[a]Initial concentration at room temperature.

solutions were degassed by means of three freeze–pump–thaw cycles before the tubes were sealed and immersed in constant temperature baths controlled to ±0.1°C.

Progress of the decomposition was monitored by ^1H nmr spectroscopy. For samples in methanol, the internal standard for normalizing integrals of all methyl signals of remaining **3** was the sum of integrals from all *tert*-butyl and methyl signals except for the propenyl methyl group signal of **19**, which was doubled before entry into the summation. For samples in benzene, the methyl group signal from added toluene was used as internal standard. Decompositions were followed to at least 80% and usually to more than 85% conversion. Good fits of the data to the first-order rate law were obtained. From the temperature dependence of the rate constant in methanol (Table 3) the activation parameters calculated were as follows: Arrhenius equation, $\log A = 13.6$, $E_a = 29.6$ kcal mol^{-1}; Eyring equation, $\Delta H^{\neq} = 29$ kcal mol^{-1}, $\Delta S^{\neq} = 1.5$ eu.

Lithiated carbanionic chelates α to P(O) groups are formed from four title compounds. Their infrared and ^{13}C and ^{31}P nuclear magnetic resonance spectra show that chelation induces peculiar structural perturbations that depend upon the nature of Y. The corresponding neutral precursors **1**–**4** are able to form bidentate coordinates with the Li cation, which can be observed in THF when Y = OMe or NMe_2 but in benzene only when Y = Me. They are probably intermediates in the lithiated base deprotonation of neutral compounds **1**–**4**.

TEKLA STRZALKO, JACQUELINE SEYDEN-PENNE, FRANÇOISE FROMENT, JACQUES CORSET et MARIE-PAULE SIMONNIN. Can. J. Chem. **66**, 391 (1988).

Les chélates anioniques lithiés en α d'un groupe P(O) sont formés à partir de quatre composés cités dans le titre. Leurs spectres infrarouge et résonance magnétique nucléaire du ^{13}C ou ^{31}P montrent que la chélation provoque des perturbations importantes du squelette organique qui dépendent de la nature de Y. Les précurseurs neutres **1**–**4** sont aptes à former des coordinats bidentés du cation lithium qui peuvent être mis en évidence dans le THF quand Y = OMe ou NMe_2 mais seulement dans le benzène quand Y = Me. Ceux-ci sont vraisemblablement les intermédiaires impliqués dans la déprotonation des composés **1**–**4** par les bases lithiées.

Phosphonates and phosphine oxides bearing a β-keto or a β-carbamoyl group $R_2P(O)CH_2COY$ are efficient extracting agents for heavy metal salts such as lanthanides (1, 2) and actinides (3–5). Their extracting ability is attributed to the formation of strong chelates between the two oxygens of the P=O and C=O bonds and the metal ions. During our previous studies on Wittig–Horner reagents we were able to show that neutral carbomethoxymethylphosphonate **1** can form, with the lithium cation, an analogous stable chelate (6), which can be an intermediate on the way to the anionic reagent.

$(EtO)_2P(O)CH_2COOMe$ **1**

It thus seemed worthy to examine whether such behaviour could also be observed with other P(O) related molecules, bearing β-keto or β-carbamoyl moieties. In the present work we report an nmr and ir study on the ability of ketophosphonate **2**, (dimethylcarbamoyl)methylphosphonate **3**, and carbomethoxymethyldiphenylphosphine oxide **4** to coordinate the lithium cation in tetrahydrofuran (THF) solution.

$(EtO)_2P(O)CH_2COMe$ **2**
$(EtO)_2P(O)CH_2CONMe_2$ **3**
$Ph_2P(O)CH_2COOMe$ **4**

We also examine the structure of the related lithiated anionic species in the same solvent, focusing our investigations on the modification of the organic framework in these systems, compared to that of the free neutral molecules.

Previous studies have been published on sodium (7) and magnesium (8) anionic chelates of **2** and on a sodium anionic chelate of the *N*-diethyl analog of **3** (9).

TABLE 1. Infrared frequencies and nuclear magnetic resonance chemical shifts for the neutral molecules in THF solution[a]

Parameter	2	3	1	4
ν(C2=O3)	1715	1652	1744	1738
ν(P=O)[b]	1260	1260	1268	1267
δ C2	199.3	164.8	166.7	167.8
δ C1	43.2	34.4	34.4	39.7
δ ^{31}P	19.6	20.9	19.6	21.9

[a]δ ^{13}C in ppm from internal Me_4Si; δ ^{31}P in ppm relative to external H_3PO_4 (85%). Positive δ values are in the direction of increasing frequency. ν in cm^{-1}.
[b]Mean value of the two components usually observed for this mode due to a Fermi resonance.

Results

The anionic species were generated from solutions of the neutral precursors in THF, using a slight excess of Bu"Li solution, under an inert and moisture-free atmosphere, as previously described for **1** (10) and **4** (11). The nmr and ir spectra of the solutions show the disappearance of the signals due to the neutral precursors (Table 1) and the total formation of carbanionic species, which coexist, as already discussed for **1** (6, 10), as monomeric chelated ion pairs (**AM**), aggregates $(\mathbf{AM})_n$, triple ions $(\mathbf{AMA})^-$, and free ions $(\mathbf{A})^-$ (Tables 2 and 3), in relative proportions depending on the concentration, where M stands for Li.

The carbanionic species, whatever their degree of association, will be designed $\mathbf{A}_1$, $\mathbf{A}_2$, $\mathbf{A}_3$, and $\mathbf{A}_4$ respectively.

TABLE 2. Infrared frequencies observed for the different anionic species formed in THF solution[a]

Frequency	A_2	A_3	A_1	A_4
ν(C2···O3)				
$(AMA)^-$		1591	1634	1630
(AM)	1530	(1528)	1594	1579
$(AM)_n$		1507	1578	1565
$(A)^-$			1525	1516
ν(P···O)				
(AM)	1197	1145	1185	1185
$(AM)_n$	1183			
ν(C1···C2)				
$(AM)_n$, (AM)	1431	1407	1376	1361

[a]In cm^{-1}, the total concentration is ≈0.25 M.

TABLE 3. Variations of the ir frequencies and nmr chemical shifts for the chelated ion pairs (AM) relative to the neutral parent molecule (THF solution)[a]

Parameter	(A_2M)	(A_3M)	(A_1M)	(A_4M)
$\Delta\nu$(C2=O3)	−185	−124	−150	−159
$\Delta\nu$(P=O)	−63	−115	−83	−82
$\Delta\delta$ C2	−13.0	10.2	9.0	6.7
$\Delta\delta$ C1	22.9[b]	7.4	6.6	5.0
$\Delta\delta$ ^{31}P	12.6	19.1	20.3	13.2

[a]Variations of ν or δ (ν or δ in (AM) minus ν or δ in the parent molecule); they are given in cm^{-1} or in ppm.
[b]This value is given in pyridine as solvent, the δ Cl for **2** being 43.5.

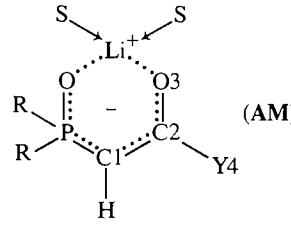
TABLE 4. Infrared frequencies and nuclear magnetic resonance chemical shifts for the intermediates (I) and their variations relative to the parent molecule (THF solution)[a]

Parameter	(I_2)	(I_3)	(I_1)	(I_4)
ν(C2=O3)	1687	1620	1675	1663
$\Delta\nu$	−28[b]	−32	−69	−75
δ C2		171.1	171.7	162.5
$\Delta\delta$		6.3	5.0	4.7
δ ^{31}P	30	16.3	28.5	33.2
$\Delta\delta$ ^{31}P	10.9[b]	−4.6	8.9	11.3

[a]Variations of ν or δ (ν or δ in (I) minus ν or δ in the parent molecule); they are given in cm^{-1} or in ppm.
[b]Benzene solutions (δ ^{31}P: 19.1 and 31.6 respectively for **2** and A_2).

When less than one equivalent of lithiated base was used to generate the anionic species from amide **3** and ester **4**, as well as from ester **1** (6), other sets of signals in the ^{31}P and ^{13}C nmr and other ir absorptions were observed: they were assigned, as in the case of **1** (6), to intermediates (I_3), and (I_4), in which neutral **3** or **4** act as ligands of a Li cation belonging to the different ionic species and coexist next to the neutral precursors (Table 4).

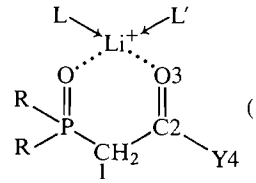
Thus L and L′ in (I) can be either the anionic part of (AM) or of $(AM)_n$, or solvent molecules; they could also be more or less aggregated Bu^{n}Li when present in the medium.



(AM)

(A_1M): R = EtO, Y = OMe
(A_2M): R = EtO, Y = Me
(A_3M): R = EtO, Y = NMe_2
(A_4M): R = Ph, Y = OMe

The same intermediates could also be observed by addition of neutral molecules to solutions of related anionic species, although their formation was slow in the amide case. However, from ketone **2**, we were not able to detect the signals corresponding to such (I_2) entities in THF, whatever the method used (Fig. 1, curve b). Interestingly, the corresponding signal could be observed using a solvent that poorly solvates the Li cation, i.e., in benzene solution when adding 0.4 equivalent of lithiated base to **2** (Table 4).



(I)

(I_1): R = EtO, Y = OMe
(I_2): R = EtO, Y = Me
(I_3): R = EtO, Y = NMe_2
(I_4): R = Ph, Y = OMe

To evaluate the relative stabilities of the anionic species and of the various intermediates, competition experiments were run: to solutions of the different carbanionic species **A**, increasing amounts of the other neutral compounds were added. Some of these experiments are illustrated in Figs. 1–3. The salient features of the spectra of such mixtures are the following:

(*i*) Concerning the ketophosphonate system, carbanionic species A_2 is always the predominating species, next to neutral **1** or **3**, whether A_2 is preformed (Fig. 1) or if neutral ketone **2** is added to a solution of carbanionic ester A_1 or amide A_3 (Fig. 3). In these solutions, intermediates (I_1) or (I_3) (Fig. 2) can also be observed. In all cases, equilibrium is quickly reached.

(*ii*) When ester **1** is added to a solution of carbanionic amide A_3 (Fig. 3), three species (A_1, A_3, and neutral **3**) coexist in slow exchange next to small amounts of intermediates (I_1) and (I_3). However, when adding neutral amide **3** to a solution of A_1 (Fig. 2), very small amounts of carbanionic species A_3 and of free ester **1** are seen; A_1 and **3** are the predominant species. In all cases, the amount of intermediates (I) is never greater than 20%.

Discussion

Neutral molecules 1–4

The ir spectra of the neutral molecules (Table 1) indicate that the keto and amide groups in **2** and **3** behave very similarly to the related ones in the unsubstituted aliphatic series: the main vibrations either of the $COCH_3$ group or of the $CONMe_2$ group are located at very close frequencies in both types of molecules. For instance, in THF, the ν(C2—N) frequency is located at 1410 cm^{-1} in $MeCONMe_2$ and at 1420 cm^{-1} in **3**. Esters **1** and **4** behave slightly differently as the ν(C2—O4) frequency is observed at 1118 cm^{-1} and 1121 cm^{-1} in **1** and **4** respectively instead of at 1248 cm^{-1} as in CH_3COOMe (12), thus showing a lengthening of this bond in **1** and **4** related to methyl acetate. It is known that the preferred conformation of methylacetate is *s-cis* (12); on the other hand, in a polar environment, ^{t}butyl formate adopts a predominating *s-trans* conformation, which corresponds to an ir ν(C—O) vibration at 1159 cm^{-1} (13). Intramolecular dipole interactions between the PO and COOMe moieties in THF might also induce an *s-trans* conformation of the ester group in neutral **1** and **4** as suggested by the value of the ν(C2—O4) elongation vibration. Assuming that, as in the case of malonates (14), the P=O and C=O bonds lie in approximately orthogonal planes, the conformations of neutral **1** and **4** should be represented by **5**.

5

The ^{13}C chemical shifts of C1 in neutral molecules is in the expected range, related to unsubstituted analogs: replacement of a hydrogen in $(MeO)_2P(O)CH_3$ by a $COCH_3$ group induces a $\simeq +30$ ppm downfield shift similar to the difference between ethane and ethylmethylketone (15). A similar observation holds for the esters ($\simeq$22 ppm downfield shift).

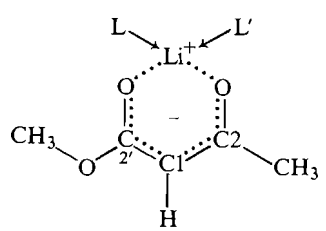
Carbanionic lithiated chelates (**AM**) (Tables 2 and 3)

The structure of externally solvated monomeric species (**AM**) will be the only one discussed.

The chemical shifts variations of C1 and C2 in A_1, A_2, and A_4 related to **1**, **2**, and **4**, may be compared to those of lithium enolates related to the corresponding neutral precursors: C1 moves downfield from a ketone or an ester to their lithium enolates in THF by +50 and +36 ppm respectively, while C2 suffers a −44 or −3 ppm upfield shift (16). In our series, the variations are quite different: $\Delta\delta C1 = +22.9$ and $\simeq +5$ ppm in the keto and ester cases respectively. Those of C2, $\Delta\delta C2 = -13$ and $\simeq +8$ ppm, are, however, in the same range as observed in methylacetoacetate (17) and the related lithium chelate **6** (18) for which $\Delta\delta C2 = -13.3$ ppm and $\Delta\delta C2' = +4.4$ ppm.

In both cases, the shielding of the C2 ketocarbonyl and the deshielding of the C2′ ester reflect the electron-donating ability of the ester's extra heteroatom. Therefore, the formation of anionic lithiated bidentates induces a similar modification of the electronic distribution around the C2 or C2′ atoms as expressed by the ^{13}C chemical shift variations, whatever the group located in the position β to the carbonyl moiety—in the present cases either C_{sp^2} O or P^{IV} O. The chemical shift of C2 in the lithiated amide A_3 (δ = 175 ppm) is very close to that in A_1 (δ = 175.7 ppm) and in the corresponding sodium derivative (9).

The chemical shift variations of C1 in these systems ($\Delta\delta$ = +22.9 and +5–7 ppm) as well as in **6** ($\Delta\delta$ = +10 ppm) reflect



6

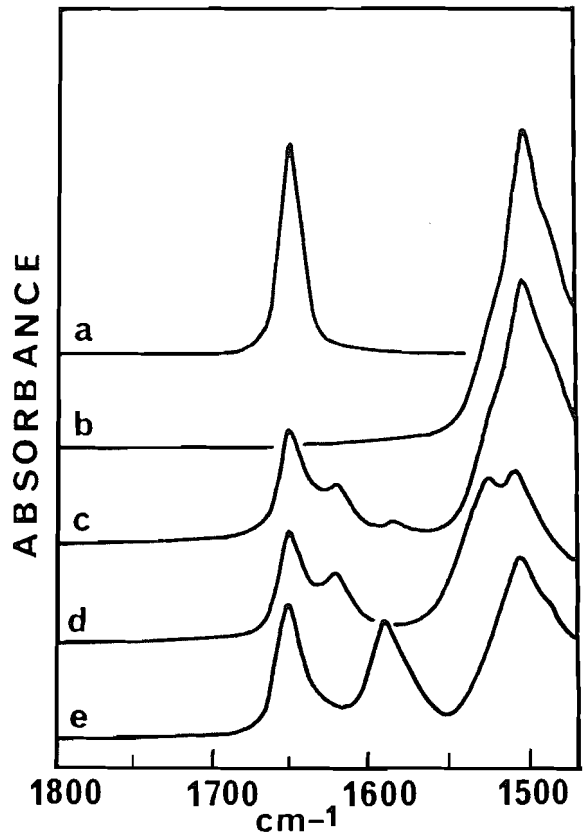


FIG. 3. Infrared spectra of carbamoylmethylphosphonate **3** (a), anionic species A_3 (b), and mixtures of A_3 with **3** (c), A_3 with **2** (d), and A_3 with **1** (e) in THF solution. (a) **3** 0.15 M; (b) A_3 0.21 M; (c) A_3 0.21 M + **3** 0.10 M; (d) A_3 0.21 M + **2** 0.10 M; (e) A_3 0.21 M + **1** 0.06 M.

two phenomena: the hybridization change from sp^3 to sp^2, which induces a large downfield shift, and the development of a negative charge, which increases the shielding. The resulting effect will depend upon the charge repartition: the experimental results suggest that the negative charge density on C1 is greater in chelated structures than in monodentate enolates. This effect can be due to the number and the strength of the oxygen lithium interactions in both types of species. Again, the presence on C2 of an extra heteroatom (Y = OMe or NMe_2) induces, as for C2, a stronger shielding of C1.

From the ir, the weakening of the C2=O3 bond in chelates (A_1M), (A_2M), and (A_4M) relative to that of **1**, **2**, and **4** is less important than in the case of acetylacetone or acetylacetonate (19). However, there is a noticeable difference in $\Delta\nu$(C2=O3) according to the nature of Y: when Y = Me, for (A_2M): $\Delta\nu = -185\ cm^{-1}$, the lengthening of this bond is the greatest in relation to a high ν(Cl···C2) frequency (1431 cm^{-1}). The $\Delta\nu$(C2=O3) decreases from (A_2M) to (A_1M): (−150) and (A_4M) (Y = OMe: $-159\ cm^{-1}$) and to (A_3M) (Y = NMe_2: $-124\ cm^{-1}$). These observations are strengthened by the value of ν(C2—O4) in (A_1M) (1118 cm^{-1}) and (A_4M) (1121 cm^{-1}), which increase by about 20 cm^{-1}, and of ν(C2—N) and ν_s(C—N—C) by 34 and 21 cm^{-1} respectively in (A_3M), thus showing that, as quoted previously, the heteroatom in Y participates in charge delocalization. An amide carbonyl being more basic than an ester carbonyl, the interaction with the lithium cation in (A_3M) will be stronger than in (A_1M), so that the carbonyl elongation in (A_3M) is less important than in (A_1M). Concurrently there is an increase in the low frequency shift of ν(P···O) when going from (A_2M) ($\Delta\nu$(P=O) = $-63\ cm^{-1}$) to (A_1M) ($-83\ cm^{-1}$) and (A_3M) ($-115\ cm^{-1}$); this sequence parallels the $\delta\ ^{31}P$ changes between (A_2M) on the one hand ($\Delta\delta$ = +12.6 ppm) and (A_1M) and (A_3M) on the other ($\Delta\delta$ = +20.3 and 19.1 ppm). All these trends probably reflect the asymmetrical charge repartition between the carbonyl and the phosphoryl oxygens, which is more important in the ketone (A_2M) than in the ester (A_1M) and the amide (A_3M). Such an asymmetry was already underlined by Brunette *et al.* (3) in β ketophosphonato thorium IV complexes. It also appears from the infrared results of Cotton *et al.* (7*a*) for ketonic sodium chelates, Guerchais and co-workers (7*b*) for zinc, and those of Kirilov *et al.* (8*a*) for magnesium chelates. X-ray structural determination shows that the formation of a magnesium anionic chelate from **2** (8*b*) induces a lengthening of the C2=O3 bond about twice that of the P=O bond; however, the latter bond is still longer than the former one. In the case of lanthanoid or thorium chelates formed from aroylphosphonates **7**, the lengthening of the two bonds is closer than in the previous cases ($\Delta\nu$(C2=O3) = −150 to $-165\ cm^{-1}$ and $\Delta\nu$(P=O) = −110 to $-100\ cm^{-1}$), as found by other authors (2*b*, 3).

$$(RO)_2P(O)CH_2COAr \qquad 7$$
$$1 \quad 2\,3$$

The results obtained for the phosphine oxide carbanionic species (A_4M) are similar to those obtained in ester (A_1M), except for the $\Delta\delta\ ^{31}P$, which is smaller (+13.2 ppm) (Table 3). As deduced from the aromatic ^{13}C chemical shifts (11), this is due to the fact that the P atom aryl substituents do not release electrons while the oxygens of the P-OEt groups in (A_1M) are able to do so (10).

Intermediate species (I)

Phosphine oxide ester **4** leads in THF to intermediate species (I_4) that are very similar to (I_1) (6) (Table 4), so that they do not deserve any further comment.

From carbamoylmethylphosphonate **3**, an intermediate species (I_3) is also generated: its peculiarities, related to (I_1) and (I_4), are the upfield ^{31}P shift related to its precursor **3** and the smaller ν(C=O) frequency shift ($\Delta\nu$(C=O) = $-32\ cm^{-1}$ instead of $-69\ cm^{-1}$ or $-75\ cm^{-1}$). Paine and co-workers (1, 2*a*) have described crystalline neutral bidentate complexes of various carbamoylmethylphosphonates and phosphine oxides with lanthanide salts: the observed $\Delta\nu$(C=O) values lie between −30 and $-56\ cm^{-1}$ according to the nature of the metal, i.e., the frequency shifts are always smaller than those observed in (I_1) and (I_4), as already quoted for the related anionic chelates (**AM**) (*vide supra*). A comparison between the ^{31}P shifts does not hold, due to the paramagnetism of the lanthanoid derivatives. Moreover, in the absence of reliable data for the ν(P=O) in (I_3), it seems difficult to discuss further the solvating ability of amide **3** towards lithium.

Intermediate species (I_2) was not detected[1] when starting from ketophosphonate **2** either in THF in the presence of lithiated bases or in acetonitrile in the presence of LiCl and diazabicycloundecene (DBU) (20), while similar intermediates were observed from ester **1** under the latter conditions (6, 21). However, in a solvent such as benzene, which has a poor solvating ability of the lithium cation, (I_2) was able to form in observable amounts as deduced from ^{31}P nmr and ir spectra. The low-field ^{31}P shift related to the nonchelated neutral ketone **2** ($\Delta\delta\ ^{31}P$ = +10.9 ppm) is nearly the same as the one observed

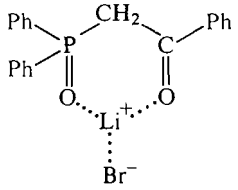
for the esters (+8.9 and +11.3 ppm). However, the carbonyl perturbation ($\Delta\nu$(C=O) = -28 cm^{-1}) is less important than that for the esters (-69 or -75 cm^{-1}), similar to the one observed with amide **3** (-32 cm^{-1}), and in the range of that published by Lestas and Truter (22) for a solid phenacyldiphenylphosphine oxide – lithium bromide chelate **8** (-45 cm^{-1}).



8

The lack of formation of ($\mathbf{I}_2$) in detectable amounts in THF and acetonitrile media can be ascribed to the better Li^+ solvating ability of these solvents and of esters **1** and **4** and amide **3** related to ketone **2**, and (or) to the high propensity of **2** to be deprotonated into anionic species $\mathbf{A}_2$ so that the concentration in ($\mathbf{I}_2$) is too low for observation. Furthermore, it was also noticed that the lithiated anionic species $\mathbf{A}_2$ has a high tendency to aggregation as it is less soluble in THF than the related ester anionic species $\mathbf{A}_1$: this propensity could also disfavor the solvation of Li^+ in ($\mathbf{A}_2\mathbf{M}$) by neutral **2** to give bidentate ($\mathbf{I}_2$).

From all these results, it appears that the lithium cation – carbonyl group interaction in all the observed intermediates is stronger in bidentates ($\mathbf{I}_1$), ($\mathbf{I}_2$), ($\mathbf{I}_3$), and ($\mathbf{I}_4$) than in the corresponding nonphosphorylated monodentate analogs such as $LiClO_4$/methylacetate ($\Delta\nu$(C=O) = 25 cm^{-1}) (23), $LiClO_4$/dimethylacetamide (11 cm^{-1}) (24), or $LiClO_4$/acetone (10 cm^{-1}) (25). The case of esters **1** and **4** is noteworthy, as the observed effects are the strongest. They are quite different from those observed with $LiClO_4$/dimethylmalonate (14) for which chelation within the 1:1 complex induces nearly no ν(C=O) mean frequency shift related to the uncoordinated diester. This difference might be due, to some extent, to a peculiar conformation of esters **1** and **4**, which deserves further investigation.

Exchange studies

The results obtained in THF when the ketophosphonate entity **2** is involved, i.e., the quantitative formation of the related anionic species $\mathbf{A}_2$, whatever the starting system, are quite in line with the well-known higher C-acidity of the ketones related to the ester (26, 27) or amide analogues (28). As expected, intermediate ($\mathbf{I}_2$) is never observed, while occasionally ($\mathbf{I}_1$) or ($\mathbf{I}_3$) are.

The exchange processes between ester (**1**, $\mathbf{A}_1$, ($\mathbf{I}_1$)) and amide entities (**3**, $\mathbf{A}_3$, ($\mathbf{I}_3$)) are more complex, the observations being dependent on the experimental procedure. Although the ester anionic species $\mathbf{A}_1$ is lower in energy than the related amide $\mathbf{A}_3$, the thermodynamic equilibrium is reached more slowly than in the previous case involving keto derivatives, and this is the reason why the relative concentrations of the various entities vary according to time. This indicates a small pK_a difference between **1** and **3**, **1** being slightly more acidic, which is in agreement with literature data on esters and amides in DMSO (28).

Conclusion

The formation of lithiated anionic species from ketophosphonate **2** and carbamoylmethylphosphonate **3**, as well as from related ester **1**, induces a strong perturbation of the carbonyl and phosphoryl bonds as seen from their nmr and ir spectra. Comparison between the neutral precursors and the related anionic species shows that the formation of the anion induces a lengthening of the C=O bond, which increases when going from the amide to the ester and finally to the ketone, while the phosphoryl elongation evolves in the reverse sequence.

All the neutral compounds studied, **1**–**4**, are able to act as bidentate chelates of the lithium cation, the formation of which gives rise to a noticeable perturbation of the organic framework. The strongest perturbation is observed with esters **1** and **4**; it is weaker with amide **3**, while from ketone *2* such a coordination only takes place in appreciable amount in a poorly Li^+-solvating medium such as benzene. These neutral bidentate intermediates (**I**) are probably involved, as already suggested by us (6), in the deprotonation of the β carbonyl phosphonates to their related anions **A**. Recently, Beak *et al.* also proposed coordination of neutral amides to Bu^{n}Li aggregates before deprotonation (31). The peculiarity observed with esters, which is reminiscent of recent results on zinc chelates (30), is probably due to conformational problems: this point is under current investigation.

Experimental

Materials

1: Methyl diethylphosphonoacetate (Janssen) was distilled under reduced pressure and kept under argon. **3**: Diethyl (*N*,*N*-dimethylcarbamoyl)methyl-phosphonate was prepared as described in ref. 29. **4**: Carbomethoxymethylenediphenylphosphine oxide was prepared according to ref. 11 (and references quoted).

Tetrahydrofuran (Merck pure) was distilled over $LiAlH_4$ and kept under argon. Benzene (Prolabo Normapur) was dried over molecular sieves Merck 4Å. Janssen *n*-butyllithium solutions (1.6 M in hexane) were standardized by acid–base titration before use.

Preparation of solutions

Solutions were prepared in a dry box or in a glove bag under argon.

Anionic species $\mathbf{A}_1$–$\mathbf{A}_4$ were obtained by adding one equivalent of Li^{n}Bu to a solution of starting material **1**–**4** (0.21 mol L^{-1} in THF). After 30 min, about 0.4–0.5 equiv. of **1**–**4** was added to the anionic solution, to observe the intermediate species (**I**), and in exchange experiments.

Infrared spectra

Infrared spectra were scanned on a Perkin–Elmer 983 spectrometer. The resolution was usually 3 cm^{-1} and the frequencies are given with a precision of at least ±1 cm^{-1}. The cell of 0.003 cm thickness was equipped with CaF_2 windows.

Nuclear magnetic resonance spectra

The ^{31}P spectra were recorded on a Bruker WP-80 spectrometer, using the FT mode and ^{1}H noise decoupling. A capillary filled with D_2O served as an ^{2}H internal lock. A spectral width of 10 000 Hz was used (digital resolution: 2.5 Hz/point).

The ^{13}C spectra were recorded at 62.9 MHz on a Bruker AM-250 spectrometer, using the FT mode and ^{1}H noise decoupling. The ^{2}H resonance of the solvent (THF-d_8) was used to provide an ^{2}H internal lock. A spectral width of 15 000 Hz was used (digital resolution: 1.85 Hz/point) for the 62.9-MHz spectra.

Acknowledgments

We are indebted to Drs. C. Charrier, B. Deschamps, and their colleagues (Laboratoire CNRS–SNPE, Thiais) for the ^{31}P spectra and to Mr. C. Mérienne (ICMO, Orsay) for the 62.9-MHz ^{13}C spectra. We thank Dr. Ph. Savignac for giving us a sample of ketophosphonate **2**.

Molybdenum-95 nuclear magnetic resonance studies on disubstituted molybdenum(0) carbonyls

ELMER C. ALYEA[1] AND ARPAD SOMOGYVARI

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received March 6, 1987[2]

ELMER C. ALYEA and ARPAD SOMOGYVARI. Can. J. Chem. **66**, 397 (1988).

Molybdenum-95 nmr spectral data are reported for 40 *cis*- and *trans*-$Mo(CO)_4LL'$ compounds and the chemical shifts discussed in relation to a simplified Ramsey expression for the paramagnetic shielding term. The identification of mixtures of products of the type $Mo(CO)_{6-n}L_n$ is shown to be easily accomplished by ^{95}Mo nmr spectroscopy. The ^{95}Mo chemical shifts provide a sensitive probe of structural and electronic effects, as illustrated for several cyclic nitrogen ligands as well as a range of phosphine ligands in the $Mo(CO)_4LL'$ complexes.

ELMER C. ALYEA et ARPAD SOMOGYVARI. Can. J. Chem. **66**, 397 (1988).

On a déterminé les spectres rmn du ^{95}Mo de 40 composés *cis*- et *trans*-$Mo(CO)_4LL'$ et on discute des déplacements chimiques en fonction d'une expression de Ramsey simplifiée pour le terme d'écran paramagnétique. On démontre que'on peut facilement détecter la présence de mélanges d'entités du type $Mo(CO)_{6-n}L_n$ en faisant appel à la rmn du ^{95}Mo. Comme on a pu le mettre en évidence avec plusieurs ligands azotés cycliques ainsi qu'avec un certain nombre de phosphines agissant comme ligands dans des complexes du type $Mo(CO)_4LL'$, les déplacements chimiques du ^{95}Mo s'avèrent une sonde sensible pour examiner les effets de structure et électroniques.

[Traduit par la revue]

Introduction

The advent of Fourier transform nuclear magnetic resonance spectrometers with stable high magnetic fields has made possible investigations of a wide range of magnetic nuclei of the Periodic Table (1–8). Applications of some transition metal nuclei (e.g. ^{51}V(5) and ^{195}Pt(6)) have virtually reached the status of routine chemical probes of the steric and electronic environment of the metal nucleus. The numerous recent reports (7–11) of ^{95}Mo nmr chemical shifts, which describe at least 400 resonances over a 7000 ppm range, are quickly bringing ^{95}Mo nmr studies to the same status. Although attempts to observe ^{95}Mo resonances in molybdoenzymes have not yet been successful (9, 10) the technique has great potential for elucidating the structure and bonding situation in biologically relevant molybdenum species of high molecular weight (11).

Applications of ^{95}Mo nmr spectroscopy to new systems have proceeded more rapidly than an understanding of the factors that influence the nmr parameters of this quadrupolar nuclei ($I = 5/2$, 15.7% natural abundance, $Q = -0.015(4) \times 10^{-28}$ m^2 (1, 12)). We have undertaken a systematic study of several series of $Mo(CO)_{6-n}L_n$ (L = N, P, As, and Sb donor ligands) complexes to gain such information and herein report the ^{95}Mo nmr spectral data for 40 mononuclear *cis*- and *trans*-$Mo(CO)_4LL'$ complexes. Preliminary communications have appeared (7(*a*), 13(*a*)) as well as our results on $[Mo(CO)_4(L—L)]^-$ complexes with bidentate sulfur ligands (13(*b*)) and details of a companion study of $Mo(CO)_5L$ derivatives (13(*c*)). Other workers (8, 14, 15) reported ^{95}Mo nmr studies of several *cis*-$Mo(CO)_4(PR_3)_2$ species while our investigation was in progress.

Experimental

Molybdenum-95 nmr spectra were obtained from naturally abundant (15.7%) samples with a Bruker WH-400 nmr spectrometer in the pulsed Fourier transform mode. The probe was tuned for molybdenum-95 at 26.08 MHz using a field strength of 9.3956 T. All samples were measured at 293 ± 2 K with chemical shifts referenced to aqueous 2 *M* $K_2[MoO_4]$ at pH 11. Pulse widths of 75 μs (for a 90° pulse) were found to usually give a signal-to-noise ratio better than 100/1 for 500 to 1000 transients on saturated solutions. A spectral width of 10 kHz was normally used to collect one block of 4000 data points; digital resolution was typically better than 5 Hz per data point.

All compounds were prepared by literature methods (16) or slight modifications thereof. The complexes *cis*-$Mo(CO)_4(pip)L$ were prepared by stirring a stoichiometric amount of L and *cis*-$Mo(CO)_4(pip)_2$ under N_2 for several hours in the appropriate deoxygenated solvent (usually CH_2Cl_2). The *cis*-$Mo(CO)_4LL'$ species were prepared similarly by adding L′ to the $Mo(CO)_4(pip)L$ solution prepared *in situ*. The *trans* samples were prepared by refluxing the *cis* compounds for 1 h under N_2 in the appropriate solvent (usually deoxygenated toluene). Infrared spectra in the carbonyl region were used to confirm the stereochemistry of the species in solution subsequent to ^{95}Mo nmr analysis. In the case of complicated mixtures, ir could not confirm the stereochemistry and those cases are noted in Table 1; however, ^{95}Mo chemical shifts (particularly if coupling to phosphorus occurs) often allowed identification of the specific species present in the mixture (see text and Fig. 1).

Results and discussion

Table 1 summarizes the chemical shift and coupling constant data for the complexes in this study. Relatively narrow signals ($\Delta\nu_{1/2}$ = 5–250 Hz) are observed for these tetracarbonyl Mo(O) complexes in the chemical shift range −978 ppm to −1867 ppm. The phosphite complexes show ~60% greater ^{95}Mo–^{31}P coupling (*ca.* 210–260 Hz) than the phosphine complexes (*ca.* 130–160 Hz), as expected (1). No coupling to nitrogen was observed for the amine complexes, but it is worth noting that $^1J(^{95}Mo—^{14}N)$ is known to be about 46 Hz for $(C_5H_5)Mo(CO)_2(NO)$ and related complexes (17). No distinction may be made between the *cis* and *trans* complexes on the basis of coupling constants which contrasts sharply with the ^{195}Pt situation (6*c*)); however, the chemical shifts for the *trans* complexes are shielded relative to the corresponding values observed for the *cis* complexes. Variations in the shielding can be discussed in relation to the terms of a simplified Ramsey expression for the paramagnetic term applicable to quadrupolar nuclei (eq. [1])

[a]Assignment of geometry is based on synthetic method, ^{95}Mo nmr, and ir spectroscopy.
[b]Assignment of geometry is based on synthetic method and ^{95}Mo nmr spectroscopy only.
[c]*cis*-complex shows ν(CO) bands at 2062w, 2005w, 1975s, 1932vs cm^{-1}; *trans*-complex shows only a 1870 cm^{-1} band.
[d]Abbreviations: Me = methyl, Et = ethyl, Pr^i = isopropyl, Bu^n = *n*-butyl, Bu^t = *tert*-butyl, Cy = cyclohexyl, Ph = phenyl, pip = piperidine, py = pyridine, pyr = pyrrolidine, quin = quinoline, MeCN = acetonitrile, DMF = *N*,*N*-dimethylformamide, NH_2Etpy = 2-aminoethylpyridine, NH_2Mepy = 2-aminomethylpyridine, and MeIM = methylimidazole.

$$[1] \quad \sigma_{para} = -K \cdot \Delta E^{-1} \{r^{-3}\}_{4d} k^2$$

where ΔE is the mean excitation energy approximated by the HOMO-LUMO energy gap and the $\{r^{-3}\}_{4d}$ and k^2 terms are associated with the nephelauxetic effect and the covalency of the metal–ligand bond, respectively (1, 3, 5). Since the paramagnetic shielding term is negative, an increase in its magnitude corresponds to deshielding of the nucleus. The predominant term in eq. [1] is ΔE, assumed to involve mainly Mo 4*d* orbitals, because the other two terms can be considered constant for ligands of the same type (i.e. phosphines) and for molybdenum in the same oxidation state (1–3, 13(*c*)). Similarly, contributions to the total shielding by the diamagnetic term is normally ignored for quadrupolar nuclei as it is considered to be constant for a related series of compounds (1–3). Therefore, the relative *trans*-to-*cis* shielding order is explicable in terms of eq. [1]. The *trans* complexes have a greater HOMO-LUMO energy gap than the *cis* samples and consequently are considered to be more shielded because of the larger magnitude of the ΔE term of the Ramsey equation; in some instances, the chemical shifts approach those found for $Mo(CO)_5L$ complexes (13(*c*)).

A decrease in ΔE correlates qualitatively with a decrease in the amount of π-electron density accepted by the ligands (i.e. $(P(OR)_3 > PR_3 > NR_3)$. The resultant deshielding thus correlates with the spectrochemical series (19) and it is seen that chemical shifts for *cis*-$Mo(CO)_4$pipL complexes are predictable "averages" of the analogous $Mo(CO)_4pip_2$ and $Mo(CO)_4L_2$

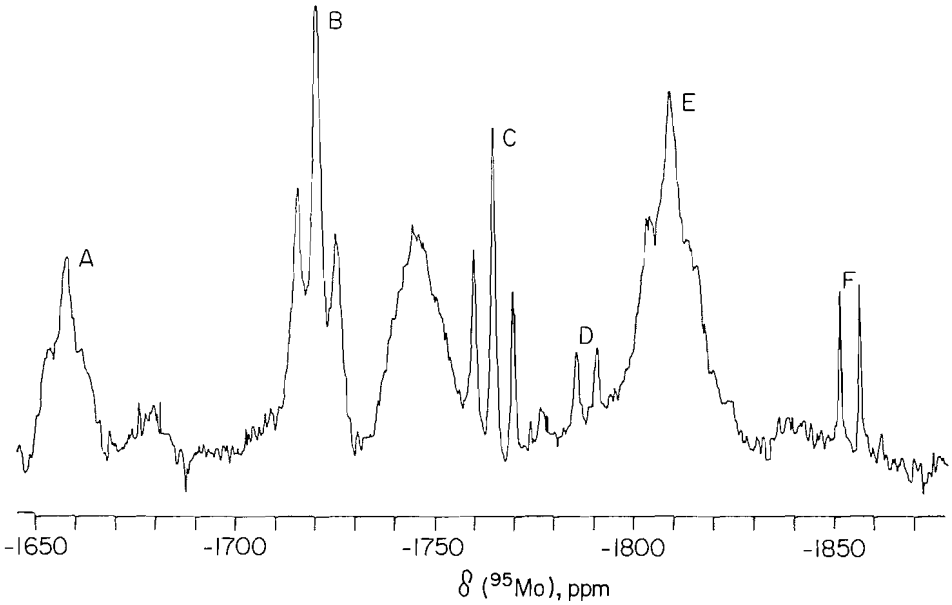

FIG. 1. The ^{95}Mo nmr spectrum of the reaction mixture following reflux of a dichloromethane solution of *cis*-{$Mo(CO)_4(PEtPh_2)(PEt_3)$}. The resonances are attributable to *cis*-$Mo(CO)_4(PEtPh_2)_2$ (A, −1657 ppm), *trans*-$Mo(CO)_4(PEtPh_2)_2$ (B, −1720 ppm), *cis*-$Mo(CO)_4(PEt_3)_2$ (C, −1765 ppm), $Mo(CO)_5(PEtPh_2)$ (D, −1788 ppm), *trans*-$Mo(CO)_4(PEt_3)_2$ (E, −1810 ppm), and $Mo(CO)_5(PEt_3)$ (F, −1854 ppm).

values. The same shielding order of the ligands (Sb > As > P > N) is found in $Mo(CO)_5L$ and $Mo(CO)_3L_3$ complexes (7, 8) and the factors influencing the order were previously discussed (13(*c*)).

Consideration of the factors influencing linewidths of resonances observed for quadrupolar nuclei (1, 5, 18) leads to a prediction of generally narrower linewidths for the *cis* as opposed to the *trans* complexes because the major parameter, the electric field gradient, is less for the former complexes (14). In practice, the linewidths for most of the *cis* complexes are considerably larger than those observed for the analogous *trans* complex. Such line-broadening might be attributed to the greater steric congestion and subsequent distortion expected for the *cis* complexes. Similarly, broad linewidths have been reported (9) for many *fac*-$Mo(CO)_3L_3$ complexes with bulky ligands even though the electric field gradient is theoretically zero for complexes with trigonal symmetry.

The identification of mixtures of products by ^{95}Mo nmr spectroscopy is readily effected without recourse to tedious column chromatographic separation. Not only can the presence of several species be inferred, as might be implied by the complexity of ir or ^{13}C nmr spectra, but each may be identified by its characteristic chemical shift, linewidth[2] and, for PR_3 and $P(OR)_3$ ligands, coupling constant. This useful application of ^{95}Mo nmr data was applied in the characterization of the products obtained during the attempted synthesis of *trans*-$Mo(CO)_4LL'$. Refluxing solutions of *cis*-$Mo(CO)_4LL'$ gave a variety of mono- and bis-substituted complexes, as expected (20). As an example, the ^{95}Mo nmr spectrum (Fig. 1) of the reaction mixture obtained by refluxing a dichloromethane solution of *cis*-$Mo(CO)_4(PEtPh_2)(PEt_3)$ illustrates dramatically how readily the "potpourri" of products can be analysed. All of the identified species were separately synthesized and characterized (Table 1 and ref. 13(*c*)) by ir and ^{95}Mo nmr spectroscopy. The only peak (at ~1745 ppm) that cannot be unambiguously assigned, due to the lack of resolution of the coupling, is nevertheless judged to be in the right location for *trans*-$Mo(CO)_4(PEtPh_2)(PEt_3)$. A range of such unsymmetrical *trans*-complexes, prepared by a "cleaner" synthetic route, is under investigation by ^{95}Mo nmr spectroscopy in order to provide further information on the relative *trans*-effect of phosphines and phosphites.[3]

In the case of cyclic nitrogen donor ligands, the chemical shift data demonstrate the effect of ring saturation (shielding from py to pip), ring contraction (shielding from pip to pyr), ring expansion to a double-ring system (shielding from py to quin), and the effect of electron donor substituents on the ring (shielding from py to 4-Bu^{t}py but deshielding from py to 2-NH_2Etpy and 2-NH_2Mepy). The need to change solvents to ensure sufficient solubility obviously complicates correlation of this data, though only a small chemical shift difference might be expected between DMF and CH_2Cl_2 (7(*a*)). The differing σ-donor/π-acceptor(donor) properties of the nitrogen ligands will influence the various terms of the Ramsey expression (eq. [1]) in a complicated fashion, as already discussed (13(*c*), 18), and thus no simple explanations of the observed chemical shifts are possible. Doubtless the ligand field strength and the polarizability of the donor atom as well as steric factors all play a role in determining the δ(^{95}Mo) values. We reserve further discussion of the complexes with N-donor ligands until completion of our ^{95}Mo nmr study of a range of related $Mo(CO)_3L_3$ compounds.

Acknowledgements

Support of this research by NSERC of Canada is gratefully acknowledged. The nmr spectra were obtained at the Southwestern Ontario NMR Centre funded by a Major Installation Grant from NSERC.

[3]McFarlane and co-workers (14) documented the expected changes in $\Delta\nu_{1/2}$ for $Mo(CO)_{6-n}(P(OMe)_3)_n$ (n = 0–6) species.

[4]Chemical shifts previously assigned (7(*a*)) to *trans*-$Mo(CO)_4(PPh_3)[P(OPh)_3]$ and *trans*-$Mo(CO)_4(PBu^n_3)[P(OPh)_3]$ are actually due to mixtures of the mono-substituted $Mo(CO)_5L$ derivatives (13(*c*)).

On the spectrophotometric determination of UO_2^{2+} with 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol

LUMÍR SOMMER AND EVA ŠAMLOTOVÁ

Department of Analytical Chemistry, J. E. Purkyně University, 61137 Brno, Czechoslovakia

Received October 22, 1986[1]

This paper is dedicated to Professor Douglas E. Ryan

LUMÍR SOMMER and EVA ŠAMLOTOVÁ. Can. J. Chem. **66**, 401 (1988).

2-(5-Bromo-2-pyridylazo)-5-diethylaminophenol (5-Br-PADAP) is a suitable reagent for the spectrophotometric determination of uranium but results are easily influenced by the reaction conditions as well as various common ions and masking agents. Optimum conditions, which must be carefully maintained, are 30% (v/v) dimethylformamide, 0.1% triton X-100, $\geq 8 \times 10^{-5}$ *M* 5-Br-PADAP, 8×10^{-2} *M* triethanolamine, 7×10^{-3} *M* sodium fluoride, 10^{-2} *M* 5-sulphosalicylic acid, and 579 nm. Sodium sulphate (10^{-2} *M*) and CDTA (5.7×10^{-3} *M*) may serve as additional masking agents. A previous separation of uranium by extraction with 0.1 *M* tri-*n*-octylamine in benzene from 4 *M* HCl and re-extraction of 0.3 *M* HCl is recommended for analysis of natural water samples.

LUMÍR SOMMER et EVA ŠAMLOTOVÁ. Can. J. Chem. **66**, 401 (1988).

Le (bromo-5 pyridyl-2 azo)-2 diéthylamino-5 phénol (Br-5 PADAP) est un réactif approprié pour la détermination spectrophotométrique de l'uranium; toutefois, les résultats sont facilement influencés par les conditions de la réaction ainsi que par divers ions communs et des agents masquants. Les conditions optimales, qui doivent être maintenues avec soins, sont les suivantes : 30% (v/v) de diméthylformamide, 0,1% de Triton X-100, $\geq 8 \times 10^{-5}$ *M* de Br-5 PADAP, 8×10^{-2} *M* de triéthanolamine, 7×10^{-3} *M* de fluorure de sodium, 10^{-2} *M* d'acide sulfo-5 salicylique et une longueur d'onde de 579 nm. On peut aussi utiliser du sulfate de sodium (10^{-2} *M*) et du CDTA ($5,7 \times 10^{-3}$ *M*) comme agents masquants. Pour l'analyse d'échantillons d'eaux naturelles, on recommande l'utilisation d'une méthode décrite antérieurement pour la séparation de l'uranium; elle implique une extraction d'une solution 4 *M* en HCl par de la tri *n*-octylamine 0,1 *M* dans le benzène suivie par une ré-extraction par du HCl à 0,3 *M*.

[Traduit par la revue]

The reaction of UO_2^{2+} belongs to the analytically most valuable reactions of pyridylazo dyes derived from *m*-aminophenol. These reagents, first introduced by Gusev and Schurova (1), show high sensitivity and adequate spectral contrast between the dye – metal ion chelate and the free dye. These properties result from intensive interaction of the lone electron pair of the alkylated amino group in the *para* position towards the azo group with the aromatic ring.

Several variants of spectrophotometric determination of UO_2^{2+} with the stable commercially available reagent 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol (5-Br-PADAP) have been described in the presence of fluoride, *o*-phenolcarboxylic acids such as 5-sulfosalicylic acid, cyclohexandiaminetetraacetic acid (CDTA), triethanolamine (TEA), and borate buffer (2–6). Johnson and Florence (3) assumed three complexes formed depending on pH and composition of solution (*a*) UO_2L^+ (λ_{max} 554 and 586 nm), formed at pH 4.1 in the presence of an excess of UO_2^{2+} or sulphate and perchlorate and extractable in polar solvents; (*b*) an unstable 1:1 complex at pH 7.6, considered a hydroxocomplex, $UO_2L(OH)$ (λ_{max} 546 nm); (*c*) a stable and strongly absorbing ternary complex, UO_2LF (λ_{max} 578 nm) at pH 7.3 in the presence of limited concentrations of fluoride, which is, however, decomposed in the presence of excess fluoride (L is the anion of 5-Br-PADAP). The 1:1 stoichiometry of UO_2^{2+} with 5-Br-PADAP was also observed in extracts of TOPO, TOA, or TBP in cyclohexane, kerosine, or dimethylformamide–ethanol mixtures (11). The stability and absorptivity of the 1:1 chelate of UO_2^{2+} with 5-Br-PADAP increases considerably after transformation to a ternary species with fluoride or *o*-phenolcarboxylic acid. These reagents in combination with CDTA and TEA may serve as suitable masking agents for interferents. On the other hand, the effect of cationic and anionic surfactants is still uncertain (5–9, 13). In complex samples, UO_2^{2+} may be separated by extraction with trioctylphosphineoxide (TOPO) in cyclohexane (2, 4, 10), tri-*n*-alkylamines in kerosine (11), or tri-*n*-octylamine or tri-*n*-butylamine in kerosine (12) prior to the spectrophotometric determination with 5-Br-PADAP in the organic phase. The absorbance is, however, influenced by the composition of the mixed phase. Extraction chromatography has also been used for separation of uranium from various interferents, the UO_2^{2+} then being determined with 5-Br-PADAP in the acidic eluate (8). In spite of the slowness of the reaction of UO_2^{2+} with 5-Br-PADAP in the presence or absence of additional reactants, flow injection analysis has been successfully used for the automated continuous determination of UO_2^{2+} in ores or rocks after sample decomposition (13–15).

In this paper, the reaction of UO_2^{2+} with 5-Br-PADAP is re-examined and a modified procedure developed in aqueous dimethylformamide suitable for the determination of uranium in natural waters.

Experimental

Chemicals, solutions, instruments

2-(5-Bromo-2-pyridylazo)-5-diethylaminophenol (5-Br-PADAP) (E. Merck, Darmstadt, B.R.D.); stock solutions were 10^{-4} *M* in 95% ethanol or in 99.5% dimethylformamide. Solutions used were not older than 1 week.

A 0.189 *M* standard uranyl chloride dihydrate solution in 0.2 *M* HCl was prepared and standardized gravimetrically via 8-hydroxyquinolate; 2% aqueous stock solution of triton X-100 (octylphenolpolyethylene glycolether) (Koch-Light Labs., G.B.).

Septonex(1-ethoxycarbonylpentadecyltrimethylammonium bromide (Czech Pharmacopoia ČsL 3) (Slovakopharma, Hlohovec, ČSSR); 0.1 *M* aqueous stock solution.

Cetylpyridinium bromide (Lachema N.C., Brno); 5×10^{-2} *M* aqueous stock solution.

[1]Revision received September 16, 1987.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

Dodecylsulphate, sodium salt; 0.05 *M* aqueous stock solution.

Ethanol 95%; commercial sample containing 4.1% methanol and 4.3% water was treated with EDTA and distilled under reflux.

Dimethylformamide 99.5% (Reachim, USSR) was distilled *in vacuo* at 51°C.

Tri-*n*-octylamine (E. Merck, Darmstadt, B.R.D.).

Triethanolamine (TEA) (E. Merck, B.R.D.); a 1 *M* aqueous buffer solution was prepared by dissolving 14.919 g of TEA in 50 mL, adjusting to pH 8.26 with concentrated $HClO_4$ and diluting with water to 100 mL.

Borate buffer: 13.09 g H_3BO_3 (E. Merck, Darmstadt) was dissolved in 50 mL of water, the pH adjusted to 9.0 with 1 *M* NaOH, and the solution diluted to 100 mL.

Sodium fluoride, 0.2 *M*.

Aqueous solution of CDTA (0.1 *M*) adjusted with sodium hydroxide to pH 7.0.

5-Sulphosalicylic acid dihydrate, 0.1 *M*.

Complexing and masking mixture: 7.1×10^{-2} *M* CDTA, 1.25×10^{-2} *M* 5-sulfosalicylic acid, 8.7×10^{-2} *M* sodium fluoride, 2.8×10^{-1} *M* sodium sulphate, i.e., 2.46 g of CDTA, 3.18 g of 5-sulfosalicylic acid, 0.365 g NaF and 4.03 g of anhydrous sodium sulphate were dissolved in water, adjusted to pH 7.3, and diluted to 100 mL.

All chemicals were of analytical grade or superpure quality. Water was doubly distilled.

Double beam spectrophotometer: Varian Techtron Superscan 3 controlled by Hewlett-Packard HP 9815 A computer, with 100 mm silica cells.

Single beam spectrophotometer: Unicam SP-500 with 10 mm glass cells. Absorbances were corrected by subtracting the blank containing all components except uranium under the same conditions.

Precision digital pH meter: Radelkis 208/1 with a combination electrode OP-0808 P. The pH meter was standardized with NBS buffers. pH values for solutions in 50% ethanol or 30% dimethylformamide in the presence of triton X-100 were not corrected.

The threshold interference of ions and components was defined as that causing ±2% relative absorbance change against the absorbance of a corresponding pure UO_2^{2+}–5-Br-PADAP complex solution.

Results

Stoichiometry of the complex

The 1:1 stoichiometry of UO_2^{2+} to 5-Br-PADAP has also been proved in 30% dimethylformamide containing 0.007 *M* fluoride, 0.01 *M* 5-sulfosalicylic acid, 5.7×10^{-3} *M* CDTA, 0.1% triton X-100, in the presence of TEA at pH 7.3 for the total concentration $c_L + c_M = 3 \times 10^{-4}$ *M* and 565–590 nm by the method of continuous variations. The customary 1:2 metal-to-ligand complex, which is usual between bivalent metal ions and 5-Br-PADAP, is not formed with UO_2^{2+}.

Effect of time and mixing of components

In 0.1 to 0.2% triton X-100 and 30% dimethylformamide, the absorbance of the complex between UO_2^{2+} and 5-Br-PADAP reaches a constant value in pure solutions containing excess reagent over the pH range 3 to 7 in 10 min. The same holds true for solutions containing fluoride, 5-sulfosalicylic acid, CDTA, and TEA. The most suitable order of mixing is acid sample solution, solvent (ethanol or dimethylformamide) surfactant, complexing and masking mixture, buffer solution, and 5-Br-PADAP reagent solution followed by pH adjustment to the desired value and dilution to the appropriate volume with water. The λ_{max} of 579 nm does not change with changes in the composition of solution or with time. Typical absorption spectra are shown in Fig. 1.

Effect of pH

The binary species of UO_2^{2+} with 5-Br-PADAP reaches its maximum absorbance at pH 3.5 in 50% ethanol or 30% dimethylformamide. The molar absorption coefficient with respect to UO_2^{2+} increases with increasing concentration of 5-Br-PADAP and even in the presence of excess nitrate, sulphate, or perchlorate. The optimum pH shifts to 6.5 in 10^{-2} *M* fluoride or to pH 7.1 in 0.05 *M* TEA, 50% ethanol, and 0.1% triton X-100. The optimum pH is 7.3 if 30% dimethylformamide is used instead of ethanol. Other components of the complexing and masking mixture do not influence the optimum pH value (Fig. 2).

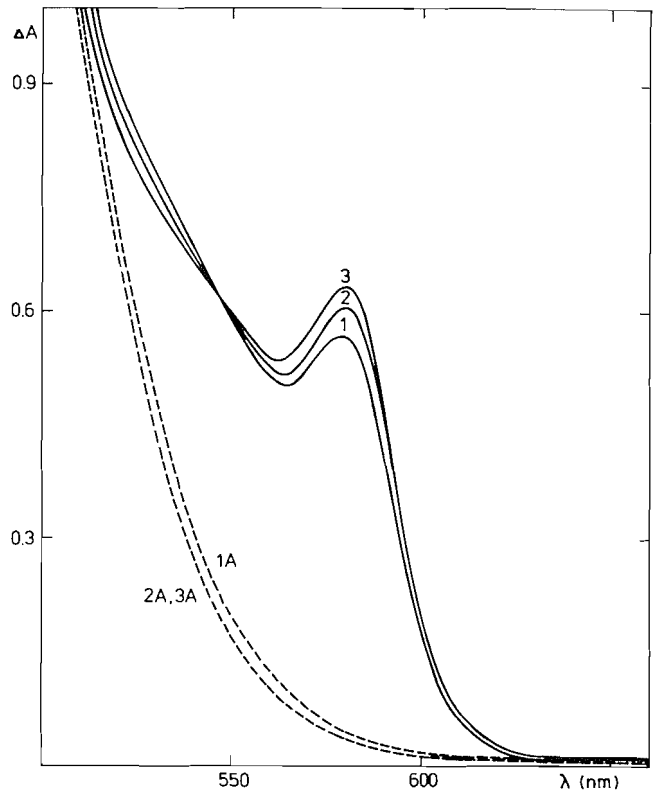

FIG. 1. Absorption curves of 8×10^{-4} *M* UO_2^{2+} and 8×10^{-5} *M* 5-Br-PADAP in 30% dimethylformamide at pH 9.7 (curve *1*), 6.0 (curve *2*), and 7.3 (curve *3*). The solutions also contain 0.1% triton X-100, 5×10^{-2} *M* TEA, 7×10^{-3} *M* NaF, 5.7×10^{-3} *M* CDTA, and 1×10^{-2} *M* sulfosalicylate; 1A to 3A show curves of the solutions without UO_2^{2+}; $\Delta A = A - A_{bl}$.

Effect of 5-Br-PADAP concentration

The maximum value of absorbance is reached for $c_l/c_M \geq 6.5$ at pH 7.0 and 579 nm, for solutions containing 8×10^{-6} *M* UO_2^{2+}, 0.01 TEA, 0.01 *M* fluoride, and 0.1% triton X-100 in 50% ethanol or 30% dimethylformamide. An 8×10^{-5} *M* 5-Br-PADAP concentration is sufficient for practical purposes.

Effect of buffers

The earlier recommended buffer mixture, triethanolamine–$HClO_4$ (2) is suitable in 0.08 *M* concentration over pH 7.0 to 7.3 in the presence of 8×10^{-5} *M* 5-Br-PADAP, 50% ethanol, or 30% dimethylformamide, 0.1% triton X-100, and 7×10^{-3} *M* fluoride. A 0.04 *M* borate buffer may also be used for the same conditions.

Effect of solvents

A 50% ethanol concentration is needed to keep the UO_2^{2+} complex with 5-Br-PADAP and the reagent excess in solution in the presence of 0.1% triton X-100. The ethanol can be replaced by 30% dimethylformamide, in which higher absorbance values are achieved under similar conditions.

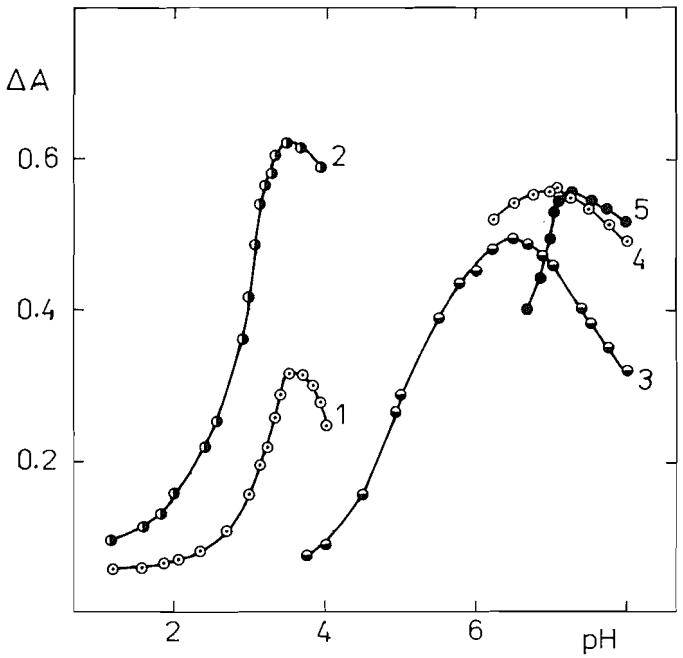

FIG. 2. Absorbance–pH plots at 579 nm for various ratios of UO_2^{2+} to 5-Br-PADAP under various conditions. 50% ethanol, 0.1% triton X-100; curve *1*, 2.1×10^{-5} *M* UO_2^{2+}, $c_L/c_M = 1$; curve *2*, $c_L/c_M = 3.0$; 3. 8×10^{-6} *M* UO_2^{2+}, $c_L = 1 \times 10^{-4}$ *M*, 1×10^{-2} *M* NaF; the same as for curves *3* and 5×10^{-2} *M* TEA; 5. 30% dimethylformamide, 0.1% triton X-100, 8×10^{-6} *M* UO_2^{2+}, $c_L = 8 \times 10^{-5}$ *M*, 7×10^{-3} *M* NaF, 5.7×10^{-3} *M* CDTA, 1×10^{-2} *M* 5-sulfosalicylate, 5×10^{-2} *M* TEA; $\Delta A = A - A_{bl}$.

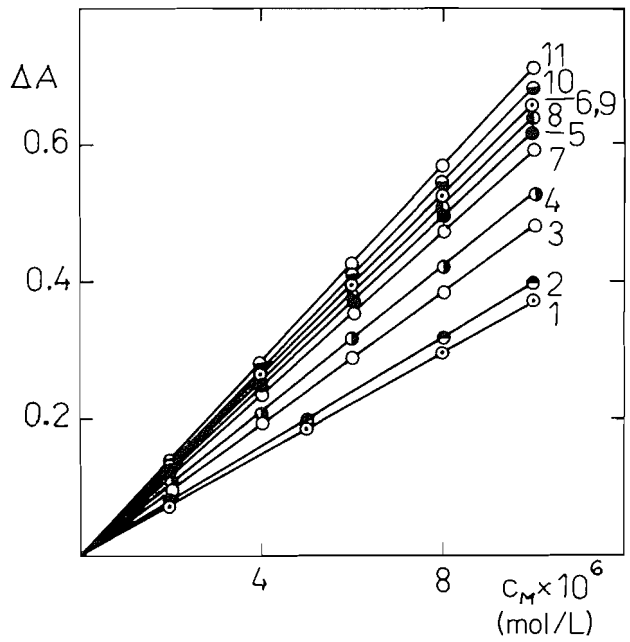

FIG. 3. Plots of absorbance vs. UO_2^{2+} concentration at 579 nm under various conditions used for spectrophotometric determination of UO_2^{2+}. All solutions contain 50% ethanol, 0.1% triton X-100, and 8×10^{-5} *M* 5-Br-PADAP at pH 7.3. Curve *1*, 9.5×10^{-3} *M* NaF, 5.7×10^{-3} *M* CDTA, 2×10^{-2} *M* sulphosalicylate, 8×10^{-2} *M* TEA; curve *2*, 7×10^{-3} *M* NaF, 8×10^{-2} *M* TEA; curve *5*, 7×10^{-3} *M* NaF, 5.7×10^{-3} *M* CDTA, 1×10^{-2} *M* sulfosalicylate, 5×10^{-2} *M* TEA; curve *6*, 7×10^{-3} *M* NaF, 5.7×10^{-3} *M* CDTA, 1×10^{-2} *M* sulfosalicylate, 8×10^{-2} *M* TEA. Particular values for $\epsilon \times 10^{-4}$ are 5.0, 5.1, 6.5, 6.6 L mol^{-1} cm^{-1}. All solutions contain 30% dimethylformamide, 0.1% triton X-100, pH 7.3, and 8×10^{-5} *M* 5-Br-PADAP. Curve *3*, 9.5×10^{-3} *M* NaF, 5.7×10^{-3} *M* CDTA, 2×10^{-2} *M* sulfosalicylate, 8×10^{-2} *M* TEA (pH 7.8); curve *4*, 7×10^{-3} *M* NaF, 8.1×10^{-3} *M* CDTA, 1×10^{-2} *M* sulfosalicylate, 5×10^{-2} *M* TEA; curve *7*, 7×10^{-3} *M* NaF, 5.7×10^{-3} *M* CDTA, 2×10^{-2} *M* sulfosalicylate, 8×10^{-2} *M* TEA; curve *8*, 7×10^{-3} *M* NaF, 8×10^{-2} *M* TEA, 4×10^{-5} *M* 5-Br-PADAP; curve *9*, 7×10^{-3} *M* NaF, 8×10^{-2} *M* TEA, 5.7×10^{-3} *M* CDTA, 1×10^{-2} *M* sulfosalicylate; curve *10*, 7×10^{-3} *M* NaF, 5.7×10^{-3} *M* CDTA, 1×10^{-2} *M* sulfosalicylate, 8×10^{-2} *M* TEA, 1×10^{-2} *M* sulphate; curve *11*, 7×10^{-3} *M* NaF, 8×10^{-2} *M* TEA; particular values for $\epsilon \times 10^{-4}$ are 5.6, 6.4, 6.9, 7.1, 7.2, 7.3, 7.4 L mol^{-1} cm^{-1}; $\Delta A = A - A_{bl}$.

Influence of various reactants

The concentration of various complexing agents is critical with respect to absorbance at 579 nm. Maximum absorbance is retained for 0.05 *M* TEA, 0.01 *M* fluoride, 5-sulfosalicylic acid, and not more than 6×10^{-3} *M* CDTA over pH 7.1 to 7.3 in 50% ethanol or 30% dimethylformamide containing 8×10^{-5} *M* ligand. Higher concentrations of the above components may considerably decrease the absorbance values of UO_2^{2+} solutions with 5-Br-PADAP and also shift the optimum pH to higher values. The effect of 5-sulfosalicylic acid on the binary UO_2^{2+}–5-Br-PADAP species is negligible in chloride medium and the conditional molar absorptivity of 3.5×10^4 L mol^{-1} cm^{-1} is similar to that of solutions without 5-sulfosalicylic acid. A chromogenic effect by 5-sulfosalicylic acid is only observed in 0.01 to 0.1 *M* nitrate (fluoride absent) containing 50% ethanol at pH 7.5. The observed molar absorptivity of 6.2×10^4 L mol^{-1} cm^{-1} is, however, considerably less than previously reported (6).

Effect of surfactants

Non-ionic surfactants such as triton X-100 in 0.1% concentration enhance the formation of the UO_2^{2+}–5-Br-PADAP complexes. A high concentration of surfactant is not desirable because of decreasing absorbance and foaming of solutions. In the presence of 1.0 to 3.2×10^{-3} *M* dodecylsulphate the resulting molar absorptivity is 5.5×10^4 L mol^{-1} cm^{-1} and the optimum pH is shifted to pH 8.1 in the presence of TEA if the chloride medium contains 50% ethanol, the complexing mixture, and 0.05 *M* TEA or 0.004 *M* borate at pH $\geq$7.3. The formation of the UO_2^{2+} complex with 5-Br-PADAP is hindered in solutions containing less than 10% ethanol, 3.2×10^{-3} *M* dodecylsulphate, and 5×10^{-3} *M* CDTA, which is in disagreement with ref. 9 and ref. 16 where the reagent 3,5-dibromo-PADAP was used for the determination of uranium. No stable ternary species is observed in the presence of 10^{-3} *M* cetylpyridinium bromide or septonex in 50% ethanol containing 0.1% triton X-100 and 1.44×10^4 *M* 5-Br-PADAP at pH 7.5. A small concentration of ternary species is formed only in the presence of 8×10^{-3} *M* 5-sulfosalicylic acid and cationic surfactant at pH 7.5 in the chloride medium (conditional $\epsilon = 2.1 \times 10^4$ L mol^{-1} cm^{-1} in the presence of septonex and 1.6×10^4 L mol^{-1} cm^{-1} in the presence of cetylpyridinium bromide at 579 nm). This negative result, which is in disagreement with ref. 7, may be the result of competition by the cationic surfactant for reagent anions bound in the UO_2^{2+}–complex.

UO^{2+}–concentration plots of absorbance

Absorbance vs. UO_2^{2+} plots are linear over the concentration range 0.4 to 3.2 μg U/mL in 30% dimethylformamide or 50% ethanol containing $\geq 8 \times 10^{-5}$ *M* 5-Br-PADAP and triton X-100, in the presence of fluoride, CDTA, TEA, sulfate, 5-sulfosalicylic acid at pH 7.3 and 579 nm. These plots, however,

TABLE 1. Limiting concentrations of selected anions in the determination of UO_2^{2+} with 5-Br-PADAP[a]

Ion	c_{Ion} (mol/L)	c_{Ion}/c_M (mol/L)	c_{Ion}/c_M (μg/mL)

[c] Sodium sulfate.

yield various conditional values for the molar absorption coefficient (cf. Fig. 3). The highest value, 74000 L mol^{-1} cm^{-1}, was reached for 30% dimethylformamide, 0.1% triton X-100, 8×10^{-5} *M* 5-Br-PADAP, 8×10^{-3} *M* TEA, and 7×10^{-3} *M* fluoride, or 73000 L mol^{-1} cm^{-1} in a medium containing 5.7×10^{-3} *M* CDTA, 10^{-3} *M* 5-sulfosalicylic acid, 7×10^{-3} *M* sodium fluoride, 10^{-2} *M* sodium sulfate, and 0.08 *M* TEA. This enables partial masking of interfering ions by such mixture.

Interferences

The effect of various ions expected in natural waters on the UO_2^{2+} reaction with 5-Br-PADAP is summarized in Tables 1 and 2 for a medium of 30% dimethylformamide containing 8×10^{-5} *M* 5-Br-PADAP at pH 7.3. Unfortunately the masking capacity of the complexing mixture containing fluoride, 5-sulfosalicylic acid, CDTA, and sulphate is limited at pH 7.3. Unlike an earlier study (2), this work shows that Ca^{2+}, Mg^{2+} and several other ions interfere even in the presence of a masking–complexing mixture. The presence of 10^{-2} *M* sodium sulphate in this mixture often decreases interferences. The masking of Th(IV) is particularly effective. In contrast, 1×10^{-2} *M* ascorbic acid, 1×10^{-3} *M* oxalic acid, $\geq 5.6 \times 10^{-4}$ *M* dihydrogeneitrate, $\geq 9 \times 10^{-4}$ *M* acetate, and 4.25×10^{-4} *M* tartrate each interferes by causing a considerable absorbance decrease.

Optimized procedure

Add in succession 3.5 mL of dimethylformamide, 1.25 mL of 2% triton X-100, 2 mL of complexing and masking mixture, 2 mL of 1 *M* TEA, and 4 mL of 5×10^{-4} *M* 5-Br-PADAP in dimethylformamide to ≤10 mL of slightly acidic sample solution containing less than 65 μg UO_2^{2+} in chloride, nitrate, sulphate, or perchlorate medium. Adjust the pH to 7.3 with dilute sodium hydroxide, transfer the solution into a 25-mL volumetric flask and dilute to volume with water. Measure the absorbance 10 min after pH adjustment at 579 nm and subtract a blank measured under the same conditions. Prepare a calibration plot of 4 standard solutions of uranyl chloride in duplicate and measure each under optimized conditions. Linear regression of the plot between $0.196–1.370 \times 10^{-5}$ *M* (0.47–3.26 μg U/mL) gave $s_{xy(A)} = 0.008$, $\epsilon = (7.20 \pm 0.05) \times 10^4$ L mol^{-1} cm^{-1}, $A_{bl} = 0.043 \pm 0.005$. The determination limit, expressed from $A_{lim} = A_{bl} + 10\ s_{A(bl)}$ at 579 nm and evaluated from eight parallel solutions of the blank, is 0.02 μg U/mL.

Recommended procedure for the determination of uranium in drinking, surface, and waste waters

Evaporate 100 mL of water sample with 2 mL of concentrated HCl and 2 mL of 30% H_2O_2 in a porcelain dish to dryness. Repeat the evaporation with a second 2 mL portion of concentrated HCl. Dissolve the wet residue in a small portion of hot distilled water and continue with the spectrophotometric determination of uranium according to the above procedure. This direct method cannot be used for hard waters with high contents of Ca^{2+} and silicate since turbidity appears after dissolution of the residue and addition of the masking mixture. In this case, a previous separation of uranium by extraction with tri-*n*-octylamine in benzene is recommended (17). The modified procedure is as follows: Dissolve the residue after preconcentration of uranium in 10 mL of 10 *M* HCl and 15 mL of doubly distilled water. Transfer the solution quantitatively into a 50-mL pommel-form separation funnel with a 20-mm stem. Add 3 g of ascorbic acid to reduce Fe^{3+} to Fe^{2+} and 5 mL of 0.1 *M* tri-*n*-octylamine in benzene. Shake vigorously for 3 min. Discard the aqueous phase after complete separation of the phases, wash the organic phase twice with 5 mL of 4 *M* HCl, and re-extract the uranium twice with 5 mL of 0.3 *M* aqueous HCl. Transfer the aqueous phase quantitatively into a suitable

Cell growth inhibitory dihydrophenanthrene and phenanthrene constituents of the african tree *Combretum caffrum*[1]

GEORGE R. PETTIT,[2] SHEO BUX SINGH, MARGARET L. NIVEN,[3] AND JEAN M. SCHMIDT
Cancer Research Institute and Department of Chemistry, Arizona State University, Tempe, AZ 85287, U.S.A.

Received October 22, 1986[4]

GEORGE R. PETTIT, SHEO BUX SINGH, MARGARET L. NIVEN, and JEAN M. SCHMIDT. Can. J. Chem. **66**, 406 (1988).

Combretum caffrum, a tree in the family Combretaceae, has been found to contain three 9,10-dihydrophenanthrenes (6,7-dihydroxy-2,3,4-trimethoxy; 7-hydroxy-2,3,4,6-tetramethoxy; and 2,7-dihydroxy-3,4,6-trimethoxy) that inhibit (ED_{50} 2.2, 2.8, and 2.6 μg/mL) growth of the murine lymphocytic leukemia cell line. One phenanthrene (7-hydroxy-2,3,4,6-tetramethoxy) was also isolated with similar (ED_{50} 2.0 μg/mL) activity. Structures for each of these substances, including a dihydrophenanthrene (2-hydroxy-3,4,6,7-tetramethoxy-9,10-dihydrophenanthrene), were determined by detailed high resolution nuclear magnetic resonance and mass spectral studies and (or) X-ray crystal structure analysis.

GEORGE R. PETTIT, SHEO BUX SINGH, MARGARET L. NIVEN et JEAN M. SCHMIDT. Can. J. Chem. **66**, 406 (1988).

On a trouvé que le *Combretum caffrum*, un arbre de la famille des Combretaceae, contient trois dihydro-9,10 phénanthrènes (les dihydro-6,7 triméthoxy-2,3,4, hydroxy-7 tétraméthoxy-2,3,4,6 et dihydroxy-2,7 triméthoxy-3,4,6) qui inhibent (ED_{50} 2,2, 2,8 et 2,6 μg/mL) la croissance des cellules de la leucémie lymphocytaire de la murine. On a aussi isolé l'hydroxy-7 tétraméthoxy-2,3,4,6 phénanthrène qui possède une activité semblable (ED_{50} 2,0 μg/mL). Pour déterminer les structures de chacunes de ces substances, y compris celle de l'hydroxy-2 tétraméthoxy-3,4,6,7 dihydro-9,10 phénanthrène, on a fait appel à la résonance magnétique nucléaire à haute résolution, à des études par spectrométrie de masse ainsi que par des analyses de diffraction des rayons-X.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

In 1979 we began, in collaboration with the U.S. National Cancer Institute (NCI), a detailed investigation of the South African tree *Combretum caffrum* (Combretaceae) in respect to antineoplastic constituents. Two years later we isolated and determined the structure of combretastatin (**1**), a new substance that caused pronounced astrocyte reversal in the NCI astrocytoma bioassay (2–4). In 1985 the principal antineoplastic constituent of *Combretum caffrum* was found and designated combretastatin A-1 (5). The *cis* stilbene **2** proved to have in vivo activity against the murine P388 lymphocytic leukemia (6) and, most importantly, was found to be the most potent inhibitor of tubulin polymerization so far known, leading to complete inhibition at 1.5 μM concentrations. Some of the fractions accompanying combretastatin A-1 were found to inhibit growth of the PS cell line, and investigation of those leads forms the basis of this report.

As previously described (5), the stem-wood of *Combretum caffrum* was extracted with methylene chloride – methanol, and the methylene chloride fraction, prepared by dilution of the extract with water, was dissolved in 9:1 methanol–water and extracted with hexane. Next, the methanol–water solution was diluted to 3:2 with water and extracted with methylene chloride. The resulting methylene chloride fraction was employed for the original isolation of combretastatin A-1 (5) and as starting point for the present study of PS cell growth inhibitory components. The methylene chloride fraction was further separated by successive gel permeation chromatography in methanol on Sephadex-LH20, and gel partition chromatography on the same substrate using hexane–toluene–methanol (3:1:1), followed by chromatography in hexane – ethyl acetate (17:3) on silica gel. By this means dihydrophenanthrenes **3***a–d* were isolated in 6.49×10^{-4}, 7.14×10^{-4}, 1.3×10^{-5}, and 1.12×10^{-4}% yields respectively. In addition, phenanthrene **4***a* was isolated in 8.69×10^{-4}% recovery. Of these, all but dihydrophenanthrene **3***c* showed acceptable inhibition of the PS cell line with ED_{50} range 2–3 μg/mL.

In 1971–1972 Letcher *et al.* (7) at the University of Rhodesia (now Zimbabwe) reported isolation of a series of dihydrophenanthrenes from petroleum ether extracts of *Combretum apiculatum*, *molle*, and *psidioides*. Some of those dihydrophenanthrenes and associated phenanthrenes appeared closely related to the *Combretum caffrum* constituents **3***a–d* and **4***a*. However, we were unable to obtain authentic samples of phenanthrenes **3***a–d* and **4***a* and they had to be approached as new structural problems. A series of coordinated chemical transformations, nmr and mass spectral analyses, and X-ray crystal structure determinations were employed to unequivo-

*Chemical shifts with same sign in the vertical columns may be reversed and similar values for the methoxy groups may also be interchanged. Additional signals: acetates (**3***e*) 20.68, 20.70, 168.48, 168.55; (**3***f*) 20.75, 169.27; (**3***g*) 2 × 20.74, 2 × 169.15; (**4***b*) 20.74, 169.19. **t, J_{CD} = 50.0 Hz.
†Acetone-d_6 as solvent.
‡**3***a*, **3***b*, **3***d*, and **4***a* at 22.67 MHz and remainder at 100.62 MHz.

cally assign structures **3***a–d*, their acetate derivatives **3***e–g*, and phenanthrenes **4***a* and **4***b*. For example, dihydrophenanthrenes **3***a* and **3***d* appeared by high resolution electron impact mass spectrometry (HREIMS) to be isomeric with a molecular ion at *m/z* 302 corresponding to molecular formula $C_{17}H_{18}O_5$. No major fragmentation pathways were observed. Acetylation led to isomeric diacetates **3***e* and **3***g*. The high resolution (400 MHz) ^{1}H nmr spectra (Table 1) of phenols **3***a* and **3***d* suggested the presence of signals corresponding to benzylic, phenolic hydroxyl (2), methoxyl (3), and aromatic (3) protons. Detailed interpretation of the ^{1}H nmr (Table 1) and ^{13}C nmr (Table 2) spectra combined with the application of nuclear Overhauser enhancement difference spectroscopy (NOEDS) and 2D-NOESY nmr experiments (Fig. 1) suggested the structures **3***a* and **3***d*. The 6,7-dihydroxy assignment for dihydrophenanthrene **3***a* was further substantiated by a base (potassium *tert*-butoxide in D_2O) catalyzed deuterium exchange reaction that afforded, following acetylation, D-5, D-8-dihydrophenanthrene **5**. The ^{1}H nmr spectrum of deuterium derivative **5** showed absence of the H-5 and H-8 proton signals and the ^{13}C nmr displayed two very weak triplets due to deuterium coupling at δ 121.57 (C-8) and δ 122.12 (C-5) with J = 50 Hz, in the proton noise-decoupled

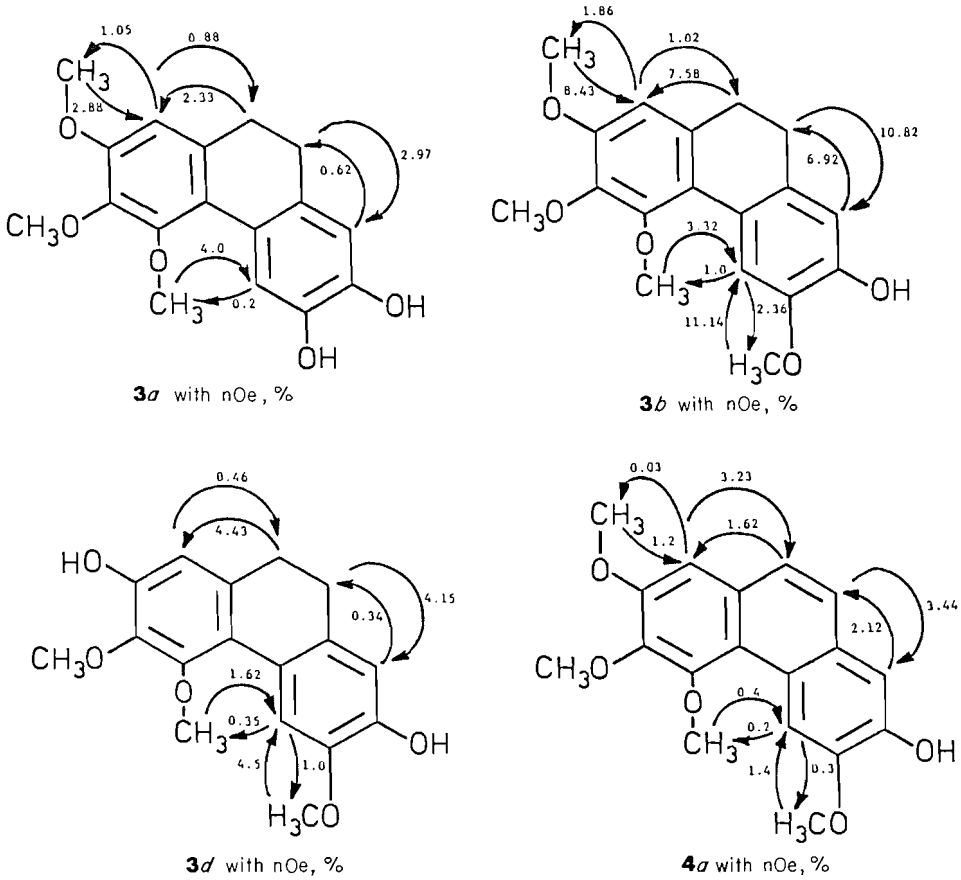

FIG. 1. Summary of nOe and 2D NOESY nmr experiments.

spectrum. Unequivocal proof for the 6,7-dihydroxy orientation was provided by fluoride–hydrogen bonding promoted methylenation of phenol **3***a* with dibromomethane to yield the 6,7-methylene dioxy derivative **6**. Support for the structure of isomer **3***d* was obtained by pyridinium chlorochromate (8) oxidation to the extended quinone **7**. Results of these experiments, combined with the crystal structure determination for the dihydrophenanthrenes **3***b* and **3***c* and subsequent nmr spectral correlations, firmly established the structures of dihydrophenanthrenes **3***a* and **3***d*. Both of these structures had previously been assigned by Letcher (*7a–c*) to *Combretum psidioides* components.

Recrystallization of dihydrophenanthrenes **3***b* and **3***c* from hexane–acetone and hexane–2-propanol gave crystalline specimens that yielded to crystal structure determination. Fractional atomic coordinates of both phenols **3***b* and **3***c* are shown in Table 3, with illustrations and atomic numbering given in Figs. 2 and 3 respectively. Relevant molecular parameters are reported in Table 4. Structure **3***b* has been determined much more precisely than structure **3***c*, as evidenced by the standard deviations of the atomic and molecular parameters. Doubtlessly this results from the difference in quality of the crystals. However, we note that the two structures are essentially very similar, with bond lengths and angles of the expected order of magnitude.

Saturation at C(9) and C(10) is clearly apparent from the C(9)—C(10) bond length and the tetrahedral orientation of the angles involving those carbons. The degree of pucker of the C(4a)C(4b)C(10)C(9)C(8a)C(8b) ring is similar in both structures. Consequently, the magnitude of the torsion angles C(4)C(4a)C(8b)C(5), which give a measure of the orientation of the two phenyl rings with respect to each other, are the same. For dihydrophenanthrene **3***b*, O(7)----O(6), measuring 2.665(3) Å within a single molecule, clearly indicates that the hydroxyl hydrogen is involved in intramolecular H-bonding. With the isomer **3***c* there are neither intra- nor inter-molecular close contacts (<3 Å) involving O(2)----O(acceptor); hence we have no evidence for any hydrogen bonding involving the phenolic hydroxyl group of **3***c*.

With the crystal structures of dihydrophenanthrenes **3***b* and **3***c* in hand, the nmr spectral assignments recorded in Tables 1 and 2 were ascertained and confirmed by results of NOEDS

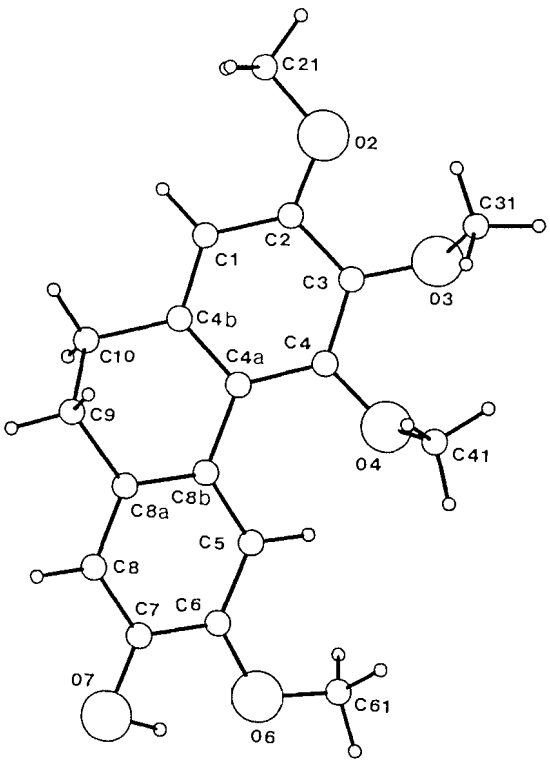

FIG. 2. 7-Hydroxy-2,3,4,6-tetramethoxy-9,10-dihydrophenanthrene (**3***b*).

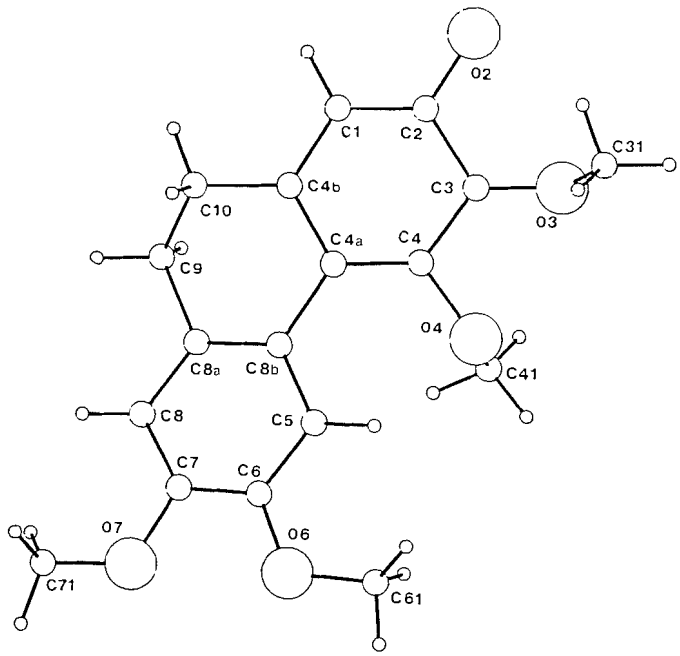

FIG. 3. 2-Hydroxy-3,4,6,7-tetramethoxy-9,10-dihydrophenanthrene (**3***c*).

experiments (cf. Fig. 1). Structure **3***b* has previously been assigned to a component of *Combretum psidioides* by Letcher (ref. 7*c*) but dihydrophenanthrene **3***c* proved to be a completely new structure. In turn, these structural assignments allowed ready access to the structure of phenanthrene **4***a*. The substituent pattern was found analogous to that in dihydrophenanthrene **3***b* and this was further corroborated by NOEDS experiments in deuteriobenzene–deuteriochloroform. The deuteriobenzene-induced shifts in the aromatic region were very useful. Irradiation of the methoxyl groups at δ 4.093 and 4.023 produced enhancement at δ 9.065 corresponding to the C-5 hydrogen. Analogous treatment of the methoxyl group at δ 4.004 attached to the C-2 carbon enhanced the C-1 proton at δ 7.071, thereby allowing assignment of the δ 7.713 chemical

shift to the C-8 hydrogen. Furthermore, irradiation of the C-1 proton enhanced the C-10 proton at δ 7.490 and, similarly, irradiation of the C-8 hydrogen at δ 7.713 was felt by the C-9 hydrogens at δ 7.530. A summary of these experiments has been displayed in Fig. 1.

Undebatable evidence for structure **4***a* was achieved by an X-ray crystal structure determination. Fractional atomic coordinates of phenanthrene **4***a* are reported in Table 3, with an illustration and atomic numbering given in Fig. 4. Relevant molecular parameters are given in Table 4. All bond lengths and angles of phenanthrene **4***a* were the expected order of magnitude. The short C(9)—C(10) bond length of 1.326(6) Å confirms the unsaturation of that bond. As expected, all three rings of the structure are planar, with angles between the normals to the ring planes small, giving the molecule some overall degree of planarity. The O(7)....O(6) nonbonded distance of 2.653(5) Å indicates that the hydroxyl hydrogen was most likely involved in intramolecular hydrogen bonding. Phenanthrene **4***a* has been proposed as a component of *Combretum psidioides* (ref. 7*c*).

Presently, investigation of *Combretum caffrum* constituents suggests a biosynthetic pathway proceeding from shikimic acid and tyrosine to the bibenzyl, styrene, dihydrophenanthrene, and phenanthrene systems illustrated by structures **1**, **2**, **3**, and **4**. On the assumption that dihydrophenanthrenes **3***a*, *b*, and *d* and phenanthrene **4***a* owe their PS cell growth inhibitory properties primarily to their phenol substituents, it would appear that the intermediary metabolites (cf. **1** and **2**) possess the most potent biological properties in this plant genus. Pertinent to this point was the recent observation that the 9,10-dihydrophenanthrene juncusol (from *Juncus roemerianus*, Juncaseae), the antimicrobial and cell growth inhibitory (KB, human epidermoid carcinoma of the nasal nasopharynx), may display those biological properties due to its phenolic substituents as indicated by structure/activity relationships (9). Eventually, when sufficient quantities of dihydrophenanthrenes **3***a–d* become available for in vivo antineoplastic and other biological evaluations, their potential will be more clearly ascertained. Regardless of the outcome, the present unequivocal structure elucidations of dihydrophenanthrenes **3***a–d* and phenanthrene **4***a* provide a very secure foundation for solving future structure problems in this area of phenanthrene biosynthetic products.

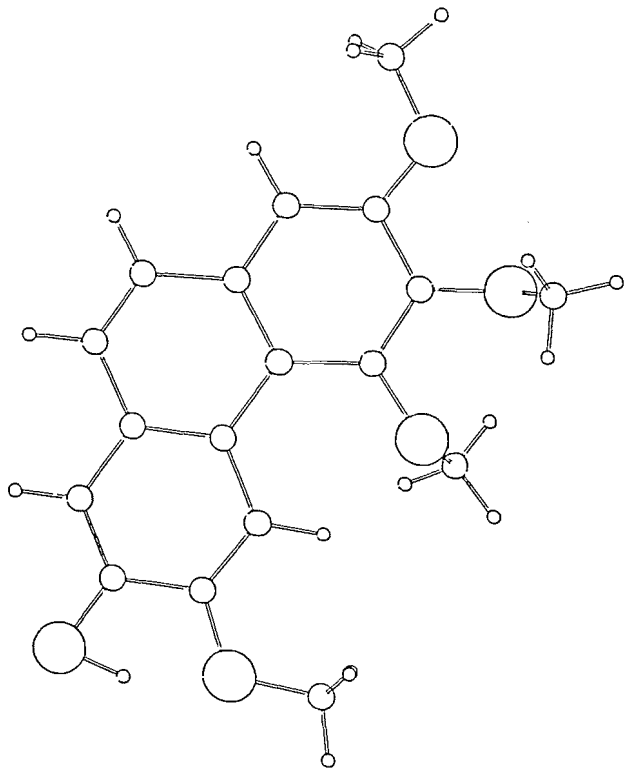

FIG. 4. 7-Hydroxy-2,3,4,6-tetramethoxy-phenanthrene (**4***a*).

Experimental

The general experimental techniques and instruments employed in this study have been summarized in ref. 5. Multiplicities in carbon spectra were determined by SFORD. Nuclear Overhauser effect difference spectroscopy (NOEDS) experiments were conducted by Dr. R. A. Nieman using an 8–12 mmol/L sample size in deuteriochloroform or deuteriobenzene–deuteriochloroform degassed (×6) by the freeze–thaw technique. In each of the nOe experiments measurements were conducted over long time intervals with variable irradiating power, decoupling time, and recovery delay. Since the T_1 for these experiments were not measured, relative enhancements between different irradiations and experiments cannot be compared.

Isolation and characterization procedures

A 77-kg (dry weight) amount of stem-wood from the South African tree *Combretum caffrum* (Eckl. and Zeyh) Kuntze was extracted with methylene chloride – methanol (1:1) and converted to a methylene chloride fraction as briefly summarized in the discussion section of this communication and in detail in our ref. 5. The methylene chloride fraction weighed 827.9 g and was further separated by gel permeation chromatography in methanol on Sephadex LH-20. Two of the fractions (A, 28.6 g, PS ED_{50} 0.36 μg/mL and B, 30.6 g, ED_{50} 0.18 μg/mL) obtained following the removal of the combretastatins (**1** and **2**) were subjected individually to partition chromatography in 3:1:1 hexane–toluene–methanol on columns of Sephadex LH-20. By that method, fraction A provided 0.50 g of *6,7-dihydroxy-2,3,4-trimethoxy-9,10-dihydrophenanthrene* (**3***a*, PS ED_{50} 1.4, 2.2 μg/mL) as a colorless powder from hexane–acetone and broad-shaped crystals from methanol melting at 212–214°C (lit. (7*a*, *b*) mp 207–210°C); R_f 0.405 (silica gel with methylene chloride – methanol–water, 88:12:1), 0.42 (benzene – methylene chloride – methanol–water, 10:80:10:1), 0.38 (methylene chloride – methanol, 9:1), 0.25 (methylene chloride – methanol, 94:6); uv (CH_3OH) λ_{max} (log ε): 227 (4.35), 280 (4.24), 314 (4.14) μm; ir (NaCl) ν_{max}: 3360, 1596, 1512, 1490, 1448, 1405, 1102, and 1075 cm^{-1}; HREIMS, *m/z* (rel. int. %): 302.1154 (100, M^+, calcd. for $C_{17}H_{18}O_5$: 302.1154); 287.0915 (14, M − CH_3, $C_{16}H_{15}O_5$); 269.0812 (11, $C_{16}H_{13}O_4$); 244.0734 (7, $C_{14}H_{12}O_4$). The ^1H nmr and ^{13}C nmr data have been recorded in Tables 1 and 2.

The 1.47-g fraction remaining from the original fraction A, following isolation of dihydrophenanthrene **3***a*, was rechromatographed on Sephadex LH20 employing hexane–toluene–methanol (3:1:1) followed by further separation in hexane – ethyl acetate (4:1) on a column of silica gel to afford 66.9 mg (PS ED_{50} 2.0 μg/mL) of *7-hydroxy-2,3,4,6-tetramethoxyphenanthrene* (**4***a*), which recrystallized from hexane–chloroform as prisms melting at 176–178°C (lit. (7*c*) mp 176–178°C); PS ED_{50} 2.0 μg/mL; R_f 0.40 (1:1 hexane – ethyl acetate); uv (CH_3OH) λ_{max} (log ε): 223 (4.39), 258 (4.86), 281 (4.56), 307 (4.06) μm; ir (NaCl) ν_{max}: 3400, 1504, 1479, 1465, 1421, 1408, 1274, 1233, 1210, 1123, and 1081 cm^{-1}; ^1H nmr and ^{13}C nmr, Tables 1 and 2; HREIMS, *m/z* (rel. int. %): 314.1159 (100, M^+, calcd. for $C_{18}H_{18}O_5$: 314.1154); 300.0987 (30, $C_{17}H_{16}O_5$); 299.0921 (44, $C_{17}H_{15}O_5$); 271.0973 (20, $C_{16}H_{15}O_4$); 256.0738 (30, $C_{15}H_{12}O_4$); 213.0553 (13, $C_{13}H_9O_3$); 185.0600 (13, $C_{12}H_9O_2$).

Parallel separation of fraction B by partition chromatography in 3:1:1 hexane–toluene–methanol on a column of Sephadex LH-20 afforded three fractions containing dihydrophenanthrenes. The first, weighing 1.46 g, was recrystallized from hexane–acetone to yield 50 mg (PS ED_{50} 2.8 μg/mL) of *7-hydroxy-2,3,4,6-tetramethoxy-9,10-dihydrophenanthrene* (**3***b*) melting at 171–172°C (lit. (7*c*) mp 156–158°C) upon recrystallization (needles) from hexane–acetone; R_f 0.69 (47:3 methylene chloride – methanol), 0.57 (1:1 hexane – ethyl acetate); uv (CH_3OH) λ_{max} (log ε): 222 (4.52), 281 (4.26), 303 (4.14), 314 (4.13) μm; ir (NaCl) ν_{max}: 3400, 1592, 1507, 1491, 1456, 1402, 1269, 1124, 1082, 1050, and 1005 cm^{-1}; ^1H nmr and ^{13}C nmr data appear in Tables 1 and 2; HREIMS, *m/z* (rel. int. %): 316.1303 (100%, M^+, calcd. for $C_{18}H_{20}O_5$: 316.1311); 269.0801 (24, $C_{16}H_{13}O_4$). The mother liquors from these recrystallizations were combined and chromatographed in 17:3 hexane – ethyl acetate on a column of silica gel to furnish another 0.50 g of dihydrophenanthrene **3***b*.

The next fraction (2.41 g) obtained from original fraction B was subjected to gradient elution chromatography (×2) in hexane – ethyl acetate on a column of silica gel to provide 10 mg (PS ED_{50} 17 μg/mL) of *2-hydroxy-3,4,6,7-tetramethoxy-9,10-dihydrophenanthrene* (**3***c*) that recrystallized from hexane-2-propanol as colorless needles, mp 177–180°C; R_f 0.56 (1:1 hexane – ethyl acetate); uv (CH_3OH) λ_{max} (log ε): 223 (4.52), 282 (4.32), 313 (4.19) μm; ir (NaCl) ν_{max}: 3420, 1587, 1514, 1482, 1457, 1450, 1437, 1399, 1220, 1116, and 1039 cm^{-1}; ^1H nmr and ^{13}C nmr, see Tables 1 and 2; HREIMS, *m/z* (rel. int.%): 316.1311 (100, M^+, calcd. for $C_{18}H_{20}O_5$: 316.1311); 301.1076 (28, M − CH_3, $C_{17}H_{17}O_5$); 270.0891 (16, M − CH_3 − CH_3O, $C_{16}H_{14}O_4$).

The third fraction (0.57 g) prepared from the initial fraction B was separated by gradient elution in hexane – ethyl acetate on a column of silica gel to afford 86.4 mg (PS ED_{50} 2.6 μg/mL) of *2,7-dihydroxy-3,4,6-trimethoxy-9,10-dihydrophenanthrene* (**3***d*). Recrystallization from hexane–chloroform yielded needles melting at 112–114°C (lit. (7*c*) mp 111–113°C); R_f 0.54 (1:1 hexane – ethyl acetate); uv (CH_3OH) λ_{max} (log ε): 223 (4.57), 281 (4.40), 3.5 (4.26) μm; ir (NaCl) ν_{max}: 3400, 1592, 1509, 1485, 1459, 1446, 1437, 1280, 1272, 1206, and 1114 cm^{-1}; ^1H nmr and ^{13}C nmr, see Tables 1 and 2; HREIMS, *m/z* (rel. int. %): 302.1162 (100, M^+, calcd. for $C_{17}H_{18}O_5$: 302.1154); 287.0928 (17, M^+ − CH_3, $C_{16}H_{15}O_5$).

Acetylation of phenols **3**a, **3**b, **3**d, *and* **4**a

A solution of the phenol (5–25 mg) in pyridine (0.25–0.5 mL) – acetic anhydride (0.5–0.75 mL) was allowed to remain at room temperature for 72 h. After addition of methanol the solvent was evaporated (cyclohexane was added to form an azeotropic mixture) under reduced pressure. The residue in 1:1 hexane – ethyl acetate was chromatographed on a column of silica gel contained in a pipette. The ^1H nmr and ^{13}C nmr data for each of the acetates have been included as part of Tables 1 and 2. The following pure acetyl derivatives were obtained: *6,7-diacetoxy-2,3,4-trimethoxy-9,10-dihydrophenanthrene*

TABLE 5. Crystal data, experimental details of data collections, and refinement parameters for dihydrophenanthrenes **3***b*, **3***c* and phenanthrene **4***a*

*Few data obtained because of CAD-4 routine, which skips very weak reflections; weakness of reflections arising from poor mosaicity and shape of crystal.

(**3***e*) crystallized as plates from methanol: mp 137.5–139.5°C (lit. (7*a*, *b*) mp 130–133°C); R_f 0.51 (1:1 hexane – ethyl acetate), 0.26 (7:3 hexane – ethyl acetate); ir (NaCl) ν_{max}: 1772, 1598, 1491, 1413, 1371, 1210, 1168, 1114, 1082, and 1045 cm^{-1}; HREIMS, *m/z* (rel. int. %): 386.1363 (23, M$^+$, calcd. for $C_{21}H_{22}O_7$: 386.1366); 344.1254 (39, M$^+$ − CH_2CO, $C_{19}H_{20}O_6$); 302.1150 (100, M$^+$ − 2 × CH_2CO, $C_{17}H_{18}O_5$).

Recrystallization of *7-acetoxy-2,3,4,6-tetramethoxy-phenanthrene* (**4***b*) from methanol gave colorless flakes melting at 137–140°C (lit. (7*c*) mp 138–140°C); R_f 0.52 (1:1 hexane – ethyl acetate), 0.26 (7:3 hexane – ethyl acetate); ir (NaCl) ν_{max}: 1767, 1512, 1505, 1470, 1434, 1254, 1241, 1213, 1198, and 1121 cm^{-1}; HREIMS, *m/z* (rel. int. %): 356.1273 (38, M$^+$, calcd. for $C_{20}H_{20}O_6$: 356.1260); 314.1128 (100, M$^+$ − CH_2CO, $C_{18}H_{18}O_5$); 300.0998 (14, $C_{17}H_{16}O_5$); 299.0934 (41, $C_{17}H_{15}O_5$).

A fine powder was obtained by recrystallization of 7-acetoxy-2,3,4,6-tetramethoxy-9,10-dihydrophenanthrene (**3***f*) from methanol; mp 115–116°C (lit. (7*c*) mp 115–116°C); R_f 0.58 (1:1 hexane – ethyl acetate), 0.34 (7:3 hexane – ethyl acetate); ir (NaCl) ν_{max}: 1765, 1453, 1398, 1240, 1219, 1196, 1144, 1120, 1083, and 1052 cm^{-1}; HREIMS, *m/z* (rel. int. %): 358.1408 (22, M$^+$, calcd. for $C_{20}H_{22}O_6$: 358.1416); 316.1306 (100, M$^+$ − CH_2CO, $C_{18}H_{20}O_5$); 269.0816 (10, $C_{16}H_{13}O_4$).

A specimen of 2,7-diacetoxy-3,4,6-trimethoxy-9,10-dihydrophenanthrene (**3***g*) crystallized from hexane – diethyl ether as an amorphous powder melting at 111–113°C (lit. (7*c*) mp 110–112°C); R_f 0.57 (1:1 hexane – ethyl acetate), 0.30 (7:3 hexane – ethyl acetate); ir (NaCl) ν_{max}: 1765, 1506, 1397, 1242, 1216, 1198, 1068, and 1017 cm^{-1}; HREIMS, *m/z* (rel. int. %): 386.1363 (15, M$^+$, calcd. for $C_{21}H_{22}O_7$: 386.1366); 344.1251 (24, M − CH_2CO, $C_{19}H_{20}O_6$); 302.1144 (100, M − 2 × CH_2CO, $C_{17}H_{18}O_5$).

*Crystal structure determinations for 7-hydroxy-2,3,4,6-tetramethoxy-9,10-dihydrophenanthrene (**3**b), 2-hydroxy-3,4,6,7-tetramethoxy 9,10-dihydrophenanthrene (**3**c), and 7-hydroxy-2,3,4,6-tetramethoxy-phenanthrene (**4**a)*

For each structure the crystal most suitable was selected and irradiated with MoKα (λ = 0.7107 Å) radiation, using an Enraf–Nonius CAD-4 diffractometer. Cell parameters were obtained by least-squares analysis of the setting angles of 24 reflections. During the data collections, intensities of three standard reference reflections were monitored every hour and centering checked every 100 measured reflections. Intensities were corrected by Lorentz and polarization effects but not for absorption.

Each structure was solved by direct methods using a preliminary version of SHELX-S-84[5] and refined using SHELX-76 (11). For phenol **3***c*, the poor quality of the crystal resulted in a paucity of data, which precluded anisotropic treatment, and the non-hydrogen atoms were modelled with isotropic thermal motion. For each structure, aromatic-H and methylene-H atoms were placed in calculated positions with a single temperature factor. All hydrogen atoms in the methyl groups were refined as rigid units, again with a single temperature

factor. With phenol **3***b* and phenanthrene **4***a*, the hydroxyl hydrogen was placed as located in the difference map and constrained to ride at 1.00(1) Å from the parent oxygen and at 1.60(1) Å from the adjacent O-(CH_3) group to comply with appropriate H-bonding considerations. In both cases, its final position was acceptable in all respects except for a high isotropic temperature factor. For phenol **3***c* no hydroxyl hydrogen could be located and has therefore been omitted from the structure factor calculation. A weighting scheme, $(\sigma^2 F)^{-1}$ was employed in the final refinements. The program PARST (12) was used for calculations concerning molecular geometry and PLUTO[6] for illustrations. Complex neutral-atom scattering factors were taken from Cromer and Mann (13) for the C and O atoms and from Stewart, Davidson, and Simpson (14) for H, with dispersion corrections from Cromer and Liberman (15). All computations were carried out using a SPERRY 1100 computer. Further details of the data collections, solutions, and refinement of the structures are given in Table 5.[7]

*6,7-Diacetoxy-2,3,4-trimethoxy-5,8-dideuterio-9,10-dihydrophenanthrene (**5**)*

A mixture prepared from deuterium oxide (3 mL), potassium *tert*-butoxide (50 mg), and phenol **3***a* (45.2 mg) was heated at 110°C (sealed tube) for 48 h. After cooling to room temperature and evaporation of the water phase the residue was acetylated with pyridine (1 mL) – acetic anhydride (1 mL) for 1 day at room temperature. The mixture was treated with ice-water, and acetate was extracted with diethyl ether. The ethereal solution was washed successively with water, dilute hydrochloric acid, water, saturated sodium bicarbonate solution, and water. Evaporation of the dry (anhydrous sodium sulfate) solvent and crystallization of the residue from methanol afforded (46 mg) deuterium derivative **5** melting at 135°C. For ^{1}H nmr and ^{13}C nmr data see Tables 1 and 2; HREIMS, *m/z* (rel. int. %): 388.1508 (M^+, 17%, calcd. for $C_{21}H_{20}O_7D_2$: 388.1491); 346.1384 (38, calcd. for $C_{19}H_{18}O_6D_2$: 346.1385); 304.1281 (100, calcd. for $C_{17}H_{16}O_5D_2$: 304.1280).

*6,7-Methylenedioxy-2,3,4-trimethoxy-9,10-dihydrophenanthrene (**6**)*

A solution of phenol **3***a* (5 mg) in dimethylformamide (1 mL) containing cesium fluoride (12.5 mg) (10) was stirred at room temperature under argon for 10 min. At that point dibromomethane (1.15 μL) was added and the mixture heated at 110°C for 3 h (tlc examination indicated completion). Upon cooling to room temperature the residue was triturated with diethyl ether (20 mL) and the ethereal solution was washed with water (20 mL), dried (sodium sulfate), and concentrated. A pure specimen of ether **6** (2 mg) was isolated from the crude product by preparative tlc on silica gel (1:1 hexane – ethyl acetate) and recrystallization from acetone to give a powder melting at 127–129°C; ir (NaCl) ν_{max}: 1595, 1483, 1463, 1454, 1423, 1408, 1243, 1216, 1137, 1102, and 1039 cm^{-1}; HREIMS, *m/z* (rel. int. %): 314.1154 (M^+, 100%, calcd. for $C_{18}H_{18}O_5$: 314.1154).

*3,4,6-Trimethoxy-9,10-dihydrophenanthrene-2,7-quinone (**7**)*

A solution of phenol **3***d* (10 mg, 0.03 mmol) in methylene chloride (1 mL) was added to a solution prepared from pyridinium chlorochromate (ref. 8, 12.9 mg, 0.06 mmol) and sodium acetate (5 mg, 0.06 mmol). After filtering through a pipette column filled with silica gel and elution with methylene chloride, evaporation of solvent yielded a red powder (9.0 mg), mp 131–135°C; uv (CH_3OH) λ_{max} (log ε): 221 (4.37), 282 (4.10), 312 (3.97), 426 (3.38) μm; ir (NaCl) ν_{max}: 1634, 1603, 1576, 1560, 1545, 1437, 1259, 1216, 1178, and 1142 cm^{-1}; ^{1}H nmr and ^{13}C nmr, see Tables 1 and 2; HREIMS, *m/z* (rel. int. %): 300.1004 (M^+, 16, calcd. for $C_{17}H_{16}O_5$: 300.0997).

Anwuweizonic acid and manwuweizic acid, the putative anticancer active principle of *Schisandra propinqua*

JIA-SEN LIU,[1] MEI-FEN HUANG, AND YONG TAO

Shanghai Institute of Materia Medica, Academia Sinica, 319 Yue-Yang Rd., Shanghai 200031, China

Received August 14, 1987

This paper is dedicated to the memory of Professor Karel Wiesner

JIA-SEN LIU, MEI-FEN HUANG, and YONG TAO. Can. J. Chem. **66**, 414 (1988).

The structures of two new triterpenoid acids, anwuweizonic acid (**1**) and manwuweizic acid (**2**), from *Schisandra propinqua* are elucidated by spectroscopic evidence and chemical correlation. Compound **2** shows significant inhibitory activity against Lewis lung cancer, brain tumor-22, and solid hepatoma in mice, and exhibits no cytotoxic action in vitro.

JIA-SEN LIU, MEI-FEN HUANG et YONG TAO. Can. J. Chem. **66**, 414 (1988).

Faisant appel à des données spectroscopiques et à des corrélations chimiques, on a élucidé les structures de deux nouveaux acides, les acides anwuweizonique (**1**) et manwuweizique (**2**), qui ont été isolés du *Schisandra propinqua*. Le composé **2** présente une activité inhibitrice importante vis-à-vis du cancer des poumons de Lewis, du tumeur 22 du cerveau et de l'hépatome solide chez la souris et il ne présente pas d'activité cytotoxique in vitro.

For personal use only.

It has been reported that Manshanxiang Complex, a herbal medicine preparation in which the stems and roots of *Schisandra propinqua* (Wall.) Hook. f. et Thoms are a major component, was used for treatment of lung carcinoma in several hospitals of Yunnan Province in China (1), and that the water extract from the stems and roots of *S. propinqua* shows activity against Lewis lung cancer in animal tests (2). To isolate the active principle, we started chemical studies on this plant. Two new triterpenoid acids, anwuweizonic acid (**1**) and manwuweizic acid (**2**), were isolated from its alcoholic extract and the second (**2**) exhibits significant inhibitory activity against Lewis lung cancer, brain tumor-22, and solid hepatoma in mice and shows no cytotoxic action in vitro.[2] Therefore, **2** is probably a major anticancer active principle of the plant under study. In this paper we wish to report the structural elucidation of the two acids.

Anwuweizonic acid (**1**), $C_{30}H_{46}O_3$, gave a monoester on reaction with diazomethane. The ^1H nmr spectrum of **1** reveals the presence of a moiety of the angelic acid terminal (3) (δ 6.10, 1H, t, J = 7, H-24; δ 1.94, 3H, s, H-27), a secondary methyl (δ 0.92, 3H, d, J = 5, H-21), and five tertiary methyls (δ 0.72, 0.90, 1.10, 1.14, 3H, 3H, 6H, 3H each, s), and its ir spectrum shows the characteristics of an α,β-unsaturated acid (1690, 3200–2500 cm^{-1}) and a ketone (1710 cm^{-1}). These features closely resemble those of anwuweizic acid (**3**) (4) except for the ketone group of **1** in place of a hydroxyl in **3**, suggesting that anwuweizonic acid possesses structure **1**. This proposal was verified by reduction of **1** with sodium borohydride in methanol, providing anwuweizic acid (**3**, 8% yield) and its 3β-hydroxyl isomer (85% yield).

Manwuweizic acid (**2**), $C_{30}H_{46}O_4$, furnished a diester on methylation with diazomethane, a feature of a dicarboxylic acid. The ^1H nmr spectrum of **2** shows the presence of an isopropenyl group (δ 4.91, 4.69, 1H each, s, H-28; δ 1.77, 3H, s, H-29) and three tertiary methyls (δ 0.74, 0.94, 0.97, 3H each, s, H-18, H-19, H-30) besides a moiety of the angelic acid terminal (δ 6.09, 1H, dd, J = 6.7/7.1, H-24; δ 1.91, 3H, s, H-27) and a secondary methyl (δ 0.96, 3H, d, J = 4.8, H-21) in the molecule. These facts indicate that manwuweizic acid possesses the 3,4-seco-ring A and a side chain identical to **1**, which led to the proposed structure **2** for manwuweizic acid.

5

The following chemical correlation among anwuweizonic acid (**1**), manwuweizic acid (**2**), and anwuweizic acid (**3**), a known compound (4), further confirmed the proposed structures. Oxidation of **3** in ether with an aqueous solution of sodium dichromate – sulfuric acid provided anwuweizonic acid (**1**, 93% yield), and then oximation of **1** with hydroxylamine hydrochloride in ethanol–pyridine (1:1) afforded an oxime (98% yield). The oxime underwent an abnormal Beckmann rearrangement (5) in anhydrous pyridine and *p*-tosyl chloride at room temperature, giving a nitrile compound (**4**, 25% yield) and a lactam (**5**, 56% yield). Hydrolysis of **4** with 10% ethanolic KOH under reflux for 4 h led to **2** (70% yield), which is identical with natural manwuweizic acid. Therefore, the attribution of structure **1**, 3-oxo-lanosta-8,24*Z*-dien-26-oic acid, to anwu-

weizonic acid and structure **2**, 3,4-secolanosta-4(28),8,24*Z*-trien-3,26-dioic acid, to manwuweizic acid was fully supported.

Experimental

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. The following instruments were used for the spectra described here: ir, Perkin–Elmer 599B with KBr as the medium; ^{1}H nmr, JEOL PS-100 (100 MHz), Bruker AM-400 (400 MHz); and ^{13}C nmr, Bruker AC-100 (25.18 MHz), with $CDCl_3$ as the solvent, δ in ppm, and J in Hz; ms, Varian MAT-711.

Manwuweizic acid (2)

The crude alcoholic extract of the roots and stems of *Schisandra propinqua* (Wall.) Hook. f. et Thoms, gathered in Yuxi District, Yunnan Province, China, was suspended in water and extracted with ether. Then the ether extract was chromatographed on a silica gel column eluting with petroleum ether/benzene (1:1), benzene, benzene/ethyl acetate (10:1 and 4:1). The fractions eluted with benzene/ethyl acetate (4:1) gave crude crystals of manwuweizic acid (**2**). Its mother liquor was rechromatographed over a silica gel column, again giving **2** (see the isolation of **1**), which was recrystallized from chloroform/petroleum ether as needles (yield 0.04%), mp 191–193°C; $[\alpha]_D^{15}$ +54.3° (*c* 0.291, $CHCl_3$); ir ν_{max}: 3200–2500, 1705, 1695, 1630 cm^{-1}; ^{1}H nmr (400 MHz) δ: 6.09 (1H, dd, J = 6.7/7.1, H-24), 4.91, 4.69 (1H each, s, H-28), 1.91 (3H, s, H-27), 1.77 (3H, s, H-29), 0.74, 0.94, 0.97 (3H each, s, H-18, H-30, H-19), 0.96 (3H, d, J = 4.8, H-21); ^{13}C nmr (25.18 MHz) δ: 179.91 (s, C-3), 172.94 (s, C-26), 147.47 (s, C-4), 146.81 (d, C-24), 139.59, 129.77 (s, C-9, C-8), 126.10 (s, C-25), 113.85 (t, C-28), 51.09, 44.75 (s, C-14, C-13), 50.48 (d, C-17), 47.45 (d, C-5), 40.66 (s, C-10), 36.46 (d, C-20), 36.02, 32.87, 31.46, 31.21, 29.74, 28.12, 26.86, 26.11, 24.37, 22.03 (t each, C-1, C-2, C-6, C-7, C-11, C-12, C-15, C-16, C-22, C-23), 18.74 (q, C-27), 20.40 (q, C-21), 22.29, 23.08, 16.16, 25.30 (q, C-18, C-19, C-29, C-30); ms *m/z*: 470.3402 (M^+, calcd. for $C_{30}H_{46}O_4$: 470.3396), 455.3195 ($M - CH_3$), 397.3078 ($M - CH_2CH_2COOH$), 261.1853 ($C_{17}H_{25}O_2$), 235.1703 ($C_{15}H_{23}O_2$), 233.1560 ($C_{15}H_{21}O_2$).

Anwuweizonic acid (1)

The fractions eluted with benzene/ethyl acetate (10:1) mentioned above and the mother liquor of **2** were combined and rechromatographed on a silica gel column using petroleum ether/acetone (10:1). The late fractions again gave **2** and the early fractions afforded anwuweizonic acid (**1**) (yield 0.012%), crystallized from ether/petroleum ether, mp 126–128°C; $[\alpha]_D^{15}$ +63.8° (*c* 0.273, $CHCl_3$); ir ν_{max}: 3200–2500, 1710, 1690, 1630 cm^{-1}; ^{1}H nmr (100 MHz) δ: 6.10 (1H, t, J = 7, H-24), 1.94 (3H, s, H-27), 0.92 (3H, d, J = 5, H-21), 0.72, 0.90, 1.10, 1.14 (3H, 3H, 6H, 3H each, s, H-18, H-30, H-19, H-28, H-29); ms *m/z*: 454.3445 (M^+, calcd. for $C_{30}H_{46}O_3$: 454.3447), 439.3192 ($M - CH_3$), 271.2082 ($C_{19}H_{27}O$).

Methyl ester of 1

Compound **1** (30 mg) in ether reacted with an ethereal solution of diazomethane affording the methyl ester (30 mg) of anwuweizonic acid, crystallized from methanol, mp 89–90°C; ir ν_{max}: 1720, 1705, 1650 cm^{-1}; ^{1}H nmr (100 MHz) δ: 3.73 (3H, s, $COOCH_3$); ms *m/z*: 468 (M^+), 453 ($M - CH_3$), 421.

Dimethyl ester of 2

The same procedure as described above provided the dimethyl ester of manwuweizic acid, amorphous, ir ν_{max}: 1740, 1720, 1650 cm^{-1}; ^{1}H nmr (100 MHz) δ: 3.60, 3.70 (3H each, s, $COOCH_3 \times 2$); ms *m/z*: 498 (M^+), 483 ($M - CH_3$), 411 ($M - CH_2CH_2COOCH_3$).

Reduction of 1 to 3 and the 3β-hydroxyl isomer of 3

A solution of **1** (100 mg) in methanol (3 mL) with $NaBH_4$ (200 mg) was allowed to stand for 2 h at room temperature. The reaction mixture, after evaporation of the methanol in vacuum, was treated with water (5 mL) and one drop of hydrochloric acid, then extracted with chloroform. The extract was applied to a silica gel column eluting with benzene/ethyl acetate (10:1). The early fractions gave anwuweizic acid (**3**, 8 mg) identical with an authentic sample (4) (mixture mp, ir), and the late fractions afforded the 3β-hydroxyl isomer (85 mg) of **3**, mp 148–149°C, which is distinguished from **3** in the fingerprint region of ir and the H-3α (δ 3.24, 1H, dd, J = 4/9) signal of ^{1}H nmr.

Oxidation of 3 to 1

Compound **3** (45 mg) in ether (5 mL) was oxidized with an aqueous solution (0.6 mL) of sodium dichromate – sulfuric acid (1 g sodium dichromate in 6 mL water mixed with 1 mL 97% sulfuric acid, then diluted to 20 mL with water) under stirring for 5 h at room temperature. The ethereal layer was separated and the water layer was extracted with ether. The combined ethereal solution was washed with a saturated solution of sodium chloride and then concentrated, giving **1** (42 mg) identical to the natural compound (mixture mp and ir).

Oxime of 1

A mixture of **1** (300 mg) in pyridine (3 mL) and hydroxylamine hydrochloride (51 mg) in ethanol (3 mL) was heated on a boiling water bath for 1 h, and then diluted with water (100 mL). The solid product was filtered and crystallized from methanol, giving the oxime (300 mg), mp 184–186°C, ir ν_{max}: 3260, 3200–2500, 1690, 1640 cm^{-1}; ms *m/z*: 469 (M^+), 454 ($M - CH_3$), 436, 418.

Products (4 and 5) of Beckmann rearrangement

To a solution of the oxime (300 mg) in anhydrous pyridine (5 mL) was added *p*-tosyl chloride (300 mg), and the solution was allowed to stand for 24 h at room temperature. After dilution with water (50 mL) and acidification to pH 2 with hydrochloric acid, the reaction mixture was extracted using $CHCl_3$. The extract was chromatographed on a silica gel column eluting with benzene/ethyl acetate (10:1). The early fractions gave the nitrile compound (**4**, 70 mg), amorphous, ir ν_{max}: 3200–2500, 2250, 1690, 1640 cm^{-1}; ^{1}H nmr (100 MHz) δ: 6.10 (1H, t, J = 7, H-24), 4.95, 4.69 (1H each, s, H-28), 1.93 (3H, s, H-27), 1.77 (3H, s, H-29), 0.99, 0.95, 0.75 (3H each, s, H-19, H-30, H-18), 0.94 (3H, d, J = 4, H-21); ms *m/z*: 451 (M^+), 436 ($M - CH_3$), 418, 397.

The late fractions afforded the lactam (**5**, 170 mg), amorphous, ir ν_{max}: 3300, 3210, 3200–2500, 1690, 1640 cm^{-1}; ^{1}H nmr (100 MHz) δ: 5.97 (1H, t, J = 7, H-24), 1.92 (3H, s, H-27), 1.37, 1.31, 1.22, 0.92, 0.74 (3H each, s, H-29, H-28, H-19, H-30, H-18), 0.93 (3H, covered, H-21); ms *m/z*: 470 (M + 1), 469 (M^+), 455, 454, 398, 397, 379, 351.

Manwuweizic acid (2) from hydrolysis of 4

The nitrile compound (**4**) was dissolved in an ethanolic solution of 10% KOH and refluxed for 4 h. After evaporation of ethanol, the reaction mixture was acidified to pH 3 with hydrochloric acid and extracted with $CHCl_3$. The extract was purified on a silica gel column eluting with $CHCl_3$, giving **2** (50 mg) identical to the natural compound (mixture mp, ms, ^{1}H nmr, ir).

^{13}C nuclear magnetic resonance and reactivity of 4*H*-3,1-benzoxazin-4-ones[1]

VALERIE J. ROBINSON AND ROBIN W. SPENCER[2]
Syntex Research (Canada), 2100 Syntex Court, Mississauga, Ont., Canada L5N 3X4

Received June 26, 1987

VALERIE J. ROBINSON and ROBIN W. SPENCER. Can. J. Chem. **66**, 416 (1988).

Complete carbon-13 nuclear magnetic resonance assignments have been made for 22 4*H*-3,1-benzoxazin-4-ones. These compounds are alternate substrate inhibitors of human leukocyte elastase, a serine protease involved in tissue degradation. Correlations between the carbon chemical shifts and rates of alkaline hydrolysis are consistent with hydrolysis via attack at C4, and are also useful in the selection of parameters for structure–activity analysis.

VALERIE J. ROBINSON et ROBIN W. SPENCER. Can. J. Chem. **66**, 416 (1988).

On a fait des attributions complètes des spectres en résonance magnétique nucléaire du ^{13}C de 22 4*H*-benzoxazine-3,1 ones-4. Ces composés sont des inhibiteurs de substrats d'élastase leucocytaire humaine, une protéase de la sérine impliquée dans la dégradation des tissus. Des corrélations entre les déplacements chimiques des carbones et les taux d'hydrolyse alcaline sont en accord avec un mécanisme d'hydrolyse impliquant une attaque en C4; de plus, ces corrélations sont utiles dans la sélection des paramètres nécessaires pour une analyse structure–activité.

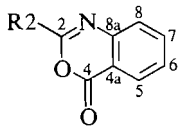
Introduction

4*H*-3,1-Benzoxazin-4-ones are potent inhibitors of serine proteases (1–6) with clinical potential in a number of degradative diseases (7). It is well established that benzoxazinones inhibit by acting as alternate substrates, acylating the target protease via attack of serine 195 at C4, and then slowly deacylating (2–6) (Scheme 1).



The carbon-13 nmr spectra of 22 benzoxazinones (Table 1) have been examined in detail, to more fully understand the chemistry of this ring system and to develop parameters that may be useful in structure–activity correlations with chemical and biological activity. This approach has been successfully used to correlate ^{13}C chemical shifts with carbonyl reactivity of cephalosporins and penicillins (8). In addition, the benzoxazinones offer an opportunity to investigate the electronic substituent effects on carbon-13 chemical shifts in a complex heterocycle of biochemical interest.

Experimental

Nuclear magnetic resonance spectra were recorded on a Bruker WP 80 spectrometer equipped with a 5-mm dual ^{13}C, ^{1}H probehead. All chemical shifts were determined from 0.3 *M* samples in DMSO-d_6 at 27°C, and more concentrated solutions were used for the ^{13}C coupled and 2D experiments.

J-modulated ^{13}C spectra were recorded using a delay τ of 7.6 ms ($\approx 1/J_{CH}$) and a relaxation delay of 6 s (9). Heteronuclear shift correlation spectra were obtained using the pulse sequence:

$$\text{delay} \rightarrow \pi/2(^1\text{H}) \rightarrow t_1/2 \rightarrow \pi(^{13}\text{C}) \rightarrow t_1/2 \rightarrow \Delta_1 \rightarrow \pi/2(^1\text{H}),$$
$$\pi/2(^{13}\text{C}) \rightarrow \Delta_2 \rightarrow \text{acquisition}$$

with broadband decoupling (10). A 1-s recycle delay was used with delay times $\Delta_1 = 1/(2J) = 1.8$ ms and $\Delta_2 = 1/(4J) = 3.3$ ms. In the f_2 and f_1 domains, 1024 and 256 points were used, respectively. Delays of 50 and 33 ms were used for Δ_1 and Δ_2, respectively, in optimizing for long-range correlations (11).

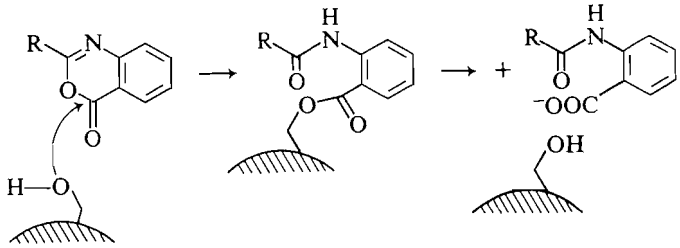

SCHEME 1

Compounds **1–4** and **8–21** have been previously reported (4, 12), as have compounds **7** and **23**[3] (13, 14). Compounds **5**, **6**, and **22** were prepared by Marshall's procedure (13). **5**: mp 65–66°C. *Anal.* calcd. for $C_{11}H_{11}NO_2S$: C 59.71, H 5.01, N 6.33, S 14.49; found: C 59.50, H 4.89, N 6.24, S 14.38. **6**: mp 135–136°C. *Anal.* calcd. for $C_{17}H_{13}NO_2S$: C 61.99, H 4.59, N 4.25, S 9.73; found: C 61.95, H 4.53, N 4.18, S 9.59. **22**: mp 60–61°C. *Anal.* calcd. for $C_{12}H_{13}NO_2S$: C 61.25, H 5.57, N 5.95, S 13.63; found: C 61.33, H 5.46, N 5.94, S 13.50. The ir and ^{1}H nmr spectra were consistent with structural assignments. Further synthetic details will be published separately.

Alkaline hydrolysis rate constants were measured at 25°C by the disappearance of the long wavelength uv chromophore (λ_{max} typically 300–345 nm) (4–6). Human leukocyte elastase (HLE) was obtained and its inhibition assayed as previously described (4–6).

Results and discussion

Assignment of ^{13}C nmr spectra

Very few reports of the carbon nmr of benzoxazinones can be found in the literature (15). All of our assignments were made after confirmation by several different techniques, with the results given in Table 1. The proton nmr spectrum was assigned by comparison to ring-substituted analogues, and the aromatic region of 2-methyl benzoxazinone **14** was then simulated for additional confirmation. All carbon nmr spectra were run using a *J*-modulated spin echo sequence to separate quaternary

[3]3-Methyl isocoumarin **23** is the carbon analog of 2-methyl benzoxazinone **14**

[a]Alkaline hydrolysis rates, with k_{OH^-} in $M^{-1}\,s^{-1}$.
[b]Inhibition constants for human leukocyte elastase, with K_i in M.
[c]These resonances were not unambiguously assigned.
[d]Previously reported shifts of 2-methyl benzoxazinone **14** (15*b*) are not in agreement with our results. The published values appear to correspond to those of *N*-acetyl anthranilic acid, a hydrolysis product readily obtained from **14** on standing, even in the solid state (21).
[e]Tabulated data for **23** use benzoxazinone numbering.

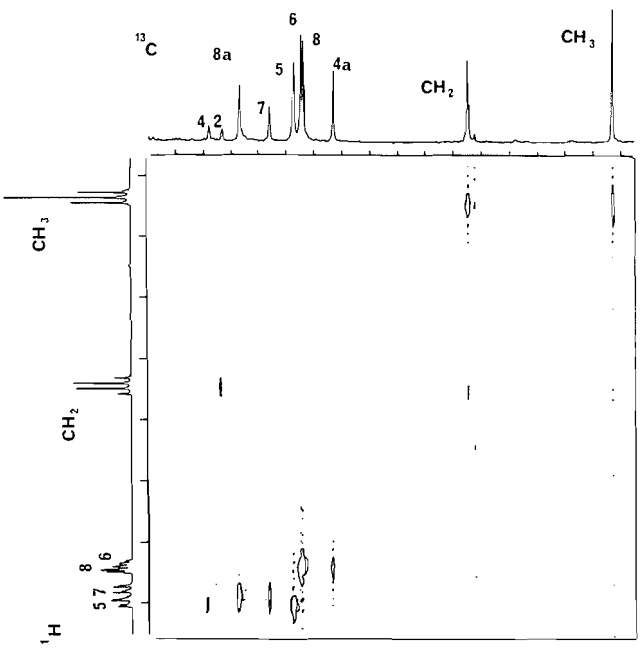

FIG. 1. The 2D heteronuclear shift correlation of 2-ethoxy benzoxazinone **13** is shown with delays optimized for long-range $^{13}C-^{1}H$ couplings.

carbons from those carbons with attached protons. Carbons 5, 6, 7, and 8 were correlated to the proton spectrum via 2D heteronuclear shift correlation for those molecules with ambiguous carbon assignments. Each quaternary carbon was then identified by a further 2D correlation optimized for long-range coupling. An example of this technique is shown in Fig. 1 for 2-ethoxy benzoxazinone **13**.

A clear correlation can be seen from C2 to the methylene of the side chain, distinguishing C2 from C4, which shows a correlation to the proton at 5. In addition, long-range correlations from C8a to H7 and H5, and C4a to H6 and H8 can be seen (noting that $J_{CCC-H} \gg J_{CC-H}$ in aromatic systems, ref. 16). For those molecules with ring substitution, carbon spectra were recorded with the decoupler gated off before the pulse and spectra were interpreted by coupling patterns.

The substituent effects on chemical shift are quite consistent. The effect of methyl substitution at C5 is pronounced, with C5 deshielded by 13.7 ± 0.3 ppm. Substitution of a methyl at C8 produces only an 8.5-ppm downfield shift of C8, which is closer to the 6.2-ppm shift observed in 1-methyl naphthalene (18). In addition, carbon 6 is deshielded by 2.6 ppm by methyl substitution at C5, while carbon 7 is only shifted 0.5 ppm by methyl substitution at C8. By comparison, 1-methyl substitution in naphthalene gives a 0.6 ppm-downfield shift. The *peri* interaction between substituents in 1,8-disubstituted naphthalenes has been shown to cause distortions of up to 3 Å from ring planarity, which are reflected in ^{13}C chemical shifts (18). The anomalous shifts in 5-substituted benzoxazinones would suggest that similar interactions may occur between the carbonyl at C4 and the substituent at C5.

Mechanism of alkaline hydrolysis

In addition to nmr assignments, Table 1 gives the rate constants for aqueous alkaline hydrolysis of the benzoxazinones. Nucleophilic attack by hydroxide could occur at either C2 or C4, and the data of Table 1 provide a unique opportunity to distinguish between these carbons, which is based on a

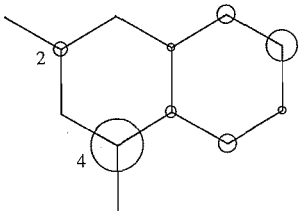

FIG. 2. Multiple regression of log (k_{OH^-}) vs. all $\delta^{13}C$ was carried out for compounds **1**–**22**. The data δ_C of Table 1 were fit to the equation log (k_{OH^-}) = constant + $\beta_2\delta_{C2} + \beta_4\delta_{C4} + \ldots + \beta_{8a}\delta_{C8a}$. The results ($n$ = 22, F = 58.4, r^2 = 0.973, s = 0.20) are shown as circles with areas proportional to the coefficient β obtained for each carbon atom.

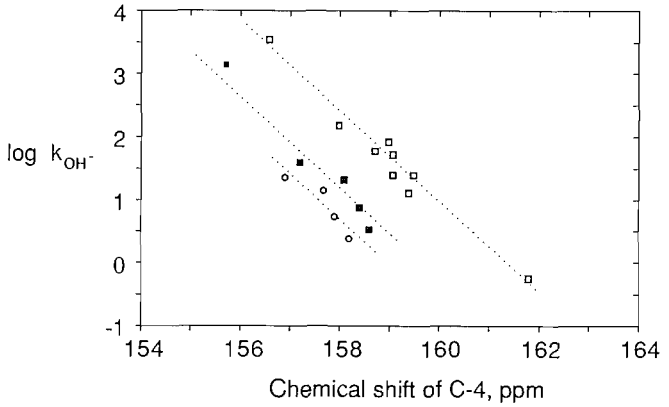

FIG. 3. Alkaline hydrolysis rates are shown vs. the chemical shift of C4 for compounds **2**, **4**, **5**, **7**–**11**, and **13**–**22**. Open squares indicate R5 = H, filled squares indicate R5 = Me, and open circles indicate R5 = Et.

correlation of carbon chemical shifts with observed hydrolytic rates. As shown in Fig. 2, the coefficient of regression of log (k_{OH^-}) with $\delta^{13}C$ is clearly largest at C4, showing that C4 is the most probable site of hydroxide attack. This is in agreement with determinations by the more traditional methods of ^{18}O labelling (19) or inference from substituent effects on reaction rates[4] (20). It is noteworthy that acid and solid-state hydrolyses of benzoxazinones proceed instead by protonation at N1 and water attack at C2 (21).

Examination of log (k_{OH^-}) vs. δ_{C4} alone (Fig. 3) shows that the benzoxazinones must be separated into two classes, those with or those without 5-methyl substitution. Since the electronic effects of 5-substitution should be intrinsically incorporated into δ_{C4}, this observation again suggests a *peri* interaction between R5 and the carbonyl oxygen that affects the rate of hydroxide attack on C4. Regression on the data of Fig. 3 gives the result that log (k_{OH^-}) = 120.6 − (0.75 ± 0.06)δ_{C4} + (1.15 ± 0.12)E_s (n = 18, F = 91.7, r^2 = 0.92, s = 0.27), where E_s is the Taft steric parameter (22) for the substituent at C5.

Thus 5-methyl and 5-ethyl benzoxazinones are $10^{1.15E_s}$ or 27-and 32-fold, respectively, more resistant to alkaline hydrolysis than their C4 chemical shifts would suggest. This shows that when steric (e.g. *peri*) interactions are taken into account, the ^{13}C chemical shift of an electrophilic carbon can be a strong predictor of reactivity. The chemical shifts also suggest that the related molecule 3-methyl isocoumarin **23** displays no enzyme inhibition because its C4 is not electrophilic enough to efficiently acylate serine 195. The chemical shifts also help to estimate the C4 electrophilicity of molecules for which ionization prevents alkaline hydrolysis (e.g. 2-methyl-quinazolin-4-one, with δ_{C4} = 161.9 (15*a*), and which deprotonates at N3 under alkaline conditions).

[4]Regression on 123 benzoxazinones with widely varying 2- and 5-substituents shows that electron withdrawal and donation are the most significant determinants of alkaline hydrolysis rates, supporting a single mechanism, i.e., attack at C4.

TABLE 2. Chemical shift dependence on R2

Carbon	$f + r$	% r
4	−2.5	22
4a	2.1	78
5	0.1	100
6	3.7	53
7	0.6	9
8	1.1	100
8a	−3.3	55

Table 1 also presents the inhibition constants pK_i (= $-\log_{10} K_i$, in M) for HL elastase, which span eight orders of magnitude. There are no significant correlations between these pK_i and the ^{13}C chemical shifts in multiple regression, though limited data sets show a clear correspondence between C4 electrophilicity and pK_i (1, 4). Clearly other factors in enzyme acylation and deacylation, such as specific steric or hydrophobic interactions and hydrogen bonding that are not reflected in ^{13}C spectra, mask any simple correlations with chemical shift.

Assignment of parameters

Structure–activity investigations require that molecular descriptors be carefully chosen. In general, such descriptors should describe the relevant properties of the molecule (e.g. size, hydrophobicity, electrophilicity, potential for hydrogen bonding, pK_a) and be readily available, either as tabulated, calculated, or measured values. Since nucleophilic attack at C4 is involved in both benzoxazinone stability and enzyme inhibition, and since R2 has a unique role in the mechanism of enzyme inhibition (it is electronically coupled to C4 in acylation but not in deacylation: Scheme 1) (4), we have used the effects on $\delta^{13}C$ to choose an appropriate descriptor of electron withdrawal by R2.

The parameters F and R are desirable for their statistical properties and for their field and resonance interpretations (23), and yet they are inadequate as descriptors of R2 for two reasons. First, F and R are tabulated for only a limited set of substituents. Second, a single electronic descriptor is preferable to simplify later regression and interpretation. We therefore investigated δ_{C4} as a function of F and R to guide the selection of one of the more readily available parameters σ_p, σ_m, or σ^*. Multiple regression for compounds **4**, **7**, **11**, **13**, **14**, **15**, and **17** (for which F and R for R2 were available) gave the result:

$$\delta_{C4} = 158.7 - (1.95 \pm 0.58)F - (0.53 \pm 0.16)R$$
$$(n = 7,\ r^2 = 0.85,\ F = 11.5,\ s = 0.47 \text{ ppm})$$

This fit implies 22 ± 8% resonance in the effect of 2-substitution on δ_{C4}, suggeting that σ_m (with 20 ± 2% resonance (23)) is preferable to σ_p (38 ± 3%) or σ^* (13 ± 2%)[5] for further structure–activity correlations.

[5]Determined from regression of tabulated σ^* (24) against F and R (23).

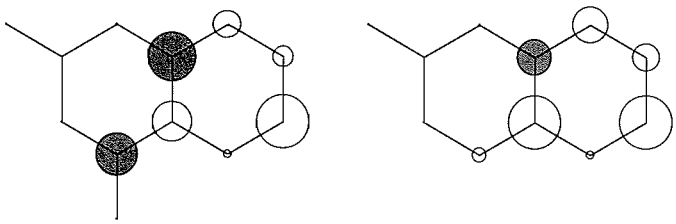

FIG. 4. (a) The data of Table 3 are shown as circles with areas proportionate to $f + r$. Filled circles indicate negative $f + r$. (b) The results for 2-substituted naphthalenes of Kitching *et al.*, Table IVB, ref. 17, are similarly shown as areas proportionate to $\sigma_I + \sigma_R$.

Similar analysis for all assigned $\delta^{13}C$ was carried out using the same set of compounds with the results in Table 2. Here f and r are the coefficients in the regression equation $\delta^{13}C$ = constant + $fF + rR$, and their sum represents the magnitude of the electronic substituent effect of R2 on each $\delta^{13}C$. These magnitudes are also shown in Fig. 4*a*, where the alternating pattern of the effect is clear. Except for the carbonyl carbon, the magnitudes and directions of these effects are very similar to those in 2-substituted naphthalenes (Fig. 4*b*, (17)). Adequate regression could not be obtained for δ_{C2}, because of the overriding local effects on chemical shift at this position.

Conclusions

Carbon 13 assignments have been made for 22 benzoxazinones. The chemical shifts are useful predictors of chemical mechanism and relative reactivities, provide evidence for *peri* interactions, and guide the selection of electronic parameters for structure–activity analysis.

Pyrazolo[3,4-*b*]pyridines: Syntheses, reactions, and nuclear magnetic resonance spectra[1]

BRIAN MAURICE LYNCH,[2] MISBAHUL AIN KHAN,[3] HUK CHIA TEO, AND FRANCISCO PEDROTTI[4]

Department of Chemistry, Saint Francis Xavier University, Antigonish, N.S., Canada B2G 1C0 and Secao de Quimica, Instituto Militar de Engenharia, Praia Vermelha, 22290 Rio de Janeiro, Brasil

Received August 10, 1987

BRIAN MAURICE LYNCH, MISBAHUL AIN KHAN, HUK CHIA TEO, and FRANCISCO PEDROTTI. Can. J. Chem. **66**, 420 (1988).

Efficient syntheses of approximately 70 simple substituted representatives of pyrazolo[3,4-*b*]pyridine **1** are reported from the following: (*a*) suitably substituted pyridines onto which a pyrazole ring is annelated, and (*b*) appropriately substituted pyrazoles onto which a pyridine ring is annelated. Selected examples of electrophilic, nucleophilic, and homolytic substitution reactions and group transformations are described, providing regiosynthetic paths to useful intermediate species. Some systematic aspects of substituent chemical shift influences in the ^1H and ^{13}C nuclear magnetic resonance spectra, aiding in structural assignments, are illustrated.

BRIAN MAURICE LYNCH, MISBAHUL AIN KHAN, HUK CHIA TEO et FRANCISCO PEDROTTI. Can. J. Chem. **66**, 420 (1988).

On a développé des synthèses efficaces pour environ 70 pyrazolo[3,4-*b*]pyridines (**1**) substituées simples; ces synthèses impliquent soit l'utilisation de pyridines substituées adéquatement sur lesquelles on referme un cycle pyrazole, soit l'utilisation de pyrazoles substitués adéquatement sur lesquelles on referme un noyau pyridine. On décrit des exemples choisis de réactions de substitutions électrophiles, nucléophiles et homolytiques ainsi que de transformations de groupes qui illustrent des voies régiospécifiques d'obtenir des espèces intermédiaires. On présente des données illustrant quelques aspects systématiques des influences des substituants sur les déplacements chimiques en résonance magnétique nucléaire du ^1H et du ^{13}C qui sont utiles pour faire des attributions de structures.

Introduction

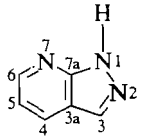
Many polysubstituted derivatives of 1*H*-pyrazolo[3,4-*b*]pyridine **1** have been synthesized as potentially biologically active materials (e.g., refs. 1–25) (for a recent general review of all pyrazolopyridines, see Hardy (26)). Our interest in synthesis and reactivity of the parent compound and its substitution products arises from promise shown as inhibitors of xanthine oxidases (27). A minor portion of our work has been reported in another study of purine analogues (28), and we have also described the synthesis of the parent system by rearrangement accompanying decarboxylation of pyrazolo[1,5-*a*]pyrimidine carboxylic acids (29).

This paper reports efficient syntheses of pyrazolo[3,4-*b*]pyridines from (*a*) suitably substituted pyridines onto which a pyrazole ring is annelated, and (*b*) appropriately substituted pyrazoles onto which a pyridine ring is annelated. We present examples of electrophilic, nucleophilic, and homolytic substitution reactions and group transformations providing regiosynthetic paths to useful intermediate species. Aspects of substituent chemical shift influences in the ^1H and ^{13}C nmr spectra are illustrated.

Syntheses of 1*H*-pyrazolo[3,4-*b*]pyridines[5]

Approach (a), from pyridines

Here, 2-halo-3-substituted pyridines were treated with hydrazines. Nucleophilic displacement of the 2-halogen and cyclizing condensation involving the pyridines' 3-substituents yield the substituted pyrazolo[3,4-*b*]pyridines **1** through **9**. Scheme 1 indicates the typical sequence. The starting materials were obtained from 3-substituted pyridines by successive *N*-oxidation and treatment with phosphorus oxychloride, effecting exclusive cine-substitutive chlorodeoxygenation at the 2-position of the pyridine ring. In principle, cyclocondensation with 2-chloro-3-cyanopyridine might proceed by *two* distinct pathways in *two* stages: initial nucleophilic hydrazinodechlorination, followed by intramolecular attack by the hydrazine component on the electron-deficient carbon of the cyano group, yielding 3-aminopyrazolo[3,4-*b*]pyridines; alternatively, initial reaction may be nucleophilic addition of hydrazines to the cyano function, generating an amidrazone moiety (-C:NH(NH·NH_2)) that then intramolecularly displaces the halogen. Independent studies (30)) show that under the reaction conditions used (excess of hydrazine component), the open-chain species **10** is an intermediate.



1*H*-pyrazolo[3,4-*b*]pyridine, **1**

2-Chloro-3-formylpyridine (2-chloronicotinaldehyde) was obtained by reduction of 2-chloro-3-cyanopyridine by Raney nickel and formic acid (31); this intermediate is inaccessible by the above *N*-oxidation route (peroxyacid oxidation of 3-formylpyridine yields pyridine-*N*-oxide 3-carboxylic acid). In the synthesis of the parent **1** from 2-chloro-3-formylpyridine, the yield was prejudiced by the formation of the azine species **11**.

Approach (b), from pyrazoles

5-Aminopyrazoles were starting materials in this approach. Grandberg (2) and Hardy and co-workers (5) have shown that highly acidic annelation conditions resembling a Skraup quinoline synthesis furnish pyrazolo[3,4-*b*]pyridines from 5-aminopyrazoles, but yields are poor and work-up tedious. The unsatisfactory results arise from the high reactivity of the 4-carbon of aminopyrazoles towards electrophilic sulfonations, precluding efficient cyclizations.

The main body of our work employed zinc chloride-catalyzed

cyclizations where 1,3-dicarbonyl compounds were reacted with the aminopyrazoles (compare refs. 29, 32, 33). This method (depicted in Scheme 2) proved efficient, yielding the pyrazolo[3,4-*b*]pyridines **2**, **3**, **5**, **12**–**36**. Where unsymmetrical dicarbonyl species were used, the assignments of methyl-group position in the products **26**, **28**–**31**, **33** follow from ^1H nmr spectra: the proton–proton coupling patterns in the pyridine rings are characteristic ($J_{4,5} > J_{5,6}$) and, generally, $\delta(CH_3)$ is approximately 0.20 ppm greater for a 6-methyl than for a 4-methyl substituent (32). Note that this cyclization procedure cannot be applied routinely to 3(5)-aminopyrazoles (with a free NH) since formation of pyrazolo[1,5-*a*]pyrimidines supervenes (see refs. 33, 37). Exceptionally, cyclizations occur preferentially at C-4, not N-1, for reactions using sodium nitromalonaldehyde; these reactions may also be effected under basic conditions.

We also applied the Gould–Jacobs method (34), in which 5-aminopyrazoles reacted with diethyl ethoxymethylenemalonate, ethyl ethoxymethylenecyanoacetate, or ethyl ethoxymethyleneacetoacetate, followed by thermal cyclization in phenyl ether or Dowtherm A to provide the pyrazolo[3,4-*b*]pyrid-4-ones (4-hydroxy pyrazolo[3,4-*b*]pyridines) **37**–**44** (see Scheme 2). The pyrazolopyridones with cyano, ester, or acetyl groups in the 5-position are intermediates for candidate enzyme-inhibitor species (compare Chu and Lynch (27)). The chlorocyclization method developed by Hoehn *et al.* (4) was also applied to some of the pyrazolylaminoacrylates, and the corresponding ring-closed products **45**–**49** were obtained in good yields.

Reactions

The reactivity of the 1*H*-pyrazolo[3,4-*b*]pyridine ring system is of interest since it fuses a pyrazole ring (relatively reactive towards electrophilic substitutions) with a pyridine ring where carbons are unreactive towards many electrophiles; however, the interaction between N-1 and the pyridine ring may resemble that of the reactive 2-aminopyridine. Although a few substitution reactions are recorded (5), detailed information is lacking for "standard" reactions, and no published suggestions exist about the preferred sites of attack. We have effected typical electrophilic nitrations (using "mixed acids") and brominations, where the preferred site of attack is the 3-position: if this position is occupied, then, under more vigorous conditions, the 5-position may be substituted. Also, if N-1 carries an aryl ring, it undergoes preferential mono- or dinitration. Such behavior resembles that of the previously studied *N*-arylpyrazoles (35).

The preferred nitration at the 3-position is in contrast to the behavior of indazole (the corresponding 7-deaza species), where mixed-acid nitrations occur at the 5-position, while brominations of indazole and of 1-substituted pyrazolo[3,4-*b*]-pyridines occur similarly at the 3-position (30, 36). The differences may be interpreted simply in terms of electrostatic deactivation through protonation (or incipient protonation) at the 2-nitrogen of indazole and at the 7-nitrogen of the pyrazolo[3,4-*b*]pyridine, the sites of highest effective π-electron density (and total electron density) in the free bases of these species (see refs. 28, 37, and Figs. 1*a*, 1*b*). The identities of the nitration and the bromination products are defined by their ^1H nmr spectra (disappearance of proton signals at the 3- and (or) 5-positions and the simplification of coupling patterns for the proton signals at positions 4 and 6). Alternatively, the ^{13}C nmr spectra of the 3-substitution products define the structures through proportionalities existing between ipso-substituent chemical shift (scs) effects in the quaternary 3-carbons in the substitution products to those in monosubstituted benzenes (cf. Lynch (38)) (see Fig. 2), while in the

substitution products derived from the 1-methylpyrazolo[3,4-*b*]pyridine, **2**, the 1-methyl ^1H shifts are related precisely to the Hammett σ_p constant of the 3-substituent (Fig. 3). In some instances, the identities of the nitration products were also established by independent, direct syntheses. Chlorinations yielded 3,5-dichloro compounds. The results of these substitution reactions are summarized in Scheme 3.

The 3-amino group in 3-aminopyrazolo[3,4-*b*]pyridines behaves as a typical aromatic amine, and provides useful entries to many other 3-substituted species. Hatt and Vass (1) have reported deamination of **7**, providing **1** in unspecified yield via the diazonium species. Aminoazoles (of which **7** is a representative) give very stable internally neutralized diazonium azolides (37) and our attempts at repetition of Hatt and Vass's work provided the compound **60**.

We have accomplished deamination (protodediazoniation) of several 1-alkyl and 1-aryl-3-aminopyrazolo[3,4-*b*]pyridines in excellent yields via aprotic diazotization employing alkyl nitrites in chloroform (39). Similar aprotic procedures (bromodediazoniation using bromoform as solvent/reactant, or chlorodediazoniation using carbon tetrachloride) provided simple, convenient alternatives to the Sandmeyer reaction. The 1-methyl-3-pyrazolo[3,4-*b*]pyridine radical generated in such procedures arylates benzene to 1-methyl-3-phenyl-pyrazolo-[3,4-*b*]pyridine **3**, identical to samples prepared by cyclization routes. The reactions of the 3-amino series are summarized in Scheme 4.

PNP = *p*-nitrophenyl; DNP = 2,4-dinitrophenyl. Numerical entries in parentheses after chemical shifts are vicinal coupling constants in Hz.

Further exploratory reactions were carried out on the derived products. Thus 3-bromo-1-methylpyrazolo[3,4-*b*]pyridine **5** undergoes smooth nucleophilic hydrazinodebromination yielding 3-hydrazino-1-methylpyrazolo[3,4-*b*]pyridine **61**, converted into 1-methyl-3-(1′-pyrazolyl)pyrazolo[3,4-*b*]pyridine **68** by condensation with 1,1,3,3-tetramethoxypropane. Vigorous oxidation of a 3-methyl group to the 3-carboxylic acids was successful with **4** and **5**, and these oxidations offer alternative routes to pyrazolo[3,4-*b*]pyridines with an unsubstituted 3-position, since the acids are readily decarboxylated. Benzylation of **1** using sodium ethoxide/benzyl chloride yielded 2-benzylpyrazolo[3,4-*b*]pyridine **64** rather than the previously synthesized 1-isomer (5), while *N*-dinitrophenylations of **1** and of **4** via 2,4-dinitro-1-fluorobenzene yielded mixtures of 1- and 2-(2,4-dinitrophenyl)pyrazolo[3,4-*b*]pyridines, readily separable by adsorption chromatography. Differentiation of structure between 2- and 1-substituted pyrazolo[3,4-*b*]pyridines is assisted by the general phenomenon that proton signals in corresponding ring sites in the 2-isomers are downfield from those in the 1-isomers (see Fig. 4, exemplifying 1- and 2-benzyl and 1- and 2-(2,4-dinitrophenyl)pyrazolo[3,4-*b*]pyridines). This is generally consistent with the calculated π-electron density distributions at the 3-, 4-, 5-, and 6-carbon atoms in such species (compare Fig. 1*b*). 2,4-Dinitrophenyl moieties attached to N-1 or N-2 of an azole species are easily displaced by nucleophiles such as methoxide or ethoxide ions (40, 41), and this strategy allows circumvention of the undesirable cyclizations of 5(3)-aminopyrazoles to pyrazolo[1,5-*a*]pyrimidines.

In this way the products **4** and **52** are obtained from the corresponding 1-(2,4-dinitrophenyl) precursors.

A limited study was made of the reactivity of pyrazolo[3,4-*b*]pyridines toward homolytic (free-radical) reagents, employing the nucleophilic carbamoyl radical, which would be expected to attack the pyridine ring preferentially. Carbamoylation using aqueous formamide and hydrogen peroxide in the presence of iron(II) sulfate (following Minisci and Gardini (42)) effected carbamoylation at the 6-position of compounds **1** and **12**, providing **69** and **70**, while **2** gave a mixture of its 4- and 6-carbamoyl derivatives, with the 6-carbamoyl species predominating. The structures again follow from the characteristic proton–proton coupling patterns in the pyridine rings ($J_{4,5} > J_{5,6}$).

Experimental

General

Melting points were determined using a Fisher–Johns block or a Kofler Heizbank and are uncorrected. The ^1H magnetic resonance spectra were acquired for dilute solutions (2% w/v) using a Varian A-60D spectrometer, and ^{13}C magnetic resonance spectra for 10% w/v solutions using a Bruker WP-80 spectrometer operating at 20.12 MHz, a 30° pulse of length 3.00 ms, and 16K data points with sweep width 5000 Hz. Data appearing in Table 3 were acquired using broadband decoupling (3 W), and signal assignments were confirmed using gated decoupling sequences. Signals are in parts per million (δ) from internal tetramethylsilane. Elemental analytical results for the compounds listed in the tables have been deposited with the Depository of Unpublished Data.[6]

Starting materials

The following were prepared according to literature procedures: 5-amino-1-methyl-3-phenylpyrazole (43); 5-amino-1,3-diphenylpyrazole (44); 3(5)-amino-5(3)-phenylpyrazole (45); 5-amino-1,3-dimethylpyrazole (45); 5-amino-3-methyl-1-*p*-nitrophenylpyrazole and 5-amino-3-methyl-1-(2,4-dinitrophenyl)pyrazole (45); 5-amino-4-

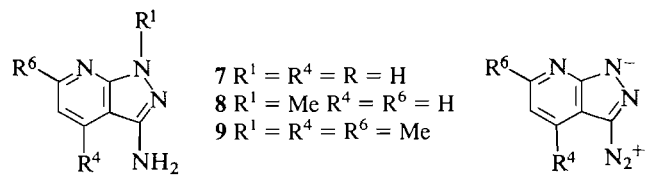

SCHEME 4

cyano-1-methylpyrazole and 5-amino-4-cyano-1-phenylpyrazole (46); 2-chloropyridine-3-aldehyde (from 2-chloro-3-cyanopyridine following ref. 31); ethyl ethoxymethyleneacetoacetate (47). Other reagents and materials were commercial products.

5-Amino-1-methylpyrazole, 5-amino-1-phenylpyrazole

These compounds were prepared by hydrolytic decarboxylation of their corresponding 4-cyano precursors: The pyrazole (30 g) and 85% phosphoric acid (100 mL) were heated at 170–180°C for 20 h. The mixture was poured onto crushed ice, basified with 60% NaOH, and extracted with $CHCl_3$. Evaporation of the extracts afforded 5-amino-1-methylpyrazole, mp 70°C (lit. (48) mp 71–72°C), 5-amino-1-phenylpyrazole, mp 50°C (lit. (49) mp 50°C) in 90% yields.

Pyrazolo[3,4-b]pyridines

The various synthetic methods employed in the syntheses and reactions yielding the compounds **1** through **72** are described below.

Method A. 2-Chloro-3-substituted pyridines with hydrazines

3-Acetylpyridine, 3-benzoylpyridine, and 3-cyanopyridine (0.2 mol) were severally heated for 10 h at 50°C in a mixture of acetic acid (200 mL) and 30% hydrogen peroxide (50 mL). The reaction mixtures were evaporated under reduced pressure and the residues treated with saturated aqueous $NaHCO_3$ and extracted with $CHCl_3$. The *N*-oxides obtained were heated under reflux with phosphorus oxychloride (2 mol) for 6 h. Excess of phosphorus oxychloride was distilled off and the residues were poured onto crushed ice, allowed to stand for 5 h, and extracted with ether, yielding the corresponding 2-chloro-3-substituted pyridines.

A sample of the appropriate 2-chloro-3-substituted pyridine (1 g) was heated under reflux with hydrazine hydrate (10 mL) or methylhydrazine (10 mL) in ethanol (50 mL) for 10 h; the excess of solvent and hydrazine was removed under reduced pressure, and the products were isolated and purified by crystallization or distillation as appropriate (see Table 1).

Reaction with 2-chloropyridine-3-aldehyde was atypical: to a solution of 2-chloropyridine-3-aldehyde (1.0 g) in ethanol (20 mL) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

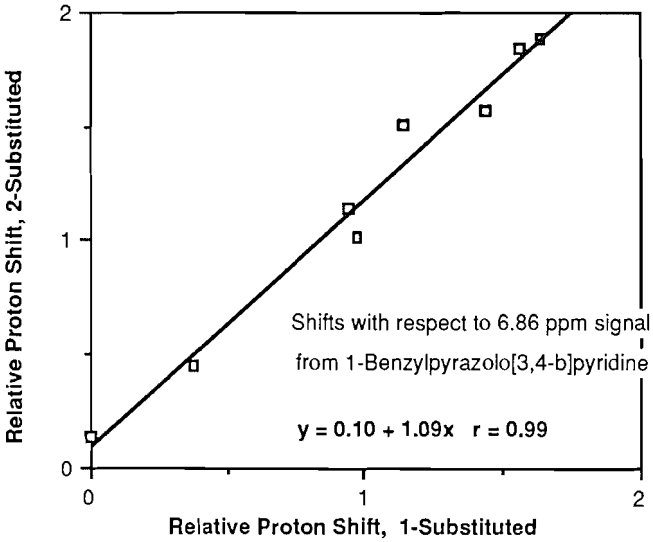

FIG. 4. Relative proton shifts, 2- vs. 1-substituted pyrazolo[3,4-*b*]pyridines.

added hydrazine (2.0 mL), and the mixture was heated under reflux for 24 h. Solvent and excess hydrazine were removed under reduced pressure and the residue was extracted with hot benzene yielding 2-hydrazinopyridine-3-aldehyde azine **11** (yellow needles, from benzene) (1.0 g), mp 191–193°C. *Anal.* calcd. for $C_{12}H_{12}N_8$: C 53.40, H 5.20, N 41.4; found: C 53.60, H 4.94, N 41.6%. The filtrate from the benzene extracts was purified by adsorption chromatography on alumina using benzene as eluent, yielding 1*H*-pyrazolo[3,4-*b*]pyridine **1**, mp 97–98°C (0.23 g), identical with an authentic sample (1, 29).

Method B. Cyclizations of 5-aminopyrazoles with 1,3-dicarbonyl compounds

An appropriate 5-aminopyrazole (0.005 mol) was dissolved in ethanol (10 mL) and 12 M HCl (0.50 mL) was added to the stirred solution, followed by granulated zinc chloride (0.30 g). The mixture was heated to reflux, and to the mixture was added a solution of 0.005 mol of the source of the appropriate 1,3-dicarbonyl compound in ethanol (5 mL), either 4,4-dimethoxy-2-butanone (acetylacetaldehyde dimethylacetal), 1,1,3,3-tetramethoxypropane (malonaldehyde bis(dimethylacetal)), 2,4-pentanedione, or sodium nitromalonaldehyde hydrate. After 1 h the reaction mixture was poured into ice-cold water (15 mL), the resultant solution was made alkaline with concentrated aqueous ammonia, and the product was isolated by suction filtration (for solids) or $CHCl_3$ extraction. The products were isolated and purified by crystallization or distillation as appropriate (see Table 1).

Method C. From 5-aminopyrazoles and ethoxymethylene compounds (see Scheme 2). β-(1-Pyrazol-5-ylaminoacrylates)

Appropriate equimolar mixtures of 5-aminopyrazoles and the ethoxymethylene compounds in ethanol were heated under reflux for 2 h, the reaction mixtures were concentrated and cooled, and the products were collected by suction filtration and crystallized from ethanol. Details of the properties of these compounds, including analytical and spectroscopic data, have been deposited with the Depository of Unpublished Data.[6]

Thermocyclizations of the β-(1-pyrazol-5-ylaminoacrylates) to 4-hydroxypyrazolo[3,4-b]pyridines (see Scheme 2)

The above β-(1-pyrazol-5-ylaminoacrylates) were heated under reflux with a fourfold weight excess of Dowtherm A or phenyl ether for 4 h. Excesses of solvent were removed under reduced pressure and the products isolated by crystallization after dilution with petroleum ether (bp 40–60°C). Details of yields are given in Table 1.

Method D. Chlorocyclization to 4-chloropyrazolo[3,4-b]pyridines (see Scheme 2)

The aminoacrylates used as starting materials for method C were heated under reflux with a fourfold weight excess of phosphorus oxychloride for 4 h. Excesses of solvent were removed under reduced pressure, the residues poured onto crushed ice, and the products crystallized from aqueous ethanol.

The pyrazolo[3,4-*b*]pyrid-4-ones (4-hydroxypyrazolo[3,4-*b*]pyridines) obtained by method C were also convertible into the corresponding 4-chloropyrazolo[3,4-*b*]pyridines by heating under reflux with phosphorus oxychloride.

*Method E. Nitrations (e.g., **1** → **52**; **2** → **53**; **4** → **51**; **5** → **23**; **19** and **21** → **24**; **24** → **25**)*

Mono- and dinitrations of pyrazolo[3,4-*b*]pyridines were carried out using the following typical procedure.

To 1*H*-pyrazolo[3,4-*b*]pyridine (**1**) (0.300 g) in sulfuric acid (d 1.84, 15 mL) was added nitric acid (90%, 0.5 mL) and the reaction mixture was heated at 90°C for 0.5 h, poured onto ice (100 g), and collected and crystallized. Additional amounts of product were recovered by extraction of the filtrates with ethyl acetate, followed by evaporation and crystallization.

*Method F. Brominations (e.g., **1** → **56**; **2** → **55**)*

The substrate pyrazolo[3,4-*b*]pyridine (0.01 mol) was dissolved in $CHCl_3$ (20 mL). Bromine (0.60 mL) was added dropwise over a period of 30 min, the reaction mixture was washed free of acid with aqueous K_2CO_3, and then dried over anhydrous K_2CO_3. The solvent was evaporated and the residue crystallized from an appropriate solvent.

*Method G. Chlorination (e.g., **2** → **57**)*

To 1-methylpyrazolo[3,4-*b*]pyridine **2** (1.3 g) in water (20 mL), acetic acid (0.5 mL) was added, followed by 5% aqueous sodium hypochlorite (15 mL). The mixture was stirred at room temperature for 3 h, neutralized with K_2CO_3, and extracted with $CHCl_3$. Evaporation of the dried extract was followed by crystallization.

*Method H. Bromodediazoniation (e.g., **8** → **55**)*

The substrate 3-aminopyrazolo[3,4-*b*]pyridine (5.0 g) was heated under reflux for 3 h with butyl nitrite (7.0 g) in bromoform (30 mL). Solvent and volatile material were removed under reduced pressure, and the residue was crystallized.

Method I. Chlorodediazoniation

The substrate 3-aminopyrazolo[3,4-*b*]pyridine (1.0 g) was heated under reflux for 3 h with butyl nitrite (1.5 g) in carbon tetrachloride (25 mL). Solvent and volatile material were removed under reduced pressure, and the residue was crystallized.

*Method J. Diazotization (**7** → **60**)*

3-Aminopyrazolo[3,4-*b*]pyridine **7** (2.6 g) in 70% nitric acid (10 mL) was diazotized at 0–5°C by a solution of 30% aqueous sodium nitrite (5 mL), and added to a further 15 mL of 30% aqueous sodium nitrite. Acetic acid (5 mL) was added after 1 h and the mixture was heated at 60–80°C for 30 min, cooled, and filtered, yielding the internal diazonium salt **60**.

*Method K. Hydrazinodebromination (**55** → **61**)*

3-Bromo-1-methylpyrazolo[3,4-*b*]pyridine **55** (1.0 g) was heated under reflux with 95% hydrazine (10 mL) for 24 h. 3-Hydrazino-1-methylpyrazolo[3,4-*b*]pyridine **61** separated from the cooled reaction mixture and was collected by filtration and purified.

Method L. Oxidations

1,3-Dimethylpyrazolo[3,4-*b*]pyridine **5** (1.0 g) was heated under reflux with sodium hydroxide (2.0 g) and potassium permanganate (4.0 g) in water (150 mL) for 2 h. The solid residue was filtered off and the filtrate was acidified with sulfuric acid and extracted with ethyl acetate. The solvent was removed and the residue was crystallized.

*Method M. Benzylation (**1** → **64**)*

1*H*-pyrazolo[3,4-*b*]pyridine **1** (1.2 g) and benzyl chloride (1.6 g) were heated under reflux in 5% ethanolic sodium ethoxide (10 mL) for 90 min. The solvent was evaporated and the residue extracted with $CHCl_3$ and the product was crystallized.

For personal use only.

Method N. N-(2,4-Dinitrophenylation)

To 1*H*-pyrazolo[3,4-*b*]pyridine **1** (0.30 g) in methyl sulfoxide (5 mL) and triethylamine (0.5 mL) was added 2,4-dinitrofluorobenzene (0.47 g). The solution was stirred for 1 h and poured onto crushed ice. The precipitate was collected, washed with water, and extracted with $CHCl_3$, and the product mixture was separated by adsorption chromatography on silica gel.

Method O. C-Arylation (8 → 3)

3-Amino-1-methylpyrazolo[3,4-*b*]pyridine **8** (0.9 g) was added to butyl nitrite (1.0 g) and benzene (50 mL) and the mixture was heated under reflux for 2 h. Volatile materials were removed and the residue was purified by adsorption chromatography on silica gel, and the product was crystallized.

Method P. Pyrazole synthesis (61 → 68)

A mixture of 3-hydrazino-1-methylpyrazolo[3,4-*b*]pyridine **61** (0.6 g), 1,1,3,3-tetramethoxypropane (0.6 g), 12 M HCl (0.5 mL), and ethanol (20 mL) was heated under reflux for 90 min. The reaction mixture was diluted with water (25 mL), neutralized with aqueous ammonia, and extracted continuously with $CHCl_3$. After removal of solvent from the extract the residue was extracted with pentane and the 1-methyl-3-(1-pyrazolyl)pyrazolo[3,4-*b*]pyridine **68** was crystallized.

Method Q. Carbamoylations

To a solution of pyrazolo[3,4-*b*]pyridine **1** (1.0 g) and sulfuric acid (d 1.84, 0.5 g) in formamide (10 mL) were added, separately and simultaneously, hydrogen peroxide (30%, 3 mL) and powdered iron(II) sulfate heptahydrate (4 g), with efficient cooling (<10–15°C) and stirring over 30 min. The excess of formamide was evaporated under reduced pressure, and the residue Soxhlet-extracted with $CHCl_3$. The carbamoylation product was obtained on evaporation of the extract.

Method R. Protodediazoniation (8 → 2)

3-Amino-1-methylpyrazolo[3,4-*b*]pyridine **8** (1.0 g), $CHCl_3$ (15 mL), and butyl nitrite (1.5 g) were heated under reflux for 1 h. Solvent and volatile material were removed under reduced pressure, and the residue was purified by adsorption chromatography on alumina and crystallized.

Method S. Decarboxylations (63 → 2)

1-Methylpyrazolo[3,4-*b*]pyridine-3-carboxylic acid **63** was heated under reduced pressure in a cold-finger sublimation apparatus until the temperature reached 270°C. The condensate was identical with an authentic sample of 1-methylpyrazolo[3,4-*b*]pyridine **2**.

C. Robert Lucas, Eric J. Gabe, and Florence L. Lee. Can. J. Chem. **66**, 429 (1988).

The ^{13}C and ^1H nmr spectra as well as the X-ray structure determination for $(\eta\text{-}C_5H_5)_2Ti(OOCPh)_2$ are described. The compound crystallizes in space group $P2_12_12_1$ with $a = 7.5135$, $b = 12.5166$, $c = 21.1416$ Å, $Z = 4$, $d_{calcd} = 1.40$ g cm^{-3} (MoKα_1, $\lambda = 0.70932$ Å). The structure was solved with MULTAN using data collected at 115 K and refined to the final $R = 0.059$ for 1500 significant reflections. The molecule has two different carboxylate ligands, one of which has a Ti—O—C angle of 135.4(6)° and longer Ti—O (1.976(5) Å) and O—C (1.300(10) Å) bonds while the other has a Ti—O—C angle of 157.0(7)° with shorter Ti—O (1.913(6) Å) and O—C (1.267(10) Å) bonds. With bromine, ring cleavage occurs giving $C_5H_5Br_3$ or $C_5H_5Br_5$ in which bromination has occurred stereospecifically. The same reaction occurs with chlorine but not with iodine or iodine monochloride. Related reactions have been observed with $(\eta\text{-}C_5H_5)_2MCl_2$ (M = Ti, Zr, and V). A non-radical mechanism is proposed in which the LUMO and HOMO of Br_2 interact simultaneously with one cyclopentadienyl ring and with the metal. This interaction is a consequence of the structure of $(\eta\text{-}C_5H_5)_2M(OOCPh)_2$.

C. Robert Lucas, Eric J. Gabe et Florence L. Lee. Can. J. Chem. **66**, 429 (1988).

On décrit les spectres rmn du ^1H et du ^{13}C ainsi que la détermination de la structure par diffraction des rayons-X du composé $(\eta\text{-}C_5H_5)_2Ti(OOCPh)_2$. Le composé cristallise dans le groupe d'espace $P2_12_12_1$ avec $a = 7{,}5135$, $b = 12{,}5166$ et $c = 21{,}1416$ Å, $Z = 4$ et $d_{calcd} = 1{,}40$ g cm^{-3} (MoKα_1, $\lambda = 0{,}70932$ Å). On a résolu la structure avec MULTAN utilisant les données recueillies à 115 K et on l'a affinée jusqu'à une valeur finale de $R = 0{,}059$ pour 1500 réflexions significatives. La molécule possède deux ligands carboxylates différents, l'un deux forme une angle Ti—O—C de 135,4(6)° et des liaisons Ti—O et O—C plus longues (1,976(5) et 1,300(10) Å respectivement) alors que l'autre forme un angle de 157,0(7)° et des liaisons plus courtes (1,913(6) et 1,267(10) Å). Soumis à l'action du brome, il se produit un clivage de cycle conduisant au $C_5H_5Br_3$ ou au $C_5H_5Br_5$ dans lequel la bromation s'est produite d'une façon stéréospécifique. La même réaction se produit avec le chlore; toutefois, elle ne se produit pas avec l'iode ou avec le chlorure d'iode. On a observé des réactions apparentées avec le $(\eta\text{-}C_5H_5)_2MCl_2$ (M = Ti, Zr et V). On propose un mécanisme radicalaire dans lequel les orbitales moléculaires basse vacante et haute occupée du Br_2 interagissent simultanément avec un cyclopentadiènyle et avec le métal. Cette interaction est la conséquence de la structure du composé $(\eta\text{-}C_5H_5)_2M(OOCPh)_2$.

[Traduit par la revue]

Introduction

It is conventional to regard the pentahapto-cyclopentadienyl group as a non-labile ligand (1). Especially in bent metallocenes, the site of molecular reactivity is not normally the cyclopentadienyl–metal bond and ring replacements are rare. Nevertheless, it has been known for over thirty years that the $\eta^5\text{-}C_5H_5$ group is occasionally transferred between metals (2) or even completely displaced (3*a*) under surprisingly mild conditions e.g. reaction [1] (Cp = $\eta\text{-}C_5H_5$):

$$[1]\quad Cp_2Ti(OEt)_2 + EtOH \xrightarrow{20°C} CpTi(OEt)_3 + \text{other products}$$

Since Cp–metal bond dissociation enthalpies all lie in the range 300–500 kJ/mol (4), the wide variation in Cp–metal bond reactivity must be kinetic in origin. This paper reports structural and synthetic studies which suggest a mechanism for non-radical Cp–metal bond cleavages in early transition metal Cp_2MX_2 species.

