < 6.55$$

$$\mathbf{1} + 2e^- + 2H^+ \rightleftharpoons \mathbf{6} \qquad 6.55 < pH < 13$$

Two comments can be made on the previous results: (*i*) the reduction product **6** is similar to that obtained from phenazine:



6



7

5,10-dihydrophenazine. However, there are some differences concerning the polarographic patterns. In the case of **5** (8*a*, 8*b*), two monoelectronic waves are observed in acidic medium up to pH 4 while a single bielectronic wave is observed for **1**.

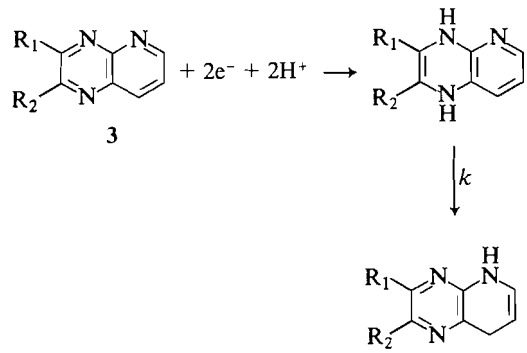
The two monoelectronic waves observed for phenazine in acidic medium have been assigned to the stepwise reduction of a diprotonated species (8*a*):

$$PH^+ + H^+ \rightleftharpoons PH_2^{2+}$$

$$PH_2^{2+} + e \rightarrow PH_2^{+\cdot} \qquad \text{1st wave}$$

$$PH_2^{+\cdot} + e \rightarrow PH_2 \qquad \text{2nd wave}$$

The pK_a of phenazinium ion is 1.23 (9) and that of the diprotonated species have been estimated to be about −5 (8*a*). In the case of **1**, the first protonation must occur on the pyridinium nitrogen as in the case of pyrido[2,3-*b*]pyrazine (10) for which the pK_a has been measured as $pK_a = 1.2$ (11). In order to observe two one-electron waves for **1**, the two nitrogens of the pyrazine ring should be protonated; the corresponding species should then be triprotonated which is highly unlikely. (*ii*) In aqueous medium at pH > 7 or in an acetonitrile–phenol solvent, we had shown previously (6) that the reduction product of pyrido[2,3-*b*]pyrazines, **3**, undergo a rearrangement leading to a 5,8-dihydro derivative:



3

In the case of **1**, the electrolysis carried out in a water–methanol or an acetonitrile–phenol medium leads only to compound **6**, the internal rearrangement involving the pyridine ring does not occur. The additional presence of a fused benzene ring in the case of **1** strongly stabilizes the 5,10-dihydro derivative.

*7,8-Dimethylpyrido[3,4-*b*]quinoxaline, 2*

The electrochemistry of **2** is similar to that of **1**. In aprotic medium (very dry acetonitrile), one observes by cyclic voltammetry a first reversible monoelectronic peak ($E_1^0 = -1.05$ V/SCE) followed by a second irreversible cathodic peak ($E_{Pc_2} = -1.88$ V/SCE). In protic medium (water–methanol 50/50), a two-electron polarographic wave is observed which corresponds to the reduction into 5,10-dihydro-7,8-dimethylpyrido[3,4-*b*]-quinoxaline, **7**, obtained through a preparative electrolysis. The half-wave potentials shift with pH as:

$$E_{1/2} = +0.30 - 0.087\text{pH} \qquad 1 < pH < 8.95$$

$$E_{1/2} = +0.04 - 0.058\text{pH} \qquad 8.95 < pH < 13$$

and the reduction schemes are

$$\mathbf{4} + 2e^- + 3H^+ \rightleftharpoons [\mathbf{7}]H^+ \qquad 1 < pH < 8.95$$

$$\mathbf{4} + 2e^- + 2H^+ \rightleftharpoons \mathbf{7} \qquad 8.95 < pH < 13$$

No intramolecular rearrangement involving the pyridine ring is observed for **7**; this could be expected as rearrangements occur

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12

in the case of 1,4-dihydropyrido[2,3-*b*]pyrazines but not in the case of 1,4-dihydropyrido[3,4-*b*]pyrazines.

Chemical reductions

Catalytic hydrogenation over Pd/C

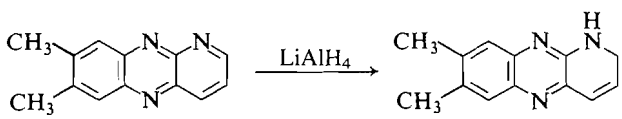
Both with **1** and **2**, the addition of one mole of hydrogen is observed leading respectively to **6** and **7**:

1 → **6**
2 → **7** (H_2, Pd/C)

In the case of pyrido[2,3-*b*]pyrazines (6, 10) the hydrogenation involves either the pyrazine or the pyridine ring with addition of 2 mol of hydrogen to give a tetrahydrogenated compound. Phenazine yields the 5,10-dihydro derivative (12).

Reduction with $LiAlH_4$

In the case of pyrido[2,3-*b*]pyrazines, **3**, and pyrido[3,4-*b*]-pyrazines, **4** (13, 14), with alkyl or aryl substituents, the reduction with $LiAlH_4$ leads exclusively to 1,2,3,4-tetrahydro derivatives of the pyrazine ring. Reduction of **1** only yields the 1,2-dihydro compound, **8**, where only the pyridine ring is reduced. No reaction is observed in the case of **2**.

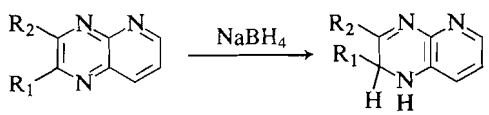


The $LiAlH_4$ reduction of **1** and **2** is different from that of pyridopyrazines as well from that of phenazine which give the 5,10-dihydro compound (15).

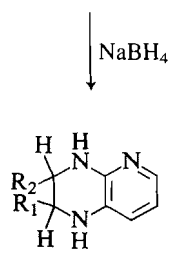
Reduction with $NaBH_4$ of pyrido pyrazines and pyrido quinoxalines

The reaction of $NaBH_4$ with pyrido pyrazines has only been described in the case of pyrido[2,3-*b*]pyrazine (which gives the 1,2,3,4-tetrahydro derivative) (16); no results are given concerning substituted pyrido[2,3-*b*] or pyrido[3,4-*b*]-pyrazines.

The reaction of $NaBH_4$ with pyrido[2,3-*b*]pyrazines, **9** and **10**, gives the 1,2-dihydro and 1,2,3,4-tetrahydro derivatives.

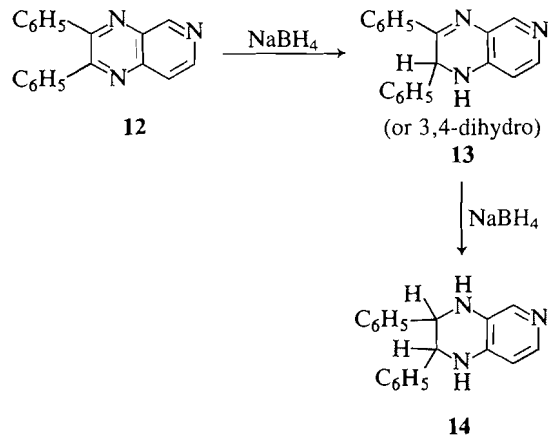


9a: $R_1 = H$; $R_2 = C_6H_5$ → **10***a*
9*b*: $R_1 = R_2 = C_6H_5$ → **10***b*

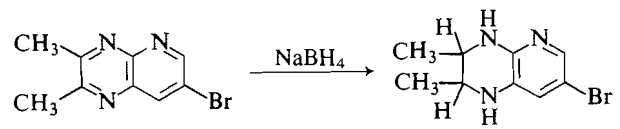


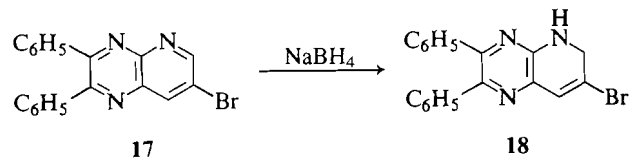
11*a*
11*b*

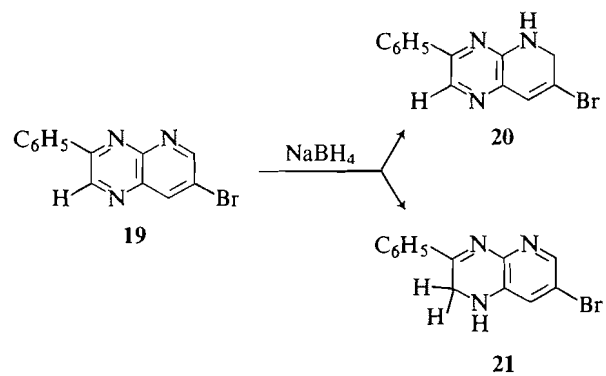
Compound **10***a* can be easily prepared but **10***b* is obtained only as a mixture with **11***b*. In the case of 2,3-diphenylpyrido-[3,4-*b*]pyrazine, **12**, the 1,2- (or 3,4-) dihydro derivative, **13**, is obtained first and then the 1,2,3,4-tetrahydro derivative, **14**.



In the case of pyrido[2,3-*b*]pyrazines with a bromine atom in the 7-position, the reduction may involve the pyridine ring. The 2,3-dimethyl-7-bromopyrido[2,3-*b*]pyrazine, **15**, gives the 1,2,3,4-tetrahydro derivative **16** but the 2,3-diphenyl-7-bromopyrido[2,3-*b*]pyrazine, **17**, gives the 5,6-dihydro derivative, **18**, and the 3-phenyl-7-bromopyrido[2,3-*b*]pyrazine, **19**, gives a mixture of the 1,2-dihydro derivative **20** and of the 5,6-dihydro derivative **21**.







The reaction of $NaBH_4$ with pyridoquinoxalines depends upon the position of nitrogen on the pyridine ring. In the case of **1**, one obtains a mixture of 1,2- and 5,10-dihydro derivatives while **2** leads to a compound tetrahydrogenated on the pyridine ring.

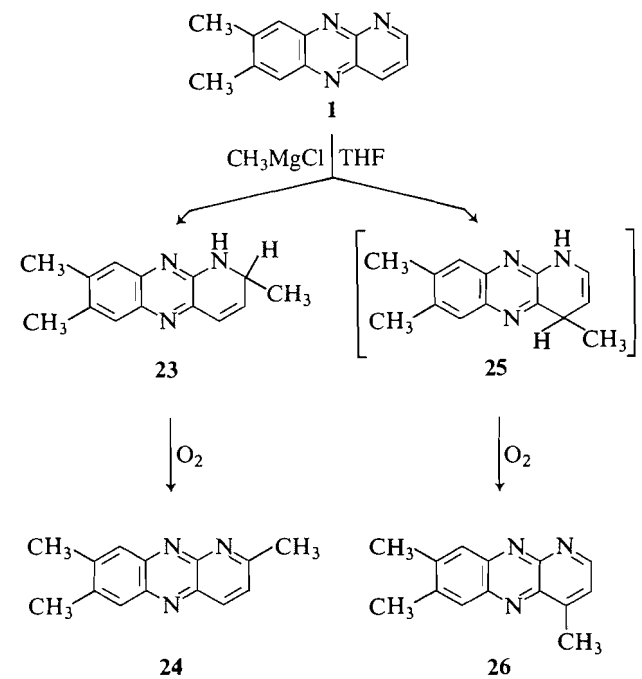
1 6 8 2 22

These results show that in the case of 2,3-alkyl- or aryl-substituted pyridopyrazines the pyrazine ring is more reactive than the pyridine ring towards $NaBH_4$, but the introduction of a bromine atom in position 7 or that of a fused benzene ring in the 2,3 positions levels off the reactivity of both rings.

Reaction of organo magnesium compounds

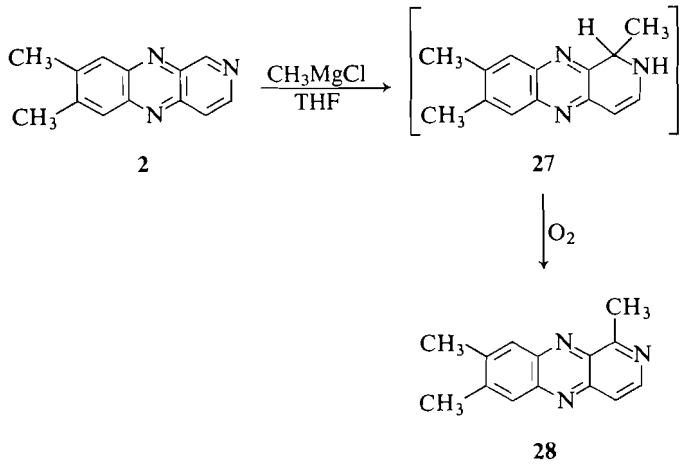
The reaction of Grignard reagents with pyrido[2,3-*b*]pyrazines has been described (13, 17). The results depend both on the substituents of the heterocyclic compounds and on the Grignard reagent. The reaction can take place either on the pyrazine or on the pyridine ring with addition of one or two moles of the reagent.

Phenylmagnesium bromide does not react with pyridoquinoxalines but methyl magnesium chloride reacts with **1** and **2**. **1** gives a mixture of **23**, **24**, and **26** which can be separated by chromatography. The intermediate compound **25** is too easily oxidized to be isolated.



1 23 25 24 26

In the case of **2**, compound **28** is obtained but the intermediate **27** is too oxidizable to be isolated.



2 27 28

Experimental

Melting points are uncorrected. ^{1}H-nmr spectra were recorded on a Bruker WH80, a Varian A60, and a Bruker 250 MHz spectrometer using tetramethylsilane (TMS) as internal standard. The apparatus and techniques used for the electrochemical studies and pH measurements have been described previously (6). All the potentials are referred to the saturated-calomel electrode (SCE); the temperature of the solutions was 20°C. Acetonitrile used in the cyclic voltammetric experiments was distilled under vacuum and dried over activated alumina. The solutions were desoxygenated with nitrogen dried over phosphorus pentoxide. The microanalyses were performed by the "Service de Microanalyse, Université Pierre et Marie Curie". The following abbreviations are used in reporting nmr results: s = singlet, d = doublet, t = triplet, q = quadruplet, m = multiplet. All the compounds described gave correct elemental analysis.

Preparation of 7,8-dimethylpyrido[2,3-b]quinoxaline, 1

A mixture of 2,3-diaminopyridine (327 mg) and 4,5-dimethyl-3,5-cyclohexadien-1,2-dione dimer (18) (411 mg) in 15 mL of methanol was kept at room temperature for 12 days. The solvent was evaporated and the solid residue was extracted five times with 100 mL of hexane. Hexane was then evaporated to give 527 mg of **1** (84% yield); mp 142–144°C dec. ^{1}H nmr ($CDCl_3$): 7-CH_3 + 8-CH_3, s, 2.55 ppm (6H); 3-H, m, 7.72 ppm (1H); 6-H + 9-H, 2 br s, 7.99 and 8.09 ppm (2H); 4-H, d × d, 8.55 ppm (1H), J_{3-4} = 8 Hz, J_{2-4} = 2 Hz; 2-H, m, 9.29 ppm (1H).

Preparation of 7,8-dimethylpyrido[3,4-b]quinoxaline, 2

A mixture of 3,4-diaminopyridine (327 mg) and 4,5-dimethyl-3,5-cyclohexadien-1,2-dione dimer (18) (411 mg) in 15 mL of methanol was kept at room temperature for 10 days, then at 0°C for 1 day. The solid which precipitated was filtered. The nmr spectrum in $CDCl_3$ shows that it is a mixture of **2** and of one or several intermediate products which give quantitatively **2** after 2 days in solution. Thus a solution of the solid in 10 mL of chloroform was kept at room temperature for 2 days and then evaporated to give 445 mg of **2** (71% yield); mp 178–180°C dec. ^{1}H nmr ($CDCl_3$) 7-CH_3 + 8-CH_3, s, 2.59 ppm (6H); 4-H + 6-H + 9-H, m, 7.95–8.10 ppm (3H); 3-H, d, 8.78 ppm (J = 6 Hz) (1H); 1-H, s, 9.72 ppm (1H).

Electrolysis of 1: preparation of 6

An electrolysis was carried out at pH = 7.4 and E = −0.6 V. The cathodic compartment contained 209 mg of **1** in 100 mL of solution (methanol 50%). At the end of the electrolysis (1.9 F per mol), the precipitate in the cell was filtered under nitrogen, washed with water, and dried to give 150 mg of 5,10-dihydro-7,8-dimethylpyrido[2,3-*b*]-quinoxaline, **6**; mp 175°C dec. ^{1}H nmr (DMSO-d_6): 7-CH_3 + 8-CH_3, s, 1.85 ppm (6H); 6-H + 9-H, 2s, 5.95 and 6.07 ppm (2H); 3-H + 4-H, m, 6.15–6.30 ppm (2H); 2-H, q, 7.05 ppm (1H); 5-H + 10-H, broad s, 7.52 and 8.00 ppm (2H) exchanged with D_2O. The electrolysis of **1** (1.19×10^{-3} M) was also performed on platinum grid in the

compartment of a uv spectrometer. In acetonitrile in the presence of phenol (10^{-2} *M*) at $E = -1.0$ V/SCE the final spectrum is identical to that of **6** (λ_{max} = 369 nm, ε = 12 100, shoulder λ = 352 nm, ε = 10 000). Upon reoxidation of $E = -0.5$ V/SCE **1** is reobtained quantitatively.

Electrolysis of 2, preparation of 7

An electrolysis was carried out at pH = 7.20 and $E = -0.6$ V. The cathodic compartment contained 209 mg of **2** in 100 mL of solution (methanol 50%). At the end of the electrolysis (2.1 F per mol), the cathodic solution which contained a solid in suspension was chilled at 0°C and filtered under nitrogen. The precipitate was washed with water and dried to give 135 mg of 5,10-dihydro-7,8-dimethylpyrido[3,4-*b*]quinoxaline, **7**, mp 185°C dec.; ^{1}H nmr (DMSO-d_6): 7-CH_3 + 8-CH_3, s, 1.85 ppm (6H); 4-H + 6-H + 9-H, m, 5.92–5.95 ppm (3H); 1-H, s, 7.09 ppm (1H); 3-H, d, 7.40 ppm (J = 6 Hz) (1H); 5-H + 10-H, 2 broad s, 7.48 and 7.99 ppm, (2H) exchanged with D_2O.

Catalytic hydrogenation of 1 and 2

Catalytic hydrogenation was carried out at room temperature with 20 mg of **1** in 1 mL of DMSO-d_6 in the presence of 20 mg of 10% Pd/C. After 2 h of stirring and consumption of 1 mol of H_2/mol of **1**, the solution was centrifugated. Its nmr spectrum shows that **1** has given **6** quantitatively. With the same procedure, **2** gives **7** quantitatively.

Reduction of 1 with $LiAlH_4$: preparation of 8

$LiAlH_4$ (250 mg) was added slowly to a solution of **1** (209 mg) in freshly distilled tetrahydrofuran (40 mL). After 24 h of stirring at room temperature, the mixture was quenched with 5 mL of water and filtered. The solution was extracted with 50 mL of chloroform. The organic layer was dried on Na_2SO_4 then evaporated to give 153 mg of **8**; mp 155°C dec. ^{1}H nmr (DMSO-d_6): 7-CH_3 + 8-CH_3, s, 2.28 ppm (3H); 2-CH_2, m, 4.45 ppm (2H); 3-H + 4-H, m, 6.2–6.35 ppm (2H); 6-H + 9-H, 2s, 7.02 and 7.23 ppm (2H); 1-H, br s, 7.11 ppm (1H) exchanged with D_2O.

Reduction of 1 with $NaBH_4$

$NaBH_4$ (130 mg) was added to a solution of **1** (130 mg) in ethanol (15 mL). After 16 h of stirring at room temperature, the mixture was poured under nitrogen into 50 mL of deoxygenated water. Ethanol was evaporated under nitrogen in vacuum, the precipitate was filtered under nitrogen and dried to give 90 mg of a solid which was shown by nmr to be a mixture of **6** (35%) and **8** (65%).

Reduction of 2 with $NaBH_4$

$NaBH_4$ (130 mg) was added to 130 mg of **2** in 15 mL of ethanol. After 4 days of stirring at 40°C, the mixture was poured into 20 mL of water. Ethanol was evaporated under vacuum and the solution was extracted with 100 mL of chloroform. The organic layer was dried then evaporated to give a solid (80 mg) which was shown by nmr to be a mixture of **2** (25%) and of 7,8-dimethyl-1,2,3,4-tetrahydropyrido[3,4-*b*]quinoxaline, **22** (75%) which were separated by chromatography. ^{1}H nmr of **22** ($CDCl_3$): 7-CH_3 + 8-CH_3, s, 2.50 ppm (6H); 1-CH_2 + 3-CH_2 + 4-CH_2, 2m, centered at 3.35 and 4.38 ppm (4H + 2H); 6-H + 9-H, br s, 7.71 ppm (2H); NH, br s at 2.80 ppm exchanged with D_2O.

Reduction of 3-phenylpyrido[2,3-b]pyrazine, 9a, with $NaBH_4$

Preparation of dihydro derivative 10a

$NaBH_4$ (300 mg) was added to a solution of **9***a* (300 mg) in 25 mL of ethanol. After 2 h of stirring at room temperature the mixture was poured into 80 mL of water. The yellow precipitate was filtered, washed with water, and dried to give 246 mg of 1,2-dihydro-3-phenylpyrido[2,3-*b*]pyrazine, **10***a*: mp 190°C. ^{1}H nmr (DMSO-d_6): 2-CH_2, s, 4.52 ppm (2H); 1-H, br s, 6.53 ppm (1H) exchanged with D_2O; 7-H + 8-H, m, centered at 7.03 ppm (2H); 6-H + 3-Ph, m, 7.55–8.35 ppm (6H).

Preparation of tetrahydroderivative 11a

With the same work-up but after stirring for 19 h, 260 mg of 1,2,3,4-tetrahydro-3-phenylpyrido[2,3-*b*]pyrazine, **11***a* (6), was obtained.

Reduction of 2,3-diphenylpyrido[2,3-b]pyrazine, 9b, with $NaBH_4$

Using the same procedure, $NaBH_4$ (200 mg) and **9***b* (200 mg) were stirred at room temperature in 20 mL of ethanol for 5 h. The solid obtained (175 mg) was shown by nmr to be a mixture of **9***b* (15%), 1,2-dihydroderivative, **10***b* (45%) (14), *cis* and *trans* tetrahydro derivatives, **11***b* (40%) (11, 14). With the same work-up but after 72 h, the solid obtained (170 mg) was shown by nmr to be a mixture of *cis* (65%) and *trans* (35%) tetrahydro derivatives **11***b*.

Reduction of 2,3-diphenylpyrido[3,4-b]pyrazine, 12, with $NaBH_4$

$NaBH_4$ (250 mg) was added to a solution of **12** (250 mg) in 20 mL of ethanol. After 4 h of stirring at room temperature, the mixture was poured into 80 mL of water. The precipitate was filtered, washed with water, and dried to give 215 mg of 1,2- or 3,4-dihydro-2,3-diphenylpyrido[2,3-*b*]pyrazine, **13** (6). With the same work-up but after stirring 72 h, 226 mg of *cis*-1,2,3,4-tetrahydro-2,3-diphenylpyrido-[3,4-*b*]pyrazine, **14** (6), was obtained.

Reduction of 7-bromo-2,3-dimethylpyrido[2,3-b]pyrazine, 15, with $NaBH_4$

$NaBH_4$ (200 mg) was added to a solution of **15** (150 mg) in 15 mL of ethanol. After 4 h of stirring at room temperature, the mixture was poured into 100 mL of water, then extracted with 100 mL of chloroform. The organic layer was dried and evaporated to give 70 mg of a solid which was shown by nmr to be a mixture of the *cis*-1,2,3,4-tetrahydro derivative (60%) (14) and the *trans*-1,2,3,4-tetrahydro derivative (40%) (17).

Reduction of 7-bromo-2,3-diphenylpyrido[2,3-b]pyrazine, 17, with $NaBH_4$

With the same procedure as for **15**, 130 mg of 7-bromo-5,6-dihydro-2,3-dimethylpyrido[2,3-*b*]pyrazine, **18** (14), was obtained.

Reduction of 7-bromo-3-phenylpyrido[2,3-b]pyrazine, 19, with $NaBH_4$

Employing the same procedure used with **15**, 115 mg of a solid was obtained. It was shown by nmr to be a mixture of 7-bromo-5,6-dihydro-3-phenylpyrido[2,3-*b*]pyrazine, **20** (65%) (14), and 7-bromo-1,2-dihydro-3-phenylpyrido[2,3-*b*]pyrazine, **21** (35%) (14).

Reaction of 1 with methylmagnesium chloride: preparation of 23, 24, and 26

A mixture of 209 mg of **1** (10^{-3} mol) 1.4 mL of a 3 *M* solution of CH_3MgCl in tetrahydrofuran (Aldrich) in 15 mL of anhydrous THF was stirred at room temperature for 30 min. The solution was quenched with 15 mL of a 5 *M* solution of NH_4Cl. The THF was evaporated and the precipitate was filtered, washed with water, and dried (195 mg). The solid was a complex mixture from which were isolated by column chromatography over silica (eluent: ethyl acetate – methanol 94/6) **23** (45%) mp 138–142°C dec. **24** (10%) and **26** (12%). ^{1}H nmr of **23** ($CDCl_3$): 2-CH_3, d, 1.44 ppm (3H); 7-CH_3 + 8-CH_3, s, 2.34 ppm (6H); 2-H, m, 4.77 ppm (1H); 1-H, br s, 5.55 ppm (1H) exchanged with D_2O; 3-H, d × d, 6.12 ppm (1H) J_{3-4} = 10 Hz, J_{2-3} = 4 Hz; 4-H, d, 6.57 ppm (1H) J_{3-4} = 10 Hz; 6-H + 9-H, 2s, 7.22 and 7.46 ppm (2 × 1H). ^{1}H nmr of **24** ($CDCl_3$): 7-CH_3 + 8-CH_3, s, 2.58 ppm (6H); 2-CH_3, s, 2.95 ppm (3H); 3-H, d, 7.60 ppm (1H) J_{3-4} = 9 Hz; 6-H + 9-H, 2s, 8.05 and 8.07 ppm (2H); 4-H, d, 8.41 ppm (1H) J_{3-4} = 9 Hz. ^{1}H nmr of **26** ($CDCl_3$): 7-CH_3 + 8-CH_3, s, 2.57 ppm (6H); 3-CH_3, s, 2.91 ppm (3H); 3-H, d, 7.54 ppm (1H) J_{2-3} = 4 Hz; 6-H + 9-H, 2s, 7.97 and 8.04 ppm (2 × 1H); 2-H, d, 9.13 ppm (1H) J_{2-3} = 4 Hz.

Reaction of 2 with methylmagnesium chloride: preparation of 28

With the same procedure as for **1** but after stirring for 1.5 h, 158 mg of 1,7,8-trimethylpyrido[3,4-*b*]quinoxaline, **28**, was obtained; mp 180°C dec. ^{1}H nmr ($CDCl_3$): 7-CH_3 + 8-CH_3, s, 2.59 ppm (6H); 1-CH_3, s, 3.21 ppm (3H); 4-H, d, 7.85 ppm (J = 6 Hz) (1H); 6-H + 9-H, 2s, 7.97 and 8.07 ppm (2 × 1H); 3-H, d, 8.61 ppm (J = 6 Hz) (1H).

Received October 5, 1987

C. Robert Lucas, Liu Shuang, Michael J. Newlands, Jean-Pierre Charland, and Eric J. Gabe. Can. J. Chem. **66**, 1506 (1988).

Preparation of the thiophenophane $C_{10}H_{14}S_4$, (L), and syntheses of its copper(I) complex $[CuL_2]ClO_4$ or $[CuL_2]BF_4$ are described. The ^{13}C and ^1H nmr spectra of L and the ir spectra (4000–200 cm^{-1}) of $[CuL_2]ClO_4$ and $[CuL_2]BF_4$ are reported. The molecular structures of L and $[CuL_2]ClO_4$ have been determined. For L: space group $P2_1/a$, a = 7.9347(2) Å, b = 18.7479(3) Å, c = 8.8596(2) Å, β = 108.446(2)°, Z = 4, R_f = 0.048, and R_w = 0.034. For $[CuL_2]ClO_4$: space group $P2_1/c$, a = 9.4363(1) Å, b = 18.2768(3) Å, c = 16.2157(3) Å, β = 96.520(2)°, Z = 4, R_f = 0.056, and R_w = 0.037. The Cu(I) complex has distorted tetrahedral coordination geometry; its perchlorate anion is non-coordinating and disordered. The Cu—S bond lengths lie in the range 2.301–2.392 Å and the S—Cu—S angles in the range 92.43–150.26°. Cyclic voltammetry of $[CuL_2]ClO_4$ (10^{-3} mol/L in dimethylsulfoxide, 0.1 mol/L Et_4NClO_4, glassy carbon working electrode, platinum counter electrode, aqueous saturated calomel reference electrode against which the ferrocenium/ferrocene potential under similar conditions was 400 mV) shows a quasi-reversible oxidation ($E_{1/2}$ = 0.150 V, ΔE_p = 170 mV at 50 mV/s). Thiophene's effect as a sub-unit in a small macrocycle upon properties of the latter is discussed.

C. Robert Lucas, Liu Shuang, Michael J. Newlands, Jean-Pierre Charland et Eric J. Gabe. Can. J. Chem. **66**, 1506 (1988).

On décrit la préparation du thiophénophane $C_{10}H_{14}S_4$, (L), ainsi que la synthèse de ses complexes du cuivre(I), $[CuL_2]ClO_4$ ou $[CuL_2]BF_4$. On rapporte les spectres rmn du ^{13}C et du ^1H du ligand L ainsi que les spectres ir (4000–200 cm^{-1}) des complexes $[CuL_2]ClO_4$ et $[CuL_2]BF_4$. On a déterminé les structures moléculaires du ligand L et du complexe $[CuL_2]ClO_4$. Pour le ligand L : groupe d'espace $P2_1/a$, a = 7,9347(2), b = 18,7479(3) et c = 8,8596(2) Å, β = 108,446(2)°, Z = 4, R_f = 0,048 et R_w = 0,034. Pour le complexe $[CuL_2]ClO_4$: groupe d'espace $P2_1/c$, a = 9,4363(1), b = 18,2768(3) et c = 16,2157(3) Å, β = 96,520(2)°, Z = 4, R_f = 0,056 et R_w = 0,037. Le complexe du Cu(I) possède une géométrie de coordination tétraédrique; son anion perchlorate ne donne pas de coordination et il est désordonné. Les longueurs des liaisons Cu—S varient de 2,301 à 2,392 Å et les angles S—Cu—S de 92,43 à 150,26°. La voltammétrie cyclique du complexe $[CuL_2]ClO_4$ (10^{-3} mol/L dans le diméthylsulfoxyde, Et_4NClO_4 à 0,1 mol/L, électrode de carbone vitreux, contre-électrode de platine et électrode de référence de calomel saturé en solution aqueuse contre laquelle le potentiel du couple ferrocénium/ferrocène était de 400 mV dans des conditions semblables) présente une oxydation quasi-réversible ($E_{1/2}$ = 0,150 V, ΔE_p = 170 mV à 50 mV/s). On discute de l'effet du thiophène, agissant comme sous-unité d'un petit macrocycle, sur les propriétés de ce dernier.

[Traduit par la revue]

Introduction

Metal complexes of thioether ligands have been studied for several years (1) but recently there has been quickening interest in them due in part to the recognition of coordinated methionine sulfur in "blue" copper proteins (2) and in part to an enhanced awareness of applications for sulfur compounds in a variety of technologies and medicine (3). Our interest in these molecules is an extension of investigations over several years (4–6) into the organometallic, coordination, and organic chemistry of sulfur compounds.

Evidence concerning the preparation, structure, stability, and redox properties of macrocyclic thioether complexes is accumulating (7–9) and it is of interest to determine the effects of a thiophene sub-unit on these ligands and their complexes. This paper reports the first results of such a study and deals with the preparation, structure and some properties of the macrocycle L (Fig. 1) and its copper(I) complex ion $[CuL_2]^+$ (Fig. 2).

Experimental

Reagents were obtained from the Aldrich Chemical Co. Inc. or from Morton Thiokol, Alfa Products Inc. and were used without further purification. Spectroscopic data were obtained using the following instruments: ir, Perkin Elmer Model 283; nmr, General Electric 300-NB; mass spectra, VG micromass 7070 HS; cyclic voltammetry, BAS CV27 Voltammograph and a Houston 2000 Omnigraph X-Y recorder. Electrochemical measurements were carried out under a nitrogen atmosphere and at room temperature in dimethyl sulfoxide. Solution concentrations were 10^{-3} mol/L in complex and 0.1 mol/L in supporting electrolyte (tetraethylammonium perchlorate). Voltammograms were recorded using a glassy carbon working electrode, a platinum counter electrode and an aqueous saturated calomel reference electrode checked periodically relative to a 1.0×10^{-3} mol/L solution of ferrocene in dimethylsulfoxide containing 0.1 mol/L Et_4NClO_4 for which the ferrocenium/ferrocene reduction potential was 400 mV.

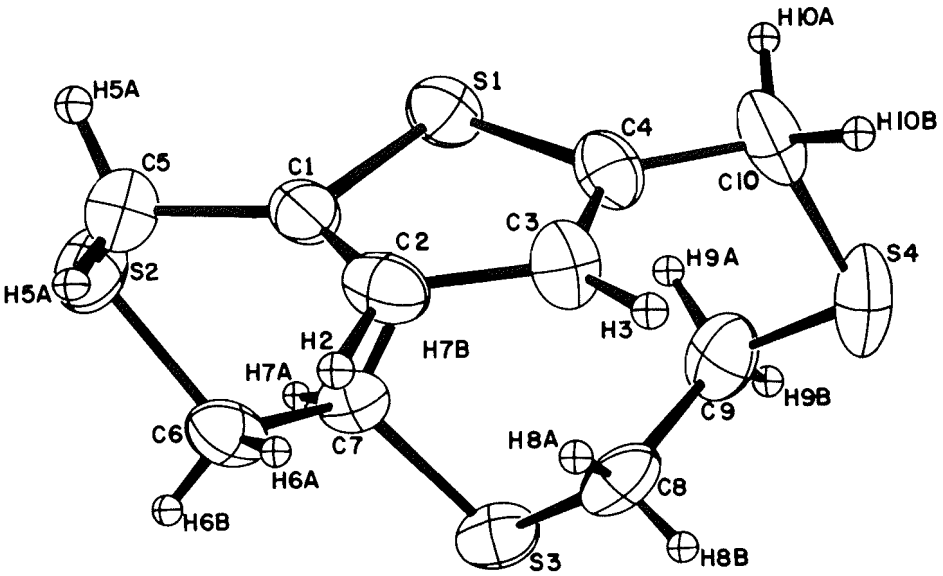

FIG. 1. ORTEP (25) drawing of L ($C_{10}H_{14}S_4$).