Experimental

Reagents were obtained from the Aldrich Chemical Co., Inc., and were used without further purification. Spectroscopic data were obtained using the following instruments: ir, Perkin Elmer Model 283; nmr, Varian EM-360 or Bruker WP80 Fourier-Transform; mass spectra, V.G. Micromass 7070HS. X-ray diffraction data were collected using a Picker FACS-1 four circle diffractometer with local (NRC) automation. Standard Schlenk techniques were used throughout and unless noted, procedures were carried out under an atmosphere of dry nitrogen. Solvents were dried over P_4O_{10}. Analyses were performed by Canadian Microanalytical Service Ltd.

(a) Preparative

$Cp_2Ti(OOCPh)_2$

First reported in the Russian literature (5), $Cp_2Ti(OOCPh)_2$ is more conveniently produced by the alternate method described here. A complete characterization is also presented herein. A suspension of sodium benzoate (1.44 g, 10.0 mmol) and Cp_2TiCl_2 (1.25 g, 5.00 mmol) in CCl_4 (100 mL) was refluxed for 6 h. The orange solution was filtered to remove NaCl, concentrated to 25 mL, and chilled at −20°C overnight to produce orange crystals which were separated by filtration and washed with cold CCl_4 (3 mL). Yield 1.87 g (89%). Mp 183°C (decomp). Mass spectrum: parent ion $m/e = 420$ not seen at 70, 20, 15, or 10 eV ionization potential. Fragments with high abundance have $m/e = 355$, 299, and 105 corresponding to $[CpTi(OOCPh)_2]^+$, $[Cp_2Ti(OOCPh)]^+$, and $PhCO^+$. ^1H nmr (ppm from TMS int. std., CCl_4) 6.55 (s, 10H), 7.31 (m, 6H), 7.87 (m, 4H). ^1H-decoupled ^{13}C nmr (ppm from TMS int. std., $CDCl_3$) 118.7 (Cp), 128.4, 130.1, 132.0, 134.0 (Ph), 172.3 (CO). Ir (Nujol): identical with lit. (5).

$C_5H_5Br_3$

To a solution of $Cp_2Ti(OOCPh)_2$ (4.2 g, 10 mmol) in CCl_4 (300 mL) was added dropwise over 15 min a solution of Br_2 (1.6 g, 0.51 mL,

For personal use only.

20 mmol) in CCl_4 (50 mL). The solvent was distilled under reduced pressure and the sticky residue was fractionally sublimed at 65°C and 0.1 Torr to give colourless cubes of product. Yield 0.64 g (88%). Mp 63.5–64°C. Mass spectrum: parent ion m/e = 308 $[C_5H_5{}^{81}Br_3]^+$, calcd. for $C_5H_5{}^{79}Br^{81}Br_2$, 305.7900; found, 305.7899. ^{1}H nmr (ppm from TMS int. std., d_6-acetone) 4.94 (m, 1H, $J < 0.6$ Hz), 5.33 (m, 2H, $J < 0.6$ Hz), 6.26 (m, 2H, $J < 0.6$ Hz). ^{13}C nmr (ppm from TMS int. std., d_6-acetone) 55.88 (d, $^1J_{CH}$ = 165 Hz), 56.48 (d, $^1J_{CH}$ = 165 Hz), 134.7 (d, $^1J_{CH}$ = 177 Hz). Ir (Nujol): 1690 (w), 1335 (s), 1282 (s), 1250 (s), 1132 (s), 991 (m), 941 (m), 918 (m), 799 (s), 774 (m), 744 (s), 720 (m), 710 (m), 680 (m), and 660 (m). Figure 1 shows the structure of $C_5H_5Br_3$.

$C_5H_5Br_5$

To a solution of $Cp_2Ti(OOCPh)_2$ (1.0 g, 2.38 mmol) in CCl_4 (100 mL) was added a solution of Br_2 (2.3 g, 0.73 mL, 14.4 mmol) in CCl_4 (25 mL). The mixture was sealed and stirred for 4 days, filtered to remove an orange precipitate, and the reddish brown solution was taken to dryness under reduced pressure. The residue was extracted with acetone (3 × 10 mL) to which water (50 mL) was then added. The precipitate was separated by filtration and the filtrate extracted with diethyl ether (3 × 50 mL). The extracts were taken to dryness under reduced pressure and the residue sublimed at 55°C and 0.1 Torr to give colourless crystals of product. Yield 1.65 g (74%). Mp 107–107.5°C. Mass spectrum: parent ion m/e = 466 $[C_5H_5{}^{79}Br_2{}^{81}Br_3]^+$ at 20 eV. ^{1}H nmr (ppm from TMS int. std., CCl_4) 4.63 (m). *Anal.* calcd. for $C_5H_5Br_5$: C 12.92, H 1.08, Br 85.99; found: C 12.47, H 1.55, Br 85.92. Ir (Nujol): 1310 (vs), 1290 (vs), 1280 (w), 1250 (m), 1230 (w), 1215 (s), 1180 (m), 1170 (s), 1155 (vs), 1080 (s), 1045 (m), 970 (w), 795 (s), 782 (m), 760 (s), 740 (s), 595 (vs) cm^{-1}.

$CpTiBr(OOCPh)_2$

To a dilute (~0.04 mol/L) solution of $Cp_2Ti(OOCPh)_2$ in CCl_4 (freshly distilled from P_4O_{10}) a solution of Br_2 (1.0 mol/L) in the same solvent was added until a mole ratio of Br_2:Ti = 2:1 had been reached. The brown–orange solution was filtered to remove a small amount of precipitate and volatiles were removed in vacuum at room temperature. The sticky residue was placed in a sublimer and $C_5H_5Br_3$ removed at 65°C and 0.1 Torr. The brown–orange residue was not purified further and was characterized spectroscopically. ^{1}H nmr ($CDCl_3$, TMS int. std.) 6.52 (s, 5H), 7.3 (m, 6H), 7.9 (m, 4H). Ir (Nujol): 3095 (w), 3070 (w), 1520 (vs), 1410 (vs), 1028 (m), 815 (s), 720 (s), 670 (s) cm^{-1}.

$Br_2Ti(OOCPh)_2$

As described above, a dilute solution of $Cp_2Ti(OOCPh)_2$ was treated with Br_2 to a mole ratio of Br_2:Ti = 4:1. Volatiles were removed in vacuum at room temperature and $C_5H_5Br_3$ was sublimed at 65°C and 0.1 Torr. The orange residue is very sensitive to hydrolysis. ^{1}H nmr ($CDCl_3$, TMS int. std.) 7.4 (m, 3H), 7.8 (m, 2). Mass spectrum: parent ion m/e = 371 $[^{81}BrTi(OOCPh)_2]^+$. Ir (Nujol): 3300 (m, br), 3090 (w), 1692 (m), 1600 (s), 1570 (m), 1495 (vs), 1400 (vs), 1310 (m), 1180 (m), 1162 (w), 1100 (w), 1075 (m), 1030 (m), 1005 (w), 940 (w), 790 (w), 715 (s), 682 (m), 670 (s), 665 (s) cm^{-1}. Satisfactory analyses for $Br_2Ti(OOCPh)_2$ have not been obtained. Results suggest hydrolysis to $Br(OH)Ti(OOCPh)_2$ had occurred in all samples.

(b) X-Ray studies

$Cp_2Ti(OOCPh)_2$ fw = 420.3

Orthorhombic, $P2_12_12_1$, a = 7.5135(14), b = 12.5166(11), c = 21.1416(17) Å, V = 1982.2 Å^3, Z = 4, ρ_c = 1.40 (−158°C: MoKα_1, λ = 0.70932 Å).

The space group was uniquely determined by the occurrence of systematic absences. The diffraction intensities of an approximately 0.3 × 0.2 × 0.1 mm crystal were collected using graphite monochromatized radiation and the $\theta/2\theta$ scan technique with profile analysis (6) to $2\theta_{max}$ = 50° at a scan speed of 4° min. A total of 2026 unique reflections were measured of which 1500 were considered significant with $I_{net} > 2.5\sigma(I_{net})$. Three standards were measured after every 100 reflections and no significant crystal decay was detected. Lorentz and polarization factors were applied but absorption correction was unnecessary (μ = 0.45 mm^{-1}). No evidence for extinction was observed. The cell parameters were obtained by least-squares refinement of the setting angles of 68 reflections with $2\theta > 40°$.

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

The structure was solved with MULTAN (7) plus a difference Fourier map and refined by full-matrix least squares with counting statistics weights. H-atom positions were calculated but their parameters were not refined. All heavier atoms were refined anisotropically. The final residuals are R_F = 0.059 and R_w = 0.039 for the significant data (R_F = 0.091 and R_w = 0.40 for all data); goodness of fit = 2.977. All calculations were performed with the NRCVAX system of programs (8). Scattering factors were taken from the International tables for X-ray crystallography (9).

The final atomic positional parameters and the equivalent isotropic temperature factors are listed in Table 1 while distances and angles

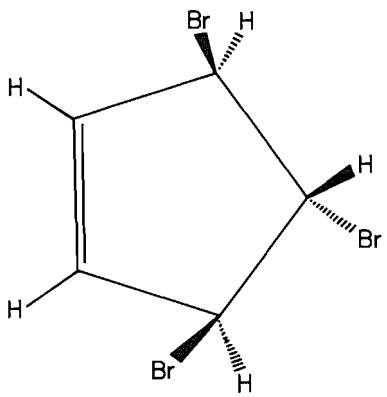

FIG. 1. Structure of $C_5H_5Br_3$.

are in Table 2. Anisotropic thermal parameters and final structure factors are available as suplementary data.[2] Figure 2 shows the atomic numbering scheme and Fig. 3 is a stereo picture of the molecule.

Results and discussion

Early studies of Cp—M cleavage reactions, while synthetically interesting, often left the mechanism of cleavage obscure. For example, reaction [2] has been proposed to occur

[2] $Cp_2Ni + HX + PPh_3 \rightarrow CpNi(PPh_3)X + \frac{1}{2}(CpH)_2$

by two different mechanisms (3*b*). One involves nucleophilic attack by PPh_3 as a first step while the other involves electrophilic attack by HX. The only feature common to both proposed mechanisms is decreased hapticity in the intermediate by the ring which is eventually lost. That Cp rings easily change their steric demands on metals is amply supported by kinetic (10), structural (11), and synthetic (12) observations. In particular, such a process seems to be facile for the early transition metal titanium since $Cp_2Ti(\eta^1\text{-}C_5H_5)_2$ is fluxional at room temperature, its rings undergoing a reversible $\eta^5 \rightarrow \eta^1$ process (13).

We felt that the cyclopentadienyl ligand of reduced hapticity which is likely to be an intermediate in Cp—M cleavages could be captured if the cleavage was carried out using bromine. This electrophilic reagent should be unlikely to attack an electron-poor titanium(IV) center. Furthermore, attack at other than the cyclopentadienyls should be prevented by having groups bound to titanium that do not normally react with bromine at their point of attachment. The reagent of choice was $Cp_2Ti(OOCPh)_2$ which was prepared in 89% yield according to reaction [3] and has an ir spectrum identical to that reported previously (5).

[3] $Cp_2TiCl_2 + 2NaOOCPh \xrightarrow{CCl_4} Cp_2Ti(OOCPh)_2 + 2NaCl$

When $Cp_2Ti(OOCPh)_2$ is treated with bromine in CCl_4, the stoichiometry of the process which occurs is indicated in reaction [4].

[4] $(\eta^5\text{-}C_5H_5)_2Ti(OOCPh)_2 + 6Br_2 \rightarrow 2C_5H_5Br_5 + Br_2Ti(OOCPh)_2$

The simplicity of this equation is, however, deceptive since a change in the stoichiometry also changes the products (reactions [5] and [6]).

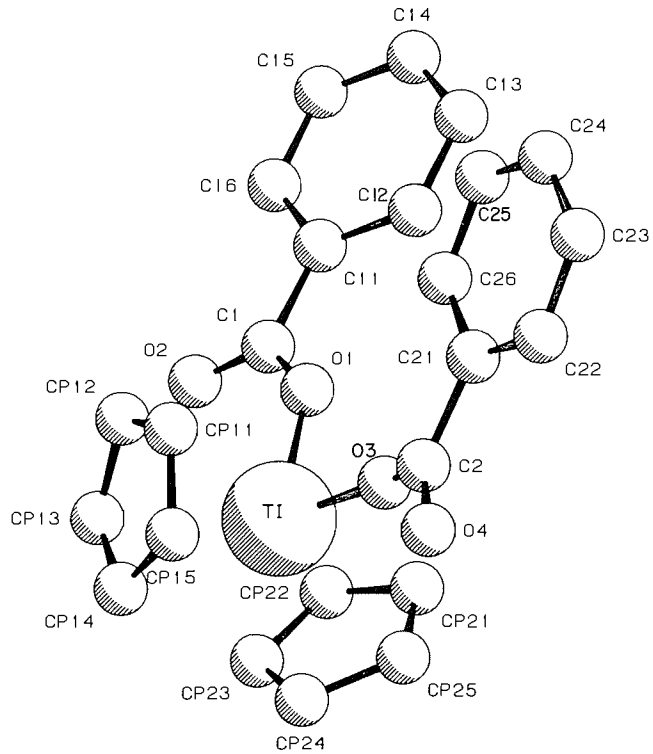

FIG. 2. Atomic numbering scheme for $(\eta\text{-}C_5H_5)_2Ti(OOCPh)_2$.

[5] $(\eta^5\text{-}C_5H_5)_2Ti(OOCPh)_2 + 5Br_2 \rightarrow C_5H_5Br_3 + C_5H_5Br_5 + Br_2Ti(OOCPh)_2$

[6] $(\eta^5\text{-}C_5H_5)_2Ti(OOCPh)_2 + 2Br_2 \rightarrow C_5H_5Br_3 + (\eta^5\text{-}C_5H_5)TiBr(OOCPh)_2$

In all cases, however, at least one ring is removed from the metal and the metal–oxygen bonds remain intact. In fact, the carbonyl stretching vibrations at 1495 and 1400 cm^{-1} in the case of $Br_2Ti(OOCPh)_2$, and at 1520 and 1410 cm^{-1} in the case of $CpTiBr(OOCPh)_2$ suggest bidentate carboxylates (14). Were the Ti—O bonds cleaved by Br_2, benzoyl hypobromite, a known intermediate in Hunsdieker decarboxylation (15) of benzoic acid would be produced leading rapidly to formation of bromobenzene. No bromobenzene was ever detected by glc of the crude reaction solutions.

Although these are synthetically useful reactions, our interest in them lay not so much in their synthetic applications but rather in the nature of $C_5H_5Br_3$, the partially brominated C_5 ring. From spectroscopic data discussed below there is no doubt that the three bromine atoms are on adjacent sp^3-hybridized carbon atoms and that the relative stereochemistry on those three carbon atoms is as shown in Fig. 1. The formula $C_5H_5Br_3$ is confirmed by low and high resolution mass spectroscopy. The presence of the H—C=C—H system is indicated by several spectroscopic properties. There is, for example, no band in the ir spectrum at 1543 cm^{-1} where Br—C=C—Br is reported (16) to absorb but there is a band at 1690 cm^{-1} appropriate for the unsubstituted system. The ^1H nmr spectrum has a signal at 6.26 ppm from TMS, in the range 5.68–6.33 reported (17) for the H—C=C—H system. The ^{13}C nmr spectrum has an absorption due to the olefinic carbons at 134.7 ppm from TMS in the ^1H-decoupled spectrum which appears as a doublet ($^1J_{C—H}$ = 177 Hz) when coupling to hydrogen occurs.

The relative stereochemistry of the sp^3 carbons is revealed by the ^1H nmr spectrum. At first glance, the spectrum appears to consist of three singlets but upon ten-fold expansion these are revealed as multiplets with $J < 0.6$ Hz. To achieve such small coupling constants, the H—C—C—H dihedral angle involving the sp^3 carbons must be close to 110° as would be the case if the bromine substituents are arranged up–down–up with respect to the plane of the ring. Were any other isomer produced, coupling constants of about 8 Hz would be expected. Thus, treatment of $Cp_2Ti(OOCPh)_2$ with bromine not only tends to remove preferentially one cyclopentadienyl ring before the other but it also brominates that ring stereospecifically as it is removed.

To explain these observations, the structure of $Cp_2Ti(OOCPh)_2$ (Figs. 2 and 3) was determined by X-ray methods in the expectation that there would be something odd about one of the C_5 rings or its bonding to the metal. The Cp_2Ti portion of the molecule is, however, unexceptional and has the geometry found commonly in Cp_2MX_2 systems. The rings are planar with normals inclined at ~131°. The Ti—C distances are in the range 2.32–2.39 Å and the C—C distances within the C_5 rings lie in the range 1.38–1.40 Å.

On the other hand, the geometry of the $Ti(OOCPh)_2$ portion of the molecule is pertinent to an understanding of the mechanism of ring cleavage. In solution, both carboxylates appear equivalent by ^{13}C nmr, there being but a single carbonyl carbon resonance at 172.3 ppm from TMS even at −110°C in CH_2Cl_2/SO_2. In the solid state, however, the two monodentate carboxylates are quite different. The most striking difference between them is that one is more sharply bent (135.4(6)°) at the metal-bound oxygen than the other (157.0(7)°). The carboxylate bond lengths are also different with the less

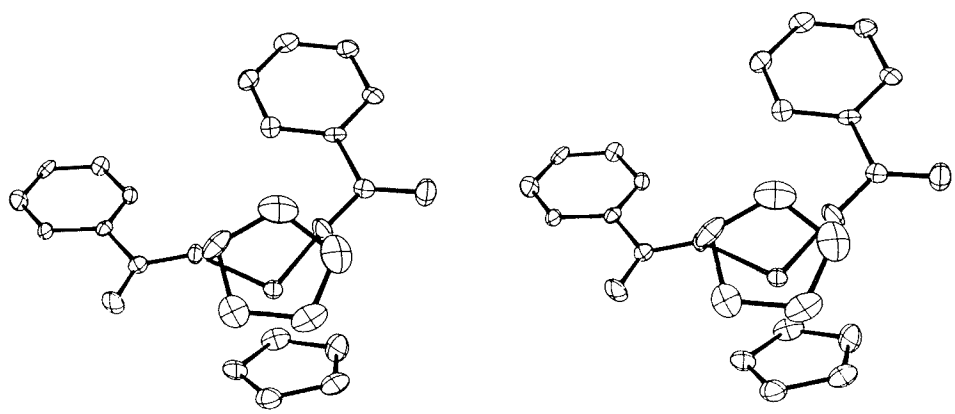

FIG. 3. Stereo picture of $(\eta\text{-}C_5H_5)_2Ti(OOCPh)_2$.

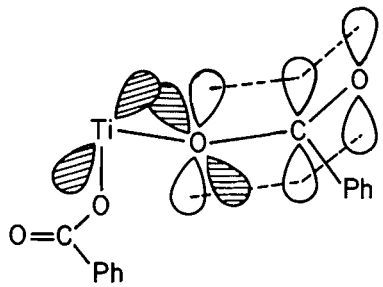

FIG. 4. Bonding in the Ti—O(3)—C(2) carboxylate.

bent Ti—O—C system having shorter Ti—O (1.913(6) vs. 1.976(5) Å) and O—C (1.267(10) vs. 1.300(10) Å) lengths and a longer C=O (1.224(10) vs. 1.207(11) Å).

These dimensions suggest that if the more sharply bent carboxylate is considered "normal" then the less bent may be considered to involve a metal-bound O-atom which is approaching *sp*-hybridization. One of the *p*-orbitals on that oxygen can overlap with a *p*-orbital on the carbonyl-carbon as shown in Fig. 4 which should shorten the O—C and lengthen the C=O bonds compared to the "normal" carboxylate as is observed. The remaining *p*-orbital on oxygen will overlap with the LUMO of the Cp_2Ti fragment which is the molecular orbital originally proposed by Alcock (18) and subsequently confirmed by Green, Green, and Prout (19) as lying in the O—Ti—O plane but outside that angle as shown in Fig. 4. In order to improve its overlap, the *p*-orbital on oxygen should tip towards the Cp_2Ti LUMO which would impart a slight outward bend (23°) to the Ti—O—C system, exactly as observed.

The structural consequences of this mode of bonding are that approach to the titanium atom is hindered on the side of the more bent carboxylate but is virtually unhindered on the side of the less bent. Thus, attack by Br_2 occurs preferentially on one side of the molecule. When a Br_2 molecule is correctly oriented on the metal side of the cyclopentadienyl ligand so that its LUMO (σ^*) can interact with the electron density of the C_5H_5 ring in the usual sense of electrophilic attack, the other end of the Br_2 molecule is correctly positioned for the HOMO (π^*) of Br_2 to interact in a nucleophilic sense with the Alcock–Green LUMO on titanium as illustrated in Fig. 5.

When this stage of the process is complete, there is an η^4-bromocyclopentadiene ligand coordinated to the titanium. All attempts to detect this ligand spectroscopically in the solution which results from mixing $Cp_2Ti(OOCPh)_2$ and Br_2 in a 1:1 molar ratio failed and at all stoichiometric ratios of Br_2:$Cp_2Ti(OOCPh)_2$ up to 2:1, the only observable process was reaction [6]. Although the η^4-bromocyclopentadiene ligand was not detected, presumably because it rapidly reacts further, η^4-diene ligands are well documented in organo-titanium, zirconium, and hafnium chemistry (20, 21). Furthermore, alternative mechanisms, such as ring "slippage" to an η^1- or η^3-structure with subsequent addition of Br_2 across exposed multiple bonds would not lead to the observed stereochemical arrangement of bromine atoms in the organic products.

Further reaction between the η^4-bromocyclopentadiene ligand and Br_2 would be expected to occur by electrophilic attack at the 1 and 4 positions of the diene unit and on the unhindered side of the ring. The resulting η^2-tribromocyclopentene ligand should dissociate readily since η^2-olefin complexes of titanium seem to be unstable, only one (22) ever having been fully characterized. Furthermore, it would have the stereochemical arrangement of bromine atoms that was observed experimentally.

Thus, the preferential cleavage of one ring and its stereospecific bromination are a consequence of preferential attack on one side of the $Cp_2Ti(OOCPh)_2$ molecule. In the case of $Cp_2Ti(OOCPh)_2$ there is an obvious structural reason for preferred attack on one side of the molecule but even in a molecule such as Cp_2TiCl_2 which is not unduly hindered on either side, preferential cleavage of one C_5-ring should still be observed. This follows from the involvement of the Alcock–Green orbital which will direct bromination to only one of the cyclopentadienyl rings at a time.

Several years ago, Gorsich (23) reported that chlorine or bromine will cleave one ring from Cp_2TiCl_2 to form $CpTiCl_3$ or $CpTiCl_2Br$. We have repeated that observation and in addition we find that the organic product of the bromination is identical to that obtained in reaction [6] under similar conditions

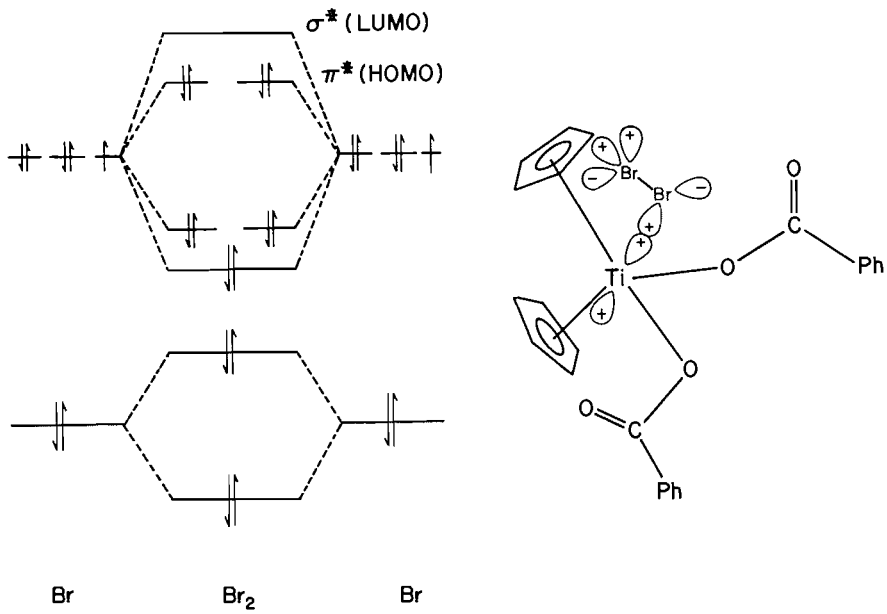

FIG. 5. HOMO–LUMO interactions between Br_2 and $(\eta\text{-}C_5H_5)_2Ti(OOCPh)_2$.

and stoichiometry while chlorination yields predominantly $C_5H_5Cl_5$. Consistent with the steric requirements of the mechanism, iodine and iodine monochloride (which models show are too large to approach the Cp_2Ti unit in the correct orientation) have been found to be unreactive even over 24 h whereas chlorine and bromine react within minutes.

Other bent Cp_2MX_2 species react similarly, *if no alternate sites for reactivity exist in their molecules*. Thus bis(cyclopentadienyl)metal dialkyls react preferentially at their metal–alkyl bonds but analogous dihalides react at their cyclopentadienyl–metal bonds. Bis(cyclopentadienyl)titanium, zirconium and vanadium dichlorides all give the stereospecifically tribrominated C_5-ring, although in the case of the vanadium compound which has an electron in the Alcock–Green orbital, an oxidation step probably occurs first to empty the orbital and make it available for interaction with the entering halogen molecule. This aspect of the process can be demonstrated by carrying out the reaction using Cp_2MoCl_2 in non-polar solvents in which case, the reaction stops after the oxidation step because the organometallic compound is precipitated as its cation $[Cp_2MoCl_2]^+$.

Although it has been shown by Erker *et al.* (24) that cleavage of a Cp ring from Cp_2ZrCl_2 by Cl_2 in CCl_4 under uv irradiation is a radical chain process, it seems unlikely that a radical mechanism is involved in the reactions discussed above. They have reproducible yields and stereospecificity and they give the same products even when carried out in the dark at reduced (−20°C) temperatures. Furthermore, no reaction occurs with I_2 or ICl (*vide supra*) and when bromination is conducted in the presence of I_2 no incorporation of iodine into the organic product occurs. Therefore, under appropriate experimental conditions, Cp—M cleavage can be achieved by either radical or non-radical processes. Under non-radical conditions, at least for early transition metal bent metallocenes, the Cp group need not behave as a "spectator" ligand providing the Cp—M bond is the molecule's preferred site for attack and providing the steric and electronic requirements of the proposed mechanism for Cp—M cleavage are met.

Received June 11, 1987

S. K. SANYAL and ASHIS K. MUKHERJEE. Can. J. Chem. **66**, 435 (1988).

The thermal diffusion of aqueous solutions of NaCl, KCl, $MgCl_2$, $BaCl_2$, $MgSO_4$, and $CuSO_4$ (0.05 *m*) contained in the pores of a sintered glass diaphragm has been studied. A cell is designed and fabricated for this purpose, and the resulting heat of transport values are compared with those available from the literature and obtained by using independent techniques.

S. K. SANYAL et ASHIS K. MUKHERJEE. Can. J. Chem. **66**, 435 (1988).

On a étudié la diffusion thermique de solutions aqueuses de NaCl, KCl, $MgCl_2$, $BaCl_2$, $MgSO_4$ et $CuSO_4$ (0,05 *m*) contenues dans les pores d'un diaphragme de verre poreux. A cette fin, on a dessiné et construit une cellule spéciale; de plus, on a comparé les valeurs des chaleurs de transport ainsi trouvées avec celles qu'on peut retrouver dans la littérature ou qu'on peut obtenir en faisant appel à des techniques indépendantes.

Introduction

The results reported for thermal diffusion are predominantly those obtained from the direct or "pure" Soret effect methods (1–5), in which the concentration gradient established in a solution at the steady state is, in general, measured. In such measurements, convection often poses a source of serious error. The present paper describes experiments on thermal diffusion in aqueous electrolyte solutions contained in the pores of a coarse glass (G4) diaphragm with an attempt to minimise the above convective remixing. This method is developed from studying thermal diffusion in thermocells by Agar and Breck (6). More recently, Gaeta and associates (7–9) and Patil (10) have described non-isothermal transport across porous non-selective partitions. The present authors have also described (11) a technique employing G4 glass diaphragm (the technique being different from the present one) which had some similarity with the methods developed earlier (12–14).

Theoretical

A solution-filled pore in a non-isothermal diaphragm may be considered as a microscopic Soret cell in which thermal diffusion proceeds at a moderately fast rate (6, 8). Thus, the relations used for the thermal diffusion studies in a binary system (15) (and for a solvent-fixed reference frame) can be adopted here assuming the chemical potential of component *i* (μ_i) just within the diaphragm at each of its surfaces being the same as that in the adjacent layer of free solution outside the diaphragm (16, 17). The latter holds true for the assumed equilibrium across each surface of the glass disc (G4) used in the present case, and the heat of transport of the solute ($\hat{Q}$) for a solvent-fixed reference frame is given by (2),

$$[1] \quad \hat{Q} = \nu RT^2\sigma\left(1 + \frac{\mathrm{d}\ln\gamma_{\pm}}{\mathrm{d}\ln m}\right)_T$$

where σ is the Soret coefficient, and is given by

$$[2] \quad \sigma = -\left(\frac{\mathrm{d}\ln m}{\mathrm{d}T}\right)_{st} = -\frac{1}{\bar{m}\cdot}\left(\frac{\Delta m}{\Delta T}\right)_{st}$$

$\bar{m}$ being the mean molal concentration, $\gamma_{\pm}$ the mean ionic activity coefficient on molality scale, and T the mean (absolute) temperature. Δm refers to the concentration difference between the cold and warm sides of the diaphragm at steady state, and ν is the total number of ions present in the solution on complete dissociation of one molecule of the electrolyte.

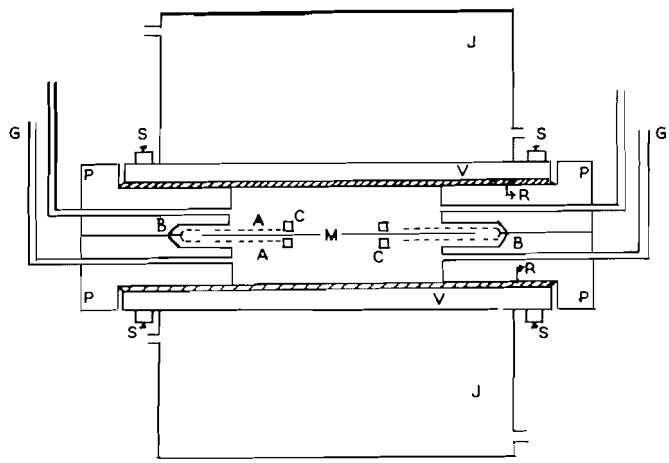

FIG. 1. Schematic diagram of the glass cell. Legend: J, water jacket (diameter 8 cm, height 5.5 cm); S, screw; P, circular perspex block of diameter 10.2 cm; V, brass plate (1 mm thick); B, O-ring; C, thermocouple junction; M, glass diaphragm (1 mm thick); A, diaphragm assembly (of diameter 4.4 cm); R, mylar sheet; G, glass capillary tube of inner diameter 1 mm; diameter of the inlet tubes fixed in grooves of the perspex block is 1.5 mm. Height of each half-cell and the diameter of the cross section of each half-cell are 0.5 cm and 3 cm, respectively.

Experimental

(a) The cell

The thermodiffusive cell (Fig. 1) consists of three parts, the porous G4 glass diaphragm (of thickness 1 mm) forming the central section, being sandwiched in horizontal position between the upper and lower solution chambers through O-ring arrangements to ensure no leakage. Each chamber (or half-cell) is cut into a perspex block in a circular section of diameter 3 cm and depth 0.5 cm. The bottom of each half-cell is closed by a thin mylar sheet (R) kept in position by a brass plate (1 mm thick, V), the outer face of which forms the inside wall of a brass water jacket (J) welded to the former. The plate fits in a well-cut

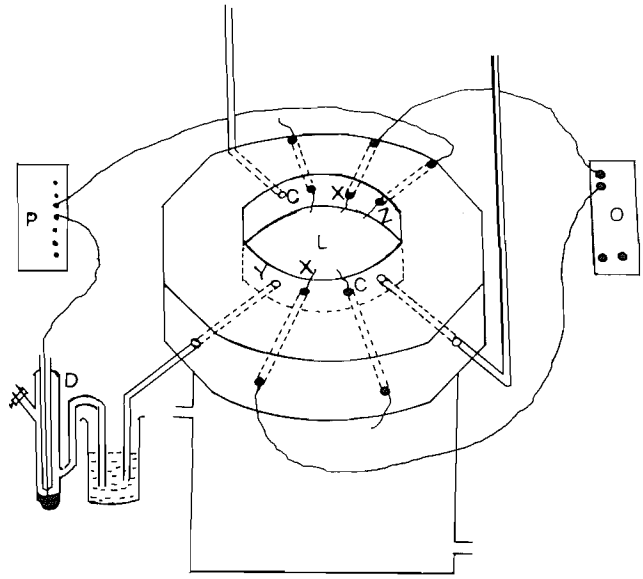

FIG. 2. Conductimetric and potentiometric circuit of lower half of the perspex cell. Legend: X, platinum electrode; Y, salt bridge; Z, Ag/AgCl electrode; C, thermocouple holes; P, potentiometer; O, conductivity meter; D, calomel electrode; L, solution chamber (with height 0.5 cm and diameter 3 cm); G, glass capillary tubes.

groove in the perspex block. The upper and lower water jackets were maintained at different temperatures by way of circulating water from two water thermostats. The entire cell with its three parts is held together by a number of brass nuts and bolts (S) screwed through the outer peripheral parts of the upper and lower brass plates (V). A number of channels (diameter 1.5 mm) ending into each half-cell are cut through the perspex block (Fig. 2). One Ag/AgCl electrode (Z) with a salt bridge (Y), used for the measurement of emf while using chloride solutions, two face-to-face platinum conductivity electrodes (X) for the determination of conductivity of aqueous solutions of electrolytes, two temperature measuring copper–constantan thermocouple junctions (by which the temperature difference across the diaphragm is measured within ± 0.02°C), and two face-to-face 1 mm inside diameter glass capillary tubes (G) (bent at right angles at a distance of 3 mm from the end of the perspex block) for recording any hydrostatic flow through the diaphragm, are held fixed in these channels in each half-cell. The portions of the glass tubes outside the block are covered with glass wool for insulation against the ambient temperature fluctuations.

(b) Materials and methods

The electrolytes used were of high purity grade and their solutions were prepared in doubly distilled (deaerated) water of conductivity 0.5 μmho cm^{-1}. The initial concentration of each solution was 0.05 *m*.

The cell was assembled and filled with the experimental solution by taking care to eliminate the entrapped air bubbles from the whole system. On applying a thermal gradient across the diaphragm, temperatures were measured by thermocouples, and the solution concentrations and their changes with time were periodically monitored by two methods, (*i*) by recording (for chlorides only) the changes of electrode potential of the $Ag/AgCl/Cl^-$ electrode by coupling the latter through a salt bridge with a micro-calomel electrode (Fig. 2), and noting the emf of the cell with a Leeds-Northrup potentiometer capable of recording ± 0.5 μV, and (*ii*) by measuring the conductivity, as a function of time, of the solution in each half-cell. The steady state was indicated by the concentration differences across the diaphragm registering constant values independent of time. The steady-state concentration differences were also checked by determining the latter (between suitable aliquots withdrawn after the steady state was attained) refractometrically, using a Brice Phoonix differential refractometer. The latter was pre-calibrated with a number of standard pairs of solutions of each solute having known concentration differences. The two sets of such values of the steady-state separations agreed within $\pm 1.5\%$ which is considered satisfactory, signifying the absence of any *in situ* concentration gradient in each half-cell.

A number of tests as described below have been applied to the present cell to ensure its satisfactory operation.

(*1*) Initial experiments were run with aqueous solutions of 0.1 *m* $CdSO_4$ at 25°C to check the reliability of the results obtained with the present cell. The Soret coefficient (σ) obtained was within $\pm 1\%$ of the corresponding literature value (18) determined by an independent technique.

(*2*) For a given solution at the mean temperature of 25°C, the apparatus has been operated at ΔT's from 3°C to about 9°C and the same values of σ, within the limits of experimental error, were obtained. The temperatures were monitored throughout a run on the Leeds-Northrup potentiometer capable of recording emf within ± 0.5 μV.

Further, from a detailed consideration of the finite distances between the thermocouple junctions (located in solutions close to the diaphragm surfaces) and the G4 diaphragm surfaces themselves, as well as the thermal conductivities of the solutions and glass used, a correction factor was worked out for arriving at the "true" temperature difference across the G4 disc from the corresponding measured (apparent) value. Thus,

$$\Delta T_{\text{true}} = \frac{\Delta T_{\text{app}}}{1.03}$$

The observed temperature differences were corrected by using the above relation and then used in eq. [2] to obtain σ.

(*3*) The relaxation time (τ) for the present solutions in the given cell was in the range of 400 s (by taking the effective path length of diffusion to be equal to the thickness (0.1 cm) of the disc, i.e., by neglecting any probable internal structure of the porous disc which would otherwise enhance the relaxation time, and by assuming the diffusion coefficient of the given solutes to be of the order of 10^{-5} cm^2 s^{-1}). Thus, for the composition of the solutions to reach within 1% of the final value at the steady state, a time of 5 τ, or about 35 to 40 min must be allowed. The given runs lasted for 50 to 80 min (except for $MgSO_4$ where readings were taken up to 100 min). Trial runs were performed for each solution to find out the time for attainment of the steady-state concentrations in each half-cell, and the former turned out to be well within 80 min in agreement with the requirement of relaxation times as above. Figure 3, showing the plots of separations obtained for various times in different trial runs with the chlorides studied, illustrates the latter.

(*4*) The sintered diaphragm is known to be effective in preventing disturbance of the Soret equilibrium by convection (2) even though for dilute electrolyte solutions (<0.05 *m*), the results may be influenced by ionic adsorption or other surface effects (2). However, the same σ obtained in the present case for different ΔT's applied across a given solution at a particular mean temperature indicates that the convective re-mixing is not appreciable between the solution chambers. The latter should have been more prominent at a higher ΔT leading to a larger separation. The absence of convective remixing was also ensured by a good agreement obtained between concentration differences measured *in situ* and the corresponding values obtained refractometrically (as explained earlier). Indeed the design of the cell is different from those of Saxton, Dougherty, and Drickamer (1954) (12), originally developed for the study of thermal diffusion is binary organic mixtures, and also from our earlier design, developed for the experiments on aqueous non-electrolytes (11), in that the rather small size of the present half-cells did not permit us to have any stirring arrangement. However, the experimental arrangement was such that the colder half-cell was at the bottom. Because the concentration of all the electrolytes studied registered an increase on the colder side of the diaphragm, natural convention was supposed to be constantly operating in each half-cell, thereby destroying any *in situ* concentration gradient developing therein. The degree of such convection for the solutions studied at the

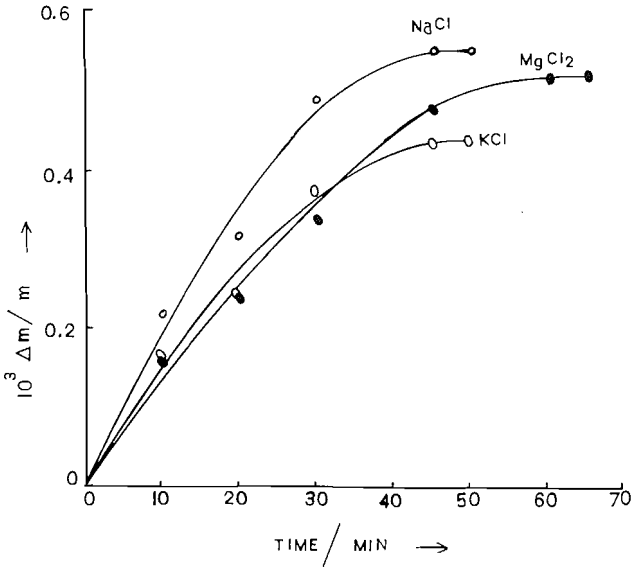

FIG. 3. Plots of the concentration differences (Δm) as noted between the lower and upper half-cells as a function of time for NaCl, KCl, and $MgCl_2$ solutions at a mean concentration of 0.05 $\bar{m}$.

given mean concentration (0.05 m) was quite similar as could be judged from the corresponding Rayleigh numbers R_c and R_T (2).

(5) In the present design, any solvent flow through the G4 diaphragm was ascertained by noting the development of hydrostatic pressure – head difference between the glass capillary tubes (G) attached to the solution chambers. Such solvent flow was found to be negligible after making proper correction for unequal thermal expansions in two halves.[1] In all cases, however, a minute solvent flow was, in fact, observed. The latter caused a small increase in the corrected height (hydrostatic level) in the capillary tubes (G) attached to the upper (warmer) half-cell. Such a volume flow to the warm side was shown (by computation) to contribute not more than 0.1% towards the observed Δm values at the steady state, and the attendant error in ignoring such solvent flow was thus considered negligible. This signifies that the adoption of the solvent – fixed reference frame in the present case is quite satisfactory.

Results and discussion

The results are incorporated in Tables 1 and 2. The errors in the determinations of σ (the mean of three determinations) and heat of transport ($\hat{Q}$) are calculated as the corresponding standard deviations and shown in the parentheses below each of the above values. The values of the thermodynamic factor,

$$1 + \frac{d \ln \gamma_{\pm}}{d \ln m} = B$$

are calculated from the activity or osmotic coefficient data at 25°C and are assumed constant over the experimental temperature range.

The positive heat of transport ($\hat{Q}$) values for the electrolytes (0.05 m) relate to an absorption of heat behind and a liberation ahead in course of diffusional migration in the pores of glass disc which corresponds to the promotion of "local" structure of water adjacent to the ions in dilute solutions. The heat of

[1]By using the known dimensions of perspex block and each half-cell, as well as the thermal expansion coefficients of water and perspex (the latter having it two orders of magnitude lower than that of water), an allowance was made to account for the unequal thermal expansion of water while recording Δh values between the two glass capillary tubes at each mean temperature of study.

$CuSO_4$	298	5400	256.3 (±18.0)	238.2	—

[a,b,c]Values of $\hat{Q}$ at the appropriate concentrations are taken from refs. 2, 20, 21 directly, or by interpolation and/or extrapolation of the literature data.

transport values of the simple electrolytes (for example, at 25°C) do not reveal any clear periodic trend even though the same (i.e., $\hat{Q}$) are generally dependent on the valency of the constituent ions (2). The latter arises primarily from the higher ionic potentials of Mg^{2+}, Ba^{2+}, Cu^{2+}, and SO_4^{2-} as compared to those of Na^+, K^+, and Cl^- (in the hydrated state) which promote, through long-range interactions, structure of water in, for instance, the B and C layers of Frank and Wen's concentric zones model (19) of electrolyte solutions, thereby raising $\hat{Q}$.

The $\hat{Q}$ values of electrolytes (at 0.05 m) obtained in the present study are compared with the appropriate literature data, reported by independent techniques (2, 20, 21) (Table 2). The agreement is considered satisfactory, thereby establishing the usefulness of the present technique.

The temperature dependence of $\hat{Q}$ has been expressed in terms of the corresponding heat capacities of transport (at 25°C) of the various electrolytes studied and given in Table 2. For calculating the heat capacities of transport ($\hat{C}$) of the solutions, the slope of the best-fit line of the plot of $\hat{Q}$ vs. T was used in the following equation (2), namely,

$$\hat{C}_T = \left(\frac{d\hat{Q}}{dT}\right) - \frac{\hat{Q}}{T}$$

JOCELYNE HELLOU, GERVAIS BÉRUBÉ, MICHAEL J. NEWLANDS, ALEX G. FALLIS, and ERIC J. GABE. Can. J. Chem. **66**, 439 (1988).

Model studies for a general intramolecular Diels–Alder approach to the tricyclo[6.3.0.$0^{2,6}$]undecene skeleton common to the capnellene marine sesquiterpenes are described. Suitably functionalized cyclopentadiene systems **14** and **21** were synthesized and their cycloaddition reactivity examined. Triene **14** cyclized to the tricyclic adducts **15** and **16**. In contrast, the anticipated product **22** from intramolecular cycloaddition of triene **21** was not formed in isolatable yield. Instead the minor adduct (10% yield) possessed an exocyclic double bond and was assigned structure **30** based on its relative stability, as determined by MM2 type calculations, and nuclear magnetic resonance data. X-ray analysis established that the major adduct (40% yield) was a tetracyclic[6.3.1.$0^{1,6}$.$0^{1,10}$]dodecene system corresponding to **32**, and which arose from competitive isomerization of the initial diene and cyclization via an *exo* transition state.

JOCELYNE HELLOU, GERVAIS BÉRUBÉ, MICHAEL J. NEWLANDS, ALEX G. FALLIS, et ERIC J. GABE. Can. J. Chem. **66**, 439 (1988).

On décrit des études modèles effectuées dans le but de déterminer l'utilité des réactions de Diels–Alder intramoléculaires comme méthode générale de synthétiser le squelette du tricyclo[6.3.0.$0^{2,6}$]undécène qui est commun aux sesquiterpènes marins du capnellène. On a synthétisé les systèmes cyclopentadiéniques **14** et **21** substitués d'une façon appropriée et on a examiné leur réactivité vis-à-vis la cycloaddition. Le triène **14** se cyclise pour donner les produits tricycliques **15** et **16**. Par opposition, le produit **22** qui devrait se former par cycloaddition intramoléculaire du triène **21** n'a pu être isolé. Il se forme plutôt un adduit mineur (rendement de 10%) qui possède une double liaison exocyclique et on lui a attribué la structure **30** en se basant sur des données de résonance magnétique nucléaire et sur sa stabilité relative telle que déterminée par des calculs du type MM2. Une étude par diffraction des rayons-X a permis d'établir que le produit principal (rendement de 40%) est un système tétracyclo[6.3.1.$0^{2,6}$,$0^{1,10}$]dodécène correspondant au composé **32** qui se forme par une isomérisation compétitive du diène initial et d'une cyclisation via un état de transition *exo*.

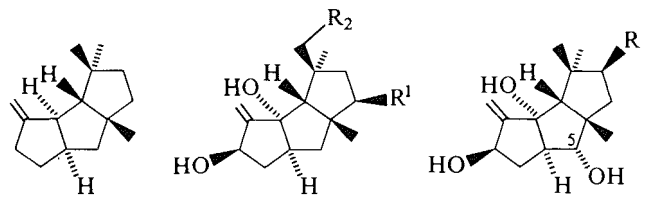
Introduction

The total synthesis of multicyclic, cyclopentanoid natural products is an area of fundamental importance and intense international activity (1, 2). Recent years have witnessed an explosive growth in the development of general methods for the construction of cyclopentanes and diverse strategies for the preparation of fused triquinane sesquiterpenes (3–8). In this regard the tricyclo[6.3.0.$0^{2,6}$]undecene skeleton encountered in the marine natural product $\Delta^{9,12}$capnellene (**1**), and shared with the terrestrial sesquiterpenes hirsutene and coriolin, has served as an attractive target about which to develop new chemistry. This interesting hydrocarbon isolated from the soft coral *Capnella imbricata* (9) has been the object of considerable attention, and several total syntheses have been reported while our studies were in progress. Very briefly these encompass the following: the 1,3-diyl trapping approach of Little *et al.* (10, 11), the Nazarov–Aldol sequence of Paquette and Stevens (12, 13), the alkynone thermolysis procedure of Drieding and co-workers (14), the transannular cyclization and solvolytic rearrangement route of Matsumoto and collaborators (15), iterative application



1 | **2** $R^1 = R^2 = H$; **3** $R^1 = OH$, $R^2 = H$; **4** $R^1 = R^2 = OH$ | **5** R = H; **6** R = OH

of the intramolecular magnesium-ene reaction by Oppolzer and Battig (16), a biogenetic approach via epiprecapnelladiene by Birch and Pattenden (17, 18), the palladium-catalyzed carbonylative organostannane coupling sequence of Stille and co-workers (19), an intermolecular Diels–Alder, intramolecular [2 + 2] photoaddition, ring cleavage route developed by Mehta *et al.* (20, 21), a repetitive conjugate addition – methylene cyclopentane annulation sequence utilized by Piers and Karumaratne (7), a combination of [2 + 2] and [4 + 2] cycloaddition reactions used by Liu and Kulkarni (22), a tandem free radical cyclization approach followed by Curran and Chen (23), while the "Tebbe Reagent" with the product of an intramolecular Diels–Alder reaction was employed by Stille and Grubbs (24). In addition to capnellene a variety of more highly oxygenated derivatives **2**–**6** are known (25–28). The diol **2** has

[1]This research constitutes part of the Ph.D. Thesis of J. Hellou, University of British Columbia, 1985, although these studies were conducted at Memorial University of Newfoundland.

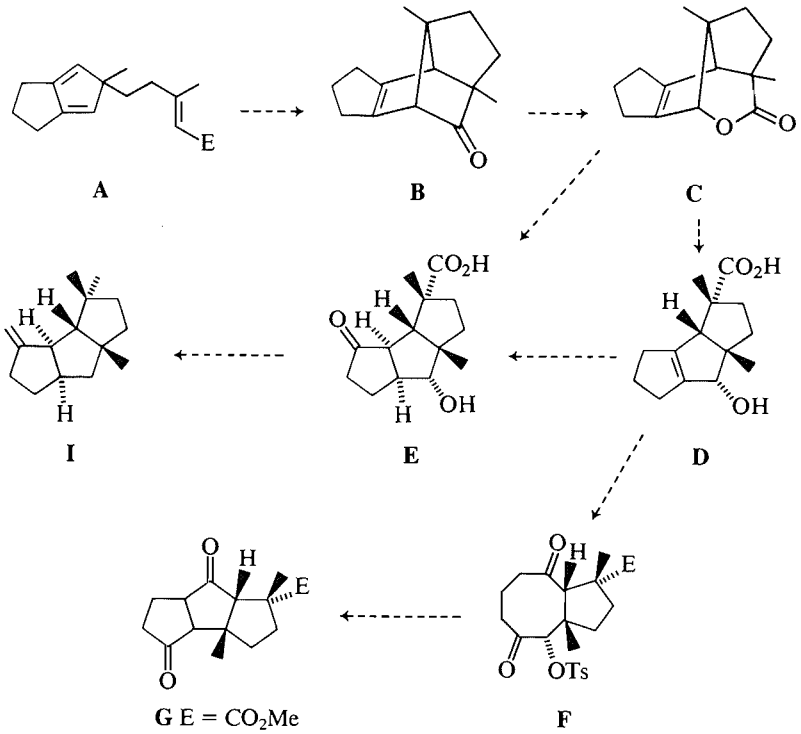

SCHEME 1

been synthesized (29), as has the 8α epimer (30). Recently the triol **3** and tetrol **4** have both been prepared from a common intermediate by Mase and Shibasaki (31). To the best of our knowledge, the C5 hydroxyl systems **5** and the 2β-5α-8β-10α-tetrol **6** (32) have not been totally synthesized. The biological activity of these compounds is not fully delineated but it has been suggested that they are part of the chemical defense mechanism that minimizes algal growth and prevents larval settlement on soft coral (33–35).

In spite of the diverse approaches to these natural products summarized above, most routes are not readily amenable to the preparation of more highly oxygenated derivatives, particularly those bearing a C5 alcohol group. Except in the recent synthesis of Stille and Grubbs (24) and a possible modification of the approach used by Sternbach *et al.* for silphinene (36), the intramolecular Diels–Alder reaction has not figured prominently. Both these routes rely on a cycloaddition sequence analogous to the one we developed earlier for cedrene in which a tricyclo[5.2.1.$0^{1,5}$]decene intermediate played a key role (37). We wish to report the results of our model studies directed toward the capnellene skeleton. These results have provided insight into the behaviour of the ring systems required and will facilitate the extension of this work for use in total synthesis.

Our approach is outlined in general terms in Scheme 1 but, because it involves a bridged intermediate, does not lend itself to simple retrosynthetic analysis. Nevertheless, synthetic strategies that involve intramolecular cycloadditions are frequently used to best advantage, and are most powerful, when the adduct constructed is not directly discernible in the final target. Thus the proposed route depends upon an intramolecular Diels–Alder reaction of a bicyclic cyclopentadiene such as **A** to generate the tetracyclic ketone **B**. It was anticipated that Baeyer–Villiger oxidation would proceed preferentially with migration of the allylic centre to give **C** so that ring opening of the lactone would provide the linear tricyclic skeleton **D** required for conversion to the natural product. The ordering of the steps may be adjusted as required and **E** obtained directly by allylic oxidation and hydrogenation of the lactone. In addition, we were intrigued by the possibility of utilizing the double bond in **D** so that, after ozonolysis and conversion of the secondary alcohol function into a suitable leaving group as illustrated in **F**, base-catalyzed transannular ring closure would provide access to related triquinane systems such as **G** in which the periphery possessed a different substitution pattern. Thus in spite of the results described below, which indicate that a modified strategy is required, the route appeared to possess a high level of stereocontrol and versatility.

Results and discussion

Although several detailed studies of the intramolecular Diels–Alder reaction have been undertaken in recent years, many facets are still imperfectly understood and some cycloadditions fail to proceed as anticipated (38–40). Thus it was considered prudent to examine the initial steps on a model system commencing with 3-methyl-2-cyclopentonone (**9**). The introduction of an α′ substituent in unsaturated ketones is often difficult, particularly the generation of β-keto-esters, but this was accomplished in 71% yield to give **10**, using our recently developed procedure employing diethyl pyrocarbonate and lithium dicyclohexylamide in ether at −78°C (41). It was anticipated that alkylation of this keto-ester with an unsaturated side chain such as **7**, prepared from ethoxy acetylene and 4-chloro-2-butanone followed by acid-catalyzed rearrangement, would provide the necessary conjugated dienophile. Unfortunately, the product was the diester **17** in which the side chain double bond was no longer in conjugation. In a similar manner the reaction of **8** and **10** afforded **18** and neither acidic nor basic conditions were discovered to isomerize the troublesome double bond back into conjugation efficiently to give **12**, although partial reconjugation was achieved with 1,5-diazabicyclo-[5.4.0]undec-5-ene in the case of the bicyclic analogue **26**.

In contrast to the alkylation experiments, Michael addition to

SCHEME 3

methyl vinyl ketone proceeded smoothly to afford **11**. The desired product was accompanied by varying amounts of the bicyclo[2.2.1]heptanone **19** resulting from intramolecular conjugate addition to the cyclopentenone system. The yield of the desired cyclopentenone **11** was raised to 95% and the side product minimized by employing a catalytic amount (1%) of potassium *tert*-butoxide as the base. Attempts to conduct Wittig or Horner–Emmons reactions at the methyl ketone group were disappointing, and there was the same tendency as observed above for the double bond to migrate out of conjugation. Therefore Knoevenagel condensation with titanium tetrachloride and dimethyl malonate was utilized to generate the triester **12** (12%) under nonbasic conditions (42). A low yield (7%) of a second product **20** was obtained due to intramolecular condensation at the cyclopentenone centre. Consistent with the assigned structure, this material displayed two olefinic signals at δ 6.57 and 6.03 in its ^1H nmr spectrum, and its ultraviolet absorption (226 nm, ε = 15 800) was indicative of an extended chromophore. Reduction of the ketone carbonyl in **12** with sodium borohydride containing cerium(III) chloride afforded the alcohol **13** as a 1:1 epimeric mixture that was dehydrated to the triene **14** by *in situ* generation and elimination of its mesylate derivative.

Heating this substituted cyclopentadiene in toluene at 140°C in a sealed tube for 10 h afforded, after chromatography, a 40% yield of an approximately 1:1 mixture of the two tricyclic adducts **15** and **16** (Scheme 3). This is a consequence of the

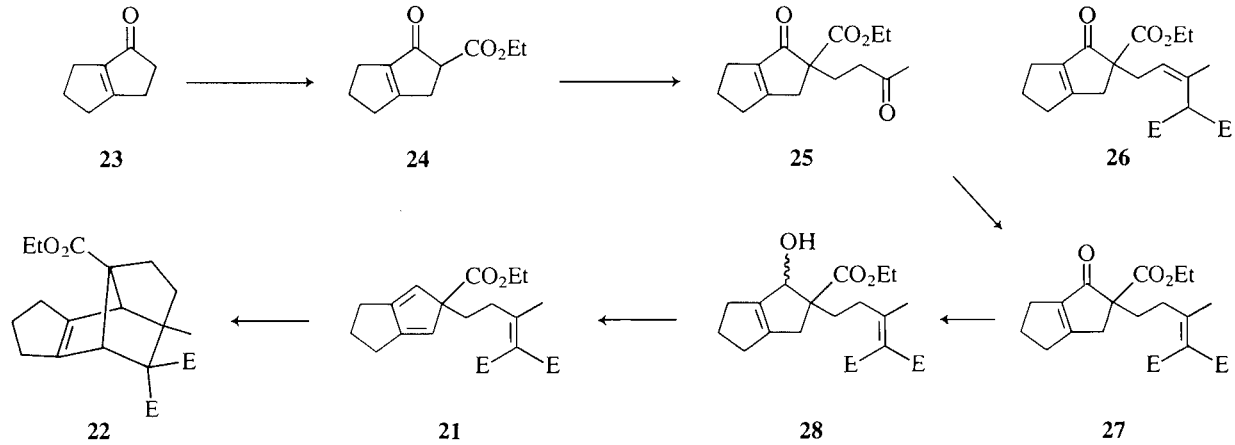

SCHEME 4

facile equilibrium that exists between the two folded triene conformers **14***a* and **14***b*, both of which must possess similar energies. The adducts could not be separated but their presence was clearly indicated by the doubling of the vinyl methyl and vinyl hydrogen signals in the ^{1}H nmr spectrum. Gratified by this result, attention was turned to the bicyclic series in the realization that due to the plane of symmetry in triene **21** the isomer problem would be eliminated. In this instance the anticipated adducts **22***a* and **22***b* are enantiomers and thus chemically equivalent.

The unsaturated bicyclic ketone **23** was prepared from 2-carbomethoxycyclopentanone according to literature precedent (43), although improved yields were realized by modifying the cyclization step using methanesulfonic acid in place of phosphoric acid (44) (Scheme 4). As above, the keto-ester **24** was prepared from the ketone with diethylpyrocarbonate, and alkylation of this material with the chlorodiester **8** gave the nonconjugated system **26** rather than the desired compound **27**. Thus the keto-ester **24** was condensed in the presence of potassium *tert*-butoxide with methyl vinyl ketone as above to give **25**. A parallel series of reactions involving Knoevenagel condensation mediated by titanium tetrachloride, sodium or zinc borohydride reduction, and dehydration via the mesylate afforded **27**, **28**, and the requisite cyclopentadiene system **21** in 18% overall yield from ketone **23**. The ^{1}H nmr spectrum of the unstable triene **21** indicated that the sample was not homogeneous but contained additional diene isomers (δ 5.20, 5.35, 5.73) in which the double bonds were not confined to the same ring.

A toluene solution of the triene **21** heated in a sealed tube in an oil bath at 140°C for 10 h afforded a 50% yield of adducts. Only one *s-cis* diene (i.e., **21**) is possible in the substituted ring, but three additional *s-cis* dienes **31, 33**, and **36** can arise if isomerization into the unsubstituted ring is rapid compared to cycloaddition. It appears from examination of molecular models that all three dienes are theoretically capable of intramolecular cyclization to the tetracyclic structures **32, 34, 37, 38** illustrated (Scheme 5). Unfortunately only a trace of the desired adduct **22** appeared to be present. The nmr spectrum of the reaction mixture indicated that the adducts (4:1 ratio) contained vinyl hydrogens (δ 5.51, 5.26). Hydrolysis of the mixed esters, chromatography, reesterification with ethereal diazomethane, and further chromatography afforded a pure sample of the major adduct. Initially structures of type **29** and **30**, in which the

double bond had migrated and was no longer confined to the norbornene nucleus, were favoured. Adduct **30** (R = $COOCH_3$) contains four C—H and four CH_2 units and the vinyl hydrogen would be expected to couple with the two methylene protons on the neighbouring carbon and experience further line broadening due to allylic coupling. Similar features are present in the adduct **29**. In contrast, **32** contains two C—H and five CH_2 groups, a feature that was confirmed from the ^{13}C nmr spectrum (Table 1). In addition, in the ^{1}H nmr spectrum the vinyl proton signal at δ 5.51 was coupled (J = 1.5 Hz), as expected for a system with a single bridgehead hydrogen neighbour, and further broadened due to coupling with the allylic methylene hydrogens. These features were most compatible with structure **32**. As illustrated in Fig. 1, this was established unambiguously by X-ray analysis. The structure does not appear particularly distorted, although the C7—C8 sp^3—sp^3 bond (1.587 Å) is significantly longer than normal. In its ^{1}H nmr spectrum the bridgehead methine appears at δ 3.37; the allylic geminal protons form an AB system δ 2.30 (*endo*), δ 2.67 (*exo*), J = 17 Hz; a second AB system arises from the hydrogens in the methylene bridge of the bicyclo[3.2.1]octane unit δ 210, 1.35, J = 9 Hz; and the remaining norbornene methylene forms multiplets at δ 1.58 and 1.95 complicated by long range coupling. As illustrated in Fig. 2, cyclization occurred via an *exo* (with respect to the vinyl methyl) transition state. This allows the bridging cyclohexane ring to adopt a favourable chair conformation compared to the boat-like arrangement required for the competing *endo* pathway, and avoids the severe nonbonded interaction between the methyl group and the transannular allylic hydrogens.

Unfortunately an isomer-free sample of the minor adduct could not be prepared; however, it may be tentatively assigned structure **30** rather than **29** on the following basis. A doublet of

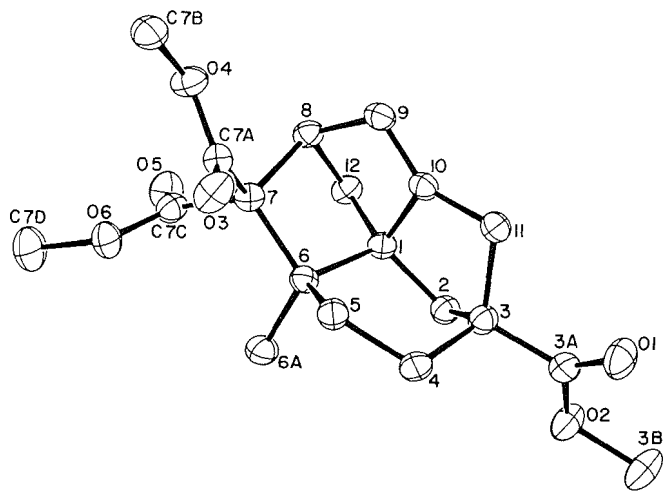

FIG. 1. ORTEP-II projection of 3,7,7-tricarbomethoxy-6-methylte tracyclo[6.3.1.$0^{1,6}$.$0^{1,10}$]-9-dodecene (**32**). H-atoms are omitted for clarity.

doublets (J = 1.5 Hz) with a triplet-like appearance is assigned to the single vinyl hydrogen at δ 5.26 and the *endo* methine proton appears as a multiplet at δ 3.01. Examination of the other structures **34, 35, 37**, and **38** reveals that the anticipated multiplicities for these signals would be different in all cases and thus the data fit **30** best. Additional support was provided by molecular mechanics calculations (MM2 type) on slightly simplified derivatives. These data (Table 2) indicated that structures such as **30***d* and **30***e*, with the fused cyclopentane ring *exo*, were approximately 1.5 kcal more stable than **22***d* and **22***e* and also more stable than adducts of type **29**.[4] Recently, related studies including molecular mechanics calculations have been published on tricyclo[5.2.1.$0^{2,6}$]dec-2(6)-ene (**22***c*) (Table 2) (45). This hydrocarbon was approximately 1.8 and 1.2 kcal more stable than the corresponding *endo* and *exo* isomers **30***f* and **30***c* respectively. Preparation of **22***c* from the related *tertiary* alcohol

(*endo* ring fusion) by dehydration (*p*-toluenesulfonyl chloride, pyridine, 21°C, 40 h) also afforded 25% of the *endo* olefin **30***f*. The additional bridge in **22***d* and **22***e*, plus the extra substituents, will further increase the strain energy and instability of the tetrasubstituted olefin, thus encouraging the formation of a less strained exocyclic system whenever circumstances permit.

The unexpected results from the cycloaddition of triene **21** indicate that this strategy will not be suitable as a route to linear triquinanes unless blocking groups are employed to prevent double bond migration. Nevertheless the facile preparation of the tetracyclic system represented by **32** has several interesting ramifications and implied synthetic potential. Clearly further study of the migratory tendencies and cycloaddition preferences of other bicyclo[3.3.0]octadiene systems is warranted, to ascertain the preferred pathways that will be followed depending upon the length of the side chain, its point of attachment, and the nature of the dienophile. Molecular models suggest that in many cases one adduct will dominate, leading to tetracyclic adducts with potential utility for a variety of synthetic objectives. Molecular mechanics calculations indicate that for the parent unsubstituted diene hydrocarbons corresponding to **21** and **31** the system with the ring fusion double bond as contained in **31** is approximately 2.9 kcal more stable.[5] Therefore this construction strategy has intriguing possibilities now that the behaviour of these ring systems is more clearly understood and a general method for their preparation has been developed.

Experimental

Melting points were determined in capillary tubes with a Thomas–Hoover Uni-Melt apparatus, or on a Fisher–Johns melting point apparatus, and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 237B or 451 grating spectrophotometer, and were calibrated with the 2850 and 1601 cm^{-1} bands of polystyrene film. Proton magnetic resonance spectra were measured at 80 MHz with a Bruker WP80 spectrometer employing a chloroform lock or at 60 MHz with a Varian EM 360 spectrometer, or at 300 MHz with a General Electric GN 300 spectrometer, or at 400 MHz (at the University of Alberta) with a Bruker WH 400 spectrometer. Signal positions are reported in ppm downfield from tetramethylsilane (δ scale) as an internal standard; multiplicity, the number of protons, coupling constants, and proton assignments are indicated in parentheses. Mass spectra were determined on a V.G. Micromass 7070 HS instrument using an ionization energy of 70 eV.

Thin-layer chromatographic analyses were carried out on commercial precoated silica gel plates with fluorescent indicator (Eastman Kodak silica gel 13181). Preparative thin-layer chromatography was conducted on 20 × 20 cm glass plates coated with silica gel $PF^{254+366}$ type 60 (E. Merck). Flash chromatography using BDH silica gel Kieselgel 60, 230–400 mesh, was employed for all column chromatography.

Petroleum ether refers to a fraction with boiling range 30–60°C. Anhydrous diethyl ether (ether), tetrahydrofuran (THF), dimethoxyethane (DME), and dioxane were obtained by distillation from lithium aluminium hydride or potassium/benzophenone. Absolute ethanol and methanol were dried by distallation from magnesium. Dry hexamethylphosphoramide (HMPA), dimethylformamide (DMF), dimethyl sulfoxide (DMSO), and diisopropylamine were prepared by distillation from calcium hydride. Solutions in organic solvents were dried over anhydrous magnesium sulfate and stripped of solvent with a Buchi rotary evaporator connected to a water aspirator. Unless otherwise indicated, all reactions were conducted under an atmosphere of dry nitrogen.

*5-Carboethoxy-3-methyl-2-cyclopentenone (**10**)*

3-Methyl-2-cyclopentenone (**9**) (0.480 g, 5 mmol, Aldrich) in ether (10 mL) containing diethylpyrocarbonate (DEPC) (1.2 g, 7.5 mmol) was added rapidly (5 min maximum) to a stirred solution of lithium dicyclohexylamide (prepared from 4.2 mL of *n*-butyllithium (2.5 M, 10.5 mmol, Aldrich) and dicyclohexylamine (2.15 mL, 11 mmol) in ether (15 mL)) at −78°C under nitrogen. After 1 h at −78°C the reaction was quenched with aqueous 10% citric acid (10 mL), allowed to warm to 21°C, extracted with ether, the combined ether extracts washed with brine, dried, filtered, and the solvent removed under reduced pressure. Distillation of the residual diethylpyrocarbonate and the keto-esther (40–60°C/0.1 Torr; 1 Torr = 133.3 Pa) followed by chromatography (15% ether – petroleum ether) gave 5-carboethoxy-3-methyl-2-cyclopentenone (**10**), 0.590 g (71%); ir (neat): 1730 (C=O), 1690 (C=O), 1615 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 1.27 (t, 3H, J = 7 Hz, CH_2CH_3), 2.19 (br s, 3H, $C=CCH_3$), 2.80 (m, 2H, CH_2—C=C), 3.31 (m, 1H, CO—CH—CO), 4.12 (q, 2H, J = 7 Hz, OCH_2CH_3), 5.80 (br s, 1H, C=CH). *Exact Mass* calcd. for $C_9H_{12}O_3$: 168.0783; found: 168.0787.

*Ethyl 5-chloro-3-methyl-2-pentenoate (**7**)*

A THF solution (50 mL) of freshly distilled (bp 49–50°C) ethoxy acetylene (18.5 g, 0.26 mmol, Farchan) was added dropwise to methylmagnesium chloride (8.3 mL, 0.24 mol, 2.99 M, Aldrich) dissolved in THF (250 mL) at 21°C, and stirring was continued for a further 0.5 h after addition was complete. Next 4-chloro-2-butanone (14 g, 0.13 mol) in THF (10 mL) was added over 5 min and stirring continued for a further 20 h at 21°C. The reaction was cooled to 0°C and water added dropwise until gas evolution ceased. The mixture was filtered through Celite, the layers separated, and the aqueous layer extracted with ether.

The combined ether extracts were dried, filtered, and the product purified by chromatography (5% ether/petroleum ether) to provide 4-chloro-2-ethoxyethynyl-2-butanol, 20 g (88%); ir (neat): 3300–3500 (br, OH), 2250 (C≡C) cm^{-1}; ^1H nmr (CCl_4) δ: 4.08 (q, 2H, J = 7Hz, O—CH_2—CH_3), 3.60 (m, 2H, CH_2Cl), 3.04 (s, 1H, OH), 1.96 (m, 2H, CH_2C—O), 1.48 (s, 3H, CH_3C—O), 1.38 (t, 3H, J = 7 Hz, CH_3CH_2) *Exact Mass* calcd. for $C_8H_{13}O_2Cl$: 176.0605; found: 176.0604.

A solution of 4-chloro-2-ethoxyethynyl-2-butanol (20 g, 0.11 mol) in ethanol (20 mL) was added dropwise to 5% sulfuric acid/ethanol (20 mL) maintained at 0°C. After addition was complete, stirring was continued for a further 20 h at 0–10°C. The reaction was diluted with water, extracted with ether, the combined ether extracts washed with 10% aqueous sodium bicarbonate, dried, filtered, and concentrated. The product was purified by chromatograpy (5% ether/petroleum ether) to give the unsaturated ester **7**, 15 g (75%), which was further purified by distillation, bp 65–68°C/0.05 Torr; ir (neat): 1710 (C=O), 1655 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 5.70 (br s, 1H, HC=C), 4.10 (q, 2H, J = 7 Hz, O—CH_2—CH_3), 3.63 (t, 2H, J = 7 Hz, CH_2Cl), 3.02, 2.67 (t, t, 2H, J = 7 Hz, 1:1, *E*:*Z*, CH_2—C=C), 2.18, 1.99 (s, s, 3H, 1:1, *E*:*Z*, CH_3C=C), 1.27 (t, 3H, J = 7 Hz, CH_3CH_2).

*4-Chloro-2-methyl-1,1-dicarbomethoxy-1-butene (**8**)*

Titanium tetrachloride (11 mL, 0.10 mol) and carbon tetrachloride (25 mL) were added dropwise over 45 min to a 1-L three-necked flask containing THF (15 mL), maintained at 0°C with an external ice bath and equipped with a mechanical stirrer, condenser, and dropping funnel. After addition was complete, a yellow precipitate had formed and a THF solution (40 mL) containing 4-chlorobutanone (5.3 g, 0.05 mol), and dimethyl malonate (6.6 g, 0.05 mol, Eastman), were added to the stirred reaction mixture over 15 min. This was followed by the dropwise addition of pyridine (16 g, 0.2 mol) in THF (20 mL) over 30 min. The resulting dark orange solution was stirred for a further 24 h at 21°C. The reaction was poured onto ice-water, the organic layer separated, and the aqueous layer extracted with ethyl acetate. The combined extracts were dried, filtered, and concentrated to afford the diester **8**, 6.6 g (60%), which was further purified by distillation, bp 96–98°C/0.3 Torr; ir (neat): 1725 (C=O), 1640 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.63 (s, 6H, CH_3O), 3.58 (t, 2H, J = 7 Hz, CH_2Cl), 2.76 (t, 2H, J = 7 Hz, CH_2C=C), 1.98 (s, 3H, CH_3C=C). *Exact Mass* calcd. for $C_9H_{13}O_4Cl - CH_3OH$: 188.0237; found: 188.0223.

*Alkylation of keto-esters **10** and **24***

An ether solution (5 mL) of the appropriate keto-ester (5 mmol) was added to a sodium ethoxide solution (prepared from sodium (5 mmol), BDH, and dry ethanol (30 mmol)) in ether (4 mL) at 21°C and resulted in an immediate precipitate. The reaction mixture was lowered into an oil bath (75–80°C), dimethyl sulfoxide (10 mL) was added, followed by the alkyl halide (6 mmol of **7** and 10 mmol of **8**), and stirring continued for 2 h. The solution was then cooled (0°C), acidified (10% HCl), and extracted with ethyl acetate. The combined extracts were washed with brine, dried, filtered, concentrated, and the product purified by chromatography (10% ether – petroleum ether). The diester **17** was isolated in 90% yield; ir (neat): 1740 (C=O), 1710 (C=O), 1630 (C=C) cm^{-1}; 1H nmr ($CDCl_3$) δ: 1.22 (t, 3H, J = 7 Hz, CH_3), 1.26 (t, 3H, J = 7 Hz, CH_3), 1.70 (br s, 3H, C=CCH_3), 2.12 (br s, 3H, COC=CCH_3), 2.86 (m, 4H, CH_2—C=C), 4.02, 4.05 (q, 4H, J = 7 Hz, O—CH_2—CH_3), 5.00 (t, 1H, J = 7Hz, HC=C), 5.72 (m, 1H, HC=CCO); the triester **18** was obtained in 45% yield; ir (neat): 1740 (C=O), 1710 (C=O), 1625 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.08 (t, 3H, J = 7 Hz, CH_2CH_3), 1.58 (br s, 3H, C=CCH_3), 2.00 (br s, 3H, CH_3C=CCO), 3.62 (s, 3H, OCH_3), 3.67 (s, 3H, OCH_3), 3.73 (s, 1H, $HC(COOCH_3)_2$), 4.06 (q, 2H, J = 7 Hz, OCH_2—CH_3), 5.08 (t, 1H, J = 7 Hz, HC=C), 5.73 (m, 1H, C=CH—CO); the triester **26** was obtained in 65% yield; ir (neat): 1745 (C=O), 1700 (C=O), 1640 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.27 (t, 3H, J = 7 Hz, CH_3CH_2), 1.78 (br s, 3H, CH_3C=C), 3.70 (s, 6H, CH_3O), 3.93 (s, 1H, $HC(COOCH_3)_2$), 4.14 (q, 2H, J = 7 Hz, OCH_2CH_3), 5.18 (t, 1H, J = 7 Hz, HC=C). *Exact Mass* calcd. for $C_{20}H_{26}O_7$: 378.1671, found: 378.1655.

*5-(3-Oxobutyl)-5-carboethoxy-3-methyl-2-cyclopentenone (**11**)*

A solution of 5-carboethoxy-3-methyl-2-cyclopentenone (5 mmol) in *tert*-butyl alcohol (2 mL) was added dropwise to a stirred potassium *tert*-butoxide solution (prepared from potassium (0.01 mmol) and *tert*-butyl alcohol (4 mL) in ether (2 mL) at 21°C. Stirring was continued for a further 16 h after addition was complete, and the reaction was cooled to 0°C with an external ice bath and acidified with aqueous 1% HCl. The aqueous layer was extracted with ethyl acetate, the combined extracts were washed with brine, dried, filtered, concentrated, and the product purified by chromatography (10% ether – petroleum ether) to give the diketone **11**, 1.20 g (95%); ir (neat): 1730 (C=O), 1700 (C=O), 1625 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 5.87 (br s, 1H, HC=C), 4.11 (q, 2H, J = 7 Hz, OCH_2CH_3), 2.19 (br s, 3H, CH_3C=C), 2.10 (s, 3H, CH_3CO), 1.22 (t, 3H, J = 7 Hz, CH_3CH_2).

endo-1-Carboethoxy-4-methyl-5-acetylbicyclo[2.2.1]heptan-2-one (**19**) was also obtained (5–50%) in early experiments when the base concentration was higher, ir (neat): 1765 (C=O strained), 1715 (C=O), 1625 (C=C) cm^{-1}; uv (EtOH): 224 nm, ε = 2000; ^1H nmr (400 MHz) ($CDCl_3$) δ: 4.22 (q, 2H, J = 7 Hz, OCH_2CH_3), 3.02 (ddd, 1H, J = 2, 6, 12 Hz, H-5 *exo*), 2.22 (s, 3H, CH_3CO), 1.45 (s, 3H, CH_3—C—), 1.30 (t, 3H, J = 7 Hz, CH_3CH_2). *Exact Mass* calcd. for $C_{13}H_{18}O_4$: 238.1200; found: 238.1211.

*5-Carboethoxy-5-(dimethyl 3-methyl-3-butenyl-4,4-dicarboxylate)3-methyl-2-cyclopentenone (**12**)*

Titanium tetrachloride (0.22 mL, 2 mmol, BDH) and carbon tetrachloride (1 mL) were added dropwise to a 25-mL three-necked flask containing THF (10 mL), maintained at 0°C with an external ice bath and equipped with a mechanical stirrer, condenser, and dropping funnel. After addition was complete, a yellow precipitate had formed and a THF solution (1 mL) containing diketone **11** (0.230 g, 1 mmol), and dimethyl malonate (0.130 g, 1 mmol, Eastman), were added to the stirred reaction mixture over 10 min. This was followed by the dropwise addition of pyridine (0.315 g, 4 mmol) in THF (1 mL). The resulting dark orange solution was stirred for a further 15 h at 21°C. The reaction was poured onto ice-water, the organic layer separated, and the aqueous layer extracted with ethyl acetate. The combined extracts were dried, filtered, concentrated and purified by chromatography (30% ethyl acetate/*n*-hexane) to afford recovered starting material **11**, 27 mg (12%), and the desired triester **12**, 187 mg (53%); ir (neat): 1750–1700 (C=O), 1630 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 5.78 (br s, 1H, HC=C), 4.11 (q, 2H, J = 7 Hz, OCH_2CH_3), 3.72 (s, 6H, CH_3OCO), 2.22 (br s, 3H, CH_3C=CH), 2.03 (s, 3H, CH_3C=C), 1.23 (t, 3H, J = 7 Hz, CH_3CH_2); and 6-carboethoxy-8-methyl-3-(dimethyl methylenedicarboxylate)bicyclo[4.3.0]nona-1,8-diene (**20**) (7%); ir (neat): 1740–1710) (C=O), 1610 (C=C), 1570 (C=C) cm^{-1}; uv (EtOH): 226 nm, ε = 15 800; ^1H nmr (CCl_4) δ: 6.57 (s, 1H, HC=C), 6.03 (br s, 1H, HC=C), 4.07 (q, 2H, J = 7 Hz, OCH_2CH_3), 3.68 (s, 6H, CH_3OCO), 1.91 (br s, 3H, CH_3C=C), 1.23 (t, 3H, J = 7 Hz, CH_3CH_2). *Exact Mass* calcd. for $C_{18}H_{22}O_6$: 334.1414; found 334.1396.

*5-Carboethoxy-5-(dimethyl 3-methyl-3-butenyl-4,4-dicarboxylate)3-methyl-2-cyclopentenol (**13**)*

Sodium borohydride (12 mg, 0.31 mmol, BDH) was added to a stirred methanol solution (10 mL) containing the ketone **12** (100 mg, 0.28 mmol) and cerous chloride ($CeCl_3 \cdot 7H_2O$, 115 mg, 0.31 mmol, BDH). Stirring was continued at 21°C for 1 h after addition was complete. The reaction mixture was then acidified with 5% aqueous HCl, and extracted with ethyl acetate. The combined extracts were washed with brine, dried, filtered, concentrated, and the product purified by chromatography (25% ethyl acetate/*n*-hexane) to afford the alcohol **13**, 65 mg (62%); ir (neat): 3300–3500 (OH), 1725 (C=O), 1625 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 5.87 (br s, 1H, HC=C), 5.35, 4.90 (m, 1H, 1:1, CH(OH)), 4.20 (q, 2H, J = 7 Hz, OCH_2CH_3), 3.78 (s, 6H, CH_3OCO), 2.27 (br s, 3H, CH_3C=CH), 2.08 (s, 3H, CH_3C=C), 1.29 (t, 3H, J = 7 Hz, CH_3CH_2).

*1-Carboethoxyl-1-(dimethyl 3-methyl-3-butenyl-4,4-dicarboxylate)4-methylcyclopentadiene (**14**)*

Gaseous sulfur dioxide (Fisher) was bubbled into a dichloromethane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

(1 mL) solution containing methanesulfonyl chloride (0.48 mL, 6 mmol, Aldrich) for 10 min, and added to alcohol **13** (200 mg, 0.6 mmol) dissolved in dichloromethane (3 mL) containing pyridine (0.56 mL, 7.2 mmol) and *N,N*-dimethylaminopyridine (2 mg, Aldrich). The solution was stirred at 20°C for 1 h, cooled at 0°C, and water added. It was then extracted with dichloromethane, and the combined extracts were dried, filtered, concentrated, and purified by chromatography (30% ether/petroleum ether) to afford **14**, 107 mg (53%); ir (neat): 1725 (C=O), 1635 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.10 (m, 2H, HC=C), 4.80 (m, 1H, HC=C), 4.07, 4.12 (q, q, 2H, 1:1, J = 7 Hz, OCH_2CH_3), 3.65 (s, 6H, CH_3OCO), 2.01 (s, 3H, CH_3C=C), 1.82 (br s, 3H, CH_3C=CH), 1.23, 1.26 (t, t, 3H, 1:1 CH_3CH_2); ms (*m/z*, relative % intensity): 336(3), 304(5) − HOMe, 19(60), 91(100).

*$\Delta^{2,3}$-5-Carboethoxy-9-dicarbomethoxy-2,8-dimethyltricyclo-[4.3.0^{1,5}.0^{4,8}]nonene (**15**) and $\Delta^{2,3}$-5-carboethoxy-9-dicarbomethoxy-3,8-dimethyltricylo[4.3.0^{1,5}.0^{4,8}] (**16**)*

A solution of triene **14** (30 mg, 0.089 mmol) in toluene (1 mL) was placed in a sealed tube and heated in an oil bath at 140°C for 10 h. The solution was then concentrated and purified by chromatography (6% ether/petroleum ether) to afford a 5:4 mixture of **15** and **16**, 14 mg (40%); ir (neat): 1730 (C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.10, 6.20 (br s, 1H, HC=C, 5:4), 4.11 (q, 2H, J = 7 Hz, OCH_2CH_3), 3.70 (s, 6H, CH_3OCO), 2.02, 2.04 (br s, 3H, CH_3C=C, 5:4). *Exact Mass* calcd. for $C_{18}H_{24}O_6$: 336.1572; found: 336.1561.

*$\Delta^{1,5}$-Bicyclo[3.3.0]octen-2-one (**23**)*

This compound was prepared from methyl 2-oxocyclopentanecarboxylate by the method of Kulkarni and Dev (43), or preferably by the procedure of Eaton, Carlson, and Lee (44) in which the yield of the final cyclization was improved to 60% using P_2O_5/CH_3SO_3H in place of P_2O_5/H_3PO_4. The largest scale on which this reaction could be performed was 0.11 mol of hydroxy-acid using five equivalents of phosphorus pentoxide and methansulfonic acid, instead of the 10 equivalents recommended in the literature; ir (neat): 1700 (C=O), 1640 (C=C) cm^{-1}; uv (EtOH) 244, ε = 3500; ^1H nmr (CCl_4) δ: 2.2–2.8 (m). *Exact Mass* calcd. for $C_8H_{10}O$: 122.0729; found: 122.0713.

*$\Delta^{1,5}$-3-Carboethoxybicyclo[3.3.0]octen-2-one (**24**)*

An ether solution (10 mL containing $\Delta^{1,5}$-bicyclo[3.3.0]oct-en-2-one (**23**) (0.610 g, 5 mmol) and diethylpyrocarbonate (1.2 g, 7.5 mmol, Aldrich) was added rapidly (5 min maximum) to a stirred solution of lithium dicyclohexylamide (prepared from 4.2 mL of *n*-butyllithium (2.5 M, 10.5 mmol, Aldrich) and dicyclohexylamine (2.15 mL, 11 mmol)) in ether (15 mL) at −78°C under nitrogen. After 1 h at −78°C the reaction was quenched with aqueous 10% citric acid (10 mL), allowed to warm to 21°C, extracted with ether, the combined ether extracts washed with brine, dried, filtered, and the solvent removed under reduced pressure. Distillation of the residual diethylpyrocarbonate and the keto-ester (40–60°C/0.1 Torr) followed by chromatography (15% ether − petroleum ether) gave $\Delta^{1,5}$-3-carboethoxybicyclo[3.3.0]octen-2-one (**24**), 0.760 g (78%); ir (neat); 1735 (C=O), 1700 (C=O), 1640 (C=C) cm^{-1}; uv (EtOH) 245, ε = 4000; ^1H nmr (CCl_4) δ: 1.28 (t, 3H, CH_2CH_3, J = 7 Hz), 2.1–2.9 (m, 8H), 3.61 (br t, 1H, J = 5 Hz, CO—CH—CO), 4.18 (q, 2H, OCH_2CH_3, J = 7 Hz). *Exact Mass* calcd. for $C_{11}H_{14}O_3$: 194.0939; found: 194.0931.

*$\Delta^{1,5}$-3-(3-Oxobutyl)-3-carboethoxybicyclo[3.3.0]octen-2-one (**25**)*

The keto-ester **24** (0.97 g, 5 mmol) in *tert*-butyl alcohol (2 mL) was added to a potassium *tert*-butoxide solution (prepared from potassium (0.01 mmol) and *tert*-butyl alcohol (4 mL) in ether (2 mL)), at 21°C. Methyl vinyl ketone (0.70 g, 10 mmol) in *tert*-butyl alcohol (2 mL) was added dropwise. After stirring for 16 h, the reaction was cooled (0°C) and acidified (1% HCl). After extraction of the aqueous layer with ethyl acetate, the combined extracts were washed with brine, dried, filtered, concentrated, and the product purified by chromatography (5% ether – petroleum ether) to give diketone **25**, 1.25 g, (95%); ir (neat): 1750–1700 (C=O), 1645 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.11 (q, 2H, J = 7 Hz, OCH_2CH_3), 2.11 (s, 3H, CH_3CO), 1.23 (t, 3H, J = 7 Hz, CH_3CH_2). *Exact Mass* calcd. for $C_{16}H_{22}O_5$: 264.1360; found: 264.1331.

*$\Delta^{1,5}$-3-Carboethoxyl-3-(dimethyl 3-methyl-3-butenyl-4,4-dicarboxylate)bicyclo[3.3.0]octen-2-one (**27**)*

Titanium tetrachloride (5.4 mL, 0.05 mol, BDH) and carbon tetrachloride (18 mL) were added dropwise over 35 min to a three-necked flask containing THF (10 mL) and equipped with a mechanical stirrer, condenser, and dropping funnel. After addition was complete, a yellow precipitate had formed and a THF solution (20 mL) containing $\Delta^{1,5}$-3-(3-oxobutyl)-3-carboethoxybicyclo[3.3.0]octen-2-one (**25**) (6.55 g, 0.025 mol), and dimethyl malonate (3.3 g, 0.025 mol, Eastman), were added to the stirred reaction mixture over 15 min. This was followed by the dropwise addition of pyridine (8 g, 0.1 mol) in THF (10 mL) over 30 min. The resulting dark orange solution was stirred for a further 22 h at 21°C. The reaction was poured onto ice-water, the organic layer separated, and the aqueous layer extracted with ethyl acetate. The combined extracts were dried, filtered concentrated, and purified by chromatography (20–30% ether/*n*-hexane) to afford recovered starting material **24**, 0.79 g (12%), and the desired triester **27**, 5.67 g (60%); ir (neat): 1755–1725 (C=O), 1650 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 4.12 (q, 2H, J = 7 Hz, OCH_2CH_3), 3.73, 3.70 (s, s, 6H, 1:1, CH_3OCO), 2.02 (s, 3H, CH_3C=C), 1.24 (t, 3H, J = 7 Hz, CH_3CH_2).

*$\Delta^{1,5}$-3-Carboethoxy-3-(dimethyl-3-methyl-3-butenyl-4,4-dicarboxylate)bicyclo[3.3.0]octen-2-ol (**28**)*

Sodium borohydride (0.38 g, 0.01 mol, BDH) was added to a stirred methanol solution (30 mL) containing the ketone **27** (3.78 g, 0.01 mol) and cerous chloride ($CeCl_3 \cdot 7H_2O$, 3.73 g, 0.01 mol, BDH). Stirring was continued at 21°C for 1 h after addition was complete. The reaction mixture was then acidified with 5% aqueous HCl, and extracted with ethyl acetate. The combined extracts were washed with brine, dried, filtered, concentrated, and the product purified by chromatography (25% ethyl acetate/*n*-hexane) to afford the alcohol **28**, 255 g (67%); ir (neat): 3500 (OH), 1750–1705 (C=O), 1650 (C=C) cm^{-1}; ^1H nmr (CCl_4) δ: 4.60 (br s, 1H, CH(OH)), 4.05 (q, 2H, J = 7 Hz, OCH_2CH_3), 3.64 (s, 6H, CH_3OCO), 1.27 (t, 3H, J = Hz, CH_3CH_2).

In an alternative procedure a zinc borohydride solution (60 mL, 0.16 M in ether, 8.8 mmol) was added to an ether solution (40 mL) containing ketone **27** (3.0 g, 7.9 mmol) at 0°C. After stirring for 30 min at 0°C, and for 30 min at 21°C, a saturated solution of sodium tartrate was added dropwise (1.5 mL) until bubbling ceased. This solution was then dried, filtered, concentrated, and the product purified by chromatography (30% ether – petroleum ether) to afford **28**, 1.6 g (58%).

*3-Carboethoxy-3-(dimethyl-3-methyl-3-butenyl-4,4-dicarboxylate)-bicyclo[3.3.0]octa-1,4-diene (**21**)*

Gaseous sulfur dioxide (Fisher) was bubbled into a dichloromethane (10 mL) solution containing methanesulfonyl chloride (3.8 g, 6.7 mmol, Aldrich) for 10 min at 21°C. This solution was added to the alcohol **28** (2.5 g, 6.7 mmol) dissolved in dichloromethane (10 mL), containing pyridine (2.9 g, 36.8 mmol) and *N,N*-dimethylaminopyridine (5 mg, Aldrich). The resulting solution was stirred at 21°C for 1 h, cooled at 0°C, and water added. The aqueous mixture was then extracted with dichloromethane, and the combined extracts were dried, filtered, concentrated, and purified by chromatography (10% ether/petroleum ether) to afford the cyclopentadiene **21**, 1.45 g (60%); ir (neat): 1730 (C=O), 1635 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.73, 5.35, 5.20 (br s, br s, br s, 2H, HC=C), 4.10, 4.06 (q, q, 2H, ≃2:1, OCH_2CH_3), 3.72, 3.64 (s, s, 6H, ≃2:1, CH_3OCO), 2.01 (s, 3H CH_3C=C), 1.51, 1.48 (t, t, 3H, ≃2:1, CH_3CH_2); ms (*m/z*, relative % intensity): 362(4), 257(5) − HOMe, COOEt or HCOOEt, OMe, 117(38).

*Cyclization of triene **21**. 3,7,7-Tricarbomethoxy-6-methyltetracyclo-[6.3.1.0^{1,6}.0^{1,10}]-9-dodecene (**32**) and 6-carboethoxy-2-dicarbomethoxy-3-methyltetracyclo-[6.4.0^{1,6}.0^{3,708,12}]-11-dodecene (**30**)*

A toluene solution (1 mL) of **21** (30 mg, 0.081 mmol) was placed in a sealed tube, flushed with nitrogen, and heated in an oil bath at 140°C for 10 h. The solution was concentrated and chromatographed (6% ether/petroleum ether) to afford the adducts, 15 mg (50%); ir (neat): 1735 (C=O) cm^{-1}; ^1H nmr (400 MHz) ($CDCl_3$) δ: 5.51, 5.26 (m, m, 1H, 4:1, J = 1.5 Hz, HC=C), 4.14, 4.15 (q, q, 2H, 4:1, J = 7 Hz, OCH_2CH_3), 3.71, 3.65 and 3.69, 3.66 (s, s, s, s, 6H, 4:4:1:1,

CH_3OCO), 3.37, 3.01 (m, m, 1H, 4:1, bridgehead H), 1.25 (t, 3H, J = 7 Hz, CH_3CH_2), 1.17 (s 3H, CH_3—C). *Exact Mass* calcd. for $C_{20}H_{26}O_6$: 362.1727; found: 362.1720.

The adducts **30** (R = COOEt, E = COOMe) and **32** (E(bridgehead) = COOEt, E = COOMe) (20 mg, 0.05 mmol) were added to a solution containing aluminum trichloride (14 mg, 0.11 mmol, Fisher) in ethanethiol (2 mL, Eastman) according to the procedure of Fujita and co-workers (46). Immediately a very viscous precipitate was formed, and stirring was continued at 21°C for 20 h. The reaction mixture was then poured into cold acid (1% aqueous HCl) and extracted with ether and chloroform. The combined extracts were dried, filtered, concentrated, and the product mixture, 17 mg (94%), chromatographed to give 3-carboethoxy-7,7-dicarboxy-6-methyltetracyclo-[6.3.1.0^{1,6}.0^{1,10}]-9-dodecene (5 mg); ir (neat): 3700–2800 (OH), 1725 (C=O) cm^{-1}; ^{1}H nmr (80 MHz) ($CDCl_3$) δ: 8.80 (br s, 2H, COOH), 5.85 (s, 1H, HC=C), 4.08 (q, 2H, J = 7 Hz, CH_2CH_3), 1.25 (t, 3H, J = 7 Hz, CH_3CH_2), 1.23 (s, 3H, CH_3), and 12 mg of fully hydrolyzed material. This was dissolved in methanol (2 mL) and treated with excess ethereal diazomethane, concentrated and chromatographed (20% acetone/*n*-hexane) to give a mixture (3 mg, 5:4) of 3,7-dicarbomethoxy-6-methyltetra-cyclo[6.3.1.0^{1,6}.0^{1,10}]-9-dodecene and 2,6-dicarbomethoxy-3-methyltetracyclo-[6.4.0^{1,6}.0^{3,7}.0^{8,12}]-11-dodecene, ^{1}H nmr ($CDCL_3$) δ: 5.72, 5.21 (m, m, 1H, 5:4, HC=C), 3.70, 3.64, 3.69, 3.62 (s, s, s, s, 3H, CH_3O); followed by the trimethylester **32** (6 mg), ^{1}H nmr ($CDCL_3$) (300 MHz) δ: 5.51 (d, 1H, J = 1.5 Hz, HC=C), 3.71 (s, 3H, CH_3O), 3.70 (s, 3H, CH_3O), 3.65 (s, 3H, CH_3O), 3.37 (br d, 1H, J = 1.5 Hz, bridgehead H), 2.67, 2.30 (AB system, 1H, 1H, J = 17 Hz, *exo* and *endo* allylic CH_2), 2.10, 1.35 (AB system, 1H, 1H, J = 9 Hz, bridge CH_2), 1.95, 1.58 (m, 1H, 1H, bridge CH_2), 1.19 (s, 3H, CH_3C); ^{13}C nmr ($CDCl_3$) δ: 19.9, 31.8, 33.4, 34.2, 35.5, 44.3, 48.3, 51.8, 51.8, 52.4, 54.9, 55.1, 63.9, 69.2, 119.8, 158.4, 170.6, 172.0, 176.1.

Crystallography

3,7,7-Tricarbomethoxy-6-methyltetracyclo[6.3.1.0^{1,6}.0^{1,10}]-9-dodecene (32)

Diffraction intensities from an approximately 0.10 × 0.10 × 0.30 mm crystal were collected with graphite monochromatized CuK$_\alpha$ radiation, using the θ/2θ technique with profile analysis (47) to 2θ$_{max}$ 153° and using an Enraf Nonius CAD4 diffractometer with a PDP-8e computer. A total of 3705 reflections were measured, all of which were unique, and 2112 were considered significant with $I_{net} > 2.5\sigma$ (I_{net}). Lorentz and polarization factors were applied, but absorption corrections were not because of the small size of the crystal and the small value of μ. Cell parameters were obtained by least-squares refinement of the setting angles of 21 reflections within the range 84.00° < 2θ < 92.00°.

TABLE 4. Selected bond lengths (esd's) in Å for 3,7,7-tricarbomethoxy-6-methyltetracyclo[6.3.1.0^{1,6}.0^{1,0}]-9-dodecene (**32**)

Bond	Length (Å)	Bond	Length (Å)
O(1)—C(3A)	1.192(5)	C(3)—C(3A)	1.510(5)
O(2)—C(3A)	1.327(5)	C(3)—C(4)	1.561(5)
O(2)—C(3B)	1.456(6)	C(3)—C(11)	1.550(5)
O(3)—C(7A)	1.193(5)	C(4)—C(5)	1.540(6)

The structure was solved by direct methods using the NRC VAX Crystal Structure programs (48) and refined by full matrix least-square methods to final residuals of R_f and R_w of 0.053 and 0.047 respectively ($R_f = \Sigma(|F_o|-|F_c|)/\Sigma(|F_o|)$; $R_w = \Sigma(w(|F_o|-|F_c|)^2/\Sigma(w|F_o|^2))$. The final difference map had no peaks higher than 0.190 eA^3.

Crystal and other numerical data

$C_{19}H_{24}O_6$ fw = 384.27

Monoclinic, $P2_1/c$, a = 15.094(7), b = 7.750(3), c = 15.985(9) Å, β = 110.50(4)°, (CuKα$_1$, λ = 1.54056 Å, 21 reflections, 84° < 2θ < 92°), V = 1751.48 Å^3, Z = 4, ρ_c = 1.321 mg m^{-3}. Nominal specimen dimensions 0.10 × 0.10 × 0.30 mm; 3705 reflections scanned (2θ$_{max}$ 153°), giving 2112 "observed" ($I_{net} > 2.56\ \sigma I_{net}$). Atomic coordinates are given in Table 3 and selected bond lengths in Table 4. Supplementary data[6] include H-atom coordinates, temperature factors, all bond lengths, and structure factors. Figure 1 is an ORTEP-II projection (49) of the molecular structure.

Structural studies of a hemicellulose B fraction (B-2) from the cork of *Quercus suber*[1]

AMPARO ASENSIO
Department of Organic Chemistry, University of Valencia, Burjassot, Valencia, Spain

Received August 7, 1987

AMPARO ASENSIO. Can. J. Chem. **66**, 449 (1988).

Polysaccharide B-2 contains xylose, arabinose, glucose, galactose, 4-*O*-methylglucuronic acid, and rhamnose in the molar ratio of 17:12:12:6:4:1. The polysaccharide has a backbone of β(1→4)- and β(1→3)-linked glucopyranosyl, β(1→4)-linked xylopyranosyl, and (1→4)- and (1→6)-linked galactopyranosyl residues. Arabinofuranosyl, rhamnopyranosyl, and some xylopyranosyl and galactopyranosyl groups are present as nonreducing end units. Glucopyranosyluronic acid side chains are attached at O-2 of some xylose residues. The anomeric configurations of the different glycosyl groups were determined by a study of the chromium trioxide oxidation of the acetylated polysaccharide and by nuclear magnetic reasonance spectra of the methylated polysaccharide.

AMPARO ASENSIO. Can. J. Chem. **66**, 449 (1988).

Le polysaccharide B-2 contient du xylose, de l'arabinose, du glucose, du galactose, de l'acide *O*-méthyl-4 glucuronique et du rhamnose dans un rapport molaire de 17:12:12:6:4:1. Le polysaccharide possède un squelette de résidus de glucopyrannosyles liés en β(1→4) et β(1→3), de xylopyrannosyles liés en β(1→4) et de galactopyrannosyles liés en (1→4) et en (1→6). Les groupements arabinofurannosyles, rhamnopyrannosyles et quelques-uns des groupements xylopyrannosyles et galactopyrannosyles sont présents sous la forme d'unités en bout de chaîne qui ne sont pas réductrices. Les chaînes latérales d'acide glucopyrannosyluronique sont attachées en position O-2 de certains résidus de xylose. On a déterminé les configurations anomériques des différents groupements glycosyles en procédant à une oxydation par le trioxyde de chrome du polysaccharide acétylé et à une étude des spectres en résonance magnétique nucléaire du polysaccharide méthylé.

In continuing studies of the polysaccharides from the cork of *Quercus suber*, the structure of the fraction B-2, inferred from the results of complete and partial hydrolysis with acid, methylation analysis, and chromium trioxide oxidation, is now discussed. Hemicelluloses A and B (fraction B-1) have been investigated in detail (1, 2). Both polysaccharides contain (1→4)-linked xylopyranosyl residues in the backbone chains, but different side chains. The polysaccharide B-2 is shown to be highly branched.

The polysaccharide B-2 was isolated as previously described (2), and some impurities of low molecular weight were removed by dialysis. It had a low, positive, optical rotation ($[\alpha]_D$ + 3.96°), indicating that this polymer was structurally different (1, 2) from hemicelluloses A and B-1. It contained xylose, arabinose, glucose, galactose, 4-*O*-methylglucuronic acid, and rhamnose in the molar ratio of 17:12:12:6:4:1. The polysaccharide gave a single peak in chromatography (3) on Sephacryl S-400.

Hakomori methylation (4) of B-2 gave a product with an $[\alpha]_D$ value of +8.3° indicative of α and β linkages, which was confirmed by the nmr spectra (5). A part of the methylated polysaccharide was reduced with lithium aluminium hydride. The two samples were hydrolysed and the sugars were analysed, as the partially methylated alditol acetates, by glc and glc (6) – ms (7). The results are summarized in Table 1.

These results gave an indication of the linkages between the different monosaccharide residues in polysaccharide B-2. The proportions of 2-*O*- and 3-*O*-methylxylose, and 2,3-di-*O*-methylglucose, show that B-2 is highly branched. Identification of 2,3,4-tri-*O*-methylrhamnose, 2,3,5-tri-*O*-methylarabinose, 2,3,4-tri-*O*-methylxylose, 2,3,4,6-tetra-*O*-methyl-glucose and -galactose indicated their derivation from nonreducing end units in the methylated polysaccharide. In the interior part of the polysaccharide, both glucose and xylose are present as (1→4)-linked residues, and the glucose also as (1→3)-linked residues. Galactose is present as (1→4)- and (1→6)-linked residues.

2,3,4-Tri-*O*-methylglucose was detected only in reduced polysaccharide, showing that this sugar was derived from terminal glucopyranosyluronic acid residues. The presence of 2,5-di-*O*-methylarabinose in the hydrolysate of the methylated polysaccharide showed that some arabinosyl groups are joined through (1→3) linkages.

TABLE 1. Products obtained by hydrolysis of the methylated (A); methylated, carboxyl-reduced B-2 (B); and methylated, carboxyl-reduced, degraded polysaccharide B-2 (C)

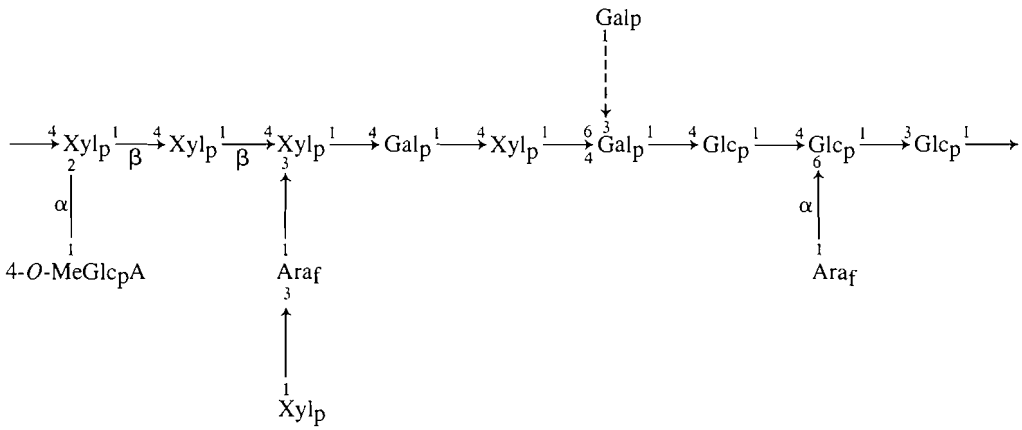

FIG. 1. Average structural features of the B-2 fraction.

The molar percentages of rhamnose, arabinose, xylose, galactose, glucose, and 4-*O*-methylglucuronic acid calculated from the methylation (carboxyl-reduced) analysis, assuming that the molar percentage of rhamnose is the same as in the original polysaccharide, are in close agreement with the sugar composition of the polysaccharide. The ratio of the end groups to branch points (calculated from Table 1) for permethylated polysaccharide is $\simeq$1:1.

As seen from Table 1, some components are not separated by glc on the ECNSS-M column. The alditol acetates derived from 2,3,6- and 2,3,4-tri-*O*-methylglucose and from 2,3,6-tri-*O*-methylgalactose were resolved on a OV-1 column. Both 2- and 3-*O*-methylxylose were also resolved on that column (cf. Fig. 2) and identified by the fragments obtained by glc–ms of their alditol acetates (7, 8). The fragments with *m/z* 43, 87, 129, and 189, characteristic of 3-*O*-methylpentoses, were the same as those of 3-*O*-methyl-D-xylose obtained in previous work (1, 2). Fragments with *m/z* 43, 117, and 261, characteristic of the 2-*O*-methylpentoses, were obtained in the peak with t_R 1.01; and this was identified as the alditol acetate from 2-*O*-methylxylose. The increase of 3-*O*-methylxylose in the methylated carboxyl-reduced polysaccharide (1.5 to 5.5) also suggests that the 4-*O*-methylglucuronic acid is attached at some xylose residues through O-2 (as confirmed below).

The aldobiouronic acid obtained by partial hydrolysis of B-2 was converted into the methyl ester methyl glycoside (9), acetylated, and then subjected to glc–ms (10), which showed it to be 2-*O*-(4-*O*-methyl-α-D-glucopyranosyluronic acid)-D-xylose.

Part of the polysaccharide was subjected to a mild acid hydrolysis, by which arabinosidic linkages should be cleaved. The resulting polymeric material was recovered and subjected to methylation analysis and carboxyl reduction with lithium aluminium hydride. The results, given in Table 1, showed an increase of 2,3,4,6-tetra-*O*-methylgalactose, 2,3,6-tri-*O*-methylglucose, and 2,3-di-*O*-methylglucose. The relatively small proportion of xylose in the degraded polysaccharide suggests that the conditions of hydrolysis were too drastic and that a part of the xylose was hydrolysed off, in addition to the arabinose and rhamnose residues. This was checked by analysis of the neutral monosaccharides from the hydrolysate on paper, and by glc (as their alditol acetates), which revealed arabinose (94%), xylose (4.5%), and galactose (traces).

Oxidation of the peracetylated polysaccharide with chromium trioxide (11) in acetic acid for 2 h resulted in a low recovery of xylose, and high recoveries of rhamnose and arabinose. These results indicated that the xylosyl groups had the β configuration, whereas the rhamnosyl groups had the α configuration. Under the conditions used, most galactose and glucose residues would have been oxidized. Sugar analysis revealed that only a small part of the glucopyranose and galactopyranose residues have been affected. Because acetylated furanoses are nonspecifically oxidized (12) by chromium trioxide, the anomeric configuration of the arabinosyl groups could not be determined by this experiment. In fact, the rate at which arabinose was hydrolysed off with 72% sulfuric acid during 2 h at 30°C indicated that it possibly had the α configuration.

From a consideration of the results of sugar analysis, methylation analysis, oxidation with chromium trioxide, and nmr studies, the average structural features of the B-2 can be tentatively represented as shown in Fig. 1; the sequence of the different branches along the polysaccharide chain is not known. In this structure (Fig. 1), a dotted line indicates a substituent that is not present in all repeating units. The proposed structure is, however, hypothetical, and the present results do not exclude less regular structures. The polysaccharide has a backbone of β(1→4)- and β(1→3)-linked glucopyranosyl, β(1→4)-linked xylopyranosyl, and (1→4)- and (1→6)-linked galactopyranosyl residues. Arabinofuranosyl, rhamnopyranosyl, and some xylopyranosyl and galactopyranosyl groups are present as nonreducing end units. Glucopyranosyluronic acid side chains are attached at O-2 of some xylose residues. For every five xylopyranosyl residues in the main chain there is one uronic acid unit, and for 10 such xylopyranosyl residues there is one 3-*O*-(xylopyranosyl-arabinofuranosyl) group (side chain). For every two glucopyranosyl residues in the main chain there is one arabinofuranosyl unit. For every six galactopyranosyl residues in the main chain there is one galactopyranosyl unit.

Because the hemicellulose has a low, positive rotation, the polymer is likely to contain both α and β anomeric configurations. As the configuration of the 4-*O*-methylglucosyluronic acid groups had already been established as α, and as the arabinofuranosyl groups are likely to have the α configuration (13) (δ 109.21 in the ^{13}C spectrum for C-1), the xylopyranosyl groups are therefore likely to have the β configuration (14) (δ 4.24 in the ^{1}H spectrum for H-1 and δ 102.51 in the ^{13}C spectrum for C-1). The other hemicelluloses

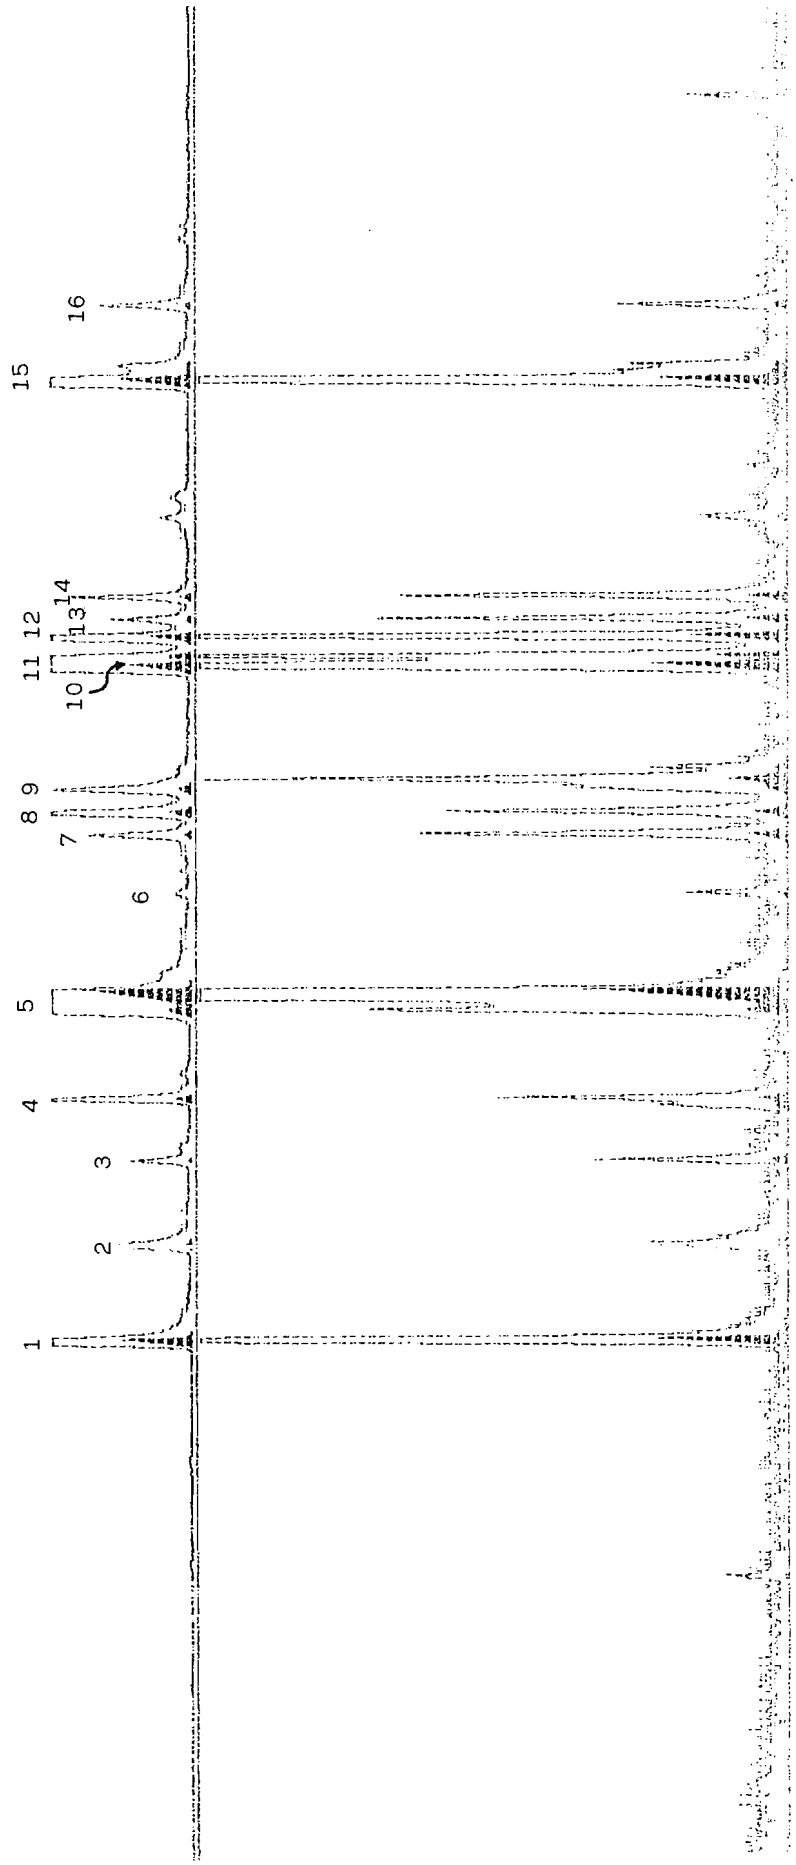

FIG. 2. Gas chromatogram of partially methylated alditol acetates on a capillary column OV-1 at 120→220°C at 4°/min. Peaks: 1 = 2,3,5-Me_3-Ara; 2 = 2,3,4-Me_3-Xyl; 3 = 2,3-Me_2-Rha; 4 = 2,5-Me_2-Ara, 5 = 2,3-Me_2-Xyl; 6 = 2,3,4,6-Me_4-Glc; 7 = 2,3,4,6-Me_4-Gal; 8 = 2-Me-Xyl; 9 = 3-Me-Xyl, 10 = 2,4,6-Me_3-Glc, 11 = 2,3,6-Me_3-Gal; 12 = 2,3,6-Me_3-Glc; 13 = 2,3,4-Me_3-Gal; 14 = 2,3,4-Me_3-Glc; 15 = 2,3-Me_2-Glc; 16 = 2,4-Me_2-Gal. 2,3,5-Me_3-Ara = 1,4-di-*O*-acetyl-2,3,5-tri-*O*-methyl-arabinitol, etc.

(1, 2) of *Quercus suber* contain xylopyranosyl groups in the β configuration. The configuration of glucose and galactose could not be confirmed by this nmr spectroscopic analysis.

Experimental

General methods

Descending paper chromatography (pc) was performed on Whatman Nos. 1 and 3 MM papers using (*A*) ethyl acetate – acetic acid – formic acid – water (18:3:1:4), (*B*) 1-butanol–ethanol–water (2:1:1), and (*C*) 1-butanol–pyridine–water (6:4:3), and detection with diphenylamine aniline (15). Optical rotations were recorded with a Perkin Elmer 141 polarimeter and ir spectra with a Perkin Elmer model 281 spectrophotometer. The ^1H and ^{13}C nmr spectra (internal Me_4Si) were recorded on a Bruker AC-200 (200 MHz) spectrophotometer. Gas–liquid chromatography (glc) was performed with a Hewlett–Packard model 5710A chromatograph fitted with flame-ionization detector and a glass column (200 × 0.6 cm) containing 3% ECNSS-M on Gas Chrom Q (100–200 mesh) at 190°C (alditol acetates) or 175°C (partially methylated alditol acetates). For glc–ms a Hewlett–Packard 5995B instrument, fitted with a capillary column (12 m × 0.2 mm) containing OV-1, was used. Electron impact (EI) mass spectra were recorded at 70 eV with a temperature program of 100→220°C at 4°/min.

Hemicellulose B-2

The extraction of the polysaccharides from the cork of *Quercus suber* and their fractionation into hemicellulose A and B have been reported (2).

To a solution of the hemicellulose B (4 g) in 5% potassium hydroxide (400 mL) was added Fehling's solution until the precipitation was complete. The copper complex was collected by centrifugation. The combined alkaline extracts were dialysed against distilled water for 24 h. The nondiffusable residue was concentrated to a small volume (under reduced pressure) and the polysaccharide was precipitated by addition of ice-cold ethanol (4 vol). After 4 h at 0°C, the precipitated polysaccharide was collected by centrifugation, and then macerated for 1 min with ice-cold ethanol containing 5% of hydrochloric acid. The residue was washed exhaustively with ethanol and then dried over phosphorus pentoxide *in vacuo* to give the polysaccharide (Fraction B-2) (1.8 g), $[\alpha]_D$ +3.96° (*c* 10.4, 1% sodium hydroxide).

The hemicellulose B-1 was isolated from the copper complex as reported (2).

(*a*) *Homogeneity*

Gel-filtration chromatography was performed on a column (46 × 1.6 cm) of Sephacryl S-400 with 0.5 M sodium chloride at 0.5 mL/min. The column was calibrated with dextrans of known molecular weight (Pharmacia). Fractions were monitored by the phenol – sulfuric acid method (3), which showed a single band.

(*b*) *Hydrolysis and sugar analysis*

The polysaccharide B-2 (7 mg) was treated with 72% sulfuric acid (0.2 mL) and kept for 1 h at 30°C. The solution was diluted with water (5 mL) and then heated for 3 h on a boiling-water bath. *myo*-Inositol (2 mg) was added as internal standard, and the hydrolysate was neutralized ($BaCO_3$) and decationized with Amberlite IR-120(H^+) resin. Part of the solution was analysed by pc (solvents *A*–*C*) and sugars were quantified as their alditol acetates by glc (16). The content of glucuronic acid in the hemicellulose B-2 was determined by the carbazole method (17) (using D-glucuronic acid as the standard), and found to be 7.5%.

(*c*) *Characterization of the aldobiouronic acid*

The polysaccharide B-2 (0.5 g) was treated with 0.0125 M sulfuric acid for 90 min at 100°C. The hydrolysate was separated, after neutralization and deionization, into neutral and acidic components (2). Paper chromatography (solvents *A*–*C*) of the acidic sugars revealed an aldobiouronic acid in addition to 4-*O*-methylglucuronic acid. Preparative pc (solvent *A*) gave the aldobiouronic acid, and this was converted into the methyl ester methyl glycosides (methanolic 3% hydrogen chloride (5 mL) for 20 h). This product was acetylated (acetic anhydride – pyridine (1:1)) and then subjected to glc–ms (10), which showed it to be 3,4-di-*O*-acetyl-2-*O*-(methyl 2,3-di-*O*-acetyl-4-*O*-methyl-α-D-glucopyranosyluronate)-α-D-xylopyranoside.

(*d*) *Methylation analysis*

To a stirred solution of sodium methylsulfinylmethanide (prepared under nitrogen from 1 g of sodium hydride and 23 mL of methyl sulfoxide) at room temperature, was added a solution of hemicellulose B-2 (148 mg) in methyl sulfoxide (5 mL). After stirring for 3 h, methyl iodide (4 mL) was added with external cooling. Stirring was continued for 15 h, water (100 mL) was then added, and the mixture was extracted with chloroform. The combined extracts were washed three times with water, dried (Na_2SO_4), and concentrated to a yellow solid, which was dried over phosphorus pentoxide *in vacuo* at 40°C for 2 days. A solution of the product in benzene was diluted with light petroleum (bp 30–60°C) to precipitate the methylated polysaccharide (107 mg), $[\alpha]_D$ +8.32° (*c* 15.7, chloroform), and showed, in its ir spectra, no absorption attributable to OH. A portion (15 mg) of the material was hydrolysed conventionally and the resulting sugars were converted into alditol acetates (18) and analysed by glc and glc (6) – ms (7).

To a solution of another portion (30 mg) in dry tetrahydrofuran (15 mL) was added lithium aluminium hydride (150 mg), and the mixture was boiled under reflux for 24 h. The mixture was worked up in the usual way and the reduced product was extracted into chloroform. The product had ir absorption at 3600 cm^{-1} (OH) but not at 1735 cm^{-1} (ester C=O). The product was hydrolysed as in (*b*) and the methylated sugars were converted into alditol acetates and analysed by glc and glc–ms.

(*e*) *Partially degraded B-2*

The polysaccharide (126 mg) was hydrolysed with 0.0125 M sulfuric acid (12.5 mL) at 100°C for 1 h. The degraded polysaccharide (62.9 mg), which was precipitated by the addition of excess of ethanol, was subjected to Hakomori methylation (4) analysis as in (*d*). Permethylated and reduced material had $[\alpha]_D$ +10.9° (*c* 1.8, chloroform); it was hydrolysed with 72% aqueous sulfuric acid and, after the usual treatment, the partially methylated sugars were converted into their alditol acetates, and these analysed by glc and glc–ms. The results are summarized in Table 1.

The centrifuged partial hydrolysate was neutralised, deionized, and the sugars were converted into alditol acetates, and these analyzed by glc.

(*f*) *Oxidation with chromium trioxide*

Polysaccharide B-2 (25 mg) was mixed with *myo*-inositol (2 mg) as the internal standard, and then dissolved in formamide (5 mL). To this solution was added acetic anhydride (4 mL) and pyridine (5 mL), and the mixture was stirred 22 h at 20°C. The acetylation product was isolated by extraction with chloroform. The peracetylated polysaccharide was oxidized (11) with chromium trioxide (400 mg) in acetic acid (4 mL), with stirring, at 50°C. Aliquots were removed at 0, 1, and 2 h, diluted with water immediately after removal, and the solutions extracted with chloroform. The products were hydrolysed and analysed, as their alditol acetates, by glc (16).

Acknowledgment

The author thanks Dr. D. Manuel Menéndez Gallego (National Institute of Toxicology of Sevilla) for the glc–ms analysis.

MICHAEL T. M. CLEMENTS, ROSS E. KLINCK, SRIYAWATHIE PEIRIS, ARTHUR J. RAGAUSKAS, and J. B. STOTHERS. Can. J. Chem. **66**, 454 (1988).

To assess the influence of the conformation of the cyclohexanone moiety in bicyclo[3.2.1]octan-2-ones on the reactivity for β-enolate rearrangement, the behavior of three derivatives under typical homoenolization conditions has been examined for comparison with 3,3-dimethylbicyclo[3.2.1]octan-2-one (**1**), which was known to be smoothly converted to the [3.3.0] isomer **2**. For this purpose, *endo*-3-*tert*-butyl-*exo*-3-methylbicyclo[3.2.1]octan-2-one (**8**), *endo*-9-*tert*-butyl-*exo*-9-methyl-*exo*-tricyclo[5.3.1.$0^{2,6}$]undecan-8-one (**9**), and 9,9-dimethyl-*endo*-tricyclo[5.3.1.$0^{2,6}$]undecan-8-one (**10**) were prepared and treated with *t*-BuO$^-$/*t*-BuOH at ≧185°C for prolonged periods. Each is much less reactive than **1**. The relative orientations of the carbonyl groups with respect to the sites for β-enolization were determined by molecular mechanics (MM2) calculations. $^1H/^2H$ exchange in **9** and **10** was also examined under strongly basic conditions at 185°C.

MICHAEL T. M. CLEMENTS, ROSS E. KLINCK, SRIYAWATHIE PEIRIS, ARTHUR J. RAGAUSKAS et J. B. STOTHERS. Can. J. Chem. **66**, 454 (1988).

Dans le but d'évaluer l'influence de la conformation de la portion cyclohexanone des bicyclo[3.2.1]octanones-2 sur la réactivité conduisant à une transposition β-énolique, on a examiné le comportement de trois dérivés dans des conditions d'homoénolisation pour comparer avec le comportement de la diméthyl-3,3 bicyclo[3.2.1]octanone-2 (**1**) qui se transforme facilement en son isomère [3.3.0] (**2**). À ces fins, on a préparé la *tert*-butyl-3-*endo* méthyl-3-*exo* bicyclo[3.2.1]octanone (**8**), la *tert*-butyl-9-*endo* méthyl-9-*endo* tricyclo[5.3.1.$0^{2,6}$]undécanone-8-*exo* (**9**) et la diméthyl-9,9 tricyclo[5.3.1.$0^{2,6}$]undécanone-8-*endo* (**10**) et on les a traitées avec du *t*-BuO$^-$/*t*-BuOH, à 185°C, pour des périodes prolongées. Chacune de ces cétones est moins réactive que le composé **1**. Les orientations relatives des groupements carbonyles par rapport aux sites de la β-énolisation ont été déterminées par des calculs de mécanique moléculaire (MM2). Utilisant des conditions fortement basiques, à 185°C, on a aussi examiné les échanges $^1H/^2H$ dans les composés **9** et **10**.

[Traduit par la revue]

Introduction

Since the discovery of homoenolization (1) many examples of both acyclic and bicyclic monoketones have been found to undergo proton abstraction from centres other than the α-carbons under strongly basic conditions (2). For most systems, β-enolization is observed, whereby proton abstraction from β-carbons occurs, and the process can lead to skeletal rearrangement and (or) deuterium exchange, if the reaction is carried out in a deuterated medium. The factors governing regioselectivity and the relative reactivity of such proton abstractions are of considerable interest since the rearrangements can provide a means of generating carbon skeletons that are not readily accessible through other routes. Some applications of β-enolization in the syntheses of some naturally occurring carbon skeletons from readily available intermediates have been described (3). The model reaction for the key step in each of these cases was the known, unidirectional conversion of 3,3-dimethylbicyclo[3.2.1]octan-2-one (**1**) to its [3.3.0] isomer **2** (4), as illustrated by the conversion of **3** → **4** (3*c*). A better understanding of both the regioselectivity and stereoselectivity of β-enolization would enhance the scope of potential synthetic applications.

Earlier, we had investigated the behavior of the 7,7-dimethyltricyclo[3.3.1.$0^{2,4}$]nonan-6-ones under typical homoenolization conditions, *t*-BuO$^-$/*t*-BuOH/185°C, and found (5) that the *endo* isomer **5** is stable while its *exo* counterpart **6** readily isomerizes to **7**. This difference in reactivity was attributed to the relative orientation of the carbonyl group and the methano bridge (C-9) in the two isomers, which is governed by the conformation of the six-membered ring. In **1**, **3**, and **6**, this ring will preferentially adopt a chair conformation, but this arrangement is destabilized for **5**, because of the *endo* orientation of C-3, and the cyclohexanone moiety presumably adopts a boat-like conformation. In the latter arrangement the π-system of the carbonyl group is tipped away from C-9, thereby rendering less likely potential overlap with a developing carbanionic site at the methano carbon. To gain further support for this conformational interpretation and to check that the three-membered ring in **5** is not primarily responsible for its deactivation towards β-enolization, we elected to investigate the behavior of other derivatives of **1** for which the cyclohexanone ring cannot exist in a chair arrangement. For this purpose we have prepared *endo*-3-*tert*-butyl-*exo*-3-methylbicyclo[3.2.1]octan-2-one (**8**), its *exo*-trimethylene derivative **9** (*endo*-9-*tert*-butyl-*exo*-9-methyl-*exo*-tricyclo[5.3.1.$0^{2,6}$]undecan-8-one), and 9,9-dimethyl-*endo*-tricyclo[5.3.1.$0^{2,6}$]undecan-8-one (**10**) and examined their behavior in *t*-BuO$^-$/*t*-BuOH at 185 and 200°C for prolonged reaction times. For comparison with our earlier results for **1** (4) and **3** (6), the regioselectivity of proton abstraction in **9** and **10** was established by the requisite H/D exchange experiments. In addition, the molecular geometry of each of the ketones was determined by molecular mechanics (MM2) computations. These results for **8–10** are presented in this paper.

Results and discussion

Syntheses

The preparation of **8** was accomplished by conversion of the

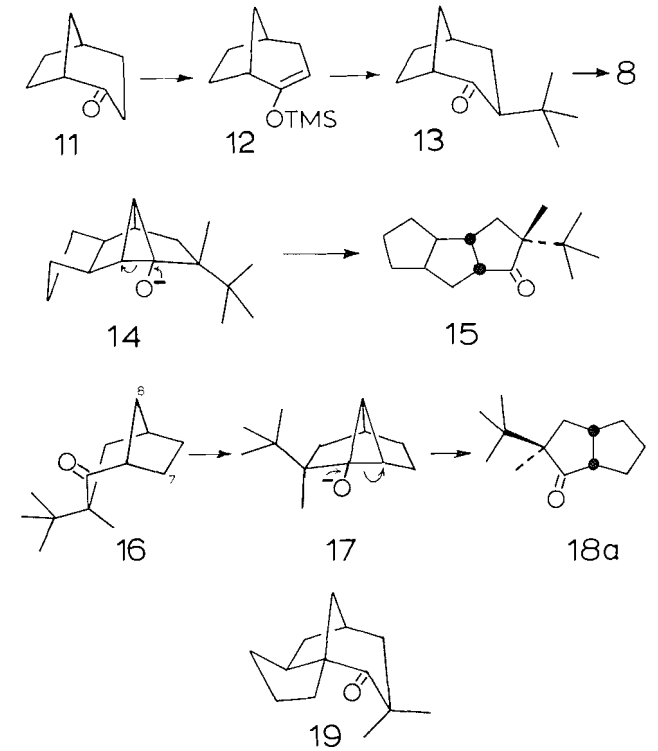
parent ketone **11** to the trimethylsilyl enol ether **12**, which was alkylated with *tert*-butyl chloride/titanium tetrachloride as described by Reetz and Maier (7) to furnish a single 3-*tert*-butyl derivative **13**. The *exo* orientation of the *tert*-butyl group was confirmed by treating **13** with MeO^-/MeOD at room temperature overnight and recovering **13**-d_1 (>95% yield, 0.97 atoms ^2H/molecule) containing no detectable isomer. Similar treatment of *exo*-3-methyl-**11** gave no evidence of epimerization (8). Methylation of **13** with LDA/MeI gave **8** in 43% overall yield from **11**. The analogous sequence with tricyclo[5.3.1.$0^{2,6}$]-undecan-8-one furnished **9** in 35% yield. The structures of **8** and **9** follow from the method of synthesis with subsequent support from their observed reactivities (see below). Alkylation of 3-methyl-**12** with *tert*-butyl chloride/$TiCl_4$ proceeded in very low yields (<10%), but a valuable comparison sample of the *exo-tert*-butyl-*endo*-methyl isomer of **8** was obtained.



Dimethylation of *endo*-tricyclo[5.3.1.$0^{2,6}$]undecanone-8-one (9) with $NaNH_2$/MeI in anhydrous Et_2O furnished **10** for our experiments.

Homoenolization experiments

The behavior of **10** upon treatment with *t*-BuO^-/*t*-BuOH at 185°C was examined initially following our usual procedures (5). The neutral organic product after 60 and 160 h was recovered in essentially quantitative yield and found to be entirely unchanged starting material by gas–liquid chromatography (glc) and ^{13}Cmr analyses. To ensure that the observed stability of **10** was not because of the inadvertent introduction of traces of water that would significantly decrease the base strength (10), 1:1 mixtures of **3** and **10** were treated with the same stock solution of base at 185°C for >500 h, and glc analysis indicated the neutral product to contain **3** (20%), **4** (30%), and **10** (50%). Since the ratio of **3** and **4** was that expected under these conditions (3*c*), **10** is indeed stable. Samples of **10** were also treated at 200°C and, again, there was no evidence of isomerization after 95 and 200 h; **10** was recovered in >95% yields.

Analogous treatment of **9** at 185°C led to the recovery of starting material in >80% yield after 65 h. However, after 130 h there was evidence of a second component in the neutral product in very low yield (~1%). In an attempt to increase the yield of this new component, we ran a series of experiments at 200°C and, after 240 h, the neutral product, >75% recovery, was found to be a 9:1 mixture of **9** and the new compound. Doubling the reaction time at 200°C did not significantly increase the proportion of the second component, which is isomeric with **9**, having the molecular formula $C_{16}H_{26}O$ by precise mass measurement. It is ketonic, containing a cyclopentanone moiety on the basis of its carbonyl absorption data (1730 cm^{-1}, δ_C 224.1), and could be tentatively assigned structure **15** from its ^{13}C spectrum and comparison thereof with that of **4** and related derivatives (11); the ^{13}C data for **4** and **15** are listed in Table 1. Proton abstraction from C-11 in **9** can lead to β-enolate **14**, or its equivalent, which subsequently opens with protonation at the original C-7 site. This rearrangement is constrained to give the *cis,anti,cis*-tricyclo[6.3.0.$0^{2,6}$]undecane skeleton. To establish that the very slow isomerization of **9** was not due to traces of water in the base solution, a 1:1 mixture of **3** and **9** was treated with the same base solution at 185°C for >500 h. Gas–liquid chromatographic (glc) analysis of the neutral product, >95% yield, showed its composition to be **3** (21%), **4** (29%), **9** (47%), and **15** (3%).

Treatment of **8** in the same manner at 185°C gave a neutral product in >85% yield that, by glc analysis on FFAP, exhibited a single band, but with a Carbowax column glc gave an indication of two very poorly resolved components. The ^{13}C spectra, however, clearly revealed the presence of two components in ratios of 85:15 (favoring **8**) and 50:50 after 40 and 240 h, respectively. The ^{13}C signals for the second component agreed precisely with those exhibited by **16**, the isomer of **8** in

which the orientations of the *tert*-butyl and methyl groups are reversed, and the preparation of which proceeded poorly as noted above. Since we had initially planned to include examination of **16** in this study, its preparation from *exo*-3-methyl-**11** had been attempted, but the very low yields obtained precluded its study separately. However, the generation of **16** from **8** was expected and showed that β-enolization occurs at C-7 in **8** as was found for **1**, for which this is a racemization process. At 185°C there was no evidence of β-enolate rearrangement involving C-8 in **8** (or **16**).

In an effort to equilibrate **8** and **16**, a series of experiments with **8** was carried out at 200°C. After 96 h, a 30:70 mixture of **8** and **16** was formed according to the ^{13}C spectrum but glc did not reveal the presence of significant amounts of other components. However, after 312 h at 200°C, **8** gave a neutral product, ~90% recovery, that gave rise to two well-resolved bands upon glc analysis. These two bands were in a 3:1 ratio and were readily separated by preparative glc. The major band was a 1:4 mixture of **8** and **16** according to its ^{13}C spectrum. The minor band also contained two components in a 3:1 ratio as judged by its ^{13}C spectrum, which also indicated that the two compounds were isomeric. The 1:4 mixture of **8** and **16** was dissolved in fresh base and heated at 200°C for 168 h. The neutral product from this experiment (90% recovery) was found to contain two bands in a 4:1 ratio by glc analysis. The major band was a 1:4 mixture of **8** and **16**, i.e., the equilibrium mixture favoring the *exo*-*tert*-butyl isomer **16**, confirming our structural assignments. The minor band consisted of a 2:1 mixture of the two new components as estimated from the ^{13}C spectra for each of the bands after collection by preparative glc. All attempts to separate the minor components were unsuccessful.

The two-component mixture of minor products from the 200°C experiments exhibited strong carbonyl absorption at 1735 cm^{-1} in the infrared spectrum and at δ_C 225.3 in the ^{13}Cmr spectrum; these values strongly indicate the presence of a cyclopentanone moiety, which would be generated by β-enolization at C-8 in **8** and **16** with protonation at the original C-1 site as shown for **16** → **17** → **18***a*. Precise mass measurements gave the molecular formula $C_{13}H_{22}O$, confirming that these products are isomeric with the starting material. Although only one carbonyl signal was resolved in the ^{13}C spectrum, there were two sets of 10 signals in the high-field region; each set included two quaternary, two methine, four methylene, and two methyl (in a 3:1 ratio) absorptions. By comparison with the ^{13}C shieldings for **2**, these signals can be tentatively assigned to **18***a*, as the major component, and its *exo*-3-methyl-*endo*-3-*tert*-butyl isomer **18***b* as the minor product; these ^{13}C data are collected in Table 1.

These results show clearly that ketones **8–10** are much less reactive than **1** and **3** with respect to β-enolate rearrangement through proton abstraction from the methano bridge carbon. Only in the case of **9** were we able to obtain evidence of the presence of isomerized material at 185°C, and that only in very low yield. This difference in reactivity is exactly analogous to that for **5** and **6** and, therefore, rules out the possibility of a major deactivating effect of the three-membered ring in **5**. However, **5**, **8**, **9**, and **10** share a common feature, which constitutes a major difference from **1**, **3**, and **6** in that the

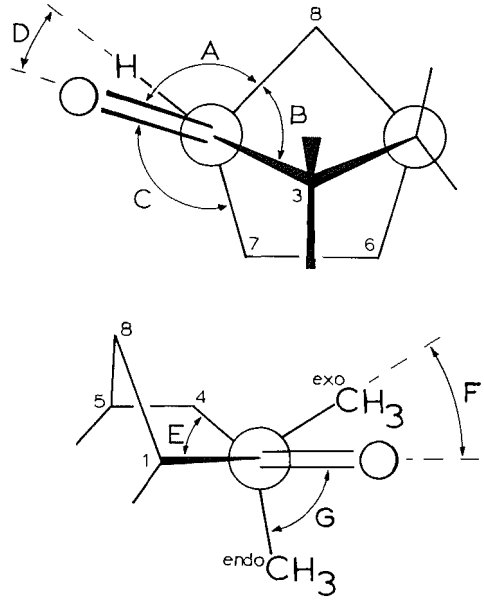

FIG. 1. Dihedral angles A–F (Table 2) defining the orientation of the carbonyl group in **1**.

six-membered ring in each of the former cannot adopt a chair conformation because of nonbonded interactions involving *endo* groups at the α-carbon and the two-carbon bridge in the "3.2.1" system of each. An inspection of molecular models indicates that the dihedral angle between the methano bridge carbon (C-8 in **1** and **8**) and the carbonyl oxygen increases from ca. 120° to ca. 170° upon conformational change of the six-membered ring from a chair to a boat. This change tips the π-system of the carbonyl group away from the site of potential proton abstraction for β-enolization, thereby significantly reducing potential overlap with a developing carbanionic site. This was the explanation offered previously to account for the marked difference in reactivity between **5** and **6** (5).

To obtain better assessments of the geometry of the cyclohexanone moiety in these systems, we carried out molecular mechanics (MM2) calculations (12) for each of the ketones examined. The dihedral angles defining the orientation of the carbonyl group in these systems are shown as A–F in Fig. 1 for **1** and the calculated values are listed in Table 2. These data show that even the introduction of the *exo*-3-*tert*-butyl group in this system, as in **16**, causes some flattening of the six-membered ring relative to its shape in **1** and **3** while the *endo*-α-*tert*-butyl group in **8** and **9** leads to boat-like conformations for the cyclohexanone moiety, which are similar to that found for **10** owing to the *endo* disposition of its trimethylene bridge. It can be seen that angle A relating the carbonyl group and β-enolization site for rearrangement to the "3.3.0" systems is increased by ca. 20° in **8–10** relative to **1** and **3**, the two compounds that undergo this process relatively readily. In **16** this angle is increased by ca. 5° and no rearrangement occurs at 185°C. Perhaps the *exo*-3-*tert*-butyl group sterically hinders the approach of base to the *syn*-8 hydrogen. The *exo*-methyl groups in **8–10** may offer analogous steric hindrance. Although deuterium incorporation was not observed at C-8 in **1** under homoenolization conditions (4), slow exchange occurs at the methano bridge in **3**, **6**, and **9** involving the *syn* proton exclusively (6). For comparison with the latter systems, $^1H/^2H$ exchange was examined in **9** and **10**.

$^1H/^2H$ exchange experiments

Samples of **9** and **10** were heated with *t*-BuO^-/*t*-BuOD at 185°C for 3, 6, 12, 24, 48 and 96 h and the ketones recovered from the neutral fractions by pentane extraction in high yield (80–90%). The ^{13}C spectra of these samples, purified by preparative glc, readily revealed that substantial exchange occurred at the α-bridgehead and *exo*-methyl sites through the appearance of characteristic triplets centred upfield from the normal signals, arising through one-bond $^{13}C-^2H$ coupling and the ^2H-induced isotope shift; absorptions for the neighboring carbons also exhibited the expected isotope shifts (13). In the spectra of the **9**-d_x samples, the α-methyl absorption consisted of a significantly attenuated singlet at δ 27.9 and a triplet, J_{CD} = 19.5 Hz, shielded by 288 ppb (1 ppb = 0.001 ppm), through the one-bond ($^1\Delta$) isotope shift. After 48 and 96 h a quintet, $^1\Delta$ 576 ppb, was also apparent, signifying the presence of species having a dideuteriated methyl group. The bridgehead methine pattern included a weak singlet, δ 57.5, and a triplet, $^1\Delta$ 405 ppb, J_{CD} = 21.6 Hz, indicative of considerable exchange at this site. Two-bond isotope shifts ($^2\Delta$) were also apparent for the C-11 methylene, C-6 methine, and C-9 quaternary absorptions at δ 26.5 (105 ppb), 45.0 (108 ppb), and 50.1 (65 ppb), respectively. The latter pattern also contained prominent components shifted by the presence of deuterium at the α-bridgehead, $^3\Delta$ 26 ppb. Other three-bond isotope shifts were observed in the C-5 and -10 methylene absorptions at δ_C 33.9 (52 ppb) and 39.2 (34 ppb) as well as for the quaternary carbon of the *tert*-butyl group, δ_C 37.2 (16 ppb). Confirmation of the presence of deuterium at only two sites was obtained from the ^2H spectra of these samples, which contained signals at δ 1.16 and 2.35, corresponding to the α-methyl singlet and a broadened doublet in the ^1H spectrum, respectively. The doublet, $J \sim 4.0$ Hz, is undoubtedly due to H-7 exhibiting resolved coupling only with the *anti*-11 proton since its dihedral angular relationship to both the *syn*-11 and -6 protons is ca. 90°. With resolution enhancement, the methyl absorption for the 48- and 96-h samples clearly consisted of three components arising from CH_2D, CHD_2, and CD_3 species (14), establishing that extensive exchange occurred at the α-methyl site. The ^2H-induced isotope effect on the deuteriomethyl shielding is 18 ppb. The total deuterium content in each of these samples was determined by mass spectrometry and the incorporation level at each of the two sites was assessed by integration of the ^2Hmr spectra (Table 3). From the latter data, approximate first-order rate constants were obtained, as is the usual practice (2); these values are given in Fig. 2.

The ^{13}C spectra of the **10**-d_x samples contained prominent triplets with the attenuated signals for the α-bridgehead (δ_C

[a]Total atoms ^2H by mass spectrometry; ^2H assay at individual sites by ^2Hmr, ±0.01.

53.0, $^1\Delta$ 365 ppb, J_{CD} = 21.4 Hz) and one of the methyl carbons (δ_C 34.3, $^1\Delta$ 300 ppb, J_{CD} = 19.5 Hz); the latter absorption can be assigned to the *exo*-methyl group by analogy with the results for several related ketones that exhibit preferential *exo*-methyl exchange (2). Two-bond isotope shifts due to deuterium at C-7 were evident for C-6 (δ_C 47.7, $^2\Delta$ 90 ppb) and C-11 (δ_C 35.6, $^2\Delta$ 100 ppb). The quaternary C-9 pattern (δ_C 40.6) contained components arising from ^2H-7 ($^3\Delta$ 25 ppb) as well as from mono- and dideuteriated methyl groups, $^2\Delta$ 70 ppb/D; these also gave rise to isotope-shifted components in the C-10 absorption, δ_C 35.4 with $^3\Delta$ 30 ppb/D. In addition, however, the methylene and methine signals at δ_C 27.3 and 46.8, respectively, were accompanied by weak isotope shifted components with $^2\Delta$ values of 110 and 100 ppb, respectively. The latter must arise from deuterium exchange at C-6. To confirm this interpretation and to assay the incorporation levels at the various sites undergoing exchange, the ^2Hmr spectra of the **10**-d_x samples were recorded. These spectra exhibited signals at δ 1.18 and 2.65, corresponding to a methyl singlet and a broadened 3-proton multiplet, respectively, in the ^1H spectrum. Upon addition of the shift-reagent Eu(fod)$_3$, a broadened doublet of doublets, J = 3 and 7 Hz, was shifted rapidly out of the 2.65-ppm pattern in the proton spectrum. The remaining two-proton pattern of overlapping multiplets exhibited sensitivity to added Eu(fod)$_3$ comparable to that of a one-proton absorption initially at δ 2.33, attributable to H-1. The overlapping multiplets could be assigned to H-6 and, perhaps, to *endo* H-5. The only other absorption with δ > 2.0 is a doublet, δ 2.20, J = 12 Hz, undoubtedly arising from *syn* H-11. The ^2Hmr spectra of the **10**-d_x samples recorded in the presence of Eu(fod)$_3$ contained three signals since the absorption initially at δ 2.65 was dispersed into a strong and a weak peak, which exhibited sensitivities identical to those found for the components of the original δ 2.65 absorption. Thus, the weak signal was assigned to ^2H-6. As in the case of **9**-d_x, the methyl absorption was found to contain components arising from CH_2D, CHD_2, and CD_3 species upon resolution enhancement, and the two-bond ^2H-induced isotope shift is 20 ppb. These isotope shifts for the methyl deuterons in **9**-d_x and **10**-d_x are the same as the 19-ppb shifts recently reported for fenchone (14), within our experimental error of 3 ppb. From the total deuterium content determined by mass spectrometry and the relative amounts at the three sites found from the ^2Hmr spectra (Table 3), the approximate rates of deuterium incorporation in **10** were extracted and are given in Fig. 2. The corresponding data for the closely related systems **1**, **3**, **5**, **6**, and **19** are included in Fig. 2. It must be noted that a reexamination of the rates of deuterium exchange in **1** has shown that the temperature

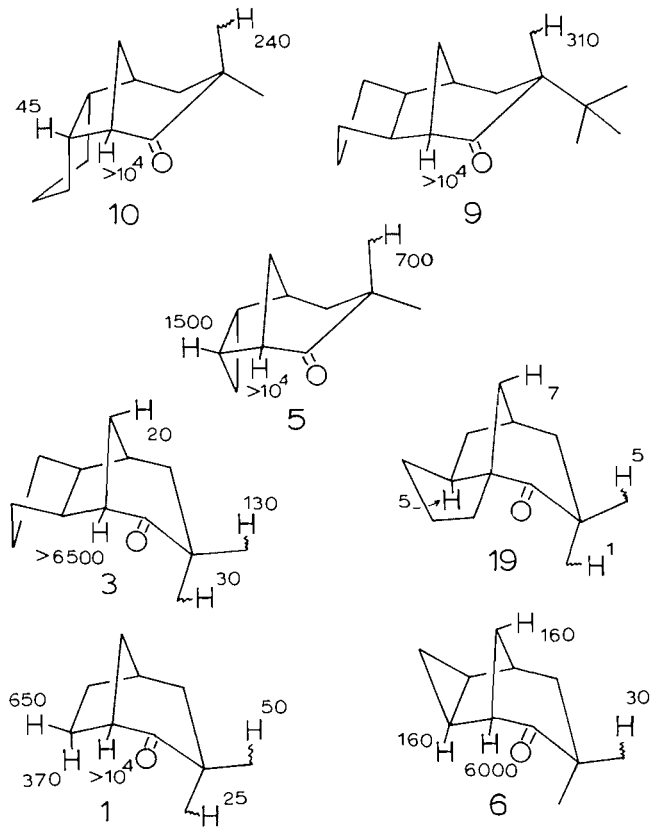

FIG. 2. Deuterium exchange rates ($k \times 10^8$ s^{-1}) at the various sites in **1**, **3**, **5**, **6**, **9**, **10**, and **19** by β-enolization at 185°C in *t*-BuOD.

control for the oven used in the original study (4) was faulty and the rate data have been redetermined using the constant temperature apparatus employed for all of our studies in recent years.

It is apparent from the data in Fig. 2 that the rate of exchange at the *exo*-methyl carbon is distinctly faster in those systems having a non-chair conformation of the cyclohexanone unit (**5**, **9**, and **10**) and no exchange was detectable at the methano carbon in the one-carbon bridge. It may be noted that for those systems that undergo exchange at the methano carbon (**3**, **6**, and **19**) the rate of exchange is significantly slower than the observed rearrangement rate and in each case *syn* exchange is strongly favored. This seems to suggest that exchange and rearrangement involving this site may proceed through different intermediates. The enhanced rate of *exo*-methyl exchange found for the ketones having a non-chair conformation for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12

For personal use only.

cyclohexanone unit may result from the increased dihedral angle relating the methyl and carbonyl groups (ca. 70° vs. ca. 35° for those in which the cyclohexanone unit is a chair). This change could improve overlap of the developing carbanionic centre at the methyl carbon with the π-system of the carbonyl group. In our earlier study of the [3.3.1.$0^{2,4}$] systems (5), it was suggested that the relatively rapid rate of exchange at C-4 is presumably due in part to the increased acidity of this proton because of its bonding to the three-membered ring; the carbonyl group is partly responsible since exchange does not occur at the other cyclopropyl methine position. Exchange at the corresponding β-site in **10**, C-6, was found to be ca. 30-fold slower.

Conclusions

The results of these β-enolization studies of **8**–**10** clearly show that systems in which the cyclohexanone moiety cannot adopt a chair conformation are much less reactive toward "[3.2.1] → [3.3.0]" rearrangement. The decreased reactivity seems strikingly dependent on the relative orientation of the methano bridge carbon and the carbonyl group, but the *exo*-α-alkyl group may also hinder proton abstraction from the bridge carbon. This conformational change, however, enhances the rate of exchange at the *exo*-methyl site but does not lead to ring expansion.

Experimental

Melting points and boiling points are uncorrected. Gas–liquid chromatography (glc) was carried out on Varian 920 and 3700 instruments using columns of 10% Carbowax, 6% FFAP, or 10% SE-30 on Chromosorb W as indicated. Thin-layer chromatography (tlc) was done on Kieselgel 60 F_{254} plates and flash chromatography columns were prepared as described in the literature (15). Tetrahydrofuran and diethyl ether were dried over Na/benzophenone and freshly distilled before use. Diisopropylamine, triethylamine, *tert*-butyl alcohol, and pyridine were distilled from CaH_2 and stored over 4 Å sieves; methyl iodide was dried over 4 Å sieves. Pentane was freshly distilled before use.

Infrared spectra were recorded with a Beckman 4250 instrument and mass spectra were obtained on a Varian MAT-311A system at 70 eV (direct inlet). Routine ^{1}H spectra were recorded with a Varian EM-360 instrument while data for pure samples were collected with Varian XL-200 or -300 systems. The ^{2}H and ^{13}Cmr spectra were obtained at 46.1 and 75.4 MHz, respectively, on the XL-300 system and comparison of the fully decoupled ^{13}C spectra with those obtained with either the APT (16) or DEPT (17) sequences identified the number of hydrogens bonded to each carbon.

endo-*3*-tert-*Butyl*-exo-*3-methylbicyclo[3.2.1]octan-2-one (8)*

Trimethylsilyl enol ether **12** was generated from **11** (0.70 g) according to the literature procedure (9) using LDA (diisopropylamine (1.26 mL), *n*-BuLi (2.5 M in hexane, 3.16 mL), THF (6 mL) at −78°C) with trimethylsilyl chloride (1.29 mL), and Et_3N (0.5 mL) in THF (1 mL) as the quenching solution. The product was recovered in our usual way (9) and purified by Kugelrohr distillation, bp 90–96°C/10 Torr (1 Torr = 133.3 Pa), to give an oil (1.05 g, 94% yield) identical to that reported previously (9).

To a flame-dried, nitrogen-purged flask equipped with a magnetic stirrer and serum cap was added **12** (0.83 g), *tert*-butyl chloride (0.70 mL), and anhydrous methylene chloride (3 mL). After cooling the solution to −47°C, titanium tetrachloride (0.67 mL) was rapidly added by syringe and the reaction mixture was stirred for 5 h before dilution with water (8 mL). The product was extracted with CH_2Cl_2 (4 × 10 mL) and the combined extracts washed with water (2 × 10 mL) before drying over $MgSO_4$. After evaporation of the solvent, glc analysis (FFAP) indicated that the major component constituted approximately 75% of the product mixture. Flash chromatography (Et_2O – petroleum ether, 4:96) furnished **13** (0.53 g, 63%); a sample (>98% pure) was collected by glc for characterization; ir (CCl_4): 1714 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.65 (bt, $J \sim 5$ Hz, 1H), 2.45 (m, 1H), 2.18 (dd, J = 7.5, 12.2 Hz, 1H), 1.6–2.0 (complex absorption, 7H), 1.50 (ddt, J = 1.3, 3.0, 12.0 Hz, 1H), 0.97 (s, 9H); ^{13}Cmr: see Table 1. *Exact Mass* calcd. for $C_{12}H_{20}O$: 180.1514; found: 180.1518.

A sample of **13** (75 mg) was dissolved in a solution of MeONa/MeOD (2.6 mL, 0.01 M) and, under a N_2 atmosphere, stirred overnight. After the addition of D_2O (4 mL), the product was isolated by pentane extraction to yield **13**-d_1 (70 mg), the ^{13}C spectrum of which indicated essentially complete deuteration at C-3, ms: 3.4% d_0, 96.6% d_1 (total 0.966 ^{2}H/molecule).

To a solution of LDA (diisopropylamine (0.58 mL) and *n*-BuLi (2.50 M in hexane, 1.41 mL) in 5 mL of THF) was added **13** (0.53 g) in THF (2 mL) dropwise. After stirring at −78°C for 0.5 h, the mixture was warmed to room temperature and stirred for an additional 0.5 h before methyl iodide (0.56 mL) was added; stirring was continued overnight. Aqueous 10% NaCl solution (10 mL) was added before the product was isolated by pentane extraction. Evaporation of the solvent gave an oil (0.47 g), which by glc analysis (FFAP) contained **8** (87%) and **13** (4%). Preparative glc furnished pure material for the homoenolization experiments and for characterization; ir (film): 1698 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.66 (m, 1H), 2.47 (m, 1H), 2.03 (d, J = 12 Hz, 1H), 1.35–1.90 (complex absorption, 7H), 1.16 (s, Me), 0.94 (s, Me_3); ^{13}Cmr: see Table 1. *Exact Mass* calcd. for $C_{13}H_{22}O$: 194.1671; found: 194.1669.

exo-*3*-tert-*Butyl*-endo-*3-methylbicyclo[3.2.1]octan-2-one (16)*

To a stirred solution of LDA, prepared from diisopropylamine (0.73 mL), *n*-BuLi (2.46 M in hexane, 1.86 mL), and THF (1.5 mL) in the usual way, was added *exo*-3-methylbicyclo[3.2.1]octan-2-one (8) (0.45 g). After stirring at −78°C for 45 min, the reaction mixture was quenched with a solution of TMSCl (0.75 mL), THF (0.75 mL), Et_3N (0.27 mL), prepared according to the literature (9). The mixture was then cooled to 0°C and a cold saturated aqueous Na_2CO_3 solution was added by syringe with vigorous stirring. The product was isolated by pentane extraction and Kugelrohr distillation, bp 105–110°C/15 Torr, to yield 0.5 g of the trimethylsilyl enol ether, which glc analysis (FFAP) indicated to be >85% pure. Preparative glc furnished material for characterization; ir (CCl_4): 2980, 1681, 1184, 880 cm^{-1}; ^{13}Cmr ($CDCl_3$) δ_C: 1.1 ($SiMe_3$), 16.0 (CH_3), 30.9, 34.8, 36.6, 40.9 (4 × CH_2), 34.4, 41.7 (2 × CH), 106.2, 149.7 (2 × quat C). *Exact Mass* calcd. for $C_{12}H_{22}Si$: 210.1434; found: 210.1435.

A solution of the silyl enol ether (0.91 g) and *tert*-butyl chloride (0.66 mL) in dry methylene chloride (3.2 mL) was cooled to −47°C and titanium tetrachloride (0.66 mL) was added with stirring. The mixture was stirred at −47°C for 1 h and for 10 h at room temperature. After the mixture was cooled to 0°C, water (8 mL) was added and the product was extracted with CH_2Cl_2 as described for **13**. Evaporation of the solvent furnished an oil (0.70 g), which glc analysis (FFAP) showed to contain ~77% of 3-*exo*-methyl-**11** and ~10% of **16**. Preparative glc afforded a sample (>98% pure) of **16** for characterization; ir ($CHCl_3$): 1698 cm^{-1}; ^{13}Cmr: see Table 1. *Exact Mass* calcd. for $C_{13}H_{22}O$: 194.1671; found: 194.1671.

endo-*9*-tert-*Butyl*-exo-*9-methyl*-exo-*tricyclo[5.3.1.0^{2,6}]undecan-8-one (9)*

8-Trimethylsilyloxy-*exo*-tricyclo[5.3.1.$0^{2,6}$]undec-8-ene (0.73 g), prepared in the course of an earlier study (12), was alkylated with *tert*-butyl chloride/titanium tetrachloride as described above for **13**. Flash chromatography (Et_2O – petroleum ether, 4:96) of the product mixture furnished *exo*-9-*tert*-butyl-*exo*-tricyclo[5.3.1.$0^{2,6}$]undecan-8-one (0.35 g, 51%), which was ca. 95% pure by ^{13}Cmr. A pure sample was obtained by sublimation; mp 69–70°C; ir ($CHCl_3$): 2945, 1706 cm^{-1}: ^{1}Hmr ($CDCl_3$) δ: 0.97 (s, 9H, Me_3), 2.34 (m, 3H), 1.85–2.20 (m, 6H), 1.70 (m, 1H), 1.45 (m, 2H), 1.25 (m, 1H), 0.90–1.15 (m, 2H); ^{13}Cmr ($CDCl_3$) δ_C: 27.7 (Me_3), 27.8, 33.2, 33.9, 34.1, 34.5 (5 × CH_2), 40.4, 46.4, 48.1, 53.2, 58.7 (5 × CH), 31.7 (quat C), 213.8 (CO). *Exact Mass* calcd. for $C_{15}H_{24}O$: 220.1827; found: 220.1823.

A sample of this α-*tert*-butyl derivative (40 mg) was dissolved in MeONa/MeOD (0.01 M, 1.3 mL) and the solution stirred overnight at room temperature. After quenching with D_2O (2 mL), the product was extracted with pentane and the ketone was recovered (0.35 mg). The ^{13}C spectrum gave no indication of any epimeric material and the signal at δ_C 53.2 was replaced with a weak triplet, J_{CD} = 18.2 Hz at δ_C 52.9 indicating essentially complete exchange of the *endo*-9 proton.

Following the procedure described above for **13**, the α-*tert*-butyl ketone (0.24 g) was added to LDA (diisopropylamine (0.21 mL), THF (2 mL), *n*-BuLi (2.46 M in hexane, 0.53 mL) at −78°C) and, after allowing for formation of the enolate, methyl iodide (0.20 mL) was added. The usual isolation procedure yielded an oil that, by glc analysis (FFAP), was only 70% methylated. Consequently, the product was recycled using the same conditions and was found to be >95% pure **9** after flash chromatography (Et_2O – petroleum ether, 5:95); ir (film): 2960, 1698 cm^{-1}; ^{13}Cmr: see Table 1. *Exact Mass* calcd. for $C_{16}H_{26}O$: 234.1984; found: 234.1981.

9,9-Dimethyl-endo-*tricyclo[5.3.1.0^{2,6}]undecan-8-one (**10**)*

The parent ketone was available from an earlier study (12) and dimethylation of this undecanone (0.42 g) was accomplished using our standard procedure (5) with $NaNH_2$ (0.55 g) in anhydrous Et_2O (16 mL) and four additions of methyl iodide (0.32 mL) after reflux periods of 2, 2, 10, and 4 h. After refluxing for an additional 3 h, the reaction mixture was extracted with pentane to yield **10** (0.33 g, 67%) and a sample (>98% pure) was collected by glc (FFAP); ir (CCl_4): 2962, 1703 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.03 (s, Me), 1.15 (s, Me), 2.63 (m, 3H), 2.32 (m, 1H), 2.18 (d, *J* = 13 Hz, 1H), 1.27–1.79 (m, 8H), 1.10 (m, 1H); ^{13}Cmr: see Table 1. *Exact Mass* calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1519.

Homoenolization experiments

Our standard procedure for these reactions in strong base (4) was followed as illustrated for **10**. To a solution of *t*-BuO^-/*t*-BuOH (1.3 M, H_2O content ~60 μg/mL) prepared *in situ* was added **10** to give a solution that was 0.26 M in ketone. A series of 0.5-mL aliquots of this solution were transferred quickly to 5-mL predried, thick-walled glass tubes; the tubes were degassed and sealed before immersion in an oil bath at 185°C. Tubes were removed at various times, cooled before opening, and the contents recovered by washing with water (10 mL). The neutral organic product was isolated by pentane extraction (3 × 15 mL) and the combined extracts back-washed with water (3 × 10 mL). The aqueous washings were reextracted with pentane (2 × 15 mL) and the combined extracts dried over $MgSO_4$. Removal of the solvent by distillation afforded the neutral organic product, in >90% yields from the various tubes, which was analyzed by glc (FFAP, Carbowax, SE-30) and found to contain only starting material; ^{13}Cmr spectra of the products also contained only the signals of **10**. The same result was obtained from experiments at 200°C.

An analogous series of experiments with **9** gave a neutral product (~85% yields) containing a small amount (~1%) of a new component. To obtain somewhat larger amounts of this material, **9** was treated as described above with the temperature raised to 200°C. The new component is ketonic (1730 cm^{-1}) and isomeric with **9**. *Exact Mass* calcd. for $C_{16}H_{26}O$: 234.1984; found: 234.1988. This new ketone was identified as **15** by ^{13}Cmr as described in the text.

A series of experiments similar to those with **9** were carried out with **8** and the results are presented in the text.

To examine the exchange processes, the fate of samples of **9** and **10** using *tert*-butyl alcohol-*O*-d_1 (99% deuterated, D_2O content <200 μg/mL) under these reaction conditions was examined; the results are described in the text.

*Rearrangement products from **8** and **16** (**18**a,b)*

From the runs with **8** and the mixture of **8** and **16** at 200°C (see text), preparative glc (FFAP) furnished samples of the new band tentatively identified as a mixture of **18***a* and *b*; ir (film): 1735 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.67 (m, 2H), 1.2–1.8 (complex absorption, 8H), 1.08 (s, Me_3, minor), 0.99 (s, Me, minor), 0.95 (s, Me_3, major), 0.91 (s, Me, major); ^{13}Cmr: see Table 1. *Exact Mass* calcd. for $C_{13}H_{22}O$: 194.1671; found: 194.1671.

Thermodynamics of transfer of glycine, diglycine, and triglycine from water to aqueous solutions of urea, glycerol, and sodium nitrate

HIMANSU TALUKDAR, SIBAPRASAD RUDRA, AND KIRON K. KUNDU[1]
Physical Chemistry Laboratories, Jadavpur University, Calcutta 700 032, India

Received August 18, 1987

HIMANSU TALUKDAR, SIBAPRASAD RUDRA, and KIRON K. KUNDU. Can. J. Chem. **66**, 461 (1988).

Standard free energies (ΔG_t^0) and entropies (ΔS_t^0) of transfer of glycine (G), diglycine (DG), and triglycine (TG), from water to aqueous mixtures of glycerol (GL) and urea (UH) have been determined from solubility measurements at different temperatures. This was also extended to an ionic cosolvent system like aqueous sodium nitrate solutions for G and DG. The observed ΔG_t^0 and $T\Delta S_t^0$–composition profiles, as well as those obtained after correcting for the "cavity effect" as estimated by scaled particle theory (SPT), were examined in the light of various interactions. The corrected ΔG_t^0 and $T\Delta S_t^0$ values show a regular function of the peptide chain length of the amino acids and impart useful information regarding the involved relative structural effects of these ionic and non-ionic cosolvents.

HIMANSU TALUKDAR, SIBAPRASAD RUDRA et KIRON K. KUNDU. Can. J. Chem. **66**, 461 (1988).

En se basant sur des mesures de solubilité effectuées à diverses températures, on a déterminé les énergies libres standards (ΔG_t^0) et les entropies (ΔS_t^0) de transfert de la glycine (G), de la diglycine (DG) et de la triglycine (TG) de l'eau vers des mélanges aqueux de glycérol (GL) et d'urée (UH). Dans le cas de la G ainsi que de la DG, on a aussi étendu cette étude à un système de co-solvants ioniques comme des solutions aqueuses de nitrate de sodium. Les profils observés pour le ΔG_t^0 et le $T\Delta S_t^0$ en fonction de la composition ainsi que ceux obtenus après avoir fait une correction pour l'effet de cavité évalué par la théorie de la particule scalaire (TPS) ont été examinés à la lumière de diverses interactions. Les valeurs corrigées de ΔG_t^0 et de $T\Delta S_t^0$ présentent une fonction régulière de la longueur de la chaîne des acides aminés et fournissent des informations utiles concernant les effets de structure relatifs de ces cosolvants qu'ils soient ioniques ou pas.

Introduction

It is well known that urea (UH) causes unfolding of native conformation of proteins, whereas glycerol (GL) and other polyols cause stabilization of the same. Although several mechanisms of these effects have been proposed from different view points (1–10), a successful explanation seems to be that the opposing effects of urea and polyols on proteins may be predominantly mediated through the changes in solvation properties or alteration of water structure. From the free energy of transfer (ΔG_t^0) studies obtained from solubilities of amino acids and peptides at 25°C in aqueous urea (2*a*), ethylene glycol (EG) (2*b*), and ethanol (EtOH) (2*c*), Nozaki and Tanford concluded that while both non-polar and polar side chains are preferentially solvated in UH + H_2O mixtures, the effect was much reduced in EtOH + H_2O mixtures and less so in EG + H_2O mixtures. Similar experiments by Gekko (10) led him to conclude that polyol can stabilize the protein conformation through hydrophobic interactions. Though their free energy of transfer (ΔG_t^0) data of these solvents are seemingly useful in imparting informations regarding denaturation processes, a more detailed understanding may be possible by evaluating entropies (ΔS_t^0) or enthalpies (ΔH_t^0) of transfer data, since these quantities in general reflect more sensitively the structural (11–13) and interactional parts of the solvent effects. But till recent years relatively little work has been reported regarding these quantities (9, 14–17). Although Gekko has recently reported ΔS_t^0 and ΔH_t^0 of some amino acids including glycine and also of a peptide like diglycine in some low concentrations of polyols including GL (17), such studies on ΔS_t^0 and ΔH_t^0 are still lacking for a series of UH + H_2O mixtures. And since the solubilities of these zwitterions at different temperatures are still unknown in these aquo-organic cosolvents, studies of the same will provide important quantities for evaluation of various thermo-chemical properties at other temperatures as well.

In the present paper we, therefore, report the solubilities of glycine (G), diglycine (DG), and triglycine (TG) in water and in a series of aqueous mixtures of glycerol and urea at five different temperatures and the related transfer energetics, i.e., ΔG_t^0, $T\Delta S_t^0$, and ΔH_t^0 from water to those mixtures. The results have been discussed in terms of the competing effects of solute polarity and the relative solvent structural changes consequent to the introduction of the solutes into those aqueous organic mixtures.

Moreover, since Larson *et al.* (18) and Lilley and co-workers (19) have shown that electrolyte solutions form vital biochemical interests for these studies, the above studies on glycine and diglycine were also extended to 1, 2, and 4 molal sodium nitrate ($NaNO_3$) solutions as these are likely to provide a precursor to suitable model systems of highly complex systems like biofluid. This is to give an idea about the relative stabilization of those amino acids in a typical electrolyte solution with respect to aquo-organic cosolvents as "electrolyte–zwitterion" interactions might play an important role on the conformational structure and stability of proteins.

Experimental

Materials

Glycine (GR grade, E Merck (India)) was recrystallised twice from low conductivity water and was dried at room temperature under vacuum in a desiccator. DG and TG were special reagent grade products from Sigma Chemical Co. and they were used after drying without further purification since their purity was found to be excellent from the solubility data in water and also from the titration of a known solution of each solute in water. Purification of glycerol (B.D.H., AnalR grade) has been described earlier (11). Urea (B.D.H., AnalR grade) was used without further purification. Preparation of solvent mixtures and $NaNO_3$ solution was similar to that described earlier (13, 20). Water employed in these measurements was triply distilled and stored in a CO_2-free atmosphere.

Solubility measurements

Samples in the solvent mixtures were taken in glass tubes fitted with

[b]Reference 6. [d]Reference 43.

ground glass stoppers and were shaken for about 24 h. After 2 days, weight amounts of aliquot from the saturated solutions were taken in stoppered conical flasks and the solubility measurements of the amino acid and peptides were made by "formal titration" using the standard NaOH (GR, E Merck) solution and phenolphthalein as indicator. Freshly neutralised formaldehyde solution (GR, E Merck) was used in the method. Equilibrium was found to attain within 3–4 days. At least two sets of measurements were made for all the solutes and the results were found to agree to within 1%.

The measurements were made at five equidistant temperatures ranging from 15 to 35°C. For TG in UH + H_2O mixtures the procedure was repeated from 10 to 30°C.

The purity of our solutes and the general validity of our methods of solubility measurements may be justified by comparing our solubility data with other reported results as shown in Table 1. The difference lying within ±0.6 unit for DG and TG with Nozaki and Tanford's data may be due to the different techniques involved.

Results

The solubilities (S) in g/100 g solvent are summarised in Table 1. As usual (12) the calculated free energies of solution (ΔG_s^0) at different temperatues were fitted by least-squares method to an equation like

$$[1] \quad \Delta G_s^0 = a + bT + cT \ln T$$

where T is the temperature in K. The values of the coefficients a, b, and c are presented in Table 2. These are found to reproduce the experimental data to within ±0.02 kJ. The free energies (ΔG_t^0), entropies (ΔS_t^0), and enthalpies (ΔH_t^0) of transfer of G, DG, and TG from the reference solvent water to the aqueous mixtures were calculated on the mole fraction scale by the equations already described in a previous paper (12). These values were included in Table 2. As in the previous paper (21), the activity coefficients of non-electrolytes ${}_wf_i$ and ${}_sf_i$ (w = water, s = solvent) in the corresponding states of saturated solution in the respective solvents are likely to be more or less equal and hence the activity coefficient factor $RT \ln {}_wf_i/{}_sf_i$ is assumed to be zero. The maximum uncertainties in these quantities are ±0.05 kJ for ΔG_t^0 and ±2.0 J K^{-1} mol^{-1} for ΔS_t^0. Nevertheless, as has been done by Nozaki and Tanford (2*a*,*b*) we have calculated ΔG_t^0 at 25°C by the eq. [2]

$$[2] \quad \Delta G_t^0 = RT \ln \frac{{}_wN_i}{{}_sN_i} + RT \ln \frac{{}_wf_i}{{}_sf_i}$$

in UH + H_2O and GL + H_2O mixtures where the N terms are the mole fractions. Due to the non-availability of activity coefficients of acids in the solvent mixtures, these were assumed to be the same as those in water at the same molality of solute. Since the solute–solute interactions are chiefly electrostatic, we have multiplied $\ln {}_sf_i$ by the ratio of the dielectric constant D_w/D_s (2*b*) where D_w and D_s are the dielectric constants of water and the mixed solvents, respectively (20, 22). The same calculations could not be done for temperatures other than 25°C, since the activity coefficients are not known at other temperatures. This activity corrected ΔG_t^0 values have been shown in Table 3 and when compared with the results obtained by the previous method (Table 2) a maximum differences of 0.2 kJ for UH + H_2O and 0.3 kJ for GL + H_2O mixtures are found, which we feel are fairly tolerable, at least considering the different methods used. The ΔG_t^0 values were then used to calculate the contribution of peptide backbone unit, i.e., the glycyl residue (—CH_2CONH) from water to the solvent mixtures designated by Δg_t^0 by subtracting the corresponding values of G from DG or of DG from TG, assuming additivity of

TABLE 2. Coefficients a, b, and c of eq. [1] and free energies (ΔG_t^0), entropies ($T\Delta S_t^0$), and enthalpies (ΔH_t^0) of transfer (in kJ mol^{-1}) of glycine, diglycine, and triglycine from water to aqueous mixtures of UH, GL, and $NaNO_3$ at 25°C (mole fraction scale)

Discussion

Free energies of transfer

Figure 1 shows the variation of ΔG_t^0 (activity corrected) of G, DG, and TG with mol% of the cosolvent GL and UH. While the profiles for GL + H_2O mixtures become increasingly positive with the relative order of DG > G > TG those for aqueous UH solutions become increasingly positive for G, less so for DG, and negative for TG with the relative order G > DG > TG. Similar profiles obtained from the data of Gekko (10) in GL + H_2O mixtures and those of Nozaki and Tanford (2*a*) in UH + H_2O mixtures have been found with little differences, as shown in the Fig. 1 (dotted lines) except for TG in high UH-content where the two profiles differ to some extent. Thus the observed increased destabilization of these zwitterionic species ($RH^{\pm}$) in GL + H_2O systems confirms the dictates of mono-ol (EtOH), di-ol (EG), and other polyol systems as shown by Gekko and others (2*b*, 2*c*, 10). Moreover, since the solvation numbers of the amino acids in water are expected to be quite high due to zwitterionic nature of these acids having two solvation sites, the observed destabilization of $RH^{\pm}$ is not only the effect of decreased solvation number of amino acids in the binary mixtures with increase in GL-content in water, but also due to immobilisation of the solvent molecules by solutes due to dipole–dipole, dipole – induced dipole, or dispersion forces etc.

But while the ΔG_t^0 values increase in the order G < DG < TG in the case of aqueous ethanol (2*c*) and ethylene glycol mixtures (2*b*) the order is changed to TG < G < DG in GL + H_2O systems. Two factors may be responsible for this. Firstly, ΔG_t^0 values of G, DG, and TG are becoming less (keeping positive values) in EG than the corresponding values in EtOH and so in GL than that in EG indicating that the probable peptide–peptide hydrogen bonds are stabilized less effectively as the hydroxy methyl chain increases in length (i.e. hydro-

phobic nature). The other factor may be the involvement of some specific interaction involving hydrophobic interactions and cavity effect that might contribute significantly enough to the total ΔG_t^0 values which have also been accounted for as follows.

It is now well recognised (12, 13, 23–26) that for large-sized species, the true interaction effect, i.e., ΔG_t^0(int) which is ΔG_t^0 but free from any cavity effect, ΔG_t^0(cav) (27), is a better indicator of the true picture of interactions between the solute and solvent molecules. We have therefore calculated ΔG_t^0(cav) by the widely used procedure (12, 13, 24) using the "scaled particle theory (SPT)" (27), taking the diameter of G, DG, and TG as 5.64 (28), 8.0 (29), and 11.5 (29), respectively and those of the cosolvent molecules as given in refs. 12 and 13. Notably, since the radius of equivalent hard sphere of DG and TG will be quite uncertain and also since DG and TG may be best considered according to Cohn *et al.* (29) to be cylindrical of length 8.0 and 11.5 Å, respectively, we have tentatively assumed the excluded volume of diameter of the same magnitudes for the respective species to be equivalent to their hard-sphere model.

Moreover, though the SPT is not applicable for species other than hard spheres and for species having strong and directional interactions with solute molecules (25, 30), the calculations done above might seem to be over exaggerated in the case of DG and TG. Since the diameter of the solute is not that sensitive a parameter as the diameters of cosolvent molecules (25, 27) are, the SPT is now increasingly used in computing thermodynamic quantities of cavity formation of different solutes not only in different organic solvents but also in aqueous mixtures of various ionic and nonionic cosolvents (13, 23–27, 30, 31) assuming tentatively an equivalent hard sphere for each of the solute species. Moreover, while Morel-Desroisers and Morel (30) have used these ΔG_t^0(cav) values as the guiding factor for solvation properties, we have, however, used the same, as some authors did (13, 23–27, 30, 31), for correcting the cavity contribution from the observed transfer free energy ΔG_t^0 to evaluate ΔG_t^0(int) values which are as shown earlier, likely to reflect the true interaction effects.

Thus, the required solvent and solute parameters along with the molar free energies of cavity formation $\bar{G}$(cav), ΔG_t^0(cav), and ΔG_t^0(int) are given in Table 5. From this table and Fig. 2 which shows the ΔG_t^0(int)–composition profiles in GL + H_2O (solid lines) it can be seen that the cavity interaction term contributes negatively in GL + H_2O mixtures. Thus the trends of the profiles in Fig. 1 for the solvation of G, DG, and TG have now become normalised indicating that TG will be more desolvated than DG and G in these systems, as has been observed in EG + H_2O and EtOH + H_2O systems.

Similarly, in the case of UH + H_2O mixtures, the ΔG_t^0(int)–composition profiles (dotted lines) in Fig. 2 for G, DG, and TG become increasingly negative since the cavity effect, i.e., ΔG_t^0(cav) for G, DG, and TG, unlike in GL + H_2O systems, contributes positively in UH + H_2O mixtures as has been seen from Table 5. Thus the observed near invariance of the ΔG_t^0–composition profile of glycine in Fig. 1 is the result of positive contributions of the cavity effect and the negative contributions of the true interaction effect, for glycine is

[a] $\alpha = -\mathrm{d} \ln d_s/\mathrm{d}T$; d_s = density of cosolvent.

expected to be solvated in these mixtures by dipole–dipole or "zwitterion–zwitterion" type attractive interaction overcoming its hydrophobic effect, as after all both the solvent and solute species possess high dipole moment (μ_{UH} = 4.56 D (32) and μ_G = 15.0 D (33)). In addition, the pronounced solvation of DG and TG is chiefly guided by the pronounced dipole–dipole and amide–amide interactions as also contended by Nozaki and Tanford (2*a*).

Unlike UH + H_2O mixtures, the true interaction profiles of glycine and diglycine in $NaNO_3$ solution (dotted lines, Fig. 3) are fairly different from the observed ΔG_t^0–composition profiles (solid lines, Fig. 3) and in fact contradict the conclusions drawn from the latter. While our observed data including those of Lilley and co-workers (19) and Bhat and Ahluwalia (34) (in NaCl solution) for glycine and diglycine indicate that the zwitterion should be solvated in salt solution through ion–ion interactions localised at the polar heads of the zwitterions, the same is not true when we consider the true interaction effect which shows pronounced salting-out and hydrophobic effects in these salt solutions. Hence the choice of the radius factor for glycine and diglycine might be suspected to cause some doubts as to the relevance of the ΔG_t^0(int) values. But since Kirkwood (28) and Cohn *et al.* (29) have already considered glycine as a spherical solute of radii 2.82 Å (and hence amenable for SPT calculations), the ΔG_t^0(int)–composition profile for glycine should by no means be considered to be an artifact but rather fairly meaningful. Likewise, the same profile for diglycine should also be taken as something real. Evidently, it is not the aforesaid ion–ion type interactions but the effect of significant contributions from the cavity interaction terms (Table 5) which led to the apparent sign and magnitudes of ΔG_t^0 values, especially of large sized species. This often

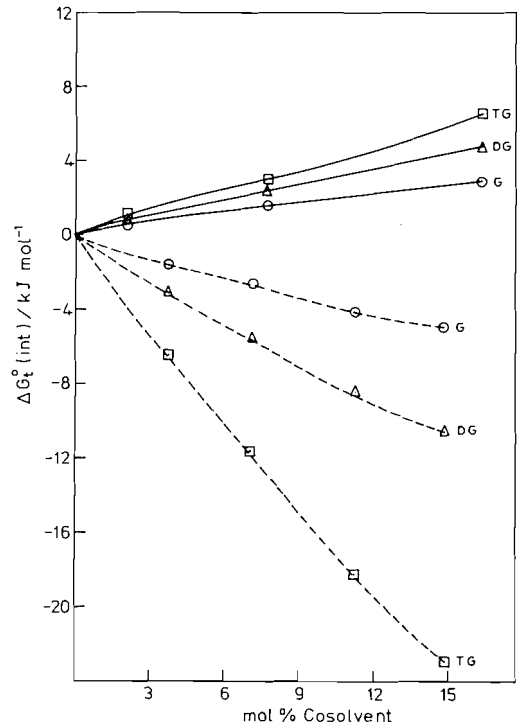

FIG. 2. Variation of ΔG_t^0(int) of glycine (○), DG (△), and TG (□) with cosolvent composition in aqueous mixtures of GL (solid lines) and UH (dotted lines) at 25°C.

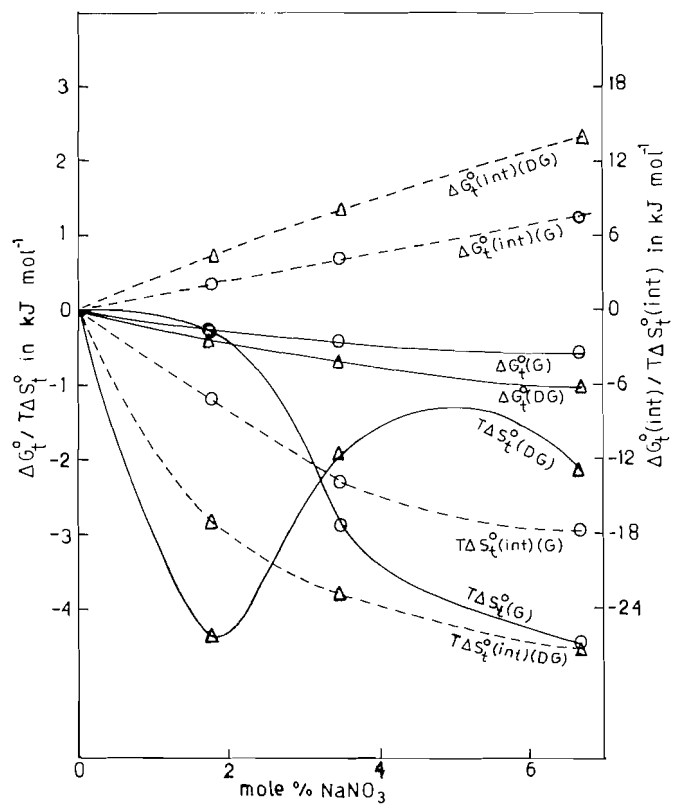

FIG. 3. Variation of ΔG_t^0 and $T\Delta S_t^0$(solid lines) and ΔG_t^0(int) and $T\Delta S_t^0$(int) (dotted lines) of glycine (○) and DG (△) with cosolvent composition in aqueous $NaNO_3$ solution at 25°C.

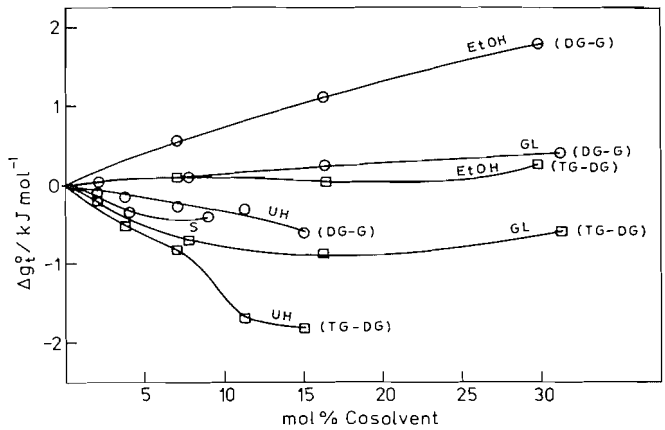

FIG. 4. Variation of Δg_t^0 (= ΔG_t^0(DG) − ΔG_t^0(G)) (○) and Δg_t^0 (= ΔG_t^0(TG) − ΔG_t^0(DG)) (□) with cosolvent composition in aqueous mixtures of EtOH, GL, UH, and $NaNO_3$(s) at 25°C.

obscures the true interaction effect which gets reflected only when one considers the cavity forming contributions. Moreover, afterall these species (G, DG) are typical non-electrolyte (35) organic solutes and might also undergo desolvation in aqueous electrolyte solutions.

Regarding the peptide-backbone unit, it is observed in Table 4 and Fig. 4 that ΔG_t^0–composition profiles of the peptide group i.e., (Δg_t^0 = ΔG_t^0(DG) − ΔG_t^0(G)) are increasingly positive for GL + H_2O and EtOH + H_2O solvents, that are increasingly negative in aqueous urea and $NaNO_3$ solutions. This also confirms the dictates of the observation made by Gekko in GL + H_2O mixtures and by Nozaki and Tanford in UH + H_2O mixtures. The increased negative magnitudes of the same profile in salt solution is still the effect of cavity contribution term which after due modification (which gives Δg_t^0(int)) imparts increasing positive magnitudes as has been seen from Table 4. But when the Δg_t^0 values are obtained from (ΔG_t^0(TG) − ΔG_t^0(DG)) an increasing negative Δg_t^0–composition profile in Fig. 4 was observed (with more or less constant difference between the two profiles) in both GL + H_2O and UH + H_2O mixtures. This is also obtained by Nozaki and Tanford in the latter cosolvent system and also in EtOH + H_2O mixtures (4) as shown in the same figure. This shows that the transfer free energy change for glycyl residue obtained by these two methods is not guided by additive property. This is of course not that unexpected as Nozaki and Tanford also concluded that the large negative values of these Δg_t^0 values obtained from the ΔG_t^0 difference of TG and DG result from the insertion of a glycyl residue into a molecule which already possesses a peptide unit. Moreover, these values when obtained from ΔG_t^0(int) values result in Δg_t^0(int) values (Table 4) which are largely negative in UH + H_2O mixtures and positive in GL + H_2O mixtures as expected from the interactions involved in the processes already discussed.

Entropies of transfer

Figure 5 illustrates $T\Delta S_t^0$–composition profiles of G, DG, and TG for the aqueous mixtures of GL and UH. If we follow the arguments of Spink and Auker (19) proposed in the case of EtOH + H_2O mixtures, the observed maximum for DG in GL + H_2O mixtures appears to suggest that cosolvent GL promotes the 3D structure of water at initial compositions and that DG is a structure breaker in this cosolvent system as is glycine in EtOH

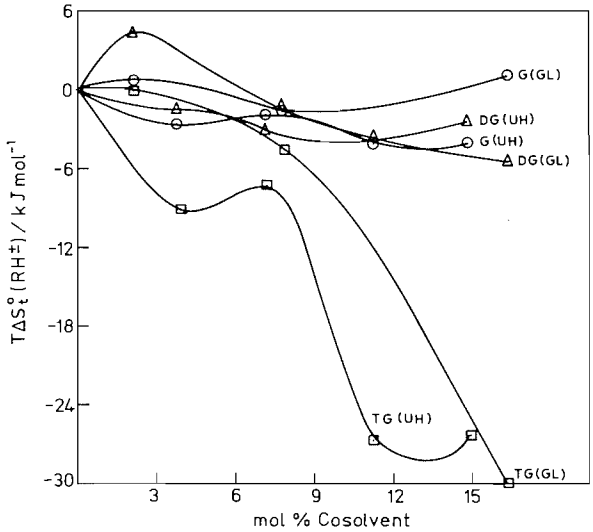

FIG. 5. Variation of $T\Delta S_t^0$ of glycine (○), DG (△), and TG (□) with cosolvent composition in aqueous mixtures of GL and UH at 25°C.

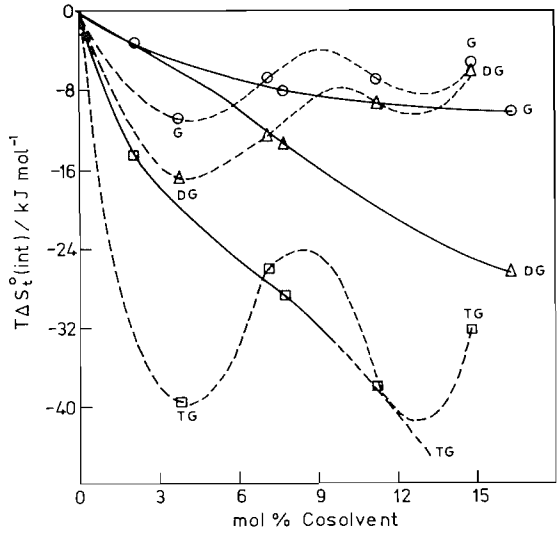

FIG. 6. Variation of $T\Delta S_t^0$(int) of glycine (○), DG (△), and TG (□) with cosolvent composition in aqueous mixtures of GL (solid lines) and UH (dotted lines) at 25°C.

+ H_2O mixtures. On the contrary, the observed downward trends of the profiles for glycine and TG imply that GL induces breakdown of 3D-structure of water. This anomalous behaviour, however, ceases to exist if we analyse the behaviour of true interaction effects on $T\Delta S_t^0$–profiles. We have, therefore, tentatively computed $T\Delta S_t^0$(cav) contributions by evaluating the values of $\overline{H}$(cav), the molar enthalpy of cavity formation, using the SPT formulations given in the previous paper (12). When $T\Delta S_t^0$(cav) values (Table 5) are subtracted from the corresponding experimentally observed $T\Delta S_t^0$ values, the resulting $T\Delta S_t^0$(int) values show a pattern similar to that observed in the cases of other non-electrolytes like benzoic acid (HBz) (12*a*) and *p*-nitroaniline (*p*-NA) (12*b*) in various aquo-organic solvents including these cosolvents. Thus the observed increasing negative $T\Delta S_t^0$(int)–composition profiles (solid lines in Fig. 6) in this solvent system are indicative of the effect of structure breaking propensity of the cosolvent GL conforming to what is contended from various other studies (11*a*, 12) and is expected from structural consideration of this cosolvent.

Similarly, in the case of UH + H_2O mixtures the observed initial downward trend of the $T\Delta S_t^0$(int)–composition profiles (dotted lines in Fig. 6) substantiate the earlier contention that urea is an effective 3D water structure breaker right from the initial composition but induces some structural order due to the possible formation of UH + H_2O aggregates around 4–10 mol% UH as indicated earlier (36). But at high urea-content the observed positive trends in both Figs. 5 and 6 are indicative of some other structural factors such as the possible formation of aggregates of urea (37, 38).

In the case of $NaNO_3$ solutions, the observed $T\Delta S_t^0$–composition profile of G and DG in Fig. 3, though apparently difficult to understand, the normalised $T\Delta S_t^0$(int)–composition profiles (dotted lines in Fig. 3) indicate a regular order conforming to what has been observed earlier in the case of HBz and *p*-NA in KBr solution (12) and lately also in $NaNO_3$ solution (39). Thus, following the arguments adopted earlier in the case of HBz and *p*-NA in aqueous KBr solutions we may conclude that like the salt KBr, $NaNO_3$ is also a 3D water structure breaker, although as per viscosity B-coefficient data (40), it appears to promote overall "electrophilic" order round the ions. Consequently the larger cavity effect is seemingly responsible for the roller-coaster type behaviour of the uncorrected $T\Delta S_t^0$–composition profile of DG as compared to that of G.

Thus, it has been observed that the true interaction effects i.e., ΔG_t^0(int) and $T\Delta S_t^0$(int) rather than ΔG_t^0 and $T\Delta S_t^0$ are more informative and easy to understand the solvation behaviour of G, DG, and TG in these ionic and non-ionic cosolvents and these are also found to be a regular function with the peptide chain length as expected. Hence care should be taken before one derives real implications of the oberved transfer energetics, although the latter undoubtedly reflect the real and overall transfer behaviour of ionic and non-ionic solutes in different aqueous ionic and non-ionic cosolvent systems. Lastly, although the present transfer entropy or enthalpy data have a limited applicability to protein systems but they may represent a basic criterion for the effects of these organics or salt solutions on entropy or enthalpy functions of protein denaturation. Admittedly of course, the magnitudes of cavity effect are somewhat tentative because of various limitations and uncertainties. Yet the conclusions, based on the relative trends of the different propensities are likely to be meaningful.

Received May 21, 1987

SIBAPRASAD RUDRA, HIMANSU TALUKDAR, and KIRON K. KUNDU. Can. J. Chem. **66**, 469 (1988).

Autoionization constants (K_s) of aqueous mixtures of 1, 2, and 4 *m* sodium nitrate used as an ionic cosolvent system have been determined from emf measurements of the cell: Pt, H_2 (g, 1 atm) / KOH (m_1) KCl (m_2), solvent / AgCl–Ag at five equidistant temperatures ranging from 15–35°C. The standard free energies (ΔG^0) and entropies (ΔS^0) of autoionisation of the solvents were then evaluated from these data. Relative free energies (ΔG^0) and entropies (ΔS^0) of autoionization of the solvents when coupled with the previously determined transfer free energies [$\Delta G_t^0(H^+)$] and entropies [$\Delta S_t^0(H^+)$] of H^+ yielded $\Delta G_t^0(OH)_{app}$ [$= \Delta G_t^0(OH^-) - \Delta G_t^0(H_2O)$], $\Delta S_t^0(OH^-)$, and $\Delta S_t^0(H_2O)$. Values of $\Delta G_t^0(H^+)$ and $\Delta G_t^0(OH^-)$ obtained after correcting for $\Delta G_t^0(H_2O)$, as well as $\Delta G_{t,tr.int}^0(H^+)$ and $\Delta G_{t,tr.int}^0(OH^-)$ obtained after correcting the "cavity effect" and Born-type electrostatic effect suggests that while the "basicity" of the aqueous $NaNO_3$ solutions decreases, the "acidity" more or less increases with $NaNO_3$ concentration. The observed $\Delta S_{t,tr.int}^0(OH^-)$– and $\Delta S_{t,tr.int}^0(H_2O)$–composition profiles were also examined in the light of Kundu *et al.*'s four-step transfer process and the involved order–disorder phenomena, respectively, as proposed earlier.

Standard free energies (ΔG_t^0) and entropies (ΔS_t^0) of transfer of *p*-nitroaniline (*p*NA) and benzoic acid (HBz) for the solvent system have also been determined from solubility measurements at different temperatures. The observed ΔG_t^0– and $\Delta G_{t,tr.int}^0$–composition profiles appear to reflect the salting-out effect of the salt and the ΔS_t^0– and $\Delta S_{t,tr.int}^0$–composition profiles confirm the applicability of either of these quantities rather than $\Delta S_{t,tr.int}^0(HX)$, as a better structural probe both for aquo-ionic and aquo-organic solvents.

SIBAPRASAD RUDRA, HIMANSU TALUKDAR et KIRON K. KUNDU. Can. J. Chem. **66**, 469 (1988).

Utilisant des mesures de f.e.m. de la cellule : Pt, H_2 (g, 1 atm) / KOH (m_1) KCl (m_2) solvant / AgCl–Ag, effectuées à cinq températures équidistantes de 15 à 25°C, on a déterminé les constantes d'auto-ionisation (K_s) de mélanges aqueux de nitrate de sodium 1, 2 et 4 *m* utilisés comme système de cosolvant ionique. On a évalué les énergies libres standard (ΔG^0) et les entropies (ΔS^0) des solvants à partir de ces données. Lorsqu'on a utilisé les énergies libres (ΔG^0) et les entropies (ΔS^0) relatives d'auto-ionisation de concert avec les énergies libres [$\Delta G_t^0(H^+)$] et les entropies [$\Delta S_t^0(H^+)$] de transfert des H^+ qui ont été déterminées antérieurement, on a pu en tirer le $\Delta G_t^0(OH^-)_{app}$ [$\Delta G_t^0(OH^-) - \Delta G_t^0(H_2O)$], le $\Delta S_t^0(OH^-)$ et le $\Delta S_t^0(H_2O)$. On a obtenu les valeurs de $\Delta G_t^0(H^+)$ et de $\Delta G_t^0(OH^-)$ après avoir fait des corrections pour le $\Delta G_t^0(H_2O)$ et on a obtenu les valeurs de $\Delta G_{t,tr.int}^0(H^+)$ et de $\Delta G_{t,tr.int}^0(OH^-)$ après avoir fait des corrections pour l'effet de cavité et pour l'effet électrostatique du type de Born; les valeurs ainsi obtenues suggèrent que pendant que la basicité de solutions aqueuses de $NaNO_3$ diminue, l'acide augmente plus ou moins avec une augmentation de la composition en $NaNO_3$. On a aussi examiné les profils observés pour les valeurs de $\Delta S_{t,tr.int}^0(OH^-)$ et de $\Delta S_{t,tr.int}^0(H_2O)$ en fonction de la composition à la lumière du processus de transfert en quatre étapes et des phénomènes d'ordre et de désordre impliqués qui ont été proposés antiéreurement par Kundu et ses collaborateurs.

En se basant sur des mesures de solubilité à diverses températures, on a aussi déterminé les énergies libres standards (ΔG_t^0) et des entropies (ΔS_t^0) de transfert de la *p*-nitroaniline (*p*NA) et de l'acide benzoïque (HBz) pour le système de solvant. Les profils observés pour le ΔG_t^0 et le $\Delta G_{t,tr.int}^0$ en fonction de la composition semblent refléter un effet de salage du sel et les profils observés pour le ΔS_t^0 et le $\Delta S_{t,tr.int}^0$ en fonction de la composition confirment la possibilité d'utiliser chacune de ces quantités, plutôt que le $\Delta S_{t,tr.int}^0(HX)$, comme une meilleure sonde de structure tant pour les solvants aquo-ioniques qu'aquo-organiques.

[Traduit par la revue]

Introduction

In our previous papers (1–3) we have reported the thermodynamics of HX, X = Cl (1), Br, and I (3), and also the transfer energetics of some electrolytes and the related "ion–ion–solvent" interactions (2) in aqueous solutions of 1, 2, and 4 *m* $NaNO_3$ taking each composition as an individual solvent and taking the infinitely dilute solution of solutes in each solvent as the standard state as in aquo-organic solvent systems.

Since autoionization constants of water in aquo-organic solvents reflect acidity and basicity of the solvents, it would be of particular interest to evaluate the same for this solvent system as well. Moreover, it is now increasingly recognised that thermodynamics of autoionization of water and the transfer energetics of various non-electrolytes including water, provide useful information regarding the three dimensional (3D) "structuredness" of the solvent (4–13). The basis of structural reflections obtainable from entropies of autoionization of water stems from the fact that while the ionization of water accompanying the formation of order-producing H_3O^+ and OH^- ions imparts negative magnitudes to $T\Delta S^0$ (ΔS^0 = entropy of ionization), the required configurational changes including depolymerization of the three dimensional (3D) ice-like structures prior to self-ionization contribute positively to $T\Delta S^0$ (5). Recent studies on $\Delta S_t^0(H_2O)$ as obtained by dissecting from the entropies of autoionization of aqueous mixtures of some aprotic solvents like tetrahydrofuran (THF), dioxane (D), and dimethoxyethane (DME) (5*d*) and quasi-aprotic solvent like 2-methoxy ethanol (5*e*) have offered important reflections about the 3D structuredness of these solvent systems.

Similarly, although there are large number of studies (14–17) on salting-out and salting-in phenomena of various solutes, including benzoic acid (HBz) and *p*-nitroaniline (*p*NA), in various salt solutions and various theories have been proposed to explain the phenomena, so far very few attempts (11, 18, 19)

have been made to study the temperature effects and the related structural changes of the solvent. However, in a series of papers Kundu and co-workers (8, 9) have recently demonstrated that ΔS_t^0 and particularly $\Delta S_{t,int}^0$ of *p*NA and HBz obtained by subtracting the cavity effect $\Delta S_{t,cav}^0$ (20) from ΔS_t^0 values, throw important suggestions on the structuredness of the aquo-organic solvents, as they are free from the "electrostatic" effect which confuses the structural content of ΔS_t^0 data of HX type of electrolytes (1–3, 8, 9).

Therefore, as a part of our comprehensive studies and to better understand the structural aspects of the aqueous $NaNO_3$ solvent system, we report the transfer energetics (ΔG_t^0 and $T\Delta S_t^0$) of some non-electrolytes like water, *p*NA, and HBz as obtained from autoionization of water from emf measurements and solubility measurements of *p*NA and HBz at different temperatures. This study will help us see the solvent acidity or basicity and the solvent structuredness from a new angle.

As in previous papers (5, 6, 21), the thermodynamics of autoionization in 1, 2, and 4 *m* aqueous $NaNO_3$ solutions have been evaluated from the autoionization constants (K_s) determined by measuring the emf's (E) of cell [A]

[A] Pt, H_2 (g, 1 atm) / KOH (m_1), KCl (m_2), solvent / AgCl–Ag

at five equidistant temperatures ranging from 15–35°C. The transfer energetics of the non-electrolytes *p*NA and HBz have been determined by measuring the solubilities of the solutes at five different temperatures.

Experimental

Sodium nitrate used was of AR quality. The preparation of $NaNO_3$ solutions has been described earlier (1). KCl (Merck, GR) was used after drying at 200°C and cooling in a vacuum desiccator. Stock KOH solutions were prepared by adding carbonate-free KOH (Merck, GR) to weighed amounts of solvent and the molalities were determined by titrations using phenolpthalein as indicator. The preparation of the cell solutions was essentially similar to that described earlier (22). Adequate care was taken to avoid exposing the solutions to atmosphere by using a chamber flushed with N_2. General experimental procedures, including the preparation of the electrodes and measurements of emf, were similar to those described earlier (5, 21, 22). The equilibrium was attained in about 3–4 h. When the emf readings became constant to about ±0.1 mV for 1 h the reaction was considered to be in equilibrium. Readings at 15°C were taken first and then at successively higher temperatures. Readings at lower temperatures, when checked, were found to agree within the experimental error of ±0.3 mV. The alkali concentrations were often checked after the experiments and no significant changes were detected.

The method for measuring the solubility of *p*NA in this solvent system was essentially similar to that described earlier (8*a*). The saturated solutions were diluted with triple distilled water as required. Absorbance values of these solutions were determined at 380 nm using the Perkin Elmer (model 200) spectrophotometer. As before (8*a*), the molar extinction coefficient of *p*NA in the diluted solutions was taken to be equal to that in pure water, viz. 1.28×10^4, as the diluted solutions are practically aqueous bereft of the effect of the "cosolvent" present. Saturation at a given temperature was attained in all the solvents within 3–4 days. The maximum uncertainties in the measured solubilities are about ±1%. HBz (E. Merck, GR) was used after similar pretreatment as described earlier (8*b*). The method adopted for the measurement of the saturated solubility of HBz in all solvents at each temperature was also exactly similar to that described earlier (8*b*). Attainment of saturation usually took 3–4 days in this solvent system. The average uncertainties involved in the measured solubilities for the solute as well are about 1%.

Results

The emf data of the cell [A] (corrected for P_{H_2} = 1 atm) at different temepratures and the corresponding molalities of KOH and KCl for each of the solvent compositions are given in Table 1. The pK_s values (molal scale) in these ionic solvents were obtained by extrapolating the observed linear plots of pK_s' values defined by eq. [1]

$$[1] \quad pK_s' = \frac{F[E^0 - (E_m^0)_{Ag-AgCl}]}{2.303RT} + \log \frac{m_{Cl^-}}{m_{OH^-}}$$

$$= pK_s - \log \frac{a_{H_2O}\gamma_{Cl^-}}{\gamma_{OH^-}} = pK_s + f(\mu)$$

against the "ionic strength" μ to $\mu = 0$. Here a, m, and γ denote the activity, molality, and molal activity coefficient of the species in subscripts. As in aquo-organic solvents (5, 21) and as discussed in our previous paper (1) the standard state in this solvent system is so chosen that at infinite dilution in any composition of $NaNO_3$ $\gamma_{Cl^-} = \gamma_{OH^-} = a_{H_2O} = 1$. Also, the "ionic strength" refers to that caused by the added KOH and KCl only to the respective compositions of $NaNO_3$ solutions. The required values of E_m^0 of the Ag–AgCl electrode in the solvents were obtained from our earlier paper (1). The pK_s values at different temperatures for all the mixed solvents are listed in Table 2. The average standard deviation in pK_s values is of the order of ±0.005.

[a]Reference 8*b*.
[b]After correcting the degree of dissociation of the acid.
[c]Reference 8*a*.

The pK_s values at different temperatures were as before (5) fitted to the Harned–Robinson expression [2] (23)

[2] $pK_s = A/T + B + CT$

by the method of least squares. The values of the coefficients A, B, and C for the solvents are given in Table 3. The thermodynamic quantities, namely, ΔG^0, ΔS^0, and ΔH^0 accompanying the autoionization of 1 mole of water at each solvent composition, were evaluated at 25°C by using the standard relations (24) comprising the coefficients in eq. [2]. The values of ΔG^0 and ΔS^0 so obtained on molal scale (m) were then converted to mole fraction scale (N) using the usual relations (5, 24) and are listed in Table 3.

The solubilities of HBz in mol kg^{-1} and pNA in molarity in different solvent compositions as well as in pure water (9) are given in Table 4. Just as in aqueous organic solvents (8*b*, 9*b*) and salt solutions (9*b*, 11) of lower dielectric constant than water, the degrees of ionization (α_s) of HBz in these salt solutions are also tentatively taken to be negligibly small as the dielectric constant decreases with increasing salt concentration (1) owing to the well known "dielectric decrement effect" (16, 25). Notably, a tentative estimate of α_s values of HBz at 25°C in the saturated solutions of 1, 2, and 4 m $NaNO_3$, based on simple Born equation (26), leads to a percent error of 2.5, 1.2, and 0.3, respectively. For water, however, the observed solubilities were corrected for the ionization of the acid (24) to give the concentrations of the uncharged acid and are listed in Table 4.

As in previous papers (8, 9), assuming the effect of activity coefficient factor to be negligibly small, the free energies of solutions ΔG^0_s on the molar scale in the case of pNA and on the molal scale in the case of HBz were calculated for each solvent composition using eq. [3]

[3] $\Delta G^0_s = -RT \ln S$

These were then fitted by the method of least squares to an equation of the form [4]

[4] $\Delta G^0_s = a + bT + cT \ln T$

where T is the absolute temperature. The values of the coefficients a, b, and c are listed in Table 5. The standard free energies and entropies of transfer, ΔG^0_t and ΔS^0_t, of both HBz and pNA from water to the mixed solvents were computed at 25°C on mole fraction scale using the formulations described in the previous paper (2). ΔG^0_t and ΔS^0_t values thus computed are given in Table 5. The maximum uncertainties in ΔG^0_t and ΔS^0_t are ±0.03 kJ mol^{-1} and ±2 J K^{-1} mol^{-1}, respectively.

Discussion

Autoionization and transfer free energies

The standard free energy changes accompanying the autoprotolytic reaction in the salt solutions ${}_s\Delta G^0_N$ relative to that in pure water ${}_w\Delta G^0_N$, $\delta(\Delta G^0_N)$ have been computed on the mole fraction scale using the usual relation as described in our previous papers (5*d*, *e*). The values of $\delta(\Delta G^0_N)$ thus obtained are listed in Table 3.

Figure 1 illustrates the variations of $\delta(\Delta G^0_N)$ values with the molality of $NaNO_3$. $\delta(\Delta G^0_N)$ values for this solvent system are found to pass through a minimum around 1.5 m $NaNO_3$ possibly indicating the opposing effects of dielectric constant as well as the acidity and basicity of the salt solutions (5*a*). As indicated in previous papers (5, 22), the quantity of $\delta(\Delta G^0_N)$ is given by

[5] $\delta(\Delta G^0_N) = \Delta G^0_t(H^+) + \Delta G^0_t(OH^-)_{app}$

where $\Delta G^0_t(H^+)$ stands for the transfer free energy of H^+ and gives a thermodynamic measure of the basicity of the salt solutions relative to that of water, and $\Delta G^0_t(OH^-)_{app}$ denotes the transfer free energy change accompanying the process [6]

[6] $OH^-(w) + H_2O(s) \rightleftharpoons OH^-(s) + H_2O(w)$

which gives the corresponding measures for the relative acidity of the salt solutions. Consequently, dissection of $\delta(\Delta G^0_N)$ to $\Delta G^0_t(H^+)$ and $\Delta G^0_t(OH^-)_{app}$ should be useful.

As indicated earlier (5), if the activity of water $(a_{H_2O})^s_w$ be referred to that in pure water $(a_{H_2O})^w_w$ as unity, then $-RT \ln (a_{H_2O})^s_w$ would give a measure of $\Delta G^0_t(H_2O)$ which when added to $\Delta G^0_t(OH^-)_{app}$ gives $\Delta G^0_t(OH^-)$, the standard

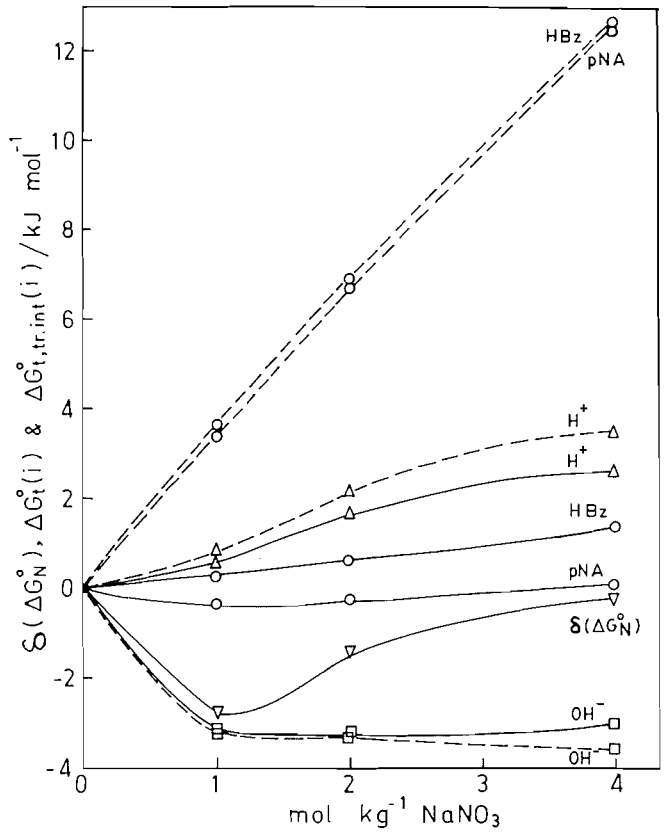

FIG. 1. Variation of $\delta(\Delta G_N^0)$ and ΔG_t^0 of H^+, OH^-, pNA, and HBz (solid lines) and $\Delta G_{t,tr.int}^0$ of H^+, OH^-, pNA, and HBz (dotted lines) in aqueous $NaNO_3$ solvents at 25°C.

free energy change accompanying the transfer of OH^-, alone from water to the mixed solvents.

Utilizing the $\Delta G_t^0(H^+)$ values based on the widely used reference electrolyte assumption (27) but duly modified for the solvent system as reported earlier (2), we have evaluated $\Delta G_t^0(OH^-)_{app}$ and then $\Delta G_t^0(OH^-)$ using $(a_{H_2O})_w^s$ from osmotic coefficient data given in the literature (25) for this solvent system. The values of $\Delta G_t^0(H^+)$ and $\Delta G_t^0(OH^-)_{app}$ and also $\Delta G_t^0(OH^-)$ are given in Table 6. Moreover, as per discussion and formulations given in the preceeding papers (1–3) we have also computed $\Delta G_{t,cav}^0$ and $\Delta G_{t,Born}^0$ for these ions using the scaled particle theory (SPT) (20) and the widely used simple Born equation (26), respectively. These values, when subtracted from $\Delta G_t^0(i)$, values yielded $\Delta G_{t,tr.int}^0(i)$ and are given in Table 6. The values of $\Delta G_t^0(i)$ and $\Delta G_{t,tr.int}^0(i)$ for H^+ and OH^- are plotted against the cosolvent compositions in Fig. 1.

Notably, there are little differences between $\Delta G_t^0(i)$– and $\Delta G_{t,tr.int}^0(i)$–composition profiles of H^+ and OH^- in the solvent system. From Fig. 1 it is observed that while $\Delta G_{t,tr.int}^0(H^+)$ becomes increasingly positive at initial composition, the corresponding values for $\Delta G_{t,tr.int}^0(OH^-)$ are increasingly negative. This implies that the basicity of the salt solutions decreases and the acidity increases with the increased proportion of the cosolvents. The observed decreased basicity or the increased destabilization of H^+ has already been explained in our previous papers (1–3). The increased acidity or the pronounced stabilization of OH^-, as explained earlier in the case of Cl^- (1), is the resultant effect of increasingly larger attractive interaction of OH^- with $(Na^+)_{aq}$ overcoming the weaker repulsive interactions between OH^- and NO_3^-, which are likely to exceed

[a]The required diameters of the solvent constituents and the values of the scale effect $RT \ln V_w/V_s$ are taken from ref. 1 and $\alpha = -d \ln d_s/dT$ also taken from ref. 1. For the solute species: $b_{H_3O^+} = 0.276$ nm (1), $b_{OH^-} = 0.312$ nm (5*d*, 34), $b_{H_2O} = 0.276$ nm (1), $b_{HBz} = 0.690$ nm (9*b*), $b_{pNA} = 0.720$ nm (9*a*).

[b]The required radii of the ionic species are obtained from the corresponding diameters of the species as indicated in *a* and that of H^+ as equal to 0.276 nm (1).

[c]The values of $\Delta G^0_t(OH^-)_{app}$.

[d]The values of $\Delta G^0_t(H_2O)$ being equated to $-RT \ln ({}^aH_2O)^s_w$ and computed from the relevant osmotic coefficient data (25).

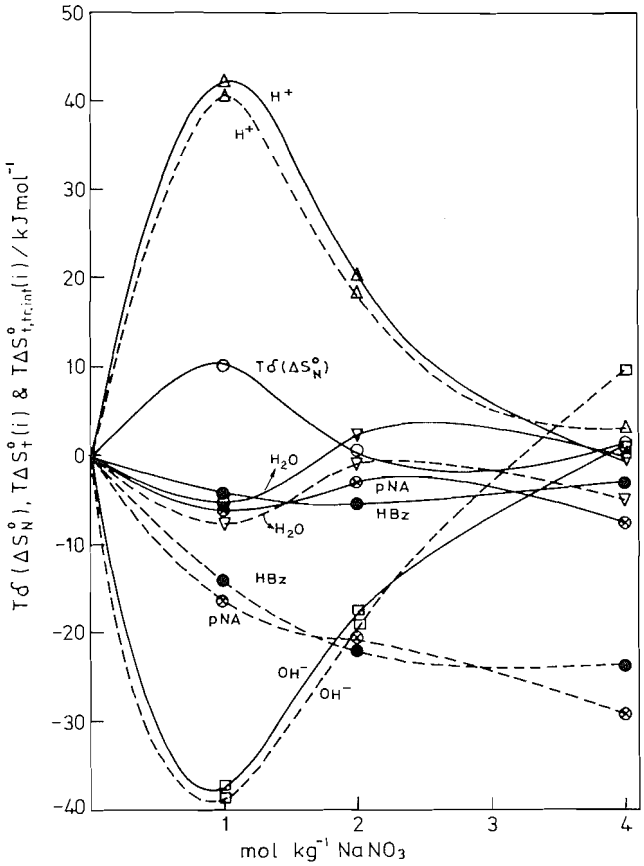

FIG. 2. Variation of $T\delta(\Delta S_N^0)$ and $T\Delta S_t^0$ of H_2O, H^+, OH^-, *p*NA, and HBz (solid lines) and $T\Delta S_{t,tr.int}^0$ of H_2O, H^+, OH^-, *p*NA, and HBz (dotted lines) in aqueous $NaNO_3$ solvents at 25°C.

the OH^-–H_2O interaction in pure water. Notably, the less pronounced destabilization of H^+ and stabilization of OH^- beyond 1.5 *m* $NaNO_3$ indicate the effect of solvent-separated ion pairs $(Na^+)_{aq}NO_3^-$ as obtained from various spectroscopic evidences (28–30).

Figure 1 also shows the variation of ΔG_t^0 and $\Delta G_{t,tr.int}^0$ of *p*NA and HBz with molality of $NaNO_3$. Though the ΔG_t^0–composition profile of HBz is increasingly positive, that of *p*NA passes through a slight minimum. Strikingly enough, the $\Delta G_{t,tr.int}^0$–composition profiles for both *p*NA and HBz are increasingly positive. The observed increased destabilization of *p*NA and HBz with increased proportion of ionic cosolvent $NaNO_3$ seemingly reflects the expected well known "salting-out" effect (14–16). It is also significant that unlike most aquo-organic solvent systems (9), the cavity effects are increasingly negative in this solvent system and thus largely obscures the expected salting-out effect in this solvent system when not duly corrected. Admittedly, however, although there are a number of theories to explain and quantify the salting-out and salting-in phenomena of various solutes including the ones studied here, they only achieve partial success (14–17). Somehow quantification of the "true salt-effect" bereft of the involved cavity effect, being an involved problem, seems difficult at this stage. This should therefore be a matter of particular interest for a future study.

Autoionization and transfer entropies

As in aquo-organic solvents since entropy changes, rather than enthalpy changes, are better indicators of the structural implications (31), analysis of the entropy changes in the present study should be useful. The values of entropy of autoionization on the mole fraction scale, ΔS_N^0, were computed at 25°C using the usual relation given in ref. 24. The variation of $T\Delta S_N^0$ at 25°C relative to that in water $T\delta(\Delta S_N^0)$ ($\equiv T({}_s\Delta S_N^0) - {}_w\Delta S_N^0$) for these solvents are shown in Fig. 2 and the values of $T\Delta S_N^0$ are given in Table 3. Moreover, as indicated in our previous papers (5*d*, *e*), since $\delta(\Delta S_N^0)$ is given by

$$[7]\quad \delta(\Delta S_N^0) = {}_s\Delta S_N^0 - {}_w\Delta S_N^0 = \Delta S_t^0(H^+) + \Delta S_t^0(OH^-) - \Delta S_t^0(H_2O)$$

we have also computed $\Delta S_t^0(H_2O)$ values by subtracting the contribution of $[\Delta S_t^0(H^+) + \Delta S_t^0(OH^-)]$ obtained by plotting the values of $[\Delta S_t^0(H^+) + \Delta S_t^0(X^-)]$ where $X^- = Cl^-$, Br^-, and I^- for those solvent mixtures (1, 3) against $(r_{X^-})^{-1}$ and reading out the values corresponding to $(r_{OH^-})^{-1}$ where r_i is the radius of the corresponding ions (5*d*, *e*). The values of $\Delta S_t^0(H_2O)$ as obtained for the solvent system are given in Table 6 and the variation with cosolvent composition in Fig. 2. $\Delta S_t^0(OH^-)$ values obtained by subtracting the values of $\Delta S_t^0(H^+)$ from $[\Delta S_t^0(H^+) + \Delta S_t^0(OH^-)]$ are presented in Table 6 and illustrated in Fig. 2. Similarly, like the corresponding quantities of free energies of transfer discussed above, the quantities $\Delta S_{t,tr.int}^0(H^+)$ and $\Delta S_{t,tr.int}^0(OH^-)$ were also obtained using the formulations given in the previous papers (1–3) and are listed in Table 6 and illustrated in Fig. 2.

Now as can be observed from Table 6 and Fig. 2, for both H^+ and OH^- the $\Delta S_{t,cav}^0$ and $\Delta S_{t,Born}^0$ contributions more or less compensate each other, and hence the composition profiles of $T\Delta S_t^0$ and $T\Delta S_{t,tr.int}^0$ for both ions hardly differ from each other. Besides, as in the case of other anions, viz. Cl^-, Br^-, and I^- (1–3), $T\Delta S_t^0$– and $T\Delta S_{t,tr.int}^0$–composition profiles of OH^- also exhibit mirror-image behaviour of that of H^+. Thus while both profiles of H^+ pass through a distinct maximum around 1.5 *m* $NaNO_3$ both profiles of OH^- pass through a distinct minimum around that composition. The entropic behaviour of OH^- in this ionic cosolvent system seems to be more or less similar to that of other anions like Cl^-, Br^-, or I^- (1–3) and hence may be accounted for by Kundu *et al.*'s four step transfer process as described in detail in the previous papers (1–3). One may of course argue that unlike halide ions, OH^- is hydrated by three H_2O molecules (32) in pure water and therefore the entropy change in the dehydration step (step 1), ΔS_1^0, of the four step process (1–3, 33) may not be more than that of the halide ions. Since the order produced round the central water molecule in step 2, $-\Delta S_2^0$, is likely to be greater than that round the central OH^-, the value of $\Delta S_1^0 - \Delta S_2^0$ might be negative. This would then augment the negative value of $(\Delta S_3^0 - \Delta S_4^0)$ as OH^- like X^- ions (2, 3) will be interacted upon by $(Na^+)_{aq}$ involved in step 3, i.e. $\Delta S_3^0 \approx 0$ and the entropy change ΔS_4^0 involved in the step 4, accompanying the solvation of OH^- will be more negative in the lower composition of $NaNO_3$. At high composition, however, as in the case of X^- (2, 3), $(\Delta S_3^0 - \Delta S_4^0)$ will be increasingly positive as the interacting species $(Na^+)_{aq}$ will be increasingly replaced by solvent-separated ion pairs $(Na^+)_{aq}NO_3^-$ (28–30).

On the other hand, as in the cases of aqueous dioxane, dimethoxy ethane (5*d*), and 2-methoxy ethanol (5*e*), the observed composition profiles of $T\Delta S_t^0(H_2O)$ as well as $T\Delta S_{t,tr.int}^0(H_2O)$ for $NaNO_3$–water mixtures imply that addition of $NaNO_3$ initially enhances the order of free water molecules around Na^+ and NO_3^- which result from the breakdown of the

For personal use only.

3D water structure induced by the ionic cosolvent $NaNO_3$. But as various spectroscopic evidences (20–30) indicate, after 1.5 *m* $NaNO_3$ the Na^+_{aq} and NO^-_3 are increasingly replaced by "solvent-separated ion pairs" (SSIP), the order around SSIP is likely to diminish as reflected in the observed roller coaster type behaviour of $T\Delta S^0_t(H_2O)$– and $T\Delta S^0_{t,tr.int}(H_2O)$–composition profiles.

Analysis of the observed $T\Delta S^0_t$– and $T\Delta S^0_{t,tr.int}$–composition profiles of *p*NA and HBz for this solvent system (vide Fig. 2) indicates that while the nature of $T\Delta S^0_t$–composition profile of *p*NA is fairly similar to that of H_2O that of HBz is seemingly slightly different. Notably, however, their respective behaviour is also more or less similar to that observed in aqueous LiCl and KBr solutions in the case of HBz (9*b*) and that in aqueous KBr solution in the case of *p*NA (9*a*). Significantly enough, the $T\Delta S^0_{t,tr.int}$–composition profiles also show sharp downward trend both for *p*NA and HBz right from the beginning, as has been observed for these solutes in the respective salt solution referred to above. If one uses the semiquantitative theory of Kundu *et al.*'s four-step transfer process (8, 9) for these solutes as a guide, then the observed sharply downward trend of $T\Delta S^0_{t,tr.int}$–composition profiles in $NaNO_3$ solutions is to be expected as a result of 3D structure breaking propensity of the salt as observed earlier in other salt solutions.

Thus it appears from the above results that just as in aquo-organic solvents (8, 9) $\Delta S^0_{t,tr.int}(i)$ for these non-electrolytes like HBr, *p*NA and particularly H_2O, rather than $\Delta S^0_{t,tr.int}(HX)$ (1) should be a better probe for the 3D structuredness of aqueous mixtures of ionic and non-ionic cosolvents.

Photochemistry of cyclic α-hydroxy ketones. II. The nature of the photoproducts from 8a-hydroxy-4a-methyl-*trans*- and -*cis*-octahydronaphthalen-1(2*H*)-one and an interpretation of the contrast between the photochemistry of these and of analogous steroidal α-hydroxy ketones[1]

PETER YATES AND SHIRLEY STIVER
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received October 8, 1987

PETER YATES and SHIRLEY STIVER. Can. J. Chem. **66**, 476 (1988).

Photolysis of either 8a-hydroxy-4a-methyl-*trans*- or -*cis*-octahydro-naphthalen-1(2*H*)-one (**3** or **4**) in benzene gives a 96:4 mixture of the lactones, 5a-methyl-*trans*- and -*cis*-octahydro-1-benzoxepin-2(3*H*)-ones (**7** and **8**). Photolysis of **3** or **4** in ethanol gives identical mixtures of the lactones **7** and **8** and ethyl (2*S**,1*R**)- and (2*R**,1*R**)-2-hydroxy-1-methylcyclohexanebutyrates (**11** and **12**). Photolysis of the 2α-deutero derivatives of **3** or **4** in benzene gives mixtures of the 9a-, 3α-, and 3β-deutero derivatives of lactone **7**. The striking difference between these results and those for photolyses of analogous 5α- and 5β-hydroxy 6-keto steroids, which are stereospecific, is interpreted in terms of the greater flexibility in the cases of **3** and **4** of the acyl side chain in the acyl alkyl diradicals formed by α-cleavage. A further difference—the sole formation of lactones on photolysis of the steroidal α-ketols in ethanol—is interpreted in terms of an analogous increased flexibility in the cases of **3** and **4** of the ketene side chain in the hydroxy ketene intermediates formed from the acyl alkyl diradicals.

PETER YATES et SHIRLEY STIVER. Can. J. Chem. **66**, 476 (1988).

La photolyse effectuée dans le benzène de l'un ou l'autre des isomères *cis* ou *trans* de l'hydroxy-8a méthyl-4a (2*H*)-octahydro-naphtalènone-1 (**3** ou **4**) conduit à un mélange 96:4 des lactones *trans* et *cis* méthyl-5a (3*H*)-octahydro-benzoxépine-1 ones-2 (**7** et **8**). Si l'on effectue la photolyse des composés **3** ou **4** dans l'éthanol, on obtient des mélanges identiques des lactones **7** et **8** et des (2*S**,1*R**) et (2*R**,1*R**) hydroxy-2 méthyl-1 cyclohexanebutyrates d'éthyle (**11** et **12**). La photolyse des composés **3** ou **4** deutérés en position 2α, effectuée dans le benzène, conduit à des mélanges de lactone **7** deutérée en 9a, 3α et 3β. On observe une différence remarquable entre ces résultats et ceux qui ont été observés lors de la photolyse des dérivés analogues hydroxy-5α (ou -5β) céto-6 stéroïdes qui sont stéréospécifiques; on interprète ces différences en fonction d'une plus grande flexibilité, dans le cas des composés **3** et **4**, des diradicaux acyle alkyle qui se forment par le clivage-α. L'autre différence qui est observée, à savoir la formation de seulement des lactones lors de la photolyse des α-cétols dans l'éthanol, est interprétée en fonction d'une augmentation analogue de la flexibilité, dans les cas des composés **3** et **4**, de la chaîne latérale des intermédiaires hydroxy-cétènes qui se forment à partir des diradicaux acyle alkyle.

[Traduit par la revue]

Introduction

In the previous paper in this series (1) we discussed the nature and genesis of the products formed on ultraviolet irradiation of 5-hydroxy 6-keto steroids of types **1** and **2** and of related 6-keto steroids. To compare the photochemical behavior of these with that of their simplest bicyclic analogues, **3** and **4**, we have investigated the nature of the photoproducts from the latter and from their 2α-deutero derivatives, **5** and **6**.[2] We first describe the determination of the structures of these products, and then discuss the origin of the contrasting photochemical behavior of the steroidal and bicyclic α-hydroxy ketones.

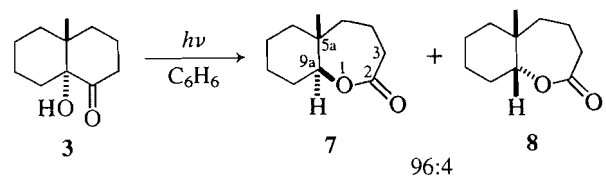
[2]The synthesis of compounds **3–6** is described in ref. 3.

Results

Photochemistry of bicyclic α-ketols

The *trans* and *cis* bicyclic α-ketols **3** and **4** were each photolyzed in benzene and in ethanol. Irradiation of **3** in benzene gave the *trans* lactone **7** as the major photoproduct, isolated in 62% yield (Scheme 1). Gas chromatographic analysis of the photolysate indicated the presence of a very small quantity of the epimeric *cis* lactone **8**. This was not isolated but was identified by the coincidence of its retention time in the gas chromatogram with that measured for an authentic sample (*vide infra*); it was present to the extent of ~4% of the *trans* lactone **7**.



SCHEME 1

The ^{1}H nmr spectrum of the major product shows the C-9a methine proton signal as a doublet of doublets (J = 11, 5 Hz) at δ 4.13 (Table 1). The larger 11-Hz coupling constant, indicative of an axial–axial interaction (4), is consistent with the *trans* ring fusion of **7** assigned to this lactone. However, the 11-Hz coupling constant does not unambiguously establish the nature

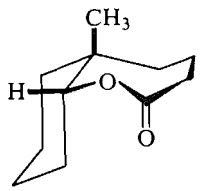
TABLE 1. ^{1}H nuclear magnetic resonance spectral data for the *trans* lactone **7** in deuterochloroform and benzene-d_6

Assignment	δ($CDCl_3$, 400 MHz)	δ(C_6D_6, 200 MHz)	Δδ[a]
CH_3	0.93(s)	0.68(s)	−0.25
C-3α-H	2.48–2.56 (m, width = 29 Hz)	1.83–1.97 (m, width = 29 Hz)	−0.6
C-3β-H	2.60–2.66 (m, width = 21 Hz)	2.35–2.47 (m, width = 21 Hz)	−0.2
C-9a-H	4.13 (dd, J = 11, 5 Hz)	3.46 (dd, J = 11, 5 Hz)	−0.67

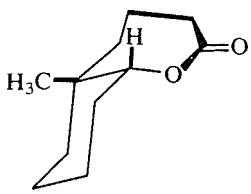
[a]Δδ = δ(C_6D_6) − δ($CDCl_3$).

of its ring fusion since an axial–axial interaction would also be present in the steroidlike conformation **8***A* of the *cis* lactone **8** (but not in the nonsteroidal conformer **8***B*).

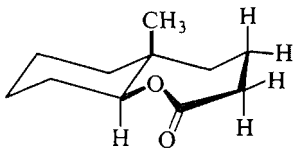
The definitive structural assignment for the major product as the *trans*-fused lactone **7** relied on the chemical shift of the methyl carbon signal in its ^{13}C nmr spectrum. The axial and equatorial methyl carbons of the equatorial conformer of 1-acetoxy-2,2-dimethylcyclohexane (**9**) resonate in the ^{13}C nmr spectrum at δ 18.6 and 29.0, respectively (5). The former serves as a model for the methyl carbon resonance of the *trans* lactone **7**, and the latter for the methyl carbon in the steroidal conformer of the *cis* lactone **8***A*. The C-5a methyl carbon signal at δ 15.5 in the ^{13}C nmr spectrum of the major photoproduct from **3** dictates the assignment to it of structure **7**. The presence of a γ-interaction between the methyl carbon and C-4 in **7** is considered to account for the shielding of this carbon relative to the model axial-methyl carbon of acetate **9**. The structural assignment for the *trans* lactone **7** was confirmed by an independent synthesis (*vide infra*).



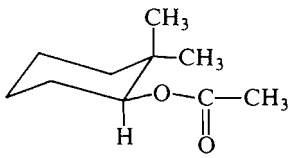
8*A*



8*B*



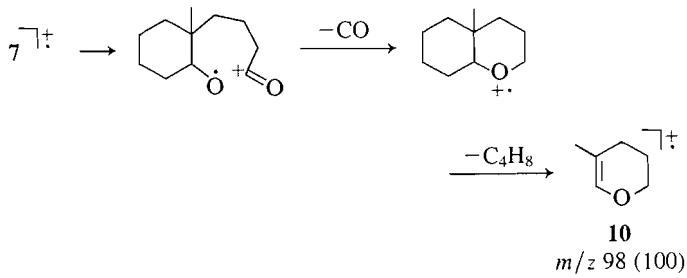
7*A*



9

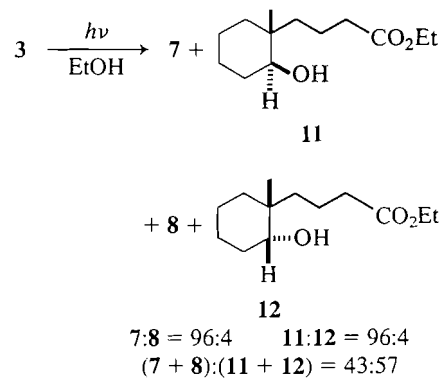
Although they partially overlap in the ^{1}H nmr spectrum at 200 MHz in deuterochloroform, the C-3 methylene proton signals of **7** are well resolved from each other in the 200-MHz ^{1}H nmr spectrum in benzene-d_6, where they appear as multiplets at δ 1.83–1.97 (width = 29 Hz) and δ 2.35–2.47 (width = 23 Hz). Coupling constants could not be extracted from either signal.

Models of **7** suggested that there are a number of conformations available to the seven-membered lactone ring, thus making individual assignment of the C-3 methylene proton signals difficult. However, as detailed in the Appendix, a favored conformation, **7***A*, can be assigned, leading to the individual assignments for the C-3 methylene proton signals given in Table 1. These assignments were required for the deuterium labelling studies (*vide infra*).



10
m/z 98 (100)

SCHEME 2



SCHEME 3

The mass spectrum of **7** shows the base peak at *m/z* 98. This is attributed to ion **10**, derived as outlined in Scheme 2 via a fragmentation analogous to that proposed by Ahmad *et al.* (6) for the related steroidal 5α-lactone (1).

Irradiation of the *trans* ketol **3** in ethanol gave a mixture of the *trans* lactone **7** and the stereochemically analogous *trans* hydroxy ester **11** as the major photoproducts (Scheme 3). As determined by gas chromatographic analysis of the total photolysate, the ratio of lactone to ester was 43:57, which corresponds well with isolated yields of 33 and 48%, respectively. Gas chromatography also indicated that each of the major photoproducts, lactone **7** and hydroxy ester **11**, was accompanied by ~4% of their epimeric counterparts, lactone **8** and hydroxy ester **12**. These minor constituents were not isolated, but were identified by comparison of their gas chromatographic retention times with the retention times of authentic samples (*vide infra*).

The 400-MHz ^{1}H nmr spectrum of the major hydroxy ester obtained from photolysis of **3** in ethanol shows a doublet of doublets at δ 3.39 (J = 10, 4 Hz), assigned to the methine proton of the hydroxyl-substituted carbon. The larger, 10-Hz coupling constant is consistent with the existence of the *trans* hydroxy ester **11** in conformation **11***A* (4), in accord with expectation (cf. ref. 7). However, an axial–axial interaction with the methine proton also exists for conformer **12***B* of the

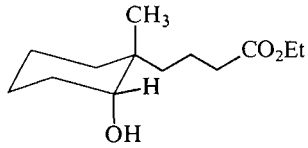
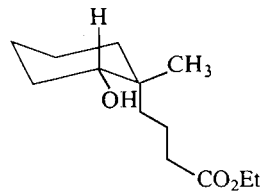
11*A*



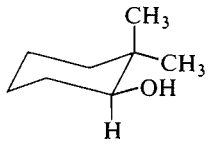
12*A*



12*B*

epimeric hydroxy ester **12**. But unlike its *trans* epimer, the *cis* hydroxy ester **12** is predicted to exist as a mixture of conformers **12***A* and **12***B* and, as such, this structure would be inconsistent with the observed coupling of the methine proton.

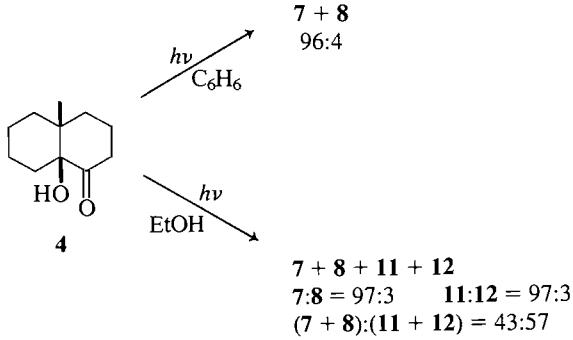
The ^{13}C nmr spectrum of the major ester product confirmed the assignment of structure **11**. Analogous to the assignment for the *trans* lactone **7**, the *trans* structure **11** was indicated by comparison of the methyl carbon resonance observed at δ 17.2 for the photoproduct with the axial and equatorial methyl carbon signals at δ 17.7 and 29.7, respectively, in the equatorial conformer of 2,2-dimethylcyclohexanol **13** (5). Moreover,



13

ethanolysis of the *trans* lactone **7** to the *trans* hydroxy ester **11**, effected by a strongly acidic Amberlite ion exchange resin, confirmed the like stereochemistry of the two major photoproducts. The structural assignment for **11** was further secured by an independent synthesis (*vide infra*).

Irradiation of the *cis* ketol **4** in benzene and in ethanol gave products identical to those obtained from photolysis of the *trans* ketol **3** (Scheme 4). From the benzene photolysate, a 96:4 mixture of the *trans* and *cis* lactones **7** and **8** was isolated in 55% yield. The total photolysate from irradiation of **4** in ethanol was shown by gas chromatography to comprise lactone and ester photoproducts in a ratio of 43:57. A 97:3 mixture of the epimeric lactones **7** and **8** and a mixture of the same ratio of epimeric hydroxy esters **11** and **12** were isolated in 33 and 41% yield, respectively. Thus not only were the photoproducts from **4** identical with those from **3**, but the product ratios were also effectively identical.

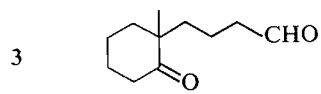


SCHEME 4

The major hydroxy ester **11** isolated from irradiation of **3** and **4** in ethanol was shown to be a primary photoproduct of the reaction and not to be the result of a "dark" ethanolysis of lactone **7**. Evidence of this was obtained by gas chromatography, which showed that the ester was detectable even in the early stages of photolysis, and that the lactone/ester ratio remained constant throughout the course of the photolysis. Furthermore, prolonged irradiation (for 10 times the time required for complete consumption of starting material) of the photolysate in ethanol did not alter this ratio, and there was no evidence for the formation of any of **11** when lactone **7** was irradiated in ethanol for a prolonged time.

The formation of an acid, either a "photo acid" originating from the ethanol used as solvent (8) or a carboxylic acid derived from oxidation of aldehydic photoproducts (*vide infra*), might possibly accompany photolysis of **3** and **4** in ethanol. Since these acids could conceivably catalyze ethanolysis of **7**, the ethanolic photolysis of each ketol was repeated in the presence of a small amount of sodium bicarbonate to test further the conclusion that ester **11** is a primary photoproduct. Filtration and concentration of the resulting photolysates from **3** and **4** gave lactone/ester ratios of 38:62 and 34:66, respectively, eliminating the possibility of acid-catalyzed ethanolysis.

The photolysates of **3** and **4** were each examined after only a portion of the starting ketol had been consumed. The ^1H nmr spectrum of the photolysates from irradiation of **3** in benzene for 0.5 h (10% of the time required for complete consumption of the starting ketol) evidenced methyl singlets attributable to the starting ketol **3** and the *trans* lactone **7**, as well as a singlet coincident with that of the methyl group of the *cis* ketol **4**. In addition, a methyl singlet at δ 1.10 and a multiplet at δ 9.73 were observed, which are ascribed to the keto aldehyde **14**. The



14

ratio of lactone **7** and keto aldehyde **14** formed was determined from the relative intensities of their methyl singlets to be 70:30.

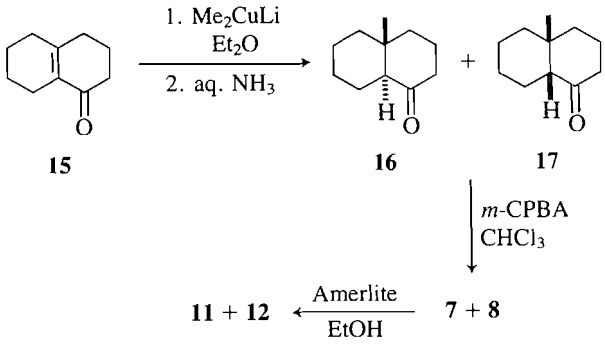
Gas chromatographic monitoring of the photolysis of **3** in benzene indicated that the *cis* ketol **4** was present as a maximum of ~20% of the volatile components of the photolysate. This was observed in the early stages of the photolysis, following which the percentage of **4** in the photolysate decreased, presumably as it underwent photoreaction. The amount of keto aldehyde **14** initially rose to ~20% of the volatile components of the photolysate and declined upon continued irradiation. Although **4** was isolated from a curtailed photolysis of **3**, several attempts to isolate **14** were unsuccessful.

Evidence for the formation of **3** during irradiation of **4** in benzene was more ambiguous. Gas chromatographic monitoring during the course of irradiation evidenced a small peak, corresponding to a maximum of 5% of the volatile components of the photolysate, whose retention time was similar to that of **3**. A neighbouring peak, reaching a maximum of 10%, is attributed to **14** but neither of these attributions was verified by ^1H nmr spectroscopy.

Independent synthesis of the photoproducts

The stereochemistry ascribed to the lactones and hydroxy esters obtained from photolysis of the bicyclic ketols **3** and **4** was confirmed by independent synthesis, as outlined in Scheme 5. Reaction of lithium dimethylcuprate with the enone **15** (3, 9),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.



SCHEME 5

according to the procedure of Boeckman and Silver (10), afforded a 40:60 mixture of the *trans* and *cis* 1-decalones **16** and **17**. The ring fusion of **16** and **17** has been previously established (11). Equilibration of a 40:60 mixture of **16** and **17** to a 70:30 mixture of these ketones established that the *trans* isomer is favored thermodynamically (12).

Baeyer–Villiger oxidation of the 40:60 mixture of decalones **16** and **17** with *m*-chloroperoxybenzoic gave a 40:60 mixture of the *trans* and *cis* lactones **7** and **8**. The minor component of this mixture, which corresponds to the major lactone formed in the bicyclic ketol photolyses, can be assigned the *trans* lactone structure **7**, since retention of configuration at the migrating center during Baeyer–Villiger rearrangements is well established (13). Treatment of a nonequilibrium mixture of **16** and **17** with a solution of *m*-chlorobenzoic acid, a stronger acid than its corresponding peroxy acid, gave no evidence of any epimerization. The possibility of equilibration between **16** and **17** prior to Baeyer–Villiger rearrangement is thereby excluded. The excellent yield of the mixture of lactones obtained from the Baeyer–Villiger reaction ensured that no fractionation of epimers had occurred during work-up.

As a further check of the product stereochemistry, a 55:45 mixture of **16** and **17**, obtained by partial epimerization, was oxidized under the same Baeyer–Villiger conditions. This yielded a 55:45 mixture of **7** and **8**. Direct correspondence of the ratio of the starting ketone mixture with the ratio of the lactones derived from Baeyer–Villiger oxidation for two significantly different decalone mixtures established that no crossover had occurred.

In the ^{1}H nmr spectrum of a partially purified sample of the *cis* lactone **8**, a narrow multiplet at δ 4.20 could be discerned for the C-9a methine proton. This signal's narrowness evidenced the preference of this lactone for the nonsteroidal conformation **8***B* (*vide supra*).

Ethanolysis of a 40:60 mixture of the lactones **7** and **8** effected by an Amerlite resin yielded a 40:60 mixture of the hydroxy esters **11** and **12**. The epimeric esters were not separated, but the methyl singlet of the minor component of the mixture, the *trans* hydroxy ester **11**, was coincident with the methyl singlet of the major hydroxy ester isolated from irradiation of the bicyclic ketols.

Photolysis of 2α-deutero bicyclic α-ketols

The 2α-deutero *trans* and *cis* bicyclic ketols **5** and **6** (3), on irradiation in benzene, each gave the same mixture of deuterated lactones **18**, **19**, and **20** (Scheme 6). This mixture of lactones was isolated from the crude photolysate by sublimation and (or) crystallization, since the presence of deuterium label α to the carbonyl group in **19** and **20** precluded purification by chromatography.

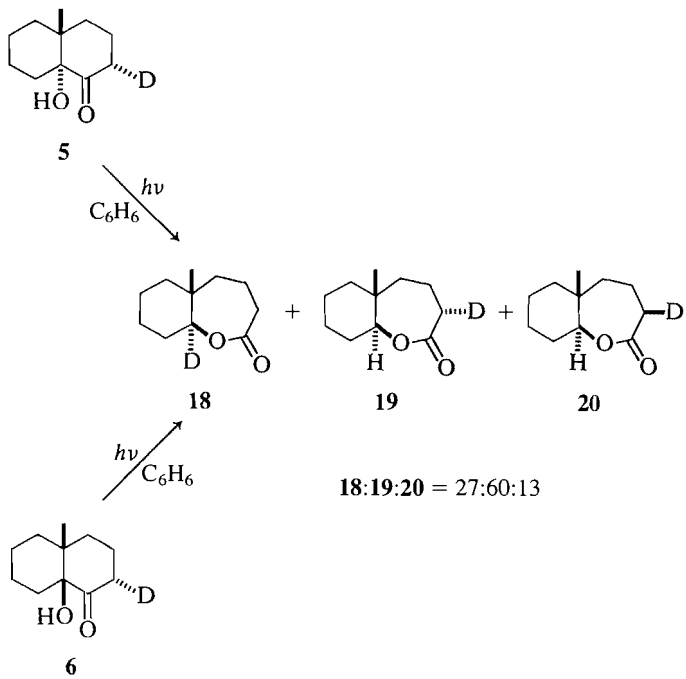

SCHEME 6

As detailed in Table 2, the 200-MHz ^{1}H nmr spectrum of the deuterated lactone mixture in deuterochloroform evidenced deuterium incorporation at the C-9a methine and C-3 methylene sites in the ratio 28:72. The mass spectrum of the deuterated lactone mixture was recorded under carefully monitored conditions, since high source or probe temperatures or high source pressures were found to engender a variable $M + 1$ contribution to the molecular ion, which could have introduced errors into the deuterium content calculations. In view of the errors that could also be associated with the quantitative ^{1}H nmr measurements, the total deuterium content accounted for by the ^{1}H nmr analysis is in reasonable accord with calculations based on the mass spectra.

Examination of the C-3 methylene proton signals in the ^{1}H nmr spectra of the deuterated lactone mixture, recorded in both deuterochloroform and benzene-d_6, revealed that the deuterium at C-3 was preponderantly situated at the α site: in

both nmr solvents, the relative area of the multiplet ascribed to the C-3α proton was significantly diminished. A detailed analysis of these spectra (see Appendix) led to the conclusion that the deuterated lactones **18**, **19**, and **20** were present in the ratio 27:60:13 (Table 2).

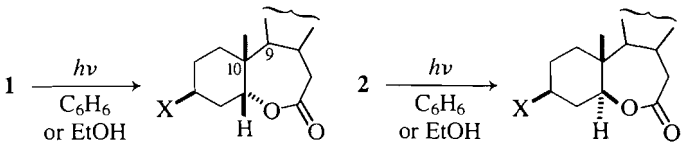
Discussion

Modes of photoreaction of bicyclic α-ketols

Irradiation of the bicyclic α-ketols **3** and **4** in benzene gives lactones **7** and **8** (Schemes 1 and 4), which are analogous to **21** and **22**, the products formed on photolysis of the steroidal α-ketols **1** and **2** (Scheme 7) (1). The structures of the photoproducts are consistent with exclusive α-cleavage to give alkyl acyl diradicals **23** that are converted to hydroxy ketene intermediates **24** via intramolecular hydrogen transfer (Scheme 8).

When the irradiation of α-ketol **3** in benzene was interrupted at an early stage, the keto aldehyde **14** was detected among the reaction products by vapor phase chromatography, together with the lactones **7** and **8**, unconsumed α-ketol **3**, and its epimer **4**. The failure to detect **14** by vapor phase chromatography after consumption of all of the α-ketols is attributed to its conversion on irradiation to nonvolatile products. The formation of **14** can best be interpreted in terms of intramolecular hydrogen transfer of the hydroxyl hydrogen atom in the diradical **23** (Scheme 9). In the cases of the steroidal α-ketols, the photochemical formation of an analogous keto aldehyde and interconversion of the ketols were not observed. We attribute this dichotomy to differences in the flexibility of the acyl side chain in the diradical intermediates (*vide infra*).

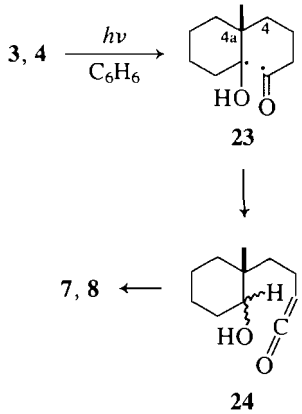
When the bicyclic α-ketols **3** and **4** were irradiated in ethanol, mixtures of lactones and hydroxy esters were formed (Schemes 3 and 4). These are considered to arise from competitive dark reactions of the intermediate hydroxy ketenes **24** involving, respectively, intramolecular reaction and intermolecular reaction with ethanol. This is in clear contrast to the behaviour of the steroidal α-ketols, which on irradiation in ethanol give only intramolecular, lactonic products (Scheme 7). We propose that this difference in behaviour results from differences in the flexibility of the ketene side chain in the hydroxy ketene intermediates (*vide infra*).



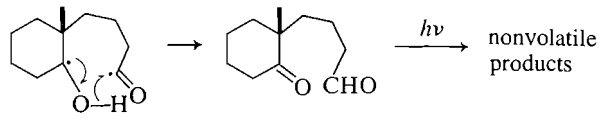
21 22

X = OAc, H, OBn

SCHEME 7



SCHEME 8



SCHEME 9

Stereochemistry of α-ketol photolyses

The most striking contrast between the photochemical behavior of the bicyclic and steroidal α-ketols pertains to the stereochemistry of the products. The reactions of the steroidal α-ketols are completely stereospecific (Scheme 7), while those of the bicyclic α-ketols, although stereoselective, are not stereospecific, and the same ratios of epimeric products are formed from both α-ketols (Schemes 1, 3, and 4).

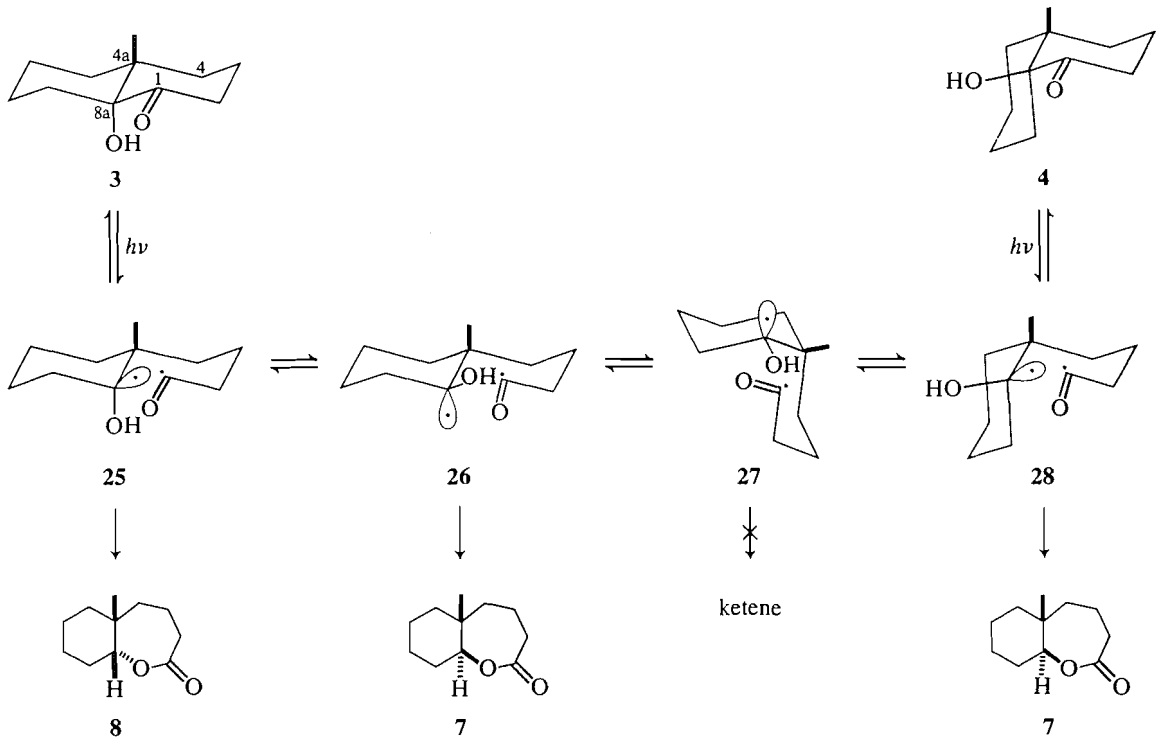
In the case of the steroidal α-ketols, we have proposed that the stereospecificity stems from two factors: the geometry of the hydroxy-alkyl radicals, and fast hydrogen transfer in the diradical intermediates (1). The rate of hydrogen transfer was postulated to be fast relative to that of ring inversion and (or) inversion of the radical centre in the diradical intermediate. This fast hydrogen transfer was attributed to the presence of the CD ring system, which restricts rotation of the acyl side chain about the C-9—C-10 bond in the steroidal analogues of the bicyclic diradical **23**, i.e., about the bond corresponding to the C-4—C-4a bond in **23**.

Since it is anticipated that the geometry of the hydroxyalkyl radicals formed from the bicyclic α-ketols will not differ significantly from that of those formed from the steroidal α-ketols, it is concluded that the second factor, the rate of hydrogen transfer, is the crucial source of difference between the bicyclic and steroidal α-ketol photolyses.

In these terms, the nonstereospecific nature of the bicyclic ketol photolyses is attributed to a relatively slow rate of hydrogen abstraction. This in turn is considered to be a consequence of the large degree of rotational flexibility available to the acyl chain in the bicyclic diradicals.[3] Comparison with the steroidal diradicals shows that the bicyclic diradicals are not formed as their favored C-4—C-4a rotamers, and the activation barrier to rotation about the C-4—C-4a bond is lower than that about the analogous C-9—C-10 bond in the steroidal diradicals. We postulate that, following α-cleavage in the photolysis of the bicyclic α-ketols, rotation about the C-4—C-4a bond occurs to relieve an unfavorable *gauche* interaction of the C-3—C-4 bond with the C-4a methyl group and the C-4a—C-8a bond. This removes the hydrogen α to the acyl radical from the vicinity of the alkyl radical center and slows the rate of hydrogen abstraction.

It is proposed that as a consequence of a slow hydrogen abstraction step in the diradical intermediates **25** and **28** first formed from α-cleavage of the *trans* and *cis* bicyclic α-ketols **3** and **4**, respectively, equilibration of the ring conformation and the stereochemistry of the radical center is established prior to hydrogen abstraction (Scheme 10). The preferred diradical that

[3]The term "bicyclic diradicals" is used to connote the diradicals formed from the bicyclic ketols.



SCHEME 10

emerges from this equilibrium is considered to determine the stereochemistry of the photoproducts.

Evidence that **3** and **4** react via a common diradical is as follows:

(*i*) Both **3** and **4** give the same mixture of photolactones **7** and **8**.

(*ii*) The high degree of stereoselectivity for each of the bicyclic α-ketol photolyses indicates that there is sufficient time for the diradical intermediates to equilibrate. Otherwise a more nearly equal mixture of **7** and **8** would be expected from photolysis of **3**.

(*iii*) Irradiation of the α-deutero labelled *trans* and *cis* ketols **5** and **6** gives an identical mixture of the deuterated lactones **18**, **19**, and **20**.

As outlined in Scheme 10, ring and radical inversions of the diradicals **25** and **28** generate two additional diradicals, **26** and **27**. Of the four diradical intermediates, diradical **26** is considered to be the most stable, since both the acyl side chain and hydroxyl groups are favorably situated in equatorial sites. Hydrogen transfer in this diradical would lead to the *trans* lactone **7**, which is observed experimentally to be by far the preponderant photolactone.

Since the diradical **26** would be expected to close to give the *cis* ketol **4**, the detection of substantial amounts of the latter during the irradiation of **3** is in accord with its intermediacy.[4] Furthermore, the diradical **26** cannot close to the *trans* ketol **3**, and this would explain the lack of evidence for the formation of significant amounts of **3** during the irradiation of **4**.

The only other diradical that might account for the formation of **7** is **28**. However, evidence suggests that the formation of **7** in the photolyses of **3** and **4** derives from hydrogen abstraction in the favored diradical **26** rather than in **28**. The formation of the keto aldehyde **14** shows that abstraction of the hydroxyl hydrogen can occur in the bicyclic ketol systems. This mode of reactivity is compatible with the intermediacy of diradical **26** since the hydroxyl group is oriented equatorially to the ring and is geometrically very accessible for hydrogen abstraction. In contrast, the axial nature of the hydroxyl group in **28** would be expected to preclude formation of **14**.

Further evidence that it is **26** and not **28** that leads to **7** is provided by the results of the irradiations of the α-deutero ketols **5** and **6**. As shown in Scheme 11, transition states **30***A* and **30***B* are available for hydrogen abstraction from the favored diradical **29**, the deuterated analogue of **26**.[5] In these two transition states the C-3—C-4 bond is favorably disposed *anti* to the methyl group. Comparison of their relative energies is difficult. While transition state **30***B* has the acyl radical side chain in an equatorial site, transition state **30***A* permits hydrogen bonding between the hydroxyl group and the acyl group in the favored mode of bonding, between the hydroxyl group and the unpaired *n* electrons of the carbonyl oxygen atom (14). This disposes the unfilled orbital in the bent acyl radical (15, 16) *anti*-periplanar to the C—D bond favoring good orbital overlap during C—D cleavage. Thus a mixture of the deuterated lactones **18** and **19**/**20** is predicted to result if ketene formation in the photolyses of **5** and **6** proceeds via the diradical **29**.

These transition states may be compared with the transition states **32***A* and **32***B* that lead to ketene formation from the diradical **31**, the deuterated analogue of **28** (Scheme 12). These transition states, in addition to being derived from the less favored diradical **31**, incorporate an unfavorable *gauche* interaction of the C-3 methylene group with the methyl group and C-8a. Transition state **32***A* in which the acyl substituent is equatorially disposed is predicted to be favored over transition

[4]The possibility that the photolysis of **3** proceeds via its total rapid conversion to **4** is excluded by the fact that the photolysis of **3** occurs much more rapidly than that of **4**.

[5]In the steroidal systems, a transition state analogous to either **30***A* or **30***B* is not possible for it would place the C-8—C-14 and C-9—C-11 bonds of ring C in a *trans* diaxial orientation.

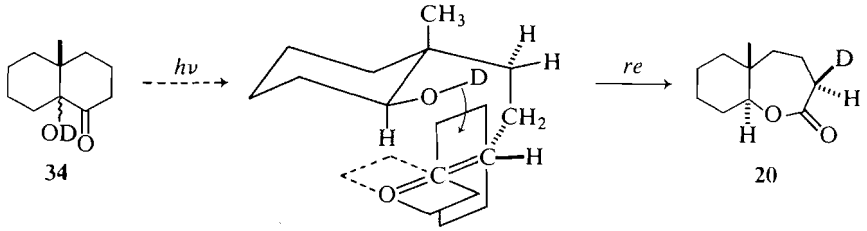
state **32***B*. Thus exclusive deuterium abstraction is anticipated if ketene formation in the photolyses of **5** and **6** were to proceed via diradical **31**.

The mixture of C-9a and C-3 deutero lactones **18** and **19/20** isolated from photolysis of **5** and **6** suggests that ketene formation occurs from the transition states **30***A* and **30***B*. Quantitatively, the 28:72 ratio of **18** to **19/20** represents a combination of the inherent stereoselectivity for 2α- versus 2β-hydrogen abstraction and the deuterium kinetic isotope effect. In the absence of similar studies with the epimeric 2β-deutero ketols, we cannot with certainty separate these effects. However, both Agosta and Wolff (17) and Duthaler and Ganter (18) have observed small deuterium isotope effects for hydrogen abstraction leading to ketene formation in the irradiation of bicyclo[3.2.1]octan-6-ones and bicyclo[3.3.1]nonan-2-ones. Using the deuterium kinetic isotope effect values of



34 35 20

SCHEME 13

1.5–2.1 observed by these workers, we can calculate (18, 19) the inherent stereoselectivity for abstraction of the α- and β-hydrogens α to the acyl radical to be ~40:60. This is in accord with expectation since neither transition state **30***A* or **30***B* is predicted to be strongly favored over the other.

Thus the divergent behavior of the steroidal and bicyclic ketols on photolysis is considered to hinge on the relative flexibilities of the acyl radical side chain formed from each. Evidence for our proposal that the acyl side chains of the bicyclic diradical intermediates have more rotational flexibility than the acyl side chains of the steroidal diradical intermediates can be obtained from T_1 relaxation correlation times. The bicyclic and steroidal esters **11** and **33** (1) serve as models for their diradical counterparts in this study, and the T_1 values for the carbons of these molecules are given in Table 3. The smaller NT_1 values (where N corresponds to the number of protons on the carbon of interest) for the carbons of the acyl chain in the steroidal ester **33** relative to those of the acyl chain of the bicyclic ester **11** indicate that molecular motion in the former is in fact more hindered.

Reactions of the ketene intermediates

Our investigation of the photochemistry of *O*-deuterated steroidal α-ketols **1** and **2** has led us to conclude that the addition of the hydroxyl group to the ketene group in the intermediate hydroxy ketenes is under product development control with the transition states for the additions being formed relatively late on the reaction coordinate (1). Such control was considered to be a consequence of the maintenance of the C-8—C-9—C-10 framework in the hydroxy ketene in an arrangement that approximates the backbone of the preferred conformation of the product lactones.

Although we have not examined the photolysis of the *O*-deuterated bicyclic ketols, our studies of the photolyses of the C-2 deuterated bicyclic ketols (Scheme 6) suggest that in these cases addition to the ketene is under steric approach rather than product development control. The fact that **19** and **20** are formed in a ratio of 82:18 indicates that the β-deutero lactone **20** would be the major product from photolysis of the *O*-deuterated ketols **34**. This is contrary to the stereoselectivity observed in the photolysis of the *O*-deuterated 5β-steroidal ketol. Thus product development control cannot be a significant factor in the mode of addition of the hydroxyl group to the ketene group in the bicyclic systems.

The difference is attributed to the greater flexibility of the ketene side chain in the bicyclic system. In this case the C-4—C-4a bond is relatively free to rotate. The favored rotamer is that which positions the C-3—C-4 bond *anti* to the C-4a—methyl bond. In this rotamer, the *si* face of the ketene system is inaccessible to the hydroxyl group, making the formation of the α-deutero lactone **19** unfavorable. In contrast, a favorable transition state **35** is available for addition to the *re* face of the ketene group (Scheme 13). This addition leads to the formation of the C-3β deutero lactone **20**, with the reaction under steric approach control.

The divergent reactivity of the steroidal and bicyclic ketene intermediates with respect to the incorporation of ethanol, when used as solvent for the α-ketol irradiations, is also attributed to the differences in the relative flexibilities of the ketene side chain in these systems. The presence of ring C in the steroidal ketene intermediate is considered to hold the C-5 hydroxyl group and the ketene system in close proximity, thus leading to exclusive addition to give lactone photoproducts. In contrast, in the bicyclic system the rotational flexibility of the ketene chain removes the ketene group from the vicinity of the hydroxyl group, and addition of ethanol to the ketene group becomes competitive with intramolecular addition, with the result that irradiation of the bicyclic α-ketols in ethanol gives rise to a mixture of lactone and ester photoproducts.

Conclusions

We have shown that the photolyses of the bicyclic α-ketols are highly stereoselective, but not stereospecific as in the case of the steroid α-ketols. This difference is attributed to the greater flexibility of the acyl side chain in the acyl alkyl diradical intermediates, which results in a relatively slow rate of hydrogen transfer leading to ketene formation. As a consequence of this slow hydrogen transfer, equilibration of the conformation of the cyclohexyl ring and the configuration of the radical center in the diradical intermediates first formed from α-cleavage is established prior to hydrogen abstraction. The preferred diradical that emerges from this equilibration is considered to determine the stereoselective formation of the *trans* lactone from the photolyses of the bicyclic α-ketols. Deuterium labeling studies suggest that hydrogen transfer in this diradical leading to ketene formation occurs with a slight preference for abstraction of the β-hydrogen.

In a similar manner, the difference in the relative flexibility of the ketene side chain formed in the bicyclic and steroidal α-ketol photolyses is considered to account for the formation of both hydroxy ester and lactone photoproducts from the former and the exclusive formation of lactones from the latter when the photolyses are carried out in ethanol. Deuterium labelling studies suggest that intramolecular addition to the ketene intermediate in the bicyclic systems is under steric approach control, whereas product development control governs this addition in the steroidal systems.

Thus, the present work confirms our previous conclusion that the stereospecificity of the photolyses of 5-hydroxy 6-keto steroids is not a general attribute of all α-ketol irradiations (1), but results from the particular structural features of the steroidal

For personal use only.

α-ketols. We consider that our observations in the case of the bicyclic α-ketols represent the more general case, where ring and radical inversion motions in the diradical are strongly competitive with hydrogen abstraction, and the relative stabilities of the diradicals that result from these inversions determine the stereochemistry of the photoproducts.

Experimental[6]

*Irradiation of 4a-methyl-8a-hydroxy-*trans*-octahydronaphthalen-1(2*H*)-one (**3**) in benzene. Formation of 5a-methyl-*trans*- and -cis-octahydro-1-benzoxepin-2(3*H*)-one (**7** and **8**)*

A solution (1.5 × 16 cm) of **3** (61 mg, 0.34 mmol) in anhydrous benzene (23 mL) was irradiated under argon, and the photolysis was followed by gas chromatography (3% OV-17 on Chromosorb W; 130°C). After 5 h, starting material was shown to have been completely consumed and the photolysate was concentrated to give a colorless oil (53 mg). Flash chromatography on silica gel (1.5 × 18 cm) with dichloromethane – ethyl acetate (95:5 v/v) as eluent gave a 96:4 mixture of the *trans* and *cis* lactones **7** and **8** (38 mg, 62%) as a colorless oil. Sublimation (80°C/15 Torr; 1 Torr = 133.3 Pa) gave the mixture of lactones as white crystals (*vide infra*).

Irradiation of trans *ketol **3** in ethanol. Formation of* trans *and* cis *lactones **7** and **8** and ethyl (2S*,1R*)- and (2R*,1R*)-2-hydroxy-1-methylcyclohexanebutyrate (**11** and **12**)*

A solution (2.5 × 32 cm) of **3** (264 mg, 1.45 mmol) in anhydrous ethanol (125 mL) was irradiated under argon and the course of the photolysis was monitored by gas chromatography (3% OV-17 on Chromosorb W; 130°C). After 5 h, when the starting material had been completely consumed, the photolysate was concentrated to a colorless oil (308 mg). Flash chromatography on silica gel (2.5 × 17 cm) with dichloromethane – ethyl acetate (98:2 v/v) as eluent gave a 96:4 mixture of *trans* and *cis* lactones **7** and **8** (87 mg, 33%) as a colorless oil. Sublimation (92°C/20 Torr) afforded white needles, mp 85–86°C, which were crystallized from hexanes – diethyl ether to give **7** as a colorless prism, mp 87.5–88.5°C; ir λ_{max}: 5.80, 7.79 (m), 9.00 (m) μm; ^{1}H nmr (200 MHz) δ: 0.93 (s, 3H), 1.07–1.94 (m, 12H), 2.44–2.71 (m, 2H), 4.14 (d, J = 11, 5 Hz, 1H); ^{1}H nmr (400 MHz) δ: 0.93 (s, 3H), 1.14–1.88 (m, 12H), 2.48–2.56 (m, width = 29 Hz, 1H), 2.60–2.66 (m, width = 21 Hz, 1H), 4.13 (dd, J = 11, 5 Hz, 1H); ^{1}H nmr (benzene-d_6, 200 MHz) δ: 0.60–1.72 (m), 0.68 (s), 1.83–1.97 (m, width = 29 Hz, 1H), 2.35–2.47 (m, width = 23 Hz, 1H), 3.46 (dd, J = 11, 5 Hz, 1H); ms m/z: 182 (5), 98 (100). *Exact Mass* calcd. for $C_{11}H_{18}O_2$: 182.1307; found: 182.1340. *Anal.* calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.96; found: C 72.19, H 9.93.

Further elution with dichloromethane – ethyl acetate (95:5 v/v) gave a 96:4 mixture of the hydroxy esters **11** and **12** (157 mg, 48%) as a colorless liquid. The mixture was molecularly distilled (134°C/20 Torr) to give **11**, containing ~5% of its epimer **12**, as a colorless liquid; ir λ_{max}: 2.88 (sh, w), 2.99 (br, w), 5.78, 7.28 (m) μm; ir λ_{max}(neat): 3.00 (br, m), 5.75, 5.81 (sh), 7.27 (m) μm; ^{1}H nmr δ: 0.90 (s, 3H), 1.23–1.95 (m) and 1.25 (t, J = 7 Hz) and 1.87 (br s, exchanges with deuterium oxide) (16H), 2.13–2.40 (m, 2H), 3.40 (br m, $W_{1/2}$ = 15 Hz, 1H), 4.13 (q, J = 7 Hz, 2H); ^{1}H nmr (400 MHz) δ: 0.88 (s, 3H), 0.94 (weak s, **12** Me), 1.16–1.80 (m) and 1.26 (t, J = 7 Hz) (16H), 2.23–2.35 (m, 2H), 3.39 (dd, J = 10, 4 Hz, 1H), 4.13 (q, J = 7 Hz, 2H); ms m/z: 228 (2), 98 (100). *Exact Mass* calcd. for $C_{13}H_{24}O_3$: 228.1725; found: 228.1714. *Anal.* calcd. for $C_{13}H_{24}O_3$: C 68.38, H 10.59; found: C 67.98, H 10.55.

*Irradiation of 8a-hydroxy-4a-methyl-*cis*-octahydronaphthalen-1(2*H*)-one (**4**) in benzene. Formation of lactones **7** and **8***

A solution (1.5 × 19 cm) of **4** (73 mg, 0.40 mmol) in anhydrous benzene (27 mL) was irradiated as described for its *trans* isomer **3**, and the concentrated photolysate was chromatographed to give a 96:4 mixture of the *trans* and *cis* lactones **7** and **8** (41 mg, 55%) as a white solid.

Irradiation of cis *ketol **4** in ethanol. Formation of lactones **7** and **8** and hydroxy esters **11** and **12***

Ketol **4** (265 mg, 1.46 mmol) was irradiated in anhydrous ethanol (125 mL) for 6 h, as in the case of **3**. The concentrated photolysate (340 mg) was flash chromatographed on silica gel (2.5 × 15 cm) with dichloromethane – ethyl acetate (98:2 v/v) as eluent to give a 97:3 mixture of *trans* and *cis* lactones **7** and **8** (88 mg, 33%) as a white solid. Further elution with the same solvent mixture gave a 97:3 mixture of the hydroxy esters **11** and **12** (135 mg, 41%) as a colorless liquid.

*4a-Methyl-*trans*- and -*cis*-octahydronaphthalen-1(2*H*)-one (**16** and **17**)*

A 40:60 mixture of **16** and **17** was prepared in quantitative yield by the reaction of lithium dimethylcuprate with 3,4,5,6,7,8-hexahydronaphthalen-1(2*H*)-one (**15**) according to the method of Boeckman and Silver (10); ir λ_{max}: 5.86 μm; ^{1}H nmr δ: 0.77 (s, *trans* Me), 1.00 (s, *cis* Me), 1.00–2.57 (m); ms m/z: 166 (32), 111 (100). The *trans*/*cis* ratio was found to be 40:60. On prolonged standing, the ketones had partially equilibrated to a 55:45 *trans*/*cis* mixture.

Equilibration of cis *ketone **17** to* trans *ketone **16***

A 40:60 mixture of **16** and **17** was equilibrated by heating under reflux with sodium carbonate in aqueous methanol for 20 h according to the method of Marshall and Hochstetler (12). This gave a 65:35 mixture of **16** and **17** in 70% yield.

Baeyer–Villiger oxidation of trans *and* cis *ketones **16** and **17**. Formation of lactones **7** and **8***

A stirred suspension of *m*-chloroperoxybenzoic acid (85%; 3.72 g, 18.3 mmol) in chloroform (20 mL) was treated with a solution of a 55:45 mixture of **16** and **17** (1.069 g, 6.44 mmol) in chloroform (20 mL). The resulting solution was protected from light and stirred at room temperature for 41 h. The fine white suspension that formed was poured into stirred aqueous 10% sodium sulfite (150 mL) and, subsequent to a negative starch – potassium iodide test, the layers were separated. The aqueous phase was extracted with chloroform (50 mL, 4 × 25 mL). The combined organic phases were washed with saturated aqueous sodium bicarbonate (2 × 50 mL) and saturated aqueous sodium chloride (3 × 25 mL), dried over anhydrous sodium sulfate, and concentrated to give a 55:45 mixture of **7** and **8** (1.14 g, 97%) as a pale yellow oil; ^{1}H nmr δ: 0.97 (s, major isomer, *trans* lactone Me), 1.03 (s, minor isomer, *cis* lactone Me). Fractional crystallization from pentane gave the *trans* lactone **7** as white needles containing ~5% of the *cis* lactone **8**. The ir and ^{1}H nmr spectra of the *trans* lactone **7** prepared in this manner were identical to those of the lactone isolated from the photolyses of the *trans* and *cis* ketols **3** and **4**. The filtrate, enriched in *cis* lactone **8**, was concentrated to a colorless oil whose ^{1}H nmr spectrum exhibited, in addition to a singlet at δ 1.03, a narrow multiplet at δ 4.20.

Baeyer–Villiger oxidation, in the same manner, of a 40:60 mixture of **16** and **17** gave a 40:60 mixture of **7** and **8** in 97% yield.

Treatment of trans *and* cis *ketones **16** and **17** with* m*-chlorobenzoic acid. Evidence that epimerization does not occur during Baeyer–Villiger oxidation*

A solution of a 40:60 mixture of **16** and **17** (19 mg, 0.11 mmol) and *m*-chlorobenzoic acid (51 mg, 0.33 mmol) in chloroform (2 mL) was stirred at room temperature for 36 h. The solution was added to saturated aqueous sodium bicarbonate (2 mL), and the mixture was extracted with diethyl ether (3 × 10 mL). The combined extracts were washed with saturated aqueous sodium chloride (3 × 5 mL), dried over anhydrous sodium sulfate, and concentrated to give a 40:60 mixture of **16** and **17** in quantitative recovery as a colorless liquid. The ^{1}H nmr spectrum of this mixture was identical to that of the starting material.

In another trial the acid treatment was prolonged to 72 h; gas chromatographic analysis evidenced no epimerization of the ketones.

[6]Photolyses were carried out in Pyrex at 300 nm in a Rayonet photoreactor. For a general description of the experimental procedures used, see ref. 1. Product ratios were determined by gas chromatographic analysis on 5% Carbowax on Chromosorb G at 140°C or 170°C, or from the relative heights of the methyl signals in the ^{1}H nmr spectra.

Ethanolysis of trans *lactone 7. Formation of hydroxy ester 11*

A solution of **7** (39 mg, 0.21 mmol) in anhydrous ethanol (0.40 mL) was shaken with strongly acidic Amberlite cation exchange resin (IR-120, Rohm and Haas; 17 mg). The progress of the reaction was followed by tlc with dichloromethane–hexanes (4:1 v/v). After 48 h, when the starting material had been completely consumed, the reaction mixture was filtered and concentrated to give **11** (47 mg, 95%) as a colorless liquid. The ir and ^{1}H spectra of **11** obtained by ethanolysis of **7** were identical to those of the hydroxy ester isolated from the photolyses of the *trans* and *cis* ketols **3** and **4**.

Ethanolysis of a mixture of trans *and* cis *lactones 7 and 8. Formation of hydroxy esters 11 and 12*

Ethanolysis of a solution of a 60:40 mixture of **7** and **8** (61 mg, 0.33 mmol) in anhydrous ethanol (0.60 mL) was effected with a strongly acidic Amberlite cation exchange resin (IR-120, Rohm and Haas; 9 mg). The reaction mixture was shaken for 24 h and allowed to sit for 72 h at room temperature. Filtration and concentration of the mixture gave a 60:40 mixture of the hydroxy esters **11** and **12** (67 mg, 88%) as a colorless liquid; ^{1}H nmr δ: 0.87 (s, ester **11** Me, ~60%), 0.93 (s, ester **12** Me, ~40%).

In a similar fashion, a 40:60 mixture of **7** and **8** (33 mg, 0.18 mmol) dissolved in anhydrous ethanol (0.33 mL) was shaken with acid resin (4 mg) for 20 h to give a 40:60 mixture of **11** and **12** (32 mg, 78%) as a pale yellow liquid.

*Irradiation of 2α-deutero-8a-hydroxy-4a-methyl-*trans*-octahydronaphthalen-1(2*H*)-one (5). Formation of 9a-deutero-5a-methyl-*trans*-octahydro-1-benzoxepin-2(3*H*)-one (18) and 3α- and 3β-deutero-5a-methyl-*trans*-octahydro-1-benzoxepin-2(3*H*)-one (19 and 20)*

A solution (1.5 × 14 cm) of **5** (49 mg, 0.27 mmol) in anhydrous benzene (20 mL) was irradiated under argon for 5 h. The colorless photolysate was washed with aqueous 5% sodium bicarbonate (4 mL) and saturated aqueous sodium chloride (3 × 5 mL), dried over anhydrous sodium sulfate, and concentrated. Sublimation (72°C/15 Torr) gave a mixture of the deuterated lactones **18**, **19**, and **20** (26 mg, 53%) as a colorless oil. Crystallization from pentane afforded the mixture as white needles, mp 85.5–86.5°C; ^{1}H nmr (200 MHz) δ: 0.93 (s, 3H), 1.10–1.94 (m, 12H), 2.44–2.69 (m, 1.42H), 4.14 (dd, J = 11, 5 Hz, 0.77H); ^{1}H nmr (benzene-d_6, 200 MHz) δ: 0.60–1.72 (m) and 0.68 (s) (15H), 1.82–1.96 (m, 0.38H), 2.35–2.47 (m, 0.87H), 3.45 (dd, J = 11, 5 Hz, 0.72H); ms m/z: d_0 6%, d_1 92%, d_2 2%.

*Irradiation of 2α-deutero-8a-hydroxy-4a-methyl-*cis*-octahydronaphthalen-1(2*H*)-one (6). Formation of the deuterated lactones 18, 19, and 20*

A solution (1.5 × 13 cm) of **6** (45 mg, 0.25 mmol) in anhydrous benzene (17 mL) was irradiated as for **5**. The colorless photolysate was worked up as before to give a colorless oil (45 mg). The oil was sublimed (72°C/15 Torr) to give a mixture of **18**, **19**, and **20** (28 mg, 63%) as a white, slightly gummy solid, mp 78–83°C; ir λ_{max}: 5.81 μm; ^{1}H nmr (200 MHz) δ: 0.93 (s, 3H), 1.10–1.94 (m, 12H), 2.44–2.69 (m, 1.42H), 4.14 (dd, J = 11, 5 Hz, 0.78H); ^{1}H nmr (benzene-d_6, 200 MHz) δ: 0.60–1.72 (m) and 0.68 (s) (15H), 1.82–1.96 (m, 0.39H), 2.35–2.47 (m, 0.86H), 3.45 (dd, J = 11, 5 Hz, 0.71H); ms m/z: 183 (18), 99 (100); d_0 7%, d_1 92%, d_2 1%.

In another run, crude product was recrystallized from pentane to give a mixture of **18**, **19**, and **20** in 20% yield as white needles, mp 85.0–86.5°C. The 200-MHz ^{1}H nmr spectrum of this mixture was identical to that of the mixture obtained in the earlier run.

Appendix

Assignment of the C-3 proton signals in the ^{1}H nmr spectrum of 7

Dreiding models of each of the various conformations available to the *trans* lactone **7**, considered in relation to the degree of delocalization within the lactone group, the relative stability of the ring, and the spectroscopic properties exhibited by **7**, suggested that its preferred conformation is that depicted in **7***A*. Of the potential conformations available, **7***A* permits the most efficient delocalization within the lactone group.[7] This conformation also has the required geometry for the observed γ-shielding of the C-5a methyl carbon by C-4 in the ^{13}C nmr spectrum of **7** (*vide supra*).

In conformation **7***A* the C-3β proton is pseudoequatorial and the C-3α proton pseudoaxial, leading to assignment of the narrower multiplet at δ 2.35–2.47 to the former and the broader multiplet at δ 1.83–1.97 to the latter (Table 1). The preference of **7** to exist in the conformation **7***A* and these assignments of the C-3 methylene proton signals based on this conformation are corroborated by the differential shieldings in the ^{1}H nmr spectra

[7]Although a boatlike conformation would allow better delocalization in the lactone group, it has several features that are irreconcilable with the ^{1}H and ^{13}C nmr spectra.

of **7** recorded in deuterochloroform and benzene-d_6, and by an nOe study.

The chemical shifts of the salient signals in the ^{1}H nmr spectra of **7** recorded in deuterochloroform and benzene-d_6 are given in Table 1. These differential shieldings are consistent with the formation of a collision complex between a benzene molecule and the carbonyl group of **7** in the conformation **7***A*. Models indicate that both the C-9a methine proton and C-3α proton are situated in the shielding cone of a benzene molecule so complexed, and, as shown in Table 1, experience a strong shielding in benzene. The C-3β proton is located near the intersection of the shielding and deshielding regions and the C-5a methyl group is remote from any significant influence by the benzene molecule in **7***A*; in accord with this their ^{1}H nmr signals are only slightly shielded in benzene. Thus, the differential ^{1}H nmr shieldings observed support the preference of the lactone for the conformation **7***A*. No other conformation is predicted to give as good a correlation of both the signs and relative magnitudes of the differential proton shifts.

Nuclear Overhauser enhancement studies of the 200-MHz ^{1}H nmr spectrum of **7** in benzene confirmed the above assignments of the C-3 methylene proton signals. Irradiation of the multiplet at δ 1.83–1.97, ascribed to the C-3α proton, induced a 3.5% enhancement in the relative area of the C-9a methine proton signal at δ 3.46. Irradiation of the C-9a methine proton signal resulted in a 6.5% enhancement of the area of the multiplet at δ 1.83–1.97. These observations of an nOe between the C-9a proton and the proton resonating at δ 1.83–1.97 verify the assignment of the latter to the C-3α proton. The smaller magnitude of the nOe observed for the bicyclic lactone **7** compared with that for the corresponding steroidal lactone (1) can be attributed to the larger internuclear distance between the relevant protons (~3 Å, as measured from the Dreiding model).

Specific interactions between amino acid side chains — a partial molar volume study

MANDAPATI V. R. RAO,[1] MAHALAKSHMI ATREYI, AND MOGANTY R. RAJESWARI[2]
Department of Chemistry, University of Delhi, Delhi-110007, India

Received September 4, 1986[3]

MANDAPATI V. R. RAO, MAHALAKSHMI ATREYI, and MOGANTY R. RAJESWARI. Can. J. Chem. **66**, 487 (1988).

Partial molar volumes of the following mixtures, $\bar{V}^0$(mix) were determined in water at 20°C: (*1*) glutamic acid : glycine; (*2*) arginine:glycine; (*3*) arginine : glutamic acid; (*4*) arginine : aspartic acid; (*5*) lysine : glutamic acid, and (**6**) lysine : aspartic acid. Partial molar volumes of the mixtures calculated using $\bar{V}^0$ of various ionic species of the amino acids agreed with the experimental values for systems *1* and *2*, but were less than the experimental values for systems *3* to *6*. The positive deviations, $\Delta\bar{V}^0$(mix), of the experimental values from the calculated values are discussed in terms of "specific interactions" between ionogenic side chains. The extent of interaction is greater in systems containing aspartic acid and/or arginine.

MANDAPATI V. R. RAO, MAHALAKSHMI ATREYI et MOGANTY R. RAJESWARI. Can. J. Chem. **66**, 487 (1988).

Opérant dans l'eau, à 20°C, on a déterminé les volumes molaires partiels de mélanges, $\bar{V}^0$(mélange), des systèmes suivantes : (*1*) acide glutamique : glycine; (*2*) arginine:glycine; (*3*) arginine : acide glutamique; (*4*) arginine : acide aspartique; (*5*) lysine : acide glutamique et (*5*) lysine : acide aspartique. Les volumes molaires partiels de mélanges calculés en utilisant les valeurs de $\bar{V}^0$ de diverses espèces ioniques des acides aminés sont en bon accord avec les valeurs expérimentales déterminées pour les systèmes (*1*) et (*2*); toutefois, elles sont en moins bond accord pour les autres systèmes. On discute des déviations positives, $\Delta\bar{V}^0$(mélanges), des valeurs expérimentales par rapport aux valeurs calculées en fonction d'interactions spécifiques entres les chaînes latérales ionogènes. L'importance de ces interactions est plus grande dans les systèmes contenant de l'acide aspartique ou de l'arginine.

[Traduit par la revue]

1. Introduction

Analysis of high resolution crystal structure data of proteins has led to a better appreciation of various interactions that stabilise the tertiary and quaternary structure of proteins (1). It is now recognised that electrostatic forces are as important as hydrophobic forces in maintaining the protein structure (1–3). In oxyhaemoglobin, for example, a number of specific inter- and intra-subunit interactions between negatively charged carboxylate groups and positively charged —NH_3^+ or guanidinium groups are observed (1–3). The significance of electrostatic interactions in stabilising the complex structure of tobacco mosaic virus (4) and thermolysin (2, 5) has recently been underscored. Side chain – side chain hydrogen bonds and salt bridges were noticed in crystal structures of amino acid – amino acid salts (6–9). It would be interesting to see whether such interactions exist in solutions of mixtures of two amino acids, one with an acidic and the other with a basic side chain. In the present report, partial molar volumes of mixtures of an acidic amino acid (aspartic acid or glutamic acid) with a basic amino acid (lysine or arginine) and mixtures of glycine and arginine/glutamic acid are presented; positive deviation of the experimental volume data from the calculated volume data indicated specific interaction between the side chains of acidic and basic amino acids.

2. Experimental

Glutamic acid, aspartic acid, glycine, and alanine were from E. Merck. Lysine and arginine were SISCO products. All amino acids were of L-configuration and chromatographically pure. Amino acids, dried overnight at about 50°C under vacuum over P_4O_{10}, were used to make solutions. Deionized water was distilled over alkaline $KMnO_4$, and was boiled and filtered through sintered glass filter C-4 before use.

Density measurements were made with the Precision Density Meter 601 (Anton Paar) which is capable of measuring density with a precision of 1 in 10^6 parts. The instrument constant K was determined daily using dry air and water as standards.

The apparent partial molar volumes of amino acid mixtures were determined (10) using the equation,

$$[1] \quad \bar{V}^0(\text{mix}) = \frac{M}{\rho_0}\left(1 - \frac{\rho - \rho_0}{c}\right)$$

where ρ and ρ_0 are, respectively, the densities of solution and solvent, c is the total concentration of solute in g/mL, and M is the apparent molecular weight given by $M = X_1M_1 + X_2M_2$, where M_1 and M_2 are the molecular weights of amino acid components 1 and 2, and X_1 and X_2 are their mole fractions.

The sum of the concentrations of the two amino acids present in any mixture is quite low ($\simeq 10^{-2}$ M), hence the experimental $\bar{V}$(mix) is taken as $\bar{V}^0$(mix) (10).

pH measurements were made with a Radiometer pHM 26 unit. The temperature of the solution in the cell of density meter was maintained at 20 ± 0.03°C using a circulating thermostatic bath (Hotpack); an Anton Paar digital precision thermometer DT 100-20 was used to measure the solution temperature. It is estimated that the maximum error in partial molar volumes would be ±0.3%.

3. Results and discussion[4]

Glutamic acid : glycine and arginine:glycine mixtures

The partial molar volumes ($\bar{V}^0$(mix)) of mixtures of (*1*) glutamic acid and glycine and (*2*) arginine and glycine were determined. The $\bar{V}^0$ of the mixtures, depicted in Fig. 1, was found to increase with increasing mole fraction of the basic or acidic amino acid. To compare the observed partial molar volume data with calculated values, one has first to take into account the fact that the pH of the mixtures varied as the mole fraction of the acidic (or basic) amino acid was increased (Fig. 1, inset). Consequently, there would be shifts in various ionic equilibria and the concentrations of various ionic species

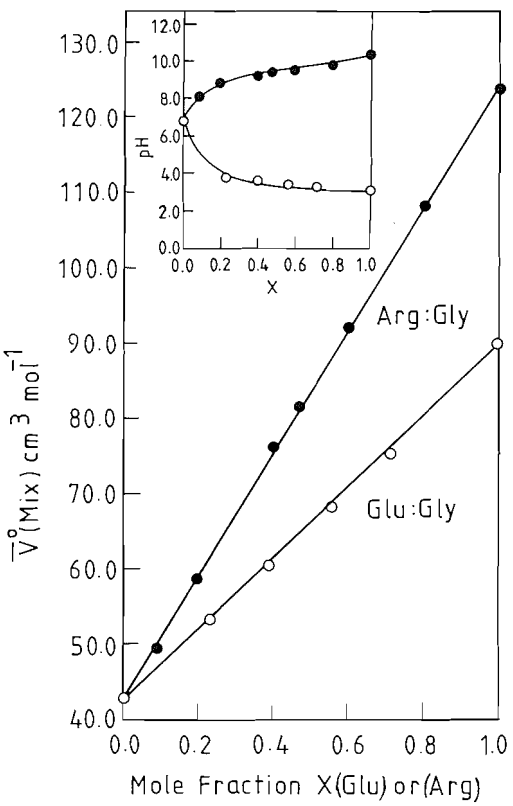

FIG. 1. $\bar{V}^0_{mix}$(expt) vs. mole fraction of Glu:Gly mixtures (○); and Arg:Gly mixtures (●) in water at 20°C. The calculated data are shown as solid lines. pH variations are shown as inset (Glu:Gly, -○-○-; Arg:Gly, -●-●-).

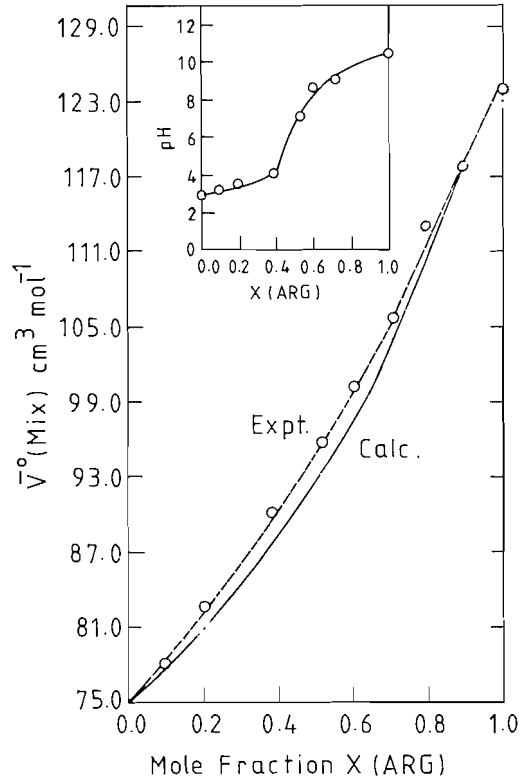

FIG. 2. $\bar{V}^0_{mix}$(expt) vs. mole fraction of arginine for Arg:Asp mixtures (○) in water at 20°C. The calculated data are shown as solid line. pH variations are shown as inset.

in each mixture would have to be evaluated taking into account the different pK's of the amino acids (11).

Glycine can exist as a cation, zwitterion, or anion depending on the pH. However, the other four amino acids under study have an additional charge center on the side chain whose ionisation leads to one more ionic species in addition to the above three. In the case of glutamic acid (also aspartic acid), a cation, a zwitterion, and two anions are possible:

$H_3\overset{+}{N}CH((CH_2)_2COOH)COOH$	$H_3\overset{+}{N}CH((CH_2)_2COOH)COO^-$
Cation	Zwitterion
$H_3\overset{+}{N}CH((CH_2)_2COO^-)COO^-$	$H_2NCH((CH_2)_2COO^-)COO^-$
Anion (i)	Anion (ii)

The side chain ε-NH_2 of lysine and δ-guanidinium (gu) of arginine can readily be charged. This leads to the formation of an additional cationic species. Various species for arginine are as follows:

$H_3\overset{+}{N}CH((CH_2)_3g\overset{+}{u})COOH$	$H_3\overset{+}{N}CH((CH_2)_3g\overset{+}{u})COO^-$
Cation (i)	Cation (ii)
$H_2NCH((CH_2)_3g\overset{+}{u})COO^-$	$H_2NCH((CH_2)_3gu)COO^-$
Zwitterion	Anion

The fractional concentration of all the ionic species can readily be evaluated as a function of pH from the ionisation constants, pK's, (11) of the charged groups. This facilitates the calculation of $\bar{V}^0$ of amino acid mixtures using the partial molar volumes of different ionic species determined for the first time recently in our laboratory (12). In general, the partial molar volumes for an amino-acid – amino-acid mixture, such as Gly:Glu, can be written, assuming the additivity principle for volumes, as:

$$[2]\quad V^0(\text{mix}) = X_{Glu}(f_{11}\bar{V}^0_{11} + f_{21}\bar{V}^0_{21} + f_{31}\bar{V}^0_{31} + f_{41}\bar{V}^0_{41}) + X_{Gly}(f_{12}\bar{V}^0_{12} + f_{22}\bar{V}^0_{22} + f_{32}\bar{V}^0_{32})$$

where X_{Glu} and X_{Gly} are the mole fractions of glutamic acid and glycine; f_{11}, f_{21}, f_{31}, f_{41} are the mole fractions and $\bar{V}^0_{11}$, $\bar{V}^0_{21}$, $\bar{V}^0_{31}$, $\bar{V}^0_{41}$ the partial molar volumes of the cation, zwitterion, anion (i), and anion (ii) of glutamic acid; f_{12}, f_{22}, and f_{32} are the mole fractions and $\bar{V}^0_{12}$, $\bar{V}^0_{22}$, and $\bar{V}^0_{32}$ are $\bar{V}^0$'s of the cation, zwitterion, and anion of glycine.

As a rule, all ionic species of an amino acid do not coexist in a solution at a given pH, and as the pH is changed, some of the terms in the above equation would vanish.

The calculated partial molar volumes for Glu:Gly and Arg:Gly mixtures (using an equation similar to [2]), along with the experimental data are depicted in Fig. 1. The calculated volumes (solid lines) agree very well with the experimental data (circles). This is a very significant observation as it clearly indicates that the partial molar volumes of the ionic species in mixtures of glycine with the acidic amino acid Glu, as well as with the basic amino acid Arg are additive. This point will be discussed further.

Arginine: aspartic acid/glutamic acid; lysine : aspartic acid/glutamic acid mixtures

The partial molar volumes of the following four mixture systems were determined as a function of mole fraction of the basic amino acid:

(3) Arg:Asp; (4) Arg:Glu; (5) Lys:Asp; (6) Lys:Glu

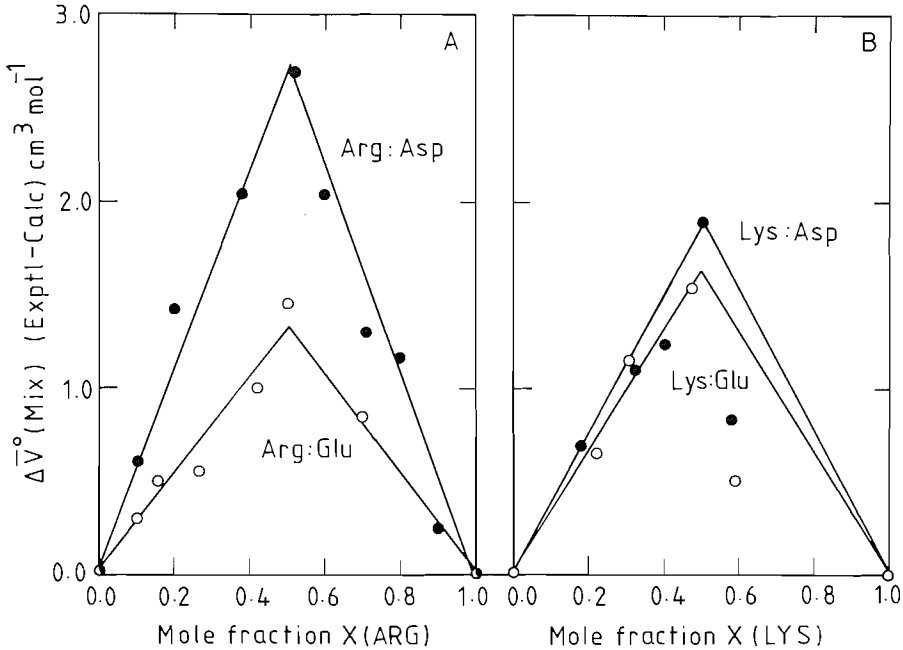

FIG. 3. $\Delta\bar{V}^0_{mix}$, ($\bar{V}^0$(expt) − $\bar{V}^0$(calc)) for mixtures of amino acids: (*A*) Arg:Asp (-●-●-); Arg:Glu (-○-○-) and (*B*) Lys:Asp (-●-●-) and Lys:Glu (-○-○-) in water at 20°C as a function of mole fraction of Arg of Lys.

The sum of the two solute concentrations in all mixtures was about 3×10^{-2} *M*; the variation in the total concentration for different mixtures was only marginal. In the case of Lys:Asp system, for example, the variation in the total concentration was between 3.48 to 3.14×10^{-2} *M*. The pH of systems, as can be expected, varied markedly, when the mole fraction of the basic amino acid was increased (Fig. 2, inset).

The experimental $\bar{V}^0$(mix) data for the basic–acidic amino acid mixtures were significantly different (see Fig. 2 for Arg:Asp systems) from the data calculated in a way similar to that for Arg/Glu:Gly mixtures. The deviation from the calculated value, $\Delta\bar{V}^0$(mix), $\bar{V}^0_{mix}$(expt) − $\bar{V}^0_{mix}$(calcd), for one mole of the mixture is depicted in Fig. 3 as a function of the mole fraction of the basic amino acid. A reference to the figure shows that $\Delta\bar{V}^0$(mix) is always positive and, further, has a maximal value when $X = 0.5$. The positive deviation in systems with asparatic acid is, interestingly, higher than in mixtures containing glutamic acid at corresponding mole fractions (Fig. 3). Again, between the two basic amino acids, arginine caused a higher deviation than lysine; thus deviations of $\bar{V}^0$(mix) from calculated values were highest for Arg:Asp mixtures.

Large volume changes, as high as 10 cm^3 mol^{-1}, were noticed when pure carboxylic acids are mixed with pure amines (13). Such volume changes are obviously due to the formation of strong salt bridges in the mixture of two pure liquids, which are media of rather low dielectric constant. The present studies were, however, made in aqueous medium, which has a high dielectric constant, and at the low concentrations used in the study ($\simeq 10^{-2}$ *M*), ion pair formation due to "non-specific" ionic interactions is more or less obviated. This is clearly seen from the fact that no volume deviations were observed in glutamic acid/arginine : glycine mixtures, even though the former component has another charge center on the side chain, in addition to the zwitterionic charge centers. The significant observation of volume deviation in the basic:acidic amino acid systems therefore suggests the presence of interactions between the positively charged and negatively charged amino acid side chains.

Monte Carlo simulation studies on clusters consisting of aspartate anion (i) or argininium cation (ii) and 250 water molecules carried out by Ranghino and co-workers (14) showed that at least five water molecules are hydrogen bonded to the side chain COO^- in Asp, while six water molecules are associated with the guanidinium group in Arg, and one of these six is simultaneously linked to α-COO^-. The calculations also showed that there are solvation gaps near the hydrophobic side chain region of Arg. Solvation of charged groups causes the well known "electrostriction" in volumes, which in the case of glycine zwitterion is estimated to be 13.0 cm^3 mol^{-1} (15).

In the crystalline state, ordering of oppositely charged groups is expected and observed (16). However, a very interesting feature reported in the crystal structure of the salt arginine glutamate monohydrate (7) is the following: the positively charged gu^+ group forms two intermolecular H-bonds with the side chain γ-COO^- of Glu and, more importantly, also with a water molecule. Nuclear magnetic resonance studies on the peptides Arg-Glu, and Arg-Ala-Gly-Glu indicated that strong interactions between side chains of Arg and Glu exist (17, 18).

The above literature data suggest firstly, that charge centers in amino acid side chains would be "hydrated" in aqueous solution and, secondly, the geometry of side chain groups provides scope for hydrogen bonds and salt bridges between oppositely charged side chains. The positive volume deviations observed in the present studies point out to "specific" side-chain – side-chain interactions which would, in principle, have electrostatic as well as H-bonding contributions.

It is being increasingly realised that specificity in biological interactions is mediated by electrostatic residues along with hydrogen bonding rather than by the latter alone. This is underscored by our observation that there are no volume changes in mixtures of arginine and glutamine; the $CONH_2$ side chain of Glu is polar but neutral (unpublished results).

The net effect of the interactions in the amino acid mixtures is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

to lift, partially, the solvation of the side chain charge centers, which in turn leads to a decreased "electrostriction" and hence the observed positive deviations in the volumes of the mixtures. The deviation in a given system would be expected to have a maximal value at $X = 0.5$, as in these mixtures the concentration of species with change on the side chains (cation ii and anion i) is maximum; but on changing $X > 0.5$ or < 0.5, the mole fraction of such species of either the basic or acidic amino acid decreased.

The existence of specific interaction between acidic and basic amino acids in dilute aqueous solution has been amply substantiated by the present data. It would be rewarding to unequivocally establish the structure of the interacting complex and the strength of the interaction.

The relative strength of interaction in the four systems under study is as follows:

Arg:Asp > Lys:Asp > Arg:Glu > Lys:Glu

This observation may be explained by the intrinsic acidity of the interacting groups; the δ-guanidinium group in Arg is more basic (pK_a 12.52) than ϵ-$\overset{+}{N}H_3$ of lysine (pK_a 10.78) and the β-carboxyl in Asp is a stronger acidic group (pK_a 3.97) than that at the γ-position in Glu (pK_a 4.36) (11).

Effect of ring substituents on the fluorescence spectra of substituted diarylcarbenes[1]

J. C. SCAIANO AND D. WEIR
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received August 19, 1987

J. C. SCAIANO and D. WEIR. Can. J. Chem. **66**, 491 (1988).

The fluorescence spectra of a series of ring-substituted diarylcarbenes have been examined. The solution spectra are generally red shifted by 25–30 nm with respect to the band positions in matrices at 77 K. The difference is believed to reflect emission from non-relaxed conformations at 77 K. Both electron-withdrawing and -donating substituents lead to red shifts in the emission. These shifts are essentially additive, and the carbene emission data show an excellent correlation with free radical fluorescence data for the corresponding diarylmethyl radicals. The temperature dependence of excited carbene lifetimes have been examined for a few representative examples.

J. C. SCAIANO et D. WEIR. Can. J. Chem. **66**, 491 (1988).

On a examiné les spectres de fluorescence d'une série de diarylcarbènes substitués sur le cycle. Par comparaison avec les spectres déterminés dans des matrices à 77 K, les spectres déterminés en solution sont généralement déplacés vers le rouge par 25 à 30 nm. On croit que la différence est le reflet d'une émission provenant de conformations qui ne sont pas soumises à la relaxation à 77 K. Tant les substituants électroaffinitaires que ceux qui sont électrodonneurs conduisent à des déplacements vers le rouge dans l'émission. Essentiellement, ces déplacements sont additifs et les données d'émission des carbènes présentent une excellente corrélation avec les données de fluorescence des radicaux libres diarylméthyles correspondants. Pour quelques exemples représentatifs, on a examiné l'influence de la température sur les temps de vie des carbènes excités.

Introduction

The fluorescence from diphenylcarbene has been the subject of several studies in glasses at low temperature as well as in solution at room temperature (1–8). For example, the lifetime of excited triplet diphenylcarbene is 123 ns in a methylcyclohexane glass at 77 K (5) and 4.2 ns in cyclohexane at 286 K (8). A recent study has compared the chemical reactivity of excited diphenylcarbene and its ground state in glass at low temperature (7); this work confirms an earlier postulate (4) that reactions of the photoexcited carbene may be involved at long exposure times. The luminescence from a few ring-substituted carbenes has also been examined in glasses at 77 K by Trozzolo and Gibbons (6) and by Ono and Ware (5). There are only two reports on the absorption spectra of excited diarylcarbenes (8, 9).

The chemistry and spectroscopy of excited reaction intermediates is a subject of current interest (10, 11). Processes involving excited reaction intermediates can be quite common under conditions of laser excitation. In this paper we report the results of a systematic study of the effects of ring substituents on the triplet–triplet fluorescence spectra from diarylcarbenes, R^1R^2C:. In a few cases we have also determined the lifetimes of the excited carbenes. Dimesitylcarbene is also the subject of a more detailed study of its transient absorption spectroscopy (12), as well as of its excited state lifetime and intermolecular reactivity.

Experimental

Materials

The majority of the diazo precursors were synthesized via the corresponding tosyl hydrazones using the method reported by Smith and Howard for diphenyldiazomethane (13). Dimesityldiazomethane was from a sample prepared by Dr. H. L. Casal following the synthetic procedure of Zimmerman and Paskovick (14), and mesityl-*o*-tolyldiazomethane had been prepared by Dr. A. S. Nazran. All diazo compounds were purified by sublimation with the exception of the dimesityl and mesityl-*o*-tolyl derivatives which were purified by flash chromatography or alumina (80–200 mesh from Fisher) using hexane as the eluent.

Cyclohexane, benzene (Aldrich, Gold Label), and toluene (BDH, Omnisolv) were used as received.

Luminescence spectroscopy

Our laser flash photolysis system and the modifications for two laser experiments have been described elsewhere (15, 16). In these experiments a Lumonics excimer laser delivering 308 nm pulses (~5 ns, ≦25 mJ/pulse) was used to generate the carbene from its diazo precursor, and a Molectron UV-24 nitrogen laser (337.1 nm, ~8 ns, ≦4 mJ/pulse) were used to excite the carbene. Occasionally a PRA LN-1000 nitrogen laser (~600 ps, ≦1 mJ/pulse) were used in place of the Molectron laser to improve the overall time resolution of the system. The system incorporates a Tektronix R-7912 transient digitizer (for kinetic studies) and an EG&G gated intensified optical multichannel analyzer. Throughout this work the gate was fixed at 20 ns and it was timed to coincide with the nitrogen laser pulse. Suitable cut-off filters were employed to eliminate scattered light from the laser.

In order for the diazo solutions to be adequately absorbing at 308 ns, while essentially transparent at 337.1 nm, it is necessary to use very dilute samples (typically $2–5 \times 10^{-5}$ *M*). Under these conditions each 308 nm laser shot causes significant diazo depletion; it was thus necessary to use a flow system to ensure that each pulse irradiated a fresh portion of solution. The cell compartment was constructed of 7×7 mm^2 Suprasil tubing and was connected with Teflon lines to reservoir in which the solutions were deaerated by a stream of nitrogen. The cell temperature was controlled by using an outer quartz jacket and flowing nitrogen at the appropriate temperature around the sample compartment and a pre-equilibration coil.

Results and discussion

The fluorescence spectra for most carbenes were recorded in benzene, where hydrogen abstraction can be ruled out. The general, one- (308 nm) or two-laser (308 followed by 337 nm) excitation led to the same emission spectra, which were readily recorded using the techniques described in the Experimental section. Generation of excited carbenes under conditions of single pulse excitation is not unexpected, since the processes leading to triplet carbene formation (i.e. diazo photodecomposition followed by carbene intersystem crossing) usually occur in

the subnanosecond time scale (17). This allows for subsequent carbene excitation within the single (~5 ns) 308 nm laser pulse. Though these processes are not uncommon, they are frequently ignored in laser photolysis studies of carbene reactions.

Table 1 gives the positions of the fluorescence maxima (λ_{max}) for the various carbenes. We note that while we report λ_{max} in most cases the shape of the spectra are such (Fig. 1) that the position of λ_{max} coincides with the 0,0 band ($\lambda_{0,0}$). Whenever possible we have also included values of $\lambda_{0,0}$ for glasses at 77 K. Both electron-withdrawing and -donating substituents lead to red shifts in the emission spectra. This is shown in Fig. 1 where we compare the fluorescence spectra of the methyl and cyano derivatives with that of the parent diphenylcarbene. The situation is similar to that previously encountered in the case of ring-substituted diphenylmethyl radicals (18). Only in the case of dimesitylcarbene do we observe a blue shift in the emission spectrum. This is probably due to geometrical changes induced by steric crowding of the *ortho*-methyl groups.

For carbenes with one substituent per aromatic ring we find the spectral shifts to be essentially additive. For example, for 4-cyano-4-methyldiphenylcarbene, λ_{max} = 543 nm, corresponding to a 38 nm shift with respect to the parent carbene. For comparison the shifts for 4-cyanodiphenylcarbene and 4-methyldiphenylcarbene are 31 and 6 nm, respectively. The same pattern is observed throughout; note for example that each *para*-chloro substituent leads to approximately an 11 nm shift.

For those carbenes where a comparison is possible, we find that the solution fluorescence is red-shifted by about 25–30 nm with respect to the band position at 77 K (5, 6). We attribute these shifts to emission from non-equilibrium conformations at low temperature. Griller *et al.* (19) have used solid state epr methods to demonstrate that dimesitylcarbene can remain in non-equilibrium conformations (presumably with a diazo-like geometry) for extended periods of time, and that the structural relaxation can be achieved by matrix annealing. For example, when an isopentane/ether matrix containing dimesitylcarbene is annealed (by warming from 77 to 188 K) the carbene R^1—C̈—R^2 angle increases towards a more linear equilibrium conformation which is not lost upon re-cooling to 77 K. In this example it is the ground state carbene which retains a non-equilibrium (19) conformation; in the examples in Table 1, it is possible that even if the ground state carbene can relax, it is quite conceivable that in a matrix the excited state retains a ground state like conformation during its short lifetime.

The questions mentioned above were further explored by examining the temperature dependence of the fluorescence lifetimes of these carbenes. The studies were carried out in toluene solutions of ~5×10^{-5} *M* diazo precursor. Figure 2 shows the corresponding Arrhenius plots. Both dimesitylcarbene and *o*-tolylmesitylcarbene show temperature-dependent fluorescent lifetimes. Both plots are curved and approach

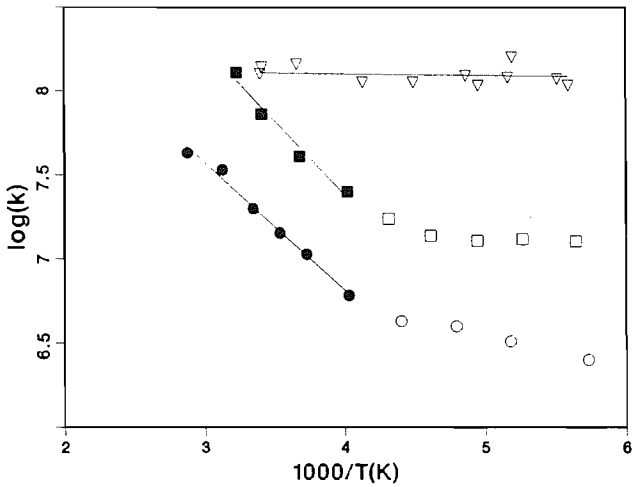

FIG. 2. Arrhenius plots illustrating the temperature dependence of the excited carbene lifetimes for dimesitylcarbene (○, ● from ref. 12), *o*-tolylmesitylcarbene (□, ■) and 4,4′-dimethyldiphenylcarbene (▽). Rate constants in s^{-1}.

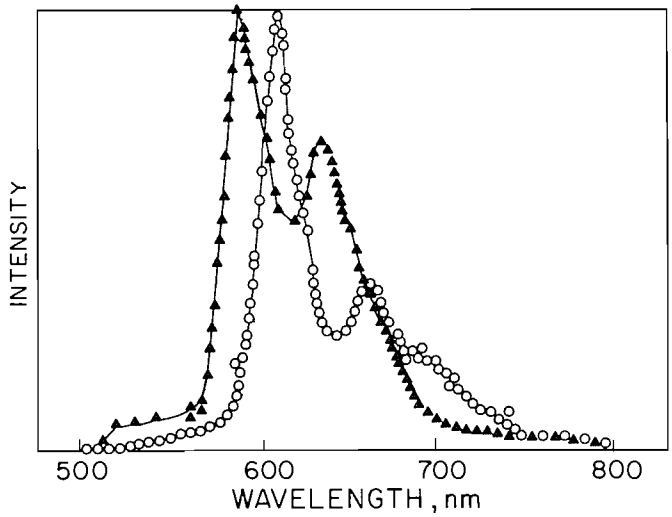

FIG. 3. Room temperature fluorescence spectra for phenyl-2-naphthylcarbene (▲) in benzene, and for the 2-naphthylmethyl radical (○).

plateau regions at low temperature. For example, for *o*-tolylmesitylcarbene the lifetime is ~80 ns at the lowest temperature and seems to extrapolate well to the value of 162 ns determined for the short component (*vide infra*) at 77 K. No temperature dependence was observed for di-*p*-tolylcarbene between 178 and 293 K. Using the high temperature data we determine the activation energies of 3.2 kcal/mol (log (A/s^{-1}) = 9.7) and 3.6 kcal/mol (log (A/s^{-1}) = 10.6) for dimesitylcarbene and *o*-tolylmesitylcarbene, respectively. These activation energies may reflect energy requirements introduced by steric restrictions to excited state relaxation. The emission spectra from phenyl-2-naphthylcarbene (λ_{max} = 588 nm) is not only shifted by 83 nm with respect to diphenylcarbene but also shows well resolved vibrational structure (Fig. 3), a feature that is not present for the other carbenes examined in this work (compare with Fig. 1). Interestingly the carbene fluorescence spectrum is very similar to that from 2-naphthylmethyl radical (20) also included in Fig. 3. This suggests that the carbenic electrons are extensively delocalized on the 2-naphthyl group. The

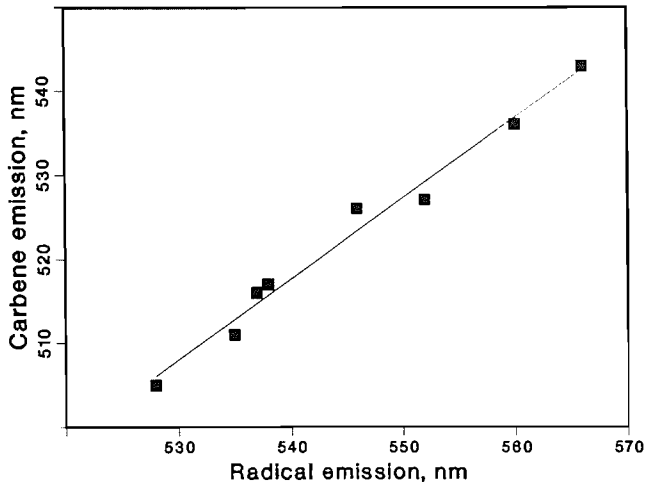

FIG. 4. Correlation between free radical and carbene luminescence spectra (see text).

vibrational separation corresponds to ~1280 cm^{-1} is similar to that in benzylic (21) and diphenylmethyl radicals (22).

It is rather interesting that while there is no correlation with the electron-withdrawing/releasing ability of the substituent, there is a remarkably good correlation between the λ_{max} position for the carbene fluorescence and for the corresponding diarylmethyl radicals which were the subject of a previous study (18). This correlation is shown in Fig. 4. The radical spectra were obtained in cyclohexane following hydrogen abstraction by the photogenerated carbene (18). The plot of Fig. 4 yields:

$$\lambda_{max}(\text{carbene}) = -1.7 \text{ nm} + 0.962\lambda_{0,0}(\text{radical})$$

with a correlation coefficient of 0.991 and λ_{max} and $\lambda_{0,0}$ in nanometers. A similar correlation can be established in terms of frequency (in cm^{-1}, not shown) and yields:

$$\lambda_{max}^{-1}(\text{carbene}) = -102 \text{ cm}^{-1} + 1.049\lambda_{0,0}^{-1}(\text{radical})$$

where λ_{max}^{-1} and $\lambda_{0,0}^{-1}$ are in cm^{-1}.

Figure 4 suggests that the same factors that determine the spectroscopic properties of excited free radicals also determine the properties of excited carbenes. A similar parallel is well established in the case of the absorption spectra of the ground state of diaryl radicals and carbenes (23, 24).

Table 2 shows a summary of the room temperature excited carbene lifetimes, along with low temperature data. In the case of free radicals we have reported an inverse correlation between the excited state lifetimes and the energy separation between the ground state and the first excited state (18). On the basis of the limited data available in Table 2 it would appear that a similar correlation does not apply in the case of carbenes. Note for example that the lifetime is longer for di-*p*-tolylcarbene compared with diphenylcarbene in spite of the red shift observed in the fluorescence spectra.

Finally, a separate study of carbene photophysics in matrices suggests that their decay frequently does not follow single exponential behaviour,[2] even in very dilute diazo solutions ($<10^{-5}$ *M*) where formation of microcrystals is unlikely. For example, for *o*-tolylmesitylcarbene in a methylcyclohexane matrix at 77 K we observe a biexponential decay with 162 and 830 ns lifetimes. It is conceivable that the two may correspond

to geometrically relaxed and unrelaxed carbenes. The details of these studies will be reported elsewhere.

Conclusion

The T_1–T_0 fluorescence spectra of several diarylcarbenes have been obtained in fluid solution. The carbene fluorescence maxima show an excellent correlation with the position of the D_1–D_0 fluorescence 0,0 bands for the corresponding diaryl radicals. The lifetimes of dimesitylcarbene and *o*-tolylmesitylcarbene show temperature-dependent behaviour which appears to result from hindered aryl motion in the excited state, reflecting the effect of the *ortho*-methyl groups. Relaxation modes involving ring motions (rotation?) may be shut-off at low temperatures, since the lifetimes appear to reach a plateau value and are much longer than those observed in unhindered carbenes. For example, in di-*p*-tolycarbene its lifetime in solution is essentially temperature independent in the 178 to 298 K range.

The fluorescence in matrices is blue shifted with respect to the solution (relaxed) spectra, suggesting that emission in matrices may occur from non-equilibrium conformations.

Neutron scattering cross sections for methyl groups and tetrahedral molecules

D. W. MATUSCHEK[1] AND A. HÜLLER

Institut für Theoretische Physik I, Universität Erlangen-Nürnberg, Glückstr. 6, 8520 Erlangen, West Germany

Received October 2, 1987

D. W. MATUSCHEK and A. HÜLLER. Can. J. Chem. **66**, 495 (1988).

Neutron scattering intensities for librational excitations of molecules provide valuable information for separating librations from translational lattice modes. We have calculated the intensities for transitions from levels within the ground state multiplet to excited states for XH_3 molecules rotating around their symmetry axis and for XH_4 molecules performing three dimensional rotations. These intensities depend characteristically on the momentum transfer which should allow one to distinguish them from translational modes and from each other. These results may be used to verify assignments of lines which in the past have been based on less reliable criteria.

D. W. MATUSCHEK et A. HÜLLER. Can. J. Chem. **66**, 495 (1988).

Les intensités de la diffusion neutronique des excitations librationnelles des molécules fournissent des informations précieuses pour discerner entre les librations et les modes de translation du réseau. Pour des molécules XH_3 tournant autour de leur axe de symétrie et pour des molécules XH_4 soumises à des rotations en trois dimensions, on a calculé les intensités des transitions à partir de niveaux à l'intérieur du multiplet de l'état fondamental jusqu'aux états excités. Ces intensités dépendent d'une façon caractéristique sur le moment de transfert et cette propriété doit permettre de les distinguer entre eux ainsi que des modes de translation. On suggère d'utiliser ces résultats pour vérifier les attributions des raies qui ont été faites antérieurement sur des bases moins rigoureuses.

1. Introduction

The spectroscopy of single particle rotations (1) in crystals is currently of considerable interest. The combined analysis of tunnelling features in the μeV regime and librational excitations around 10 meV has in some cases permitted a determination of the rotational potential (2–6). The data interpreted are usually experimentally measured frequencies, but intensities also contain valuable information. Calculated structure factors for tunnelling transitions (7) have been successfully used to assign tunnelling lines for physisorbed methane.

The assignment of librations is often a problem because they usually fall into a frequency range where the density of states of the translational modes also has maxima. In this case one may sometimes argue that at low temperatures the librations of hydrogen-containing molecules are the strongest features in the spectrum and that they are rapidly smeared when temperatures increase. In many cases this is not a safe statement. In a few cases several librational peaks have been measured (8) and it would be highly advantageous to uniquely assign the different lines to transitions between rotational states with definite quantum numbers.

Two recent experiments have prompted us to undertake a calculation of the structure factors for librational transitions. One is the Li acetate experiment (5) and its difficulties in assigning observed librational peaks to calculated transition frequencies (9). The second experiment (10) concerns the librational excitations in solid methane. There the ground state tunnelling splitting is 210 μeV or 2.5 K. Above liquid helium temperature the A, T, and E levels in ground state multiplet are all populated, giving rise to allowed transitions to excited librational states. For $T = 0.1$ mK only the A states are occupied and indeed the experiment shows significant changes in the spectrum. Some of the lines disappear whereas other lines show a dramatic increase in intensity. To better interpret these findings we calculated the transition matrix elements between states of definite symmetry within the ground state multiplet to the excited states.

[1]Present address: Physikalisches Institut EP IV, Universität Bayreuth, 8580 Bayreuth, West Germany.

We begin with the XH_3 groups rotating around the threefold symmetry axis. Here the rotational wave functions are well known (Mathieu problem) and the operator causing transitions can be expanded into a Fourier series in the operator for the rotation angle. The calculated results are scattering cross sections for individual transitions valid for all values of the momentum transfer. For XH_4 molecules with three rotational degrees of freedom the eigenstates are approximated by a linear combination of pocket states. With these states we find an expansion of the cross section valid for small values of momentum transfer. We observe marked differences in the intensities of individual transitions. These can be used to interpret temperature scans as in ref. 10. Despite the fact that the calculations are made for the spin-dependent part of the scattering length of the protons there is a pronounced dependence on the momentum transfer $\boldsymbol{Q}$. Angle dependencies are hard to measure. Therefore we have performed powder averages which show a characteristic $|\boldsymbol{Q}|$ dependence. We propose to exploit this $|\boldsymbol{Q}|$ dependence of the scattering cross section for a reliable assignment of the librational lines.

II. Neutron scattering cross section

The spin-dependent part of the double differential cross section for scattering of unpolarized neutrons by a single molecule with N hydrogen atoms is given by

$$[1]\qquad \frac{d^2\sigma}{d\Omega\, dE}(\boldsymbol{Q}) = \frac{8}{3} a_{sd}^2 \frac{k'}{k} \times \sum_{i,f} p_i \sum_{\mu,\mu=\pm 1/2} |\langle \mu' | \langle f | \hat{W} | i \rangle | \mu \rangle|^2 \times \delta(\hbar\omega + E_i - E_f)$$

with the operator $\hat{W}$ for the interaction between a neutron and the molecule

$$[2]\qquad \hat{W} = \sum_{j=1}^{N} \hat{\boldsymbol{S}}\hat{\boldsymbol{I}}(j) \exp\left(i\boldsymbol{Q}\hat{\boldsymbol{R}}(j)\right)$$

where $|\mu\rangle$, $|\mu'\rangle$ are the spin states and k, k' are the moduli of the wave vectors of the neutron before and after scattering, respectively; $|i\rangle$ and $|f\rangle$ are the initial and final states of the

Printed in Canada / Imprimé au Canada

molecule; E_i and E_f are the corresponding energies; p_i denotes the probability for the population of the initial state $|i>$ of the molecule; $\hat{\boldsymbol{S}}$, $\hat{\boldsymbol{I}}(j)$, and $\hat{\boldsymbol{R}}(j)$ are the operators for the neutron spin and the spin and the position of the jth hydrogen atom, respectively; $\hbar\boldsymbol{Q}$ and $\hbar\omega$ denote the momentum and the energy transferred to the molecule. The spin-dependent scattering length a_{sd} is proportional to the difference of the scattering lengths a_+ and a_- for parallel and antiparallel orientation of the spin of the neutron and the proton, respectively:

$$[3] \qquad a_{sd} = (3^{1/2}/4)(a_+ - a_-)$$

To calculate the matrix element in [1], the molecular eigenstates have to be known.

III. Molecular eigenstates

(1) General

A simple model for the description of the molecular motion is a rigid rotator which neglects translations and internal vibrations of the molecule. Molecules in a solid generally do not rotate freely. Hence they can be described by Hamiltonians of the form

$$[4] \qquad \hat{H} = \hat{\boldsymbol{L}}^2/2\theta + \phi(\hat{\alpha})$$

with the operator $\hat{\boldsymbol{L}}$ of the angular momentum and the operator $\phi(\hat{\alpha})$ of an angle-dependent potential ($\hat{\alpha}$ denotes an operator for the rotational angles; θ is the moment of inertia). Furthermore, it is assumed that the only symmetry operations with respect to which the Hamiltonian is invariant are the rotations which map the molecule upon itself.

In this model the molecular eigenstates are elements of the product space $\mathcal{H}^{rot} \otimes \mathcal{H}^{spin}$ which is built from Hilbert spaces for rotational states and spin states. The atoms at the corners of the rotating molecule XH_N are indistinguishable. Therefore the eigenstates have to belong to the irreducible representation A of the group A_N of the even permutations of N particles. Because rotational eigenstates are basis states of the irreducible representation of group A_N, it is useful to classify the spin states according to their relationship to these irreducible representations. Then one can project the products of the symmetrized rotational states and the symmetrized spin states upon the states out of $\mathcal{H}^{rot} \otimes \mathcal{H}^{spin}$ which correspond to the irreducible representation A.

(2) Rotational states

Rotational states are often obtained by inserting an expansion into free rotator states in the Schrödinger equation. Eigenstates for the one dimensional rotator XH_3 and rotational potential $\phi(\alpha) = V\cos(3\alpha)$ are calculated this way.

Another way to obtain at least approximate rotational eigenstates is to use the concept of the pocket states (11). A pocket state is described by a wave function which shows a maximum at an orientation with minimal potential energy and decreases rapidly with deviations from this orientation. Because of the symmetry of the rigid molecule XH_N and its surroundings in our model, there exist $\frac{1}{2}N!$ such minima corresponding to even permutations. For strong potentials certain linear combinations of these pocket states are considered good approximations for the eigenstates (12). To describe different rotational excitations of the molecule one needs various pocket states which correspond to wave functions differing in the number of nodes. The pocket states are denoted by $|\lambda^{(\delta)}>$, where $\lambda = 1, \ldots, N$ counts the energetically equivalent minima, and the index δ denotes the rotational excitation. In the following only the rotational ground states ($\delta = 0$) and the first excited states ($\delta = 1$) are considered. For convenience the index δ is suppressed when it is not important. With one pocket state $|1>$ given, the others follow by rotations:

$$[5] \qquad |\lambda> = \hat{P}_\lambda|1>, \quad \hat{P}_\lambda^+\hat{P}_\lambda = \hat{1}, \quad \lambda = 1, \ldots, \tfrac{1}{2}N!$$

The unitary operators $\hat{P}_\lambda$ describe the symmetry operations of the molecule in its surroundings and hence form the symmetry group A_N of the problem.

The required rotational eigenstates are the basis states of the irreducible representations of the symmetry group. They are built by application of the projectors

$$[6] \qquad \hat{O}_k^\Gamma = \frac{d(\Gamma)}{g}\sum_{\lambda=1}^{g} D_{kk}^\Gamma(\lambda)^*\hat{P}_\lambda, \quad 1 \le k \le d(\Gamma)$$

to the pocket states. $g = \frac{1}{2}N!$ and $d(\Gamma)$ in [6] are the dimensions of the group and of the irreducible representation Γ, respectively. $D_{kk}^\Gamma(\lambda)^*$ is the complex conjugate of the kth diagonal element of the unitary matrix $D^\Gamma(\lambda)$ of the irreducible representation Γ.

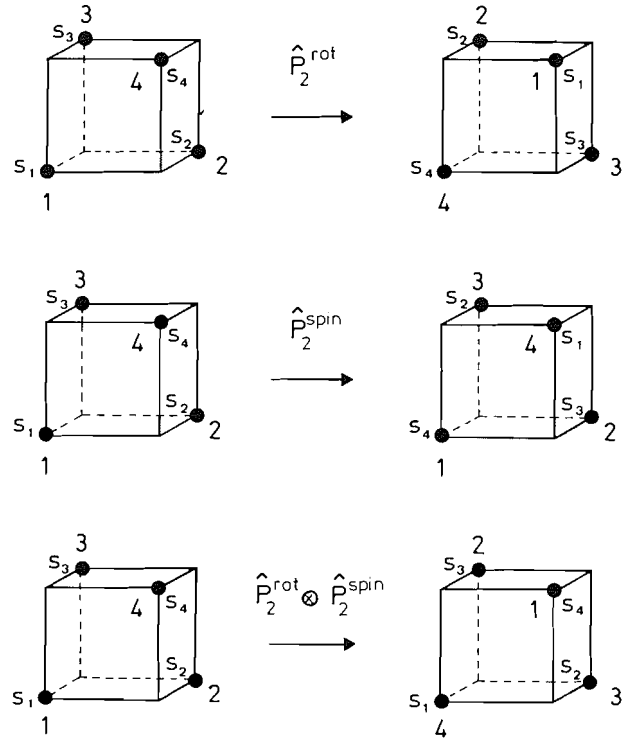

FIG. 1. Example for the action of permutations of the coordinates and the spin values of a tetrahedral molecule. j and S_j denote the number of an atom and the value of the corresponding spin, respectively ($j = 1, 2, 3, 4$).

(3) Spin states

The construction of basis states of the irreducible representations in spin space $\mathcal{H}^{spin}$ is again made by the application of projectors $\hat{O}_k^\Gamma$ from [6] to the product basis of the spin space of the N hydrogen atoms. But now the operators $\hat{P}_\lambda$ on $\mathcal{H}^{spin}$ are interpreted as operators for the permutation of spins similar to $\hat{P}_\lambda$ on $\mathcal{H}^{rot}$ are interpreted as operators for the permutation of the spatial coordinates (cf. Fig. 1).

$$[7] \qquad \hat{P}_\lambda|s_1 \ldots s_N> = |s_{\pi_\lambda(1)} \ldots s_{\pi_\lambda(N)}>$$

for each permutation π_λ of the alternating group A_N ($\lambda = 1, \ldots, \frac{1}{2}N!$).

For personal use only.

(4) Complete states of A *symmetry*

To obtain the required molecular eigenstates one has to project upon the states of irreducible representation A in $\mathcal{H}^{\text{rot}} \otimes \mathcal{H}^{\text{spin}}$. This is done by applying the projector

$$[8] \qquad \hat{O}^A = \frac{1}{g} \sum_{\lambda=1}^{g} \hat{P}_\lambda^{\text{rot}} \otimes \hat{P}_\lambda^{\text{spin}}$$

to the products of symmetrized rotational states and symmetrized spin states and by normalization.

IV. Decomposition of $\hat{W}$

It is useful to factorize operator $\hat{W}$ into parts $\hat{W}_\gamma$ which transform under spatial rotations according to irreducible representations γ of symmetry group A_N:

$$[9] \qquad \hat{W} = \sum_\gamma \hat{W}_\gamma$$

For XH_3 and XH_4, $\hat{W}_\gamma$ is proportional to the product of operator $\hat{G}_\gamma$ involving the position operators and operator $\hat{S}_{\gamma^*}$ which involves the spin operators:

$$[10] \qquad \hat{G}_\gamma = \sum_{j=1}^{N} g_\gamma(j) \exp(i\boldsymbol{Q}\hat{\boldsymbol{R}}(j)), \quad \hat{S}_\gamma = \sum_{j=1}^{N} g_\gamma(j)\hat{\boldsymbol{S}}\hat{\boldsymbol{I}}(j)$$

Under permutations of the spins S_{γ^*} transforms according to the complex conjugate of irreducible representation γ.

The matrix elements of $\hat{W}_\gamma$ corresponding to states with rotational parts of symmetry Γ' and Γ vanish if the product $\Gamma'^* \otimes \gamma \otimes \Gamma$ does not contain the irreducible representation A.

V. Applications

(1) The one-dimensional rotator XH_3

(a) Molecular eigenstates

At low temperatures XH_3 (e.g. a methyl group) rotates around the axis of the bond to the rest of the molecule. Because of the molecular symmetry the angle-dependent potential is invariant under operations of group A_3:

$$[11] \qquad \phi(\alpha + 2\pi/3) = \phi(\alpha)$$

Bloch's theorem (13) dictates that the rotational eigenstates of the Hamiltonian with this periodic potential are characterized by a librational index (the usual band index) $n = 0, 1, 2, \ldots$ and a symmetry label (the usual wave number) $\varkappa = -1, 0, +1$:

$$[12] \qquad <\alpha|n, \varkappa> = \exp(i\varkappa\alpha) u_{n,\varkappa}(\alpha)$$

with a $2\pi/3$ periodic function $u_{n,\varkappa}(\alpha)$.

They are basis states of the irreducible representations A, E^a, and E^b (for $\varkappa = 0, +1, -1$, respectively) of the group A_3. For simplicity the potential will be approximated by the first term $V \cos(3\alpha)$ of the appropriate Fourier series. The potential strength V is measured in units of the rotational constant, $B = \hbar^2/2\theta$, of XH_3. If one writes the periodic function $u_{n,\varkappa}$ as a Fourier series, one obtains a recursion formula for the Fourier coefficients by inserting the Fourier series for $<\alpha|n, \varkappa>$ into the time-independent Schrödinger equation. Consequently the rotational eigenstates are known.

To obtain the eigenstates in $\mathcal{H}^{\text{rot}} \otimes \mathcal{H}^{\text{spin}}$ the rotational states with A, E^a, and E^b symmetry have to be combined with spin states with A, E^b, and E^a symmetry, respectively (see ref. 8). The symmetrized spin states are found in ref. 1. For each librational index there is one level with four states of symmetry A (spin 3/2) and one level with twice two eigenstates of symmetry E (spin 1/2).

To test how well a pocket state approach yields the cross sections the rotational states are approximated by linear combinations of pocket states. To each equivalent orientation of a XH_3 group a pocket state $|1>$, $|2>$, or $|3>$ is assigned. With these pocket states the librational ground states ($\delta = 0$) and the first excited librational states ($\delta = 1$) are constructed as basis states of the irreducible representations A, E^a, and E^b ($\varkappa = 0, +1, -1$, respectively):

$$[13] \qquad |\delta, \varkappa> \cong 3^{-1/2}(|1^{(\delta)}> + \epsilon^{-\varkappa}|2^{(\delta)}> + \epsilon^{\varkappa}|3^{(\delta)}>)$$

$$\epsilon = \exp(i2\pi/3)$$

The corresponding wave functions are chosen to be

$$[14] \qquad <\alpha|1^{(0)}> = (\pi\rho^2)^{-1/4} \exp(-\alpha^2/2\rho^2)$$
$$<\alpha|1^{(1)}> = (\pi\rho^6)^{-1/4}\, \alpha \exp(-\alpha^2/2\rho^2)$$

which are normalized

$$[15] \qquad <1|1> = \int_{-\pi}^{+\pi} |<\alpha|1>|^2 \, d\alpha \cong \int_{-\infty}^{+\infty} |<\alpha|1>|^2 \, d\alpha = 1$$

The other wave functions follow from $<\alpha|1>$ by

$$[16] \qquad <\alpha|2> = <\alpha + 2\pi/3|1>, \quad <\alpha|3> = <\alpha - 2\pi/3|1>$$

The connection between the parameter ρ for the width of the wave functions and the potential strength V is made by the Ritz variational principle.

(b) Fourier series for $\hat{W}$

The interaction operator $\hat{W}$ reads

$$[17] \qquad \hat{W} = \frac{1}{3} \sum_{s=-1}^{+1} \hat{S}_{-s}\hat{G}_s$$

where

$$\hat{S}_s = \hat{\boldsymbol{S}}(\hat{\boldsymbol{I}}(1) + \epsilon^{-s}\hat{\boldsymbol{I}}(2) + \epsilon^{s}\hat{\boldsymbol{I}}(3))$$

$$[18] \qquad \hat{G}_s = \exp(i\boldsymbol{Q}\hat{\boldsymbol{R}}(1)) + \epsilon^{-s} \exp(i\boldsymbol{Q}\hat{\boldsymbol{R}}(2)) + \epsilon^{s} \exp(i\boldsymbol{Q}\hat{\boldsymbol{R}}(3))$$

$$\epsilon = \exp(i2\pi/3)$$

$s = +1, 0, -1$ corresponds to the symmetry E^a, A, E^b, respectively. To obtain a Fourier series for the operator $\hat{G}_s$ it is useful to introduce the following space fixed coordinate system (cf. Fig. 2). The x–y plane is the rotational plane of the XH_3 with the z axis as the rotational axis. q is the projection of $\boldsymbol{Q}$ into the x–y plane; q denotes its modulus. ϕ and θ are azimuthal and polar angles of $\boldsymbol{Q}$.

Now the scalar products are

$$[19] \qquad \boldsymbol{QR}(j) = \boldsymbol{qR}(j) = qr \times \begin{cases} \cos(\alpha - \phi) & j = 1 \\ \cos(\alpha - \phi + 2\pi/3) & \text{if } j = 2 \\ \cos(\alpha - \phi - 2\pi/3) & j = 3 \end{cases}$$

where $r = |\boldsymbol{R}(j)|$ is the radius of the methyl group.

With these expressions the Fourier expansion of the operator $\hat{G}_s$ reads (cf. Appendix A)

$$[20] \qquad \hat{G}_s = 3\sum_{l \in Z} I_{|3l+s|}(iqr) \exp[i(3l + s)(\hat{\alpha} - \phi)]$$

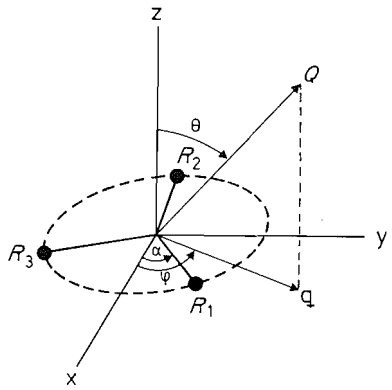

FIG. 2. Space fixed coordinate system for an XH_3 group ($\boldsymbol{R}_j$ denotes the positions of the protons, $j = 1, 2, 3$, ϕ and θ characterize the orientation of the momentum transfer $\boldsymbol{Q}$.

$\hat{\alpha}$ is the operator for the rotational angle, I_m denotes the modified Bessel function of the first kind and of order m; Z is the set of all integers.

(c) Calculation of the matrix elements of $\hat{W}$

The determination of the matrix elements of $\hat{G}_s$ reduces to the calculation of

$$[21] \quad <n',\varkappa'|\exp(i(3l+s)(\hat{\alpha}-\phi))|n,\varkappa>$$

This matrix element equals the integral over all rotational angles:

$$[22] \quad \int_{-\pi}^{+\pi} <n',\varkappa'|\alpha><\alpha|n,\varkappa>\exp(i(3l+s)(\hat{\alpha}-\phi))\mathrm{d}\alpha = 2\pi[\exp(-i(3l+s)\phi)P(n,\varkappa,n',\varkappa',s,l)f(\varkappa,\varkappa',s)$$

with the abbreviations

TABLE 1. Selection rule $f(\varkappa,\varkappa',s)$

		$\varkappa$		
s	$\varkappa'$	-1	0	$+1$
-1		0	1	0
0	-1	1	0	0
$+1$		0	0	1
-1		0	0	1
0	0	0	1	0
$+1$		1	0	0
-1		1	0	0
0	$+1$	0	0	1
$+1$		0	1	0

$$[23] \quad P(n,\varkappa,n',\varkappa',s,l) = \sum_{p\in Z}^{*} a_{n'\varkappa'}(p+l+\eta)a_{n\varkappa}(p)$$
$$\eta = (\varkappa-\varkappa'+s)/3$$

where $a_{n\varkappa}(p)$ denotes the Fourier coefficients in the expansion of $<\alpha|n,\varkappa>$. In the pocket state approach (where $n = 0$ and $n' = 1$) the expression [21] can be calculated by neglecting the overlaps as a Fourier integral and [23] is replaced by

$$[23a] \quad P(n,\varkappa,n',\varkappa',s,l) = i(3l+s)\rho\exp(-(3l+s)^2\rho^2/4)/(2^{3/2}\pi)$$

which is obviously independent of $\varkappa$ and $\varkappa'$.

For fixed $\varkappa$ and $\varkappa'$ the function $f(\varkappa,\varkappa',s)$ equals unity for exactly one value of $s \in \{-1, 0, +1\}$ and vanishes otherwise (cf. Table 1). The squared modulus of the required matrix element of $\hat{G}_s$ is

$$[24] \quad |<n',\varkappa'|\hat{G}_s|n,\varkappa>|^2 = 9\sum_{l,l'\in Z} I_{|3\lambda'+s|}(iqr)^* I_{|3l+s|}(iqr)\exp(i3(l'-l)\phi) \times 4\pi^2 P(n,\varkappa,n',\varkappa',s,l')^* P(n,\varkappa,n',\varkappa',s,l)f(\varkappa,\varkappa',s)$$

So far one would obtain scattering cross sections which depend on the direction of the momentum transfer (characterized by ϕ and $q = Q\sin\theta$) and hence are adapted for scattering by single crystals. For powder samples one needs the squared matrix element [24] averaged over all orientations of $\boldsymbol{Q}$ (cf. Appendix B):

$$[25] \quad g_s(n,\varkappa,n',\varkappa') = (4\pi)^{-1}\int|<n',\varkappa'|\hat{G}_s|n,\varkappa>|^2\mathrm{d}\Omega = (9/2)\sum_{l\in Z}\int_0^{\pi}|I_{|3l+s|}(iQr\sin\theta)|^2\sin\theta\,\mathrm{d}\theta \times 4\pi^2|P(n,\varkappa,n',\varkappa',s,l)|^2 f(\varkappa,\varkappa',s)$$

where

$$[26] \quad \int_0^{\pi}|I_{|3l+s|}(iQr\sin\theta)|^2\sin\theta\,\mathrm{d}\theta = 2(-1)^{l+s}\sum_{p\geq|3l+s|}\frac{(-Q^2r^2)^p}{(2p+1)(p+|3l+s|)!(p-|3l+s|)!}$$

By interchanging the order of the two sums over l and p in [25] the following series results (cf. Appendix C)

$$[27] \quad g_s(n,\varkappa,n',\varkappa') = 9\sum_{p\geq 1}\frac{(-Q^2r^2)^p}{2p+1}\sum_{l=-\mathrm{Int}\left[\frac{p+s}{3}\right]}^{\mathrm{Int}\left[\frac{p-s}{3}\right]}\frac{(-1)^{l+s}}{(p+|3l+s|)!(p-|3l-s|)!} \times 4\pi^2|P(n,\varkappa,n',\varkappa',s,l)|^2 f(\varkappa,\varkappa',s) + 9\delta_{n,n'}\delta_{\varkappa,\varkappa'}$$

where Int ( ) denotes the integer part of a number. The spin-dependent factors

$$[28] \quad F(\varkappa,\varkappa') = (1/9)\sum_{\mu,\mu'=\pm 1/2}\sum_{\varkappa_\varkappa\varkappa'_{\varkappa'}}|<\mu'|<\varkappa'_{\varkappa'}|\hat{S}_{-s}|\varkappa_\varkappa>|\mu>|^2$$

are easily calculated with the knowledge of the spin matrix of XH_3 (14).[2] $|\varkappa_\varkappa>$ and $|\varkappa'_{\varkappa'}>$ are the spin states belonging to the rotational states $|n,\varkappa>$ and $|n',\varkappa'>$, respectively. $|\mu>$ and $|\mu'>$ are spin states of the neutron before and after scattering. The values of $F(\varkappa,\varkappa')$ are given in Table 2.

[2]To get $F(\mathcal{H},\mathcal{H}')$, the values in Table 1 of ref. 14 have to be divided by 3.

0	5/6	1/3	1/3
+1	1/3	1/12	1/3
−1	1/3	1/3	1/12

(d) Results

The scattering cross section for the transition $n\varkappa \rightarrow n'\varkappa'$ is given by

$$[29]\quad \frac{d^2\sigma}{d\Omega dE}(n\varkappa \rightarrow n'\varkappa') = (8k'/3k)a_{sd}^2 p_{n,\varkappa} F(\varkappa,\varkappa') \times g_s(n,\varkappa,n',\varkappa')\delta(\hbar\omega + E_{n\varkappa} - E_{n'\varkappa'})$$

For thermal energies which are high compared to the tunnelling energy and low compared to the energy of the librational excitation, the multiplet of the ground states ($n = 0$) is equally populated whereas all other states are not occupied. The cross sections for the transitions between the energy levels are obtained by addition of the cross sections for the transitions between the adequate states:

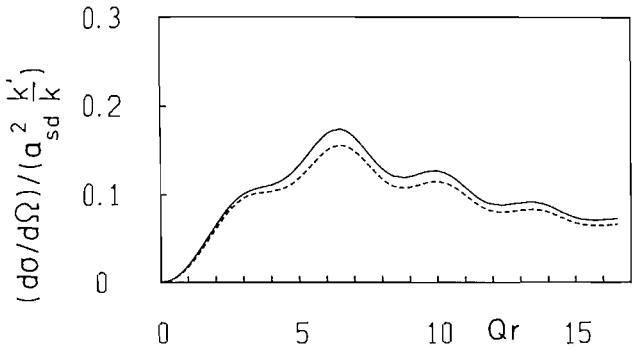

FIG. 3. Cross sections for calculations with exact rotational states (dashed line) and pocket states (solid line) for an XH_3 group and a potential strength of $20B$ (transition $0A \rightarrow 1E$).

$$[30]\quad \frac{d^2\sigma}{d\Omega dE}(0\Gamma \rightarrow n\Gamma', Q) = (k'/3k)a_{sd}^2\delta(\hbar\omega + E_{0\Gamma} - E_{n\Gamma'}) \times \begin{cases} (5/6)g_0(0,0,n,0) & \Gamma = A,\ \Gamma' = A \\ (1/3)[g_{+1}(0,0,n,+1) + g_{-1}(0,0,n,-1)] & \Gamma = A,\ \Gamma' = E \\ (1/3)[g_{-1}(-1,0,n,0) + g_{+1}(0,+1,n,0)] & \text{if}\quad \Gamma = E,\ \Gamma' = A \\ (1/3)[g_{+1}(0,+1,n,-1) + g_{-1}(0,-1,n,+1)] & \\ \quad + (1/12)[g_0(0,+1,n,+1) + g_0(0,-1,n,-1)] & \Gamma = E,\ \Gamma' = E \end{cases}$$

The leading term in Q of the cross section for the transition $0A \rightarrow nA$ is Q^6. Therefore, the cross section for this transition is suppressed for $Qr \lesssim 2$ as seen in Fig. 3 where the cross sections for equal population of the whole librational multiplet are plotted. In Fig. 4 the result of the pocket state approach is compared with the calculation with the exact wave functions. For a potential strength of $20B$ or more, the deviations do not exceed 10% even for large momentum transfers $Qr > 2$. Therefore one can hope that also in the case of XH_4 and for sufficiently strong potentials the rotational states would well be approximated by linear combinations of pocket states. If the potential strength increases, the intensities grow for large momentum transfers and decrease for small momentum transfers.

(2) The three dimensional rotator XH_4

(a) Molecular eigenstates

Here a tetrahedral molecule in surroundings with tetrahedral symmetry is considered. To describe the rotational motion of the molecule, one has to find the eigenstates of the Hamiltonian [4] where the potential energy shows 12 equivalent pockets corresponding to the 12 symmetry operations of the group A_4. The orientation of the molecule with respect to its surroundings is described by a normalized quaternion τ (11).