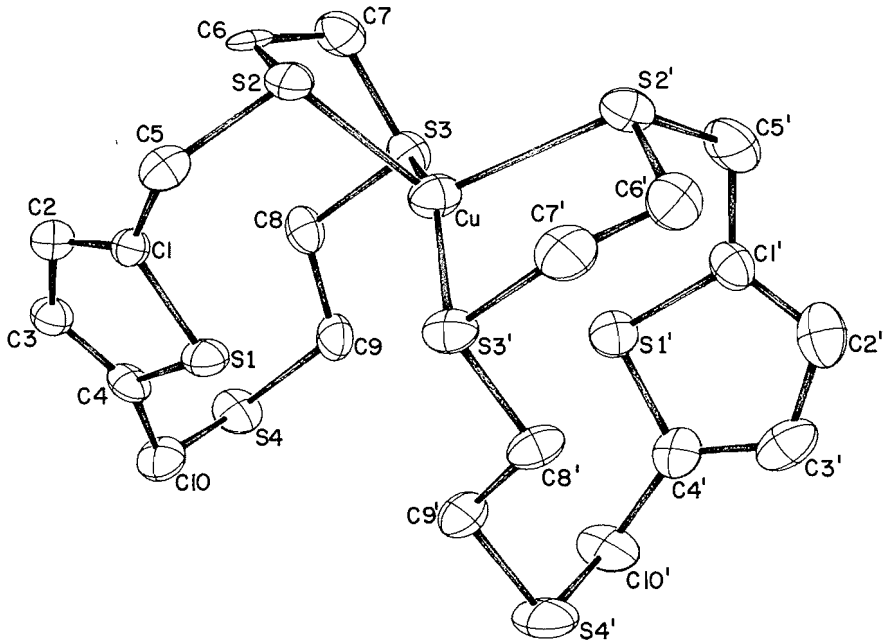

FIG. 2. ORTEP drawing of $[CuL_2]^+$.

The reference electrode was separated from the bulk of the solution by a porous Vycor tube. Junction potential corrections were not used. X-ray diffraction data were collected using an Enraf Nonius CAD-4 diffractometer. Analyses were performed by Canadian Microanalytical Service Ltd.

Preparative

(a) $C_{10}H_{14}S_4$ (ligand L)

Sodium (1.15 g, 50.0 mmol) was dissolved in commercial absolute ethanol (500 mL) under an atmosphere of dry nitrogen and 2-mercaptoethyl sulfide (3.85 g, 24.9 mmol) was added. The mixture was refluxed for 10 min. Over 8 h, a solution of purified 2,5-bis(chloromethyl)thiophene (4.52 g, 25.0 mmol) (10) in commercial absolute ethanol (200 mL) was added dropwise with stirring to the refluxing mixture. (It is important that the reagents for this preparation be pure or the yield will be low. Purification of 2,5-bis(chloromethyl)thiophene can be achieved by washing the crude brown liquid with saturated sodium carbonate solution and then water until the washings are neutral, drying over anhydrous $MgSO_4$ and recrystallizing from petroleum ether.) Refluxing and stirring were continued for a further 4 h. Volatiles were removed on a rotary evaporator and the residue was taken up in CH_2Cl_2, washed with water several times, dried over anhydrous $CaCl_2$ and taken to dryness. The yellow solid was recrystallized twice from benzene to give white needles, mp 151–153°C. Yield 3.6 g (55%). Mass spectrum: major peaks at m/e = 262 and 110 corresponding to $[C_{10}H_{14}S_4]^+$ and $[C_6H_6S]^+$. Nuclear magnetic resonance: ($CDCl_3$, ppm from TMS int. std., assignments based on $^{13}C-^1H$ heteronuclear correlation and attached proton test, position identification from Fig. 1), ^{13}C: 140.2 C1—C4, 128.1 C2—C3, 31.6 C7—C8, 31.4 C5—C10, 30.2 C6—C9; ^1H: 6.92(s) C2—C3 (2H), 3.95(s) C5—C10

(b) $[CuL_2]ClO_4$

Method A

Solutions of ligand L (300 mg, 1.14 mmol) in CH_2Cl_2 (5 mL) and of $Cu(ClO_4)_2 \cdot 6H_2O$ (185 mg, 0.500 mmol) in acetonitrile/commercial absolute ethanol (1:1) (15 mL) were mixed. The resulting green solution was filtered and left to stand in a 100 mL beaker for one week. The pale yellow crystals were collected by filtration, washed with dichloromethane and diethyl ether, and dried in air. Melting point 170°C (dec). Yield 175 mg (51%). Infrared: (Nujol mull) 1412(s), 1246(m), 1192(m), 1180(w), 1135(w), 1075(vs), 1021(m), 1016(m), 910(vw), 900(vw), 870(w), 824(s), 810(s), 763(w), 691(s), 686(s), 660(m), 617(s), 570(w), 492(w), 446(vw), 410(w), 348(vw), 315(vw), 272(w), 265(w), 250(w) cm^{-1}. *Anal.* calcd. for $C_{20}H_{28}ClCuO_4S_8$: C 34.9, H 4.10, Cu 9.24, S 37.3; found: C 34.9, H 4.10, Cu 9.05, S 35.4.

Method B

Cuprous chloride (25 mg, 0.25 mmol) was dissolved in acetonitrile (10 mL) and a solution of $AgClO_4$ (52 mg, 0.25 mmol) in acetonitrile (5 mL) was added. The mixture was filtered and to the filtrate was added a solution of ligand L (131 mg, 0.500 mmol) in CH_2Cl_2 (5 mL). The resulting suspension was filtered and the filtrate was left to evaporate slowly, giving pale yellow crystals identical to those produced by Method A as shown by ir, mp, and elemental analysis. Yield 125 mg (73%).

(c) $[CuL_2]BF_4$

Preparations of this compound are analogous to those for the perchlorate salt already described, although the yield by Method A is low. By Method B, the yield is 115 mg (68%). Melting point 165°C (dec). Infrared (Nujol mull) similar to perchlorate salt except that bands at 1075 and 617 cm^{-1} have been replaced by bands at 1050(vs) and 521(w) cm^{-1}. *Anal.* calcd. for $C_{20}H_{28}BCuF_4S_8$: C 34.3, H 3.84; found: C 34.0, H 3.81.

X-ray studies

A summary of crystal data for L and for $[CuL_2]ClO_4$ is in Table 1. The diffraction intensities were collected at 295 K with graphite monochromatized MoKα radiation using the θ/2θ scan technique with profile analysis (11) at a scan speed of 4°/min. Three standards were measured after every 100 reflections and no significant crystal decay was detected. Space groups were uniquely determined by systematic absences. Unit cell parameters in Table 1 were obtained by a least-squares refinement of the setting angles for 21 reflections (60° ≤ 2θ ≤ 89°) for $[CuL_2]ClO_4$ and for 46 reflections (50° ≤ 2θ ≤ 79°) for

L. Lorentz and polarization factors were applied but no corrections were made for absorption.

The structures were solved with MULTAN (12) plus a difference Fourier map and refined by full-matrix least-squares with counting statistics weights. H-atom positions were calculated but their parameters were not refined. All heavier atoms were refined anisotropically. All calculations were performed with the NRC VAX Crystal Structure programs (13). Scattering factors were taken from the International tables for X-ray crystallography (14). The final atomic positional parameters, the equivalent isotropic temperature factors and important bond lengths are listed in Tables 2–5. Anisotropic thermal parameters, a full listing of bond lengths and bond angles, and final structure factors are available as supplementary data.[3] Figures 1 and 2 show the molecules and the atomic numbering schemes. In $[CuL_2]ClO_4$, three oxygen atoms of each ClO_4^- ion are disordered. Two distinct positions

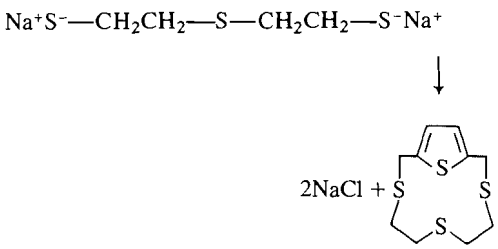
[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

of each of these three oxygen atoms were refined with isotropic thermal parameters and occupancy factors of 0.5.

Results and discussion

Traditional synthetic methods for macrocyclic compounds possessing heterocyclic sub-units have been reviewed (15). Synthesis of ligand L was carried out in 55% yield by a traditional high dilution S_N2 cyclization (reaction [1]). Ring closure

[1] 



to a 12-membered macrocycle is the preferred process in ethanol for no trace of the 24-membered macrocycle containing two thiophene sub-units was detected. Successful cyclization, however, depends upon the purity of the reagents (see Experimental) and even small amounts of impurities seem to have a significant, adverse effect on the yield. Although the preparation of this compound and a complex of it with copper(II) have been reported (16), there is some discrepancy between the properties of that substance and the material described herein.

It has been shown (17) that cavity size and orientation of the non-bonding pairs of electrons on the donor atoms of a macrocyclic ligand are factors of major importance to the formation, stability, and properties of its complexes. Conformational changes required in a ligand upon complex formation or upon a change in oxidation state of a coordinated metal atom reveal themselves as kinetic barriers which must be overcome or as thermodynamic penalties which must be paid during these processes. Inclusion of a thiophene sub-unit in a macrocycle should impose limitations on the possible orientations of donor atom electron pairs and on the size and shape of the cavity. The effect of these limitations on the molecular structures of the free ligand (Fig. 1) and a copper(I) complex (Fig. 2) were examined by X-ray methods.

The free ligand consists of a puckered polythioether chain

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

extending in space at roughly 60° to the plane defined by the thiophene ring. The macrocyclic ring's cavity is roughly triangular with the S2—S4 distance (6.662 Å) representing the base and the S3—S1 distance (4.579 Å) representing the height of the triangle. These dimensions may be compared with those of the cavities in the series of complexes of the type $Cu^{II}([n]aneS_4)^{2+}$ where n = 12 to 16 (18). In that series a ring of at least 14 members was found necessary to achieve a cavity of 4.61 Å which was the minimum that would accommodate Cu(II) co-planar with the four S-donors. In its solid state conformation, ligand L has no capability as a macrocyclic ligand not because of the size of its cavity, however, but because its cavity is shielded on one side by hydrogens on C9 and C7 and on the other by hydrogens on C8 and C6. Furthermore, all lone pairs of electrons on all sulfur atoms are exocyclic and are oriented in such a way that no two sites may bond to the same metal atom simultaneously. As a ligand in solution, the molecule might coordinate in a monodentate manner at several sites and so form a polymer, or a conformational change might occur so that the ligand becomes multidentate.

From models it can be seen that rigidity of the C10—thiophene—C5 portion of the molecule prevents conformations in which more than two thioether sulfurs may be coordinated simultaneously to the same metal atom. Thus, the solid state structure of ligand L suggests that its complexes should be polymeric if the barrier to conformational rearrangement is large. If the barrier is small, complex formation should be accompanied by conformational change to achieve chelate formation and in both cases, the possibility of coordination by thiophene sulfur must at least be considered although such behaviour is not common.

In acetonitrile mixed with either ethanol or dichloromethane, ligand L forms a complex of copper(I), $[CuL_2]ClO_4$ in which conformational change, mainly involving inversion at S3 and C8 of the free ligand has occurred. After the inversions, electron pairs of S3 and S2 are correctly oriented to form a five-membered chelate ring with copper (Fig. 2). The complex can be prepared directly from copper(I) salts or by alcohol reduction of copper(II) salts in presence of the ligand.

The copper atom is coordinated by two pairs of thioether sulfurs, each pair lying in a separate ligand molecule so that the coordination geometry about copper is distorted tetrahedral. When two coordinated sulfurs are in the same ligand molecule, the S—Cu—S angle is compressed to ~92° (Table 3) as is often found in 5-membered chelate rings of copper(I) complexes (19, 20). When the sulfurs are in different ligand molecules, the S—Cu—S angles are close to the tetrahedral value except for one which is opened to ~150° to alleviate crowding of hydrogens on C8, C8′, C9, and C9′, all of which have C—H vectors pointing into the middle of the ion's structure. The Cu—S bond lengths vary between 2.301 and 2.392 Å with an average length of 2.340 Å. These results may be compared to those from the cation $[Cu^{I}([15]aneS_5)]^{+}$ (19) which range from 2.243 to 2.338 Å with an average of 2.286 Å or those from bis(3,6-dithiaoctane)copper(I) tetrafluoroborate (20) which range from 2.280 to 2.318 Å with an average of 2.303 Å. There are no major changes in bond lengths within ligand L as a result of its coordination to copper and the greatest changes in bond angles are those associated with formation of the chelate ring. The failure of ligand L to use all its possible coordination sites is reminiscent of the behaviour of $[14]aneS_4$ with copper(I) (21) or mercury(II) (22). In the case of $[Cu([14]aneS_4)]^{+}$, only three sulfurs are used because of the strain that would be introduced if all four were coordinated to one copper atom while for $(HgCl_2)_2([14]aneS_4)$ only two sulfurs coordinate to each mercury atom due to the presence of chloride which forms stronger bonds than sulfur to mercury(II). In the case of ligand L, the use of all three thioether sulfurs is precluded by the orientation of their non-bonding electron pairs (*vide supra*).

The ir spectrum of the complex as its perchlorate has a very strong band at 1075 cm^{-1} and a strong band at 617 cm^{-1} corresponding to $\nu 3$ and $\nu 4$, respectively, of ionic perchlorate. In the analogous tetrafluoroborate, these bands vanish and are replaced by equivalent ones at 1050 and 521 cm^{-1}. Between 450 and 200 cm^{-1}, only weak bands at 446, 410, 348, 315, 265, and 250 cm^{-1}, also found in the free ligand's spectrum were detected except for a weak band at 272 cm^{-1}. This band, which is not found in the free ligand's spectrum or in the spectra of other complexes of L,[4] is tentatively assigned to a Cu—S stretching vibration.

Cyclic voltammetry for $[CuL_2]ClO_4$ showed a single quasi-reversible redox wave (Fig. 3) ($E_{1/2}$ = 0.150 V vs. aqueous SCE against which the ferrocenium/ferrocene potential under

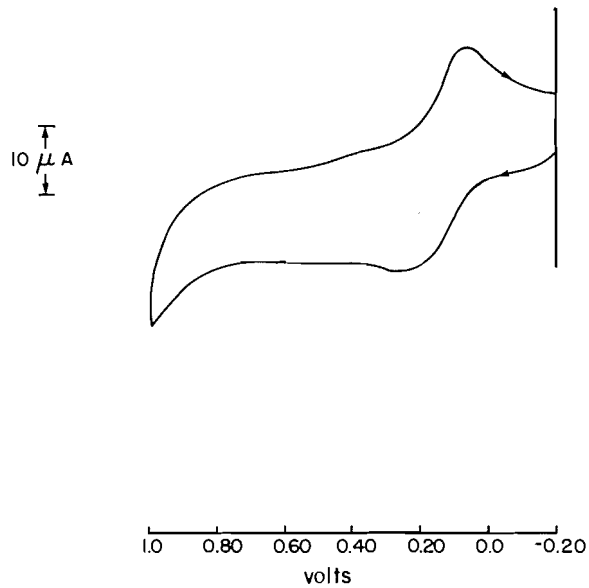

FIG. 3. Cyclic voltammogram of $[CuL_2]ClO_4$.

similar conditions was 400 mV; ΔE_p = 170 mV at 50 mV/s) associated with a Cu^I/Cu^{II} process. Solutions of the free ligand under similar conditions show no redox activity in the voltage range −1.5 to +0.8 V vs. aqueous SCE. Although measured under somewhat different conditions, a series of open chain and macrocyclic tetrathioether complexes of copper have been reported (23) to show $E_{1/2}$ for a Cu^{II}/Cu^I process in the range 0.46 to 0.66 V vs. SCE. Stabilization of copper(I) relative to copper(II) by ligand L would therefore seem to be less effective than that achieved by either open-chain or macrocyclic tetrathioethers in which all four sulfurs bound to the metal are in one ligand molecule.

In conclusion, it has been shown that presence of the rigid thiophene sub-unit as part of a small macrocyclic ring limits the conformations available to that ligand and so prevents "nesting" or "perching" of a metal ion as is often the case in small macrocyclic ring complexes (24). The coordination environment of a complexed Cu(I), although consisting of four coordinated thioether sulfurs, is different from that found in open-chain or macrocyclic tetrathioethers and this difference is reflected in the redox properties of the complex. It seems reasonable to assume that this observation may be exploited to design macrocyclic ligand complexes with enforced stereochemistry or other special characteristics. Details of these and other studies currently in progress will be reported shortly.

La photochimie de l'isoprène gazeux dans la région de l'ultraviolet très lointain

HÉLÈNE DESLAURIERS, SYLVAIN DUFOUR ET GUY J. COLLIN[1]

Département des sciences fondamentales, Université du Québec à Chicoutimi, Chicoutimi (Québec), Canada G7H 2B1

Reçu le 5 janvier 1988

HÉLÈNE DESLAURIERS, SYLVAIN DUFOUR et GUY J. COLLIN. Can. J. Chem. **66**, 1513 (1988).

On a mesuré les rendements des produits observés dans la photochimie de l'isoprène éclairé à 184,9, 213,8 et 228,8 nm sous des pressions variant de 1 à 400 Torr. On observe aux trois longueurs d'onde le processus de fragmentation de la liaison C—CH_3 avec formation concomitante des radicaux méthyle et CH_2=CCH=CH_2. Ce dernier radical est en résonance électronique avec le radical allènique CH_2=C=$CHCH_2$. Ce processus a un rendement quantique de 0,83 ± 0,08 à 213,8 nm. L'intermédiaire responsable de cette fragmentation a un temps de vie de l'ordre de 20 ns à 184,9 nm. On observe aussi de petites quantités équivalentes d'une part d'éthylène et de C_3H_4 ($\Phi \cong 0{,}050$) et d'autre part de propène et d'acétylène ($\Phi \cong 0{,}023$). Tous les rendements des produits mesurés décroissent avec l'augmentation de la pression. À ces réactions de fragmentation, il faut ajouter des réactions d'isomérisation particulièrement à 228,8 nm. Les pentadiène-1,4 et -1,3, ainsi que le méthyl-3 butadiène-1,2 sont de ces isomères. Les courbes de type Stern–Volmer sont différentes dans chacun des cas et présentent des courbures importantes, indiquant la complexité des mécanismes réactionnels. Les temps de vie des intermédiaires ont été évalués à 2 ns ou moins.

HÉLÈNE DESLAURIERS, SYLVAIN DUFOUR, and GUY J. COLLIN. Can. J. Chem. **66**, 1513 (1988).

Yields of various products have been measured in the photolysis of isoprene at 184.9, 213.8, and 228.8 nm and at pressures between 1 and 400 Torr. At each wavelength, the major process is the rupture of a C—CH_3 bond, which leads to the formation of methyl and CH_2=C=$CHCH_2$. The quantum yield for this process is 0.83 ± 0.08 at 213.8 nm. The lifetime of the intermediate involved in this process is 20 ns at 184.9 nm. Similar quantities of ethylene and C_3H_4 ($\Phi \cong 0.050$) and propene and acetylene ($\Phi \cong 0.023$) are measured. All the measured yields decrease with an increase in the pressure. In addition to these fragmentation processes, isomerization reactions are also observed, particularly at 228.8 nm. They lead to the formation of 1,3- and 1,4-pentadiene as well as 3-methyl-1,2-butadiene. The Stern–Volmer plot for each isomer is different and each plot shows a strong negative curvature, indicating the complexity of the reaction process. The lifetime of each intermediate is 2 ns or less.

Introduction

La photochimie des diènes conjugués a été depuis longtemps placée sous la loupe de plusieurs laboratoire. Déjà, en 1933, l'isopropène gazeux a été irradié avec un arc au mercure et un solide blanc avait été observé (1). Plus récemment, ces études ont été reprises et une documentation, assez importante relativement à la photochimie dans le proche uv et à 253,7 nm (photosensibilisation), du butadiène-1,3 et de ses homologues substitués existe (2). Plusieurs réactions de fragmentation ont été considérées dans le cas de la photolyse directe du butadiène-1,3. Dans celui de l'isoprène, des réactions d'isomérisation (3) et de dimérisation (4) ont été observées. Cependant, peu d'attention a, semble-t-il, été apportée à la photochimie directe de l'isoprène dans la région de l'ultraviolet lointain (en deça de son seuil d'absorption) (5). Dans ce dernier travail, nous mentionnions que la réaction principale de fragmentation implique la rupture de la liaison C—CH_3 avec un rendement de 0,70 ± 0,05 dans la région du spectre électromagnétique située entre 174 et 147 nm. Il faut ajouter que la diminution de la longueur d'onde (donc de l'augmentation de l'énergie du photon incident) favorise la fragmentation subséquente du radical C_4H_5 :

[1] iso-C_5H_8 + $h\nu \Rightarrow$ (iso-C_5H_8)**

[2] (iso-C_5H_8)** $\Rightarrow$ CH_3 + C_4H_5*, k_2

[3] C_4H_5* $\Rightarrow$ C_4H_4 + H

[4] C_4H_5* + M $\Rightarrow$ C_4H_5 + M

Le rendement en vinylacétylène, C_4H_4, suit une loi de type Stern–Volmer : $[\Phi(C_4H_4)]^{-1} = a + bP$, où P est la pression dans le réacteur (5, 6). Plus récemment, la photolyse de l'isoprène a été étudiée à 123,6 nm : elle montre une fragmentation primaire et secondaire très importante en plus de la photoionisation (7). Il faut enfin rappeler que nous avions observé la formation d'isomères lorsque l'isoprène est photoéclairé dans la région de son seuil d'absorption, c'est-à-dire entre 220 et 235 nm, bien qu'à ce moment, des doutes subsistaient quant à leur identification.

Après avoir repris l'étude de la photochimie du butadiène-1,3 à 213,8 nm, c'est-à-dire assez proche de son seuil d'absorption,[2] nous reprenons ici celle de l'isoprène entre 185 et 229 nm pour mieux en cerner les mécanismes réactionels et, si possible, les généraliser.

Partie expérimentale

(a) Photoirradiation

Les techniques expérimentales sont bien connues. Les lampes (Philipps) à mercure, à zinc et à cadmium émettent principalement et respectivement à 184,9, 213,8 et 228,8 nm (9), entre le seuil de transmission du quartz (≅180 nm) et celui d'absorption de l'isoprène (≅240 nm) (2). Les photoirradiations durent en général quelques minutes, de telle sorte que le taux de transformation (nombre de photons entrant dans la cellule/nombre de molécules d'isoprène) demeure inférieur à 1%. L'actinométrie a été réalisée à 184,9 et à 213,8 nm par comparaison en photolysant dans les mêmes conditions l'éthylène ou l'éthanethiol respectivement à 184,9 et à 213,8 nm et elle a été décrite (9). Aucune actinométrie n'a été réalisée à 228,8 nm. Toutes les irradiations ont été réalisées à la température de la chambre : T = 20 ± 2°C. Les coefficients d'absorption ont été mesuré à l'aide d'un monochromateur McPherson d'un demi-mètre.

(b) Produits chimiques

L'isoprène est un produit A.P.I. (99,96 ± 0,03%). Plusieurs ampoules ont été utilisées. Les principales impuretés observées dans une ampoule particulièrement sale sont les suivantes : pentadiène-1,4, 0,024%; *trans*- et *cis*-pentadiène-1,3, 0,030% et 0,091%; méthyl-

[c]Non mesuré.

2-butène-2, 0,030% et le méthyl-3-butène-1, 0,0050%. Ces proportions varient d'un échantillon à l'autre. L'oxygène (99,99%), l'hexafluorure de soufre (99,99%) et l'oxyde nitrique (99%) viennent de chez Matheson et l'iodure de deutérium provient de chez Merck Sharp & Dohme du Canada. Ces produits ont été utilisés tels que reçus, après dégasage à la température de l'azote liquide quand leur pression de vapeur saturante le permet.

(c) Analyses

Toutes les analyses ont été réalisées par chromatographie en phase gazeuse (10).

Résultats

Les coefficients d'absorption de l'isoprène ont été mesuré aux trois longueurs d'onde d'intérêt. Ces coefficients sont de 8 170 ± 500 et 7 000 ± 500 $dm^3\,mol^{-1}\,cm^{-1}$, respectivement, à 184,9 et à 228,8 nm. Il y a absorption complète à 213,8 nm avec une pression de 0,4 Torr (1 Torr = 133 N m^{-2}) à travers un chemin optique de 10 cm. Ces coefficients sont en accord avec le spectre d'absorption connu de l'isoprène (11).

(a) Photochimie à 184,9 nm

Les principaux produits formés en présence d'oxygène et de diverses quantités de soufre hexafluoré sont l'éthylène, les C_3H_4 (allène + propyne), l'acétylène et le propène ainsi que des traces de divers isomères (tableau 1). En présence de soufre hexafluoré seulement, aux produits déjà identifiés s'ajoutent l'éthane et le méthyl-2 pentène-2. Lorsque 10% de DI est ajouté à l'isoprène, des quantités importantes de méthane ainsi que de méthyl-3 butène-1 et de méthyl-2 butène-2 apparaissent. Il faut aussi noter une forte dépendance des rendements qui décroissent avec l'augmentation de la pression. Il faut enfin ajouter la ressemblance des rendements en acétylène et en propène d'un part et en éthylène et en C_3H_4 d'autre part.

(b) Photochimie à 213,8 et à 228,8 nm

Les résultats rapportés dans les tableaux 2 et 3 sont très similaires à ceux déjà observés et commentés à 184,9 nm. Par exemple : $\Phi(C_3H_4)/\Phi(C_2H_4) = 0,89$ ($\sigma = 0,07$) et $\Phi(C_2H_2)/\Phi(C_3H_6) = 1,10$ ($\sigma = 0,10$) à 213,8 nm. Ces mêmes valeurs sont égales à 0,79 ($\sigma = 0,10$) et 1,08 ($\sigma = 0,08$) à 228,8 nm. Ces résultats seront également rapportés mais de façon plus détaillée dans de prochaines figures. Enfin il faut mentionner l'importance relativement grande des rendements en isomères de l'isoprène à 228,8 nm comparativement à ce qui est observé à plus courtes longueurs d'onde : tableaux 1–3.

Discussion

(a) Fragmentation : produits formés seulement en présence de DI

Que ce soit en présence ou en l'absence d'oxygène, les rendements quantiques des produits sont faibles puisqu'aucun de ceux-ci n'atteint 0,06! Au contraire, en présence d'iodure de deutérium, on observe une formation très importante de méthane, de méthyl-3 butène-1 et surtout de méthyl-2 butène-2 (tableaux 1–3). On peut raisonnablement expliquer la formation de méthane par la réaction de transfert d'un atome d'hydrogène (ici de deutérium) du DI vers le radical méthyle (12) :

[5] $CH_3 + HI \Rightarrow CH_4 + I\cdot$

Ce processus a été amplement observé et utilisé pour identifier la présence de radicaux et en mesurer les rendements (13, 14). Ainsi le rendement quantique $\Phi(CH_3)$ est au moins de 0,3–0,4 (tableaux 1 et 2). Il faut ajouter un effet de pression tout à fait évident : le rendement décroît avec l'augmentation de pression du monomère. Ces résultats peuvent s'expliquer sur la base du mécanisme de type Stern–Volmer (6). Aux réactions [1] et [2] s'ajoutent les réactions suivantes :

[6] $(\text{iso-}C_5H_8)^{**} + M \Rightarrow C_5H_8 + M, \quad k_6$

et

$$[\Phi(CH_3)]^{-1} = [\Phi_0(CH_3)]^{-1}\cdot(1 + k_6/k_2\cdot[M])$$

où k_2 et k_6 sont respectivement les constantes de vitesse des réactions de fragmentation (1er ordre) ou de stabilisation par collision (2ème ordre) de l'espèce excitée $(\text{iso-}C_5H_8)^{**}$ et Φ_0 est le rendement obtenu par extrapolation à pression nulle. La figure 1 résume les observations expérimentales. Il faut tout d'abord remarquer la bonne tenue des droites Stern–Volmer dans chacun des cas. Par extrapolation à pression nulle, on obtient $[\Phi_0(CH_3)]^{-1} \cong [\Phi_0(CH_4)]^{-1} = 2,2 \pm 0,2$ et $1,2 \pm 0,2$, respectivement, à 184,9 et à 213,8 nm. Ainsi une réaction majeure observable à ces deux longueurs d'onde est la réaction [2] tout au moins à basse pression : $\Phi_0(CH_3) = 0,46 \pm 0,05$ et $0,8 \pm 0,2$, respectivement, à 184,9 et à 213,8 nm (tableau 4). En outre, l'interception de ces droites Stern–Volmer avec l'axe des pressions est une mesure (exprimée en unités de pression) du rapport $-k_2/k_6$. En utilisant un rayon moléculaire de 0,583 nm pour l'isoprène (15) (σ(isoprène) ≅ σ(méthyl-3 butène-1) = 0,583 nm), on obtient une vitesse de collision $\omega = 1,58 \times 10^7$ s^{-1}. Les vitesses de fragmentation ainsi calculés de la molécule excitée $(\text{iso-}C_5H_8)^{**}$ sont donc de l'ordre de $(2–3) \times 10^{-8}$ s^{-1} (tableau 4). Les temps de vie sont similaires à celui calculé pour le diméthyl-2 butène-2 photoexcité à 193,2 nm : 70 ns (16), mais beaucoup plus longs que ceux d'autres hexènes ou méthylpentènes excités à 184,9 nm : 0,35–5 ns (17). La présence de deux liaisons conjuguées a très certainement un effet stabilisant sur la molécule photoexcitée.

La formation des butadiène-1,3 et -1,2 en présence de DI constitue une preuve de ce mécanisme. On s'attend en effet à ce qu'une part des radicaux C_4H_5 libérés par les processus [2]–[4] soient interceptés au moins partiellement dans une réaction analogue à la réaction [5], bien qu'il ne soit pas assuré que cette réaction soit quantitative étant donnée la compétition que peut

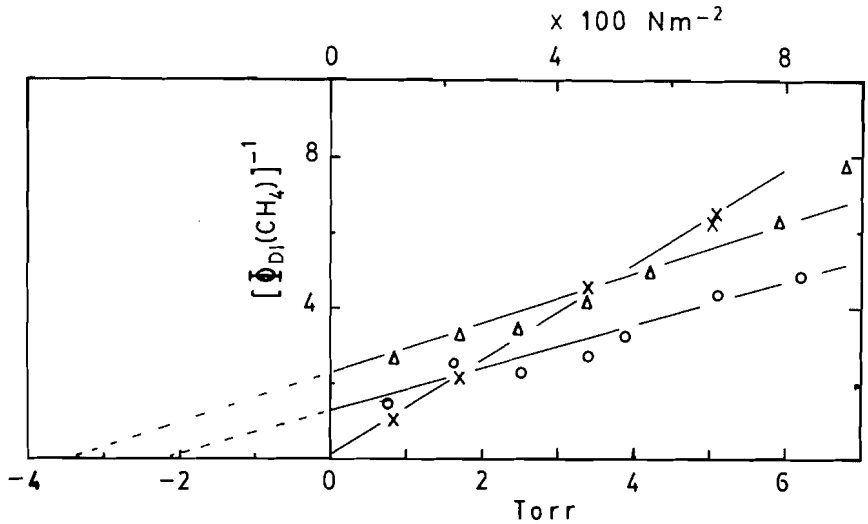

FIG. 1. Inverse du rendement quantique du méthane en fonction de la pression du monomère et en présence de DI (10%) : 184,9 nm, △; 213,8 nm, ○ et 228,8 nm, × (échelle arbitraire). Contrairement à ce que pourrait laisser croire cette dernière droite, son ordonnée à l'origine n'est pas zéro, mais bien positive. L'absence de rendements quantiques ne permet pas d'en préciser davantage cette ordonnée à l'origine.

TABLEAU 4. Photolyse de l'isoprène. Fragmentation d'une liaison C—CH_3

λ (nm)	Équation de Stern–Volmer[a] a	b	r^2	b^{-1}	$-k_2/k_6$ (Torr)	Temps de vie (10^{-8} s)
184,9	0,648	2,18	0,99	0,46	3,4	2
213,8	0,576	1,20	0,95	0,83	2,1	3
228,8	[b]	[b]	0,98	[b]	0,1	80[c]

[a] $f = aP + b$, où [P] ≡ Torr.
[b] Absence de rendements quantiques.
[c] Précision dérisoire.

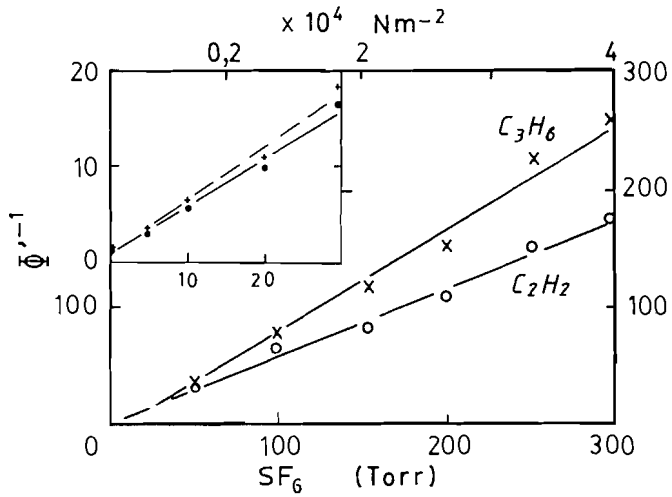

FIG. 2. Inverse des rendements des produits en fonction de la pression du soufre hexafluoré à 228,8 nm : ○, $[\Phi'(C_2H_2)]^{-1} = -0{,}35 + 0{,}58\,P$, $r = 0{,}99$; ●, $[\Phi'(C_2H_2)]^{-1} = +0{,}48 + 0{,}51\,P$, $r = 0{,}99$; ×, $[\Phi'(C_3H_6)]^{-1} = -18{,}0 + 0{,}92\,P$, $r = 0{,}99$; +, $[\Phi'(C_3H_6)]^{-1} = +0{,}32 + 0{,}57\,P$, $r = 0{,}99$.

offrir l'isoprène vis-à-vis certains radicaux (14). La présence des butadiène-1,3 et -1,2 est en accord avec la structure de l'isoprène après perte de son groupe méthyle. Il y a en effet possibilité de résonance électronique entre les structures $CH_2{=}CCH{=}CH_2$ et $CH_2{=}C{=}CHCH_2$ (18), et l'interception par DI conduit aux deux butadiènes mentionnés. Quant aux méthyl-2 butène-2 et méthyl-3 butène-1 dont les rendements quantiques peuvent dépasser l'unité (tableaux 1 et 2), ils sont probablement le résultat d'un mécanisme en chaîne impliquant soit des atomes d'hydrogène, soit d'iode, ou les deux en même temps (19).

(b) Fragmentation : produits formés en présence d'oxygène

Ce sont essentiellement des produits en C_2 et C_3 (tableaux 1–3). Compte tenu des rendements observés, on peut proposer les réactions suivantes où sont exclues les espèces radicalaires thermalisées puisque celles-ci seraient normalement interceptées par l'oxygène moléculaire.

[7] $(\text{iso-}C_5H_8)^{**\text{ ou v}} \Rightarrow C_2H_4 + C_3H_4$

[8] $(\text{iso-}C_5H_8)^{**\text{ ou v}} \Rightarrow C_2H_2 + C_3H_6$

[9] $(\text{iso-}C_5H_8)^{**\text{ ou v}} \Rightarrow C_2H_3^* + C_3H_5^*$

[10] $C_2H_3^* \Rightarrow C_2H_2 + H$

[11] $C_3H_5^* \Rightarrow C_3H_4 + H$

[12] $C_2H_3^*$ ou $C_3H_5^* + M \Rightarrow C_2H_3$ ou $C_3H_5 + M$

Le comportement Stern–Volmer des rendements des produits «moléculaires» s'explique par la stabilisation de l'intermédiaire isoprène excité ou bien par celle du radical chaud (vibrationnellement excité). Si les deux intermédiaires participent à la formation de l'acétylène et de l'éthylène et s'ils sont suceptibles de stabilisation par collision, une courbure positive ou négative à la droite de Stern–Volmer peut éventuellement être observée (20) : figures 2–4. Il faut ajouter que les réactions [9], [10] et [11] ne peuvent se réaliser simultanément car l'énergie initiale des photons est insuffisante pour satisfaire aux exigences thermodynamiques requises par la rupture de trois liaisons. Cela peut expliquer les différences sensibles dans les rendements en acétylène et propène particulièrement à 213,8 et 228,8 nm (voir résultats). Il faut en outre ajouter que les réactions de fragmentation moléculaires demandent une isomérisation préalable de la molécule photoexcitée. Ainsi,

[8a] $(CH_2{=}C(CH_3)CH{=}CH_2)^{**\text{ ou v}}$
$\Rightarrow (CH_3C(CH_3){-}CH{=}CH)^{**\text{ ou v}}$

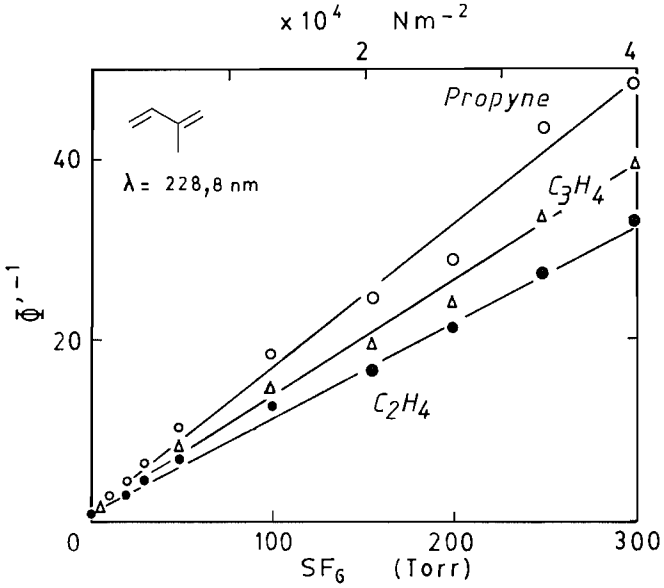

FIG. 3. Inverse des rendements des produits en fonction de la pression du soufre hexafluoré à 228,8 nm : ○, $[\Phi'(CH_3C{\equiv}CH)]^{-1} = 1{,}15 + 0{,}157\,P$, $r = 0{,}99$; △, $[\Phi'(C_3H_4)]^{-1} = 0{,}805 + 0{,}127\,P$, $r = 1{,}00$; ●, $[\Phi'(C_2H_4)]^{-1} = 0{,}809 + 0{,}106\,P$, $r = 1{,}00$.

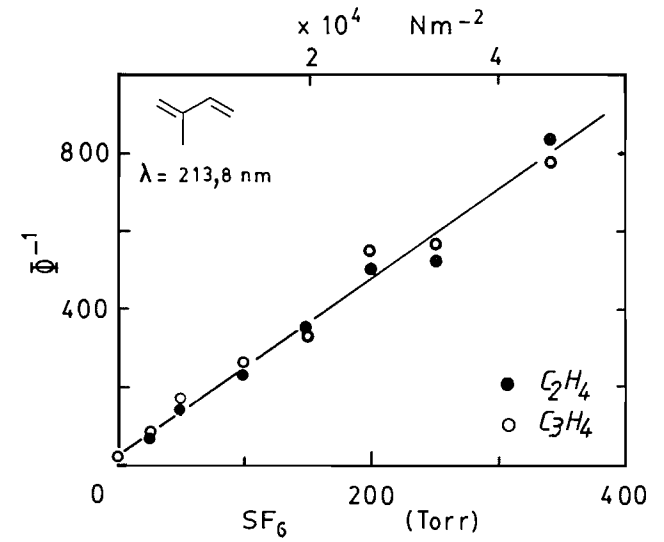

FIG. 4. Inverse des rendements quantiques des produits en fonction de la pression du soufre hexafluoré à 213,8 nm : ●, $[\Phi(C_2H_4)]^{-1} = 18{,}5 + 2{,}30\,P$, $r = 0{,}99$; ○, $[\Phi(C_3H_4)]^{-1} = 48{,}5 + 2{,}25\,P$, $r = 0{,}99$.

[8*b*] $(CH_3C(CH_3)—CH{=}CH)^{**\,ou\,v} \Rightarrow CH_3CCH_3 + CH{\equiv}CH$

[8*c*] $CH_3CCH_3 \Rightarrow CH_3CH{=}CH_2\cdot$

Il en est de même des réactions [7] et [9]. Les résultats sont insuffisants pour apprécier l'importance relative de chacun des processus [7]–[11]. Enfin deux autres produits sont formés avec des rendements qui dépendent fortement de la pression entre 0 et 10 Torr de soufre hexafluoré, puisqu'ils demeurent relativement stables. L'un de ces produits est le méthyl-3 butène-3 yne-1 (méthylvinylacétylène) et l'autre n'a pu être identifié (figure 5).

[13] $(CH_2){=}C(CH_3)CH{=}CH_2)^{**\,ou\,v} \Rightarrow CH_2{=}C(CH_3)C{\equiv}CH + H_2$

Compte tenu de l'énergie disponible à 228,8 nm (523 kJ mol^{-1}),

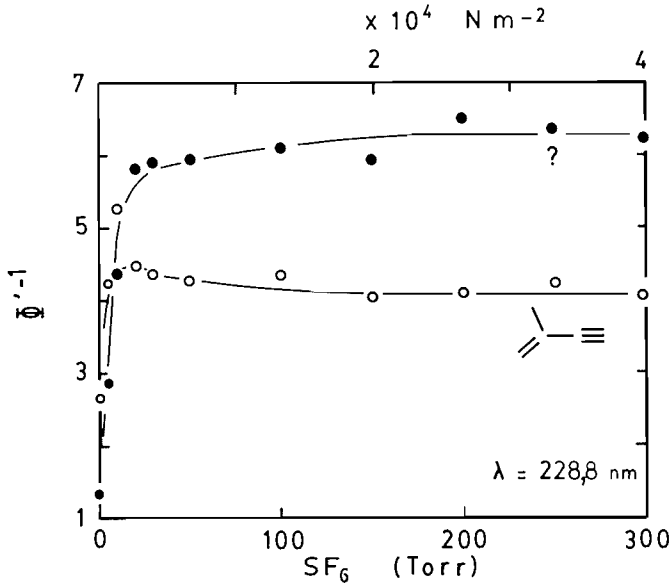

FIG. 5. Inverse des rendements des produits en fonction de la pression du soufre hexafluoré à 228,8 nm : ○, $[\Phi'(\text{Méthylvinylacétylène})]^{-1}$; ●, $[\Phi'(\text{Inconnu})]^{-1}$.

la réaction précédente produit, sinon exclusivement, de l'hydrogène moléculaire plutôt que monoatomique. La fragmentation à partir d'un état électronique excité à courte durée de vie pourrait être responsable de la formation qui apparaît indépendante de la pression, tandis que celle qui est fortement affectée par la pression provient d'un état excité à très long temps de vie.

(c) Fragmentation : produits formés en l'absence d'oxygène ou de DI

La formation d'éthane doit être mise au compte de la recombinaison entre une partie des radicaux méthyles. Une autre partie de ces radicaux réagit avec les autres radicaux présents, comme ceux, par exemple, provenant de l'addition de l'atome d'hydrogène sur le monomère. La présence de ces atomes d'hydrogène est observable à travers la formation de diverses oléfines en C_6. Provenant des réactions [3], [10] et [11], ces atomes s'additionnent sur l'isoprène et forment divers radicaux allylliques C_5H_9. Ceux-ci, à leur tour se recombinent entre eux ou avec les radicaux méthyles. Ces réactions sont responsables de la formation de monooléfines substituées en C_6, et dont certaines ont pu être observées. Ce sont le diméthyl-2,3 butène-1 et les méthyl-2 pentène-1 et -2.

[14] $H + \text{iso-}C_5H_8 \Rightarrow (CH_3)_2CCH{=}CH_2$ ou $(CH_3)_2C{=}CHCH_2$

[15] $H + \text{iso-}C_5H_8 \Rightarrow CH_2{=}C(CH_3)CHCH_3$ ou $CH_2C(CH_3){=}CHCH_3$

[16] $(CH_3)_2CCH{=}CH_2 + CH_3 \Rightarrow (CH_3)_3CCH{=}CH_2$

[17] $CH_2{=}C(CH_3)CHCH_3 + CH_3 \Rightarrow (CH_3)_2CHC(CH_3){=}CH_2$

[18] $(CH_3)_2C{=}CHCH_2 + CH_3 \Rightarrow (CH_3)_2C{=}CHCH_2CH_3$

[19] $CH_2C(CH_3){=}CHCH_3 + CH_3 \Rightarrow CH_3CH_2C(CH_3){=}CHCH_3$

(d) Isomérisation à 228,8 nm

Les représentation Stern–Volmer des rendements en isomères, $[\Phi(x)]^{-1} = f(\text{pression})$, sont loin d'être linéaires : figures 6–8. On observe en général une courbure négative plus ou moins prononcée dans la zone de pression située vers 50 Torr de soufre hexafluoré. Il n'est pas aisé, a priori, d'expliquer ces observations puisque plusieurs raisons peuvent être invoquées

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12

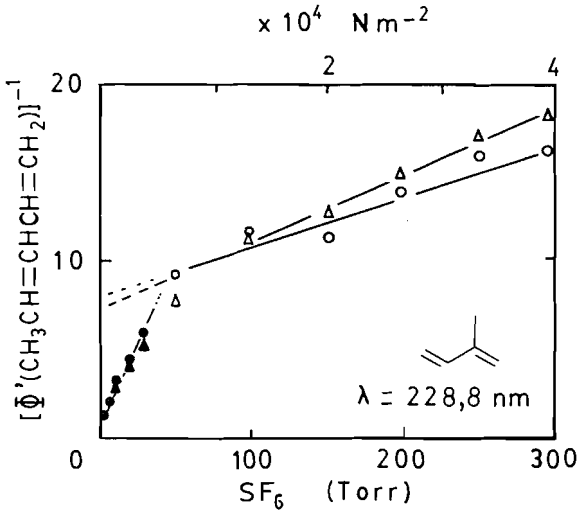

FIG. 6. Inverse des rendements des produits en fonction de la pression du soufre hexafluoré à 228,8 nm : ○, $[\Phi'(\textit{trans}\text{-Pentadiène-1,3})]^{-1} = 7{,}96 + 0{,}028\,P$, $r = 0{,}96$; ●, $[\Phi'(\textit{trans}\text{-Pentadiène-1,3})]^{-1} = 1{,}33 + 0{,}155\,P$, $r = 1{,}00$; △, $[\Phi'(\textit{cis}\text{-Pentadiène-1,3})]^{-1} = 6{,}25 + 0{,}042\,P$, $r = 0{,}99$; ▲, $[\Phi'(\textit{cis}\text{-Pentadiène-1,3})]^{-1} = 1{,}29 + 0{,}14\,P$, $r = 1{,}00$.

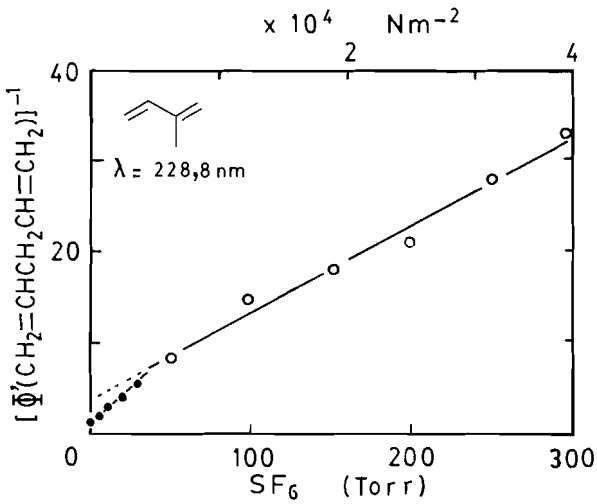

FIG. 7. Inverse des rendements des produits en fonction de la pression du soufre hexafluoré à 228,8 nm : ○, $[\Phi'(C_5H_8\text{-}1,4)]^{-1} = 3{,}43 + 0{,}097\,P$, $r = 0{,}99$; ●, $[\Phi'(C_5H_8\text{-}1,4)]^{-1} = 1{,}25 + 0{,}14\,P$, $r = 1{,}00$.

(6). On ne peut retenir, tout d'abord, une distribution énergétique relativement large des molécules photoexcitées puisque celles-ci contiennent, outre l'énergie thermique initiale (≅20 kJ mol^{-1}), l'énergie du photon incident, soit 523 kJ mol^{-1} (5,44 eV). Une première possibilité peut être retenue : chacun de ces isomères serait le résultat de deux mécanismes réactionnels indépendants et tout à fait différents. La courbe serait alors la «somme» de deux courbes Stern–Volmer indépendantes, comme nous l'avions proposé dans le cas de la photochimie des butènes vers 163–174 nm (21). Dans ce cas, et à haute pression, les courbes Stern–Volmer sont de la forme ($y = a + bP$) : $[\Phi']^{-1} = [\Phi_0']^{-1} + [\Phi_0']^{-1} k_s[P]/k_d$. Du rapport a/b, on obtient la valeur du rapport k_d/k_s pour les différents intermédiaires apparaissant dans les figures 6–8 (tableau 5). Les temps de vie des intermédiaires ainsi calculés sont de l'ordre de, ou inférieur à, la nanoseconde, donc beaucoup plus courts que

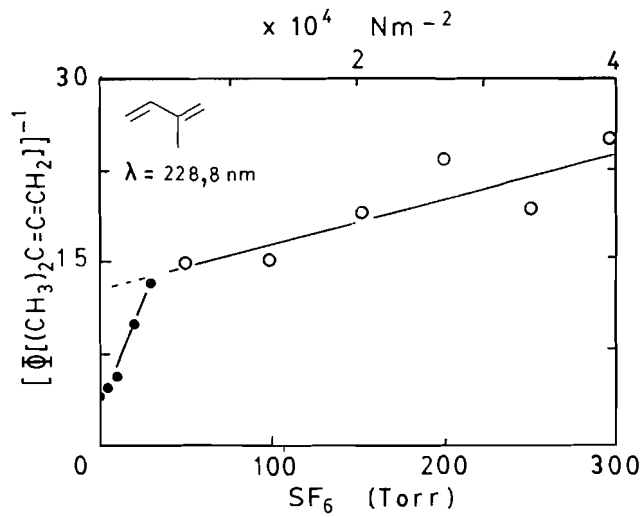

FIG. 8. Inverse du rendement en méthyl-3 butadiène-1,2 en fonction de la pression du soufre hexafluoré à 228,8 nm : ○, $[\Phi']^{-1} = 12{,}7 + 0{,}097\,P$, $r = 0{,}84$; ●, $[\Phi']^{-1} = 3{,}62 + 0{,}32\,P$, $r = 0{,}99$.

TABLEAU 5. Photolyse de l'isoprène. Isomérisation du monomère à 228,8 nm

Isomère	k_s/k_d (Torr)	Temps de vie (10^{-10} s)[a]
trans-Pentadiène-1,3	285	2,3
cis-Pentadiène-1,3	150	4,4
Pentadiène-1,4	35	19
Méthyl-2 butadiène-1,2	130	5,1

[a]Rayon moléculaire de SF_6 : 0,55 nm ($\sigma(SF_6)$ = 0,55 nm. Voir référence 15) et $\omega = 1{,}5 \times 10^7$ s^{-1}.

celui mesuré pour l'intermédiaire responsable de la rupture de la liaison C—CH_3. La même approche pourrait être appliquée à la portion «basse pression» des courbes Stern–Volmer. Cependant, le nombre de données, combiné à la précision expérimentale, enlève une grande part de crédibilité aux résultats obtenus. Une autre explication, tout aussi plausible, réside dans un mécanisme de faisant intervenir successivement deux états excités différents, chacun de ces deux états étant suceptibles d'être stabilisés par collision (20).

[20] $(\text{iso-}C_5H_8)^{**} \Rightarrow \text{iso-}C_5H_8^*$

[21] $\text{iso-}C_5H_8^* \Rightarrow \text{iso-}C_5H_8^v$

[22] $\text{iso-}C_5H_8^* + M \Rightarrow \text{iso-}C_5H_8 + M$

[23] $\text{iso-}C_5H_8^v + M \Rightarrow \text{iso-}C_5H_8 + M$

[24] $\text{iso-}C_5H_8^v \Rightarrow (M_i)^v$

[25] $\text{iso-}C_5H_8^v \Rightarrow (M_i)^v$

[26] $(M_i)^v + M \Rightarrow M_i + M$

Si la molécule $(\text{iso-}C_5H_8)^{**}$ formée dans le processus de photoexcitation, reaction [1], représente un état électronique excité, on n'en connaît pas la nature exacte. Mentionnons qu'à l'énergie incidente utilisée plusieurs états électroniques singulets, et éventuellement triplets (?), sont disponibles (22). On ne peut guère en dire plus de l'état électronique $\text{iso-}C_5H_8^*$. Quant à l'état fondamental vibrationnellement excité, il est identifié par l'exposant v. La molécule M_i est un isomère de l'isoprène,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

isomère qui peut prendre plusieurs configurations différentes. Il en résulte que les mécanismes disponibles sont tout aussi nombreux, sinon plus. Il faut ajouter que si ce dernier mécanisme est convenable, il requiert des paires d'intermédiaires excités différents puisque, hormis pour le couple *cis-* et *trans*-pentadiène-1,3 (figure 6), il ne semble pas y avoir de constance entre les rapports de rendements observés (figures 6–8). Par contre, on peut raisonablement estimer que les premiers états excités stabilisés par collision sont ceux de l'isoprène. En effet, et contrairement à ce qui a été observé, par exemple, dans le cas du tétraméthyléthylène photoexcité dans la région de 185–229 nm où les rendements en isomères croissent avec l'augmentation de la pression (23), dans le cas présent les rendements en isomères décroissent avec l'augmentation de la pression. Une situation également différente a été observée dans le cas du cyclopentène (8).

Remerciements

Nous tenons à exprimer notre reconnaissance au Conseil de recherche en sciences naturelles et en génie du Canada qui a financé cette étude ainsi que Emploi et Immigration Canada qui ont chacun payé une partie des salaires (H.D. et S.D.).

Excess molar volumes of methyl alkanoate with *n*-alkanols at 298.15 K

J. ORTEGA AND J. D. GARCIA

Cátedra de Termodinámica y Fisicoquímica, Escuela Superior de Ingenieros Industriales, Polytechnic University of Canarias, Spain

Received October 6, 1987

J. ORTEGA and J. D. GARCIA. Can. J. Chem. **66**, 1520 (1988).

This work reports on the excess molar volumes at 298.15 K of fifteen binary systems formed by $\{xC_mH_{2m+1}CO_2CH_3$ $(m = 1, 2, 3) + (1 - x)C_nH_{2n+1}(OH)$ $(n = 6, 7, 8, 9, 10)\}$. The V_m^E values were calculated using densities obtained in a vibrating-tube densimeter, the excess molar volumes being positive for all these systems. A qualitative interpretation of the results is presented on the basis of the appearance of specific interactions between the —CO—O— groups of the ester and the —OH of the *n*-alkanol.

J. ORTEGA et J. D. GARCIA. Can. J. Chem. **66**, 1520 (1988).

Dans ce travail, on a déterminé les volumes molaires en excès, à 298,15 K, de quinze systèmes binaires formés par $\{xC_mC_{2m+1}CO_2CH_3$ $(m = 1, 2$ ou $3) + (1 - x)C_nH_{2n+1}(OH)$ $(n = 6, 7, 8, 9$ ou $10)\}$. Les valeurs de V_m^E ont été calculées en utilisant les densités qui ont été obtenues à l'aide d'un densimètre à tube vibrant; les volumes molaires en excès sont positifs pour tous les systèmes. On présente une interprétation qualitative des résultats qui est basée sur l'apparition d'interactions spécifiques entre les groupements —CO—O— des esters et —OH des *n*-alcools.

[Traduit par la revue]

Introduction

In previous papers (1–3) data of the V_m^E were presented for several binary systems of aliphatic esters with *n*-alkanols, in which the volumetric behaviour of this type of mixtures was analysed and the results obtained were qualitatively justified. As was stated in the above-mentioned articles, we are particularly interested in confirming the considerations put forward on the behaviour of the —CO—O— ester group. For this purpose it is also necessary to consider the effects of the interactions of compounds having the same functional group with other type of substances, such as *n*-alkanes (4, 5). This interaction is analysed using other excess thermodynamic functions such as H_m^E and G_m^E.

A summary of the studies published to date reveals that there are at least two effects in the interactions of an ester with non-electrolytes. The first and most prominent effect for any ester is that an increase in the V_m^E value is a function of the length of the chain of the binary component in the non-electrolyte. However, the second effect due to the ester is attributed to a specific interaction which causes the decrease of the V_m^E as the number of carbons of the ester increase, for both R_1 and R_2 in R_1—CO—O—R_2.

In this work we studied the changes in volume produced upon mixing methyl alkanoates, starting from acetate to butanoate, with normal alkanols, from hexan-1-ol to decan-1-ol, at a temperature of 298.15 K and at atmospheric pressure. The data presented here will contribute to the study of binary mixtures of ester + *n*-alkanols, providing additional information on the behaviour of the liquid state of these types of compounds.

Experimental

Component liquids

Both the esters and the *n*-alkanols were supplied by Fluka. The characteristics indicated by the manufacturer for the products employed were "purum" > 99 mol% for all the methyl alkanoates, "puriss" > 99.5 mol% for hexan-1-ol, heptan-1-ol, octan-1-ol, and decan-1-ol and "purum" > 98 mol% for nonan-1-ol. All products were dried prior to use with a molecular sieve (Union Carbide, Type A4, by Fluka) and partially degassed with ultrasound. After these operations, the purity of the liquids was tested and the values of density and refractive index determined at 298.15 K. The comparison of these values with those found in the literature is presented in Table 1, a good agreement being obtained for both esters and *n*-alkanols.

Determinations of excess volumes

The binary mixtures over the entire range of concentrations were prepared by weighing, using hermetically sealed vials to avoid evaporation. The molar fractions, x, of the ester were determined with an error of less than 2×10^{-5}. The excess volumes, determined indirectly from the densities, were calculated with

$$[1] \quad V_m^E/(\text{cm}^3\ \text{mol}^{-1}) = (\Sigma x_i M_i)/\rho - \Sigma(x_i M_i/\rho_i)$$

where ρ is the density of the mixture and ρ_i, x_i, and M_i are, respectively, the density, the molar fraction, and the molecular mass of compound i. The molecular masses were determined to within $\pm 10^{-4}$ units and the densities to within ± 0.01 kg m^{-3}. On this basis, the V_m^E values were calculated with an accuracy above ± 0.001 cm^3 mol^{-1}.

For the determination of the densities an Anton Paar digital densimeter, model DMA-55, was used, which was calibrated for each mixture using bidistilled water and *n*-nonane as standard substances, as proposed in an earlier work (9). The densimeter was thermostated by a Heto Birdkerod ultrathermostat which controlled the temperature automatically to within ± 0.01 K.

Results

The V_m^E values of the fifteen systems $\{xC_mH_{2m+1}CO_2CH_3$ $(m = 1, 2, 3) + (1 - x)C_nH_{2n+1}(OH)$ $(n = 6, 7, 8, 9, 10)\}$ are given in Table 2 as a function of the ester concentration, x. These data were correlated by means of the following equation:

$$[2] \quad V_m^E/(\text{cm}^3\ \text{mol}^{-1}) = x(1 - x)\Sigma A_i[x/(x + k(1 - x))]^i \qquad i = 0, 1, 2, \ldots$$

The values of the A_i coefficients were determined, for a constant value of k, by the least-squares method and employing an F-test to evaluate the confidence of each coefficient and optimize the grade of eq. [2]. The equation thus obtained was analysed for the different values of the parameter k in an attempt to minimizing the standard deviation, $s(V_m^E)$, of the experimental data and therefore give the best fit. The parameters of the equation that give the best fit for each system are presented in Table 3, while Fig. 1 shows the distribution of the curves obtained for the fifteen systems studied.

Discussion

No data have been found of V_m^E at 298.15 K for the mixtures studied here. As was expected for this type of systems, all the

excess molar volumes were positive. For any one ester, the V_m^E values increase almost linearly with the number of carbon atoms of the *n*-alkanol; however, the opposite effect takes place when the number of carbon atoms of the ester increases on either side of the —CO—O— group. The first of the effects mentioned, the size effect, takes place also in mixtures of ester + *n*-alkane (4) and is justified by the steric hinderance brought about by the increase of the *n*-alkanol chain. If this fact is considered together with the dissociation of the polymers of the *n*-alkanol, by way of the hydrogen bonds, against the inertia presented by the *n*-alkanes it is found that, with an equal number of carbon atoms, the following is verified for any one ester: V_m^E, *n*-alkane > V_m^E, *n*-alkanol.

It was considered worthwhile to compare the V_m^E values in the interactions of the certain *n*-alkanol with different esters having the same empirical expression. This work shows clearly that the V_m^E values of methyl butanoate are very similar to those of ethyl propanoate (3) and propyl acetate (10) when mixed with the same *n*-alkanols. However, the differences become more significant when the comparison is made of esters with fewer carbon atoms, such as of methyl acetate and ethyl formate (2) upon mixing, as before, with the same *n*-alkanols. These greater differences seem logical since, quantitatively, the V_m^E values are quite high and their absolute error increased considerably. Thus the volumetric effects for R_1—CO—O—R_2 type molecules are the same when substituents R_1 and R_2 are interchanged. Leaving aside esters with a low number of carbon atoms, special considerations would also have to be made when comparing systems containing esters that form pseudocycles, as will be discussed forthwith.

The preceding paragraph bears relation to the second of the aspects pointed out at the beginning of this section, and which proves to be characteristic of those compounds containing a =C=O carbonyl group. We are referring to the decrease in the V_m^E values with the increase in the number of carbon atoms of the ester, for any one *n*-alkanol. This interesting aspect also appears in mixtures of aliphatic ketones with *n*-alkanes (5), and even when one of the radicals of the ketone or of the ester is substituted by phenyl groups (5). The evolution of the results obtained here for the V_m^E is analogous to that of thermodynamic magnitudes of mixtures, such as H_m^E and G_m^E (11). The sequence

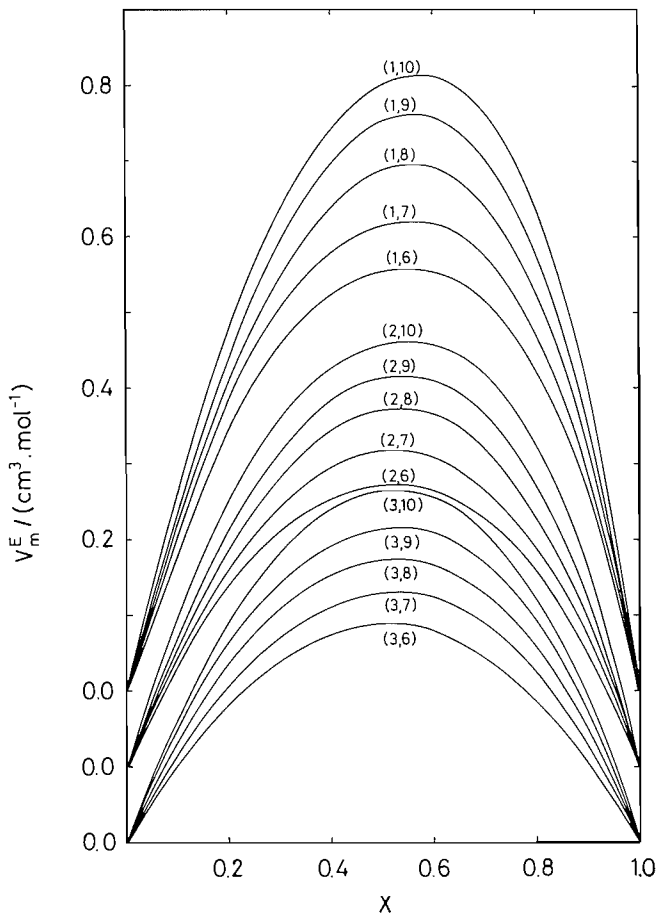

FIG. 1. V_m^E curves at 298.15 K calculated by eq. [2] for the binary systems, (*m*,*n*) {$xC_mH_{2m+1}CO_2CH_3$ (*m* = 1, 2, 3) + (1 − *x*)$C_nH_{2n+1}(OH)$ (*n* = 6, 7, 8, 9, 10)}.

observed in the V_m^E for the mixtures of methyl acetate, methyl propanoate, and methyl butanoate with *n*-alkanols can be explained taking into account that the basic nature of the carbonyl group increases with the length of the chain of the methyl ester, the interactions between the molecules of the ester

weakening, to allow a greater contact between the *n*-alkanol and the ester. This effect causes the positive contribution to the V_m^E values of the mixture to decrease progressively.

Upon plotting the excess molar volumes at infinite dilution of the *n*-alkanols, $V_{m,2}^{E\infty}$, as a function of m in $C_mH_{2m+1}CO_2CH_3$, the distribution of points appears as shown in Fig. 2, where the values of $V_{m,2}^{E\infty}$ are also presented for *n*-heptane with different methyl alkanoates (Dusart *et al.* (5)). No values are available for methyl pentanoate or methyl hexanoate, but it seems that the $V_{m,2}^{E\infty}$ obtained with methyl butanoate are slightly higher than expected, a behaviour analogous to that reported by Dusart *et al.* and which can be readily observed in the graph. This anomaly of methyl butanoate was explained by the formation of an intramolecular cyclization in the molecule of the ester, a

relatively stable 6-atom cycle being formed. This cyclization causes the solute–solvent interactions to decrease and, moreover, produces a shortening of its apparent volume, originating the increase of the excess volume at infinite dilution. In this case, the formation of the quasi-cycle by a hydrogen bond may be enhanced by the presence of the —OH group in the *n*-alkanol.

Étude des courants périodiques observés lors de la dissolution électrochimique du nickel en présence d'ions iodure et chlorure en milieu aqueux

LI BEN LE[1] ET OLIVIER VITTORI[2]

Laboratoire d'électrochimie analytique, Unité associée n° 417 du Centre national de la recherche scientifique, Laboratoire des interphases, Université Lyon 1, 43 boulevard du 11 novembre 1918, 69622 Villeurbanne CEDEX, France

Reçu le 24 novembre 1987

LI BEN LE et OLIVIER VITTORI. Can. J. Chem. **66**, 1525 (1988).

Faisant appel à la voltamétrie à faible balayage (<2 mV/s), on a étudié l'électrodissolution du nickel en présence d'ions chlorure et iodure. On a observé que la vitesse de dissolution du nickel est liée à la concentration en chlorure et que l'addition d'iodure modifie la forme des courbes. On a noté que des oscillations du courant se produisent après un délai qui devient plus court au fur et à mesure de l'augmentation de la concentration en iodure. Si la concentration en iodure est maintenue à un niveau faible, ces oscillations se produisent sur un large éventail de potentiels. Une augmentation de cette concentration supprime les oscillations et il apparaît alors deux pics; le plus cathodique devient de plus en plus important. On discute de l'effet produit par l'addition d'agents de surface; le *p*-octylbenzènesulfonate de sodium est le seul à supprimer les oscillations, même à faible concentration alors que l'amidon agit progressivement de 1 à 40 g/L. Les changements de couleur qu'on note à la surface du nickel durant les oscillations suggèrent qu'il se produit une dissolution préférentielle aux jonctions des grains. Ceci explique la couleur noire qu'on peut observer en alternance avec l'aspect métallique; le nickel se couvre alors de particules finement divisées qui se dissolvent rapidement. L'iodure qui apparaît occasionnellement à de tels potentiels anodiques est probablement impliqué dans le processus de dissolution.

LI BEN LE and OLIVIER VITTORI. Can. J. Chem. **66**, 1525 (1988).

Electrodissolution of nickel in the presence of chloride and iodide ions has been investigated using low sweep voltammetry (<2 mV/s). It has been observed that the rate of dissolution of nickel is related to the concentration of chloride, and that addition of iodide modifies the shape of the curves. Oscillations of the current are noticed after a delay shortened by increasing the iodide concentration. These oscillations occur over a wide range of potential provided the iodide concentration is kept low. Increasing this concentration suppresses the oscillations, while two peaks appear, the more cathodic becoming progressively larger. Addition of some surfactants is discussed and progressively larger. Addition of some surfactants is discussed and only SOBS (sodium *p*-octylbenzene sulfonate) suppresses the oscillations even at low concentration, while starch acts progressively from 1 to 40 g/L. Changes of color of the nickel surface during the oscillations suggests a preferential dissolution at the grain boundaries, explaining the black color observed alternatively with a metallic appearance, the nickel being at this time covered with finely divided particles that dissolve quickly. Iodide, appearing only occasionally at such anodic potentials, is probably involved in the dissolution process.

L'étude du comportement anodique des métaux est un vaste domaine d'un grand intérêt pour les études de corrosion, comme l'a souligné Rangarajan et coll. (1). Cet auteur a rassemblé un grand nombre d'exemples de courants périodiques apparaissant lors d'un balayage anodique des potentiels, en milieu aqueux. Ce phénomène est observé avec différents métaux tels que le zinc (2), l'or (3), le fer (4), et le nickel (5). Sauf pour le zinc qui présente des oscillations en milieu alcalin, tous les autres exemples ont été décrits en milieu acide (1, 3–5). D'autres études dans les acides chlorhydrique et sulfurique ne citent pas de telles oscillations mais soulignent le rôle des ions chlorure dans l'accélération du processus de corrosion (6–9). Un comportement identique a été signalé dans des mélanges méthanol – acide chlorhydrique (10) ou en milieu neutre (11). Dans ce dernier cas un film protecteur d'oxyde peut apparaitre, mais la présence d'ions chlorure, bromure et fluorure a une grande influence sur la vitesse de destruction du film. Plusieurs tentatives pour donner une explication théorique satisfaisante au comportement du nickel ont été proposées récemment par Saraby-Reintjes (11), mais les modèles requièrent la connaissance de plusieurs constantes du système et de ce fait se révèlent difficiles à appliquer. Il apparait aussi que la corrosion par piqûre du nickel est influencée par la taille des grains comme l'ont souligné Cid et Petit (12), qui ont traité thermiquement du nickel polycristallin pour accroitre la taille des grains. Ainsi la corrosion se produit en général d'abord aux joints de grains et se trouve très ralentie après un tel traitement.