Hence the potential energy is defined as a function on the unit sphere in four dimensions. In the following it is approximated by the first term $AH_1^{(3)}(\tau)$ of its expansion into cubic rotator functions (11) ($A < 0$ is the parameter of the potential strength). One of its twelve minima is at the position (0 0 0 1) to which the pocket states $|1^{(\delta)}>$ are assigned. The corresponding wave functions with the librational index $\delta = 0$ and $\delta = 1$ are chosen to be (11)

$$[31]\quad <\tau|1^{(0)}> = ((2M_0 + 1)!)^{1/2}(2\pi^2(4M_0 - 1)!!)^{-1/2}2^{M_0}\tau_4^{2M_0}$$

$$<\tau|1^{(1)}> = ((2M_1 + 3)!/(4M_1 + 1)!!)^{1/2}(2\pi^2)^{-1/2}2^{M_1+1}\tau_1\tau_4^{2M_1+1}$$

These wave functions are normalized on the four dimensional unit sphere:

$$[32]\quad <1|1> = \int_{\tau^2=1} |<\tau|1>|^2 d^4\tau = 1$$

where M_0 and M_1 are width parameters connected to the potential strength via the Ritz variational principle. For strong potentials where the overlap of different pocket states is negligible, only the knowledge of these wave functions is necessary to compute the scattering cross section.

With the unitary matrices of the irreducible representations A, E^a, E^b, and T of the group A_4 (compare Table 3) the rotational eigenstates are given by

$$[33]\quad |\eta> = N_\eta \sum_{\lambda=1}^{12} g_{\eta\lambda}|\lambda> \qquad \eta \in \{A, E^a, E^b, T_{xj}, T_{yj}, T_{zj} | j = 1, 2, 3\}$$

with the coefficients $g_{\eta\lambda}$ given in Table 1 of ref. 4 (there, $E1$ and $E2$ correspond to E^a and E^b, respectively).

The normalization constants in the limit of negligibly small overlaps are (4)

$$[34]\quad N_A = N_E = 1/\sqrt{12},\quad N_T = 1/2$$

The levels with E symmetry as well as the levels with T symmetry are degenerated (1).

The symmetrized spin states are found in ref. 15. They are denoted by $|\eta,I_z>$ where η indicates the symmetry and I_z denotes the z component of the total nuclear spin of the four protons. The resulting eigenstates in $\mathcal{H}^{rot}\otimes\mathcal{H}^{spin}$ are listed in Table 4. In another notation, they are also found in ref. 4.

(b) Approximate calculation of the matrix elements of $\hat{W}$

Operator $\hat{W}$ may be written as

$$[35]\qquad \hat{W}=\frac{1}{4}\sum_{\gamma=A,T_x,T_y,T_z}\hat{S}_\gamma\hat{G}_\gamma$$

(the coefficients $g_\gamma(j)$ in the definitions of $\hat{G}_\gamma$ and $\hat{S}_\gamma$ in [10] are given in Table 5 (1)). To obtain $<1^{(1)}|\hat{G}_\gamma|1^{(0)}>$ the matrix element $<1^{(1)}|e^{i\boldsymbol{QR}}|1^{(0)}>$ will be approximated for small $|\boldsymbol{QR}|$ (cf. Appendix E):

$$[36]\qquad <1^{(1)}|e^{i\boldsymbol{Q}\hat{\boldsymbol{R}}}|1^{(0)}> = F(M_0,M_1)\exp(i\boldsymbol{Q}.\boldsymbol{R}')\boldsymbol{Q}.\mathbf{U}.\boldsymbol{R}'\left\{\frac{i}{M^{1/2}}+\frac{1}{M^{3/2}}\left(2\boldsymbol{Q}.\boldsymbol{R}'-i\left[\frac{9}{8}+\frac{1}{2}(\boldsymbol{Q}\times\boldsymbol{R}')^2\right]\right)\right.$$
$$+\frac{1}{M^{5/2}}\left(i\left[\frac{275}{64}+\frac{37}{16}(\boldsymbol{Q}\times\boldsymbol{R}')^2-3(\boldsymbol{Q}.\boldsymbol{R}')^2+\frac{1}{8}(\boldsymbol{Q}\times\boldsymbol{R}')^4\right]-\frac{3}{2}(\boldsymbol{Q}\times\boldsymbol{R}')^2\boldsymbol{Q}.\boldsymbol{R}'\right)$$
$$+\frac{1}{M^{7/2}}\left(i\left[-\frac{24163}{1152}+\frac{1807}{128}(\boldsymbol{Q}\times\boldsymbol{R}')^2+\frac{135}{8}(\boldsymbol{Q}.\boldsymbol{R}')^2-\frac{1}{48}(\boldsymbol{Q}\times\boldsymbol{R}')^6\right]+\frac{931}{32}\boldsymbol{Q}.\boldsymbol{R}'+\frac{183}{16}(\boldsymbol{Q}\times\boldsymbol{R}')^2\boldsymbol{Q}.\boldsymbol{R}'\right.$$
$$\left.\left.-\frac{77}{64}(\boldsymbol{Q}\times\boldsymbol{R}')^4-4(\boldsymbol{Q}.\boldsymbol{R}')^3+3(\boldsymbol{Q}\times\boldsymbol{R}')^2(\boldsymbol{Q}.\boldsymbol{R}')^2+\frac{1}{2}(\boldsymbol{Q}\times\boldsymbol{R}')^4\boldsymbol{Q}.\boldsymbol{R}'\right)+O\left(\frac{1}{M^{9/2}}\right)\right\}$$

where M denotes the average width parameter $\frac{1}{2}(M_0+M_1)$, the matrix $\boldsymbol{U}$ is defined to be

$$[37]\qquad \boldsymbol{U}=\begin{pmatrix}0&0&0\\0&0&1\\0&-1&0\end{pmatrix}$$

In the range of potential strength considered $30B \le |A| \le 150B$, F varies between 1.04 and 1.02. $<1^{(1)}|\hat{G}_\gamma|1^{(0)}>$ follows from [37] by taking the coordinate vectors $\boldsymbol{R}'_j$ of the four corners of the tetrahedron in an arbitrary coordinate system and summing over j according to the prescription for the operator $\hat{G}_\gamma$, what is done — like the computing of the cross sections — by a computer program.

(c) Results

The scattering cross section for the transition from an energy level 0Γ in the librational ground state multiplet to an energy level $1\Gamma'$ in the first excited librational multiplet reads (in the limit of small overlap)

$$[38]\qquad \frac{d^2\sigma}{d\Omega dE}(0\Gamma\rightarrow 1\Gamma') = (k'/864k)a_{sd}^2 Y(\Gamma,\Gamma')\delta(\hbar\omega+E_{0\Gamma}-E_{1\Gamma'})$$
$$\times\left(a(\Gamma,\Gamma')|<1^{(1)}|\hat{G}_A|1^{(0)}>|^2+t(\Gamma,\Gamma')\sum_{\gamma=T_x,T_y,T_z}|<1^{(1)}|\hat{G}_\gamma|1^{(0)}>|^2\right)$$

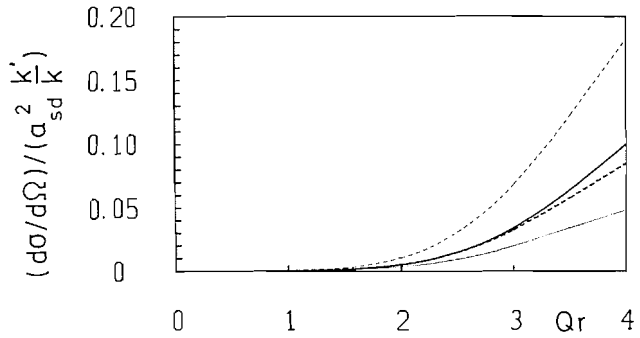

FIG. 5. Cross section for the transition from the level $0A$ into the level $1A$ of XH_4 in different orders of the approximation [36].

The factors $a(\Gamma,\Gamma')$, $t(\Gamma,\Gamma')$, and $Y(\Gamma,\Gamma')$ are listed in Table 6. (For their calculation, compare Appendix E.)

In [38] it is assumed that the sixteen librational ground states are equally populated whereas the excited librational states are not populated. If one considers the case where the temperature is so low that only the lowest energy level is populated and all other states not, one has to multiply the right hand side of expression [38] with 16/5.

The spin matrix elements appear in the factor $Y(\Gamma,\Gamma')$. With the data from ref. 4, the corresponding factors for XD_4 are also available. Because of the 81 states within a librational multiplet, the correction factor 16/81 is necessary. This factor is already taken in consideration in $Y(\Gamma,\Gamma')$ for XD_4. By sole population of the $0A$ level, the additional factor then is 81/15 because of the 15-fold degeneration of the A level.

In Figs. 5 to 7 cross sections for powder samples and a potential strength of $A = -50B$ are plotted. For potential strengths with moduli greater than $50B$, the overlaps of the pocket states are smaller than 1% of the norm of one pocket state and hence are negligible.

To check the reliability of the expansion of the matrix element in expression [36] we plot in Fig. 5 the cross section for the transition $0A \rightarrow 1A$ the different orders of the approximation. The dashed, solid, bold dashed, and bold solid lines are terms up to order $M^{-1/2}$, $M^{-3/2}$, $M^{-5/2}$, and $M^{-7/2}$, respectively. One concludes that the approximation seems to be reliable for $Qr \lesssim 3.5$. For this transition the leading term for small momentum transfers is again $(Qr)^6$. This result is already given in ref. 18. All other cross sections start with the term $(Qr)^2$. Hence, for small transfers $Qr \ll 1$, the transition $0A \rightarrow 1A$ is suppressed with respect to transition $0A \rightarrow 1T$ (there is no transition from the A level into an E level because of the lack of an E symmetric part of the operator $\hat{W}$). The cross sections for the transitions $0E \rightarrow 1E$ for XH_4 and for XD_4 differ only slightly (in the considered units) although for XH_4 there are no

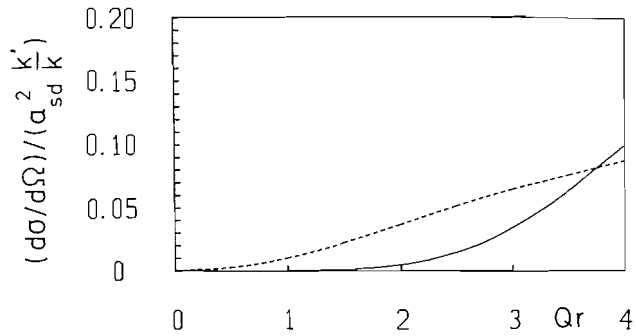

FIG. 6. Cross section for the transition into level $1A$ from the levels $0A$ (solid line) and $0T$ (dashed line) at equal populated librational multiplet 0.

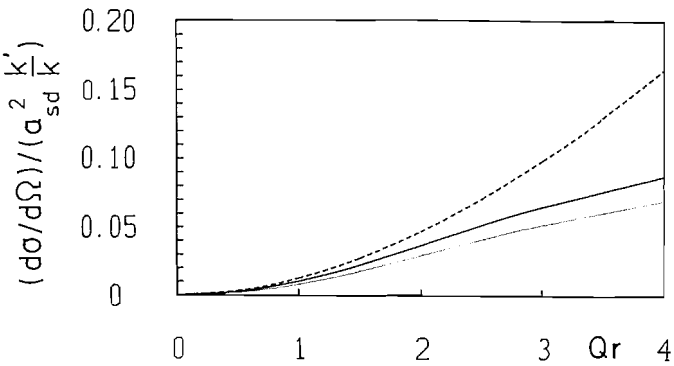

FIG. 7. Cross sections for transitions into level $1T$ from levels $0A$ (bold solid line), $0T$ (bold dashed line), and $0E$ (solid line).

contributions of a transition between E states in contrast to the case of XD_4. The intensities for the transition into the level $1E$ (which equals the intensities for the transition $0E \rightarrow 1T$) is suppressed with respect to the other transitions (Figs. 6 and 7).

VI. Conclusions

In recent years a considerable amount of spectroscopic information on the rotational energy levels of small molecules has been obtained from neutron scattering experiments. Tunnelling transitions are found at energies below 200 μeV, i.e. in a region where no other excitations are expected and therefore the tunnelling lines are easily identified. Except for a few cases (7, 19) line intensities have not been necessary for an interpretation of the spectra. This is completely different for librational excitations of molecules which share the energy range around 10 meV with the translational modes of the lattice. The identification so far has been rather uncertain and it is hoped that our calculations will help to remedy this unsatisfactory situation. To this end we have calculated the line intensities for librational transitions of XH_3 and XH_4 molecules. For protons the overwhelming contribution comes from the spin-dependent scattering amplitude and because of the correlation of the proton spins within one molecule it shows a pronounced dependence on $\boldsymbol{Q}$. The angle dependence is hard to measure and therefore we have averaged the intensities for powder samples. We have obtained characteristic variations with $|\boldsymbol{Q}|$ with marked differences for transitions from the ground state multiplet into excited states of different symmetry. We propose to use the $|\boldsymbol{Q}|$ dependence of the intensities as signatures for the different transitions. Even better discrimination may be achieved by cooling the sample to a temperature where only the A level

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

in the ground state multiplet is occupied. Then the observed transitions occur between initial and final states of definite symmetries. For small momentum transfers the intensity for transitions between A states e.g. is proportional to $|\boldsymbol{Q}|^6$. Up to now the $|\boldsymbol{Q}|$ dependence of the librational modes has not been studied systematically, but it would be interesting to check earlier assignments (20–22) of lines in the 10 meV regime to librational modes by determining the $|\boldsymbol{Q}|$ dependence of intensities. The experiment (10) which has prompted this work is hard to interpret. Only the intensity above 4 meV is due to the librations of the ordered molecules and it consists of a few narrow but rather weak features on broad and intense band. The band is probably due to the dispersion of the librational modes whereas the narrow features stem from the van Hove singularities at extrema of the dispersion curves. A much more detailed analysis would be necessary to explain these intensity variations with temperature and momentum transfer.

Our calculations for XH_3 molecules which perform a unidimensional rotation around their symmetry axis is valid for all potential strengths. An experiment to check our predictions for the almost free NH_3 rotators in $Co(NH_3)_6(PF_6)_2$ (23) is in progress (24).

Appendices

Appendix A: Fourier expansion of the operator $\hat{G}_s$

With the abbreviations

[A1] $$\xi = \alpha - \phi \ , \quad \epsilon = \exp(i2\pi/3)$$

the operator $\hat{G}_s$ reads (compare the definition (18))

[A2] $$\hat{G}_s = \exp[iqr\cos(\xi)] + \epsilon^{-s}\exp[iqr\cos(\xi + 2\pi/3)] + \epsilon^{+s}\exp[iqr\cos[\xi - 2\pi/3)]$$

The Taylor expansion of the exponential function reads (after application of the binomial formula)

[A3] $$\exp[iqr\cos(\xi + x)] = \sum_{N=0}^{\infty}\sum_{k=0}^{N}\frac{1}{k!(N-k)!}\left(\frac{iqr}{2}\right)^N \exp[i(\xi + x)(2k - N)]$$

By insertion in [A2] one gets

[A4] $$\hat{G}_s = \sum_{N=0}^{\infty}\sum_{k=0}^{N}\frac{1}{k!(N-k)!}\left(\frac{iqr}{2}\right)^N \times \{\exp[i\xi(2k - N)]\}L(2k - N - s)$$

where $L(m)$ is defined for integer m by

[A5] $$L(m) = 1 + \epsilon^m + \epsilon^{-m} = 3\sum_{l\in Z}\delta_{m,3l}$$

By interchanging the order of summations and execution of the sum over N, all indices N are replaced by $2k - 3l - s$.

For $N = 2k - 3l - s \geq k$, $k \geq 3l + s$, and hence

[A6] $$\hat{G}_s = \sum_{l\in Z}\exp[i\xi(3l + s)]\sum_{\substack{k\geq 0\\ k\geq 3l+s}}\frac{3}{k!(k - 3l - s)!}\left(\frac{iqr}{2}\right)^{2k-3l-s}$$

For $3l + s \leq 0$, $-3l - s$ equals $|3l + s|$, and the series over k results in (16)

[A7] $$3\left(\frac{iqr}{2}\right)^{|3l+s|}\sum_{k\geq 0}\frac{1}{k!(k + |3l + s|)!}\left(-\frac{q^2r^2}{4}\right)^k = 3I_{|3l+s|}(iqr)$$

For $3l + s > 0$ and the replacement $\tilde{k} = k - 3l - s$ one again gets expression [A7] with the dummy index $\tilde{k}$ instead of k.

Appendix B: Powder averaging of [24]

The integration over the azimuthal angle ϕ leads to the Kronecker delta

[B1] $$\int_0^{2\pi} e^{i3(l'-l)\phi}\,d\phi = 2\pi\delta_{l,l'}$$

and hence to expression [25].

The Bessel function in the integral in [25] is replaced by its Taylor series (16). Because $q = Q\sin\theta$, the following integral appears to hold for a natural number n (16).

[B2] $$\int_0^{\pi}(\sin\theta)^{2n+1}\,d\theta = \frac{\Gamma(n + 1/2)\Gamma(1/2)}{\Gamma(n + 3/2)} = 2\frac{4^n(n!)^2}{(2n + 1)!}$$

The right equation in [B2] is verified by applying the Γ function.

	$\|T_x,I_z>$	$\|T_y,I_z>$	$\|T_z,I_z>$	$\|T_x1>$	$\|T_x2>$	$\|T_x3>$	$\|T_y1>$	$\|T_y2>$	$\|T_y3>$	$\|T_z1>$	$\|T_z2>$	$\|T_z3>$
$\hat{P}_1$	x	y	z	1	2	3	1	2	3	1	2	3
$\hat{P}_2$	x	$-y$	$-z$	1	−2	−3	−1	−2	3	−1	2	−3
$\hat{P}_3$	$-x$	y	$-z$	−1	2	−3	1	−2	−3	−1	−2	3
$\hat{P}_4$	$-x$	$-y$	z	−1	−2	3	−1	2	−3	1	−2	−3
$\hat{P}_5$	y	z	x	2	3	1	2	3	1	2	3	1
$\hat{P}_6$	y	$-z$	$-x$	2	−3	−1	−2	−3	1	−2	3	−1
$\hat{P}_7$	$-y$	z	$-x$	−2	3	−1	2	−3	−1	−2	−3	1
$\hat{P}_8$	$-y$	$-z$	x	−2	−3	1	−2	3	−1	2	−3	−1
$\hat{P}_9$	z	x	y	3	1	2	3	1	2	3	1	2
$\hat{P}_{10}$	z	$-x$	$-y$	3	−1	−2	−3	−1	2	−3	1	−2
$\hat{P}_{11}$	$-z$	x	$-y$	−3	1	−2	3	−1	−2	−3	−1	2
$\hat{P}_{12}$	$-z$	$-x$	y	−3	−1	2	−3	1	−2	3	−1	−2

For the integral in [25] the series reads

$$[B3]\quad 2\sum_{\mu,\mu'\geq 0}(-1)^{\mu+\mu'}\binom{\mu+\mu'+|3l+s|}{\mu}\binom{\mu+\mu'+|3l+s|}{\mu'}\frac{(Q^2r^2)^{\mu+\mu'+|3l+s|}}{[2(\mu+\mu'+|3l+s|)+1]!}$$

Substituting $p = \mu + \mu' + |3l + s| \geq |3l + s|$ one gets for [B3]

$$[B4]\quad 2\sum_{p\geq|3l+s|}\frac{(-Q^2r^2)^p p^{-|3l+s|}}{(2p+1)!}\sum_{\mu=0}^{}\binom{p}{\mu}\binom{p}{\mu+|3l+s|}$$

The inner sum in the expression [B4] can be replaced by the binomial coefficient $\binom{2p}{p+|3l+s|}$. This reflects the normalization of the probabilities

$$[B5]\quad \frac{\binom{p}{p-\mu}\binom{p}{\mu+|3l+s|}}{\binom{2p}{p+|3l+s|}}$$

Appendix C: Determination of the power series [27]

By interchanging the summations over p and l in [25], the following values of l contribute to the coefficient of $(-Q^2r^2)^p$ (i) if $p \geq 1$

for $l > 0$, one has $p \geq +3l + s$, i.e. $l \leq \text{Int}\left(+\frac{p-s}{3}\right)$;

for $l < 0$, one has $p \geq -3l - s$, i.e. $l \geq -\text{Int}\left(\frac{p+s}{3}\right)$.

$l = 0$ gives a contribution, because $p \geq |s|$ and $|s| \leq 1$

(ii) if $p = 0$, then $l = 0$ and $s = 0$.

Because $f(\varkappa,\varkappa',0) = \delta_{\varkappa,\varkappa'}$, one has $\eta = (\varkappa - \varkappa' + s)/3 = 0$ (cf. [24]), and the coefficient of $(-Q^2r^2)^0$ reads

$$4\pi^2|\sum_{r\in Z}a_{n,\varkappa}(r)^*a_{0,\varkappa}(r)|^2\delta_{\varkappa,\varkappa'} = \delta_{n,0}\delta_{\varkappa,\varkappa'}$$

To establish the equal sign, one has to remember that the sum vanishes for $n \neq 0$, because the eigenstates to different eigenvalues are orthogonal. For $n = 0$, the product of 2π and the sum over r equals unity, because the eigenstates are normalized.

Appendix D: Approximation of $<1^{(1)}|e^{i\mathbf{Q}\hat{\mathbf{R}}}|1^{(0)}>$

In refs. 4 and 17, the matrix element is calculated as an integral over the surface of the four dimensional sphere.

$$[D1]\quad <1^{(1)}|e^{i\mathbf{Q}\hat{\mathbf{R}}}|1^{(0)}> = \int_{\tau^2=1}<1^{(1)}|\tau><\tau|1^{(0)}>e^{i\mathbf{Q}\hat{\mathbf{R}}(\tau)}\,d^4\tau$$

with the wave functions [4] and [5], and the identity

$$\boldsymbol{R}(\tau) = (\mathbf{C}(\tau) + \mathbf{1})\boldsymbol{R}'$$

$$[D2]\quad \mathbf{C}(\tau) = 2\begin{pmatrix} -(\tau_2^2+\tau_3^2) & \tau_1\tau_2+\tau_3\tau_4 & \tau_1\tau_3-\tau_2\tau_4 \\ \tau_1\tau_2-\tau_3\tau_4 & -(\tau_1^2+\tau_3^2) & \tau_2\tau_3+\tau_1\tau_4 \\ \tau_1\tau_3+\tau_2\tau_4 & \tau_2\tau_3-\tau_1\tau_4 & -(\tau_1^2+\tau_2^2) \end{pmatrix}$$

$$(\tau_1,\tau_2,\tau_3,\tau_4) = \tau$$

If $\boldsymbol{R}'$ denotes the position of a proton in a molecule fixed system, which is rotated about τ with respect to the space fixed system, then $\boldsymbol{R}(\tau)$ denotes the coordinate vector of the position in the reference system.

To calculate [D1], the exponential function is approximated by the appropriate Taylor polynom of seventh degree. Then only power functions in the quaternions have to be integrated. Those integrals are given in ref. 4.

T_y	5	3	3	3	2	2
T_z	5	3	3	3	2	2
E^a	0	2	2	2	0	0
E^b	0	2	2	2	0	0

[D3] $$\int_{\tau^2=1} \tau^{N_1}\tau^{N_2}\tau^{N_3}\tau^{N_4}\,d^4\tau = \begin{cases} 2\pi^2 \prod_{j=1}^{4} (N_j-1)!!/[2^N(1+N)!] & \text{all } N_j \text{ even} \\ 0 & \text{otherwise} \end{cases}$$

with the abbreviation

$$N = \sum_{j=1}^{4} N_j/2$$

(*I*) In analogy to ref. 2, $\boldsymbol{R}'$ is first set to be $\begin{pmatrix}0\\0\\1\end{pmatrix}$. The vector $\mathbf{C}(\tau)\begin{pmatrix}0\\0\\1\end{pmatrix}$ will be named $\begin{pmatrix}x\\y\\z\end{pmatrix}(\tau)$. Because of [D3], only terms with odd powers in y, even powers in x, and arbitrary powers in z provide nonvanishing contributions to the integral [D1].

For integration, all terms in the average width parameter $M = (M_0 + M_1)/2$ are used up to the order $(1/M)^{7/2}$.

(*II*) In the calculation with $\mathbf{C}(\tau)\begin{pmatrix}0\\1\\0\end{pmatrix} = \begin{pmatrix}x'\\y'\\z'\end{pmatrix}$, only terms with odd powers in z', even powers in x', and arbitrary powers in y' contribute. Because of the different signs in the expressions for $x'(\tau)$ and $z'(\tau)$ — compared with those in $x(\tau)$ and $y(\tau)$ — one has to multiply the result of (*I*) with (-1) and to interchange Q_2 and Q_3 to obtain the desired result.

(*III*) No term in the calculation for $\mathbf{C}(\tau)\begin{pmatrix}1\\0\\0\end{pmatrix} = \begin{pmatrix}x''\\y''\\z''\end{pmatrix}$ contributes, because no power in x'', y'', or z'' has a term in which τ_1 and τ_4 appear in odd power and τ_2 and τ_3 appear in even power.

Appendix E: Calculation of the cross sections

For the different transitions, the following sum has to be calculated:

[E1] $$f(\Gamma,\Gamma') = \sum_{0\Gamma\,\text{states}\,|i>} \sum_{i\Gamma'\,\text{states}\,|f>} \sum_{\mu,\mu'=\mp 1/2} |<\mu'|<f|\hat{W}|i>|\mu>|^2$$

The states $|i>$ of the lowest librational multiplet $|f>$ of the first excited librational multiplet are listed in Table 4. The transformation properties of the states and of the operators $\hat{G}_\gamma$ and $\hat{S}_\gamma$ for rotations of the tetrahedron are calculated and listed in Tables 7 and 8. A simple example is the calculation of $f(A,A)$. Here, only the operator $\hat{S}_A\hat{G}_A$ contributes. Because the state $|\tilde{A},I_z>$ is a tensor product in $\mathcal{H}^{\text{rot}} \otimes \mathcal{H}^{\text{spin}}$, the matrix element in [E1] factorizes.

[E2] $$f(A,A) = \frac{1}{16} \sum_{I_z;I_z'=-2}^{2} \sum_{\mu,\mu'=\mp 1/2} |<\mu'|<A,I_z'|\hat{S}_A|A,I_z>|\mu>|^2 |<A^{(1)}|\hat{G}_A|A^{(0)}>|^2$$

For tiny overlaps, the matrix element of $\hat{G}_A$ is diagonal in the pocket states.

[E3] $$<A^{(1)}|\hat{G}_A|A^{(0)}> \cong \frac{1}{12}\sum_{\lambda,\mu=1}^{12} \delta_{\lambda,\mu}<\mu^{(1)}|\hat{G}_A|\lambda^{(0)}> = \frac{1}{12}\sum_{\lambda=1}^{12} <1^{(1)}|\hat{P}_\lambda^+\hat{G}_A P_\lambda|1^{(0)}> = <1^{(1)}|\hat{G}_A|1^{(0)}>$$

The spin-dependent factors formed by the sums over the squared matrix element of $\hat{S}_A$ in [E1] are found in Table 9. The result is

[E4] $$f(A,A) = \frac{1}{16}\frac{135}{9}|<1^{(1)}|\hat{G}_A|1^{(0)}>|^2$$

Multiplication with $1/16$ for the probability of the population and $8/3$ from [1] yields

[E5] $$a(A,A) = 1, \quad t(A,A) = 0, \quad Y(A,A) = 135$$

The abbreviations a, t, and Y are chosen so that [38] holds when a equals 0, 1, or 3.

Metabolites of *Lachnellula fuscosanguinea* (Rehm). Part 2.[1] The structure of lachnellulone

WILLIAM A. AYER, J. DANIEL FIGUEROA VILLAR, AND BARBARA S. MIGAJ
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 15, 1987

WILLIAM A. AYER, J. DANIEL FIGUEROA VILLAR, and BARBARA S. MIGAJ. Can. J. Chem. **66**, 506 (1988).

Lachnellulone, an antifungal metabolite produced by *Lachnellula fuscosanguinea* (Rehm) Dennis is shown to possess structure **8**. The structure was determined by consideration of the ultraviolet, infrared, ^1H and ^{13}C nuclear magnetic resonance, and mass spectra of **8** and its derivatives and was confirmed by an X-ray crystallographic study of lachnellulone *p*-nitrobenzoate. In solution lachnellulone undergoes facile isomerization to isolachnellulone (**9***a*), which explains the observed mutarotation of **8**. The ^{13}C nuclear magnetic resonance spectra of lachnellulone and the related lachnelluloic acid (**1**) are discussed in some detail. The absolute configuration of lachnellulone has not been determined.

WILLIAM A. AYER, J. DANIEL FIGUEROA VILLAR et BARBARA S. MIGAJ. Can. J. Chem. **66**, 506 (1988).

On a démontré que la lachnellulone, un métabolite fongicide produit par le *lachnellula fuscosanguinea* (Rehm) Dennis, possède la structure **8**. On a déterminé la structure en se basant sur les spectres ultraviolet, infrarouge, résonance magnétique nucléaire du ^1H et du ^{13}C et de masse du produit **8** et on l'a confirmée par des études de diffraction des rayons-X réalisées sur le *p*-nitrobenzoate de la lachnellulone. En solution, la lachnellulone se transforme facilement en isolachnellulone (**9***a*); cette propriété explique la mutarotation observée avec le composé **8**. On discute en détail les spectres en résonance magnétique nucléaire du ^{13}C de la lachnellulone et de l'acide lachnelluloïque (**1**) qui lui est apparenté. On n'a pas déterminé la configuration absolue de lachnellulone.

[Traduit par la revue]

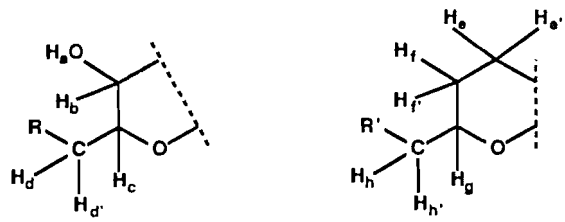
For personal use only.

Lachnellula fuscosanguinea (Rehm) Dennis is a brightly colored fungus of the family Hyaloscyphaceae (Ascomycotina), which is saprophytic on pine and other conifers. It has been shown to be antagonistic to the Dutch elm disease fungus *Ceratocystis ulmi* and to several wood rotting fungi (1). The antifungal activity is due to lachnelluloic acid, shown earlier to possess structure **1**, and to a second and more active component $C_{18}H_{28}O_5$, which we have named lachnellulone (1). In this article we report the structure of lachnellulone.

Lachnellulone, mp 126–127°C, has one oxygen more than lachnelluloic acid (**1**) and has an additional unsaturation. The ultraviolet (uv) spectrum is similar to that of **1** and shows a similar base induced shift. The infrared (ir) spectrum shows concentration independent, hydrogen bonded, hydroxyl absorption (3400 cm^{-1}) and double bond absorption at 1708, 1670, and 1560 cm^{-1}. The compound is optically active, but the specific rotation changes with time, becoming constant after a certain length of time depending on the solvent. Unlike lachnelluloic acid (**1**), lachnellulone does not give a positive ferric chloride test.

The ^1H nuclear magnetic resonance (nmr) spectrum shows the presence of the two isolated spin systems illustrated in Scheme 1. The concentration independent, D_2O exchangeable, H-bonded, proton H_a is spin coupled (3.0 Hz) to a proton (H_b) at δ 4.45. The latter signal is further coupled (6.5 Hz) to a proton (H_c) *geminal* to an ethereal oxygen (δ 4.57). H_c is further coupled to the nonequivalent protons of a methylene group (H_d, $H_{d'}$). The other isolated spin system illustrated in Scheme 1 originates with a somewhat downfield nonequivalent methylene group (H_e, $H_{e'}$, δ 3.76, 3.32, J_{gem} 20 Hz), each hydrogen of which is further coupled to the protons of another nonequivalent methylene pair (H_f, $H_{f'}$, *geminal* coupling 13 Hz). One of these *geminal* protons shows coupling to a hydrogen (H_g) *geminal* to an ethereal oxygen (δ 5.02). This hydrogen is also coupled to the protons of another methylene group (H_h, $H_{h'}$). The ^{13}C nmr spectrum shows sp^2 carbons at



SCHEME 1

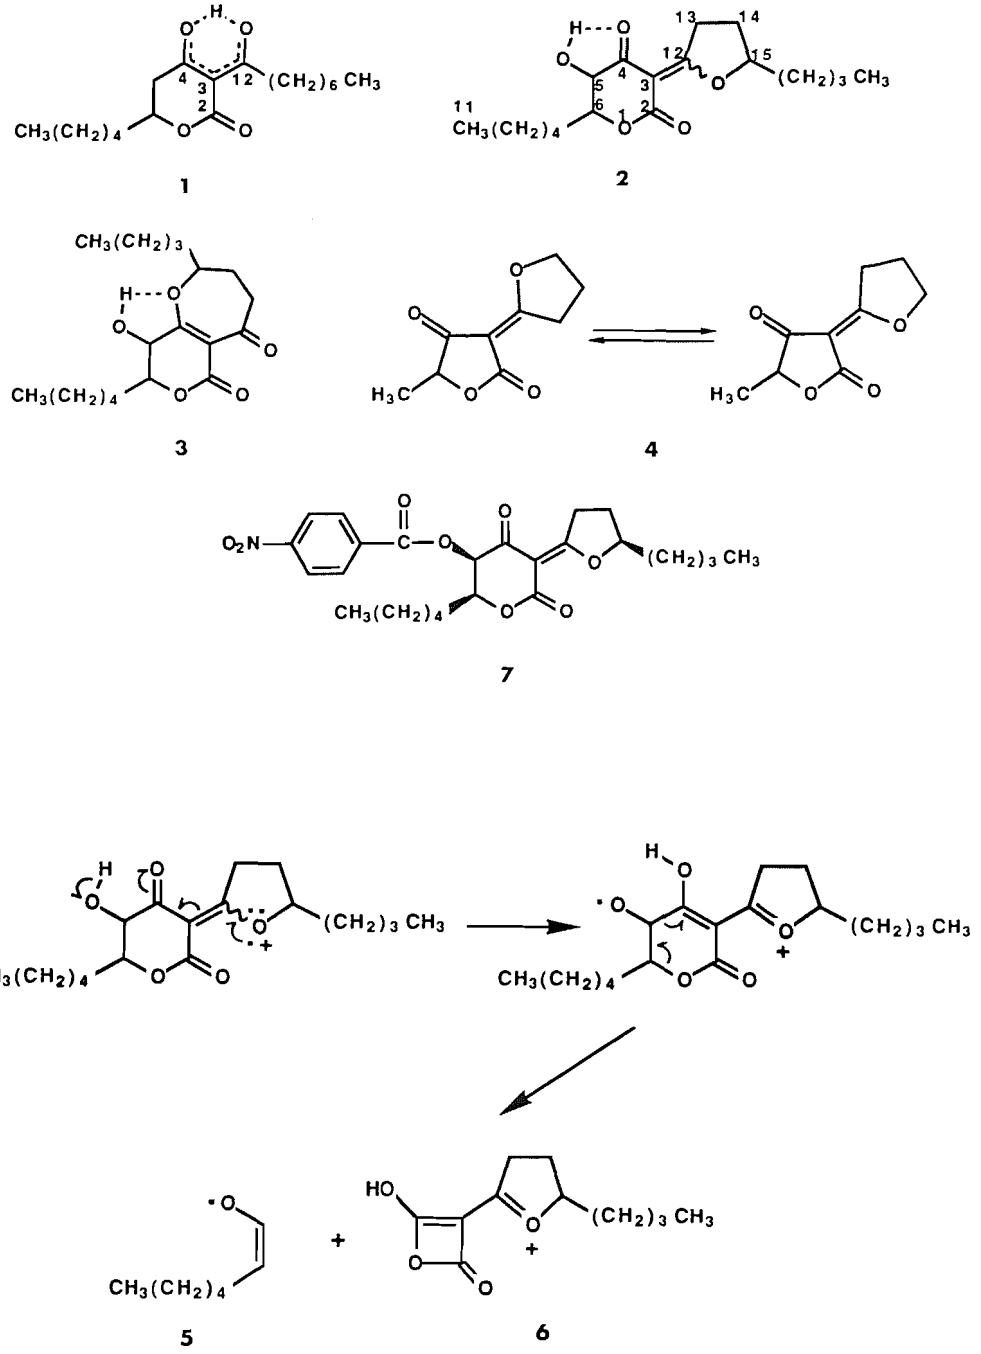
δ 191.1, 189.0, 165.3, and 100.2, similar in chemical shift to those in lachnelluloic acid. Oxygenated methine carbons appear at δ 91.4, 77.6, and 71.9 and these are shown by decoupling to be directly bonded to H_g, H_c, and H_b, respectively. In addition, there are signals for nine methylene carbons and two methyl carbons, confirming the presence of two unbranched alkyl chains.

Considering the likely relationship between lachnellulone and lachnelluloic acid (**1**), structures **2** and **3** reasonably explain the evidence presented to this point, with structure **2** favored since it best explains the mutarotation (similar to that observed for carolic acid (**4**), ref. 2), and the strongly H-bonded hydroxyl group.

The base peak in the mass spectrum of lachnellulone appears at *m/z* 211 ($M^+ - C_7H_{13}O$), consistent with the loss of the fragment **5** from the molecular ion as shown in Scheme 2. This serves to locate the five-carbon side chain relative to the hydroxyl group. The *m/z* 211 ($C_{11}H_{15}O_4$) peak may be represented as **6** (one canonical form) on the basis of structure **2**. When the hydroxyl hydrogen is replaced by deuterium, the base peak in the mass spectrum is shifted to *m/z* 212, consistent with the hydrogen transfer depicted in Scheme 2. Acetylation of lachnellulone gave an oily product, which on thin-layer chromatography seems to contain two components. These could not be separated by chromatography, but the ^1H nmr spectrum shows two sets of signals for the hydrogen *geminal* to the acetoxyl group (see below).

Lachnellulone crystallizes as very fine needles, unsuitable for X-ray crystallographic analysis. The *p*-bromobenzoate

[1]For part 1, see ref. 1.



SCHEME 2

behaves similarly. The *p*-nitrobenzoate, which in solution shows two isomers, gives somewhat thicker needles and the crystal structure was determined. Figure 1 is a computer generated perspective drawing of the final X-ray model of lachnellulone *p*-nitrobenzoate.[2] This confirms structure **2** for lachnellulone and defines the relative stereochemistry of the *p*-nitrobenzoate as shown in **7**.

Since the crystalline *p*-nitrobenzoate shows structure **7**, we assign structure **8** to lachnellulone itself. It was noted above that lachnellulone mutarotates. It has also been observed that the ^{1}H nmr spectra of lachnellulone and its derivatives usually reveal the presence of two closely related compounds. For example, the ^{1}H nmr spectrum of freshly dissolved lachnellulone *p*-nitrobenzoate (**7**) in $CDCl_3$ shows a signal at δ 5.80 (J = 4.5 Hz) attributable to the C-5 hydrogen, along with a small signal at δ 5.77 (J = 4.5 Hz). With time the signal at δ 5.77 grows in intensity at the expense of the δ 5.80 signal until the signals are of approximately equal intensity. Similarly, the signals for the protons at C-6, C-15, and especially C-13 become more complicated (overlapping multiplets) with time. We attribute this to the isomerization of **7** to **9** until an equilibrium mixture (approximately 1:1) of the two is obtained. As noted, a similar isomerization has been observed, and studied in detail, in the case of carolic acid (**4**) (2). This

[2]The X-ray crystallographic study was carried out by R. G. Ball, Structure Determination Laboratory, Department of Chemistry, University of Alberta, Edmonton, Alberta, T6G 2G2. Inquiries regarding the crystallographic results should be directed to Dr. Ball at the above address, quoting report number SR:012505-03-85.

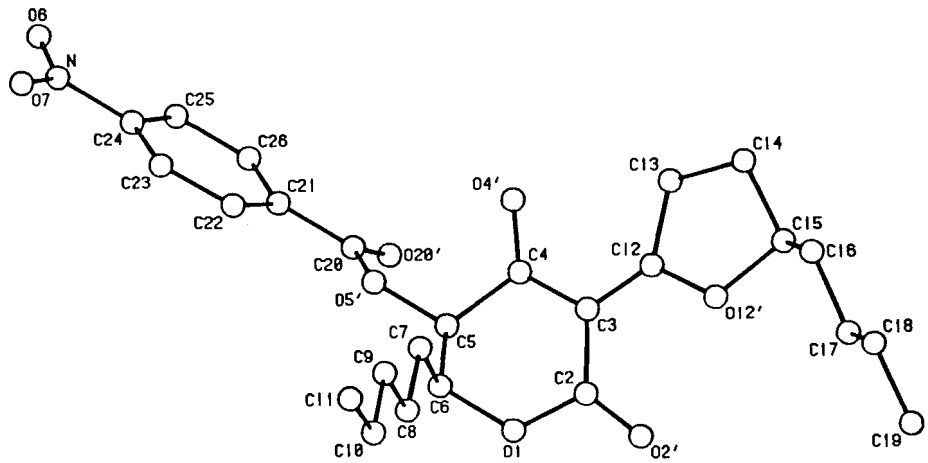

FIG. 1. Computer generated perspective drawing of the X-ray model of lachnellulone *p*-nitrobenzoate.

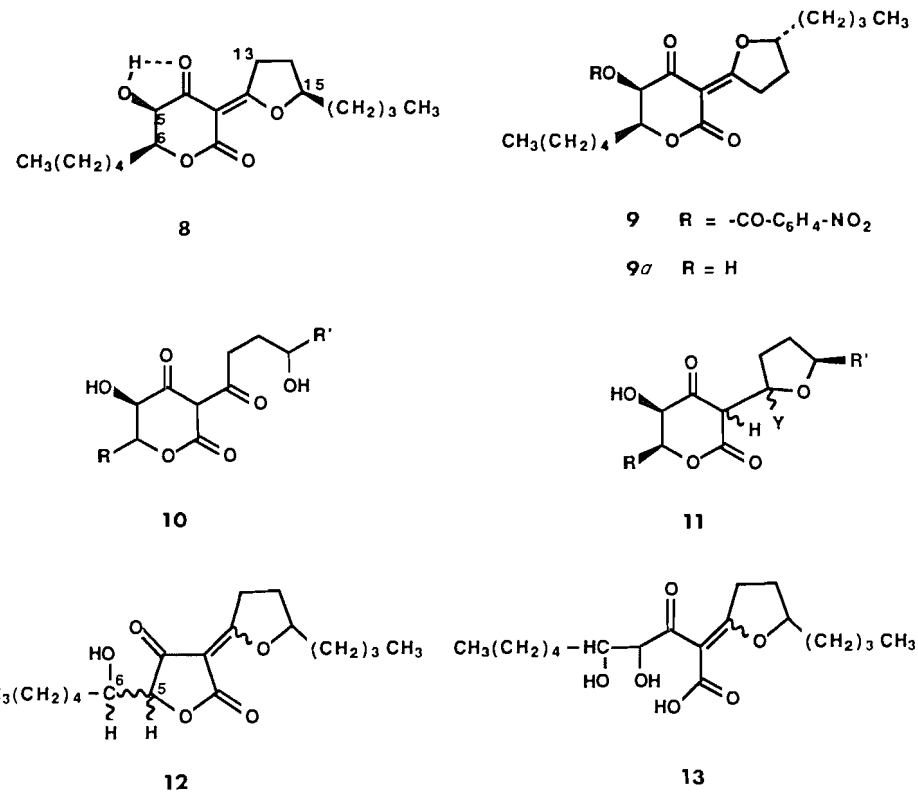

isomerization accounts for the formation of the mixture of acetates, in which case the signals for the two different C-5 protons are observed at δ 5.53 (J = 4.5 Hz) and δ 5.48 (J = 4.5 Hz). The fact that the H-5 coupling constants are the same in both isomers indicates that the change is not due to epimerization at C-5. This isomerization is also detectable in the ^{13}C nmr spectra of lachnellulone and its derivatives.

The isomerization of lachnellulone (**8**) to isolachnellulone (**9***a*) occurs extremely rapidly in methanol, but more slowly in acetonitrile. The change in rotation with time is observed in acetonitrile (+91° to +55° over 24 h). In methanol, no significant change in rotation (+35 ± 2°) is observed. We attribute this to the fact that in methanol equilibrium between **8** and **9***a* is established before the rotation can be measured (~10 min). When the ^1H nmr spectrum of lachnellulone is measured in deuterated methanol, the spectrum immediately shows the presence of approximately equal amounts of the two isomers. When crystalline lachnellulone is dissolved in $CDCl_3$ and the spectrum is recorded immediately, only one set of signals is observed. After the solution has been allowed to stand for several hours a second set of signals (for **9***a*) is apparent. After approximately 24 h (this time period is variable), **8** and **9***a* appear to be present in approximately equal amounts. When either a chloroform solution or a methanol solution of the two isomers is evaporated to dryness, only **8** is present as determined by ^1H nmr spectroscopy (in $CDCl_3$). This suggests that **8** is the least soluble of the two isomers that constitute the natural product.

The coupling between the protons on C-5 and C-6 in the *p*-nitrobenzoate (both isomers) and the other derivatives of lach-

19

nellulone (acetate, 3,5-dinitrobenzoate, α-naphthylurethane) is 4.5–5.0 Hz, consistent with a dihedral angle of approximately 30–40° (3). In lachnellulone itself, this coupling is 6.5 Hz, perhaps reflecting a slight conformational change, with lessening of the dihedral angle, brought about by the strong hydrogen bond between the hydroxyl hydrogen and the oxygen of the C-4 carbonyl group. A nuclear Overhauser effect (nOe) experiment confirmed the proximity of the C-5 hydrogen to the C-6 hydrogen (irradiation of H-5 caused a 12% enhancement of the signal for H-6, irradiation of H-6 caused a 10.5% enhancement of H-5).

The mechanism of isomerization of lachnellulone (**8**) to isolachnellulone (**9***a*) may involve hydrolytic ring opening to give intermediate **10**, followed by ring closure to give either **8** or **9***a*. However, the fact that isomerization occurs in anhydrous solvents (methanol, chloroform, acetonitrile) suggests that an addition–elimination sequence, perhaps catalyzed by traces of acid and proceeding via an intermediate such as **11** (Y = OCH_3, Cl, etc.), is also a possibility. As noted previously, the uv spectrum of lachnellulone in methanol (λ_{max} 275 nm) is similar to that of lachnelluloic acid (λ_{max} 274 nm) and shows a similar base induced shift.

In describing the structure of lachnelluloic acid we originally portrayed a distinct hydrogen bonded enol structure (**14**) although we now feel that it is more meaningful to use the delocalized structure **1**. We have mentioned the similarities of the uv spectra and the ^{13}C nmr spectra of lachnellulone to those of lachnelluloic acid. The sp^2 carbons of lachnellulone absorb at δ 191.1, 189.0, 165.3, and 100.2, those of lachnelluloic acid at δ 204.2 (C-12), 194.9 (C-4), 163.9 (C-2), and 102.9 (C-3). These shift assignments are based on the following considerations. The chemical shifts for the model compound dihydrodehydroacetic acid (**15**) have been assigned as shown in **15** (4). We have prepared **15** labelled with ^{13}C at the sp^2 carbon of the side chain and confirmed that this carbon does give rise to the signal at δ 201.1. Heteronuclear decoupling of the hydrogen at C-6 in lachnelluloic acid causes a sharpening of the signal at δ 194.9; thus it is safe to conclude that the assignments given above are correct for lachnelluloic acid. Attempts to methylate dihydrodehydroacetic acid (**15**) with diazomethane and by treatment with methyl iodide under basic conditions were unsuccessful. However, treatment of **15** with methanolic HCl provides the enol ether **16** in moderate yield. Enol ether **16** shows sp^2 carbon signals at δ 188.1, 177.7, 166.1, and 112.0, assigned as shown in **16**. When the side chain ^{13}C enriched **15** was used to prepare **16**, the signal at 177.7 (which is coupled to the methyl hydrogens at δ 2.21) is increased in intensity. The enol ether is assigned structure **16** rather than **17** since the ketonic carbonyl would not be expected at such a high field (δ 177.7) position. This conclusion is confirmed in the case of lachnelluloic acid methyl ether (**18**), prepared by treating **1** with methanolic HCl. The sp^2 carbons have the chemical shifts shown in **18**. Reduction of **18** with sodium borohydride provides the alcohol **19**, the ^{13}C nmr spectrum of which lacks a signal in the δ 188 region (see **19** for shift assignments). In lachnellulone, heteronuclear decoupling of the C-6 hydrogen causes the carbon signal at δ 191.1 to collapse to a broadened singlet, while the signal at δ 189.0 is very little affected. Since the three-bond coupling is expected to be much larger than that over five bonds (5), the signal at δ 191.1 is assigned to the C-4 carbonyl and the signal at δ 189.0 to the enol ether carbon C-12.

Treatment of lachnellulone with methanolic sodium hydroxide

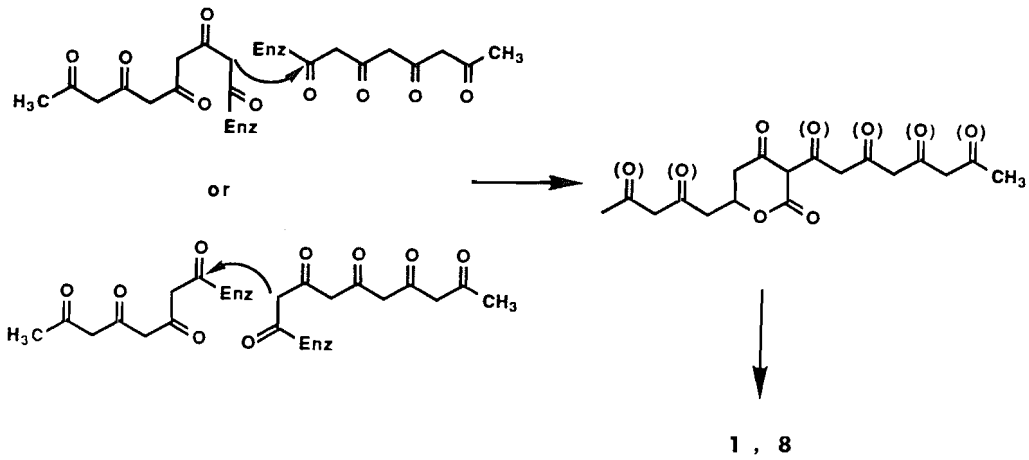

SCHEME 3

followed by acidification gives rise to a mixture of diastereoisomeric products to which we assign structures **12**. This assignment is based on ir (1760, 1695 cm^{-1}), uv (λ_{max} 220, 274 nm), and ^1H nmr spectral evidence. The ir and uv data compare favorably with those quoted for carolic acid (**4**) (6), and the nmr spectrum shows a series of doublets (δ 4.37, 4.39, 4.41, 4.43) coupled to multiplets centered at δ 3.95, which we attribute to the C-5 hydrogens (four diastereoisomers) coupled to the C-6 hydrogens. Compounds **12** arise by opening of the lactone ring in **8** and **9***a* followed by relactonization of hydroxy acid **13** to give the 5-membered ring compounds.

Lachnellulone shows antifungal activity against *Ceratocystis ulmi* (the causative agent of Dutch elm disease), *Hypoxylon mammatum* (which causes canker in poplar) (7), and *Marasmius oreades* (the fairy ring mushroom).[3] It did not show antibacterial activity against the standard test organisms[4] (7).

The biogenesis of lachnellulone and lachnelluloic acid may be rationalized as a condensation of two polyketide chains, a tetraketide and a pentaketide, in either of the two ways illustrated in Scheme 3. As in the case of alternaric acid (4, 8), it is very difficult to distinguish biosynthetically between these alternative routes, and biosynthetic studies have not been pursued.

Experimental

For general experimental details see part 1 (1). In reporting mass spectra, unless diagnostically significant, peaks with intensities less than 20% of the base peak are omitted. Ion formulae reported were determined by high resolution mass spectrometry (hrms).

Isolation of lachnellulone[5]

A 50 mm diameter column was filled with 20 cm of silica gel for flash chromatography and packed using $CHCl_3$. The crude extract of the mycelium of *L. fuscosanguinea* (1.5 g) (1) was applied to the top of the column as a concentrated solution in $CHCl_3$, and eluted with solvent at a rate of 5 cm/min while collecting 50-mL fractions. Fractions 35–40, eluted with 1% CH_3OH in $CHCl_3$, afforded a white crystalline material, which was recrystallized from acetone – Skellysolve B to yield 20 mg of pure lachnellulone, mp 126–127°C; R_f 0.44 ($CHCl_3$): $[\alpha]_D$ +35.0 ± 2° (*c* 1.0, CH_3OH); +91.4° (5 min after dissolution), +55.0° (24 h after dissolution) (*c* 0.77, CH_3CN); λ_{max} (ε) (CH_3OH): 218 (8670), 275 (16 200) nm; λ_{max} (CH_3OH + 0.1 *M* NaOH): 255 nm; λ_{max} (isooctane): 269 (18 200); ir ($CHCl_3$ cast): 3400, 2950, 2925, 2860, 1708, 1670, 1560, 1460, 1380, 1305, 1090, 600 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.02 (1H, ddd, *J* = 7.0, 7.0, 7.0 Hz), 4.57 (1H, ddd, *J* = 3.0, 6.5, 10.0 Hz), 4.45 (1H, dd, *J* = 3.0, 6.5 Hz), 3.92 (1H, d, *J* = 3.0 Hz), 3.76 (1H, ddd, *J* = 6.0, 10.0, 20.0 Hz), 3.32 (1H, ddd, *J* = 7.0, 10.0, 20.0 Hz), 2.33 (1H, dddd, *J* = 6.0, 7.0, 10.0, 13.0 Hz), 1.87 (1H, dddd, *J* = 7.0, 7.0, 10.0, 12.0 Hz), 1.71 (2H, m), 1.60 (2H, m), 1.42 (4H, m), 1.30 (6H, m), 0.96 (3H, vt), 0.89 (3H, vt); ^{13}C nmr (CD_2Cl_2) δ: 191.1 (s), 189.0 (s), 165.3 (s), 100.2 (s), 91.4 (d), 77.6 (d), 71.9 (d), 36.4 (t), 34.9 (t), 31.9 (t), 28.7 (t), 27.9 (t), 27.2 (t), 25.9 (t), 22.9 (t), 22.8 (t), 14.1 (q), 14.0 (q); hrms, *m/z*: 324 ($C_{18}H_{28}O_5$, 1.3, M^+), 239 ($C_{13}H_{19}O_4$, 2), 224 ($C_{12}H_{16}O_4$, 10), 211 ($C_{11}H_{15}O_4$, 100), 193 ($C_{11}H_{13}O_3$, 46).

Acetylation of lachnellulone

Lachnellulone (3.0 mg) was dissolved in CH_2Cl_2 (0.5 mL). Acetyl chloride (0.5 mL) was added, with constant stirring, to the lachnellulone solution. After 2 h at room temperature a drop of dry pyridine was added and the solution was stirred overnight. The reaction was worked up by adding water (2 mL) and $CHCl_3$ (1 mL) and vigorously shaking the two-phase system. The organic layer was separated, washed with distilled water, dried over anhydrous Na_2SO_4, filtered, and concentrated to dryness to give lachnellulone acetate (3.0 mg); R_f 0.30 (1% CH_3OH in $CHCl_3$); ir ($CHCl_3$ cast): 1730 cm^{-1}; ^1H nmr ($CDCl_3$), mixture of two isomers, δ: 5.53 and 5.48 (1H, d's, *J* = 4.5 Hz), 4.92 (1H, m), 4.44 (1H, m), 3.65 (1H, m), 3.32 (1H, m), 2.30 (1H, m), 2.21 and 2.19 (3H, s's), 1.89 (1H, m), 1.64 (2H, m), 1.40–1.31 (12H, bm), 0.94 (3H, vt), and 0.90 (3H, vt); hrms, *m/z*: 366 ($C_{20}H_{30}O_6$, 2.5, M^+), 253 ($C_{13}H_{17}O_5$, 51), 211 ($C_{11}H_{15}O_4$, 100), 193 ($C_{11}H_{13}O_3$, 17).

p-Nitrobenzoate of lachnellulone (7)

Lachnellulone (12.0 mg) was dissolved in 10 mL of CH_2Cl_2 under nitrogen. 4-*N*,*N*-Dimethylaminopyridine (7.2 mg) and *p*-nitrobenzoyl chloride (8.4 mg) were added and the reaction mixture was stirred at room temperature. The reaction was monitored by tlc until no lachnellulone was present (about 1.5 h). A small amount of water was then added and the organic solvent was removed. The aqueous residue was extracted with ethyl ether, and the ethereal solution was washed successively with 1 *M* HCl, Na_2CO_3, water, and then dried. The solvent was evaporated and the pale yellow solid residue was crystallized from isopropyl alcohol, mp 138–139°C; R_f 0.65 (5% CH_3OH in $CHCl_3$); λ_{max} (ε): 217 (2460), 274 (21 500); ir ($CHCl_3$ cast): 3075, 2930, 1735, 1680, 1530, 1460, 1265, 1120, 1100, 873 cm^{-1}; ^1H nmr ($CDCl_3$), mixture of two isomers, δ: 8.33 (2H, m), 8.20 (2H, m), 5.80 and 5.77 (1H, d's, *J* = 4.5 Hz), 4.97 (1H, ddd, *J* = 7.0, 7.0, 7.0 Hz), 4.62 (1H, ddd, *J* = 4.5, 7.0, 14.0 Hz), 3.72 and 3.68 (1H, ddd's, *J* = 5.0, 10.0, 20.0 Hz), 3.37 and 3.33 (1H, ddd's, *J* = 7.5, 9.0, 20.0 Hz), 2.34 (1H, dddd, *J* = 2.5, 5.0, 10.0, 20.0 Hz), 1.96 (1H, m), 1.85 (1H, m), 1.74 (1H, ddd, *J* = 3.0, 7.0, 7.0 Hz), 1.56 (1H, m), 1.48 (1H, m), 1.37 (4H, m), 1.33 (6H, m), 0.93

(3H, t, J = 6.5 Hz), 0.88 (3H, vt); ^{13}C nmr ($CDCl_3$), mixture of two isomers, δ: 190.0 and 189.8, 187.6, 184.4, 165.3, 163.5, 134.7, 131.2, 123.73 and 123.68, 91.5, 90.8, 75.3, 74.8, 73.2 and 73.0, 36.7 and 36.6, 34.7 and 34.5, 31.5, 30.1 and 29.8, 27.5, 27.2, 25.1, 25.0, 22.5, 22.4, 13.9, 13.8; hrms, m/z: 473 ($C_{25}H_{31}NO_8$, 1.5, M^+), 360 ($C_{18}H_{18}NO_7$, 29), 279 ($C_{17}H_{27}O_3$, 16), 211 ($C_{11}H_{15}O_4$, 67), 193 ($C_{11}H_{13}O_3$, 18), 167 ($C_{10}H_{15}O_2$, 15), 150 ($C_7H_4NO_3$, 100). The crystals for X-ray diffraction studies were grown in a $CHCl_3$/pentane solvent system using the vapour diffusion technique (9).

3,5-Dinitrobenzoate of lachnellulone

Lachnellulone (6.6 mg) was dissolved in 5 mL of CH_2Cl_2 under nitrogen. 4-*N*,*N*-Dimethylaminopyridine (4.4 mg) and 3,5-dinitrobenzoyl chloride (freshly crystallized from CCl_4) (7.0 mg) were added. The reaction was carried out as described for the preparation of the *p*-nitrobenzoate. The product was crystallized from isopropyl alcohol, mp 102–104°C; R_f 0.55 (5% CH_3OH in $CHCl_3$); λ_{max} (ε): 274 (38 800); ir ($CHCl_3$ cast): 3055, 2956, 2930, 1740, 1680, 1547, 1345, 1260, 1162, 728; ^{1}H nmr ($CDCl_3$), mixture of two isomers, δ: 9.38 (1H, ddd, J = 2.0, 2.0, 4.5 Hz), 9.18 (2H, dd, J = 2.0, 4.5 Hz), 5.88 and 5.84 (1H, d's, J = 5.0 Hz), 4.99 (1H, ddd, J = 7.0, 7.0, 7.0 Hz), 4.66 (1H, ddd, J = 5.0, 5.0, 14.0 Hz), 3.74 and 3.68 (1H, ddd's, J = 5.0, 10.0, 20.0 Hz), 3.39 and 3.30 (1H, ddd's, J = 8.0, 10.0, 20.0 Hz), 2.34 (1H, m), 1.85 (1H, m), 1.76 (1H, m), 1.63 (6H, m), 1.47 (1H, m), 1.33 (6H, m), 0.91 (3H, t, J = 7.0 Hz), 0.89 (3H, t, J = 7.0 Hz); hrms, m/z: 518 ($C_{25}H_{30}N_2O_{10}$, 1, M^+), 212 ($C_7H_4N_2O_6$, 12), 211 ($C_{11}H_{15}O_4$, 100), 193 ($C_{11}H_{13}O_3$, 33), 167 ($C_{10}H_{15}O_2$, 30), 149 ($C_7H_3NO_3$, 29).

Base catalyzed rearrangement of lachnellulone

Lachnellulone (8 mg) was dissolved in methanol (1.0 mL), and the solution was adjusted to pH 10 with 1 *M* NaOH. The solution was stirred for 3 h at room temperature. The resulting mixture was acidified to pH 1 with 5% HCl and diluted with water. Extraction of the aqueous solution with ethyl acetate afforded a yellow solid, which was purified by flash chromatography (10 mm diameter column, 2% CH_3OH in $CHCl_3$). Isolachnellulone was obtained as a white solid (4.8 mg); R_f 0.3 in 2% CH_3OH in $CHCl_3$; ir ($CHCl_3$ cast): 3470, 1760, 1695, 1197 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 4.94 (1H, m), 4.43 and 4.41 (1/2H, d's, J = 1.0 Hz), 4.39 and 4.37 (1/2H, d's, J = 6.0 Hz), 4.02 (1/2H, bm), 3.86 (1/2H, bm), 3.59 (1H, ddd, J = 4.5, 9.0, 18.0 Hz), 3.26 (1H, 2 ddd, J = 2.0, 9.0, 18.0 Hz), 2.70 (1H, bdd, J = 3.0, 11.5 Hz), 2.37 (1H, m), 1.95 (1H, m), 1.87 (1H, m), 1.75 (1H, m), 1.68 (1H, m), 1.62 (1H, m), 1.50 (1H, m), 1.41 (4H, m), 1.32 (5H, m), 0.94 (3H, vt), 0.90 (3H, vt); ^{13}C nmr ($CDCl_3$), mixture of isomers, δ: 197.5 and 193.7 (s), 186.6 and 185.6 (s), 171.0 and 167.4 (s), 105.0 (s), 92.1 and 91.5 (d), 84.6 and 84.3 (d), 71.0 and 70.9 (d), 34.4 and 34.3 (t), 33.9 and 33.5 (t), 33.6 (t), 31.7 and 31.6 (t), 27.5 and 27.3 (t), 27.1 and 27.0 (t), 25.4 and 25.2 (t), 22.5 (t), 20.4 (t), 13.9 (q), 13.8 (q); hrms, m/z: 324 ($C_{18}H_{28}O_5$, 1), 306 ($C_{18}H_{26}O_4$, 2), 253 ($C_{13}H_{17}O_5$, 2), 224 ($C_{12}H_{16}O_4$, 100), 206 ($C_{12}H_{14}O_3$), 195 ($C_{11}H_{15}O_3$, 3), 195 ($C_{10}H_{11}O_4$, 2), 193 ($C_{11}H_{13}O_3$, 3), 181 ($C_9H_9O_4$, 3), 154 ($C_7H_6O_4$, 12), 142 ($C_6H_6O_4$, 9), 127 ($C_5H_3O_4$, 3).

^{13}C labelled dihydrodehydroacetic acid

^{13}C labelled dihydrodehydroacetic acid was prepared using Tanabe's method (10) for synthesis of 3-acyl-4-hydroxy-2-pyrones. The [1-^{13}C] acetyl chloride used was prepared following the literature procedure (11). [1-^{13}C] acetyl chloride (0.5 mL) in toluene (1 mL) was added to a cool (0°C) solution of 6-methyl-5,6-dihydropyran-2,4-dione (730 mg, 5.7 mmol) and 1,8-diazabicyclo[5.4.0]undec-7-ene (912 mg, 6.0 mmol) in toluene (20 mL). The reaction mixture was stirred for 2 h at 0°C. A saturated aqueous solution of NaCl was added, the layers were separated, and the aqueous layer was extracted with toluene. The combined organic extracts were washed with 5% HCl and saturated sodium chloride solution, and dried over $MgSO_4$. The drying agent was filtered off, 4-*N*,*N*-dimethylaminopyridine (34.1 mg, 0.28 mmol) was added, and the mixture was refluxed for 3 h. The solvent was removed under reduced pressure and the crude reaction mixture was purified by flash chromatography using a $CHCl_3$ – Skellysolve B – acetic acid (100:50:3) solvent system. Crystallization of the crude product from Skellysolve B – acetone gave ^{13}C labelled dihydrodehydroacetic acid (162 mg, 20% yield), identical (ir, tlc) with an authentic sample.

*Dihydrodehydroacetic acid methyl ether (**16**)*

Dihydrodehydroacetic acid (30.0 mg) was dissolved in methanol saturated with hydrogen chloride and stirred at room temperature for 7 days. The HCl was neutralized with sodium methoxide and the reaction mixture filtered and evaporated to dryness. The dry residue was dissolved in ethyl ether, and filtered and purified by preparative tlc using Skellysolve B – ethyl acetate (1:2) as the solvent system. Dihydrodehydroacetic acid methyl ether (9.8 mg, 30% yield) was obtained as an oil; R_f 0.43 (5% CH_3OH in $CHCl_3$); λ_{max} (ε) (CH_3OH): 264 nm (9020); ir ($CHCl_3$ cast): 2970, 1735, 1710, 1675, 1595 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 4.58 (1H, qt, J = 6.5, 8.0 Hz), 3.80 (3H, s), 2.49 (2H, d, J = 8.0 Hz), 2.21 (3H, s), 1.47 (3H, d, J = 6.5 Hz); ^{13}C nmr ($CDCl_3$) δ: 188.1 (s), 177.1 (s), 166.1 (s), 112.0 (s), 76.7 (d), 53.0 (q), 43.0 (t), 21.5 (q), 21.1 (q); hrms, m/z: 184 ($C_9H_{12}O_4$, 95, M^+), 153 ($C_8H_9O_3$, 55), 152 ($C_8H_8O_3$, 39), 143 ($C_6H_7O_4$, 100), 127 ($C_5H_3O_4$, 16), 114 ($C_5H_6O_3$, 26), 75 ($C_3H_7O_2$, 48), 69 (C_4H_5O, 26), 59 (C_3H_7O, 32).

*Lachnelluloic acid methyl ether (**18**)*

Lachnelluloic acid (21.8 mg) was dissolved in methanol saturated with HCl (10 mL) and stirred at room temperature for 5 days. The reaction mixture was worked up as described for dihydrodehydroacetic acid methyl ether. The product was purified by ptlc using 0.5% CH_3OH in $CHCl_3$ as the solvent system; R_f 0.55 (0.5% CH_3OH in $CHCl_3$); λ_{max} (ε) (CH_3OH): 266 nm (7700); ir ($CHCl_3$ cast): 2955, 1720, 1680, 1592, 1080 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 4.40 (1H, dddd, J = 5.0, 7.5, 8.0, 9.0 Hz), 3.82 (3H, s), 2.49 (4H, m), 1.82 (2H, m), 1.63 (4H, m), 1.30 (12H, m), 0.91 (6H, 2 t, J = 6.5 Hz); ^{13}C nmr ($CDCl_3$) δ: 188.7, 180.2, 166.3, 112.1, 79.3, 52.1, 40.9, 34.2, 33.7, 31.7, 31.4, 29.2, 28.9, 27.0, 24.4, 22.6, 22.5, 14.1, 13.9; hrms, m/z: 324 ($C_{19}H_{32}O_4$, 34, M^+), 293 ($C_{18}H_{29}O_3$, 19), 265 ($C_{17}H_{29}O_2$, 32), 253 ($C_{14}H_{21}O_4$, 31), 250 ($C_{15}H_{22}O_3$, 15), 227 ($C_{12}H_{19}O_4$, 33), 221 ($C_{13}H_{17}O_3$, 46), 198 ($C_{11}H_{18}O_3$, 22), 169 ($C_8H_9O_4$, 15), 142 ($C_6H_6O_4$, 20), 127 ($C_8H_{15}O$, 80), 125 ($C_8H_{13}O$, 77), 57 (C_4H_9, 100).

Reduction of lachnelluloic acid methyl ether

Lachnelluloic acid methyl ether (11.0 mg) was dissolved in methanol (2.7 mL) containing $CeCl_3 \cdot 7H_2O$ (11.6 mg), and sodium borohydride (1.2 mg) was added. The reaction mixture was stirred at room temperature for 15 min and then quenched with saturated aqueous ammonium chloride. The product was extracted with ether and the solution was dried over $MgSO_4$. The crude reaction mixture contained 3 components (tlc). The major product was separated by ptlc, using 2% CH_3OH in CH_2Cl_2 as the solvent system, giving alcohol **19** as an amorphous solid (4.5 mg); R_f 0.45 (2% CH_3OH in CH_2Cl_2); λ_{max} (ε) (CH_3OH): 245 (9040); ir ($CHCl_3$ cast): 3510, 2954, 1716, 1606, 1460, 1087, 1054 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 4.68 (1H, dd, J = 8.0, 8.0 Hz), 3.93 (1H, dddd, J = 2.0, 5.0, 10.0, 10.0 Hz), 3.81 (1H, d, J = 2.0 Hz), 3.77 (3H, s), 2.68 (1H, ddd, J = 7.5, 8.0, 13.0 Hz), 2.56 (1H, ddd, J = 7.5, 8.0, 13.0 Hz), 2.17 (1H, ddd, J = 2.5, 7.0, 14.0 Hz), 1.74 (2H, m), 1.56 (3H, m), 1.31 (14H, m), 0.89 (6H, 2 t, J = 6.5 Hz); ^{13}C nmr ($CDCl_3$) δ: 171.7 (s), 168.9 (s), 105.0 (s), 75.5 (d), 63.1 (d), 51.2 (q), 34.9 (t), 34.3 (t), 33.7 (t), 31.8 (t), 31.6 (t), 29.5 (t), 29.1 (t), 27.6 (t), 25.0 (t), 22.7 (t), 22.6 (t), 14.1 (q), 14.0 (q); hrms, m/z: 326 ($C_{19}H_{34}O_4$, 47, M^+), 308 ($C_{19}H_{32}O_3$, 37), 293 ($C_{18}H_{29}O_3$, 25), 267 ($C_{17}H_{31}O_2$, 22), 249 ($C_{17}H_{29}O$, 42), 242 ($C_{13}H_{22}O_4$, 56), 237 ($C_{14}H_{21}O_3$, 100), 201 ($C_{11}H_{21}O_3$, 28), 153 ($C_8H_9O_3$, 38), 144 ($C_6H_8O_4$, 32), 129 ($C_6H_9O_3$, 33), 127 ($C_8H_{15}O$, 57).

Ground and excited-state interactions of coumarin and nucleotide base

GRAŻYNA WENSKA AND STEFAN PASZYC
Faculty of Chemistry, A. Mickiewicz University, 70-780 Poznań, Poland

Received April 13, 1987[1]

GRAŻYNA WENSKA and STEFAN PASZYC. Can. J. Chem. **66**, 513 (1988).

Steady-state and time-resolved fluorescence measurements for a series of bichromophoric compounds containing 7-methoxycoumarin and nucleotide base residues have been performed in water and in organic solvents. The data from these studies have been used to calculate the relative proportion of folded and extended conformations of bichromophores. Ground-state stacking interactions of coumarin and nucleotide base have been found to be limited to aqueous solution. The contribution of the dynamic quenching mechanism to the total fluorescence quenching in water has been estimated. The absence of dynamic quenching in organic solvents is explained on the basis of the very short lifetime of the fluorophore in methanol.

GRAŻYNA WENSKA et STEFAN PASZYC. Can. J. Chem. **66**, 513 (1988).

Opérant dans l'eau et dans des solvants organiques, on a mesuré la fluorescence à l'état stationnaire ainsi que celle résolue en fonction du temps d'une série de composés bichromophoriques contenant des résidus méthoxy-7 coumarine et une base nucléotide. On a utilisé les données ainsi obtenues pour calculer les proportions relatives des conformations repliée et étendue des bichromophores. On a trouvé que les interactions d'empilement dans l'état fondamental de la coumarine et de la base nucléotide sont limitées aux solutions aqueuses. On a évalué la contribution du mécanisme de piégeage dynamique au piégeage total de la fluorescence dans l'eau. On explique l'absence de piégeage dynamique dans les solvants organiques par le temps de vie très court du fluorophore dans le méthanol.

[Traduit par la revue]

Introduction

It is well known that heteroaromatic compounds from the psoralen family form noncovalent complexes with nucleic acids (1, 2). The formation of the complex by weak forces, i.e., aromatic ring stacking due to hydrophobic and van der Waals forces, is one of several parameters contributing to the overall photobiological activity of psoralens (furocoumarins). The complexation is usually described in terms of the "intercalation model", which predicts that the psoralen molecule is placed between two adjacent nucleotide base pairs. Both ultraviolet absorption and fluorescence spectroscopy can be used to detect the intercalation complex. Its formation is generally accompanied by the bathochromic shift and hypochromicity of the near ultraviolet (uv) absorption band of the psoralen derivative. The fluorescence properties of psoralens also vary upon intercalation. The ability of nucleic acid bases to form such complexes with psoralen has been tested using model compounds in which both interacting molecules were connected with a hydrocarbon chain. The percentage of stacked or folded conformation, as opposed to extended, was determined by the study of the variation of the hypochromic effect with temperature (3, 4).

Recently we synthesized a series of compounds containing 7-methoxycoumarin and nucleic acid base: adenine, thymine, and uracil, linked together with a polymethylene chain. Intramolecular ring–ring stacking in the compounds was assessed by hypochromism measurement in the ultraviolet [5]. The compounds fluoresce at room temperature, the 7-methoxycoumarin residue being the fluorophore responsible for the observed emission. Our preliminary results indicated that in aqueous solution the emission from a selectively excited 7-methoxycoumarin residue incorporated in the system was efficiently quenched. We have therefore investigated the intramolecular complexing of the units of bichromophoric compounds using fluorescence spectroscopy, and in this paper we would like to present our results.

[1]Revision received November 9, 1987.

Results and discussion

The fluorescence intensity of 7-methoxycoumarin (**1**, Scheme 1), which was used as a reference compound, is strongly dependent on solvent polarity (Table 1). Fluorescence quantum yield has the highest value in aqueous solution and decreases with decreasing polarity of the solvent. A variation of the fluorescence intensity of 7-methoxycoumarin in methanol–water mixtures was noted previously (6). On the other hand, the

[c]Data from ref. 5.

location of the emission maximum is only slightly solvent dependent and is red shifted in polar solvents. An explanation of the solvent dependence of the fluorescence of **1** was postulated, based on the variation in energy of excited $^1\pi\pi^*$ and $^3n\pi^*$ levels of coumarin with solvent polarity (6). In nonpolar solvents the $n\pi^*$ singlet and triplet states are just above and just below the S_1 ($\pi\pi^*$) state, respectively. Under these conditions intersystem crossing from the S_1 ($\pi\pi^*$) state to the closely lying $^3n\pi^*$ state is efficient and the fluorescence yield is small. In polar solvents the energy of the S_1 ($\pi\pi^*$) state is lowered below that of the $n\pi^*$ triplet state. As a consequence the efficiency of intersystem crossing decreases and the fluorescence quantum yield increases. However, another explanation is possible. Lai *et al.* (7) have recently studied the photophysical properties of some furocoumarins in different solvents. The authors conclude that the photophysical behaviour of the compounds studied is controlled by the "proximity effect", which is a consequence of vibronic interaction between closely lying $^1\pi\pi^*$ and $^1n\pi^*$ states. In their paper, the strong, coumarin-like solvent dependence of the fluorescence of the furocoumarins was accounted for in terms of the solvent dependent $^1\pi\pi^*$–$^1n\pi^*$ electronic energy gap, which affects the $S_1 \rightsquigarrow S_0$ internal conversion rate.

In compounds **2–6** containing the 7-methoxycoumarin chromophore and nucleotide base the coumarin fluorescence in aqueous solution is much less intense than that of the reference, i.e., 7-methoxycoumarin (**1**) (Table 2, I_{fl}/I_{fl}^0). No new bands are observed in the fluorescence spectra of **2–6** that could be attributed to exciplex emission. The efficiency of the intramolecular quenching process is sensitive to the identity of the attached nucleotide base and to the length of the chain linking the two chromophores.

Quenching of excited states can be achieved either by resonance energy transfer involving large molecular separation or by contact quenching. Since there is no overlap between the emission of coumarin and the absorption spectra of the nucleotide base (5), the observed quenching is not due to energy transfer (10). Two types of contact quenching are known: static and dynamic quenching.[2] Although both types of quenching decrease the emission yield, only the dynamic quenching reduces the emission lifetime. Measurements of the lifetimes allow evaluation of the contribution of the two mechanisms to the total quenching. Static quenching can then be quantitatively related to the proportion of the folded, i.e., intramolecularly complexed, conformations of **2–6**.

[2]Reference 10, pp. 441–443.

The fluorescence emissions of all the compounds **1–6** decay monoexponentially, as shown in Fig. 1. The fluorescence lifetimes of 7-methoxycoumarin (**1**) and bichromophoric compounds **2–6** in water and in methanol are presented in Tables 2 and 3. Monoexponential fluorescence decay of 7-ethoxycoumarin (11) and 7-hydroxycoumarin (12) was reported and it contrasts with that of the furocoumarins. The latter show bi- and triexponential decays in water and in methanol due to the formation of fluorescent complexes with the solvent (12, 13).

A comparison of relative fluorescence intensities and lifetimes in aqueous solution (Table 2) reveals that both quenching processes operate, as illustrated in Scheme 2. Using the approach described previously for the nucleotide base – indole system (14), the fraction γ of light absorbed by the extended form of the bichromophoric compound and the fraction α of unfolded conformations of **2–6** in the ground state can be calculated from eqs. [1] and [2].

$$[1] \quad \gamma = \frac{I_{fl}}{I_{fl}^0} \cdot \frac{\tau^0}{\tau}$$

$$[2] \quad \alpha = \frac{\bar{\varepsilon}}{\varepsilon_0} \cdot \gamma$$

where I_{fl} and τ are the fluorescence intensity and lifetime of **2–6**, I_{fl}^0 and τ^0 the fluorescence intensity and lifetime of **1**, $\bar{\varepsilon}$ is the measured molar extinction coefficient of the bichromophoric compound, and ε_0 the molar extinction coefficient of the extended form of **2–6**, respectively, assumed to be the same as for **1** at λ = 324 nm. The calculated values of $(1-\alpha)$ then represent the fraction of bichromophoric molecules that exist in folded conformation in the ground state; i.e., they correspond to the degree of intramolecular association present in each compound.

The structural preference for ground state interaction of 7-methoxycoumarin with adenine rather than with the pyrimidines (uracil and thymine) is evident from the data obtained (Table 2). The degree of stacking interaction CouO-C_3-Ade > CouO-C_3-Thy ~ CouO-C_3-Ura, obtained here from fluorescence measurements, is in agreement with that obtained from uv absorption (hypochromism) (5). Similar results were obtained for nucleotide base – psoralen pairs. The calculation based on temperature dependence of hypochromism showed that 80% of trimethylene chain linked adenine–psoralen molecules exist in folded conformation at 20°C in H_2O–EtOH (95:5) solution. The preference for interaction of psoralen with adenine rather than with thymine was also observed (4).

allow the calculation of the intramolecular quenching rate constant k_q using eq. [3] (14, 15) (Table 2):

$$[3] \quad k_q = \frac{1}{\tau} - \frac{1}{\tau^0}$$

The differences in the rate constant k_q for all the compounds are evident, and the variation with chain length and structure of nucleic acid base is observed.

In methanol and acetonitrile both the fluorescence quantum yield and fluorescence lifetime of 7-methoxycoumarin are significantly reduced as compared to aqueous solution (Table 1). Possible explanations for this have been discussed above. However, in organic solvents no fluorescence quenching of the 7-methoxycoumarin residue incorporated in the systems **2**–**6** is observed. The relative fluorescence intensities I_{fl}/I_{fl}^0 for **2**, **4**, and **6** presented in Table 3 are close to unity. The compound CouO-C_3-Ade (**2**) is an exception. In this case the fluorescence quenching, inefficient compared to aqueous solution, is, however, only dynamic because the value of I_{fl}/I_{fl}^0 is equal to the value of τ/τ^0 within experimental error. The absence of static quenching indicates that the fraction of folded forms is negligible.

The stacking interaction of 7-methoxycoumarin residue with nucleotide bases is thus limited to aqueous solution. The observation has precedent, lack of any stacking interaction in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

organic solvents having been noted previously for nucleotide base and psoralen (4), indole (14), and quinoline (15) pairs, respectively. The effect of solvents on stacking interaction is not yet completely understood. It is thought, however, that hydrophobic forces play an important role in stabilization of the stacked conformation in aqueous solution (4).

The fluorescence of the 7-methoxycoumarin residue in **4** and **6** is not quenched even through the dynamic quenching mechanism in organic solvents. This fact can be explained by taking into account a very short fluorescence lifetime of 7-methoxycoumarin (0.20 ns in methanol). The intramolecular fluorescence quenching rate is limited by the rate of conformational change around a hydrocarbon chain. The maximum value of the rate constant for changes around a trimethylene bridge was reported to be $10^9\ s^{-1}$ (16); the self-deactivation rate of 7-methoxycoumarin (**1**) was calculated from $1/\tau^0 = 5 \times 10^9\ s^{-1}$ in methanol. It appears that in **4** and **6** the excited state of the fluorophore self-deactivates before the fluorophore and quencher residues in the bichromophoric molecules are brought into close proximity.

Experimental

The synthesis of compounds **2**, **3**, and **4** was reported previously (5). The compounds **5** and **6** were synthesized by alkylation of 7-hydroxycoumarin with 1-(5-bromopentyl)thymine and 1-(3-bromopropyl)uracil, respectively. The purity of all the compounds was checked by ^{1}H nmr and microanalysis, as well as by tlc and gc techniques.

Doubly distilled water, spectroscopic grade methanol (Fisher), and acetonitrile (Merck) were used as solvents. Relative fluorescence intensities were determined by integration and comparison of uncorrected emission spectra of **2**–**6** (I_{fl}) and the reference compound **1** (I_{fl}^0). Solutions of both bichromophoric compound and reference compound had equal absorbance at the exciting wavelength (λ_{exc} = 324 nm). The fluorescence quantum yield for **1** was measured from corrected spectra using quinine sulfate as a standard (0.1 M H_2SO_4, φ_{fl} = 0.55 (8)). Steady-state fluorescence measurements were performed on a Perkin–Elmer MPF-44B spectrofluorimeter. Absorbances of the samples (10-mm cells) for fluorescence studies were all ca. 0.05, i.e., concentrations of the solutions were in the range $(2.2–6.8) \times 10^{-6}$ M. Fluorescence lifetimes were measured with a Spectra-Physics synchronously pumped, cavity-dumped, frequency doubled dye laser system using a time-correlated single photon counting technique. The apparatus, as well as the technique for analyzing the decay curves, has been previously described (17).

Synthesis and conformational analysis of several *cis*- and (or) *trans*-2-amino-1,2,3,4-tetrahydro-1-naphthalenols are described. Introduction of the nitrogen atom at the C(2) position of the starting tetralones **3** has been carried out through nitrosation followed by reduction of the intermediate hydroxyimino tetralone and (or) Neber rearrangement of the tosyloxy derivatives **7***a–e*. Stereoselective reduction of the C(1) carbonyl group of acetamidotetralones **5***a–e* or aminotetralones **8***a–e* afforded the corresponding acetamido or aminotetralols, respectively, of OH/N *trans* stereochemistry whereas an opposite stereoselectivity was observed in reduction of C(8)-OCH_3 derivatives **5***f* and **8***f* under the same experimental conditions. Finally, acid hydrolysis of *trans*-acetamidotetralols led to *cis*-aminoalcohols in high yields. Conformational analysis has been carried out by ^1H nuclear magnetic resonance techniques and MM2 theoretical calculations. All *cis* derivatives showed a major conformation in which the C(1)-OH group adopts a pseudoaxial disposition. On the other hand, *trans*-aminoalcohols in $CDCl_3$ showed a major or exclusive OH/N *trans*-dipseudoequatorial conformation in which stabilization by intramolecular OH/N hydrogen bonding is possible. The only exception was found in C(8)-OCH_3 *trans*-aminoalcohols in DMSO-d_6 solution, which showed a major OH/N *trans*-diaxial conformation.

ANTONIO DELGADO, JOSÉ MIGUEL GARCIA, DAVID MAULEON, CRISTINA MINGUILLON, JOAN RAMON SUBIRATS, MIGUEL FELIZ, FRANCISCO LOPEZ et DOLORES VELASCO. Can. J. Chem. **66**, 517 (1988).

On décrit la synthèse et l'analyse conformationnelle de plusieurs amino-2 tétrahydro-1,2,3,4 naphtalénols-1-*cis* et -*trans*. Pour introduire un atome d'azote en position C(2) des tétralones **3** de départ, on a fait appel soit à une nitrosation suivie d'une réduction de l'hydroximino tétralone intermédiaire soit à une transposition de Neber des dérivés tosyloxy **7***a–e*. La réduction stéréosélective du groupement carbonyle en C(1) des acétamidotétralones **5***a–e* ou des aminotétralones **8***a–e* conduit aux acétamido ou aminotétralols correspondants de stéréochimie OH/N *trans*; par ailleurs, on obtient la stéréochimie inverse lorsqu'on réduit les dérivés C(8)-OCH_3, **5***f* et **8***f*, en utilisant les mêmes conditions expérimentales. Enfin, l'hydrolyse acide des acétamidotétralols-*trans* conduit au aminoalcools-*cis*, avec d'excellents rendements. On a réalisé l'analyse conformationnelle à l'aide de la résonance magnétique nucléaire du ^1H et de calculs théoriques MM2. Pour chacun des dérivés *cis*, la conformation prédominante comporte un groupement C(1)-OH dans une position pseudo-axiale. Par ailleurs, en solution dans le $CDCl_3$, les aminoalcools *trans* présentent une conformation majeure, sinon exclusive, OH/N di-pseudo-équatoriale *trans* dans laquelle une stabilisation par liaison OH/N intramoléculaire est possible. On a noté une seule exception; il s'agit des aminoalcools *trans* C(8)-OCH_3 qui, en solution dans le DMSO-d_6, existent dans une conformation OH/N *trans*-diaxiale.

[Traduit par la revue]

As part of our research concerning the synthesis of conformationally restrained arylethanolamines, this paper deals with the synthesis and conformational analysis of several *cis*- and (or) *trans*-2-amino-1,2,3,4-tetrahydro-1-naphthalenols **1***a–i* and **2***a–i* (Scheme 1) as potential adrenergic agents.

In all cases, synthesis started from the corresponding 1-tetralones **3***a–f*, prepared by standard procedures. Introduction of the nitrogen atom at the C(2) position of the 1-tetralone system was carried out according to two alternative procedures (Scheme 2).

First, nitrosation of 1-tetralones **3***a,b,d–f* with butyl- or isoamyl nitrite in the presence of potassium *tert*-butoxide afforded the desired hydroxyiminotetralones **4***a,b,d–f* in 50–80% yield. The comparatively lower yields observed for **4***b*, *d*, and *f* can be explained as a consequence of the concomitant formation of benzoates **9***b,d,f* or **10**, resulting from alkoxide

attack upon the C(1) position of the initially formed nitroso derivatives and subsequent Beckmann fragmentation (1) (Scheme 3). Nitrile **10** (arising from alkaline cleavage of the oximino ketone) (2) was obtained instead of the oxime, upon nitrosation of **3***d* with butyl nitrite. In general, short reaction times and low temperatures minimize or avoid the formation of the above fragmentation products.

Attempts to elaborate the 2-amino-1-tetralol moiety by direct reduction of hydroxyiminotetralones **4** were unsuccessful. Thus, hydrogenation of **4***d* over palladium–charcoal in acidic medium (3) afforded naphthylamine **11** as the only isolable product (Scheme 4). On the other hand, treatment of both **4***d* and **4***f* with lithium aluminum hydride (4) afforded only trace amounts of a *cis–trans* mixture of aminoalcohols **1***d* and **1***f*, respectively. In consequence, a stepwise reduction of oximino-tetralones **4***a*, *b*, *d–f* was envisaged. Thus, treatment of crude

SCHEME 5

oximinotetralones with zinc dust in acetic acid – acetic anhydride solution (Scheme 2, pathway A), led to 2-acetamido-1-tetralones **5***a,b,d–f* in 55–65% yield. Reduction of **4***f* under the above conditions afforded a 5:1 mixture of **5***f* and naphthol **12** in 77% yield. Formation of **12** can be interpreted as a redox reaction between the hydroxyiminotetralone **4***f* and the initially formed acetamidotetralone **5***f* (Scheme 5). Alternative reduction of **4***f* by hydrogenation over Pd 10%/$BaSO_4$ in AcOH–Ac_2O (5) did not modify the above results.

Neber rearrangement (6) was used as the key step for the second (alternative) pathway to synthesize 2-amino-1-tetralols. The required tosyloxyderivatives **7***a–e* (Scheme 2, pathway B) were routinely obtained in two steps from the corresponding tetralones **3***a–e*. Neber rearrangement was not applied to the preparation of the 5,8-dimethoxylated aminoketone hydrochloride **8***f* since it is known that the steric hindrance exerted by the 8-OCH_3 group precludes formation of **7***f* from **3***f*-oxime (7). However, **8***f* could be obtained by acid hydrolysis of acetamidotetralone **5***f*.

The stereoselective course of the reduction of the carbonyl group in 2-acetamido- and 2-amino-1-tetralones to give the corresponding *trans*-2-acetamido- or *trans*-2-amino-1-tetralols is well documented (5, 8, 9, 10). As expected, sodium borohydride reduction of compounds **5***a,b,d,e* in CH_3OH–H_2O (Scheme 2, pathway A) afforded the corresponding *trans* derivatives **6***a,b,d,e* as the major products (about a 90:10 *trans/cis* ratio based on C(1)H signal integration in the high resolution ^{1}H nmr spectra). The stereochemistry of compounds **6***a,b,d,e* was also confirmed by the $W_{1/2}$ value of about 16 Hz observed for the C(1)H proton, thus indicating a C(1)H–C(2)H pseudoaxial relationship. Alkaline hydrolysis of acetamidotetralols *trans*-**6***a,b,d,e* afforded the desired aminoalcohols *trans*-**1***a,b,d,e* in good yields, whose stereochemistry was confirmed by derivatization into conformationally restrained oxazolidin-2-one derivatives (11) as well as on the basis of the C(1)H chemical shift and coupling constant values (12, 13) of the cycloaliphatic protons (see below). On the other hand, aminoalcohols *trans*-**1***a–e* could be obtained by stereoselective sodium borohydride reduction of 2-amino-1-tetralone hydrochlorides **8***a–e* (again, about a 90:10 *trans/cis* ratio based on C(1)H signal integration was found).

The reverse stereoselectivity observed in the sodium borohydride reduction of the dimethoxylated derivatives **5***f* and **8***f* deserves comment. Thus, treatment under the above experimental conditions afforded in each case a mixture of diastereoisomers in which *cis* derivatives were predominant (about a 65:35 *cis/trans* ratio). Analysis of C(1)H signals in the high resolution ^{1}H nmr spectrum of the crude reaction mixture arising from sodium borohydride reduction of **5***f* revealed a doublet at 4.93 ppm (major isomer) whose coupling constant value (J = 4.3 Hz) was indicative of a *cis*-OH_{axial}/$NHR_{equatorial}$ relationship. Alkaline hydrolysis of this major isomer afforded aminoalcohol *cis*-**1***f*, whose stereochemistry was also confirmed on the basis of ^{1}H nmr data (see below). In the same way, sodium borohydride reduction of hydrochloride **8***f* afforded predominantly aminoalcohol *cis*-**1***f*. These results are opposite to those described by other authors (14), who assigned a *trans* stereochemistry to compound *cis*-**1***f*. The observed reversal of stereoselectivity can be rationalized according to House *et al.* (15, 16), assuming that the geometry of the transition state and that of the final product are similar and adequate to predict the major stereochemical course of borohydride reductions. Thus, the most stable transition state in the reduction of **5***a,b,d,e* and **8***a–e* would lead to a *trans*-OH/NHR diequatorial relationship, whereas the transition state leading to *cis*-**1***f* and *cis*-**6***f* from **5***f* and **8***f*, respectively, would be the most stable one, since steric crowding due to the "*peri*" effect between C(8) and C(1) groups is minimized. This interpretation does not preclude complexation between the 2-acetamido group and borane, which has been postulated in reduction of 2-amino-1-indanones (17).

In contrast to borohydride reductions, hydrogenation over Adams catalyst of 2-acetamidotetralone **5***f* afforded predominantly *trans*-acetamidoalcohol **6***f* (about 80:20 *trans/cis* ratio based on ^{1}H nmr analysis), whose stereochemistry was confirmed by alkaline hydrolysis to aminoalcohol *trans*-**1***f*. The low coupling constant value (J = 4.9 Hz) between C(1)H–C(2)H for *trans*-**6***f* in $CDCl_3$ solution was indicative of the preferred OH/NHR *trans*-diaxial conformation in which *peri* interactions between C(1)H and C(8)OCH_3 groups are avoided. Likewise, the C(1) chemical shift observed for *trans*-**6***f* (see Table 3) is in agreement with the proposed OH-pseudoaxial disposition (18).

In summary, aminoalcohols *trans*-**1***a,b,d,e* could be obtained in comparable yields from the corresponding tetralones **3** by either of the two alternative pathways outlined in Scheme 2 (overall yields: pathway A, 18–20%; pathway B: 12–15%). Finally, hydrogenolysis of aminoalcohols *trans*-**1***c–e* over 5% palladium–charcoal (200 psi; 1 psi = 6.9 kPa) afforded the desired phenolic derivatives *trans*-**1***g–i* in about 50% yield. Attempts to carry out hydrogenolysis under atmospheric pressure gave only starting aminoalcohols whereas hydrogenation under acidic conditions resulted in simultaneous hydrogenolysis of benzyl and 1-hydroxyl groups.

Aminoalcohols *cis*-**1***a*, *b*, and *f* could be readily obtained by acid hydrolysis of acetamidotetralols *trans*-**6***a,b*, and *f*, through a process that is known to proceed via an oxazoline intermediate with inversion of configuration at the C(1) carbon atom (10). Formation of the intermediate oxazoline was found to be very favourable upon acidic treatment of both *cis*- and *trans*-**6***f*. In fact, acidic work-up after sodium borohydride reduction of **5***f* afforded exclusively tetrahydronaphtho[2,1-*d*]oxazol derivative **13** (Scheme 7). Formation of

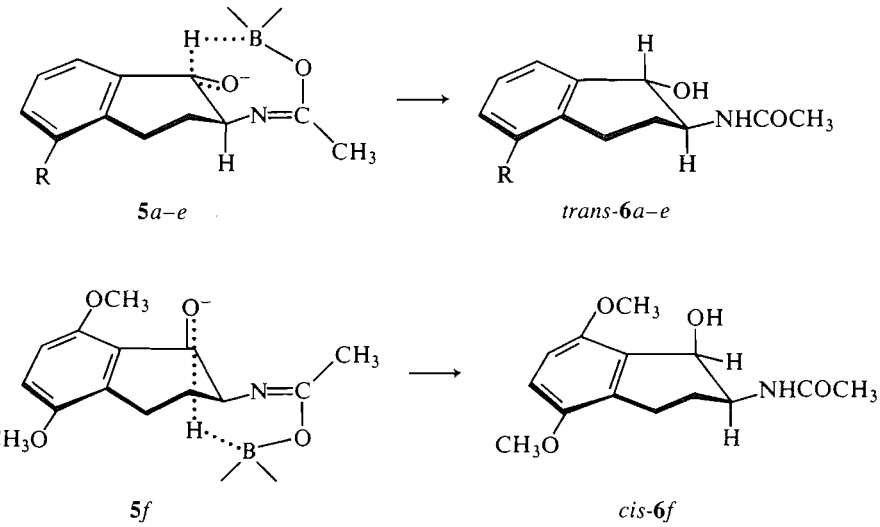
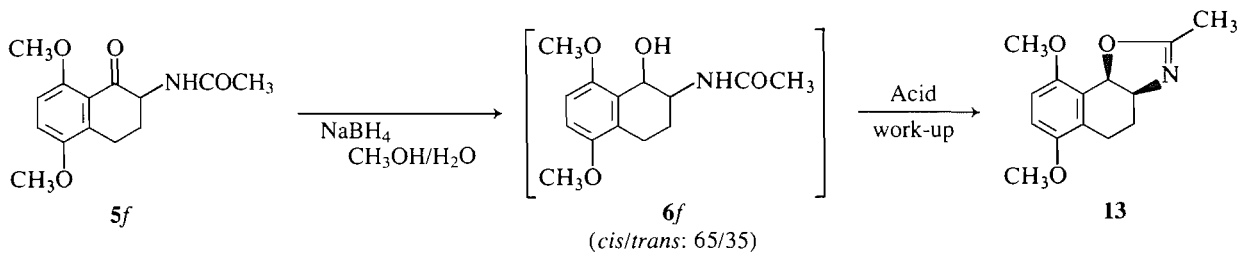
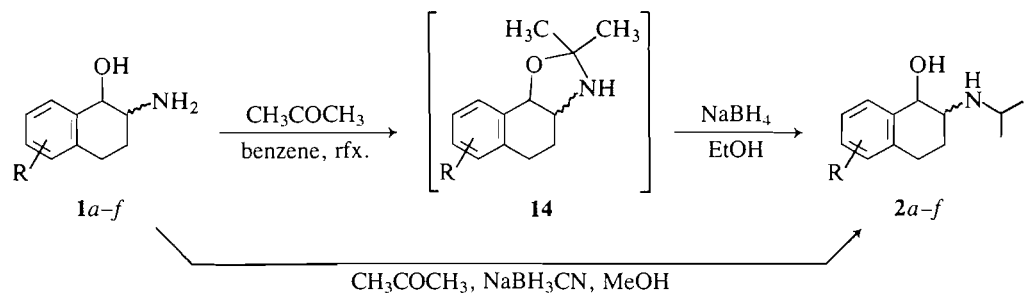


SCHEME 6



SCHEME 7



SCHEME 8

13 could be also carried out in an ^{1}H nmr tube. Thus, in the presence of a few drops of TFA, both *cis*- and *trans*-**6***f* in $CDCl_3$ gave an identical product whose ^{1}H nmr signals were superimposable on those of **13** recorded on $CDCl_3$ + TFA. On the other hand, alkaline hydrolysis of **13** afforded aminoalcohol *cis*-**1***f* as the only reaction product. The straightforward formation of **13** from *trans*-**6***f* can be explained in the light of the major *trans*-diaxial OH/NHR conformation of the starting 2-acetamidotetralol (see below).

Isopropyl derivatives **2** were obtained in each case from the corresponding *cis* or *trans* aminoalcohols either by reductive alkylation with excess acetone in benzene followed by sodium borohydride reduction of the intermediate oxazolidine system **14** (19) or in a one-step procedure with acetone – sodium cyanoborohydride in methanol (20) (Scheme 8). As in the amino series, isopropylamino derivatives *trans*-**2***g–i* were obtained by benzyl group hydrogenolysis as described above.

Conformational analysis

Although 2-aminotetrahydro-1-naphthols can be regarded as conformationally restrained analogues of adrenergic arylethanolamines, two limited half-chair conformations are still possible for each compound. Since interpretation of pharmacological data requires the knowledge of the preferred conformation in solution of the molecule under study, we have carried out a conformational analysis of the target aminotetrahydronaphthols by means of nmr data and theoretical calculations.

Assignment of the *cis* or *trans* OH/NHR relationship in amino or isopropylaminotetralols **1** and **2** can usually be carried out by simple inspection of ^{1}H nmr spectra, on the basis of C(1)H chemical shift and coupling constant differences in each diastereomer (12, 13). Thus, whereas compounds *cis*-**1***a,b,f* and *cis*-**2***a,b,f* showed a mean $\delta_{C(1)H}$ ($\pm$SD) of 4.68 ($\pm$0.16) ppm and a mean coupling constant J_{1-2} = 3.7 ($\pm$0.3) Hz, *trans* derivatives **1***a–i* and **2***a–i* (except for *trans*-**1***f* and *trans*-**2***f*, see

below) showed average values of $\delta_{C(1)H} = 4.26$ (±0.13) ppm and $J_{1-2} = 8.6$ (±0.8) Hz. Finally, stereochemistry of 2-amino-1-tetralols has also been confirmed independently by derivatization into the corresponding tricyclic oxazolidin-2-one derivatives (11).

The cycloaliphatic region of the ^1H nmr spectra of *cis* derivatives **1***a*,*b*,*f* and **2***a*,*b*,*f* was almost superimposable. Consequently, we decided to carry out the spin system analysis by means of the LAOCOON-3 program of compound *cis*-**1***b*, which was taken as standard for this purpose (Table 1). Coupling constant values between C(2)H and $C(3)H_\alpha/C(3)H_\beta$ indicate a C(2)H axial disposition and, accordingly, a major or exclusive conformation in which the OH group is pseudoaxial and the NHR group is pseudoequatorial. In this conformation, *peri* interaction between the C(1)OH and C(8) groups (H in *cis*-**1***b*) is avoided and intramolecular OH–NHR hydrogen bonding can be established. Pseudoequatorial C(1)H disposition in *cis* derivatives was confirmed by a nuclear Overhauser effect (nOe) (21) enhancement. Thus, irradiation of the $C(8)OCH_3$ group of *cis*-**1***f* gave rise to a C(1)H nOe enhancement of 13%. On the other hand, a long-range *W* coupling (22) ($J = 0.9$ Hz) was also observed for C(1)H with C(3α)H in *cis*-**1***f* and *cis*-**2***f* derivatives, thus indicating a pseudoequatorial disposition for the above proton.

Theoretical calculations may be used as an independent criterion for performing conformational analysis. By means of the highly reliable Allinger's MM2 force field program (23), energies and geometries of both limited conformers *cis*-A and *cis*-B (Scheme 9) of compounds *cis*-**1***b* and *cis*-**1***f* have been calculated (Table 2). In both cases, *cis*-A conformers turned out to be more stable than the corresponding *cis*-B ones; the observed steric energy differences between them indicate a *cis*-A/*cis*-B relative population of 99:1, which is in agreement with the results of the ^1H nmr study. Moreover, application of the Karplus–Altona equation (24) to the dihedral angles obtained from MM2 analysis afforded a set of coupling constants (Table 2) very similar to those experimentally found (Table 1).

As in the *cis* series, *trans* derivatives **1***a–e* and **2***a–e* showed a nearly superimposable cycloaliphatic region in their ^1H nmr spectra. Spin system analysis of the model compound *trans*-**1***b* (Table 1) indicates a pseudoaxial C(2)H disposition and, consequently, a dipseudoequatorial relationship between amino and hydroxyl groups. This conformation is stabilized by intramolecular hydrogen bonding (broad signal between 3500 and 3000 cm^{-1} in the ir spectra), which overcomes the low *peri* interaction between C(1)OH and C(8)H groups. Accordingly, MM2 calculations for *trans*-A and *trans*-B conformers indicate the higher stability of the diequatorial *trans*-B conformer ($\Delta E =$ 1.21 kcal/mol) as well as a relative population of about 90:10 *trans*-B vs. *trans*-A. Once again, application of the Karplus–Altona equation to the predicted C(2)H coupling constants afforded mean *J* values in agreement with the experimental ones.

Dimethoxylated derivatives *trans*-**1***f* and *trans*-**2***f* were exceptional, since C(1)H protons showed lower J_{1-2} coupling constant and chemical shift values (0.3–0.4 ppm) with respect to C(8) unsubstituted derivatives, such as *trans*-**1***b* (Table 1). This is consistent with an equilibrium between *trans*-A and *trans*-B conformers in which participation of *trans*-A would be important to avoid the strong *peri* interaction between C(1)OH and $C(8)OCH_3$ groups. This situation stands out in DMSO-d_6

*See Scheme 9.

solution (J_{1-2} = 3.5 Hz for *trans*-**1***f*) more than in $CDCl_3$ solution (J_{1-2} = 7.2 Hz for *trans*-**1***f* and 6.2 Hz for *trans*-**2***f*), probably due to the solvating properties of DMSO, which stabilizes the *trans*-A conformation by intermolecular hydrogen bonding. As expected, intramolecular hydrogen bonding is reinforced by protonation of the amino group. Thus, the J_{1-2} value for *trans*-**1***f* in DMSO-d_6 + TFA rises to 6.4 Hz, which is in agreement with a major *trans*-B conformation as in *trans*-**1***a–e* derivatives. The major *trans*-A conformation of *trans*-**1***f* in DMSO-d_6 solution was confirmed by a C(1)H nOe enhancement of 10% on irradiation of the C(8)OCH_3 group. However, although these findings are indicative of conformational equilibrium, no variation of J_{1-2} coupling constants was observed in the temperature range between −60°C ($CDCl_3$) and +60°C (DMSO-d_6).

As above, results of MM2 force field calculations of *trans*-**1***f* (Table 2) were in agreement with ^{1}H nmr experimental data. Thus, the *trans*-A diaxial conformer turned out to be more stable than the *trans*-B (ΔE = 1.07 kcal/mol), and a relative population of about 85% could be estimated for the former. Coupling constant values derived from the Karplus–Altona equation (Table 2) correlate well with those found experimentally in DMSO-d_6 (Table 1). However, spin system analysis of *trans*-**1***f* in $CDCl_3$ afforded a set of coupling constants similar to those found for *trans*-**1***b* by MM2 calculations, which implies the predominance of the diequatorial *trans*-B conformation in nonpolar solvents.

Finally, ^{13}C nmr data (Table 3) are also in good agreement with the above results. Thus, in $CDCl_3$ solution, carbon atom C(1) is observed at 73.2 (±1.4) ppm in *trans* isomers and at 66.5 (±3.2) ppm in *cis* ones. The upfield shift found in *cis* isomers is consistent with the known shielding effect exerted by a pseudoaxial C(1)OH group upon the benzylic carbon atom in a tetralol system (18). On the other hand, carbon atom C(3) is also shielded in some *cis* isomers with respect to *trans* ones, due to a γ-*gauche* effect exerted by the pseudoaxial C(1)OH group. As expected, the C(1) chemical shift of *trans*-**1***f* in DMSO-d_6 solution showed an upfield shift of about 6 ppm, whereas C(3) and C(4) carbon atoms were shielded 3.8 and 2.9 ppm, respectively. Once again, this is consistent with the major *trans*-A diaxial conformation expected for *trans*-**1***f* in this solvent.

Experimental

Melting points were determined in a capillary tube on a Buchi apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 1430 spectrophotometer. Proton magnetic resonance spectra were measured at 60 MHz with a Perkin–Elmer R 24B instrument or at 200 MHz with a FT Varian XL-200 spectrometer. Signal positions are reported in ppm downfield from tetramethylsilane (δ scale) as an internal standard, and $CDCl_3$ as a solvent, unless otherwise indicated. The ^{13}C nmr spectra were measured at 50.3 MHz with a Varian XL-200 spectrometer, with internal tetramethylsilane as a reference. Multiplicity of the signal was determined by the ADEPT program (25). Homonuclear chemical shift correlation ^{1}H/^{1}H was determined by the HOMCOR program (26) and heteronuclear chemical shift correlation ^{13}C/^{1}H by the HETCOR program (27). MM2 calculations were performed on an IBM/3083 computer. Mass spectra were recorded on a Hewlett–Packard 5930 A spectrometer. Solutions in organic solvents were dried over anhydrous sodium sulfate and stripped of solvent with a rotary evaporator connected to a water aspirator. Microanalyses were performed by the Departamento de Quimica Organica Biologica (C.S.I.C.), Barcelona.

General synthetic methods

*Benzyl-3,4-dihydro-2*H*-1-naphthalenones (***3***c–e)*

Method A

To a mixture of 0.1 mol of the corresponding hydroxytetralone **3***g* (28), **3***h* (29), or **3***i* (30) and 0.25 mol of anhydrous potassium carbonate, 0.1 mol of benzyl chloride in 150 mL of dry dimethylformamide was added dropwise. The reaction mixture was stirred at 80–100°C for 4 h, poured into ice-water and extracted with ether. The organic extracts were washed with brine, dried, and evaporated to afford **3***c–e*. Compound **3***c* (see also Table 4), ir ($CHCl_3$): 1680 (C=O); ^{1}H nmr (CCl_4): 2.0 (m, 2H, C(3)H_2), 2.4 (m, 2H, C(2)H_2), 2.8 (m, 2H, C(4)H_2), 4.9 (s, 2H, $CH_2C_6H_5$), 6.7–7.5 (m, 3H, ArH), 7.1 (s, 5H, C_6H_5). Compound **3***d* (see also Table 4), ir (KBr): 1660 (C=O), 1600; ^{1}H nmr (CCl_4): 2.0 (m, 2H, C(3)H_2), 2.4 (t, 2H, C(2)H_2), 2.7 (t, 2H, C(4)H_2), 4.8 (s, 2H, $OCH_2C_6H_5$), 6.5 (s, 1H, C(5)H), 6.6 (dd, 1H, C(7)H), 7.1 (s, 5H, C_6H_5), 7.6 (d, 1H, C(8)H). Compound **3***e* (10) (80%).

*2-Hydroxyimino-3,4-dihydro-2*H*-1-naphthalenones (***4***a,b,d–f)*

Method B

An ice-cooled solution of 30 mmol of potassium *tert*-butoxide,

in 35 mL of *tert*-butanol and 150 mL of dry ether under a nitrogen atmosphere, was treated with 28 mmol of the appropriate tetralone **3***a*–*f* and 36.5 mmol of freshly distilled butyl nitrite or isoamyl nitrite. After heating at reflux temperature (3 h for tetralones **3***a*, **3***c*, and **3***d*, and 10 min for tetralone **3***e*) or stirring at room temperature for 30 min (tetralones **3***b* and **3***f*) the reaction mixture was quenched with water and washed with ether. The aqueous phase was made acidic with 2 *M* HCl and extracted with dichloromethane to afford hydroxyiminotetralones. Compounds **4***a* (5) (85%), **4***b* (66%), and **4***f* (52%) were used without further purification. Compound **4***b*, ir (KBr): 3300–3100 (OH), 1720 (C=O), 1580 (C=N); ^1H nmr: 2.9 (m, 4H, C(3)H_2 + C(4)H_2), 3.8 (s, 3H, OCH_3), 6.6–7.7 (m, 3H, arom.). Compound **4***d* (*E* isomer) (see also Table 4), ir (KBr): 3500–3000 (OH), 1680 (C=O), 1590 (C=N); ^1H nmr (DMSO-d_6): 2.9 (s, 4H, C(3)H_2 + C(4)H_2), 4.9 (s, 2H, $OCH_2C_6H_5$), 6.6 (s, 1H, C(5)H), 6.7 (dd, J = 8 Hz and J = 2 Hz, 1H, C(7)H), 7.1 (s, 5H, C_6H_5), 7.7 (d, J = 8 Hz, 1H, C(8)H); ms, *m/e* (relative intensity): 281 (0.2), 91 (100). Compound **4***e*, (10) (60%). Compound **4***f*, ir (KBr): 3200 (OH), 1695 (C=O); ^1H nmr: 2.9 (s, 4H, C(3)H_2 + C(4)H_2), 3.7 (s, 3H, OCH_3), 6.7 (s, 2H, arom.), 7.8 (br, 1H, =N—OH).

Evaporation of the ethereal washings from reaction of tetralone **3***d* with isoamyl nitrite afforded a residue, which was chromatographed on silica gel. On elution with benzene – ethyl acetate (95:5), the *Z* isomer of oxime **4***d* was isolated (Table 4); ir ($CHCl_3$): 2900–2800 (OH str), 1600 (N=O); ^1H nmr: 2.9 (s, 4H, C(3)H_2 + C(4)H_2), 4.9 (s, 2H, $OCH_2C_6H_5$), 6.6 (s, 1H, C(5)H), 6.8 (dd, J = 9 Hz and J = 2 Hz, 1H, C(7)H), 7.2 (s, 5H, C_6H_5), 7.8 (d, J = 9 Hz, 1H, C(8)H), 15.2 (s, 1H, =NOH); ms, *m/e* (relative intensity): 281 (0.2), 91 (100). On elution with benzene – ethyl acetate (90:10), a mixture of *E*- and *Z*-4-benzyloxy-2-(2-formylethyl)isopentyl benzoate oximes (**9***d*) was isolated (Table 4); ir (NaCl): 3500–3150 (N—OH), 1710 (C=O), 1610 (C=N); ^1H nmr: 0.9 (d, 6H, CH_3-ipr), 1.5 (m, 3H, CH_2CH), 2.5 (m, 2H, CH_2CH=N), 3.1 (m, 2H, CH_2Ar), 4.1 (m, 2H, $COOCH_2$), 4.9 (s, 2H, $CH_2C_6H_5$), 6.6 (m, 1H, CH=N), 6.6 (s, 1H, C(5)H), 7.2 (s, 5H, C_6H_5), 7.2 (m, 1H, C(7)H), 7.8 (d, 1H, C(8)H), 8.3 (br, 1H, N—OH); ms, *m/e* (relative intensity): 369 (0.05), 91 (100).

Ethereal washings from reaction of tetralone **3***d* with butyl nitrite afforded a residue, which was chromatographed on silica gel. On elution with benzene – ethyl acetate (90:10), butyl 4-benzyloxy-2-(2-cyanoethyl)benzoate **10** (Table 4) was obtained; ir (NaCl): 2240 (CN), 1710 (C=O); ^1H nmr (CCl_4): 0.9 (m, 3H, CH_3), 1.1–1.8 (m, 4H, $CH_2CH_2CH_3$), 2.5 (t, 2H, CH_2CN), 3.1 (t, 2H, CH_2Ar), 4.1 (t, 2H, $COOCH_2$), 4.9 (s, 2H, $OCH_2C_6H_5$), 6.6 (dd, 1H, C(7)H), 6.7 (s, 1H, C(5)H), 7.1 (s, 5H, C_6H_5), 7.7 (d, 1H, C(8)H); ms, *m/e* (relative intensity): 337 (1), 105 (20), 91 (100).

Similarly, ethereal washings from reaction of tetralones **3***b* and **3***f* with butyl nitrite afforded oximes **9***b* and **9***f*, respectively (Table 4). Compound **9***b*, ir (KBr): 3300–3100 (OH), 1720 (C=O), 1580 (C=N); ^1H nmr: 0.8–1.9 (m, 7H, $CH_2CH_2CH_3$), 2.5 (m, 2H, CH_2=CH), 3.1 (m, 2H, $ArCH_2$), 3.7 (s, 3H, OCH_3), 4.2 (m, 2H, $COOCH_2$-), 6.5–7.5 (m, 4H, CH=N + 3H arom.), 8.3 (br, 1H, OH). Compound **9***f*, ir ($CHCl_3$): 3550, 3300, 1725, 1610; ^1H nmr: 0.7–1.9 (m, 7H, $CH_2CH_2CH_3$), 2.2–3.0 (m, 4H, $ArCH_2CH_2$), 3.6 (s, 6H, $2OCH_3$), 4.2 (t, 2H, $COOCH_2$), 6.6 (s, 2H, arom.), 7.2 (m, 1H, CH=N), 8.3–9.3 (br, 1H, =NOH); ms, *m/e* (relative intensity): 309 (13), 236 (24), 218 (50), 193 (100).

*2-Acetamido-3,4-dihydro-2*H*-naphthalenones (***5***a,b,d–f) Method C*

Zinc dust (190 mmol) was added portionwise to an externally cooled solution of 2-hydroxyiminotetralone (65 mmol) in 110 mL of acetic anhydride and 150 mL of acetic acid. After stirring for 1 h at room temperature, solids were removed by filtration and the solution was evaporated *in vacuo*. The residue was made alkaline with 2 *M* sodium hydroxide solution and extracted with dichloromethane. Evaporation of the organic phase afforded crude acetamidotetralones **5**. Acetamidotetralones **5***a* (5) (65%) and **5***b* (31) (62%) afforded analytical data comparable to those described in the literature. Compound **5***d* (see also Table 4), ir (KBr): 3320 (NH amide), 1680 (C=O), 1645–1620 (CONH); ^1H nmr: 1.3–2.0 (m, 1H, C(3)H_e), 2.0 (s, 3H, CH_3), 2.4–3.2 (m, 3H, C(3)H_a + C(4)H_2), 4.2–4.7 (m, 1H, C(2)H), 5.0 (s, 2H, $OCH_2C_6H_5$), 6.4–6.8 (dd, 1H, C(5)H), 6.5 (s, 1H, NHCO), 6.5 (s, 1H, C(7)H), 7.1 (s, 5H, C_6H_5), 7.7 (d, 1H, C(8)H). Compound

*Cl or S according to the formula.
†Literature (7) mp 199–202°C, mixture of *cis*-**1***f* and *trans*-**1***f* hydrochlorides.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

5*e* (10) (60%). Compound **5***f* (see also Table 4), ir (KBr): 3300, 3100, 1705, 1670, 1640; ^{1}H nmr: 2.0 (s, 3H, CH_3CO), 2.6–3.3 (m, 4H, C(3)H_2 + C(4)H_2), 3.73 (s, 3H, OCH_3), 3.76 (s, 3H, OCH_3), 4.6 (m, 1H, C(2)H), 6.8 (dd, 3H, C(6)H + C(7)H + NHCO).

Reduction of acetamidotetralone **5***f* also afforded 2-acetamido-5,8-dimethoxy-1-naphthol **12** (Table 4) after chromatography of the crude reaction mixture (elution system: hexane – ethyl acetate 1:1); ir (KBr): 3430, 3340, 2850, 1690, 1530; ^{1}H nmr (200 MHz): 2.23 (s, 3H, CH_3CO), 3.91 (s, 3H, OCH_3), 3.99 (s, 3H, OCH_3), 6.57 (dd, 2H, C(6)H + C(7)H), 7.71 (d, J = 8 Hz, 1H, C(3)H), 7.84 (br, 1H, NHCO), 8.51 (d, J = 8 Hz, 1H, C(4)H), 9.69 (s, 1H, OH); ^{13}C nmr ($CDCl_3$): 28.4 (CH_3), 101.7, 103.7 (C-6 or C-7), 113.6 (C-3), 115.0 (C-4a), 120.1 (C-4), 122.8 (C-8a), 124.2 (C-2), 141.0 (C-1), 149.3, 150.3 (C-5 and C-8), 168.2 (CO).

trans-*2-Acetamido-1,2,3,4-tetrahydro-1-naphthalenols* (trans-**6**a,b,d,e) *Method D*

A solution of 285 mg (75 mmol) of sodium borohydride in 4 mL of water was added dropwise with external cooling to a solution of 15 mmol of the corresponding acetamidotetralone **5** in 15 mL of methanol. After stirring at room temperature until formation of a white precipitate, the resulting solid was washed with water and dried to afford *trans*-**6***a* (5) (80%), *trans*-**6***b* (31) (82%), *trans*-**6***d* (Table 4), and *trans*-**6***e* (10) (95%). Compound *trans*-**6***d*, ir (KBr): 3400–3100 (OH, NHCO), 1630; ^{1}H nmr (DMSO-d_6): 1.7 (s, 3H, CH_3CO), 1.8 (m, 2H, C(3)H_2), 2.7 (m, 2H, C(4)H_2), 3.4–4.0 (m, 2H, C(2)H), 4.3 (m, 1H, C(1)H), 4.9 (s, 2H, $OCH_2C_6H_5$), 6.5 (s, 1H, C(5)H), 6.7 (dd, 1H, C(7)H), 7.2 (d, 1H, C(8)H), 7.3 (s, 5H, C_6H_5), 7.6 (d, 1H, NH).

trans-*2-Acetamido-5,8-dimethoxy-1,2,3,4-tetrahydro-1-naphthalenol* (trans-**6**f)

A solution of 2.0 g (7.6 mmol) of acetamidotetralone **5***f* in 125 mL of methanol was hydrogenated (1 atm, 25°C) over 153 mg (0.78 mmol) of Adams catalyst. After absorption of the theoretical volume, the solution was filtered and the solvent was removed to afford a mixture of diastereomeric acetamidotetralols **6***f* (*trans*/*cis* ratio 9:1, based on ^{1}H nmr). Successive crystallizations afforded pure *trans*-**6***f* (Table 4), ir (KBr): 3350, 2950, 1660, 1540; ^{1}H nmr (200 MHz): 1.80 (m, 1H, C(3)H_a), 1.93 (s, 3H, CH_3CO), 2.16 (m, 1H, C(3)H_a), 2.76 (m, 2H, C(4)H_a + C(4)H_e), 3.78 (s, 3H, OCH_3), 3.82 (s, 3H, OCH_3), 4.20 (m, 1H, C(2)H), 4.84 (d, J = 4.97 Hz, 1H, C(1)H), 6.74 (s, 2H, C(6–7)H); ^{13}C nmr ($CDCl_3$): 20.0 (C-4), 22.7 (CH_3 and C-3), 50.7 (C-2), 66.1 (C-1), 108.6, 109.9 (C-6 and C-7), 126.2, 127.4 (C-4a and C-8a), 151.6, 153.1 (C-5 and C-8), 172.2 (CO).

cis-*2-Acetamido-5,8-dimethoxy-1,2,3,4-tetrahydro-1-naphthalenol* (cis-**6**f)

To an ice-cooled stirred suspension of 2.0 g (7.6 mmol) of 2-acetamidotetralone **5***f* in 20 mL of methanol, a solution of 144 mg (3.8 mmol) of sodium borohydride in 4 mL of water was added dropwise. After 1 h stirring at room temperature the reaction mixture was poured into 100 mL of water, and the methanol was removed *in vacuo*. The aqueous phase was extracted with dichloromethane and the organic extracts afforded a residue, which was chromatographed on silica gel. On elution with ethyl acetate, 1.4 g of a *cis–trans* mixture of acetamidotetralols **6***f* were obtained (*cis*/*trans* ratio, 65:35 based on ^{1}H nmr). Analytically pure *cis*-**6***f* was obtained by crystallization (Table 4); ir (KBr): 3350, 2950, 1640; ^{1}H nmr (200 MHz): 1.9 (m, C(3)H_{a+e}), 2.01 (s, 3H, CH_3CO), 2.58 (m, 1H, C(4)H_a), 2.95 (m, 1H, C(4)H_e), 3.78 (s, 3H, OCH_3), 3.82 (s, 3H, OCH_3), 4.02 (m, 1H, C(2)H), 4.93 (d, J = 4.25 Hz, 1H, C(1)H), 6.74 (m, 2H, C(6–7)H); ^{13}C nmr ($CDCl_3$): 22.7, 23.2 (C-3 and C-4), 23.5 (CH_3), 48.9 (C-2), 63.2 (C-1), 107.7, 109.5 (C-6 and C-7), 126.8, 127.0 (C-4a and C-8a), 151.4, 151.7 (C-5 and C-8), 169.6 (CO).

When the above reaction mixture was poured into 6 *M* hydrochloric acid, and the methanol was removed *in vacuo* on a steam-bath, similar work-up afforded *cis*-2-methyl-6,9-dimethoxy-3a,4,5,9b-tetrahydronaphtho[2,1-*d*]oxazol (**13**) (Table 4); ^{1}H nmr (200 MHz): 1.84 (m, 1H, C(3)H_a), 1.96 (s, 3H, CH_3), 2.10 (m, 1H, C(3)H_e), 2.48 (m, 1H, C(4)H_a), 2.89 (m, 1H, C(4)H_e), 3.84 (s, 3H, OCH_3), 3.91 (s, 3H, OCH_3), 4.48 (m, 1H, C(3)H_a), 5.87 (d, J = 9.7 Hz, 1H, C(9b)H), 6.74 (d, J = 8.9 Hz, 1H, arom.), 6.83 (d, J = 8.9 Hz, 1H, arom.); ms, *m*/*e* (relative intensity): 248 (6), 247 (30), 188 (100), 173 (96); ^{13}C nmr ($CDCl_3$): 14.1 (CH_3), 17.5 (C-5), 27.4 (C-4), 63.2 (C-3a), 73.3 (C-9b), 108.3, 110.0 (C-7 and C-8), 122.4 (C-5a), 130.4 (C-9a), 150.4, 152.8 (C-5 and C-8), 165.7 (C-2).

*3,4-Dihydro-2*H*-1-naphthalenone oximes* (**3**a–e *oximes*) *Method E*

A solution of 50 mmol of tetralone **3***a–e* and 8.0 g (115 mmol) of hydroxylamine hydrochloride in 25 mL of dry pyridine was heated at reflux temperature for 12 h. After pouring into water, the reaction mixture was extracted with dichloromethane and the organic layers were washed with 1 *M* hydrochloric acid and 0.5 *M* sodium bicarbonate. Evaporation of the organic solvent afforded the required oximes; **3***a*-oxime (33) (96%), **3***b*-oxime (34) (84%), **3***c*-oxime (14) (97%), **3***d*-oxime (32) (97%), and **3***e*-oxime (Table 4); ir (KBr): 3340–3000 (OH), 1620 (C=N); ^{1}H nmr: 1.4–1.9 (m, 2H, C(3)H_2), 2.4–2.8 (m, 4H, C(2)H_2 + C(4)H_2), 4.8 (s, 2H, $OCH_2C_6H_5$), 6.6–7.5 (m, C(5) + C(6) + C(8)), 7.2 (s, 5H, C_6H_5), 9.3 (br, 1H, N—OH).

*3,4-Dihydro-2*H*-1-naphthalenone* O*-tosyloximes* (**7**a–e) *Method F*

A solution of 43 g (75 mmol) of *p*-toluenesulfonyl chloride in 80 mL of dry pyridine was added dropwise to an ice-cooled solution of the requisite naphthalenone **6***a–e* oxime (75 mmol) in 80 mL of dry pyridine. After stirring for 16 h at room temperature, the reaction mixture was poured into water and extracted with dichloromethane. The organic layers were washed with 2 *M* hydrochloric acid, 0.5 *M* sodium bicarbonate, and dried. Evaporation afforded crude tosyloximes **7***a* (5) (83%), **7***c* (14) (90%), **7***d* (32) (89%), **7***b*, and **7***e* (Table 4). Compound **7***b*, ir (KBr): 1600, 1575; ^{1}H nmr: 1.5–2.0 (m, 2H, C(3)H_2), 2.4 (s, 3H, CH_3-Ar), 2.5–2.7 (m, 4H, C(2)H_2 + C(4)H_2), 3.7 (s, 3H, OCH_3), 6.6–7.4 (m, 3H, C(6–8)H), 7.2 (d, J = 8 Hz, 2H, C(3′)H + C(5′)H), 7.8 (d, J = 8 Hz, 2H, C(2′)H + C(6′)H). Compound **7***e*, ir (KBr): 1590; ^{1}H nmr: 1.7 (m, 2H, C(3)H_2), 2.3 (s, 3H, CH_3-Ar), 2.6 (m, 4H, C(2)H_2 + C(4)H_2), 4.9 (s, 2H, $OCH_2C_6H_5$), 6.7–7.3 (complex, 3H, C(5–8)H), 7.2 (s, 5H, C_6H_5), 7.4 (dd, 4H, C_6H_4—CH_3).

*2-Amino-3,4-dihydro-2*H*-1-naphthalenone hydrochlorides* (**8**a–e) *Method G*

To a stirred suspension of 16 mmol of tosyloxime **7***a–e* in 15 mL of dry benzene a solution of 16.5 mmol of potassium ethoxide in 10 mL of absolute ethanol was added at 0°C under a nitrogen atmosphere. After 24 h at room temperature, the reaction mixture was filtered and the filtrates were poured into 100 mL of 5 *M* hydrochloric acid. After 15 min stirring at room temperature, the aqueous phase was evaporated *in vacuo* (to afford crude hydrochlorides **8***a*,*b*) or the resulting precipitate was collected and dried (hydrochlorides **8***c–e*). In each case, crystallization from ethanol–ether afforded analytically pure samples. Compound **8***a* (33) (35%), **8***c* (14) (75%), **8***d* (32) (65%), **8***e* (10) (60%). Compound **8***b* (see also Table 4), ir (KBr): 3100, 2800, 1690–1640; ^{1}H nmr (D_2O): 2.1–3.3 (m, 4H, C(3)H_2 + C(4)H_2), 3.7 (s, 3H, OCH_3), 4.3 (dd, 1H, C(2)H), 7.2 (m, 3H, C(6–8)H).

*2-Amino-3,4-dihydro-5,8-dimethoxy-2*H*-1-naphthalenone hydrochloride* (**8**f)

A solution of 250 mg (0.95 mmol) of 2-acetamidotetralone **5***f* in 20 mL of 0.3 *M* hydrochloric acid was heated at reflux temperature. After 5 h, the reaction mixture was evaporated *in vacuo* to afford crude hydrochloride **8***f* (14), which was purified by crystallization from ethanol–ether 1:1 (overall yield, 75%).

trans-*2-Amino-1,2,3,4-tetrahydro-1-naphthalenols* (trans-**1**a–f) *Method H*

Alkaline hydrolysis of *trans*-**6***a*,*b*,*d–f*: To a solution of 7.5 mmol of the requisite acetamidotetralol *trans*-**6***a*,*b*,*d–f* in 80 mL of ethanol, a solution of 6.3 g (110 mg) of potassium hydroxide in 30 mL of water was added dropwise under nitrogen. After 12 h at reflux temperature, the reaction mixture was poured into water, and the ethanol was removed *in vacuo*. The residue was made acidic with 2 *M* hydrochloric acid and washed with ether. The aqueous layer was basified and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

extracted with dichloromethane. The organic extracts were dried and evaporated to afford aminoalcohols *trans*-**1***a–f* (Table 4).

Method I

Sodium borohydride reduction of hydrochlorides **8***a–f*: Hydrochloride **8***a–f* (4 mmol) was added portionwise to an ice-cooled solution of sodium borohydride (200 mmol) in 5 *M* sodium hydroxide (4 mL) and methanol (40 mL). When the addition was complete, the reaction mixture was treated with another 20 mmol of sodium borohydride. After 15 min stirring, 100 mL of water were added, methanol was removed *in vacuo*, and the aqueous phase was extracted with dichloromethane. Evaporation of the aqueous layer afforded crude aminotetralols *trans*-**1***a–f*, which were purified by crystallization of the corresponding hydrochloride.

Compound *trans*-**1***a* (35) (Methods H and I, 45%), *trans*-**1***c* (14) (Method I, 91%), *trans*-**1***d* (32) (Method H, 75%; Method I, 60%). Compound *trans*-**1***b* (Table 4), ir (KBr): 3250, 1610, 1590; ^{1}H nmr (200 MHz, base, see also Table 1): 1.64 (m, 1H, C(3)H$_a$), 2.04 (m, 1H, C(3)H$_e$), 2.60 (m, 1H, C(4)H$_a$), 2.80 (m, 1H, C(4)H$_e$), 2.88 (m, 1H, C(2)H), 3.81 (s, 3H, OCH_3), 4.33 (d, J = 8.6 Hz, 1H, C(1)H), 6.72 (m, 1H, C(6)H), 7.18 (m, 2H, C(7–8)H); ^{13}C nmr: Table 3. Compound *trans*-**1***e* (Table 4), ir (KBr): 3310, 3250, 1610; ^{1}H nmr (200 MHz, base): 1.56–1.82 (m, 1H, C(3)H$_a$), 1.94–2.10 (m, 1H, C(3)H$_e$), 2.76–3.00 (m, 3H, C(4)H$_2$ + C(2)H), 3.10 (3H, exch.), 4.30 (d, J = 8.8 Hz, 1H, C(1)H), 5.06 (s, 2H, $OCH_2C_6H_5$), 6.82 (dd, J_o = 8.43 Hz, J_m = 2.72 Hz, 1H, C(6)H), 6.99 (d, J_o = 8.43 Hz, 1H, C(5)H), 7.19 (d, J_m = 2.72 Hz, 1H, C(8)H), 7.31–7.46 (m, 5H, C_6H_5); ^{13}C nmr: Table 3. Compound *trans*-**1***f* (Table 4), ir (KBr): 3400–3300, 2950, 1610; ^{1}H nmr (200 MHz, base, see also Table 1): 1.64 (m, 1H, C(3)H$_a$), 2.01 (m, 1H, C(3)H$_e$), 2.60 (m, 1H, C(4)H$_a$), 2.84 (m, 1H, C(4)H$_e$), 3.17 (m, 1H, C(2)H), 3.78 (s, 3H, OCH_3), 3.84 (s, 3H, OCH_3), 4.68 (d, J = 7.2 Hz, 1H, C(1)H), 6.70 (s, 2H, C(6–7)H); ^{13}C nmr ($CDCl_3$): Table 3; ^{13}C nmr (DMSO-d_6): 18.6 (C-4), 23.6 (C-3), 50.8 (C-2), 66.8 (C-1), 107.9, 108.6 (C-6 and C-7), 126.3, 127.1 (C-4a and C-8a), 150.5, 152.7 (C-5 and C-8).

cis-*2-Amino-1,2,3,4-tetrahydro-1-naphthalenols* (cis-**1**a,b,f)

Method J

A suspension of 650 mmol of acetamidotetralol *trans*-**6***a,b,f* in 15 mL of 0.3 *M* hydrochloric acid was heated under nitrogen at reflux temperature. After 5 h, the reaction mixture was washed with ether and the aqueous phase was evaporated *in vacuo*. The resulting crude hydrochloride was purified by crystallization from ethanol–ether. Compound *cis*-**1***a* (5) (60%). Compound *cis*-**1***b* (Table 4), ir (KBr): 3300, 1590, 1520; ^{1}H nmr (200 MHz, base, see also Table 1): 1.72–2.06 (m, 2H, C(3)H$_{a+e}$), 2.86 (m, 2H, C(4)H$_{a+e}$), 3.66 (m, 1H, C(2)H), 4.90 (d, J = 3.9 Hz, 1H, C(1)H), 7.30 (m, 5H, arom.); ^{13}C nmr: Table 3. Compound *cis*-**1***f* (Table 4), ir (KBr): 3330, 3280, 1600; ^{1}H nmr (200 MHz, base, see also Table 1): 1.82 (m, 2H, C(3)H$_{a+e}$), 2.50 (m, 1H, C(4)H$_a$), 2.92 (m, 2H, CH-iPr + C(2)H), 3.78 (s, 3H, OCH_3), 3.84 (s, 3H, OCH_3), 4.87 (d, J = 3.9 Hz, 1H, C(1)H), 6.70 (s, 2H, C(6)H + C(7)H); ^{13}C nmr: Table 3.

Alkaline hydrolysis of *cis*-**6***f* (Method H) also afforded aminoalcohol *cis*-**1***f* (Table 4). Alkaline hydrolysis of crude *cis*-**6***f* (*cis*/*trans* ratio 65:35) afforded a mixture of aminoalcohols *cis*-**1***f* and *trans*-**1***f*, which were separated by chromatography on neutral alumina (activity III) on elution with methanol.

2-Isopropylamino-1,2,3,4-tetrahydro-1-naphthalenols (**2**a–f)

Method K

To a suspension of 0.8 mmol of the corresponding 2-amino-1-tetralol in 7 mL of dry benzene, 4.5 mmol of anhydrous acetone was added. After 3 h stirring at reflux temperature, the solvent was removed *in vacuo*, the residue was dissolved in 5 mL of absolute ethanol, and sodium borohydride (2.1 mmol) was added portionwise to the above solution with external cooling. After 2 h stirring at room temperature, the reaction mixture was quenched with 2 *M* hydrochloric acid and the ethanol was removed *in vacuo*. The aqueous phase was washed with ether, made alkaline with 5 *M* sodium hydroxide, and extracted with dichloromethane. The organic extracts were dried and evaporated to afford isopropylamino derivatives *trans*-**2***c* (14) (85%), *trans*-**2***d* (32) (82%), *cis*-**2***b*, *trans*-**2***b*, and *trans*-**2***e* (Table 4). Compound *cis*-**2***b*, ir (KBr): 3250, 2890, 1560; ^{1}H nmr (200 MHz, base): 0.70 (d, 3H, CH_3CH), 1.10 (d, 3H, CH_3CH), 1.70 (m, 1H, C(3)H), 1.92 (m, 1H, C(3)H′), 2.60 (m, 1H, C(4)H$_a$), 2.86 (m, 1H, C(4)H$_e$), 3.04 (m, 2H, C(2)H + $CH(CH_3)_2$), 3.81 (s, 3H, OCH_3), 4.57 (d, J = 4.0 Hz, 1H, C(1)H), 6.76 (d, 1H, C(6)H), 7.08 (d, 1H, C(8)H), 7.18 (d, 1H, C(7)H); ^{13}C nmr: Table 3. Compound *trans*-**2***b*, ir (KBr): 3310, 2990, 1580; ^{1}H nmr (200 MHz, base): 0.98 (d, J = 6.2 Hz, 3H, CH_3CH), 1.05 (d, J = 6.2 Hz, 3H, CH_3CH), 1.46 (m, 2H, C(3)H$_{a+e}$), 2.12 (m, 1H, C(3)H$_a$), 2.68 (m, 3H, C(2)H + C(4)H$_2$), 2.96 (m, 1H, $CH(CH_3)_2$), 3.72 (s, 3H, OCH_3), 4.30 (d, J = 8.9 Hz, 1H, C(1)H), 6.64 (m, 1H, C(6)H), 7.12 (m, 2H, C(7–8)H); ^{13}C nmr: Table 3. Method L

To a solution of 2-amino-1-tetralol (0.7 mmol) in 6 mL of methanol under nitrogen, sodium cyanoborohydride (3.5 mmol), acetone (3.5 mmol), and molecular sieve 3Å were added. After 18 h stirring at room temperature, the reaction mixture was poured into water and the methanol was removed *in vacuo*. The aqueous phase was made alkaline with 2 *M* sodium hydroxide and extracted with dichloromethane. The organic extracts were washed with water, dried, and evaporated to afford the corresponding isopropyl derivative (Table 4). Compound *cis*-**2***a*, ^{1}H nmr (200 MHz, base): 1.10 (d, 3H, CH_3CH), 1.14 (d, 3H, CH_3CH), 1.70 (m, 1H, C(3)H), 1.98 (m, 1H, C(3)H′), 2.84 (m, 2H, C(4)H$_2$), 3.06 (m, 2H, CH-iPr + C(2)H), 4.60 (d, J = 4.1 Hz, 1H, C(1)H), 7.30 (m, 5H, arom.); ^{13}C nmr: Table 3. Compound *trans*-**2***a*, ^{1}H nmr (200 MHz, base): 1.07 (d, J = 6.2 Hz, 3H, CH_3CH), 1.13 (d, J = 6.2 Hz, 3H, CH_3CH), 1.58 (m, 2H, C(3)H$_2$), 2.18 (m, 1H, C(4)H$_a$), 2.76 (m, 1H, C(2)H), 2.84 (m, 2H, C(4)H$_e$), 3.0 (m, 1H, CH-iPr), 4.37 (d, J = 9.1 Hz, 1H, C(1)H), 7.14 (m, 4H, C(5–8)H; ^{13}C nmr: Table 3. Compound *cis*-**2***f*, ^{1}H nmr (200 MHz, base): 1.09 (d, 3H, CH_3CH), 1.12 (d, 3H, CH_3CH), 1.74 (m, 2H, C(3)H$_{a+e}$), 2.50 (m, 1H, C(4)H$_a$), 2.84 (m, 1H, C(4)H$_e$), 2.92 (m, 1H, C(2)H), 3.09 (m, 1H, CH-iPr), 3.76 (s, 3H, OCH_3), 3.84 (s, 3H, OCH_3), 4.87 (d, J = 3.9 Hz, 1H, C(1)H), 6.71 (s, 2H, C(6–7)H; ^{13}C nmr: Table 3. Compound *trans*-**2***f*, ^{1}H nmr (200 MHz, base): 1.10 (t, 6H, CH-iPr), 1.61 (m, 1H, C(3)H$_a$), 2.04 (m, 1H, C(3)H$_e$), 2.67 (m, 2H, C(4)H$_{a+e}$), 3.05 (m, 2H, C(2)H + CH-iPr), 3.77 (s, 3H, OCH_3), 3.82 (s, 3H, OCH_3), 4.76 (d, J = 6.2 Hz, 1H, C(1)H), 6.69 (s, 2H, C(6–7)H); ^{13}C nmr: Table 3.

trans-*2-Amino-1,2,3,4-tetrahydronaphthalenediols* (trans-**1**g–i *and* trans-**2**g–i)

Method M

A solution of 3.5 mmol of the corresponding benzyloxy-2-amino-1-tetralol *trans*-**1***c–e* or *trans*-**2***c–e* in 100 mL of absolute methanol was hydrogenated in a Parr apparatus in the presence of 5% palladium on charcoal (350 mg) at 300 psi. After 24 h, the reaction mixture was filtered and the methanol was removed *in vacuo* to afford debenzylated aminotetralols **1***g–i* and **2***g–i* (Table 4). Compound *trans*-**1***g*, ^{1}H nmr (hydrochloride, D_2O, 200 MHz): 1.60 (m, 1H, C(3)H$_a$), 2.05 (m, 1H, C(3)H$_e$), 2.43 (m, 1H, C(4)H$_a$), 2.63 (m, 1H, C(4)H$_e$), 3.13 (m, 1H, C(2)H), 4.50 (d, J = 8.8 Hz, 1H, C(1)H), 6.59 (dd, J = 1.9 Hz, and J = 7.8 Hz, 1H, C(6)H or C(8)H), 6.84 (dd, J = 1.9 Hz, and J = 7.8 Hz, 1H, C(6)H or C(8)H), 6.96 (t, 1H, C(7)H). Compound *trans*-**2***g*, ^{1}H nmr (hydrochloride, D_2O, 200 MHz): 1.37 (d, J = 6.36 Hz, 3H, CH_3-iPr), 1.46 (d, J = 6.46 Hz, 3H, CH_3-iPr), 1.95 (m, 1H, C(3)H$_a$), 2.36 (m, 1H, C(3)H$_e$), 2.71 (m, 1H, C(4)H$_a$), 2.95 (m, 1H, C(4)H$_e$), 3.24 (dd, 1H, C(2)H), 3.58 (m, 1H, CH-iPr), 4.89 (d, J = 9.4 Hz, 1H, C(1)H), 6.73 (dd, 1H, C(7)H), 7.06–7.10 (m, 2H, C(6)H + C(8)H). Compound *trans*-**1***h* (10) (47%). Compound *trans*-**2***h* (32) (85%). Compound *trans*-**1***i*, ^{1}H nmr (base, 200 MHz): 1.65 (m, 1H, C(3)H$_a$), 1.99 (m, 1H, C(3)H$_e$), 2.80 (m, 3H, C(4)H$_2$ + C(2)H), 4.16 (br, 4H, exch.), 4.27 (d, J = 8.87 Hz, 1H, C(1)H), 6.67

(dd, J_o = 8.39 Hz, J_m = 2.57 Hz, 1H, C(6)H), 6.91 (d, J_o = 8.39 Hz, 1H, C(5)H), 6.96 (d, J_m = 2.57, 1H, C(8)H). Compound *trans*-**2***i* (hydrochloride, D_2O, 200 MHz): 1.17 (d, J = 6.5 Hz, 3H, CH_3-iPr), 1.22 (d, J = 6.5 Hz, 3H, CH_3-iPr), 1.28 (m, 1H, C(3)H_a), 1.65 (m, 1H, C(3)H_e), 2.19 (m, 2H, C(4)H_2), 2.72 (m, 1H, C(2)H), 3.03 (m, 1H, CH-iPr), 4.04 (d, J = 11.2 Hz, 1H, C(1)H), 6.64 (dd, J_o = 8.4 Hz, J_m = 2.6 Hz, 1H, C(6)H), 6.8 (d, J_m = 2.6 Hz, 1H, C(8)H), 6.92 (d, J_o = 8.4 Hz, 1H, C(5)H).

*6-Amino-5,6,7,8-tetrahydro-2-naphthalenol (**11**)*

A solution of 1.35 g (4.7 mmol) of hydroxyiminotetralone **4***d* in 50 mL of absolute methanol was hydrogenated (1 atm) in the presence of 5% palladium on charcoal (450 mg) and 9 mL of 2 *M* hydrochloric acid at 30–40°C until hydrogen uptake ceased. Filtration and evaporation of the reaction mixture afforded naphthol **11** (HCl) in quantitative yield (Table 4); ^{1}H nmr (DMSO-d_6): 1.3–3.6 (m, 7H, C(5–8)H), 6.3 (s, 1H, C(1)H), 6.4 (dd, 1H, C(3)H), 6.7 (d, 1H, C(4)H), 8.2 (br, 3H, NH_3^+), 9.0 (br, 1H, OH); ms, *m/e* (relative intensity): 164 (8), 163 (39), 146 (68), 120 (100).

COMMUNICATION

Total synthesis of natural quadrone

HSING-JANG LIU AND MONTSE LLINAS-BRUNET
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 2, 1987

This paper is dedicated to Professor Zdenek Valenta on the occasion of his 60th birthday

HSING-JANG LIU and MONTSE LLINAS-BRUNET. Can. J. Chem. **66**, 528 (1988).

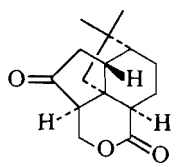
Starting from the ammonium salt of (−)-10-camphorsulfonic acid (**4**), an efficient synthesis of quadrone (**1**) in natural form has been accomplished.

HSING-JANG LIU et MONTSE LLINAS-BRUNET. Can. J. Chem. **66**, 528 (1988).

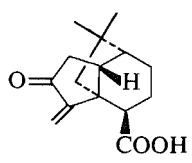
Utilisant le sel d'ammonium de l'acide (−)-camphresulfonique-10 (**4**), on a réalisé une synthèse efficace de la forme naturelle de la quadrone (**1**).

[Traduit par la revue]

(−)-Quadrone (**1**) (1) and (+)-terrecyclic acid A (**2**) (2) are metabolites isolated recently from *Aspergillus terreus*. The interesting cytotoxic properties (1*a*, 2*a*) and the challenging structural features of these novel sesquiterpenes have elicited extensive synthetic activity and, over a rather short period of time, a large number of elegant total syntheses have been achieved (3), including two asymmetric syntheses leading to (+)-quadrone (3*h*) and (−)-terrecyclic acid A (3*i*). Herein we wish to report the first synthesis of natural (−)-quadrone (**1**), providing direct evidence for its absolute configuration.



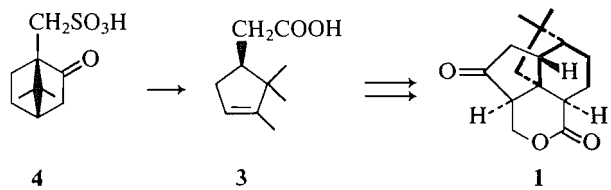
1



2

In approaches to the synthesis of the target compound **1**, (−)-α-campholenic acid (**3**) presents itself as a highly attractive potential precursor. As can be seen in Scheme 1, this chiral substrate, which is readily accessible from the ammonium salt of (−)-10-camphorsulfonic acid (**4**) by fusion with potassium hydroxide pellets (4), embodies nicely the complete B ring and part of the C ring (boldfaced portion) of compound **1** with the correct chirality. Furthermore, the functionalities of this molecule are adequately situated at the strategic positions facilitating the construction of the required framework.

Reduction of (−)-α-campholenic acid (**3**) with lithium aluminum hydride in ether followed by methylation of the resulting alcohol with dimethyl sulfate in 1,2-dimethoxyethane using sodium hydride as a base gave methyl ether **5** in 85% yield (Scheme 2). Irradiation (tungsten lamp) of a solution of **5** in methylene chloride in the presence of oxygen, acetic anhydride, pyridine, and 4-dimethylaminopyridine (5) using 5,10,15,20-tetraphenyl-21*H*,23*H*-porphine as a photosensitizer gave rise to a 78% yield of enone **6**. The ensuing removal of the methylidene group of enone **6** was initially attempted via a combination of hydration and retro-aldol reaction. In practice, this proved not to be viable. Under none of the conditions applied could the desired ketone **7** be generated. Interestingly, when the 1:1 mixture of the epimeric epoxides, prepared in 90% yield from enone **6** by treatment with hydrogen peroxide and lithium



4 **3** **1**

SCHEME 1

hydroxide in methanol, was heated with sodium hydroxide in aqueous methanol at reflux, ketone **7** was produced in 68% yield.

Selective alkylation of ketone **7** with lithium diisopropylamide and diethyl 3-bromo-2-ethoxypropenylphosphonate in tetrahydrofuran (6), followed by acid-catalyzed hydrolysis of the resulting enol ether **8**, afforded diketo phosphonate **9** (48% yield). The intramolecular Horner–Emmons reaction was performed initially using sodium hydride in 1,2-dimethoxyethane (6). Under these conditions, extensive decomposition of the starting material was detected. However, the cyclization proceeded smoothly to give a high yield (85%) of the desired bicyclic enone **10** when carried out in benzene in the presence of 18-crown-6 ether using potassium carbonate as a base (7).

For the formation of ring C, a carbomethoxymethyl group was introduced to the C-1 position of enone **10** as follows. Photocycloaddition of **10** to allene (8) in tetrahydrofuran afforded the desired head-to-head adduct **11** as the chief product along with a small amount of the head-to-tail isomer. Ozonolysis of the mixture in methanol followed by reductive work-up using dimethyl sulfide gave keto ester **12** in 56% yield based on **10**.

Treatment of keto ester **12** with an excess of chlorotrimethylsilane and sodium iodide in acetonitrile (9) at 60°C induced the selective replacement of the ethereal methoxy moiety with an iodine atom. Acid-catalyzed transketalization of the resulting iodo ketone **13** with 2-ethyl-2-methyl-1,3-dioxolane in refluxing benzene gave rise to a 65% yield of the corresponding ketal **14** over two steps. This compound was subjected to cyclization using lithium hexamethyldisilazide in tetrahydrofuran. Subsequent removal of the ketal protecting group via acid-catalyzed transketalization with acetone afforded (−)-keto ester **15** (60% yield from **14**), which was shown to be spectroscopically identical to the corresponding racemic mixture prepared pre-

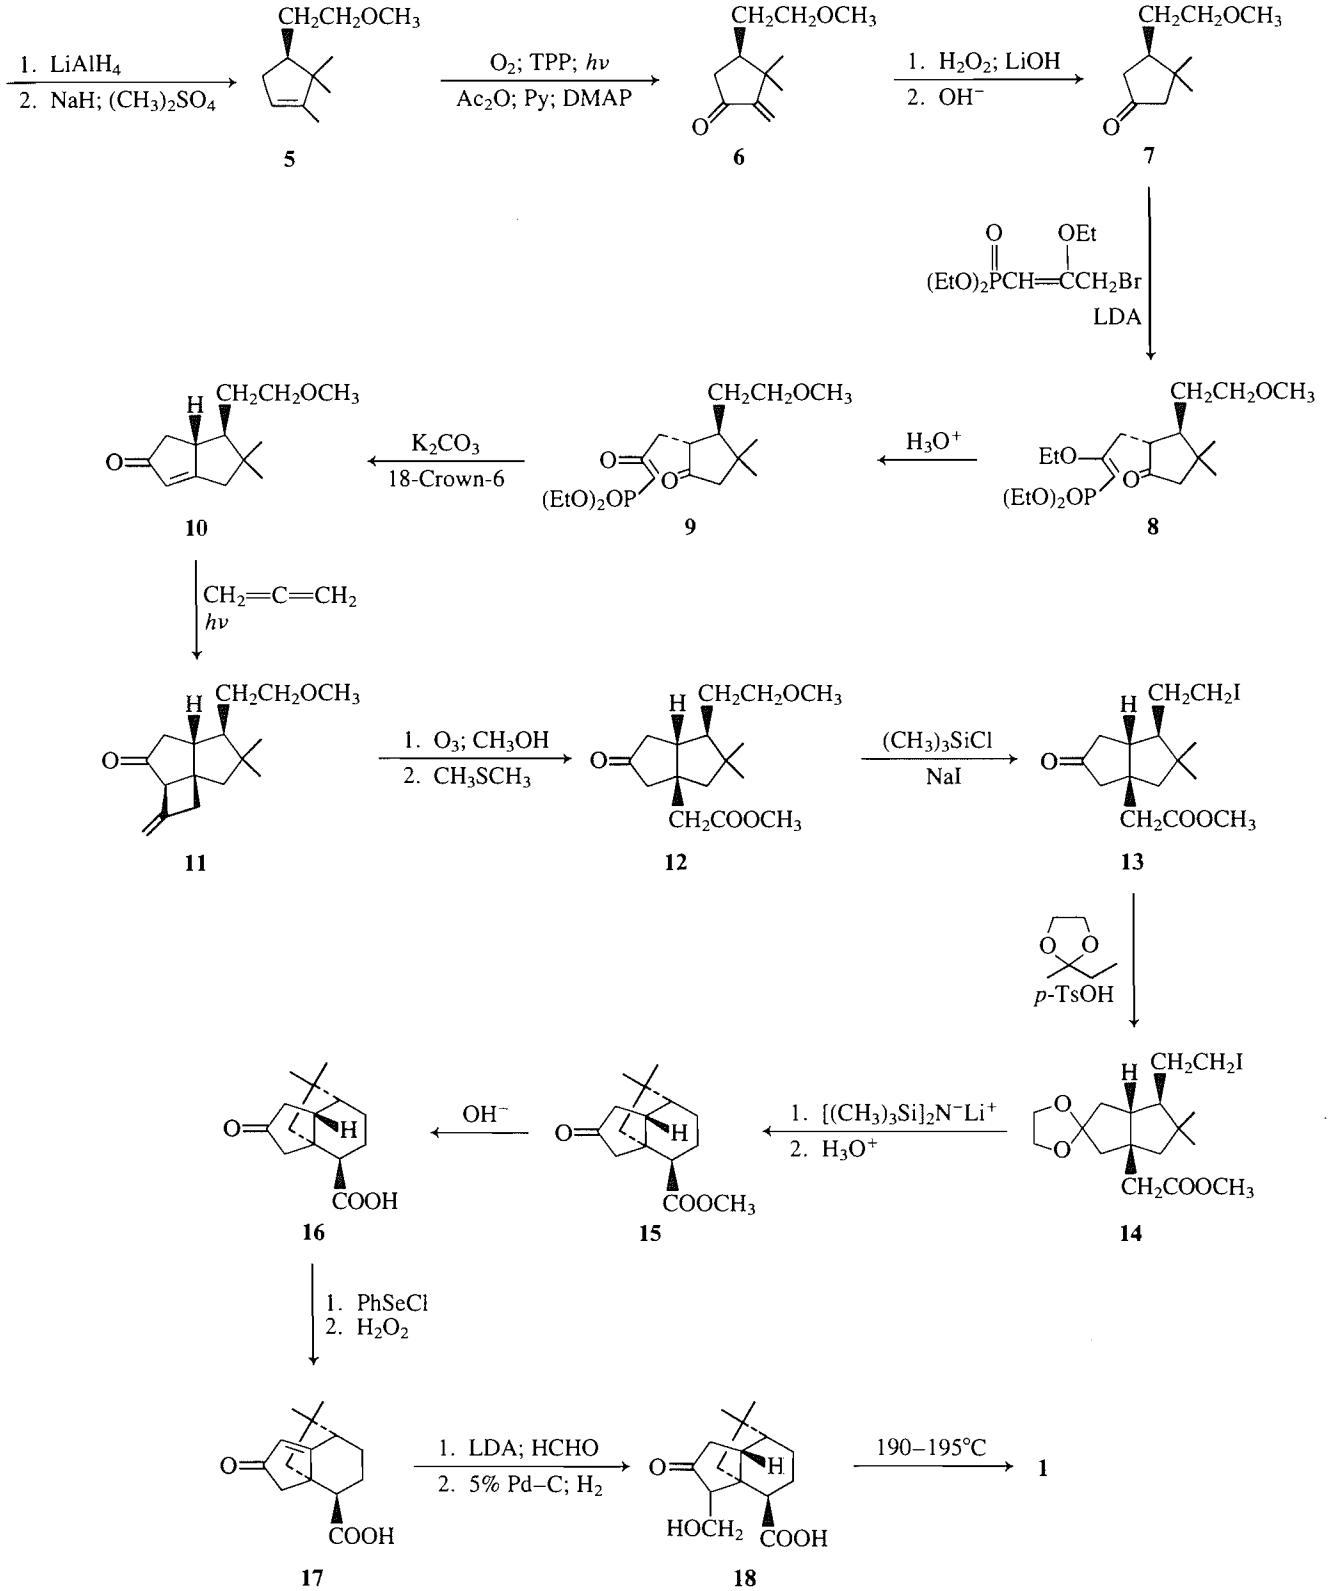

SCHEME 2

viously by Danishefsky and co-workers using a different route (3*a*). These investigators have also succeeded in the transformation of the racemic **15** to (±)-quadrone (3*a*). Application of the reported synthetic sequence to the levorotatory **15** resulted in the total synthesis of the naturally occurring (−)-quadrone (**1**). Alkaline hydrolysis of **15** afforded (−)-acid **16**, which was subjected to selenenylation. Oxidative work-up with hydrogen peroxide resulted in the formation of enone **17**. Treatment of **17** with lithium diisopropylamide and formaldehyde was followed by hydrogenation using 5% palladium on carbon as a catalyst. Pyrolysis of the hydroxy acid **18** thus obtained at 190–195°C resulted in the formation of (−)-quadrone (**1**). The melting point, specific rotation, and spectral data (^{1}H nmr, ir, and mass) of the synthetic material were found

Excess enthalpies of dibutyl ether + *n*-alkane mixtures at 298.15 K

GEORGE C. BENSON, BEICHEN LUO, AND BENJAMIN C.-Y. LU

Department of Chemical Engineering, University of Ottawa, 770 King Edward Avenue, Ottawa, Ont., Canada K1N 9B4

Received July 2, 1987

This paper is dedicated to Professor J. A. Morrison

GEORGE C. BENSON, BEICHEN LUO, and BENJAMIN C.-Y. LU. Can. J. Chem. **66**, 531 (1988).

Calorimetric measurements of excess enthalpies are reported over the entire composition range for dibutyl ether + *n*-heptane, + *n*-deeane, + *n*-dodecane, and + *n*-hexadecane at 298.15 K. The results are compared with data from the literature, and a correlation of the excess enthalpies of dibutyl ether + *n*-alkane mixtures in terms of the Flory theory is described.

GEORGE C. BENSON, BEICHEN LUO et BENJAMIN C.-Y. LU. Can. J. Chem. **66**, 531 (1988).

Opérant à 298,15 K, on a effectué des mesures calorimétriques d'enthalpies en excès pour l'ensemble des compositions des mélanges d'éther dibutylique + *n*-heptane, + *n*-décane, + *n*-dodécane et + *n*-hexadécane. On compare ces résultats aux données que l'on peut retrouver dans la littérature; de plus, on décrit un corrélation des enthalpies en excès de mélanges d'éther dibutylique + *n*-alcanes en fonction de la théorie de Flory.

The excess thermodynamic properties of *n*-ether + *n*-alkane mixtures have not been investigated sufficiently to provide a good understanding of the molecular interactions in such systems. Some progress has been made in the application of quasi-chemical models in terms of group surface interactions (1), but further experimental studies are needed to adjust the values of the interchange coefficients to include steric and orientational effects (2, 3).

A recent paper (4) from our laboratory reported measurements of the excess enthalpies of the binary mixtures: diethyl ether + *n*-heptane, + *n*-decane, + *n*-dodecane, and + *n*-hexadecane. As an extension of that investigation, we have determined the excess enthalpies of binary mixtures of dibutyl ether with the same set of *n*-alkanes.

Experimental

Component liquids

The dibutyl ether (Gold Label Reagent) and *n*-hexadecane, both with 99 mol% minimum purity, were obtained from the Aldrich Chemical Co. The other *n*-alkanes were Pure Grade Reagents (99 mol% minimum purity) from the Phillips Petroleum Co. The dibutyl ether was kept under dry nitrogen; the *n*-alkanes were stored over Type 4A moelcular sieve beads. The component liquids were used without further purification. Their densities, measured at 298.15 K in an Anton-Paar densimeter, were 763.84, 679.64, 726.26, 745.28, and 770.03 kg cm^{-3} for dibutyl ether, *n*-heptane, *n*-decane, *n*-dodecane, and *n*-hexadecane, respectively.

Calorimetric measurements

Excess enthalpies were determined in an LKB flow microcalorimeter (Model 10700-1) thermostated at 298.15 ± 0.002 K. Details of this equipment and its modification have already been described (5, 6). Over most of the mole fraction range, the errors of the excess molar enthalpy, H_m^E, and the mole fraction, x, are estimated to be less than 0.5% and 5×10^{-4}, respectively.

Results and discussion

The experimental values of H_m^E at 298.15 K for $\{x(C_4H_9)_2O + (1 - x)C_nH_{2n+2}\}$ with $n = 7$, 10, 12, and 16 are summarized in Table 1 and plotted in Fig. 1. Each set of results was fitted with the smoothing function

$$[1] \quad H_m^E/(\mathrm{J\,mol^{-1}}) = x(1 - x)\sum_{j=1}^{m} h_j(1 - 2x)^{j-1}$$

Values of the coefficients h_j, determined by the method of least-squares with all points assigned unit weight, are listed in Table 2 along with the standard deviations s of the representations. Curves calculated from eq. [1] are shown in Fig. 1.

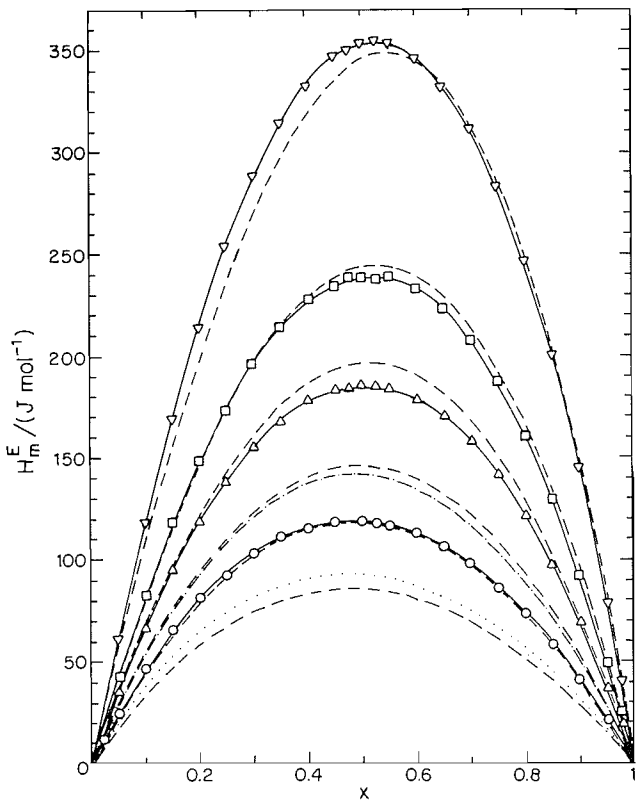

FIG. 1. Excess molar enthalpies H_m^E for $\{x(C_4H_9)_2O + (1 - x)C_nH_{2n+2}\}$ mixtures at 298.15 K. Experimental results: ○, $n = 7$; △, $n = 10$; □, $n = 12$; ▽, $n = 16$. Curves: —, calculated from eq. [1] with coefficients from Table 2; ·····, $n = 6$ taken from ref. 9; - - - -, $n = 8$ taken from ref. 10; ---, calculated from Flory theory with X_{12} from eq. [2].

As far as we are aware, only the system with *n*-heptane has been studied previously (7, 8). The deviation plot in Fig. 2 shows that, over most of the mole fraction range, the results of Villamañan *et al.* (8) are 1.5 to 2.0% higher than the representation of our results by eq. [1]. The results of the earlier investigation (7), for which an error of ±20 J mol^{-1} at $x = 0.5$

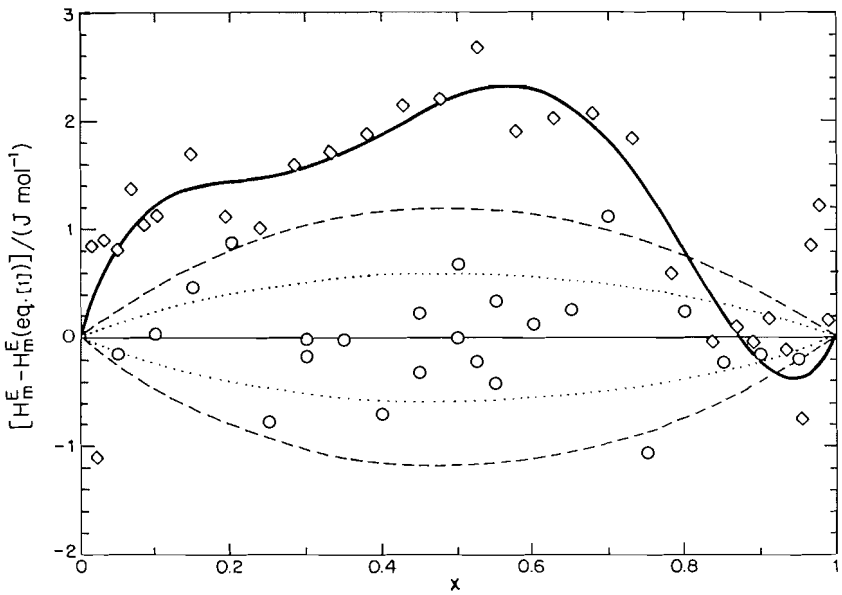

FIG. 2. Comparison of results for $\{x(C_4H_9)_2O + (1 - x)C_7H_{16}\}$ mixtures at 298.15 K. Points and curves represent deviations of excess molar enthalpy H_m^E from eq. [1] with coefficients from Table 2: ○, present work; ◇ and —, Villamañan *et al.* (8); ····, ±0.5% deviation; ---, ±1.0% deviation.

has been estimated (7*a*), are much lower, and fall off the scale of Fig. 2. At $x = 0.5$, the deviation from our value is ~ -10 J mol^{-1} (i.e. −8.5%).[1]

Excess enthalpies at 298.15 K have been reported for dibutyl ether + *n*-hexane (9) and + *n*-octane (10). Smooth representations of these results are included in Fig. 1 for comparison.

It can be seen that H_m^E for dibutyl ether + *n*-alkane mixtures increases fairly regularly with increasing size of the *n*-alkane molecule. The curves are nearly symmetrical about $x = 0.5$, but there is a slight skew of the curves toward $x = 1$ as the size of the *n*-alkane increases.

[1] NOTE ADDED IN PROOF: Since the submission of this paper, another study of dibutyl ether + *n*-heptane at 298.15 K has come to our attention (18). At $x = 0.5$, the deviation from our value is ~ -18 J mol^{-1} (i.e. −15%).

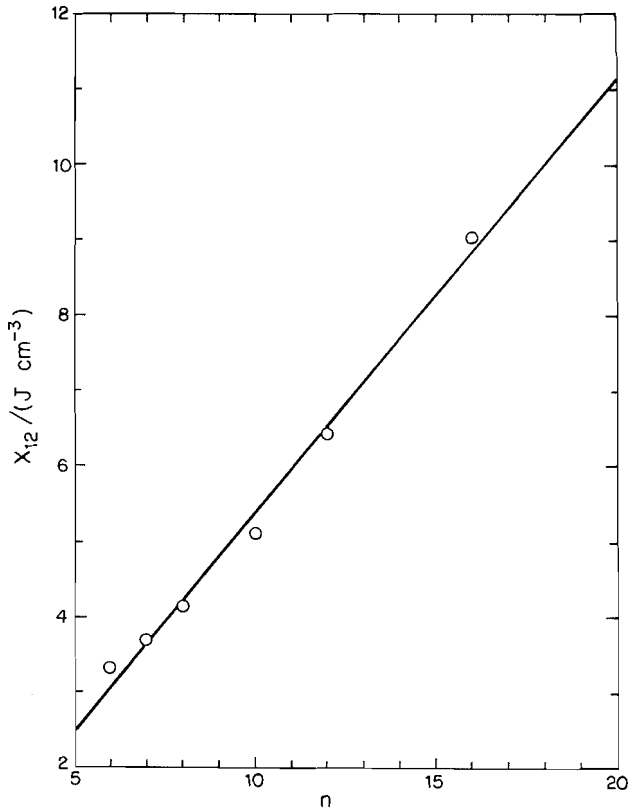

FIG. 3. Flory interchange-energy parameter X_{12} for mixtures of dibutyl ether with *n*-alkanes C_nH_{2n+2} at 298.15 K. Points: ○, from fit of H_m^E (column 9 in Table 3). Line: —, plotted from eq. [2].

In the case of the *n*-decane system, excess enthalpies calculated according to the quasi-chemical model with the interchange parameters given in ref. 1 are in good agreement with the experimental results. However, calculations for the other systems provide further evidence of the need to refine the parameters, since the variations of the excess enthalpies with changes in the length of the *n*-alkane component are underestimated, and the curves for the longer *n*-alkanes are much more skewed toward $x = 1$ than those found experimentally.

Previously (4) we found that the excess enthalpies of diethyl ether + *n*-alkane mixtures could be correlated by the Flory theory (11). The same treatment was applied to the present dibutyl ether mixtures. The calculations used the molar volumes V_m, isobaric thermal expansivities α_p, and isothermal compressibilities κ_T listed for the components in Table 3. In the case of dibutyl ether, α_p was derived from tabulated densities (12), and κ_T was calculated from the thermal pressure coefficient (13). Data for the *n*-alkanes were taken from our previous publications (14–17). The characteristic pressures p^*, molar volumes V_m^*, and temperatures T^*, obtained from the Flory formalism, are also listed in Table 3, together with the ratio s_{12} of (ether/alkane) molecular surface areas of contact per segment and the interchange-energy parameter X_{12} for each mixture. The values of s_{12} are based on the simple assumption that the molecules are spherical. The values of X_{12}, given in the second last column of Table 3, were obtained from least-squares analyses in which the Flory formula for the excess molar enthalpy was fitted to the representations of the experimental results by eq. [1].

As in the case of the diethyl ether mixtures, the values of X_{12} for dibutyl ether + *n*-alkane mixtures increase nearly linearly with the number *n* of carbon atoms in the alkane molecule. This is illustrated in Fig. 3, where the line

$$[2] \quad X_{12} = -0.3961 + 0.5776n$$

corresponding to a correlation coefficient $r = 99.56\%$ is also plotted. Values of X_{12} calculated from eq. [2] are given in the last column of Table 3, and curves obtained from the Flory theory with these values are shown in Fig. 1. The agreement with the experimental curves is reasonable, and suggests that eq. [2] in combination with the Flory theory can provide useful estimates of H_m^E for mixtures of dibutyl ether with other *n*-alkanes.

Reactions of α-carbon- and nitrogen-centered radicals of piperazine with lumiflavin and paranitroacetophenone at pH 7

PARMINDER S. SURDHAR AND DAVID A. ARMSTRONG
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received June 3, 1987

This paper is dedicated to Professor J. A. Morrison

PARMINDER S. SURDHAR and DAVID A. ARMSTRONG. Can. J. Chem. **66**, 535 (1988).

Analysis of data from radiation chemical and photochemical studies shows that the reactions of hydroxyl radicals and flavin triplets (Fl^3) with amines produce aminyl as well as α-amino radicals. This must be taken into account, since the former tend to oxidise $^{\bullet}FlH$ and FlH^-, while the latter are inherently reducing. In the reaction of $^{\bullet}OH$ with piperazine the ratio of aminyl to α-amino radicals at pH 7 is about 60:40. The former undergo complexation to form a $N.^{\bullet}.N^+$ bonded species, which possess a broad absorption peaking at 520 nm and are inert to lumiflavin (Fl) and paranitroacetophenone on a 30 μs time scale. However, they oxidise dihydrolumiflavin anion (FlH^-) to flavin semiquinone radical ($^{\bullet}FlH$). The α-amino radicals of piperazine reduced lumiflavin to $^{\bullet}FlH$ with a rate constant of $3.3 \pm 0.3 \times 10^9\ M^{-1}\ s^{-1}$. This rate constant is similar to that observed for the $CH_3S(CH_2)_2\dot{C}HNH_2$ radical formed from methionine.

The 40:60 mixture of α-amino and $N.^{\bullet}.N^+$ radicals produced in N_2O-saturated piperazine solutions decayed by a second order process with a rate constant of $7.2 \times 10^8\ M^{-1}\ s^{-1}$. Similar mixtures of $^{\bullet}FlH$ and the $N.^{\bullet}.N^+$ species also underwent second order decay ($k = 2.7 \times 10^9\ M^{-1}\ s^{-1}$) with reoxidation of $^{\bullet}FlH$ to Fl as the major process.

PARMINDER S. SURDHAR et DAVID A. ARMSTRONG. Can. J. Chem. **66**, 535 (1988).

Une analyse des données provenant d'études radio- et photochimiques démontre que les réactions des radicaux hydroxyles et des triplets de la flavine (Fl^3) avec des amines conduit à des radicaux aminyles ainsi qu'à des radicaux α-aminés. On doit tenir compte de ces résultats puisque les premiers ont tendance à oxyder les entités $^{\bullet}FlH$ et FlH^- alors que les derniers sont d'une façon inhérente des réducteurs. Lors de la réaction du radical $^{\bullet}OH$ avec la pipérazine, à un pH de 7, le rapport des radicaux aminyles aux radicaux α-aminés est d'environ 60:40. Les premiers subissent une réaction de complexation conduisant à des espèces liées $N.^{\bullet}.N^+$ qui présentent un large maximum d'absorption à 520 nm et qui sont inertes vis-à-vis de la lumiflavine (Fl) et la *p*-nitroacétophénone, à une échelle de temps de 30 μs. Toutefois, ils oxydent l'anion dihydrolumiflavine (FlH^-) en radical flavine semiquinone ($^{\bullet}FlH$). Les radicaux α-aminés de la pipérazine réduisent la lumiflavine en $^{\bullet}FlH$ avec une constante de vitesse de $3{,}3 \pm 0{,}3 \times 10^9\ M^{-1}\ s^{-1}$. Cette constante de vitesse est similaire à celle qui a été observée pour le radical $CH_3S(CH_2)_2\dot{C}HNH_2$ qui se forme à partir de la méthionine.

Le mélange 40:60 des radicaux α-aminés et $N.^{\bullet}.N^+$ qui se forme dans des solutions de pipérazine saturées de N_2O se décompose par un processus du deuxième ordre avec une constante de vitesse de $7{,}2 \times 10^8\ M^{-1}\ s^{-1}$. Des mélanges semblables d'espèces $^{\bullet}FlH$ et $N.^{\bullet}.N^+$ se décomposent aussi par un processus du deuxième ordre ($k = 2{,}7 \times 10^9\ M^{-1}\ s^{-1}$) impliquant une réoxydation de $^{\bullet}FlH$ en Fl comme réaction principale.