Dans le présent article on décrit les oscillations du courant qui peuvent être observées quand un fil de nickel est immergé dans une solution d'ions chlorure dans laquelle la concentration en ion iodure est croissante, et que le potentiel appliqué est rendu progressivement anodique.

Partie expérimentale

Les balayages de potentiel ont été appliqués avec un polarographe Tacussel (France), type PRG5, associé à un enregistreur EPL2 de même marque. Les vitesses usuelles ont été 1 ou 2 mV/s. Une cellule a trois électrodes a été employée, avec une électrode de référence au calomel, saturée. L'électrode auxiliaire était un fil de platine et l'électrode de travail un fil de nickel de 0,5 mm de diamètre de pureté 99,99% Aldrich (U.S.A.). La longueur immergée était de 5 mm dans tous les essais et la surface de l'électrode de 7,85 mm^2.

Les réactifs ont été choisis de qualité analytique. Le pH des solutions a été a vérifié et trouvé situé entre 6 et 7, exception faite pour NH_4Cl 1 M (tableau 2), pour lequel il était de 5. L'eau était déionisée puis distillée. L'oxygène n'était pas chassé par l'azote, et les essais ont été effectués à 20 ± 0,1°C.

Résultats et discussion

Le potentiel de départ a été fixé à −0,1 V/ecs, une valeur à laquelle aucune réaction électrochimique ne se produit. La vitesse maximum de balayage n'a jamais excédé 2 mV/s pour s'approcher des conditions d'un état quasi-stationnaire lors de la dissolution. Les courbes intensité–potentiel tracées dans des solutions de concentration croissante en KCl montrent que le

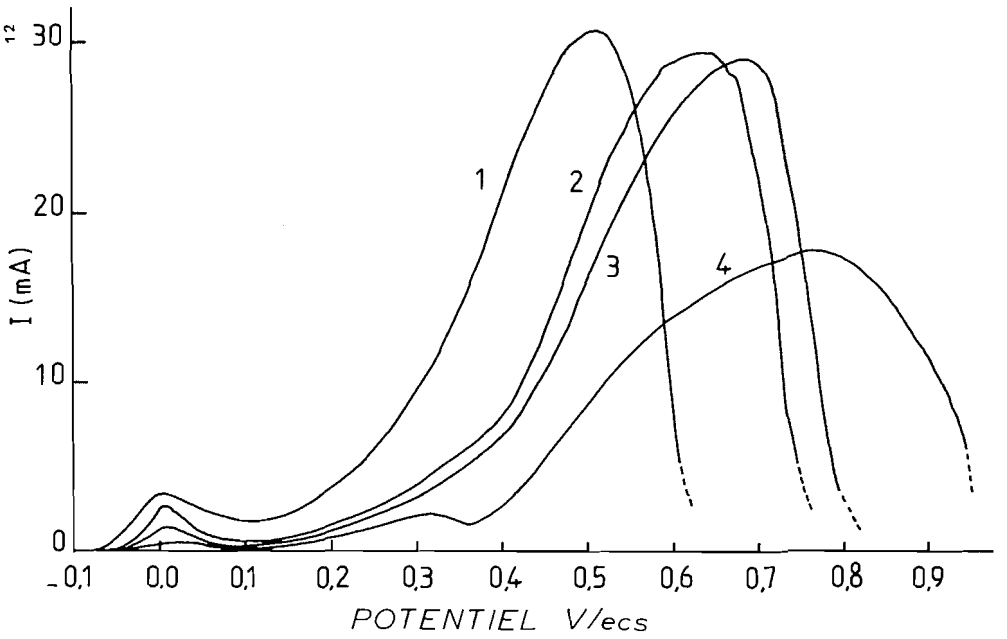

FIG. 1. Courbes de dissolution électrochimique du nickel en fonction de la concentration en ions chlorure. Courbes : 1, 2,68 M; 2, 1,34 M; 3, 1,00 M; 4, 0,67 M.

nickel se dissout progressivement plus rapidement. On observe toujours un premier pic proche de 0,0 V/ecs, dont l'importance est en relation avec la concentration des ions chlorure, et si celle-ci est faible le pic n'est pas observable (figure 1). Il semble que ce pic peu important correspond à la formation d'une couche d'hydroxyde de nickel $Ni(OH)_2$ en surface. Le second pic très intense correspond à la dissolution totale du nickel (figure 1). En solution non agitée on observe sous le fil de nickel la formation d'une colonne liquide verticale de densité supérieure à celle de la solution. Cette observation visuelle est d'autant plus nette que la dissolution est importante. La faible stabilité des ions complexes du nickel en présence d'ions chlorure et iodure incline a penser que le nickel est simplement sous forme d'aquocomplexes.

Les ions Ni^{2+} formés descendent par gravité au fond de la cellule, où ils réagissent avec les ions hydroxyles apparus à l'électrode auxiliaire qui est alors cathodique. L'hydroxyde de nickel apparait progressivement mais le pH au voisinnage du fil de nickel ne varie pas si la cellule est de dimension suffisante (environ 100 mL d'électrolyte support), et si l'électrode auxiliaire n'est pas trop proche. La correction de chute ohmique ne s'impose pas ici compte tenu de la conductivité élévée de l'électrolyte et de la faible vitesse de balayage.

Une concentration de 1 M en KCl a été retenue pour l'étude de l'influence des ions iodure. Un essai préliminaire dans KI 0,024 M, soit 4 g/L, a montré que le nickel ne se dissout que très lentement. L'addition de quantités croissantes de KI dans KCl 1 M révèle une grande différence par rapport aux tracés précédents dans KCl seul (figure 2). En premier on n'observe plus le pic de faible intensité, à 0,0 V/ecs, mais on remarque que la dissolution débute assez brutalement vers +0,15 V/ecs. Puis la courbe intensité–potentiel devient quasi-rectiligne et de pente positive. La figure 3 montre l'évolution progressive des courbes. Il faut noter l'apparition d'oscillations de façon assez brutale au sommet de la partie rectiligne. Le potentiel auquel se produisent ces oscillations est d'autant moins anodique que la concentration en ions iodure s'accroit. Sur la figure 3 les oscillations sont schématisées pour simplifier le dessin. En fait

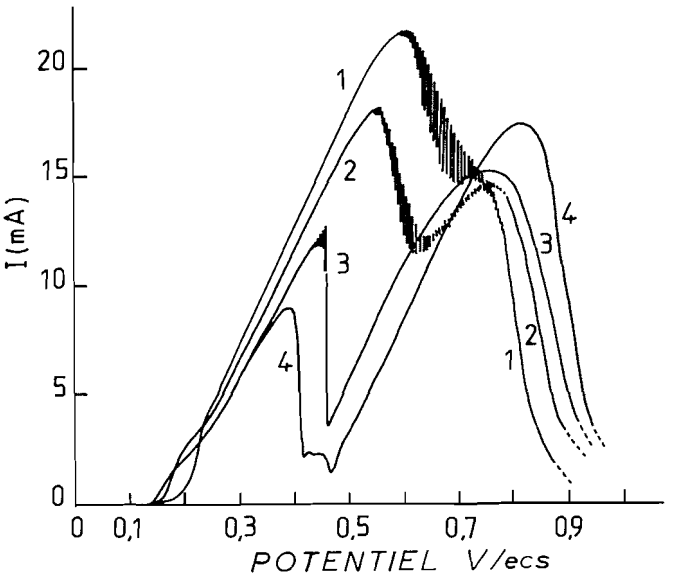

FIG. 2. Courbes de dissolution électrochimique du nickel en fonction de la concentration en ions iodure, pour une concentration constante en ions chlorure ([KCl] = 1 M). Courbes : 1, 0,012 M; 2, 0,024 M; 3, 0,048 M; 4, 0,12 M.

leur fréquence fait que l'enregistrement apparait comme une zone teintée et il faut augmenter nettement la vitesse d'enregistrement pour les discerner. Durant les oscillations le courant moyen décroit et un second pic se forme d'importance croissante avec l'augmentation de la concentration en ion iodure.

Parallèlement on constate que la zone d'oscillations diminue pour pratiquement disparaitre si $[I^-] > 0,12$ M environ. Les deux pics sont alors toujours observables et la dissolution est totale. Durant les oscillations on observe que lorsque le courant décroît le fil est de couleur métallique et lorsqu'il croît la couleur devient noire. Des examens sur plaque de nickel de 0,5 cm^2 de surface ont confirmé cette observation. La dissolution du fil reste progressive et de symétrie radiale.

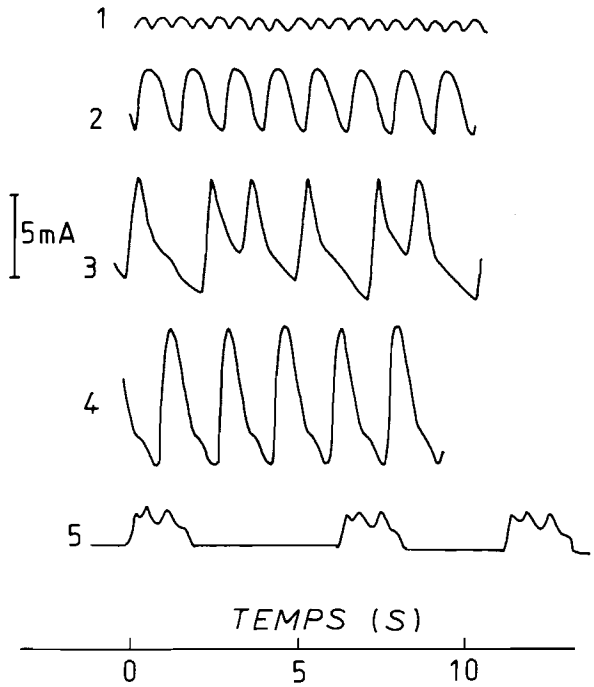

FIG. 3. Observation des oscillations de courant en milieu KCl 1 M pour une concentration en ions iodure de 0,096 M, à différents potentiels. 1, 640 mV; 2, 660 mV; 3, 700 mV; 4, 750 mV; 5, 860 mV.

On note l'apparition d'iode sous la forme I_3^- lors des oscillations et pas avant dans la partie rectiligne croissante du courant. De nouveau la densité plus élevée de la colonne liquide sous le fil de nickel permet l'accumulation d'iode au fond de la cellule. Toutefois les quantités d'iode formé restent très faibles, ce qui indique qu'il ne s'agit ici que d'une réaction secondaire minoritaire. Pour observer plus précisément les oscillations on a balayé en potentiel jusqu'à la zone où elles se produisent, puis enregistré à grande vitesse en maintenant le potentiel fixe. En fait la valeur moyenne du courant reste élevée (figure 3). On constate sur la figure 3 que ces oscillations sont assez régulières à court terme : 10–20 oscillations, mais elles évoluent un peu au cours du temps. Parfois une oscillation irrégulière apparait. La forme du courant dépend du potentiel appliqué et de la concentration en iodure. On a même constaté entre des trains d'oscillations des périodes de quelques secondes durant lesquelles le courant reste constant (exemple à +0,86 V/ecs, figure 3.)

L'étude par fluorescence X d'une plaque de nickel de 5 mm de coté, soumise à des balayages de potentiels arrêtés à +0,45 et +0,55 V/ecs dans KCl 1 M et KI 0,024 M montre que $Ni(OH)_2$ est présent (raie à 0,2340 nm). Le nickel seul donne deux raies à 0,2020 et 0,1750 nm. Si on se réfère à la courbe 2, figure 3, on constate que 0,45 V/ecs est situé avant les oscillations tandis que +0,55 V/ecs est au début de celles-ci. Ceci montre que les ions iodure attaquent essentiellement le nickel métal. Comme l'alternance de couleur, métallique et noire, traduit lors des oscillations le passage d'un état poli à un état granulaire avec de très fines particules (type nickel de Raney), on est conduit à penser que ce sont les joints de grains qui sont préférentiellement attaqués.

Lors de changements alternés de la couleur de la surface il a été observé, par examen à la loupe, que l'iode se forme quand la surface du nickel a l'aspect métallique, ce qui provoque des variations de teinte de la colonne liquide sous l'électrode.

TABLEAU 1. Influence de quelques agents tensioactifs

Composé tensioactif	Concentration (g/L)	Influence
Bromure de *N*-cétyltriméthylammonium	1	Sans
	7	Faible
Chlorure de benzenethonium	1	Sans
	8	Faible
SDS, dodécylsulfate de sodium	1	Faible
Alizarine sulfonate de sodium	1	Sans
SOBS *p*-octylbenzene sulfonate de sodium	1	Oui
Amidon	1–40	Oui

Ces observations suggèrent un double mécanisme pour la dissolution du nickel lorsqu'il est porté à un potentiel suffisamment négatif pour que deux réactions se produisent.

Dans la partie montante de la courbe *i–E* et jusqu'au début des oscillations il se produit la réaction simple :

$$Ni \rightarrow Ni^{2+} + 2e$$

Compte tenu de la valeur du produit de solubilité de $Ni(OH)_2$ qui est de l'ordre de 10^{-14} et du fait que le milieu KCl + KI peut être considéré neutre, la formation de l'hydroxyde en surface s'explique par le fait que c'est en surface que la concentration instantannée de Ni^{2+} est la plus forte. Quand la zone des oscillations débute, une deuxième réaction concurrence la première :

$$3I^- \rightarrow I_3^- + 2e$$

Cependant la faible quantité d'iode observée suggère qu'il y a réaction chimique selon :

$$Ni + I_3^- \rightarrow Ni^{2+} + 3I^-$$

Cette réaction se produit préférentiellement aux joints de grains que l'on peut considérer comme plus fragiles que les microcristaux. Ceci est en accord avec les remarques de Cid et Petit (12) qui indiquaient que le recuit du nickel diminuait la corrosion par piqûre.

Comme il s'agit d'un phénomène qui se produit à l'interface métal–solution, on peut penser que l'addition de composés organiques, tels que les agents tensioactifs, peut modifier ou supprimer les oscillations en limitant l'apparition d'iode, ou en uniformisant l'attaque du nickel. Comme le montre le tableau 1 plusieurs composés à la concentration de 1 g/L ont été essayés. Il s'avère que seuls le SOBS, ou *p*-octylbenzenesulfonate de sodium, et l'amidon provoquaient une disparition des oscillations. Le SOBS est très actif car dés 0,001 M (figure 4) il fait disparaitre les fluctuations de courant tandis que l'amidon a un rôle progressif entre 1 et 40 g/L. Tous les agents tensioactifs n'ont pas été testés sur une large gamme de concentration et on s'est limité à ceux qui donnaient le résultat le plus net à 1 g/L. Les sels d'ammonium quaternaire qui sont chargés positivement ne peuvent s'adsorber à ces potentiels et sont donc sans influence. On peut également signaler que l'addition de faibles quantités de thiourée supprime les oscillations et décale la courbe vers les potentiels cathodiques, c'est à dire rend plus aisée la dissolution du nickel et parait inhiber l'action des ions iodure (figure 4).

Enfin on a recherché d'autres milieux salins dans lesquels les oscillations pouvaient apparaitre (tableau 2). Deux remarques peuvent être faites. La première est que seuls les milieux riches en ions chlorure ou bromure permettent les oscillations à la

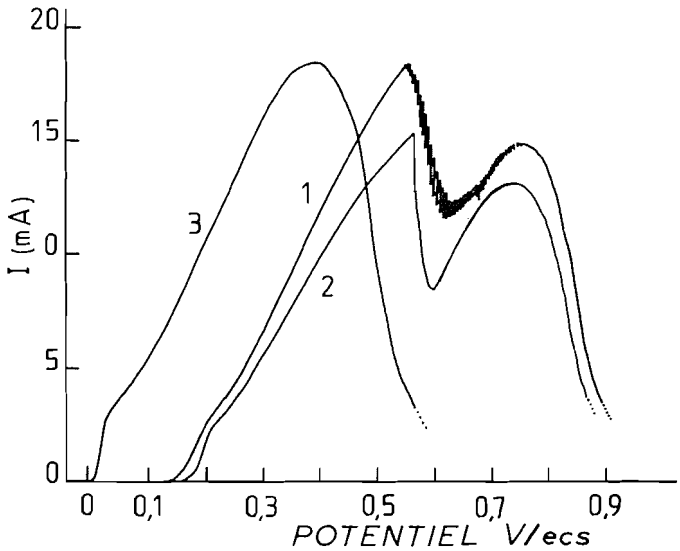

FIG. 4. Courbes de dissolution électrochimique du nickel en milieu KCl 1 M en présence d'ions iodure 0,024 M. Courbe 1 : sans additif; courbe 2 : avec 0,0001 M de SOBS; courbe 3 : avec 0,0026 M de thiourée.

TABLEAU 2. Milieux donnant des oscillations

Système	Concentration (g/L)	Oscillations
KCl 1 M + KI	2	Oui
KBr 1 M + KI	2	Oui
NaCl 1 M + NaI	2	Oui
NH_4Cl 1 M + NH_4I	2	Oui
NH_4Cl 1 M + KI	2	Oui
KCl 1 M + KF	4	Non
KCl 1 M + KBr	2	Non
KF 1 M + KI	2	Non
$(NH_4)_2SO_4$ 1 M + NH_4I	2	Non
$NH_4OOC\text{-}CH_3$ 1 M + KI	2	Non

condition d'être associés aux ions iodure. La seconde est que la présence d'ions iodure n'est pas une condition suffisante puisque les milieux sulfate et acétate n'ont pas permis d'observer la moindre oscillation. L'insolubilité de certains sels ne peut être évoquée puisqu'avec les ions chlorure, iodure, acétate et sulfate, le nickel donne des composés très solubles, et le fluorure moins soluble (4 g/L) ne peut intervenir dans un blocage partiel de la dissolution, qui reste totale dans toutes les expériences.

En conclusion, l'étude de l'oxydation anodique du nickel en présence d'ions chlorure et iodure a révélé un comportement particulier du métal, et les oscillations du courant ont été attribuées à des réactions parallèles avec formation intermédiaire d'iode, dont la réactivité se manifeste par une attaque du métal dans ses zones les moins résistantes.

Kinetics of crystal growth of calcium sulfate dihydrate. The influence of polymer composition, molecular weight, and solution pH

ZAHID AMJAD
The BFGoodrich Company, Avon Lake, Technical Center, Avon Lake, OH 44012, U.S.A.

Received October 23, 1987

ZAHID AMJAD. Can. J. Chem. **66**, 1529 (1988).

A seeded crystal growth technique has been used to study the influence of solution pH and temperature ranging from 25 to 50°C on the performance of polymers of varying functional groups as calcium sulfate dihydrate ($CaSO_4.2H_2O$, gypsum) crystal growth inhibitors. Results indicate that at constant temperature and at a constant solution pH, crystallization in the presence of polyacrylic acids is preceded by an initial slow growth reaction, hereafter called induction period, following which crystal growth of gypsum proceeds with a rate close to that in pure supersaturated solution. Results suggest that at a constant pH, polyacrylic acid concentration, molecular weight, and temperature greatly affect the duration of induction period. Kinetic data collected as a function of solution pH in the range 2.5 to 9.0 suggest that solution pH has a marked effect on the induction period. The observed dependence of induction period on solution pH may be explained in terms of the degree of ionization of polyacrylic acid. Among the polymers of varying functional groups studied, i.e. carboxyl, sulfonate, acrylamide, dimethyldiallylammonium, etc., only those polymers having carboxyl group showed marked inhibitory activity for the growth of gypsum crystals.

ZAHID AMJAD. Can. J. Chem. **66**, 1529 (1988).

On a fait appel à une technique de croissance de cristaux ensemencés pour étudier l'influence du pH de la solution ainsi que de la température (allant de 25 à 50°C) sur la performance de polymères portant divers groupements fonctionnels comme inhibiteurs de la croissance de cristaux du sulfate de calcium dihydraté ($CaSO_4.2H_2O$, gypse). Les résultats indiquent que, à température constante et à un pH de solution constant, la cristallisation en présence d'acides polyacryliques est précédée par une réaction initiale de croissance qui est lente, appelée par la suite période d'induction, et qui est suivie par une croissance du cristal de gypse se produisant à une vitesse qui est proche de celle qui est observée avec une solution sursaturée pure. Les résultats suggèrent que, à des pH constants, la concentration en acide polyacrylique, le poids moléculaire et la température influencent beaucoup la période d'induction. Les données cinétiques recueillies en fonction du pH allant de 2,5 à 9,0 suggèrent que le pH de la solution a une influence marquée sur la période d'induction. On peut expliquer cette observation en fonction du degré d'ionisation de l'acide polyacrylique. Parmi les polymères portant divers groupements fonctionnels, comme carboxyle, sulfonate, acrylamide, diméthyldiallylammonium, etc, seuls les polymères portant des groupements carbonyles présentent une activité inhibitrice marquée sur la croissance des cristaux de gypse.

Introduction

Considerable attention has been given to the various forms of calcium sulfate crystallizing from aqueous solution as affected by temprature, pH, solution stoichiometric ratio of lattice ions, and impurities level (1–4). These and other important factors involved in the nucleation and growth of calcium sulfate dihydrate ($CaSO_4.2H_2O$, gypsum), hemihydrate ($CaSO_4.\frac{1}{2}H_2O$, plaster of Paris), and anhydrite ($CaSO_4$) should have direct application to the control and inhibition of scale formation in industrial water systems, oil production, geothermal, and desalination systems (5–7). In many cases the deposition of hard crystalline scale on heat transfer surfaces results in decreased thermal efficiency of the system. To preclude an excessive rise of operating costs, scale formation has to be prevented.

The effectiveness of a number of inhibitors in preventing or reducing the crystallization of calcium sulfate has been the subject of numerous investigations. McCartney and Alexander (8) have examined the effect of a number of polyelectrolytes on the growth rate of calcium sulfate dihydrate. It was found that polymers-containing carboxyl groups such as carboxymethyl cellulose, aliginic acid, polymethacrylic acid, and polyacrylic acid were particularly effective as $CaSO_4 \cdot 2H_2O$ crystal growth inhibitors. Kuntz (9) arrived at similar conclusions after studying the effect of various protein hydrolyzates and their synthetic analogues on the crystallization of calcium sulfate.

The influence of molecular weight on the polyelectrolytes on the precipitation of $CaSO_4.2H_2O$ from aqueous solutions have been the subject of numerous investigations. Jones (10) in his study on the effect of molecular weight (50 000 – 400 000) of carboxymethyl cellulose (CMC) reported that high molecular weight CMC polymers were the least effective and the effectiveness increases as the molecular weight of the polymer decreases. Flesher *et al.* (11) in their study on the evaluation of a variety of polyelectrolytes at high temperature, as $CaSO_4.2H_2O$ scale inhibitors showed that the efficiency of the polyelectrolyte decreases with increasing molecular weight in the range 2 000 – 750 000. Amjad (12) in a recent study on the influence of polyacrylates in controlling $CaSO_4.2H_2O$ dihydrate scale formation on heat transfer surfaces reported that the molecular weight of the polyacrylate plays an important role in the inhibition of $CaSO_4.2H_2O$ crystal growth from aqueous solution. The amount of $CaSO_4.2H_2O$ scale deposited on heat exchanger was found to be higher in the case of higher molecular weight polyacrylate (mw = 240 000) than that obtained in the presence of 2 100 molecular weight polyacrylate.

Several studies have been reported on the influence of solution pH on the performance of polymeric and non-polymeric inhibitors on the crystal growth of sparingly soluble salts. Recently Griffiths *et al.* (13) have shown that the performance of phosphonic acids as $CaSO_4.2H_2O$ crystal growth inhibitor improves with increasing pH, and have attributed this improvement to an increase in the degree of deprotonation. Leung and Nancollas (14), using seeded growth technique, arrived at similar conclusions after studying the effect of benzene polycarboxylic acids on the crystal growth of $BaSO_4$. Recently,

TABLE 1. Analytical characteristics of polymers

Sheehan and Nancollas (15) have examined the effect of pH in the range 6–9 on the growth rate of $CaC_2O_4.H_2O$ in the presence of polyacrylate. It was found that the rate of growth was independent of solution pH over the pH range studied. Because of the recent interest in the inhibitory effect of polymeric carboxylic acids as crystal growth inhibitors for sparingly soluble salts, in the present work the seeded growth method has been used to investigate the influence of solution pH in the range 2.5–9.0, on the rate of $CaSO_4.2H_2O$ crystal growth in the presence of poly(acrylic acid) (mw 2 600 – 50 000), poly(acrylamide), poly(isopropylacrylamide), poly(2-acrylamido 2-methylpropane sulfonic acid), and poly(dimethyldiallylammonium chloride).

Experimental

Reagent grade chemicals and grade A glassware were used. Stock solutions of calcium chloride and sodium sulfate were prepared using distilled water, filtered through 0.22-μm filter paper (Millipore Corp.) and analyzed as described previously (4). The polymers used in this study were selected from the range of commercial and experimental (BFGoodrich Chemical) materials. Polymer concentrations given in this report are on dry polymer basis. All polymers were tested under equal growth conditions, i.e. at the same supersaturation and pH of the bulk solution. Some of the polymers were also tested at different pH values. Buffers employed for pH control were acetic acid/sodium acetate, trihydroxymethylaminomethane/trishydroxymethylaminomethane hydrochloride, and ammonia/ammonium chloride. pH was measured at 25°C using a Brinkmann pH meter (model 632, Brinkmann Instruments, Westbury, NY) equipped with a pair of glass and calomel electrodes. The system was calibrated before each set of measurements and checked afterwards, against NBS standard buffers. Calcium ion analyses were performed by standard EDTA titration.

Calcium sulfate dihydrate crystals were prepared (4) by the slow dropwise addition of 500 mL of 0.2 *M* calcium chloride solution to 500 mL 0.2 *M* sodium sulfate solution at 70°C. The crystals were washed repeatedly with distilled water until free of chloride ions and were aged at least six months before being filtered to get dry powder for use in the crystal growth experiments. The crystals were characterized by X-ray powder diffraction.

As described elsewhere (1, 4, 16) the seeded crystal growth of a sparingly soluble salt provides a sensitive and reproducible technique for the evaluation of inhibitor effects. The technique involves the addition of a fixed amount of seed crystals to a metastable solution of the inorganic salt followed by periodic analysis for changes in the salt concentration. In the present study, seeded crystal growth experiments were conducted in a stirred double-walled glass cell maintained at 25°C, containing a metastable calcium sulfate solution. The metastable solution (150 mL) was prepared by carefully mixing equimolar volumes of calcium chloride and sodium sulfate such that the final $CaSO_4$ solution concentration would be 3.50×10^{-2} *M*. Solution pH was controlled by the addition of buffers at a total conjugate acid/base concentration of 2.0×10^{-3} *M*, a concentration at which the influence of the buffering components on the rate of crystal growth was proved to be negligible. Polymers were added after the addition of $CaCl_2$, but before the addition of Na_2SO_4, as dilute solutions in water. Crystal growth was initiated in these supersaturated solutions by the addition of a known weight of seed crystals and the reaction monitored by analyzing aliquots of the filtered (0.22 micron filter, Millipore) solution for calcium by EDTA titration.

Results and discussion

The analytical characteristics of the polymers and the experimental conditions used in this study are summarized in Tables 1 and 2, respectively. The typical curves for calcium concentrations against time are shown in Fig. 1. It can be seen that the growth of $CaSO_4.2H_2O$ takes place immediately upon the addition of gypsum seed crystals to the metastable supersaturated solutions. The rate of crystal growth, R, of $CaSO_4.2H_2O$ from supersaturated solutions containing equivalent concentration of ions has been found to follow an equation of the form

$$[1] \quad R = -\mathrm{d}Ca/\mathrm{d}t = ks(T\mathrm{Ca} - T_e\mathrm{Ca})^2$$

in which TCa is total calcium concentration at time t, T_eCa is the equilibrium solubility value, k is a rate constant, s is a function of number of available growth sites present in the seed crystals, and t is the time in minutes. Figure 2 illustrates the linearity of the plots of the integrated form of eq. [1]. Reproducibility is illustrated by the agreement between the results of experiments 2 and 5, respectively. Results of experiments 3 and 5 in Table 2 indicate that the rate of crystallization is directly proportional to the amount of seed crystals added initially. This confirms that crystallization occurred only on the added seed material, without any secondary nucleation or spontaneous precipitation.

Studies were made on the rate of $CaSO_4.2H_2O$ seed crystal growth at 25°C and pH values from 2.5 to 9.0 in buffered calcium sulfate supersaturated solutions. Typical plots of the data plotted according to the integrated form of eq. [1] are shown in Fig. 3. Rate data summarized in Table 2 show that in the pH range 3.5–9.0, second-order rate constant is independent of solution pH, indicating that the bisulfate ion, which was suggested to be rate controlling in the crystallization of the hemihydrate at higher temperatures (7), had a negligible influence on the seeded crystal growth of calcium sulfate dihydrate. Results presented in Table 2 for seeded growth experiments conducted in buffered solution show that rate

[a]Unbuffered solution.

constants are within ±6% of that in the unbuffered solution. This suggests that buffering components at a total conjugate acid/base concentration of $2.0 \times 10^{-3}\ M$ does not have any significant effect on the rate of crystal growth.

Table 2 summarizes the results of crystal growth experiments made in the presence of polymers. Figure 4 illustrates typical growth curves at pH 7.0 in the presence of commercial polymer B (mw 6 000). As shown in Fig. 5, the crystallization reaction in the presence of 0.25 ppm of commercial polymer B is preceded by an induction period of 240 min after which the rate commences with a measurable rate. Figure 4 further indicates that an increase in polymer concentration only results in a prolongation of the induction period and at a 1.0 ppm polymer concentration, the rate of crystallization was completely inhibited for at least 20 h. Table 2 also shows data on induction periods as a function of polymer concentration for commercial polymer B. It can be seen (exps. 25, 32, 33, 39, Table 2) that the duration of the induction period is greatly increased by increasing the polymer concentrations.

presence of varying concentration of commercial polymer B shown in Fig. 5 demonstrate the success of this rate equation in interpreting the results in the presence polymer. As shown in Table 2 the rate of crystal growth of $CaSO_4 . 2H_2O$ following the induction period has very little correlation with the concentration of polymer. A similar temporarily growth inhibition was reported in the seeded growth of $CaSO_4 . 2H_2O$ in the presence of phosphonates, polyphosphonates, and other polyelectrolytes (17, 18). It is also interesting to note that seeded growth of $BaSO_4$ in the presence of trace amount of sodium tripolyphosphate, Liu and Nancollas (19) found that crystallization reaction following the initial induction period takes place at a rate comparable to the rate of crystallization from pure solution.

The influence of pH on the performance of several phosphonic acids as $CaSO_4 . 2H_2O$ crystal growth inhibitors has been recently studied by seeded growth technique (13). Results of this study show that an increase in the pH of the crystal growth medium over a pH 4 to 9 range brings about an improvement in

inhibitor performance that runs parallel to the phosphonic acid titration curve.

For polymeric inhibitors, such as polyacrylic acids, the degree of deprotonation should, just as phosphonate inhibitors, be considered in explaining their action. Unfortunately their acid dissociation constants are not available. It can nevertheless be expected that the affinity of polymeric inhibitor molecules towards the crystal surface should also be influenced by the solution pH due to the dissociation of the carboxylic acid group.

The effect of the solution pH on the crystal growth of $CaSO_4.2H_2O$ in the presence of commercial polymer B was studied using the seeded growth technique. The results presented in Table 2 indicate that at constant temperature and polymer concentration (0.25 ppm), the induction time is strongly dependent upon solution pH. For example, the induction times observed at pH 2.5, 3.5, 5.5, 7.0, and 9.0 are 0, 170, 230, 240, and 260, respectively. Data in Table 2 demonstrates the ineffectiveness (induction time <2 min), of commercial poly-

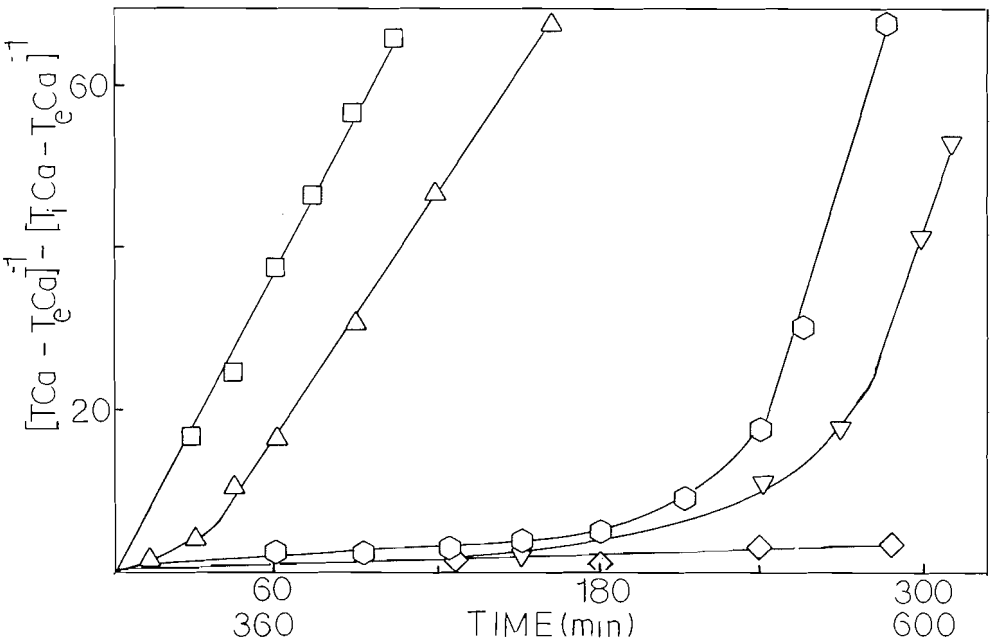

FIG. 5. Kinetic plots of eq. [1] for the growth of $CaSO_4.2H_2O$ in the presence of varying concentration of comm-B polyacrylate at pH 7.0, 25°C. (□) 0.0, (△) 0.10, (◯) 0.25, (▽) 0.35, (◇) 1.0 (0.35 ppm and 1.0 ppm lower time scale).

mer B as an $CaSO_4.2H_2O$ crystal growth inhibitor at pH 2.5 and at 0.25 to 1.0 ppm of polymer concentration. It should be noted that under similar conditions at pH 7.0 induction times observed for commercial polymer B at 0.25 and 1.0 ppm were 240 and >1200 min respectively. The poor inhibitory performance exhibited by commercial polymer B at pH 2.5 may be explained due to insignificant deprotonation of carboxylic acid group at this pH value. Although it has been reported (20) that adsorption capacity of polyelectrolyte increases with decreasing pH values, the absence of induction time or relatively poor performance of commercial polymer B at pH 2.5 may be explained due to insufficient electrostatic interaction of inhibitor molecule at the crystal surface, since at pH 2.5 inhibitor molecule will have very low anionic charge density. Thus at low pH values polymeric inhibitor i.e. commercial polymer B acts like non-ionic polymer and perhaps acquires a loopy configuration at the crystal surface.