[Traduit par la revue]

Introduction

Reactions of flavins with amine radicals are of contemporary interest for a number of reasons. In the first place amine (AH_2) molecules can be used as hydrogen donors to convert flavins (Fl) to their dihydro forms (1–4) through the reaction sequence:

[1] $Fl + h\nu \rightarrow Fl^1 \rightarrow Fl^3$

[2] $AH_2 + Fl^3 \rightarrow {}^{\bullet}AH + {}^{\bullet}FlH$

[3] $^{\bullet}AH + {}^{\bullet}FlH \rightarrow A + FlH_2$

This highly practical photo-initiated reduction has been extensively exploited in recent research on reduced derivatives of flavins. At the same time step [3] in the above mechanism is also a key process in the radical pair mechanism proposed for the action of monoamine oxidase enzymes on normal substrates (3, 5). The formation of stable adducts in the alternative reaction:

[4] $^{\bullet}AH + {}^{\bullet}FlH \rightarrow HA—FlH$

would lead to enzyme inactivation. Studies of these reactions thus have a bearing on our understanding of important biological processes and the pharmacology related to them (4).

An earlier study of the reactions of lumiflavin with amine radicals formed in the sequence [1]–[2], and via reaction [5]

[5] $AH_2 + {}^{\bullet}OH \rightarrow {}^{\bullet}AH + H_2O$

demonstrated that the relative importance of steps [3] and [4] depended on the amine structure (4). It was pointed out in ref. 4 that further progress required a knowledge of the proportions of nitrogen-centered (viz.: $\rangle N^{\bullet+}$) and carbon-centered radicals (viz. —NH—$\dot{C}$H—) formed in reactions [3] and [5] and the separate characterisation of their reactions with flavins.

Since the submission of ref. 4 two studies which are very relevant to the above question have been published. In the first place Mönig *et al.* (6) have shown that deprotonated α-amino acids have a high tendency to form α-carbon-centered radicals, which are strongly reducing. This results from initial attack of the $^{\bullet}OH$ on the nitrogen lone pair and subsequent elimination of CO_2, e.g. for glycine:

[6a] $^{\bullet}OH + \ddot{N}H_2—CH_2—CO_2^- \rightarrow HO.^{\bullet}.NH_2—CH_2—CO_2^-$

[6b] $HO.^{\bullet}.NH_2—CH_2—CO_2^- \rightarrow HO^- + NH_2—\dot{C}H_2 + CO_2$

The second paper is that of Das and von Sonntag (7), who studied the radicals produced from $^{\bullet}OH$ attack on trimethylamine. Their work provided evidence for three radical forms, which were related by the protonation–deprotonation equilibria below:

[7] $(CH_3)_2HN^+CH_2^{\bullet} \underset{+H^+}{\overset{-H^+}{\rightleftharpoons}} (CH_3)_2NCH_2^{\bullet} \underset{-H^+}{\overset{+H^+}{\rightleftharpoons}} (CH_3)_3N^{\bullet+}$

$pK \sim 3.6$ $\qquad$ $pK = 8.0$

Both studies point toward a key role played by the nitrogen.

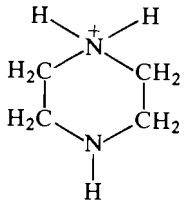
When it is deprotonated it appears to represent the main site for •OH attack, except when the carbon chain becomes excessively long. In short chain alkyl amines, the α-carbon-centered radicals are mainly formed via deprotonation as in scheme [7], or, in the case of α-amino acids, via CO_2 elimination (6) as in [6].

This study was designed to utilise the approaches in refs. 6 and 7 to determine the proportions of the two radicals forms and elucidate the nature of their reactions with lumiflavin at neutral pH. The amine chosen was piperazine (Pip). The pKs of this molecule (pK_1 = 5.33) and (pK_2 = 9.73) (8) are such that at pH 7 the monoprotonated form dominates. The structure of this species is shown below:



Thus one nitrogen lone pair should be accessible to •OH and other electrophiles. Also one may note that all carbon-centered radicals would be of the α form. As in ref. 4 the •OH radicals were produced by pulse radiolysis of nitrous oxide-saturated solutions containing the amine.

Experimental

Materials

Lumiflavin (Fl), piperazine (Pip), and methionine were purchased from Sigma Chemical Co. The *t*-butyl peroxide and paranitroacetophenone (PNAP) were from Aldrich. All other chemicals were the purest grade available and used as supplied. The water for preparing the solutions was redistilled, first from potassium permanganate and then from acid dichromate (9).

Apparatus and procedures

All experiments were conducted at room temperature (23 ± 2°C) with solutions containing 10 mM phosphate buffer. All solutions were degassed during preparation by prebubbling with nitrous oxide or argon as required. The gases were first passed through a column of "Ridox" (Fisher Scientific Co.) to remove traces of oxygen. Prereduction and oxidation of N_2O-saturated Fl containing 0.1 M Pip was carried out using the technique described in ref. 10.

The pulse radiolysis experiments were performed by utilising 2 μs pulses of electrons with doses of 4–10 Gy/pulse from a 1.5-MeV Van de Graaff generator. Details of the generator and dosimetry have been described earlier (11).

Results and discussion

Formation of —NH—ĊH—

The work of Das and von Sonntag (7) demonstrated that at pHs significantly above the pK of the N-centered radical, the C-centered species dominated and its absorbance spectrum could be obtained separately. The filled circles in Fig. 1*a* show the absorbance of the —NH—ĊH— radical of piperazine at pH 11.2 in the wavelength range of relevance here. Below 300 nm it increases gradually and then rises to a maximum near 260 nm,[1] thus resembling the spectrum for the corresponding radical of trimethylamine in ref. 7. We found that a similar spectrum could be produced at pH 7 by reacting methyl radicals formed via reaction [8] or

[8] $e_{aq}^- + CH_3Cl \rightarrow {}^{\bullet}CH_3 + Cl^-$

[1]P. S. Surdhar and D. A. Armstrong. Unpublished results.

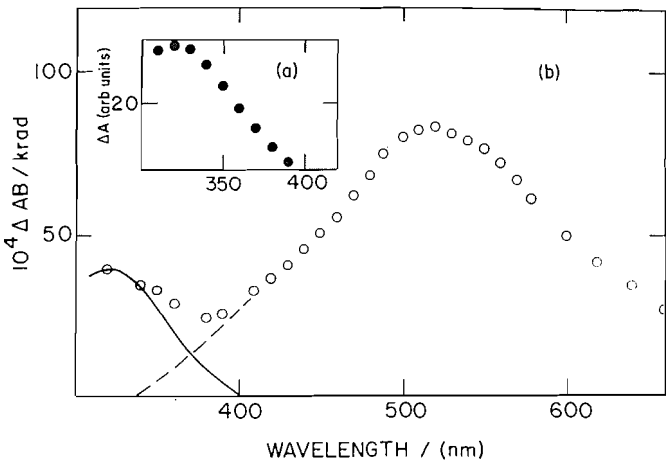


FIG. 1. (*a*) Difference spectrum observed at 20 μs after pulse in N_2O-saturated 0.01 M piperazine at pH 11.2. (*b*) ○○○ Difference spectrum observed at 20 μs after pulse in N_2O-saturated solutions containing 0.1 M piperazine. — Spectrum from (*a*) normalised at 320 nm to ○○○. ---- Spectrum after correcting for the absorption of the —NH—ĊH— radical.

the sequence:

[9a] $e_{aq}^- + t\text{-ButOOt—But} \rightarrow t\text{-ButO}^- + t\text{-ButO}^{\bullet}$

[9b] $t\text{-ButO}^{\bullet} \rightarrow {}^{\bullet}CH_3 + CH_3COCH_3$

Reactions [8] and [9a] proceed at a diffusion-controlled rate (12), while [9b] has a first order rate constant of $1.4 \times 10^6\ s^{-1}$ (13) and would have occurred mostly within our pulse width. Methyl radicals should abstract C—H hydrogens much more rapidly than N—H hydrogens because of the larger N—H bond dissociation energies (14) and data given later confirm this. Residual *t*-ButO• radicals also would have a strong preference for attacking the C—H bonds (14).

Products of •OH + Pip reactions

The spectra of species formed in these reactions was investigated in N_2O-saturated solutions containing 0.001 to 0.1 M Pip. The spectrum observed at 20 μs after pulse in a 0.1 M Pip solution, when the growth was complete, is shown by the circles in Fig. 1*b*. The broad maximum at 520 nm demonstrates that radical species other than —NH—ĊH— are present. The wavelength of maximum absorbance does not correspond to the absorbance of the nitrogen-centered $\rangle N^{\bullet+}$ radical seen by Das and von Sonntag (7), since that species absorbed only below 300 nm. It conforms more closely to the absorbance maxima reported for $N.^{\bullet}.N^+$ species by Alder and co-workers (15, 16). Formation of such a structure would be much more likely with piperazine at pH 7 than with trimethylamine, because of the presence of an unprotonated nitrogen in the former molecule. At Pip concentrations below 0.5 mM other absorption peaks are seen. The dependence of the absorbance on the concentration of Pip, which indicates that it is due to a dimer complex, and its rate of formation will be reported elsewhere, along with other results on the piperazine and related radical systems.[1]

The absorbance of the Pip radicals in the region below 300 nm must be due at least in part to the Pip (—NH—ĊH—) species. We have arbitrarily assumed that at 320 nm the absorbance of the •OH-produced radicals is due *entirely* to the —NH—ĊH— component and have normalised the spectrum from Fig. 1*a* (see solid line in Fig. 1*b*) to the circles at that wavelength. The

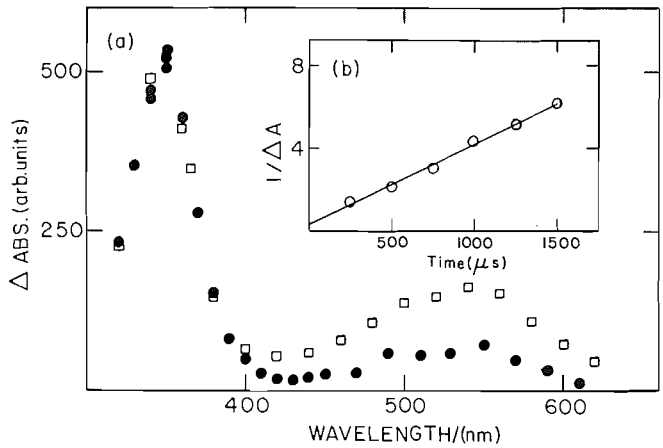

FIG. 2. (*a*) Difference spectra observed in N_2O-saturated solutions. ●●● 50 μ*M* PNAP containing 20 m*M* sodium formate. □□□ 50 μ*M* PNAP containing 40 m*M* piperazine normalised to the former at 340 nm. (*b*) Plot of $1/\Delta A$ versus time at 540 nm.

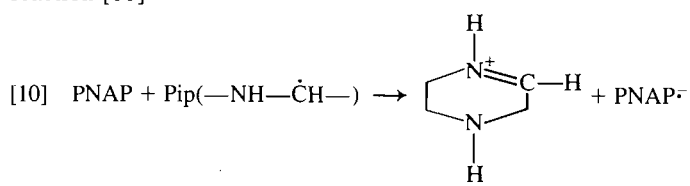
fact that the normalisation factor was ~0.5 implies that •OH must produce roughly equal proportions of —NH—ĊH— and $\diagdown N^{\bullet\pm}\diagup$ radicals for the conditions of Fig. 2*b*. In order to measure this yield more precisely, the —NH—ĊH— radicals were titrated with PNAP. This compound is known to be reduced by these species but evidently does not react rapidly with $\diagdown N^{\bullet\pm}\diagup$ centered species (6, 7).

The spectrum observed 30 μs after pulsing an N_2O-saturated solution containing 40 m*M* Pip and 50 μM PNAP at pH 7 has been displayed by the squares in Fig. 2*a*. The strong peak at 350 nm is characteristic of $PNAP^{\bullet-}$ (17) and demonstrates that reaction [10]



occurred. From the pseudo first order rate constants for the growth of this absorbance a second order rate constant of $3.6 \times 10^9\ M^{-1}\ s^{-1}$ was calculated for k_{10}. This is to be compared with $3.9 \pm 0.4 \times 10^9$ and $4 \times 10^9\ M^{-1}\ s^{-1}$ for the reduction of PNAP by the α-amino radicals of methionine (6) and trimethylamine (7), respectively.

The solid circles in Fig. 2 show the spectrum of $PNAP^{\bullet-}$ obtained in the absence of Pip on reduction by $^{\bullet}CO_2^-$ formed from the reaction of •OH with 20 m*M* of HCO_2^-. Here the yield of $PNAP^{\bullet-}$ should be equal to $g_{\cdot CO_2^-}$ or 6.4 molecules per 100 eV, based on the equation of Schuler *et al.* (18). Assuming that after reaction [10] no species other than $PNAP^{\bullet-}$ contributed to the absorbance at 350 nm, the circles have been normalised to the squares at that wavelength. The value of the normalisation factor (= 0.43) requires that the yield of $PNAP^{\bullet-}$ derived from the Pip (—NH—ĊH—) radicals is $0.43 \times 6.4 = 2.7_4$ molecules per 100 eV. Taking the total yield of Pip radicals also as 6.4, it follows that roughly 43% are able to produce $PNAP^{\bullet-}$ and may be identified as reducing —NH—ĊH— radicals. The remaining 57% of the Pip radicals must be N-centered $\diagdown N^{\bullet\pm}\diagup$ radicals.

Returning to Fig. 1*b*, one may note that subtraction of the solid line from the unfilled circles should give a first approximation to the spectrum of the $N.^{\bullet}.N^+$ species. This is shown by the dashed line. A similar broad absorption is obtained when the contribution of the normalised $PNAP^{\bullet-}$ spectrum produced by $^{\bullet}CO_2^-$ is subtracted from the spectrum formed by Pip radicals obtained from [5] in Fig. 2*a*. This implies that *N*-centered Pip radicals do not react with PNAP on the 30 μs time scale, but form the same species as in its absence. Also interconversion of the $N.^{\bullet}.N^+$ and —NH—ĊH— radical forms of Pip is evidently slower than the time scale of the reaction of —NH—ĊH— with PNAP.

When PNAP was absent the absorption of the Pip radicals at 540 nm decayed by second order kinetics as demonstrated by the reciprocal of Δ*A* plot in Fig. 2*b*. Since mutual reactions of $N.^{\bullet}.N^+$ species would be slow, due to like charges, it seems probable that the main reaction would be between the two different types of radicals, viz.

[11] —NH—ĊH— + $N.^{\bullet}.N^+$ → Products

Thus k_{11} can be estimated from the slope of the line in Fig. 2, divided by the absorbance coefficient of the species at 540 nm for 5 m*M* Pip. This absorbance coefficient was found from Δ*A* at that wavelength and the *g* value for *N*-centered species (= 6.4 × 0.57 = 3.6 molecules per 100 eV) to be 1800 $M^{-1}\ cm^{-1}$. Hence, from the slope in Fig. 2*a*, k_{11} was estimated to be $7.2 \times 10^8\ M^{-1}\ s^{-1}$.

Reactions of —NH—ĊH— radicals with Fl

Three sources of —NH—ĊH— radicals were used: (*a*) $^{\bullet}CH_3$/*t*-ButO• + Pip, (*b*) •OH + methionine, and (*c*) •OH + Pip.

Case (a): The $^{\bullet}CH_3$/*t*-ButO• was formed in reactions [9a] and [9b] and •OH radicals were scavenged by *t*-ButOH. It was shown by pulsing N_2O-saturated *t*-ButOH solutions in the absence of $(t\text{-ButO})_2$ that the radicals from *tert*-butyl alcohol reacted very slowly with Fl and produced only a very weak spectrum. This was also true for methyl radicals from reaction [8] in the absence of Pip. The changes in Δ*A* versus wavelength observed 25 μs after pulsing the argon-saturated system containing $(t\text{-ButO})_2$ have been shown by the squares in Fig. 3*a*. The changes in the absorbance during build up of •FlH for 44 μ*M* Fl took place with $t_{1/2}$ of ~3 μs. The second order rate constant for the reaction:

[12] Pip(—NH—ĊH—) + Fl → Pip(—N=CH—) + •FlH

is therefore about $5 \times 10^9\ M^{-1}\ s^{-1}$.

Case (b): The reactions of •OH with methionine have been investigated by Hiller and Asmus (19). The primary attack is mainly at sulphur, with some abstraction of H from the methyl and —CH_2— groups. The —CH_2• radicals resulting from the former process are expected to be relatively inert to Fl, as are the —CH_2• radicals from *t*-ButOH. Also the combined yield of these and the —C•(H)— radicals is small (19). The reaction of •OH with the S atom leads to elimination of OH^-, interaction of the positive —Ṡ—$^+$ center with the amino group, electron transfer from the carboxylate group and finally elimination of CO_2 to produce the α-amino CH_3—S—CH_2—$CH(NH_2)CH_2$• radical at pH 7. These intramolecular processes all occur on a 0.3 μs time scale. The solid circles in Fig. 3*a* show the changes in absorbance 25 μs after pulsing an N_2O-saturated 10 m*M* solution of methionine in the presence of 54 μ*M* Fl. The spectrum very closely resembles that formed by the Pip(—NH—ĊH—) radical (i.e. the squares). Both spectra can

be compared to the spectrum of ·FlH produced via reaction [13]

[13] $\cdot CO_2^- + Fl\,(+ H^+) \rightarrow CO_2 + \cdot FlH$

in 20 m*M* HCO_2^- solutions saturated with N_2O. The agreement demonstrates that the α-amino radicals produced from Pip via *t*-ButO·/·CH_3 and from methionine via ·OH both produce ·FlH on a 25 μs time scale. The present data do not permit a distinction between H atom transfer, as in [12] above, and electron transfer, followed by protonation, viz.

[12a] $—NH—\dot{C}—H— + Fl \rightarrow —NH^+{=}CH— + \cdot Fl^-$

[12b] $H^+ + \cdot Fl^- \rightarrow \cdot FlH$

However, in the case of methionine the overall reaction rate constant was determined. The inset of Fig. 3*a* presents a plot of the pseudo first order rate constants for the growth of the absorbance at 550 nm as a function of [Fl]. The slope leads to $k_{12} = 3.2 \pm 0.2 \times 10^9\, M^{-1}\, s^{-1}$.

Case (c): As was demonstrated above with PNAP, the α-carbon-centered and *N*-centered radicals of Pip have quite different characteristics. The results under (*a*) above demonstrated that the α-carbon-centered radical species reduced Fl to the ·FlH radical. If the *N*-centered radicals are inert to Fl as they are to PNAP, it follows that the net result of pulsing N_2O-saturated solutions of Pip in the presence of Fl should be to produce a mixture of ·FlH and $N.^{\cdot}.N^+$ radicals. Since the absorbance of the $N.^{\cdot}.N^+$ must correspond closely to that shown by the dashed line in Fig. 1*b*, the spectrum of the ·FlH species can be obtained from the overall changes in ΔA when reaction [12] and or [12a] + [12b] are complete by subtracting the $N.^{\cdot}.N^+$ contribution. The triangles in Fig. 3*b* show the spectrum of ·FlH obtained by this method. The circles show similar data for argon-saturated solutions, where e_{aq}^- reacts with Fl:

[14] $e_{aq}^- + Fl\,(+ H^+) \rightarrow \cdot FlH$

Since the yield of ·OH is about half ($g_{OH} = 2.8$ molecules per 100 eV), the correction for $N.^{\cdot}.N^+$ absorbance is similarly reduced. Again both sets of data are in agreement with the absorbance changes for ·FlH formed via reaction [13] (see solid line). Thus the assumption that nitrogen-centered species are inert to Fl on the 25 μs time scale appears to be justified.

As in the case of the methionine system the build up of the absorbance at 550 nm was followed as a function of [Fl] in N_2O-saturated 0.1 *M* Pip solutions. The slope gave a value of $k_{12} = 3.3 \pm 0.3 \times 10^9\, M^{-1}\, s^{-1}$, which is to be compared with $3.2 \pm 0.2 \times 10^9\, M^{-1}\, s^{-1}$ obtained above for methionine. The value with Pip(—NH—ĊH—) is not however, as reliable, due to the contribution of the $N.^{\cdot}.N^+$ species to the total absorbance at 550 nm. The present rate constants for reduction of lumiflavin are similar to those reported for amine radical reductions of methyl viologen and benzil (20).

The decay of the mixture of $N.^{\cdot}.N^+$ and ·FlH was followed on a 500 μs time scale for a 0.01 *M* Pip solution with 45 μM Fl by observing the combined absorbances at 550 nm. This process was second order and gave a mean rate constant of $2.7 \times 10^9\, M^{-1}\, s^{-1}$, which must be attributed to a combination of reactions between ·FlH + ·FlH, $N.^{\cdot}.N^+$ + ·FlH, and $N.^{\cdot}.N^+ + N.^{\cdot}.N^+$. Due to the like charges, the last process is probably of least importance. The net yield of FlH^- at the end of the decay was negligibly small, showing that the oxidising radicals re-oxidised virtually all ·FlH.

Oxidation of FlH_2 by the nitrogen-centered species

The earlier work in ref. 4 showed that, although the quantum yield was low, Fl could be reduced almost quantitatively to FlH_2 in the presence of Pip on photolysis at 400–480 nm. This must be attributed to a net yield of —NH—ĊH— radicals from reaction [2] (i.e. $\phi(—NH—\dot{C}H—) > \phi(\rangle N^{\cdot\pm})$). Our main

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

interest in process [2] here is that photolysis provides a facile method for preparing a solution of FlH^- (pK of FlH_2 = 6.7 (21)) in 0.1 M Pip. When this was effected in a N_2O-saturated solution, subsequent pulsing with electrons would produce the 43% —NH—ĊH— + 57% N-centered radical species of Pip. Since effectively all flavin is now in the reduced form, reaction [12] (or [12a] + [12b]) could not occur. However, a spectrum characteristic of $^{\bullet}FlH$ was still formed, and this must be attributed to reaction [15]:

[15] $N.^{\bullet}.N^+ + FlH^- \rightarrow 2Pip + {}^{\bullet}FlH$

At 20 μM FlH_2 the yield of $^{\bullet}FlH$ estimated from the known $\epsilon(FlH_2)$ at 550 nm (= 4300 M^{-1} cm^{-1}) was similar to the yield of $>N^{\bullet+}$ radicals estimated above by other methods (3.6 per 100 eV). The half life for the growth of $^{\bullet}FlH$ was about 4 μs, showing that the second order reaction must be close to diffusion controlled. The dependence on $[FlH^-]$ was not pursued in sufficient detail to get an accurate value, because it was difficult to ensure complete reduction of Fl at lower concentrations and there is the interference of the absorbance of the Pip radical with $^{\bullet}FlH$ absorbance at 550 nm.

Conclusions

The present study has demonstrated unequivocally the formation of reducing —NH—ĊH— radicals and oxidising nitrogen-centered radicals from reaction [5] with piperazine at pH 7. The fact that the nitrogen-centered radicals form an $N.^{\bullet}.N^+$ complex involving a second piperazine molecule represents a point of difference from the findings on trimethylamine. However, this is not surprising because the piperazine molecule has one unprotonated lone pair on the nitrogen at this pH (8), while trimethylamine is well below its pK for deprotonation. As pointed out above, a more detailed account of the chemistry of the piperazine system per se will be given elsewhere. One point of similarity to the study of Das and von Sonntag is that the yields seen here at low (10 mM) buffer concentration appear to be frozen. That is, there was little evidence of interconversion of the two major radical types on the time scale of their reaction with added substrates. This is not surprising for the $N.^{\bullet}.N^+$ species, because the equilibrium constant for dimerisation is quite large,[1] and relatively little $>N^{\bullet+}$ species should be present. Protonation of the —NH—ĊH— to form $>N^{\bullet+}$ was evidently also slow relative to reaction with PNAP or Fl at our buffer concentrations. However, in the absence of these solutes, when FlH^- was to be oxidised, there was some evidence for a dependence of the $^{\bullet}FlH$ yield on $[FlH^-]$. This suggests that there could have been some slow conversion to $>N^{\bullet+}$ under those circumstances.

As pointed out in the Introduction, studies of amine radical – flavin reactions are of interest because "radical pair intermediates" (i.e. $^{\bullet}AH$ + $^{\bullet}FlH$) have been postulated in one of the mechanisms proposed for monoamine oxidases (5). They are also relevant to an understanding of the quantum yields for photoreduction. From the present observations of the oxidising properties of the N-centered radicals toward $^{\bullet}FlH$ and FlH^- it is evident that the low quantum yields reported for photoreduction by Pip in ref. 4 must mean that high proportions of these species are formed in reaction [2] as well as [5]. As this will also be true for other amines, it means that the reactions of these species with Fl, $^{\bullet}FlH$, $^{\bullet}Fl^-$, and FlH^- will have to be taken into account in interpretations of the photochemical reductions.

Reference 4 was concerned to a large degree with determining whether the products formed by $^{\bullet}AH$ + $^{\bullet}FlH$ radical pairs were recyclable reduced flavins (FlH^-) or inert adducts HA—FlH. Piperazine gave primarily (>90%) the former. Thus evidently the presence of $N.^{\bullet}.N^+$ species does not cause significant addition. It remains to be seen whether some of the large adduct yields seen at pH 7 with diethylamine and ethylamine, where $N.^{\bullet}.N^+$ formation should not occur, were due to reactions of the uncomplexed $>N^{\bullet+}$ radicals or to the β-carbon-centered radicals as assumed in ref. 4.

The involvement of the $>N^{\bullet+}$ centered species in the EDTA system has been recognised for some time (22), and the reaction of EDTA radicals with lumiflavin has been pursued in greater detail in ref. 23. For the case of glycine, the production of FlH^- observed in ref. 4 was >99%. The data of Mönig *et al.* (6) now show that, due to the role of reaction [6], the radicals from reaction of $^{\bullet}OH$ with glycine were not all $NH_2\dot{C}HCO_2^-$, as assumed in ref. 4, but approximately 45% and 60% $NH_2CH_2^{\bullet}$ at pH 7 and 10, respectively. It appears that either one or both of these radicals must react more slowly with lumiflavin at pH 7 than do the Pip or methionine —NH—ĊH radicals, since we observed $k_{10} = 1.8 \pm 0.3 \times 10^9\ M^{-1}\ s^{-1}$ for the combined glycine radicals produced via reaction [5] as opposed to $3 \times 10^9\ M^{-1}\ s^{-1}$ reported here.

Brillouin scattering near the α–β phase transitions of N_2 and CO

V. ASKARPOUR, H. KIEFTE, AND M. J. CLOUTER
Physics Department, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received August 21, 1987

This paper is dedicated to Professor J. A. Morrison

V. ASKARPOUR, H. KIEFTE, and M. J. CLOUTER. Can. J. Chem. **66**, 541 (1988).

The technique of high resolution Brillouin spectroscopy has been used to determine the adiabatic elastic constants of single crystals of β-N_2 and β-CO as a function of temperature, in an effort to study the α–β phase transition. For all elastic constants, there is an increase of approximately 1%/K on cooling and there is no evidence of further mode softening, even within 0.5 K of the phase transition. Three large single crystals of α-CO were grown. The orientations were determined, by Laue X-ray diffraction, and correlated to the orientations of the parent β-crystals. The β-phase hexagonal basal planes appear to transform to planes of the form {1 1 0} in the α-phase cubic structure.

V. ASKARPOUR, H. KIEFTE et M. J. CLOUTER. Can. J. Chem. **66**, 541 (1988).

Dans le but d'étudier la transition de phase α–β, on a utilisé la technique de la spectroscopie de Brillouin à haute résolution pour déterminer les constantes élastiques adiabatiques de cristaux uniques de β-N_2 et β-CO en fonction de la température. Pour toutes les constantes élastiques, on observe une augmentation d'environ 1%/K lorsqu'on refroidit; de plus, on ne détecte pas d'autre assouplissement de mode, même à 0,5 K de la transition de phase. On a fait croître trois gros cristaux uniques d'α-CO. On en a déterminé les orientations par diffraction des rayons-X selon Laue et on a établi un corrélation avec les orientations des cristaux β apparentés. Il semble que les plans hexagonaux de base de la phase β se transforment en plans de la forme {1 1 0} lorsqu'on passe à la structure cubique de la phase α.

Introduction

Brillouin spectroscopy is a very effective technique for probing the dynamical behaviour of phonons in crystals and lattice instability associated with phase transitions. In particular, it allows for accurate determination of elastic constants in single crystals. The present work constitutes an attempt to use Brillouin spectroscopy (and Laue X-ray diffraction) to study very simple phase transitions in diatomic molecular solids, namely, the α–β transitions in solids N_2 and CO. This represents a continuation of previous Brillouin scattering experiments on single crystals of β-N_2 (1) and β-CO (2) very close to their triple points.

The α and β phases of solids N_2 and CO represent systems that undergo orientationally-disordered hexagonal close-packed (hcp) to orientationally-ordered face-centered cubic (fcc) phase transitions. Knowledge of the elastic constants is important in the sense that certain elastic constants may decrease in magnitude as the phase transition temperature is approached. This is caused by softening of acoustic phonon modes in the crystal as mechanical instability increases and molecular binding forces decrease. Eventually the associated frequencies are so low and the associated amplitudes are so high that molecules adopt new sites (3).

CO, while chemically distinct, is similar to N_2 in its condensed phases. The molecules are isoelectronic and have the same size and identical masses. Melting and boiling points and, in fact, the entire low-pressure phase diagrams are very similar and nearest neighbor distances and lattice constants are almost identical (4). In addition to the α and β phases, at very high pressures, N_2 exhibits γ, ε, δ, and ζ phases, whereas CO does not have a γ phase (5), probably because the quadrupole moment of CO is greater than that of N_2 (6). Most of these phases were detected and studied by Raman spectroscopy (see, for example, refs. 4, 7–11). There is a small dipole moment in CO due to its heteronuclear structure. A study of the temperature dependence of molar volume (12) shows that CO and N_2 behave similarly above 70 K and below about 30 K. Between these temperatures, under its own vapour pressure, both solidify to a disordered hcp β phase, the so-called plastic phase, with space group symmetry $P6_3/mmc$ (13–17). At the lower temperatures, they form an ordered cubic α phase where the molecules of N_2 occupy centrosymmetric positions in space group $Pa3$ (18, 19), while CO, because it is heteronuclear, lacks inversion symmetry and packs as $P2_13$ (7). In $Pa3$ the molecular centers are located on fcc lattice points; in $P2_13$ each molecular center is very slightly shifted, from fcc, along the direction of the molecular axis (11, 20). For purposes of the present study, fcc molecular sites may be (as already noted) assumed for α phases of both N_2 and CO.

The vapour–liquid–solid triple points for the β phases are 68.15 K and 63.15 K for CO and N_2, respectively; whereas the α–β phase transition temperatures are 61.55 and 35.6 K, respectively (21). The latter represents the biggest dissimilarity between the two. There are various possible reasons for this: one being that the quadrupolar interaction causes CO to orientationally order more readily (22), the other being that rotation–translation (RT) coupling is stronger for CO because of its physical asymmetry (23). Evidence for RT coupling in these systems is discussed in the last section.

In the present work, the elastic constants of β-N_2 are determined at 47.5 K and those of β-CO at 63.5 and 62.0 K; they are compared to the values previously measured at the respective triple points (1, 2). In addition, the orientations of single crystals of α-CO and β-CO are correlated using Laue X-ray diffraction and a possible phase-transition mechanism is suggested.

Experimental technique

Large single crystals of β-N_2 and β-CO of excellent quality can be grown by slow solidification from the liquid at the triple point, i.e., a modified Bridgman's method (4). Cooling such single van der Waal's crystals is difficult, mainly because of their generally very high coefficient of thermal expansion. On cooling, a crystal prefers to stick to the cell wall rather than to itself and contracts faster than the cell such that it very readily shatters (usually within 2 K of the triple point). In addition to the cooling problem, large single crystals of α-N_2 and α-CO are extremely difficult to produce due to the considerable change

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

in molar volume and the consequent highly disruptive nature of the $\alpha-\beta$ transition (as observed by Gannon and Morrison (15) in the birefringence study of α-N_2). Streib *et al.* (13) and Kjems and Dolling (24), however, after many tries, managed to produce one single crystal of α-N_2. Venables (25) has grown a single crystal segment of α-N_2 in a very thin film and studied it by electron microscopy. Aside from the present work, single crystals of α-CO, particularly oriented single crystals, have never been produced.

The crystals were grown in a cylindrical quartz cell, of 3 mm i.d. and 5 mm o.d., which was mounted vertically, in vacuum, in a modified commercial liquid-He cryostat (Janis Research Co., Model 10DT) as shown and discussed in detail in ref. 26. The sample cell was connected to the heat exchanger in the tail section of the cryostat via flexible copper braids and allowed for rotation of the entire cell assembly. One copper braid was fastened with a phosphor-bronze spring clamp to the lower end of the cell, and a miniature GaAs diode was mounted on this clamp close to the quartz tube. The second braid was similarly fastened 1 cm above the lower one and a differential thermocouple was mounted across them. Resistance wires of 50 Ω were wound on each clamp to permit control of the cell temperature. All electrical wires and copper braids were so arranged that the X-rays as well as the light scattered along the direction of the collection optics was not blocked when the cell was rotated through about 120°. The lower end of cell was sealed with a highly polished quartz plug, utilizing epoxy resin cement. This window provided for passage of incident laser light with minimum spurious scattering and provided a cold spot as a nucleation site for formation of the crystal. Because of problems with dust particles settling on the bottom window, a "dust trap" was installed between the cell and the inlet tube.

The cell itself, however, has been changed crucially from that illustrated in ref. 27. A thin optically transparent, electrically conducting coating was deposited (Evaporated Coatings Inc.) on the cell body to allow for melting and hence releasing the crystals from the walls of the cell. The film has a 70% optical transmission coefficient and 10 ohms electrical resistance and covers a height of about 1 cm. Two thin brass clamps, lined inside with indium, were used for electrical contact to the film. Teflon rings electrically isolated these clamps and the film from the rest of the system. The cell arrangement is shown in Fig. 1.

Temperature control was achieved in four stages: (*1*) by automatically adjusting the flow of liquid He into the heat exchanger, using an externally controlled needle valve, (*2*) by automatically and finely adjusting the temperature of the heat exchanger to about 4 K below the cell temperature, using a GaAs sensor and an electric heater in a feedback control system (Lakeshore Cryotronics Inc., Model DTC500), (*3*) by electronically controlling the temperature at the bottom of the cell as in (*2*), and (*4*) by electronically controlling the temperature at the top of the cell, (and therefore the temperature gradient across the cell) utilizing a differential copper-Constantan thermocouple. The absolute calibrated temperature was estimated to be accurate within 0.2 K. The temperature of the cell was controlled to within ± 0.01 K over long periods of time and could be varied automatically at adjustable and set rates.

N_2 gas of 99.9995% purity and CO gas of 99.99% purity (Matheson Gas Products), in each case, was condensed into the cell until it was filled with liquid to a height of about 1 cm. Crystal growth was initiated by maintaining a gradient of about 2.5 K between the top and the bottom of the cell (with the top being warmer) and lowering the temperature by about 0.05–0.1 K per hour until a small (0.5 mm) seed formed on the bottom window. This was annealed for about 1 day and then grown slowly for about 1 day to a height of ~2 mm while the temperature gradient was adjusted to about 1 K/cm. Polaroid transmission Laue X-ray photographs were then taken to determine the quality of the sample and (if possible) the orientation of the crystallographic axes with respect to the laboratory frame of reference. Many crystals were melted at this point either because they were not completely single (even though they might appear perfectly clear or show no birefringence between crossed polaroids) or because of their small range of angle γ. This is the angle between the acoustic wavevector, as

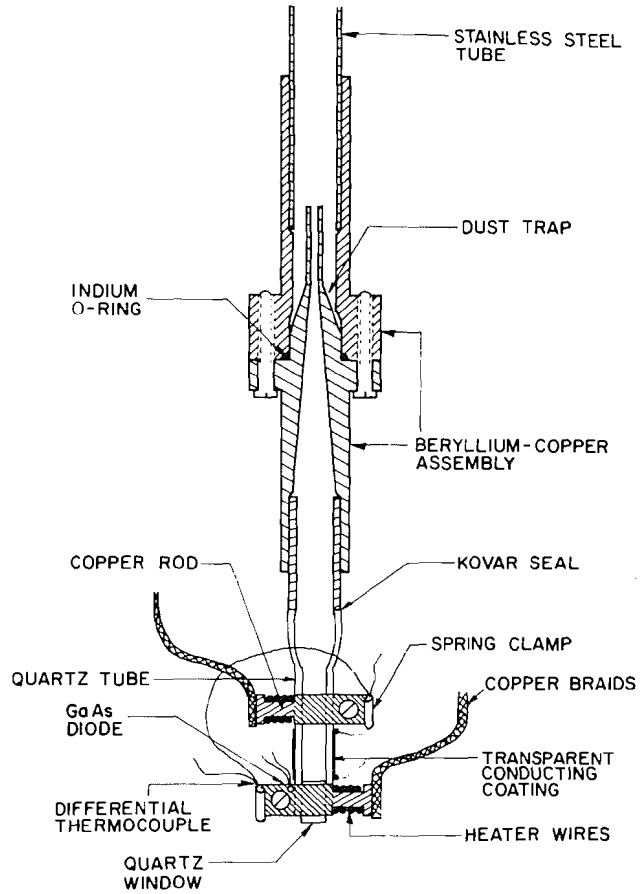

FIG. 1. Detailed diagram of the sample cell and dust trap arrangement.

determined by the geometry of the experimental setup, and the *c* axis of the crystal. A large γ range is necessary to meaningfully determine all five elastic constants.

Appropriate crystals were further grown, for another day, to a height of ~8 mm. The liquid above the crystal was removed completely and the remaining crystal was reduced in size (~6 mm) by pumping very slowly on the cell. Further cooling involved a very delicate combination of heating the walls of the cell and simultaneous pumping on the crystal. The film voltage was raised to 1.6 V in steps of 0.2 V each hour, allowing for continual establishment of equilibrium. The crystal melted at the boundary with the walls of the cell and the resulting liquid was removed by slight and careful pumping. When the crystal was almost completely released (from the walls), having a dome-shaped appearance, it was cooled very quickly, at about 8 K/h, to the desired temperature. For N_2, because of the larger temperature range, this process was carried out three times, whereas for CO once was enough to cool the crystal to just above the $\alpha-\beta$ phase transition temperature. After the cooling process, the pumping was stopped and the gap between the crystal and walls of the cell slowly filled again with solid. The film temperature was then lowered by reducing the voltage to 1.2 V in steps of 0.1 V. Keeping the film temperature fairly high appeared to allow for a more strain-free phase transition. Further cooling through the phase transition was carried out extremely slowly i.e. at about 0.05 K/h. Cooling was stopped periodically, for several hours, to check the crystal and to ensure near-equilibrium conditions.

As noted above, many Laue diffraction photographs were taken throughout these experiments using a Philips (MG 101) X-ray source, a lead collimator, and a Polaroid (XR-7) Land camera, with the film plane perpendicular to the Y axis (see Fig. 2). From the position of spots on the photographs, the crystal orientation with respect to the laboratory frame of reference, as shown in Fig. 2, was determined in terms of Euler angles (θ,ϕ,χ). These were utilized to determine angle

γ by the expression: $\cos\gamma = -q_y(\text{lab})\sin\theta\cos\phi + q_z(\text{lab})\cos\theta$, where q_y and q_z are $\pm 1/\sqrt{2}$ and $\mp 1/\sqrt{2}$, respectively, the wavevector direction cosines for 90° scattering. This procedure has been completely computerized in this laboratory and is based on stereographic projection techniques (28). Care was taken to ensure that each and every spot on a photograph was accounted for in the orientation procedure and that Miller indices were assigned, as shown in Fig. 3. It was also important that consistent orientations were obtained as the crystal was rotated, i.e. only the angle ϕ was changed.

The basic experimental layout is shown in Fig. 2 and a more detailed description is given in ref. 26. The incident radiation was produced by a single mode Ar^+ laser (Spectra Physics 165-08) at a wavelength of 514.5 nm. The laser beam, which was limited to 20 mW intensity by neutral density filters and polarized perpendicular to the scattering plane, i.e., polarized along the X axis, was focussed and deflected into the Z direction, along the cell axis. The scattered light was collected at 90°, i.e. along the Y axis, and analyzed with a commercial triple-pass Fabry-Perot interferometer (Burleigh) at a spectral free range of 11.716 GHz. The light was detected by a cooled photomultiplier (ITT FW130) and its output was processed by photon counting techniques using a data acquisition and stabilization system (Burleigh DAS-1). The DAS-1 automatically corrected for frequency and any other drifts in the system as well as optimizing the Fabry-Perot finesse during the course of an experiment. Alphanumeric readout on the DAS-1 display permitted convenient and accurate measurement of the spectra.

Analysis and results

(a) Elastic constants

Brillouin scattering of light is attributed to those inhomogeneities, or fluctuations, in the optical dielectric constant of the scattering medium that are associated with the propagation of thermally excited sound waves. Theory (29, 30) can successfully predict intensity, polarization, and frequency shift of the scattered light with the result that, for a crystal, the spectrum consists of three sets of doublets located symmetrically about the incident laser frequency. The frequency shifts are given by the usual Brillouin equation

$$\nu_\mu(\boldsymbol{q}) = \pm 2\frac{n}{c}\nu_0 v_\mu(\boldsymbol{q})\sin\left(\frac{\alpha}{2}\right)$$

where ν_0 is the frequency of the incident radiation, ν_μ and v_μ are the frequency and phase velocity, respectively, for the μth acoustic mode of wavevector $\boldsymbol{q}$, n is the index of refraction of the medium, c is the velocity of light in vacuum, and α is the (measured) scattering angle.

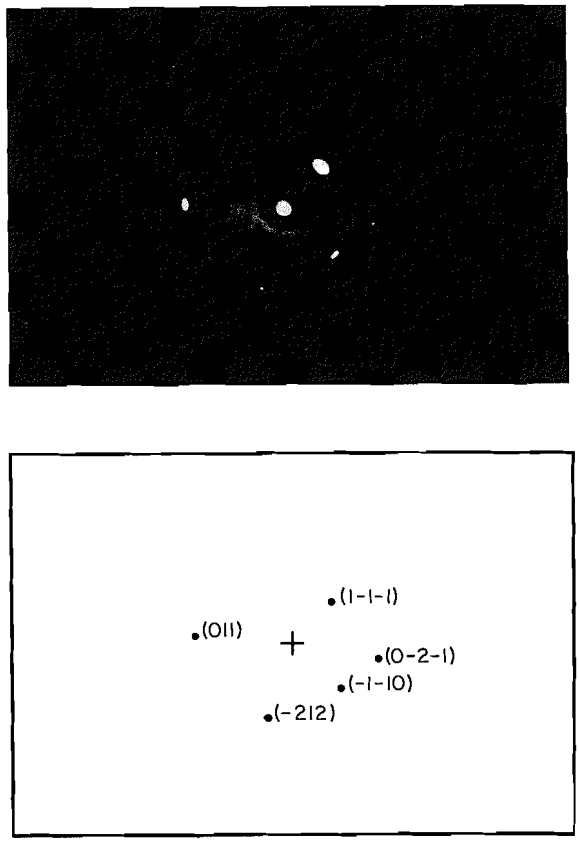

FIG. 3. Transmission Laue photograph of a β-CO crystal. Below it are shown computer-fitted Laue spots labeled by Miller indices of the corresponding reflecting planes as determined by the orientation procedure.

Solution of the eigenvalue equations for the acoustic-wave dynamical matrix yields the relationship between the velocities from the frequency shifts of the Brillouin spectra (as above), density ρ, angle γ, and the five elastic constants c_{11}, c_{12}, c_{13}, c_{33}, and c_{44} for a hexagonal crystal in closed form (1, 31). The three acoustic modes are identified according to their predominant polarization characteristics as the "slow" transverse mode T_1, the "fast" transverse mode T_2, and the longitudinal mode L. The frequency shift data were analyzed to yield the elastic constants by finding solutions to the above equations which best fit the data using a computerized iterative least-squares fit procedure (32).

β-CO: A Brillouin spectrum of β-CO is shown in ref. 2. None of the spectra for the cooled crystals were of as good quality as those taken at the triple point. One of the transverse components T_2 could usually be recognized readily but T_1 appeared infrequently. Generally the longitudinal components were about 150 times weaker than the Rayleigh and about 10 times stronger than the transverse ones. Brillouin spectra were recorded for 15 orientations of one single crystal of CO at 63.5 K and 20 orientations of 5 other single crystals at 62.0 K by rotating the crystals about the cell axis, thereby yielding the frequency shifts for various spectral features at different crystal orientations. The measured frequency shifts are shown on Fig. 4 for different γ angles at 63.5 and 62.0 K, respectively.

A knowledge of density and refractive index is essential in determining the elastic constants. The density for CO crystals at 63.5 and 62.0 K were obtained from molar volume graphs by

[a]All noted errors are relative as per text. Elastic constants for β-N_2 at 63.0 K are good to within 1% and at 37 K to about 2–3%.
[b]References 24 and 42.

Fukushima *et al.* (12). The values used were: ρ(63.5 K) = 0.920 g/cm^3 and ρ(62.0 K) = 0.921 g/cm^3 with about 1% uncertainty. There was no measured value of the refractive index of solid CO in the literature. However, the refractive index at the triple point has previously been calculated (2) via the Lorentz–Lorenz relation using measured values of liquid refractive index and density. Again the Lorentz–Lorenz relation yields: n(63.5 K) = 1.255 and n(62.0 K) = 1.257 with about 2% uncertainty. The best-fit adiabatic elastic constants and calculated bulk moduli for β-CO at 63.5 and 62 K are given in Table 1. The quoted errors in elastic constants were determined by the quality of the fit and the experimental self consistency corresponding to a single standard deviation. In addition, there was a systematic error of about 4% due to uncertainties in the values of the wavelength, index of refraction, density and the scattering angle.

β-N_2: The spectrum of β-N_2 was very similar to the spectrum of β-CO an example is shown in ref. 1. Both tranverse components were observed more frequently and the shifts were slightly larger than the shifts in β-CO. Longitudinal components were about 100 times weaker than the Rayleigh and about 10 times stronger than the transverse components. Again the spectra of cooled crystals were not of very good quality, in fact, it was not feasible to maintain a good quality crystal for light scattering purposes lower than 47.5 K. Crystals tended to heat up and fracture on exposure to the laser beam. Brillouin spectra were recorded for 35 orientations of four different single crystals of β-N_2 at 47.5 K. The measured frequency shifts are shown in Fig. 5 for different γ angles at 47.5 K.

The density of N_2 at 47.5 K was obtained in a similar manner to that of CO (12) and was ρ = 0.976 g/cm^3 with about 1% uncertainty. The refractive index was also calculated using the density and refractive index at the triple point and Lorentz–Lorenz relation, and was found to be n = 1.244 with less than 1% uncertainty. The best-fit adiabatic elastic constants and calculated bulk moduli for β-N_2 at 47.5 K are given in Table 1. The systematic error for β-N_2 is estimated to be about 2%.

(b) X-ray studies

Several attempts were made to carry out the phase transition in N_2. Close to the phase-transition temperature, pumping (and heating) did not have much affect on freeing and shaping the sample because of the low vapour pressure of N_2. The large temperature range for cooling N_2 required very slow and painstaking progress. It was therefore decided to concentrate on CO because of the much smaller cooling range from the triple point to the phase transition temperature.

Three large single crystals of α-CO were grown out of hcp β-CO single crystals. Just before the phase transition occurred, the β phase underwent some dramatic changes. Tiny spaces and vacancies appeared and the crystal lost transparency and became translucent. After several hours the interface appeared as shown in Fig. 6. Although the interface visually separated the two phases, X-ray diffraction patterns generally indicated traces of the β-phase left in the new α-structure. The complete transition occurred when more cooling was done (0.1 to 0.3 K) and subsequent X-ray patterns indicated pure cubic structure.

By determining the orientation of each crystal relative to the laboratory frame of reference, it was possible to correlate the orientations of the two phases of CO. Any vector $\boldsymbol{X}$ defined in the body frame of reference can be transformed to the lab frame of reference through the relation $\boldsymbol{X}' = \mathbf{A}\boldsymbol{X}$ where $\boldsymbol{X}'$ is the transformed vector and **A** is the Euler angle rotation matrix as defined by Goldstein (33). The components of the c axis of the hcp phase were determined in the laboratory frame using the rotation matrix **A**. These components (of the transformed c axis) were transformed to the body frame of the fcc phase using the inverse of the rotation matrix. Since the c axis is normal to the basal planes in hcp crystals, it was possible to identify those fcc planes to which the hcp basal planes were transformed. The crystal axes for the hcp phase are defined in terms of the usual (body) Cartesian coordinates.

Crystal I: The orientation of the crystal axes of the β-phase crystal relative to the lab frame (for 0° rotation of the cell) was determined to be: (θ, ϕ, χ) = (110.4, 334.4, 104.6). The orientation of the crystal axes of the α-phase crystal (for 0° rotation of the cell) was determined to be: (θ, ϕ, χ) = (110.5, 130.8, 211.4). Using the above procedure, the hcp c axis was found to transform to the [0.64 0.33 −0.68] direction in the fcc crystal which is at an angle of 16° to the $[1\,1\,\bar{1}]$ and 19° to the $[1\,0\,\bar{1}]$ axes. This means that the hcp basal planes transformed to close to the $(1\,0\,\bar{1})$ and $(1\,1\,\bar{1})$ planes of the fcc phase. The transformation was not complete, in that, the Laue pattern of the α crystal showed signs of other crystallites in it. The α phase was melted and regrown again out of the β phase; however, no further improvement was observed for

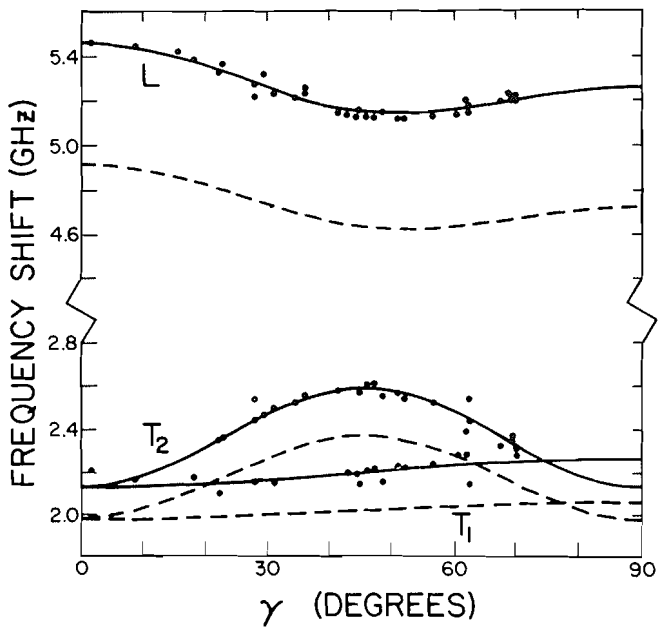

FIG. 5. Measured Brillouin frequency shifts (indicated by the solid dots) and calculated best-fit (solid) curves for β-N_2 vs. angle γ at 47.5 K. The dashed curves are calculated from the elastic constants at 63.0 K.

FIG. 6. Photograph showing sample in the cell. The horizontal line halfway up in the cell is the boundary that visually separates the single-crystal β-phase, at the top, and the single-crystal α-phase, at the bottom.

this particular sample although the orientation was similar to the original α sample.

Crystal II: The orientation of the crystal axes of the β phase relative to the lab frame was determined to be: (θ, ϕ, χ) = (96.0, 128.7, 195.5). The phase transition was carried out leading to a polycrystalline α sample which was melted and the original β phase recovered. This happened because in the cooling process, the crystal was cooled to the extent that half of it was transformed and the other half was still β. A second attempt was made to cool the crystal through the transition temperature. This time the diffraction patterns consisted of more or less well-defined Laue spots. The orientation of the crystal axes of the α phase was found to be: (θ, ϕ, χ) = (94.2, 286.2, 157.2). This phase was regrown twice through the β phase and each time the same orientation was obtained. The corresponding direction for the *c* axis in the fcc structure was found to be [0.29 0.30 −0.90] which is about 30° to both $[0\,1\,\bar{1}]$ and $[1\,1\,\bar{1}]$ and 25° to $[0\,0\,\bar{1}]$. The transition was again somewhat incomplete.

Crystal III: This phase transition was an excellent one, and the diffraction patterns consisted of well defined spots which showed no signs of crystal strain. The orientation of the crystal axes of the β phase relative to the lab frame was determined to be: (θ, ϕ, χ) = (57.7, 32.6, 339.5). The phase transition was carried out and a single crystal of α-CO was obtained. The orientation of the crystal axes of the α phase was (θ, ϕ, χ) = (23.2, 273.9, 339.0). The transformed *c* axis in the fcc structure was [0.48 0.81 0.33] which is within 19° of [1 1 1]. The next day, the crystal had spontaneously changed orientation to: (θ, ϕ, χ) = (34.7, 170.6, 356.4), and remained stable afterwards. This orientation indicated that the *c* axis had transformed to [−0.60 0.70 0.09] which is almost exactly the $[\bar{1}\,1\,0]$ axis of the fcc structure. The spots were well defined and the crystal

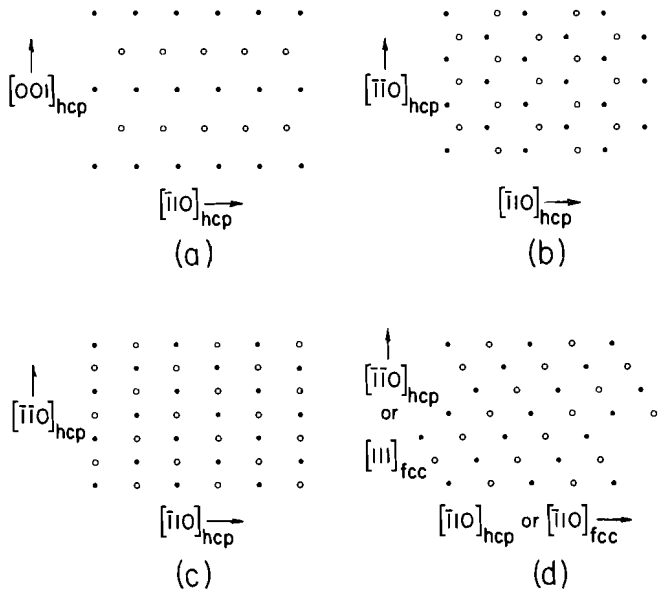

FIG. 7. Configuration of molecular sites as per suggested phase transition mechanism. (*a*) The hcp structure with *c* axis upwards. Solid circles represent one layer (A) and open circles the next layer (B), i.e. ABAB... stacking. (*b*) The hcp structure looking along *c* axis, i.e. into page. (*c*) Same structure with alternate planes moved as per text. (*d*) Basal planes after shearing movement as per text. Note the resulting ABCABC... stacking.

transition appeared to be complete. From crystal III which involves the best transition among the three it is clear that the final stable state for the hcp basal planes were planes of the form {1 1 0} and it did not seem to be happy close to {1 1 1}. This is consistent with crystals I and II where there appears to be competition between {1 1 1} and {1 1 0}. On this basis it is assumed, for purpose of the following discussion, that the basal planes of the hcp structure transform to the planes of the form {1 1 0} in the fcc structure.

There are several ways to imagine the mechanism of this transformation. One possibility is proposed here. Figure 7*a* shows the layering configuration of molecules or lattice sites for an hcp structure. The solid circles represent one layer A and open circles the next layer B, i.e., ABAB... stacking. Looking along the *c* axis the hexagonal nets are seen as in Fig. 7*b*, where the distance between two successive circles (open or solid) is $3a/\sqrt{6}$ in the [$\bar{1}$ 1 0] direction and *a* is the side of the cube in the fcc structure. It is assumed that all the A and B layers then move relative to one another (in the same way) in the [$\bar{1}$ 1 0] direction by $a/\sqrt{6}$ such that the arrangement becomes as shown in Fig. 7*c*. Finally, further relative shearing movement of only $a/2\sqrt{6}$ between successive layers is allowed such that, in seven planes (or layers), the first and last planes remain stationary and the second plane moves to the right by $a/2\sqrt{6}$, the third plane to the right by $a/\sqrt{6}$, the fourth plane to the right by $3a/2\sqrt{6}$, the fifth plane to the left by $a/\sqrt{6}$ (or to the right by $2a/\sqrt{6}$) and the sixth plane to the left by $a/2\sqrt{6}$ relative to the first or last planes in the [$\bar{1}$ 1 0] direction, the result is as shown in Fig. 7*d*. This has the same arrangement as that of the planes of the form {1 1 0} in the fcc structure with the cubic [1 1 1] axis upwards in the plane of the page (note the ABCABC... stacking). In the actual process, the suggested movement described between Fig. 7(*b*) and (*d*) would obviously occur as a single step while the molecules are becoming ordered.

Discussion

(a) Elastic constants

It has long been known that in molecular, especially plastic, crystals there should be a coupling between rotations and translations of molecules. This coupling follows clearly from the distance and orientation dependence of the intermolecular potential. A theoretical approach to RT coupling, for ionic crystals with molecular ions, was first worked out by Michel and Naudts (34). They pointed out the importance of RT coupling near structural phase transitions where ordering and change in lattice structure occur simultaneously. In particular, they obtained good agreement with the measured elastic constants of KCN where c_{44} softens markedly with temperature near the phase transition (35).

Recently, Fracassi and Klein (36) investigated RT coupling and the lattice dynamics of solid CO using several intermolecular potentials. It was concluded that RT coupling leads to an anomaly in the transverse acoustic phonon branch and consequent drastic anomalies in the dispersion curves of α-CO. Signorini *et al.* (23), in their anharmonic lattice dynamics calculations on solid N_2, specifically comment on the much smaller temperature range of existence of β-CO as compared to β-N_2. They point out that this likely denotes the effect of stronger RT coupling in CO, due to the asymmetry of the CO molecule, so that the rotational barrier is easily overcome only when the system is close to melting. This stronger coupling is also reflected in the (above mentioned) anomalous dispersion in α-CO, which is absent in α-N_2.

Also very recently, van der Avoird *et al.* (37) have emphasized the inadequacy of quasi-harmonic approaches to crystal dynamics even in the ordered phases and have developed a new and more general lattice dynamics scheme for handling large amplitude librational motions or hindered rotations, anharmonic translational vibrations, and RT coupling in molecular crystals. This scheme gives very accurate results for the ordered α and γ phases of solid N_2, while it also yields, for the first time, a quantum dynamical description of the molecular motions in the plastic β phase and an accurate α–β transition temperature (37). This theory also suggests that the orientational disorder in β-N_2 is caused by rapid 60° jumps around the *c* axis between localized librational states, and further predicts the correct experimental libron and translational phonon bands at 50 and 25 cm^{-1}, respectively (24, 38).

Experimental evidence for RT coupling, specifically related to the determination of elastic constants in these simple van der Waals systems, was discussed in ref. 26. Rand and Stoicheff (39) identified an anomalously "slow" T_1 mode in the disordered phase of CH_4 and attributed this to RT coupling. On comparison, this effect is not shown in the ordered phase of NH_3 (40). Calculations by Goldman and Klein (41) were found to be in disagreement with β-N_2 transverse-mode data by more than a factor of 2 and they suggested that the anomalously low measured transverse velocities indicated strong RT coupling or, at least, was probably caused by the role of orientational correlations. Elastic constants of single crystals of fcc and hcp argon alloys were determined by Brillouin spectroscopy (26). Slight mode softening was reflected in the dependence of c_{44} on solute concentration as phase instability increased. The Cauchy ratio c_{13}/c_{44} also consistently increased with increasing solute concentration and is relevant in recalling (2) the anomaly in this ratio between β-CO and β-N_2 (see Table 1). It was concluded that RT coupling almost certainly defines the role of diatomic impurities (solute) in stabilizing the hcp Ar structure and that the

ratio c_{13}/c_{44} (for hexagonal symmetry) is a sensitive measure of this effect.

From the above, it is clear that RT coupling is an important mechanism in van der Waals solids, especially for phase transitions, and that transverse acoustic modes are very sensitive to this effect (36). It was therefore expected that more clear-cut evidence for strong (and different) RT coupling would exhibit itself in elastic constant determinations in cooled crystals of the β phases of N_2 and CO, especially close to the α–β phase transitions and in the α phases.

The results in Table 1, as reflected in any of the elastic constants, show no clear evidence for mode softening in either β-CO or β-N_2, even within 0.5 K of the phase transition in the case of CO. There is no significant change in the ratio c_{13}/c_{44} on cooling CO crystals, although there appears to be an increase for N_2. All elastic constants tend to show an increase of about 1%/K, or slightly better, on cooling. It is unfortunate that it was not possible to obtain spectra for β-N_2 near the phase transition or for α-CO (of which three single crystals were grown) where mode softening effects would presumably be more evident (especially in the [1 1 1] direction (36)). It should, however, be emphasized that the transverse acoustic modes, i.e., characterized by c_{44}, are already very soft in both β phases. This is particularly evident on comparison with the rare gas solids (2, 26, 30) and the calculations (41) already noted above.

Comparison with other experimental data includes the inelastic neutron work of Kjems and Dolling (24). Three elastic constants, for β-N_2 at 37 K, could be deduced from slopes of their dispersion curves and are shown in Table 1. Agreement is reasonable with the present 47.5 K results when extrapolated at 37 K. Powell *et al.* (42) used this technique to determine three elastic constants c_{11}, c_{33}, and c_{44} for β-N_2, at 55 K and 400 MPa, and they appear to increase dramatically with pressure.

(b) Phase transformation mechanism

The α–β phase transformation in CO appears to be, as has been suggested in the literature, a martensitic transformation. There are several characteristics of these transformations (43) that were observed in the phase transition of CO. The transformation was time independent, i.e., the sample could be left for long times with the interface separating the two phases (as seen in Fig. 6) and only a temperature change would affect the height of the interface. The other aspect of this transformation was its reversibility. The interface between the phases could be lowered and made to vanish by increasing the temperature, the resulting hcp crystal having the same orientation as that of the parent hcp crystal as noted before. Most importantly, there seems to exist a definite relation between the orientations of the original structure and that of the new phase, namely, in the present work, the [0 0 1] and [$\bar{1}\,\bar{1}$ 0] axes of the hcp crystal appears to transform parallel to the [$\bar{1}$ 1 0] and [1 1 1] axes of the fcc crystal, respectively.

Kjems and Dolling (24) obtained a single crystal of α-N_2, surrounded by many small disoriented fragments, by slow cooling of a β-N_2 crystal and apparently were able to correlate the two phases, although not by X-ray analysis. The orientation of the crystal was related to that of the initial β phase crystal: [1 1 1] and [0 $\bar{1}$ 1] cube axes being parallel to the initial [0 0 1] and [1 1 0] hexagonal axes, and is not consistent with the present work. Metallurgists have studied several fcc–hcp phase transitions in metals and alloys. Work on aluminum alloys (44), CuGe alloys (45), cobalt (46), and cobalt alloys (47) all seem to indicate that the *c* axis of the hcp becomes the [1 1 1] direction in the fcc crystal. This may be attributed to the fact that the atomic interaction in metals is much stronger than in molecular crystals although there are also inconsistencies in the metallurgy work. For instance, Christian's study of cobalt (46) suggests that the fcc [1 $\bar{1}$ 0] direction transforms parallel to the hcp [1 1 0] direction, whereas Laird and Aaronson's work on aluminum (44) suggests that it transforms parallel to the hcp [2 $\bar{1}$ 0] direction.

Little other phase-transition work has been done on molecular crystals because of the difficulty in cooling large single crystals and maintaining good quality single crystals during and after phase transitions. The hcp–fcc transition in He has been studied by Frank (48) who concludes that the transition is martensitic. Schuch *et al.* (49) studied the hcp–fcc structure change in H_2 and D_2 using X-ray diffraction techniques. Although solidification occurred as a mass of crystallites, they found that there was always a noticeable preference for the *c* axis to be perpendicular to the cold cell wall. By measuring the intensity of X-ray reflection, they found that no intensity change took place when the hexagonal {0 0 2} reflection became the cubic {1 1 1} reflection. Neutron studies by Yarnell *et al.* (50) showed the hcp–fcc transition in H_2 and D_2 to be martensitic and suggested a substantial density of stacking faults of hexagonal planes evidenced by shifts and widths of the elastic neutron lines in both phases. Hardy *et al.* (51) studied Raman scattering in solid H_2 and D_2 and inferring from the intensity measurements suggested that the hcp–fcc transition takes place by shifting of the hexagonal planes such that the *c* axis becomes the cubic [1 1 1] axis. Silvera (52), however, mentioned that in a H_2 crystal there is a large potential barrier for such a shifting motion and although the energy gained per molecule by orientational ordering is of the order of 3–4 K, the barrier is at least of the order of melting temperature (15–20 K) and hence the thermodynamic probability for such a motion is extremely small. He further suggested that the transition takes place by motion of faults so that the barrier does not have to be crossed. It is interesting to note that Impey and Klein (53), making molecular dynamics computer simulation calculations on different phases of solid ammonia, determined that in the hcp–bcc (body centered cubic) phase transition, the hcp basal planes become bcc {1 1 0} planes and is the least energetic way for the transition.

There were competing factors that contributed to the incomplete phase transition in crystals I and II and to the lack of agreement with some of the above experimental evidence and the usual simple models. In addition, of course, to the orientation of the parent crystal at the top from which the daughter phase is initiated, the walls of the cell are boundary conditions imposing constraints on the transition. The possible presence of a tiny particle or sharp edges at the bottom of the cell could influence the growth of the daughter phase. Perhaps the most important factor is the possibility that the slight $P2_13$ distortion in CO (as noted earlier) is responsible for an inherently different α–β phase-transition mechanism in CO as opposed to N_2 (or some of the other molecular crystals mentioned above). Understanding of the fcc–hcp phase transition in these very simple molecular solids is still clearly not satisfactory.

Acknowledgements

The authors wish to express thanks to S. F. Ahmad for experimental work during the initial stages of this project and to

T. G. White for providing an almost continuous supply of liquid helium. Aside from the authors' desire to contribute to the honouring of J. A. Morrison, they wish also to express gratitude for his willingness to recently have acted as an external examiner for a thesis encompassing the above work.

This paper is dedicated to Professor J. A. Morrison

JANE E. CALLANAN, RON D. WEIR, and EDGAR F. WESTRUM, JR. Can. J. Chem. **66**, 549 (1988).

We have measured the heat capacity of the fast ion conductor $PbSnF_4$ at $10.3 < T < 352$ K by adiabatic calorimetry. Our results show anomalous values in the $C_{p,m}$ in the region $300 < T < 352$ K. These are associated with the $\alpha-\beta$ crystallographic transition reported at 353 K. Because the upper temperature limit of our cryostat is around 354 K, it was impossible to follow the phase transition to completion. A more subtle anomaly in the $C_{p,m}$ was detected between 130 and 160 K. Standard molar thermodynamic functions are presented at selected temperatures from 5 to 350 K.

JANE E. CALLANAN, RON D. WEIR, et EDGAR F. WESTRUM, JR. Can. J. Chem. **66**, 549 (1988).

On a mesuré la chaleur spécifique du conducteur d'ions rapides $PbSnF_4$ par calorimétrie adiabatique sur le domaine de températures entre 10.3 K et 352 K. Les résultats obtenus montrent des anomalies pour les valeurs de $C_{p,m}$ dans la région entre 300 K et 352 K. Celles-ci sont associées à la transition cristallographique $\alpha-\beta$ rapportée à 353 K. Il n'a pas été possible de suivre complètement la transition de phase à cause du cryostat dont la température maximum n'était que de 354 K environ. On a cependant décelé une anomalie plus subtile de la valeur de $C_{p,m}$ entre 130 K et 160 K. Les fonctions standard de thermodynamique molaire sont présentées pour un choix de températures de 5 K à 350 K.

Introduction

The existence of the stable compound $PbSnF_4$ was first revealed by the work of Donaldson and Senior (1), who reported the phase diagram and structural studies of mixtures containing stannous fluoride, SnF_2, and divalent metal fluorides, MF_2. $PbSnF_4$ has been found to possess a high ionic conductivity (2), and is among the best-known anionic conductors. Because of the use of fluoride electrolytes as thin films in galvanic cells, specific electrodes for fluoride ions, or gas detectors (3–6), considerable attention has been directed at experimental work on fluorides with the fluorite-type structure, including the family $MSnF_4$ where M = Pb, Ba, Sr.

Several allotropic forms of $PbSnF_4$ have been shown to exist at temperatures above 273 K by DTA and X-ray diffraction studies (1, 2, 7–10). The normal α-phase at room temperature, which depends upon the method of preparation, has a monoclinic, sometimes called a pseudo-orthorhombic monoclinic, structure with $a = 4.204$, $b = 4.205$, $c = 11.414$ Å, $\gamma = 91°34'$, a space group of $P_{2/n}$ and stability to about 353 K. The β-phase, stable between about 353 and 623 K, possesses a tetragonal structure with a space group of $P_{4/nmm}$ (7–9). When $PbSnF_4$ is prepared via the dry method, the α-phase appears only after annealing (8). The γ-phase, which has a fluorite structure with a space group of F_{m3m}, exists above 623 K to the melting point around 661 K (2, 7–9). Neither Pannetier *et al.* (7) from DTA and DSC studies nor Birchall *et al.* (10) from neutron diffraction work were able to confirm the presence of the monoclinic α-phase. The method of their sample preparation was not described. Whether the same sample was used in each study is not clear.

Within the α-phase of $PbSnF_4$, the cationic framework is made up of layers perpendicular to *c*-axis with a sequence PbPbSnSnPbPb... The F^- sub-lattice is highly disordered and contains a high concentration of F^- vacancies as well as F^- interstitial ions (11). The high ionic conductivity of this crystal is thought to be due to the high defect mobilities in the fluorite structure.

Heat capacity data have not been reported for $PbSnF_4$ and it seemed worthwhile to undertake these measurements by adiabatic calorimetry from very low temperature up to the α-to-β phase transition. All the DTA and structural work reported have been at temperatures above 273 K, although nmr measurements have been done down to 200 K (12), and 125 K (13), and a Mössbauer spectrum has been recorded at 77 K (10).

Experimental

The sample was prepared by a solid state reaction of a 1:1 mixture of PbF_2 and SnF_2. These materials were ground to a fine powder, pressed into pellets within a stainless steel die, and loaded into a copper tube evacuated to 0.133×10^{-5} kPa. Sintering was performed by heating the copper tube in an evacuated silica outer tube for 12 h at 523 K. After sintering, the copper vessel showed no visible signs of reaction with the pellets. An X-ray powder pattern at room temperature confirmed the structure of the sample as α-$PbSnF_4$ in agreement with literature data (8). Once annealed at 523 K for 1 h, the sample was cooled to room temperature where it remained until loading into the calorimeter. It was then cooled to 118 K for heat capacity measurements.

The calorimetric results were determined using the Mark X cryostat, which is an upgraded version of the Mark II cryostat already described (14). A guard shield was incorporated around the adiabatic shield. A capsule-type platinum resistance thermometer (laboratory designation A-5) was used for temperature measurements. The thermometer was calibrated at the U.S. National Bureau of Standards (N.B.S.) against the IPTS-1948 (as revised in 1960) (15) for temperatures above 90 K, against the N.B.S. provisional scale from 10 to 90 K, and by the

technique of McCracken and Chang (16) below 10 K. These calibrations are judged to reproduce thermodynamic temperatures to within 0.03 K between 10 and 90 K and within 0.04 above 90 K (17). Measurements of mass, current, voltage, and time are based upon calibrations done at N.B.S. The heat capacities from about 10 to 352 K were acquired with the assistance of a computer (18, 19), which was programmed for a series of determinations. During the drift periods, both the calorimeter temperature and the first and second derivatives of temperature with respect to time were recorded to establish the equilibrium temperature of the calorimeter before and after the energy input. While the calorimeter heater was on, the heater current and voltage as well as the duration of the heating interval were determined. Also recorded was the apparent heat capacity of the system which included the calorimeter, heater, thermometer, and sample.

A gold-plated copper calorimeter (laboratory designation W-99) without internal vanes, but with a central re-entrant well for the heater and thermometer, was loaded with $PbSnF_4$. After loading, the calorimeter was evacuated and then helium gas was added to the vessel to a pressure of 2.1 kPa at 297 K to facilitate thermal equilibrium. The vessel was then sealed by means of an annealed gold gasket pressed tightly on the 4 mm diameter stainless steel knife edge of the calorimeter top using a screw closure. Buoyancy corrections were calculated on the basis of the crystallographic density of 6.614 g cm^{-3} from the X-ray diffraction studies on the salt (8). The mass of $PbSnF_4$ amounted to 19.14767 g, *i.e.*, 0.04764482 mol based on its molar mass of 401.8836 g mol^{-1}.

TABLE 2. Standard molar thermodynamic functions for $PbSnF_4$ [molar mass: 401.8836 g mol^{-1}; p^0 = 101.325 kPa; R = 8.3145 J K^{-1} mol^{-1}; $\Phi_m^0(T, 0)^{def} = -\Delta_0^T H_m^0(T)/T + \Delta_0^T S_m^0(T)$; $\Delta_0^T X(T) = \{X(T) - X(0)\}$]

Results and discussion

The experimental molar heat capacities, $C_{p,m}/R$, of our $PbSnF_4$ sample are presented in Table 1, where the results are given in order of increasing temperature. The measurements were made in two series. The first series extended from 118.7 to 353.9 K without passing completely through the $\alpha-\beta$ transition, and the second extended from 10 to 126 K, thereby overlapping

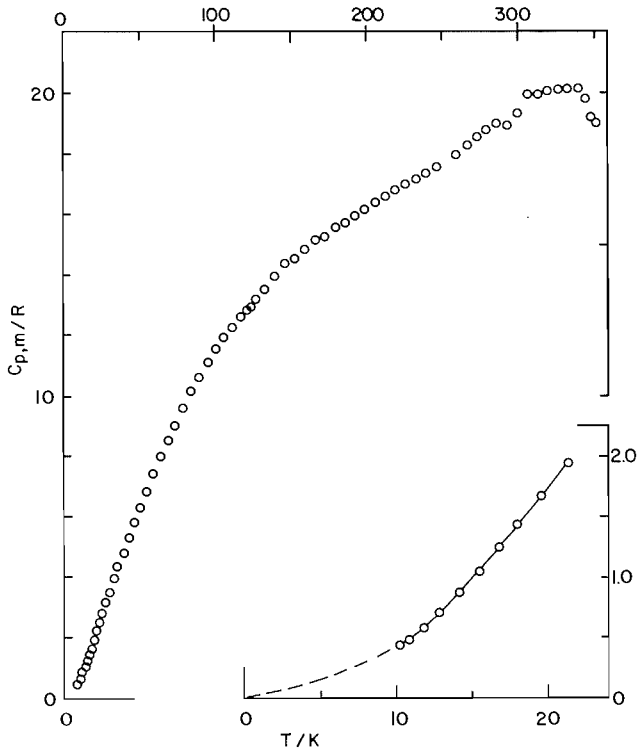

FIG. 1. Molar heat capacity $C_{p,m}/R$ for $PbSnF_4$.

the first series. The probable errors in heat capacity drop from about 1% at 10 K to less than 0.15% at temperatures above 30 K.

Shown in Fig. 1 is the $C_{p,m}/R$ curve for $PbSnF_4$ from 10 to 352 K. Two anomalies occur in the heat capacity. The more obvious region lies above 300 K where the transformation from the monoclinic α-phase to the tetragonal β-phase is in progress. Because the upper temperature limit of our cryostat is around 354 K, it was impossible to follow the phase transition to completion. Neither its enthalpy change nor actual temperature of occurrence could be obtained. The first signs of the transition were detected by us at 300 K. In their DSC and X-ray study, Claudy *et al.* (9) noted the first signs at 320 K for thermal effects and at 340 K for more rapid changes in lattice parameters. Their β-phase was present at 358 K.

The less obvious anomaly is shown in Fig. 2. A smooth curve drawn by using all our experimental points below 280 K shows those between 130 and 160 K to lie consistently above the curve. The deviation plot of the experimental heat capacity minus the smoothed heat capacity resulted in a random difference of less than 0.2% $C_{p,m}$ for $120 > T > 170$. However, for temperatures between 130 and 160 K, the differences are outside the normal deviations. The plot in Fig. 2 shows these deviations approaching 1.2% $C_{p,m}$ in the vicinity of 145 K. The fit of $C_{p,m}$ points from both series of measurements is excellent to the point of being indistinguishable. A critical reevaluation of our experimental conditions and calculations confirms that the tiny anomaly in the heat capacities is real. This rise in experimental $C_{p,m}$ correlates nicely with the nmr work by Chadwick *et al.* (13), whose results show a gentle drop in the ^{19}F spin–lattice relaxation time T_1 for the region $140 < T < 170$ K. Their T_1 then falls rapidly as temperature rises until the α–β transition is reached around 357 K.

Birchall *et al.* (10) found by examining the Mössbauer parameters that the quadrupole splitting increased at 77 K when compared with the values at 298 K. Because the line asymmetry also decreased, they suggest that structural rearrangement may have taken place, which could be consistent with a low temperature phase transformation. The specific temperature for the onset of these effects cannot be determined from their paper, since no parameters are presented between 77 and 298 K. From our heat capacity work, a phase transition can be ruled out for this temperature range, but the anomaly occurring between 130 and 160 K suggests that some rearrangement may be taking place.

The standard molar thermodynamic functions for $PbSnF_4$ are presented at selected temperatures in Table 2. The heat capacities below 10 K were obtained by fitting our experimental values below 20 K to the limiting form of the Debye equation, using a plot of $C_{p,m}/T$ against T^2 and extrapolating to 0 K. A plot of $C_{p,m}/T^3$ against T^2 was not used because our results do not extend to temperatures low enough to pass below the maximum value of $C_{p,m}/T^3$. It is the linear part of the curve below the maximum $C_{p,m}/T^3$ that is required for the extrapolation to 0 K.

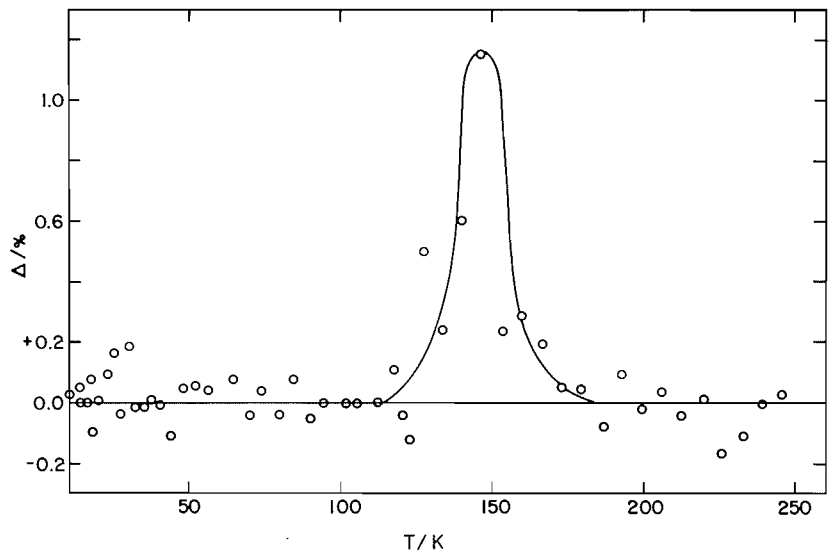

FIG. 2. A comparison of heat capacity results for $PbSnF_4$. $\Delta\% = 100\,[C_{p,m}(\text{exp}) - C_{p,m}(\text{smooth})]/C_{p,m}(\text{exp})$

This paper is dedicated to Professor J. A. Morrison

DONALD E. SULLIVAN, and REINHARD LIPOWSKY. Can. J. Chem. **66**, 553 (1988).

The contributions to the free energy of a nematic wetting layer as a function of its thickness l are analyzed. The longest-range contribution is due to distortion of the nematic director across the film, resulting from different preferred molecular orientations at the two interfaces bounding the film. Van der Waals forces as well as the decaying tails of the interfacial order-parameter profiles yield contributions to the free energy of successively shorter range. These effects lead to crossovers between different scaling régimes for variation of the mean wetting-layer thickness with temperature. Experimental implications of the results are described.

DONALD E. SULLIVAN, et REINHARD LIPOWSKY. Can. J. Chem. **66**, 553 (1988).

On a étudié l'influence de l'épaisseur (l) de couches nématiques mouillantes sur l'énergie libre. La contribution qui se fait sentir à la plus grande distance est dûe à une distorsion du directeur nématique à travers le film; cette distorsion résulte elle-même d'orientations moléculaires préférentielles différentes aux deux interfaces qui lient le film. Utilisant les forces de van der Waals ainsi que les profils de l'ordre interfacial/paramètres, on a pu déduire les contributions à l'énergie libre pour des distances de plus en plus courtes. Ces effets conduisent à des croisements entre divers régimes d'échelles pou la variation de l'épaisseur moyenne de la couche mouillante avec la température. On décrit les implications expérimentales de ces résultats.

[Traduit par la revue]

Consider a liquid crystalline material at a temperature T slightly above the transition temperature T_{NI} for the onset of nematic (N) ordering. While the bulk of the material then exists as an isotropic (I) liquid phase with no long-range orientational order, some degree of local nematic order may be spontaneously induced at the interface with another phase α such as a solid substrate or the vapour in coexistence with the liquid. If, on lowering the temperature, the mean thickness $\bar{l}$ of that nematic layer diverges over microscopic length scales as $T \rightarrow T_{NI}$, then we say that the nematic phase *completely wets* the α–I interface. Experimental evidence of this effect has been seen for a number of nematic substances, at both solid–liquid (1–3) and liquid–vapour (3–5) interfaces.[2] Entirely analogous wetting phenomena involving three distinct thermodynamic phases have recently come under extensive study for a variety of physical systems (7).

In this note we draw attention to some novel critical properties characterizing the approach to complete wetting in the case of a nematic layer. In particular, we focus on the asymptotic scaling laws describing the divergence of the mean wetting-layer thickness $\bar{l}$ in the limit that $t \equiv (T - T_{NI})/T_{NI}$ goes to zero. Our approach is similar to ones used successfully to describe wetting in other systems (7–10), based on analysis of the free energy $\sigma(l)$ per unit area of the layer as a function of its thickness l, when the latter is viewed as a thermodynamic order parameter. This approach is meaningful if l is large compared with the characteristic widths $\xi_{\alpha N}$ and ξ_{NI} of the two interfaces bounding the film. We shall discuss later the consequences of a large interfacial width ξ_{NI}, associated with the coherence length for fluctuations in the bulk liquid crystal. In mean-field theory, which neglects *interface* fluctuations, the equilibrium thickness $\bar{l}$ follows from $[\partial\sigma(l)/\partial l]_{l=\bar{l}} = 0$.

The free energy $\sigma(l)$ has the form (7–10)

$$[1] \quad \sigma(l) = Hl + \sigma_{\alpha N} + \sigma_{NI} + V(l)$$

where $\sigma_{\alpha N}$ and σ_{NI} are the equilibrium surface tensions of the α–N and N–I interfaces, respectively, in the limit of infinite separation l and at $T = T_{NI}$. The term Hl describes the increase in free energy due to the presence of a metastable nematic layer when $T > T_{NI}$, where H is the difference in (grand canonical) free energies per unit volume between the bulk nematic and either one of the coexisting α or l phases. For small t, we have

$$[2] \quad H \approx \Lambda t, \; \Lambda \equiv T_{NI}(S_I - S_N)$$

where S_I and S_N are the bulk entropies per unit volume at $T = T_{NI}$. The remaining term $V(l)$ in [1] represents all other contributions to the film free energy when its thickness l is finite rather than infinite. Here we shall *assume* that $V(l)$ has its absolute minimum at infinite l, consistent with the occurrence of complete wetting at N–I coexistence. Whether this indeed occurs or not ultimately depends on the short-range behaviour of $V(l)$, which in turn is related to the nature of microscopic forces in the system (7–10). In contrast, *if* complete wetting does occur, then it is the long-range behaviour of $V(l)$ which determines the critical properties that we shall examine here.

The leading-order contribution to $V(l)$ at large thickness l is due to distortion of the nematic director across the film. This effect arises whenever the separate α–N and N–I interfaces favour different orientations of the molecules, which we argue should be the rule rather than the exception. For example, the director at isolated N–I interfaces is usually observed to be obliquely aligned, with tilt angle Θ_{NI} (relative to the co-ordinate direction z perpendicular to the interface) falling in the range

[1]To whom correspondence should be addressed.

[2]In a recent study (6), near-complete-wetting growth of a *smectic-A* film at a liquid–vapour interface was observed.

0.8–1.3 radians (11, 12). This has been found for several different nematic substances, and thus appears to be a universal phenomenon. On the other hand, the alignment at isolated vapour–nematic interfaces is most often found to be homeotropic (4–6, 13), with $\Theta_{VN} = 0$, although one exception is currently provided by the liquid crystal PAA, for which $\Theta_{VN} = \pi/2$ (14). The alignment at a solid substrate is well-known to be highly variable, depending on the specific nature of both the liquid crystal and the substrate surface.

When $\Theta_{\alpha N}$ and Θ_{NI} differ, the director is distorted across the nematic layer if the latter is sufficiently thick. Using standard arguments of the Frank elastic theory (15, 16), in the approximation where one keeps only one elastic constant K,[3] the distortion is described by the tilt-angle variation

$$[3] \quad \Theta(z) = \Theta_{\alpha N} + (\Delta\Theta)z/l, \; \Delta\Theta \equiv \Theta_{NI} - \Theta_{\alpha N},$$

where the α–N and N–I interfaces are located at $z = 0$ and $z = l$, respectively. This yields a contribution (16)

$$[4] \quad V_d(l) \approx \tfrac{1}{2}K(\Delta\Theta)^2/l$$

to the free energy $V(l)$. The power-law dependence $V_d(l) \sim l^{-1}$ is the same,[4] and arises by the same mechanism, as that characterizing distortions of the magnetization vector through domain walls in a Heisenberg ferromagnet. Strain effects in a *solid* wetting layer also produce an l^{-1} contribution to the film free energy, which leads to a thinning of the layer (19). In contrast, $V_d(l)$ as discussed here is positive and thus gives a *repulsive* interaction between the α–N and N–I interfaces, which stabilizes wetting-layer growth at large l.

The mean-field prescription $[\partial\sigma/\partial l]_{l=\bar{l}} = 0$ is valid here, as it is more generally whenever $V(l)$ is dominated by power-law terms in three dimensions (9, 20). The asymptotic behaviour of $\bar{l}$ then follows from [1], [2], and [4] as

$$[5] \quad \bar{l} \approx Bt^{-\psi},$$

where $\psi = 1/2$ and $B = |\Delta\Theta|\sqrt{K/2\Lambda}$. Although the relevance of the distortion energy [4] to nematic wetting was first recognized some time ago (16), we believe that [5] is a new theoretical result.[5] This is the exact leading-order result describing spontaneous growth of a nematic wetting layer as $t \to 0$ in the presence of director distortion. A number of additional asymptotic relations follow from this analysis. For instance, the deviation of the equilibrium α–I surface tension from its value at N–I coexistence, $\Delta\sigma \equiv \sigma(\bar{l}) - (\sigma_{\alpha N} + \sigma_{NI})$, is given by $\Delta\sigma \approx Ct^{2-\alpha_s}$ where $\alpha_s = 3/2$ and $C = (2K\Lambda)^{1/2}|\Delta\Theta|$. This leads to a critical divergence $\sim t^{-\alpha_s}$ in the interfacial specific heat. The parallel correlation length $\xi_{||}$ for interface fluctuations, which is in principle measurable by scattering expeiments with momentum transfer parallel to the interface, follows from standard Ornstein–Zernike arguments (7, 9) to be given by $\xi_{||} = [\sigma_{NI}/V_d''(\bar{l})]^{1/2}$, where the primes denote derivatives with respect to l.[6] Thus one finds $\xi_{||} \approx Dt^{-\nu_{||}}$, with $\nu_{||} = 3/4$ and $D = (|\Delta\Theta|\sigma_{NI})^{1/2}K^{1/4}/(2\Lambda)^{3/4}$.

There is a possible limitation on the above results due to the fact that the tilt angles at the separate α–N and N–I interfaces are not fixed but have finite anchoring energies, $A_{\alpha N}$ and A_{NI}. This leads to l-dependent deviations $\delta\Theta_{\alpha N}(l)$ and $\delta\Theta_{NI}(l)$ of the tilt angles from their equilibrium values at infinite l, and corresponding deviations $\delta\sigma_{\alpha N}(l) \approx A_{\alpha N}(\delta\Theta_{\alpha N})^2$, $\delta\sigma_{NI}(l) \approx A_{NI}(\delta\Theta_{NI})^2$ of the separate surface tensions. Extension of the elastic–theoretic arguments (16) which led to [4] now gives

$$[6] \quad V_d(l) \approx \frac{K}{2l}(\Delta\Theta)^2 \Big/ \left[1 + \frac{K}{2l}\left(\frac{1}{A_{\alpha N}} + \frac{1}{A_{NI}}\right)\right]$$
$$= \frac{K}{2l}(\Delta\Theta)^2 - \left(\frac{K}{2l}\right)^2\left(\frac{1}{A_{\alpha N}} + \frac{1}{A_{NI}}\right)(\Delta\Theta)^2 + O(l^{-3})$$

The linearization in the second line of [6] is valid, hence the asymptotic formula [4] is realizable only for distances $l \gtrsim l_0 \equiv K/A$, where A is the weaker of the two anchoring energies. This is consistent with arguments given in the context of macroscopic nematic films, namely, that director distortion occurs only when l exceeds the "extrapolation length" l_0 (15, 16). Using a typical value for K of 10^{-7} erg/cm and current estimates (11) that $10^{-4} \leq A_{NI} \leq 10^{-2}$ erg/cm^2, we have $10^{-5} \leq l_0 \leq 10^{-3}$ cm. This rather substantial magnitude for l_0 suggests that it would be difficult to observe the power law [5] within the temperature range of current experiments. However, this does not rule out the fact that [5] is what *should* be observed for sufficiently small t. Furthermore, we conjecture that distortion-induced corrections of $O(l^{-2})$ to the leading-order result in [4] may result from other mechanisms besides that based on the anchoring energies of the separate α – N and N–I interfaces. Model calculations, for example, based on a Landau – de Gennes theory allowing for director tilt (22), are needed to elucidate this point.

In the absence of director distortion, the longest-ranged contribution to $V(l)$ is expected to result from van der Waals forces between the molecules. For l on the order of 10–100 nm, this has the form (7–10)

$$[7] \quad V_{vdw}(l) \approx W/l^2$$

where the Hamaker constant W depends on the polarizability densities of the different phases present. Due to anisotropy of the polarizability of liquid crystalline molecules, W has a more complex character than in recent treatments of wetting by ordinary liquids (7–10), but a detailed analysis of this is beyond the scope of the present paper. Here we shall simply make the following observations. For complete nematic wetting to occur, it is necessary (though not sufficient) that $W > 0$. In that case, we obtain the well-known result (8) that the mean thickness $\bar{l}$ obeys [5] with exponent $\psi = 1/3$. This is universally observed at the approach to complete wetting by ordinary liquids (7). In the absence of director distortion, a negative value of W would preempt complete wetting by giving an absolute minimum in $V(l)$ at some finite value of l. It is not clear, however, that this outcome is maintained if the expected crossover to director distortion develops at very large l. Note that the sign of W bears no direct relation to the nature of shorter range intermolecular forces, e.g., due to steric interactions, which can also be important in determining wetting behaviour (7–10).

[3]Generalizations of [3] and [4] to account for anisotropy of the elastic constants are derived in ref. 17. These exhibit a slightly more complex angle-dependence than the present equations.

[4]A repulsion $\sim 1/l$ between two interfaces will also be present for other physical systems, provided the order parameter in the layer breaks a continuous symmetry and the two interfaces bounding the layer prefer different states of the order parameter. This follows quite generally from finite-size scaling (18) when applied to such layers.

[5]The scaling relation [5] with exponent $\psi = 1/2$ also applies to complete wetting in a quite different context, namely for systems containing quenched random impurities (21).

[6]This expression for $\xi_{||}$ holds when only the N–I interface bounding the layer is rough, as in the case where α is a solid. If the α–N interface is also rough, then σ_{NI} is replaced by $\sigma_{NI}\sigma_{\alpha N}/(\sigma_{NI} + \sigma_{\alpha N})$, see ref. 9*b*.

As remarked earlier, it is important to account for the large magnitude (e.g., up to several hundred Å (11)) of the bulk coherence length ξ_{NI}, which in turn results from the *weakly* first-order nature of the nematic–isotropic transition. The effects of this can be analyzed in the framework of Landau – de Gennes type theories (15, 22, 23) for the spatial variation of orientational order parameters. As also found in Landau theories of wetting by ordinary liquids (7–10, 24), the exponentially decaying tails of the order-parameter profiles yield a contribution to $V(l)$ of the form

$$[8] \quad V_{SR}(l) \approx a\sigma_{NI} \exp -l/\xi_{NI}$$

where $a \sim O(1)$ is a numerical coefficient. Even in the presence of long-range (i.e., van der Waals) forces, the order-parameter profiles will still decay exponentially on intermediate length scales as long as ξ_{NI} is sufficiently large (25). In such a situation, a contribution of the form [8] should be added to the film free energy (26). Neglecting other contributions to $V(l)$, minimization of [1] in the case $a > 0$ now leads to

$$[9] \quad \bar{l} \approx b\xi_{NI} \ln (t_0/t)$$

where $t_0 \equiv a\sigma_{NI}/(\Lambda\xi_{NI})$ and b is a non-universal numerical coefficient which is appended to account for effects of interface fluctuations (9*a*, 27). We therefore envision the possibility for a sequence of crossovers between the behaviours indicated by [9] and [5], with successively $\psi = 1/3$ and 1/2 in the latter, as t approaches zero.

The logarithmic growth of $\bar{l}$ according to [9] agrees with the ellipsometric results of Beaglehole (5) for a nematic wetting layer at the liquid–vapour interface of 5CB, obtained over a reduced temperature range $5 \times 10^{-5} \leq t \leq 10^{-3}$. These results do not rule out the existence of a crossover to power-law behaviour at smaller t. In a more recent experiment, Hsiung *et al.* (28) observed a divergence in the thickness of a *weakly* ordered nematic layer of 5CB at a liquid–solid interface. Their data in the range $4 \times 10^{-4} \leq t \leq 4 \times 10^{-3}$ are well fitted by [5] with $\psi = 1/2$ and $B \approx 7$ Å. This value of the critical amplitude B agrees closely with that predicted by the expression after [5], using values for 5CB of $\Delta\Theta = \Theta_{NI} = 1.1$ (11), $K = 2.1 \times 10^{-7}$ erg/cm, and $\Lambda = 2 \times 10^7$ erg/cm^3 (29). The maximum film thickness measured in this experiment corresponds to about 400 Å, considerably less than current estimates for the length l_0 mentioned earlier. On the other hand, the nematic order parameter (OP) near the substrate, $Q(0)$, was found to be much smaller than the order parameter of the bulk nematic phase. As remarked by Hsiung *et al.* (28), this is difficult to reconcile with present theories of wetting (7, 23). An alternative interpretation of the results in ref. 28 is that they do not describe complete wetting but rather a different surface phenomenon which one might call near-critical adsorption.

If the surface OP $Q(0)$ is positive but close to the value, $Q = 0$, in the bulk isotropic phase, then the Landau – de Gennes theory yields an exponentially decaying OP profile,

$$[10] \quad Q(z) \approx Q(0) \exp -z/\xi_{NI}$$

at large distances from the substrate. In terms of the adsorption Γ, i.e., the integrated value of $Q(z)$, then [10] leads to $\Gamma \sim Q(0)\xi_{NI}$. This is similar to [9], but lacks the logarithmic term associated with complete wetting that arises when $Q(0)$ approaches the bulk nematic OP and the profile $Q(z)$ develops a kink. The above scaling for Γ should hold even beyond the Landau – de Gennes theory as long as $Q(0)$ is small compared to the bulk order parameter of the ordered phase at the transition. A similar effect occurs whenever a *continuous* transition point is approached from the disordered phase in the presence of a wall (30). In such a case, Γ diverges at the bulk transition temperature. Due to the weakly first-order nature of the N–I transition, ξ_{NI} does not actually diverge as $t \to 0$ but presumably obeys $\xi_{NI} \sim (T - T^*)^{-\nu}$, where T^* is slightly less than T_{NI} and ν is an appropriate exponent. At present, there is still some uncertainty (31) about the correct theoretical values for both T^* and ν (in the Landau – de Gennes theory, $\nu = 1/2$), as well as in the analysis of experimental data from different types of measurements in terms of these parameters. Hence the results of ref. 28, i.e., $T^* \approx T_{NI}$ and $\nu = 1/2$, are not inconsistent with an interpretation based on near-critical adsorption. Another factor which could well contribute to the small difference (about 1 K) between the value $T^* \approx T_{NI}$ deduced in ref. 28 and previous estimates (32) of T^* is the presence of impurities.

In conclusion, further experiments on nematic systems which clearly exhibit complete wetting would be useful. In particular, one should try to extend measurements such as those of refs. 5 and 28 to smaller values of t. While on the basis of current theory, the crossover to the distortion régime with $\psi = 1/2$ in [5] may be difficult to observe, it is possible that the correction terms discussed below [6] are sufficiently small to render this régime experimentally accessible. Furthermore, there may exist other possibilities (16) for adsorption of a nematic layer between two phases both of which exhibit large anchoring energies and hence yield a smaller value of l_0, to which the present analysis can be adapted. For example, one could in principle study adsorption of the nematic phase out of the vapour phase in the presence of a solid substrate.

NOTE ADDED IN PROOF

In a subsequent erratum to ref. 28, Hsiung *et al.* (33) report that new measurements on a purer sample of 5CB yield results consistent with partial wetting, with a value of T^* distinctly less than T_{NI}. This finding supports the arguments described here. A short account of these arguments has been given by Lipowsky and Sullivan (34).

Neutron scattering spectra associated with rotational tunnelling and low frequency vibrations of CH_4 adsorbed on graphite at 4 K and coverages from 0.2 to 1.5 monolayers are reported. Particular consideration is given to the changes which occur across the commensurate–incommensurate phase transition. It is shown that the incommensurate phase has a domain wall structure and is not a floating phase as had previously been proposed from theory.

R. P. HUMES, M. V. SMALLEY, T. RAYMENT et R. K. THOMAS. Can. J. Chem. **66**, 557 (1988).

Opérant à 4 K et à des couvertures allant de 0,2 à 1,5 monocouches, on a déterminé les spectres de diffusion des neutrons associés avec l'effet tunnel de rotation ainsi que les vibrations à basse fréquence du CH_4 adsorbé sur du graphite. On s'est particulièrement intéressé aux changements qui se produisent lors de la transition de phase commensurable–incommensurable. On démontre que la phase incommensurable possède une structure et qu'il ne s'agit pas d'une phase flottante comme il avait été proposé antérieurement en se basant sur la théorie.

[Traduit par la revue]

Introduction

When small molecules such as methane are adsorbed on the basal planes of graphite at sub-monolayer coverages they usually form two types of phase, a $(\sqrt{3} \times \sqrt{3})R30°$ structure, commensurate with the underlying surface, and an incommensurate (I) structure. There are still general features of the C–I transition that need to be understood and little is known experimentally about the transition in the particular system of methane on graphite. For example, it is not known whether the I phase of methane is a domain walled structure or a floating phase. We describe the changes that take place in the rotational tunnelling and vibrational spectra across the C–I transition.

The phase change at low temperatures ($T < 30$ K) has already been followed by neutron diffraction (1–3). Below a coverage of about a monolayer, CH_4 adopts the commensurate structure referred to above with the molecules 4.26 Å apart in a tripod down configuration. As the coverage increases above a monolayer the (10) diffraction peak shifts to higher angles corresponding to a decrease in the mean lattice parameter. This is consistent with the van der Waals diameter of the molecule being less than the $\sqrt{3} \times \sqrt{3}$ separation. Within the resolution of the diffraction experiment the change appears to be a continuous one and there is nothing to suggest that the I phase does not have a uniform spacing. However, for Kr, which has an identical phase diagram to CH_4, higher resolution X-ray studies show satellite peaks from the I phase indicating a domain wall structure (4–6). Phillips has done extensive calculations on the CH_4/graphite system and finds that a transition from the C phase to a freely floating, unwalled, phase preempts the formation of an I phase with domain walls (7, 8).

We have previously used incoherent neutron scattering to investigate rotational tunnelling transitions of CH_4 in its commensurate phase below about 10 K (1, 9). The potential field controlling the reorientation of the molecule is characterized by two barriers, one for rotation about the C—H bond normal to the surface (202 cm^{-1}) and one for rotation about the three equivalent C—H bonds (172 cm^{-1}). Comparison with atom–atom potential calculations indicates that CH_4–CH_4 interactions make a substantial contribution to both barriers, although it is the CH_4–surface interaction which makes the molecule adopt the tripod down configuration (see, for example, ref. 10).

Experimental details

The instruments used were the spectrometers IN4 and IN5 at the Institut Laue-Langevin, Grenoble (11) and the samples were prepared and mounted as described previously (1).

The graphite used was in two forms, Papyex (recompressed, exfoliated graphite) and Vulcan III (2700) (graphitized carbon black) with specific areas of about 20 $m^2\ g^{-1}$ and 71 $m^2\ g^{-1}$, respectively. In comparing results on the two materials it would be an advantage to know the absolute value of the coverage. This cannot be determined accurately because there is no method for doing it. Definition of the coverage with respect to a phase change seems to be the most satisfactory procedure (12). On this basis our absolute accuracy in the coverage measurements is probably about 15% but the relative accuracy is much better, about 2%. The coverages quoted are based on a molecular diameter of 4.26 Å.

Results

Rotational tunnelling spectra of CH_4 on Papyex at various coverages at 4.5 K are shown in Fig. 1. The momentum transfer (κ) here is perpendicular to the surface so the spectrum is expected to be dominated by the two transitions $T \leftrightarrow A$ and $2T \leftrightarrow E$ (9). At low coverage the spectra are those of the commensurate phase, as previously analysed (9). In the figure the intensi-

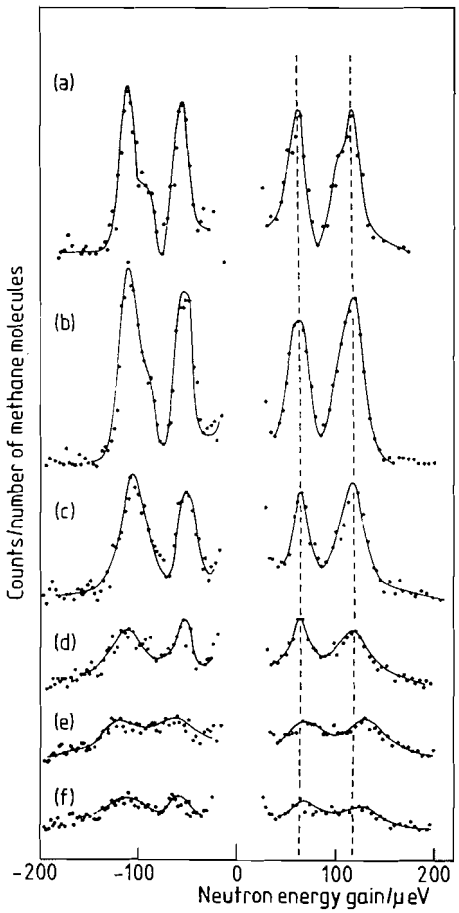

FIG. 1. Rotational tunnelling spectra of CH_4 on Papyex at 4.2 K with κ perpendicular to the surface. Coverages are (*a*) 0.23, (*b*) 0.94, (*c*) 1.03, (*d*) 1.12, (*e*) 1.20, and (*f*) 1.37. The intensities have been ratioed to the coverage.

ties have been divided by the coverage so that they represent the average spectrum per CH_4. From these spectra and others taken with κ parallel to the surface the main features are (*i*) the intensities of the lines per CH_4 molecule for the C phase increase slightly with coverage up to the C–I transition at $\theta = 1.0$; (*ii*) between $\theta = 1.0$ and 1.2 the intensities drop rapidly with increasing coverage but above 1.2 they decrease more slowly; (*iii*) there is a slight increase in the frequency of the transitions on increasing the coverage from 0.2 to 1.0 (only seen in the κ parallel spectra); (*iv*) there is a further small increase in the tunnelling splittings when the coverage changes from 1.0 upwards.

The intensity changes are shown more directly in Fig. 2, both as absolute values and per CH_4 molecule. There is some uncertainty in the exact coverage at the phase transition so the continuous lines in Fig. 2 are only schematic.

Incoherent scattering spectra at higher energies, for CH_4 adsorbed on Vulcan III at 10 K, are shown in Fig 3. Once again they are ratioed to the number of CH_4 molecules present. There are three main features: (*i*) the low coverage spectrum of the C phase has sharper bands than the higher coverage spectrum; (*ii*) across the C—I transition there is a marked change in the spectrum, the most intense peak shifting downwards from about 8.6 to 6 meV; (*iii*) at coverage where bilayer formation must be occurring to a significant extent the spectrum becomes broad and rather featureless.

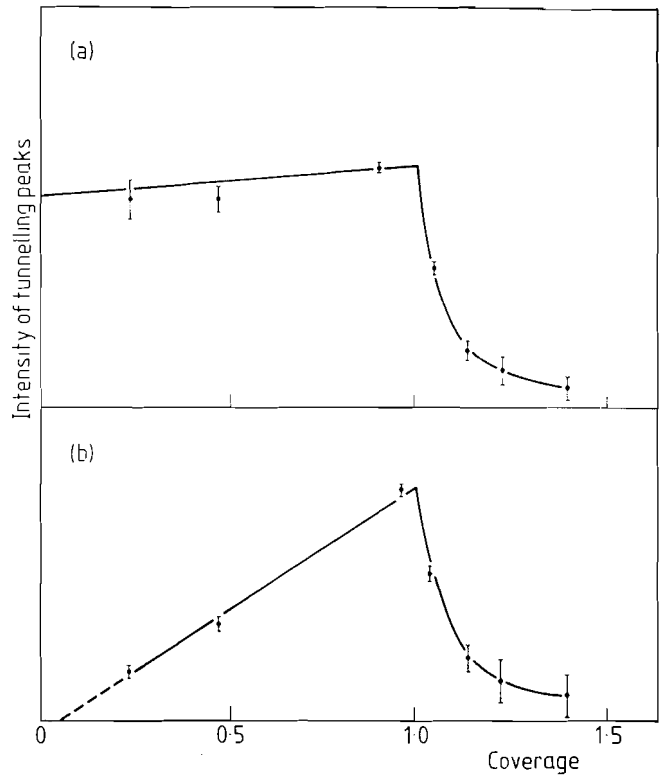

FIG. 2. Intensity of the tunnelling peaks of Fig. 1 against coverage, (*a*) per methane molecule, (*b*) absolute.

Discussion

For barriers to rotation close to those for CH_4 in its C phase the tunnelling spectrum is extremely sensitive to the barrier height. Figure 4 shows the effect of varying the two barrier heights on the tunnelling frequencies. The method of calculation is that of ref. 9. It is difficult to display the variation because the frequencies of all the transitions in the spectrum are changed by alteration of either barrier. Figure 4(*a*) shows the change in the A–$2T$ splitting with unique barrier height, the non-unique barrier being adjusted to keep the T–$2T$ splitting constant. This is approximately equivalent to reducing the barriers between all pocket states while keeping the distortion from a tetrahedrally shaped potential constant. In this case the κ parallel and perpendicular spectra would be related in a similar way to those observed for commensurate CH_4. Figure 4(*b*) and (*c*) show the variation of A–T and T–$2T$ splittings with the value of the non-unique barrier height while the unique barrier is held constant. This would lead to substantial differences between the κ perpendicular and parallel spectra. The conclusions from these calculations are that a small change in the barrier height causes a much larger relative change in the tunnelling splitting and that if the change in one barrier height is more than the other the differences between the κ parallel and perpendicular spectra will be more pronounced than for the C phase.

Molecule–molecule interactions make a significant contribution to the orientational potential of methane on graphite. This may be deduced from atom–atom potential calculations (1) or from the large change which occurs in the tunnelling spectrum of CH_4 when it is surrounded by Kr atoms (13). From the discussion in the previous paragraph it then follows that any change in the intermolecular spacing must lead to a substantial change in the tunnelling spectrum. It may therefore be con-

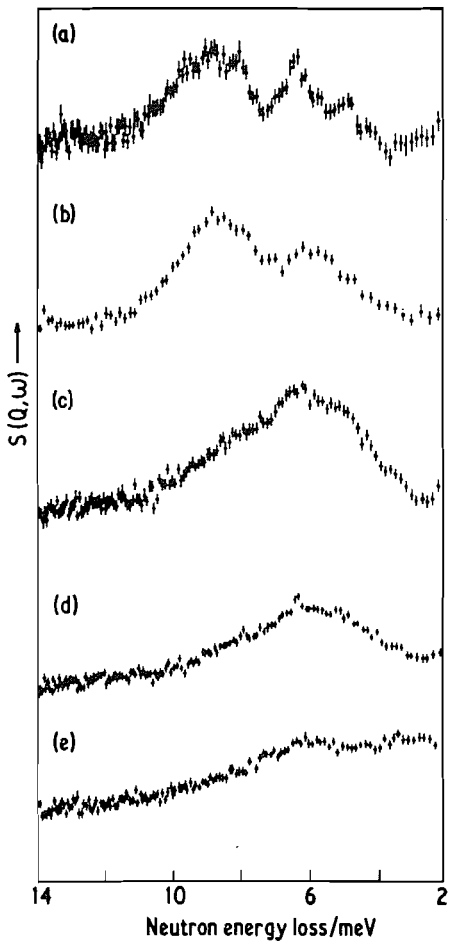

FIG. 3. Incoherent scattering spectra of CH_4 on Vulcan III at 10 K and coverages of (*a*) 0.4, (*b*) 0.8, (*c*) 1.06, (*d*) 1.2, and (*e*) 1.5. The intensities have been ratioed to the coverage to give a spectrum per methane molecule.

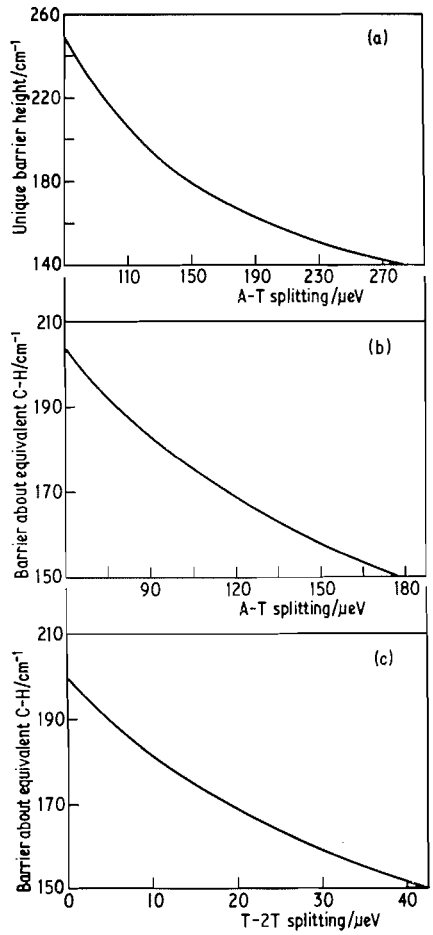

FIG. 4. Predicted variation of tunnelling splittings with barrier heights for CH_4 adsorbed on graphite, (*a*) unique barrier height varying with constant $T-2T$ splitting (18 μeV), (*b*) and (*c*) non-unique barrier varying with unique barrier held constant (200 cm^{-1} = 25 meV).

cluded that the sharp lines observed in the tunnelling spectrum at all the coverages of Fig. 1 must originate from molecules in an orienting potential similar in magnitude and identical in symmetry with that of the C phase. Given the sensitivity of the tunnelling splitting to the potential, this must even be true for the slightly shifted lines in Fig. 1(*f*). Domains of the C phase must therefore be present at coverages above 1.0, i.e. the incommensurate phase contains domains of C phase. The intensity of the lines is a measure of the proportion of molecules in these C domains.

The domains of C phase which are present at coverages above 1 may be of two general types, either part of an intrinsic domain walled structure (regular or irregular, hexagonal or striped, superlattice (14)) or surface domains of different size. The surface of Papyex itself consists of coherent domains of basal plane structure with an average diameter 200–400 Å (12). It is possible that the coverage at which the C–I transition takes place varies with the size of this surface domain. Thus the presence of C domains above a coverage of one could be attributed to surface domains where the C–I transition takes place at a higher coverage. To decide which of the two types of domain produces the sharp tunnelling lines we first discuss the small shifts in the positions of the lines at low and high coverages.

At a coverage of 0.2 the tunnelling frequencies in the κ parallel spectrum are slightly smaller than at 1.0. This corresponds to a change in the unique barrier parameter h_4 from -8 to -8.7 ± 0.3 μeV and no change in the other parameter. Thus the barrier to reorientation about the unique axis decreases slightly as the coverage increases. This can be attributed to the effects of surface domain size. There must be two contributions. One is that the binding energy of CH_4 to the graphite is slightly different according to the size of the surface domain. The second is that the barriers to reorientation depend on the average potential experienced by a molecule and this in turn depends on the amplitude of the zero point motion of the whole layer. Depending on whether molecules at the boundary of the domain are more or less strongly bound, the zero point amplitude of molecules within the domain will be reduced or increased, respectively. The different binding energy in different surface domains will lead to the more energetic being filled preferentially at lower coverage. These will then contain the more tightly bound molecules and therefore those with lower zero point amplitude and a more restricting reorientational potential. This might seem too small an effect to observe. However, tunnelling splittings are extraordinarily sensitive to small changes in the potential. If Vulcan III is used as adsorbent the tunnelling frequencies are observed to be about 3% higher than the weighted average of those observed on Papyex. Since the surface domains on Vulcan are much smaller than on Papyex (3) this suggests that tunnelling frequencies are larger on small surface domains and that the

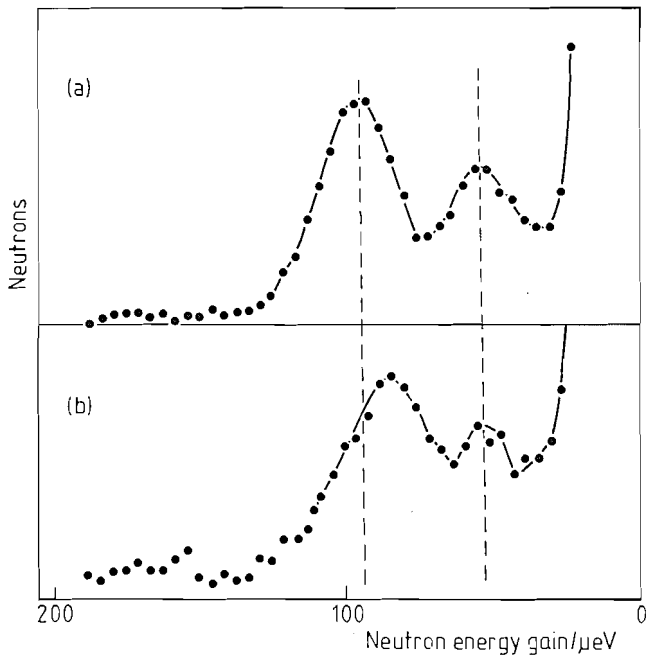

FIG. 5. Rotational tunnelling spectrum of CH_4 on Papyex at 4.2 K in the presence of CD_4. (*a*) CH_4 alone, and (*b*) CH_4 in a 3:1 CD_4/CH_4 mixture. The momentum transfer is parallel to the surface.

larger domains on Papyex are preferentially occupied at low coverage. An example of the effect of zero point energy is given in Fig. 5 where the tunnelling spectrum of CH_4 in a CH_4/CD_4 mixture is shown. The zero point motion in the mixed layer is lowered because the mass of the layer is increased and the tunnelling frequencies show the expected decrease. These correspond to an increase of 8% in the unique barrier and a decrease of 1% in the non-unique one when the layer contains 75% CD_4.

We can use these observations to decide whether CH_4 above one monolayer coverage has an intrinsic domain structure or whether isolated surface domains persist to a higher coverage because of their different size. The tunnelling frequencies at high coverage are greater than in the commensurate phase. The argument of the previous paragraph shows that they must be characteristic of molecules in small domains. If these were surface domains they would be the ones filled up as the coverage approached one monolayer. However, they would produce a greater overall broadening of the lines than observed in the spectrum of Fig. 1(*b*). It can therefore be concluded that the lines in Fig. 1(*d*), (*e*), and (*f*) are not from residual surface domains but from an intrinsic domain walled structure, in which the domains decrease in size as the coverage increases.

In a domain wall structure molecules at the domain walls will be subject to a potential different in both magnitude and symmetry from that at the centre of the domain. This potential will vary with distance from the domain wall in a way that depends on the thickness of the wall. It may also vary within and along a domain wall because the intermolecular spacing may vary and the surface molecule interaction may vary. Molecules in the domain walls will have a range of tunnelling frequencies giving rise to a band of lines, which when combined with the instrument resolution will be similar to a quasielastic spectrum, as observed.

The broad background could also be genuine quasi-elastic broadening, either from molecules in the second layer undergoing diffusive rotational motion or because motion of the molecules in the second layer causes broadening of the tunnelling transitions of molecules in the first layer. It would not be easy to distinguish this broadening mechanism from a domain wall mechanism, although at 4 K the latter is more plausible. Whatever the mechanism it does not affect the conclusion that commensurate domains of CH_4 persist above the C–I transition.

The most intense peak in the low coverage spectra of Fig. 3 (at about 8.7 meV) is associated with librations of the CH_4 molecules in the C phase (1). Although these are cooperative motions of the whole layer, their behaviour at the phase transition can be described qualitatively in terms of a single molecule libration. In contrast to tunnelling splittings, single particle librations are rather insensitive to barriers to reorientation. For example, for a one dimensional rotor in the range of barriers appropriate to CH_4 on graphite, a 10% decrease in the barrier height leads to a 30–40% increase in the tunnelling splitting (see also Fig. 4) but only a 5% decrease in the librational frequency. The large change in the librational peak at the C–I phase change must therefore be associated either with a large reduction in the reorientational potential or with an unusually large damping of the librational phonons. Either of these mechanisms could also give rise to the broad quasi-elastic background observed in the tunnelling spectra. However, librations of the commensurate domains would not necessarily remain unchanged in the vibrational spectrum. The librations are cooperative modes and show significant dispersion (15, 16). These modes would remain cooperative in a domain wall structure and the spectrum would be characteristic of the whole system rather than of the separate domains and walls. In this respect the librational spectrum is totally different in nature from the tunnelling spectrum.

The evolution of the spectra of Fig. 3 with increasing coverage suggests that the librations may be affected both by a reduction in the barriers to rotation and by damping. For example, the change in appearance between Fig. 3(*b*) and (*c*) may require both mechanisms. It seems surprising that the barriers to reorientation should be reduced as the molecules move closer together. However, the tripod down configuration of the C layer is a result of surface molecule interactions dominating the molecule–molecule interactions. A free standing CH_4 layer is predicted to adopt quite a different structure (10). Thus in the heavy walls of the domain structure the competition between the two forces might well act to reduce the reorientational barriers.

A possible mechanism for an increase in damping of the librational modes in the I phase is translation rotation coupling. This is likely to become very strong in the I phase because the barriers to reorientation will be sensitive to the positions of the molecules, both relative to one another and relative to the underlying surface. Tildesley and Lynden-Bell (17) have predicted large translation–rotation coupling effects at the corresponding phase transition in N_2 on graphite.

Unfortunately, neither librational nor tunnelling spectra can be used to characterize the domain wall structure in any detail. It could be argued that because the tunnelling spectra of the C domains retain the features characteristic of trigonal symmetry, so must the domain structure, that is, the domains must be hexagonal. Although it has been shown that what happens at the edges of the domains must influence the barrier, the averaging may be such that the spectrum of any molecule in the domain is not sensitive to the symmetry of the actual domain wall structure. The symmetry of the potential depends on both molecule and environment and where the change in environment is so

For personal use only.

small it may well be that the spectrum is dominated by the molecular symmetry.

Whatever detailed interpretation is correct, the persistence of the C phase tunnelling spectrum at coverages above the phase change shows that there must be some kind of domain wall structure in the I phase of CH_4 at 4.2 K. Although the existence of such domain structures in adsorbed layers has been demonstrated previously by diffraction, it has not been done for CH_4. This may be because only neutron diffraction has been applied to the CH_4 system. The signal to noise and resolution appear to be somewhat lower for neutrons than for X-rays and most of the successful experiments of this kind have been done with X-rays (4, 5, 6, 18).

Phillips and co-workers (7, 8) have predicted that the CH_4 layer will form a floating rather than a domain wall structure. The basic reason for this is that their calculations, in agreement with others, show that the barrier to translation of a methane molecule across the surface is very low, less than about 20 K. This is then predicted to be too weak a periodic substrate potential to induce wall formation. However, although Phillips has included many contributions to the substrate methane interactions, he is not able to include them all. For example, when the barrier is so low, interactions like the coupling of the vibrations of the layer to those of the substrate may have a significant effect. These Phillips has had to neglect. It may also be that in the experimental system the effect of surface domain boundaries may stabilize wall formation at the expense of the floating layer, in which case the existence of the domain wall structure would be in part a consequence of the imperfect structure of the graphite surface.

At temperatures higher than 4.2 K it is expected that the domain wall structure will become unstable with respect to the floating solid. However, the tunnelling spectrum cannot be used to probe the structure to much higher temperatures because the levels are broadened and the consequent broadening of the lines would greatly or totally reduce the sensitivity of the experiment.

Solvation of urea and methyl-substituted ureas by water and DMF

J. N. SPENCER AND JAMES W. HOVICK
Department of Chemistry, Franklin and Marshall College, Lancaster, PA 17604, U.S.A.

Received June 23, 1987

This paper is dedicated to Professor J. A. Morrison

J. N. SPENCER and JAMES W. HOVICK. Can. J. Chem. **66**, 562 (1988).

The hydrogen bond enthalpies of urea and methyl-substituted ureas with water and DMF have been determined by the pure-base calorimetric method. Transfer enthalpies between water and DMF have been calculated for dilute solutions of the ureas according to a previously developed model. The first solvation sphere of urea in water consists of five water molecules. Solvation spheres are given for other methyl-substituted ureas in water and DMF.

J. N. SPENCER et JAMES W. HOVICK. Can. J. Chem. **66**, 562 (1988).

Utilisant la méthode calorimétrique des bases pures, on a déterminé les enthalpies des liaisons hydrogènes de l'urée et d'urées portant des groupements méthyles sur les azotes avec de l'eau et du DMF. Faisant appel à un modèle mis au point antérieurement, on a calculé les enthalpies de transfert entre l'eau et le DMF pour des solutions diluées d'urées. Dans l'eau, la première sphère de solvation de l'urée comporte cinq molécules d'eau. On a aussi déterminé les sphéres de solvation d'autres urées substitués dans l'eau et dans le DMF.

Introduction

Due to the ability of urea to act as a strong protein denaturant considerable theoretical and experimental research has been focused on aqueous urea solutions (1–5). In particular, Somsen and co-workers (3–5) have studied the thermodynamic enthalpies of aqueous solutions of urea and methyl-substituted ureas. We have made additional calorimetric measurements on these ureas and have applied a previously developed model (6) to provide more detailed information on the first solvation sphere of dilute solutions of urea in DMF and water.

The enthalpies of hydrogen bond formation by the ureas with *N*,*N*-dimethylformamide (DMF) and water were determined by the pure-base calorimetric method (7) and the transfer enthalpies between DMF and water were calculated by making use of these hydrogen bond enthalpies. These enthalpies are of interest by themselves because DMF has been proposed as a model for the interior of a protein (3). The hydrogen bonding of urea and its methyl analogues will provide insight into the effect of these compounds on the structure of water.

Experimental

The enthalpies of solution were measured with a modified Parr solution calorimeter equipped with a 100 mL reaction vessel and electrical calibration. The experimental procedure and data treatment have been previously reported (8, 9). All enthalpies are at infinite dilution.

An abbreviated system for the naming of the ureas was utilized: urea (U), methylurea (MU), 1,1-dimethylurea (1,1-DMU), 1,3-dimethylurea (1,3-DMU), 1,1,3-trimethylurea (TriMU), and 1,1,3,3-tetramethylurea (TetMU).

MU (Aldrich) was recrystallized from absolute ethanol. Both 1,1-DMU (Aldrich) and 1,3-DMU (Aldrich) were sublimed, and TriMU (Alfa Products) and TMU (Aldrich) were used without further purification. All of the ureas were stored in a desiccator which contained $CaSO_4$. Spectroscopic grade DMF was dried over $CaSO_4$, and chloroform was refluxed over P_2O_5 under a nitrogen atmosphere and fractionally distilled.

Hydrogen bond enthalpies were calculated by the pure-base calorimetric method (7). The pure-base method assumes that when the pure base serves as solvent each acid molecule will be hydrogen bonded to a base molecule. The interactions between the acid and surrounding base molecules are isolated by choosing a model compound as nearly like the acid as possible but without hydrogen bonding capability. The enthalpy of solution of the acid and model is measured in the pure base and a reference solvent. The function of the reference solvent is to account for the differences in the dissociation of the acid and the model. The enthalpy of hydrogen bond formation, ΔH_{HB}, may then be calculated from

$$[1]\quad \Delta H_{HB} = (\Delta H_s^A - \Delta H_s^M)_{base} - (\Delta H_s^A - \Delta H_s^M)_{ref} - (\Delta H_c^A - \Delta H_c^M) - (\Delta H_i^A - \Delta H_i^M) - (\Delta H_c^{M'} - \Delta H_c^{A'}) - (\Delta H_i^{M'} - \Delta H_i^{A'})$$

where ΔH_s^A and ΔH_s^M are the enthalpies of solution of the acid and model compounds; ΔH_c^A and ΔH_c^M are the cavity formation terms for the pure base; $\Delta H_c^{A'}$ and $\Delta H_c^{M'}$ are the cavity terms for the reference solvent; ΔH_i^A and ΔH_i^M are the interaction terms due to dipolar and van der Waals forces for the pure base; and $\Delta H_i^{A'}$ and $\Delta H_i^{M'}$ are the corresponding terms for the reference solvent. A complete discussion of this method has been previously reported (6, 7).

For this study, the model compound was TetMU and the reference solvent was $CHCl_3$. Thus the assumption is made that the weak H-bond formed by $CHCl_3$ with the carbonyls of the model compound and urea of interest have comparable enthalpies.

Methylurea and urea were sufficiently insoluble in the reference solvent $CHCl_3$ that the pure base method had to be modified. The enthalpy of sublimation of urea, 21.0 kcal mol^{-1} (10), and the enthalpy of vaporization of TetMU, 10.9 kcal mol^{-1} (11), were used as reference states for the calculation of hydrogen bond enthalpies for urea in DMF and water so that in eq. [1] the reference term becomes

$$[2]\quad (\Delta H^{sub} - \Delta H^{vap})_{U} \quad _{TetMU}$$

Enthalpies of solution determined in the present work and those previously reported by other investigators are given in Table 1.

Results and discussion

The enthalpies of N—H hydrogen bond formation per mole of compound with water and DMF are given in Table 2. The enthalpies for 1,1- and 1,3-DMU were calculated from direct application of eq. [1] with correction terms taken from ref. 6. The urea enthalpies were calculated using the enthalpy of sublimation for urea and the enthalpy of vaporization for TetMU as the reference state. The N—H hydrogen bond enthalpies for MU were calculated from models and will be discussed later.

The relative correctness of these N—H hydrogen bonds may be checked by comparing experimental transfer enthalpies to

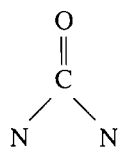
[a]Calculated from the enthalpies of sublimation of urea and the enthalpy of vaporization of TetMU by eq. [2].
[b]Calculated by using 1,1-DMU and 1,3-DMU as models, *vide infra*.
[c]The enthalpy changes refer to one mole of the urea. The cavity and interaction terms in $CHCl_3$ are 1.5 and 2.3 kcal mol^{-1}, respectively. Cavity and interaction terms for DMF and H_2O are given in the text.

those calculated according to a model which incorporates these N—H enthalpies. Previous work on the aqueous solvation of amides had allowed the determination of various terms which contribute to the transfer enthalpy of these ureas (6):

$$\underset{(H_2O\rightarrow DMF)}{\Delta H_{tr}} = \underset{CONN}{\Delta H_{tr}} + \underset{C{=}O}{\Delta H_{tr}} + \underset{CH_3}{\Delta H_{tr}} + \underset{N—H}{\Delta H_{tr}}$$

The transfer enthalpy term, $\underset{CONN}{\Delta H_{tr}}$, consists of the dipolar and cavity terms due to the transfer of the



portion of the urea. This transfer had previously determined to be −4.0 kcal mol^{-1} for the *N,N*-dimethylacetamide (DMA) transfer from H_2O to DMF. DMA is taken as the model for the ureas of this work. The increased stability of CONN in DMF is attributed to larger dipole and dispersion interactions in DMF than in water, interactions which outweigh the larger enthalpy required for cavity formation in DMF.

$\underset{C{=}O}{\Delta H_{tr}}$ refers to the enthalpy involved in removing the water molecules hydrogen bonded to the carbonyl of the urea. NMA was chosen as a model for these two bound water molecules and the enthalpy of two molecules bound to the carbonyl previously reported was used (6). Thus

$$\underset{C{=}O}{\Delta H_{tr}} = \underset{DMF}{H_{HB}} - \underset{H_2O}{H_{HB}} = +5.9 \text{ kcal mol}^{-1}$$

of carbonyl group, and was taken to be constant for all ureas.

The transfer enthalpy of a CH_3 group from water to DMF was calculated from parameters determined in earlier work (6).

$$\underset{CH_3}{\Delta H_{tr}} = \underset{DMF}{H_c} - \underset{H_2O}{H_c} - \underset{DMF}{H_i} + \underset{H_2O}{H_i}$$

where H_c and H_i have the meanings previously given. Thus

$$\underset{H_2O\rightarrow DMF}{\underset{CH_3}{\Delta H_{tr}}} = +2.5 - 0.3 + (-3.1) - (-1.9) = +1.0$$

The large interaction enthalpy for water is due to the structuring effect of water molecules about the non-polar methyl group.

The transfer enthalpy of the N—H hydrogen bonds is

$$\underset{N—H}{\Delta H_{tr}} = \underset{DMF}{H'_{HB}} - \underset{H_2O}{H'_{HB}}$$

where H'_{HB} is the N—H hydrogen bond enthalpy in the solvent of interest and is given in Table 2.

Thus the transfer enthalpy of the ureas can be found from

$$\underset{(H_2O\rightarrow DMF)}{\Delta H_{tr}} = -4.0 + 5.9 + 1.0N + \underset{DMF}{H'_{HB}} - \underset{H_2O}{H'_{HB}}$$
$$= +1.9 + N + \underset{DMF}{H'_{HB}} - \underset{H_2O}{H'_{HB}}$$

where N is the number of methyl groups being transferred.

Transfer enthalpies calculated from this model are given in Table 3 along with experimental transfer enthalpies. The agreement is excellent and not only provides clear insight into the origin of these heats but also shows the relative correctness of all terms including the hydrogen bond enthalpies.

An important conclusion which emerges from this analysis is that the methyl groups on the substituted ureas appear to be solvated equally and independently. The differences in transfer enthalpies comes not from differences in solvation of the methyl groups but rather from differences in the way in which the N—H hydrogen bonds are formed.

It is now possible to analyze the solvation spheres of the ureas in more detail. Work by Del Bene (12) has shown that methyl groups in amides are *cis* to the carbonyl group and it has been assumed that the methyl groups of substituted ureas would adopt this conformation. First the N—H···DMF hydrogen bond of TriMU is calculated by the pure-base method to be −3.2 kcal mol^{-1} for the one hydrogen bond that can be formed with DMF. It would be anticipated that two hydrogen bonds would form with 1,1-DMU and that the formation of the second hydrogen bond with the DMF carbonyl would be less energetic than that of the first. Huyskens (13) has shown that electronic changes produced by the formation of the first hydrogen donor weakens the hydrogen bonding capabilities of the second. Thus the enthalpy for the formation of the two hydrogen bonds to 1,1-DMU would be expected not to be twice that of TriMU but rather something between −3.2 and −6.4 kcal mol^{-1}. The H-bond enthalpy calculated is −4.4 kcal per two bonds.

It would be expected that the hydrogen bond enthalpy for the formation of two hydrogen bonds by 1,3-DMU would be twice that of TriMU if the bonds were formed linearly. The N—H protons in 1,3-DMU are considered to be *trans* to the carbonyl. The enthalpy found is −5.4 kcal per two H-bonds. Unless hydrogen bond effects are transmitted from one side of the molecule to the other, it seems clear that the bonds are not the same in TriMU and 1,3-DMU. The most consistent explanation for the discrepancy is that only one DMF molecule binds for

TABLE 3. Enthalpies of transfer from H_2O to DMF

Calculated	−2.2	+0.1	+1.8	+2.4	+4.4	+5.9

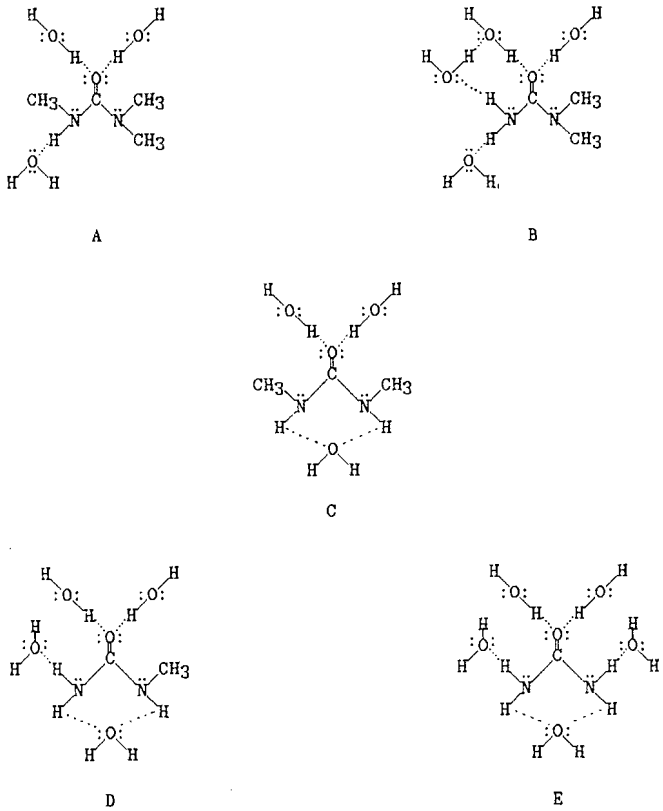

FIG. 1. Possible solvation spheres for urea and substituted ureas in aqueous environment. *A*. Trimethyl urea. *B*. 1,1-DMU. The cyclic structure shown here has been calculated to be less stable than a non-cyclic structure. The solvation sphere of this compound most probably consists of three water molecules, two bound to the carbonyl, one to the nitrogen proton. *C*. 1,3-DMU. The nitrogen protons are considered to be *trans* to the carbonyl group. *D*. Methyl urea. The solvation sphere is assumed to be non-cyclic. *E*. Urea.

each 1,3-DMU molecule which results in a non-linear and, hence, weaker bond. This is consistent with theoretical calculations made on urea and water (2) and seems to be the best rationale in the present case.

The hydrogen bond enthalpy in MU could not be calculated by the pure base method due to the insolubility of MU in $CHCl_3$. This enthalpy was estimated by using the enthalpy for 1,1-DMU and one-half the enthalpy for 1,3-DMU.

Finally the first DMF solvation sphere of urea was taken to consist of three DMF molecules with a combined enthalpy of −11.1 kcal mol^{-1} as calculated by the pure-base method.

Similar means were used to arrive at the enthalpies of N—H···H_2O hydrogen bonds for the ureas in water. Figure 1 shows possible solvation spheres for the ureas. Again the N—H protons have been considered to be *trans* to the carbonyl. For TriMU a single linear N—H hydrogen, −2.7 kcal mol^{-1}, bond is formed with water and two carbonyl to water hydrogen bonds are formed with bond enthalpy of −5.9 kcal mol^{-1} (6). The linear hydrogen bonded structure running from the water molecule bonded to the carbonyl through the water molecule bonded to the *trans* nitrogen proton provides an arrangement which is more stable than the structure which results if the N—H is *cis* to the carbonyl (12).

In amides, a cyclic structure involving a water molecule on the carbonyl oxygen and a water molecule bonded to a nitrogen proton is destabilizing (12). Thus a cyclic structure for 1,1-DMU as shown in Fig. 1*B* may actually be destabilized relative to the formation of a single hydrogen bond to the nitrogen proton. The hydrogen bond enthalpy for 1,1-DMU is less than that for TriMU and it seems likely that only one hydrogen bond is formed.

As with the DMF solvation sphere, the relative hydrogen bond enthalpies of TriMU (−2.7 kcal mol^{-1}) and 1,3-DMU (−3.9 kcal mol^{-1}) suggests one non-linear hydrogen bonded water molecule rather than two separate linear hydrogen bonded water molecules between the nitrogens for 1,3-DMU. The solvation sphere shown in Fig. 1*C* is thus assigned to 1,3-DMU.

Figure 1*D* shows a possible solvation sphere for MU. Comparison of the hydrogen bond enthalpies of MU to 1,3-DMU suggests that a fourth water molecule may be involved in the solvation of MU. Because the transfer enthalpies seem to be correctly calculated using a value of −5.9 kcal mol^{-1} for two water molecules bonded to the carbonyl for all ureas, a value determined from measurements on *N*-methylacetamide, it does not seem likely that a cyclic structure is formed for any urea. If such a cyclic structure were formed the enthalpy of the water molecules bonded to the carbonyl would be expected to be altered from that found for NMA. The solvation sphere of urea, Fig. 1*E*, was assigned by analogous reasoning.

Liquid zinc chloride vaporization thermodynamics by modified entrainment

PETER J. GARDNER AND PETER PANG

Chemistry Department, Royal Holloway and Bedford New College, Egham Hill, Egham, Surrey, TW20 0EX, United Kingdom

Received July 31, 1987

This paper is dedicated to Professor J. A. Morrison

PETER J. GARDNER and PETER PANG. Can. J. Chem. **66**, 566 (1988).

The thermodynamics of the vaporization of liquid zinc chloride has been studied in the temperature range 638–978 K by the modified entrainment method. Enthalpy and entropy changes for vaporization have been derived for the monomer and dimer species. These values are unchanged in a melt contaminated with water at a mole ratio of 1%. The proportion of dimer in the saturated vapour is found to decrease with increasing temperature. The vapour pressure equations for monomer and dimer vaporization, $ZnCl_2(l) = ZnCl_2(g)$ and $2ZnCl_2(l) = Zn_2Cl_4(g)$ are $\ln [p_1^0/p^\ominus] = -(15\,300 \pm 60)K/T + (15.39 \pm 0.06)$ and $\ln [p_2^0/p^\ominus] = -(11\,000 \pm 970)K/T + (6.5 \pm 1.3)$ for the temperature range 640–980 K.

PETER J. GARDNER et PETER PANG. Can. J. Chem. **66**, 566 (1988).

Utilisant une méthode d'entrainement modifée et opérant à des températures allant de 638 à 978 K, on a étudié les valeurs thermodynamiques pour la vaporisation du chlorure de zinc liquide. On a déterminé les changements dans les valeurs de l'enthalpie ainsi que de l'entropie de vaporisation des espèces tant monomères que dimères. Ces valeurs ne changent pas dans un mélange fondu contenant de l'eau jusqu'à un rapport molaire de 1%. On a trouvé que, avec une augmentation de la température, la proportion de dimère diminue dans la vapeur saturée. Pour des températures allant de 640 à 980 K, les équations respectives de la tension de vapeur, pour les vaporisations du monomère et du dimère, $ZnCl_2(l) = ZnCl_2(g)$ et $2ZnCl_2(l) = Zn_2Cl_4(g)$, sont les suivantes: $\ln [p_1^0/p^\ominus] = -(15\,300 \pm 60)K/T + (15{,}39 \pm 0{,}06)$ et $\ln [p_2^0/p^\ominus] = -(11\,000 \pm 970)K/T + (6{,}5 \pm 1{,}3)$.

Introduction

There is commercial interest (1) in the use of molten zinc chloride as a hydrocracking solvent. Sulphur in the feedstock causes progressive contamination of the melt with zinc sulphide. Several regeneration procedures have been explored including fluidized-bed combustion (1) in which zinc chloride is vaporized. Although the thermodynamics of vaporization has been studied by several workers (2–7), there remains considerable uncertainty in the published enthalpy and entropy changes. The most contentious aspect of these investigations is the extent of polymerization in the gas phase and the manner in which the extent varies with temperature. Neither vibrational spectra (8–10), both from matrix isolation studies and high temperature gas phase examination, nor mass spectrometry (3, 7, 11) provide unequivocal evidence for the presence of vapour dimers. Most thermodynamic results (from torsion effusion, transpiration, quasistatic vapour phase manometry) are interpreted with the assumption of vapour dimer concentrations of up to 10% between the melting point (591 K) and 1200 K. Furthermore, two independent (3, 5, 6) careful manometric studies predict a quite different variation in dimer concentration with temperature in the vapour in equilibrium with melt. The results of Keneshea and Cubicciotti (3) indicate the pressure fraction of dimer falls with increasing temperature whereas the more recent work of Polyachenok *et al.* (5, 6) suggests the opposite.

The vaporization has been re-examined in the temperature range 638 to 968 K by the modified extrainment method (MEM) in an attempt to resolve this uncertainty in the variation of dimer concentration with temperature.

Experimental

The modified entrainment rig has been described in detail elsewhere (12–14). Briefly, the sample is contained in a spherical quartz capsule approximately 1 cm in diameter and suspended from one arm of a recording microbalance. The capsule orifice is in the form of a vertical capillary (ca. 2 cm long × 1 mm internal diameter); this acts as a diffusive resistance to the ingress of the downward flowing carrier gas (argon, 80 cm^3 min^{-1} at STP) and the egress of the sample vapour. The experimental parameter is the rate of mass loss of the sample ($\dot{\omega}$) at a preset temperature. Improvements to the earlier design include (*i*) the capillary being inset into the capsule by about 2 mm rather than being joined via a short flared section; this permits the capillary resistance (l/r^2: l = length, r = radius) to be measured more precisely, (*ii*) the argon was purified by passage through a rare gas purifier, and (*iii*) carrier gas flows were controlled by mass flow controllers (model AFC 260, Epak Electronics Ltd.). The measuring thermocouple (Pt – 13% Rh/Pt) was calibrated at a commercial calibration laboratory (Harwell Instrument Test Laboratories) to a precision of ±2 K. Two separate capsules were used with capillary resistances 6.090×10^4 m^{-1} and 6.918×10^4 m^{-1}; 192 experimental points in the temperature range 638 ($\dot{\omega} \approx 1.0 \times 10^{-12}$ kg s^{-1}) to 978 K ($\dot{\omega} \approx 8.7 \times 10^{-9}$ kg s^{-1}) were recorded, 32 of these being with a specially doped sample (see Results and discussion).

Materials

Zinc chloride (380 g, AnalaR, BDH Ltd.) was purified and analysed in the laboratories of the Department of Metallurgy and Materials Science, Imperial College. The bulk sample was evacuated to ca. 0.1 Torr and heated slowly over 21 days to about 100 K above its melting point (591 K). All subsequent handling took place in an argon-filled dry box purged to ≤ 10 ppm water. The solid was transferred to a purpose-built purification cell (15), melted under vacuum, and purged with argon. Dry hydrogen chloride followed by dry argon were then bubbled through the melt to remove OH^- and O^{2-}. There followed a pre-electrolysis stage using a stainless steel cathode and a vitreous carbon anode to remove all electroactive species within the zinc chloride potential window. Continuous pumping was maintained during this stage to remove anodic gases and reduce anodic polarization. The base of the cell was fractured remotely permitting the melt to filter through a No. 4 porosity glass frit.

Cyclic voltammetry was used to assay the purity of the resulting melt. Voltammograms were obtained at ramp rates of 50 mV s^{-1} at 636 K using a polished tungsten disc as working electrode, a large Pt flag counter electrode, and an $Ag/AgCl/(ZnCl_2 + NaCl + AgCl)$ (liq) reference electrode. No significant peaks were observed due to electroactive impurities; of the likely impurities (16) (OH^-, O^{2-}, H_2O), O^{2-} should be detected in the anodic sweep and H_2O will appear as a broad diffuse "water wave". Unfortunately the reduction of HO^- is certainly more cathodic than Zn^{2+} reduction so unlikely to be detected directly. However, a polarographic study (17) of NaCl:KCl and LiCl:KCl melts

has shown that treatment with hydrogen chloride and chlorine reduces the OH^- concentration in these melts to negligible levels. The small residual current was ascribed to water impurity and the amount estimated using the Randles-Sevcik equation (18–20) at 0.002 mass%. Considerable care was invested in obtaining a high purity sample as one aspect of this study was to determine the effect of water contamination in the melt on the vaporization thermodynamics.

The carrier gas (argon) was purified by passsage through a commercial rare gas purifier (model RGP-4, BOC Ltd.) which includes a titanium getter operating at 700°C to remove O_2 and N_2, copper oxide at 450°C to remove H_2, hydrocarbons, and CO, and molecular sieves to remove CO_2 and H_2O.

Results and discussion

In the modified entrainment method (12), the partial pressure (p_i^0) of the minority component in a two component system is given by

$$[1] \quad p_i^0 = P[1 - \exp(-\xi_i)]$$

where

$$[2] \quad \xi_i = \dot{\omega}RTl/AM_iP\mathfrak{D}_i$$

Such a system would be the evaporation of zinc in an argon carrier gas. The total pressure is P (commonly close to 1 atm in our experiments), $\dot{\omega}$ is the rate of mass loss, l/A is the ratio of the length to the cross-sectional area of the capillary, M_i is molecular mass of i, and $\mathfrak{D}_i$ is the binary diffusion coefficient of i in the carrier gas. The term, $1 - \exp(-\xi_i)$, may be approximated to ξ_i to an accuracy of 5% if the transport function $\xi_i < 0.1$. In some cases it is necessary to retain a quadratic term in the exponential expansion when the same accuracy is obtainable for $\xi_i < 0.5$. Mass transport in the capillary is via diffusive and convective flow and Cussler (21) has shown that the first of the exponential approximations above is equivalent to the dilute gas approximation where mass transport is assumed to be exclusively diffusive. In systems where more than one component, e.g., monomer and dimer, contribute to the transport this exponential approximation is nearly always invoked (12) because of algebraic tractability. In this work monomeric and dimeric zinc chloride were assumed to be present in the vapour and solving the flux equations for these species, the following expression for $\dot{\omega}$ is obtained ($p^\ominus$ is the standard state pressure, 101 325 N m^{-2}).

$$[3] \quad \dot{\omega} = \frac{AM_1K_1D_1p^\ominus}{RTl}\left\{1 + \frac{2D_2K_2K_1}{D_1}\right\}$$

where M_1 is the molecular mass of the monomer and K_1 and K_2 are the respective equilibrium constants for

$$[4] \quad ZnCl_2(l) = ZnCl_2(g) \qquad K_1, \Delta H_1, \Delta S_1$$

$$[5] \quad 2ZnCl_2(g) = Zn_2Cl_4(g) \qquad K_2, \Delta H_2, \Delta S_2$$

The second term in parentheses in eq. [3] is the contribution made to the mass transport by the dimer. Also, as eq. [3] describes the behaviour of a three component (Ar, $ZnCl_2$, Zn_2Cl_4) system the effects of multicomponent diffusion (22) are included. D_i are the multicomponent diffusion coefficients of the ith component into the mixture; the estimation of $\mathfrak{D}_i$ and D_i is described in the Appendix.

The results from this work were processed by two separate procedures: (*i*) in combination with other published work to establish the compatibility of literature thermodynamic results with ours and (*ii*) independently. By substitution of the equilibrium partial pressures of monomer (p_1^0) and dimer (p_2^0), eq. [3] may be recast as

$$[6] \quad \dot{\omega} = \frac{AM_1}{RTl}\{D_1p_1^0 + 2D_2p_2^0\}$$

This equation may be solved simultaneously with literature equations for total pressure ($P_T = p_1^0 + p_2^0$) to give p_1^0 and p_2^0 separately over the common temperature range and hence ΔH_1, ΔS_1, ΔH_2, and ΔS_2 by regression. Keneshea and Cubicciotti (3) quote

$$[7] \quad \log_{10}(P_T/\text{Torr}) = (9.55 \pm 0.085) - (6\,598 \pm 21)\text{K}/T \qquad 693\text{–}883\ \text{K}$$

and Polyachenok *et al.* (5) give

$$[8] \quad \log_{10}(P_T/\text{Torr}) = (8.866 \pm 0.012) - (6\,032 \pm 11)\text{K}/T \qquad 773\text{–}973\ \text{K}$$

The thermodynamic constants for monomer vaporization and dimerization (equilibria [4] and [5]) obtained by combining eq. [6] with [7] or [8] are collected in Table 1. The results for monomer vaporization have been converted to a common temperature of 800 K using C_p for the liquid and gas quoted by Barin and Knacke (23). The precision of the dimerization results did not warrant correction. Table 1 also includes the thermodynamic constants for equilibria [4] and [5] obtained independently by Keneshea and Cubicciotti (3) and by Polyachenok *et al.* (5, 6).

[a]The uncertainty intervals quoted are standard deviations from the linear regression of $\ln p_i^0$ vs. T^{-1}.

Although the uncertainty in the results for the dimerization equilibrium is large it is clear that the MEM results are compatible with those of Keneshea and Cubicciotti (3) and not with those of Polyachenok *et al.* (5).

It is readily shown that the temperature derivative of the dimer pressure fraction ($p_2^0/(p_1^0 + p_2^0)$) is proportional to $(\Delta H_1 + \Delta H_2)/T^2$ which is positive when substituting Polyachenok's data (6) but negative using Cubicciotti's results (3). This fact was utilized in the independent processing of the MEM results. The dimer pressure fraction at 900 K is ca. 2% from the results of Keneshea and Cubicciotti (3) and decreasing at higher temperatures. It was assumed therefore that the dimer made negligible contribution to the transport above 900 K and consequently the MEM results above this temperature (58 data points) were processed via the exact equation [1] assuming a two component ($ZnCl_2$ + Ar) system and yielding ΔH_1 and ΔS_1 only. These results when converted to the mid-point of the temperature range of the MEM data points below 900 (102 points) were used with eq. [3] to extract K_2 and hence ΔH_2 and ΔS_2 for a three component system (see Table 2).

It is possible in principle to extract optimum values of ΔH_1, ΔH_2, ΔS_1, and ΔS_2 from the MEM results without making any assumptions about the extent of dimer contribution because there are 160 data points and 4 unknowns. Several minimization routines from the Numerical Algorithms Group (24) were ex-

[a]Uncertainty intervals (except for the simplex results) are standard deviations of regression coefficients.
[b]Obtained by separating the results into two temperature ranges and making an assumption about dimer concentration above 900 K (see text).

plored but the results were unsatisfactory in that the convergence criteria were not met or absurd local minima were located. A simplex routine based on Nelder and Mead's (25) algorithm proved more satisfactory in minimizing the sum of the squares of the differences of $\dot{\omega}$ (experimental) and $\dot{\omega}$ (from eq. [3]). Only points at temperatures below 856 K were used for which the transport function, ξ_i, is ≤ 0.1 and points were weighted as recommended by Kohman (26). Some lack of robustness in the algorithm was apparent in that optimum values of ΔH_2 and ΔS_2 varied depending on the choice of the initial simplex but ΔH_1 and ΔS_1 were stable. No uncertainty intervals are obtained from simplex minimization routines as derivitization is not involved and the intervals quoted for the simplex results in Table 2 reflect the range of minima located. It is clear that the MEM results are in satisfactory agreement with those of Keneshea and Cubicciotti (3).

It is of some concern in the industrial exploitation of zinc chloride melts as hydrocracking solvents as to how a steady accumulation of water in the melt will affect the thermodynamic vaporization constants. The water contamination can arise from a damp feedstock or from the reduction of oxygen heteroatoms during cracking. For example, minimal contamination by water has a marked effect (27) on the tranport properties of melts and it has been established that the crystal structure (28) of zinc chloride is profoundly affected by water contamination. A sample of zinc chloride at room temperature was doped *in situ* with water vapour to the extent of 0.3 mass% (2.3% mole ratio). Increasing the temperature to just below the melting point resulted in the loss of about half of the added water. It is assumed that the residue remained in the melt. The fate of this water is uncertain. Zielke (1) reports that molten zinc chloride is resistant to hydrolysis. Water is surprisingly soluble (15) in many melts and, for example, water in 60:40 LiCl:KCl shows Henry's law behaviour up to 5% mole ratio. Hydrolysis via $H_2O + Cl^- = OH^- + HCl$ and $H_2O + 2Cl^- = O^{2-} + 2HCl$ has been detected (29) in other halide melts. Thirty-two data points were recorded for this artificially contaminated melt over the temperature range 640 to 864 K. Predictably, $\ln [\dot{\omega}/\text{kg s}^{-1}]$ correlates well with T^{-1} ($r^2 = 0.998$) and the two linear regression lines, one obtained from the results of the pure sample and the other from the doped sample, were compared by analysis of covariance. This test showed there was no significant difference between the adjusted means or the regression coefficients and consequently it is highly probable that the results derive from the same population. Therefore water doping of $ZnCl_2$ at the 1% molar ratio level has no effect on the thermodynamics of vaporization.

An independent check on ΔS_1 can be obtained by combining McBride's (30) value of $S_{298}(ZnCl_2, c)$ with Cubicciotti and Eding's (31) $C_p(ZnCl_2, l)$, $C_p(ZnCl_2, c)$, and $\Delta S(ZnCl_2, c \rightarrow l)$ to give $S_{800}(ZnCl_2, l) = 208 \pm 2$ J K^{-1} mol^{-1}. Givan and Loewenschuss (9) derive statistical thermodynamic functions for $ZnCl_2(g)$ based on vibrational spectra of matrix isolated zinc chloride; $S_{800}(ZnCl_2, g) = 335.9$ J K^{-1} mol^{-1}. Therefore $\Delta S_1(800) = 128 \pm 2$ J K^{-1} mol^{-1} in good agreement with the MEM results in Table 2. Finally it is obvious from the results collected in Table 2 that the values for ΔH_2 and ΔS_2 from ref. 6 are almost exactly one half of the corresponding values of other workers. This does not appear to be a stoichiometry mistranscription as the authors (6) comment explicitly on their low value of ΔS_2 compared with that of Keneshea and Cubicciotti (3).

Conclusions

The proportion of dimer in the equilibrium vapour above molten zinc chloride decreases with increasing temperature. This is at variance with the most recent examination (5, 6) of this system but supports an earlier study (3). The vapour pressure equations for

[4] $ZnCl_2(l) = ZnCl_2(g)$

[9] $2ZnCl_2(l) = Zn_2Cl_4(g)$

may be derived from the results in Table 2 and are

[10] $\ln [p_1^0/p^{\ominus}] = -(15\,300 \pm 60)\,\text{K}/T + (15.39 \pm 0.06)$ 640–980 K

[11] $\ln [p_2^0/p^{\ominus}] = +(11\,000 \pm 970)\,\text{K}/T + (6.5 \pm 1.3)$ 640–980 K

Appendix: Diffusion coefficients

There are no literature data for the gaseous diffusion coefficients of zinc chloride monomer or dimer. However, estimation procedures (32) are well-developed and are precise to about 7% if Lennard–Jones potential parameters are available and to ≈12% in their absence. The procedure adopted in this work was to scale results for zinc chloride from a system with structural similarity and for which reliable experimental data exist. The chosen reference system was CO_2–Ar for which (33)

$$[A1] \quad \mathfrak{D}/m^2\,s^{-1} = 1.74 \times 10^{-9} T^{1.646}/\exp(89.1/T) \qquad 296 \text{ to } 1800 \text{ K}$$

Mason and Kronstadt (34) stress that Grahams's Law scaling is a gross oversimplification and a more rigorous scaling expression is

$$[A2] \quad \frac{\mathfrak{D}_{13}}{\mathfrak{D}_{12}} = \left(\frac{M_2}{M_3}\right)^{1/2} \left\{\left(\frac{M_1 + M_3}{M_1 + M_2}\right)^{1/2} \frac{\sigma_{12}^2 \Omega_{12}}{\sigma_{13}^2 \Omega_{13}}\right\}$$

where 1 is Ar, 2 is CO_2, 3 is zinc chloride, M_i are molecular masses, σ_{ij} are Lennard–Jones mixture force constants, and Ω_{ij} is a collision integral, a function of $k_B T/\epsilon_{ij}$ where ϵ_{ij} are Lennard–Jones mixture well-depths. Diffusion coefficients are relatively insensitive to the choice of ϵ_{ij} and, for both the monomer and dimer, ϵ_i were estimated from Svehla's linear correlation (35) of ϵ_i with T_B, the normal boiling point. Hence $(\epsilon/k_B)ZnCl_2 = 1180$ K and $(\epsilon/k_B)Zn_2Cl_4 = 1833$ K. Reid and Sherwood (32) tabulate Lennard–Jones constants for 76 species including 18 diatomic or linear polyatomics. Rejecting data for I_2 and HI, the L–J force constants for the remaining 16 species gave a satisfactory linear correlation ($r^2 = 0.91$) with the square root of the moment of inertia, I/g cm^2.

$$[A3] \quad \sigma/\text{Å} = (3.411 \pm 0.087) + (0.549 \pm 0.047) \times 10^{19}\sqrt{I}$$

Using this correlation, $\sigma(ZnCl_2) = 4.63$ Å and $\sigma(Zn_2Cl_4) = 5.24$ Å. For Zn_2Cl_4, D_{2h} symmetry was assumed, the internal bond angles set to 90°, and the bridging bond lengths set to 1.1 times the terminal bond lengths which were assumed to be 2.05 Å as in $ZnCl_2$. Finally $I(Zn_2Cl_4) = (I_x I_y I_z)^{1/3}$ where I_i are the principal moments. These structural assumptions are common to all M_2Cl_4 species quoted in JANAF tables (36). With the usual combining rules (32) for σ_{ij} and ϵ_{ij} and interpolating Ω_{ij} using Chen's formula (37), diffusion coefficients for zinc chloride monomer and dimer were calculated from eq. [A2] over the temperature range 630 to 980 K and then linearly regressed to a power formula in T.

$$[A4] \quad \mathfrak{D}(ZnCl_2,Ar)/m^2\,s^{-1} = 8.624 \times 10^{-6}(T/273.15)^{1.760}$$

$$[A5] \quad \mathfrak{D}(Zn_2Cl_4,Ar)/m^2\,s^{-1} = 6.793 \times 10^{-6}(T/273.15)^{1.761}$$

Diffusion coefficients in ternary systems will show concentration dependence (22) and a second order treatment (12*c*) of ternary diffusion with one majority component (argon) yields eqs. [A6] to [A10].

$$[A6] \quad D_1 = D(ZnCl_2\text{–}Ar,Zn_2Cl_4) = \mathfrak{D}(ZnCl_2\text{–}Ar)/\gamma_1$$

$$[A7] \quad D_2 = D(Zn_2Cl_4\text{–}Ar,ZnCl_2) = \mathfrak{D}(Zn_2Cl_4\text{–}Ar)/\gamma_2$$

$$[A8] \quad \gamma_1 = 1 + \{[D(3,2)D(1,2)/(\alpha + 1)] - 1\}\xi_1/2$$

$$[A9] \quad \gamma_2 = 1 + \{[D(3,1)D(2,1)\alpha/(\alpha + 1)] - 1\}\xi_2/2$$

$$[A10] \quad D(k, l) = (M_l/M_k)^{1/2} - 1$$

where $\alpha = D_1/(D_2 K_1 K_2)$ and $\xi_i = \omega RTl(\alpha + 1)/[(AM_1 PD_i)(\alpha + 2)]$.

In these equations, 3 is argon and α is a coupling parameter linking the equilibria [3] and [4] and defined as the flux ratio of monomer to dimer. The equations for γ_i contain both α and ξ_i which are themselves functions of the multicomponent diffusion coefficients, D_i. As D_i are evaluated from a knowledge of γ_i, a reiterative procedure is employed with an initial guess of unity and a termination criterion that successive estimates of γ_i differ by less than 1 in 10^4.

Rotational tunneling in a disordered system: nonequilibrium methane CH_4 II

M. PRAGER

Institut für Festkörperforschung der Kernforschungsanlage Jülich, Postfach 1913, D-5170 Jülich, West Germany

Received July 21, 1987

This paper is dedicated to Professor J. A. Morrison

M. PRAGER. Can. J. Chem. **66**, 570 (1988).

A pure methane sample was condensed onto a cold surface (T = 5 K) under conditions used in matrix-isolation spectroscopy. The sample shows a disturbed long range orientational order of CH_4 II. The free rotor and tunneling transitions are considerably broadened. Stacking faults and defects are believed to cause the disorder. The disorder is largely reduced with increasing annealing temperatures T_a but, surprisingly, even at $T_a \simeq 0.7T_m$ the long range order is not fully reestablished.

M. PRAGER. Can. J. Chem. **66**, 570 (1988).

On a condensé un échantillon de méthane pur sur une surface froide (T = 5 K), dans des conditions identiques à celles utilisées en spectroscopie par isolation en matrice. L'échantillon présente un ordre d'orientation à longue distance perturbé de CH_4 II. Les transitions dûes à la rotation libre et à l'effet tunnel sont très élargies. On considère que des failles et des défauts dans l'empilement sont à l'origine du désordre. Le désordre est beaucoup moins important lorsqu'on augmente la température de recuisson, T_a; toutefois, mème lorsque $T_a \simeq 0{,}7T_m$, on observe avec surprise que l'ordre à longue distance n'est pas complètement rétabli.

I. Introduction

Disorder is caused by the partial or complete loss of the three dimensional periodicity of a physical property. In classical glasses the relevant property is the center-of-mass position. In magnetic glassy systems the center of mass structure is still periodic but the magnetic periodicity is removed due to a statistical replacement of magnetic atoms by nonmagnetic ones. Glasses show universal low temperature properties, which are well described by the generally accepted "tunneling model". The physical structure of these tunneling states, however, is probably characteristic for every special system (1).

In molecular solids orientational disorder can be produced if e.g. a part of the anisotropically interacting molecules is replaced by isotropic units (2–4). Usually for low concentrations of the isotropic species (4) and/or weak anisotropic coupling (5), the effects of disorder can be considered as a perturbation of the ordered state. For highly diluted systems (6, 7), however, the long range orientational order can be completely removed, which in some cases is discussed under the aspect of an orientational glass (2) or "frozen-in" orientational disorder (3, 4).

There is the question whether pure molecular systems can be stabilized in an orientationally disordered state also. Long range orientational order can be disturbed if the solid is produced in a nonequilibrium procedure, e.g. by very fast cooling (analogous to glassy metals) or by condensing it from the gas phase onto a cold substrate directly in the solid phase. Such samples are used especially in the matrix-isolation spectroscopy technique to study individual molecules or molecular aggregates. They are known to be composed of small crystallites and to contain defects and stacking faults in rather large concentrations (8). Stacking faults lead to inequivalent molecular sites (fcc and hcp surrounding) and are often used to explain the spectroscopic observations (9). Defects interrupt the long range orientational interaction (as an isotropic impurity) and lead to a relaxed local orientational order. In the present work we tried to get an orientationally disordered sample using a matrix-isolation technique of preparation.

In some materials the effect of disorder can be monitored via its influence on the quantum transitions of a weakly hindered rotor. Rotational tunneling, observable in various molecular solids by incoherent neutron scattering, offers an extremely sensitive probe. Besides solid hydrogen (10), methane is the most intensively studied quantum rotor system (11, 12). In thermal equilibrium methane first crystallizes in an fcc orientationally disordered phase, CH_4 I. Below T_c = 20.4 K the molecules partially order while the center of mass structure is unchanged. The ordering is caused by the octopole–octopole interaction (13). The topology is such that this interaction vanishes at 25% of the sites for symmetry reasons. These sites of 432 symmetry feel only a weak crystalline field and the methane molecules are almost free quantum rotors. The remaining 75% are orientationally ordered at sites of symmetry $\bar{4}2m$ in a relatively strong rotational potential. Due to this potential one observes a tunnel splitting of the librational ground state with transitions at 75 and 140 μeV. Both, free rotors (FR) and tunneling molecules (TM), will be affected by disorder but in different ways. The more sensitive probes certainly are the FR because the relaxation of orientations around a defect removes the compensation of the octopole–octopole interactions. The TM, on the other hand, will feel only a rather weak change of the basic potential.

II. Experiments and results

Inelastic and elastic neutron scattering experiments were performed using light and heavy methane of 99.99% and 99% purity, respectively.

II.1. Sample preparation

Both samples were prepared under similar conditions in the same special inlet system described elsewhere (14), which allows the condensation of large size matrix-isolation samples for neutron scattering experiments. A reference volume of 1 L was filled up to a pressure of 2 bar with CH_4 or CD_4. This volume is connected with the sample holder via a regulation valve. The inlet line is heated to $T \approx 110$ K up to the sample container consisting of Al which was at T = 5 K. During condensation a very slow flux of 10 cm^3/min was maintained. Thus the adsorbed methane had enough time to come close to thermal equilibrium with the cold surface despite the bad thermal conductivity of the matrix. The sample temperature during condensation was always below 15 K (see below).

For personal use only.

II.2 Inelastic spectra

The quantum rotor states of the methane molecules were measured using the high resolution neutron time-of-flight spectrometer IN5 of the Institut Laue-Langevin (ILL) in Grenoble. Two setups with energy resolutions of 34/59 μeV FWHM at incident wavelengths of 8.5/6.0 Å were used. Standard data corrections were performed and the measured spectra transformed into $S(\theta,\omega)$ using the ILL-program package PRIME/CROSSX (15). Figure 1, bottom, shows the spectrum in the energy range up to 1.5 meV (λ_i = 6 Å) as taken immediately after condensation at a sample temperature T = 2 K. Various characteristic changes compared to equilibrium CH_4 II are found: (*i*) The free rotor states at E_{FR} = 1.09 meV are strongly suppressed and asymmetrically broadened to lower energy transfers. (*ii*) The tunneling transitions, shown with better energy resolution in Fig. 2, bottom (λ_i = 8.5 Å), are also strongly asymmetric with the tail to higher energy transfer. (*iii*) The energy region between tunneling and free rotor lines contains a large number of new states. (*iv*) The energy levels are not in thermal equilibrium. A parametrization of the spectrum has been tried by using various lineshapes in potential space (Gaussian, Lorentzian, constant in a range, linear in a range, exponential, power-function, all may be asymmetric) to extract the intensities. The relation between rotational potentials V and quantum transition energy ω_{TM}, ω_{FR} was taken from Hüller and Raich (16) for the TM

$$[1]\quad \hbar\omega_{TM} = 143\ \mu\text{eV}\exp\left(0.0758(37 - V/B)\right)$$

and was just extended phenomenologically to the FR-range as was done in ref. 6

$$[2]\quad \hbar\omega_{FR} = 1.31\ \text{meV}\exp\left(-\frac{(V/B)^2}{400}\right)$$

where B is the rotational constant of a methane molecule.

The solid lines in Figs. 1 and 2 are fits with asymmetric Lorentzians. The distributions of rotational potentials in the freshly prepared sample had widths of $\Gamma_{FR} \approx 8$ B and $\Gamma_{TM} \simeq 6$ B. Gaussians do not reproduce the large intensity between the tunneling and free rotor lines while constant lineshapes overemphasize it. Using the results from the fit with Lorentzians we see that the spin temperature T_s describing the intensities of the FR lines is considerably higher ($T_s \simeq (8 \pm 2)$ K) than the sample temperature T = 2 K. In the tunnel system the population of the E and T states relative to the A states corresponds to a spin temperature around $T_s \simeq 4$ K. The spin temperature approaches somewhat the sample temperature with increasing annealing. However, all these numbers suffer from the problem that it is rather difficult to attribute the intensities of broad distributions unambiguously to FR and TM.

At T = 10 K the described spectra have changed slightly, mainly by broadening. At T = 15 K we observe a broad quasi-elastic line beside the elastic line which is characteristic for rotational diffusion in CH_4 I.

Spectra taken during the condensation of the methane show an intermediate shape. No well-defined inelastic lines can be detected but the broad inelastic intensity is not yet quasi-elastic.

The sample was annealed at temperatures T_a = 30, 50, 70 K for 30 min each. After each annealing, spectra were again measured at a sample temperature T = 2 K. Annealing at T = 30 K did not change the spectra. After heat treatment at T_a = 50 K the tunneling lines are considerably sharpened and the free rotor lines get much more pronounced. The broad intensity between the free rotor and tunneling energies is reduced (Figs. 1 and 2, top). The sharpening of the inelastic features in the spectrum further increases after annealing at T_a = 70 K. Although this temperature is only 22% below the melting point this annealing is not sufficient to produce an equilibrium CH_4 II sample (17).

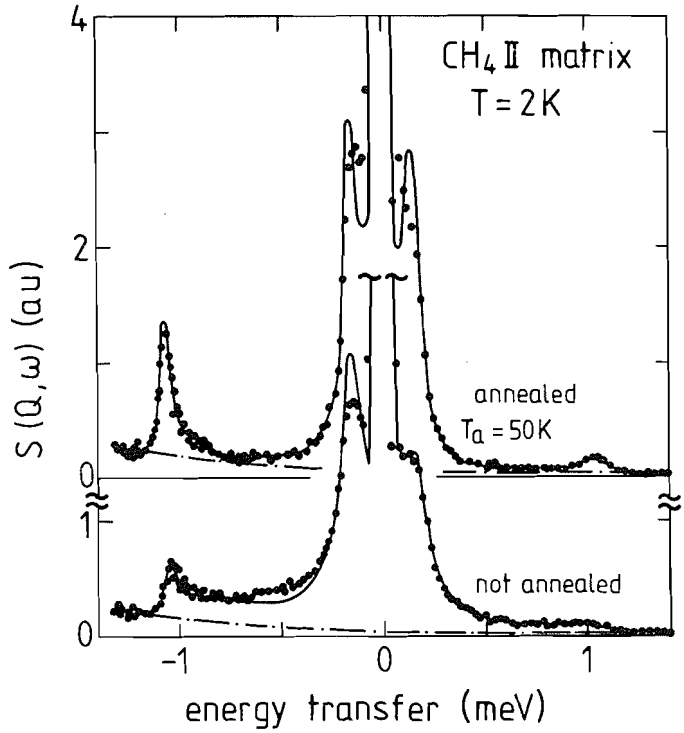

FIG. 1. Inelastic neutron scattering spectra of condensed methane as measured with the high resolution time-of-flight spectrometer IN5 using a wavelength λ_i = 6 Å (energy resolution δE = 59 μeV). Top: annealed at T_a = 50 K for 30 min; bottom: not annealed. The nonzero background is an artefact due to an incomplete empty can subtraction.

II.3 Diffraction experiments

To characterize the structure of our sample neutron powder diffraction patterns were measured using the diffractometer D1a of the ILL, Grenoble, with an incoming wavelength λ_i = 2.98 Å in a range of momentum transfers $1.6 < Q\ (Å^{-1}) < 3.3$. Spectra were taken at three different temperatures T = 7, 15, 25 K from the unannealed sample and after annealing for 30 min at T_a = 60 K. To get pronounced diffraction peaks, the coherent scatterer CD_4 had to be used instead of CH_4. Unfortunately, CD_4 has a phase diagram somewhat different from that of CH_4 (for details see e.g. ref. 18). The pattern at T = 7 (15, 25) K are found, by comparison with earlier unpublished measurements, to be characteristic of phase III (II, I). We only show parts of the diffraction pattern taken at T = 7 K and 25 K before and after annealing (Fig. 3). The essential difference between the two spectra consists in a considerable sharpening of the lines originating from the methane sample. If one assumes that a finite crystal size causes the line broadening $\epsilon_{1/2}$ in the cold condensed sample one estimates a characteristic diameter of the crystallites D ≃ 400 Å from the standard expression (19).

$$[3]\quad D \approx \frac{\lambda_i}{\epsilon_{1/2}\cos\vartheta}\,[\rho]$$

ϑ being the Bragg angle and ρ the vdW-radius of a methane molecule.

Additional Bragg peaks are due to the Al container and to N_2

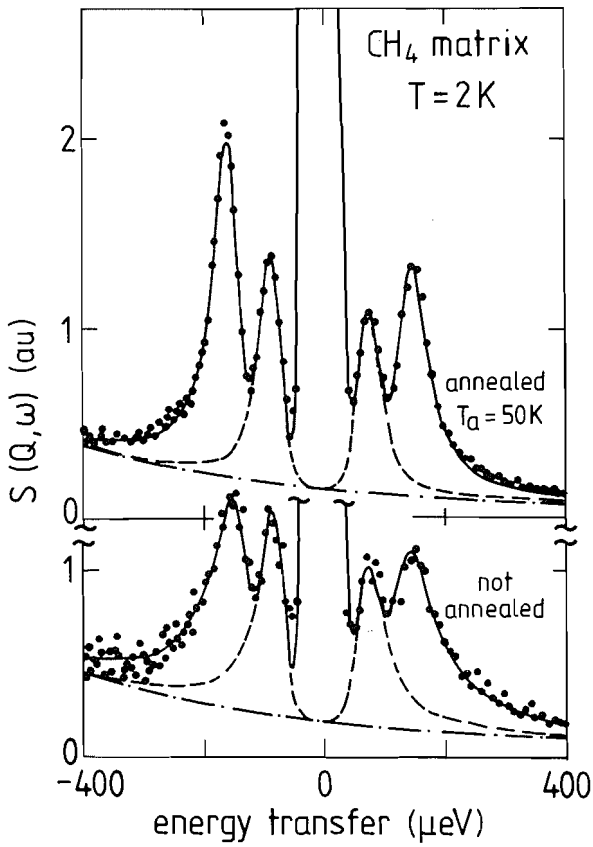

FIG. 2. Inelastic neutron scattering spectra of condensed methane. Spectrometer: IN5. $\lambda_i = 8.5$ Å ($\delta E = 34$ μeV). Top: annealed at $T_a = 50$ K for 30 min; bottom: not annealed. The nonzero background is an artefact due to an incomplete empty can subtraction.

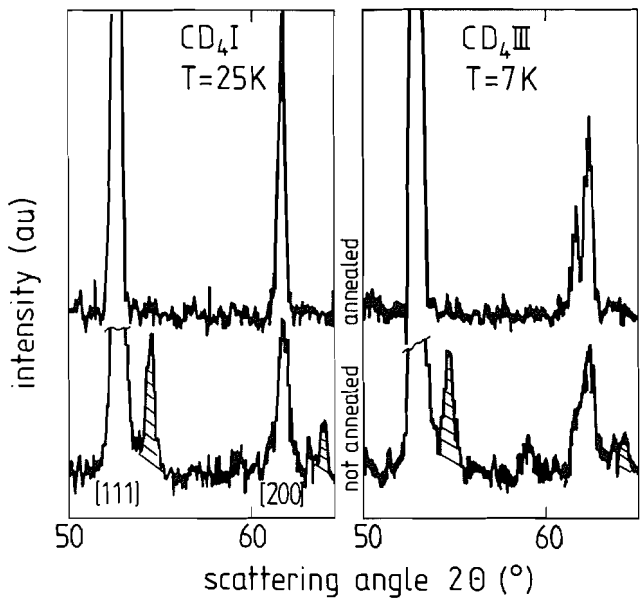

FIG. 3. Neutron diffraction patterns of condensed methane CD_4 in the range of the {111} and {200} reflections as measured with the powder diffractometer D1a of the ILL with a wavelength $\lambda_i = 2.98$ Å. The shaded peaks are due to a N_2 surface contamination. Left: $T = 25$ K, CD_4 I; right: $T = 7$ K, CD_4 III. Top: Sample annealed at $T_a = 60$ K for 30 min; bottom; Sample not annealed.

probably condensed on the outer surface of our sample container.

III. Discussion

The data we have presented on a one-component disordered quantum system would be difficult to obtain by methods other than INS. In particular, we have investigated:

(*i*) *Control of preparation conditions*

To prevent annealing of a matrix during condensation, very low condensation rates are usually used in the matrix production procedure. The temperature in the sample, however, cannot really be measured. In our system this is possible via an internal probe since the tunneling transitions of CH_4 molecules show a characteristic temperature dependence in the range from He temperature to the phase transition temperature T_c (11, 20) above which the molecule is orientationally disordered. Comparing the spectrum taken during condensation with those obtained later under conditions of thermal equilibrium we conclude that the sample temperature during preparation was $T = (12 \pm 2)$ K, even for such large samples as necessary for neutron scattering experiments. Temperature gradients in the sample certainly affect somewhat the accuracy of this statement.

(*ii*) *Perturbed long range orientational order and rotational potentials*

In spite of strong differences, the inelastic spectrum of the unannealed sample is qualitatively similar to spectra from CH_4 II cooled down from the liquid. The crude diffraction patterns are also characteristic for long-range-ordered methane of the phases III, II, I. The finite linewidth of the Bragg peaks can be attributed to finite crystallite sizes. Thus it seems possible that surface effects are influencing the rotational potentials. If one assumes that they are significant in a depth of about 3 molecular diameters below the surface one expects, from the relative volumes, disorder for 5% of the molecules. This is much smaller than the observed value. We note that in particular the free rotor states which in an undisturbed lattice represent already 25% of the molecules are nearly completely suppressed. Thus, the disorder must be of different origin. The matrices used in matrix isolation spectroscopy are known to represent nonequilibrium states, containing stacking faults, dislocations, and so on (8, 9). In methane, rather low concentrations of such statistically distributed defects will remove the compensation of the octopole–octopole interaction at the FR sites and modify the potential strengths at the tunneling sites. The general effects on the spectra thus should be similar to those found in the system CH_4/Kr where the anisotropic octopole–octopole interaction between methane molecules is diluted by some percentages of isotropic Kr atoms (4). Indeed, the spectra resemble each other but there are also differences. In the mixed CH_4/Kr sample the distinction between FR and tunneling states, both weighted according to the probabilities found in the undisturbed lattice, could be maintained up to rather large Kr concentrations ($C_{Kr} \approx 0.1$) while the disorder in the present cold condensed sample strongly suppresses the FR states compared to the TM. The system thus seems to be closer to a fully disordered state.

It is a question whether an orientational "glassy state" can be described by a general distribution function as in the tunneling standard model (STM) of normal glasses (21). There must be some fundamental differences, however. It is a symmetry property of rotational potentials that their minima are equivalent. This means an asymmetry parameter, called Δ is the STM, is always zero. On the other hand, the tunneling parameter λ is

related to the potential strength V since the tunneling frequency depends almost exponentially on V according to [1]. A possible function for molecular system analogous to the STM thus would read simply

[4] $p(V)\,dV = \text{constant}\,dV$

and yields a distribution of tunneling splittings

[5] $p(\omega_t)\alpha \exp(-\beta V)$

In some matrix isolation systems we have indeed found a distribution compatible with [5]. The tunneling states are observed as wings close to the elastic line. The shape of this spectrum remained unchanged if the instrumental resolution was improved (22). In the present case, however, such a distribution function is not able to describe the spectra. Instead rather broad Lorentzians in potential space with cutoffs at the free rotor energy on the one side and at the tunneling energy on the other yield the best fits.

(iii) Influence of disorder on the phase diagram

Due to the presence of disorder the phase diagram of methane is somewhat changed. While the equilibrium sample shows the phase transition to orientationally disordered CH_4 I at $T_c = 20.4$ K, we observe already the quasielastic spectra corresponding to disordered methane at $T = 15$ K. Thus the phase transition temperature T_c is lowered by more than 25% due to disorder, as in the CH_4/Kr mixtures (4). The diffraction patterns reflect the same effect for CD_4. We did not try, however, to get more accurate values of the transition temperatures.

(iv) Effects of annealing

With increasing annealing the inelastic intensity is more and more concentrated into the FR and tunneling lines, which have grown much sharper. But even after annealing at $T_a = 70$ K the spectrum reflects disorder. The inelastic lines still have asymmetric tails and the intensity of the FR transitions is still considerably below the 25% of the inelastic scattering measured for an equilibrium structure of CH_4 II. The remaining defects clearly have to overcome rather large activation barriers. This is in contrast to the assumption that the onset of diffusion fully reconstructs a matrix at annealing temperatures $T_a \simeq 0.4T_m$. With annealing, the size of the methane crystallites has considerably increased, yielding sharp Bragg peaks. All these effects prove that the disorder in our system is not due to surface effects.

(v) Spin conversion

In the unannealed and the annealed matrix the quantum rotor levels, especially the FR, are not in thermal equilibrium with the lattice. While in disordered CH_4/Kr mixtures with rather large Kr concentrations spin conversion is accelerated (23), this seems to be not the case for the matrix system. Thus, it is not the disorder but the presence of Kr atoms that must be responsible for the effect in the CH_4/Kr system. The deviation from the thermal equilibrium, however, is also different to that of quenched CH_4 II (24). In the quenched material E-state molecules do not convert, while in our matrix an increased population of T-states is found. This observation, however, needs a more detailed study.

The interpretation of the present spectra arising from a three-dimensionally-coupled, disordered quantum rotor system must remain incomplete. Theoretical models usually use a molecular field theory to describe the system in a single-particle picture and hence cannot explain the present observations. Here computer simulation seems to be possible and helpful for a deeper understanding of our data.

The single-particle picture is certainly more adapted to single molecular defects in an atomic matrix. Thus, complementary information can be obtained by investigating CH_4 matrix-isolated in rare gases. Such experiments were already performed with limited energy resolution and for equilibrium samples (5). In a cold condensed sample several transitions belonging to inequivalent sites (9, 25) and an additional broad distribution of states is found (25). This is direct evidence for the existence of the defects used to explain the present results.

IV. Conclusions

Methane condensed slowly (10 cm^3/min) onto a cold surface ($T = 5$ K) maintains a long range orientational structure as in CH_4 II but displays orientational disorder, which manifests itself in a significant broadening and weakening of the quantum transitions compared to the undisturbed material. In the disturbed structure the transition temperature into the orientationally ordered phase II is reduced by more than 25%. The disorder shows remarkable differences to that produced by diluting the orientation-dependent interaction with small percentages of rare gases. The free rotor states are strongly suppressed and represent more a broad band of states at energies below that of the free rotor, but no system with random orientations is formed. The disorder, most probably, is caused by stacking faults and defects and is considerably reduced with increasing annealing. Surprisingly even at the highest annealing temperatures $T_a/T_m \approx 0.7$ it could not be completely removed.

Rydberg states in adamantanethione, thiofenchone, and thiocamphor

K. J. FALK AND R. P. STEER[1]

Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received May 15, 1987

This paper is dedicated to Professor J. A. Morrison

K. J. FALK and R. P. STEER. Can. J. Chem. **66**, 575 (1988).

The absorption spectra of adamantanethione (**I**), thiofenchone (**II**), and thiocamphor (**III**) have been measured in the quartz ultraviolet region in both the vapor phase and in perfluoroalkane solutions. Rydberg as well as $\pi \rightarrow \pi^*$ transitions are identified in the gas phase spectra, and are discussed in terms of the known photochemistry of these compounds.

K. J. FALK et R. P. STEER. Can. J. Chem. **66**, 575 (1988).

Opérant dans la région ultaviolette du quartz, tant en phase gazeuse que dans des solutions dans des perfluoroalcanes, on a mesuré les spectres d'absorption de l'adamanthanthione (**I**), de la thiofenchone (**II**) et du thiocamphre (**III**). Dans la phase gazeuse, on a identifié la transition de Rydberg ainsi que la transition $\pi \rightarrow \pi^*$ et on en discute en fonction de la photochimie connue de ces composés.

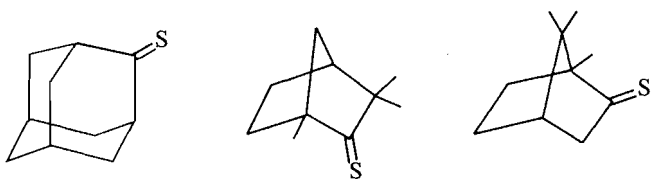
Introduction

States of $^1(\pi, \pi^*)$ character are known to be involved in the unusual ultraviolet photochemistry and photophysics of molecules containing the thiocarbonyl function (1, 2). The lowest Rydberg states of aliphatic thiones such as adamantanethione (**I**), thiofenchone (**II**), and thiocamphor (**III**) are



I **II** **III**

therefore of interest because their energies are expected to be similar to those of the $^1(\pi, \pi^*)$ valence states. Early *ab initio* SCF and CI calculations (3, 4) on smaller aliphatic thiocarbonyls placed the $n \rightarrow 4s$ Rydberg transitions at lower energies than the vertical $\pi \rightarrow \pi^*$ transitions. However, substantial bodies of photochemical, photophysical, and spectroscopic evidence have been used to unequivocally establish that the electronic origins of the $\pi \rightarrow \pi^*$ transitions are at least 20–30 kJ mol^{-1} lower than those of the lowest ($n \rightarrow 4s$) Rydbergs (1, 5–7). Subsequent large scale CI calculations (8) have resulted in a downward revision of the calculated $^1(\pi, \pi^*)$ state energy in H_2CS, consistent with this experimental evidence.

The lowest few Rydberg states of several small aliphatic thioketones, including thioacetone, have been identified experimentally (5–7) from their vapor phase absorption spectra. In each of these molecules the electronic transitions to the $^1(n, 4s)$ state ($^1B_2$ in C_{2v} local symmetry) is located between 220 and 230 nm, whereas the onset of the broad $\pi \rightarrow \pi^*$ continuum is near 260 nm. Transitions to the $(n, 4p_y)$, $^1A_1$, and $(n, 4p_z)$, $^1B_2$, states are both found on the short wavelength wing of the $\pi \rightarrow \pi^*$ absorption at $\lambda < 220$ nm. The symmetry forbidden transitions to the $^1(n, 4p_x)$, $^1A_2$, state have not been observed.

The spectrum of thioacetaldehyde (6) suggests that there may be substantial mixing of the $^1(\pi, \pi^*)$ and $^1(n, 4s)$ states (both A' in C_s symmetry) in this molecule. Calculations (8) also suggest that substantial mixing of the valence $^1(\pi, \pi^*)$ and conjugate Rydberg $^1(\pi, 3d)$ configurations may take place in thioformaldehyde. The possible involvement of Rydberg states in the ultraviolet, solution phase photochemistry of larger aliphatic thioketones such as **I**, **II**, and **III** thus has been the subject of some discussion (9, 10). However, the Rydberg states of these larger thiones have never been observed experimentally.

[1]To whom correspondence should be addressed.

Experimental

I, **II**, and **III** were prepared from the corresponding ketones by reaction with P_4S_{10} (11). The crude thiones were purified by column chromatography (silica gel – hexane), sublimed, and stored under vacuum in the dark at −20°C. Cells of 1.0 cm length fitted with suprasil windows were filled with the vapor of the thione at its room temperature vapor pressure (<0.3 Torr). Spectra were taken on a Cary 118C uv–visible spectrophotometer which had been purged with dry N_2 to permit access of $\lambda \sim 190$ nm. An evacuated cell was used as a reference. Spectra in perfluoroalkane solvents ($\lambda > 200$ nm) were also taken in 1 cm cells with the pure perfluoroalkane as a reference. All experiments were performed at 23 ± 2°C.

Results and discussion

The ultraviolet spectra of **I**, **II**, and **III** at their room temperature vapor pressures are shown in Fig. 1. The broad, structureless absorption feature in each spectrum is assignable to the $\tilde{B} \leftarrow \tilde{X}$, $\pi \rightarrow \pi^*$ transition centered on the thiocarbonyl chromophore (1). The gas phase spectra exhibit three additional transitions in the 190–230 nm region. By analogy with thioacetone and other thioketones (5–7), these should be assignable (using notation appropriate for C_{2v} local symmetry) to the $\tilde{C}(^1B_2) \leftarrow \tilde{X}(^1A_1)$, $(^1A_1) \leftarrow \tilde{X}(^1A_1)$, and $(^1B_2) \leftarrow \tilde{X}(^1A_1)$ Rydberg $n \rightarrow 4s$, $n \rightarrow 4p_y$, and $n \rightarrow 4p_z$ transitions, respectively.

The lowest energy Rydberg band system, located at 220–230 nm on the high energy side of the broad $\tilde{B} \leftarrow \tilde{X}$ absorption, is readily assignable to the $n \rightarrow 4s$, $\tilde{C}(^1B_2) \leftarrow \tilde{X}(^1A_1)$ transition in all three molecules. The assignment of the remaining two Rydberg transitions in the 200–210 nm region is less clear. Calculations predict the $^1A_2$ $(n, 4p_x)$, $^1A_1$ $(n, 4p_y)$, and $^1B_2$ $(n, 4p_z)$ states should have almost identical energies in small thiocarbonyls such as thioformaldehyde (8) and thioacetone (3, 4). We rule out an $^1A_2 \leftarrow \tilde{X}(^1A_1)$ assignment for either band system on the grounds that such a transition will be electric dipole forbidden in C_{2v} (local) symmetry.

Whereas the $\tilde{C} \leftarrow \tilde{X}$ transitions are strong in all three molecules, thiofenchone and adamantanethione both have strong $\tilde{D} \leftarrow \tilde{X}$ transitions near 206–209 nm and weaker $\tilde{E} \leftarrow \tilde{X}$ transitions

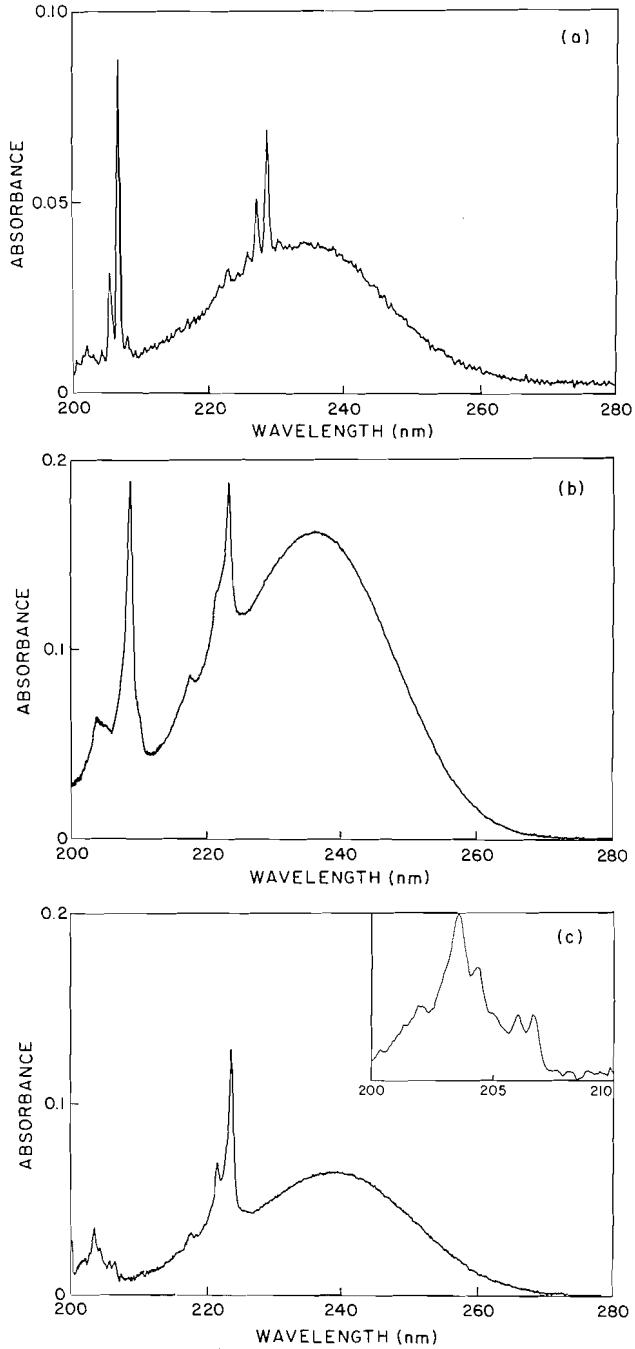

FIG. 1. Ultraviolet absorption spectra of (*a*) adamantanethione, (*b*) thiofenchone, and (*c*) thiocamphor in the gas phase at their room temperature vapor pressures.

near 201–204 nm. In contrast, thiocamphor (see insert, Fig. 1*c*) exhibits a weak $\tilde{D} \leftarrow \tilde{X}$ Rydberg transition at ca. 207 nm and a somewhat stronger $\tilde{E} \leftarrow \tilde{X}$ transition at ca. 204 nm. Their intensity differences notwithstanding, the fact that these two Rydberg transitions occur at almost identical energies in all three molecules (cf. Table 1) leads us to propose that those transitions at similar energies are between states of the same symmetry. Based upon the *ab initio* SCF-CI calculations of Bruna *et al.* (3, 4) on thioacetone, and the absence of contrary evidence, we assign the transitions at ca. 206–209 nm as $\tilde{D}(^1A_1) \leftarrow \tilde{X}(^1A_1)$ and those at ca. 201–204 nm as $\tilde{E}(^1B_2) \leftarrow \tilde{X}(^1A_1)$. The assignments are summarized in Table 1.

The Rydberg transitions of **I** have the most distinct vibrational structure and exhibit Franck–Condon envelopes expected of a rigid molecule. Unlike thioacetaldehyde (6) of C_s symmetry and to a lesser extent 3,3-dimethylbutane-2-thione and 3-methylbutane-2-thione (5), there is little ultraviolet spectral evidence of Rydberg-valence configuration mixing in adamantanethione. The only apparent vibrational progression is one of three members in each of the $\tilde{C} \leftarrow \tilde{X}$ and $\tilde{D} \leftarrow \tilde{X}$ systems. The separation between adjacent bands is 280–300 cm^{-1}, and this is similar to the spacing of the most prominent progression in the corresponding Rydberg transitions in thioacetone (7). In the latter molecule this vibration is attributed to the C—C—C bending mode of a_1 symmetry. No band attributable to the C—S stretching mode is strong enough to be assigned.

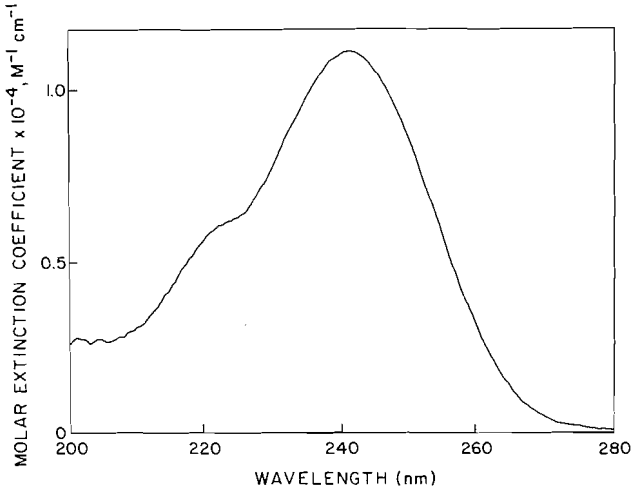

FIG. 2. Ultraviolet absorption spectrum of thiocamphor in perfluorodimethylcyclohexane at a concentration of 2.2×10^{-5} *M*.

The vibrational structure in the Rydberg transitions of thiofenchone and thiocamphor is less well resolved. While this may reflect the greater structual rigidity of tricyclic **I** compared with bicyclic **II** and **III**, the fact that **II** and **III** (but not **I**) are known (9, 10) to exhibit net intramolecular photochemistry when excited to their $\tilde{B}(^1A_1)$ states is an indication of the presence of unbound (with respect to H migration) portions of the potential hypersurface which are accessible at energies lower than those of the lowest Rydberg states. Broadening of the vibrational bands due to shortening of the Rydberg state lifetimes of **II** and **III** is thus possible.

The sharp features ascribed to the Rydberg transitions are missing from the spectra taken in perfluoroalkane solutions. Perfluoroalkanes are very weakly interacting solvents and have been shown (12) to significantly perturb neither the radiative nor the non-radiative electronic transitions of aromatic thiones in their ($^1(\pi, \pi^*)$ states. Sulfur Rydberg orbitals are spatially much larger, however, and, given the exposed location of the S atoms in these molecules, are very susceptible to repulsive solvent perturbation. Thus, as expected on the basis of many other high pressure gas phase and solution studies (13), the Rydberg transitions are obscured even in the perfluoroalkanes. Nevertheless, the solution spectrum of **III** (Fig. 2) exhibits a broad feature consisting of a distortion of the Franck–Condon envelope on the short wavelength side of the strong $\pi \rightarrow \pi^*$ transition. This can be ascribed to the residuum of the $n \rightarrow 4s$ Rydberg transition in solution. Similar, but less distinct features may be seen on close examination of the spectra of **I** and **II** in perfluoroalkane solutions.

Many studies of molecular Rydberg spectra as a function of the pressure of a chemically inert gas reveal that perturbations cause Rydberg bands to broaden asymmetrically to *higher* ener-

gies (13). Thus, in solution, excitation of the three thiones studied to the red of the maxima of their broad uv absorption systems will not involve overlapping Rydberg absorptions. It would therefore appear that de Mayo and coworkers (9, 10) are correct in their conclusion that Rydberg states having symmetries different from that of the $^1(\pi, \pi^*)$ state are not directly involved in the ultraviolet photochemistry of the bicyclic thiones. The existence of partial Rydberg character in the $^1(\pi, \pi^*)$ states is nevertheless still possible through the mixing of Rydberg-valence conjugates, as discussed by Burton *et al.* (8), and Robin (14). Moreover, the lowest Rydberg triplet state, $^3B_2$ of $^3(n, 4s)$ character, might still play a role in the decay dynamics of **I**, **II**, or **III** initially excited to the $^1(\pi, \pi^*)$ state.

Relative rate constants for abstraction of hydrogen by methyl radicals from ethane and from ethylene

S. I. AHONKHAI[1] AND M. H. BACK

Ottawa-Carleton Institute for Graduate Studies and Research, University of Ottawa Campus, Ottawa, Ont., Canada K1N 6N5

Received June 26, 1987

This paper is dedicated to Professsor J. A. Morrison

S. I. AHONKHAI and M. H. BACK. Can. J. Chem. **66**, 578 (1988).

A method is described for the measurement of relative rate constants for abstraction of hydrogen by methyl radicals from ethane and from ethylene based on the effect of the addition of small quantities of ethane on the rates of formation of products in the thermal reactions of ethylene. The ratio of rate constants for reactions

[3] $CH_3 + C_2H_4 \rightarrow CH_4 + C_2H_3$

[4] $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$

over the temperature range 673–733 K was given by the following expression:

$$\log k_4/k_3 = 0.0 \pm 0.1 + \frac{3500 \pm 500}{2.3RT}$$

($R = 1.987$ cal mol^{-1} deg^{-1}). Using a value of k_4 from the literature the following expression was obtained for k_3, over the same range of temperature:

$$\log k_3 \,(\text{L mol}^{-1}\,\text{s}^{-1}) = 8.8 \pm 0.1 - \frac{15500 \pm 500}{2.3RT}$$

It was concluded that a previous measurement of k_3 in a lower range of temperature was too close to the value of k_4.

S. I. AHONKHAI et M. H. BACK. Can. J. Chem. **66**, 578 (1988).

On décrit une méthode permettant de mesurer les constantes relatives de vitesse pour les réactions d'enlèvement d'hydrogène, par des radicaux méthyles, de l'éthane et de l'éthylène; la méthode est basée sur l'effet de l'addition de faibles quantités d'éthane sur les vitesses de formation des produits dans les réactions thermiques de l'éthylène. Le rapport des constantes de vitesse pour les réactions

[3] $CH_3 + C_2H_4 \rightarrow CH_4 + C_2H_3$

[4] $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$

à des températures allant de 673 à 733 K, peut être exprimée par l'équation suivante:

$$\log k_4/k_3 = 0{,}0 \pm 0{,}1 + \frac{3500 \pm 500}{2.3RT}$$

($R = 1{,}987$ cal mol^{-1} deg^{-1}). En se basant sur une valeur de k_4 tirée de la littérature, on a pu obtenir l'expression suivante pour k_3, aux températures considérées:

$$\log k_3 \,(\text{L mol}^{-1}\,\text{s}^{-1}) = 8{,}8 \pm 0{,}1 - \frac{15500 \pm 500}{2{,}3RT}$$

On en conclut qu'une mesure antérieure de k_3 dans la zone inférieure des températures était trop proche de la valeur de k_4.

[Traduit par la revue]

Introduction

The rates of abstraction or transfer reactions of methyl radicals with various types of hydrocarbons have been throughly studied during the past three decades and the general features of these reactions are well understood (1–3). Although rate constants for the transfer reaction with several olefins have been reported, values of the rate constant for abstraction from ethylene are conspicuously absent. Only two measurements have been reported, one relative to abstraction from acetone (4) and the other relative to acetaldehyde (5). No measurements have been reported above 833 K. Nevertheless this reaction is important in many thermal reactions of hydrocarbons over a wide range of temperatures and a reliable value for the rate constant is crucial in the evaluation of mechanisms through modelling studies. The reaction is also important through its relation to the fundamental properties of the vinyl radical.

Recently a method was developed for measuring the rate of initiation of thermal chain reactions of ethylene in the neighbourhood of 750 K (6, 7). The method was based on the analysis of the effect of small quantities of certain additives on the rate of reaction. The measurement of the ratio of rates of formation of products in the presence and absence of the additive was shown to be directly related to the rates of initiation of the chain reactions in the presence and absence of the additive. The system was a special case of the general effect of additives on the kinetics of the thermal reactions of hydrocarbons analyzed extensively by Professor M. Niclause and his colleagues at the Université de Nancy, France (8–10). Studies of these systems have provided a wealth of information on the mechanism of these reactions and on the values of rate constants for the elementary reactions occurring in these systems.

The effect of small quantities of additives on the rate of a thermal chain reaction usually occurs by two main mechanisms. The additive may enter into chain propagation reactions, particularly if it has a labile hydrogen atom, and as a result the overall rate of the reactions may be either accelerated or inhibited. The additive itself may also undergo dissociation and thus increase the total rate of initiation. This effect increases the overall rate of the reactions. In the analysis of the effects of the additive the basic assumption is made that neither the addition of a new initiation step nor the contribution to the propagation reactions alter significantly the general features of the chain reaction. The dominant chain-carrying radicals and termination steps remain the same. Under these conditions if the additive increases the rate of initiation of radicals the rate of product formation increases but the relative amounts of each product remain unchanged. On the other hand, if the additive enters into the propagation steps and alters the relative rates of these steps, the product distribution may change.

In the studies of the ethylene system (7) both effects of additives were observed but most of the measurements were made where the only effect of the additive was the addition of a new initiation process. Consider as an example the effects of small quantities of ethane on the kinetics of chain reactions of ethylene, the system which will be discussed further in this study. Because ethylene is very reactive toward chain propagation through addition of radicals, small quantities of ethane, whose reactivity toward radical attack is smaller, do not disturb the chain propagation reactions. On the other hand, ethane undergoes bond dissociation more readily than ethylene and small amounts provide a significant increase to the initiation of radicals. In previous studies additions of less than about 2% ethane increased the rate of formation of the main products, methane, propylene, and butene-1 equally, indicating an increased rate of initiation, in other words, an increased concentration of radicals, rather than an alteration to the rates of the various propagation reactions.

In the absence of ethane the main initiation process is the bimolecular formation of radicals,

[1] $2C_2H_4 \rightarrow C_2H_5 + C_2H_3$

while in the presence of ethane the additional process

[E] $C_2H_6 \rightarrow 2CH_3$

occurs. When this is the only effect of ethane the ratio of rates of product formation may be expressed as (7),

$$[2] \quad \frac{(V^0)_a}{V^0} = \left[1 + \frac{k_E[C_2H_6]}{k_1[C_2H_4]^2}\right]^{1/2}$$

where $(V^0)_a$ and V^0 refer to the initial rate of product formation with and without an additive, respectively. This ratio is also an expression of the relative concentration of radicals with and without an additive. Note that although reaction [E] produces methyl radicals the identity of the radical is not important. The methyl radicals rapidly convert to the mix of radicals present in ethylene reacting by itself, since the propagation reactions are not disturbed by the addition of ethane.

With concentrations of ethane greater than about 5% the product distribution changed and the ratio of rates of formation of methane in the presence and absence of ethane was considerably larger than similar ratios for propylene and butene-1. Since methane is formed by abstraction of hydrogen by methyl radicals, while propylene and butene-1 are formed by decomposition of larger radicals, this effect was interpreted to indicate that in addition to the effect on the total initiation, ethane entered into propagation reactions by providing a more easily abstractable hydrogen atom. Ethane did not affect the rate of formation of unsaturated products formed by a sequence of addition and decomposition reactions which did not involve abstraction. The rate of formation of these products increased only when the rate of initiation was significantly increased.

In the presence of ethane, methane was therefore formed by both of the following reactions,

[3] $CH_3 + C_2H_4 \rightarrow CH_4 + C_2H_3$

[4] $CH_3 + C_2H_6 \rightarrow CH_4 + C_2H_5$

The ratio of the initial rate of formation of methane in the presence and absence of ethane, taking into account the change in concentration of radicals given by eq. [2], may be expressed as follows,

$$[5] \quad \frac{(V^0_{CH_4})_a}{V^0_{CH_4}} = \left[1 + \frac{k_E[C_2H_6]}{k_1[C_2H_4]^2}\right]^{1/2}\left[1 + \frac{k_4[C_2H_6]}{k_3[C_2H_4]}\right]$$

Thus to measure k_4/k_3 it is necessary to measure only methane, the product formed by abstraction, and other reactions of the methyl radical need not be considered.

When the additive affects both initiation and propagation, extraction of the ratios of rate constants is subject to some uncertainty, although some systems have been successfully analyzed (11). To exploit the system to obtain ratios of rate constants for abstraction reactions, reaction conditions were sought where the saturated hydrocarbon additive affected only the rates of propagation reactions. These conditions were low temperatures, where the rate of dissociation of the additive becomes negligible compared to the rate of initiation by ethylene itself, and higher concentration of additive where the saturated hydrocarbon may compete with ethylene for abstraction of hydrogen. The present paper describes the results of the addition of ethane to ethylene over the temperature range 673–777 K and illustrates the alteration in the effect of the additive from only new initiation, as observed previously over a higher temperature range, to only new propagation reactions.

Experimental

The experiments were performed in a conventional static pyrolysis system, similar to that described previously (6) but with some modifications. The quartz reaction vessel, with a volume of 210 cm^3 and S/V ratio of 1 cm^{-1}, was housed in a stainless steel cylinder inside a Lindberg cylindrical furnace with three separately-controlled heating zones. The temperature gradient along the length of the vessel was less than one degree and temperatures were reproducible to $\pm 1°$ in a set of experiments. Mixtures of gases were prepared in flasks designed with minimum connecting tubing by admitting first a low pressure of ethane followed by a higher pressure of ethylene. Reactants were thoroughly de-gassed in small quantities before mixing and mixtures were not condensed after preparation. The concentration of ethane in the mixture was analyzed in each experiment.

Products were analyzed by gas chromatography (Hewlett Packard Model 5790). A phenylisocyanate column (3.4 m × 4 mm) gave separation of the four main products, methane, ethane, propylene, and butene-1 from the reactant ethylene, although small yields of propylene and butene-1 were sometimes lost in the tail of the ethylene peak. Analysis centered on these products because they served to describe the effect of an additive on the reaction rate. Ethylene and ethane were research purity gases from Matheson, Whitby, Ont., Canada L1N 5R9. The main impurity in ethylene was ethane. Since ethane was the additive, purification was not pursued. Further purification of ethane also was not required because only small quantities were used.

The success of the method depends on the accuracy of measurement of the ratio of rates with and without an additive. In previous studies (6, 7) several experiments were performed in pure ethylene for measuring the rates of formation of products, followed by a similar series on the mixtures. The ratios were then obtained from these two averaged rates. In the present study one experiment using pure ethylene was followed immediately by an experiment using a mixture under identical conditions. In this way the measurement of the ratio of rates was emphasized rather than the measurement of separate rates of formation in pure ethylene and in mixtures. The ratios of rates were measured under a variety of conditions of reaction time, composition of the mixtures, and total pressure.

In previous studies (6, 7) measurements in packed vessels with a large increase in S/V ratio had shown that surface reactions are not important in the thermal reactions of ethylene at these temperatures, and such measurements were not repeated in this study.

Results and discussion

The ratios of rates of formation of the main products, methane, propylene, and butene-1 in the presence and absence of ethane were measured over the temperature range 673–764 K at total pressures between 186 and 365 Torr and with ratios of ethane/ethylene between 0.013 and 0.106. The results are summarized in Table 1. In contrast to the results of the previous study, which were well described by eq. [2], the ratios of the rates of formation of methane in the presence and absence of ethane were a linear function of the ratio of ethane/ethylene. For experiments in the lower temperature range the rate of initiation by ethane is negligible compared to the rate of initiation in pure ethylene and the term in the first square brackets in eq. [5] is not significantly greater than one. Two examples are shown in Fig. 1.

The rates of formation of propylene and butene-1 were essentially unchanged by the addition of ethane at temperatures up to 705 K. With further increase in temperature the rates of formation of these products showed a small increase on addition of ethane, the ratio approaching a value of about 1.3 for both products at the highest temperature of 764 K. As discussed in the Introduction this increase in the rates of formation of these products indicates that addition of ethane has increased the total rate of initiation. This effect causes a corresponding increase in the rate of formation of methane. Above 705 K addition of ethane therefore affects the rate of formation of methane in two ways, abstraction from ethane and an increased rate of initiation.

To obtain the increase in rate due only to abstraction, the ratio of rates must be corrected for the effect of the new initiation. From eq. [5] the correction factor is

$$\left[1 + \frac{k_E[C_2H_6]}{k_1[C_2H_4]^2}\right]^{1/2}$$

This factor may be calculated using the value for k_1 measured in the previous study (7) and a value for k_E from the literature (12).

$$k_1 = 11.27 - \frac{64200}{2.3RT} \text{ (L mol}^{-1}\text{ s}^{-1}\text{)}$$

$$k_E = 16.72 - \frac{88850}{2.3RT} \text{ (s}^{-1}\text{)}$$

The factor is also equal to the ratio of rates of formation of propylene or butene-1, on the assumption that these products are not formed by abstraction reactions. Values of k_4/k_3, obtained from the slopes of plots shown in Fig. 1, were corrected using both calculated and experimental factors. The results are given in Table 2. The estimated errors span the values obtained using two methods of correction. The experimental correction is approximate because in many of the experiments the yields of propylene and butene-1 were too small for accurate measurement, appearing as they did on the tail of the large ethylene peak. The average values of k_4/k_3 are shown in an Arrhenius plot in Fig. 2.

*Previous measurement, ref. 7.

Also included in Table 2 and Fig. 2 is the result of a measurement made in the previous study (7) where the ratio of ethane/ethylene was 0.0828 and the ratio of the rate of formation of methane in the presence and absence of ethane was 2.53 compared to 1.6 for the similar ratio for the products propylene and butene-1. In this case the experimental and calculated correction for initiation is the same, since the value of k_1 was obtained from these measurements.

Before analyzing the values of k_4/k_3 in terms of an Arrhenius expression, the applicability of this expression for this ratio in this temperature range should be examined. Reaction [4] has been measured over a wide range of temperature and the results

have been summarized and evaluated by Kerr and Moss (2). They recommend the following expression for k_4,

$$[6] \quad \log k_4\,(\text{L mol}^{-1}\,\text{s}^{-1}) = 8.75 - \frac{11600}{2.3RT}$$

and suggest this may be valid up to 800 K. The non-Arrhenius dependence of the rate constant has been illustrated and analyzed (13–15). Clark and Dove (13) derived an expression for k_4 to describe a continuous curve on an Arrhenius plot and linked values measured in the high and low temperature ranges. Their values are greater than those obtained from eq. [6] by a factor of

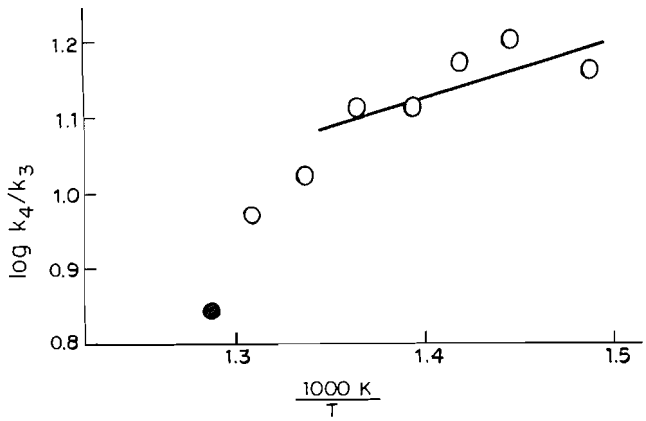

FIG. 2. Average values of k_4/k_3 as a function of $1/T$. ●: ref. 7.

about 2.5 in this temperature range. Furue and Pacey (15) clarified the effects leading to non-Arrhenius behaviour and modified the expression suggested by Clark and Dove. The values obtained from their expression are indistinguishable from those of eq. [6] up to about 730 K. The temperature range of the present experiments is therefore placed just at the beginning of the region where non-Arrhenius effects should become important.

This may be illustrated by an Arrhenius plot of the values for k_3 (Fig. 3) obtained by combining the present measurement of the ratio k_4/k_3 with values of k_4 obtained from the expression proposed by Furue and Pacey and the evaluated Arrhenius expression of Kerr and Moss. It seems clear that non-Arrhenius effects are significant at the three highest temperatures and that Arrhenius parameters should therefore be obtained using only results of the five lowest temperatures. This leads to an average value for k_3 in this region given by

$$[7] \quad \log k_3\,(\text{L mol}^{-1}\,\text{s}^{-1}) = 8.8 \pm 0.1 - \frac{15500 \pm 500}{2.3RT}$$

Similarly, from Fig. 2, the Arrhenius expression for the ratio, k_4/k_3 derived from the five lowest temperatures only, is given as follows:

$$[8] \quad \log k_4/k_3 = 0.0 \pm 0.1 + \frac{3500 \pm 500}{2.3RT}$$

This result suggests that the frequency factors for abstraction from ethane and ethylene are virtually the same, at least in the

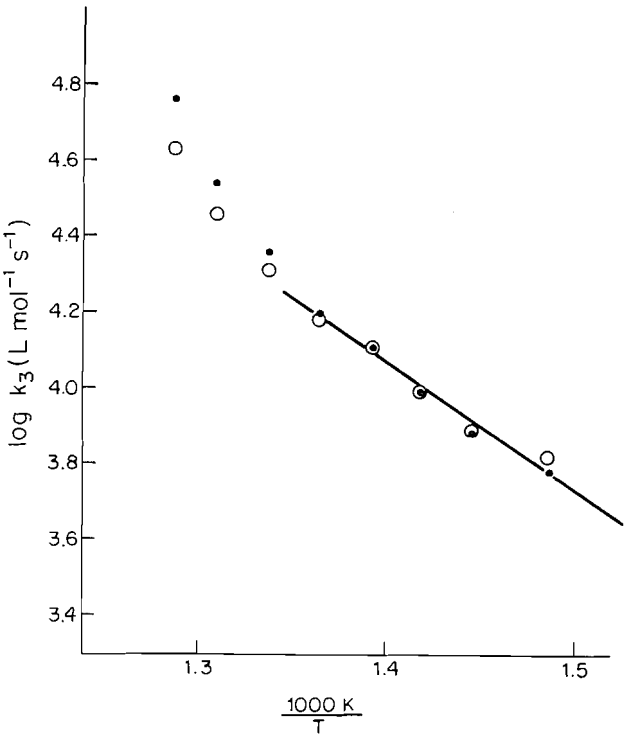

FIG. 3. Arrhenius plot of k_3 obtained using values of k_4 from ●, Furue and Pacey (15) and ○, Kerr and Moss (2).

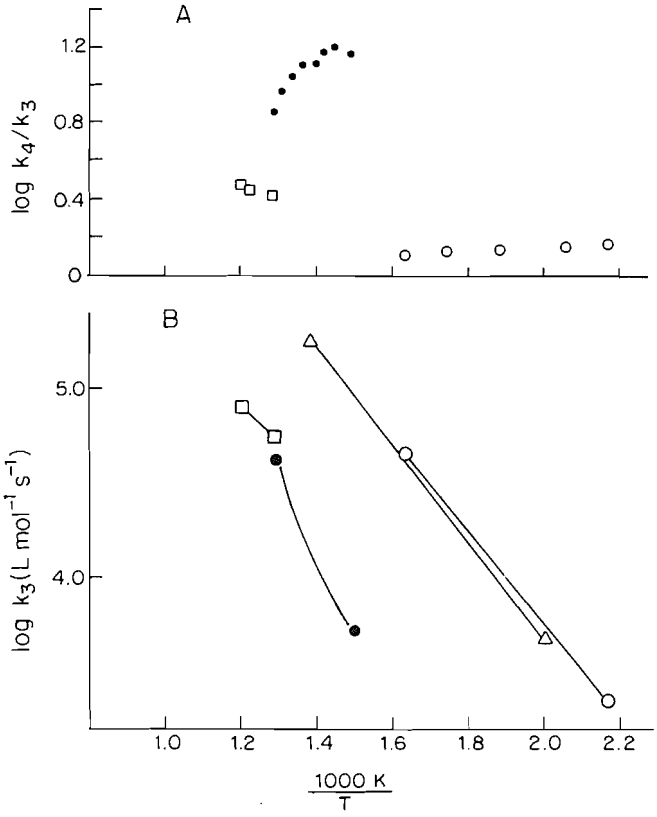

FIG. 4. Comparison of k_3 and the ratio k_4/k_3 with previous measurements, as an Arrhenius plot. ●, Present measurements; ○, Trotman-Dickenson and Steacie (4); □, Rice and Varnerin (5); △, k_4 from Kerr and Moss (2).

region where the rate constant follows an Arrhenius dependence. Most measurements of rates of abstraction from alkanes and from alkenes give frequency factors of approximately the same value. To estimate the difference in activation energies, it seems justified if we neglect the results at the three highest temperatures. It should be noted that the non-Arrhenius behaviour of the ratio at the higher temperatures implies that the curvature in k_3 with increasing temperature is more pronounced than in k_4.

The value for k_3 obtained in the present measurements may be compared with the two previous measurements, both made in rather different systems. The system studied by Trotman-Dickenson and Steacie (4) involved the photolysis of deuterated acetone in the presence of ethylene and the measurements gave the ratios of rate constants for abstraction from ethylene and from acetone.

[9] $CD_3 + C_2H_4 \rightarrow CD_3H + C_2H_3$

[10] $CD_3 + CD_3COCD_3 \rightarrow CD_4 + CD_2COCD_3$

Values of k_9 were obtained using the well-documented values for k_{10} (2). Rice and Varnerin (5) studied the pyrolysis of deuterated acetaldehyde in the presence of ethylene and their measurements gave the ratio of rate constants for abstraction from ethylene and from acetaldehyde.

[9] $CD_3 + C_2H_4 \rightarrow CD_3H + C_2H_3$

[11] $CD_3 + CD_3CDO \rightarrow CD_4 + CD_3CO$

Similarly, values of k_9 were obtained using measured values for k_{11} (2). For the purpose of this comparison k_9 is assumed to be indistinguishable from k_3, since the difference is the result of a secondary isotope effect and well inside the other errors in these measurements.

These values of k_3 are shown in Fig. 4*B*, together with the values for k_4 recommended by Kerr and Moss. In spite of the much lower activation energy for k_3 obtained by Rice and Varnerin the extrapolation of the present measurements of k_3 correlates well with their rate constants. On the other hand, measurements by Trotman-Dickenson and Steacie are more than ten times greater than the present results, and are in fact practically the same as the recommended value for k_4.

These differences are not due to discrepancies in the reference reactions, because the same differences are apparent in the ratio k_4/k_3, Fig. 4*A*, derived from the results reported for both ethane and ethylene in each system. The present results show that abstraction from ethane is considerably faster than from ethylene but the results of Trotman-Dickenson and Steacie indicated that these rates of abstraction were similar, which seems unlikely. Although it is difficult to identify a reason for the apparently fast rate of abstraction from ethylene observed in the experiments of Trotman-Dickenson and Steacie, it seems likely that a small impurity with a labile hydrogen atom could lead to an erroneously fast production of CD_3H.

The present results indicate that the activation energy for abstraction from ethylene is higher than that for abstraction from ethane, in accord with the greater C—H bond dissociation energy in ethylene as compared to ethane. The relation between activation energy and bond dissociation energy for a series of similar reactions has been discussed many times, particularly for hydrogen atom abstraction reactions. Recently a simple correlation has been described for such reactions involving small radicals (16). For the case of methyl radicals, the following relation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

was suggested,

$$E = 0.609D_1 - 0.473D_2$$

for a reaction of the type

$$CH_3 + AH \rightarrow CH_4 + A$$

where E is the activation energy for the reaction and D_1 and D_2 are the C—H bond dissociation energies for AH and CH_4, respectively. For reaction [4], taking $D_1 = 100$ kcal mol^{-1} and $D_2 = 104$ kcal mol^{-1},

$$E = 11.7 \text{ kcal mol}^{-1}$$

in good agreement with the value recommended by Kerr and Moss. For reaction [3], setting $E = 15.5$ kcal mol^{-1} leads to a value of 106 kcal mol^{-1} for D_1. The uncertainty is at least ± 1 kcal mol^{-1}.

It should be pointed out that this value for the dissociation energy in ethylene indicates an activation energy for reaction [1] of 67 kcal mol^{-1} rather than the value of 64.2 kcal mol^{-1} used in the calculation of the correction factor. Since the calculated and experimental correction factors were similar within each uncertainty it seems likely that the value used for k_1 was reasonable. If E_1 is larger the frequency factor may also be larger, leading to a similar value for k_1. The Arrhenius parameters for reaction [1] are not yet firmly established.

Summary

The present results have shown that the rate constant for abstraction of hydrogen by methyl radicals from ethane is between ten and twenty times faster than that for abstraction from ethylene in the temperature range 673–777 K. The difference in activation energy between the two reactions in the low temperature region is 3.5 kcal mol^{-1}. It is concluded that a previous measurement of the rate constant for abstraction from ethylene in the temperature range 461–613 K is too large.

Molecular orbital calculations and ^1H nuclear magnetic resonance spectra as indicators of internal rotational potentials in some methyl derivatives of styrene

TED SCHAEFER, RUDY SEBASTIAN, AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 4, 1987

This paper is dedicated to Professor J. A. Morrison

TED SCHAEFER, RUDY SEBASTIAN, and GLENN H. PENNER. Can. J. Chem. **66**, 584 (1988).

The ^1H nuclear magnetic resonance spectra of the α-methyl, *cis* and *trans*-β-methyl, 4-methyl, and β,β-dimethyl styrenes are analyzed to yield long-range proton–proton coupling constants. With the assumptin that the internal rotational potential for styrene in the gas phase is unaltered in solution, a consistent treatment of over 40 of the long-range coupling constants is given in terms of the known coupling mechanisms. Expectation values of $\sin^2\theta$, where θ is the angle of twist about the exocyclic carbon–carbon bond, are presented for these molecules. These are compared with theoretical potentials at the 6-31G level of molecular orbital theory. The present data indicate rather larger average twist angles than those in the literature. The extrema (at θ = 0° and 90°) in the angle dependent long-range coupling constants appear to be rather smaller in magnitude than are theoretical values obtained from valence bond and molecular orbital approaches.

TED SCHAEFER, RUDY SEBASTIAN et GLENN H. PENNER. Can. J. Chem. **66**, 584 (1988).

On a analysé les spectres en résonance magnétique nucléaire du ^1H des α-méthyl, β-méthyl-*cis* et -*trans*, méthyl-4et β,β-diméthyl styrènes afin d'en tirer les constantes de couplage proton–proton à longue distance. En faisant l'hypothèse que le potential à la barrière interne du styrène est le même en phase gazeuse qu'en solution, on peut traiter d'une façon consistante plus de 40 constantes de couplage à longue distance en fonction des mécanismes connus de couplages. Pour ces molécules, on présente les valeurs attendues pour $\sin^2\theta$, dans lesquelles θ est l'angle torsion autour de la liaison carbone–carbone exocyclique. On les compare aux potentiels calculés par la théorie des orbitales moléculaires au niveau 6-31G. Les données obtenues dans notre travail suggèrent que les angles moyens de torsion sont plus grands que ceux rapportés dans la littérature. Les amplitudes des valeurs extrêmes (à des valeurs de θ de 0° et de 90°) dans les constantes de couplage à longue distance qui dépendent de l'angle semblent être plus faibles que celles que nous laissent prévoir les approches des liaisons de valence et des orbitales.

[Traduit par la revue]

Introduction

The torsional potential (1) about the C(1)—C(α) bond in styrene in the gas phase can be written (2) as eq. [1], where θ is zero

$$[1]\quad V/\text{kJ mol}^{-1} = V_2 \sin^2\theta + V_4 \sin^2 2\theta$$
$$= (12.80 \pm 0.10)\sin^2\theta - (3.29 \pm 0.01)\sin^2 2\theta$$

in the planar form and a sixfold component, V_6, of 0.08 kJ/mol is ignored. Computations, with full geometry optimization, at the 6-31G level of *ab initio* molecular orbital theory give V_2 as 13.19 ± 0.15 kJ/mol and V_4 as −3.18 ± 0.15 kJ/mol (3). Even the 4-31G calculations (2) do not deviate dramatically from eq. [1].

It is not known whether eq. [1] governs the internal motion in solution, although solvent effects might well be small for a hydrocarbon of low polarity. Even for a polar compound like benzyl fluoride the internal rotational potential changes by only 2 kJ/mol as the solvent changes from CS_2 to a polar solvent like acetone (4). In ethyl benzene the internal rotational potential appears to be independent of solvent (5).

Substitution by methyl groups to yield α-methyl- or *cis*-β-methylstyrenes can alter the internal potential drastically. These potentials have not been determined but various angles θ have been deduced by a number of techniques (6–10). A recent variation (6) on the usual (7) interpretation of the photoelectron spectra of these molecules yields some θ values and it is stated (6) that, unfortunately, no accurate data are available on their conformations, knowledge of which is useful for the interpretation of their photochemistry.

It appears that the θ values in the literature, really arc cos $\langle\cos^2\theta\rangle^{1/2}$, are based on an assumed zero for styrene itself, implying that revision is in order.

The success of the molecular orbital calculations on styrene suggests their application to the α- and β-methylstyrenes and such computations are reported here.

In addition, the analyses of the ^1H nmr spectra of the α, *cis*-β, *trans*-β, and 4-methylstyrenes, as well as a partial analysis of the ^1H nmr spectrum of β,β-dimethylstyrene, are performed. A pioneering study of the long-range spin–spin coupling constants between ring and side-chain protons in halostyrene derivatives demonstrates their potential as conformational indicators (11). This study also presents valence bond and molecular orbital formulation of the coupling mechanisms and provides a base for the work described in the present paper.

It turns out that a reasonably consistent treatment of the long-range coupling constants in the methylstyrenes is possible, leading to estimates of $\langle\sin^2\theta\rangle$ somewhat larger than those commonly accepted.

Results and discussion

Molecular orbital calculations

The 6-31G MO computations allowed geometry optimization with the constraint, however, that the benzene carbon framework remain a planar hexagon. Even so, only three values of θ, at 0°, 45°, and 90°, could reasonably be accommodated (the total cpu time was 36.5 h for *trans*-β-methylstyrene on an Amdahl 470). These three values allow a fit to a potential consisting of twofold and fourfold components.

For *trans*-β-methylstyrene, V_2 and V_4 (see eq. [1]) are computed as 11.2 and -3.5_4 kJ/mol, respectively (the total energy at θ = 0° is −346.501 643 au). At 300 K, one has a $\langle\sin^2\theta\rangle$ of 0.203_4.

For *cis*-β-methylstyrene, in which substantial repulsive interactions between the methyl group and the *ortho* ring C—H bond are anticipated, V_2 is calculated as 1.9_7 and V_4 as -7.3_2 kJ/mol, implying $\langle\sin^2\theta\rangle$ as 0.459 at 300 K. The latest value in the literature is 22 ± 6° for θ, but is based on a θ of zero for

For personal use only.

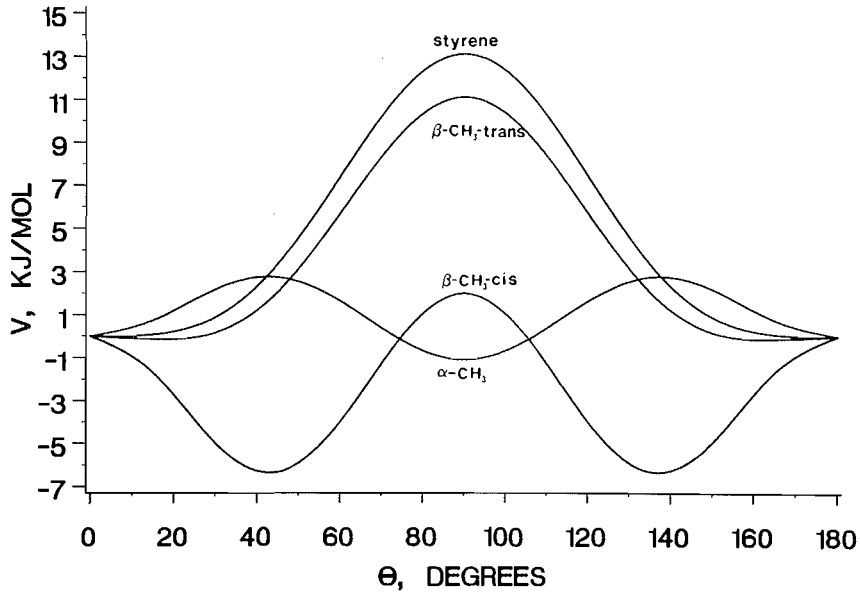

FIG. 1. The 6-31G MO internal rotational potentials about the C(1)—C(α) bond are plotted as a function of the angle θ. The latter is zero for the planar conformation. The potentials contain twofold and fourfold components. That for styrene comes from ref. 3 and has V_2 as 13.19 ± 0.15 kJ/mol and V_4 as −3.18 ± 0.15 kJ/mol. For *trans*-β-methylstyrene, *cis*-β-methylstyrene, and α-methylstyrene, respectively, $V_2(V_4)$ are 11.2 (−3.5), 2.0(−7.3), and −1.1(3.3) kJ/mol. All bond angles and lengths were allowed to vary for these three molecules, but the carbon framework of the phenyl group was constrained to be a regular hexagon and the methyl groups retained threefold symmetry.

styrene (6). At θ = 0°, the total 6-31G energy is −346.495 383 au. The STO 3G MO computations, with geometry optimization at seven values of θ, gave V_2 and V_4 as −1.6 ± 0.2 and −6.1 ± 0.2 kJ/mol, respectively. Hence, at 300 K, $\langle \sin^2 \theta \rangle$ is 0.535. The two calculations agree that V_2 drops markedly from its value of 12.8 kJ/mol in styrene.

For α-methylstyrene, V_2 and V_4 become -1.0_7 and 3.2_7 kJ/mol, respectively, at the 6-31G level of MO theory (the total energy is −346.496 346 au). At 300 K, $\langle \sin^2 \theta \rangle$ is 0.570. V_2 and V_4 have interchanged their signs and the conformation at θ = 90° is now 1.1 kJ more stable than the planar form at θ = 0°.

In Fig. 1 the 6-31G MO potentials are plotted for styrene and the three methylstyrenes. For styrene and its *trans*-β-methyl derivative, these potentials lead to $\langle \sin^2 \theta \rangle$ estimates at 300 K effectively the same as that measured for styrene. For the *cis*-β-methyl derivative, it is anticipated that a strongly nonplanar conformation is caused by large repulsive forces between the methyl group and the *ortho* C—H bond, just as the nonplanarity of styrene itself is plausibly attributable (1) to Pauli overlap of the β and *ortho* C—H bonds. The minimum in the potential curve in Fig. 1 is consistent with this attribution. However, the relatively low energy computed for the perpendicular conformation in this molecule is striking and, at first sight, implies an attractive interaction, perhaps between the methyl group and the aromatic π system, at this θ value. The perpendicular conformation of α-methylstyrene is also unexpectedly stable when viewed from the vantage of conjugative delocalization between the two π electron systems. The following discussion may be of use.

The computed structure of planar α-methylstyrene is shown in Fig. 2. In planar styrene the C(1)C(α)C(β) angle is computed as 127.6° at the same level of MO theory (3), probably so large because of repulsive forces acting between the *ortho* and β C—H bonds. This angle reduces to 124.6° at θ = 90° (3). In the planar α-methylstyrene, this angle is 123.4°. Part of the anticipated increase in the repulsive interaction is relieved by the lengthening of the C(1)C(α) bond from 1.477 to 1.502 Å. The

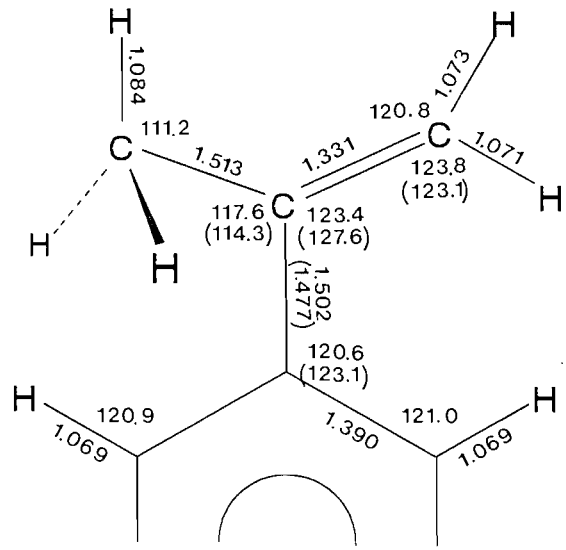

FIG. 2. The 6-31G MO structure of planar α-methylstyrene is shown. Numbers in parentheses are those from another 6-31G computation for planar styrene (3). The present structure assumes threefold symmetry for the methyl group and a regular planar hexagon for the phenyl group. Reference 3 discusses how to adjust the computed bond lengths in styrene to obtain putative experimental lengths. In the computed perpendicular conformer of α-methylstyrene, the C(1)C(α)C(β) angle decreases to 121.5° while the angle C(1)C(α)C(H3) reduces to 115.8°. See the text for similar comparisons for *cis*-β-methylstyrene.

decrease in the C(1)C(α)C(β) angle may arise from the space requirements of the methyl group. The C(1)C(α)C(H3) angle is computed as 117.6°, some 3° larger than the angle C(1)C(α) H in styrene. Note also that the C(2)C(1)C(α) angle in the planar form is 120.6°, some 2.5° less than in planar styrene and consistent with "balancing" steric repulsions at the two *ortho* sites. In the perpendicular conformation, the C(1)C(α)C(H3) angle becomes 115.8°, the C(1)C(α) bond does not change in length, and

[j]At 300.135 MHz and 300 K, the ν values of the benzene protons are 2198.1_4 Hz for a 16 mol% solution acetone (close to 2 mol/L) and 2205.6_7 Hz for a 2.5 mol% solution in acetone.

the C(i)C(α)C(β) angle reduces to 121.5°, suggesting steric strain involving both *ortho* sites in the planar form. The relatively flat potential curve for α-methylstyrene is then a consequence of a combination of steric destabilization of the planar form, which also reduces π electron conjugation along the C(1)—C(α) bond), followed by partial cancellation of the opposing steric and conjugational energy changes as θ increases. A similar qualitative interpretation of the computed rotational potential for *cis*-β-methylstyrene seems reasonable, altered somewhat by the rather larger destabilizing steric forces in this molecule. Thus, the C(1)C(α)C(β) and C(α)C(β)C(H3) angles are computed as 132.1° and 129.8°, respectively, in the planar form, and decrease by 6.7° and 3.9° in the perpendicular structure. Again, it does appear that conjugational energies may be smaller in this molecule than in styrene. If they were zero, then an attractive interaction of the methyl–π system at θ = 90° would not be present.

^{1}H nuclear magnetic resonance spectral parameters

Tables 1 and 2 contain the ^{1}H nmr spectral parameters for five methylstyrenes. The literature values for styrene (12) are included for comparison. The signs of the long-range coupling constants are based on those determined for styrene (12) and the halostyrenes (11). Signs in brackets are assigned on the basis of the known coupling mechanisms (11).

Theoretical long-range coupling constants

The following discussion refers to the numbering in **1**. The original valence bond calculations (11) predict substantial π electron contributions to *all* coupling constants between ring and olefinic protons, ^nJ (n = 4, 5, 6, or 7 intervening bonds). These contributions have the general form $^nJ/\text{Hz} = A\cos^2\theta + B\sin^2\theta$, where A and B are positive for odd n and are negative for even n. The terms in A arise from π electron delocalization between the conjugated vinyl and phenyl moieties, while those in B come from σ–π interactions.

The INDO MO FPT computations (11) are meant to include also the σ electron components of ^nJ, as well as effects caused by proximity of the bonds containing the coupled nuclei. The details (11) of the numerical results from both types of calculations will not be repeated here.

TABLE 2. Inter-ring proton coupling constants for styrene and some of its methyl derivatives[a]

Parameter[b]	Styrene	4-CH_3	*trans*-β-CH_3	*cis*-β-CH_3	β,β-diCH_3	α-CH_3
$^6J_{47}$	−0.227(3)	{(+)0.243(1)}[c]	−0.231(1)	−0.417(1)	0.470(8)	±0.084(1)
$^7J_{49}$	0.281(3)	{(−)0.259(1)}[d]	{(−)0.239(1)}	0.223(1)	—[f]	0.172(1)
$^7J_{48}$	0.237(3)	{(−)0.257(1)}	0.226(1)	{(−)0.153(1)}	—[f]	0.168(1)
$^5J_{37}$	0.368(3)	0.377(1)	0.364(1)	0.356(1)	0.352(6)	{±0.022(0)}
$^6J_{39}$	—	±0.020(1)[e]	{±0.095(0)}	±0.015(1)	—	±0.025(0)
$^6J_{38}$	—	±0.041(1)	±0.033(2)	{±0.030(0)}	—	±0.032(1)
$^4J_{27}$	−0.525(3)	−0.533(1)	−0.529(1)	−0.645(1)	−0.668(9)	{±0.037(0)}
$^5J_{29}$	0.158(3)	0.164(1)	{(−)0.243(1)}	0.280(1)	—	0.166(1)
$^5J_{28}$	—	±0.045(1)	±0.018(1)	±0.185(1)	—	0.000(1)

[a]For the solutions detailed in Table 1.

[b]Note that H-7 is the α proton of the vinyl group, whereas H-8 is the *cis*-β proton.

[c]Numbers in curly brackets involve coupling constants of the methyl protons and therefore refer to a coupling interaction over one more formal bond than is indicated in column 1.

[d]Signs in parentheses are assumed on the basis of the methyl group replacement technique (13), i.e., $^nJ(H,H) \cong -^{n+1}J(H,CH_3)$.

[e]Magnitudes less than 0.035 Hz are probably accurate only to 0.01 Hz, although the presence of these coupling constants is indubitable. Magnitudes of coupling constants below 0.02 Hz are uncertain.

[f]The methyl protons were decoupled, superpositions of quartets from these protons leading to an unanalyzable ring proton spectrum.

Now, it seems quite clear from the pattern of ^nJ in Table 2 that not only the magnitudes of the theoretical contributions to ^nJ but, in some instances, also their very existence is in question (assuming that the conformational preferences of the molecules are not drastically altered in solution).

Consider $^5J_{37}$, for example. According to the valence bond model, $^5J_{37} = 0.39 \cos^2\theta + 1.18 \sin^2\theta$, equivalent to $^5J_{37} = 0.39 + 0.79 \sin^2\theta$. Here 0.39 Hz represents the delocalization term and 1.18 Hz the σ−π term. As $\langle\sin^2\theta\rangle$ increases, therefore, $^5J_{37}$ must increase. Yet $^5J_{37}$ in Table 2 varies hardly at all. Furthermore, in 2,6-dichlorostyrene, $^5J_{37}$ is 0.39 ± 0.04 Hz, equal to the values in Table 2 to within experimental error. According to our STO 3G MO computations for this molecule, $\langle\sin^2\theta\rangle$ is 0.723 at 300 K, as compared to an experimental $\langle\sin^2\theta\rangle$ of 0.175 for styrene and a 6-31G value of 0.167. Furthermore, in α-methylstyrene $^6J_{37} \equiv {}^6J(\text{H-3},CH_3)$ is 0.02 ± 0.01 Hz in magnitude (Table 2). This coupling constant should measure the π electron contribution[1] to $^5J_{37}$. Apparently this contribution is effectively zero. The INDO results have $^5J_{37}$ as 0.75 Hz in the planar form of styrene (average over $\theta = 0°$ and 180°) and as 0.93 Hz at $\theta = 90°$. As for similar calculations for toluene (16), a large stereospecific $^5J_{37}$ is calculated for the all-*trans* arrangement ($\theta = 180°$), mainly a σ electron contribution.[2] However, in toluene, $^5J(H,CH_3)$ appears to obey the relation $C \sin^2\theta + D \sin^2(\theta/2)$, where C represents a σ−π and D a σ component (17, 18). Of course, for an internal rotational potential containing only evenfolded terms, $\langle\sin^2(\theta/2)\rangle$ is 0.5. The data in Table 2 indicate quite strongly that $^5J_{37}$ in styrene depends predominantly on $\sin^2(\theta/2)$ and, therefore, that π and σ−π contributions to $^5J_{37}$ are very small indeed. If this is true, then, intuitively, the theoretical models may well significantly overestimate the π and σ−π components of $^6J_{47}$, a coupling constant presumably dominated by such components.

The valence bond expression (11) for $^6J_{47}$ is $-0.43 \cos^2\theta - 1.25 \sin^2\theta$. That given (11) by INDO is plausibly written as $-0.24 \cos^2\theta - 1.05 \sin^2\theta$ for styrene. Both expressions overestimate the magnitude of $^6J_{47}$ in styrene, which is −0.227(3) Hz (Table 2), assuming that $\langle\sin^2\theta\rangle$ is very near 0.17, as in the gas phase at 300 K. There is no obvious way of assessing the value of $^6J_{47}$ at $\theta = 0°$, that is, of $^5J_0^\pi$, the coefficient of $\cos^2\theta$. An elaborate set of modified INDO MO FPT computations (20) suggests that $^6J_{47}$ be written as $^6J_{47} = {}^6J_0 + {}^6J_{90}\langle\sin^2\theta\rangle$ and that $^6J_0$ is about −0.075 Hz. The following empirical approach to $^6J_{47}$ is designed to reproduce eventually most of the long-range coupling constants in Table 2.

Empirical conformational analysis

Write $^6J_{47} = -0.149 \cos^2\theta - 0.597 \sin^2\theta$. This equation reproduces the $^6J_{47}$ of −0.227(3) Hz in styrene in solution on the assumption that $\langle\sin^2\theta\rangle$ is 0.175 at 300 K, as in the gas phase. In 4-methylstyrene, $^7J(H,CH_3)$ is (+)0.234(1) Hz, as expected if the spin state information about the side-chain proton reaches H-4 via the π electron system of the phenyl group (15, 21). $^6J_{47}$ in *trans*-β-methylstyrene is −0.231(1) Hz, again as expected from intuition and the 6-31G results. For *cis*-β-methylstyrene the $^6J_{47}$ of −0.417(1) Hz then implies a $\langle\sin^2\theta\rangle$ of 0.598, rather higher than the 0.459 implied by 6-31G calculations but nearer the 0.535 obtained from the STO-3G potential. For the β,β-dimethylstyrene $\langle\sin^2\theta\rangle$ becomes 0.716, while the $^6J_{47}$ of −0.53 Hz in 2,6-dichlorostyrene (11) then has $\langle\sin^2\theta\rangle$ as 0.850. Now arc sin $\langle\sin^2\theta\rangle^{1/2}$ is 67° for the latter and for the former it is 58°. The latter number, calculated as is usually done in the literature for styrenes but not to be taken as exact, is rather larger than that of 51° for *cis*-β-methylstyrene. It may well have its origin in the so-called parallel 1:3 interactions between the C—H bond of the two methyl groups. In consequence, a C—H bond of the *cis*-β-methyl group is forced to have a larger repulsive interaction with the *ortho* C—H bond of the ring than in the absence of the second β-methyl group. In the absence of the latter, near-planar conformations are accommodated by a staggering of two C—H bonds about the *ortho* C—H bond.

Now, in α-methylstyrene, $^7J(H,CH_3)$ is (+)0.084(1) Hz and, when multiplied by 0.65/0.75 as required for olefinic systems (22, 23), measures the π electron contribution (as distinct from the σ−π). Hence $\langle\cos^2\theta\rangle$ is 0.073/0.149 or 0.490.

To test this result (the 6-31G value for $\langle\sin^2\theta\rangle$ is 0.43 and the STO-3G value is 0.48), one may examine $^7J_{48}$ and $^7J_{49}$ for the compounds in Table 2. Any σ electron contributions to these coupling constants should be very small (11), yet $^7J_{49}$ is ca. 0.04

[1]The σ−π component does not appear in $^6J(\text{H-3},CH_3)$, in our experience. For example, $^6J(H,CH_3)$ in toluene is a σ−π coupling constant (14–17). In ethylbenzene, $^7J(H,CH_3)$ is undetectable to within 0.02 Hz (5).

[2]The INDO results for toluene have a significant $^5J(H,CH_3)$ at $\theta = 0°$ (16). The experimental evidence suggests a vanishing $^5J(H,CH_3)$ at this angle (18, 19).

Hz larger than $^7J_{48}$ in styrene.[3] In 4-methylstyrene, however, the $^8J(H,CH_3)$ values are identical and equal to the mean of $^7J_{49}$ and $^7J_{48}$ in styrene (perhaps there are σ contributions of 0.02 Hz to $^7J_{49}$ and of −0.02 Hz to $^7J_{48}$ in styrene). Take 0.259 Hz as the mainly π electron component, proportional to $\cos^2\theta$, of $^7J_{48}$ and $^7J_{49}$ in styrene, but allow for small σ−π components, proportional to $\sin^2\theta$, as indicated by valence bond and molecular orbital theories. If $^7J_0$ is 0.300 Hz and $^7J_{90}$ is 0.065 Hz, then the $\langle\sin^2\theta\rangle$ values derived from $^6J_{47}$ yield 0.259 Hz for styrene, 0.180 Hz for α-methylstyrene, and 0.100 Hz for 2,6-dichlorostyrene (the observed value is 0.12 ± 0.04 Hz (11)). Approximate numbers for $^9J(CH_3,CH_3)$ in β,β,4-trimethylstyrene are ±0.10 to ±0.15 Hz for the *trans* methyl group and ±0.05 to ±0.10 Hz for the *cis* (24). The $\langle\sin^2\theta\rangle$ of 0.716 above yields 0.132 Hz and the π component should be multiplied by 0.75/0.65 to give 0.14 Hz for $^9J(CH_3,CH_3)$. In β-*cis*-methylstyrene, the estimate above of 0.598 for $\langle\sin^2\theta\rangle$ yields 0.16 Hz for $^7J_{49}$ and $^7J_{48}$. The observed value of $^8J(H,CH_3)$ is (−)0.15 Hz, in reasonable agreement with the predicted $^7J_{48}$, dominated as it is by the π electron term. However, $^7J_{49}$ is 0.23(1) Hz, about 0.06 Hz larger than expected. This disagreement joins that for another coupling constant involving H-9 in this compound (see below).

Turning to $^4J_{27}$, an equation in $^4J_0\cos^2\theta$ and $^4J_{90}\sin^2\theta$ is assumed. The term in $\cos^2\theta$ contains $^4J_0^\pi$ and quite possibly also, as in toluene (25), a σ electron component; that in $\sin^2\theta$ is again σ−π contribution. The numbers for $^4J_{27}$ in styrene and β-*cis*-methylstyrene in Table 2, together with the expectation values of $\langle\sin^2\theta\rangle$ based on $^6J_{47}$, entail $^4J_{90}$ as −0.759 Hz and $^4J_0$ as −0.476 Hz. These parameters imply $^4J_{27}$ as −0.679 Hz in β,β-dimethylstyrene, whereas the experimental value is −0.668(9) Hz.

It is interesting that $^5J(H,CH_3)$ in α-methylstyrene is barely detectable (Table 2). Two explanations are possible. The first notes again that $^5J(H,CH_3)$ measures the π as opposed to the σ−π contribution and that therefore $^4J_0$ is mostly a σ electron term. The second explanation recognizes the possibility of negative through-space or proximate coupling interactions between the methyl and *ortho* ring protons, analogous to those in anisole (26–28). This explanation would need $-0.476\langle\cos^2\theta\rangle$ or about −0.2 Hz for an averaged proximate mechanism if $^4J_0$ is solely a π term, and rather a smaller magnitude were $^4J_0$ to contain a significant σ electron term. In anisole the proximate coupling magnitude for the planar conformation is about −0.3 Hz (note that significant planar populations of α-methylstyrene are implied by the 6-31G potential).

The coupling constants involving the *meta* and β-protons, $^6J_{38}$ and $^6J_{39}$, were not detected in styrene (12), but do appear in 4-methylstyrene. They are very small in magnitude, as they also are in the other methylstyrenes. However, $^7J(H,CH_3)$ in β-*trans*-methylstyrene lies very near 0.1 Hz in magnitude, implying a π electron contribution of (−)0.08 Hz to $^6J_{39}$. The computational results on styrene (11) imply that the σ electron component of $^6J_{39}$ is positive and of opposite sign to the π component. It appears that these components are indeed present and that they effectively cancel each other in styrene. $^6J_{38}$ in the three methylstyrenes in Table 2, and $^7J(H,CH_3)$ in β-*cis*-methylstyrene, all have the same small magnitudes to within experimental error. $^6J_{38}$ is computed as negative and larger in magnitude than $^6J_{39}$ for all angles θ by valence bond and INDO MO methods (11), in line with the data in Table 2. It seems impossible to deduce θ values from these very small coupling constants.

Consider $^5J_{28}$. It is computed and observed as negative at θ = 0°, quite possibly because of a proximate mechanism (11), and is then expected to become positive at angles appreciably removed from zero. The π electron term is positive (11), calculated to depend mainly on $\cos^2\theta$. In styrene and its β-*trans*- and α-methyl derivatives, $^5J_{28}$ is effectively zero and is only ca. 0.05 Hz in 4-methylstyrene. In β-*cis*-methylstyrene, $^6J(H,CH_3)$ is (−)0.185(1) Hz. If this number does not represent a proximate coupling, then it measures the magnitude of the π electron component of $^5J_{28}$ at a $\langle\cos^2\theta\rangle$ of 0.402. If so, then either the π and σ electron mechanisms have opposite signs or $^6J(H,CH_3)$ is a composite of proximate and π electron components. If the former is true, $^5J_{28}$ at θ = 0° is roughly 0.40 Hz. The vanishing $^5J_{28}^\pi$ in α-methylstyrene, at a $\langle\cos^2\theta\rangle$ of 0.49, then implies a composite σ and proximate mechanism of −0.20 Hz. This number appears unlikely. Furthermore, $^6J(H,CH_3)$ in the β-*trans* isomer is (−)0.243(1) Hz, implying the π component of $^5J_{29}$ at 0° as 0.25_5 Hz. The π components of $^5J_{28}$ and $^5J_{29}$ in the present coupling model are required to be equal. A consistent treatment of $^5J_{28}$ is therefore not available at present.

Finally, INDO MO calculations required the average $^5J_{29}$ to be largely independent of θ, as observed for the 4-methyl and α-methyl styrenes in Table 2. However, in the β-*cis* isomer, $^5J_{29}$ is 0.1 Hz larger than in the former molecules. This discrepancy joins that mentioned above for $^7J_{49}$ in the same molecule.

TABLE 3. Values of arc cos $\langle\cos^2\theta\rangle^{1/2}$ in degrees for styrene and some of its methyl derivatives

Molecule	UPS[a]	UVS[b]	6-31G[c]	NMR(*J*)[d]
Styrene	(0)	(0)	24	25[e]
4-Me	11±11	(0)	—	25
trans-β-Me	12±12	(0)	27	25
cis-β-Me	22±6	35	43	51
β,β-di-Me	—[f]	—	—	58
α-Me	29±6	33	49	46

[a]Based on photoelectron spectroscopy (6) and assuming that styrene is planar. An earlier value for α-methylstyrene (7) is 38°. These are effectively arc cos $\langle\cos^2\theta\rangle^{1/2}$ values.

[b]Based on ultraviolet absorption bands, again assuming a planar styrene (8) molecule and yielding arc cos $\langle\cos^2\theta\rangle^{1/2}$. Another value for α-methylstyrene is 30° (29). The Faraday effect gives 32° (10).

[c]These are based on the 6-31G MO internal rotational potentials; arc cos $\langle\cos^2\theta\rangle^{1/2}$ are computed classically at 300 K.

[d]These are arc cos $\langle\cos^2\theta\rangle^{1/2}$ values at 300 K, are derived from the model in this paper, and are based on the experimental gas phase internal potential (1), which yields 25° for arc cos $\langle\cos^2\theta\rangle^{1/2}$ at 300 K.

[e]Note that the larger value for styrene inevitably yields θ values for its derivatives that are larger than those given by UPS and UVS.

[f]An arc cos $\langle\cos^2\theta\rangle^{1/2}$ of 40° was estimated (24) from $^9J(CH_3,CH_3)$ for β,β-trimethylstyrene, assuming planar styrene.

Comparison with other estimates

In Table 3 estimates of the angles arc cos $\langle\cos^2\theta\rangle^{1/2}$ obtained by various methods are given. The early work assumes that styrene is a rigid planar molecule. Consequently these angles, which seem to be essentially values of arc cos$\langle\cos^2\theta\rangle^{1/2}$, are all smaller than those obtained from the MO calculations. Note that at 300 K the value of arc cos$\langle\cos^2\theta\rangle^{1/2}$ is 25° for styrene, based on the experimental (1) gas phase potential. It should again be stressed that the present model assumes the gas phase potential as applicable to solution. The 6-31G computations, when com-

[3]To check this point, the ^{1}H nmr spectrum of 3,5-dibromostyrene for a CS_2 solution was analyzed, confirming the larger magnitude of $^7J_{49}$.

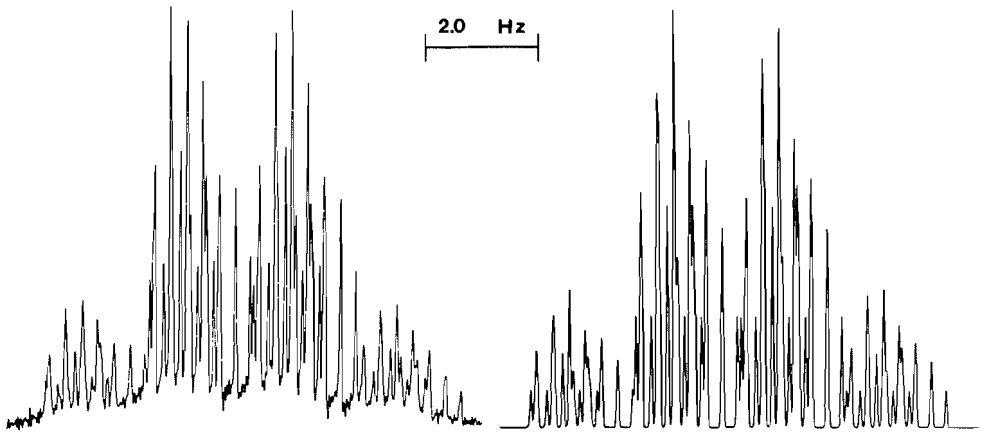

FIG. 3. Half the ^{1}H nmr spectrum of the α proton of *cis*-β-methylstyrene is shown for a 2.5 mol% solution in acetone-d_6, at a probe temperature of 300 K and a spectrometer frequency of 300 MHz. The computed spectrum is also shown and had an assumed linewidth at half-height of 0.04 Hz. Not all the observed peaks are as narrow as this, although some seem to be even narrower. One noticeable discrepancy between the observed and computed spectra occurs at their extreme left.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

pared with the nmr data in Table 3, are in rough agreement with this assumption.

Remarks on the extrema in ^{n}J

The value of −0.6 Hz for $^6J_{47}$ at θ = 90° in the present model is less than 60% of that computed by the INDO MO FPT approach and less than half of the valence bond prediction (11). Similar remarks apply to the majority of the coupling constants in Table 2. Attempts at fitting these data with larger magnitudes of the extrema at θ = 0° and 90° were unsuccessful. Theory does appear also to overestimate the π and σ−π contributions, particularly to the coupling constants for the *meta* protons. For example, $^5J_{37}$ has a π component of 0.39 Hz at 0° and a σ−π component of 1.18 Hz at 90°, according to the valence bond formulation. Yet the numbers in Table 2 are best explained if such components are less than about 0.05 Hz in magnitude.

Of the 45 long-range coupling constants in Table 2, all but two are rationalized by the present discussion. These two involve the β-*trans* olefinic proton. They show that the present model is incomplete. Their interpretation escapes us.

Proton chemical shifts

The ^{13}C chemical shifts of many styrene derivatives, as well as the ^{1}H shifts of their olefinic protons, have been extensively studied and interpreted (29–33), notably by Reynolds and coworkers. Here we note that H-4 in styrene is shielded by 0.10 ppm relative to benzene at the same concentration (footnote in Table 1). This number can be compared to the analogous 0.21 ppm for H-4 in toluene (17), in line with the statement (31) that the vinyl group is almost neutral electronically. The presence of a *trans*-β-methyl group in the side chain coincides with an increase in shielding of H-4 by 0.17 ppm relative to benzene, the molecule having conformational properties very similar to those of styrene. An α-methyl group, however, increases the shielding of H-4 by only 0.08 ppm relative to benzene, less than a vinyl group. The obvious explanation involves the larger twist angle in this compound than in styrene, causing a decreased delocalization or polarization of electron density. Experimentally, $\langle \sin^2 \theta \rangle$ is effectively the same for styrene and its *trans*-β-methyl derivative (see $^6J_{47}$ in Table 2). Consequently it appears from the H-4 chemical shifts that the methyl substituent enhances the π electron donation of the vinyl group.

Experimental

The methylstyrene derivatives, of commercial origin, were diluted to concentrations of 2.5 mol% in acetone-d_6, which contained about 0.5 mol% tetramethylsilane. These solutions were filtered into 5-mm o.d. nmr sample tubes and were degassed by a number of freeze–pump–thaw cycles on a vacuum line. They were then flame sealed to produce symmetrical closed tops. Acetone-d_6 was used as a solvent because the work on styrene used this solvent, but also because narrow peak widths were obtained in acetone-d_6. This was important for satisfactory analyses of the spectra arising from extensively coupled 10-spin systems.

The ^{1}H nmr spectra were accumulated on a Bruker AM300 spectrometer at a probe temperature of 300 K. The procedure has been described in detail previously (17). The ^{1}H nmr spectra were analyzed with the computer program NUMARIT (34), as modified by R.S. Figure 3 displays half of the measured and calculated ^{1}H nmr spectrum of the α proton of *cis*-β-methylstyrene. At least some of the peaks display linewidths at half-height of less than 0.05 Hz. The computed spectrum assumed linewidths of 0.04 Hz.

The molecular orbital computations employed GAUSSIAN 82(35) and an Amdahl 5870 system.

This paper is dedicated to Professor J. A. Morrison

RAYMOND EVANS MARCH and ALEXANDER BALDWIN YOUNG. An investigation of the structures of isomeric ions derived from acetone, diacetone alcohol, and mesityl oxide. Can. J. Chem. **66**, 591 (1988).

An investigation of the structures of isomeric ions formed in ion/molecule reactions occurring in 2-propanone (acetone), 4-hydroxy-4-methyl-2-pentanone (diacetone alcohol), and 4-methyl-3-penten-2-one (mesityl oxide) has been performed using a hybrid mass spectrometer of reversed geometry. Ions of *m/z* 117, which have been observed as products of ion/molecule reactions in acetone and in diacetone alcohol, may have a single structure if an aldol type condensation reaction occurs under acidic conditions in the gas phase; however, high energy collision induced dissociation (CID) results proved the two ions to be isomeric only.

Dehydration of the *m/z* 117 ions produced a species of *m/z* 99 which, in the case of diacetone alcohol, may have the structure of protonated mesityl oxide. That the *m/z* 99 ion formed was unique to each system was demonstrated by high energy CID and kinetic energy release (KER) spectrometry. In the acetone system, CID results suggested that *m/z* 99 was an ion–dipole complex of $C_3H_5^+(CH_3)_2CO$; this hypothesis was tested by clustering $C_3H_5^+$ with $(CD_3)_2CO$ and comparison of its CID results with those obtained above. In the case of *m/z* 99 derived from diacetone alcohol or mesityl oxide, the neutral lost via metastable decomposition in the second field-free region was found to be C_4H_8, presumably 2-methyl propene. While the ion of *m/z* 99 may also eliminate methane to yield a species of *m/z* 83, the dominant metastable elimination from this ion is carbon monoxide rather than ethene as shown by collision induced dissociative ionization (CIDI). The ions of *m/z* 83 observed in the two systems exhibit very similar CID spectra; however, a small variation in the yield of products of *m/z* 41 and 43 suggests two structures for the ion derived from diacetone alcohol, one of which is identical to that seen in mesityl oxide.

RAYMOND EVANS MARCH et ALEXANDER BALDWIN YOUNG. An investigation of the structures of isomeric ions derived from acetone, diacetone alcohol, and mesityl oxide. Can. J. Chem. **66**, 591 (1988).

Utilisant un spectromètre de masse de géométrie inversée, on a étudié les structures des ions isomères qui se forment au cours des réactions moléculaires se produisant dans la propanone-2 (acétone), l'hydroxy-4 méthyl-4 pentanone-2 (diacétone alcool) et la méthyl-4 pentène-3 one-2 (oxyde de mésityle). Il est possible que les ions de *m/z* 117, qui sont observés comme produits dans les réactions ion/molécules de l'acétone et du diacétone alcool, aient une structure unique si une réaction de type aldolique se produit dans des conditions acides, en phase gazeuse; toutefois, il est possible que des résultats de dissociations induites par des collisions à hautes énergies (DIC) prouvent que les produits ne sont que des isomères.

La déshydratation des ions de *m/z* 117 fournit une espèce de *m/z* 99 qui, dans le cas du diacétone alcool, pourrait correspondre à un oxyde de mésityle protoné. Faisant appel à des DIC à hautes énergies et à la spectromètrie d'émission d'énergie cinétique (EEC), on a démontré que l'ion de *m/z* 99 est unique à chaque système. Dans le système de l'acétone, les résultats de DIC suggèrent que l'ion de *m/z* 99 est un complexe ion–dipôle de $C_3H_5^+(CH_3)_2CO$; on a vérifié cette hypothèse en provoquant la formation d'un agrégat entre l'ion $C_3H_5^+$ et le $(CD_3)_2CO$ et en comparant ses résultats de DIC avec ceux obtenus plus haut. Dans le cas de l'ion de *m/z* 99 qui est dérivé du diacétone alcool ou de l'oxyde de mésityle, on a trouvé que l'espèce neutre — qui est perdue par le biais d'une décomposition métastable dans le deuxième champ de la région libre — est du C_4H_8, probablement du méthyl-2 propène. Alors que l'ion de *m/z* 99 peut aussi éliminer du méthane pour fournir une espèce de *m/z* 83, l'ionisation dissociative induite par des collisions (IDIC) permet de démontrer que l'élimination métastable la plus importante qui est observée à partir de cet ion est celle du monoxyde de carbone plutôt que de l'éthène. Les ions de *m/z* 83 qui sont observés dans les deux systèmes présentent des spectres DIC qui sont très semblables; toutefois, une faible variation dans le rendement en produits de *m/z* 41 et 43 suggère qu'il existe deux structures pour l'ion provenant du diacétone alcool et que l'une d'elle est identique à celle provenant de l'oxyde de mésityle.

[Traduit par la revue]

Introduction

Often, the only tractable evidence from gas phase ion/molecule reactions is the variation in intensities of ionic species as a function of reaction time or pressure, thus it is always a temptation to invoke the reaction mechanisms and product structures observed from solution chemistry. A case in point is the well known aldol condensation followed by dehydration reaction:

[1] 
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

in the gas phase, the condensation product may be fully covalently bonded;

[2] 
I (m/z 117)

or proton-bound;

[3] 
II (m/z 117)

The ionic products of these reactions are indistinguishable by conventional measurements of m/z ratio, necessitating further experiments for their differentiation. The ionic species investigated were derived from 2-propanone (acetone), 4-methyl-4-hydroxy-2-pentanone (diacetone alcohol), and 4-methyl-3-penten-2-one (mesityl oxide), as it had been suggested earlier (1) that the species of m/z 117 formed via self-CI of acetone was identical to protonated diacetone alcohol, and that dehydration of this ion produced m/z 99, tentatively identified as protonated mesityl oxide.

A recent study (2) employed slow infrared multi-photon dissociation (IRMPD) to demonstrate that the species of m/z 117 obtained from acetone differed from protonated diacetone alcohol (reaction [2], structure **I**). Unfortunately, the species of m/z 99 and 83 proved unreactive with slow IRMPD and thus no decision could be made as to common or isomeric structures for these ions generated by different precursors. In an attempt to probe the structures, further experiments were performed with a reversed geometry mass spectrometer. The techniques employed were collision induced decomposition (CID) at high (keV) energy, kinetic energy release (KER) from metastable decomposition in the second field-free region (2ndFFR) and dissociative reionization of fast neutrals produced from metastable decomposition in the 2ndFFR. In addition, the exothermicity of the initial protonation reaction was varied and the effect of the subsequent change in internal energy upon metastable decomposition pathways was investigated.

Experimental

A mass spectrometer of reversed geometry (3) (Vacuum Generators ZAB2F) was employed. Ion/molecule reaction products were formed in the source at an estimated pressure of ca. 13 Pa using a conventional Vacuum Generators' combined electron impact/chemical ionization source. The second field-free region of this instrument is slightly more than a meter in length, and has been fitted with two gas collision cells for the study of bimolecular processes. The upstream collision cell, CC_1, is permanently grounded and the downstream collision cell, CC_2, which is located at the first focal point of the instrument, is electrically isolated so that a variable voltage in the range +5 kV to −5 kV may be applied to it. In the region between the cells, which are separated by some 56 mm, is interposed an ion deflector electrode which may be grounded or to which a variable voltage to +5 kV may be applied so as to prevent ions from entering CC_2. The reversed geometry instrument has the advantage that a particular ion species may be selected by the magnet and any decomposition products formed in the 2ndFFR between the magnet (B) and the electrostatic sector (E) may be mass analyzed employing the well known MIKES technique (4); such decomposition may be either unimolecular or collision induced. The internal energy of the ions formed in the source was varied by employing either isobutane or methane as the chemical ionization reagent. The proton affinities of isobutane and methane are 683 kJ mol^{-1} and 552 kJ mol^{-1}, respectively (5).

CID spectra of mass-selected ion species were obtained by pressurizing the second collision cell (CC_2) with helium to produce a reduction of ca. 30% in the ion signal intensity. The indicated pressure from the ion gauge situated below the cell was 1×10^{-5} Pa. CID spectra were corrected for metastable (unimolecular) decomposition by performing a second experiment in the absence of collision gas, and subtracting the metastable decomposition product intensities from those obtained in the CID experiment. Fast neutrals of several keV of kinetic energy produced through metastable decomposition in the 2ndFFR were examined by collision induced dissociation ionization. In this technique, ions are deflected by means of the deflector electrode situated just prior to CC_2, and only fast neutral fragments may enter the cell. When an appropriate reagent gas is added to CC_2, the neutrals are ionized and dissociated; the charged species produced are subsequently analyzed via the MIKES technique. In the experiments involving m/z 99, O_2 was employed as the reionization gas to reduce the fragmentation of the reionized neutral. He was used for reionization, in the other experiments.

Acetone, diacetone alcohol, mesityl oxide, and 3-bromopropene were supplied by Aldrich Chemical Co. and used without further purification. Perdeutero-acetone was supplied by Merck Sharp and Dohme Isotopes of Montreal, Quebec, Canada.

Results and Discussion

The experiments to be described were concerned with establishing the structures of ions of identical m/z values formed via ion/molecule reactions occurring in either acetone, diacetone alcohol, or mesityl oxide. The ions investigated were, m/z 117 which is common to acetone and diacetone alcohol; m/z 99 which arises from dehydration of m/z 117 and which may have the structure of protonated mesityl oxide (**III**); m/z 83 observed in diacetone alcohol and mesityl oxide, and which is presumably formed by methane elimination from excited m/z 99 (reaction [4]),

[4] 
III (m/z 99) m/z 83

where * denotes internal excitation. This ion may also have a common structure from its precursors, m/z 117.

m/z 117

Ions of m/z 117, formed from acetone via isobutane CI in the source, were mass-selected in the magnetic sector and directed into the 2ndFFR. A fraction of metastable ions of m/z 117 fragmented unimolecularly to produce m/z 59 (99%) and m/z 99 (1%). Isobaric metastable ions formed similarly from diacetone alcohol dissociated to form the same fragment ions but with the inverse ratio of products. The internal energy of the m/z 117 ions was then increased by employing methane rather than isobutane as the CI agent; the proton affinity of methane is less than that of isobutane. Enhanced internal energy brought about an additional reaction channel, that is the loss of H_2. m/z 117 from acetone produced m/z 59 (96%), m/z 99 (1%) and m/z 115 (3%), while isobaric ions from diacetone alcohol produced the same fragment ions but with the composition 25%, 73%, and 2%.

m/z 117 ions, again produced by isobutane CI, were subjected to CID using helium as target gas in CC_2. After correction of product ion intensities for unimolecular decomposition, it was found that CID of m/z 117 from acetone produced m/z 41 (1%), m/z 43 (5%), m/z 58 (6%), m/z 59 (86%), and m/z 99 (2%). m/z 117 from diacetone alcohol produced m/z 41 (1%), m/z 43 (18%), m/z 59 (5%), m/z 61 (1%), m/z 83 (2%), and m/z 99 (73%).

71							1		
79									4
81	4	4	68	10	36	58	3	2	14
83		1	2		1	1		4	21
84		2	2		1	1			2
98		7	2	5	12	2	2	2	6

These results demonstrate that the species of *m/z* 117 derived from acetone is an isomer of that produced in diacetone alcohol. The dominant pathway of the former is loss of a neutral fragment of 58 amu, neutral acetone, and this result is consistent with a proton bridged dimer structure **II**. In contrast, the dominant pathway observed in protonated diacetone alcohol is the loss of water, a known reaction of protonated ketones (6, 7). The ion of *m/z* 43 from the CID of this latter ion may be due to loss of a neutral fragment of 74 amu, presumably *t*-butanol, or via losses of acetone and methane or losses of isobutene and water. Protonated acetone, produced by acetone elimination from the ion of *m/z* 117, has been shown to eliminate methane to produce an ion of *m/z* 43 (6).

m/z 99

In Table 1 are shown the corresponding unimolecular fragmentations and CID of *m/z* 99, produced by isobutane CI and methane CI, from acetone, diacetone alcohol, and mesityl oxide. The species produced from mesityl oxide is simply the protonated parent molecule;

[5]  + F

98 **III** (*m/z* 99)

whereas the other species are derived via dehydration of protonated diacetone alcohol;

[6]  + H_2O

I (*m/z* 117) **IV** (*m/z* 99)

or the proton-bound dimer of acetone;

[7]  + H_2O

II (*m/z* 117) **V** (*m/z* 99)

Structure **V** has been suggested previously (2).

Inspection of the data in Table 1 shows that the three ion species differ in their metastable decomposition pathways. The species derived from acetone produces predominantly $C_3H_5^+$, *m/z* 41 and as the exothermicity of the initial protonation reaction is increased by changing from isobutane to methane CI, the relative yield of $C_3H_5^+$ is reduced whereas dehydration to *m/z* 81 is increased. In addition, loss of C_3H_4, presumably allene to yield *m/z* 59, is apparently reduced upon methane CI, however, the concomitant appearance of $C_2H_3O^+$, *m/z* 43, may be due to methane elimination from *m/z* 59, protonated acetone. The appearance of the moiety *m/z* 57 is postulated as the loss of a neutral fragment of 42 amu from *m/z* 99. Protonated acetone has been shown not to dehydrogenate readily (6), thus the genesis of *m/z* 57 from *m/z* 59 is thought to be unlikely, hence the neutral lost is suggested as propene or ketene. *m/z* 99 derived from diacetone alcohol primarily eliminates C_4H_8 to produce *m/z* 43 upon isobutane CI. The increase of protonation exothermicity afforded upon methane CI results in an increase in the efficacy of the dehydration pathway, producing *m/z* 81. In addition, minor amounts of *m/z* 57 and 59 are produced. Protonated mesityl oxide, *m/z* 99, exhibits two major fragmentation routes in the absence of collision gas; dehydration to *m/z* 81 and loss of a neutral fragment of 56 amu to produce *m/z* 43. As protonation exothermicity is increased, the dehydration channel is diminished, and the genesis of *m/z* 43 is increased. Minor pathways include methyl radical loss to produce *m/z* 84; methane loss to afford *m/z* 83; allene loss to yield *m/z* 59 and loss of 42 amu to give *m/z* 57.

In Table 1, the CID behaviour of the three ions is depicted, employing helium as the collision gas. Each of the ions exhibited unique behaviour and may be readily distinguished. In acetone, the major fragmentation route produced $C_3H_5^+$, *m/z* 41. The species derived from diacetone alcohol predominantly lost a neutral fragment of 56 amu affording *m/z* 43, whereas the isomeric protonated mesityl oxide exhibited a plethora of products, the three major routes being the production of *m/z* 43, 81, and 83.

The species of *m/z* 99 derived from acetone is intriguing. Although the enthalpy of formation of the ion of structure **V** is unknown, it is the progenitor of both $C_3H_5^+$ and $(CH_3)_2C^+OH$:

[8]  $C_3H_5^+ + (CH_3)_2CO$

$\Delta H = 724 - x$ kJ mol^{-1}

[9] **V**, *m/z* 99 $\longrightarrow$ $(CH_3)_2C^+OH + C_3H_4$

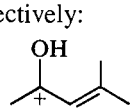
$\Delta H = 682 - x$ kJ mol^{-1}

$\Delta H_f^0 = x$

The observed preponderance of $C_3H_5^+$ indicates that *m/z* 99 dissociates via kinetic control, not thermodynamic, suggesting a loose ion/molecule complex formed between the 2-propenyl cation (or if a 1,2 H shift occurs, the allyl cation) and acetone. The appearance of $C_3H_5^+$ from the postulated structure **V** involves only simple bond cleavage, whereas the reaction producing the protonated ketone, *m/z* 59, involves a proton transfer, hence the former reaction exhibits a more favourable frequency factor than the latter, and predominates despite a greater endothermicity of ca. 40 kJ mol^{-1}.

The structure of **V** was further investigated by reacting 3-bromopropene with acetone-d_6 and mass selecting the $C_3H_5^+$ $(CD_3)_2CO$ species of *m/z* 105. Acetone-d_6 was employed to avoid complications arising from the *m/z* 99 species observed in acetone CI. The CID results obtained with helium in the second collision cell are depicted in Fig. 1, lower trace. For comparison purposes, the upper trace of Fig. 1 shows the CID behaviour of the fully deuterated species of *m/z* 110. This ion was produced via isobutane CI of perdeutero-acetone, the DOH elimination product ion being mass-selected. In the lower trace, the predominant fragmentation pathway is the loss of acetone-d_6 to yield $C_3H_5^+$. The thermodynamically favoured route, producing $(CD_3)_2C^+OH$, *m/z* 65, occurs with approximately equal facility to that shown in Table 1. The ion of *m/z* 46 is CD_3C^+O and is presumed to result through CD_3H elimination from *m/z* 65.

In the upper trace of Fig. 1, the ion of *m/z* 46 may have both the $C_3D_5^+$ and CD_3C^+O structure. The deuteronated d_6-acetone product yield (*m/z* 66) is enhanced in comparison to the lower trace and Table 1, however, due to the isobaric products of *m/z* 46, it is not clear as to whether this enhanced yield is due to a lowered activation energy for deuteron transfer or a diminution of the further fragmentation of *m/z* 66 to yield *m/z* 46. The cluster ion CID behaviour shown in the lower trace of Fig. 1 supports structure **V** for the dehydration product of the proton-bound dimer of acetone, *m/z* 117, although it may be argued that the species of *m/z* 99 observed in acetone is derived by clustering of *m/z* 41 with the neutral acetone, rather than by dehydration. Structures for the isomeric species of *m/z* 99 observed in both diacetone alcohol and mesityl oxide were proposed as **III** and **IV**, respectively:



Mesityl oxide, **III**

Diacetone alcohol, **IV**

Upon methane CI, the metastable fragmentation spectrum of *m/z* 99 from diacetone alcohol differs significantly from that obtained upon isobutane CI, as shown in Table 1, and approaches the fragmentation spectrum of *m/z* 99 from mesityl oxide. This change in fragmentation patterns may be due to the formation of *m/z* 99 with structures **III** and **IV**. The metastable decomposition of these ions to yield isobutene and *m/z* 43 may be written:

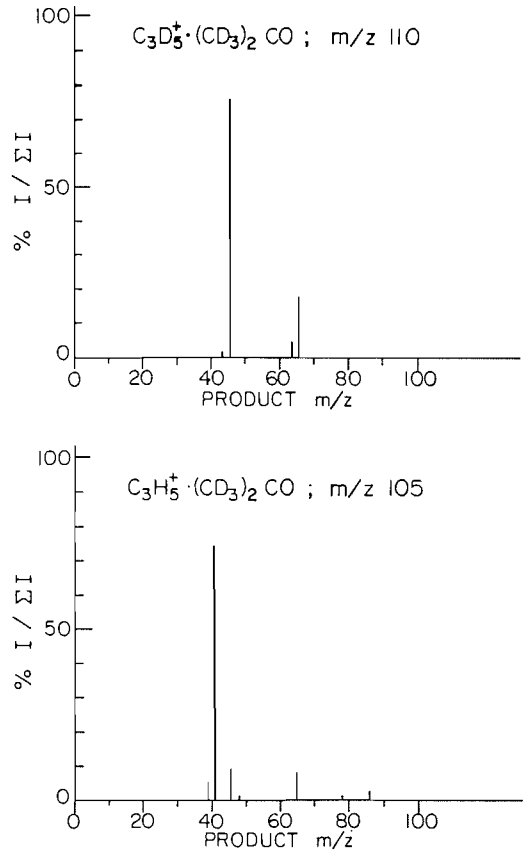


FIG. 1. Percentage ion composition of CID products derived via high energy collisions with helium in CC_2. Metastable decompositions have been subtracted. In the lower trace, the 2-propenyl cation, $C_3H_5^+$, was reacted with perdeutero acetone, and the cluster ion of *m/z* 105 was mass-selected via the magnet for high energy CID. In the upper trace, the fully deuterated analogous species formed in the source from self-CI of perdeutero acetone was mass-selected and collisionally dissociated in CC_2.

[10]  $CH_3C^+O +$

III

[11]  $\longrightarrow$ $CH_3C^+O +$

IV

It is anticipated that reaction [10] which involves a proton transfer should require a greater activation energy than reaction [11]. This difference in endothermicity should be reflected in the metastable peak shapes for the two reactions (8), the peaks are shown in Fig. 2. In each of the traces, the energy spread of the mass-selected *m/z* 99 ion beam was reduced to ca. 0.3 eV which corresponds to approximately 3 eV translational energy. The upper trace was obtained from the metastable decomposition of protonated mesityl oxide (reaction [10]); the lower trace corresponds to reaction [11]. From the measured widths of the ion kinetic energy peaks at half height, corrected for the energy spread inherent in the precursor ion, the translational energy realease, $T_{50\%}$, may be calculated (8). The elimination of C_4H_8

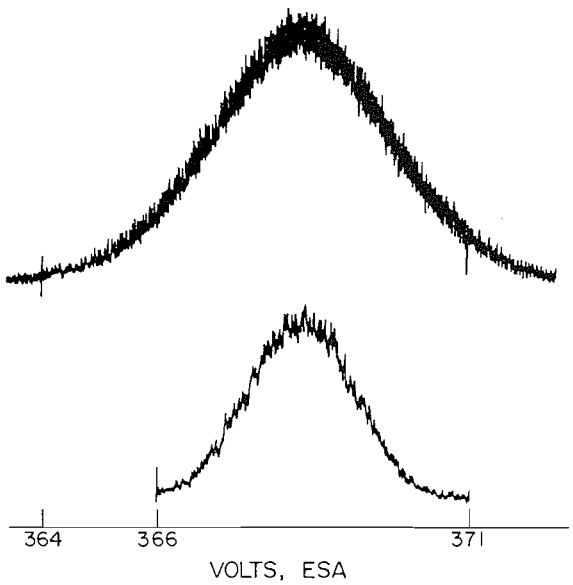

FIG. 2. Ion kinetic energy peaks of the metastable decomposition of *m/z* 99 in the 2ndFFR. The signals correspond to the process $99^+ \rightarrow 43^+ + 56^0$. In the upper trace, *m/z* 99 was generated via isobutane CI of mesityl oxide; in the lower trace, *m/z* 99 was formed via isobutane CI of diacetone alcohol.

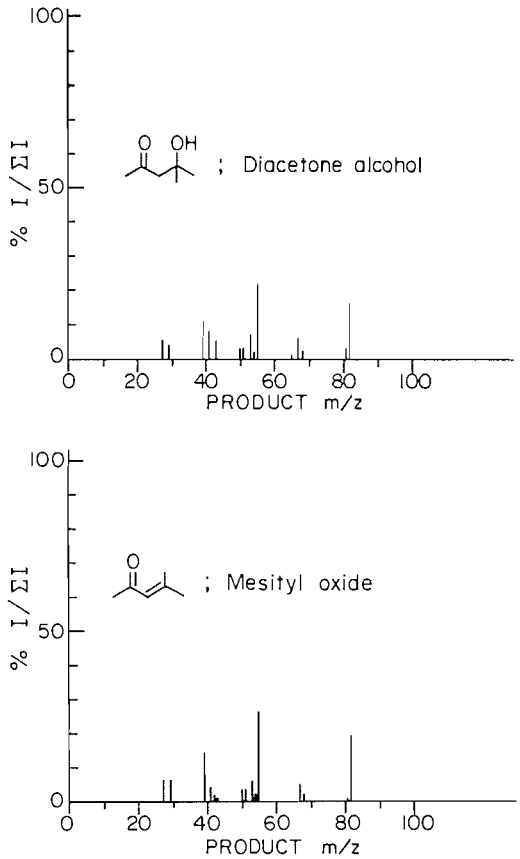

FIG. 3. Percentage ion composition of CID products obtained upon high energy collisions with helium in CC_2. Isobutane CI was employed to generate the *m/z* 83 ions, and contributions to the ion signal intensities due to metastable decompositions have been subtracted.

from protonated mesityl oxide (upper trace) exhibits $T_{50\%} = 32$ meV; the same loss from *m/z* 99 observed in diacetone alcohol has $T_{50\%} = 10$ meV. The larger ion kinetic energy release seen in the upper trace of Fig. 2 is attributed to a greater activation energy for the process. Such an observation is in agreement with reactions [10] and [11].

That the neutral produced in these reactions was C_4H_8 was verified by collision induced dissociative ionization (CIDI) (9). The precursor ion (*m/z* 99) was prepared via isobutane CI, and although the dominant metastable pathway of this ion in the case of mesityl oxide is dehydration, no signals were observed for this H_2O species due to the low collection efficiency for reionized neutrals of low kinetic energy (ca. 1.5 keV for H_2O from *m/z* 99 of 8 keV). Oxygen was employed as collision gas in order to enhance the appearance of the molecular ion (10), and results obtained for the neutral species of reactions [10] and [11] were similar.

m/z 83

The ion of *m/z* 83 was observed only in the diacetone alcohol and mesityl oxide systems and, in the case of the latter, must arise through methane elimination from the protonated molecule. In the diacetone alcohol experiments, *m/z* 83 was observed in minor abundance in the metastable decomposition of *m/z* 99 and in somewhat greater abundance in the high energy CID experiment. This ion was also observed in the high energy CID of protonated diacetone alcohol, although its progenitor may be *m/z* 99.

m/z 83 was generated in the ion source from four separate sets of progenitors, diacetone alcohol and mesityl oxide with each of isobutane and methane as CI agents. The MIKE spectra were virtually indistinguishable for diacetone alcohol and mesityl oxide, and varied only with the CI gas used. With isobutane CI the predominant pathway is the loss of CO (*vide infra*) to produce *m/z* 55. Minor abundances, totalling 7% of the base peak and comprised of *m/z* 43, *m/z* 56, *m/z* 81, and *m/z* 82, were observed with diacetone alcohol. With methane CI, enhanced protonation exothermicity resulted in an enhancement of H$^\bullet$ and H_2 losses at the expense of the pathway producing *m/z* 55, such that the intensities of ion signals due to *m/z* 55 and *m/z* 82 were equal. Approximately 10% of ion abundance was due to *m/z* 81.

In Fig. 3, the CID products of the two ions are depicted. The ions were generated via isobutane CI and the CID experiments were performed at identical reductions (ca. 30%) in precursor ion beam intensities. The major differences between the two spectra lie in the larger signals due to *m/z* 41 and 43 obtained from *m/z* 83 derived from diacetone alcohol, otherwise the spectra are similar.

A possible rationalization of the results may be made by postulating two isomeric ions of *m/z* 83 in the diacetone alcohol experiments, one of which is identical to *m/z* 83 observed in mesityl oxide.

The reaction to produce this ion may be written in the case of mesityl oxide;

[12] 
m/z 99, **III** *m/z* 55, **V**

and with *m/z* 99 as the precursor in diacetone alcohol;

[13] 
m/z 99, **IV** **V**

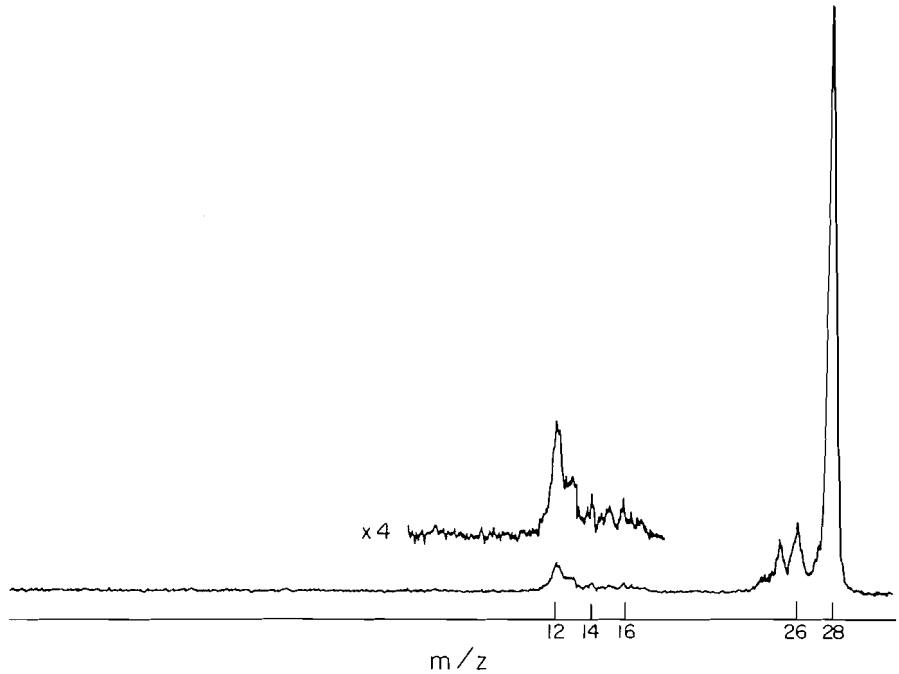

FIG. 4. Collisional reionization spectrum of the neutral fragment formed in the reaction $83^+ \rightarrow 55^+ + 28^0$. Isobutane CI was employed to generate *m/z* 83 from mesityl oxide, and ions were prevented from entering CC_2 by the application of ca. 3 kV to the deflector electrode situated prior to CC_2. Helium was employed as the reionization gas in CC_2; the collision cell was held at a potential of +2.5 kV in order to accelerate the ions formed in CC_2, and thus to enhance the signal intensity (11).

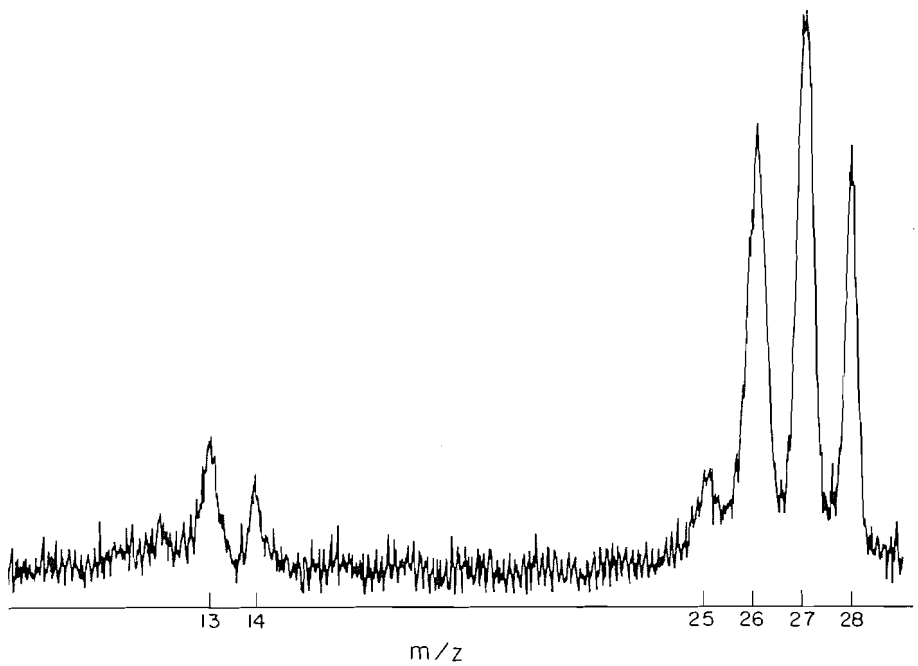

FIG. 5. Collisional reionization spectrum of ethylene obtained via the McLafferty rearrangement of the molecular ion of 2-pentanone. Helium was employed as the reionization gas and CC_2 was biased at +2.5 kV in order to enhance the signal intensities.

The loss of CO may be readily rationalized from structure **V**. An alternative reaction of *m/z* 99 from diacetone alcohol to produce *m/z* 83 may be written:

[14] 
m/z 99 *m/z* 83, **VI**

where **VI** is a mixed associative species which may decompose to CH_3C^+O, *m/z* 43 or via a more endothermic pathway to $C_3H_5^+$, *m/z* 41.

The identity of the neutral produced via metastable decomposition of *m/z* 83 to *m/z* 55 in the 2ndFFR was investigated by CIDI. Briefly, *m/z* 83 was prepared from mesityl oxide via isobutane CI and mass-selected by the magnet. With the deflector electrode potential set at approximately 3 kV and He in CC_2 at an indicated pressure of 1.2×10^{-5} Pa, very little signal was observed due to the poor collection efficiency of $28^{+\cdot}$ at a

translational energy of 2.7 keV (accelerating voltage for *m/z* 83 was 8 kV). To enhance the weak signals, CC_2 was biased at +2.5 kV, hence any positively charged CIDI products received an acceleration from the cell and were more readily detected (11). The results are depicted in Fig. 4, where the dominant peak is *m/z* 28. Although the peaks at *m/z* 12, 13, 14, 15, 25, and 26 might suggest C_2H_4 as the neutral lost, the lack of a peak at *m/z* 27 and the low intensities of *m/z* 26 and *m/z* 25 indicate that C_2H_4 is a minor component only. The CIDI spectrum of C_2H_4 generated via a McLafferty rearrangement from the molecular ion of 2-pentanone (and hence potentially contaminated with some reionized $\cdot CH_3$) is depicted in Fig. 5. The spectrum was obtained under identical conditions to that shown in Fig. 4, and is clearly different, thus the identity of the neutral lost from *m/z* 83 is carbon monoxide.

Summary

Gas phase ion/molecule reactions of acetone lead to the formation of an ion of *m/z* 117 which has the structure of a proton-bound dimer. No evidence was found for an aldol condensation reaction occurring in the gas phase as the ion of *m/z* 117 formed from diacetone alcohol has been shown to be isomeric. The dehydration products of these isomeric ions yielded isomeric ions of *m/z* 99. In the case of acetone, CID studies suggested an ion–dipole complex of acetone and $C_3H^+_5$ as the structure of *m/z* 99. This conclusion was substantiated by clustering $C_3H^+_5$ with perdeutero-acetone and performing the CID experiment. The dehydration product of protonated diacetone alcohol, *m/z* 99, differed from protonated mesityl oxide as revealed by CID experiments and KER measurements. Reionization of the neutral produced in the metastable decomposition of *m/z* 99 from both diacetone alcohol and mesityl oxide revealed that the species lost was C_4H_8. The latter two ions also eliminate methane yielding an ion of *m/z* 83. CID studies of these ions showed nearly identical results; the differences observed were ascribed to two ionic structures present in the ion derived from diacetone alcohol, one of which was identical to that seen in mesityl oxide. Reionization of the neutral produced in the metastable decomposition of these ions showed it to be CO rather than ethylene, C_2H_4.

Experimental tests for many-body forces in noble gas fluids

P. A. EGELSTAFF
Physics Department, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received July 24, 1987

This paper is dedicated to Professor J. A. Morrison

P. A. EGELSTAFF. Experimental tests for many-body forces in noble gas fluids. Can. J. Chem. **66**, 598 (1988).

Effects due to many-body potentials may be studied by comparing the predictions of precise computer simulations (using a good pair potential) with real experimental data. The differences observed may be of almost any relative magnitude, varying with state parameters and other experimental variables. Results of this kind will be discussed regarding P.V.T. data, transport coefficients, and static and dynamic structure factors of noble gas fluids. They are compared to the predictions of a simple mean field model for each effect, in which pair potential simulation is used as the reference system. The model is used as a tool to determine the information content of each property. Reasonable agreement is found for bulk properties, while the extra sensitivity offered by the microscopic data allows a number of deficiencies in the model to be observed. In contrast, a similar series of tests using a computer model, made from the pair potential and the A–T potential in place of the experimental data, shows significantly better overall agreement with the mean field model. This is believed to be due to the neglect of important short range terms in the A–T model. It is concluded that at least three types of many-body forces are important in discussing dense noble gas fluids.

P. A. EGELSTAFF. Experimental tests for many-body forces in noble gas fluids. Can. J. Chem. **66**, 598 (1988).

Il est possible d'étudier les effets dûs aux potentiels de plusieurs corps en comparant les valeurs expérimentales réelles avec les valeurs que l'on peut prédire par des simulations précises par ordinateur (utilisant une bonne paire de potentiels). L'amplitude des différences que l'on observe est relative et varie avec les paramètres d'état et d'autres variables expérimentales. On discutera de ce type de résultats pour des données de P.V.T., pour des coefficients de transport et pour les facteurs structuraux statiques et dynamiques de gaz nobles fluides. On les compare aux valeurs prédites par un modèle de champ moyen simple pour chacun des effets dans lequel la simulation des potentiels par paire est utilisée comme système de référence. On utilise le modèle comme outil pour déterminer l'information contenue dans chacune des propriétés. On trouve une bonne corrélation pour les propriétés globales; par ailleurs, la sensibilité extrême que présentent les données microscopiques fait que l'on observe un certain nombre de déficiences dans le modèle. Pour fins de comparaison, on a aussi fait une série de tests semblables en faisant appel à un modèle par ordinateur qui a été fait à partir de la paire de potentiels et d'un potentiel A–T à la place des données expérimentales; dans ce cas, l'accord global avec le modèle de champ moyen est bien meilleur. On croit que cette différence est dûe au fait que, dans le modèle A–T, on néglige des termes à courte distance qui sont importants. On en conclut que, pour discuter des gaz nobles fluides denses, au moins trois types de forces entre plusieurs corps sont importants.

[Traduit par la revue]

1. Introduction

The study of dense fluids has now reached the stage where realistic interaction potentials must be considered. Reasonably accurate pair potentials (e.g. Aziz (1)) have been obtained for noble gas atoms, and using these results the properties of a dense fluid (within which there are only pair interactions) may be derived through an extensive computer simulation. The simulation must be extensive to give accurate results, but even so logic demands that these results should not fit the data on the real substance. The reason is simple: in deriving the pair potential it is assumed that atoms are polarizable, while in using the pair theory of fluids it is assumed that they are not. Several effects are related to this discrepancy, but the most obvious are the substantial differences in the critical parameters for the computer pair fluid and the corresponding real experimental fluid. These differences are not well known at present, because of the time taken in this field to extend the data on the Lennard–Jones fluid (2) to model noble gas pair fluids. Nevertheless, differences in T_c and ρ_c of about 10% are expected (3); consequently in the neighbourhood of either critical point there will be infinite differences between numerous corresponding properties of the two fluids. These large differences are caused by many-body forces.

The nature of many-body forces has been discussed in many papers (e.g. Meath and Aziz (4)). From a qualitative point of view there are three effects to be considered. First, there are long range effects which can be discussed through a multipole expansion, and it may be shown that the triple-dipole term is the most important. Secondly, there are medium range effects — say from an atomic diameter to three atomic diameters on a distance scale — which are not well understood even in the case of pair interaction. In the latter case they have been approximated by an ad-hoc formula (1), which may have an incorrect mathematical shape (5). Nevertheless, the pair potential is well known for each noble gas. For many-body potentials some formulae are being proposed (6) which extend into the third scale. Thirdly, there are short range effects observed in many atom collisions and which have been considered in (relatively) complicated theoretical discussions of exchange and correlation effects, etc. More than one effect could be significant here. However, one important effect may be described by a simple physical picture of collisions of deformable atoms. At low density the minimum distance of approach of the nuclei of two flexible atoms, involved in a fast collision, will be less than that for similar rigid atoms involved in a similar collision. This reduced distance appears in the pair potential. In contrast, at high density a given atom might experience many impacts, averaging uniformly over all directions, and thus this reduction in internuclear distance would be less at high density than at low density (see Appendix 1). This implies that the effective atomic diameter should increase as a function of increasing density due to many-body forces.[1] Such an effect might be seen most clearly through changes in the position of the second nearest neighbour peak of the pair correlation function.

Text books on the theory of liquids usually cover pair theory in great detail and ignore or neglect effects of many-body forces. This has no bearing on the importance of these forces, but is because of the enormous difficulties in producing a tractable many-body theory. Therefore it may be argued that an experimental approach is required to define the principal features in relevant experimental data. This idea is not new although in the past we tended to oversimplify the many-body force question. However, to properly exploit this idea it is necessary to analyse each set of data to determine its information content. After this, information from the different kinds of data may be integrated, and we shall explore such possibilities in this article. Moreover, such analysis can emphasize experiments that test different features and contribute to a new understanding of the significant features of this problem. Thus experimentalists should try to define the contribution of many-body forces to various experimental quantities and suggest physical interpretations of their principal features.

The effect of many-body forces on a property may be defined as the difference between its experimental value for the real substance and its computer simulated value for the artificial fluid composed of atoms interacting with a realistic pair potential only. In this context numerous published papers giving computer results for hard-sphere, Lennard–Jones, or other fluids are inappropriate. Only extensive simulations using the most realistic pair potentials are of value: there are very few, perhaps none, of these. Thus in addition to new experiments, a program of new simulations is also required. As a guide to many-body force effects the difference between two computer simulations can be useful. These are the artificial pair potential fluid and a corresponding artificial fluid for which a many-body force model (e.g. the triple-dipole interaction (7)) has been added. It is difficult to carry out the second simulation as accurately as the first, and hence these differences are not satisfactorily obtained in some cases. This difference technique will also be discussed here.

In the following sections the P.V.T. data, static structure factor, transport coefficients, and dynamic structure factor data will be discussed from the above points of view.

2. A mean-field model for pressure and energy

The third virial coefficient of pressure is the sum of two kinds of terms. The first kind involves pair potential ($u(r)$) only, while the second involves both pair and three-body ($u_3(r, s)$) potential, and is

$$[1] \quad C_2(T) = -\tfrac{1}{3}\int\int \exp -\beta[u(r) + u(s) + u(r-s)]\{\exp[-\beta u_3(r-s)] - 1\}dr\,ds$$

This term is relatively easily measured and has been used to discuss three-body effects for many years. But it is clear from the form of the expression that $C_2(T)$ is relatively insensitive to the details of u_3. Consequently, it would be useful to extend the study of many-body effects to higher density, but this requires one to subtract the total pair terms from experimental data. This in turn means that one must complete extensive computer simulations for many densities along each isotherm to find the total pair terms. This was done for krypton on the 297 K isotherm by Ram and Egelstaff (10) and later by Barker (ref. 8, additional data on xenon are given in ref. 9*a*, and the method is given in ref. 9*b*). These two sets of data are shown in Fig. 1*a* and are in good agreement. The difference between the experimental and simulated pressures is shown in Fig. 1*b*. Ram and Egelstaff (10) commented that if the virial series was truncated at the

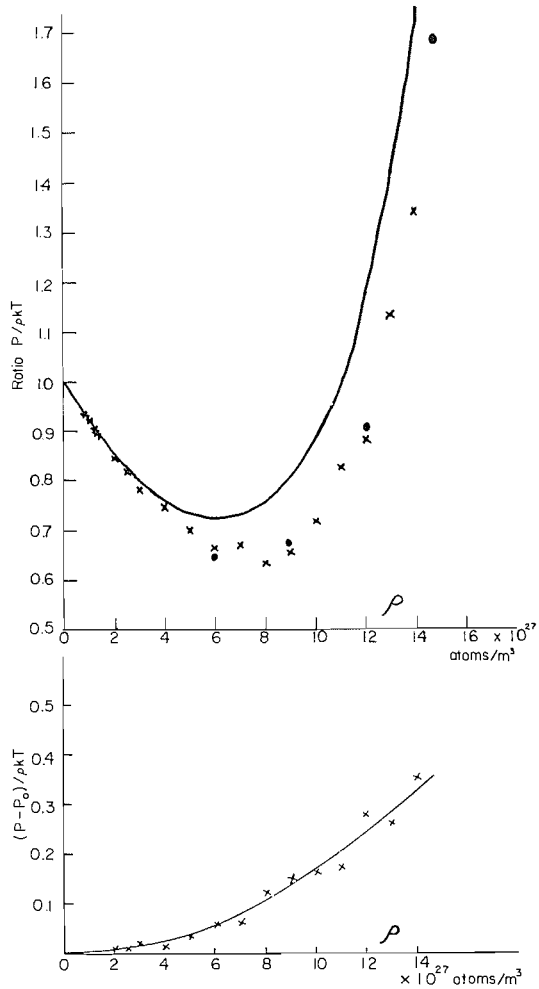

FIG. 1. (*a*) The experimental pressure for krypton on the room temperature isotherm (full line —) compared to the computer simulated pressure using the krypton pair potential (crosses ref. 10, circles ref. 8). (*b*) The difference (10) between the line and the crosses in (*a*) is shown as crosses here. The line is an extrapolation of the many-body force part of the third virial coefficient determined from low density data.

$\rho^3 C_2(T)$ term — eq. [1] — an extrapolation to higher densities would almost fit the difference data in Fig. 1*b*. This is shown by the full line in the figure. Later Egelstaff (11) noted that this result suggested that a mean-field theory of many-body effects might be successful, and proposed a zero order version of such a theory.

Van der Waals theory for the P.V.T. data of a fluid interacting with a pair potential has been reasonably successful, and consequently it might be expected that a generalized version involving the many-body forces could also work. In this case the reference system is the artificial pair theory fluid and the perturbation is a background term due to all the many-body forces taken together. Again the reference system properties can be evaluated only through extensive computer simulations. Thus in Fig. 1*a* the crosses show the simulated pair results having a marked curvature as a function of density, while in Fig. 1*b* the crosses show the total many-body effect with simpler density dependence. It is this greater simplicity, analogous to the simple behaviour proposed by Van der Waals for attractive pair forces, that suggests a mean-field theory might be successful. Also because many-body forces contribute only a maximum of about

30% of the total pressure, small defects in the theory may not have an important influence on the calculated total pressure. Egelstaff (ref. 11*a*, the theory is based on ref. 11*b*) presented a zero-order theory, which could be the starting point for a conventional perturbation expansion, although for the present we are interested in exploiting the zero-order theory.

This theory starts from the thermodynamic relationships used by Widom in his treatment of the Van der Waals model:

$$[2]\quad \rho \left.\frac{\partial \ln (z/z_0)}{\partial \beta}\right|_{\rho} = \rho \left.\frac{\partial (U - U_0)/v}{\partial \rho}\right|_{T} = \left.\frac{\partial \beta (P - P_0)}{\partial \beta}\right|_{\rho} + \frac{U - U_0}{V}$$

and

$$\rho \left.\frac{\partial \ln (z/z_0)}{\partial \rho}\right|_{T} = \left.\frac{\partial \beta (P - P_0)}{\partial \rho}\right|_{T}$$

where P, V, T, ρ, U, and z are the pressure, volume, temperature, density, energy, and fugacity, respectively, of the real fluid, and quantities with subscript zeroes are for the artificial pair fluid. These two fluids are related by the equation:

$$[3]\quad \psi_0 = \psi + c$$

where ψ is the potential seen by a test particle in the real fluid and c is a uniform background potential which "cancels" the effect of many-body forces. In this case it may be shown, following Widom, that:

$$[4]\quad \ln z/z_0 = -\beta c \text{ and } \frac{U - U_0}{V} = -\frac{\rho c}{\alpha}$$

where α is the order of many-body forces (α = 3, 4 etc). Further, we assume, for simplicity, that the background potential is proportional to a single power of density, and if it is also temperature independent it may be shown that this power is $\alpha - 1$. The above equations may then be solved to give:

$$[5]\quad P - P_0 = a\rho^{\alpha}$$
$$\frac{U - U_0}{V} = \frac{a\rho^{\alpha}}{\alpha - 1}$$

where a is a constant. If only weak long-ranged three-body forces are present it may be shown that:

$$[6]\quad a \simeq -\int\int u_3(\boldsymbol{r}\cdot\boldsymbol{s})\mathrm{d}\boldsymbol{r}\mathrm{d}\boldsymbol{s}$$

but, in general, the expression for a would be more complicated. Also while eq. [6] is independent of density and temperature, this may not be so generally. It may be possible to redefine the parameters a and α appearing in eq. [5] so that the density dependence in a (for example) is transferred to α, thus maintaining a as a constant. This question will be examined empirically. The constant a may be eliminated from eq. [5] to give:

$$[7]\quad \alpha = 1 + \frac{(P - P_0)V}{(U - U_0)}$$

and this equation may be used to calculate α from experimental and simulated data. Following the usual Van der Waals picture, we expect this treatment to work best at high temperature or high density.

3. Discussion of pressure and energy

It is useful to compare the above results to a computer simulation model, and the simplest case is to take a realistic pair potential (well depth ϵ at position r_m) and then add the Axilrod–Teller triple-dipole term (or A.T.) where

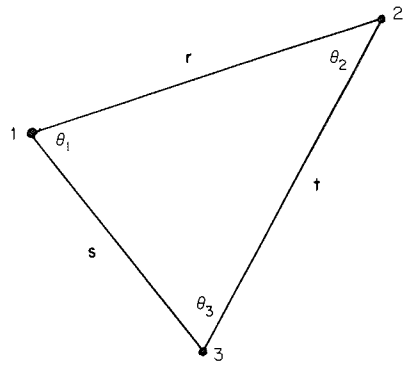

FIG. 2. Diagram showing the definition of angles (θ_1, θ_2, and θ_3) and vectors ($\boldsymbol{r}$, $\boldsymbol{s}$, $\boldsymbol{t}$) appearing in eq. [8].

$$[8]\quad \text{A.T.} = \frac{3C_6P}{4} \cdot \frac{3\cos\theta_1\cos\theta_2\cos\theta_3 + 1}{r^3s^3t^3}$$

The definitions of angular variables for three particles are shown in Fig. 2, and C_6 and P are the two-body r^{-6} coefficient and the atomic polarizability, respectively. The use of the product C_6P in this equation is an approximation, good to about ~4% for krypton and xenon. However, for the work discussed here this error is unimportant, and we point out this form to emphasize the interrelationship between pair potential and higher order potentials. This model of many-body forces is correct only for infinite separation between the particles and has been used widely in the literature for computer simulations and for other calculations. Three errors arise in computer simulations of this kind, statistical errors, errors due to the finite size of the system, and errors due to truncation of the potential model. Many papers do not report adequate details on either the simulation or the errors, and so we shall assume that "reasonable" comparisons will be valid in our context.

We begin by comparing the calculated density dependence of the model pressure of "argon" (at high density) with the predictions of eq. [5]. Loubeyre (6) has made "self consistent harmonic" calculations for solid noble gases using the above potential model. His results for "argon" are shown in Table 1*a*: the errors are not available. The number density is expressed in units of r_m^{-3}, where r_m is the position of the minimum in the pair potential. It can be seen that eq. [5] with α = 4 predicts accurately the variation of pressure with density. Presumably the fact that α = 4 rather than 3, arises because higher order terms are important and they can be incorporated simply into the index α. In other words, the zero-order theory can be extended in a simple way in this case (Apendix 2). To test this idea further we look at the temperature dependence at constant density. The density chosen is that for the triple point liquid or $\rho r_m^3 = 1.10$, and the pressure difference (for this density and $k_BT = 2.09\,\epsilon$) is also predicted in Table 1*a*.

Barker (8) performed the most extensive simulation of the pressure and energy for noble gas fluids using this model. He used a Monte Carlo method with 108 particles but did not give estimates of the errors. An approximate formula was used for pressure and energy and a truncation correction was applied. Levesque *et al* (13) also used this model for one state of xenon. They used a 108-particle system for an M.D. simulation, and corrected their results for truncation of the three-body potential. The range of truncation was the same as Barker's and was

related to box size and so varied with density. They reported errors on pressures and energies. These various features are common to simulations involving a three-body potential. A comparison between these two results is useful as widely different temperatures were used ($k_BT/\epsilon = 1.48$ in refs. 8, 9 and 0.62 in ref. 13), so that the temperature independence of eq. [5] may be tested. To obtain results from Barker's xenon data at the same density used by Levesque *et al.*, a small extrapolation is required. Since Barker's (8, 9) krypton and xenon calculations are for almost the same state (i.e. k_BT/ϵ and $k_BTr_m^9/C_6P$ are almost the same), this was accomplished using the krypton data as a guide because the maximum density exceeded the density required. The results are given in Table 1*b*, for comparisons with those from Table 1*a*. To convert from "argon" to "xenon" the data in Table 1*a* were scaled, following eq. [6], with the coefficient of the A–T potential.

The errors involved may be expected to exceed the temperature-dependent differences in this table, and so temperature independence is observed over a relatively wide range. The data also confirm the independence of a on state parameters, that is, its density and temperature independence are shown by Tables 1*a* and 1*b*, respectively. Moreover, the conversion from "argon" to "xenon" using eq. [6] supports the mean field approximation. Finally for the two "xenon" states the result for α, using eq. [7], is close to 4, in agreement with Table 1*a* and Appendix 2. Consequently, the model satisfies the mean-field approximation at high density provided the parameter α is adjusted. This empirical conclusion should be explored in greater detail with further calculations, including estimates of errors on $P - P_0$ and $U - U_0$.

The behavior of the test model at lower density may be examined using Barker's data (9); this is displayed in Table 2. The values in this table appear to increase with increasing

TABLE 2. Test of density independence of eq. [7] for A–T model

0.77	2.0	2.2
0.58	1.6	1.6

*$k_BT/\epsilon = 0.62$ (13); other cases $k_BT/\epsilon = 1.48$ (8, 9). Errors are not known. For $\rho \to 0$ the ratio listed (11) is $\lesssim 2$.

density. This is probably outside the statistical error (e.g. a 1% error in total energy would contribute an error of 0.3 to 0.4 in this table). Thus if it does not represent a density-dependent systematic error, the mean field is established only at the highest density. In the mean-field theory temperature independence (Table 1*b*) is inconsistent with the trend (with density) in Table 2. Other evidence (on the pair correlation function) suggests the mean-field theory works in principle for the A–T model, and hence it would be desirable to carry out a large scale simulation to reduce systematic errors. For a logical development of this field it is important to compare such simulations and the mean-field predictions accurately.

In order to compare the mean-field predictions with experimental results, we used simulation data which employed the "best" pair potential recommended by Aziz (1). Barker (8, 9) and Levesque *et al.* (13) used 108-particle systems and made truncation corrections, but Barker's errors are not known. Salacuse and Egelstaff (12) used a 256-particle system, made truncation corrections, and quoted statistical errors. Sources of experimental data were given by Barker (9) and Salacuse and Egelstaff (12), but to employ the simulations of Levesque *et al.* (13) we used the experimental results of Street and Sagan (14). All these data are summarized in Table 3. Column 4 shows the pressure change due to many-body effects, and is remarkably constant. Because of the uncertainty in the estimates of α in column 6, we have preferred to divide the data of columns 4 and 5 by $(\rho^*)^n$ (with $n = 2$ or 3), implying from eq. [5] that $\alpha \sim 3$ to 4. Thus the constancy of columns 4 and 5 is a demonstration of the constancy of the parameter a in eq. [5]. The average value in column 6 for α is 3.5. The fluctuations in column 5 are significant, and it is possible that a large part arises from errors in the simulations: the ratio U/U_0 is close to unity in several cases. This view is supported by the fact that the fluctuations in column 4 are less, and that the ratio P/P_0 is normally significantly different from unity. From column 4, one might conclude that $\alpha = 4$ is better than $\alpha = 3$, but clearly simulations of improved quality and known errors are required.

The range of data in Tables 1 and 2 for the model system could be encompassed within the experimental range exhibited in Table 3, after allowance has been made for likely errors. But this means that the model and real fluids behave in the same way to a first approximation (i.e. sufficient for the mean field theory), and more detailed studies are needed to understand how the real system behaves. Thus in an overall way, the mean field approach is supported by existing data on krypton and xenon and on the pair plus A.T. potential model. Only a few parameters are needed to describe the basic behaviour of the equation of state and energy. The order of magnitude of parameter a is given by

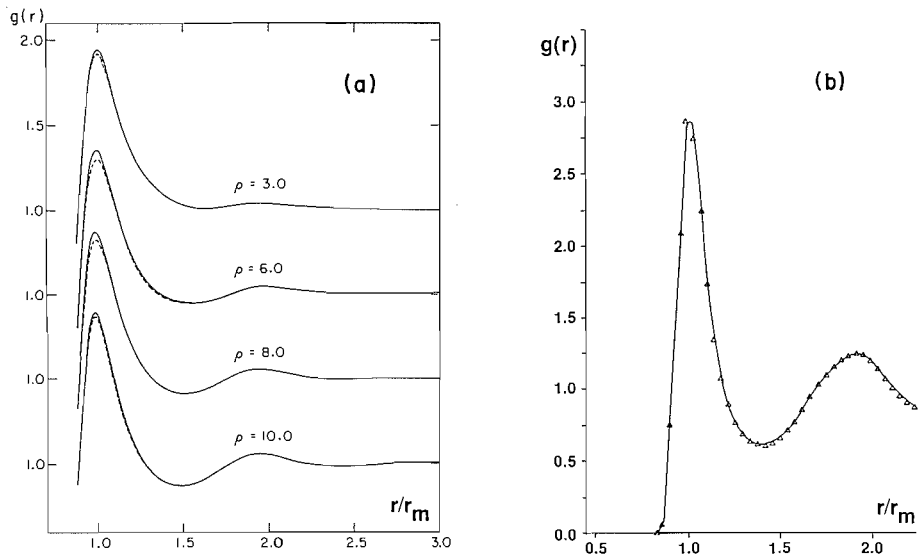

FIG. 3. (*a*) Examples (15) of pair distribution functions using a pair potential for krypton (full line) and those for the addition of eq. [8] to the potential (dashed line). Note the increase in the difference followed by a decrease with increasing density. (*b*) A similar case for the parameters of the triple point of xenon (13). The full line shows the simulation using the pair potential plus eq. [8], and the triangles show the result for the pair potential alone.

the 3rd virial coefficient of pressure, so that the fluids may find it easy to develop mean-field behaviour with increasing density. However, with bulk data of the present quality, exact conclusions cannot be drawn and we turn to microscopic data for more information.

4. The pair correlation function [$g(r)$]

If the mean field is uniform over the whole system, the pair correlation functions will be the same in both real and reference systems. However, if fluctuations in background potential are important, there will be differences on the scale of fluctuations. This may be seen in the low density virial expansion, where the integrand in eq. [1] may be thought of as representing a three-body collision effect. Thus at low density the two pair correlation functions will differ, and as the uniformity of the mean field is established with increasing density this difference should vanish. This matter may be examined through computer simulations involving a pair potential and a model three-body potential. The work of Egelstaff *et al.* (15) is a useful example: they compared simulated $g(r)$'s using the model described by eq. [8] and the krypton pair potential. They modeled krypton for number densities from 3 to 10 atoms/nm^3 (ρr_m^3 from 0.2 to 0.6) and a temperature of 297 K (or 1.48ϵ). Their results are shown in Fig. 3*a*. The principal difference due to adding eq. [8] to the pair potential occurs near the principal maximum in $g(r)$, that is, for atoms in contact. This arises from the strong distance dependence in eq. [8], and indicates that a significant contribution to calculated many-body effects can arise from short distances even when an expression only valid at infinite separations is employed! Thus any results derived from the A–T term have an "illogical aspect" because a significant part arises from a region where this formula is not valid. However, for our purpose eq. [8] may take the status of a "test model" rather than a valid theory. We refer to it as a test model below.

We can see from Fig. 3*a* that the effect at the peak $g(r)$ increases from 3 to 6 atoms/nm^3 and thereafter decreases. This

is expected qualitatively as density is increased in a mean-field picture and suggests that for densities of $\rho r_m^3 \sim 0.6$ the mean field works with eq. [8]. This is lower than suggested ($\rho r_m^3 \sim 1$) by the data in Tables 1 and 2, and may indicate that small differences (extended along the r-axis) exist between the two calculations for $0.6 < \rho r_m^3 < 1$. Small extended differences would be difficult to observe in the simulations of $g(r)$, but might be expected to occur at the onset of the mean-field behaviour. Similar calculations near the triple point of the Lennard–Jones fluid were reported by Hoheisel (16) ($\rho r_m^3 \simeq 1.17$ and $k_B T \simeq 0.83\epsilon$), who found no difference between the two $g(r)$'s. Recently Levesque *et al.* (13) have used a realistic potential for xenon near its triple point ($\rho r_m^3 \simeq 1.10$ and $k_B T \simeq 0.62\epsilon$) and again found no change in $g(r)$ when the A–T term is added. These results are shown in Fig. 3*b*, and confirm the deductions from Fig. 3*a*. The errors on simulated data are of the order of 2%, due to the difficulty of calculating the three-body case accurately. Thus, within this limit, the test A–T model behaves as a fluid satisfying the basic requirement of a mean-field system.

Two series of experiments on krypton have been reported in which the static structure factor, $S(Q)$ has been measured carefully for a number of densities at 297 K, where

$$[9] \quad S(Q) = 1 + \rho\int\{g(r) - 1\}(\exp - i\boldsymbol{Q}\cdot\boldsymbol{r})d\boldsymbol{r}$$

Teitsma and Egelstaff (3) measured densities ≤ 6 atoms/nm^3 ($\rho r_m^3 < 0.4$), and Fig. 4 is the summary of some of their data (circles) compared to their computer simulation and virial expansion calculations using a realistic pair potential (crosses). This is the region of densities where the effect in $g(r)$ (Fig. 3) is increasing, and we see that in Fourier space the corresponding effect increases with density. It is concentrated in the low Q region because relatively large distances in real space are needed to accommodate three or more particles. As $Q \rightarrow 0$ the integrated effect over all r in $g(r)$ is observed, and this is found to be approximately equal to that calculated from the A–T term (eq. [8]). Thus in addition to the change in the peak of $g(r)$ (Fig. 3*a*) there will be smaller changes spread along the r-axis, which are not seen in the simulations, but which accumulate in the Fourier space data. For densities ≥ 6 atoms/nm^3 ($\rho r_m^3 > 0.4$), Egelstaff *et al.* (17) report a series of measurements of $S(Q)$ extending to ~14 atoms/nm^3 ($\rho r_m^3 \sim 0.9$). In Fig. 5, some of their data are compared to the simulations given in ref. 15. If the mean-field picture was as successful for the real experimental fluid as for the test model, we would expect the effects shown in Fig. 4 to decrease when ρ increases (this was confirmed in the test model by Ram and Egelstaff (10)). In particular, the range of Q affected should decrease. However, in Fig. 5 some differences extend up to $Q \simeq 1$ Å^{-1} and beyond, and in contrast to the discussion of the previous section there is no indication that they vanish for $\rho r_m^3 \sim 1$.

We shall examine the experimental position of the principal peak in $S(Q)$ compared to the prediction from simulations. It appears to shift to lower Q, especially for $\rho \simeq 14$ atoms/nm^3. This would be in accord with the change in diameter suggested by the collision picture given in the Introduction, and is outside the scope of both the mean-field theory and the test model simulations. A recent paper by Fredrikze (18) on krypton at 200 and 220 K reports larger shifts of the same type. In addition A. Teitsma (unpublished results, 1980) measured four high density states of xenon at 297 K, and his peak positions are shifted relative to the simulations too. It is convenient to plot the peak positions from these three experiments in one figure, compared to the simulated positions. This is done in Fig. 6:

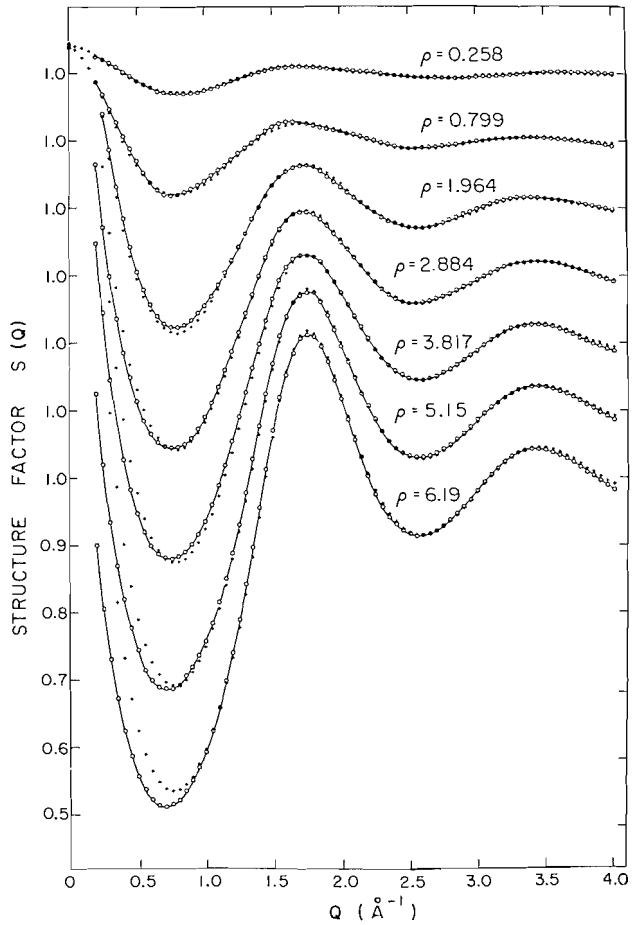

FIG. 4. Experimental structure factors (3) (eq. [9]) at 297 K for several krypton densities (in units of atoms/nm^3) shown by the circles and lines, compared to calculations (15) based on the pair potential alone (crosses).

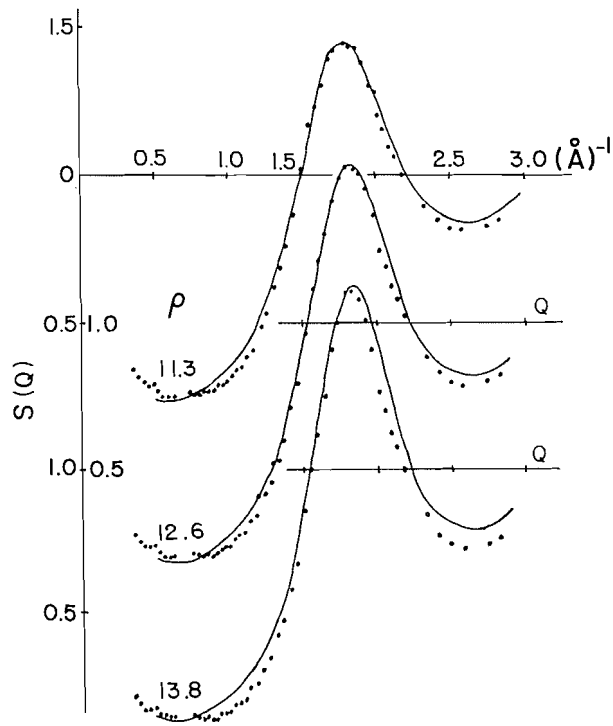

FIG. 5. Experimental structure factors (17) ($S(Q)$-eq. [9]) for krypton on the 297 isotherm, shown by circles, and compared to comptuer simulations (15) shown by the lines.

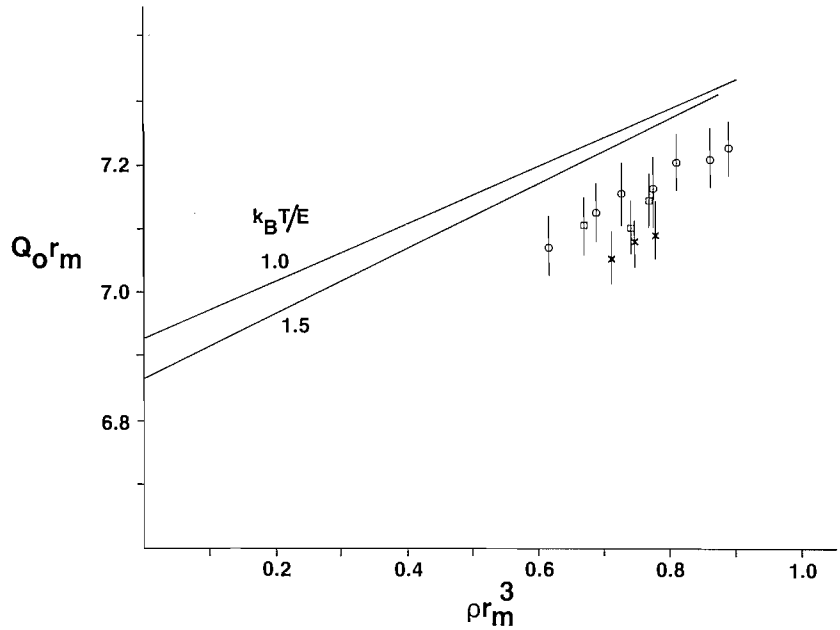

FIG. 6. A summary of the principal peak position, Q_0, in $S(Q)$ as a function of density. The full lines are predictions for $k_BT/\epsilon = 1.0$ and 1.5. The circles, crosses, and squares are experimental results from refs. 17 and 18 and A. Teitsma (1980, unpublished results) for krypton at 297 K, krypton at 200 K, and xenon at 297 K, respectively. Through eq. [9] this peak shift corresponds to a larger diameter in the real fluid than in the model.

where the lines show data from virial coefficient calculations at low ρ and computer simulations using a pair potential at high ρ. Because of the above discussion, the model calculations (10), and computer simulations using the A–T potential model, it is expected that these lines would be unchanged if the A–T potential were added. There is a small shift of the line with temperature ($k_BT/\epsilon = 1.5$ to 1.0), but this is relatively unimportant. All experimental results cluster together at lower peak positions than predicted, thus confirming (through the relationship between $S(Q)$ and $g(r)$) that an effect analogous to a change in effective diameter with increasing density has been observed. If this is due to the collision effect described in the Introduction, it could be modeled by the "shell model" for heavy atoms used in lattice dynamics (Appendix 1). In this event one would expect that the dynamics would be affected also if the appropriate frequencies and wave numbers could be observed. Simulations (19, 20) using the shell model have been made for ionic liquids, and suggest that the effects of the right order of magnitude would be found in noble gas simulations with similar shell constants.

To demonstrate the deviation of the data from the A–T potential test model (eq. [8]) in greater detail, we plot the data from refs. 3 and 17 in the form proposed by Teitsma and Egelstaff (3). Their proposal is to take the difference in direct correlation functions, $c(Q)$, where:

$$[10] \quad c(Q) = \frac{1}{\rho}\left\{1 - \frac{1}{S(Q)}\right\}$$

When considered as a function of density (ρ), the difference between $c(Q)$ for the computer simulation and the experimental result should start from the origin (for $\rho \rightarrow 0$) and initially vary as ρ. The coefficient of ρ may be calculated from the integrand in eq. [1]. In some theoretical papers (e.g. refs. 21, 22) it is noted that on the scale of Fig. 4, the test model will appear to fit the experimental data. However, if the quality of the experimental and simulated data is such as to allow the difference in $c(Q)$'s to be taken, the test model can be examined more severely than by comparing $S(Q)$'s.

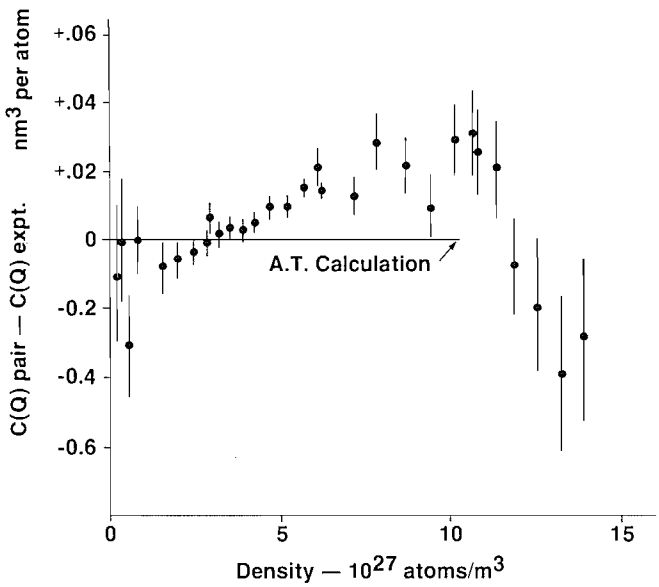

FIG. 7. A difference plot of the kind used in ref. 3. The experimental $c(Q)$ — eq. [10] — and simulated $c(Q)$ are subtracted using the results (3, 17) from Figs. 4 and 5, and plotted as a function of density for $Q = 0.6$ Å^{-1}. The errors increase towards low densities because of the ρ^{-1} factor in eq. [10]. The line shows the prediction (15) using data for the potential at eq. [8] in place of the experimental data.

As an example we show in Fig. 7 the difference in direct correlation functions for $Q = 0.6$ Å^{-1}. At this Q the test model term almost vanishes (i.e. $Q = 0.6$ is a node, if the $c(Q)$ difference is plotted as a function of Q). It can be seen that there is a marked difference between the model result and the experimental result, indicating that the model fails at all densities.

Also the mean field is seen to be inadequate as the difference data should lie along the $\Delta c(Q) = 0$ axis at higher densities. In addition, this difference is a severe test of the pair potential employed in the simulation. If $u(r)$ is correct in detail, the data should vanish as $\rho \rightarrow 0$ for all Q. It can be seen that this is improbable at $Q = 0.6$ Å^{-1} in Fig. 7. These discrepancies at all Q have been summarized in Fig. 6 of ref. 15 (for the pair potential) and Fig. 8 of ref. 3 (for the three-body potential). The advantages of measuring $S(Q)$ are that there is an internal check on the adequacy of the published pair potentials, and that the test of many-body potential models and of mean field behaviour is both detailed and severe. It is to be expected that the power of this method can be improved using techniques developed in recent years (23).

It thus appears that the test model exhibits good mean-field behaviour and describes bulk data quite well, but that at higher densities the real fluid deviates from both the model and the mean-field picture if examined in appropriate detail. On the other hand, the work of Teitsma and Egelstaff (3) shows that the A–T model (eq. [8]) does yield the right scale for these effects, even though the detail (in Fig. 7 for example) is incorrect. It would appear therefore that two theoretical improvements are required. The first would be an improved three-body potential which would give the correct slopes at low ρ in (for example) Fig. 7. The second would be improved models of the many-body potential short range effects (4) which lie outside the mean field approximation.

5. Non-equilibrium properties

For reasons discussed for the pair correlation function, these properties should be unaltered by the mean field. The transport coefficients for the pair fluid and the test model (eq. 8) have been examined in a number of papers. In the high density work of Hoheisel (16) on an argon model and of Levesque *et al.* (13) on a xenon model, a system of 108 particles near the triple point was examined. Because these systems are small, the time over which valid data may be collected is small. If this time is chosen conservatively to be the time for a sound wave to cross half the width of the box, we obtain $t \leq 1$ ps in Hoheisel's case and $t \leq 1.6$ ps in Levesque *et al.*'s case. In the former example, time integrals extending to more than 2.5 ps were used, and in the latter case time integrals extending to more than 5 ps were used. Levesque *et al.* (13) reported finding no difference in the three collective transport coefficients (shear and bulk viscosity and thermal conductivity) within an error of 5–10%. Their data are listed in Table 4. Hoheisel (16) reported that self-diffusion coefficient was nearly unchanged, but concluded a small difference of ~5% occurred. This arose from parts of the time integral for $t > 1$ ps.

Both papers report data on time correlation functions. Levesque *et al.* (13) show that the stress–stress and energy–energy correlation functions are the same (within error) to 5 ps, while Hoheisel (16) reports the velocity auto-correlation function (VAF) is the same for times < 1 ps, but some differences are seen in the tail beyond 1 ps. For his cases Hoheisel computes the change in the VAF over argon densities of 20–23 atoms/nm^3, and finds smaller changes with increasing ρ. The van Hove space–time correlation function $G(r,t)$ is also discussed in these papers. Again Levesque *et al.* (13) find no effect (within the errors) for $0.31 < Q < 2.43$ Å^{-1} and $t < 5$ ps, when plotting the intermediate scattering function (or space Fourier transform of $G(r,t)$). Hoheisel (16) finds no change in $G(r,t)$ itself for times ~ 1 ps, but a small change for times ~ 2.5 ps. Within the probable limits of these two 108-particle simulations, it may be concluded that the mean-field picture is working satisfactorily. Therefore for all properties, static and dynamic, microscopic or bulk, the test model behaves approximately like a mean-field model at high enough densities.

TABLE 4. Theoretical transport coefficients for xenon at 176 K and 13.2 atoms/nm^3 from ref. 13

Coefficient	Pair potential	Pair + A–T potential
Shear viscosity (m Pa s)	0.40±0.03	0.41±0.03
Bulk viscosity (m Pa s)	0.30±0.03	0.31±0.04
Thermal conductivity (W K^{-1} m^{-1})	0.068±0.004	0.064±0.003

Simulations at lower densities have been carried out by Schommers (22), using the krypton pair potential and the test model (A–T potential). He used densities of 2.9 and 6.2 atoms/nm^3 at 297 K. For the velocity auto-correlation function at 2.9 atoms/nm^3 he found a slower decay for the pair fluid than that for the pair plus A–T potential case. However, this effect virtually disappeared at 6.2 atoms/nm^3. He also studied the force–force correlation function and for the lower density observed a difference near $t \sim 1$ ps, which virtually disappeared at the higher density. If we interpret this as the onset of mean-field behaviour, it has appeared at a similar density in both dynamic and static results. It is likely, however, that for all the above simulations (13, 15, 16, 22) more extensive calculations with larger systems are necessary to improve and confirm the data.

The dynamic structure factor (space and time Fourier transform of $G(r,t)$) has been measured by Egelstaff *et al.* (17), for a number of densities along the room temperature isotherm of krypton. Their highest density was 13.8 atoms/nm^3 or $\rho r_m^3 = 0.9$ (compared to the triple point density of 17 atoms/nm^3 for krypton). For this case Salacuse *et al.* (24) made computer simulations using realistic pair potentials, and compared their results to the experimental ones. Their data at lower values of Q (which are of interest in our case) are shown in Fig. 8, where the dynamic structure factor, $S(Q,\omega)$, is plotted as a function of ω for fixed Q. When $Q \simeq 1.8$ Å^{-1}, which is the maximum of the static structure factor, Fig. 5, there is good agreement. In this case we expect the collisions of two atoms to dominate in $S(Q,\omega)$. However, if Q is decreased from this value, increasing discrepancies between simulation and experiment are observed. For $Q < 1$ Å^{-1}, more than two particles can be seen and the width of $S(Q,\omega)$ is less in the real fluid than in the artificial simulated fluid. This implies that many-body effects slow down the motions at the atomic level. Levesque *et al.* (13) showed that $S(Q,\omega)$ for the A–T potential test model and the pair potential model are the same within simulation errors. Consequently the mean-field approximation is less satisfactory for the real fluid than for the A–T potential test model.

It is interesting that Levesque *et al.* (13) also made test model simulations (of 108 particles) for a system at the same pressure as the pair system (this required a 10% increase in the density). In this case the computed changes in $S(Q,\omega)$ are similar to those seen in Fig. 8, namely, that the atomic motions are slowed down relative to the lower density case and collective modes extend to higher Q. However, in the constant pressure simulation this would appear to be an expected result due to an increase in

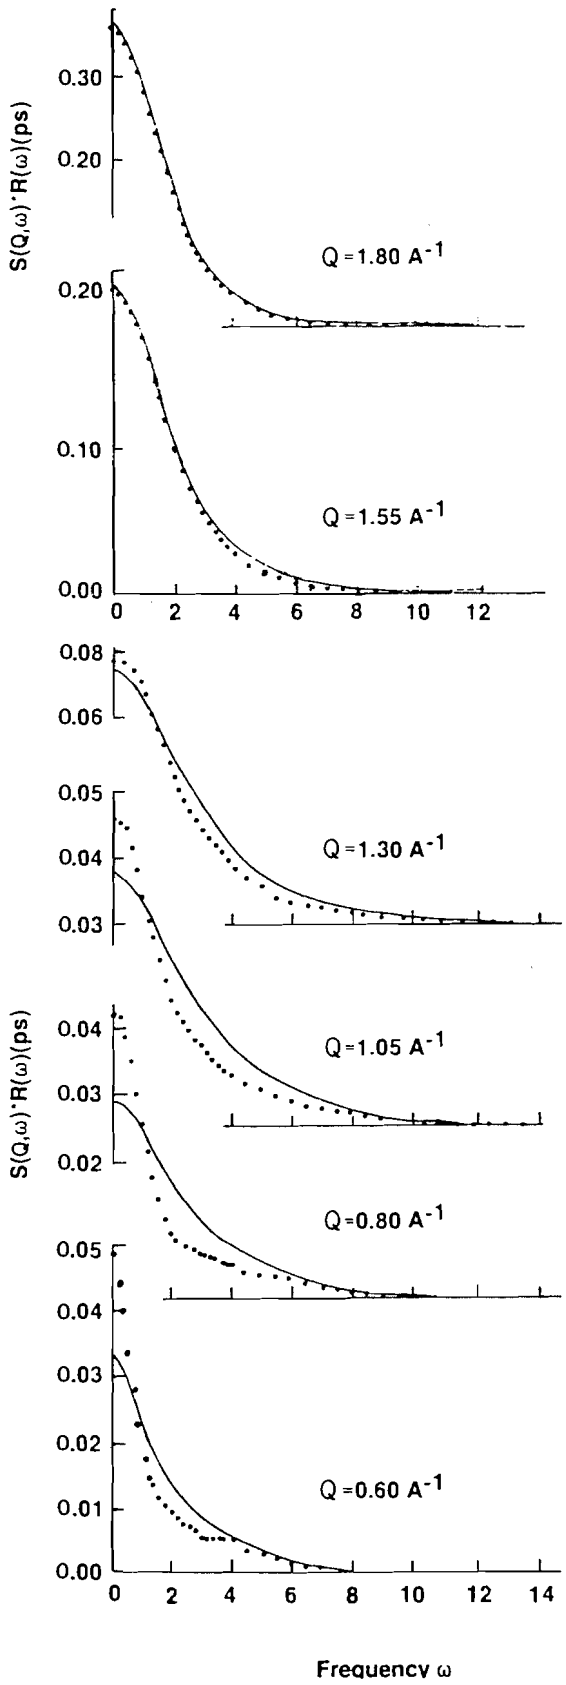

FIG. 8. The dynamic structure factor $S(Q,\omega)$ compared to computer simulated results (24) using the pair potential only. The data are from ref. 17 and $R(\omega)$ is the instrumental resolution function. Circles are the experimental data and the lines are the simulation.

density, whereas in the real substance the many-body forces mimic this higher density effect on a local scale, presumably through an increase in the effective atomic diameter. It is interesting that the same effect would lead to a sharper principal peak in the static structure factor, and this seems to be observed in the data of Fig. 5. These results thus correlate with the position shifts in $g(r)$ and $S(Q)$ which were discussed earlier.

6. Discussion

As pointed out in the Introduction, it is important to consider a range of properties, to understand the information content of each property, and to appreciate the significance of errors in both experimental and simulated data. Otherwise oversimplified conclusions will be reached, as in the case of Barker's conclusions (7–9 using the A–T model where insufficient attention was paid to each of these three issues. Nevertheless, the simple model in which all many-body forces are replaced by the Axilrod–Teller triple-dipole term only gets some of the overall picture right. Thus it alone can establish the scale parameters, i.e. effective distance and well depth parameters, which determine approximate values of integrals such as eqs. [1] or [6]. But on close examination it fails to reproduce much of the detail required from a model (e.g. Figs. 7 and 8) which would also cover the microscopic data. A partial explanation of this phenomenon has been given in various theoretical papers (e.g. ref. 4), but more work is needed to explain it properly especially on the various short range many-body forces.

The predictions of a zero-order mean field model were compared to the published results for the pair potential plus A–T three-body potential model of a fluid, and the index α, representing the order of the many-body forces, was adjusted to fit the data. For high densities it was found that the fluid behaved as a mean-field system with $\alpha = 4$, and that the mean-field behaviour was developed gradually over a range of densities extending up to $\rho r_m^3 = 1$. These empirical observations require further theoretical work to understand their origin properly (Appendix 2).

The picture being presented here is that the minimum number of many-body effects required to explain the data is three: namely, terms arising at large separations and expressed through a multipole expansion, an effect due to deformable outer shells which has been given a simple physical representation as an increase in effective diameter with increasing density and arising from multiple collisions, and a short range exchange effect (6). All three effects are important in the study of the pressure of noble gas fluids and solids. At low pressures the multipole terms give the mean effect because the other two appear to cancel each other approximately. It should be remembered that this cancellation refers to $Q \rightarrow 0$ static properties only (see Figs. 7 and 8), and also that all three effects will contribute to the pair potential. Thus for many-body forces the individual contributions depend in part on the parameters of the pair force (eq. [8] is an example of an approximate relation). The most plausible explanations for any near cancellation of effects might lie either in this connection or in the relationships between all the short range forces.

At intermediate pressures it is possible that all three effects matter. For example, Loubeyre (6) shows that for krypton at 300 K and 27 atoms/nm^3 ($\rho r_m^3 \sim 1.7$), the pair potential alone contributes about 95% of the observed pressure (about 2 GPa), the A–T term adds about 5%, while the exchange term subtracts about 15%. At higher pressures (e.g. 20 GPa) the experimental pressure is only 7% higher than that obtained after the A–T and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

exchange terms have been applied. However, Barker (8, 9) points out that if the core of the Aziz (1) potential is adjusted by a reasonable amount (i.e. P_0 is adjusted), the A–T model (eq. [8]) will fit the experimental pressure difference ($P - P_0$) up to 50 GPa. Both Barker (8, 9) and Loubeyre (6) report calculations at high pressures using this model, and these calculations may be compared to the predictions of the mean-field model using eq. [5] and the data in Table 1*b* for parameter *a*. On the scale of their figures the prediction, for densities up to three times greater than that in Table 1*b*, is in reasonable agreement with their calculations. This confirms the similarity of the A–T model to a mean-field model up to high pressures and that essentially no new information can be obtained from the pressure data alone.

The argument that exchange interactions are important rests partly on the helium data (6) and their scaling to heavier noble gases, partly on other solid state data and partly on theoretical arguments. If the importance of the exchange terms has been established in one experimental regime, it is a matter of calculation to discover their importance in another part of the phase diagram, and hence establish that the known A–T and exchange terms taken together do not fit the bulk data on fluids over the states reviewed here. There is thus room for the "shell-model" contribution suggested by the diffraction experiments, and calculations of its contribution to the pressure (for example) are needed.

Because the mean-field model works reasonably well for the bulk data, such data can be represented by a few parameters involving the scale of these effects. Consequently bulk data are insensitive to the details of many-body potentials, and if the mean-field model was as successful for the microscopic properties, very little could be concluded about the details of many-body forces. Thus it is useful to concentrate on measuring and exploring the detailed effects appearing in microscopic properties, even though the experiments are difficult (23). The structure factor (or pair correlation function) is the most useful and definitive quantity in this field; it can provide clear cut answers to a number of questions. One reason that microscopic properties are more sensitive is because the distance and time parameters may be adjusted to enhance the effect sought.

For studies in $g(r)$ and $S(Q)$ at high pressure where $Q \neq 0$, the change in effective diameter is the dominant effect. Work reviewed here has demonstrated that the multipole effects are unimportant (10) in $S(Q)$, while Reatto[2] has studied the effect of terms similar to those used by Loubeyre (6) and demonstrated that they produce a negligible effect in $S(Q)$. Thus the pair correlation function at high pressure is sensitive to a different effect than the principal ones which influence the pressure. This result demonstrates the importance of analysing the information content of each piece of data. In this article this was achieved partly by comparisons to the mean-field model and partly by comparison to computer simulations. The extension of this approach using other models and other data, particularly data on molecular clusters (25), would be useful.

The reason that the A–T potential test model behaves like a mean-field model in all properties may be seen by examining eq. [1]. A mean field works for long range low amplitude potentials, so why is eq. [8] cut off before the potential reaches a large amplitude at low r? In eq. [1], and all similar equations, the hard core of the pair potential switches off the three-body potential. Except for very low temperatures (where the liquid freezes), this cut-off occurs before the A–T term has a large enough amplitude to destroy its mean field behaviour. Because correlation functions of real systems behave differently (Figs. 6 and 7), it appears that the real many-body potentials have some large amplitude components for distances comparable to or greater than the pair potential cut-off. For $g(r)$ at high pressure these may be represented pictorially as an increase in effective diameter. A more detailed examination of experimental data, more precise experiments, and large scale simulations are required before such effects can be understood properly.

Appendix

1. A simple model to illustrate the change of effective diameter with density in a fluid made of deformable particles

We consider two fluids. One is a simple hard sphere fluid made of spheres of diameter d and mass m. The other consists of deformable particles of mass m; but each particle is made of a massless rigid spherical shell of diameter d and a hard sphere of diameter $d' < d$ located inside the shell and attached to it with springs. Thus under suitable conditions the centre of the shell may be displaced relative to the centre of the interior sphere.

Now we compare the pair potentials for these two fluids. The first case is just the hard sphere potential. The second case differs from this in that the pair potential looks like a soft sphere for distances between d and d'. In fact, if we define an effective diameter d'' by any reasonable formula, we shall find $d' < d'' < d$. The diameter d'' determines the position of the principal peak in $S(Q)$, according to eq. [9]. Thus at low densities the peak positions (Q_{01} and Q_{02}, respectively) of the two fluids differ, with the second fluid having a higher peak position than the first. Roughly we shall have

$$Q_{01}d \approx Q_{02}d''$$

Now consider the situation for a close-packed density, and a temperature such that the normal modes of the springs are not excited. Both fluids will exhibit the pair correlation function for a simple hard sphere fluid of diameter d, because in the second system the shell will not be free to move relative to the inner sphere except for a large scale cooperative motion of the particles. Thus the peaks of the two functions $S(Q)$ will be in the same position for the two fluids (i.e. at Q_{03}).

Now compare the low density case to the high density case for the second fluid using the simple hard sphere fluid as a reference. The usual practice in this field is to begin by scaling the low density results, and then to use the same scaling factor at high density. This would yield the result:

$$Q_{03}d > Q_{03}d''$$

or the peak in $S(Q)$ for the deformable particles will appear to move to lower Q with increasing density relative to a hard sphere system of diameter d''.

It is clear from the above discussion that this effect is a short range *many* body effect. It would be useful to perform computer simulations for this model.