As shown in Table 2 the induction times observed for commercial polymer B at 0.25 ppm concentration are 0, 170, and 230, at pH 2.5, 3.5, and 5.5, respectively. However, upon raising the solution pH from 5.5 to 7 to 9, no significant increase in induction times were observed. This suggests that the deprotonation of commercial polymer-B may near complete at pH = 6 or higher.

The influence of polymer structure as $CaSO_4.2H_2O$ crystal growth inhibitor at 0.25 ppm concentration and at pH 7.0 was also studied at the same calcium sulfate supersaturation. Kinetic data for polymers of varying functional group, i.e. acrylamide, isopropylacrylamide, 2-acrylamido-2-methylsulfonic acid, and quarternaryamine, etc., are summarized in Table 2. The results on these polymers (exps. 38, 27, 24, 35) which do not contain carboxyl group show that at 0.25 ppm of polymer concentration these polymers do not show any significant effect on both the induction period and the rate of crystal growth.

The effect of the molecular weight of polyacrylates at a concentration of 0.25 ppm was studied using the seeded growth technique. The results are presented in Table 2. Typical growth curves in the presence of polyacrylates of varying molecular weight are shown in Fig. 6. Data shown in Table 2 indicates that at pH 7.0, 25°C, and constant polymer concentration, the induction time increases with decreasing molecular weight from 20 000 to 2 600 and thereafter decreases with decreasing molecular weight (2 600 – 800). In addition, the rates of crystal growth in the presence of polyacrylates of varying molecular weight (Table 2) are within ±7% of the rate in pure solution. Figure 7 illustrates the effect of molecular weight of polyacrylates on the induction period at various temperatures. It can be seen that an increase in temperature only results in reduction of induction period.

Recently, the influence of a variety of polyelectrolytes in controlling scale formation has attracted the attention of several investigators. It is generally agreed that the polyelectrolytes which have an effect on controlling scale formation are highly substituted with carboxyl groups. In addition, it has also been shown that one of the factors determining the effectiveness of a polyelectrolyte is its molecular weight. Williams and Ruehrwein (21) suggested that molecular weight influences the kinetics of adsorption of the polyelectrolyte onto the growing crystals. It was postulated that there should be an optimum molecular weight for a given polyelectrolyte at which maximum effect would be obtained. In the discussion on the effect of a variety of polyelectrolytes on crystal growth of $CaSO_4.2H_2O$, Smith and Alexander (22) suggested that the adsorbed polymer molecules acted as immobile impurities on the crystal surface and that they inhibited crystal growth by reducing the rate of step movement across the crystal surface. In addition, growth inhibition was found to be strongly dependent on the structure and the molecular weight of the polyelectrolyte. Based upon the results for the similar molecular weight polyelectrolyte, Smith and Alexander (22) reported that polyacrylic acid was more effective than polymethacrylic acid. Furthermore, growth inhibition results for series of experiments with styrene maleic anhydride copolymers suggest an optimum effectiveness with molecular weight of 1600 for this polyelectrolyte. Recently

Libutti *et al.* (23) in their study on the evaluation of polyacrylates as antiscalants for cooling water applications showed that the rate of fouling increases with an increase in molecular weight in the range 2 000 – 100 000.

In summary, the results presented in this paper on the influence of polymers of varying functional groups as $CaSO_4.2H_2O$ crystal growth inhibitors, show that the most effective inhibitors are those which are highly anionic in nature (e.g., carboxyl group in polyacrylic acid) whereas cationic charged polymers do not exhibit any significant inhibitory activity. This observation is consistent with results of earlier investigations on the effect of various anionic charged additives such as polyphosphate, phosphonate, polyaspartic acid, and phosphonocarboxylic acid, as crystal growth inhibitors for barium sulfate, calcium carbonate, and calcium oxalate.

The results presented in this paper on $CaSO_4.2H_2O$ crystal growth inhibition by polyacrylic acid suggest an optimum effectiveness with molecular weight of ~2 000. At values below 2 000 a marked decrease in the polyacrylic acid effectiveness occurs with decreasing molecular weight, which can be due to a decreasing number of bonding possibilities. The same tendency is observed with increasing values of the molecular

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

weight above ~2 000. This is rather surprising since the number of bonding possibilities increases with increasing chain lengths. It is not likely that large molecules adopt a "loopier" configuration with less effective bonds than smaller ones, since even very high molecular weight polyelectrolytes appear to be able to adopt a flat configuration upon the crystal surface, in spite of the entropy lost in a flat configuration (20). The phenomenon of a markedly decreasing polyacrylic acid effectiveness with increasing molecular weight above ~2 000 can thus not be explained. Adsorption studies are currently underway in our labs to better understand the role of molecular weight of polyacrylic acid and acrylic acid-based copolymers of varying compositions and functional groups in inhibiting crystal growth of sparingly soluble salts in aqueous solutions. In the industrial application of these polymers as scale inhibitors, the presence of induction period observed for crystal growth in the presence of polyacrylic acids, may be perfectly acceptable provided that the induction period is longer than the period required for scale protection.

Mechanism of $CaSO_4.2H_2O$ crystal growth inhibition

The marked effect of P-AA on the induction period preceding the crystal growth of gypsum from supersaturated solution may be attributed due to one or more of the following factors: (*1*) P-AA may change the ionic strength of the solution and hence the effective solubility of the calcium sulfate; (*2*) P-AA may form stable complexes with calcium ion and reduce supersaturation; (*3*) the inhibitor may be adsorbed on the crystal surface either generally or at the active growth sites.

Under the experimental conditions employed in the present investigation the presence of induction period preceding the crystal growth must be attributed to the surface adsorption factor rather than calcium–P-AA complex formation or the concomitant increase in ionic strength of the supersaturated solution in the presence of poly(acrylic acid).

The results discussed in this paper on $CaSO_4.2H_2O$ crystal growth inhibition by a variety of inhibitors suggest that those inhibitors under this study can be classified into the following two general categories: (*a*) Those such as poly(isopropylacrylamide), poly(acrylamide), and poly(2-acrylamido-2-methyl-2 propane sulfonic acid), and poly(dimethyldiallyl ammonium chloride), which have no pronounced effect on the rate of $CaSO_4.2H_2O$ crystal growth and show induction period of less than 2–5 min. (*b*) Those such as poly(acrylic acid) which also exhibit no significant effect on the rate of $CaSO_4.2H_2O$ crystal growth but show rather well-defined induction periods (few to several hundred minutes). In addition, the duration of the induction periods is greatly influenced by changing the concentration of poly acrylic acid.

The striking effect of the polyacrylic acid on the induction periods with subsequent growth of $CaSO_4.2H_2O$ observed in the present study may be explained by an incorporation of polyacrylic acid into the growing crystals. During the induction period, most of the active growing sites may be poisoned by adsorbed polyacrylic acid molecules. However, some of the growth sites of lower energy may still be free to grow, and the reaction proceeds at a very slow rate. The changes in solution concentration during this stage may be too small to be detected. After these slowly advancing steps cover the poisoned sites, the adsorbed molecules are incorporated into growing crystal and the crystal growth can resume at a rate comparable to that of unpoisoned systems.

2-Picolyl thioesters; a useful synthon for the preparation of 1-β-alkyl carbapenem intermediates[1]

ALAIN MARTEL,[2] JEAN-PAUL DARIS, CAROL BACHAND, JACQUES CORBEIL, AND MARCEL MENARD
Bristol–Myers Pharmaceutical Group, 100 Industrial Boulevard, Candiac (Qué.), Canada J5R 1J1

Received January 19, 1988

ALAIN MARTEL, JEAN-PAUL DARIS, CAROL BACHAND, JACQUES CORBEIL, and MARCEL MENARD. Can. J. Chem. **66**, 1537 (1988).

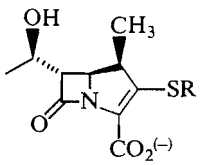
In this study, a highly stereoselective preparation of (3*S*,4*S*)-3-[(1*R*)-1-*tert*-butyldimethylsilyloxyethyl]-4-[(1*R*)-1-carboxyethyl]-azetidin-2-one (**2**) is reported. It involves a Lewis acid mediated condensation of (3*S*,4*R*)-4-acetoxy-3-[(1*R*)-1-*tert*-butyldimethylsilyloxyethyl]azetidin-2-one (**3**) with simple *O*-silylenol ethers of thiopropionates. From all the examples reported in this paper the 2-picolyl thiopropionate or similar arrangements were found to be essential for this stereoselection. Finally, a mechanism involving chelation control seems to be operative.

ALAIN MARTEL, JEAN-PAUL DARIS, CAROL BACHAND, JACQUES CORBEIL et MARCEL MENARD. Can. J. Chem. **66**, 1537 (1988).

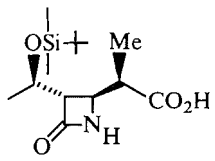
Dans ce travail, on rapporte une préparation hautement stéréosélective de la (3*S*,4*S*)-[(1*R*)-*tert*-butyldiméthylsilyloxy-1 éthyl]-3 [(1*R*)-carboxy-1 éthyl]-4 azétidinone-2 (**2**). Cette synthèse implique une condensation, sous l'influence d'un acide de Lewis, de la (3*S*,4*R*)-acétoxy-4 [(1*R*)-*tert*-butyldiméthylsilyloxy-1 éthyl]-3 azétidinone-2 (**3**) avec des éthers énoliques *O*-silylés simples de l'acide thiopropionique. En se basant sur tous les exemples rapportés dans cette publication, on a trouvé que le thiopropionate de picolyle-2 ou des composés semblables sont essentiels pour obtenir cette stéréosélectivité. Enfin, il semble que le mécanisme implique un contrôle par une chélation.

[Traduit par la revue]

The recent report, by Shih *et al.* (1), that a 1-β-methyl group imparts enzymatic as well as chemical stability to the carbapenem nucleus **1** has stimulated a rapid development of synthetic methods (2) directed towards the preparation of the key intermediate **2**. Although highly diastereoselective preparations of **2** have been recently published (2*i*,*j*,*k*), there remains a need for more efficient methods. Therefore an investigation of the C-4 alkylation of 4-acetoxyazetidinone **3** with simple *O*-enolsilyl ethers of thiopropionates **4** (Scheme 1) was initiated. Even though similar couplings have been reported (2*c*), poor or no β-diastereoselection was achieved. In this paper we would like to report a highly diastereoselective preparation of derivative **2** via a Lewis acid mediated condensation of 4-acetoxyazetidinone with simple *O*-silylenol ethers of thiopropionates.[3]



1



2

Preparation (see Experimental) of enol ethers **4**, generally obtained as mixtures of *E*/*Z* isomers, occurred upon trapping the enolates of thiopropionates **6** with *tert*-butyldimethylsilyl triflate (3). Reaction of these enol ethers **4** with the 4-acetoxyazetidinone **3** in the presence of $ZnCl_2$ afforded derivatives **5** with various α/β ratios, which are listed in Table 1.

In examples 1, 2, 3, 4, 6, 7, and 9 the α-methyl isomer **5** (R^2 = Me) was obtained as the major product. Formation of the α-methyl isomer **5** can be rationalized as occurring (4) via a 6-membered transition state as depicted in **7**. Here the steric interaction between the methyl group of the incoming nucleophile and H-3 of azetidinone **4** is minimized when the methyl group takes the pseudo equatorial position, thus leading to the α-methyl isomer **5**.

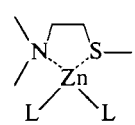
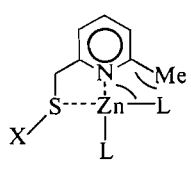
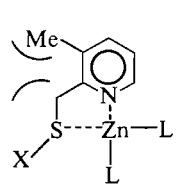
Me) was formed either as the major isomer or almost in a stereospecific manner (example 14). It is suggested that the ability of Zn(II) to form a chelate (see structure **8**) with the sulfur and nitrogen[4] atoms of the thioester is essential for high β-methyl stereoselection. Factors interfering with this chelation bring about a reduction in selectivity. For example, changing the N-heteroatom for O or S resulted in complete loss of β-methyl selectivity (examples 10, 12 vs. examples 6 and 7). Disruption of the chelate (steric factors) was apparent in example 5 and more strikingly in example 13 where the 6′-methyl group could interfere with the ligand around Zn. In this latter case the α/β ratio was 6:4 (see structure **9**). Alternatively, introduction of a 3′-methyl group (see structure 10) appears to favor the formation of the chelate **8** (example 14), and therefore a greater proportion of β-methyl isomer **5** was obtained relative to that for the parent compound (example 10).



8



9

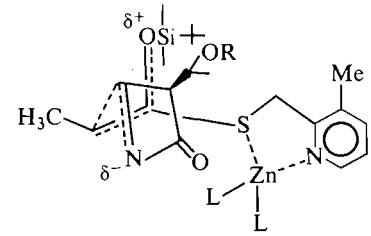


10

[4]There are ample literature precedents for chelates of type **8** (see ref. 5).

The effect of enol geometry on the stereochemical outcome of the reaction was examined in one case (example 14). The two geometric isomers of **4**-14 were separated (column chromatography) and reacted individually with azetidinone **3**. A high β-methyl stereoselectivity (>98%) was observed with the *Z*(O)-enol (isomer B, **4**-14) (assignment tentative) and an 84:16 ratio of β/α isomers was found with the *E*(O)-enol (isomer A, **4**-14) (6). This excellent β-methyl stereoselectivity was tentatively rationalized as resulting from the reaction occurring via a linear transition state such as **11** in which the Lewis acid is not intimately involved with the silyloxy group (2*d*, 7).

In summary, a highly stereoselective preparation of the β-methyl carbapenem precursor **2** has been developed. A mechanism involving chelation control seems to be operative. The 2-picolyl thiopropionates or similar structural arrangements were found to be essential for this stereoselection.



11

Experimental

Base treatment (TEA) of thiopropionates **6** in CH_2Cl_2 and subsequent quenching with TBDMS–OTf gave enol **4** in generally good yields (60–95%). In the case of the 3-methyl-2-picolyl thiopropionate, formation of the enolate required a stronger base (LiHMDS, THF, −78°C). Coupling of **4** (2 equiv.) with the azetidinone **3** was started at 0°C (ice bath) under N_2 using $ZnCl_2$ (2 equiv.) as the Lewis acid. The mixture was allowed to stir at ca. 20°C for 18 h and then worked up (see Table 1). Generation of acid **2** occurred upon treatment of **5** in THF with aqueous NaOH in the presence of H_2O_2.

All new compounds gave ir, ^{1}Hmr, and combustion analyses consistent with their assigned structures.

Physical data of selected derivatives

4-*10*: Mixture of 2 isomers (45:55); ir (CH_2Cl_2) ν_{max}: 1635 (double bond) and 1595 (ar) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 8.55–6.95 (4H, m, ar), 4.98 (1H, 5 lines, isomeric H-vinyl), 4.04 and 3.97 (2H, 2s, isomeric -CH_2-), 1.54 and 1.55 (3H, 2d, J = 6.9 Hz, J = 6.7 Hz, isomeric -CH_3), 0.99 and 0.95 (9H, 2s, *tert*-butyl), 0.19 and 0.23 (6H, 2s, dimethyl) ppm.

4-*14*: A 2:8 mixture of 2 isomers; *isomer A* (R_f 0.75, 25% ether – petroleum ether): ir (CH_2Cl_2) ν_{max}: 1635 (olefin) cm^{-1}; ^{1}Hmr ($CDCl_3$, 80 MHz), δ: 8.40–8.34 (1H, m, H-aromatic), 7.37–7.06 (2H, m, H-aromatic), 5.03 (1H, d, J = 6.8 Hz, olefinic-H), 4.10 (2H, s, CH_2), 2.38 (3H, s, CH_3), 1.56 (3H, d, J = 6.8 Hz, CH_3), 0.96 (9H, s, *tert*-butyl-Si), 0.20 (6H, s, $(CH_3)_2$-Si) ppm; *isomer B* (R_f 0.68, 25% ether – petroleum ether): ir (CH_2Cl_2) ν_{max}: 1635 (olefin) cm^{-1}; ^{1}Hmr (80 MHz, $CDCl_3$) δ: 8.39, 8.34 (1H, m, H-aromatic), 7.37–6.95 (2H, m, H-aromatic), 5.00 (1H, q, J = 6.8 Hz, olefinic-H), 4.04 (2H, s, CH_2), 2.35 (3H, s, CH_3), 1.34 (3H, d, J = 6.8 Hz, CH_3), 0.97 (9H, s, *tert*-butyl-Si), 0.21 (6H, s, $(CH_3)_2$-Si) ppm.

5-*10*: (88.7% oil, 80% crystalline, heptane) mp 55–58°C; an 87:13 mixture of β- and α-methyl isomers. *β-methyl*: ir (CH_2Cl_2) ν_{max}: 3410 (N-H), 1765 (β-lactam), 1682 (thioester), and 1594 (ar) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 5.82 (1H, s, N-H), 4.30 (2H, s, -CH_2), 4.30–4.00 (1H, m, H-1′), 3.88 (1H, dd, J = 2.2 Hz, J = 6.4 Hz, H-4), 3.15–2.7 (2H, m, H-3, -CH—C—S-), 1.25 (3H, d, 6.9 Hz, CH_3-2′), 1.07 (3H, d, J = 6.3 Hz, -CH_3), 0.86 (9H, s, *tert*-butyl), 0.05 (6H, dimethyl-Si-) ppm. *α-methyl*: ir (CH_2Cl_2) ν_{max}: 3410 (N-H), 1765 (β-lactam C=O) and

1680 (thioester) cm^{-1}; ^{1}Hmr (80 MHz, $CDCl_3$) δ: 8.55, 8.54, 8.50, 8.49 (1H, m, H-arom), 7.75, 7.72, 7.65, 7.62, 7.55, 7.53 (1H, m, H-arom), 7.22–7.00 (2H, m, H-arom), 6.21 (1H, 6s, N-H), 4.42, 4.29, 4.25 (2H, part of ABq, J = 14 Hz, CH_2-S), 4.17, 4.09, 4.08 (1H, m, part of H-1), 3.78, 3.75, 3.66, 3.63 (1H, dd, J = 2.0 Hz, J = 9.6 Hz, H-4), 2.95–2.55 (2H, m, H-3, H-1″), 1.31, 1.22 (3H, d, J = 7.0 Hz, CH_3), 1.26, 1.18 (3H, d, J = 6.2 Hz, CH_3), 0.87 (9H, s, *tert*-butyl-Si), 0.07 (6H, $(CH_3)_2$-Si) ppm.

The prototropic equilibria in pentenylphosphonic systems

AGNES M. MODRO AND TOMASZ A. MODRO[1]
Department of Chemistry, University of Pretoria, Pretoria 0002, South Africa

Received December 21, 1987

AGNES M. MODRO and TOMASZ A. MODRO. Can. J. Chem. **66**, 1541 (1988).

Dialkyl 2-chloropentylphosphonates, $C_3H_7CHClCH_2P(O)(OR)_2$, and monoalkyl 2-chloropentylphosphonic acids, $C_3H_7CHClCH_2PO_2H(OR)$, have been dehydrohalogenated by strong bases to the corresponding pentenylphosphonic compounds. In all cases the kinetically controlled product was shown to be the *E*-1-pentenylphosphonic derivative. The α,β-unsaturated products underwent base-catalysed isomerization to the thermodynamically controlled *E*-2-pentenylphosphonic systems, thus indicating that the PO_3R_2 and PO_3R^- groups destabilize (relative to hydrogen) the adjacent olefinic bond. The hydrogen–deuterium isotope exchange was studied for the α,β- and β,γ-unsaturated products and the results obtained were in full agreement with the isomerization results.

AGNES M. MODRO et TOMASZ A. MODRO. Can. J. Chem. **66**, 1541 (1988).

Sous l'influence de bases fortes, les chloro-2 pentylphosphonates de dialkyle, $C_3H_7CHClCH_2P(O)(OR)_2$, ainsi que les acides chloro-2 pentylphosphoniques monoalkylés, $C_3H_7CHClCH_2PO_2H(OR)$, subissent une réaction de déshydrohalogénation conduisant aux composés pentènylphosphoniques correspondants. On a démontré que, dans tous les cas, le produit de contrôle cinétique est le dérivé pentène-1(*E*) phosphonique. Sous l'influence du milieu basique, les produits α,β-insaturés subissent une isomérisation conduisant aux systèmes pentène-2(*E*) phosphoniques qui sont thermodynamiquement plus stables; ces résultats indiquent que, par rapport à l'hydrogène, les groupements PO_3R_2 et PO_3R^- déstabilisent la double liaison adjacente. On a étudié l'échange isotopique hydrogène/deutérium sur les produits α,β- et β,γ-insaturés; les résultats obtenus sont en parfait accord avec les résultats des isomérisations.

[Traduit par la revue]

Structural effects on the prototropic equilibria in allylic systems (eq. [1]) have been studied for more than six decades and are discussed in detail in classical monographs on physical organic chemistry (see, for example, ref. 1). Analysis of the free energy change for reaction [1] allowed Hine (2) to determine the "Double-Bond Stabilisation Parameter" for various substituents. According to Hine's and other (3) data, the olefinic bond can be stabilized by resonance donors as well as acceptors, the OR and CO_2R substituents being the respective examples. The only substituent listed as distinctly *destabilizing* (relative to hydrogen) the vinylic system is the methylsulfonyl group; for X = Pr, Y = SO_2Me, the equilibrium constant for reaction [1] was found (4) to be greater than 99.

[1] $\underset{\mathbf{1}a}{X{-}CH_2{-}CH{=}CH{-}Y} \overset{K}{\rightleftharpoons} \underset{\mathbf{1}b}{X{-}CH{=}CH{-}CH_2{-}Y}$

The effect of phosphorus-containing functional groups on the stability of the corresponding propenylic systems is not well established. For the phosphonium group, PR_3^+, the effect on the stability of the propenylphosphonium derivatives depends on substituents at phosphorus (5). While allyltriphenylphosphonium ion (**1***a*, X = PPh_3^+; Y = H) in the presence of a base isomerizes easily and completely to the corresponding vinylic product (**1***b*), the tri-*n*-butylphosphonium analogue (**1***a*, X = PBu_3^+; Y = H) is stable under the same conditions. Reactions of electrophiles with delocalized carbanions obtained by deprotonation of allylphosphonic diamidates (6), diesters (7), or tertiary phosphine oxides (8) show low chemoselectivity and give both α- and γ-substituted products depending on the groups at phosphorus and on the nature of other substituents present in the allylic system.

In this paper we report our studies of the pentenylphosphonic system (**2**) obtained by the dehydrohalogenation of the 2-chloropentylphosphonic derivative **3**. The chemistry of 2-halogenophosphonic acids attracts considerable attention (9) because of the well-known (10) fragmentation of their dianions to alkenes and metaphosphate species, the reaction responsible for the plant-growth regulating properties of 2-chloroethylphosphonic acid (Ethephon) (11). We were, however, interested in base-promoted reactions of **3** proceeding with the retention of the P—C bond, to determine the structure of the elimination products and the possibility of their mutual interconversion.

Results and discussion

Dialkyl (**3***b*) and monoalkyl (**3***c*) esters of 2-chloropentylphosphonic acid (**3***a*) were prepared from 1-pentene according to Scheme 1.

Diethyl 2-chloropentylphosphonate (**4**) (**3***b*, R = Et) does not undergo any change when heated as a neat liquid for 12 h at 115°C. It has also been found resistant to base-promoted elimination when heated in pyridine for 90 h at 70°C or in benzene in the presence of the "proton sponge" (14) for 70 h at 50°C. Ester **4** and its dimethyl analogue **5** (**3***b*, R = Me) could,

however, be easily converted to the pentenyl derivatives (**2**) by means of stronger bases such as alkoxide ions or butyllithium. When **4** or **5** was treated with strictly 1 mole-equivalent of a base (to ensure the neutrality of the final reaction mixture) at room temperature for 2–3 h, the high-resolution ^{1}H nmr spectra of the products revealed that the *E*-1-pentenylphosphonic esters **2***a* and **2***b* were the exclusive products of the elimination reaction (eq. [3]).

[3] 
4, R = Et **2***a*, R = Et

B = EtONa/EtOH; EtOK/EtOH; $(EtO)_2Mg$/EtOH; *t*-BuOK/*t*-BuOH; KOH/EtOH; BuLi/C_6H_{14}

5, R = Me **2***b*, R = Me

B = MeONa/MeOH; BuLi/C_6H_{14}

Since the pK_a value for the α-methylene groups in **4** and **5** should be of the order of 20 (15), the regioselectivity of elimination results from the difference in the acidity of the hydrogen atoms at C1 and C3, while the configuration of the products follows the usual (16) stereochemical requirements for the E2 reaction. Esters **2***a* and **2***b* could be easily purified by high-vacuum distillation without any structural changes. However, when incubated at room temperature in an alcohol containing the corresponding sodium alkoxide (1 mole-equivalent) for ca. 60 h, **2***a* and **2***b* isomerized completely to the corresponding *E*-2-pentenyl-1-phosphonic derivatives, **2***c* and **2***d* (eq. [4]).

[4] 
2*a*, **2***b*

2*c*, R = Et
2*d*, R = Me

The same result was obtained when dehydrohalogenation of **4** and **5** was carried out for longer periods in the presence of excess base. In this case, however, if the base used was the RONa/ROH system, up to 20% of the substitution product (**6**) was found in the reaction mixture (eq. [5]). The formation of ethers (**6**) could be eliminated by using *t*-BuOK/*t*-BuOH as a dehydrohalogenating agent; β,γ-unsaturated phosphonates **2***c*, **2***d* were then the exclusive reaction products. It is obvious that the α,β-unsaturated phosphonates (**2***a*, **2***b*) and the β,γ-unsaturated compounds (**2***c*, **2***d*) correspond respectively to the kinetic and thermodynamic products of the dehydrohalogenation of the precursors **4** and **5**. Our results therefore identify the dialkoxyphosphoryl group, $P(O)(OR)_2$, as a substituent strongly destabilizing an olefinic bond and indicate that, similar to the methylsulfonyl,[2] the PO_3R_2 group interacts with adjacent centers mostly via its inductive effect with only a minor resonance component.

[2]For the SO_2Me group the ratio of the resonance to the inductive substituent constants, $\sigma_R^0/\sigma_I = 0.10$, while for the CO_2Et group the corresponding ratio is as high as 0.60 (17).

[5] 
6*a*, R = Et
6*b*, R = Me

Isomerization of α,β- to β,γ-unsaturated phosphonates proceeds via the allylic carbanion intermediate **7** (eq. [6]). According to this scheme, the allylic positions of both substituents, i.e. methylene groups α, γ, and δ, should be susceptible to the hydrogen–deuterium exchange. Ester **2***b* was incubated at room temperature in methanol-d_4 containing an excess of CD_3ONa. After 5 h the ^{1}H nmr spectrum of the solution revealed that the isomerization to **2***d* was complete, and that 100% of the H/D exchange took place at C_α and 23% at C_δ; however, no exchange at C_γ was observed. The absence of the exchange at C_γ shows that in eq. [6] $k_2 \gg k_{-1}$, i.e., the carbanion **7**, once formed, is protonated exclusively at C_α. Additional support for the high rate of isomerization relative to the exchange was provided by the behavior of the β,γ-unsaturated ester **2***d*. When incubated in the CD_3OD/CD_3ONa solution, **2***d* did not, as expected, undergo any isomerization but showed H/D exchange at positions α and δ. The relative rate of the exchange at these two positions was determined as $k(\alpha)/k(\delta) \approx 160$, and can be taken as a measure of the difference in acidities of the two respective methylene groups. After 5 h of incubation the exchange at the δ position in **2***d* was ca. 20%, very close to the conversion observed under the same conditions for C_δ (23%) when **2***b* was used as a precursor for **2***d*. These results indicate that eq. [6] involves fast isomerization, followed by fast exchange at C_α and slow at C_δ of the isomerization product.

The monoanion of the monoester (**3***c*, R = Me) was dehydrohalogenated under the same conditions as neutral esters **2***a* and **2***b* and yielded the *E*-1-pentenylphosphonic derivative **2***e* as the exclusive elimination product (eq. [7]). The regio- and stereoselectivity of the reaction was determined from the high-resolution ^{1}H nmr spectrum of **2***e*. When an excess of the base was used in reaction [7] or when **2***e* was incubated in methanol containing MeONa (3 mole-equivalents) at 40°C for up to 46 h, no isomerization to the β,γ-unsaturated compound was observed. The β,γ-unsaturated isomer **2***f* was then prepared by the demethylation of the stable isomer of the dimethyl ester, **2***d* (eq. [8]). Product **2***f* was also resistant to the isomerization; it remained unchanged after incubation in methanolic MeONa (2 mole-equivalents) at 40°C for 33 h. Stability of both **2***e* and **2***f* toward base-catalysed interconversion implied very slow deprotonation of the corresponding allylic methylene groups to give the necessary allylic carbanion, most likely the result of the insufficiently strong effect of the negatively charged substituent on the acidity of allylic hydrogens. This conclusion was confirmed by exchange experiments; neither **2***e* nor **2***f* showed any evidence of the H/D exchange after incubation in methanol-d_4 containing 6- to 13-fold excess of CD_3ONa at room temperature for 144 h. However, the H/D exchange at the allylic positions in both isomers could be observed under more basic conditions, e.g., in solutions of CD_3ONa (3.6 mole-equivalents) in DMSO-d_6 (18). Allylic phosphonate **2***f* after 20 h at 40°C gave no evidence of isomerization but exchanged completely at the α-CH_2, and to the extent of 30% at the δ-CH_2 group. The most informative results were obtained after incubation of the vinylic derivative **2***e* under the same conditions. In this case the

2f

complete isomerization took place and the isomerized product incorporated 100% of D at C_α, ca. 5% of D at C_δ, and ca. 90% of D at the γ-olefinic carbon (eq. [9]). The high yield (90%) of the H/D exchange at C_γ together with the low (5%) degree of exchange at C_δ indicate that in the case of the ionic substrate **2e**

[9] 
2e

2f, L = H or D

the reaction involves fast exchange at C_γ, accompanied by slow isomerization, i.e., $k_2 < k_{-1}$ (eq. [6]). This result can be easily explained in terms of charge distribution in the allylic carbanion **7**, in which (opposite to the case of the diester **2b**) most of the negative charge is located on C_γ, away from the anionic substituent. Since the isomerized product **2f** is formed slowly, only a low degree of exchange is observed at position δ.[3]

In conclusion, our results enable us to classify both phosphonic substituents, the neutral diester $P(O)(OR)_2$ and the ionic monoester $P(O_2^-)OR$, as *deactivating* (relative to hydrogen) the adjacent olefinic bond. In both cases, under conditions of sufficiently high basicity, both α,β-unsaturated systems, formed in the elimination as products of the kinetic control, rearrange completely to the thermodynamically stable β,γ-unsaturated derivatives.

As expected, the dehydrohalogenation of the free 2-chloropentylphosphonic acid **3a** could not be studied because of its fragmentation (10) according to eq. [10].

Experimental

All solvents and commercially available reagents were purified by distillation immediately before use. The following media were used for recording ^1H nmr spectra: $CDCl_3$ (Aldrich, Gold Label, 99.8 at.% D); methanol-d_4 (Merck, min. 99%); DMSO-d_6 (Aldrich, Gold Label, 99.9 at.% D); deuterium oxide (Merck, min. 99.75%) containing the required quantity of NaOD (Wilmad Glass, 40% in D_2O, min. 99.0% D). Solutions of sodium alkoxides in alcohols were prepared by dissolving the required quantity of sodium in the corresponding alcohol under nitrogen with exclusion of moisture. Solution of CD_3ONa in DMSO-d_6 was obtained by preparing the solution of sodium methoxide in methanol, evaporation of methanol under reduced pressure, and dissolving the residue in DMSO-d_6 under nitrogen with exclusion of moisture. All reactions were carried out with rigorous exclusion of moisture. Bulb-to-bulb distillations were carried out using a Buchi GKR-50 glass tube oven. Elemental analyses (C, H) were performed at the University of Cape Town using a Heraeus Universal combustion analyser.

The nmr (^1H, ^{13}C, ^{31}P) spectra were recorded on a superconducting FT Bruker AC300 spectrometer with TMS (^1H, ^{13}C) or trimethyl phosphate (^{31}P) as internal standards.

Substrates

2-Chloropentylphosphonic dichloride was obtained by following the procedure given (9*a*) for 2-chloropropylphosphonic dichloride; 67%, bp 86–88°C (1 Torr; 1 Torr = 133.3 Pa); n_D^{20} 1.4906; ^1H nmr ($CDCl_3$) δ: 0.94 (3H, t, J_{HH} 6.5 Hz, CH_3), 1.25–1.72 (2H, m, δ-CH_2), 1.72–2.08 (2H, m, γ-CH_2), 2.51 (2H, d of d, J_{HP} 18.8 Hz, J_{HH} 6.8 Hz, α-CH_2), 4.37 (1H, t of t, J_{HH} 7.3, 6.7 Hz, β-CH); ^{31}P nmr ($CDCl_3$) δ: 40.0 ppm.

Diethyl 2-chloropentylphosphonate (4) was prepared according to the procedure for 2-phenylvinylphosphonates (12); 84%, bp 140°C (0.45 Torr); n_D^{20} 1.4470; ^1H nmr ($CDCl_3$) δ: 0.94 (3H, t, J_{HH} 6.5 Hz, ω-CH_3), 1.34 (6H, t, J_{HH} 7.0 Hz, 2 × CH_3 of Et), 1.30–1.65 (2H, m, δ-CH_2), 1.65–2.00 (2H, m, γ-CH_2), 2.32 (2H, d of d, J_{HP} 19.5 Hz, J_{HH} 6.5 Hz, α-CH_2), 4.13 (4H, quint, $J_{HP} = J_{HH}$ 8.6 Hz, 2 × OCH_2), 4.00–4.40 (1H, m, β-CH). *Anal.* calcd. for $C_9H_{20}O_3PCl$: C 44.5, H 8.3%; found: C 44.4, H 8.1%.

Dimethyl 2-chloropentylphosphonate (5) was prepared as **4**; 71%, bp 84°C (0.85 Torr); n_D^{20} 1.4537; ^1H nmr ($CDCl_3$) δ: 0.94 (3H, t, J_{HH} 6.4 Hz, ω-CH_3), 1.38–1.65 (2H, m, δ-CH_2), 1.65–2.02 (2H, m, γ-CH_2), 2.28 (2H, d of d, J_{HP} 20.5 Hz, J_{HH} 6.5 Hz, α-CH_2), 3.77 (6H, d, J_{HP} 11.0 Hz, 2 × OCH_3), 4.00–4.50 (1H, m, β-CH). *Anal.* calcd. for $C_7H_{16}ClO_3P$: C 39.2, H 7.5%; found: C 40.0, H 7.5%.

Methyl 2-chloropentylphosphonic acid (3c) was prepared by demethylation of **5** with sodium iodide (13) followed by the isolation of the free acid as described in the literature (20); 88%, oil; ^1H nmr ($CDCl_3$) δ: 0.94 (3H, t, J_{HH} 6.7 Hz, ω-CH_3), 1.27–1.82 (2H, m, δ-CH_2), 1.45–2.00 (2H, m, γ-CH_2), 2.31 (2H, d of d, J_{HP} 18.7 Hz,

[3]As one of the referees pointed out, 100% D exchange occurring at C_α in **2f** is interesting in view of the fact that a carbanion α to the PO_3Me^- group is destabilized. For **2f** to exchange it has to become deprotonated either at C_α or C_δ. In the first case most of the negative charge is indeed located at C_γ, but it is only C_α that becomes reprotonated, as it yields the thermodynamically stable (observed) β,γ-unsaturated product. In case of the deprotonation at C_δ, it is this carbon atom which undergoes reprotonation (and exchange); protonation at C_β would yield unobserved γ,δ-unsaturated products. The exchange results indicate that deprotonation of C_α in **2f** is favoured over the deprotonation of C_δ.

J_{HH} 6.8 Hz, α-CH_2), 3.72 (3H, d, J_{HP} 11.0 Hz, OCH_3), 4.00–4.50 (1H, m, β-CH), 10.34 (1H, bs, OH). *Anal.* calcd. for $C_6H_{14}ClO_3P$: C 35.9, H 7.0%; found: C 36.1, H 7.1%. Na salt of **3***c*: ^{1}H nmr (D_2O) δ: 0.90 (3H, t, J_{HH} 6.7 Hz, ω-CH_3), 1.12–1.82 (2H, m, δ-CH_2), 1.53–1.98 (2H, m, γ-CH_2), 2.19 (2H, d of d, J_{HP} 17.2 Hz, J_{HH} 7.0 Hz, α-CH_2), 3.56 (3H, d, J_{HP} 10.5 Hz, OCH_3), 4.00–4.48 (1H, m, β-CH).

*2-Chloropentylphosphonic acid (**3**a)* was prepared according to the procedure given (9*a*) for 2-chloropropylphosphonic acid; 13%, mp 95.0–95.8°C (from $CHCl_3$/pet. ether); ^{1}H nmr (acetone-d_6) δ: 0.94 (3H, t, J_{HH} 6.7 Hz, ω-CH_3), 1.35–1.73 (2H, m, δ-CH_2), 1.60–1.83 (2H, m, γ-CH_2), 2.35 (2H, d of d, J_{HP} 20.0 Hz, J_{HH} 8.0 Hz, α-CH_2), 4.19–4.39 (1H, m, β-CH), 11.1 (2H, bs, 2 × OH). *Anal.* calcd. for $C_5H_{12}ClO_3P \cdot H_2O$: C 29.4, H 6.9%; found: C 29.1, H 6.1%.

*Preparation of **2**a*

Compound **4** (0.002 mol) was dissolved in 0.9 mL of a 2.2 M solution of sodium ethoxide in ethanol and the solution was incubated at 25°C for 3 h. Water (10 mL) was added (pH of the aqueous solution was 7.0) and the mixture was extracted with chloroform (4 × 3 mL). After drying ($MgSO_4$) and evaporating the solvent under reduced pressure the product was purified by bulb-to-bulb distillation at oven temperature 100–130°C (1 Torr); 62%, n_D^{25} 1.4392; ^{1}H nmr ($CDCl_3$) δ: 0.94 (3H, t, J_{HH} 6.5 Hz, ω-CH_3), 1.33 (6H, t, J_{HH} 7.0 Hz, 2 × CH_3 of EtO), 1.40–1.70 (2H, m, δ-CH_2), 2.08 (2H, d of t, J_{HH} 6.8, 6.7 Hz, γ-CH_2), 4.08 (4H, quint, J_{HP} = J_{HH} 7.8 Hz, 2 × CH_2 of EtO), 5.53 (1H, d of d of t, J_{HP}(*gem*) 21.2 Hz, J_{HH}(*trans*) 17.3 Hz, J_{HH}(1,3) 1.7 Hz, α-CH), 6.67 (1H, d of d of t, J_{HP}(*cis*) 22.1 Hz, J_{HH}(*trans*) 17.3 Hz, J_{HH}(1,2) 6.7 Hz, β-CH) (literature values for CH_2=CH—P(O)$(OEt)_2$: J_{HP}(*gem*): 22.3 Hz (21); 22.0 Hz (22); J_{HH}(*trans*): 18.7 Hz (21, 22); J_{HP}(*cis*): 25.1 Hz (21); 25.0 Hz (22)); ^{13}C nmr ($CDCl_3$) δ: 13.4 (CH_3 of C_5H_9), 16.1 (d, J_{CP} 6.2 Hz, 2 × CH_3 of EtO), 20.8 (C_δ), 36.0 (d, J_{CP} 21.7 Hz, C_γ), 61.3 (d, J_{CP} 5.3 Hz, 2 × CH_2 of EtO), 116.7 (d, J_{CP} 186.2 Hz, C_α), 153.5 (d, J_{CP} 4.1 Hz, C_β) (literature (23) values for CH_2=CH—P(O)$(OEt)_2$: δ 16.7 (d, J_{CP} 7.3 Hz, CH_3 of EtO), 61.7 (d, J_{CP} 5.9 Hz, OCH_2), 127.9 (d, J_{CP} 182.1 Hz, C_α), 134.9 (d, J_{CP} 1.9 Hz, C_β)); ^{31}P nmr ($CDCl_3$) δ: 16.6. *Anal.* calcd. for $C_9H_{19}O_3P$: C 52.4, H 9.3%; found: C 52.3, H 9.1%.

*Preparation of **2**c*

Compound **2***a* (0.002 mol) was dissolved in 0.9 mL of a 2.2 M (1 mole-equivalent) solution of EtONa in EtOH and the solution was incubated at 25°C for 63 h. The product was recovered as for **2***a* and purified by bulb-to-bulb distillation at oven temperature 130°C (0.8 Torr); 69%, n_D^{25} 1.4372; ^{1}H nmr ($CDCl_3$) δ: 0.96 (3H, t, J_{HH} 7.0 Hz, ω-CH_3), 1.29 (6H, t, J_{HH} 7.5 Hz, 2 × CH_3 of EtO), 1.90–2.20 (2H, m, δ-CH_2), 2.53 (2H, d of d, J_{HP} 22.5 Hz, J_{HH} 7.5 Hz, α-CH_2), 4.08 (4H, quint, J_{HP} = J_{HH} 7.8 Hz, 2 × CH_2 of EtO), 5.40 (1H, d of t, J_{HH}(*trans*) 20.0 Hz, J_{HH}(allyl) 7.5 Hz, γ-CH), 5.62 (1H, m, β-CH); ^{13}C nmr ($CDCl_3$) δ: 13.5 (CH_3 of C_5H_9), 16.4 (d, J_{CP} 6.0 Hz, 2 × CH_3 of EtO), 25.6 (d, J_{CP} 2.7 Hz, δ-CH_2), 30.4 (d, J_{CP} 138.9 Hz, α-CH_2), 61.8 (d, J_{CP} 6.4 Hz, 2 × CH_2 of EtO), 117.4 (d, J_{CP} 11.1 Hz, γ-CH), 137.6 (d, J_{CP} 14.2 Hz, β-CH) (literature (19) values for CH_2=CH—CH_2—P(O)$(OEt)_2$: J_{PC} 138.7 Hz, J_{POC} 6.7 Hz, J_{POCC} 5.3 Hz); ^{31}P nmr ($CDCl_3$) δ: 26.1. *Anal.* found: C 52.2, H 9.2%.

When **2***c* was prepared directly from **4** and 2 mole-equivalents of EtONa, and isolated as before, the product contained, besides **2***c*, 17% of diethyl 2-ethoxypentyl-1-phosphonate (**6***a*), as determined by the signal of the ether OCH_2 group (δ 3.53, quart, J_{HH} 7.3 Hz) in the ^{1}H nmr spectrum of the reaction product.

*Preparation of **2**b* was carried out as for **2***a* and the product was distilled at oven temperature 90°C (0.5 Torr); 75%, n_D^{25} 1.4478; ^{1}H nmr ($CDCl_3$) δ: 0.94 (3H, t, J_{HH} 6.5 Hz, ω-CH_3), 1.20–1.80 (2H, m, δ-CH_2), 2.23 (2H, d of t, J_{HH} 7.0, 6.8 Hz, γ-CH_2), 3.72 (6H, d, J_{HP} 11.0 Hz, 2 × OCH_3), 5.60 (1H, d of d of t, J_{HP}(*gem*) 21.2 Hz, J_{HH}(*trans*) 17.2 Hz, J_{HH}(1,3) 1.6 Hz, α-CH), 6.81 (1H, d of d of t, J_{HP}(*cis*) 22.1 Hz, J_{HH}(*trans*) 17.2 Hz, J_{HH}(1,2) 6.4 Hz, β-CH). *Anal.* calcd. for $C_7H_{15}O_3P$: C 47.2, H 8.4%; found: C 47.0, H 8.3%.

*Preparation of **2**d*

Compound **5** (5.0 g, 0.0233 mol) was dissolved in 10 mL of the 2.2 M (1.3 mole-equivalents) solution of *t*-BuOK in *t*-BuOH and incubated at 25°C for 47 h. *tert*-Butanol was removed under reduced pressure, ice water (5 mL) was added, and the mixture was extracted with chloroform (3 × 5 mL). After drying ($MgSO_4$) and evaporation of solvent, **2***d* was purified by bulb-to-bulb distillation at oven temperature 100°C (0.2 Torr); 63%, n_D^{25} 1.4460; ^{1}H nmr ($CDCl_3$) δ: 0.99 (3H, t, J_{HH} 7.3 Hz, ω-CH_3), 1.82–2.30 (2H, m, δ-CH_2), 2.61 (2H, d of d, J_{HP} 21.2 Hz, J_{HH} 6.7 Hz, α-CH_2), 3.75 (6H, d, J_{HP} 10.8 Hz, 2 × OCH_3), 5.42 (1H, d of t, J_{HH}(*trans*) 20.1 Hz, J_{HH}(allyl) 7.5 Hz, γ-CH), 5.65 (1H, m, β-CH). *Anal.* found: C 47.1, H 8.2%.

*Preparation of **2**e*

Compound **3***c* (3.8 g, 0.019 mol) was dissolved in 15 mL of the 2.2 M (2 mole-equivalents) solution of *t*-BuOK in *t*-BuOH and stirred at 25°C for 45 h. *tert*-Butanol was removed under reduced pressure, ice water (10 mL) was added, and the solution was made acidic with trifluoroacetic acid and extracted with chloroform (4 × 5 mL). After drying ($MgSO_4$) and removing the solvent, **2***e* was obtained as free acid; 80%, oil; ^{1}H nmr ($CDCl_3$) δ: 0.93 (3H, t, J_{HH} 6.7 Hz, ω-CH_3), 1.49 (2H, t of quart, J_{HH} 8.1, 7.8 Hz, δ-CH_2), 2.16 (2H, d of t, J_{HH} 7.0, 6.7 Hz, γ-CH_2), 3.69 (6H, d, J_{HP} 11.3 Hz, 2 × OCH_3), 5.68 (1H, d of d of t, J_{HP}(*gem*) 21.5 Hz, J_{HH}(*trans*) 16.9 Hz, J_{HH}(1,3) 1.3 Hz, α-CH), 6.77 (1H, d of d of t, J_{HP}(*cis*) 22.3 Hz, J_{HH}(*trans*) 16.9 Hz, J_{HH}(1,2) 6.7 Hz, β-CH), 9.75 (1H, bs, OH). *Anal.* calcd. for $C_6H_{13}O_3P$: C 43.9, H 7.9%; found: C 44.0, H 7.9%.

*Preparation of **2**f*

Compound **2***f* was prepared from **2***d* (1.85 g, 0.0104 mol) by demethylation with NaI (2 mole-equivalents) in acetone (17 mL). After refluxing the solution for 30 h and cooling, the sodium salt of **2***f* precipitated out. The product was filtered off, washed thoroughly with cold acetone, and dried; 88%; ^{1}H nmr (methanol-d_4) δ: 0.97 (3H, t, J_{HH} 7.5 Hz, ω-CH_3), 1.72–2.36 (2H, m, δ-CH_2), 2.36 (2H, d of d, J_{HP} 20.2 Hz, J_{HH} 7.2 Hz, α-CH_2), 3.54 (3H, d, J_{HP} 10.5 Hz, OCH_3), 5.39–5.62 (2H, overlapping m, β-H, γ-H). *Anal.* calcd. for $C_6H_{12}O_3NaP$: C 38.7, H 6.5%; found: C 39.0, H 6.5%.

Free acid **2***f* was obtained from the sodium salt by acidification (CF_3CO_2H) and extraction with chloroform; 96%, oil, n_D^{25} 1.4528.

*Fragmentation of **3**a*

Compound **3***a* (0.020 g, 0.0001 mol) was dissolved in D_2O (0.6 mL), a 40% solution of NaOD in D_2O (0.02 mL, 2.8 mole-equivalents) was added, and the solution was left at 25°C for 15 min. The mixture was then extracted with chloroform-*d* (0.6 mL), the $CDCl_3$ solution was dried ($MgSO_4$), and ^{1}H nmr of this solution revealed the presence of 1-pentene as the sole reaction product; δ: 0.91 (3H, t, J_{HH} 6.5 Hz, CH_3), 1.41 (2H, t of quart, J_{HH} 6.5, 6.7 Hz, 4-CH_2), 2.05 (2H, d of t, J_{HH} 6.7, 6.5 Hz, 3-CH_2), 4.90–5.15 (2H, m, 1-CH_2), 5.82 (1H, t of quart, J_{HH} 6.5, 7.3 Hz, 2-CH).

H/D exchange experiments were carried out by dissolving substrates in the required medium in an nmr tube, sealing the tube, placing it in a thermostated water bath, and periodically recording the ^{1}H nmr spectrum. The percentage of the exchange was determined from the integral of the remaining signal of the exchanging group relative to the intensities of signals of the non-exchanging groups.

Phenyl group as a probe in the ^1H nuclear magnetic resonance study of the conformations of quaternary heteroaromatic carbapenem antibiotics. Identification of the site of quaternization in -SCH_2- substituted nitrogen-containing heteroaromatic derivatives

VANGA S. RAO,[1] JEAN-PAUL DARIS, AND MARCEL MENARD
Bristol–Myers Pharmaceutical Group, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received December 9, 1987

VANGA S. RAO, JEAN-PAUL DARIS, and MARCEL MENARD. Can. J. Chem. **66**, 1546 (1988).

The phenyl group is shown as a useful probe in sensing the environment in the ^1H nuclear magnetic resonance conformational study of a variety of quaternary heteroaromatic carbapenem derivatives. The influence of the -SCH_2- substituent in determining the site of quaternization in nitrogen-containing heteroaromatic compounds is demonstrated through the acidity measurements of these methylene protons.

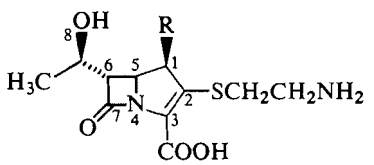
VANGA S. RAO, JEAN-PAUL DARIS et MARCEL MENARD. Can. J. Chem. **66**, 1546 (1988).

Au cours d'études conformationnelles, faites à l'aide de la résonance magnétique nucléaire du ^1H sur un certain nombre de dérivés carbapénem hétéro-aromatiques, on a démontré que le groupement phényle est une sonde sensible pour déceler l'environnement. Utilisant des mesures d'acidité des protons méthyléniques, on a démontré l'influence du substituant -SCH_2- sur le site de quaternisation de composés hétéro-atomiques contenant de l'azote.

[Traduit par la revue]

Introduction

Thienamycin, **1** (R = H), is an unusually potent β-lactam antibiotic isolated[2] from the fermentation broth of the soil microorganism *Streptomyces cattleya*. A major drawback of these β-lactams is their susceptibility to renal dehydropeptidase (DHP-I), an enzyme responsible for their metabolic inactivation in vivo (2). However, introduction of a β-methyl substituent at the C-1 position (R = CH_3) has resulted in an exceptional increase in stability to this devastating enzyme (3), presumably by way of partially blocking the carbonyl moiety of the β-lactam from being attacked by the serine OH group. Since the discovery of **1** (R = H), a large number of this carbapenem



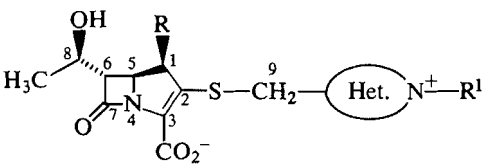
1

family have been synthesized by several research groups, in order to achieve better antibacterial activity and reduced toxic side effects.

The most desirable approach towards this goal is to evaluate the precise receptor binding site of these molecules. When this information is not easily attainable, then an understanding of the three-dimensional shape of these molecules becomes pivotal in the design and development of new and superior drugs.

Results and discussion

Although the bicyclic part of **1** is fairly rigid, the side chains at positions 2 and 6 can be seen as flexible and can adopt different rotameric states to a varying degree depending on the type of substituent. The present discussion is restricted to side-chain orientation at C-2. A number of quaternary carbapenem derivatives (4) of the type **2** have been synthesized in our laboratories with the aim of finding a better antibacterial agent with no or reduced toxicity.



2

In an attempt to understand the results of biological screening of these compounds (4), the role of the methylene protons, flanked by the sulfur on one side and the positively charged heteroaromatic ring on the other side, has been studied by ^1H nmr spectroscopy. These protons are found to be acidic enough to be exchanged for the deuterium isotope in D_2O under mildly basic conditions. The origin of this acidity is discussed in a later section. Under controlled conditions the rate of exchange of these protons can be moderated to a measurable rate. Under these conditions the two diastereotopic protons of **10** are exchanged at different rates, as studied by ^1H nmr spectroscopy, implying that one of them is more acidic than the other. This may be attributed to a preferential rotameric distribution around the S—CH_2 bond, as depicted in **3**.

CHART 1. Structures of zwitterionic compounds.

The *gauche* conformer around the S—CH_2 bond (**3**) places H_a doubly *gauche* to the sulfur lone pairs whereas H_b is *gauche* to only one lone pair. This, in principle, should allow H_a to be exchanged faster than H_b due to favorable "*gauche*" interactions (5) between the electron pairs of sulfur and the negative charge of the conjugate base (carbanion generated after removing H_a and (or) H_b by a suitable base). This conformation also allows a favorable secondary electrostatic stacking interaction between the oppositely charged pyridinium and the carboxylate moiety (**3**). To obtain experimental support for the existence of a folded (*gauche*) conformation, **3**, the pyridine nitrogen of **4** was quaternized with a benzyl group to give **7**, within which there exists a highly anisotropic probe, namely a phenyl moiety. The CH_2 group anchoring the pyridinium and the phenyl group gives just enough flexibility in this region to allow the phenyl group to stay in close proximity to the H-1 and H-5 protons of the β-lactam moiety (see **24**). A longer bridge ($(CH_2)_3$) as in **8** only makes the ends floppy, thus allowing the phenyl group to orient itself away from these protons in which case the magnitude of the phenyl anisotropic effect is expected to diminish.

Thus, it can be seen from Table 1 that the chemical shifts of

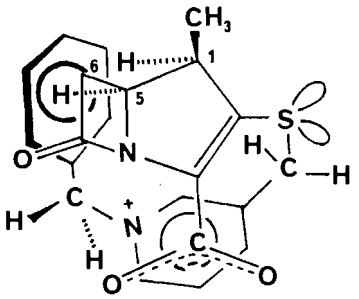
H-1 and H-5 of **7** are dramatically shifted upfield by 0.32 and 0.5 ppm, respectively, as compared to the H-1 and H-5 of **6**. This may be attributed to the through-space anisotropic effect of the phenyl group on these protons. As the rest of the chemical shifts (Table 1) are practically unaffected, particularly those attached to C-9 (AB), which forms a link between the positively charged heterocycle and the β-lactam moiety, it may be concluded that these upfield shifts do not arise because of through-bond (σ-skeleton) effects. The fact that the H-1 and H-5 protons are below the plane of the bicyclic ring and are most affected by quaternizing the pyridine ring with a benzyl group indicates a preferential underside folding of this group in the C-1 β-methyl series of compounds. In this conformation the phenyl moiety may be oriented appropriately to shield the H-1 and H-5 protons as depicted in **24**.



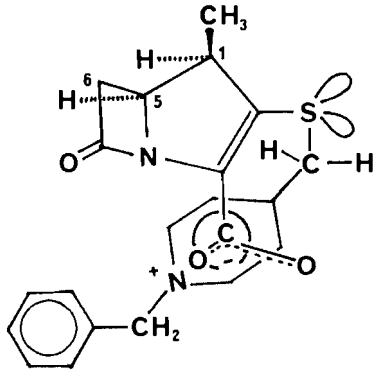
24 (6-hydroxyethyl group omitted for clarity)

In the case of the C-1 *non* β-methyl series, a comparison of the chemical shifts of compounds **22** and **23** indicates that the upfield shift effect of the phenyl anisotropy on one of the protons at C-1 and on H-5 is approximately half of that observed in the C-1 β-methyl series, thereby suggesting that both folded conformations (above and below) are significant in this series. Just how much of this particular conformer (**3** or **24**) contributes to the overall equilibrium mixture of conformers is difficult to assess without elaborate experimental and theoretical studies.

Furthermore, the pyridine ring was quaternized with a three-carbon chain at the end of which the same phenyl probe is present (**8**). As alluded to earlier, the increased number of bonds and in turn the increased rotational freedom is reflected in the magnitude of the phenyl anisotropic effect on the H-1 and H-5 protons. Thus the H-1 and H-5 chemical shifts are shifted upfield by only 0.05 and 0.17 ppm, respectively (Table 1; compare **6** and **8**).

The effect of changing the substitution pattern of the pyridine ring has also been examined. Compound **9** was quaternized with a benzyl group to give **11**, which differs from **7** only in its substitution pattern. In its folded conformation (**25**), it can be seen that the phenyl ring in **11** is unable to occupy an appropriate spatial position to exert its anisotropic effect on the H-1 and H-5 protons. In accordance with this expectation, the H-1 and H-5 protons of **11** are found to be affected to a negligible extent (0.07 and 0.05 ppm, Table 1) when compared to those of **10**. Thus the chemical shift data are consistent with the prominent role of *gauche* conformer around the S—CH_2 bond, which also allows a favorable interaction between the oppositely charged moieties in these zwitterionic derivatives.

The chemical shift changes observed for H-1 and H-5 protons due to the phenyl anisotropic effect in the allyl and methyl ester derivatives are similar to those in the corresponding zwitterionic

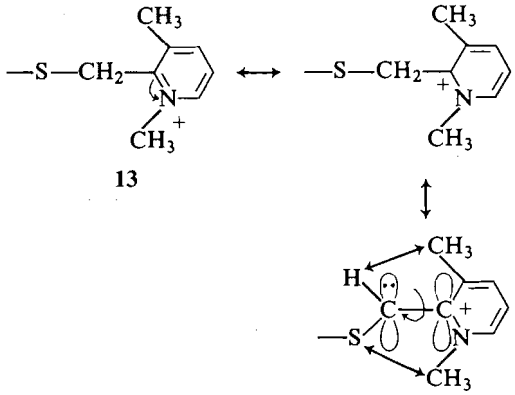


25 (6-hydroxyethyl group omitted for clarity)

compounds (Table 1, compare **6** and **7**, **26** and **27**, **33** and **34**). The shift changes for the H-1 and H-5 protons in the allyl and methyl ester derivatives are also similar. From these observations, it appears reasonable to rule out the possibility of any π-stacking interactions between the allyl group and the pyridinium ring. However, π interactions between the pyridinium nucleus and the electron-rich oxygen atoms of the ester seem quite possible and cannot be neglected. In conclusion, the data clearly show that there is an intrinsic preference for the *gauche* conformer around the S—CH_2 bond in these quaternized, heteroaromatic carbapenem derivatives.

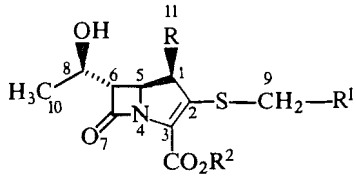
Acidity of -SCH_2- protons

It was previously mentioned that the -SCH_2- protons in some compounds are acidic and can be exchanged for the deuterium isotope in D_2O under mildly basic conditions. It appears that they owe their acidity to some structural feature that allows the negative charge of the conjugate base to be stabilized by delocalization in such a way that the bond polarization terminates at the positive nitrogen atom. In corollary, by polarizing the —C=$\overset{+}{N}$—R bond, if the positive charge can be brought adjacent to the methylene carbon, then these protons become acidic. However, a few exceptions have been found and are discussed below. In the case of **13** (Chart 1) the non-acidic nature of the methylene protons can be rationalized by invoking a steric compression between sulfur/methyl/*N*-methyl/hydrogen, which can prevent the p-lobe of the incipient carbanion from being coplanar with the ring π-system necessary for effective delocalization as depicted below.



13

In another case the methylene protons of **15** (Chart 1) have been found to be exceptionally acidic. The reason for this may lie in the fact that the ring hydrogen (H-5′) is so acidic that it



26 R = CH_3; R^1 =  /TfO^-; R^2 = —CH_2CH=CH_2 : NO

32 R = H; R^1 =  /Br^-; R^2 = —CH_2CH=CH_2 : NO

33 R = CH_3; R^1 =  /Br^-; R^2 = —CH_3 : NO

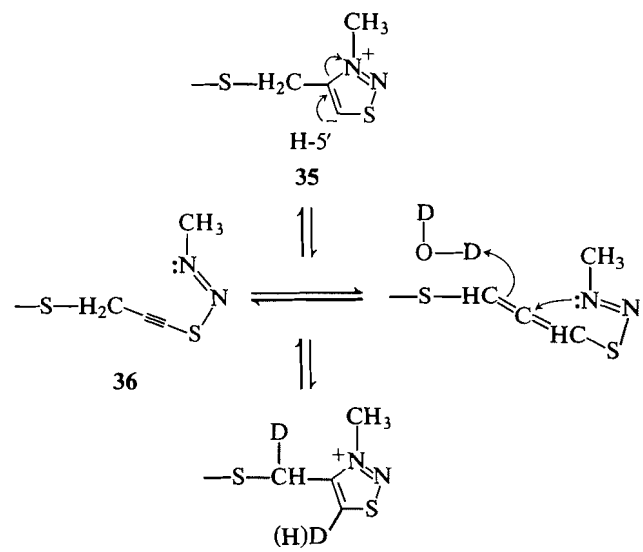
34 R = CH_3; R^1 =  /Br^-; R^2 = —CH_3 : NO

YES or NO denotes whether or not the methylene protons (SCH_2) exchange with the deuterium isotope in D_2O under the basic conditions described in the experimental section

CHART 2. Structures of quaternary ester compounds.

exchanges rapidly for deuterium as soon as it is dissolved in D_2O. The negative charge generated at this position can initiate a transient ring opening and closing process with an end result of imparting unexpected acidic character to these protons, as shown below.[3]

When the H-5′ proton was replaced by a CH_3 group as in **17** (Chart 1), the methylene protons were found to be non-acidic. This lends strong support to the above scheme of events because an intermediate such as **35** cannot be generated from **17**. Moreover, there is literature precedence (7) for the ring opening



[3]Although acetylenic thioethers generally require a strong base to effect acetylene–allene interconversion, the unique structural features present in the acetylenic intermediate (**36**) may be responsible for the enhanced acidity of the methylene protons and, in turn, the facile acetylene–allene interconversion process. For some general information regarding interconversion of allene and alkyne, and rearrangements involving acetylenes, see ref. 6*a*; for heterosubstituted allenes, allenyl thioethers, etc., see ref. 6*b*.

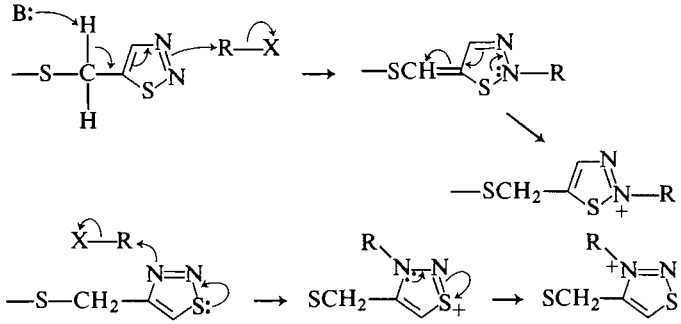
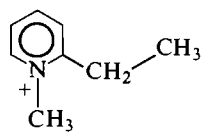
For personal use only.

of a quaternary tetrazole, involving a carbanion intermediate of the type **35**, and also the ring-opening processes are well known in many heterocyclic systems (8).

The results of the above acidity measurements can be helpful in the identification and the prediction of the site of quaternization in multi-nitrogen heteroaromatic rings, when they occur as part of a carbapenem derivative of the general structure **2**. That is, if the carbanion, generated after removing the proton from the -S—CH_2- moiety, can linearly conjugate with the ring π-system at the end of which there is an annular nitrogen atom, then that nitrogen atom is the one most likely to show increased affinity for an alkyl group and thus the preferred site of quaternization. Otherwise, the hetero atom in the ring is likely to direct the alkylation as illustrated below for both these cases.

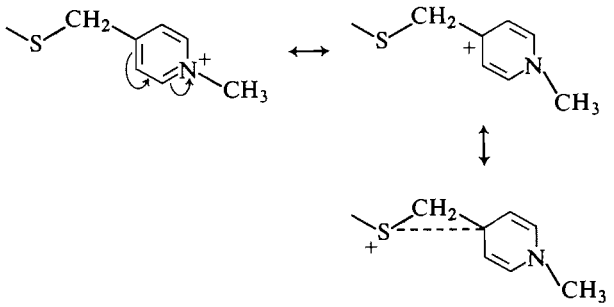


Finally, it may be pointed out that the methylene protons require simultaneous activation by sulfur and the positively charged heteroaromatic moiety (the nitrogen atom being in the proper location) for them to be acidic. Thus it has been found that the -SCH_2- protons of **9** (Chart 1), in which the pyridine ring is not quaternized, are not acidic; this is also the case for the methylene protons of the ethyl group of **37**, due to the lack of an adjacent sulfur atom.



37

It may be concluded then that neighboring group participation by sulfur is crucial in stabilizing the positive charge, which in turn makes the SCH_2 protons acidic.



Experimental

Proton magnetic resonance spectra were recorded with a Bruker AC200SY instrument operating at 200 MHz. Chemical shifts (δ) are reported with reference to sodium 3-trimethylsilylproprionate-2,2,3,3-d_4 (TSP) in D_2O as solvent.

General procedure for the measurement of acidity of SCH_2 protons

In a typical experiment, the ^1H nmr spectrum of the compound (5 mg) is recorded in D_2O (~0.5 mL) to locate the SCH_2 protons. If these protons are not detectable due to severe overlap with other signals, then the spectrum may be recorded in DMSO-d_6. A second spectrum is recorded with the sample (~5 mg) in 0.5 mL of a solution of $KHCO_3$ in D_2O (2.5% w/v; pH 8.65). If the sample is scarce, after recording the first spectrum the sample may be mixed with ~8 equivalents of solid $KHCO_3$ and then the second spectrum is recorded. From these two spectra the evidence for the disappearance of the SCH_2 protons is obtained if these are exchangeable with the deuterium isotope in the solvent. If exchange rate measurements are necessary it is possible to spread the time required for complete exchange over a reasonable length (~2–3 h) by adding only ~1 equivalent of $KHCO_3$ and recording the spectra at regular intervals.

Acknowledgments

The authors are extremely grateful to their colleagues for making available a number of the compounds required in the study. The authors wish to thank Dr. M. Gorman and Dr. R. Partyka for their interest and encouragement, together with Professor B. Belleau and Dr. A. Martel for stimulating and very helpful discussions.

The photochemistry of electron donor–acceptor (EDA) complexes in micellar solutions. I. The stilbene–methylviologen system

M. HAMITY AND R. H. LEMA

Universidad Nacional de Río Cuarto, Departamento de Química y Física, 5800 Río Cuarto, Córdoba, Argentina

Received August 14, 1987[1]

M. HAMITY and R. H. LEMA. Can. J. Chem. **66**, 1552 (1988).

The association constants for the electron donor–acceptor (EDA) complexes formed between both *cis*-stilbene (cS) and *trans*-stilbene (tS) as donors and methylviologen (MV^{+2}) as acceptor were determined in ethanol and micellar sodium dodecyl sulfate (SDS) solutions in the range of SDS concentration 0.05–0.1 M. The values obtained in micellar solutions were much higher than those in ethanol and were heavily dependent upon SDS concentration. This effect is due to an increase in the local concentration of the reactants in the micellar pseudophase. The tS fluorescence quenching by MV^{+2} was also studied in the same solvent media. In ethanol, the Stern–Volmer plot was found to be linear, with quenching constant (K_{SV}) similar to the association constant determined by the absorption method. In micellar solutions, although upward curvature of the Stern–Volmer plots was observed, a reaction scheme based on static quenching via ground state EDA complex is proposed, which explains the experimental results. Irradiation in the absorption band of the EDA complexes formed by tS or cS and MV^{+2} was carried out in ethanol and SDS solutions, in the absence of oxygen. Only *cis–trans* isomerization of cS in SDS solution was observed, with a quantum yield value of $\Phi_{cis} = 0.012$.

M. HAMITY et R. H. LEMA. Can. J. Chem. **66**, 1552 (1988).

Opérant dans l'éthanol ainsi que dans des solutions micellaires de dodécylsulfate de sodium (DSS) à des concentrations de DSS allant de 0,05 à 0,1 M, on a déterminé les constantes d'association des complexes donneur d'électron/accepteur (DEA) qui se forment entre les stilbènes *cis* et *trans* (Sc et St) agissant comme donneurs et le viologène de méthyle (VM^{+2}) agissant comme accepteur. Les valeurs obtenues en solutions micellaires sont beaucoup plus élevées que celles obtenues en solutions dans le méthanol et elles dépendent beaucoup de la concentration en DSS. Cet effet est dû à une augmentation de la concentration locale des réactifs dans la pseudo-phase micellaire. Opérant dans les mêmes solvants, on a aussi étudié le piégeage de la fluorescence du St par le VM^{+2}. Dans l'éthanol, on a observé que la courbe de Stern–Volmer est linéaire et que la constante de piégeage (K_{SV}) est semblable à la constante d'association déterminée par la méthode d'absorption. Dans les solutions micellaires, on a observé une courbure montante dans les courbes de Stern–Volmer; malgré cette observation, on propose un schéma réactionnel, basé sur un piégeage statique se produisant par le biais d'un complexe DEA dans son état fondamental, qui explique les résultats expérimentaux. Opérant en solution dans l'éthanol ou dans le DSS et en l'absence d'oxygène, on a effectué une irradiation de la bande d'adsorption des complexes DEA qui se forment entre le St ou le Sc et le VM^{+2}. En solution dans le DSS, on n'a observé que l'isomérisation *cis–trans* du Sc et le rendement quantique $\Phi_{cis} = 0{,}012$.