2. Alternative derivation of eqs. [5] and [6], with an alternative interpretation of the index α

Our purpose is to derive eqs. [5] and [6] from the conventional liquid theory expressions for pressure and energy

$$P - P_0 = -\frac{\rho^2}{6}\int r\,\frac{\partial u_2}{\partial r}\,[g_2(r) - g_2^0(r)]\mathbf{dr} - \frac{\rho^3}{6}\int r\,\frac{\partial u_3}{\partial r}\,g_3(\mathbf{r}, \mathbf{s})\mathbf{dsdr}$$

$$\frac{U - U_0}{V} = \frac{\rho^2}{2}\int u_2[g_2(r) - g_2^0(r)]\mathbf{dr} + \frac{\rho^3}{6}\int u_3 g_3(\mathbf{r}, \mathbf{s})\mathbf{dsdr}$$

where $g_2^0(r)$ is the pair correlation function when $u_3 = 0$. We shall assume (*i*) that $g_2(r) \simeq g_2^0(r)$, such that the terms involving u_2 are negligible compared to those in u_3 and (*ii*) that the state dependence of g_3 is unimportant over the range of (**r**, **s**) important to these integrands, and (*iii*) that $u_3 \sim r^{-n}s^{-n}t^{-n}$ over the range important to these integrands. Then we can reduce these equations to the form of eq. [5]. To do this we define a constant a as:

$$a \simeq \frac{n}{6N^{n-2}}\int u_3 V^n g_3(\mathbf{r}, \mathbf{s})\,\frac{\mathbf{dr}}{V}\,\frac{\mathbf{ds}}{V}$$

so we obtain

$$[5'] \quad \frac{U - U_0}{V} \simeq \frac{a\rho^{n+1}}{n} \quad \text{and} \quad P - P_0 \simeq a\rho^{n+1}$$

For a to be a constant we need to work in a regime where the "uniform fluid model" is applicable, so that all distances scale as $V^{1/3}$.

If all the above conditions apply, this model has all the properties of the mean-field model with $\alpha = n + 1$, and n is the inverse power appearing in the model for u_3. For the Axilrod–Teller potential $\alpha = 4$. It is also possible to show that $\alpha = 3$ when $u_3 \sim e^{-\gamma(r+s+t)}$ and $\gamma \to 0$, to give the usual mean-field result.

It would be helpful to examine the four conditions on which [5'] is based, and to calculate how the fluid approaches this limit.

The infrared multiphoton dissociation of hexafluoroethane

CARL E. BROWN AND DONALD R. SMITH
Department of Chemistry, McMaster University, 1280 Main Street West, Hamilton, Ont., Canada L8S 4K1

Received August 25, 1987

This paper is dedicated to Professor J. A. Morrison

CARL E. BROWN and DONALD R. SMITH. The infrared multiphoton dissociation of hexafluoroethane. Can. J. Chem. **66**, 609 (1988).

The infrared multiphoton dissociation (IRMPD) of "neat" hexafluoroethane has been investigated for the first time. The stable products of photolysis are CF_4, C_2F_4, C_3F_8, and C_4F_{10}. Product analysis involved tunable diode laser (TDL) and fourier transform infrared spectroscopy, as well as gas chromatography where applicable. The high sensitivity and resolution of the TDL allows for measurement of the stable products CF_4 and C_2F_4 after irradiation by a single infrared laser pulse. The yield of $\cdot CF_3$ radicals produced by the IRMPD of C_2F_6 as a function of fluence was measured via the TDL high frequency modulation technique. The role of added H_2, leading to elimination of CF_4 and increase of C_2F_4 as products, is clarified.

CARL E. BROWN et DONALD R. SMITH. The infrared multiphoton dissociation of hexafluoroethane. Can. J. Chem. **66**, 609 (1988).

On a étudié pour la première fois la dissociation multiphotonique infrarouge (DMPIR) de l'hexafluoroéthane à l'état pur. Les produits stables de la photolyse sont le CF_4, le C_2F_4, le C_3F_8 et le C_4F_{10}. Dans les cas où ces techniques pouvaient être appliquées pour l'analyse des produits, on a utilisé un laser à diode ajustable (LDA), la spectroscopie infrarouge par transformation de fourier ainsi que la chromatographie en phase gazeuse. La sensibilité élevée et la grande résolution du LDA permettent de mesurer les produits stables, comme le CF_4 et le C_2F_4, après une irradiation par une seule pulsation du laser infrarouge. On a utilisé la technique de modulation de la haute fréquence du LDA pour mesurer le rendement en radicaux $\cdot CF_3$ produits par DMPIR du C_2F_6, en fonction de la fluidité. On a éclairci le rôle du H_2 ajouté sur l'élimination de CF_4 et l'augmentation du C_2F_4, comme produits de la réaction.

[Traduit par la revue]

Introduction

In earlier work Fisk (1) reported C_2F_4 and CHF_3 as the products of the infrared multiphoton dissociation (IRMPD) of hexafluoroethane in the presence of H_2 or C_6H_{14}. Several years later Arai *et al.* (2) studied the IRMPD of hexafluoroethane in the presence of Br_2, the results of their experiments indicated that the major reaction products were CF_3Br and CF_2Br_2. Our exploratory work on the IRMPD of "neat" hexafluoroethane showed that CF_4 was the major photolysis product, with lesser amounts of C_2F_4, C_3F_8, and C_4F_{10}. Thermodynamically, the most favourable dissociation pathway of C_2F_6 leads to the production of CF_4 and $:CF_2$. However, shock tube studies (3) suggest that this pathway possesses a large energy barrier. The next most favourable pathway is the result of C—C bond scission forming two $\cdot CF_3$ radicals, reaction [2]. Presumably the pre-exponential factor favours reaction [2] as well, since it only involves C—C bond breakage.

[1] $C_2F_6 \rightarrow CF_4 + :CF_2$ $\quad \Delta H_0 = +225.94$ kJ/mol

[2] $\rightarrow 2\cdot CF_3$ $\quad \Delta H_0 = +400.83$ kJ/mol

[3] $\rightarrow \cdot C_2F_5 + \cdot F$ $\quad \Delta H_0 = +512.96$ kJ/mol

[4] $\rightarrow C_2F_4 + F_2$ $\quad \Delta H_0 = +680.32$ kJ/mol

In view of the uncertainty in the dominant reaction channel, and major discrepancy between our work and the literature, we initiated a programme to determine the overall mechanism of IRMPD of hexafluoroethane.

C_2F_6 was subjected to CO_2 laser pulses ≈ 30 cm^{-1} to the low frequency side of its ν_5 absorption band (see Fig. 1). Efficient IRMPD of C_2F_6 was found to occur at relatively low fluences. The major products of photolysis are CF_4, C_2F_4, C_3F_8, and C_4F_{10}. A reaction mechanism involving the production of trifluoromethyl radicals followed by abstraction and radical recombination reactions will be presented. It will be shown that secondary photolysis of $\cdot CF_3$ radicals during the laser pulse is the source of C_2F_4.

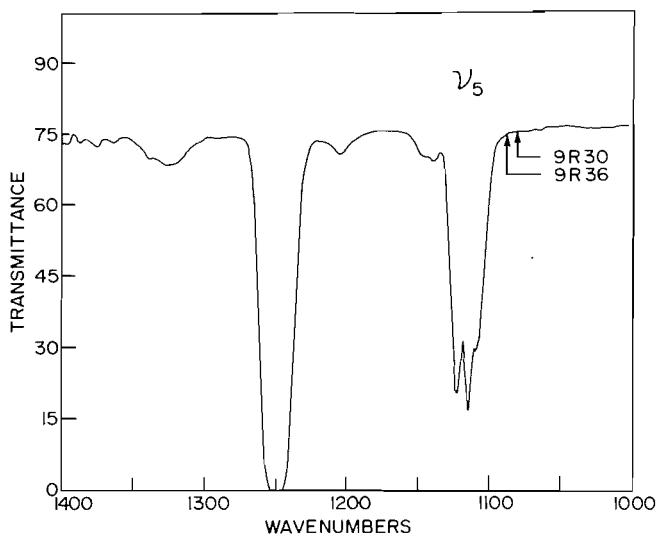

FIG. 1. FTIR spectrum of 2.1 Torr C_2F_6 in a 10 cm long Pyrex cell, 4 cm^{-1} resolution, indicating the CO_2 laser pump lines used in irradiation.

Experimental

Irradiations were performed on 2 Torr samples of C_2F_6 in 10 cm long, 2.5 cm diameter Pyrex or Monel cells equipped with sodium chloride windows, using a Lumonics K-922S pulsed CO_2 laser. The CO_2 laser pulse was focussed with a 25 cm focal length BaF_2 lens. The focal fluence was calculated from the measured focal burn spot area on thermal paper and the pulse energy as measured on a Gentec model ED-500 Joulemeter. The energy of the incident laser pulse was attenuated by a series of polyethylene sheets as necessary, to obtain the desired pulse energy and hence the desired fluence. The stable products

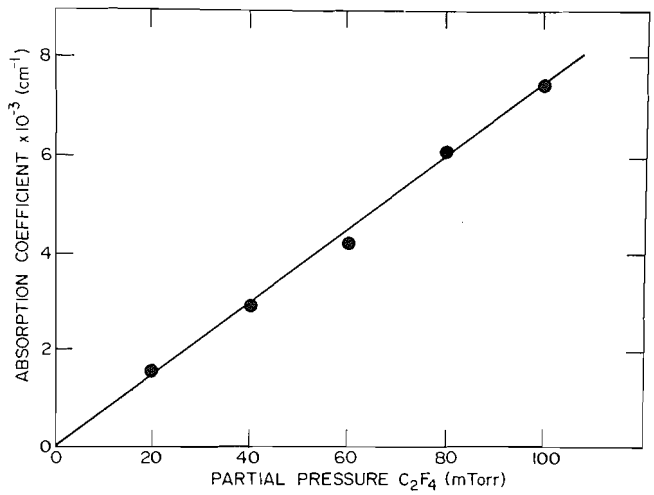

FIG. 2. Line center absorption coefficient (α_0) vs. partial pressure C_2F_4 (mTorr in C_2F_6, 2 Torr total pressure), measured by TDL absorption spectroscopy at 1196.7 cm^{-1}.

were measured following irradiation using a gas chromatograph (GC) and a tunable diode laser (TDL) spectrometer where applicable. The gas chromatograph employed was a Varian Model 3700 equipped with a flame ionization detector, and a 6 foot long Porapak Q 50-80 column. The TDL spectrometer utilises a Spectra Physics Lead-salt diode capable of tuning between 1080 and 1280 cm^{-1}. Both direct absorption and second-harmonic detection of the products are possible. The general concepts and techniques of TDL absorption measurement can be found in ref. 4. For direct measurement of absorbance, Beer's law ($I = I_0 \exp(-\alpha_0 L)$) calibration plots of absorption coefficient vs. partial pressure of the gas were made. In all cases, these plots were linear over the range of partial pressures involved in our studies. For example, Fig. 2 illustrates absorption coefficient versus partial pressure for C_2F_4. Plots involving CF_4 and CHF_3 are also linear over the range studied.

Second harmonic ($2f$) detection is used for high sensitivity work when measurement of less than 1% line centre absorption is required. The TDL frequency is modulated at a few kHz by modulating the diode current. Synchronous detection at twice the modulation frequency, using a lock-in amplifier, achieves a major reduction in background noise. Quantification of the photolysis products was done by comparison of the $2f$ signal strength to that of a standard sample containing a known and comparable amount of the fluorocarbon being measured. CF_4, C_2F_4, and CHF_3 are measured by TDL spectroscopy. C_2F_4, C_3F_8, and C_4F_{10} are measured by gas chromatography. Product identities were verified by Fourier Transform Infrared (FTIR) and quadrupole mass spectrometry in addition to TDL and GC detection.

A description of the apparatus used in the detection of transient species such as trifluoromethyl radicals can be found in ref. 5. Briefly, the precursor C_2F_6 is flowed through a 1 mm diameter 15 cm long waveguide cell and is irradiated by a focussed beam (25 cm focal length lens, ≈0.25 J/pulse) from a Lumonics TEA-801A CO_2 laser. The TDL beam also passes colinearly through the waveguide cell before falling upon a fast (risetime with preamp ≈400 ns) HgCdTe detector. Between the waveguide cell and the detector, a diffraction grating and gas cell are used to separate the intense TEA CO_2 beam from the TDL beam.

To obtain the time-resolved $^{\cdot}CF_3$ absorption spectra the TDL is repeatedly tuned in wavelength back and forth across the expected position of a $^{\cdot}CF_3$ absorption line by modulating the TDL current at 40 kHz. The transient changes in TDL power transmitted by the sample cell are measured by the detector. Successive data sets are collected and averaged on a Tektronics 468 digital oscilloscope and then stored on an IBM-PC microcomputer. The start of each set is synchronized with the CO_2 laser pulse. Background scans of the precursor C_2F_6, obtained with the CO_2 laser beam blocked, can be stored for subtraction of any stable precursor lines. Electrical noise associated with the CO_2 laser pulse prevents the accurate measurement of any absorption signals for approximately 25 μs following the pulse. Elimination of the early noise from the CO_2 laser would allow modulation at frequencies up to 250 kHz and the study of temporal behaviour with a resolution of 2 μs.

C_2F_4, C_4F_{10}, and CF_3I were obtained from SCM Chemicals of Florida, CF_4, CHF_3, and H_2 from Canada Liquid Air Ltd., C_3F_8, $(CF_3)_2CO$, and C_2F_6 from Matheson Gas Products of Canada Ltd. All fluorocarbons were degassed and purified by bulb-to-bulb distillations.

Results and discussion

In our work, irradiation of "neat" hexafluoroethane samples using the 9R(30) and 9R(36) CO_2 laser lines leads to the production of major products CF_4, C_2F_4, C_3F_8, and C_4F_{10}. Typical results are shown in Figs. 3–6. Although these plots illustrate yields after many pulses, it should be noted that TDL absorption measurements of CF_4 and C_2F_4 are possible after a single 13.4 J cm^{-2}, 9R(36) pulse (see Fig. 7). The following trends should be noted: CF_4 is the dominant product at all wavelengths and fluences studied. Conversely, C_4F_{10} is the least abundant product in all cases. At low fluence C_3F_8 is the second most abundant product at both wavelengths. As the fluence is increased the yield of C_2F_4 increases relative to C_3F_8. Separate experiments with C_2F_4 added before irradiation indicate that C_2F_4 is also consumed in the presence of C_2F_6 under similar experimental conditions. Therefore absolute quantitative yields of C_2F_4 after several ir laser pulses are possibly not a true reflection of the overall photochemistry involved.

Previous studies on the IRMPD of hexafluoroethane in the presence of scavengers (1, 2) have suggested that the principal dissociation pathway involves the scission of the C—C bond to produce two $^{\cdot}CF_3$ radicals. These trifluoromethyl radicals were either scavenged by H_2 (1) or Br_2 (2), forming CHF_3 or CF_3Br, or they absorbed more infrared photons and underwent secondary dissociation to difluorocarbene and a fluorine atom. Tetrafluoromethane, octafluoropropane, and decafluorobutane were not mentioned in these reports.

How does one account for the presence of the observed products in the absence of scavengers? It would appear that the primary IRMPD pathway indeed involves scission of the C—C bond to form two $^{\cdot}CF_3$ radicals. We propose that the secondary photolysis of trifluoromethyl radicals (as observed in several cases such as ref. 7) can account for the production of CF_4 and C_2F_4 at high fluence as follows:

$$[5] \quad {}^{\cdot}CF_3 + h\nu \rightarrow :CF_2 + {}^{\cdot}F$$

$$[6] \quad 2\,:CF_2 \rightarrow C_2F_4$$

$$[7] \quad {}^{\cdot}CF_3 + {}^{\cdot}F \rightarrow CF_4$$

Formation of CF_4 and C_2F_4 via disproportionation of two $^{\cdot}CF_3$ radicals has been ruled out in shock-tube studies (3) and in very-low-pressure photolysis experiments (6) and is thus not considered to be the source of these species in the present experiments.

Kato *et al.* (7) have studied the dissociation probability of $^{\cdot}CF_3$ radicals as a function of fluence and found that this probability is greatly reduced at fluences < 2–3 J cm^{-2}. We believe that the C_2F_4 formed in the IRMPD of "neat" hexafluoroethane arises from the recombination of two $:CF_2$ radicals resulting from the secondary dissociation of trifluoromethyl radicals. A lowering of the irradiation fluence should eventually eliminate secondary photolysis and thus the production of C_2F_4. We have irradiated 2 Torr samples of hexafluoroethane at 9R(36) for 4000 pulses at a fluence of about 1 J cm^{-2}. FTIR analysis revealed the presence of CF_4 and C_3F_8, while there was no

evidence of C_2F_4 even via second harmonic TDL detection. Thus the secondary dissociation of trifluoromethyl radicals has been suppressed at this fluence. Without ·F atoms present, an additional mechanism for the production of CF_4 is required. Hence we suggest the abstraction of a ·F atom by vibrationally excited $\cdot CF_3^{\dagger}$ from the parent C_2F_6 as follows:

[8] $\cdot CF_3^{\dagger} + C_2F_6 \rightarrow CF_4 + \cdot C_2F_5$

This reaction should be about 17 kJ/mol exothermic. It should be noted that in experiments done using the 9R(30) CO_2 laser pump line, the relative yield of CF_4/C_2F_4 increases as the pressure of C_2F_6 is increased from 1 to 2 Torr. The increase is more evident at low fluence (5.3 J cm^{-2}, 200 pulses) where the relative yield at 2 Torr is 5.8 times that at 1 Torr. At higher fluence (13.4 J cm^{-2}, 200 pulses) the increase in the relative yield at 2 Torr is 2.5 times that at 1 Torr. Reaction [8] therefore becomes more dominant as the pressure of C_2F_6 is increased, especially at low fluence where less secondary photolysis of $\cdot CF_3$ has occurred. Reactions similar to [8] have been proposed in the radiolysis of pentafluoroethyl iodide (8) and trifluoromethyl iodide (9). $\cdot C_2F_5$ may then react with $\cdot CF_3$ to form C_3F_8, reaction [9], or recombine to form decafluorobutane, reaction [10].

[9] $\cdot CF_3 + \cdot C_2F_5 \rightarrow C_3F_8$

[10] $\cdot C_2F_5 + \cdot C_2F_5 \rightarrow C_4F_{10}$

The secondary dissociation of pentafluoroethyl radicals has been observed previously by Hackett *et al.* (10) in the IRMPD of pentafluoroethyl iodide. In our work, the increased yield of C_2F_4 relative to C_3F_8 as the fluence is increased at both 9R(30) and 9R(36) may be due to the secondary photolysis of pentafluoroethyl as well as trifluoromethyl radicals.

[11] $\cdot C_2F_5 + h\nu \rightarrow :CF_2 + \cdot CF_3$

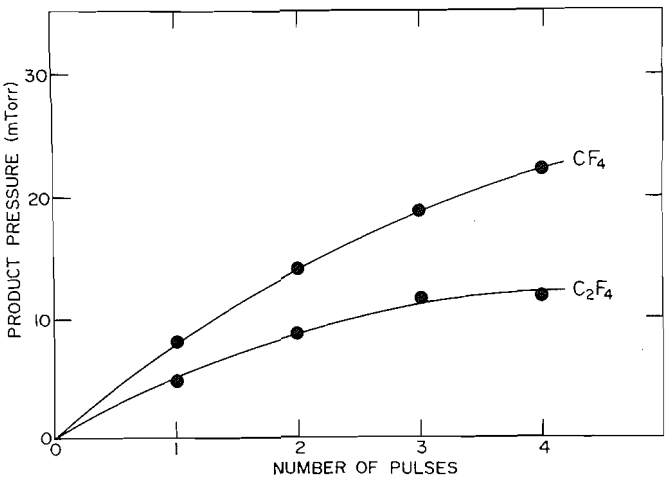

FIG. 7. Yield of CF_4, C_2F_4 vs. number of pulses, following irradiation of 2 Torr C_2F_6, 25 cm focal length BaF_2 lens, 9R(30) 13.4 J cm^{-2}, in a 10 cm long, 2.5 cm diameter Monel cell. The products were measured by second harmonic TDL absorption spectroscopy at 1269.0 and 1196.7 cm^{-1}, respectively. Note that in a Pyrex cell (Fig. 4), the curvature appears to be absent at this low number of pulses.

followed by

[6] $:CF_2 + :CF_2 \rightarrow C_2F_4$

Reactions of $^{\cdot}CF_3$ (11) or $:CF_2$ (12) with C_2F_4 to form heptafluoropropyl radicals or hexafluorocyclopropane are much too slow to be observed under the present experimental conditions.

Detection of trifluoromethyl radicals

The production of $^{\cdot}CF_3$ radicals was monitored immediately following the IRMPD of C_2F_6 via the high frequency modulation technique employing the tunable diode laser (5). Unfortunately there is spectral interference in the region of the $^{\cdot}CF_3$ $^rR_{16}(20)$ line calibrated by Orlando *et al.*,[1] thus a different absorption line was employed for quantification of the $^{\cdot}CF_3$ yield. The absorption line used for quantification of the trifluoromethyl radicals in these experiments has not been identified by Yamada and Hirota (13), however this line is also present immediately following the IRMPD of CF_3I and $(CF_3)_2CO$. To obtain a relative linestrength for the chosen analysis line at $\approx$1264.699 cm^{-1}, the intensity of this line was compared to the measured intensity of the $^rR_{16}(20)$ $^{\cdot}CF_3$ line at 1264.739 cm^{-1}. To accomplish this 600 mTorr of hexafluoroacetone was irradiated at a fluence of $\approx$23 J cm^{-2} using the 10R(14) CO_2 laser pump line. Three sets of 32 laser pulses were averaged for each of the lines, under identical experimental conditions. The ratio of the line intensities (1264.699/1264.739) was found to be 1.47 $\pm$ 0.04. The calibrated linestrength for the chosen $^{\cdot}CF_3$ analysis line at 1264.699 cm^{-1} is therefore $(2.0 \pm 0.5) \times 10^{-20}$ cm $molecule^{-1}$. The $^{\cdot}CF_3$ absorption line at 1264.699 cm^{-1} in the C_2F_6 system exhibits the same temporal growth and decay behaviour as the $^rR_{16}(20)$ line produced in the IRMPD of hexafluoroacetone.[2] In the hexafluoroacetone experiments a measurement of the gas temperature following the absorption of a CO_2 laser pulse was undertaken. A trace of N_2O was added to the photolysis cell, and the time-resolved absorption of N_2O on a temperature-sensitive transition (P(45) at 1243.795 cm^{-1}) was performed. After absorption of a CO_2 laser pulse by the hexafluoroacetone and N_2O mixture, no measurable increase in N_2O absorption (to within 10%) was noted over 20 ms. Thus there was no significant temperature increase. (A 10% increase in N_2O absorption on P(45) would correspond to a temperature change of less than 10K.) Furthermore, from the calculated linestrength, a plot of the reciprocal $^{\cdot}CF_3$ concentration versus time, in C_2F_6 gives a second order recombination rate of $(1.7 \pm 0.4) \times 10^{-12}$ cm^3 $molecule^{-1}$ s^{-1}, which is within the experimental error of the rate as previously determined by us.[2] We are therefore confident that we are indeed measuring the concentration of thermalized $^{\cdot}CF_3$ radicals. From this linestrength, the peak yield of $^{\cdot}CF_3$ produced per laser pulse via IRMPD of 600 mTorr of hexafluoroethane using the 9R(30) CO_2 laser pump line as a function of fluence has been measured. As one can see from Fig. 8, a significant amount of $^{\cdot}CF_3$ is produced by each CO_2 laser pulse (>3% dissociation per pulse at 19.8 J cm^{-2}). The lower limit in Fig. 8 was caused by low TDL power, and is not intended to indicate a threshold for the production of $^{\cdot}CF_3$.

Hydrogen donors

The addition of 2 Torr of a hydrogen-donating species such as H_2 or C_6H_{14} to 2 Torr of C_2F_6, followed by irradiation at the same wavelengths and fluences as above, leads to the elimination of the CF_4 yield. CF_4 is absent whenever the donor is present at pressures $\geq$0.5 Torr. The lack of CF_4 confirms that it is not a primary dissociation product (as predicted), and that reaction [8] is effectively eliminated when H_2 is added. Some of the trifluoromethyl radicals formed in IRMPD may be scavenged by the hydrogen donor as follows:

[12] $^{\cdot}CF_3 + H_2 \rightarrow CHF_3 + {}^{\cdot}H$

and

[13*a*] $^{\cdot}CF_3 + {}^{\cdot}H \rightarrow CHF_3^* \rightarrow :CF_2 + HF$

$\downarrow$ [M]

[13*b*] CHF_3

C_3F_8 and C_4F_{10} are still observable, however they cannot now be produced as previously indicated or CF_4 would also be observed (i.e. reaction [8] does not occur in the presence of a hydrogen donor). Thus we propose that a second dissociation pathway [3] must also be occurring:

[3] $C_2F_6 + h\nu \rightarrow {}^{\cdot}C_2F_5 + {}^{\cdot}F$

as well as

[9] $^{\cdot}CF_3 + {}^{\cdot}C_2F_5 \rightarrow C_3F_8$

and

[10] $^{\cdot}C_2F_5 + {}^{\cdot}C_2F_5 \rightarrow C_4F_{10}$

Fluorine atoms from reaction [3] or from secondary dissociation, reaction [5] will then be efficiently removed by reaction with the hydrogen donor:

[14] $H_2 + {}^{\cdot}F \rightarrow HF + {}^{\cdot}H$

The rate constants for reactions [7] (14) and [14] (15) are roughly equal, ($k_7 = (1.1\text{–}1.7) \times 10^{-11}$ cm^3 $molecule^{-1}$ s^{-1}, k_{14} $= 1.7 \times 10^{-11}$ cm^3 $molecule^{-1}$ s^{-1}), however under the present experimental conditions $[H_2] \gg [^{\cdot}CF_3]$ and reaction [14] should dominate.

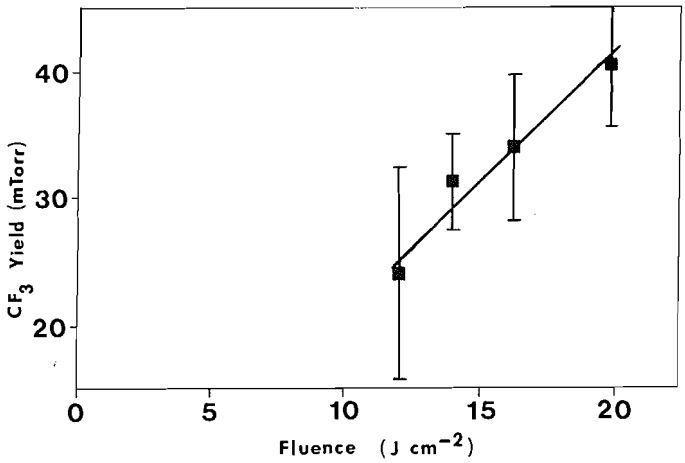

FIG. 8. Peak yield of $^{\cdot}CF_3$ vs. fluence, 50 μs after single pulse irradiation of 600 mTorr C_2F_6, in a 15 cm long, 1 mm diameter quartz waveguide cell, 25 cm focal length BaF_2 lens, 9R(30). The illustrated points are the average of three sets of 32 CO_2 laser pulses.

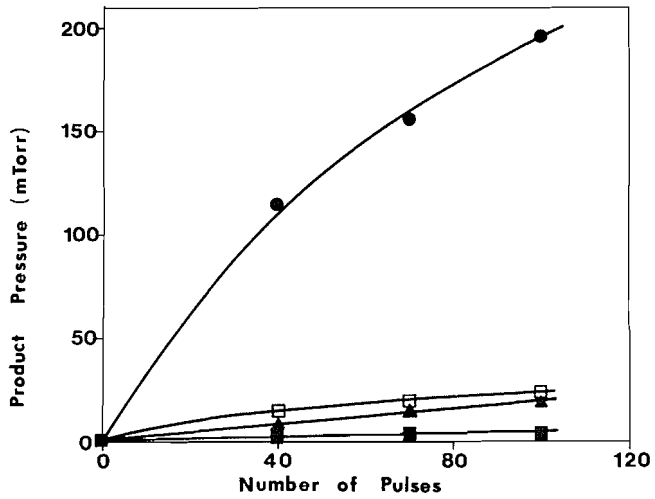

FIG. 9. Yield of products (mTorr) vs. number of pulses, following irradiation of 2 Torr C_2F_6 + 2 Torr H_2, in a 10 cm long, 2.5 cm diameter Pyrex cell, 25 cm focal length BaF_2 lens, 9R(36) 13.4 J cm^{-2}. ● C_2F_4 GC, □ CHF_3 TDL (1162.6 cm^{-1}), ▲ C_3F_8 GC, ■ C_4F_{10} GC.

The major products in the presence of a hydrogen donor are C_3F_8, C_4F_{10}, and CHF_3, as well as greatly increased C_2F_4 yields. Their yields as a function of number of pulses with 2 Torr of H_2 added to 2 Torr C_2F_6 are shown in Figs. 9 and 10.

The question arises as to why the C_2F_4 yield is greatly enhanced in the presence of hydrogen donors. Certainly the secondary dissociation of trifluoromethyl radicals should still occur to some extent, however other sources must contribute to the large increase in yield. To this end we investigated the possibility that the CHF_3 formed in reactions [12] and [13] itself undergoes IRMPD. Samples were prepared containing 20 mTorr of CHF_3 in C_2F_6 at 2 Torr total pressure and then subjected to 100 pulses 9R(36), 5.3 J cm^{-2}. After photolysis TDL measurements showed that 17.2 mTorr of the CHF_3 remained. Thus 14% of the fluoroform was consumed, indicating that it undergoes IRMPD in the presence of hexafluoroethane under the conditions used in the scavenging experiments. Control experiments containing the same known amount of CHF_3 in N_2 show no consumption of CHF_3. It appears that collisional energy transfer between vibrationally excited $C_2F_6^{\dagger}$ and CHF_3 is required to place CHF_3 in the

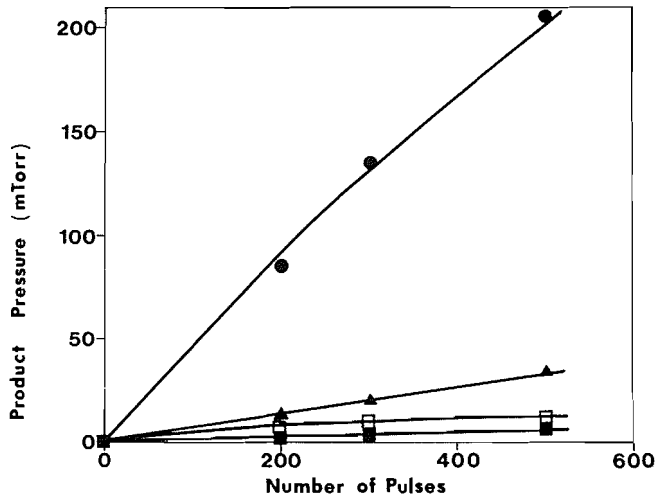

FIG. 10. Yield of products (mTorr) vs. number of pulses, following irradiation of 2 Torr C_2F_6 + 2 Torr H_2, in a 10 cm long, 2.5 cm diameter Pyrex cell, 25 cm focal length BaF_2 lens, 9R(36) 5.3 J cm^{-2}. ● C_2F_4 GC, □ CHF_3 TDL (1162.6 cm^{-1}), ▲ C_3F_8 GC, ■ C_4F_{10} GC.

vibrational quasicontinuum from which it may absorb further photons and dissociate.

[15] $C_2F_6^{\dagger} + CHF_3 \rightarrow C_2F_6 + CHF_3^{\dagger}$

[16] $CHF_3^{\dagger} + h\nu \rightarrow :CF_2 + HF$

The difluorocarbene thus produced would then dimerize to form C_2F_4. In view of the extremely large yield of C_2F_4, it is doubtful that the mechanisms proposed thus far can account for the total C_2F_4 yield. the difference could arise from a reaction between vibrationally excited $C_2F_6^{\dagger}$ and H_2 forming $C_2F_5H^{\dagger}$ which then eliminates HF to form C_2F_4, as proposed by Fisk (1). Alternatively, a more energetically favoured route would be via elimination of HF from excited $CHF_3^{\dagger}$, formed by combination of $^{\cdot}H$ and $^{\cdot}CF_3$, reaction [13*a*], followed by $:CF_2$ combination, reaction [6].

[17] $C_2F_6^{\dagger} + H_2 \rightarrow C_2F_5H^{\dagger} + HF$

[18] $C_2F_5H^{\dagger} \rightarrow C_2F_4 + HF$

In summary, we propose the following reaction mechanism for the IRMPD of "neat" hexafluoroethane:

[2] $C_2F_6 + h\nu \rightarrow 2\ ^{\cdot}CF_3$

[3] $C_2F_6 + h\nu \rightarrow {}^{\cdot}C_2F_5 + {}^{\cdot}F$

[−2] $^{\cdot}CF_3 + {}^{\cdot}CF_3 \rightarrow C_2F_6$

[−3] $^{\cdot}C_2F_5 + {}^{\cdot}F \rightarrow C_2F_6$

[7] $^{\cdot}CF_3 + {}^{\cdot}F \rightarrow CF_4$

[8] $^{\cdot}CF_3^{\dagger} + C_2F_6 \rightarrow CF_4 + {}^{\cdot}C_2F_5$

[9] $^{\cdot}CF_3 + {}^{\cdot}C_2F_5 \rightarrow C_3F_8$

[10] $^{\cdot}C_2F_5 + {}^{\cdot}C_2F_5 \rightarrow C_4F_{10}$

and at higher fluence, in addition to the above:

[5] $^{\cdot}CF_3 + h\nu \rightarrow :CF_2 + {}^{\cdot}F$

[6] $:CF_2 + :CF_2 \rightarrow C_2F_4$

[11] $^{\cdot}C_2F_5 + h\nu \rightarrow :CF_2 + {}^{\cdot}CF_3$

and in the presence of a hydrogen donor the following reactions will replace reactions [7] and [8]:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

[12] $^{\cdot}CF_3 + H_2 \rightarrow CHF_3 + {}^{\cdot}H$

[13a] $^{\cdot}CF_3 + {}^{\cdot}H \rightarrow CHF_3^* \rightarrow :CF_2 + HF$

$\downarrow$ [M]

[13b] CHF_3

[14] $H_2 + {}^{\cdot}F \rightarrow HF + {}^{\cdot}H$

[15] $C_2F_6\dagger + CHF_3 \rightarrow C_2F_6 + CHF_3\dagger$

[16] $CHF_3\dagger + h\nu \rightarrow :CF_2 + HF$

[17] $C_2F_6\dagger + H_2 \rightarrow C_2F_5H\dagger + HF$

[18] $C_2F_5H\dagger \rightarrow C_2F_4 + HF$

Conclusion

The IRMPD of "neat" hexafluoroethane at moderate fluence leads to the formation of CF_4, C_2F_4, C_3F_8, and C_4F_{10}. The major IRMPD dissociation pathway involves the scission of the C—C bond to form two $^{\cdot}CF_3$ radicals. Above several J cm^{-2} fluence, secondary photolysis forms $:CF_2$. Evidence for the participation of a second dissociation pathway, forming a fluorine atom and a pentafluoroethyl radical is also presented. With the addition of a hydrogen donor, the predominant photolysis product CF_4 is eliminated. The elimination of CF_4 is accompanied with an increased yield of C_2F_4, along with the production of a small amount of CHF_3.

This paper is dedicated to Professor J. A. Morrison[5]

R. J. PAZUR, ASHOK KUMAR, R. A. THURAISINGHAM, and WILLIAM J. MEATH. Can. J. Chem. **66**, 615 (1988).

Globally reliable dipole oscillator strength distributions (DOSDs) have been constructed for the H_2S molecule in its ground state. An adopted DOSD is used to evaluate a variety of dipole oscillator strength sums S_k, logarithmic dipole sums L_k, and mean excitation energies I_k, for H_2S; these dipole properties are important in various physical processes. It is also used to obtain reliable results for the dipole–dipole dispersion energy coefficients C_6 for the interaction of H_2S with itself, and with thirty-nine other atoms and (mostly) molecules, and the triple-dipole dispersion energy coefficient C_9 for $(H_2S)_3$. A pseudo-DOSD for H_2S is presented which facilitates the evaluation of C_6's, and in particular C_9's.

R. J. PAZUR, ASHOK KUMAR, R. A. THURAISINGHAM et WILLIAM J. MEATH. Can. J. Chem. **66**, 615 (1988).

On a développé des distributions globalement fiables de la force d'oscillateurs dipolaires (DFOD) pour la molécule de H_2S dans son état fondamental. Pour le H_2S, on a utilisé une valeur adaptée de DFOD pour évaluer une variété d'oscillateurs dipolaires dont les sommes sont S_k, les sommes dipolaires logarithmiques sont L_k et les énergies d'excitation moyennes sont I_k; ces propriétés dipolaires sont importantes dans divers processus physiques. Elles sont aussi utilisées pour obtenir des résultats fiables concernant les coefficients C_6 d'énergie de dispersion dipôle–dipôle pour l'interaction du H_2S lui-même et pour celle de trente neuf autres atomes et (principalement) molécules ainsi que pour les coefficients C_9 d'énergie de dispersion triple-dipôle du $(H_2S)_3$. Pour le H_2S, on présente un pseudo DFOD qui facilite l'évaluation des coefficients C_6 et en particulier des C_9.

1. Introduction

The main purpose of this paper is to present reliable values for a variety of dipole properties of the ground state H_2S molecule and for the dipole–dipole dispersion energies for the interaction of H_2S with itself and with a variety of other atoms and molecules. The reliable or accurate *ab initio* or direct experimental evaluation of most of the dipole properties we consider, and of dispersion energies for interactions involving molecules of the size of H_2S, is at present not tractable. This can be accomplished (1–6) by combining experimental information on dipole oscillator strengths with theoretical techniques and this is the approach used here.

The construction of the dipole oscillator strength distribution (DOSD) for ground state H_2S, and the evaluation of the dipole properties of this molecule, are discussed in Section 2. Specific results are given for the dipole sums S_k, $k = -12, -10, -8(1)-4, -3(½)0, 1$, and 2, and for the logarithmic dipole sums L_k and mean excitation energies I_k, for $k = -2(1)2$. Section 3 discusses the evaluation of the dipole–dipole and triple-dipole dispersion energy coefficients, C_6 and C_9, respectively, for interactions involving H_2S through the use of pseudo-DOSDs for the interacting species. Specific results are given for C_6 (H_2S,B), for forty species B, and for C_9 for $(H_2S)_3$. The estimated uncertainties and the usefulness of our results, and the methods by which they are obtained, are discussed in Section 4.

2. The adopted DOSD and dipole properties for H_2S

The method used to construct DOSDs has been discussed in detail previously (1, 7) and applied to many atoms and molecules (the species analyzed are listed in Table 4). Succinctly the approach uses all available experimental and theoretical data for the dipole oscillator strengths (photoabsorption cross sections) for the species of interest, as a function of photon energy E, and modifies this data, to remove errors inherent in the input data, by use of quantum mechanical constraint procedures. The constraints, in principle, can be furnished by any reliably known dipole properties of the molecule; in practice the Thomas–Reiche–Kuhn sum rule (8), $S_0 = N$ where N is the number of electrons in the molecule, and the experimental molar refractivity as a function of wavelength, $R(\lambda)$ versus λ, are the most often used constraints. The end product is a DOSD which is reliable in a global sense (9) as a function of E, that is, it yields reliable results for a variety of dipole properties which are just integrals, over E, of simple functions of E weighted by the DOSD. It should be emphasized that the dipole properties evaluated in this way, including the dispersion energy constants of Section 3, are rotationally averaged or isotropic results since they are evaluated using rotationally averaged DOSDs for the relevant molecules. The input used to construct the DOSDs consists of isotropic dipole oscillator strength and constraint data; the analogous symmetry analyzed or anisotropic molecular information is in general not available.

Constraints for constructing the DOSD for H_2S are provided by $S_0 = 18$ and by experimental molar refractivity data (10–13). Two molar refractivity values (estimated errors 0.01%) were used as explicit constraints, $R(\lambda_1 = 5729\ \text{Å}) = 9.5747\ \text{cm}^3\ \text{mol}^{-1}$ and $R(\lambda_2 = 4047\ \text{Å}) = 9.9725\ \text{cm}^3\ \text{mol}^{-1}$; both are taken from Huxley and Lowery (12). The adopted DOSD for H_2S yields molar refractivity data that agrees well (disagreement <0.5%) with all the experimental data for 2577 Å $\leq \lambda \leq$ 6564 Å. Disagreements exceeding ~0.1% occur only with the data of Larsen (10) for $\lambda < 2926$ Å and Frivold *et al.* (11) for $\lambda = 6564$

*This table contains the adopted integrated dipole oscillator strengths, obtained by applying the constraint procedure outlied briefly in the main text, and the integrated oscillator strengths obtained by using the unmodified experimental or mixture rule DOS data used in constructing the adopted DOSD. The references associated with the adopted DOSD indicate the source of the DOS data for the indicated spectral region. For the mixture rule data, (M1), (M2), and (M3) correspond to eqs. [1], [2], and [3], respectively, and (S) indicates Stobbe formula data. Powers of ten are denoted by $(n) = 10^n$. The absorption edges for H_2S occur at 164.1 eV ($S_{L_{II},L_{III}}$), 228.5 eV (S_{L_I}), and 2472 eV (S_K).

Å. A table comparing our results with experiment can be found in ref. 14.

The sources of experimental dipole oscillator strengths (DOSs) are rather few (15–17) and limited to $E \lesssim 90$ eV with experimental errors of between 10–20%. These data are augmented by DOSs obtained from the following mixture rules:

$$[1]\quad \frac{df}{dE}(H_2S) = \frac{df}{dE}(H_2) + \frac{df}{dE}(SO_2) - \frac{df}{dE}(O_2)$$

$$[2]\quad \frac{df}{dE}(H_2S) = \frac{df}{dE}(H_2O) + \frac{df}{dE}(CS_2) - \frac{df}{dE}(OCS)$$

$$[3]\quad \frac{df}{dE}(H_2S) = \frac{df}{dE}(H_2O) + \frac{1}{2}\frac{df}{dE}(CS_2) - \frac{1}{2}\frac{df}{dE}(CO) - \frac{1}{2}\frac{df}{dE}(O_2)$$

where df/dE is the differential dipole oscillator strength for the appropriate molecule and DOSDs ((df/dE) versus E, refs. 1, 7*b*, 9) for H_2, SO_2, O_2, CS_2, OCS, H_2O, and CO are used to furnish the data for the right hand side of eqs. [1]–[3]. For energies greater than 100 keV the input DOS data were evaluated by using the non-relativistic dipole Stobbe formula (18) following earlier work (1, 7, 19).

The initial DOSD for H_2S was divided into 24 energy intervals as suggested by the structure of the spectra from the individual sources of DOS input data; the integrated DOSs for all the sources for each interval are given in Table 1. The number of different initial DOSDs obtainable by taking various combinations of these data numbers in the millions. This was reduced to 48 initial DOSDs by (*i*) combining energy intervals that correspond to common data sources and (*ii*) recognizing that much of the DOS data from different sources is similar. Each of the resulting initial DOSDs was adjusted using a least squares constraint method (1) to satisfy the imposed constraints. The amount of modification of the initial data that is required to satisfy the constraints can be represented by a standard deviation defined by (3, 7*a*, 7*b*)

$$\mathrm{STD} = \left[\sum_{i=1}^{N} (a_i - \bar{a})^2/N\right]^{1/2}$$

Here the constrained or optimized DOSD, df^c/dE versus E, is related to the initial DOSD, df^0/dE versus E, by a modification factor a_i for each energy interval i, $df^c/dE = (1 + a_i)df^0/dE$, and $\bar{a}$ is the mean value of all the a_i's. This procedure lead to 48 optimized DOSDs with STDs ranging from about 3.4 (least modified) to about 8.8 (most modified). Additional adjustments of the DOS input data based on these modified DOSDs lead to other DOSDs requiring less modification of the initial data. The adopted DOSD for H_2S, corresponding to the adopted values of the integrated oscillator strengths reported in Table 1, has a STD of 2.2 which corresponds favourably to many other DOSDs constructed by this method.

For some molecules integrated dipole oscillator strengths, such as those given here for H_2S, can be used to help assess the reliability of the initial DOS data used to construct the molecular DOSD (1, 7, 9). The analysis for H_2S shows that the limited experimental data for this molecule are consistent with each other, and with the adopted values, if account is taken of the estimated experimental uncertainties (~20%). There are several

DOSDs, with STD's ranging from 2.2 to 5, that give similar (agreement to within <1–2%) values for the dipole properties of H_2S and that vary in the initial DOS data used in various of the spectral regions of Table 1.

The adopted DOSD is represented by a set of data points, E_j and $(df/dE)_j$, for $j = 1, \ldots, N_p \gg 24$ where $N_p \sim 335$ for H_2S, and a set of interpolating functions to connect the points. For very high photon energies df/dE is represented by the Born dipole formula (20), $AE^{-3.5}$. The dipole properties are readily evaluated (1) using this representation of the DOSD. The properties of interest here are defined by

$$[4] \quad S_k = \int_{E_0}^{\infty} (df/dE) \left(\frac{E}{2\mathcal{R}}\right)^k dE$$

$$[5] \quad L_k = \int_{E_0}^{\infty} (df/dE) \left(\frac{E}{2\mathcal{R}}\right)^k \ln\left(\frac{E}{2\mathcal{R}}\right) dE$$

$$[6] \quad I_k = 2\mathcal{R} \exp(L_k/S_k)$$

where $\mathcal{R}$ is the Rydberg of energy and E_0 is taken to be the electronic absorption threshold for the molecule. The recommended properties, for various values of k, evaluated using the adopted DOSD for H_2S are given in Table 2.

3. Pseudo-DOSD and dispersion energy coefficients

The dipole–dipole and triple–dipole dispersion energy coefficients, C_6 and C_9, respectively, are conveniently evaluated by using a discrete representation of the adopted DOSDs for the interacting species (21, 22). These pseudo-DOSDs are determined from the known values of the dipole sums S_k by requiring

$$[7] \quad S_k = \sum_{i=1}^{n} \left(\frac{E_i}{2\mathcal{R}}\right)^k f_i \qquad k = 2, 1, 0, -1, \ldots, 3 - 2n$$

and correspond to n pseudo-dipole (excitation energy − oscillator strength) pairs (E_i, f_i). Up to 20 of these pseudo-states have been evaluated for H_2S and the 10 pseudo-state representation of the adopted DOSD for H_2S given in Table 3 is more than adequate for evaluating C_6 and C_9 for interactions involving H_2S to well within the accuracy expected from using the original adopted DOSD for this molecule (21–23).

The dipole–dipole dispersion energy, $-C_6(A,B)R^{-6}$ where R is the intermolecular distance, is the dominant long range interaction energy for the interaction of two rotationally averaged molecules or S state atoms A and B. The pseudo-state expression for C_6 is given by (21)

$$[8] \quad C_6(\mathrm{A,B}) = \frac{3}{2}(2\mathcal{R}a_0^6) \sum_{i=1}^{n_A} \sum_{j=1}^{n_B} \times \frac{f_i(\mathrm{A}) f_j(\mathrm{B})}{E_i(\mathrm{A})E_j(\mathrm{B})[E_i(\mathrm{A}) + E_j(\mathrm{B})]}$$

where a_0 is the Bohr radius. The triple–dipole dispersion energy is the dominant long range non-additive interaction energy for a collection of more than two isotropic molecules and has the form

$$[9] \quad W^{(3)} = [3 \cos\theta_a \cos\theta_b \cos\theta_c + 1] \times C_9(\mathrm{A,B,C}) R_{ab}^{-3} R_{bc}^{-3} R_{ac}^{-3}$$

where R_{ab} is the intermolecular separation between molecules A and B, θ_a is the angle between R_{ab} and R_{ac}, and an expression analogous to [8] is available (22) for C_9. The C_6 coefficients for the interaction of H_2S with itself, and thirty-nine other species, are given in Table 4. Most of the required pseudo-DOSDs are available in the literature (3, 9, 21, 23–25); those for the alkenes and alcohols are available upon request (26). The result for $(H_2S)_3$ is $C_9 = 3897.0$, where the unit for C_9 is $2\mathcal{R}a_0^9$.

4. Discussion

Following procedures developed and used previously (1, 7*b*, 19), error estimates can be provided for the dipole properties of H_2S calculated in this paper. For the properties that depend significantly (2, 27) on the spectral regions which dominate the constraints used in constructing the DOSD for H_2S, namely S_k, L_k, and I_k for $-4 \leq k \leq 1$, the errors are $\lesssim$2% for $k = 1$ and $\lesssim$ 1% for the other values of $k \leq 0$. The errors can increase slowly from ~1% for $k < -4$ and for $k = 2$ are ~3% since they are dominated by uncertainties (2, 27) inherent in the DOS input data used to construct the higher energy portion of the DOSD. The uncertainties in the C_6 coefficients given in Table 4, and in our result for C_9 for $(H_2S)_3$, are $\lesssim$1–2% except in the case of N and O where they could be as high as 5% and 15%, respectively, due to the quality of the input data used to construct the DOSDs for the ground state N and O atoms (1, 28).

The accurate *ab initio* or direct experimental evaluation of most of the properties considered here, for molecules the size of H_2S, is a very difficult problem (1, 29–31) and our results for H_2S are, in most cases, the only available reliable values for

*For the organic molecules the results are for normal alkanes, 1-alkenes, and primary alcohols.

these properties and dispersion energy constants. *Ab initio* calculations of the dipole polarizability S_{-2} have been carried out (32, 33). Martin *et al.* (32) obtained values of 23.5 and 23.2 using self consistent field (SCF) and configuration interaction methods respectively; these are ~7% lower than our recommended result of 24.7 which agrees with the experimental result of 24.8 given by Landolt and Bornstein (34) and used by Martin *et al.* to help assess the reliability of their calculation. Ahlström *et al.* (33) report a value of 22.5, at an SCF-level of calculation, which is ~10% smaller than our result. As indicated in Section 3 our values for the molar refractivity of H_2S are generally in excellent agreement with experiment.

The dipole properties for H_2S obtained here, and for the other molecules considered earlier, are important in a variety of research areas (2, 8, 19, 28, 35). Of particular interest are the radiation parameters (I_1,S_1), I_0, and (I_{-1},S_{-1}) which can be used to help evaluate the straggling, the stopping, and the total inelastic scattering cross sections of fast charged particles in molecular matter (19, 35, 36). The various uses and applications of the dipole properties S_k, L_k, and I_k have been reviewed well by Hirschfelder *et al.* (8) and Fano and Cooper (35), see also the more recent discussions of refs. 2, 37, and 38.

Reliable results for the dipole–dipole dispersion energies are useful in many fields. They furnish important input in the construction of interaction potential energies that are valid for all important values of the intermolecular separation R; see for example refs. 39–45, and references therein. Many of the interactions involving H_2S represented in Table 4 should be of considerable interest. For example, recently there have been several investigations (46–48) of dimer potentials involving interactions of H_2S with itself, and with H_2O, HF, and HCl, including a study of stacking interactions (48) for $(H_2S)_2$. The importance of the dispersion energy contribution to the interaction energies has been discussed in these studies and hopefully our reliable results for the relevant dispersion energy coefficients will be of importance in future investigations of potentials of this type.

The pseudo-DOSD for H_2S given in Table 3 is a very useful representation of the original DOSD for this molecule. It can be used to effectively evaluate multiple integrals, over excitation energies, involving the original continuous distribution as has been demonstrated in calculations of the triple-dipole dispersion energy coefficients for a variety of molecules (22, 24). The result given in Section 3 for $C_9(H_2S, H_2S, H_2S)$ can be readily extended to other interactions involving H_2S by using available pseudo-DOSDs for other species (see Section 3). Another use of the pseudo-DOSDs is that they provide part of the information needed to evaluate (1) the (asymptotic) dispersion energy coefficient for the interaction between an adsorbate molecule and a surface and (2) substrate-mediated dispersion energies between adsorbate molecules (49). Also required are the bulk dielectric constant function for the substrate. In this context H_2S is a particularly important molecule since the interaction of H_2S with metallic surfaces, and with other adsorbates, is of importance in studies concerned with sulfur poisoning and hydrodesulfurization processes that occur in heterogeneous catalysis (50).

The method used in this paper is a practical and reliable approach for evaluating a wide variety of rotationally averaged or isotropic molecular dipole properties if sufficient input data are available. It avoids difficulties that occur in other procedures based on less input information (2, 3, 9, 19, 28). The extension to anisotropic dipole properties is not straightforward due to a lack of the required anisotropic oscillator strengths and/or reliable constraints for most species (2, 30). This extension is an important problem since generally the only direct route for the determination of anisotropic properties is through *ab initio* calculations which are reliable only for small atoms and molecules for the wide range of properties of interest in the present context. In some cases, for example, anisotropic dispersion energies, isotropic results, and multiplicative anisotropy parameters are used to generate anisotropic results; this connection is not always rigorous and can involve the use of average energy-like approximations (51).

This paper is dedicated to Professor J. A. Morrison

I. R. TASKER, P. A. G. O'HARE, BRETT M. LEWIS, G. K. JOHNSON, and E. H. P. CORDFUNKE. Can. J. Chem. **66**, 620 (1988).

Three precise calorimetric methods, viz., low-temperature adiabatic, high-temperature drop, and solution-reaction, have been used to determine as a function of temperature the key chemical thermodynamic properties of a pure sample of schoepite, $UO_2(OH)_2 \cdot H_2O$. The following results have been obtained at the standard reference temperature $T = 298.15$ K: standard molar enthalpy of formation $\Delta_f H_m^0(T) = -1825.4 \pm 2.1$ kJ mol^{-1}; molar heat capacity $C_{p,m}^0(T) = 172.07 \pm 0.34$ J K^{-1} mol^{-1}; and the standard molar entropy $S_m^0(T) = 188.54 \pm 0.38$ J K^{-1} mol^{-1}. The molar enthalpy increments relative to 298.15 K and the molar heat capacity are given by the polynomials: $\{H_m^0(T) - H_m^0(298.15\ \text{K})\}/(\text{J mol}^{-1}) = -38209.0 + 84.2375(T/\text{K}) + 0.1472958(T/\text{K})^2$ and $C_{p,m}^0(T)/(\text{J K}^{-1}\ \text{mol}^{-1}) = 84.238 + 0.294592(T/\text{K})$, where $298.15\ \text{K} < T < 400$ K. The present result for $\Delta_f H_m^0$ at 298.15 K has been combined with three other closely-agreeing values from the literature to give a recommended weighted mean $\Delta_f H_m^0 = -1826.4 \pm 1.7$ kJ mol^{-1}, from which is calculated the standard Gibbs energy of formation $\Delta_f G_m^0 = -1636.8 \pm 1.7$ kJ mol^{-1} at 298.15 K. Complete thermodynamic properties of schoepite are tabulated from 298.15 to 423.15 K.

I. R. TASKER, P. A. G. O'HARE, BRETT M. LEWIS, G. K. JOHNSON, et E. H. P. CORDFUNKE. Can. J. Chem. **66**, 620 (1988).

On a utilisé trois méthodes calorimétriques précises, adiabatique à basse température, abaissement d'une température élevée et solution-réaction, pour déterminer les propriétés thermodynamiques chimiques clés d'un échantillon pur de schoepite, $UO_2(OH)_2 \cdot H_2O$, en fonction de la température. A la température de référence standard de $T = 298,15$ K, on a obtenu les résultats suivants: enthalpie molaire standard de formation, $\Delta_f H_m^0(T) = -1825,4 \pm 2,1$ kJ mol^{-1}; capacité calorifique molaire, $C_{p,m}^0(T) = 172,07 \pm 0,34$ J K^{-1} mol^{-1} et entropie molaire standard, $S_m^0(T) = 188,54 \pm 0,38$ J K^{-1}. Les incréments à l'enthalpie molaire relative à 298,15 K et la capacité calorifique molaire peuvent être représentés par les polynômes suivants: $\{H_m^0(T) - H_m^0(298,15\ \text{K})\}/(\text{J mol}^{-1}) = -38209,0 + 84,2375(T/\text{K}) + 0,1472958(T/\text{K})^2$ et $C_{p,m}^0(T)/(\text{J K}^{-1}\ \text{mol}^{-1}) = 84,238 + 0,294592(T/\text{K})$, dans lesquels $298,15\ \text{K} < T < 400$ K. On a combiné les résultats obtenus pour $\Delta_f H_m^0$ à 298,15 K avec trois autres valeurs qui lui sont en très bon accord et qui ont été tirées de la littérature pour obtenir une valeur moyenne recommandée du $\Delta_f H_m^0 = -1826,4 \pm 1,7$ kJ mol^{-1} à partir de laquelle on a calculé l'énergie de formation de Gibbs standard à 298,15 K, $\Delta_f G_m^0 = -1636,8 \pm 1,7$ kJ mol^{-1}. On présente une table résumant les propriétés thermodynamiques complètes de la schoepite de 298,15 à 423,15 K.

[Traduit par la revue]

Introduction

Schoepite, $UO_3 \cdot 2H_2O$, is, on the basis of X-ray diffraction and infrared spectroscopic evidence (1), more accurately depicted as $UO_2(OH)_2 \cdot H_2O$. However, the more compact formula will be used for convenience in the present paper. The hydrate has an orthorhombic unit cell (*Pbna*) with $a = 1.3977$ nm, $b = 1.6696$ nm, and $c = 1.4672$ nm, and there are 32 molecules in the cell. Uranium exhibits eight-fold octahedral coordination; the structure is layered with the hydrate water situated between the layers (2).

Our current technical interest in schoepite arises from modelling studies connected with the burial of nuclear waste. Specifically, the question being addressed is the fate of dissolved uranium in contact with concrete at 298.15 K. Under such conditions, and on the basis of existing thermodynamic values, schoepite is calculated to be the phase that limits the uranium activity in solution (3).

The objective of the present research was to obtain by high-precision calorimetry the following molar thermodynamic properties of a single specimen of pure schoepite: the standard enthalpy of formation $\Delta_f H_m^0$ at 298.15 K; the low-temperature heat capacity $C_{p,m}^0$ and, thence, the standard entropy S_m^0; and the enthalpy increments relative to 298.15 K, up to the limit of stability of the material.

Experimental

Schoepite was prepared at ECN by hydration of anhydrous, amorphous UO_3 which had been obtained by thermal decomposition at 625 K of ammonium diuranate $(NH_4)_2U_2O_7$. The UO_3 was hydrated by equilibration with water which was stirred in a round-bottom flask equipped with a reflux condenser. The hydration was performed initially for 5 days at 315 K, and then for 14 days at 345 K, after which the sample was cooled slowly, filtered, washed with water, and dried in the air at room temperature. The X-ray diffraction patterns were identical to those in the literature for schoepite (2). By ignition to U_3O_8, the uranium content of the preparation was determined to be (73.89 ± 0.01) mass%, very close to the theoretical value of 73.91%. The schoepite was boiled with deionized H_2O and the supernatant aqueous extract was analyzed by ion chromatography. Only F^-(aq), NO_3^-(aq), SO_4^{2-}(aq), NH_4^+(aq), and Na^+(aq) were detected, but all were at or below the 1×10^{-6} mass fraction level. All the analytical results, therefore, indicate that our sample of schoepite was very pure.

For the low-temperature heat-capacity measurements, 7.6699 g of schoepite was loaded into the calorimeter (laboratory designation 6-GS-1) with gentle tamping. The calorimeter was constructed from oxygen-free high-thermal-conductivity copper, had an internal volume of 5.976 cm^3 at 298.15 K, and was sealed by means of a gold gasket. Prior tests had shown, as expected, that intimate contact between copper and schoepite produced no reaction. The calorimeter was cooled to 195 K, evacuated, and 2.317×10^{-5} mol of He was introduced to act as an exchange gas and promote rapid thermal equilibration. For buoyancy and volume corrections, the density of schoepite was taken as 4.65 g cm^{-3} (2). Descriptions of the cryostat, peripheral equipment, the calorimetric procedure, and other relevant details are available in the literature (4).

Our determination of the standard molar enthalpy of formation was based on solution-calorimetric measurements of the enthalpy of the reaction:

[1] $UO_3 \cdot 2H_2O(cr) + 2HF(aq) = UO_2F_2(aq) + 3H_2O(aq)$.

The calorimeter, an LKB-8700 model (LKB Produkter, Bromma, Sweden) was equipped with a stirrer and a 100-cm^3 reaction vessel made of 18-ct gold. Calorimetric specimens of schoepite, each of mass ≈0.56 g, were weighed in air and encapsulated in Teflon as described in an earlier publication (5). The calorimeter was calibrated electrically immediately before and after each enthalpy of reaction measurement, and the arithmetic mean of the values was used for the energy equivalent of the calorimetric system $\langle \epsilon(\text{calor}) \rangle$. The reaction of schoepite with HF(aq), prepared by dilution of reagent-grade acid, was quite rapid and the calorimeter reached equilibrium about 600 s after the sample came into contact with the solution. Temperatures were recorded automatically with a quartz-crystal thermometer (Hewlett-Packard, Model 2804-A) interfaced with a computer which calculated the corrected temperature rise for each experiment and calibration. In order to check the performance of the calorimetric system, we measured the specific enthalpy of protonation in 0.1 mol kg^{-1} HCl(aq) of tris(hydroxymethyl)aminomethane, National Bureau of Standards Reference Material 724a. Our result, $-(246.09 \pm 0.11)$ J g^{-1}, overlapped the certified value of $-(245.76 \pm 0.26)$ J g^{-1}, and indicated that the calorimeter was operating properly.

The drop-calorimetric system (6) used for the enthalpy measurements consisted of a resistance-heated molybdenum-core furnace and a copper-block calorimeter. Furnace-temperature measurements were made with platinum-to-(platinum + mass fraction 0.1 of rhodium) thermocouples. Calorimetric temperatures were determined with a quartz-crystal thermometer (Hewlett-Packard Model 2804-A). The energy equivalent ϵ(calor) of the empty copper-block calorimeter was determined by electrical calibration.

The schoepite (mass 8.7960 g) was loaded into a (platinum + mass fraction 0.1 of rhodium) capsule (mass 19.1948 g and internal volume 6.42 cm^3), which was then welded shut. The capsule also contained 1.85×10^{-4} mol of air. Enthalpy measurements were also conducted on an empty capsule of similar mass and dimensions in order to correct for the enthalpy of the capsule. Experiments were performed at temperatures between 350 and 500 K. However, the enthalpy values at $T \geq 425$ K, when plotted against temperature, lay on a different line than those at lower temperatures. This suggested that the sample had decomposed or undergone a transition. Upon completion of the experiments, the capsule was opened and the schoepite examined. The material was visibly wet and readily lost mass when exposed to the air. It was concluded that the schoepite had undergone decomposition to some form of dehydrated schoepite and water. Hence, only the enthalpy values at approximately 350, 375, and 400 K are valid for pure schoepite.

Results

The molar heat capacities $C^0_{p,m}(T)$ of schoepite given in Table 1 were calculated as the difference, with some minor corrections, between the values obtained with the loaded calorimeter and the results of a prior set of experiments with the empty calorimeter.

Such a correction had to be made to allow for decomposition of the schoepite. There is convincing evidence from the studies of Dawson *et al.* (7), Lindval' and Kuznetsova (8), and Perez-Bustamante *et al.* (9) that schoepite undergoes dehydration upon heating. Thus, in the low-temperature heat-capacity measure-

ments made at $T \geq 273.5$ K, a small part of the electrical energy input contributed to dehydration of the schoepite, and not heating of the sample, as would have occurred in the absence of decomposition. There is, unfortunately, no experimental vapor-pressure equation for the decomposition of schoepite which would enable us to make a precise correction for the thermal effect of dehydration. We have, however, constructed an approximate equation on the basis of our present $\Delta_f H^0_m$ value for schoepite and that for dehydrated schoepite (10) and $H_2O(g)$ (11), along with an estimated standard entropy change for the dehydration. That equation is as follows:

$$[2] \quad \log_{10}(p/p^0) = -2523.8\,(\mathrm{K}/T) + 6.722$$

Because of the vaporization correction, the original (uncorrected) heat-capacity values have been *reduced* in Table 1 by (J K^{-1} mol^{-1}): 0.08 at 273.50 K; 0.15 at 283.59 K; 0.28 at 293.67 K; 0.50 at 303.69 K; 0.81 at 313.23 K; 1.32 at 323.62 K; 2.07 at 333.70 K; and 3.17 at 343.88 K. Thus, above 330 K, the correction exceeds 1% of the calculated heat capacity. Although the uncertainty increases above this temperature, the correction is only 0.25% at 298.15 K and the corresponding errors are not significant here. Other minor corrections were made for differences in the amounts of helium, Apiezon-T grease (Metropolitan-Vickers, U.K.), copper, and gold between the results for the empty and filled calorimeters. A small curvature correction equal to $-(\mathrm{d}^2C_{p,m}/\mathrm{d}T^2)(\Delta T)^2/24$ was applied to each heat-capacity determination.

At 5 K, the heat capacity of the sample was 35% of the total, at 20 K it was 34%, at 100 K it was 19%, and from 200 to 350 K it was about 25%. The values given in Table 1 are estimated to be uncertain by ±5% near 6 K, ±1% near 14 K, and by ±0.2% above 25 K. A plot of $C^0_{p,m}(T)$ against $\langle T \rangle$ showed the normal sigmoidal shape and exhibited no anomalies.

The experimental heat capacities in Table 1 were fitted by means of a weighted least-squares procedure using two polynomials in T, one for the region below 40 K, the other for the region above 20 K. The standard deviations from the fits were ±0.14% and ±0.15%, respectively, with the polynomials merging smoothly at 23.5 K. In the region below the lowest experimental determination, it was assumed that $C^0_{p,m} = AT^3$. At $T = 6$ K, $C^0_{p,m}(T) = 0.3955$ J K^{-1} mol^{-1}, $\{S^0_m(T) - S^0_m(0)\} = 0.1318$ J K^{-1} mol^{-1}, and $\{H^0_m(T) - H^0_m(0)\} = 0.5933$ J mol^{-1}.

[a]$\{H_m^0(T) - H_m^0(298.15\text{ K})\} = -\{\epsilon(\text{calor})(-\Delta\theta) + \Delta H(\text{capsule}) + \Delta H(H_2O) + \Delta H(\text{corr})\}/(0.027315\text{ mol})$. The capsule contained 0.027315 mol of $UO_3 \cdot 2H_2O$.

[b]Correction for the vaporization of H_2O is based on eq. [2].

[c]Correction made on the basis of the enthalpy of vaporization of $H_2O(l)$.

Above 6 K, the thermodynamic properties were obtained by appropriate integrations of the two polynomials over their respective temperature ranges, and values at selected temperatures are given in Table 2.

Calorimetric results for the reaction of schoepite wth HF(aq) are given in Table 3 and the column headings are explained in a footnote. The $\Delta_{vap}H$ term was calculated based upon the assumption that the internal volume of each ampoule was 1 cm^3 and the molar enthalpy of vaporization of water was taken as 44016 J mol^{-1} (11). The apparent sample masses were converted to mass based on a density of 4.65 g cm^{-3} for schoepite (2). The thermochemical cycle for the derivation of $\Delta_f H_m^0$ of schoepite is shown in Table 4. The enthalpies of reaction of γ-UO_3 and of schoepite with HF(aq) are taken from an earlier study (12) at this laboratory and from Table 3, respectively. Standard molar enthalpies of formation of γ-UO_3 and $H_2O(l)$ are CODATA-selected values (11).

The drop-calorimetric results are presented in Table 5. The entries in the table have their usual meanings (13). The correction for the water-vapor pressure over the schoepite sample was calculated from eq. [2] except for the experiment at 400.55 K, where the equilibrium vapor pressure was taken to be that of water at the same temperature. These enthalpy values, as well as those between 298.15 and 350 K obtained by low-temperature calorimetry, were fitted by the method of least squares to various polynomials. The following fit was satisfactory:

380	23.595	1218	28.034	23.264	−219.44	−190.94
400	24.303	2291	29.262	23.534	−219.34	−189.45
423.15	25.124	2864	23.885	30.652	−219.23	−187.82

[a] $\Delta^T_{T'}H^0_m = H^0_m(T) - H^0_m(T')$.
[b] $\Phi^0_m = -\{G^0_m(T) - H^0_m(T')\}/T$.
[c] $\Delta^T_0S^0_m = S^0_m(T) - S^0_m(0)$.

[3] $\{H^0_m(T) - H^0_m(298.15\ K)\}/(J\ mol^{-1}) = -38209.0 + 84.2375(T/K) + 0.1472958(T/K)^2$ $(298.15\ K < T < 400\ K)$

The fit was constrained to give $\{H^0_m(T) - H^0_m(298.15\ K)\} = 0$ and $C^0_{p,m}(T) = 172.07\ J\ K^{-1}\ mol^{-1}$ at $T = 298.15$ K. The heat capacity of $UO_3{\cdot}2H_2O$ between 298.15 and 400 K is given by the first derivative of eq. [3]:

[4] $C^0_{p,m}(T)/(J\ K^{-1}\ mol^{-1}) = 84.238 + 0.294592(T/K)$

Discussion

There have been no previous determinations of the low-temperature heat capacity or high-temperature enthalpy increments of schoepite. An earlier estimate (14) of the standard entropy at 298.15 K, 176 ± 8 J K^{-1} mol^{-1}, is somewhat lower than the experimental result, 188.5 ± 0.4 J K^{-1} mol^{-1}.

The standard molar enthalpy of formation has previously been reported by Santalova *et al.* (15), Drobnič and Kolar (16), and Cordfunke (17). Santalova *et al.* measured the enthalpy of reaction of schoepite with $HF{\cdot}267H_2O$. In their experiments, the HF was more dilute than ours, and $n(UO_2^{2+})/n(HF)$ was also quite different. It is not surprising, therefore, that the enthalpy of reaction of schoepite given by Santalova *et al.*, −72.7 ± 0.9 kJ mol^{-1}, differs from our value, −76.25 ± 0.35 kJ mol^{-1}. The magnitude of the difference is, perhaps, unexpected. When the Santalova *et al.* result is combined with their enthalpy of hydrolysis of UF_6(cr) and the best modern $\Delta_fH^0_m$ values for UF_6(cr) (18), H_2O(l) (11), F^-(aq) (11), and the enthalpy of dilution of HF(aq) (19), $\Delta_fH^0_m(UO_3{\cdot}2H_2O, cr) = -1831.1 \pm 4.4$ kJ mol^{-1} is obtained, in fair agreement with the present result.

Drobnič and Kolar measured directly the enthalpy of hydration of a highly-reactive specimen of UO_3(am):

[5] $UO_3(am) + 2H_2O(l) = UO_3{\cdot}2H_2O(cr)$

Their corrected results give $\Delta_rH^0_m = -45.9 \pm 0.4$ kJ mol^{-1} for reaction [5]. Combination of this value with selected $\Delta_fH^0_m$ values for UO_3(am) (18) and H_2O(l) (11) yields $\Delta_fH^0_m = -1825.9 \pm 2.0$ kJ mol^{-1} for schoepite, in excellent agreement with the present determination.

Cordfunke has measured the enthalpies of reaction of γ-UO_3 and schoepite with ≈6 mol dm^{-3} HNO_3. His reported values yield $\Delta_rH^0_m = -30.2 \pm 0.3$ kJ mol^{-1} for the reaction:

[6] $UO_3(cr, \gamma) + 2H_2O(aq) = UO_3{\cdot}2H_2O(cr)$

where H_2O(aq) is for a medium of ≈6 mol dm^{-3} HNO_3. We have taken $\Delta_fH_m(H_2O, aq) = -286.44 \pm 0.04$ kJ mol^{-1} (11, 18) and calculate $\Delta_fH^0_m(UO_3{\cdot}2H_2O) = -(1826.9 \pm 2.0)$ kJ mol^{-1}; this result also agrees very well with the present determination.

The weighed mean value of $\Delta_fH^0_m$ from the four studies just discussed yields $\Delta_fH^0_m$ ($UO_3{\cdot}2H_2O$, cr, 298.15 K) = −1826.4 ± 1.7 kJ mol^{-1}, which is our recommended value for the formation reaction:

[7] $U(cr) + 2H_2(g) + \frac{5}{2}O_2(g) = UO_3{\cdot}2H_2O(cr)$

The thermodynamic quantities determined in the present study have been combined with auxiliary quantities from the literature for U (18), H_2 (11), and O_2 (11) to compute the complete set of properties given in Table 6.

It is believed that the thermodynamic properties of schoepite determined and reviewed in the present study may be used with a high degree of confidence in thermodynamic calculations and modelling studies such as those referred to at the beginning of this paper.

Heats-of-mixing for the liquid system nitrogen/ethane have been measured at 92.3 K and 0.6309 MPa using a cryogenic flow calorimeter. The heat-of-mixing versus composition curve shows that the system is only partially miscible; the compositions between which liquid–liquid separation occurs have been estimated.

JORGE C. G. CALADO, PRAKASH GOPAL, JOHN A. ZOLLWEG, et W. REID THOMPSON. Can. J. Chem. **66**, 626 (1988).

Utilisant un calorimètre à flux cryogénique, on a mesuré les chaleurs de mélange du système liquide azote/éthane à 92,3 K et 0,6309 MPa. La courbe de la chaleur de mélange en fonction de la composition démontre que le système n'est que partiellement soluble; on a évalué les compositions entre lesquelles il se produit une séparation liquide–liquide.

Introduction

Enthalpy data for liquid mixtures at low temperatures are scarce compared with thermal property data for low temperature solids. As Lobo and Staveley (1) have pointed out, experimental results have been reported from only four or five laboratories over the last 20 years. The Leiden (2) and Bristol (3) low temperature flow mixing calorimeters as well as the Oxford (4) batch mixing calorimeter have been disassembled. The recently constructed mixing calorimeters at Cornell (5, 6) presently provide capability for making enthalpy measurements on fluid mixtures at low temperatures.

Flow calorimetry is a well-established technique for measurements on fluid mixtures near room temperature, but the extension of this method to measurements at cryogenic temperatures has required some modification, particularly in the method of flow measurement. For measurements on fluids, flow calorimeters have several important advantages over batch calorimeters. Flow calorimeters avoid troublesome vapor space and thus do not require extensive auxiliary information for the reduction of raw experimental data to heat-of-mixing values. In addition, flow calorimeters make it possible, by variation of the flow rates, to eliminate errors caused by heat leaks or incomplete mixing. A drawback of flow calorimeters is that they require large quantities of fluids.

Measurements in a flow calorimeter are effected by first bringing the pure fluid streams to the cryostat bath temperature and then supplying energy to the calorimeter so that the temperature of the fluid mixture at the exit is the same as that of the incoming streams. The heat-of-mixing is then given by

$$[1] \quad H^M = (W + q)/F$$

where W is the electrical power input to the calorimeter heater, q is the heat-leak into the calorimeter, F is the total molar flow rate, and H^M is the the enthalpy of mixing. It must be noted that q can be made small relative to W by operating at high flow rates. Since temperature compensation cannot be perfect, a $C_p\Delta T$ correction would need to be effected, so that (assuming $q \ll W$) the heat-of-mixing can now be determined from the equation:

$$[2] \quad H^M = W/F - C_{p_{mix}}(T_{exit} - T_{in})$$

where $C_{p_{mix}}$ is the heat capacity of the mixture and may be evaluated (for the purpose of this small correction) as the mole fraction weighted sum of the pure component heat capacities, and $(T_{exit} - T_{in})$ is the temperature difference between the fluid at the exit and the inlet of the calorimeter.

Heat-of-mixing measurements are reported here for the nitrogen/ethane system at 92.3 K and 0.6309 MPa. The system and conditions were chosen with Titan — a moon of Saturn — in mind. One of us (7) has shown that for a detailed study of the nature of Titan's surface, clouds, and oceans, it was necessary to obtain phase equilibrium information for the nitrogen/methane/ethane system. L–L–V studies on this ternary system at temperatures between 102 and 116 K by Lu *et al.* (8) showed that liquid–liquid phase separation boundaries existed. Lunine *et al.* (9) and Dermott *et al.* (10) have noted the possibility of liquid–liquid phase separation at conditions prevailing on Titan (about 95 K and 5 bar). It was with the intent of enabling better modeling of the nitrogen/methane/ethane system, such as that attempted by Thompson (7), that we undertook this study. Another use for these results is in testing molecular thermodynamic perturbation theories as applied to molecules with small elongation (11).

Experimental

Measurements were conducted using a computer-interfaced low temperature, high pressure flow calorimeter designed and constructed by Gopal (5). The apparatus was used with only one modification; ethane was preliquefied in an isopropyl alcohol – dry ice bath before being allowed to enter the liquid nitrogen cryostat bath. This helped to conserve the liquid nitrogen in the bath and thus permitted longer experimentation before refilling the cryostat.

The experiment involved three stages. First, the zero of the thermocouple that senses the temperature difference between the exit and the inlet of the mixing calorimeter was measured by passing liquefied nitrogen through both arms of the calorimeter. In the second stage of the experiment, the flow rates of the two components were adjusted and the fluids were allowed to mix in the calorimeter. Finally, the power supply to the calorimeter heater was adjusted so that the thermocouple signal returned approximately to its original value.

The composition was determined as the ratio $f_A/(f_A + f_B)$, where f_A and f_B, the molar flow rates of the components, were measured with Micro Motion™ vibrating tube mass flow meters. The heat-of-mixing was then determined from eq. [2], with the $C_{p_{mix}} \cdot \Delta T$ correction to W/F never accounting for more than 6.0 J/mol.

Results and discussion

Heat-of-mixing measurements for the liquid system nitrogen/ethane at (92.3 ± 0.3) K and (0.6309 ± 0.035) MPa

0.971	17.4

[a] x_{N_2} is the overall mole fraction of nitrogen in the mixture.

are presented in Table 1. The nitrogen used in this work was supplied by Airco and had a certified purity of 99.997%, the main impurities being oxygen and water. Ethane was supplied by MG Industries and had a certified purity of 99.5%; the major impurities were hydrogen and methane.

A linear portion in the H^M–x curve (see Fig. 1) suggests that the nitrogen/ethane system is only partially miscible at 92.3 K and 0.6309 MPa. To the best of our knowledge, this is only the second calorimetric investigation of a partially miscible liquefied gas system, the first one having been performed by Lobo and Staveley (1) on HCl/CF_4. The experimental points in the immiscible-regime fit the equation: $H^M = A + Bx_{N_2}$ with $A = 178.15$ J/mol and $B = -114.71$ J/mol, the standard deviation of the fit being ≈3.4 J/mol. The scatter in the experimental points is attributed to the limited mutual solubility of the two liquids. The standard deviation, while being fairly large, is roughly one-third the standard deviation obtained by Lobo and Staveley (1) for a comparable heat-of-mixing value. (It may be worthwhile mentioning here that flow rates in excess of 6.5 mmol/s had to be employed in the liquid–liquid separation region to ensure that equilibrium had been established, while a flow rate of 5.0 mmol/s was found adequate for compositions where the liquids were miscible.)

The temperature and pressure for different measurements varied over ±0.3 K and ±0.035 MPa, respectively. No effort was made to effect corrections for these variations in experimental conditions. Since the conditions were far removed from the critical temperature of the more volatile component, N_2, it is expected that the corrections would be small compared to the scatter in the data.

From the H^M–x curve shown in Fig. 1, on the ethane-rich side, the nitrogen/ethane mixture is immiscible for nitrogen mole fractions >(0.17 ± 0.03). On the nitrogen-rich side, the liquids are miscible only for nitrogen mole fractions >(0.92 ± 0.03). While heat-of-mixing measurements are no substitute for actual L–L–V experiments, we have demonstrated the usefulness of low temperature calorimetry in identifying compositions at which phase separation may occur.

Local mode assignments for the CD-stretching overtone spectra of deuterated methyl iodide and deuterated methyl cyanide: effects of increased interoscillator coupling on local mode states of C_{3v} symmetry

M. KHALIQUE AHMED[1] AND BRYAN R. HENRY[2]

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 17, 1987

This paper is dedicated to Professor J. A. Morrison

M. KHALIQUE AHMED and BRYAN R. HENRY. Can. J. Chem. **66**, 628 (1988).

The overtone spectra of CD_3I and CD_3CN are measured at room temperature in the liquid phase in the regions of CD-stretching local mode overtones corresponding to $\Delta v_{CD} = 2–5$. The spectra are analyzed in terms of a harmonically coupled local mode model. The local mode parameters ω, ωx, and $\gamma' v$, the interoscillator coupling between the methyl CD bonds, are determined. A comparison of the spectra of the CH_3Z molecules (Z = Cl, Br, I, CN) to the spectra of CD_3I and CD_3CN reveals the spectral effects of increased interoscillator coupling between the CD bonds.

M. KHALIQUE AHMED et BRYAN R. HENRY. Can. J. Chem. **66**, 628 (1988).

Opérant à la température ambiante et en phase liquide, on a mesuré les spectres d'harmonique du CD_3I et du CD_3CN dans les régions des harmoniques du mode d'élongation CD local correspondant à un $\Delta v_{CD} = 2–5$. On a analysé les spectres en fonction d'un modèle impliquant un couplage harmonique local. On a déterminé les paramètres ω, ωx et $\gamma' \omega$ ainsi que le couplage entre les oscillateurs des liaisons CD du groupement méthyle. Une comparaison entre les spectres des molécules CH_3Z (Z = Cl, Br, I et CN) et ceux du CD_3I et du CD_3CN mettent en évidence les effets spectraux provenant d'une augmentation du couplage entre les oscillateurs des liaisons CD.

[Traduit par la revue]

Introduction

Although the local mode model has been used extensively to interpret and understand the XH-stretching overtone spectra of polyatomic molecules (X = C, O, N, or S) (1–5), comparatively little attention has been paid to the XD-stretching overtone spectra of deuterated molecules. In the local mode model, the XH oscillators are assumed to behave anharmonically but essentially independently (6–8). Zero order vibrational wave functions are constructed as products of functions associated with the individual equivalent XH bonds. High energy overtone spectra ($\Delta v_{XH} \geq 3$) are dominated by transitions to pure local mode states whose components have all of the vibrational energy localized in one of a set of equivalent XH oscillators. The various pure local mode states corresponding to different symmetrized combinations of these components are effectively degenerate for $\Delta v_{XH} \geq 3$ (7–11). Therefore symmetry energy splitting of such states, which arises from coupling between the equivalent XH oscillators, is generally not observed for higher overtones.

Kinetic energy coupling between XD bonds is significantly greater than for XH bonds. This increase of interoscillator coupling on replacement of hydrogen by deuterium can cause a marked change in the local mode overtone spectral pattern. Recently we have observed such changes in a comparison of the overtone spectra of CH_2Z_2 and CD_2Z_2 molecules (Z = Cl, Br, or I) (12). In this paper, we extend our previous work to a study of the effects of increased interoscillator coupling on local mode states of C_{3v} symmetry. We compare the CD-stretching overtone spectra of CD_3I and CD_3CN to the spectra of the CH_3Z molecules (Z = Cl, Br, I, or CN) that we have recently measured (13).

Experimental section

High purity samples (99%) of CD_3I and CD_3CN were obtained from Aldrich Chemical Co. and were used without further purification. Liquid phase overtone spectra in the CD stretching regions of $\Delta v_{CD} = 2–5$ were recorded at room temperature on a Beckman 5270 spectrophotometer with the near ir light source. A 0.1 cm path length cell was used to record the $\Delta v_{CD} = 2$ spectra. The spectra in the regions of $\Delta v_{CD} = 3–5$ were recorded with a 3 cm path length cell. All of the spectra, in a digital format, were transferred to a Nicolet 1280 computer and converted to a linear energy scale. The spectra were plotted in wavenumber units with a Nicolet Zeta 160 plotter.

A single measurement of the $\Delta v_{CD} = 5$ spectra of both CD_3I and CD_3CN gave a very poor signal-to-noise ratio. The signal-to-noise ratio was improved by signal averaging four base line corrected scans on the Nicolet 1280 computer.

The spectra in the region of $\Delta v_{CD} = 2$ of both molecules and of $\Delta v_{CD} = 3$ of CD_3I consist of relatively well resolved peaks. The positions of the peak maxima in these spectra were determined from the digital data with a Nicolet 1280 program which simply identified the wavelength setting at the highest absorbance value in the vicinity of the peak. The spectra in the regions of $\Delta v_{CD} = 3–5$ for CD_3CN and of $\Delta v_{CD} = 4, 5$ for CD_3I were composed of overlapping peaks. These spectra were decomposed with a Fortran 77 curve analysis program, NIRCAP (14), which fitted Lorentzian peaks to the observed bands. The experimental and fitted spectra were plotted and compared to check the quality of the deconvolution fit.

Results and discussion

1. Spectral analysis

The liquid phase overtone spectra of CD_3I and CD_3CN in the regions of $\Delta v_{CD} = 2–5$ are shown in Figs. 1–4. The peak positions for these spectra and for the CD-stretching fundamentals are given in Tables 1, 2, and 3. Two types of peaks are observed. The first type is only associated with CD-stretching and is listed in Table 1. We assign these peaks within the local mode description to symmetrized combinations of Morse oscillator product functions $|v_1,v_2,v_3\rangle$, where v_1, v_2, and v_3 denote the vibrational quanta in each of the three methyl CD

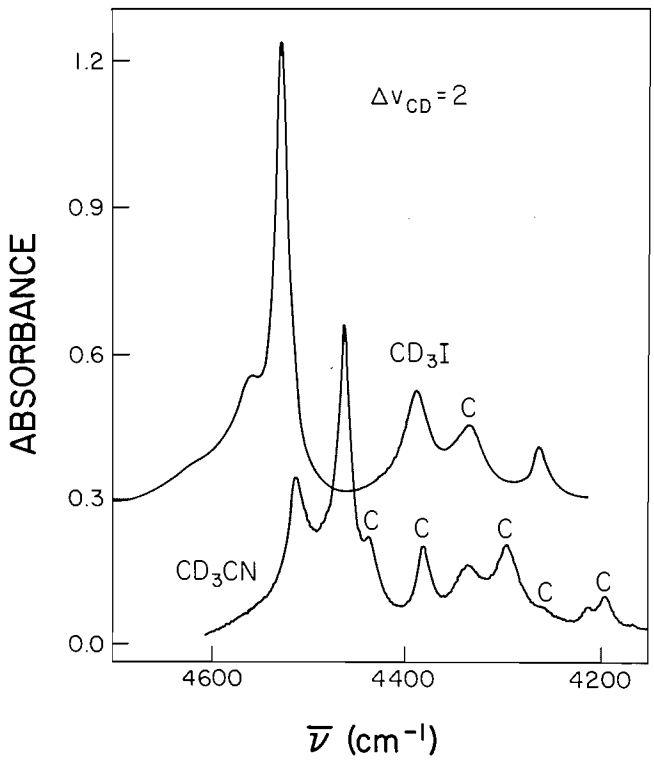

FIG. 1. Liquid phase overtone spectra of CD_3CN and CD_3I in the region of $\Delta v_{CD} = 2$. Spectra were measured at room temperature with a path length of 0.1 cm. The absorbance of CD_3I has been offset by 0.3 absorbance units.

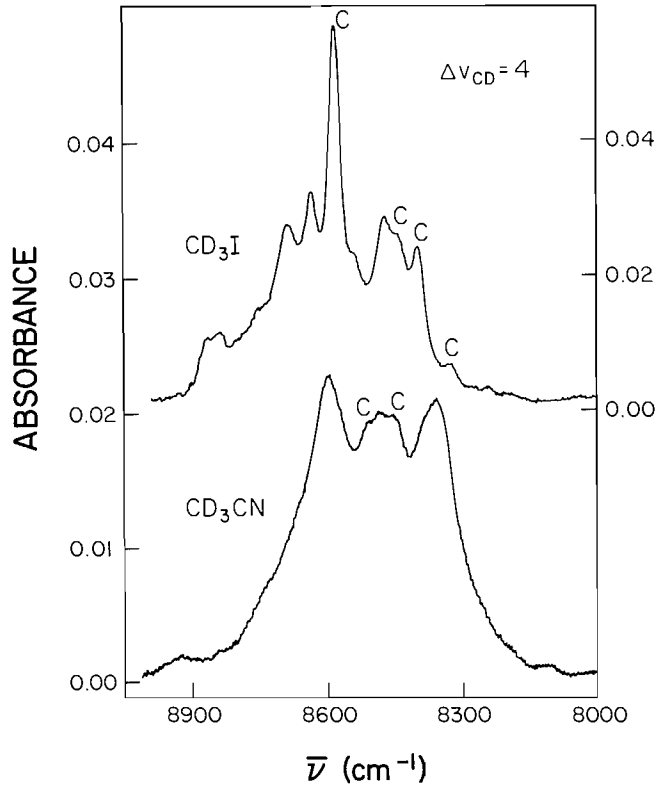

FIG. 3. Liquid phase overtone spectra of CD_3CN and CD_3I in the region of $\Delta v_{CD} = 4$. Spectra were measured at room temperature with a path length of 3.0 cm. The right hand ordinate scale represents the absorbance of CD_3I.

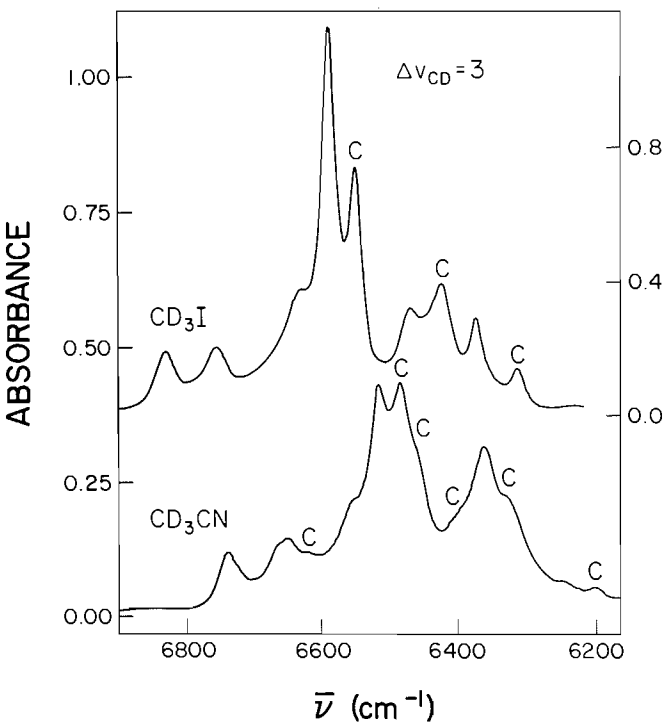

FIG. 2. Liquid phase overtone spectra of CD_3CN and CD_3I in the region of $\Delta v_{CD} = 3$. Spectra were measured at room temperature with a path length of 3.0 cm. The right hand ordinate scale represents the absorbance of CD_3I.

bonds, respectively, and $v_1 + v_2 + v_3 = \Delta v_{CD}$. The second type of peak is marked by a C in Figs. 1–4. In most cases, these local mode – normal mode combination peaks involve two quanta of DCD-bending combined with $v - 1$ quanta of CD-stretching for a given vibrational manifold v.

In assigning the CD-stretching peaks of Table 1, we make use of the harmonically coupled local mode model for an XH_3 system (8, 9, 13, 15) that we have applied previously to the overtone spectra of neopentane (9, 11) and the methyl halides (13). The product functions are symmetrized under the point group C_{3v}. The Hamiltonian is written in the form

$$[1]\quad H = E_0 + (v_1 + v_2 + v_3)\omega - (v_1^2 + v_2^2 + v_3^2 + v_1 + v_2 + v_3)\omega x + (p_1p_2 + p_1p_3 + p_2p_3)\gamma\omega + (q_1q_2 + q_1q_3 + q_2q_3)\phi\omega$$

where E_0 is the wavenumber energy of the ground state, and γ and ϕ characterize the off-diagonal kinetic and potential energy coupling, respectively. These parameters are defined in terms of Wilson **G** and **F** matrix elements ($\gamma = (-\frac{1}{2})G_{ij}/G_{ii}$; $\phi = (\frac{1}{2})F_{ij}/F_{ii}, i, j = 1, 2, 3$). p_i and q_i are normalized momentum and coordinate variables, and are conveniently expressed in terms of creation a^+ and annihilation a operators ($p = a^+ - a$; $q = a^+ + a$).

The details of this model have been described in our previous work (8, 9, 13). The model accounts for all of the anharmonicity that is diagonal in a single CH/CD oscillator. However, coupling between the simple product basis functions is restricted to

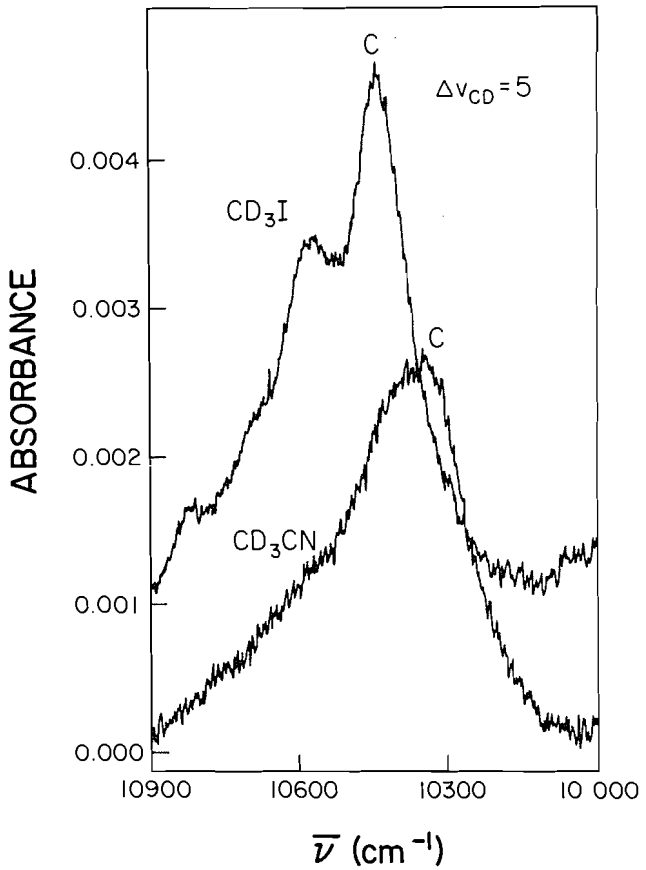

FIG. 4. Liquid phase overtone spectra of CD_3CN and CD_3I in the region of $\Delta v_{CD} = 5$. These spectra are the sum of four base line corrected scans. Individual scans were measured at room temperature with a path length of 3.0 cm. The absorbance of CD_3I has been offset by 0.001 absorbance units.

a given vibrational manifold and to the harmonic limit, i.e., functions couple only when their respective bond excitations differ by a single quantum. A calculation of the CD-stretching vibrational state energies requires the harmonic frequency ω, the anharmonicity constant ωx, and the effective coupling parameter $\gamma'\omega$ ($\gamma' = \gamma - \phi$) which appear in the intramanifold coupling matrices (9, 15, 16) of eq. [1].

As we have noted, in CH-stretching overtones for $\Delta v_{CH} \geq 3$, the spectra are dominated by transitions to pure local mode states whose components have all of the vibrational energy localized in one of a set of equivalent CH bonds. For example, in the methyl halides (13), the dominant peaks correspond to the states $|v,0,0\rangle_{A_1,E}$. Moreover such pure local mode states of different symmetry are effectively degenerate for $\Delta v_{CH} \geq 3$ (7–11). The parameters ω and ωx can be evaluated by fitting the observed energies of these pure local mode peaks to the energy equation of a diatomic Morse oscillator

$$[2] \quad \Delta E(v) = v\omega - (v^2 + v)\,\omega x$$

However, eq. [2] cannot be used to obtain ω and ωx for CD_3I and CD_3CN because extensive interactions between CD stretching states and combination states involving DCD-bending strongly perturb the peak positions. Therefore, in the present work an alternative procedure was used to obtain these local mode parameters.

When deuterium is substituted for hydrogen in a CH oscillator, the change in the harmonic frequency is given by

[a] $\delta_A = 1103\ cm^{-1}$, $\delta_E = 1039\ cm^{-1}$ from ref. 18.

$3101 \pm 4\ cm^{-1}$). The resultant values of ω_D are $2296\ cm^{-1}$ and $2275\ cm^{-1}$ for CD_3I and CD_3CN, respectively.

The effective interoscillator coupling parameter $\gamma'\omega$ can be obtained from the observed splitting (17, 18) between the fundamental CD-stretching modes of A_1 and E symmetries (9).

$$[4] \quad 3\gamma'\omega = E(|1,0,0\rangle_E) - E(|1,0,0\rangle_{A_1})$$

Values of $\gamma'\omega$ of 49.7 and 49.0 cm^{-1} are obtained for the CD oscillators of CD_3I and CD_3CN, respectively.

The only parameter left to be determined is the anharmonicity ωx. We determined this parameter by fitting ω, $\gamma'\omega$, and the observed energy of the $|1,0,0\rangle_E$ fundamental (17, 18) to the equation

$$[5] \quad E(|1,0,0\rangle_E) = \omega - 2\omega x + \gamma'\omega$$

Equation [5] expresses the expected energy of the $|1,0,0\rangle_E$ transition on the basis of the harmonic coupling model (9) and yields values of $\omega x = 28.3$ and 30.5 cm^{-1} for CD_3I and CD_3CN, respectively. The anharmonicity could also be extracted from an analogous expression for the energy of the $|1,0,0\rangle_{A_1}$ fundamental. Identical anharmonicity values are obtained on the basis of the observed frequencies (17, 18) of both fundamentals.

Substitution of these local mode parameters into the intramanifold coupling matrices of the Hamiltonian (eq. [1]) followed by diagonalization of these matrices gives the calculated energies of the peaks corresponding to the methyl CD bonds. The calculated and observed energies of these methyl CD-stretching peaks are given in Table 1, along with the peak assignments. The agreement between calculated and observed peak energies is reasonably good. The larger of the discrepancies at $\Delta v_{CD} = 3$ and 4 are generally associated with weak poorly resolved peaks where the experimental uncertainties in peak position are relatively high.

In assigning the spectra, we have identified a given state with the component designation that has the highest coefficient in the eigenvector associated with that particular energy. However, because of the relatively large value of $\gamma'\omega$, these states are often strongly mixed, and so such assignments are not always informative and serve primarily as state labels. In general, state mixing is more pronounced the higher the overtone level.

At $\Delta v_{CD} = 5$, the lowest energy vibrational states are clearly involved in a significant interaction with a close lying combination. The expected energy shift is undoubtedly a factor in the relatively poor agreement between the observed and calculated values in Table 1. At $\Delta v_{CD} = 5$, because the individual states are totally unresolved and because of extensive vibrational mixing, we have only given a calculated value in Table 1 from the simple Morse relation of eq. [2].

We have assigned the highest intensity peak in the spectra in the region of $\Delta v_{CD} = 2$ (Fig. 1) to the transition to the $|2,0,0\rangle_{A_1}$ state. The spectra are well resolved, particularly for CD_3I where there is only a single combination peak, in contrast to the spectra of CD_3CN where many combination peaks appear. From low to high energy, the four CD-stretching peaks correspond to transitions to the states $|1,1,0\rangle_{A_1}$, $|2,0,0\rangle_E$, $|2,0,0\rangle_{A_1}$, and $|1,1,0\rangle_E$. The splitting between the $|2,0,0\rangle_{A_1}$ and $|2,0,0\rangle_E$ peaks is much greater than the corresponding splitting in the spectra of the undeuterated methyl halides (13). This splitting arises from the harmonic coupling of the $|2,0,0\rangle_{A_1,E}$ states with the $|1,1,0\rangle_{A_1,E}$ states of the same symmetry via the γ and ϕ parts of the Hamiltonian (eq. [1]).

In the spectra in the region of $\Delta v_{CD} = 3$ (Fig. 2), the purely CD-stretching peaks again are better resolved in CD_3I than in CD_3CN because of the greater number of combination peaks in the latter spectrum. The splitting between the $|3,0,0\rangle_{A_1}$ and $|3,0,0\rangle_E$ peaks is similar to the corresponding splitting at $\Delta v_{CD} = 2$. The peaks corresponding to the states $|2,1,0\rangle_{A_1,E}$ and $|1,1,1\rangle_{A_1}$ appear with lower intensity than those corresponding to the pure local mode states $|3,0,0\rangle_{A_1,E}$.

The spectra in the region of $\Delta v_{CD} = 4$ (Fig. 3) are congested due to a large number of transitions. Transitions occur to several CD-stretching states of comparable intensity as well as to several combinations. Many of these peaks severely overlap and so the observed peak positions that are listed in Table 1 should be considered only as estimates. The splitting between the $|4,0,0\rangle_{A_1}$ and $|4,0,0\rangle_E$ peaks is reduced from the splittings at the two lower overtones.

"Local mode character" begins to develop at $\Delta v_{CD} = 5$ (Fig. 4). Despite a very strong interaction between the combination state and the two lowest energy CD-stretching vibrational states, it is clear that these latter states are unresolved and that they carry most of the CD-stretching oscillator strength. From diagonalization of the appropriate matrices, we can identify one of these lower energy states as predominantly $|5,0,0\rangle_E$. The other is very highly mixed but it has significant $|5,0,0\rangle_{A_1}$ character. For CD_3CN, the calculated splitting between the $|5,0,0\rangle_E$ state and the state with the greatest amount of $|5,0,0\rangle_{A_1}$ character is 32 cm^{-1}. This splitting is significantly reduced from the splitting at $\Delta v_{CD} = 4$.

Most of the local mode – normal mode combination states denoted "C" in Figs. 1–4 involve transitions to states with $v - 1$ quanta of CD-stretching and two quanta of DCD-bending, i.e., states of the type $|v - 1,0,0\rangle_{A_1,E} + 2\delta_{A_1,E}$. The frequencies of the DCD-bending modes ($\delta_A(CD_3I) = 938\ cm^{-1}$ (19), $\delta_E(CD_3I) = 1040\ cm^{-1}$ (17), $\delta_A(CD_3CN) = 1103\ cm^{-1}$ (18), $\delta_E(CD_3CN) = 1039\ cm^{-1}$ (18)) are approximately one-half of the CD-stretching frequencies. Thus these combination states can effectively interact with the states $|v,0,0\rangle_{A_1,E}$. Such peaks are commonly observed in the overtone spectra of several molecules (8, 13, 20–28).

Tentative assignments of these combination peaks are given in Tables 2 and 3 for the spectra of CD_3I and CD_3CN, respectively. The combinations can steal intensity from the CD-

For personal use only.

stretching peaks through resonant or near resonant interactions. Intensity stealing is particularly pronounced for the $\Delta v_{CD} = 4$ spectra of CD_3I and for the $|3,1,0\rangle_{A_1} + 2\delta_E$ combination in the $\Delta v_{CD} = 5$ spectra of both molecules.

2. Comparison of the spectra of the deuterated and undeuterated methyl halides

The principal differences between the spectra of CD_3Z and CH_3Z molecules can be understood on the basis of the relative values of ωx and $\gamma'\omega$. A similar analysis was possible in the comparison of the spectra of CD_2Z_2 and CH_2Z_2 molecules (12). The parameter $\gamma'\omega$ is determined primarily by kinetic energy coupling, and therefore it increases markedly with the replacement of hydrogens by deuteriums. In the molecules CH_3Z, $\gamma'\omega < \omega x$ (13) ($\omega x/\gamma\omega \sim 2$ for CH_3Cl, CH_3Br, and CH_3I, $\omega x/\gamma'\omega \sim 3$ for CH_3CN). In contrast, for CD_3I and CD_3CN, $\gamma'\omega > \omega x$ ($\omega x/\gamma'\omega \sim 0.6$). This change in the relative values of these local mode parameters affects the energy ordering of the CH/CD-stretching states, the splittings between the symmetrized states $|v_1,v_2,v_3\rangle_{A_1,E}$, and the relative intensities of states $|v_1,v_2,v_3\rangle_{A_1,E}$, where at least two of v_1 and v_2 are non-zero.

In the general local mode pattern, the pure local mode states have the lowest energies among all the CH-stretching states at each overtone level. For example, for the molecules CH_3Z (13), the $|v,0,0\rangle_{A_1}$ states are lowest in energy at each overtone manifold Δv. However, for the molecules CD_3Z, the $|v-1,1,0\rangle_{A_1}$ states are the lowest in energy for $\Delta v_{CD} = 2, 3$, and 4. A primary factor which contributes to a lower energy for these latter states is the subtraction of the term (constant) $\gamma'\omega$ in the diagonal elements of the energy matrices (9, 15, 16) and the increased importance of this term in the CD_3Z molecules.

The energy separation betwen the states $|v,0,0\rangle_{A_1}$ and $|v,0,0\rangle_E$ is much greater in the spectra of CD_3Z molecules than of CH_3Z molecules. As we have noted this splitting increases with an increase in the interoscillator coupling parameter $\gamma'\omega$ because of increased vibrational mixing. Thus the greater splitting in the CD_3Z molecules is not unexpected. The splitting is larger at $\Delta v_{CD} = 2$ and 3 than it is at $\Delta v_{CD} = 4$, and it decreases even more at $\Delta v_{CD} = 5$. Therefore at some higher overtone, the states $|v,0,0\rangle_{A_1}$ and $|v,0,0\rangle_E$ will become degenerate as they are for the molecules CH_3Z at $\Delta v_{CH} \geq 4$.

In the general local mode pattern, as v increases, intensity is increasingly concentrated in transitions to the pure local mode states. For example, in the spectra of the CH_3Z molecules, transitions to the $|v,0,0\rangle_{A_1,E}$ states are the dominant CH-stretching transitions for $\Delta v_{CH} \geq 3$ (13). On the other hand, for the CD_3Z molecules, states whose components have the vibrational energy spread out over more than one methyl bond show considerable intensity at all overtone levels. In fact the local mode combination states $|3,1,0\rangle_{A_1}$, $|3,1,0\rangle_E$, $|2,1,1\rangle_{A_1}$, and $|2,1,1\rangle_E$ carry most of the CD-stetching overtone intensity at $\Delta v_{CD} = 4$. In recent theoretical work on overtone intensities in the spectra of CH_2Cl_2 and CD_2Cl_2 (29, 30), we have suggested that the dominant source of intensity for such local mode combination states is vibrational state mixing of these states with the pure local mode states. As we have noted such vibrational state mixing increases with increasing values of $\gamma'\omega$ and is particularly important for the CD_3Z molecules. Local mode – normal mode combination states "C" are also involved in intensity stealing from the pure local mode states. Their prominence in the overtone spectra of the CD_3Z molecules further perturbs the intensity distribution. The question of individual contributions to overtone band intensity within a given manifold Δv is a complicated one and requires further study.

In summary, the harmonically coupled local mode model can be used to analyze the CD-stretching peak positions in the overtone spectra of the CD_3Z molecules. However, the spectral patterns are not as simple as the familiar local mode patterns exhibited by the spectra of the CH_3Z molecules (13). Moreover, the relative increase in the interoscillator coupling parameter $\gamma'\omega$ causes a greater mixing of the zero order vibrational states in CD_3Z molcules than in CH_3Z molecules and, as a result, the vibrational analysis is not as straightforward.

This paper is dedicated to Professor J. A. Morrison

J. Z. LARESE, L. PASSELL, and B. RAVEL. Can. J. Chem. **66**, 633 (1988).

A neutron diffraction study of the low temperature structure and loss of orientational order was performed for the low density phase of ethylene adsorbed on graphite. At temperatures below 30 K the ethylene molecules form a centered-rectangular herringbone structure with their C═C bond parallel to the surface. At $T > 30$ K we observe a gradual loss of orientational order and a simultaneous increase in the near-neighbor spacing. This correlates well with the onset of rotational motions about an axis perpendicular to the C═C bond which remains predominately parallel to the surface plane. We speculate that the transition to this rotator phase is accompanied by a structural change to a triangular lattice.

J. Z. LARESE, L. PASSELL, et B. RAVEL. Can. J. Chem. **66**, 633 (1988).

On a réalisé une étude par diffraction électronique de la structure présente à basse température ainsi que de la perte de l'ordre d'orientation de la phase de basse densité de l'éthylène adsorbé sur du graphite. A des températures inférieures à 30 K, les molécules d'éthylène forment une structure rectangulaire à face centrée, en forme d'arête de poisson, dans laquelle les liaisons C═C sont parallèles à la surface. Lorsque $T > 30$ K, on observe une perte graduelle de l'ordre d'orientation et une augmentation simultanée de l'espacement entre les voisins rapprochés. Ces résultats sont en bonne corrélation avec le début des mouvements de rotation autour de l'axe perpendiculaire à la liaison C═C qui reste d'une façon prédominante parallèle à la surface du plan. On croit que la transition de cette phase de rotation s'accompagne d'un changement de structure conduisant à un réseau triangulaire.

1. Introduction

The structures and dynamics of rare gas and molecular films physisorbed on the basal plane of graphite have been intensively investigated during the past decade. It is by now well established that at sufficiently low temperatures molecules with non-spherical outer electron contours form structures in which the molecular axes retain distinct orientations within the unit cell. The majority of the systems studied to date have been of diatomic or elongated molecules that form herringbone structures which are related to the shape of the adsorbed molecule (1–4).

Here we describe a neutron diffraction study of the structural arrangement of one of the solid phases of ethylene on graphite — the low density (LD) phase — which is of particular interest because it is known to undergo a continuous melting transition (5–7). Ethylene, C_2H_4, is a planar molecule with carbon–carbon distance 1.338 Å, carbon–hydrogen distance 1.093 Å, and hydrogen–carbon–hydrogen angle 117.2°. Both steric arguments and configuration energy calculations suggest that the C═C axes of the molecules in the LD phase are aligned parallel to the substrate surface (8, 9). It is also known from Larese and Rollefson's nmr study of the spin–lattice relaxation time, T_1, that some type of orientational ordering occurs near 37 K, although the structure of the ordered phase could not be identified (10). Additional evidence of ordering is seen in the high resolution heat capacity measurements of Kim *et al.* (11) who find a weak heat capacity signal near 40 K which they conjecture to be associated with orientational ordering. The molecular dynamics (MD) simulations of Nosé and Klein (12) and Moller and Klein (13) on smooth and corrugated graphite substrates respectively also suggest the formation of an orientationally-ordered phase.

Our previous efforts to detect orientational ordering in the LD-solid phase of ethylene on graphite with neutrons had been inconclusive (8). Encouraged by the nmr and heat capacity studies, however, and by the success of the MD simulations in describing the melting behavior of the films, we set out once again to examine this challenging question.

2. Experimental details

The neutron scattering experiments were performed at Brookhaven National Laboratory's High Flux Beam Reactor on the H4M triple axis spectrometer operated in the elastic mode. The incident neutron wave number was set at 2.65 $Å^{-1}$ using a pyrolytic graphite (PG) monochromator. A PG filter was used before the sample to suppress any higher order contamination present in the incident beam. Collimation before and after the sample was 40′. No collimation was used in front of the detector. This resulted in an instrumental resolution of 0.0263 $Å^{-1}$ full width at half maximum (FWHM).

The substrate was a vermicular form of crystalline graphite (Union Carbide GTA grade) which was baked *in vacuo*, recompressed and then loaded in a sample can in a helium-filled glove box. The sample was mounted on the cold tip of a closed-cycle helium refrigerator which was regulated to within 0.1 K of the desired temperature. Deuterated ethylene (C_2D_4) was used in preference to C_2H_4 because it is superior as a coherent scatterer of neutrons.

Diffraction profiles from the ethylene film were obtained as usual by plotting the difference between the scattering with and without adsorbate in the sample cell. The C_2D_4 gas was loaded into the cell at ~140 K and then cooled immediately to 80 K. It was then slowly (~1 K/min) cooled to 50 K where it was annealed for about 3 h. This procedure was followed because previous studies indicated that a slow relaxation process, perhaps due to some type of structural readjustment, occurs between 50 and 60 K.

The ethylene coverage (X) used throughout this study was 0.6 monolayers, where $X = 1.0$ corresponds to a completed $\sqrt{3} \times \sqrt{3}$ monolayer as determined from a nitrogen isotherm. $X = 0.6$ monolayers corresponds to the LD phase as identified in an earlier study (8). It should be pointed out that at all coverages and temperatures the ethylene monolayer is incommensurate with the graphite substrate.

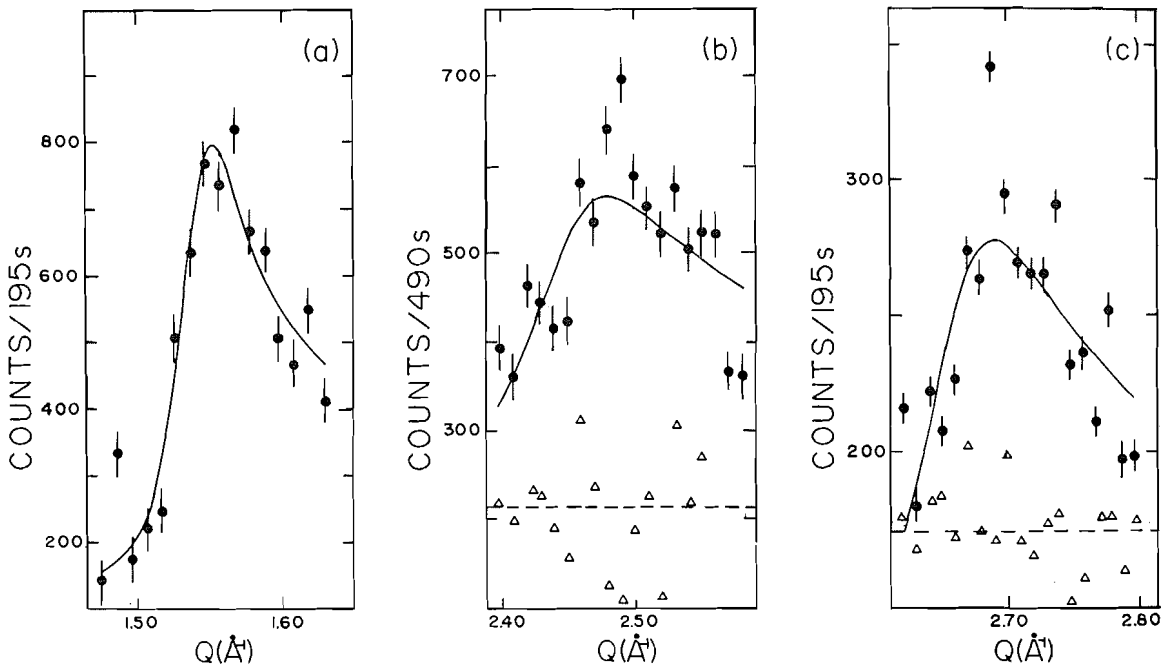

FIG. 1. Diffraction profiles (solid dots) of the (*a*) (1,1), (*b*) (2,0), and (*c*) (2,1) index peaks for a 0.6 monolayer ethylene film at 20 K. The solid lines represent a least-square fit to the experimental data using a powder-averaged Lorentzian lineshape folded with the instrumental resolution. The open triangles in (*b*) and (*c*) are scans made at 50 K. They show clearly that no peaks are present in the difference spectrum at the higher temperature.

The first experiments were made using a sample can constructed out of aluminum. Unfortunately, the aluminum (111) peak appears at $Q = 2.69$ Å^{-1} which is close to the scattering vector range where the superlattice peaks of the orientationally-ordered phase were predicted to appear. Later measurements were therefore made with a copper can, chosen because its contribution to the background scattering (i.e. the (111) copper Bragg peak) would be outside the range of experimental interest. The amount of graphite loaded into the copper cell was roughly half of that in the aluminum cell. This resulted in a decrease of monolayer gas capacity by the same fraction. Except for a change in the background scattering due to the different sample cans, the results of both runs were the same.

3. Results

Figure 1 shows the results of elastic diffraction scans performed at ~20 K with a C_2D_4 coverage of $X = 0.6$. Three diffracted peaks can clearly be resolved within the q range studied. All have the "sawtooth" profiles characteristic of diffraction from randomly-orientated, two-dimensional crystalline arrays. Using the unit cell constants predicted by Moller and Klein (13), these index respectively as the (1,1) (*a*), (2,0) (*b*), and (2,1) (*c*) peaks of a centered-rectangular lattice. An increase in scattering consistent with the existence of a fourth diffracted peak, the (0,2), is evident near $Q \sim 1.76$ Å^{-1}. Unfortunately, the scan was not extended beyond this point because previous attempts to resolve weak peaks lying in the neighborhood of the intense graphite (002) peak ($Q \sim 1.87$ Å^{-1}) have been unsuccessful. The solid lines in the figure are fits to the experimental data using a powder-averaged Lorentzian lineshape folded with the instrumental resolution.

Figure 2*a* illustrates the temperature dependence of the integrated intensity for the three peaks in Fig. 1. In Fig. 2(*b*) we show how the lowest index peak (which becomes the (1,0) peak in the orientationally disordered LD phase) shifts with temperature. Empty cell scans were taken at 20 and 55 K so that any thermal dependence of the background could be compensated. No evidence of peaks other than that observed at $Q \sim 1.53$ Å^{-1} was detected for $T > 40$ K. In interpreting the total integrated intensities for the ranges 2.65–2.8 Å^{-1} and 2.4–2.55 Å^{-1} in Fig. 2*a* it is important to note that both superlattice peaks sit on the trailing edge of the very intense peak at 1.53 Å^{-1}. Above 40 K all of the intensity can be acounted for as background scattering and scattering from the trailing edge of the $q = 1.53$ Å^{-1} peak: the peaks at 2.49 and 2.69 Å^{-1}, i.e. the superlattice peaks of the fully-ordered structure, have disappeared. Figures 1*b* and 1*c* show difference profiles at $T \sim 50$ K for both peaks which illustrate that no intensity is left in the peaks above the transition. The decrease in integrated intensity in the 1.5–1.59 Å^{-1} range at higher temperatures is due to the Debye–Waller effect. Figure 3 gives the results of a detailed examination of the decrease in integrated intensity for $30 \text{ K} < T < 40$ K. The dotted lines estimate the background level at 40 K.

Figure 2*c* shows the rotational diffusion rates as a function of temperature. These data, derived from a separate incoherent, quasi-elastic neutron scattering study of C_2H_4 (6), demonstrate — as the loss of orientational order implies — that rotational diffusive motions about an axis with an effective proton radius of ~1.5 Å (essentially all of the observed incoherent scattering is produced by the protons) occurs at ~35 K. The reader is reminded that the proton radius for ethylene rotations about an axis normal to the film plane is 1.55 Å.

4. Discussion

Table 1 provides a comparison of the experimental centered-rectangular cell constants with the MD predictions of Moller and Klein (13). The experimental values were determined from the peak positions derived from lineshape analysis. The agreement is very satisfactory. The possibility that the peak near $q \sim 2.65$ Å^{-1} is the superposition of two closely spaced yet unresolved peaks (i.e. the (0,3) and the (2,1)) leads to some systematic uncertainty in our cell constants.

To test the MD orientational parameters a structure factor

b (Å)	7.05	7.05±0.05

calculation was performed using the molecular configurations from the simulation. The relative intensity of the three observed peaks agrees qualitatively with expectations, however, our inability to recover a greater number of reflections limits what we can say about the orientation of the molecules. Past neutron experiments employing a multi-detector array (14) to cover a broad Q range demonstrate that orientational parameters can be obtained for overlayer systems and future experiments incorporating such a device are, in fact, already being planned.

Examining the results shown in Fig. 2 and Fig. 3 suggests the following interpretation. First, the intensities of the (2,0) and the (2,1) peaks decrease steadily between 30–40 K indicating the onset of rotational disorder. Over the same temperature interval the intensity of the (1,1) peak ($q \sim 1.54$ Å^{-1}) grows. This behavior is consistent with loss of orientational order and a redistribution of scattered intensity back into the primary peak of the high-temperature orientationally-disordered phase. Second, we see in Fig. 2*b* that the position of the (1,1) peak remains fixed, apparently until most of the orientational order is destroyed (i.e. $T < 40$ K), at which point it shifts progressively toward lower q. This clearly shows that the 2D lattice expands once the orientational order is lost. The rotational diffusion constants of Fig. 2*c*, indicating the onset of rotational motion about an axis perpndicular to the C=C bond (radius 1.5 Å), are, as we earlier noted, consistent with the loss of the ordered structure.

The above facts seem to point naturally to the following physical picture. Once rotational diffusion about an axis perpendicular to the C=C bond becomes significant, the unit cell expands to minimize the energy associated with the overlap of the outer electron contours of the molecules. Recall that a centered-rectangular cell with sides in the ratio of $1 \times \sqrt{3}$ is a non-primitive unit cell for an equilateral triangular lattice. Therefore, associating the thermal expansion of the ordered solid with a change to a triangular structure can be easily understood. Molecules executing random rotations of the type depicted in Fig. 4*a* project a circular cross-section onto the surface. Combining the experimental results presented above with the fact that the simplest packing of circular discs in two dimensions is triangular, one concludes that a change in symmetry from centered rectangular (unit cell dimensions in the ratio $1 \times \sqrt{2}$) to triangular occurs once the loss of orientational

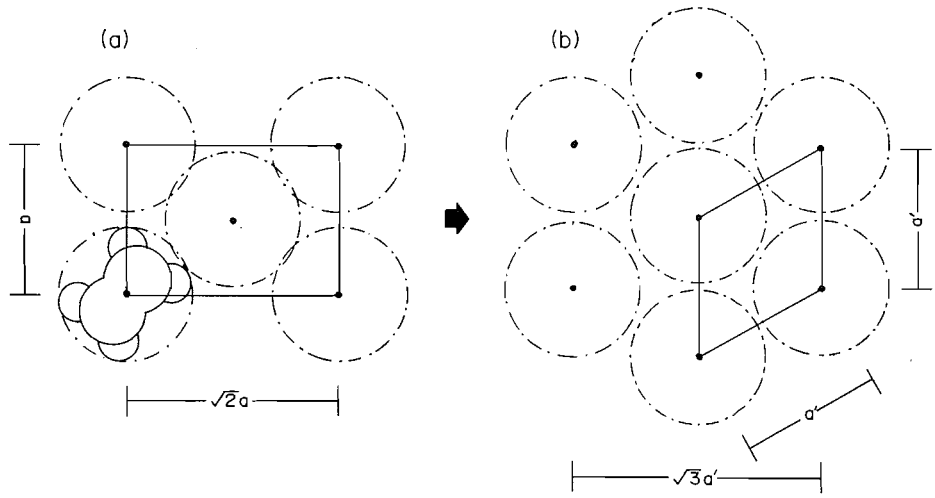

FIG. 4. (a) Schematic view of the centred-rectangular structure with sides of length a and $\sqrt{2}a$. Dash–dotted lines indicate the estimated outer electron contours of ethylene molecules rotating about an axis perpendicular to C=C bond at $T > 40$ K. Notice that some overlap occurs. (*b*) Schematic view of the same molecules on an expanded equilateral triangular lattice with lattice constant a'. Note the analogy with the centered-rectangular structure.

order is complete. Figure 4 shows schematically how this might happen using a simple hard sphere model.

A comment concerning the absence of any higher index peaks for the higher temperature LD triangular phase is necessary. At $q \sim 2.65$ Å^{-1}, for example, the (2,1) index peak would be expected to appear. The only peak observed at $T > 40$ K, however, was the (1,0) peak at ~ 1.53 Å^{-1}. This is because the rapid reorientation of the ethylene molecules above 40 K causes a redistribution of the scattered intensity. Several years ago, Press and Eckert (15) suggested a form factor for ethylene molecules in bulk ethylene which assumes spherical reorientation of the molecules. Examination of this function shows that the intensity of the (2,1) peak would be about 50 times smaller than the (1,0) peak, making it undetectable at our level of sensitivity.

5. Conclusion

Using neutron diffraction we have determined the low temperature unit cell of the orientationally-ordered LD solid phase of ethylene on graphite and observed the loss of orientational order at higher temperatures. The experimental cell constants (5.03 ± 0.05 Å, 7.05 ± 0.05 Å) for the ordered phase agree well with the MD simulations (4.95 Å, 7.05 Å). A definitive determination of the orientational arrangement of the molecules within the unit cell was not possible since an insufficient number of diffracted peaks were observed. Nonetheless, our experimental data strongly suggest a change from rectangular to triangular structure once orientational disorder sets in.

The transition to the orientationally disordered state (as determined by the thermal variation of the integrated intensity) appears to be continuous. This is consistent with the heat capacity results of Kim *et al.* (11). No attempt was made to extract a critical exponent due to the poor statistics associated with the weak diffraction peaks.

Thermodynamic properties of multicomponent electrolyte solutions in mixed solvents. 5. HCl + NaCl + urea + water at 278.5–318.15 K

DIAN-YUAN MEN, JIA-ZHEN YANG, CHUN-YU LIANG, LI-TIAN ZHANG, HUAN GAO, AND RU-LAN YANG
Department of Chemistry, Liaoning University, Shenyang, People's Republic of China

Received August 4, 1987

This paper is dedicated to Professor James A. Morrison

DIAN-YUAN MEN, JIA-ZHEN YANG, CHUN-YU LIANG, LI-TIAN ZHANG, HUAN GAO, and RU-LAN YANG. Can. J. Chem. **66**, 637 (1988).

This paper reports electromotive force measurements of the cells

$$\text{Pt}|\text{H}_2(\text{g, 101.325 kPa})|\text{HCl}(m_A), x \text{ urea}, (1-x)\text{H}_2\text{O}|\text{AgCl}|\text{Ag} \quad \text{(A)}$$

and

$$\text{Pt}|\text{H}_2(\text{g, 101.325 kPa})|\text{HCl}(m_A), \text{NaCl}(m_B), x \text{ urea}, (1-x)\text{H}_2\text{O}|\text{AgCl}|\text{Ag} \quad \text{(B)}$$

in mixed solvents of urea, mole fraction $x = 0.05$, at five temperatures from 278.15 to 318.15 K. The standard potentials of Ag–AgCl electrode in mixed solvents were obtained from the emf of cell (A) for HCl of molality m_A from 0.02 to 0.11 mol kg^{-1}, both by extrapolation on the basis of an extended Debye–Hückel equation and by a polynomial approach proposed in this paper on the basis of Pitzer's electrolytic solution theory. The standard free energies of transfer for HCl are discussed. The activity coefficients of HCl γ_A in HCl + NaCl + urea + water have also been obtained from the emf of cell (B) at constant total ionic strength $I = 0.5$, 1.0, 1.5, and 2.0 mol kg^{-1}. The experimental results show that HCl obeys Harned's rule and log γ_A is a linear function of absolute temperature T. They also indicate that the relative partial molar enthalpy of HCl obeys a similar Harned's rule.

DIAN-YUAN MEN, JIA-ZHEN YANG, CHUN-YU LIANG, LI-TIAN ZHANG, HUAN GAO et RU-LAN YANG. Can. J. Chem. **66**, 637 (1988).

On a effectué des mesures de force électromotrice sur les cellules

$$\text{Pt}|\text{H}_2(\text{g, 101.325 kPa})|\text{HCl}(m_A), x \text{ urée}, (1-x)\text{H}_2\text{O}|\text{AgCl}|\text{Ag} \quad \text{(A)}$$

et

$$\text{Pt}|\text{H}_2(\text{g, 101.325 kPa})|\text{HCl}(m_A), \text{NaCl}(m_B), x \text{ urée}, (1-x)\text{H}_2\text{O}|\text{AgCl}|\text{Ag} \quad \text{(B)}$$

dans des solvants mixtes, à une fraction molaire d'urée $x = 0{,}05$ et à cinq températures allant de 278,15 à 310,15 K. On a obtenu les potentiels standards pour l'électrode Ag–AgCl dans des solvants mixtes en utilisant les fem de la cellule (A) pour des molalités de HCl m_A allant de 0,08 à 0,11 mol kg^{-1} et en faisant appel soit à une extrapolation sur le base d'une équation de Debye–Hückel étendue soit à l'approche polynomiale proposée dans ce travail sur la base de la théorie des solutions électrolytiques de Pitzer. On discute des énergies libres standard de transfert du HCl. On a déduit les coefficients d'activité du HCl (γ_A) dans le système HCl + NaCl + urée + eau à partir des fem de la cellule (B), à force ionique totale constante de $I = 0{,}5$, 1,0, 1,5 et 2,0 mol kg^{-1}. Les résultats expérimentaux démontrent que le HCl obéit à la loi de Harned et que le log γ_A est une fonction linéaire de la température absolue. Ils indiquent aussi que l'enthalpie molaire partielle relative du HCl obéit à une loi semblable à celle de Harned.
[Traduit par le journal]

Introduction

Thermodynamic properties of mixed electrolytes in aqueous solution have been widely investigated by the emf method, but very rarely in mixed solvents of water with organic solvent. Except for the work of Akerlof *et al.* (1) for HCl + NaCl at a constant ionic strength $I = 1$ mol kg^{-1} in methanol + water and that of Khoo and co-workers (2, 3) for HCl + KCl (or NH_4Cl) in the same mixed solvents at the same ionic strength, the only other reported work of comparable precision appears to be ours (4–6) for HCl + NaCl at $I = 0.1$, 0.5, 1.0, 2.0, and 3.0 mol kg^{-1} in mixed solvents.

In a continuation of previous studies, the present investigation has been carried out by using HCl–NaCl in $x = 0.05$ urea + water mixture. The structure of urea + water is of great importance in understanding protein denaturation in NaCl + urea + water. This paper consists of two parts. In the first, using the emf of cell (A) without liquid junction

$$\text{Pt}|\text{H}_2(\text{g, 101.325 kPa})|\text{HCl}(m_A), x \text{ urea}, (1-x)\text{H}_2\text{O}|\text{AgCl}|\text{Ag} \quad \text{(A)}$$

where m_A is the molality of HCl, the standard electrode potentials of the Ag–AgCl electrode in the mixed solvent at each temperature were determined, both by extrapolation on the basis of the extended Debye–Hückel equation and by a polynomial approach proposed in this paper on the basis of Pitzer's electrolytic solution theory (7, 8); the standard free energies of transfer for HCl are discussed. In the second, using the emf of cell (B)

$$\text{Pt}|\text{H}_2(\text{g, 101.325 kPa})|\text{HCl}(m_A), \text{NaCl}(m_B), x \text{ urea}, (1-x)\text{H}_2\text{O}|\text{AgCl}|\text{Ag} \quad \text{(B)}$$

where m_B is the molality of NaCl, the activity coefficients γ_A of HCl were obtained at total ionic strength $I = 0.50$, 1.00, 1.50, and 2.00 mol kg^{-1} in the mixture at each temperature. The results show that HCl still obeys Harned's rule and indicate the linear relation between log γ_A and absolute temperature T, and that the relative partial molar enthalpy of HCl similarly obeys Harned's rule.

2. Experimental

Urea of A.R. reagent grade was recrystallized twice from 50 mass% alcohol + water and dried *in vacuo* at 303 K.

Hydrochloric acid used in all preparations of the solution was

TABLE 1. The standard electrode potential of Ag|AgCl in pure water

T(K)	278.15	288.15	298.15	308.15	318.15
E^0_{exp}(V)	0.23412	0.22859	0.22236	0.21558	0.20823
E^0_{lit}(V)	0.23410	0.22857	0.22238	0.21566	0.20836

prepared from G.R. reagent grade by distilling in an all-glass apparatus. Only the middle fraction was collected. The stock solution of HCl was standardized gravimetrically by weighing silver chloride. The average difference among five replicate determinations was less than ±0.02%. The water, which was deionized, was distilled using a quartz still, and its conductance was $(0.9–1.2) \times 10^{-4}\ \Omega^{-1}\ m^{-1}$. NaCl of reagent grade was dried for 3 h before use. All solutions to be measured were freshly prepared by weight with correction for air buoyancy. The concentrations of all solutions were known to within ±0.02%.

The Ag|AgCl electrodes were of the thermal electrolytic type (9) aged in 0.1 mol kg^{-1} HCl, which was deoxygenated by bubbling hydrogen. Three days after preparation, the finished electrodes were compared and had bias potentials of usually less than ±0.05 mV. Standard electrode potentials of Ag|AgCl in pure water were measured by Bates's method (10) and, with the literature data, are listed in Table 1. The hydrogen electrodes were lightly coated with platinum black before each measurement according to the method of Hills and Ives (11). Electrolytically generated hydrogen, purified in the usual manner (11), served as the source of hydrogen.

The cells were of all-glass construction with three isothermal presaturators containing the experimental solution. The cells were thermostated at each temperature with an accuracy of ±0.02 K.

All measurements were made with two Ag–AgCl electrodes and two hydrogen electrodes. Equilibrium was reached about 2–3 h after the initiation of hydrogen bubbling. The potentials of the cells were measured at 298.15, 278.15, 288.15, 298.15, 308.15, 318.15, and 298.15 K by a UJ-25 type potentiometer, which was calibrated against a standard cell. A mirror-type galvanometer was used as a null detector. The criterion for attainment of equilibrium was a steady reading to the nearest 0.05 mV for a period of about 1 h. The standard deviation of readings for four cells was less ±0.1 mV. The emf was measured at 298.15 K at the beginning, in the middle, and at the end of each run. These three readings at 298.15 K agreed within ±0.07 mV. The atmospheric pressure was measured by a barometer and was calibrated for temperature, altitude, and degree of latitude. Observed values of emf were converted to a hydrogen partial pressure of 101.325 kPa.

The densities of solvent mixtures over the range of temperatures involved were determined by the usual pycnometric technique. The dielectric constants of the solvent mixtures were measured by means of a DK-300 type dekemeter.

3. Results and discussion

The emf's of cell (A), which were measured at temperatures from 278.15 to 318.15 K at HCl molalities from 0.02 to 0.11 mol kg^{-1} in mixed solvents of 0.05 mole fraction of urea, are listed in Table 2 where each value of emf is the average of four cells.

1. Standard emf

The most common method used to evaluate the standard potential involves the graphical extrapolation of linear plots of emf of the cell against concentration of HCl on the basis of the extended Debye–Hückel equation, as in the following:

$$[1]\quad E^{0\prime} = E + 2k \log (m_A/m^0_A) - 2kA\sqrt{(m_A\rho)}/[1 + a^0B \times \sqrt{(m_A\rho)}] - 2k \log (1 + 0.002m_AM) = E^0_A - 2bm_A$$

where $m^0_A = 1$ mol kg^{-1}, E^0_A is the standard potential of the cell on the molal scale, E is the observed emf of the cell, ρ is the density of mixed solvent, M is the mean molecular weight of the solvent, $k = RT\ (\ln 10)/F$, R is the gas constant, T is the absolute temperature, F is Faraday's constant, a^0 is the ion-size parameter, chosen as equal to 0.4 nm, and A and B are the Debye–Hückel parameters. When $E^{0\prime}$ was plotted against m_A at each temperature, a good straight line was obtained (see Fig. 1). All linear correlation coefficients r were over 0.99. The intercepts of these straight lines are the standard emf, E^0_M, of cells whose values and standard deviation σ all are listed in Table 2.

Because the ion-size parameter a^0 cannot be measured, the chosen value of a^0 is an arbitrary decision and causes some uncertainty in the extrapolation on the basis of the extended Debye–Hückel equation. However, we here propose a polynomial approach to determine E^0_M on the basis of Pitzer's recent electrolyte solution theory.

The relevant equations for a 1–1 single electrolyte solution derived by Pitzer are

$$[2]\quad \ln \gamma_{MX} = f^\gamma + mB^\gamma_{MX} + m^2C^\gamma_{MX}$$

where each symbol has the same meaning as in Pitzer's article (12, 13). Since the molality of HCl used in the experiment is so dilute, C^γ_{MX} may be recognized as zero. Other quantities in eq. [2] are defined as follows:

$$[3]\quad f^\gamma = -A_\phi x$$

$$[4]\quad x = I^{1/2}(1 + bI^{1/2}) + (2/b)\ln(1 + bI^{1/2})$$

$$[5]\quad B^\gamma_{MX} = 2\beta^{(0)} + 2\beta^{(1)}y$$

$$[6]\quad y = [1 - \exp(-\alpha I^{1/2})(1 + \alpha I^{1/2} - 1/2\alpha^2 I)]/(\alpha^2 I)$$

$$[7]\quad A_\phi = (1/3)(2\pi N_0\rho)^{1/2}(e^2/DkT)^{3/2}$$

where N_0 is Avogadro's constant, D is the dielectric constant, k is Boltzmann's constant, e is the electron charge, and $\beta^{(0)}$ and $\beta^{(1)}$ are parameters characteristic of the electrolyte. According to Khoo's suggestion (12), $\alpha = 2$, $b = 1.2$ in mixed solvents. Then, the Nernst equation reduces to

$$[8]\quad E^{0\prime} = E + 2k' \ln(m/m_0) - 2k'A_\phi x = E^0_M - 2mk'\beta^{(0)} - 2mk'\beta^{(1)}y$$

where $k' = RT/F$ and $m_0 = 1$ mol kg^{-1}. Equation [8] is homologous to the following polynomial:

$$[9]\quad u = a_0f_0 + a_1f_1 + a_2f_2$$

Setting $f_0 = 1$, $f_1 = -2mk'$, $f_2 = -2mk'y$, coefficients of the polynomial were obtained by a polynomial approach program on a computer, where $a_0 = E^0_M$, which were noted as E^0_M(P) and are listed in Table 2. These results show that E^0_M(P) obtained by the polynomial approach nearly agree with those obtained by extrapolation. We also examined other authors' experimental data (13–15) by the method proposed in this paper, and the calculated results are listed in Table 3. From Table 3, the standard emf's of cells obtained by the polynomial approach on the basis of Pitzer's theory agree with traditional extrapolation, within the experimental error.

r: linear correlation coefficient.

The standard emf on the mole fraction scale E^0_N has been calculated by means of the relationship

[10] $E^0_N = E^0_M - 2k' \ln(1000/M)$

The values of E^0_N could be expressed as a function of temperature in the following form, for pure water:

[11] $${}^{W}E^0_N = 0.14972 + (4.6208 \times 10^{-4})T - (2.9904 \times 10^{-6})T^2$$

and for mixed solvent:

[12] $${}^{S}E^0_N = 0.37426 - (7.4871 \times 10^{-4})T - (9.4296 \times 10^{-7})T^2$$

2. Transfer quantities of HCl

Since solvent effects on the thermodynamic properties of HCl related to the present study will be best reflected in the standard free energy of transfer (ΔG^0_t), the entropy (ΔS^0_t), and the enthalpy (ΔH^0_t) changes accompanying the transfer of a mole of HCl from water (w) to mixed solvent (s), these were evaluated at different temperatures by application of the following relations:

[13] $\Delta G^0_t = -({}^{S}E^0_N - {}^{W}E^0_N)$

[14] $\Delta S^0_t = F(\partial \Delta E^0_N / \partial T)$

[15] $\Delta H^0_t = \Delta G^0_t + T\Delta S^0_t$

The mole fraction scale has been used, because that will eliminate effects arising from concentration changes of HCl accompanying the transfer process and will reflect solvent effects more clearly. The values obtained from eqs. [13]–[15] are listed in Table 4.

As can be seen from the table, all negative ΔG^0_t's suggest that the transfer of HCl from water to the urea–water mixture is favourable. This relative ease of transfer of HCl is of course

TABLE 4. Standard free energy, entropy, and enthalpy of transfer of HCl from water to urea + water on the basis of the mole fraction scale

T(K)	278.15	288.15	298.15	308.15	318.15
ΔG_t^0 (kJ mol^{-1})	−4.967	−4.929	−4.943	−4.994	−5.075
ΔS_t^0 (J mol^{-1})	−5.00	−1.11	+2.79	6.69	10.58
ΔH_t^0 (kJ mol^{-1})	−6.359	−5.249	−4.111	−2.934	−1.707

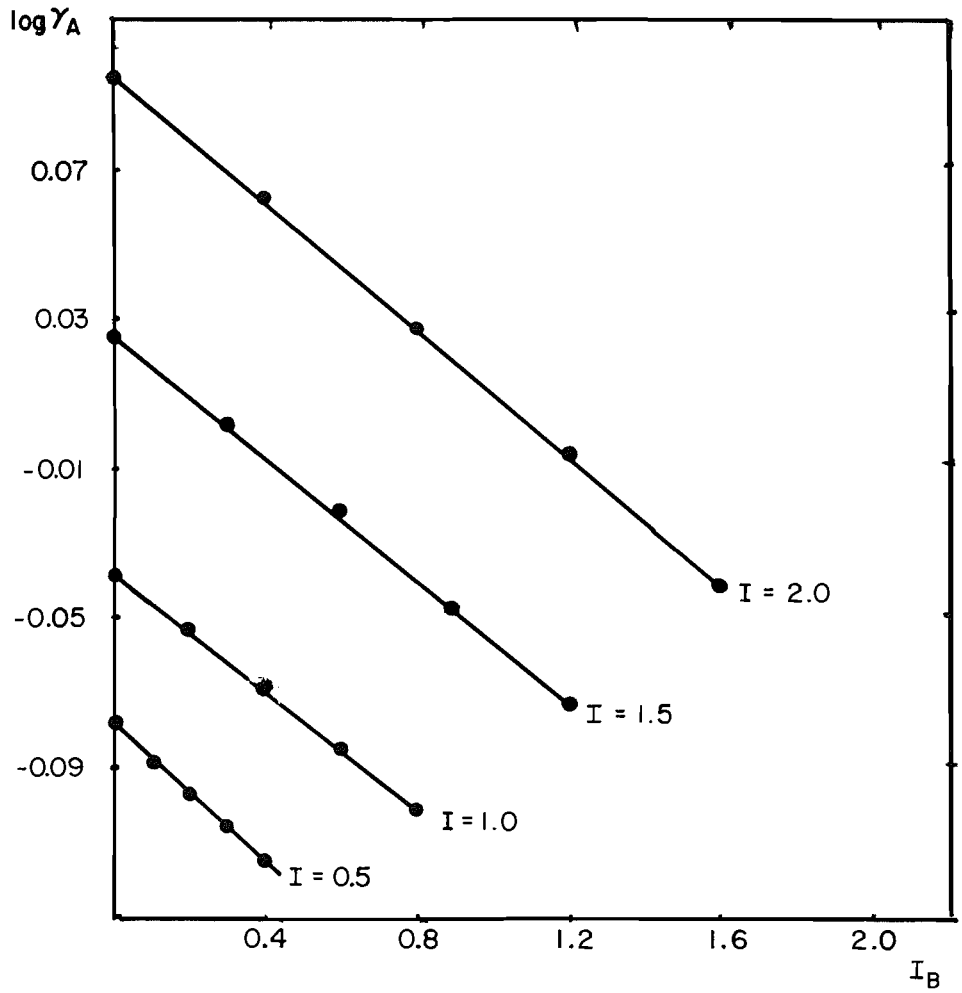

FIG. 2. Plot of log γ_A against I_B at 298.15 K.

partly due to the electrostatic effect arising from a higher dielectric constant of the mixed solvent than of water.

The values of ΔS_t^0 are positive at 298.15, 308.15, and 318.15 K. However, the values are negative at 278.15 and 288.15 K. This suggests more disorder at 298.15–318.15 K in the mixed solvent than in pure water. However, more order at 278.15 and 288.15 K in comparison with pure water is evident.

3. Harned's rule

The emf's of cell (B), which were measured at constant total ionic strength $I = 0.50$, 1.00, 1.50, and 2.00 mol kg^{-1}, ionic strength fraction of NaCl $y_B = 0.00$, 0.20, 0.40, 0.60, and 0.80, at five temperatures from 278.15 to 318.15 K in 0.05 mole fraction urea–water mixed solvent, are summarized in Table 5. The ionic strength fraction y_B of NaCl is given by

[16] $$y_B = m_B/(m_B + m_A) = m_B/I$$

Mean ionic activity coefficients γ_A for HCl in the presence of NaCl were readily calculated from the emf E, the standard emf E_M^0 of cell (B), and y_B by the relationship

[17] $$\log \gamma_A = (E_M^0 - E)/(2k) - 0.5 \log [(1 - y_B)I^2$$

The values of log γ_A calculated from eq. [17] are listed in Table 5.

A good straight line was obtained when log γ_A was plotted against m_B at constant total ionic strength I. All linear correlation coefficients r were over 0.999. These results show that HCl still obeys Harned's rule in these experimental systems,

[18] $$\log \gamma_A = \log \gamma_A^0 - \alpha_A m_B$$

where γ_A^0 is the activity coefficient of HCl in solution containing only the HCl and $m_A = m = I$; α_A is Harned's

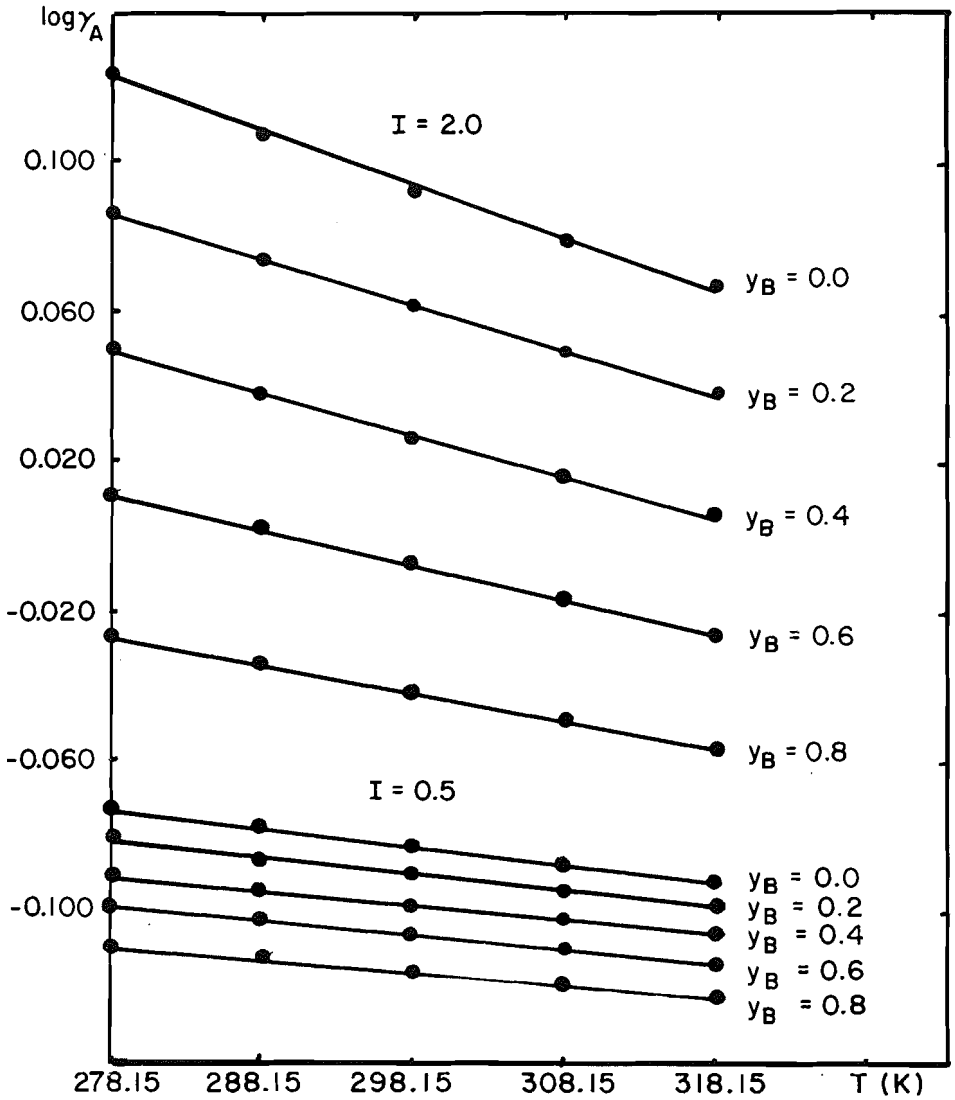

FIG. 3. Plot of log γ_A against T at I = 2.0 and 0.5 mol kg^{-1}

coefficient. The values of α_A, which were obtained from linear regression, are listed in Table 5.

The linear regression of log γ_A against absolute temperature T was carried out; all linear correlation coefficients were over 0.99. The results show that a good straight line may be obtained when log γ_A is plotted against T. The relationship between log γ_A and T may be expressed in the following equation:

$$[19] \quad \log \gamma_A = h + gT$$

where h and g are empirical constants. From eqs. [18] and [19], it can be shown that there is a linear relationship between α_A and T.

The relative partial molar enthalpy of HCl, L_A, may be calculated by the following equation:

$$[20] \quad L_A = 2 \ln (10)\, RT^2\, [\partial \log \gamma_A/\partial T]_{P,M}$$

The values calculated with eq. [20] are summarized in Table 6. The derivative of eq. [18] with respect to T at constant pressure and constant composition of solution was calculated and multiplied by the factor $[-2 \ln (10)RT^2]$, so that the following equation may be used:

$$[21] \quad L_A = L_A^0 + 2 \ln (10)RT^2(\partial\alpha_A/\partial T)_{P,M} I_B$$

where L_A^0 is the relative partial molar enthalpy of HCl in its own solution at the same total ionic strength as the mixture. As above, the $(\partial\alpha_A/\partial T)_{P,M}$ is a constant, then

$$[22] \quad Q = 2 \ln (10)RT^2(\partial\alpha_A/\partial T)_{P,M}$$

Q is also constant at a given temperature. Then

$$[23] \quad L_A = L_A^0 + QI_B$$

Equation [23] shows that the relative partial molar enthalpy L_A is a linear function of NaCl molality. In this sense, eq. [14] is analogous to Harned's rule, so that eq. [23] may be temporarily referred to as the "similar" Harned's rule of relative partial molar enthalpy. When the values of L_A in Table 6 are plotted against I_B at constant ionic strength and against T at constant composition, a good straight line is obtained; all linear correlation coefficients are over 0.999. These agree with results obtained in aqueous solution by Macaskill *et al.* (16).

Calorimetric studies of the phase transition in iodoform

JULIANA BOERIO-GOATES[1] AND BRIAN F. WOODFIELD
Chemistry Department, Brigham Young University, Provo, UT 84602, U.S.A.

Received August 24, 1987

This paper is dedicated to Professor J. A. Morrison

JULIANA BOERIO-GOATES and BRIAN F. WOODFIELD. Can. J. Chem. **66**, 645 (1988).

The heat capacity of crystalline iodoform prepared by vacuum sublimation has been measured from 50 to 340 K and that of iodoform prepared by recrystallization from acetone measured from 120 to 300 K. Both samples exhibit a phase transition near 260 K. The heat capacity anomaly in the sublimed material shows several small maxima which appear with variable positions and heights depending upon the thermal pretreatment of the sample. The transition, which was undetected by previously-reported spectroscopic measurements, is ascribed to an incomplete ordering of the molecular dipole.

JULIANA BOERIO-GOATES et BRIAN F. WOODFIELD. Can. J. Chem. **66**, 645 (1988).

On à mesuré la capacité calorifique de l'iodoforme cristallin préparé par sublimation sous vide à des températures allant de 50 à 340 K et celle de l'iodoforme préparé par recristallisation de l'acétone de 120 à 300 K. Les deux échantillons présentent une transition de phase près de 260 K. Dans l'échantillon préparé par sublimination, on note une anomalie dans la capacité calorifique qui se traduit par plusieurs petits maxima qui apparaissent à des positions variables et dont les hauteurs dépendent du pré-traitement thermique qu'a subi l'échantillon. C'est à arrangement incomplet du dipôle moléculaire qu'on attribue la transition qui n'avait pas été détectée au cours des mesures spectroscopiques réalisées antérieurement.

Introduction

Halogenated methane derivatives are of interest to theorists and experimentalists probing molecular dynamics in the solid state. These compounds also exhibit an interesting range of crystallographic structures and polymorphic phase transitions at different temperatures. The haloforms, CHX_3 with X = F, Cl, Br, and I, have been widely studied by techniques like X-ray (1, 2) and neutron (3, 4) diffraction, Raman and ir spectroscopy (5–7) and dielectric measurements (8) which probe structural details of the solid-state and characterize phase transitions. However, high-precision heat capacity measurements, frequently used to study phase transitions, have been published only for fluoroform (9); differential scanning calorimetric (DSC) measurements (8) near the solid–liquid and solid–solid phase transitions in bromoform have been made, but no quantitative data were published from this study.

In this paper we report heat capacity measurements of iodoform in order to resolve a discrepancy regarding the existence of a phase transition in this compound. The disagreement arises between spectroscopic (5, 7) studies which show no evidence for a phase transition as the temperature is lowered, and temperature-dependent photoconductivity measurements (10) which exhibit anomalous behavior below 270 K that has been attributed to the onset of a phase transition. The manner of sample preparation differed between two of the investigations: one spectroscopic study (5) used crystals grown from acetone solution while the photo-conductivity measurements (10) were performed on samples of CHI_3 prepared by vacuum sublimation. In order to determine if the two preparation methods yield different types of crystals, one undergoing a transition and the other not, we have made measurements using samples prepared in both fashions.

We present here heat capacity measurements from 50 to 340 K which are in the temperature region of interest with respect to the disputed transition. These measurements are the first to be reported using the automated, adiabatic calorimetric system we have recently assembled; thus, details of its construction and operation will also be given in this paper.

Percent contribution to measured heat capacity of empty calorimeter	50 K 16 200 K 25 350 K 25	120 K 33 200 K 19 300 K 21

Experimental

Sample preparation

Iodoform was purchased from Pfaltz and Bauer (11) and purified either by slow vacuum sublimation or recrystallization from reagent-grade acetone under a nitrogen atmosphere, followed by drying for several hours in a vacuum oven at room temperature to remove adsorbed acetone. Both preparations were carried out in the dark to prevent photo-initiated decomposition. The samples prepared by vacuum sublimation have been analyzed by carbon, hydrogen, and iodine analyses and both samples have been analyzed by mass spectrometry. The C,H,I analyses gave the following compositions in mass percent (±0.3% uncertainty): C 3.04 actual, 3.05 theoretical; H 0.28 actual, 0.28 theoretical; and I 96.43 actual, 96.69 theoretical. Analysis by mass spectroscopy indicated that the recrystallized sample was contaminated with an amount of acetone considerably less than one mass percent, but precise quantization of the impurity was not possible. No contaminants were found in the sublimed crystals.

The pertinent information concerning the loading of the samples in the cryostat is summarized in Table 1.

Description of the calorimetric apparatus and measurement system

The calorimetric system incorporates an aneroid cryostat of the Westrum design (12) with modifications of the wiring to allow interchange of thermometers. Electrical leads coming from the heater/thermometer assembly are soldered to gold-plated pins, and the

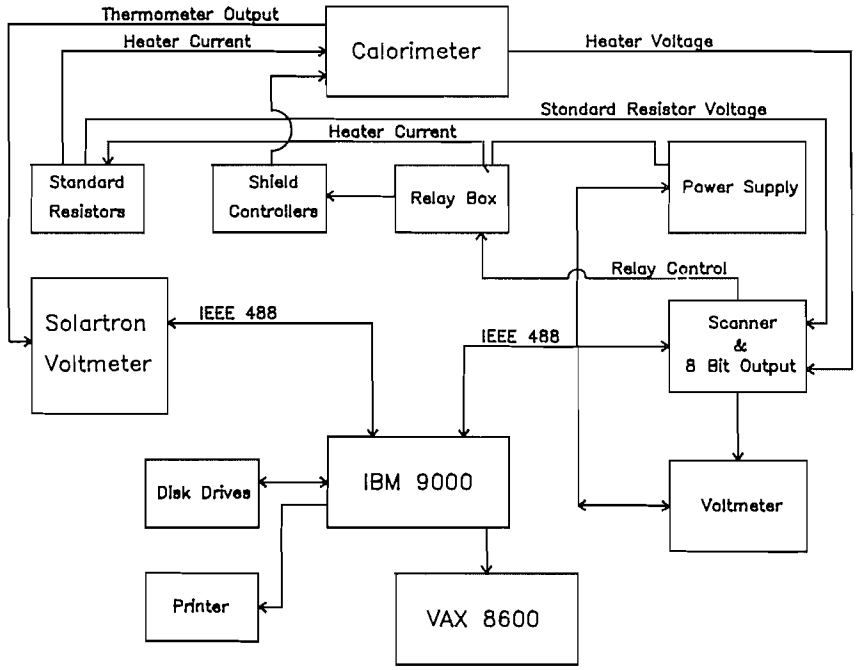

FIG. 1. Block diagram of the instrument control and data acquisition system.

mating connectors and leads are contained in a gold-plated copper block soldered to the bottom of the adiabatic shield.

The gold-plated copper calorimeter vessel used in the experiments is similar in design to that described in ref. 12 for solid samples. It has an internal volume of 73.19 cm^3 and is sealed by pressing a gold gasket onto a knife edge around the mouth of the calorimeter.

Temperatures are measured using a Leeds and Northrup capsule thermometer (# 1624058) first calibrated on the International Practical Temperature Scale of 1948 (IPTS-48). The original thermometer calibration has been converted to yield temperatures on the IPTS-68 scale by applying corrections (13) to the temperature scale supplied by Leeds and Northrup to bring it to the 1968 scale, and fitting the corrected temperature / resistance data within appropriate regions to obtain the necessary coefficients. To check the calibration, the temperatures of the $Na_2SO_4 \cdot 10H_2O$ triple point, ice point, Hg freezing point, and the N_2 boiling point were measured. The maximum deviation from the accepted values was 0.01 K, obtained with the N_2 boiling point.

A Solartron Model 7081 8½ digit voltmeter operating in the true ohms mode is used to measure resistances. This mode is a four-wire resistance measurement using a 1 mA current with corrections for thermal emfs made internally.

Current for the calorimeter heater is provided by an Electronic Development Corporation Model 520A power supply operated with a controlled current output. Energy measurements are made in the conventional manner: voltages across the calorimeter heater and a Guildline 100 Ω standard resistor in series with the calorimeter heater are measured using a Hewlett-Packard Model 3456A 6½ digit voltmeter. A Keithley Model 705 Scanner with a low thermal-voltage card is used to channel the different voltage outputs into the HP DVM. During the equilibration periods, the heater current passes through a 100 Ω dummy resistor; a high-speed, low-thermal mercury relay switches the current to the calorimeter heater during energy inputs.

The temperature of the adiabatic shields surrounding the calorimeter is maintained by home-built controllers in which differential thermocouple voltages are amplified by Ancom amplifiers (14), and the shield heater output is controlled by proportional–integral–derivative circuitry. The thermocouple between the main adiabatic shield and the calorimeter consists a Au(0.07 at% Fe)–Chromel P thermocouple in series with one of Au(0.02 at% Co)–Chromel P. The top and bottom shield heaters are controlled by the output from differential thermocouples referenced to the main shield. These thermocouples consist of two Au(0.07 at% Fe)–Chromel P junctions in series. A fourth control unit maintains the temperature of a tempering ring around which the electrical leads are wound before going to the adiabatic shields; this thermocouple is a double-leg copper–constantan thermocouple. Typical temperature drifts of the calorimeter range from 10^{-4} to 10^{-6} K min^{-1}. Equilibration periods are typically 20 to 30 min from 50 to 350 K. For the iodoform measurements, the equilibration times occasionally increased to about 3 h in the transition region.

Data collection and control

Instrument control and data acquisition have been completely automated using an interface to an IBM Instruments System 9000 computer. The hardware configuration of the various instruments and the computer are depicted in Fig. 1. Communication between the commercial instruments and the System 9000 is done via the IEEE-488 bus; switching relays are interfaced through a parallel port on the Keithley Scanner and controlled through the IEEE-488 bus. All data are printed on rhe System 9000 printer as they are collected and also stored on floppy disk. As the appropriate data become available, the raw heat capacities are calculated and saved on disk. The data are uploaded to a VAX 8600 for further processing upon completion of the experiments, thus freeing the System 9000 for additional data collection.

The controlling program on the System 9000 has been written for maximum flexibility. The number and type of energy input and the type of algorithm to determine the equilibrium temperature can be specified. Two options are available for the type of energy input: a normal heating period or a long heating interval for an enthalpy measurement. Parameters which can be varied in the drift measurements include the time between temperature measurements, the number of points to be included in the drift-termination calculation, and the criterion which establishes equilibrium. One may base the decision of whether equilibrium has been reached by a consistent agreement of either a drift rate or a calculated final temperature for the preceding energy input.

The electrical energy input into the calorimeter is measured by taking periodic voltage measurements across the standard resistor and calorimeter heater for a known length of time. Resulting current and voltage values are multiplied and fit to a cubic polynomial versus time and integrated to obtain the power used during the energy addition. For each energy addition the following two parameters may be specified: duration of energy addition and the desired increase in temperature. The temperature increase may be given as a default increment determined by the temperature, a specified increase, or a value of the current to be set on the power supply.

The shield controllers must be switched to a higher power setting while energy is added to the calorimeter and then back to the normal setting during the drift. The program allows for this switch at variable times before and after the energy addition to facilitate better shield control.

Performance of the system

Benzoic acid (NBS-Standard Reference Material 39i) was measured in the calorimeter to check the accuracy of the system. The results are consistently high (0.1–0.3%) relative to the data of Furukawa *et al.* (15). The discrepancy is probably sample-related since the work of ref. 15 was performed using the Calorimetry Conference Standard benzoic acid (NBS-SRM 39g) rather than NBS-SRM 39i. Also, the possibility of a systematic error arising from the main adiabatic shield controller is under investigation. Because the conclusions regarding the phase transition of iodoform do not rest on absolute values of heat capacity, nor on derived thermodynamic properties like S°_{298}, the systematic deviation does not pose a significant problem for this research.

The system proved capable of producing very precise results: a smoothed curve could be fit through the experimental points with deviations of about 0.05%.

Results

The results of heat capacity measurements from 50 to 340 K on iodoform crystals prepared by vapor sublimation are given in Table 2. These results are reported in chronological order with the series designation indicating a continuous set of measurements. The size of temperature increment used in the measurements can be inferred from consecutive temperatures within a series.

The heat capacity results obtained from the sublimed crystals are plotted in Fig. 2 along with those obtained on the iodoform crystals grown from acetone solution. The acetone-grown samples exhibited a slightly higher heat capacity over the entire region of measurement than the sublimed crystals and showed a small anomaly near 175 K, which is close to the melting point (177 K) of pure acetone (16). Since acetone has a much higher heat capacity per gram (16) than iodoform, contamination of the iodoform results in a higher heat capacity than would be obtained with pure iodoform. Estimates of the extent of contamination, based upon integration of the excess enthalpy in the acetone fusion region and on the heat capacity difference between the two samples, yield values of about 0.1 mass %, which is consistent with the mass spectrometric measurements. Because we have the results from the uncontaminated, sublimed crystals, we made no efforts to correct the heat capacity from the acetone-grown sample. We include it in Fig. 2 to show the similarity in the region near 260 K with the behavior observed from the sublimed crystals.

Both samples were found to have a region of anomalous heat capacity from 250 to 270 K. When studied with relatively large temperature increments of 5 K (e.g. Series 2 and 4 in Table 2 on the sublimed crystals), both heat capacity curves appear to step up abruptly in this region in a manner suggestive of a glass transition.

The temperature region from 250 to 270 K was studied more extensively with the sublimed crystals using measurements with temperature increments of 1 K (Series 9, 10, 11, and 12) to search for sharp features in the heat capacity more typically associated with phase transitions. Cooling rates, minimum cooling temperatures, and annealing times, factors which can affect the extent of conversion to a low-temperature phase, were varied to ascertain if these had any effects on the heat capacity. The description of the thermal treatment preceding each series in the transition region is given in Table 3.

The results of measurements obtained in the region from 238 to 288 K are displayed in Fig. 3. To show these data with clarity, two curves are presented in Fig. 3. Data from Series 2, 4, 5, 8, 9, and 10 are plotted on curve *a*, while data from Series 11 and 12 are given in curve *b* with the ordinate displaced. Omitted from Fig. 3 are data from Series 2, 4, and 8 in the region from 258 to 270 K which have been obtained with temperature increments larger than 2 K.

As is evident from Fig. 3, neither a long annealing time nor a large degree of undercooling produced significant maxima in the heat capacity curve. Lowering the cooling rate from 0.7 K min^{-1} (Series 5, 8, 9, and 10) to 0.1 K min^{-1} (Series 11 and 12) appeared to have a small but discernible effect on the features observed in the heat capacity. Each series that was cooled at the higher rate exhibited one or more points (e.g. points 9 and 11 of Series 5, points 7 and 8 of Series 8, points 8 and 9 of Series 9, and points 6 and 9 of Series 10) that were about 0.8 to 1.5% above a smooth curve drawn through the remainder of the points of these series. (This smooth curve is given as the solid line in Fig. 3*a* and 3*b*.) A larger positive deviation, 1 to 3.5%, from this same smoothed curve was observed with points from Series 11 and 12, before which the sample had been cooled at the slower rate.

To determine an estimate of the scatter to be expected from measurements made with small increments, a series of 15 points (Series 13), each with ΔT about 1.0 K, was obtained at temperatures well below 250 K. A maximum deviation of −0.4% from the smooth curve generated by the larger-increment data in this region was obtained for a single point while the remainder of the points were well within ±0.2% deviation.

The equilibration times of Series 13 data were comparable to those obtained during the Series 5, 8, 9, and 10 measurements and to some measurements in Series 11 and 12. Therefore, comparable scatter might be expected in these data. Points 3, 4, 5, 6, and 7 of Series 11 and 1, 2, 7, 9, 11, and 13 of Series 12, however, took from 1 to 3 h to equilibrate, with the higher heat capacity points requiring longer equilibration times. The uncertainty associated with these points is consequently larger because of the greater uncertainty in the ΔT measurement.

With these observations in mind, the question then becomes one of determining if the high points arise from one or more sluggish phase transitions, or if long equilibrium times lead to inaccuracies in the temperature measurements which make the points artificially high.

There are several factors which point toward the existence of phase transitions. First, long equilibrium times are frequently associated with phase transitions in molecular crystals. Equilibrium times of several days have been observed in such transitions (17).

The long equilibrium times in the iodoform study appear repeatedly in the temperature region 256 to 270 K, but not once outside it, thus ruling out the possibility of a random system error. Also, the magnitude of the temperature drifts at the end of the long equilibrium periods are consistent with those obtained after runs which come to equilibrium at a faster rate.

Second, calculations have been made to determine the change in heat capacity using the widest range of values of the temperature drift which could conceivably be extracted from the time–temperature data of points with long equilibration times. For point 4 of Series 11, which showed the largest change, the heat capacity could be lowered from 99.09 to 98.67 J K^{-1} mol^{-1}. Such a change still leaves this point about 3% above the smooth curve connecting the non-transition data below 255 and above 270 K shown in Fig. 3*a*. Similar but smaller decreases in

the other high points can be obtained if one carefully selects the drift values. These hand-picked drifts, however, do not have the consistency of the original computer-determined values, which makes their validity suspect.

The scatter and reproducibility in the data from Series 5 and 8–12 having 2 K increments or less is consistent, then, with that obtained in Series 13, if the high points noted above are rejected from the fit. Inclusion of the high points in an attempt to generate a smooth curve with no maxima causes unreasonably large deviations, even if the lower heat capacity values of the points recalculated using the hand-picked drifts are considered.

Discussion

Iodoform has a structure (4) isomorphous with the α-phase of bromoform (3) in which there is disorder involving the molecular dipole. Figure 4 shows a schematic representation of the unit cell. There are two molecules in the unit cell, with two possible molecular orientations at each of the lattice sites. The

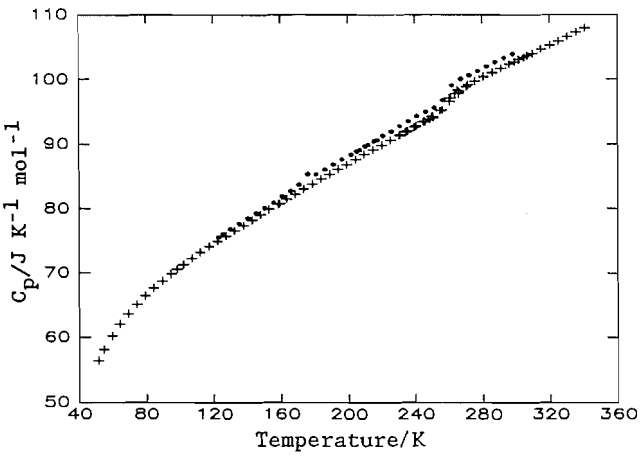

FIG. 2. Results of the heat capacity measurements on iodoform. + curve obtained with sample prepared by vacuum sublimation; ● curve obtained from crystals prepared by recrystallization from acetone. Some data in the transition region of the lower curve have been omitted for clarity.

TABLE 3. Summary of thermal pretreatment in the transition region[a]

Series	Thermal history immediately before measurements
2	Cooled to 150 K; heated up during Series 1; Series 2 continued approximately 6 h after the completion of Series 1
4	Cooled to 230 K; no annealing
5	Cooled to 245 K; no annealing
8	Cooled to 50 K; taken up to 150 K during Series 7; heated approximately 3 K min^{-1} to 230 K; annealed at 230 K for 48 h
9	Cooled to 230 K; no annealing
10	Cooled to 50 K; heated to 230 K; annealed at 230 K for 72 h
11	Cooled to 150 K slowly; heated to 250 K; no annealing
12	Cooled to 100 K slowly; heated to 230 K; annealed at 230 K for 120 h

[a]All cooling with the exception of Series 11 and 12 was performed with the calorimeter in maximum contact with the refrigerant, resulting in a cooling rate of about 0.7 K min^{-1}. For Series 11 and 12, the cooling rate was about 0.1 K min^{-1}.

molecular dipole can be aligned parallel or antiparallel to the c axis of the unit cell. The α-phase of bromoform is known to undergo a phase transition with partial ordering (3) of the molecular dipole to a β-phase 13 degrees below the melting point.

Conflicting evidence has been reported in the literature about the existence of a corresponding phase transition in iodoform. Raman spectroscopic investigations (5, 7) of low-frequency lattice vibrations conclude that no ordering transition occurs down to low temperatures. Temperature-dependent photoconductivity studies (10) of iodoform, however indicated a phase transition near 270 K. In a related study of the drift mobility of photo-generated holes in CHI_3 (18), results indicative of the onset of ferroelectricity in this temperature region were observed. Since the fully-disordered phase is not ferroelectric, the appearance of ferroelectricity means some ordering has taken place.

Despite the lack of a large peak in the heat capacity, we conclude that there is indeed a phase transition in iodoform between 250 and 270 K. There is evidence for at least a small

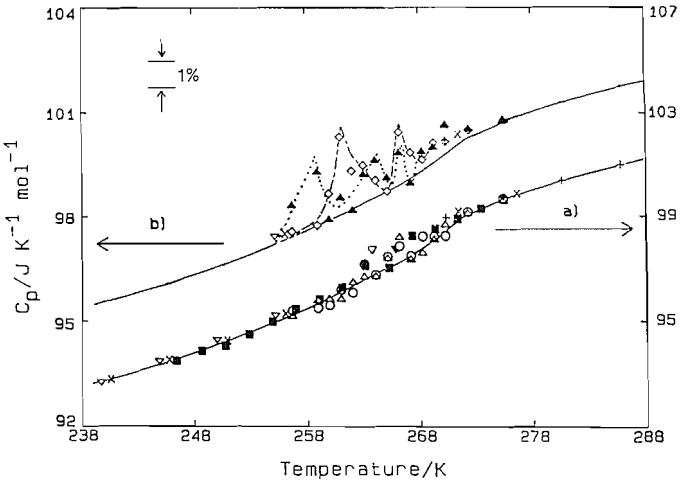

FIG. 3. Details of heat capacity measurements in the transition of vapor-sublimed crystals. Data given by series in Table 2 are identified in the figure by the following symbols: Curve a: Series 2, +; Series 4, ×; Series 5, ■; Series 8, ▽; Series 9, △; and Series 10, ○; curve b: Series 11, ◇; and Series 12, ▲. The solid lines in a and b are the fit of data from Series 2, 4, 5, 8, 9, and 10 and the low points of Series 11 and 12, while the dashed and dotted lines in curve b are estimates of the heat capacity curves generated by Series 11 and 12 data, respectively. Data taken in the transition region with temperature increments larger than 2° have been omitted for clarity.

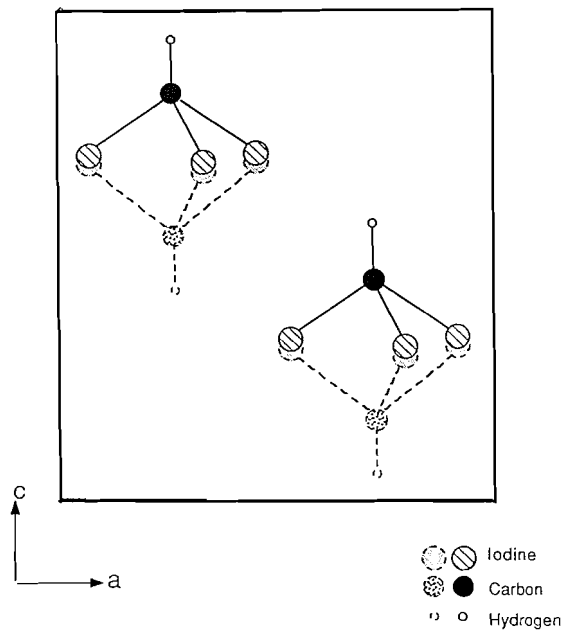

FIG. 4. Schematic representation of the unit cell of iodoform at room temperature illustrating the disorder of the molecular dipole because of the two possible positions of the C—H bond relative to the plane of the iodine atoms.

excess heat capacity, and the long equilibration times and lack of reproducibility of the heat capacity observed in this region are typically associated with sluggish phase transitions in molecular crystals. The temperature region of the heat capacity anomaly as well as its variability are in agreement with the observations of the photoconductivity (10) and drift-mobility (18) work, and show that the same phenomenon is responsible for the effects observed in these studies.

The authors of the neutron diffraction study of iodoform (4)

depict the crystal structure as being determined by the close-packing of the triangle of iodine atoms with the C—H accommodated non-preferentially on either side. In such a structure, where energetic forces favoring ordering of the dipole are small, and reorientational motion is expected to be hindered (4), extremely slow cooling and/or very long annealing times will be necessary to achieve complete order. The variability in the height of the maxima observed in the heat capacity measurements reflect differences in the extent to which the thermal pretreatment caused ordering to occur.

Since the anomalous C_p behavior was observed on both the solution-grown and vapor-sublimed crystals, the possibility that the two methods of preparation produced different crystal structures can be eliminated.

In view of our inability to obtain a large peak in the heat capacity which would more conclusively identify a phase transition and the overall *S*-shape of the heat capacity generated by large temperature-increment data in this region, one may wish to consider invoking a glassy-crystalline transition rather than an incomplete order–disorder transition to explain our data.

A glassy-crystalline (19) phase is formed when, upon cooling, the reorientational motions of molecules in a solid cease, thereby freezing in some kind of configurational disorder. As the temperature is increased again, the metastable disordered state begins to relax toward an equilibrium state, and the heat capacity curve takes on the appearance of a smoothed step function in this region.