[Traduit par la revue]

Introduction

Photo-induced reactions of stilbenes have been the subject of a great quantity of experimental work (1). These photoprocesses have been carried out, in homogeneous solution, by means of straightforward excitation (2), triplet sensitization (3, 4), via radical cations (5) or exciplexes (6), and through the excitation of charge-transfer complexes formed by stilbenes and organic neutral molecules (7, 8). There have been, however, very few studies in microheterogeneous media (micelles, semiconductor particles, etc.), which present interesting properties that can be used to contribute to the knowledge of these photoreactions (9–11). Semiconductor particle photomediated *cis–trans* isomerization of stilbene was studied by Al-Ekabi and de Mayo (12). They found a photostationary state (>99% *trans* isomer) close to that corresponding to thermodynamic equilibrium and they proposed that isomerization was produced via a radical cation intermediate. Whitten and co-workers reported the synthesis of surfactant molecules that contain *trans*-stilbene incorporated both as a terminal and intrachain chromophore group. They studied the properties of these molecules as micellar fluorescence probes (13–15). Very slightly curved Stern–Volmer plots were determined by them for methylviologen quenching of the fluorescence of stilbene surfactants in 0.03 M SDS. They proposed a static quenching mechanism due to the occurrence of a ground state complex. They also attributed the slight deviation of linearity observed in these experiments to either the small influence of a dynamic process (13) or to neglecting the contribution of a term containing the complex concentration in the quencher concentration of the Stern–Volmer equation (14).

In this work, we have studied the *trans*-stilbene fluorescence quenching by methylviologen in ethanol and micellar solutions at several concentrations of sodium dodecyl sulfate. We have also studied, using absorption spectroscopy, the formation of ground-state charge-transfer (EDA) complexes by *cis*- and *trans*-stilbene and methylviologen in the same solvent media. We propose an alternative treatment of static quenching that satisfactorily explains our experimental data. We finally report some results on *cis–trans* isomerization of stilbene through the photolysis of EDA complexes with methylviologen, which to the best of our knowledge has not been studied in micellar systems. We are particularly interested in photoreactions of EDA complexes in microheterogeneous media. This work represents the beginning of such studies.

Experimental

Materials

Commercial *trans*-stilbene (Schuchardt Munchen) and *cis*-stilbene (Koch-Light) were used without further purification. Their purity grade was >99%, checked by glc.

Methylviologen, chloride was obtained from commercial Gramoxone solution by conventional techniques and purified as previously described (16).

Sodium dodecyl sulfate (SDS) (B.D.H.) was washed with diethyl ether and recrystallized from ethanol.

Absorption measurements

The ultraviolet–visible absorption measurements were performed with a Cary 17 spectrophotometer. Association of methylviologen (MV^{+2}) with both *cis*-stilbene (cS) and *trans*-stilbene (tS) in ethanol and SDS solutions was monitored by the absorption of the charge-transfer band. In all cases, the reference cell contained the same MV^{+2} concentration as the sample cell.

In micellar solutions, the MV^{+2} concentration was varied between 10^{-3} M and 10^{-2} M and stilbene concentration was kept constant at 3×10^{-4} M. The charge-transfer complex formation constants were determined through a Benesi–Hildebrand analysis and an iterative treatment of the data (17). Both methods yielded the same results.

In ethanolic solutions, for solubility reasons, the MV^{+2} concentration was kept constant (5×10^{-3} M) and the stilbene concentration was varied between 2×10^{-3} M and 2.5×10^{-2} M for tS and between 4×10^{-3} M and 4×10^{-2} M for cS. The iterative procedure was used to determine the association constants in ethanol.

Fluorescence measurements

The tS fluorescence quenching by MV^{+2} was monitored with an Aminco SPF 125 spectrofluorometer. The measured fluorescence intensities were corrected by the absorption of MV^{+2}.

Excitation wavelength was 330 nm in SDS solutions and 340 nm in ethanol, and emission intensity was measured at 355 nm in SDS solutions and 360 nm in ethanol.

Absolute isomerization quantum yields

Stilbene samples with and without MV^{+2}, in ethanol and micellar solutions, were degassed in a high vacuum line. The concentrations used were as follows: cS 4×10^{-2} M, tS 2×10^{-2} M in ethanol, and both stilbenes 6×10^{-4} M in 0.1 M SDS. MV^{+2} concentration was 5×10^{-3} M in all cases. Uranyl oxalate was used as actinometer.

The samples, in a merry-go-round apparatus, were irradiated at $\lambda >$ 430 nm with a Philips 1000-W quartz–halogen lamp as a light source and a Corning 3-72 filter. Temperature was maintained at 25 ± 0.1°C.

Stilbene concentrations were monitored by glc with a Varian 2800 chromatograph using an OV-101 on Chromosorb G H/P 100–120 mesh column. The samples in micellar solutions, after irradiation, were treated with $CaCl_2$ to precipitate SDS and then with CS_2, containing *n*-dodecane as external standard, to extract organic components and separate them from water-soluble MV^{+2} (18). Samples in ethanolic solution, after irradiation, were chromatographed, after adding *n*-dodecane as external standard.

Oxalate loss in ethanolic solutions was determined by titration with $KMnO_4$. During photolysis, the ampoules were open to the atmosphere.

Results and discussion

Determination of formation constants of EDA complexes

Stilbene and MV^{+2} solutions, when mixed, show an absorption band in a longer-wavelength region where neither S or MV^{+2} absorb (Fig. 1). This new band can be attributed to the occurrence of a ground-state EDA complex. The formation constants of these EDA complexes were determined in ethanol and micellar solutions at several SDS concentrations (Tables 1 and 2). The constants K_{BH} in micellar solutions are dependent on surfactant concentration. This trend is similar to that observed in micelle-catalyzed bimolecular reactions (19) and it has also been observed in the system naphthylamines–MV^{+2} in SDS (20).

Under our experimental conditions, the fraction of MV^{+2} bound to micelles is nearly unity (20), as is the case for stilbenes (21). The association of MV^{+2} with stilbene takes place in the micellar pseudophase, and therefore a volume change of the pseudophase could affect the equilibrium, thus changing the local concentration of reactants. The results can be analyzed by means of the following equations:

$$[1] \quad (S)_m + (MV^{+2})_m \overset{K_{ct}}{\rightleftharpoons} (S\ldots MV^{+2})_m$$

where the reactants are in the micellar pseudophase, K_{ct} is the

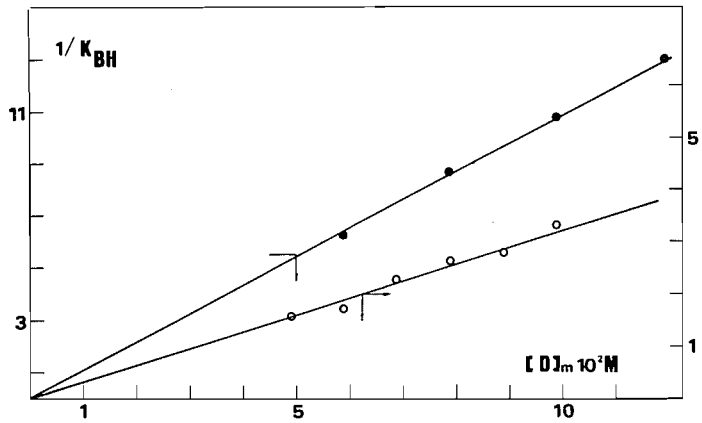

FIG. 2. Inverse of Benesi–Hildebrand formation constant as a function of micellized detergent concentration in SDS solutions, for (●) cS + MV^{+2}; (○) tS + MV^{+2}.

formation constant for the EDA complex $(S...MV^{+2})_m$, and the reaction occurs within the micelle and is not an intermicellar reaction. The concentration of any one of the reactants in the micellar pseudophase is

$$[2] \quad [R]_m = \frac{[R]_0 - [R]_w}{V[D]_m} \simeq \frac{[R]_0}{V[D]_m}$$

where $[R]_m$ is the concentration of the reactant in the micellar pseudophase; $[R]_0$ and $[R]_w$ are the analytical and water reactant concentrations, respectively, $[D]_m$ is the micellized detergent concentration ($[D]_{total}$ − cmc), and V is the molar volume of the micellized detergent (cmc is the abbreviation for critical micelle concentration).

Introducing the corresponding analytical concentrations in the equilibrium constant (K_{ct}) of reaction [1], by means of eq. [2] and assuming that Beer's law holds for the EDA complex, we have

$$[3] \quad \frac{[S]_0}{O.D.} = \frac{1}{\varepsilon_c} + \frac{1}{\varepsilon_c}\frac{V[D]_m}{K_{ct}}\frac{1}{[MV^{+2}]_0}$$

This is a Benesi–Hildebrand type equation, where

$$[4] \quad \frac{1}{K_{BH}} = \frac{V[D]_m}{K_{ct}}$$

O.D. is the optical density per cm, ε_c is the extinction coefficient for the complex, and $[S]_0$ and $[MV^{+2}]_0$ are the analytical concentrations of stilbene (*cis* or *trans*) and methylviologen, respectively. Equation [4] predicts the observed dependence of the formation constant for the EDA complex upon the detergent concentration. Plotting $(K_{BH})^{-1}$ vs. $[D]_m$, a straight line is obtained (Fig. 2) and K_{ct} can be calculated from the slope. The values given in Table 3 were determined using $V = 0.14\ M^{-1}$ (21) and cmc = 1×10^{-3} M. The latter is the appropriate value to use with the MV^{+2} concentration range in the present working conditions, since cmc for SDS changes with MV^{+2} concentration.[2]

The K_{ct} values determined by us are higher than those displayed by EDA complexes formed by stilbenes with moderately strong electron acceptors, such as the electron-poor alkenes ($K_{ct} \leq 1$) (1). We think that these high values are due to the ability of MV^{+2} to form a stable CT complex, since our

cS + MV^{+2}	SDS	1.29
cS + MV^{+2}	Ethanol	8

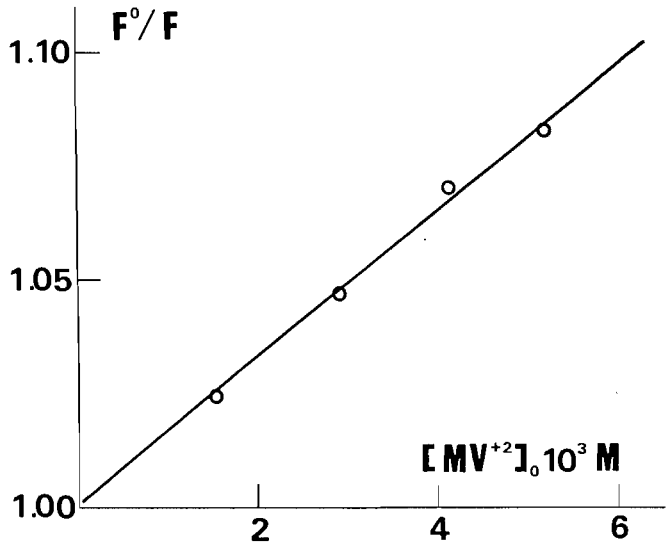

FIG. 3. Stern–Volmer plot for tS fluorescence quenching by MV^{+2} in ethanol; $[tS]_0 = 10^{-3}$ M.

values of K_{ct} are typical of complexes formed by MV^{+2} with electron donors ($2 \leq K_{ct} \leq 20$) (23).

As Table 3 shows, K_{ct} values for the complex $(tS...MV^{+2})$ are higher than those for the cS complex. This could be due to steric effects, which are magnified in SDS micelles. On the other hand, for a given complex, K_{ct} values in ethanol are higher than in SDS solutions. The difference in this case could be attributed to polarity effects, even when the band shift from ethanol to SDS (Fig. 1) indicates a small polarity difference between the two solvent media (24).

From Tables 1 and 2 it can be seen that the extinction coefficients of the complexes are nearly constant (376 ± 16 M^{-1} cm^{-1}) in SDS solutions. On the other hand, the extinction coefficients in ethanol are approximately one order of magnitude lower. This effect can be taken as indicative that micelles could diminish the random orientation of both molecules in the complex and lower the intermolecular distance, thus favouring orbital overlap and charge-transfer transition (25).

MV^{+2} quenching of tS fluorescence

Stern–Volmer plots for tS fluorescence quenching by MV^{+2} in ethanol are found to be linear (Fig. 3). The slope value (16 M^{-1}) is in agreement with that obtained by Russell and Whitten for a surfactant stilbene in acetonitrile (13) and with the K_{ct} value obtained in ethanol (Table 3). These facts strongly suggest that static quenching via a ground-state charge-transfer complex is the only quenching process occurring in this solvent.

In SDS micellar solutions, MV^{+2} quenching of tS fluorescence shows an upward curving of the Stern–Volmer plots (Fig. 4). This could be attributed to the simultaneous occurrence of both static and dynamic quenching. Nevertheless, taking into

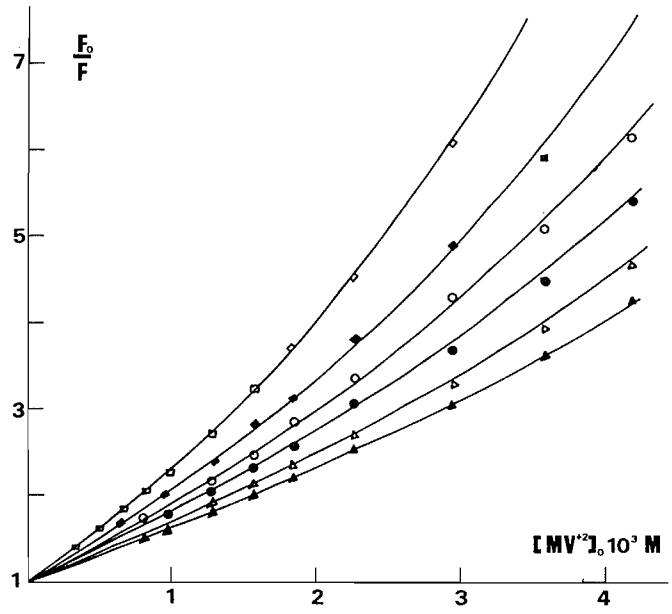

FIG. 4. Stern–Volmer plots for tS fluorescence quenching by MV^{+2} in micellar solutions of the following SDS concentrations: (□) 5×10^{-2} M; (■) 6×10^{-2} M; (○) 7×10^{-2} M; (●) 8×10^{-2} M; (△) 9×10^{-2} M; and (▲) 9.75×10^{-2} M. $r = [tS]_0/[M] = 0.03$.

account the short stilbene lifetime (approximately 0.1 ns) and the MV^{+2} concentration range, the value of the bimolecular quenching rate constant ought to be at least $k_q = 10^{12} \times M^{-1}\ s^{-1}$ for dynamic quenching to be appreciable. This is much higher than the value expected for a diffusion controlled process. Accordingly, we consider that the only process occurring in SDS micelles is static quenching. This could be a valid model assuming that emission is occurring only from micelles with fluorophore molecules that are free of quencher (case 1, Turro and co-workers (26)). According to Poisson statistics, in this case:

$$\ln \frac{F_0}{F} = \langle Q \rangle = \frac{[Q]_0}{[M]}$$

where [M] is the micelle concentration. A curving of the plots of $\ln F_0/F$ vs. $[MV^{+2}]_0$ is observed with our data. This is indicative that the above assumption is not valid in this case. Since quencher molecules entering a fluorophore-containing micelle are not 100% effective in quenching fluorescence, we assume that quenching is occurring only for quencher molecules bound to fluorophore molecules that form the charge-transfer complex. Emission can thus occur from micelles having MV^{+2} molecules, but not bound to tS molecules. With this assumption, we propose the following scheme to explain our experimental results:

$$[1a] \quad (tS)_m + (MV^{+2})_m \overset{K_{ct}}{\rightleftharpoons} (tS\ldots MV^{+2})_m$$

$$[1b] \quad K_{ct} = \frac{[(tS\ldots MV^{+2})_m]}{[(MV^{+2})_m]\{[(tS)_m]_0 - [(tS\ldots MV^{+2})_m]\}}$$

$$[5] \quad (tS)_m + h\nu \rightarrow {}^1(tS)_m^*$$

$$I_a = I_0(1 - 10^{-A})$$

$$[6] \quad {}^1(tS)_m^* \xrightarrow{k_f} (tS)_m + h\nu'$$

$$F = k_f[{}^1(tS)_m^*]$$

$$[7] \quad {}^1(tS)_m^* \xrightarrow{k_d} (tS)_m$$

$$\tau_0 = (k_f + k_d)^{-1}$$

where I_0, I_a, and F_0 are the incident, absorption, and emission light intensity; k_f and k_d are fluorescence and non-radiative rate constants, and A represents the tS absorbance at excitation wavelength.

Considering the stationary state for ${}^1(tS)_m^*$ and expanding in a power series the exponential $10^{-A} = \exp(-2.303\ A)$, neglecting terms of the third and higher order (since $A_0 = 0.3$), the ratio between fluorescence intensity in the absence and presence of quencher, respectively, becomes:

$$[8] \quad \frac{F_0}{F} = \frac{(A_0 - 1.15A_0^2)}{(A - 1.15A^2)} = \frac{[(tS)_m]_0 - 1.15\varepsilon l[(tS)_m]_0^2}{[(tS)_m] - 1.15\varepsilon l[(tS)_m]^2}$$

where A_0, $[(tS)_m]_0$ and A, $[(tS)_m]$ are tS absorbance and concentration in the absence and presence of quencher, respectively, and ε is the extinction coefficient of the tS.

Since $[(tS)_m] = [(tS)_m]_0 - [(tS\ldots MV^{+2})_m]$, we have

$$[9] \quad \frac{F_0}{F} = \frac{[(tS)_m]_0 - 1.15\varepsilon l[(tS)_m]_0^2}{[(tS)_m]_0 - [(tS\ldots MV^{+2})_m] - 1.15\varepsilon l\{[(tS)_m]_0^2 - B\}}$$

where

$$B = 2[(tS)_m]_0[(tS\ldots MV^{+2})_m] - [(tS\ldots MV^{+2})_m]^2$$

Since EDA complex concentration is lower than tS concentration, the term B inside the brackets can be neglected. Thus, after rearranging, eq. [9] becomes:

$$[10] \quad \frac{F_0 - F}{F_0} = \frac{[(tS\ldots MV^{+2})_m]}{[(tS)_m]_0\{1 - 1.15\varepsilon l[(tS)_m]_0\}}$$

Introducing in this equation the ratio $[(tS\ldots MV^{+2})_m]/[(tS)_m]_0$ from eq. [1b] and replacing $[(MV^{+2})_m]$ with $[MV^{+2}]_0$ from eq. [2], eq. [10] can be rewritten as:

$$[11] \quad \frac{F_0}{F_0 - F} = \{1 - 1.15\varepsilon l[(tS)_m]_0\} + \{1 - 1.15\varepsilon l[(tS)_m]_0\}\frac{V[D]_m}{K_{ct}[MV^{+2}]_0}$$

Two series of experiments were carried out, one in which $[(tS)_m]_0$ was kept constant and another keeping the ratio $r = [(tS)_m]_0/[M]$ at constant values of 0.03 and 0.3, respectively. In all cases, SDS concentration was varied between 0.05 and 0.1 M. Straight lines were obtained in all cases by plotting eq. [11] as shown in Fig. 5 for $r = 0.03$. Equation [11] yields an expression (slope/intercept = $V[D]_m/K_{ct}$) equivalent to eq. [4] and which is plotted in Fig. 5 (inset) for the ratio r of 0.03, giving, as in the rest of the cases, a straight line. From the slope the formation constant for the EDA complex is obtained ($K_{ct} = 7.2\ M^{-1}$, $r = 0.03$). Similar values of K_{ct} were determined for the different experiments and are comparable to those given in Table 3.

Equation [11] can be rewritten as:

$$[12] \quad \frac{F_0}{F} = \frac{W + Y_0[MV^{+2}]_0}{W - [MV^{+2}]_0(1 - Y_0)}$$

where Y_0 and W are the intercept and slope of eq. [11], respectively. Equation [12] satisfactorily fits the experimental

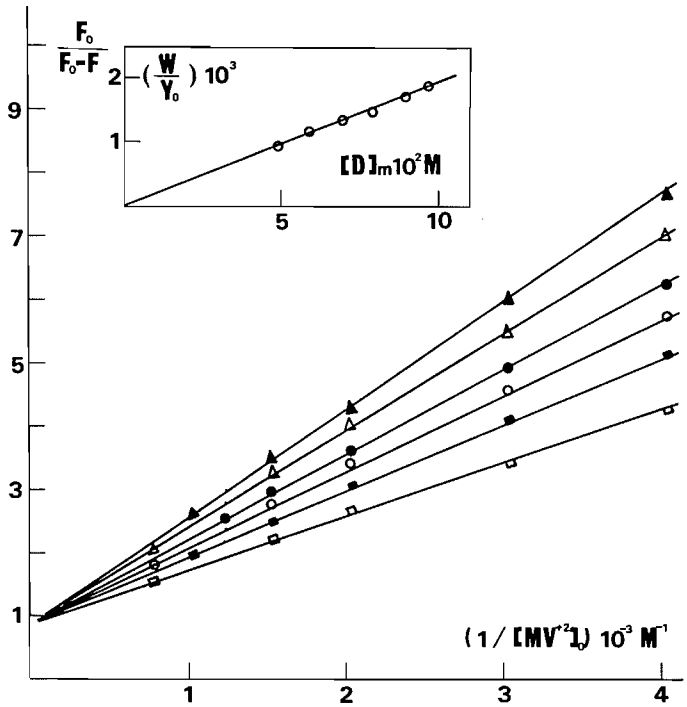

FIG. 5. Inverse of relative fluorescence intensity lowering as a function of inverse of quencher analytical concentration in micellar solutions of the following SDS concentrations: (□) 5×10^{-2} M; (■) 6×10^{-2} M; (○) 7×10^{-2} M; (●) 8×10^{-2} M; (△) 9×10^{-2} M; and (▲) 9.75×10^{-2} M. $r = [tS]_0/[M] = 0.03$. Inset: Ratio (slope/intercept) vs. micellized SDS concentration.

Stern–Volmer plots (Fig. 4, solid curves). Therefore we conclude that the only quenching process to occur is static quenching by formation of EDA complex in the micellar pseudophase. At low quencher concentrations, $[MV^{+2}]_0 (1 - Y_0) \ll W$ and the Stern–Volmer plots must be nearly linear, as observed for similar systems at lower MV^{+2} concentrations by Russell and Whitten (13, 14). They obtained a linear Stern–Volmer equation because they implicitly assumed $A_0 \ll 1$ (A_0 is tS absorbance before adding quencher), taking only the first-order term in the power series expansion for 10^{-A} in eq. [8]. This is equivalent to considering $Y_0 = 1$ in eq. [12], which thus yields a linear Stern–Volmer expression. Our reaction scheme satisfactorily explains the experimental results. This fact suggests that, in this particular system, micelles in which fluorophore and quencher are both present still yield emission if both molecules are not bound as an EDA complex. This, in turn, could be due to the existence of preferential sites inside the micelle. Each one of the reactants (tS and MV^{+2}) may be in two different sites, which are farther apart than the action sphere radius, so they do not interact to form an EDA complex. Another explanation may be that tS, being in equilibrium with the EDA complex, can fluoresce. This implies that the EDA complex formation rate constant is much lower than ($k_f + k_d$). We believe this latter to be the case, according to the reaction scheme presented.

Isomerization quantum yields

Stilbene isomerization, in the absence of oxygen, was studied under excitation of the EDA complex formed by cS and tS with MV^{+2} in ethanol and 0.1 M SDS. The same maximum irradiation time was used in all cases, but isomerization was observed only by photolysis of cS complex in SDS solution.

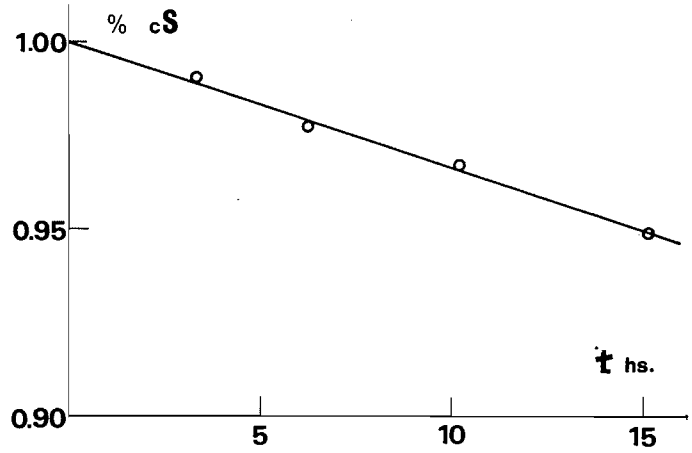

FIG. 6. Percentage of residual *cis*-stilbene as a function of irradiation time.

Quantum yield determination was made at low conversion (approximately 5%), thus not obtaining a photostationary state. Nevertheless, the lack of detectable isomerization of tS in SDS could indicate that the photostationary state that could be reached is almost completely on the side of the *trans* isomer.

Absolute quantum yield of isomerization (Φ_{cis}) was obtained through the equation:

$$[13] \quad \%cS = 100 - \frac{100\Phi_{cis} I_a}{[cS]_0} t$$

where %cS (= $[cS]/[cS]_0 \cdot 100$) is cS percentage remaining at time t, $[cS]_0$ is the analytical concentration of cS, and I_a is the light intensity absorbed by the EDA complex. The latter was determined by uranyl oxalate actinometry. Plotting eq. [13] (Fig. 6), the slope gives a value of $\Phi_{cis} = 0.012 \pm 0.002$.

The EDA complex photolysis to give stilbene isomerization products could occur either via the stilbene triplet state ($^3S^*$) or via the stilbene radical ($S^{+\cdot}$).

Isomerization of tS to cS by photolysis of charge-transfer complexes formed by tS with electron-poor alkenes has been proposed to occur via $^3tS^*$ (7, 27). Isomerization quantum yields for these systems show a strong dependence on solvent polarity and complex polarity (i.e., for tS/fumaronitrile complex $\Phi = 0.11$ in benzene, decreasing to $\Phi = 0.001$ in acetonitrile). The excited singlet state of the complex would lead either to $^3tS^*$ or to $tS^{+\cdot}$. Ion-pair formation from the excited complex is enhanced by increasing solvent polarity or exciplex polarity and so the isomerization quantum yield is lowered (27).

When isomerization is mediated by the stilbene radical cation, the formation of tS is heavily favoured (1, 5, 12). The $cS^{+\cdot}$ is believed to undergo rapid and essentially irreversible isomerization to $tS^{+\cdot}$ (1, 5).

In view of the above, we consider that our experimental observations are consistent with the intermediacy of the stilbene radical cation. This assumption can account for the lack of detectable isomerization in photolysis of the tS complex in both ethanolic and micellar solution, since the more stable $tS^{+\cdot}$ would not isomerize to $cS^{+\cdot}$. In the case of the cS complex, the lack of photoisomerization in ethanol could be due to ion-pair recombination in the solvent cage, which thus would inhibit subsequent isomerization from $cS^{+\cdot}$ to $tS^{+\cdot}$. Anionic micelles like SDS, however, could stabilize the intermediate $cS^{+\cdot}$, leading to the isomerization product tS. This stabilization effect

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

has already been observed for radical ions in micellar solutions (22). Micelles would thus play a catalytic role in the isomerization process. Even when the isomerization quantum yield in SDS, $\Phi_{cis} = 0.012$, is not high, comparison of this value with the near-zero value observed in homogeneous ethanolic solution indicates the occurrence of micellar catalysis.

Acknowledgments

We wish to thank CONICOR (Provincia de Córdoba) and CONICET (República Argentina) for financial support. We are gratefully indebted to M. V. Bohorquez (Indiana Radiation Laboratory, U.S.A.) for estimating the tS lifetime in SDS micelles.

Obtention de nouveaux squelettes diterpéniques lors de l'isomérisation d'époxydes diterpéniques sur alumine active

MARTINE TARAN[1] ET BERNARD DELMOND[2]

Laboratoire de chimie organique et organométallique, Unité associée n° 35 du Centre national de la recherche scientifique, Institut du Pin, Université de Bordeaux I, 351, cours de la Libération, 33405 Talence CEDEX, France

Reçu le 5 juin 1987[3]

MARTINE TARAN et BERNARD DELMOND. Can. J. Chem. **66**, 1558 (1988).

L'isomérisation d'époxydes diterpéniques sur alumine neutre active a permis de mettre en évidence des transpositions nouvelles du squelette diterpénique de base. Nous obtenons à partir de l'époxy-8,14β sandaracopimarate de méthyle des composés diterpéniques bicycliques par fragmentation de Grob, des dérivés à squelette cleistanthane par migration-1,2 du groupe vinyle, ainsi qu'un composé cycloditerpénique. Les dérivés époxy-7,8 et -8,9 de l'isopimarate de méthyle conduisent essentiellement à des hydroxy-oléfines provenant d'un mécanisme bifonctionnel acide–base à la surface de l'alumine.

MARTINE TARAN and BERNARD DELMOND. Can. J. Chem. **66**, 1558 (1988).

The isomerization of diterpene epoxides on active neutral alumina has established the existence of new rearrangements of the diterpene skeleton. Methyl 8,14β-epoxysandarcopimarate leads to bicyclic diterpene compounds by a Grob fragmentation, to derivatives of cleistanthane by a 1,2 migration of the vinyl substituent, as well as to one cycloditerpene compound. The 7,8 (or 8,9) derivatives of methyl isopimarate lead essentially to hydroxyolefins formed by a bifunctional acid–base mechanism at the alumina surface.

Il a été noté par divers auteurs (1–7) que, lors de la purification d'époxydes par chromatographie en phase liquide sur alumine ou sur silice, on constate parfois la perte totale de l'époxyde et l'obtention de produits d'isomérisation.

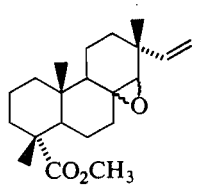
Ces observations ont par la suite été mises à profit pour analyser le comportement de certains époxydes terpéniques (8–13) vis-à-vis de ces supports solides.

Les conditions expérimentales sont très variées : agitation à température ambiante de l'époxyde en présence de support solide (8, 9), traitement prolongé à haute température (200–280°C) (14, 15), utilisant de quantités catalytiques du support solide à ébullition du toluène (16–21), dopage par la soude et les halogénures alcalins (13) ou divers autres réactifs (22).

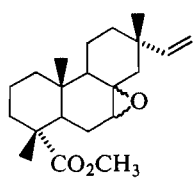
Ayant observé au cours de travaux antérieurs (23) que certains époxydes diterpéniques s'isomérisaient partiellement au cours de leur séparation sur colonne d'alumine active, le protocole expérimental qui consiste à agiter l'époxyde en présence du support solide à température ambiante nous a semblé le plus approprié pour être appliqué aux époxydes diterpéniques.

Peu de travaux (24–26) ont à ce jour été entrepris concernant l'étude de la réactivité de tels époxydes vis-à-vis de l'alumine ou de la silice; les plus détaillés sont ceux d'ApSimon et Hall (26).

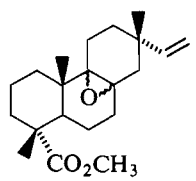
Nous décrivons dans ce mémoire le comportement vis-à-vis de l'alumine des époxy-8,14 sandaracopimarate de méthyle (**1** et **2**), et des époxy-7,8 (**3**, **4**) et -8,9 (**5**, **6**) isopimarate de méthyle.



1 époxy-8,14β
2 époxy-8,14α



3 époxy-7,8β
4 époxy-7,8α



5 époxy-8,9β
6 époxy-8,9α

Chacun de ces époxydes en solution dans du cyclohexane est agité à température ambiante avec de l'alumine neutre active. La récupération des produits de la réaction est réalisée après filtration et lavage de l'alumine avec successivement de l'éther et un mélange éther/méthanol.

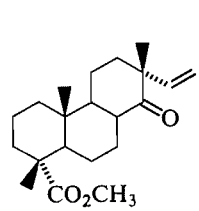
Résultats

1. *Époxy-8,14 sandaracopimarate de méthyle **1** et **2***

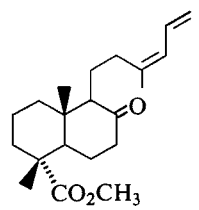
Le traitement de *l'époxy-8,14β sandaracopimarate de méthyle* **1** par de l'alumine neutre active dans les conditions standards précédemment définies conduit à l'obtention d'un mélange de composés carbonylés (18%) et de composés hydroxylés (56%).

La fraction constituée par les dérivés carbonylés se compose des cétones **7** (2%) (27) et **8** (11%) et de l'aldéhyde **9** (5%).

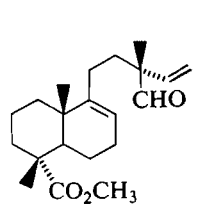
Les derivés carbonylés **8** et **9** sont des composés nouveaux, dont nous avons déterminé les structures au moyen de leurs caractéristiques physicochimiques.



7



8



9

Dans le spectre de rmn ^1H du composé **8** on observe à champ faible un ensemble de signaux correspondant à 4 protons éthyléniques, dont l'analyse montre qu'il se compose d'un système ABX dû à un groupe vinyle (AB entre 4,89 et 5,20 ppm, X entre 6,27 et 6,69 ppm) et d'un proton éthylénique (H_m) résonnant sous forme d'un doublet (J = 11 Hz) à δ 5,89 ppm et couplé avec H_x.

Ces données sont compatibles avec la structure partielle suivante :

	133,6 (C-15)	133,1	CH	C-15
	126,4 (C-14)	127,3	CH	C-14
	135,5 (C-13)	139,4	C	C-13
	25,9 (C-17)	23,5	CH_3	C-17

L'analyse des spectres de rmn ^{13}C de ce composé qui indique la présence de deux doubles liaisons (mono et trisubstituées) et d'un groupe cétonique permet d'envisager une structure bicyclique pour ce composé (28).

Nous avons pu préciser cette structure au moyen de la rmn ^{13}C en examinant les valeurs des déplacements chimiques observés pour chaque carbone ainsi que leur multiplicité avec ceux de trois composés modèles **A** (31), **B** (32) et **C** (tableau 1).

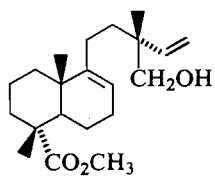
L'ensemble conjugué de ces données nous a donc permis de proposer la structure **8** pour ce dérivé carbonylé.

La configuration (*Z*) de la double liaison C13—C14 a été précisée au moyen de la rmn ^{13}C. Nous avons pu localiser à δ 23,5 ppm le groupe méthyle CH_3-17 porté par cette double liaison. Cette valeur est compatible avec une disposition *cis* entre ce groupe et l'hydrogène H-14 (29).

La spectrométrie de masse nous a également permis de confirmer la position de la chaîne latérale en C-9. La présence d'une fonction aldéhydique dans le composé **9** est déduite de l'analyse du spectre ir ($\nu_{C=O}$ 1710 cm^{-1}, ν_{C-H} 2720 cm^{-1}) et du spectre de rmn ^1H (singulet à δ 9,44 ppm).

Dans le spectre de rmn ^1H de ce composé on observe à champ faible, outre les signaux correspondant au système ABX caractéristique du groupe vinyle, un singulet élargi à δ 5,24 ppm attribuable à un proton éthylénique.

Ce composé étant particulièrement instable, l'étude par rmn ^{13}C a été réalisée sur l'alcool correspondant **10**:

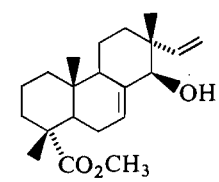


10

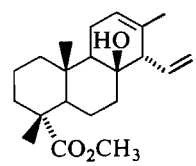
L'examen des spectres de rmn ^{13}C de ce composé confirme la nature primaire de l'alcool (triplet à δ 70,1 ppm), la présence d'une double liaison trisubstituée (singulet à δ 147,4, doublet à 119,2) et permet d'envisager une structure bicyclique pour ce composé, de même pour l'aldéhyde dont il dérive.

La spectrométrie de masse réalisée sur l'aldéhyde **9** nous a permis de positionner la double liaison en -8,9 et la chaîne latérale en C-9.

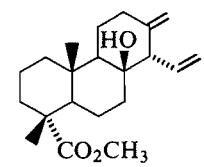
La fraction constituée par les composés hydroxylés se compose des hydroxy-oléfines **11** (43%) (23), **12** (2%), **13** (1%) et **14** (10%).



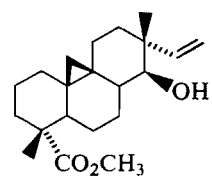
11



12



13



14

Le spectre de rmn ^1H du composé **12** révèle la présence d'une signal faiblement couplé à δ 1,62 ppm attribuable à un méthyle porté par une double liaison. On observe d'autre part à champ faible entre δ 4,92 et 5,80 ppm un ensemble de signaux correspondant à 4 protons ethyléniques se décomposant en un système ABX (—CH=CH_2) et en un proton éthylénique H_y résonnant vers δ 5,56 ppm. Une expérience de double irradiation montre que le proton H_x du système précédent est couplé (J = 9 Hz) avec un proton H_d résonnant sous la forme d'un doublet à 2,23 ppm. Ces données sont compatibles avec la structure partielle suivante **D**:

D

Les spectres de rmn ^{13}C du composé **12** indiquent la présence de deux doubles liaisons (mono et trisubstituée) et précisent la nature tertiaire de la fonction alcool (singulet à δ 72,5 ppm) que nous localisons en C-8, ce qui est confirmé par spectrométrie de masse.

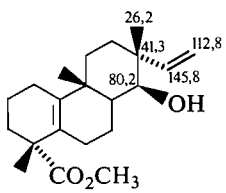
Le spectre de rmn ^1H du composé hydroxylé **13** revèle à champ faible un multiplet (2H) à 4,82 ppm compatible avec la présence d'un méthylène exocyclique ($\rangle C{=}CH_2$) et des signaux entre δ 5,00 et 6,22 ppm correspondant au système vinylique (—CH=CH_2).

Par analogie avec le composé précédent, et d'après l'ensemble des données, nous proposons la structure **13** pour ce dérivé.

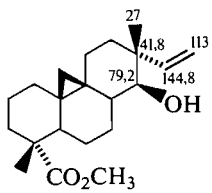
Dans le spectre de rmn ^1H du composé **14** on note comme principales caractéristiques : un singulet élargi à 3,20 ppm ($W_{1/2}$ = 4 Hz) correspondant à un proton en α d'un groupe hydroxyle et deux doublets à δ 0,11 et 0,92 ppm constituant un système AB (J = 4 Hz) attribuable à deux protons géminés situés sur un cycle cyclopropanique.

Nous observons d'autre part un effet significatif (blindage de 4,5 ppm) sur le déplacement chimique du CH_3-17, attribué à une interaction γ-*gauche* entre ce groupement méthyle et le groupe hydroxyle (30).

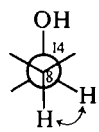
Ceci permet d'une part de localiser le groupe hydroxyle en C-14 et de proposer une configuration β pour celui-ci, par comparaison avec le composé **15**.



15

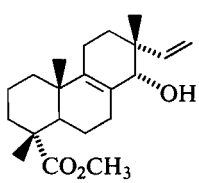


14

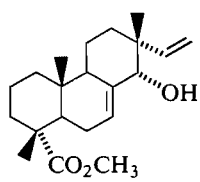


Nous avons pu noter d'autre part tant en rmn ^1H qu'en rmn ^{13}C l'absence de tout signal correspondant à la résonance du groupe méthyle CH_3-20, ce qui nous permet de localiser le pont cyclopropanique entre C-9 et C-10.

L'isomérisation de *l'époxy-8,14α sandaracopimarate de méthyle* **2** sur alumine active s'effectue avec un rendement de 84% en produits isolés après chromatographie. Il s'agit des composés carbonylés **7** (2%) et **9** (2%) obtenus et décrits précédemment et des composés hydroxylés **16** (20%) et **17** (60%).



16

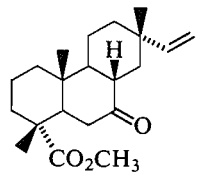


17

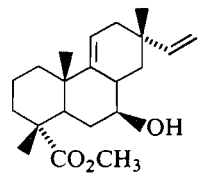
Le comportement de cet époxyde est tout à fait conforme aux résultats obtenus par ApSimon (26, 31).

2. *Époxy-7,8 isopimarate de méthyle* ***3*** *et* ***4***

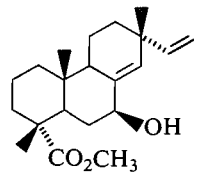
Le traitement de *l'époxy-7,8β isopimarate de méthyle* **3** par l'alumine neutre active conduit à l'obtention d'un composé majeur, la cétone **18** (40%) (32), et à un mélange des composés hydroxylés **19** (4%) (32), **20** (5%) et **21** (8%).



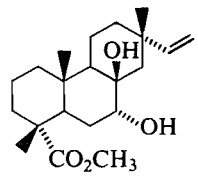
18



19

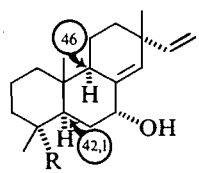


20

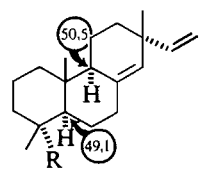


21

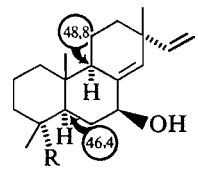
La structure du composé **20** et en particulier la stéréochimie du groupe hydroxyle en C-7 ont été précisées au moyen de la rmn ^{13}C par la comparaison des déplacements chimiques de ce composé avec ceux du sandaracopimarate de méthyle (3) et de son épimère **23** (23).



23

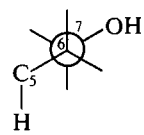


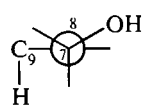
22



20

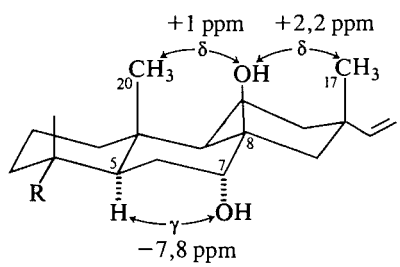
R = —CO_2CH_3



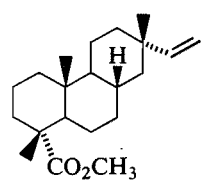


Nous observons en particulier sur les carbones C-5 et C-9 situés en γ par rapport au groupe hydroxyle des effets à champ fort plus faibles que ceux notés pour le composé épimère **23**. Cette tendance implique donc une interaction γ-*anti* entre le groupe hydroxyle et H-5 et H-9, ce qui nous permet d'attribuer une configuration β pour le groupe hydroxyle en C-7 dans l'alcool **20**.

Dans le spectre de rmn ^{13}C du composé hydroxylé **21** on note à δ 75 ppm la superposition de 2 signaux (CH et C) dus à deux carbones porteurs d'un groupe hydroxyle. La position de ces deux groupes hydroxyles et leur orientation respective ont été déduites de l'analyse des effets caractéristiques observés en rmn ^{13}C par comparaison avec le dihydroisopimarate de méthyle **24**, composé modèle.



21



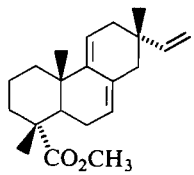
24

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

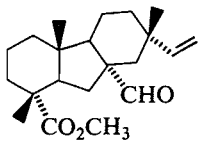
En effet nous observons :

(*i*) sur le carbone C-5 un effet à champ fort important (−7,8 ppm). Son amplitude est compatible avec une interaction γ-gauche entre H-5α et OH, ce qui implique une configuration α pour le groupe hydroxyle en C-7.

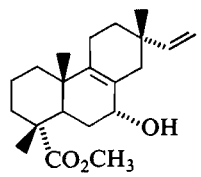
(*ii*) sur les carbones CH_3-17 et CH_3-20 des déblindages significatifs (+2,2 ppm et +1 ppm) qui découlent d'interactions δ *syn*-axiale entre ces carbones et le groupe hydroxyle en C-8, ce qui entraîne une configuration γ pour le groupe hydroxyle en C-8.



25



26



27

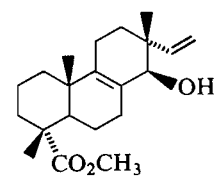
L'isomérisation de *l'époxy-7,8α isopimarate de méthyle* **4** par l'alumine neutre active conduit à un mélange constitué du triène **25** (2%), des dérivés carbonylés **18** (9%) et **26** (10%) et des hydroxy oléfines **23** (37%) et **27** (29%).

Les composés **25**, **18**, **26** et **23** ont été décrits dans un travail précédent (32). Le seul composé nouveau qui apparaît au cours de cette réaction est l'hydroxy-oléfine **27** dont la structure a pu être précisée au moyen de son analyse physicochimique.

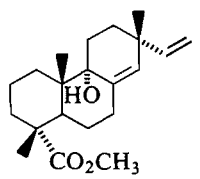
3. *Époxy-8,9 isopimarate de méthyle* **5** *et* **6**

L'époxy-8,9β isopimarate de méthyle **5** est relativement stable vis-à-vis de l'alumine, puisque dans les conditions standards on récupère 30% d'époxyde n'ayant pas réagi. Les produits obtenus et identifiés au cours de cette réaction sont essentiellement le triène **25** (24%) et l'hydroxy-oléfine **28** (4%) (23, 33).

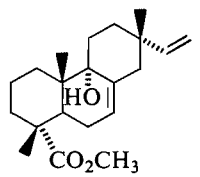
L'isomérisation de *l'époxy-8,9α isopimarate de méthyle* **6** conduit au triène **25** (24%) et à un mélange des hydroxy-oléfines **29** (28%) (4) et **30** (23%).



28



29

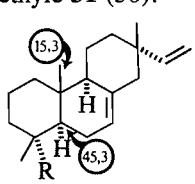


30

La nature tertiaire de l'hydroxy-oléfine **30** est précisée grâce à la rmn ^{13}C (singulet à δ 74,4 ppm). La présence d'une double liaison trisubstituée est également confirmée (singulet à δ 136,1 et doublet à δ 125,2 ppm).

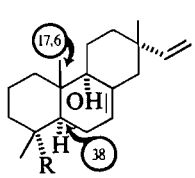
Dans le spectre de rmn ^{13}C enregistré selon la technique de découplage «off resonance» à faible puissance, seulement deux des carbones tétrasubstitués sp^3 sont en position de couplage longue distance (^2J,^3J) avec des protons éthyléniques, ce qui est compatible avec la position de la double liaison en 7-8.

Nous avons pu préciser la configuration du groupe hydroxyle au moyen de la rmn ^{13}C, en comparant les valeurs des déplacements chimiques mesurés avec ceux de l'isopimarate de méthyle **31** (30).

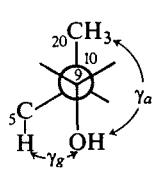


31

R = $-CO_2CH_3$



30



On observe deux effets significatifs : d'une part un effet à champ fort sur C-5 dû à une interaction γ-*gauche* H5/OH; et un effet à champ faible sur CH_3-20, dû à une disposition γ-*anti*, transmis par un hydroxyle tertiaire (7, 8).

Ces deux effets permettent donc de localiser le groupe hydroxyle en C-9 et de proposer une orientation α.

Discussion

La réactivité des époxydes vis-à-vis de l'alumine est attribuée à son caractère bipolaire (34–36) : elle possède à sa surface des sites électroaccepteurs de type acide de Lewis et des sites électrodonneurs.

L'obtention des différents composés fonctionnels met en jeu deux types d'intermédiaires (37) :

(*i*) la formation *d'alcools allyliques* qui s'explique par le caractère *bifonctionnel acide/base* du support.

(*ii*) le passage par une *espèce carbocationique* qui peut être responsable de l'obtention de *dérivés carbonylés* et de *diols*.

La plupart des composés que nous avons obtenus au cours de ces réactions peuvent s'expliquer en faisant intervenir ces deux types de mécanismes.

Ainsi, à partir de l'époxy-8,14β sandaracopimarate de méthyle **1**, on peut envisager l'intervention d'espèces carbocationiques.

Après adsorption de l'oxygène époxydique sur un site acide de l'alumine, l'ouverture du cycle époxydique peut conduire, selon le sens de la rupture à la formation de deux espèces carbocationiques.

(*i*) La rupture de la liaison C8—O conduit au carbocation **1***a* (schéma 1).

La migration de l'ion hydrure H-14α vers le carbone C-8 est à l'origine de la formation de la cétone **7** (voie 1).

La migration de l'hydrure H-9α pour stabiliser le carbocation en C-8 fait apparaître un carbocation tertiaire en C-9 **1***b* en position 1,3 par rapport à l'atome d'oxygène, disposition favorable à une réaction de Grob (38). Le carbocation **1***b* subit ainsi une fragmentation conduisant à l'aldéhyde éthylénique bicyclique **9** (voie 2).

(*ii*) La rupture de la liaison C14—O (schéma 2) fait apparaître un carbocation secondaire **1***c* qui peut se stabiliser par migration du groupe vinyle pour donner le carbocation tertiaire **1***d*.

Celui-ci peut évoluer soit par élimination 1,2 d'un atome d'hydrogène (H-12 ou H-17) conduisant alors aux alcools éthyléniques **12** et **13** (voie 1), soit par fragmentation de Grob à la formation de la cétone diénique **8** (voie 2).

Le mécanisme bifonctionnel acide–base, dans lequel nous avons une adsorption simultanée de l'oxygène époxydique sur un site acide situé à la surface du catalyseur et d'un hydrogène, convenablement disposé, sur un site basique permet d'expliquer la formation des composés hydroxylés **11** et **14** (schéma 3).

Ainsi, l'élimination de H-7 conduit au composé **11** (voie 1).

Par contre, si le site basique intervient au niveau des hydrogènes du méthyle angulaire C-20 on obtient selon un mécanisme concerté la formation d'un cycle cyclopropanique, par migration de H-9α et ouverture du noyau oxiranne pour aboutir à l'alcool **14** (voie 2).

Le mécanisme réactionnel que nous proposons pour expliquer la formation du dérivé cycloditerpénique **14** présente une certaine analogie avec celui qui intervient dans le schéma de biosynthèse du cycloarténol décrit par Goodwin et coll. (39).

L'époxy-8,14α sandaracopimarate de méthyle **2** est particulièrement sensible au contact de l'alumine. Cette instabilité

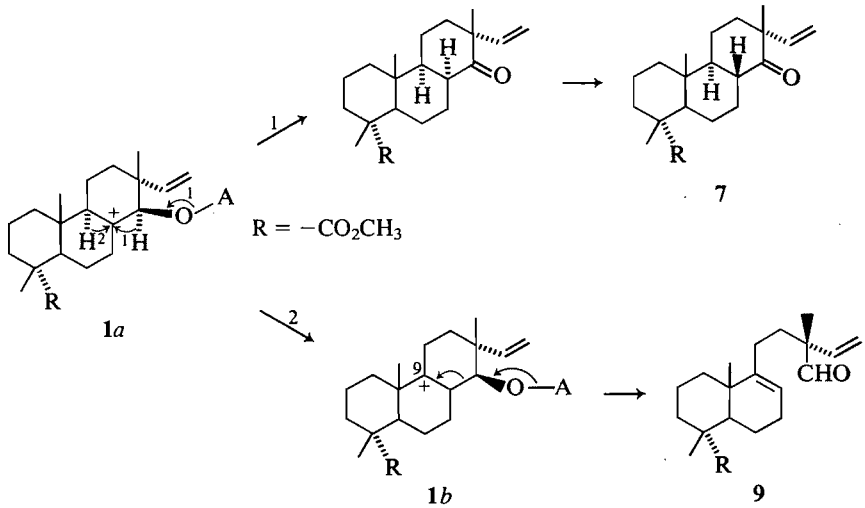


SCHÉMA 1

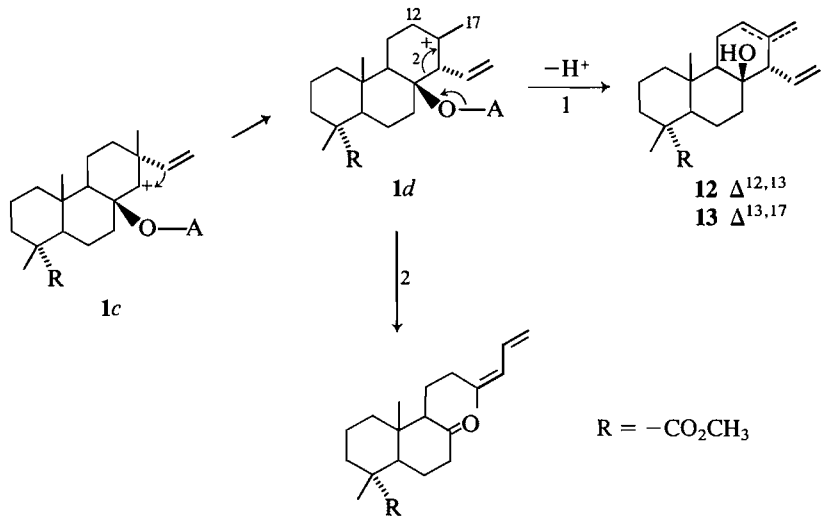

SCHÉMA 2

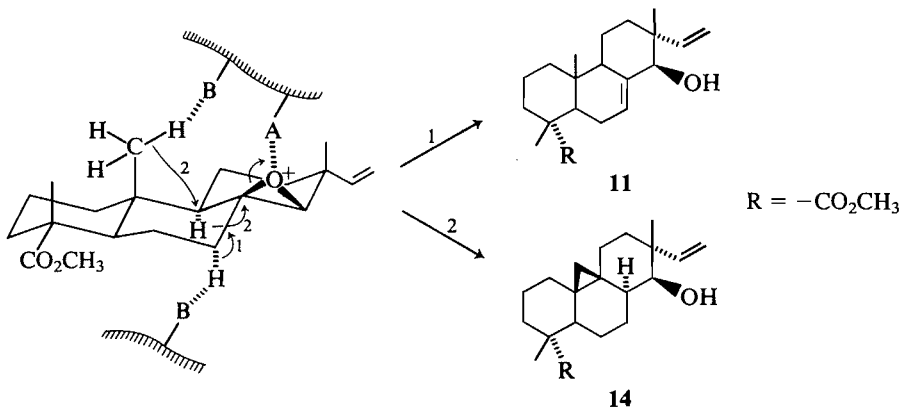

SCHÉMA 3

provient de la configuration du cycle époxydique qui entraîne une jonction de cycles B/C *cis*.

Nous obtenons essentiellement des alcools allyliques, **16** et **17**, dont on peut envisager la formation par une élimination 1,2 respectivement de H-9 et H-7.

À partir des époxy-7,8 isopimarates, la formation des dérivés carbonylés **18** et **26** peut s'expliquer par des mécanismes faisant intervenir des carbocations en C-8.

Ainsi à partir de l'isomère époxydique de configuration β, le carbocation en C-8 (schéma 4) formé par rupture de la liaison

SCHÉMA 7

C8—O se stabilise par migration de H-7 vers C-8 conduisant ainsi à la cétone thermodynamiquement instable (jonction B/C *cis*), qui s'épimérise au contact de l'alumine, comme nous l'avons vérifié précédemment.

Par contre, à partir de l'isomère époxydique de configuration α (schéma 5) l'ouverture de la forme complexée conduit à l'intermédiaire carbocationique **4***a* en C-8 dans lequel les deux liaisons C6—C7 et C7—H occupent des positions favorables pour migrer vers C-8. On obtient alors les deux composés carbonylés **18** et **26**.

La mise en jeu d'un mécanisme bifonctionnel acide/base permet par contre d'expliquer la formation des hydroxy-oléfines **19** et **20** (schéma 6).

Il en est de même à partir de l'isomère époxydique de configuration α, l'élimination des hydrogènes H-14α et H-9α permettant d'expliquer la formation respective des alcools allyliques **23** et **27**.

Par contre, une autre possibilité d'évolution de l'époxyde β est l'ouverture avec la création d'un centre carbocationique en C-7 (schéma 7). On peut admettre que cet intermédiaire, éventuellement stabilisé par les sites basiques de l'alumine, subisse une attaque par une espèce nucléophile présente dans le milieu. Il a été montré (37) que 10% d'ions OH^- demeurent à la surface de l'alumine. L'attaque du côté opposé par la surface de l'alumine elle-même conduira donc au glycol *trans*.

En ce qui concerne les époxy-8,9 isopimarates **5** et **6**, nous n'avons pas observé la formation de dérivés carbonylés, contrairement aux réarrangements avec l'éthérate de trifluorure de bore (33). Nous mettons en évidence des hydroxy-oléfines dont la formation fait intervenir une élimination 1,2 selon un mécanisme bifonctionnel.

Conclusion

Les réactions d'isomérisation des époxydes diterpéniques en présence d'alumine neutre active nous ont permis de mettre en évidence des transpositions nouvelles du squelette diterpénique.

Partie expérimentale

Les points de fusion *F* (°C) non corrigés ont été pris avec l'appareil de Kofler. Les spectres ir ont été enregistrés au moyen d'un spectrographe SP 200 soit en film, soit en solution dans le tétrachlorure de carbone. Les spectres de rmn ^1H ont été enregistrés avec un appareil Bruker WH-90. Les échantillons sont étudiés en solution dans $CDCl_3$ avec pour référence interne le tétraméthylsilane; les déplacements chimiques sont exprimés en unités δ (ppm); les abréviations utilisées sont s (singulet), se (singulet élargi), d (doublet), t (triplet), q (quadruplet), m (massif complexe). Les spectres de rmn ^{13}C sont enregistrés en solution dans $CDCl_3$ sur un appareil Bruker WH-60 fonctionnant à 15,08 MHz, les déplacements chimiques sont exprimés en ppm par rapport au TMS. Les attributions des déplacements chimiques des carbones sont réalisées en utilisant les techniques de découplage large bande et «off resonance». Les spectres uv ont été enregistrés sur un appareil Beckman 25 en solution dans l'éthanol.

Isomérisation des époxydes diterpéniques sur alumine active

Mode opératoire type

Les époxydes diterpéniques sont obtenus par époxydation au moyen de l'acide paranitroperbenzoïque des hydrocarbures éthyléniques correspondants (23).

L'époxyde diterpénique (3 mmol) en solution dans 30 mL de cyclohexane anhydre (séché sur tamis moléculaire 4 Å) est mis à agiter en présence de 25 g d'alumine neutre active (grade I) à température ordinaire pendant 15 h. Après filtration, l'alumine est lavée successivement avec de l'éther puis un mélange éther/méthanol (1:1). L'ensemble des phases organiques est réuni et concentré sous vide. Le résidu est ensuite soumis à une analyse par chromatographie en phase liquide sur colonne d'alumine neutre désactivée (6% H_2O).

Isomérisation de l'époxy-8,14β sandaracopimarate de méthyle 1

L'isomérisation de 1,805 g d'époxy-8,14β sandaracopimarate de méthyle **1** sur alumine active conduit, après séparation par chromatographie en phase liquide, à des composés carbonylés (18%) et à

The basic hydrolysis of diazepam and several *N*-alkyl nitrazepam derivatives has been studied in the presence of reactive counterion micelles of cetyltrimethylammonium hydroxide (CTAOH) and vesicles of didodecyldimethylammonium hydroxide (DDAOH). In both surfactants, the rate of hydrolysis of all compounds was found to be dependent on the hydroxide concentration at constant surfactant concentration and this was interpreted as evidence for initial amide hydrolysis. The hydrolysis in CTAOH was inhibited by added salts in the order $Br^- < NO_3^- < SO_4^{2-}$. At concentrations above 3 m*M* surfactant, the rate of hydrolysis of each compound was similar in CTAOH and in DDAOH. At lower concentrations of CTAOH, however, the rate of hydrolysis was significantly lower than that in DDAOH. On the basis of this evidence, it was concluded that the cmc of CTAOH was between 2–3 m*M*, which is in good agreement with the value of 1.8 m*M* obtained by Zana from conductivity measurements. For diazepam, a mechanistic change is indicated on transfer from water to either micelles or vesicles and since vesicles are considered good models of biological membranes, this suggests that conclusions concerning the bioavailability of diazepam should not be based on studies in water but rather on studies in either micelles or vesicles.

Opérant en présence de micelles réactives d'hydroxyde de cétyltriméthylammonium (CTAOH) ou de vésicules d'hydroxyde de didodécyldiméthylammonium (DDAOH), on a étudié l'hydrolyse en milieu basique du diazépam de plusieurs dérivés nitrazépam *N*-alkylés. Dans chacun de ces agents de surface, on a trouvé que la vitesse d'hydrolyse de chacun des composés dépend de la concentration en ion hydroxyde, à concentration d'agent de surface constante; on interprète ces résultats en fonction d'une hydrolyse initiale de l'amide. Dans le CTAOH, l'hydrolyse est inhibée par l'addition de sels, dans l'ordre suivant : $Br < NO_3^- < SO_4^{2-}$. A des concentrations en agent de surface plus grandes que 3 m*M*, les vitesses d'hydrolyse de chacun des composés sont semblables dans le CTAOH et dans le DDAOH. Toutefois, à des concentrations plus faibles en CTAOH, la vitesse d'hydrolyse est beaucoup plus faible que dans le DDAOH. En se basant sur ces résultats, on en conclut que la cmc du CTAOH s'établit entre 2 et 3 m*M*; ceci est en bon accord avec la valeur de 1,8 m*M* qui a été obtenue par Zana à l'aide de mesures de conductivité. Pour le diazépam, la passage de l'eau à des micelles ou à des vésicules provoque un changement de mécanisme; puisque les vésicules sont considérées comme de bons modèles des membranes biologiques, il est suggéré que les conclusions concernant la bio-disponibilité du diazépam ne devraient pas être basées sur des études dans l'eau mais plutôt sur des études dans des micelles ou dans des vésicules.

Introduction

Previous studies (1) of the basic hydrolysis of diazepam **1***a* in water and in micelles of cetyltrimethylammonium bromide (CTAB) have indicated a mechanistic change on transfer from water **1–3–4** to micelles **1–2–4**. On the other hand, for *N*-alkyl nitrazepam derivatives (**1***b–e*), hydrolysis is catalysed by micelles of CTAB but the mechanism (initial amide hydrolysis **1–2–4**) is the same in water and in the presence of micelles (Scheme 1).

Attempts to argue the biological relevance of these studies were hampered by the fact that micelles are poor models of biological membranes (2) because, although they have a polar exterior and a non-polar interior, they are composed of single chain surfactant molecules with only a single interface between the spherical aggregate and bulk water. Furthermore, micelles are dynamic species continually breaking up and reforming. Surfactant vesicles, on the other hand, are considered much better models of biological membranes (3) because, like membranes, they have a polar exterior and a non-polar interior and they are composed of double chain surfactant molecules arranged to form a bilayer.

For this reason, we have extended our studies to include the basic hydrolysis of benzodiazepinones in the presence of surfactant vesicles to determine if the mechanistic changes observed in micelles also occur in vesicles.

If similar behaviour is found in micelles and vesicles it should be reasonable to claim the biological relevance of our previous studies in micelles to reactions occurring in membranes. Vesicles formed from didodecyldimethylammonium hydroxide (DDAOH) are particularly suitable for this purpose. They are widely reported to form spontaneously on dissolving the solid (DDAOH) in water without the need for sonication or any other special treatment (4–6). Furthermore, the hydroxide ion required for basic hydrolysis of the substrate is provided by the reactive counterion surfactant.

To allow direct comparison between the vesicular studies and results obtained in micellar solution, the hydrolysis of substrates **1***a–e* was also studied in the presence of reactive counterion micelles of cetyltrimethylammonium hydroxide (CTAOH). The use of CTAOH rather than CTAB and NaOH avoids the added complication of competition between hydroxide and bromide ions for sites on the micellar surface. With both CTAOH and DDAOH, the only counterion present in solution is the hydroxide ion. We thus report our results for the first phase of hydrolysis of compounds **1***a–e* in CTAOH and in DDAOH in this paper.

Results and discussion

Previous studies (1) of the basic hydrolysis of diazepam **1***a* and nimetazepam **1***b* in the presence of micelles of CTAB have shown a biphasic reaction. This has now also been observed for hydrolysis of these compounds in micelles of CTAOH and vesicles of DDAOH. For nimetazepam **1***b* and for other *N*-alkyl nitrazepam derivatives **1***c–e*, the first phase was characterized by an increase in absorbance at 385–390 nm and an isosbestic point at 340 nm. For diazepam **1***a*, however, the first phase was characterized by an increase in absorbance at 252 nm. This large difference in λ_{max} for the first phase of hydrolysis of compound **1***a* and for the other compounds **1***b–e*, is due to the production of a *p*-chloroaniline chromophore **2***a* from compound **1***a*, but a *p*-nitroaniline chromophore **2***b–e* from all of the other compounds.

Rate constants for the hydrolysis of diazepam **1***a* in micelles of CTAOH and in vesicles of DDAOH are in Table 1. In both surfactants, it can be seen that the rate of hydrolysis increased with detergent concentration. In principle, this may be due either to an increase in the concentration of hydroxide ion or to an increase in the CTA/DDA concentration resulting in an increased proportion of reaction in the surfactant aggregate. However, for both surfactants, it can be seen that the rate of hydrolysis of **1***a* increased as the surfactant concentration was increased at constant total hydroxide concentration (0.1 *M*) and as the concentration of added NaOH was increased at constant surfactant concentration (12 m*M*).

Since amide hydrolysis is first order in hydroxide concentration in surfactant aggregates (7) while azomethine hydrolysis is independent of hydroxide concentration, the above results are consistent with initial amide hydrolysis **1***a* → **2***a* in both surfactant systems.

Rate constants for the basic hydrolysis of *N*-alkyl nitrazepam derivatives **1***b–e* in CTAOH and in DDAOH are in Table 2.

For all compounds, the rate of hydrolysis increased with surfactant concentration. As for diazepam, it was found that the rate of basic hydrolysis of nimetazepam **1***b* increased with added NaOH at constant surfactant concentration (3 m*M*) and also increased with detergent concentration at constant total hydroxide concentration (5 m*M*).

Thus, we conclude that the hydrolysis of nitrazepam derivatives involves initial amide hydrolysis (mechanism **1**–**2**–**4**). However, on looking closely at the results for the different *N*-alkyl nitrazepam derivatives in DDAOH, we find that the dependence of DDAOH concentration in the range 1–5 m*M* varies from a 2.5-fold increase for compound **1***e* to a 6-fold increase for compound **1***b*.

This variation in rate dependence on DDAOH concentration for compounds **1***b–e* could arise from a number of different sources, including a different blend of concurrent amide hydrolysis (which is dependent on base concentration) and azomethine hydrolysis (which is independent of base concentration) for each compound, but we favour different orientational effects for substrates **1***b–e* in the surfactant aggregates as a possible explanation for these differences.[3] It is noteworthy that the compounds bearing the hydrophobic alkyl groups (**1***d* and *e*), which may anchor the benzodiazepinone nucleus into the surfactant aggregates, experience the smallest increase in rate as the concentration of DDAOH is increased, while compound **1***b*, which has only the methyl group at N-1, experiences a larger increase in rate.

The presence of the hydrophobic alkyl chains at N-1 in

[3]We thank a referee for suggesting this alternative explanation.

compounds **1***d* and **1***e* may result in the penetration of the amide group more deeply into the non-polar region of the aggregate where it is less sensitive to changes in the bulk solution. For the methyl compound (**1***b*), it is possible that the phenyl group on C-5 will be the anchoring group resulting in the amide moiety residing at the interface and being more sensitive to changes in bulk solution.

In the presence of a constant concentration of CTAOH (3 m*M*), the rate of hydrolysis of compound **1***b* also showed a slightly greater dependence on hydroxide concentration (2.12-fold as the total hydroxide concentration was increased from 4–12 m*M*) than that for compound **1***d* (1.7-fold increase).

Salt effects

In CTAOH the addition of salts (e.g., KBr, KNO_3, or K_2SO_4) resulted in decreased rates of hydrolysis. This inhibitory effect may be caused either by a reduction of the hydroxide ion concentration in the surfactant aggregate caused by a less favourable exchange constant or by the exclusion of the substrate from the surfactant aggregate. The inhibitory effect for 10 m*M* added salt in 5 m*M* CTAOH increased in the order $Br^- < NO_3^- < SO_4^{2-}$ for all *N*-alkyl nitrazepams studied. The magnitude of inhibition for each salt was less for the most hydrophobic substrate **1***e* than for the other compounds. For example, the addition of 10 m*M* KBr resulted in a decrease in rate to 19% of that in the absence of KBr for compound **1***e* (i.e., 81% inhibition), to between 12–15% of the rate in the absence of KBr for the other compounds **1***b–d* (i.e., 85–88% inhibition). Although these differences (between compounds **1***b–e*) are small, it is interesting to note that the most hydrophobic compound (**1***e*) is affected least. This may indicate that the inhibition is due to the exclusion of the substrate molecule from the surfactant aggregate, but further work would be necessary to prove this point. In DDAOH, the addition of 10 m*M* salt caused precipitation of the surfactant. Only 5 m*M* KBr could be added without causing precipitation. As expected, 5 m*M* KBr resulted in significant inhibition (72%) of the rate of hydrolysis of compound **1***c* over the concentration range 1–5 m*M* DDAOH. A similar result (76% inhibition) was achieved with 5 m*M* KBr in 5 m*M* CTAOH.

Comparison of CTAOH and DDAOH

The rate of hydrolysis at 30.4°C in CTAOH (5 m*M*) was slightly greater (2–26%) than that in DDAOH (5 m*M*) at 29.4°C for all *N*-alkyl nitrazepam derivatives studied. For diazepam, however, the rate of hydrolysis in CTAOH (10 m*M*) was 33% less than in DDAOH (10 m*M*) at the same temperature. At 5 m*M* surfactant concentration, the magnitude of inhibition of the hydrolysis of compound **1***c* by the addition of 5 m*M* KBr was similar in CTAOH (76%) and in DDAOH (72%). In both surfactants, the rate of hydrolysis of both diazepam **1***a* and nimetazepam **1***b* was dependent on the surfactant concentration (at constant total hydroxide concentration) and on the hydroxide concentration (at constant surfactant concentration).