Heat capacity studies of such transitions in RbCN (20) and molecular crystals like thiophene (21) exhibit a common feature missing from our work, however. We did not see the large exothermic drifts observed immediately below the transition temperature in these papers. The positive drifts arise when the metastable disordered state acquires enough thermal energy and spontaneously converts to a more stable state. The lack of such drifts in our iodoform measurements appears to rule out the existence of a glass transition here.

Vibrational spectroscopy studies rely either on changes in the linewidth of the lattice-vibration peaks or the appearance of new peaks to detect a phase transition as the sample temperature is varied. The Raman spectroscopic peaks of iodoform are very broad (5, 7) at room temperature due to anharmonicities of the lattice vibrations as well as the molecular disorder, and the broadness persists even to 20 K. Since the heat capacity measurements indicate that only a partial ordering takes place under typical cooling conditions, the narrowing associated with the transition will be small and probably undetectable in view of the overall width of the peaks. Also, the transition may effect acoustic modes, which are generally undetectable by Raman spectroscopy, more than the optic modes studied in the spectroscopic work. We suspect that these two factors prevented observation of the transition by spectroscopic methods.

Our work provides another example of the importance of investigating phase transitions by a variety of techniques and the utility of using heat capacity measurements to detect subtle phase transitions. Other studies, such as solid-state nmr or dielectric measurements, could determine if changes in molecular motion are associated with the phase transition and would be of interest. A low-temperature neutron diffraction study could provide details of the extent of ordering below 260 K.

Standard enthalpies of formation of tris(β-diketonate)manganese(III) complexes: the mean (Mn—O) bond-dissociation enthalpies

MANUEL A. V. RIBEIRO DA SILVA[1] AND M. LUISA C. C. H. FERRÃO

Centro de Investigação em Química, Departamento de Química, Faculdade de Ciências, Universidade do Porto, 4000 Porto, Portugal

Received August 19, 1987

This paper is dedicated to Professor James A. Morrison

MANUEL A. V. RIBEIRO DA SILVA and M. LUISA C. C. H. FERRÃO. Can. J. Chem. **66**, 651 (1988).

The standard molar enthalpies of formation of the crystalline complexes of manganese(III) with 1-phenyl-1,3-butanedione (HBZAC) and 2,2,6,6-tetramethyl-3,5-heptanedione (HDPM) were determined, at 298.15 K, by solution–reaction calorimetry:

$$\Delta_f H_m^0\{Mn(BZAC)_3, cr\} = -1044.9 \pm 8.8 \text{ kJ mol}^{-1}$$

$$\Delta_f H_m^0\{Mn(DPM)_3, cr\} = -1863 \pm 12 \text{ kJ mol}^{-1}$$

The mean molar bond-dissociation enthalpies, $\langle D\rangle$(Mn—O), were derived as 163 ± 10 kJ mol^{-1} and 170 ± 10 kJ mol^{-1}, respectively.

MANUEL A. V. RIBEIRO DA SILVA et M. LUISA C. C. H. FERRÃO. Can. J. Chem. **66**, 651 (1988).

Faisant appel à la calorimétrie par solution–réaction et opérant à 298,15 K, on a mesuré les enthalpies molaires standard de formation des complexes cristallins du manganèse(III) avec la phényl-1 butanedione-1,3 (HBZAC) et la tétraméthyl-2,2,6,6 heptanedione-3,5 (HDPM) qui sont

$$\Delta_f H_m^0(Mn(BZAC)_3, cr) = -1044{,}9 \pm 8{,}8 \text{ kJ mol}^{-1}$$

$$\Delta_f H_m^0(Mn(DPM)_3, cr) = -1863 \pm 12 \text{ kJ mol}^{-1}$$

On en a déduit les enthalpies moyennes des dissociations molaires de liaison, D(Mn—O), qui sont respectivement 163 ± 10 kJ mol^{-1} et 170 ± 10 kJ mol^{-1}.

[Traduit par la revue]

Introduction

The standard molar enthalpies of formation of the crystalline tris(2,4-pentanedionates), $M(ACAC)_3$, of Al(III), Ga(III), Cr(III), Mn(III), and Fe(III) were determined by Irving and co-workers (1–3) using solution–reaction calorimetry. The enthalpies of combustion of $M(ACAC)_3$ (M = Al(III), Ga(III), and In(III)) measured by Cavell and Pilcher (4) confirmed the corresponding results from reaction calorimetry, giving confidence in the reaction calorimetric method.

In this paper, the standard molar enthalpies of formation of two manganese(III) β-diketonates were determined, using the solution–reaction method, to investigate the effect of structural changes in the ligand upon the mean molar manganese–oxygen bond-dissociation enthalpy.

Experimental

The solution calorimeter

The isoperibol LKB 8700 reaction-and-solution precision calorimeter was used. The operation and calculation methods have been described (5). The accuracy of the calorimeter was checked by measuring the molar enthalpy of solution of tris(hydroxymethyl)aminomethane (THAM) in aqueous 0.100 mol dm^{-3} HCl at 298.15 K; $\Delta_{sol}H_m^0 = -29.766 \pm 0.024$ kJ mol^{-1}, in good agreement with the value of Kilday and Prosen (6), $\Delta_{sol}H_m^0 = -29.770 \pm 0.032$ kJ mol^{-1}.

Materials

1-Phenyl-1,3-butanedione: HBZAC (Koch–Light Laboratories Ltd.) was purified by repeated crystallization from ethanol + water. *Anal.* calcd. for $C_{10}H_{10}O_2$: C, 74.06, H 6.22%; found: C 73.89, H 6.25%.

2,2,6,6-Tetramethyl-3,5-heptanedione: HDPM was prepared by Claisen condensation according to the methods of Adams and Hauser (7) and of Kopecky *et al.* (8), was purified by fractional distillation in vacuum, and the purity was assessed as better than 99.9 mol% by glc, using two different columns. The liquid β-diketone was stored under nitrogen in the dark and was freshly distilled prior to use.

Tris(1-phenyl-1,3-butanedionato)maganese(III): $Mn(BZAC)_3$ was prepared as described by Fay and Piper (9), purified by crystallization from acetone + hexane, and dried at 483 K. *Anal.* calcd. for $C_{30}H_{27}O_6Mn$: C 66.92, H 5.05, Mn 10.20%; found: C 66.90, H 5.09, Mn 10.48%.

Tris(2,2,6,6-tetramethyl-3,5-heptanedionato)maganese(III): $Mn(DPM)_3$ was prepared as described by Hammond *et al.* (10) and was purified by vacuum sublimation. *Anal.* calcd. for $C_{33}H_{57}O_6Mn$: C 65.54, H 9.50, Mn 9.08%; found: C 65.28, H 9.43, Mn 9.17%.

Manganese(II) chloride tetrahydrate: Manganese(II) chloride tetrahydrate (AnalaR, BDH) was dried over silica gel; its composition was determined by means of manganese analyses and found to be $MnCl_2 \cdot 4.00H_2O$.

Iron(II) and iron(III) chloride: CERAC samples of $FeCl_2$ and $FeCl_3$ (stated minimum purity 99.99%) were used.

Hydrochloric acid: Concentrated HCl (AnalaR, BDH) was diluted with distilled water. The concentration was determined by titration against $Na_2B_4O_7 \cdot 10H_2O$ and found to be (series of six titrations) 4.590 ± 0.003 mol dm^{-3}, which corresponds (11) to the composition $HCl \cdot 10.98H_2O$.

1,4-Dioxan: 1,4-Dioxan (Carl Erba) was purified as described previously (12).

Carbon and hydrogen analyses were carried out by the Microanalytical Service of the University of Surrey; manganese was analysed by the ethylenediaminetetracetic acid method (13); under the conditions used, the error associated with the manganese analyses is less than 0.02%.

For the hydrolysis and reduction reactions the solvents were

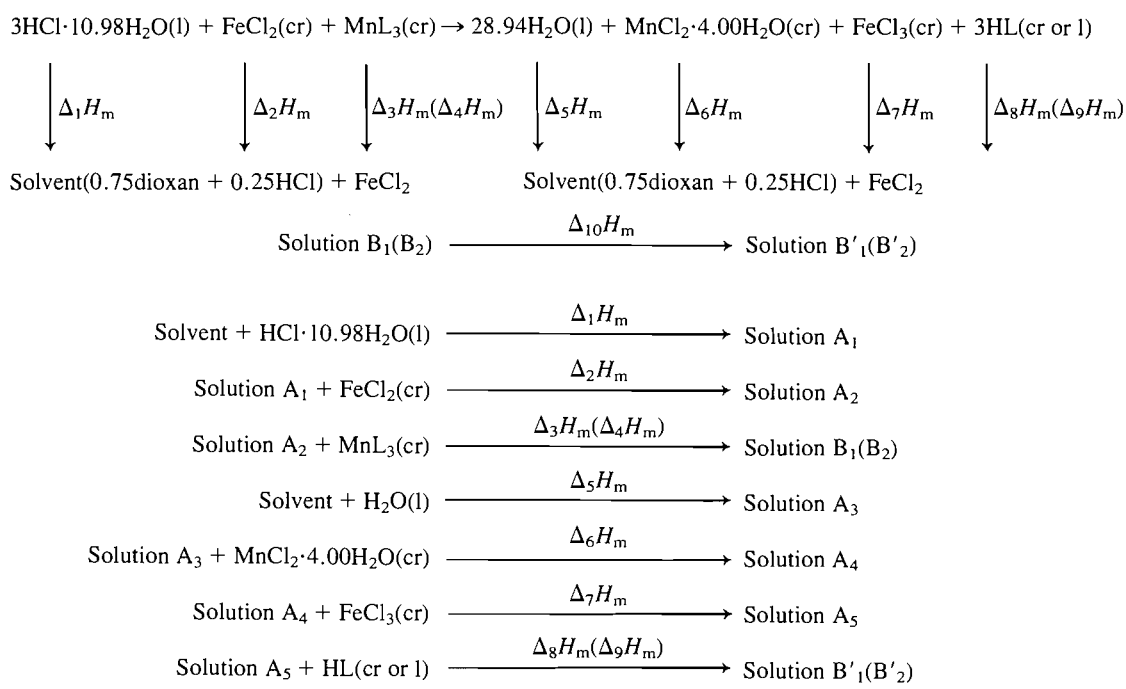

SCHEME 1

degassed and saturated with purified nitrogen prior to each determination.

The relative atomic masses used were those recommended by the IUPAC Commission (14).

All uncertainty intervals given are twice the standard deviation of the mean.

Results and discussion

Preliminary tests showed that the manganese(III) β-diketonates hydrolyse rapidly using 0.75(1,4-dioxan) + 0.25HCl(aq, 4.5 mol dm^{-3}) by volume as the initial calorimetric solvent and, furthermore, that the manganese(III) ion was quantitatively reduced to the manganese(II) ion in the presence of an excess of ferrous salt.

The standard enthalpies of formation of $Mn(BZAC)_3$ and $Mn(DPM)_3$ were determined from the thermochemical reaction

$$MnL_3(cr) + FeCl_2(cr) + 3HCl\cdot 10.98H_2O(l) \rightarrow 28.94H_2O(l) + MnCl_2\cdot 4.00H_2O(cr) + FeCl_3(cr) + 3HL(cr\ or\ l)$$

which was studied in the presence of an excess of $FeCl_2$: to the calorimetric solvent (95.00 cm^3), 5.00 cm^3 of $FeCl_2$, 0.1 mol dm^{-3}, was added. The same batch of solvent was used for both complexes.

The standard enthalpies of the thermochemical reactions ($\Delta_r H_m^0$) were determined by measuring the enthalpies of solution of the reactants and products successively in the initial calorimetric solvent, so that the final solution resulting from the dissolution of all the reactants was of the same composition as that from dissolution of all the products.

The thermochemical cycle and the general procedure for the calorimetric study of the manganese(III) complexes is given in Scheme 1. The quantities of reactants in a particular series of experiments were determined by the amount of $MnL_3(cr)$ (approximately 2.5×10^{-4} mol) in a particular ampoule, so that control of the stoichiometry was maintained for each series.

Thus, the difference between the molar enthalpies of solution of products and reactants, in the correct stoichiometric ratio, gives the enthalpy of the thermochemical reaction ($\Delta_r H_m^0$), provided equilibrium is reached from either side, within the period of the experiment. As a check of the validity of this statement, ampoules of the final solution of reactants were broken, in the calorimeter, into the final solution of products: no heat was detected.

The results are summarized in Table 1, and they lead to

$$\Delta_r H_m^0\{Mn(BZAC)_3\} = 3\Delta_1 H_m + \Delta_2 H_m + \Delta_3 H_m - 28.94\Delta_5 H_m - \Delta_6 H_m - \Delta_7 H_m - 3\Delta_8 H_m$$
$$= -76.9 \pm 1.2\ kJ\ mol^{-1}$$

$$\Delta_r H_m^0\{Mn(DPM)_3\} = 3\Delta_1 H_m + \Delta_2 H_m + \Delta_4 H_m - 28.94\Delta_5 H_m - \Delta_6 H_m - \Delta_7 H_m - 3\Delta_9 H_m$$
$$= -17.0 \pm 1.2\ kJ\ mol^{-1}$$

With the following auxiliary data, $\Delta_f H_m^0$(kJ mol^{-1}): $H_2O(l)$, -285.83 ± 0.04 (15); HCl in $10.98H_2O(l)$, -161.77 ± 0.01 (16); $FeCl_3(cr)$, -399.49 ± 0.29 (16, 17); $FeCl_2(cr)$, -341.79 ± 0.21 (16, 17); $MnCl_2\cdot 4.00H_2O(cr)$, -1687.4 ± 2.1 (16); HBZAC(cr), -335.1 ± 2.8 (18); HDPM(l), -587.7 ± 3.8 (18), the standard molar enthalpies of formation of the crystalline manganese(III) β-diketonates were derived.

$$\Delta_f H_m^0\{Mn(BZAC)_3, cr\} = -1044.9 \pm 8.8\ kJ\ mol^{-1}$$
$$\Delta_f H_m^0\{Mn(DPM)_3, cr\} = -1863 \pm 12\ kJ\ mol^{-1}$$

The values for the sublimation enthalpies of $Mn(BZAC)_3$ and $Mn(DPM)_3$ are not available. Estimates based on their structure, molecular weight, and other known values for similar complexes, using an estimation scheme (19), were used to derive the standard enthalpies of formation of the complexes in the gaseous state. Attempts to measure the enthalpies of sublimation of the Mn(III) β-diketonates, using the "vacuum sublimation" drop-microcalorimetric method (20), were unsuccessful because it was verified that extensive decomposition was associated with the sublimation process. This has also been confirmed by Murray and Hill (21) for the sublimation of $Mn(ACAC)_3$.

[a]Reference 3.
[b]Estimated value, ref. 22.

Table 2 lists the estimated enthalpies of sublimation (22) and the standard enthalpies of formation in the crystalline and gaseous states of the Mn(III) β-diketonates studied, together with the corresponding values for the tris(2,4-pentanedionato)manganese(III), recalculated from the value of Hill and Irving (3) using the most recent auxiliary data.

By regarding the six Mn—O bonds in a particular complex as equivalent (23), which is supported by the known X-ray crystal structure of tris(2,4-pentanedionato)manganese(III), where the manganese–oxygen bond lengths are equal (198.5 ± 1.7 pm) (24), the mean manganese–oxygen bond-dissociation enthalpy, $\langle D \rangle$(Mn—O), in MnL_3, may be defined as one sixth of the molar enthalpy of the disruption reaction

$$ML_3(g) \rightarrow Mn(g) + 3L(g)$$

$$\Delta_{disr}H_m^0 = \Delta_f H_m^0(Mn, g) + 3\Delta_f H_m^0(HL, g) - 3\Delta_f H_m^0(H, g) - \Delta_f H_m^0(MnL_3, g) - 3D(O—H, HL, enol)$$

where D(O—H, HL, enol) is the molar enthalpy of dissociation of the enolic hydrogen in the parent ligand

$$HL(g) \rightarrow H(g) + L(g)$$

There are no measured values for this quantity; values have been proposed ranging from 365 to 430 kJ mol^{-1}, and the situation has been recently reviewed (19). In this work, for comparison reasons, the value D(O—H, HL, enol) = 418 ± 20 kJ mol^{-1} (19) is used.

With the auxiliary data, $\Delta_f H_m^0$(kJ mol^{-1}): HACAC(enol, g), −384.4 ± 1.3 (25); HBZAC(enol, g), −251.3 ± 2.9 (18); HDPM(enol, g), −528.4 ± 3.9 (18); H(g), 218.00 ± 0.01 (15); Mn(g), 280.7 ± 4.2 (16), values of $\Delta_{disr}H_m^0$ and $\langle D \rangle$(Mn—O) were derived and are given in Table 3.

The calculated mean manganese–oxygen bond-dissociation enthalpies for the three complexes are almost the same, within the uncertainties associated with them. Inductive or bulky effects due to —C_6H_5 or —$C(CH_3)_3$ substitution in the ligand appear to have no influence, or only a very small one, on the donor properties of the coordinated oxygen atoms. This effect has already been observed for complexes of β-diketones with Be(II) (26), Al(III) (26), Co(II) (27), Cu(II) (28, 29), Cr(III) (30), Fe(III) (31), and Co(III) (32).

TABLE 3. $\langle D \rangle$(Mn—O) at 298.15 K

Complex	$\Delta_{disr}H_m^0$/kJ mol^{-1}	$\langle D \rangle$(Mn—O)/kJ mol^{-1}
$Mn(ACAC)_3$	987±61	164±10
$Mn(BZAC)_3$	977±62	163±10
$Mn(DPM)_3$	1019±61	170±10

JOHN S. RUTHERFORD, BEVERLY E. ROBERTSON, RICHARD J. GUTTORMSON, and DAVID B. RUSSELL. Nitrosodisulphonates and hydroxylamine-*N*,*N*-disulphonates. V. A potassium salt of hydroxylamine-*N*,*N*-disulphonic acid with a displacive superlattice structure. Can. J. Chem. **66**, 655 (1988).

The structure of the potassium salt of hydroxylamine-*N*,*N*-disulphonate, with the formula $K_5HN_2S_4O_{14}\cdot H_2O$, has been determined by X-ray diffraction. The crystals are triclinic, a = 14.011(6), b = 16.118(9), c = 11.867(6) Å, α = 103.28(6), β = 106.76(3), γ = 86.38(3)°, $P\bar{1}$ with Z = 6. The integrated intensities of 8694 independent reflections were measured on a four-circle diffractometer, 5236 of which were used in the refinement to give a final least-squares weighted residual of 0.107 and a conventional R factor of 0.081.

The structure forms a six-fold derivative lattice, which arises by small displacements (ca. 0.2 Å) of the atom positions from an average structure which is triclinic with Z = 1. This results in three very short H bonds, average length 2.46 Å, which link the three independent anion-dimers, being symmetry-free in this structure. Other bond lengths and angles in the anions are very similar to those in the Rb salt. The K^+ ions show 8, 9, and 10 coordination, in a number of different polyhedral types. The three independent water molecules are each coordinated to three totally distinct K^+ ions, and are linked to the anions by weak H bonds. The structural complexity may be explained in terms of a Lewis acid–base "mismatch" of the cations and anions present.

JOHN S. RUTHERFORD, BEVERLY E. ROBERTSON, RICHARD J. GUTTORMSON et DAVID B. RUSSELL. Nitrosodisulphonates and hydroxylamine-*N*,*N*-disulphonates. V. A potassium salt of hydroxylamine-*N*,*N*-disulphonic acid with a displacive superlattice structure. Can. J. Chem. **66**, 655 (1988).

Faisant appel à la diffraction des rayons-X, on a déterminé la structure du sel de potassium du *N*,*N*-disulfonate de l'hydroxylamine, de formule $K_5HN_2S_4O_{14}\cdot H_2O$. Les cristaux sont tricliniques avec a = 14,011(6), b = 16,118(9) et c = 11,867(6) Å, α = 103,28(6), β = 106,76(3) et γ = 86,38(3)°, Z = 6 et groupe d'espace $P\bar{1}$. On a mesuré les intensités intégrées de 8694 réflexions à l'aide d'un diffractomètre à quatre cercles et on a utilisé 5236 de ces réflexions pour l'affinement jusqu'à des valeurs de R_w = 0,107 et R = 0,081.

La structure forme un réseau sénaire qui provient de petits déplacements (environ 0,2 Å) des positions des atomes par rapport à une structure moyenne qui est triclinique avec Z = 1. Il en résulte qu'il existe trois liaisons hydrogènes qui sont très courtes, longueur moyenne de 2,46 Å, qui relient les trois anions-dimères indépendants et qui sont sans symétrie à l'intérieur de cette structure. Les autres angles et longueurs de liaison des anions sont très semblables à ceux qui ont été observés dans le sel de Rb. Les ions K^+ présentent des coordinations de 8, 9 et 10, dans un certain nombre de types différents de polyèdres. Les trois molécules d'eau indépendantes sont chacune coordonnées à trois ions K^+ totalement différents et elles sont liées aux anions par des liaisons hydrogènes faibles. La complexité de la structure peut être expliquées en fonction d'une mauvaise adaptation acide–base de Lewis des cations et des anions présents.

[Traduit par la revue]

Introduction

Previous articles in this series (1–3) have discussed the preparation and characterisation of a number of alkali metal salts of hydroxylamine-*N*,*N*-disulphonate and related ions, and have examined the epr spectra of these salts when irradiated to compare the spectra obtained with the spectra obtained from Fremy's salt, both as a pure solid, when a triplet state species is observed (2, 4), and as a dilute solid solution in the corresponding potassium hydroxylamine-*N*,*N*-disulphonate, when a free radical species is observed (5). In particular, the triplet state epr spectra obtained from a single crystal of γ-irradiated $Rb_5\{[ON(SO_3)_2]_2H\}\cdot 3H_2O$ could be explained as a consequence of two very distinct centrosymmetric sites for the dimeric ion of the formula $\{[ON(SO_3)_2]_2H\}^{5-}$, where the species formed involves the two NO groups in close proximity, and where, in the unirradiated salt, the two NO groups are linked by a central hydrogen bond N—O...H...O—N (1). The corresponding potassium salt, $K_5\{[ON(SO_3)_2]_2H\}\cdot H_2O$, however, showed a superposition of six very similarly oriented such triplet state spectra[4] and since a preliminary X-ray examination of this salt showed six formula units per triclinic unit cell, it seemed apparent that a more detailed study by X-ray diffraction would be required in order to venture an interpretation of the epr spectrum.

At an early stage of the diffraction study it became clear that the structure of the potassium salt probably contained a six-fold superstructure; i.e., the basic sublattice structure contained only one-half of one formula unit. Some interest has developed regarding group theoretical methods of describing such structures (6) and also regarding relevant phase-determining methods (7–11), since clearly the normal direct method assumptions regarding randomness must break down. We therefore sought to classify this superlattice structure as substitutional or displacive, as commensurate or incommensurate and as to whether it could be considered a modulated structure as described below.

The central hydrogen bonds in the rubidium salt are very short with O...O distances of 2.41(2) and 2.43(2) Å in the two independent dimers. In common with almost all other very short and apparently symmetrical H bonds, as pointed out by Catti and Ferraris (12), these bonds in the rubidium salt are constrained to lie on crystallographic symmetry elements, centres of symmetry in this particular case. Since no such constraint applies to the potassium salt, it would therefore present a rare case of symmetry-free (SF) hydrogen bonds, which should help determine whether such very short H bonds are truly asymmetric.

Experimental

$K_5HN_2S_4O_{14}\cdot H_2O$ Mol. wt. = 599.47

Triclinic, space group $P\bar{1}$, a = 14.011(6), b = 16.118(9), c = 11.867(6) Å, α = 103.28(6), β = 106.76(3), γ = 86.38(3)°, T = 20°C, V = 2497(2) Å^3, Z = 6, D_x = 2.373 g cm^{-3}, μ(MoKα) = 18.9 cm^{-1}, F(000) = 1776, MoKα_1, λ = 0.70926 Å.

The preparation of the crystals was described previously (2). A single crystal too large for X-ray work was ground into a sphere of radius 0.02 cm, and on this measurements were made using a Picker FACS-1 automated diffractometer fitted with graphite monochromator. Lattice parameters and crystal orientation were determined from 20 reflections in the range $32° \leq 2\theta \leq 45°$, and intensities were measured in the 2θ scan mode with a scan rate of 2.0° min^{-1} and a 20 s background count. Of the 8694 unique reflections so measured ($\sin\theta/\lambda \leq 0.639$) 5236 were classified as observed ($I \geq 1.3\sigma(I)$). The data were corrected for Lorentz and polarisation effects but not for absorption.

When the structure was recognised as being based on a superlattice, the diffraction pattern was carefully reexamined in order to confirm the commensurability of the superlattice and the absence of additional features in the diffraction pattern. Also, since the superlattice might arise from a modulating displacement wave (effectively a frozen lattice vibrational mode), the diffraction pattern was examined at various temperatures above room temperature in order to investigate the possible presence of a phase transition to the basic sublattice structure, such as occurs, for instance, in some pyrophosphates (13, 14). No such phase transition was found below 70°C, the decomposition temperature of the crystals.

γ-Irradiated single crystals of the salt $[K_5\{H[ON(SO_3)_2]_2\}\cdot H_2O]$ have a very complicated epr spectrum. The spectrum does, however, show six triplet state spectra with the same splitting parameters but with their principle axes oriented slightly differently in the crystal. This indicates that there are six sites all very similar in environment and close to each other in orientation. This observation led to the detection of a marked subcell, related to the true unit cell by the transformation

$$\begin{pmatrix} 1/6 & -1/3 & 1/6 \\ -1/2 & 0 & -1/2 \\ 1/2 & 0 & -1/2 \end{pmatrix},$$

a subcell where the shortest translation vector (1/6) [1 $\bar{2}$ 1] has length 6.218 Å. The average subcell was solved first, using Patterson methods and the subcell reflections. The subcell showed a centrosymmetric intensity distribution. The subcell Patterson map showed several multiple weight peaks and its was not possible to fit them with a centrosymmetric arrangement of the nine heavy atoms in the subcell. Assuming superposition, a seven atom solution was found which contained the five K atoms and two O atoms. Further electron density calculations revealed the four S atoms. Difference Fourier calculations revealed the remaining non-hydrogen atoms and the subcell was refined by full-matrix least squares to $R = 0.18$. This yielded a complete average subcell structure, in the space group $P\bar{1}$, containing a centrosymmetric anion-dimer similar to those in $Rb_5\{H[ON(SO_3)_2]_2\}\cdot 3H_2O$.

When the reflections are classified according to an index m = [$(h - 2k + l)$ modulo 6], such that the sublattice reflections have $m = 0$, the relative intensity averages for the various classes provide information on the nature of the superstructure. We found

$$\frac{\langle I_{super}\rangle}{\langle I_{sub}\rangle} = \frac{0.13d^{*2}}{1 - 0.65d^{*2}}$$

where the right hand side represents the formula

$$\frac{\frac{4}{3(n-1)}\pi^2 d^{*2}\partial^2}{1 - \frac{4}{3}\pi^2 d^{*2}\partial^2}$$

which is a generalisation of an expression due to Mackay (15) to three dimensions and an n-fold superlattice. This formula applies to a displacive superlattice having a root-mean-square displacement of ∂. In this case ∂ calculates to be 0.22 Å. This test confirms that the superlattice is displacive; i.e., it is based purely on spatial deviations on an identical set of atoms in each subcell, rather than substitutional, where different atomic species (or atoms and voids) occur in different subcells, possibly together with displacements. In the case of a substitutional superlattice the intensity of the superlattice reflections should be significantly non-zero at zero angle. One important type of displacive superlattice is the modulated structure, where the displacements follow a sinusoidal pattern. Superlattice scattering from such a structure should occur predominantly (in the ideal case, exclusively) from the reciprocal lattice vectors corresponding to the modulation wave.

Also, we found the ratios $\langle Im = n\rangle/\langle Im = 0\rangle$ to be 2.2, 0.1, and 0.4 for $n = \pm 1$, ± 2, and 3, respectively. The fact that reflections for which $m = \pm 1$ are the strongest superlattice reflections suggests that the superlattice resembles a modulated structure. The average values of $\langle Im = n\rangle/\langle Im = 0\rangle$ for this model and another were calculated and compared with the observed values of the ratio. The average displacement of the atoms from its average position in each subcell for the two models considered is given in Table 1*a*. The results for $\langle Im = n\rangle/\langle Im = 0\rangle$ are given in Table 1*b*.

Both models are similar in that the displacements are assumed to vary in a regular and predictable way from one subcell to the next, and are identical in the effective "wavelength" of this displacement pattern. In the light of the general agreement of both models, it was decided to choose as a compromise a starting model with displacements 0.9∂, 1.2∂, 0.9∂, -0.9∂, -1.2∂, -0.9∂ in the subcells labelled A to F respectively.

There now remained two problems, one being to assign an origin to the true cell in terms of the co-ordinates used for the subcell, the other of finding values for the ∂_j's, the individual atomic displacements from the average positions. The origin problem arises because in the subcell model, since it conforms to space group $P\bar{1}$, there are eight centres of symmetry (the eight equipoints of order one). In transforming to an n-fold supercell also in space group $P\bar{1}$ only $1/n$ of these centres will be retained. Whether all 8, or 4, 2, or 1 of the subcell equipoint types are represented among the true symmetry centres in the resulting supercell depends on whether the n-fold increase in volume involves a factor of 2 not at all, or in 1, 2, or 3 independent directions. Here, since $n = 6$ involves only one factor of 2, four of the eight subcell equipoint types must be completely eliminated in the transformation. Effectively this means that there is a choice between two possible sets of 4 origins for the supercell, only one of which is correct.

Fortunately in this case the choice is relatively easy, since the three

TABLE 1

occupied equipoints in the subcell structure mentioned previously all belong to one set. It seemed reasonable to pursue the choice of origin which eliminated all symmetry restrictions on atomic positions, rather than the alternative, which placed some atoms in chemically unreasonable environments. This point will be developed further in the discussion. Initial values of ∂_j for each atom were derived from the observed splitting of the atom K(3) in the average structure. Since the electron density corresponding to these atoms, unlike that of any others, was resolved into two peaks of equal weight, it was assumed that one peak position was occupied in three successive subcells and the other in the remaining three. It was further assumed that the environment of these atoms moved in the same direction but to a varying extent in each subcell. These values were then refined by least squares by placing atoms at $+\partial_j$ and $-\partial_j$ in subcells B and E, respectively, and leaving the other subcells empty. This required using only the data $m = 0, \pm 1$, rescaled with $F_0 = F_0/3$ for $m = 0$ and $F_0 = F_0/2$ for $m = \pm 1$. After the ∂_j's were found, all the subcells were filled and refinement proceeded smoothly using all the data.

Anisotropic temperature factors were introduced at an appropriate point, and subsequently the hydrogen atoms, found from a difference map, were introduced and refined with isotropic temperature factors.

The final R factor and R_w factor were 0.081 and 0.107. The weights were assigned as $w^{-1/2} = 2.048 + 0.130\,|F_0| + 0.00005\,|F_0|^2$.

The atomic coordinates and equivalent isotropic thermal parameters are listed in Table 2.[5]

Discussion

The phase-determining procedures used in the solution of the structure are extensions of those previously developed and applied successfully to displacive superlattices by Calvo and co-workers (16–19). In each case an average structure was determined first, using only the sublattice reflections, and subsequently the superlattice reflections were used to derive the small displacements characterising the true structure. There are good reasons to believe[6] that any attempt to phase-determination by a one-step process is likely to fail for these structures which have extremely high non-random variance of the normalised structure factors. Such processes include those direct methods techniques (7–11) which use the renormalisation approach (20).

Figure 1 shows a general view of the structure. Each subcell has associated with it one hydroxylamine anionic moiety and two potassium ions. In addition, the total structure contains three hydrogen atoms, three water molecules, and three further potassium ions, all of which were at centres of symmetry in the averaged supercell structure. The hydrogen atoms join the hydroxylamine moieties in pairs AF, BE, and CD to form the pentavalent dimeric anions which were assumed to exist in the rubidium salt (1). However, the symmetrically bonded hydrogen atoms which join the dimers are readily observed in the potassium salt. The nine atoms which were constrained to be on centres of symmetry in the supercell have been given the labels of subcells A, B, and C.

Average distances and bond angles for the hydroxylamine anion are given in Table 3, with the average of the estimated standard deviations given by least squares and a standard deviation calculated from the variation in the quantities averaged, assuming that their true values are the same. Taylor and Kennard (21) have compared independent determinations of the same structure and concluded that esd's from least squares are underestimated on the average by a factor of approximately 1.5. If we assume such a correction for the average esd in Table 3, the sample standard deviation exceeds the average esd in eleven of 24 cases, and in none of the 24 cases does the sample standard deviation exceed twice the average esd. We conclude that these variations are probably not significant.

Also, the variation among chemically equivalent bond lengths appears not to be significant. However, variation among chemically equivalent bond angles is clearly significant, particularly the N—S—O angles, ranging from 101.0(3, 9) to 109.4(4, 3). These variations in average values reflect features in the packing of the average structure, carried over to the subcells of the superstructure.

The distance O(1)—N(1)—O(1) for the dimers AF, BE, and CD are 2.474(7), 2.446(7), and 2.473(7) Å, respectively. The average, 2.464(16) Å, is larger than in the Rb salt (2.41(2) and 2.43(2) Å).

The dimer configuration is basically the same as in the rubidium salt, with the hydroxylamine moiety in the *trans*-configuration, but, while the central sections of the two independent dimers in the rubidium compound both approximate $2/m$ symmetry, in the potassium compound only one (dimer BE) approaches this symmetry, while the other two dimers (AF and CD) do not. However, in each case they maintain the local pseudo-centre of symmetry at the central H bond intact. The structure is indeed a six-fold displacive superlattice, and the displacements from the average subcell positions are roughly sinusoidal in form, except for atoms K(3A) to K(3F) and the water molecules. If these particular atoms are excluded, the weighted mean of the displacements has the predicted value of 0.22 Å, the values for the individual heavy atoms being K(1A) to K(1C), 0.24 Å; K(2A) to K(2F), 0.17 Å; S(1A) to S(1F), 0.24 Å; and S(2A) to S(2F), 0.25 Å.

All of the oxygen atoms in this structure are co-ordinated to K^+ ions, which, as a result, show irregular eight, nine, or ten co-ordination. The 15 K^+ co-ordination polyhedra in the

[a]The co-ordinates of potassium and sulphur atoms are multiplied by 10^5. Those of oxygen and nitrogen atoms are multiplied by 10^4 and those of hydrogen atoms by 10^3. All temperature factors have been multiplied by 10^4. The subcells are labelled A to F.
[b]Temperature factors are of the form $\exp[-2\pi^2(U_{11}h^2a_1{}^{*2} + \ldots 2U_{12}hka_1{}^*a_2{}^* \ldots)]$ and $U_{eq} = (1/3)\,\Sigma_i \Sigma_j U_{ij}a_i{}^*a_j{}^*\mathbf{a}_i\cdot\mathbf{a}_j$.

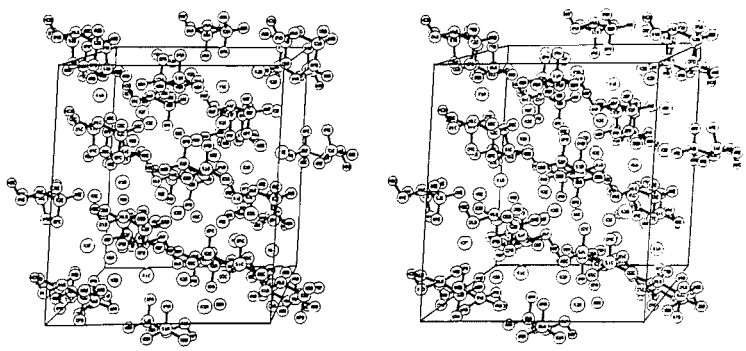

FIG. 1 General stereoscopic view of the structure and atomic labelling. The ***a*** axis is to the right, the ***b*** axis up, and the ***c*** axis is out of the plane of the page.

supercell structure are stereochemically preferred over those forced by the symmetry of the subcell and will be discussed in some detail later.

So irregular are these polyhedra that in some cases the co-ordination number depends on the criterion used to determine it. In what follows a geometric criterion was applied; i.e., is that the co-ordinated oxygen atoms form a significant face, according to the esd's, of the polyhedral domain of the central potassium ion. The convenience of this criterion is that it can be applied using a table of bond lengths and angles without constructing the corresponding figure or its dual, which is the co-ordination polyhedron itself, and without recourse to chemical information such as ionic radii or potential functions. Using this criterion, for atom B to be part of the co-ordination polyhedron of central atom A, requires simply that

$$r_{AB} = \frac{r_{AC}}{\cos < BAC}$$

for all atoms C closer to A than B, for which cos < BAC is positive.

The co-ordination polyhedra so formed were reduced to points on a sphere, and analysed in terms of the interfacial angles by a program described previously (19).

The dimeric anions contain the strong central H bond, which is, however, slightly longer than that in the rubidium salt. The water molecules form H bonds to the anions, but these are relatively weak. The hydrogen bond scheme has been confirmed by neutron diffraction results.

In order to understand the reasons for the formation of this complicated superstructure, bond valence sums were calculated. The parameters collected by Brown (22) were used, except for the N—S bonds, where Brown's values seemed to be inappropriate to the N—S(VI) combination, because they gave bond orders markedly lower than the formal valences required. Instead the value $R_0 = 1.75$ and $B = 0.36$ were chosen as having the same exponent as other similar bonds, and as giving the expected sums at N and S. Since the hydrogen position were not known accurately, they were assumed on the following bases: N—O...H...O—N at the midpoint of the O—O vector, and for water molecules, at a distance of 0.95 Å in the direction from the oxygen atom given by the least-squares refinement. Again following Brown, the N—O group was treated as a

[a]The first number in parentheses after a parameter x is the average estimated standard deviation of the least significant digits of the parameter; i.e. $(1/6)\ \Sigma_{i=1}^{6}\ \sigma_i(x)$. The second number in parentheses is the sample standard deviation for the parameter; i.e. $\{(1/5)\ \Sigma_{i=1}^{6}\ (x_i - \langle x \rangle)^2\}^{1/2}$, $\langle x \rangle = (1/6)\ \Sigma_{i=1}^{6}\ x_i$.

combined negative atom, taking account of the N—O bond order.

In the average subcell structure K^+ ions and the water molecules occur at centres of symmetry. As was mentioned earlier, this restriction is chemically unlikely, and it is instructive to examine what happens to these sites in the true structure. A water molecule cannot hydrogen bond in a centrosymmetric way to surrounding oxygen atoms unless disordered. Also the bond valence balance would also require it to be bonded to three K^+ ions, which again cannot be achieved in a centrosymmetric site. In actuality the water molecules and the K^+ ions of the K(3) type shift in such a way that the water molecule forms part of the co-ordination of one such K^+ ion per subcell, while the other moves away to a distance greater than 4 Å. The co-ordination of each water molecule is then essentially the same, with two potassium ions symmetrically placed above and below the plane of the molecule, a third co-ordinated in the plane on the side opposite the hydrogen atoms, and weak H bonds on the other side.

With regard to possible eight, nine, and ten co-ordinate polyhedra available to the K^+ ions, an analysis in terms of ligand–ligand repulsions, such as that carried out previously by one of us (19), would suggest that a centrosymmetric polyhedron, even when possible, will not be the most stable for that co-ordination number. For eight co-ordination the lowest energy centrosymmetric arrangement is the cube, while the polyhedra normally found are the square antiprism, bisdisphenoid and bicapped trigonal prism.

For nine co-ordination a centrosymmetric arrangement is clearly impossible, and the polyhedra found usually fall in the range intermediate between the monocapped square antiprism (MSAP) and the tricapped trigonal prism (TTP). The co-ordinate normally used to describe this distortion path is the interfacial angle which becomes the diagonal of the square base of the MSAP, labelled δ_a in the previous paper, which is zero for the MSAP and 26.4° for the TTP. Some exceptions to the above rule are found to be derivable from the basic polyhedron by change in the connectivity of the vertices as an interfacial angle other than δ_a becomes negative. (When an interfacial angle is zero, two triangular faces become one quadrilateral one, and a further distortion in the same sense produces two new triangular faces by connection of the opposite diagonal.) For example, such an exceptional polyhedron is found for Nd(3) in $NdOHCO_3$ (23).

For ten co-ordination the two principal polytopes are the bicapped square antiprism (BSAP) and the spenocorona (SC), both of which are far from centrosymmetric. Again intermediate forms correspond to values of the two equivalent interfacial angles δ_m which become the diagonals of the two rectangular faces of the SC. They range from zero for the SC to about 31° for the BASP.

Taking this all into account, we would therefore expect deviations from a centrosymmetric environment for K(1A) to K(1C).

If we examine the polyhedra found, these predictions are borne out. The polyhedron around K(1C) is indeed a slightly distorted cube, the distortion being a trigonal one such that the connectivity of the hexagonal bipyramid results. However, the polyhedra for K(1A) and K(1B) are cubes with one face capped; again a distortion similar to that for K(1C) produces two 6-connected vertices. In contrast the polyhedra for K(2A) to K(3F) comprise one 8 co-ordinate SAP, eight 9 co-ordinate polyhedra (six based on the MSAP—TTP with δ_a ranging from 2.1 to 17.8° and three connected as the $NdOHCO_3$ polyhedron), and three 10 co-ordinate SC with δ_m's ranging from small negative values to +4.8°.

This distinction between K(1A) to K(1C) and K(2A) to K(3F) is also borne out by the bond valence sums. Whereas the sums for the K^+ ions as a whole average to 1.03 ± 0.11 valence units (v.u.), they clearly fall into two classes, for which the averages are 0.85 ± 0.02 v.u. (K(1A) to K(1C) and 1.07 ± 0.08 v.u. (K(2A)...K(3F)), respectively. This supports the view that the distorted cubic environment of the former group is less effective than the other co-ordination polyhedra in allowing the close approach of a large number of ligands to the central atom.

If we apply the same sort of analysis to the K^+ environments in the average structure, we find that K1 is surrounded by a simple distorted cube of oxygens, K2 has a 9 co-ordinate MSAP–TTP polyhedron as might be expected, while K3 shows an extremely elongated and irregular 10 co-ordination, arising from its two types of position in the true structure. When valence sums were calculated for these polyhedra, these yielded values differing markedly from unity, namely 0.70, 1.16, and 1.15 v.u., respectively.

Other results of these sums are as expected. The average sum at the nitrosyl oxygen atom (omitting contribution from the N—O bond) is 0.74 ± 0.02 v.u. in comparison to 0.75 v.u. in $Na_3ON(SO_3)_2 \cdot 3H_2O$. However, the manner in which these

sums are made up differs markedly from one compound to the other, consisting of contributions as follows (average individual contributions in valence units in parentheses): in one case of three Na^+ ions (0.19) and one H bond (0.19), and in the other, the short H bond (0.47) and various combinations of weak H bonds and K^+ ions (0.10). This result supports Brown's contention that the role of water in structures such as these is to mollify the effects of a mismatch in the Lewis acid and base strengths of the cation and anion. In these compounds the average base strength of the nitrosyl oxygen atom (omitting the strong H bond where it occurs) is 0.19 and 0.10 v.u., and of the sulphonate oxygens 0.16 and 0.13 v.u., for the Na and K compounds, respectively. Brown gives the acid strengths of the Na^+ as 0.16 v.u. and K^+ as 0.13 v.u. The obvious conclusion is that the lower Lewis acid strength of K^+ requires the central strong H bond of the dimer to allow a matching to the base strength of the nitrosyl oxygen atom, while in the case of Na^+ the presence of additional water molecules is sufficient. For the Rb compound (Lewis acid strength of Rb^+ is 0.10 v.u.), this mismatch should be greater still. Although a failure to locate the hydrogen atoms makes a complete analysis of the Rb compound impossible, we can observe two effects compatible with the above arguments: shortening of the central H bond and an increase in the hydration compared to the K compound.

Our conclusions regarding $K_5H[ON(SO_3)_2]\cdot H_2O$ run therefore as follows. The presence of the dimeric anion and the extent of hydration are probably determined by the cation/anion matching requirement described above. Since a simple structure with space group $P\bar{1}$, and one formula unit in the unit cell and with this stoichiometry would place the unreasonable restraint of a centrosymmetric environment on certain atoms, instead a superstructure develops which removes these constraints, and which gives a chemically reasonable structure, whether judged in terms of bond lengths and angles, co-ordination polyhedra, or bond valence sums.

So far nothing has been said about the H-atom positions within the three short symmetry-free H bonds in the structure. We felt that this aspect warranted the neutron diffraction study alluded to above, and that discussion of this topic should await the detailed results of that study.

Excess properties (V^E, ϵ^E, and H^E) of the binary system pyridine (1) + sulfolane (2)

LILIANA JANNELLI[1] AND MICHELE PANSINI

Thermodynamic Section, Department of Materials and Production, Faculty of Engineering, The University of Naples, Piazzale Tecchio, Naples, Italy

Received October 5, 1987

This paper is dedicated to Professor James A. Morrison

LILIANA JANNELLI and MICHELE PANSINI. Can. J. Chem. **66**, 662 (1988).

Volumes of mixing and dielectric constants of the binary system pyridine (1) + sulfolane (2) were measured over the entire composition range, $0 \leq x \leq 1$, at selected temperatures ranging between 293.16 and 323.16 K. Mixing enthalpies were also measured at 303.16 K. Deviations from ideality of the measured properties are consistent with the regular behaviour of sulfolane systems, as evidenced by previous works. Nevertheless the occurrence, in the pyridine-rich region, of a sharp maximum in excess dielectric constants versus composition curves, and of a deep minimum in enthalpies of mixing curves, substantiates the supposition that small dipolar interactions occur between molecules of the components. These steadily decrease in magnitude with increasing temperature and sulfolane content in solution.

LILIANA JANNELLI et MICHELE PANSINI. Can. J. Chem. **66**, 662 (1988).

On a mesuré les volumes de mélange et les constantes diélectriques du système binaire pyridine (1) + sulfolane (2), à toutes les compositions, $0 \leq x \leq 1$, et à des températures sélectionnées entre 293,16 et 323,16 K. On a aussi mesuré les enthalpies de mélange à 303,16 K. Les déviations des propriétés mesurées par rapport à l'idéalité sont en accord avec le comportement régulier des systèmes de sulfolane que l'on a mis en évidence dans nos travaux antérieurs. Toutefois, dans la région riche en pyridine, on observe un maximum net dans les courbes de la constante diélectrique versus la composition aussi que un minimum net dans les courbes des enthalpies de mélange; ce résultat confirme l'hypothèse que des faibles interactions dipolaires se produisent entre les molécules des composants du mélange. Ces interactions diminuent régulièrement avec une augmentation de la température et de la proportion de sulfolane dans la solution.

[Traduit par la revue]

Introduction

As a part of extensive research (1–6) into the behaviour and classification of sulfolane solutions, the binary system pyridine (1) + sulfolane (2) has been selected for investigation. Both components are dipolar substances ($\mu_1 = 2.3$ D; $\mu_2 = 4.8$ D). The mixtures possess fairly high dielectric constants, ranging between 12.4 (pyridine) and 43 (sulfolane) at 25°C. Hence the study of this system may also supply useful data for electrochemical studies. The aromatic character of pyridine and its exposed dipole allow interactions between either like or unlike molecules. On the other hand, the steric hindrance of the sulfolane globular molecule reduces the occurrence of strong interactions of any kind, protonation included, in spite of the fairly high dipole moment of which only the negative end is exposed.

We report herewith volumes of mixing and dielectric constants of these mixtures measured at four selected temperatures (293.16, 303.16, 313.16, 323.16 K), as well as mixing enthalpies measured at 303.16 K in the composition range $0 \leq x \leq 1$.

Experimental

Materials, apparatus, and procedure

Sulfolane, kindly supplied by Shell Italia, was purified and carefully dried as already reported (7); properties of the purified sample strictly agree with the most reliable literature data and with our own previous data (8). Rudy Point Reagent grade pyridine was dried on sodium hydroxide and distilled from barium oxide repeatedly; the middle fraction was stored in dark containers and protected from moisture as far as possible. Properties of the purified sample strictly agree with literature data (9). Solutions were made by weight (reduced to mass), stored in dark containers, and protected from moisture as far as possible.

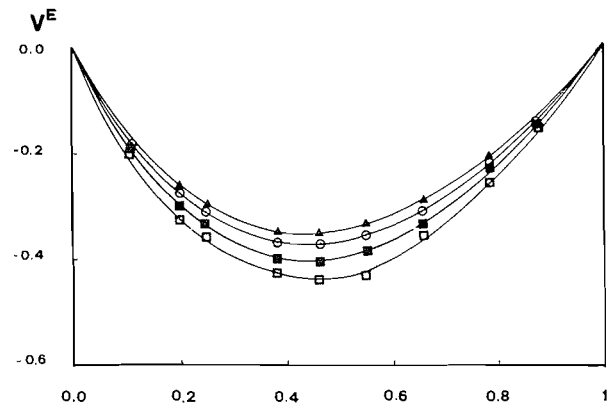

FIG. 1. Excess volumes V^E ($cm^3\ mol^{-1}$) plotted against sulfolane mole fraction x_2, at 293.16 K (full triangles); 303.16 K (open circles); 313.16 K (full squares); 323.16 K (open squares).

Densities were measured at 293.16, 303.16, 313.16, and 323.16 K by an Anton Paar (Austria) vibrating tube densimeter, described elsewhere (10). The maximum error in density did not exceed 1×10^{-5} g cm^{-3}.

Dielectric constants were measured, at 2 MHz, by a W.T.W. dielectric constant measuring apparatus, using the heterodyne beat method. The measuring cell, DFL 2/S type, was thermostatted by water circulation within 0.001 K. The apparatus as well as the calibration procedure have been described elsewhere (11). The maximum error in the dielectric constant was estimated to be 0.01. Mixing enthalpies were determined in an LKB flow microcalorimeter (Model 2107-121) using the auxiliary equipment and operating procedure described in previous works (12). Studies of the test system indicate that the precision of the results is 1% or better over most of the mole fraction range. All measurements were carried out at a temperature of 303.16 ± 0.005 K because at temperatures below 301.61 K

*Value in parentheses is an extrapolated value, because sulfolane is a solid at 293.16 K.

sulfolane is a solid. For the sake of uniformity with previous works sulfolane is indicated as component 2.

Results and discussion

Excess volumes, V^E, of mixing pyridine (1) + sulfolane (2) (volume ratio V_2^0/V_1^0 1.2) at the selected temperatures are shown graphically in Fig. 1. The negative deviations of the systems from ideality never exceed $-0.45\ cm^3\ mol^{-1}$ and only slightly increase with the temperature. The minimum is skewed slightly towards the region rich in the smaller component (pyridine), as expected. The experimental data for V^E, at each temperature, were fitted by a least-squares computer program to smoothing equations of the kind:

$$[1] \quad V^E = x_1x_2\{A + B(x_2 - x_1)\}$$

The parameters A and B of eq. [1] and the standard deviations, σ, are included in Table 1. V^E values, as a function of mole fraction, x_2, of sulfolane, are summarized in Table 2, as well as deviations δV^E from the smoothing equations. The V^E data supply evidence for the supposition that the intermolecular interactions in this system are small. The small volume contractions in this system do not differ in magnitude from those that usually occur on mixing molecules with different geometry.

Deviations from ideality of dielectric constants, $\epsilon_{1,2}^E$, over the entire composition range, at the selected temperatures, are shown graphically in Fig. 2. They are calculated on the basis of a linear dependence of $\epsilon_{1,2}$ values on ideal volume fractions, ϕ_2, in the case of ideal mixtures. The equation:

$$[2] \quad \epsilon_{1,2} = \epsilon_1\phi_1 + \epsilon_2\phi_2 = \epsilon_1^0\phi_1 + \epsilon_2^0\phi_2 + \epsilon_{1,2}^E$$

as well as the symbols have been illustrated elsewhere; $\epsilon_{1,2}$ is the measured dielectric constant of a solution with ideal volume fraction ϕ_i, ϵ_i^0 and ϵ_i are the dielectric constants of the component i, in the pure state and at the mole fraction ϕ_i,

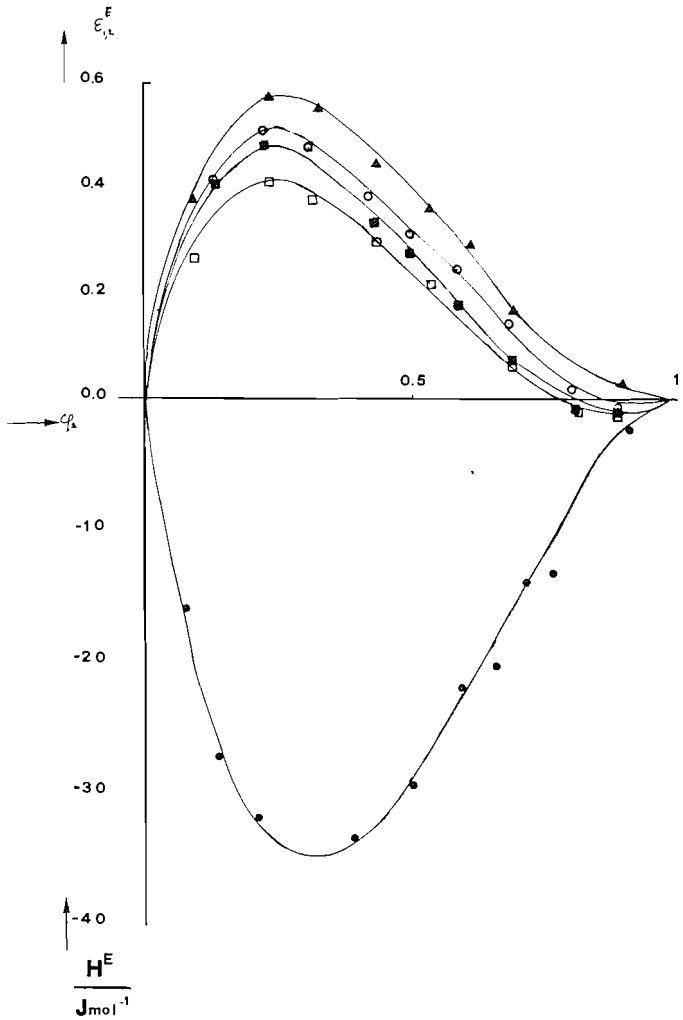

FIG. 2. Dielectric constants, $\epsilon_{1,2}^E$, and enthalpies of mixing, H^E, as a function of ideal volume fraction, ϕ_2.

respectively. The $\epsilon_{1,2}^E$ values were fitted by a least-squares computer program to smoothing equations of the kind:

$$[3] \quad \epsilon_{1,2}^E = x_1x_2\{A' + B'(x_2 - x_1) + \epsilon'(x_2 - x_1)^2 \ldots\ldots\}$$

The parameters A', B', C', ... of eq. [3] and the standard deviations σ are included in Table 3. The $\epsilon_{1,2}^E$ values, as a function of mole fraction ϕ_2 of sulfolane, are summarized in Table 4, as well as $\delta\epsilon^E$ of the smoothing equations. Deviations

from ideality of the dielectric constants, $\epsilon_{1,2}^E$, are generally positive and never exceed 0.6.

The $\epsilon_{1,2}^E$ vs. ϕ_2 curves (Fig. 2) exhibit a maximum, which steadily decreases in magnitude with temperature, approximately at $0.24\phi_2$, in the region richer in pyridine.

Mixing enthalpies measured at 303.16 K are negative over the composition range $0 \leq x_2 \leq 1$ and never exceed −40 J mol^{-1}. Data are summarized in Table 5; coefficients A'', B'', C'' .... of the smoothing equation:

$$[4] \quad H^E = x_1x_2\{A'' + B''(x_2 - x_1) + C''(x_2 - x_1)^2 \ldots.\}$$

are included in Table 5. H^E values are recorded in Fig. 2 as a function of ϕ_2, the volume fraction of sulfolane, for the sake of comparison with the excess dielectric constant data. A minimum occurs in the H^E vs. ϕ_2 curves at roughly the same composition at which a maximum occurs in the $\epsilon_{1,2}^E$ vs. ϕ_2 curves.

The small positive $\epsilon_{1,2}^E$ values, as well as the small negative H^E values, provide evidence for the supposition of very low intermolecular interactions. Self-association forces should be

limited in the case of pyridine because of the fairly high dielectric constant of the medium, ranging between 12 and 43. Self-association should be nonexistent in the case of sulfolane because of the steric hindrance resulting from its globular structure. Hence the presence of the sharp maximum in the excess dielectric constant curves at $\phi_2 = 0.24$, and of a deep minimum at roughly the same composition in the H^E curve, should be interpreted in terms of a likely complex formation arising from dipole–dipole interactions between unlike molecules. The maximum in the $\epsilon_{1,2}{}^E$ curves decreases with temperature, along with a decrease in complex formation, as expected from the exothermic effect cited above.

H. ZABEL and D. A. NEUMANN. Neutron scattering studies of potassium-ammonia layers in graphite. Can. J. Chem. **66**, 666 (1988).

Neutron scattering investigations of the structural and dynamical properties of ammonia molecules in the stage 1 compound $KC_{24}(NH_3)_{4.3}$ are discussed. The K–NH_3 intercalate layers represent the two-dimensional analogue of the well-known metal–ammonia solutions. At room temperature the intercalate liquid structure factor can be described by a model in which the K ions are surrounded on the average by four NH_3 molecules, and the remaining molecules are essentially free. Quasi-elastic neutron scattering revealed two independent rotational motions of the NH_3 molecule, one associated with the rotation about the C_3 symmetry axis and the other one about the K ions. Above 200 K translational diffusion also becomes noticeable. The phonon dispersion of the [00q] longitudinal modes show clear signs of a phonon–libron coupling which causes the acoustic branch to split.

H. ZABEL et D. A. NEUMANN. Neutron scattering studies of potassium-ammonia layers in graphite. Can. J. Chem. **66**, 666 (1988).

Utilisant des études de diffusion neutronique on a étudié les propriétés structurales et dynamiques des molécules d'ammoniac dans le composé de stage 1, $KC_{24}(NH_3)_{4.3}$. Les couches intercalées de K–NH_3 représentent l'analogue bi-dimensionnel des solutions bien connues de métal–ammoniac. A température ambiante, on peut décrire le facteur de structure liquide des couches intercalées par un modèle dans lequel les ions de K sont entourés en moyenne par quatre molécules de NH_3 alors que les autres molécules sont essentiellement libres. La diffusion neutronique quasi-élastique permet de mettre en évidence deux mouvements rotationnels indépendants de la molécule de NH_3; un est associé avec la rotation autour de l'axe de symétrie C_3 et l'autre avec la rotation autour des ions de K. Au dessus de 200 K, on commence à noter une diffusion de translation. La dispersion phonique des modes longitudinaux [00q] présente des signes certains d'un couplage phonon–libron qui fait que la branche acoustique se divise.

[Traduit par la revue]

I. Introduction

In this festschrift we would like to provide a short overview of recent neutron scattering studies on potassium–ammonia solutions intercalated in graphite. Although this subject appears highly focused, it nevertheless relates to many other topics of current research interest. Those encompass metal–insulator transitions in two dimensions (2D), the structure of 2D complex molecular liquids, and the translational and rotational excitations of the NH_3 molecules, including coupling of rotational and translational modes.

The layered structure of graphite provides a unique host frame for the investigation of the motions of molecules in spatially confined environments. NH_3 is one example which has attracted intense research activity in recent years. Other examples are the molecules H_2 and HNO_3 which have also recently been studied in much detail by X-ray and neutron scattering experiments. A brief review of the dynamics of these molecules in graphite is presented in ref. 1, and for more general reviews of the structural properties of graphite intercalation compounds (GIC's) we refer to refs. 2–4.

II. Structure

Ammonia molecules are soluble in monatomic layers of potassium which, in turn, are intercalated in graphite, forming a stage 2 (GIC) KC_{24} (5, 6). Here the stage index refers to the number of graphite planes between any consecutive intercalate layers. With increasing ammonia concentration the compound undergoes a staging transformation to a stage 1 compound by filling all galleries between the graphite basal planes with K–NH_3 solution. Saturation is reached at a concentration $x(NH_3/K) = 4.3$, which requires an ammonia gas pressure of about 10 bar at room temperature (6). The ammonia uptake also causes an expansion of the C–I–C (C = graphite basal plane, I = intercalate layer) package thickness from 5.35 Å for a homogeneous potassium intercalate layer to 6.63 Å for the saturated K–NH_3 layer. Figure 1 shows a neutron (00l) scan showing the structural purity and staging fidelity of this stage 1 compound.

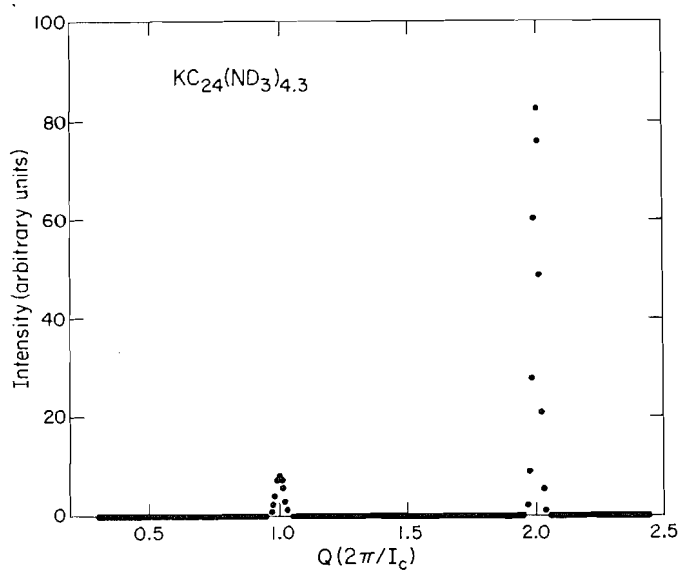

FIG. 1. Neutron elastic (00l) scan of the stage 1 $KC_{24}(ND_3)_{4.3}$ compound (from ref. 14).

Recent X-ray (7) and neutron (8) structural investigations

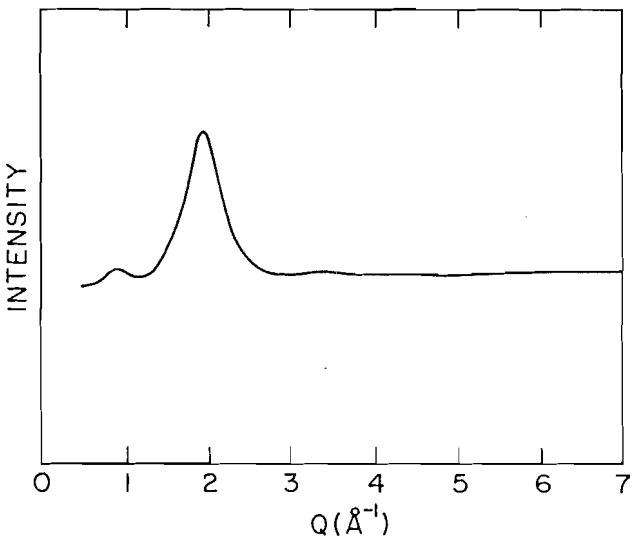

FIG. 2. Elastic neutron (hk0) scan at 300 K showing the liquid structure factor of the K–ND_3 intercalate layer. The graphite (100) (at 2.94 $Å^{-1}$) and (110) at (5.08 $Å^{-1}$) have been removed for clarity (from ref. 8).

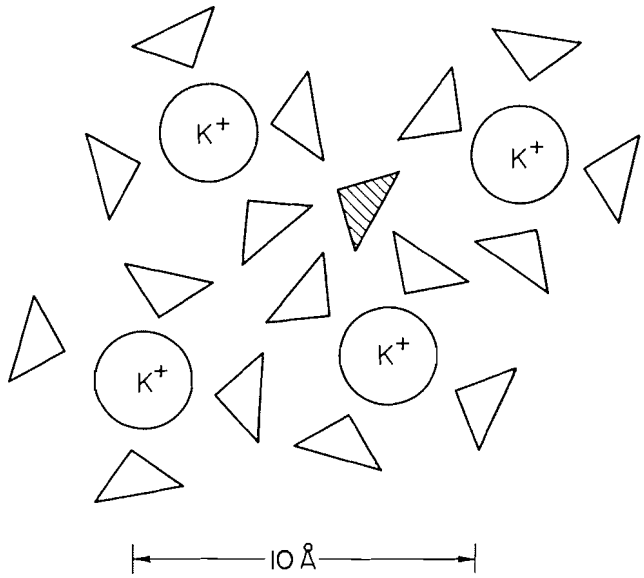

FIG. 3. Schematic diagram of the two-dimensional in-plane structure of the K–ND_3 intercalate liquid in graphite. The circles represent K ions, the open triangles ND_3 molecules which are bonded to the K ions, and the shaded triangle represents a "free" ammonia molecule (from ref. 18).

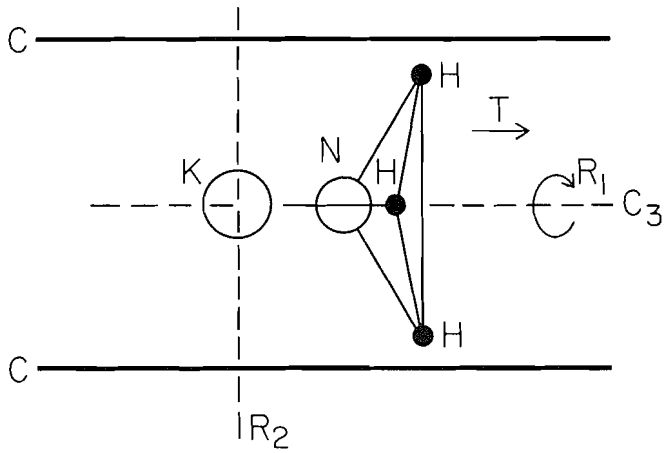

FIG. 4. Schematic diagram of possible motions of NH_3 molecules in $KC_{24}(NH_3)_{4.3}$ (from ref. 14).

have revealed that the K–NH_3 intercalate layer is a 2D liquid at room temperature and that the liquid structure factor can reasonably well be described by a model in which four ammonia molecules are loosely associated with a single K^+ ion and the rest of the ammonia molecules are free. The liquid structure factor of $KC_{24}(ND_3)_{4.3}$ as determined by neutron scattering is shown in Fig. 2. In this scan the scattering vector is pointing parallel to the layers and therefore the structure factor $S(\boldsymbol{Q})$ represents the Fourier transform of six pair correlation functions involving K, N, and D. The (100) and (110) graphite Bragg peaks at 2.94 and 5.08 $Å^{-1}$, respectively, are eliminated for clarity. In spite of the large number of correlation functions the structure factor is surprisingly simple with only one major peak at 1.95 $Å^{-1}$ which is dominated by the ammonia–ammonia pair correlation. The structural model of the 2D liquid is schematically shown in Fig. 3 and is based on a structure factor calculation which assumes that the K–ammonia clusters are four-fold coordinated and that the molecular three-fold axis lies parallel to the graphite and intercalate layers, in agreement with recent nmr results (9).

Neutron scattering scans in which the scattering vector has a component in the c^* direction perpendicular to the planes yield clear evidence that no correlation exists between adjacent intercalate layers, demonstrating the 2D nature of the metal–ammonia layers in these GIC's. Thus the K–ammonia layers form the two-dimensional structural analogue of the well-known three-dimensional metal–ammonia solutions in which the K^+ ion is six-fold coordinated (10, 11). In fact, resistivity anomalies and optical reflectivity measurements (12) as a function of the ammonia concentration have recently provided strong evidence for a metal–insulator transition in two dimensions. In homogeneous stage 1 KC_8 or stage 2 KC_{24} compounds the outer K-4*s* electron is either completely or almost completely donated to the graphite π^*-bands (13). The metal–insulator transition in the K–NH_3 intercalate layer relies crucially on a partial back transfer of electrons from the graphite to the intercalate bands. This back transfer along with the layer expansion implies that the intercalate–graphite interaction is weakened, which should result in a softening of the phonon energies for modes propagating normal to the planes. This effect will be discussed in further detail in part IV of this paper.

While there exists no correlation between the metal–ammonia intercalate layers, the graphite layers maintain the proper A/A/A... stacking sequence typical for stage 1 compounds (8). Here A refers to the graphite basal planes and the slash to the liquid intercalate layer. The graphite stacking order, in addition, indicates that the intercalate layer cannot be described as a simple 2D liquid on a smooth substrate but that it must be, however weakly, modulated by the graphite corrugated substrate potential. This modulation should be observable in a liquid structure factor reflecting the six-fold symmetry of the graphite basal planes. However, corresponding experiments on single crystals have not been carried out yet to verify this conjecture. At 190 K an order–disorder transition takes place, and the low temperature structure presumably represents a discommensuration domain structure. But the structural details of this phase remain to be determined.

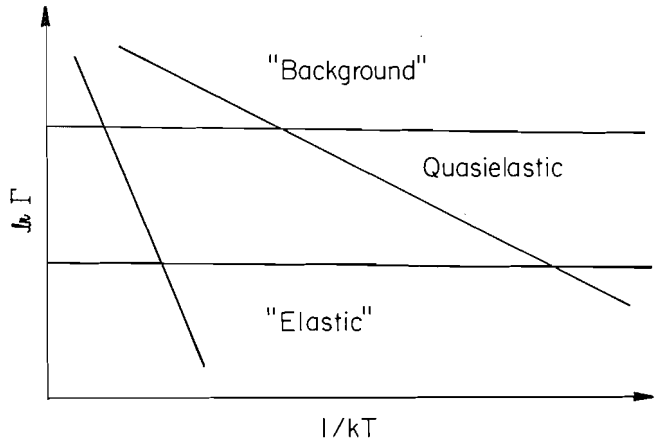

FIG. 5. Schematic Arrhenius plots of two different molecular excitations with different activation energies. Γ is the width of the neutron quasi-elastic line shape which is related to the jump frequency or to the diffusion constant. The "quasielastic" region designates the dynamical range of a neutron spectrometer within which quasi-elastic line shapes can be measured. Any signal outside of this range appears either as an "elastic" peak or contributes to the "background" of the sprectrum.

III. Single molecule dynamics

In the presence of NH_3 molecules several kinds of rigid molecular motions have to be considered, discounting the internal vibrational excitations. The rigid molecular excitations for the bound NH_3 molecules are depicted in Fig. 4, and comprise a rotation of the molecule about its C_3 symmetry axis (R_1), rotation about the enclosed K^+ ion (R_2), translational motion of single molecules of $K(NH_3)$ complexes (T), and finally possible librations or tumbling motions of the molecule. Some of those excitations may be highly coupled. For the free molecules an even more complex picture may be expected which resembles the excitations of molecules in a homogeneous molecular liquid. However, since the number of "free" NH_3 molecules is comparatively small (<10%), we will tentatively neglect their contribution to the excitation spectrum. Recent quasi-elastic neutron scattering (QUENS) work (14) was attempted to unravel these different molecular excitations.

In general, the neutron dynamical scattering function $S(\boldsymbol{Q}, \omega)$ has a Lorentzian line shape for translational diffusion, whereas for re-orientational motions the line shape is composed of a δ-function superimposed on a Lorentzian component (15, 16). The Lorentzian line shape is due to the time-exponential decay of the self correlation function, while the δ-function reflects the fact that the rotating molecule always returns to its original position. The width of the Lorentzian part, $\Gamma(\boldsymbol{Q}, T)$, is related to the diffusion constant or jump frequency of the molecule, and it is therefore very difficult to separate out the different kinds of motion if they appear on similar time scales. A schematic Arrhenius plot for two different excitations is shown in Fig. 5, demonstrating that the energy range over which a particular quasi-elastic broadening is observable depends on the dynamical range of the instrument used to perform the measurement. Quasi-elastic widths which are too narrow to be resolved appear as "elastic" peaks, Lorentzian line shapes that have grown too broad with increasing temperature disappear in the "background" of the spectrum. Thus motions occurring on different time scales can be separated simply by observing them in different temperature regimes or by performing measurements using instruments with different resolution an dynamical ranges.

Rotational and tranlational diffusion can, in addition, be distinguished by their characteristic Q dependence of the dynamical scattering function. Also reorientational jumps versus rotational diffusion and translational jump diffusion versus continuous diffusion are distinguishable in carefully recorded neutron spectra. Space limitation does not allow us to go here in further detail. We simply note that for small scattering vectors $\boldsymbol{Q}$ the Lorentzian width $\Gamma \propto Q^2$ for translational diffusion and $\Gamma =$ constant for rotational diffusion.

In Fig. 6 are shown representative QENS scans from $KC_{24}(NH_3)_{4.3}$ at several temperatures in the ordered as well as in the disordered phase of the K–NH_3 intercalate layer (14). These data were taken at samples containing NH_3 in order to take advantage of the large incoherent cross-section of the H atoms for neutron scattering. In the top panel of Fig. 6 a quasi-elastic scan is shown at 78 K and at $Q_{\parallel} = 2.0$ Å^{-1}, where the subscript $\parallel$ designates the orientation of the scattering vector parallel to the intercalate layers. At this temperature a good fit to the data is obtained using a two component peak, a δ and a Lorentzian component both broadened by the Gaussian instrumental resolution. The two component line shape is indicative of a rotational motion of the NH_3 molecule at this temperature. As the temperature is increased, the width of the broad component increases from 0.79 meV at 78 K to 1.3 meV at 150 K. An Arrhenius plot of the deconvoluted Lorentzian width indicates that this rotation has an activation energy of about 5 meV. Upon further increase of the temperature to 200 K, which is just above the order–disorder temperature, it is found that the scattering due to the first rotational motion has broadened into a flat background, and that a second rotational excitation appears in the spectrum. This spectrum was recorded at a smaller scattering vector than the data below the phase transition, because of the coupling of rotational and diffusion motion which becomes noticeable at higher Q's. At 300 K and at approximately the same Q as the 200 K spectrum, it becomes now aparent that the central peak is broader than the instrumental resolution caused by the translational motion of the ammonia molecules. The translational self-diffusion constant was estimated to be of the order of 10^{-5} cm^2/s at room temperature, and the activation energy of the second rotational excitation was determined to be of the order of 100 meV.

The results described above were obtained with a triple-axis spectrometer at a thermal neutron source. Therefore they do not contain enough spectra at different Q values to allow unique assignments of the observed spectra to certain types of molecular motions. The most reasonable interpretation of the data, however, starts with the fact that at the lowest temperature the quasi-elastic broadening is almost certainly due to rotations of the molecule about the axis with smallest moment of inertia, which is the C_3 symmetry axis. The rotation observed at higher temperatures may then be due to a spin-wheel type motion of the ammonia molecules about the encaged K ions. Finally, the translational diffusion may either involve whole K–NH_3 complexes, diffusion of individual NH_3 molecules between different complexes, diffusion of "free" ammonia molecules, or a combination thereof. Even with more Q values and higher resolution it will be very difficult if not impossible to distinguish between these possibilities. The assignment of the rotational motions is in agreement with recent nmr results (9) which indicate that at room temperature both spinning of the NH_3 molecule about the C_3 axis and precession of the molecular axis about the graphite c axis are present, and that both occur with frequencies greater than 10^5 Hz.

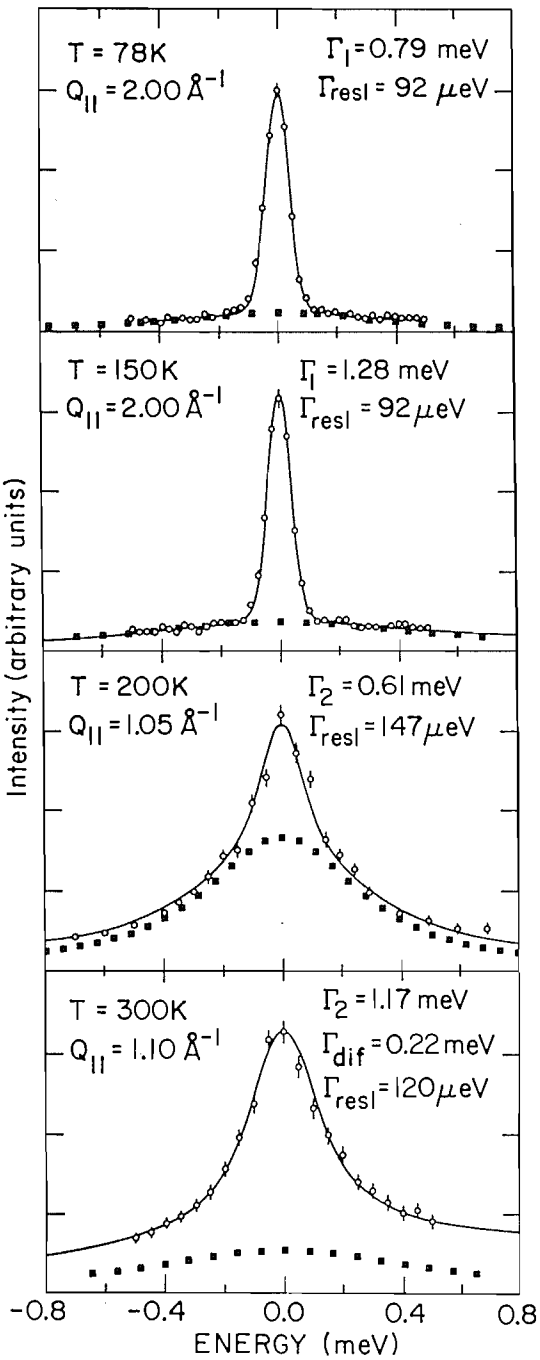

FIG. 6. Quasielastic spectra obtained by inelastic neutron scattering. Open circles represent experimental points, the solid lines are fits to δ functions and Lorentzians, both convoluted with the Gaussian instrumental resolution, and the squares represent the Lorentzian contributions only to the scattering. The data extend to higher positive and negative energy values than shown in the figure. For further details see text (from ref. 14).

Very recent high resolution neutron scattering studies (17) showed a rich tunneling spectrum between 4 and 30 K, which evolves at higher temperatures into the quasi-elastic spectrum discussed above. But since the low temperature intercalate structure is unresolved at the present time, any interpretation of the tunneling spectrum would be premature.

IV Phonon–libron coupling

Additional insight into the dynamics of the K–NH_3 – GIC has also been gained by measuring the phonon dispersion of this system (18). The measured energies of the [00q] longitudinal (L) phonon modes of stage 1 $KC_{24}(ND_3)_{4.3}$ are shown in Fig. 7. These measurements were carried out with deuterated ammonia to reduce the incoherent scattering and enhance the coherent scattering thereby allowing the measurement of the phonon dispersion. Three branches are clearly observed as shown in Fig. 7. However, it is well known that stage 1 compounds typically display only two [00q] L branches because the c axis repeat distance comprises two planes with different areal mass densities (19). Comparison with these homogeneous stage 1 compounds indicates that the lower two branches of $KC_{24}(NH_3)_{4.3}$ belong to the same acoustic branch which has been split by the hybridization of the phonons with an additional excitation at about 7 meV. As will be discussed later, the nature of this mode is not yet certain, but it must be associated with librations of the ammonia molecules. A zone center scan reveals a broad feature centered at 7 meV due to the additional excitation. Thus the librational mode is essentially dispersionless along the c axis, indicating a very weak interaction between ND_3 molecules in adjacent layers. This finding is in accordance with the complete absence of interclate interlayer correlations displayed in the elastic scattering data.

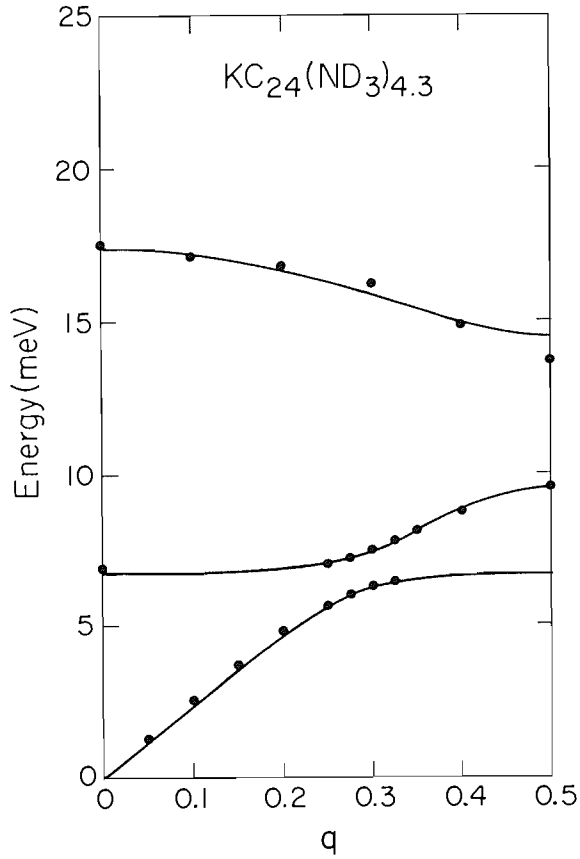

FIG. 7. [00q] longitudinal phonon dispersion of the stage 1 compound $KC_{24}(ND_3)_{4.3}$. The solid lines represent a fit to the data of the one-dimensional Born – von Karman model including phonon–libron coupling term described in the text (from ref. 18).

The observed dispersion relation has been modeled with a 3 × 3 dynamical matrix, **D**, which includes a virtual crystal, one-force constant Born – von Karman model, an Einstein oscillator of energy α representing the libration, and a term containing the coupling constant γ:

$$\mathbf{D} = \begin{bmatrix} \frac{2\phi}{M} & \frac{-\phi}{\sqrt{mM}}(1 + e^{iql_c}) & -\gamma\alpha(1 - e^{i2ql_c}) \\ \frac{-\phi}{\sqrt{mM}}(1 + e^{-iql_c}) & \frac{2\phi}{m} & 0 \\ -\gamma\alpha(1 - e^{-i2ql_c}) & 0 & \alpha^2 \end{bmatrix}$$

Here ϕ is the intercalate-graphite force constant per carbon atom, M is the carbon areal mass density, m is the intercalate areal mass density per carbon atom, and l_c is the c-axis lattice constant. The upper left corner marked by the dotted lines represents the uncoupled phonon dispersion. The best fit parameters corresponding to the dispersion relations displayed as the solid lines in Fig. 7 are $\phi = 2090$ dyn/cm, $\alpha = 6.7$ meV, and $\gamma = 0.70$ meV. The interlayer force constant ϕ is by a factor of two smaller than the value obtained for the binary stage 1 compound KC_8 (19, 20). This decrease is mostly due to the c-axis layer expansion in the ternary compound as compared to the binary compound and partially also to the back transfer of electrons from the graphite π^*-band to the intercalate bands, as alluded to previously.

The actual physical motion corresponding to the observed librational excitation has not been unambiguously determined yet. However, it is possible to make a reasonable speculation. From the quasi-elastic neutron scattering results discussed earlier, it is clear that rotations about the C_3 molecular axis persist to low temperatures. The fact that this component of the quasi-elastic line broadens to an essentially flat background at room temperature, implying almost free rotation, indicates that the libration is certainly not about the C_3 symmetry axis. Thus we are led to consider oscillations of the C_3 axis. A simple model for such excitations is obtained by noting that this is also the axis along which the molecular dipole moment is directed and that the potassium atoms are almost completely ionized. Then if one considers the electrostatic interaction between a point dipole p and a point charge e, both of which are fixed in space, the librational frequency of the dipole is given by $\omega_{lib} = (pe/R^2I)^{1/2}$, where I is the moment of inertia about the librational axis, and R is the dipole-charge separation. For ND_3, $p = 1.3$ Debyes, $I_{cm} = 3 \times 10^{12}$ meV Å$^2/c^2$ (c = speed of light), and the metal–ammonia distance is roughly 3 Å. This gives an energy for librations occurring about the molecular center-of-mass of about 24 meV, far different from the observed value of 7 meV. Thus the barrier is an order of magnitude too large to explain the energy of the observed excitation. However, if the barrier were a factor of 10 smaller, it would then be comparable to the thermal energy and anharmonicity would render the librational excitation, as well as the coupling to the acoustic phonons, unobservable.

The way to resolve these difficulties is to find a mechanism which increases the effective moment of inertia thereby leaving the potential barrier high enough to account for the relatively small degree of anharmonicity. This can be done in two ways. The first is to shift the rotational axis away from the molecular center-of-mass. In order to reduce the librational energy from 25 meV to the observed 7 meV this displacement must be about 1.4 Å, which places the axis of rotation outside of the ND_3 molecule approximately half way between the potassium and ammonia distance. The observed excitation was therefore tentatively named a K–ND_3 "bond-bending" mode (18). It is, however, difficult to picture such a mode since the displacements of the D atoms, which are sterically constrained by the bounding graphite layers, would be large. On the other hand, strong evidence that the librational excitation must have an out-of-plane component is provided by the fact that it couples to the longitudinal phonons propagating normal to the planes, and by nmr results (9) which indiate that the out-of-plane potential is approximately what is required to account for a 7 meV bond-bending mode. There is only one known case in which an in-plane motion leads to a splitting of the [00q]L acoustic branch and this is for alkali-intercalates in stage 2 GIC's (21, 22). Thus, while the bond-bending model explains the observations in a relatively complete fashion, it is not the only model which seems to be capable of doing so. Further experiments are therefore necessary to unambiguously determine, if either, of these models is appropriate for K–ammonia intercalated graphite.

V. Conclusion

We have provided a brief overview of the intriguing structural and dynamical properties of K–ammonia intercalate layers in graphite recently determined by elastic, quasi-elastic, and inelastic neutron scattering experiments. These measurements show that the K–NH_3 layers represent two-dimensional liquids consisting of four-fold coordinated K–ammonia clusters and a small percentage of "free" ammonia molecules. The dynamics of this liquid is very rich, comprising simultaneous rotation of the ammonia molecules about their three-fold symmetry axis, precession of this axis about the encaged K ions, and translational motion of the clusters within the intercalate plane. In addition, a librational excitation of the ammonia molecules couples to longitudinal [00q] phonon modes propagating normal to the graphite and interclate planes. Although the last years have witnessed much progress in unraveling the fascinating properties of two-dimensional metal–ammonia solutions, there are a number of questions which require close attention in future work. Those are the low temperature ordered structure of the K–ammonia layers, the nature of the diffusional motion, the diffusion–rotation coupling, and the origin of the librational excitation.

The 9.3547 GHz complex permittivity of water in the temperature interval 0–10°C

T. H. T. VAN KALLEVEEN AND H. A. BUCKMASTER[1]

Department of Physics, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received August 31, 1987

This paper is dedicated to Professor J. A. Morrison

T. H. T. VAN KALLEVEEN and H. A. BUCKMASTER. Can. J. Chem. **66**, 672 (1988).

This paper reports the results of a high precision study of the 9.3547 GHz complex permittivity of water in the temperature interval from 0–10°C. Measurements were made in ≈0.5°C steps in the interval 0–5°C and ≈1.0°C steps in the interval 5–10°C. The precision for the permittivity and for the dielectric loss was typically ≈0.03% and ≈0.04%, respectively, whereas the accuracy is better than 0.15%. The values of the permittivity $\epsilon'(T)$, the dielectric loss $\epsilon''(T)$, the attenuation per unit length $\alpha(T)$, and the phase shift per unit length $\beta(T)$ have been fitted to the empirical polynomial expressions

$$\epsilon'(T) = 44.68 + 1.318\,T - 0.0253\,T^2 + 0.000378\,T^3 \qquad \sigma(\epsilon') = 0.030$$
$$\epsilon''(T) = 40.54 - 0.0901\,T - 0.0298\,T^2 + 0.000537\,T^3 \qquad \sigma(\epsilon'') = 0.012$$
$$\alpha(T) = 550.3 - 7.08\,T - 0.15\,T^2 + 0.0029\,T^3 \qquad \sigma(\alpha) = 0.17$$
$$\beta(T) = 1416.3 + 15.11\,T - 0.45\,T^2 + 0.0090\,T^3 \qquad \sigma(\beta) = 0.36$$

T. H. T. VAN KALLEVEEN et H. A. BUCKMASTER. Can. J. Chem. **66**, 672 (1988).

Dans ce travail, on a effectué une étude à haute précision du complexe de permittivité de l'eau à 9,3547 GHz, à un intervalle de température de 0 à 10°C. On a effectué les mesures à tous les 0,5°C entre 0 et 5°C et à tous les degrés entre 5 et 10°C. Les précisions sur la permittivité et sur la perte diélectrique sont respectivement de 0,03% et ≈0,04% alors que l'exactitude est mieux que 0,15%. On a ajusté les valeurs de la permittivité $\epsilon'(T)$, de la perte diélectrique $\epsilon''(T)$, de l'atténuation par unité de longueur $\alpha(T)$, et du déplacement de phase par unité de longueur $\beta(T)$ aux expressions polynomiales empiriques suivantes :

$$\epsilon'(T) = 44{,}68 + 1{,}318\,T - 0{,}0253\,T^2 + 0{,}000378\,T^3 \qquad \sigma(\epsilon') = 0{,}030$$
$$\epsilon''(T) = 40{,}54 - 0{,}0901\,T - 0{,}0298\,T^2 + 0{,}000537\,T^3 \qquad \sigma(\epsilon'') = 0{,}012$$
$$\alpha(T) = 550{,}3 - 7{,}08\,T - 0{,}15\,T^2 + 0{,}0029\,T^3 \qquad \sigma(\alpha) = 0{,}17$$
$$\beta(T) = 1416{,}3 + 15{,}11\,T - 0{,}45\,T^2 + 0{,}0090\,T^3 \qquad \sigma(\beta) = 0{,}36$$

1. Introduction

The complex permittivity of water has been measured near 9 GHz to a precision of ≈1–2% below 10°C by a number of authors including Collie *et al.* (1), Saxton and Lane (2), Cook (3), Hasted and El Sabeh (4), Buchanan and Grant (5), and at a number of frequencies from 5 to 36 GHz by Pottel (private communication, quoted by Hasted (6)). Kaatze and Uhlendorf (7) have reported a comprehensive synthesis of these and other complex permittivity measurements at microwave frequencies.

Recently, McAvoy and Buckmaster (8) reported the measurement of the 9.346 GHz complex permittivity of water at 20°C and 25°C with a precision of ≈0.06% for the permittivity and ≈0.15% for the dielectric loss. The measurements had been made using a dual channel, double superheterodyne signal processing system and a variable length transmission sample cell described initially by McAvoy and Buckmaster (9). Subsequently, Zaghloul and Buckmaster (10) improved this instrumentation system and reported the measurement of the 9.356 GHz complex permittivity of water in the temperature interval from 10 to 40°C with a typical precision 0.06% for the permittivity and the dielectric loss. It was found that condensation on the sample waveguide windows precluded making measurements below 10°C and that sample temperature inhomogeneity in excess of 0.1°C was the limiting factor above 40°C.

This paper reports the measurement of the 9.3547 GHz complex permittivity of water at temperatures below 10°C using a further improved version of the instrumentation system. The permittivity and dielectric loss have been obtained with a typical precision of 0.03% and 0.04%, respectively.

2. Theory

The complex permittivity ϵ of a dielectric is

$$[1] \quad \epsilon = \epsilon'' - i\epsilon''$$

where the real part ϵ' is the permittivity and the imaginary part ϵ'' is the dielectric loss. The permittivity and dielectric loss can be calculated from the attenuation per unit length α and the phase shift per unit length β using the equations

$$[2a] \quad \epsilon' = (\lambda/2\pi)^2[\beta^2 - \alpha^2] + (\lambda/\lambda_c)^2$$

$$[2b] \quad \epsilon'' = (\lambda/2\pi)^2 2\alpha\beta$$

where λ is the free space wavelength and λ_c is the cutoff wavelength (11). The attenuation and phase per unit length are obtained from the amplitude and the phase of the microwave power which passed through the variable length transmission sample cell. The expressions for α and β are

$$[3a] \quad \alpha = (l/z) \ln [V(z)/V(0)]$$

$$[3b] \quad \beta = (l/z)[\phi(z) - (0)]$$

where $V(z)$ is the signal amplitude and $\phi(z)$ is the signal phase at a sample length z. $V(0)$ is the signal amplitude and $\phi(0)$ is the signal phase at $z = 0$. The cutoff wavelength $\lambda_c = [(m/2a)^2 + (n/2b)^2]^{-1/2}$ (11) and for TE_{mn} mode in the rectangle waveguide of dimensions a and b. It was assumed that only the fundamental mode TE_{10} was excited so $\lambda_c = 2a$.

3. Instrumentation

The instrumentation system used to perform the experiments described in this paper is a modified version of that detailed by Zaghloul and Buckmaster (10). Modifications were only made

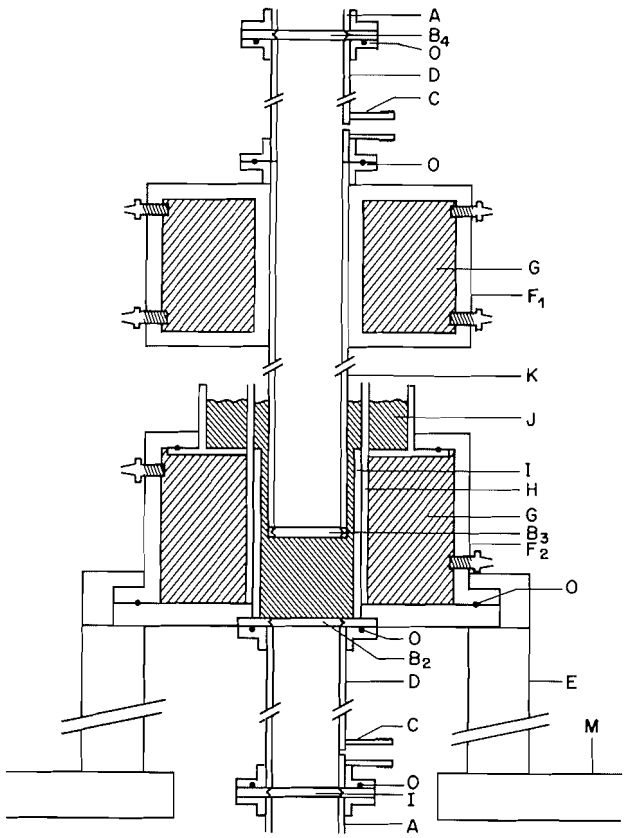

FIG. 1. Schematic diagram of the variable length transmission sample cell: A ≡ Input waveguide, B1, B2, B4 ≡ waveguide windows (MDL-90WF56), B3 ≡ solderable waveguide window (MDL-90WD86), C ≡ evacuation port, D ≡ thin wall stainless steel waveguide, E ≡ Tufnol thermal insulating system support, F1, F2 ≡ upper and lower thermalizing jackets, G ≡ thermalizing fluid, H ≡ temperature measurement tube, I ≡ transmission sample cell outer waveguide (WR102), J ≡ sample fluid, K ≡ transmission sample cell inner waveguide (WR90), M ≡ main system support, O ≡ O-ring.

to the variable length transmission cell. A schematic diagram of the transmission cell is shown in Fig. 1. The upper thermalizing jacket F1 was elongated so that it encased the entire exposed portion of the waveguide K when the transmission sample cell length was zero, i.e., the distance between windows B2 and B3. The stainless steel waveguides D with the evacuation ports C and the waveguide windows (MDL-90WF56) B1 and B4 were added to the system; this permitted the waveguide sections between windows B1 and B2 and between windows B3 and B4 to be evacuated. These features provide greater thermal isolation of the transmission sample cell. A platinum resistance thermometer using a Omega 1Pt100 K2015 Ceramic RTD Element was placed in tube H to measure and to monitor the sample temperature. This thermometer has a resolution of 0.01°C and it was calibrated using a Guideline 9540 Digital Platinum Resistance Thermometer which has an absolute accuracy of 0.01°C and a resolution of 0.001°C. The sample temperature was stable to at least ±0.005°C during the measurement interval of all data sets at a particular temperature.

The measurements were made using a Varian V-153C reflex klystron, a HP-716A klystron power supply, and a Microwave Systems Inc. MOS-1 Microwave Oscillator Synchronizer. This configuration provided ≈ 100 mW of power at 9.3547 GHz with a frequency stability of better than $1:10^8/h$ and spectral purity of ≈ 10 Hz. The frequency stability and spectral purity were transferred to a Gunn diode local oscillator with 60 MHz difference frequency using a Microwave Systems Inc. PLS 2600 Microwave Oscillator Synchronizer.

TABLE 1. The measured values of the attenuation per unit length α, the phase shift per unit length β, and the standard deviations for five typical measurement sequences for water at 9.3547 GHz and at 3.06°C; the calculated values for the permittivity ε′ and the dielectric loss ε″ are also included for the five measurement sequences

5	526.944	0.068	1458.440	0.134	48.493	39.985

The dual channel, double superheterodyne signal processing system was described initially by McAvoy and Buckmaster (9); refinements and improvements to this system were detailed by Zaghloul and Buckmaster (10). This signal processing system enables the amplitude and phase of a microwave signal to be measured to ≈ 0.001 dB and ≈ 0.01° respectively by translating the microwave signal from 9 GHz to 60 MHz and finally to 1 kHz using quasi-synchronous demodulation at each frequency. The amplitude of the 1 kHz signal was measured using a Dana Model 5900 5½ digit Digital Multimeter; the phase of this signal was obtained using a Ithaco 391 Lock-In Analyzer. The amplitude and phase were digitized with 14 bits resolution and stored in a Data Precision 6000 Universal Waveform Analyzer.

4. Experimental Procedure

The measurement procedure is similar to that described by Zaghloul and Buckmaster (10). A measurement was started at a transmission sample cell length of 0.25 in. to eliminate the effects of reflections at the waveguide windows. The transmission sample cell length was incremented in 0.0025 in. steps until the transmission sample cell output power decreased by 20 dB. The microwave power into the transmission sample cell was then increased by 20 dB and the measurement was continued until the transmission sample cell output power had again decreased by 20 dB. After each increment of the cell length, the amplitude and the phase of the transmission sample cell output microwave signal were stored in the Data Precision 6000 memory. At the end of each measurement the amplitude and phase data were transferred from the Data Precision 6000 to a Sun 3/160M workstation for analysis. The total number of increments is dependent on the temperature of the sample and it varied from 133 (≡ transmission sample cell lengths of 0.5825 in.) at 0.04°C to 157 (≡ 0.6425 in.) at 10.09°C.

The attenuation per unit length α and the phase shift per unit length β were calculated from the amplitude and phase data using eqs. [3*a*] and [3*b*]. The permittivity and the dielectric loss were obtained from α and β using eqs. [2*a*] and [2*b*]. All values of ε′ and ε″ reported in this paper are the average of five or six consecutive amplitude and phase measurement data sets. It was found that this number of measurement data sets was sufficient, i.e., an increase in the number of measurement data sets did not appreciably improve the standard deviation of ε′ and ε″.

The complete set of measurements was made without changing the water sample during a period of days because deviations in ε′ and ε″ ≈ 5σ were observed on one occasion although the water was obtained from the same reservoir. If the water is not changed and water is added to the sample to make up for evaporization, measurements made on different days but for the same sample temperature produce average values which are within one standard deviation from each other. Subsequently, it was determined that this deviation probably occurred

because an air bubble had developed between the Teflon seal and window B2 at the bottom of the transmission sample cell. Care in filling this cell with water has eliminated this effect.

The values of $\epsilon'(T)$, $\epsilon''(T)$, $\alpha(T)$, and $\beta(T)$ were fitted to empirical polynomials with the temperature (°C) as the independent variable using the method of least squares. A computer programme, which is a variation of that described by Bevington (12), calculated the degree of the polynomial for which the goodness of fit to the data is at a minimum.

5. Results and discussion

The values of the attenuation per unit length α, the phase shift per unit length β, and the standard deviations in α and β for water at 3.06°C for a set of five measurement sequences are presented in Table 1. The permittivity ϵ' and the dielectric loss ϵ'' calculated using eqs. [2*a*] and [2*b*], respectively, are also included. The standard deviations $\sigma(\alpha)$ and $\sigma(\beta)$ correspond to the goodness of the fit of the experimental amplitude and phase data to eqs. [3*a*] and [3*b*], respectively. These values are about a factor of 1.5 smaller than those reported by Zaghloul and Buckmaster (10) for a typical measurement sequence. This improvement was achieved by measuring the amplitude of the 1 kHz signal using the Dana Digital Multimeter instead of the Ithaco Lock-In Analyzer. The latter measurement device was used by Zaghloul and Buckmaster (10) to obtain both the phase and the amplitude of the 1 kHz signal. The reason for the improvement became clear when the amplitude data for each measurement sequence was scrutinized to ensure that the incremental changes in the attenuation were constant. This was accomplished by the graphical display of the consecutive differences for the attenuation as a function of the increment number defined as the labelled sequence of the transmission sample cell lengths. This procedure revealed that the consecutive differences varied sinusoidally with the increment number when the amplitude of the 1 kHz signal was measured using the Ithaco Lock-In Analyzer. The technique used by the Lock-In Analyzer to measure the amplitude of an unknown signal involves shifting the phase of the reference input signal by 90° and multiplying the resultant with the unknown signal. The above mentioned sinusoid has been attributed to the reference signal phase shifter in the Lock-In Analyzer. A computer simulation showed that if the phase shift of the reference input signal is not exactly 90°, the consecutive differences of the attenuation will vary sinusoidally with the increment number. The use of the Dana Digital Multimeter for the measurement of the signal amplitude also revealed that the minimum length of the transmission sample cell had to be increased from that used by Zaghloul and Buckmaster (10) by 0.05 in. to 0.25 in. to eliminate the effects of reflections at the waveguide windows.

The values for the permittivity ϵ', the dielectric loss ϵ'', the attenuation per unit length α, the phase shift per unit length β, and their standard deviations in the temperature interval 0–10°C are listed in Table 2. Each value is the average of the values obtained from five or six measurement sequences at each temperature. The values of $\epsilon'(T)$, $\epsilon''(T)$, $\alpha(T)$, and $\beta(T)$ in Table 2 were fitted to empirical polynomials with the temperature (°C) as the independent variable using the method of least squares. The results of this analysis are

$$[4a]\quad \epsilon'(T) = 44.68 + 1.318\,T - 0.0253\,T^2 + 0.000378\,T^3 \qquad \sigma(\epsilon') = 0.030$$

$$[4b]\quad \epsilon''(T) = 40.54 - 0.0901\,T - 0.0298\,T^2 + 0.000537\,T^3 \qquad \sigma(\epsilon'') = 0.012$$

$$[4c]\quad \alpha(T) = 550.3 - 7.08\,T - 0.15\,T^2 + 0.0029\,T^3 \qquad \sigma(\alpha) = 0.17$$

$$[4d]\quad \beta(T) = 1416.3 + 15.11\,T - 0.45\,T^2 + 0.0090\,T^3 \qquad \sigma(\beta) = 0.36$$

Figures 2*a* and *b* depict the permittivity and dielectric loss as a function of the temperature in the interval 0–10°C using the data in Table 2 and eqs. [4*a*] and [4*b*], respectively. These figures show that both quantities vary smoothly with the sample temperature and that no dramatic changes are observed around 4.0°C which corresponds to the temperature at which the absolute density of water goes through a maximum (13). Similarly, no drastic changes are observed below 1°C as the liquid–solid phase transition at 0°C is approached.

The permittivity and dielectric loss of water at 0 and 10°C and at microwave frequencies around 9 GHz as reported in literature and in this paper are summarized in Table 3. The standard

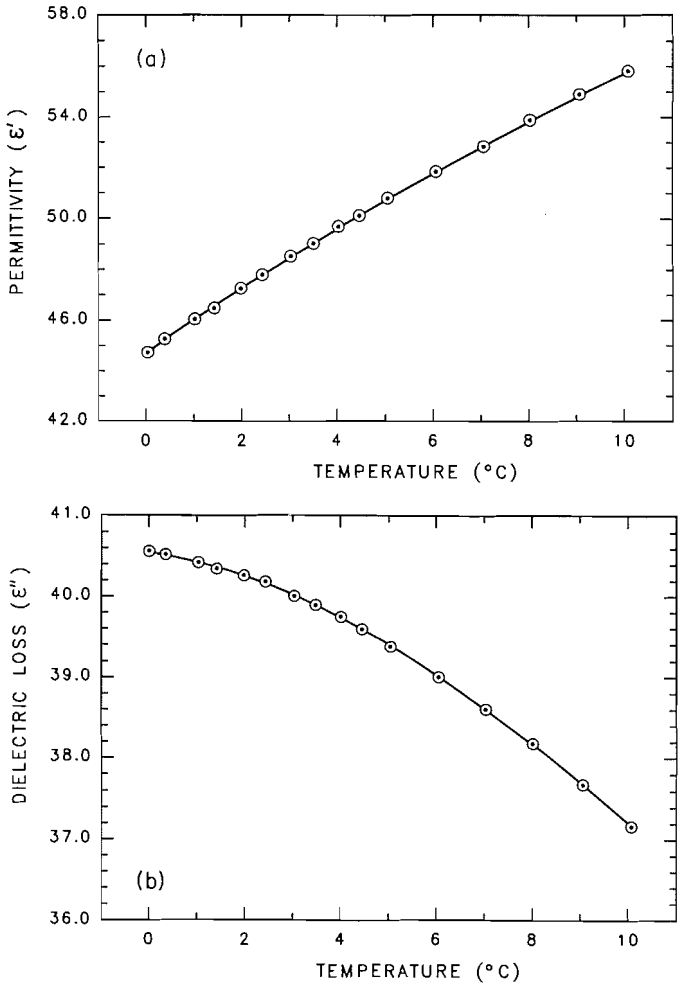

FIG. 2. The permittivity ϵ' (*a*) and the dielectric loss ϵ'' (*b*) as a function of the temperature in the interval 0–10°C at 9.3547 GHz using the data from Table 2 and eqs. [4*a*] and [4*b*], respectively.

deviations of ϵ' and ϵ'' have been included for the values from Zaghloul and Buckmaster (10) and from this work. The standard deviations of the other values are not available, but the precision is reportedly not better than 1–2% (1–5). A comparison of the precision obtained here to that reported by Zaghloul and Buckmaster (10) shows that a much greater degree of precision has been attained in this work. Two factors may have contributed to this. Firstly, Zaghloul and Buckmaster (10) obtained their experimental data using a Ithaco Lock-In Analyzer. A reanalysis of their data revealed that the above mentioned sinusoid was present in all of their attenuation difference graphs. This will affect the value of α to some extent. Secondly, the thermal isolation of the transmission sample cell has been improved greatly and so the sample will have better thermal homogeneity. Also the temperature of the sample can now be measured with greater accuracy.

A comparison of the permittivity at 10°C obtained here to that reported by Zaghloul and Buckmaster (10) shows that the values for ϵ' differ by $\approx$0.5%. However, this difference can be due to the above mentioned improvement in the determination of the sample temperature. An error of $\approx$0.1°C corresponds to $\approx$0.3%. It should be emphasized that measurements made on different days but at the same sample temperature produced average values within one standard deviation from each other.

TABLE 3. The permittivity ϵ' and the dielectric loss ϵ'' of water at 0 and 10°C and microwave frequencies around 9 GHz as reported in this paper and by various authors

T (°C)	ν (GHz)	ϵ'	ϵ''	Reference

The nuclear magnetic resonance line shape in solid CHD_3 is calculated under the assumption of consecutive interspin modifications conversion. A variable concentration of nuclear spin species can be used to fit the temperature variation of the nuclear magnetic resonance absorption lines as observed at low temperatures with the help of a simple Gaussian line width.

KENKICHI OKADA, YOSHIAKI OZAKI et KAZUO MAKI. Can. J. Chem. **66**, 676 (1988).

Faisant l'hypothèse qu'il se produit une conversion consécutive des modifications de spin, on a calculé la forme des raies en résonance magnétique nucléaire du CHD_3 à l'état solide. On peut utiliser une concentration variable des espèces de divers spins nucléaires pour ajuster la variation, en fonction de la température, des raies d'absorption en résonance magnétique nucléaire qui sont observées à basses températures à l'aide d'une largeur de raie de Gauss simple.

I. Introduction

The observation of nuclear magnetic interactions has given valuable information on the structure and molecular motion in the solid methanes. Among the many investigations in this field one might mention an early systematic T_1 measurement (1), information on tunnel splitting (2), structure determination of phase II (3), and a high pressure study of phase diagrams (4). A recent nmr study at very low temperatures revealed new aspects of the methane problem. Precise measurements of nmr line shapes in solid deuterated methanes by Buchman *et al.* (5–7) show remarkable temperature variation of the line shapes, especially of CHD_3. From their results these authors claim that there is no nuclear spin conversion in CHD_3 at low temperatures. Although they obtained good results for the nmr line shape, their analysis gave a poor fit to the heat capacity data (8) in spite of the employment of many adjustable parameters.

In the present article we shall give an alternative and better explanation of the nmr data for solid CHD_3. Our model of rotational tunneling in solid CHD_3 is the same one already found by one of the present authors to give an excellent fit to the experimental data for the heat capacity of all the isotopic methanes (11). We shall show that the nmr data can also be explained on the basis of the occurrence of spin conversion without introducing many additional parameters.

The theoretical treatment of nmr line shapes in phase III of solid CHD_3 is developed in Sect. II. Comparison of theoretical results with experimental data is given, with some remarks, in Sect. III.

II. Theory of the nuclear magnetic resonance absorption line shape

In the following, we employ a mean field approximation to describe the rotational states of a molecule in solid CHD_3. A rotation–nuclear spin state of a molecule may be classified by means of the molecular symmetry group C_{3v}, whose irreducible representations Γ are A_1, A_2, or E. Each molecule will contribute independently to the total nmr line whether it occupies a C_2 or a C_s site. The effective nuclear spin Hamiltonian for the CHD_3 molecule may be written as:

$$[1] \quad H_N = H_Z + H_Q + H_D$$

where the unperturbed system is governed by the deuteron Zeeman term H_Z:

$$[2] \quad H_Z|\Gamma; I, M\rangle = -\hbar\omega_0 M|\Gamma; I, M\rangle, \qquad \omega_0 = \gamma_D H_0$$

$$I = \begin{cases} 3, 1 & \text{for } \Gamma = A_1 \\ 0 & A_2 \\ 2, 1 & E \end{cases} \qquad (M = I, I-1, \ldots, -I)$$

Here the molecular spin function is constructed from the deuteron spin functions $|\mu\rangle$ ($\mu = 1, 0$, or -1) by means of simple product functions $|\mu, \nu, \lambda\rangle$:

$$[3] \quad |\Gamma; I, M\rangle = \sum_{\mu,\nu} C^{\Gamma I}_{M,\mu,\nu} |\mu, \nu, M - \mu - \nu\rangle$$

The explicit forms of these functions are given in the Appendix. The electric quadrupole interaction term H_Q gives the following first-order perturbations upon the Zeeman levels:

$$\begin{aligned}[4] \quad \langle \Gamma; I, M|H_Q|\Gamma; I, M\rangle = \sum_{\mu,\nu} |C^{\Gamma I}_{M,\mu,\nu}|^2 \{e^2qQ/8I(2I-1)\} \\ \times [\{3\mu^2 - I(I+1)\}(3\cos^2\beta_1 - 1 + \eta\cos 2\alpha_1 \sin^2\beta_1) \\ + \{3\nu^2 - I(I+1)\}(3\cos^2\beta_2 - 1 + \eta\cos 2\alpha_2 \sin^2\beta_2) \\ + \{3(M-\mu-\nu)^2 - I(I+1)\}(3\cos^2\beta_3 - 1 \\ + \eta\cos 2\alpha_3 \sin^2\beta_3)]\end{aligned}$$

Here we denote by (α_i, β_i) the polar angles of the CD direction at the ith deuteron with respect to the frame determined by the static magnetic field H_0 and rf field. In this expression,

$$[5] \quad q = (\partial^2 V/\partial Z^2)_0,$$

$$\eta = \{(\partial^2 V/\partial X^2)_0 - (\partial^2 V/\partial Y^2)_0\}/(\partial^2 V/\partial Z^2)_0$$

AB	−0.1759	A	0.1202
AA	0.1924	A	0.1731
AB	0.9061	A	0.8092
EB	−0.2620	E	−1.1300
EA	−0.1974	E	0.1257
EB	0.2305	E	0.1782
EA	0.9349	E	0.8402

In the table, the molecular symmetry symbol A occurs in the upper entries and E in the lower ones. The site symmetry symbol A or B follows after the molecular symbol in the case of a C_2 site. See ref. 11 for details.

TABLE 2. Nonvanishing values of $N_{\Gamma,I,M}$

I	M	$N_{A_1,I,M}$
3	±3	−5
	±1	3
	0	4
1	±1	−3
	0	6

The value of $N_{\Gamma,I,M}$ is zero when $\Gamma = A_2$ or E and when $\Gamma = A_1$ with $M = \pm 2$.

are the usual symbols for the field gradient parameter and its anisotropy, respectively.

Since the total wavefunction of a CHD_3 molecule should belong to the irreducible representation A_1 of C_{3v} symmetry, we may take a form of the rotation–deuteron spin part as follows:

[6] A_1 species: $\psi_R(A_1)\psi_D(A_1)$

A_2 species: $\psi_R(A_2)\psi_D(A_2)$

E species: $\sqrt{1/2}\,\{\psi_R(E_1)\psi_D(E_2) + \psi_R(E_2)\psi_D(E_1)\}$

where we denote $\psi_R(\Gamma)$ as a rotational wavefunction and put $\psi_D(\Gamma) = |\Gamma; I, M\rangle$. The rotational eigenfunctions are the same as in ref. 11 and the eigenvalues to which these states belong are given in Table 1. Note that the angular variables to describe the rotational motion of a molecule are referred to the crystal-fixed frame.

The nuclear spin matrix elements [4] may be written as

[4′] $\langle\Gamma; I, M|H_Q|\Gamma; I, M\rangle = N_{\Gamma,I,M}h\tilde{\nu}$

where $\tilde{\nu} = -(e^2qQ/40h)f_{1,2,3'}$

[7] $f_{1,2,3} = 3(\cos^2\beta_1 + \cos^2\beta_2 + \cos^2\beta_3 - 1)$
$+ \eta(\cos 2\alpha_1 \sin^2\beta_1 + \cos 2\alpha_2 \sin^2\beta_2 + \cos 2\alpha_3 \sin^2\beta_3)$

This results from carrying out the summation over μ and ν on the right-hand side of eq. [4]. The nonvanishing values of $N_{\Gamma,I,M}$ are given in Table 2.

Since the transition probability $W^{\Gamma,I}_{M\to M-1}$ between Zeeman levels is proportional to

[8] $|\langle\Gamma; I, M-1|I_-|\Gamma; I, M\rangle|^2 = I(I+1) - M(M-1)$

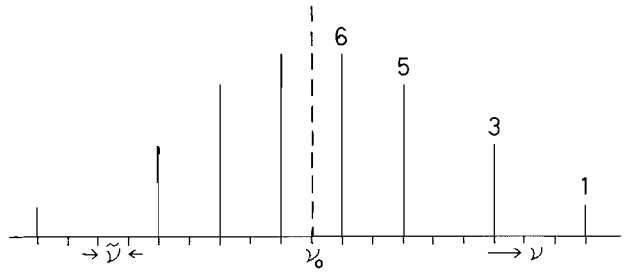

FIG. 1. Calculated pattern of the deuteron nmr absorption spectrum for single crystalline CHD_3. The height of a vertical line is proportional to the line intensity for A_1 species. Numerals are attached to each line to indicate relative heights. The relative heights between A_1 and E species (the latter contributes only to the central peak at the Larmor frequency ν_0, shown as a broken line) depend on temperature. There is no central line at 0 K and the intensity of the nearest wing has one third of the central intensity at high temperature.

the D nmr spectrum associated with CHD_3 molecules in A_1 spin states has the pattern shown in Fig. 1 for a single crystal. The molecules in E spin states contribute only to a central line at the Larmor frequency ν_0 and those in A_2 spin states make a zero contribution. If a powder sample is assumed, any pair of wings in Fig. 1 will deform as shown in ref. 10, for example, into a Pake doublet for the case $\eta = 0$. Further, magnetic dipole–dipole interactions H_D in eq. [11], which come mainly from intramolecular proton–deuteron pairs, broaden every peak in the spectrum. For simplicity, we take these terms into account with the help of a Gaussian convolution having a width σ, for each line and at each temperature.

III. Results and discussion

We agree with the reasoning of Buchman *et al.* (7) that the tunneling is fast compared with e^2qQ/h and gives rise to the A and E spin species. We should, therefore, treat molecular motion with the properly symmetry-adapted wavefunctions given above. Our rotational wavefunctions can reproduce the heat capacity data (8) quite well on the basis of a two-site model in which the molecules occupy both sites of C_2 and C_s symmetries with equal probability.

A temperature variation does not shift peak positions in the present system and therefore does not change the nuclear quadrupole parameters significantly. Without nuclear spin species conversion, one might see essentially the same D nmr spectral pattern over some temperature range. Judging from the observed spectra given in ref. 7, which show that the central peak grows rapidly as temperature increases, it is necessary to increase the E species concentration from 0 at 0 K to the equilibrium value at about 4 K. In Fig. 2, we present typical theoretical line shapes with various abundance ratios of A and E species. For the sake of convenience in comparing with the experimental results, the derivative D nmr spectra are given in Fig. 2. Here we have no intention of giving the "best fit" of theory with experiment but simply wish to demonstrate the comparison between them. Thus, we put $e^2qQ/H = 160$ kHz as experimentally determined (7). We assume the anisotropy factor η is equal to 0 and choose a Gaussian width σ equal to $0.20\,\tilde{\nu}$. Here $\tilde{\nu}$ stands for that in eq. [4′] as averaged over the rotational states $\psi_R(A_1)$. Finite values for η give rise to growth in the central peak for any pair of wings. The temperature indicated beside each spectrum in Fig. 2 refers to the spin species concentrations used in calculating the line shape, these having been determined by Fig. 3 at that temperature. On the

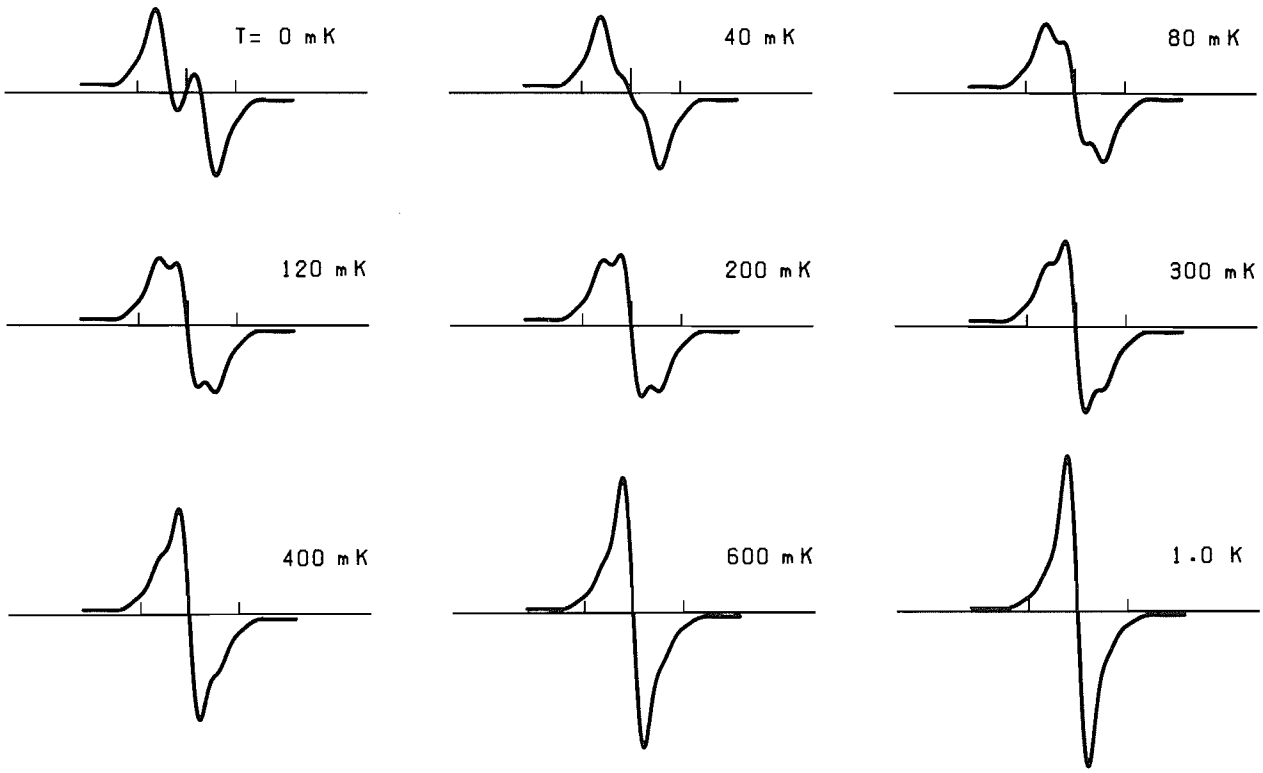

FIG. 2. Calculated deuteron nmr derivative line shapes for polycrystalline CHD_3. The concentrations of A_1 and E molecules at every temperature assigned are taken from those given in Fig. 3 under the assumption of consecutive conversion for molecules at different sites. The abscissa is in units of 30 kHz and the ordinate is in arbitrary units.

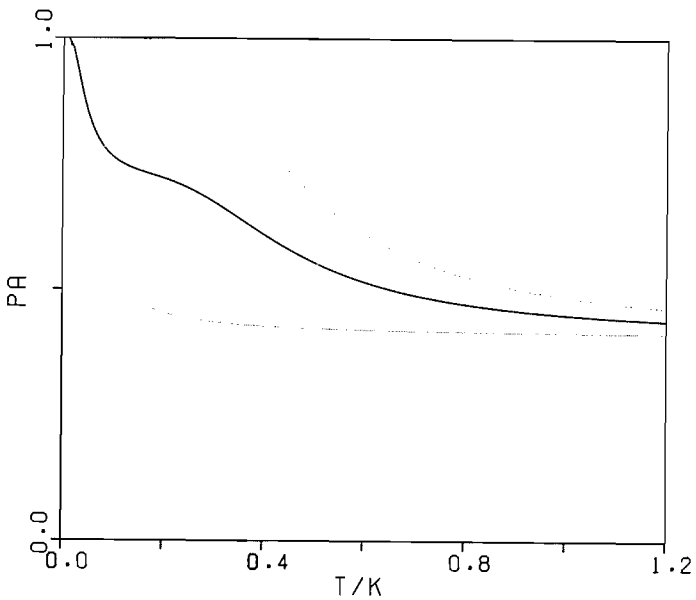

FIG. 3. Assumed temperature variation of concentration of A molecules ($A_1 + A_2$). The solid line gives the total concentration, the light line is for those at the C_2 site, and the dotted line is for those at the C_s site.

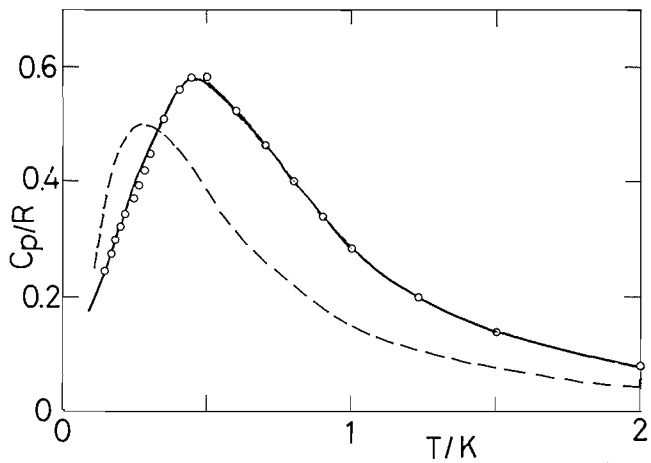

FIG. 4. Temperature variation of the heat capacity of CHD_3. Circles are taken from ref. 8 as smoothed experimental values. The solid line shows the calculated heat capacity based on the 2-site model given in ref. 11. The dashed line shows the calculated heat capacity from the 3-site model, the model 1 given in Fig. 5 of ref. 7.

whole the comparison between the calculated results of Fig. 2 and the experimental results of Buchman *et al.* (7) is quite good.

Buchman *et al.* (7) choose a 3-site model for molecular rotation in phase III of solid CHD_3 instead of our 2-site model (11), to which they failed to refer. In Fig. 4, we present the temperature variation of the theoretical heat capacities of CHD_3 from both models for the sake of comparison with the experimental data. Since heat capacity data are of primary importance to test the model, their model must be modified if it is to reproduce the thermal data. Parameter values obtained from a least-squares fit are not necessarily unique. Generally, different sets of parameter values make equally good fits to the heat capacity data. It is strange to see that their rotational level structures do not contain a difference between the A and E ground state levels (Fig. 4 in ref. 7). We do not as yet, however, know the true crystalline structure of methanes in phase III. Consequently, we had better proceed with the simplest possible model in the present situation. At the very least, it may be premature to assume that there is no spin conversion in CHD_3 at low temperature.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

The order of magnitudes of the nuclear spin conversion time τ differs for molecules at different sites in the solid methanes. We take this fact into account to derive the theoretical spectra of Fig. 2 by making use of the two typical variations of concentration given in Fig. 3. The conversion time for a molecule in the "free" site is about 10 times shorter than in the "hindered" site for the methanes in general. Since a reliable theoretical calculation has not yet been made of the conversion time in solid CHD_3, we have to employ certain tentative assumptions, as in Fig. 3, to analyze the experimental data. As deuteration proceeds from CH_4 to CD_4, τ becomes longer as implied by the intramolecular magnetic dipole–dipole interaction mechanism (9). We believe that this mechanism would yield a τ for CHD_3 that is too long compared with the experimental values at very low temperatures. However, there may be some other mechanisms that might give a smaller value for τ. For example, it may be important to include the effects of certain impurities on the spin conversion rate. Future experiments in equilibration would be desirable.

Acknowledgments

The authors would like to thank the late Professor J. A. Morrison for his kind cooperation and hospitality. They are grateful to Prof. D. Goodings for careful reading of the manuscript and helpful discussions. They also acknowledge the Data Processing Centers of Kyoto and Nagoya University and of the Institute for Molecular Sciences.

Appendix

The C_{3v}-symmetry adapted deuteron spin functions $|\Gamma; I, M\rangle$ from which the molecular rotation – deuteron spin wavefunctions for CHD_3 in eq. [3] are constructed may be written as follows:

$$|A_1; 3, \pm 3\rangle = |\pm 1, \pm 1, \pm 1\rangle$$

$$|A_1; 3, \pm 2\rangle = \sqrt{1/2}\{|0, \pm 1, \pm 1\rangle + |\pm 1, 0, \pm 1\rangle + |\pm 1, \pm 1, 0\rangle\}$$

$$|A_1; 3, \pm 1\rangle = \sqrt{1/15}\{|\mp 1, \pm 1, \pm 1\rangle + |\pm 1, \mp, \pm 1\rangle + |\pm 1, \pm 1, \mp 1\rangle + 2(|\pm 1, 0, 0\rangle + |0, \pm 1, 0\rangle + |0, 0, \pm 1\rangle)\}$$

$$|A_1; 3, 0\rangle = \sqrt{1/10}\{|0, 1, -1\rangle + |0, -1, 1\rangle + |1, 0, -1\rangle + |-1, 0, 1\rangle + |1, -1, 0\rangle + |-1, 1, 0\rangle + 2|0, 0, 0\rangle\}$$

$$|A_1; 1, \pm 1\rangle = \sqrt{1/15}\{|\pm 1, 0, 0\rangle + |0, \pm 1, 0\rangle + |0, 0, \pm 1\rangle - 2(|\mp 1, \pm 1, \pm 1\rangle + |\pm 1, \mp 1, \pm 1\rangle + |\pm 1, \pm 1, \mp 1\rangle)\}$$

$$|A_1; 1, 0\rangle = \sqrt{1/15}\{3|0, 0, 0\rangle - |0, 1, -1\rangle - |0, -1, 1\rangle - |1, 0, -1\rangle - |-1, 0, 1\rangle - |1, -1, 0\rangle - |-1, 1, 0\rangle\}$$

$$|A_2; 0, 0\rangle = \sqrt{1/6}\{|1, -1, 0\rangle - |-1, 1, 0\rangle + |-1, 0, 1\rangle - |1, 0, -1\rangle + |0, 1, -1\rangle - |0, -1, 1\rangle\}$$

$$|E_1; 2, \pm 2\rangle = \sqrt{1/3}\{|0, \pm 1, \pm 1\rangle + \omega^2|\pm 1, 0, \pm 1\rangle + \omega|\pm 1, \pm 1, 0\rangle\}$$

$$|E_1; 2, \pm 1\rangle = \sqrt{1/6}\{|\mp 1, \pm 1, \pm 1\rangle - |\pm 1, 0, 0\rangle + \omega^2(|\pm 1, \mp 1, \pm 1\rangle - |0, \pm 1, 0\rangle) + \omega(|\pm 1, \pm 1, \mp 1\rangle - |0, 0, \pm 1\rangle)\}$$

$$|E_1; 2, 0\rangle = \sqrt{1/6}\{|0, 1, -1\rangle - |0, -1, 1\rangle + \omega^2(|-1, 0, 1\rangle - |1, 0, -1\rangle) + \omega(|1, -1, 0\rangle - |-1, 1, 0\rangle)\}$$

$$|E_1; 1, \pm 1\rangle = \sqrt{1/6}\{|\mp 1, \pm 1, \pm 1\rangle + |\pm 1, 0, 0\rangle + \omega^2(|\pm 1, \mp 1, \pm 1\rangle + |0, \pm 1, 0\rangle) + \omega(|\pm 1, \pm 1, \mp 1\rangle + |0, 0, \pm 1\rangle)\}$$

$$|E_2; I, M\rangle = (|E_1; I, M\rangle)_{\omega \leftrightarrow \omega^2}$$

Here the spin function $|\mu, \nu, \lambda\rangle$ for three deuterons is a simple product of deuteron spin functions $|\mu\rangle$ ($\mu = 1, 0$, or -1). Also $\omega = e^{2\pi i/3}$.

J. H. WALTON, MENG-CHOU WU, and MARK S. CONRADI. Can. J. Chem. **66**, 680 (1988).

The nmr lineshapes and linewidths of KCN/KBr, N_2/Ar, and $CO/N_2/Ar$ are compared at corresponding states and are found to agree closely. This indicates a similar kind of orientational freezing, despite major differences in the anisotropic molecular interactions. The line narrowing and T_2 data are explicable by two different theories. The one involves an orientation probability function, while the other invokes a broad homogeneous distribution of correlation times. Spin–lattice relaxation measurements indicate that T_1 and dielectric loss are controlled at low temperatures by nearly π flips of CO molecules.

J. H. WALTON, MENG-CHOU WU et MARK S. CONRADI. Can. J. Chem. **66**, 680 (1988).

On a comparé les formes et les largeurs des raies de rmn du KCN/KBr, du N_2/Ar et du $CO/N_2/Ar$ dans des états correspondants et on a trouvé qu'ils sont très semblables. Ce résultat indique que, malgré des différences majeures dans les interactions moléculaires anisotropes, leurs orientations lors de leurs congélations sont semblables. Les données relatives au rétrécissement des bandes et aux valeurs de T_2 peuvent être expliquées par deux théories différentes. La première implique une fonction de probabilité dand l'orientation alors que l'autre fait appel à une distribution homogène large des temps de corrélation. Des mesures de relaxation spin–réseau indiquent que la valeur de T_1 ainsi que la perte diélectrique sont contrôlées, à basse température, par pratiquement π inversions des molécules de CO.

[Traduit par la revue]

I. Introduction

There are three well-studied material systems which form orientational glasses at low temperatures: *ortho*-H_2/*para*-H_2 (1), KCN/KBr (2, 3), and N_2/Ar (4–8). In each of these, non-spherical molecules possessing orientational degrees of freedom (*ortho*-H_2, CN^-, or N_2) are randomly diluted on the crystal lattice by spherical atoms or molecules (*para*-H_2 which is $J = 0$ at low temperatures, Br^-, or Ar). For concentrations x of the non-spherical species which are high enough (typically $x \gtrsim 0.7$) a first-order transition to an orientationally ordered structure occurs as temperature is decreased. For lower concentrations x, no such transition occurs; instead, a continuous freezing is found. Orientational disorder and rapid reorientations at high temperature smoothly change to apparent orientational disorder with static molecular orientations at low temperature. Because of the continuous freezing and the lack of any apparent long-range order, the term orientational *glass* is used to describe the frozen state. Orientational glasses involve random dilution and frustration and are therefore related to spin glasses.

The fundamental physics question surrounding orientational glasses is the exact nature of the continuous freezing. For example, is the freezing a kinetic effect as in window glass or is some kind of order established? Does the system tend towards a unique ground state?

The $CO/N_2/Ar$ system differs from the simpler binary orientational glass former N_2/Ar in that some of the rotors (the CO) are asymmetric head-for-tail. The CO asymmetry was a key aspect of a recent test (9) of a theory of glassy two-level systems (10, 11). It was proposed that the two-level systems responsible for the excess low temperature heat capacity of KCN/KBr orientational glass were head–tail π flips of individual CN^- molecules. In short, the anomalous heat capacity at temperature T is believed due to the small fraction of CN^- that: (*a*) have energy minima within kT of each other, and (*b*) have minima separated by a small enough energy barrier that tunneling can occur within experimental time scales (10, 11). It was remarked (9) that this theory should also describe the physics of $CO/N_2/Ar$, another orientational glass with some asymmetric rotors. Because an energy difference of order kT between the two orientations of a molecule is required to generate a heat capacity at temperature T, the low temperature excess heat capacity would be expected to be due only to π flips of CO and not to π flips of symmetric N_2 molecules. However, it was found experimentally that the excess low temperature specific heat does not depend on CO concentration and has the same value in N_2/Ar. Thus, head–tail flips of asymmetric molecules are not important to the glassy thermal anomalies of $CO/N_2/Ar$, contrary to the expectations from the theory.

However, it remains to be demonstrated that $CO/N_2/Ar$ is an orientational glass like KCN/KBr. The nmr experiments reported here indicate a great deal of similarity between these two systems. We believe this strengthens the previous test of the theory of microscopic origin of the two-level systems.

A further purpose of this work was to experimentally determine whether N_2 and CO are functionally interchangeable in the orientational glass (as has been claimed (12)), except for the dipole moment of CO. The molecules are known to have nearly equal sizes and equal masses and the phase diagrams of pure N_2 and CO are remarkably similar (13). However, the quadrupole moment (14) of CO is 1.7 times that of N_2 and the phase diagrams of CO/Ar and N_2/Ar are very different (15,

[1]On leave of absence from College of William and Mary.

For personal use only.

16). From the experiments reported here, the principal effect of increasing the CO concentration is to slightly increase the temperature of orientational freezing.

Finally, much less is known about the phase diagram and miscibility of $CO/N_2/Ar$ than about the binary solid systems CO/N_2 (17), N_2/Ar (15), and CO/Ar (16). Therefore, the nmr lineshapes have been examined for evidence of phase separation.

II. Experimental

The phase diagram (15) of N_2/Ar shows that N_2 and Ar are miscible in the solid state at low temperatures for all concentrations, but CO/Ar solid solutions segregate below about 50 K (16). Recent work on N_2/Ar indicates that solutions are metastable at low temperatures (18). Our dielectric experiments indicated that $CO/N_2/Ar$ was stable as a uniform solid solution provided the CO concentration was kept below about 30% (12). Unfortunately, there is no other phase information available for this system.

The N_2 and Ar gases were purchased from Matheson and were of greater than 99.99% purity. The CO gas was enriched to 99% in ^{13}C and was purchased from Merck. The gases were mixed in a 75 cm^3 vessel at room temperature and then condensed into the sample cell as a liquid solution at about 60 K. The liquid was allowed to homogenize by being held at this temperature for typically 2 h. The sample was frozen and the temperature reduced to about 6 K in about 5 mins; this was accomplished by turning off the heater on the gas flow dewar.

For most of the samples no evidence of phase separation was found. Specifically, the data taken upon increasing and decreasing temperature agreed and no discontinuities were observed in T_1, lineshape, etc. For the 30/30/40 ($CO/N_2/Ar$) sample, we observed the nmr lineshape to develop a broader component upon briefly warming the sample to 35 K. This broad component had the powder pattern lineshape characteristic of orientationally immobile CO, such as occurs (19) at these temperatures in pure α-CO or in the α phase of CO/N_2. Thus, this solution had partly segregated. We noticed a similar result in a 20/40/40 sample that was cooled from 60 K to 6 K much more rapidly than usual. The same solution showed no sign of phase separation or history dependence provided the initial freezing from 60 K to 6 K was done in the usual ~5 min time. We report here only data from the well-behaved samples.

The sample cell had a volume of about 0.3 cm^3 and was cooled by thermostated, flowing helium gas in a flow dewar. The sample temperature was measured by a calibrated carbon-in-glass thermometer. The temperatures are certain to less than 0.3 K (and probably better than that), much smaller than any feature in the nmr data.

The early nmr experiments were performed at 14.7 MHz and the later ones at 13.3 MHz. The magnetic field was stabilized for long signal averaging. The spectrometer is superheterodyne with quadrature detection. Typical pulse times were 7 μs for $\pi/2$ nutation. A detailed description of the spectrometer, dewar, and temperature control and measurement apparatus is available (20).

III. Results and discussion

In Fig. 1 are presented ^{13}C nmr spectra from $CO/N_2/Ar$ (20/40/40) along with ^{15}N spectra from KCN/KBr (50/50) for comparison (21). In both cases the linewith is dominated by the chemical shift anisotropy of the molecule, a uniaxially symmetric tensor. The chemical shift arises from shielding of the external magnetic field by the electrons of the molecule; this shielding depends on the orientation of the molecule with respect to the external field. For a molecule at fixed angle θ relative to the field, the resonance frequency ω is given by (22)

$$[1] \quad \omega = \omega_0 + \omega_0 \Delta\sigma(\tfrac{3}{2}\cos^2\theta - \tfrac{1}{2})$$

Here ω_0 is the angular average frequency and $\Delta\sigma$ is the anisotropy of chemical shift (about 400 ppm for CO and CN^-).

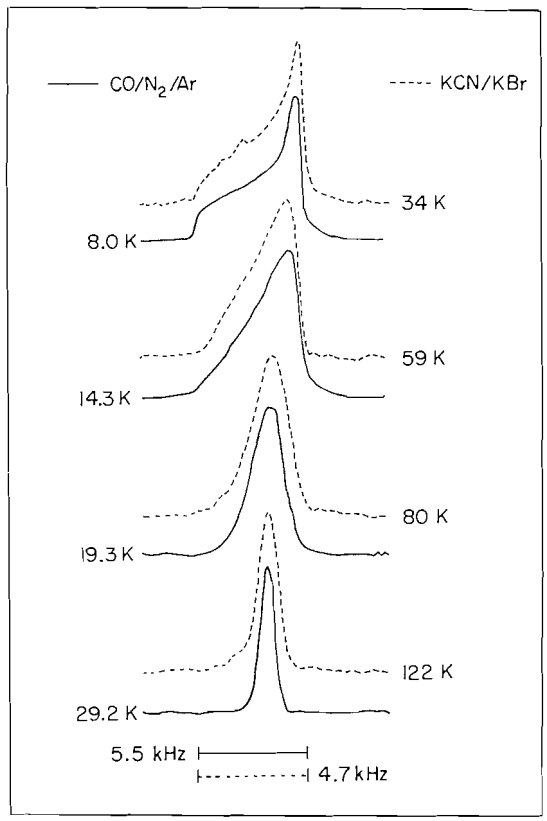

FIG. 1. Temperature evolution of nmr lineshapes in two orientational glass-forming systems: $CO/N_2/Ar$, 20/40/40 (solid curves) and KCN/KBr, 50/50 (dashed curves). The frequency scales are indicated at the bottom and are different because of different resonant frequencies and different anisotropies of chemical shift. Spectra from the two systems are compared for temperatures in the ratio of 4.1:1.

At low temperatures in both systems, the spectra become independent of temperature and display the "powder pattern" lineshape (23). This indicates that at low temperatures the molecules have static and random orientations. As the temperature is increased, the resonance line narrows indicating the onset of rotational motion. However, as discussed below, the motional narrowing is rather different from the traditional discussion of BPP (23–25).

To allow comparison of the $CO/N_2/Ar$ spectra and KCN/KBr spectra, we have scaled the two sets of data. First, the vertical axis in Fig. 1 is absorption intensity and has been scaled trivially to produce spectra of the same height. The shift anisotropies $\Delta\sigma$ and resonance frequencies ω_0 are different for ^{13}CO and $C^{15}N$. Consequently, we have scaled the frequency axes in Fig. 1 to obtain agreement in the low temperature, rigid limit spectra; this scaling is indicated at the bottom of Fig. 1. Finally, the orientational freezing in KCN/KBr occurs at a considerably higher temperature than in $CO/N_2/Ar$, as indicated by the nmr lineshapes. Thus, we compare in Fig. 1 spectra at temperatures in the ratio of 4.1 to 1, an empirically chosen value. This is a kind of corresponding states application. Incidentally, we note that 4.1 is approximately the ratio of orientational ordering transition temperatures T_c for pure KCN (168 K) (2) and pure N_2 (35.6 K (26); our sample has more N_2 than CO). Here we regard the T_c values as crude measures of the anisotropic molecular interaction strengths, which also determine the glassy freezing temperatures in the solid solutions.

There is good general agreement between the two sets of nmr

For personal use only.

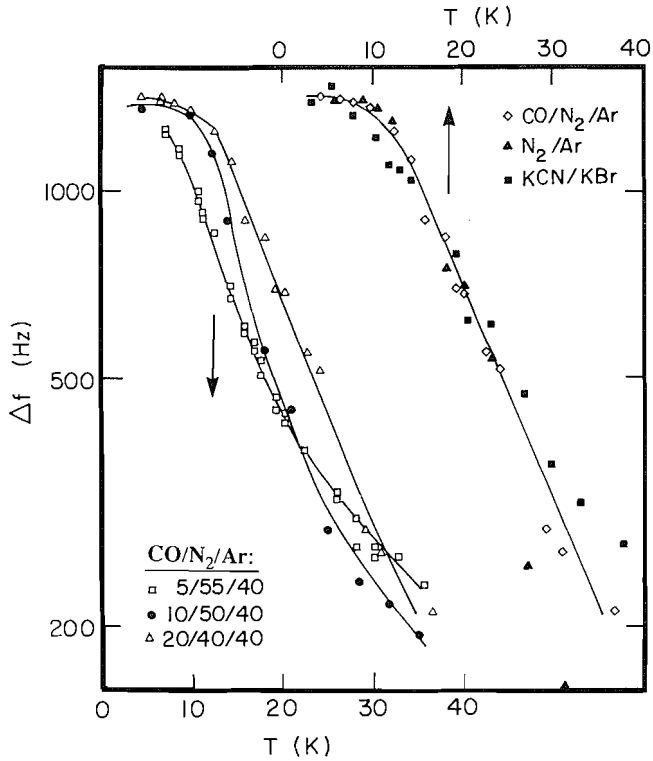

FIG. 2. Comparison of linewidths as functions of temperature for several orientational glasses. The left-hand set of data are from $CO/N_2/Ar$ at three different concentrations. The data demonstrate a weak increase of freezing temperature with increasing CO concentration. The right-hand set of data are offset for clarity and refer to the upper temperature scale. There the data of $CO/N_2/Ar$ (20/40/40), KCN/KBr (50/50), and N_2/Ar (67/33) are compared. The linewidths and temperatures of the KCN/KBr and N_2/Ar data have been scaled as described in the text. The similarity of the linewidth data indicates that a similar orientational freezing occurs in all these materials. The curves fit to the data are eye guides only.

spectra appropriately scaled. The largest differences occur at the highest temperatures where the line narrowing is becoming limited by intermolecular dipolar interactions between the spins. Our scaling arguments refer only to the intramolecular chemical shift anisotropy and should not work in the high temperature regime. The similarities in the KCN/KBr and $CO/N_2/Ar$ spectra suggest that the two systems undergo similar freezings.

The similarities in the line narrowing between KCN/KBr and $CO/N_2/Ar$ are also demonstrated in Fig. 2. The linewidths Δf plotted there are peculiar moments of the resonance absorption spectra $g(f)$. The spectra $g(f)$ were obtained by fourier transformation of spin echoes. We define Δf as

$$[2] \quad \Delta f \equiv \int g(f)|f|df \,/\, \int g(f)df$$

where f is frequency from the center of resonance. The center was always chosen to eliminate the first moment of $g(f)$. The integrals in [2] were performed as discrete sums. The definition of Δf above is experimentally preferable to the more conventional square root of the second moment, because of the sensitivity of second moments to the hard-to-measure tails of the resonance. We stress that the conventionally defined Δf behaves very much like that defined in [2] and shown in Fig. 2.

The N_2/Ar data are not available as published spectra. The data have been fitted as a sum of powder patterns of relative widths σ (4). The σ is generally known as the order parameter and is not related to $\Delta\sigma$ of eq. [1]. Specifically, the distribution of order parameters $P_{(\sigma)}$ has been obtained. As σ is non-negative, the Δf defined in [2] is easily shown to be proportional to $<\sigma>$, the first moment of $P_{(\sigma)}$. Conveniently, the temperature variation of $<\sigma>$ for N_2/Ar has been published recently (27).

The right-hand set of data in Fig. 2 are from $CO/N_2/Ar$ (20/40/40), KCN/KBr (50/50), and N_2/Ar (67/33). For KCN/KBr the linewidths Δf (and for N_2/Ar, the $<\sigma>$ values) were scaled to obtain agreement with $CO/N_2/Ar$ in the low temperature limit. The temperature of the KCN/KBr data was divided by 4.1 (see discussion above) and the N_2/Ar temperatures were multiplied by 1.45. The linewidth data of these three systems agree well, except where the lines are narrow and the linewidths are influenced by dipolar interactions. The scaled linewidths are not expected to be similar at the high temperatures.

The similarities between the $CO/N_2/Ar$, KCN/KBr, and N_2/Ar linewidth results in Figs. 1 and 2 are remarkable. The natures of the continuous orientational freezings appear to be the same, despite very different anisotropic molecular interactions driving the freezings. In KCN/KBr the CN^- interact through lattice distortions. This coupling between phonons and rotations in KCN and KCN/KBr has been studied extensively (28–30). Direct interactions between the CN^- are less important because of the shielding shell of K^+ ions around each anion. In $CO/N_2/Ar$, the dominant anisotropic interactions are the direct electrical quadrupole–quadrupole coupling and the anisotropic part of the Van der Waals potential (26, 31). From Figs. 1 and 2 it appears that orientational glass state formation has a certain universality, extending beyond the details of the physical system.

The left-hand set of data in Fig. 2 refer to $CO/N_2/Ar$ with three different CO concentrations but identical Ar concentrations. An increase in the freezing temperature with increasing CO content is evident. For example, this may be seen by defining the freezing temperature T_F to be the temperature at which the linewidth has decreased to one half of its low temperature limiting value.

The increase of T_F upon substitution of some N_2 by CO is not unexpected — the quadrupole moment of CO is 1.7 times that of N_2 (14). The orientational ordering transition temperature $T_{\alpha\beta}$ of pure N_2 is 35.6 K (26) and of CO is 61.6 K, reflecting the stronger anisotropic interactions in CO. For intermediate concentrations of CO/N_2 the variations of $T_{\alpha\beta}$ is nearly linear (17). Because in a mean field approach $T_{\alpha\beta}$ is a measure of the anisotropic interaction strength, one might expect the ratio of $T_{\alpha\beta}$ of CO/N_2 to T_F of $CO/N_2/Ar$ to be constant for fixed Ar concentration. If this were so, the freezing temperatures T_F would be in the ratio of 1 to 1.05 to 1.17 for samples with 40% Ar and 5, 10, and 20% CO, respectively. Experimentally, with T_F defined by the half narrowing temperature (see above), the T_F values are in the ratio of 1 to 1.1 to 1.3. Thus, the simple notions about mean interaction strengths underestimate the variation of T_F with CO concentration by about a factor of two. However, the important result from the left-hand set of data in Fig. 2 is that replacement of some N_2 by CO serves only to slightly increase the freezing temperature. The character of the freezing appears unchanged.

It should be emphasized that all of the orientational glass forming systems reported in Fig. 2 appear to have no discontinuities in their freezing, as indicated by nmr linewidths. A

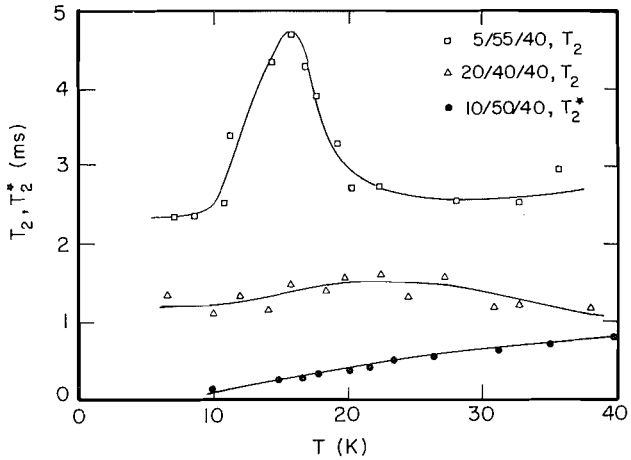

FIG. 3. Relaxation times T_2^* ($1/e$ time of FID) and T_2 (decay time of spin echo envelope) for $CO/N_2/Ar$. The T_2^* data are from the 10/50/40 solution but the other concentrations studied behave similarly, as shown in left-hand part of Fig. 2.

similar conclusion about H_2 orientational glass has been emphasized (32).

The spin–spin relaxation times T_2 reported in Fig. 3 were taken from the envelope of spin echoes. That is, the echo amplitude was plotted as a function of 2τ for the $\pi/2-\tau-\pi-\tau$ echo pulse sequence. The decays were intermediate between gaussian and exponential in shape. The times T_2 were taken as the e^{-1} values of the time 2τ.

For the 20/40/40 sample of $CO/N_2/Ar$, T_2 is essentially independent of temperature. This indicates that intermolecular dipolar interactions between the spins control T_2. The magnitude of T_2 is in fair agreement with the value predicted from a local field calculation (23) and also is in reasonable agreement (19) with the rigid limit T_2 of a solid α-CO sample containing 10% ^{13}C. For the 10/50/40 sample (not shown), T_2 is slightly longer. The 5/55/40 sample displays a maximum of T_2 near 15 K, which we do not understand.

Also plotted in Fig. 3 is the time T_2^*, which is the $1/e$ time of a free induction decay (FID). The time T_2^* was obtained experimentally as the half-width at e^{-1} of maximum of a spin echo. T_2^* is proportional to the reciprocal of the linewidth. The T_2^* data in Fig. 3 refer to the 10/50/40 sample, but the other two samples show similar behavior (i.e., see Fig. 2, left-hand set of data). The interesting observation is that $T_2 \gg T_2^*$, even at temperatures where narrowing occurs. This also occurs in KCN/KBr (21) and in *ortho*-H_2/*para*-H_2 (33, 34).

The formation of any spin echo requires a pulse sequence (here, a π pulse) capable of time-reversing the interaction responsible for the dephasing of the FID (here, the anisotropic chemical shift). Further, the interaction must remain constant or have a static component on the time scale of 2τ. Thus, the observation that $T_2 \gg T_2^*$ indicates that the molecular orientation has a component which is static on the 10^{-3} s time scale.

The theory (BPP) (23–25) most widely used to describe motional narrowing in nmr is incompatible with the observation of $T_2 \gg T_2^*$ in the narrowing regime. In BPP theory, the motion is characterized by a single (exponential) correlation time τ_c. For motional narrowing to occur, τ_c must be $\tau_c \leq T_{2RL}^*$, where T_{2RL}^* describes the decay of the FID in the rigid limit. But since the echo envelope decays at least as slowly as the FID, we have $T_2 \geq T_2^*$. Since the broadest line and shortest FID occur in the rigid limit, $T_2^* \geq T_{2RL}^*$. Together these inequalities imply that $\tau_c \leq T_2$, showing that the motion is *not* static on the time scale of echo formation in the line narrowing regime. The single τ_c model is therefore not appropriate to the orientational glasses.

A model with an inhomogeneous distribution of τ_c is also unsuitable. In such a model, the reorientation of each molecule is described by a single τ_c, but with different τ_c for different molecules. For a very broad distribution of τ_c, the molecules will fall into two classes: $\tau_c \gg T_{2RL}^*$ and $\tau_c \ll T_{2RL}^*$. The former will not experience narrowing at all and the latter will be extremely narrowed. The resulting lineshape, a sharp line superimposed upon a powder pattern line, is completely different than the lineshapes of Fig. 1 or of any orientational glass (1, 4, 21).

One way that motional narrowing can occur with $T_2 \gg T_2^*$ is the favored orientation model (35). Each molecule executes rapid reorientations, but does not spend equal times at all orientations. Thus, each molecule has an orientational probability function $P_{(\Omega)}$ which is nearly spherical at high temperatures, yielding narrow lines. At lower temperatures the anisotropic molecular interactions cause $P_{(\Omega)}$ to become increasingly non-spherical, broadening the line. At very low temperatures, $P_{(\Omega)}$ is sharply peaked and the resulting spectrum is that of a non-rotating collection of molecules: a powder pattern. Since at all temperatures there is a truly static component of molecular orientation due to the non-spherical nature of $P_{(\Omega)}$ and only rapid fluctuations about the average, spin echoes can be formed at long times. In this model, what changes with temperature is not the *rate* of reorientation (as in BPP theory), but the angles to which the orientations are *restricted*. The lineshapes of *ortho*-H_2/*para*-H_2 and N_2/Ar have been well described by the favored orientation model, using the formalism of a distribution of order parameters σ (1, 4, 36).

A second model that can explain the results is a kinetic model with a very broad, *homogeneous* distribution of correlation times τ_c. That is, the orientation of each molecule may be regarded as a linear combination of many "normal coordinates", each of which has a unique τ_c (37). Each molecule shares in the entire distribution of τ_c. Now, provided the distribution is very broad, all the τ_c can be separated into those with $\tau_c \gg T_{2RL}^*$ and those with $\tau_c \ll T_{2RL}^*$. The trivial fraction with $\tau_c \simeq T_{2RL}^*$ is neglected. In this limit, the fast motions can be averaged over and the slow motions can be ignored (they are frozen). As the temperature is decreased, some τ_c values go from the fast to the slow group, broadening the line. The result is identical to the favored orientation model, except that the slow motions are not truly static.

We have observed stimulated (three pulse) echoes at very long times in $CO/N_2/Ar$. At all temperatures below 32 K, stimulated echoes in 5/55/40 have a decay constant longer than 2 s, a factor of 10^5 longer than T_{2RL}^*. Thus, if the homogeneous distribution of τ_c model is correct, the distribution must be exceedingly broad. At 16 K, the decay time is longest (12 s); this is the same temperature as the maximum in T_2 and minimum in T_1 (see below). Stimulated echoes at long times also can be formed in H_2 (33, 38) and in KCN/KBr (21).

Although these experiments cannot distinguish the two models, the models are physically quite distinct and need to be distinguished by some measurement.

The spin–lattice relaxation times T_1 of two $CO/N_2/Ar$ samples are presented in Fig. 4. The data for the intermediate concentration sample falls between the two sets of data in Fig. 4. We focus on the minimum in T_1 near 15 K. The minimum indicates that the rate of some kind of reorientation passes

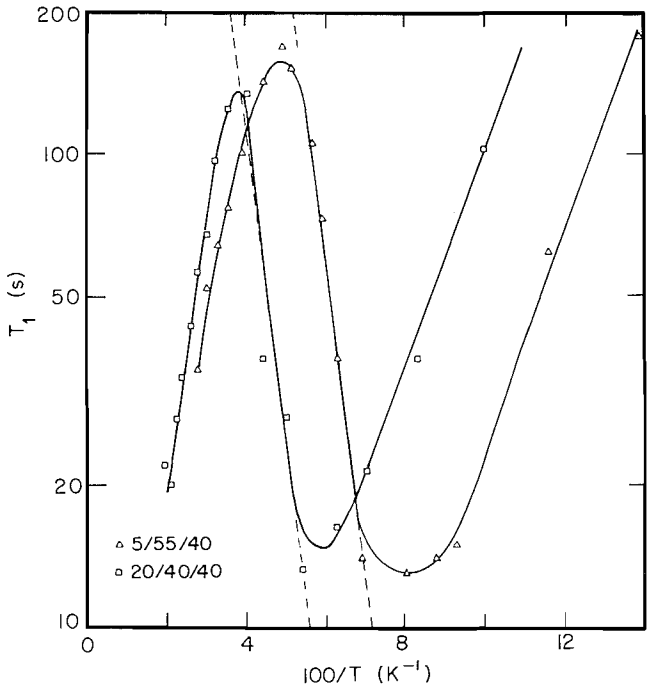

FIG. 4. Spin–lattice relaxation time T_1 in two samples of $CO/N_2/Ar$. The minima in T_1 at temperatures near 15 K indicate that head–tail flips occur at a rate approximately equal to the resonance frequency at that temperature. The solid lines are eye guides. The dashed lines correspond to an activation energy of 150 K. The asymmetric and broad minima are common features in disordered systems.

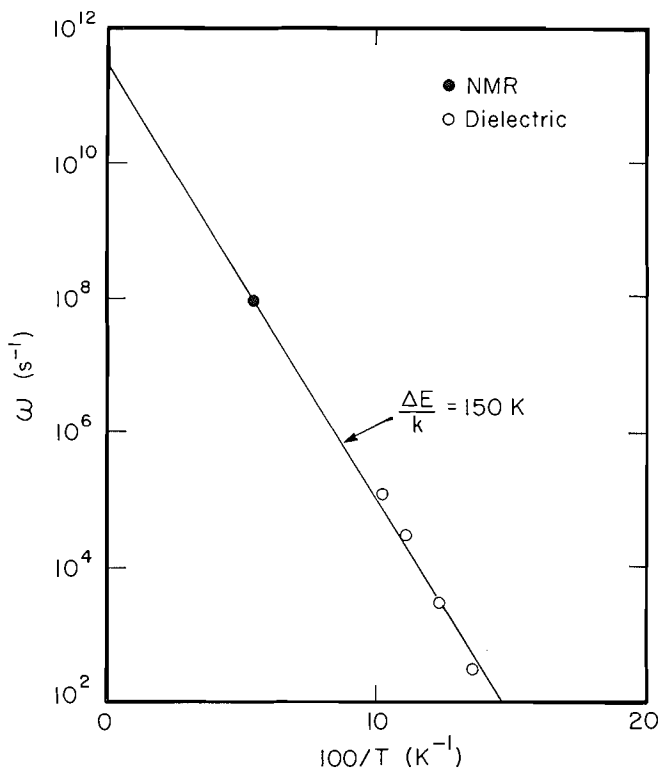

FIG. 5. Relaxation map indicating the frequency and temperature of maxima in the spin–lattice relaxation rate (●) and in the dielectric loss at lower frequencies (○). The reasonable fit to the straight line (slope = 150 K) indicates that the same motion (head–tail flips) is responsible for the spin–lattice relaxation and the dielectric loss.

through the resonance frequency ($2\pi \times 14$ MHz) near 15 K. Figure 5 is a relaxation map showing the temperature–frequency location of the spin–lattice relaxation rate peak as well as dielectric loss maxima at lower frequencies (12), for the 20/40/40 sample (the only one with both kinds of data available). Both kinds of data fit on the straight line describing an activation energy of 150 K. Thus, the same motion is responsible for both the spin–lattice relaxation and the dielectric loss.

In Fig. 4, the dashed lines passing through the data correspond to an activation energy of 150 K. In glassy systems the distribution of motion rates frequently causes an asymmetric T_1 minimum (unequal slopes), as in Fig. 4[2]. The high temperature side is found to have a slope equal to the average activation energy, while the low temperature slope is smaller than the activation energy. This is precisely the case in Fig. 4.

The activation energy of 150 K from Figs. 4 and 5 is somewhat smaller than the 181 K from dielectric data alone (i.e., see Fig. 5). This disagreement may reflect a deviation from simple thermal activation. It is more likely that the disagreement is due to the difficulty in obtaining accurate values from very broad loss peaks (six decades wide or more (12)).

The thermally activated motion responsible for T_1 and the dielectric loss is head–tail (π) flips of CO molecules, as deduced by comparing the nmr line narrowing and the dielectric loss. For comparison, 5 kHz dielectric data are selected because that frequency matches the nmr linewidth in the low temperature limit. The dielectric loss in $CO/N_2/Ar$ (20/40/40) is maximum near 8 K (12). Thus molecules are re-orienting on the 30 μs time scale (= $1/2\ \pi \cdot 5$ kHz). However, the 8 K ^{13}C spectrum of the same material (Fig. 1) is a powder pattern of full width — decreasing the temperature to 4.4 K does not change the line. The nmr seems to imply very little motion at 8 K on the 30 μs time scale. However, the chemical shift and resonance frequency ω are invariant under π flips, which take θ to $\pi-\theta$ in eq. [1]. Thus, the nearly rigid limit nmr spectrum at 8 K can be reconciled with the substantial dielectric loss at 8 K only if the motion is restricted to π (or nearly π) flips.

In pure KCN and in α-CO it has been shown that the molecules flip by $\pi \pm \delta$, where $\delta \ll 1$ (40–43). The deviation from π is due to molecular asymmetry. Because the flips are not by exactly π, a small (undetected) amount of line narrowing occurs. More importantly, the flips can provide a T_1 mechanism (proportional to δ^2), because the flips do slightly modulate the chemical shift (or electric field gradient in $C^{17}O$). In $CO/N_2/Ar$, similar $\pi \pm \delta$ flips should occur and provide a T_1 mechanism.

IV. Conclusions

Because of chemical shift anisotropy, the nmr spectra of $C^{15}N^-$ and ^{13}CO are sensitive to rotational motions. For the orientational glass forming systems KCN/KBr, N_2/Ar, and $CO/N_2/Ar$ the lineshapes and linewidths are in good agreement, after properly scaling the rigid limit linewidths and after scaling the temperatures to account for the different freezing temperatures. It appears that the continuous orientational freezing is similar in KCN/KBr and $CO/N_2/Ar$ (N_2/Ar as well), despite the very different anisotropic molecular interactions driving the freezing.

The lineshapes in the narrowing regime and the observation

[2]Reference 39. The T_1 ρ minimum of their Fig. 4 is a good example of the asymmetry.

that $T_2 \gg T_2^*$ are incompatible with the usual explanations of line narrowing (in which the variation of reorientation rate with temperature drives the line narrowing). One theory that is compatible involves a molecular orientation probability function $P_{(\Omega)}$ which smoothly evolves from spherical at high temperatures to sharply peaked at low temperatures. The other model that is in accord with the nmr results postulates a *homogeneous* distribution of correlation times, with each molecule sharing in the entire distribution. Provided the distribution of correlation times is broad enough, the nmr experiments reported here cannot distinguish between the two models. These remarks apply equally to the H_2 and KCN/KBr systems, which also have $T_2 \gg T_2^*$ in the narrowing regime.

A broad minimum in T_1 near 15 K in $CO/N_2/Ar$ is produced by the same motion responsible for dielectric loss at lower temperatures. By comparing the lack of line narrowing at 8 K and the substantial dielectric loss at the same frequency, it is concluded that the motion is π flips of CO molecules. Thus, as in KCN/KBr (44, 21), the dipolar degrees of orientational freedom (head–tail orientation of CN^- or CO) freeze at a lower temperature than the quadrupolar degrees of freedom.

The excitation spectrum of solid methane (CH_4) with all molecules converted to the nuclear spin state with A symmetry has been measured with incoherent inelastic neutron scattering. For energies $\hbar\omega \gtrsim 1$ meV, there are no dramatic differences with samples consisting of a mixture of all three spin states A, T, and E. A qualitative understanding of the measurements is achieved by comparison with calculations of Ozaki *et al.*

Utilisant la diffusion inélastique incohérente de neutrons, on a mesuré le spectre d'excitation du méthane (CH_4) solide dans lequel toutes les molécules ont été transformées à l'état de spin nucléaire de symétrie A. Pour les énergies $\hbar\omega \gtrsim 1$ meV, ce spectre ne présente pas de différences dramatiques avec ceux d'échantillons consistant de mélanges des trois états de spin A, T et E. On arrive à une compréhension qualitative de ces mesures grâce à une comparaison avec les calculs d'Ozaki *et al.*
[Traduit par la revue]

Introduction

For several years solid methane (CH_4) has been used as a model example for the investigation of rotational excitations. At low temperatures CH_4 has a relatively simple structure, with the carbon atoms located on an fcc lattice. There is little doubt that the structure of CH_4 II is the same as that of CD_4 II, with a space group $Fm3c$ and 8 molecules in the unit cell (1, 2): 6 sites (symmetry $\bar{4}2m$) are occupied by orientationally ordered molecules while at 2 sites (symmetry 432) the molecules are orientationally disordered. Early studies employing incoherent inelastic neutron scattering have focused on excitations in the meV range (3–6). Much of the recent progress is due to high-resolution experiments ($\Delta E \simeq 10\ \mu$eV). These experiments have allowed rather precise information on the librational ground states of the ordered molecules ("rotational tunneling") as well as the almost free rotations of the disordered ones (7, 8). For a more complete picture, however, an improved knowledge of the higher energy excitations seemed desirable. This undertaking appears rather simple for the molecules at disordered sites. These excitations have been regarded as single particle excitations possibly without noticeable dispersion of modes if described within the phonon picture. This is clearly not the case for the librational excitations at the ordered sites, except for the ground state splitting where coupling effects complicate the situation (7) but do not lead to dispersion. Due to the anisotropic coupling, mainly octupole–octupole interaction, collective (phonon-like) librations of the ordered molecules occur. At points in reciprocal space with low symmetry there are 18 such modes for each wave vector. Calculations have been made for the collective excitations in both CD_4 II (9) and CH_4 II with all molecules in the A state (10). In the latter case differences with CD_4 II are due to the smaller moment of inertia of the CH_4 molecules and consequently due to more pronounced quantum aspects. Also the disordered molecules are included in the calculation and give rise to additional branches with weaker dispersion. The rather complicated dispersion curves mean that when measuring the incoherent scattering (the scattering of the H atoms dominates by far) one may expect somewhat broad features in the phonon density of states rather than well-defined peaks. More specifically, as the contributions from ordered and disordered molecules cannot be observed separately, one should observe broad features and lines. The situation is complicated further by the fact that there is also a contribution of translational phonon modes. If rotation–translation coupling is neglected, this contribution is about the same above and below the order–disorder phase transition at $T_0 = 20.4$ K. The contribution of the translational phonons should be less intense than that of the rotational excitations, due to a less favourable structure factor. More serious is the fact that it is not only the ground states of the librational states which split up into states with different nuclear spin symmetry, but also the excited ones. Yamamoto *et al.* (11), for example, have pointed out that both the molecular symmetry ($\tilde{\Gamma}$) and the site symmetry (Γ) are needed for completely specifying the rotational states (Fig. 1). For the purposes of the present paper it is sufficient for the description to use the molecular symmetry, which is connected with nuclear spin symmetry via the Pauli principle (A state: $I = 2$; T state: $I = 1$; E state: $I = 0$; here I denotes the total nuclear spin of the CH_4 molecule). Spin incoherent neutron scattering allows transitions between all spin species, except between A and E states. This considerably reduces the applicability of ref. 10 for the present purpose. For this reason we shall mainly use the calculations of Yamamoto *et al.* (11) and, even more specifically for neutron scattering experiments, those of Ozaki *et al.* (12). They,

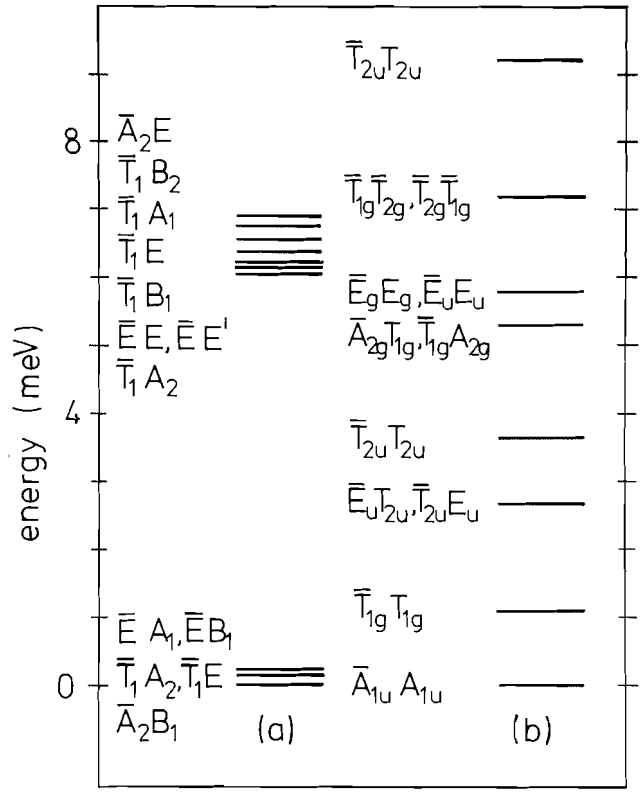

FIG. 1. The figure represents the level scheme of CH_4 molecules on the two sites in CH_4 II (from ref. 11). The complete symmetry labels are given.

however, do not include collective excitations. A level scheme, as obtained with the extended James and Keenan model (that is, octupole–octupole interaction and inclusion of a crystal field term), is shown in Fig. 1 for the two inequivalent CH_4 sites. On the basis of these results, Ozaki *et al.* (12) have calculated the double differential spin-incoherent scattering cross section for CH_4:

$$[1]\quad \left.\frac{d^2\sigma}{d\Omega dE}\right|_{s.d.} = \frac{k_f}{k_i}\exp(-\langle u^2\rangle Q^2)\frac{\sigma^p_{inc}}{4\pi} \times \sum_{i,f} p_i(T) W_{i\to f}\delta(E_i - E_f + \hbar\omega)$$

Here k_i and k_f denote the wave vectors of the incoming and outgoing neutrons, E_i and E_f their respective energies, $\langle u^2\rangle$ the mean-squared amplitude of the molecular centre of mass, σ^p_{inc} = 80 barn (the scattering cross section of a bound proton), $P_i(T)$ the thermal population of the ground state, and $W_{i\to f}$ the square of transition matrix elements from the initial to the final states. The authors group states of the same symmetry together and rather define an "average transition integral" $\bar{W}$ (12) with

$$[2]\quad \bar{W}(\bar{\Gamma}_i \to \bar{\Gamma}_f) = \sum_{J=0}^{\infty}(2J+1) j_J{}^2(Q\rho)\bar{G}_J(\bar{\Gamma}_i \to \bar{\Gamma}_f)$$

The summation index J denotes the rotational quantum number of a free rotor, the $j_J{}^2$ represent spherical Bessel functions of order J, ρ = 1.093 Å is the C—H distance in a molecule, and the $\bar{G}_J$ are tabulated in the paper (12).

By varying the temperature the population $P_i(T)$ can be used as a handle for a more straightforward understanding of measured spectra, e.g., the assignment of peaks.

The population of the A state of ordered molecules, for example, is $P_A(T) = 5/Z$ with

$$[3]\quad Z = 5 + 9\exp(-\Delta_{AT}/k_BT) + 2\exp(-\Delta_{AE}/k_BT)$$

Here Δ_{AT} and Δ_{AE} denote the ground state energy with T and E symmetry (Fig. 1). For a first set of experiments at "high temperatures" (that is, T = 5 K), P_A (5 K) = 0.40, P_T (5 K) = 0.52, and P_E (5 K) = 0.08, are not far from P_A (∞) = 5/16, P_T (∞) = 9/16, and P_E (∞) = 2/16, and indicate the concentration in an "alloy" of spin species. A second set of experiments was done at $T \lesssim 100$ mK with all the molecules converted to the A state (at both sites). To achieve nuclear spin conversion in reasonable times, 0.2% of the paramagnetic molecule O_2 was admixed to the sample. Samples of A-CH_4 II, like pure p-H_2 or o-H_2, mean a considerable simplification because disorder problems, present in equilibrium mixtures at high temperatures, are absent. Previously, high-resolution neutron spectroscopy (7), as well as nmr experiments (13), were performed with A-CH_4. The calculation of the lattice dynamics of A-CH_4 has already been mentioned (10).

Experimental

Samples of solid methane were prepared by condensing CH_4 gas of a quoted purity of 99.995% into a flat aluminium sample container (50 × 30 × 0.35 mm³). After condensation the samples were cooled to low temperatures. The sample cell was mounted at the bottom end of the insert of a dilution refrigerator. Details of this setup have been reported elsewhere (14). Experiments were done both at temperatures T = 5 K and $T \simeq$ 50–100 mK. The cooling from 5 K to 0.1 K was possible in about 3–4 h and then the temperature was stabilized in the stated temperature range for several days. The described procedure was used for pure CH_4 samples, which did not show any measurable conversion during the measurements (≃ 2 days), at least concerning the disordered molecules. A second set of experiments was performed with CH_4 with 0.2% O_2 admixed in the gas phase. In this case complete nuclear spin conversion was achieved. To avoid incomplete conversion of the T-state molecules (7), the samples were cooled down (*i*) several hours before the start of the neutron experiments and (*ii*) the temperature range between 0.3 and 0.7 K was covered much more slowly than was possible with the maximum cooling rate of the dilution cryostat. An alternative method consists in irradiating the sample, thus generating CH_3 radicals and atomic hydrogen, whose Zeeman levels are tuned to resonance with the rotational states by means of strong magnetic fields (13).

The incoherent inelastic neutron scattering experiments were performed on the 3-axis spectrometer IN3 at the high-flux reactor of the Institute Laue–Langevin in Grenoble (15). The combination of a dilution refrigerator and relatively high energy transfer did rule out the use of the time-of-flight spectrometer IN4 with its vertical flight path arrangement. The instrument IN3 was operated with a pyrolytic graphite 002 monochromator and a horizontally curved graphite 002 analyser (15), used for reasons of intensity. The analyser was kept fixed at an energy E_f = 4.06 meV and was used with a cooled Be filter. The measurements were done at constant monitor rates, corresponding to times of about 12 min per setting of the instrument. Apart from effects of higher order neutrons, this procedure renders further corrections of the measured intensities unnecessary.

Results and discussion

The measurements were performed at constant momentum transfer Q = 2.2 Å^{-1}; some additional scans were done at Q = 1.8 Å^{-1}. These values were chosen to maximize the structure factors for the inelastic transitions (eq. [2]). Unfortunately there was not sufficient time to map out the Q dependence from small values to the maximum value (Q = 2.2 Å^{-1}) with satisfactory counting statistics. In Fig. 2*a–c* the results are shown for (*a*) pure methane at $T \lesssim 100$ mK, (*b*) CH_4 with 0.2% O_2 and T =

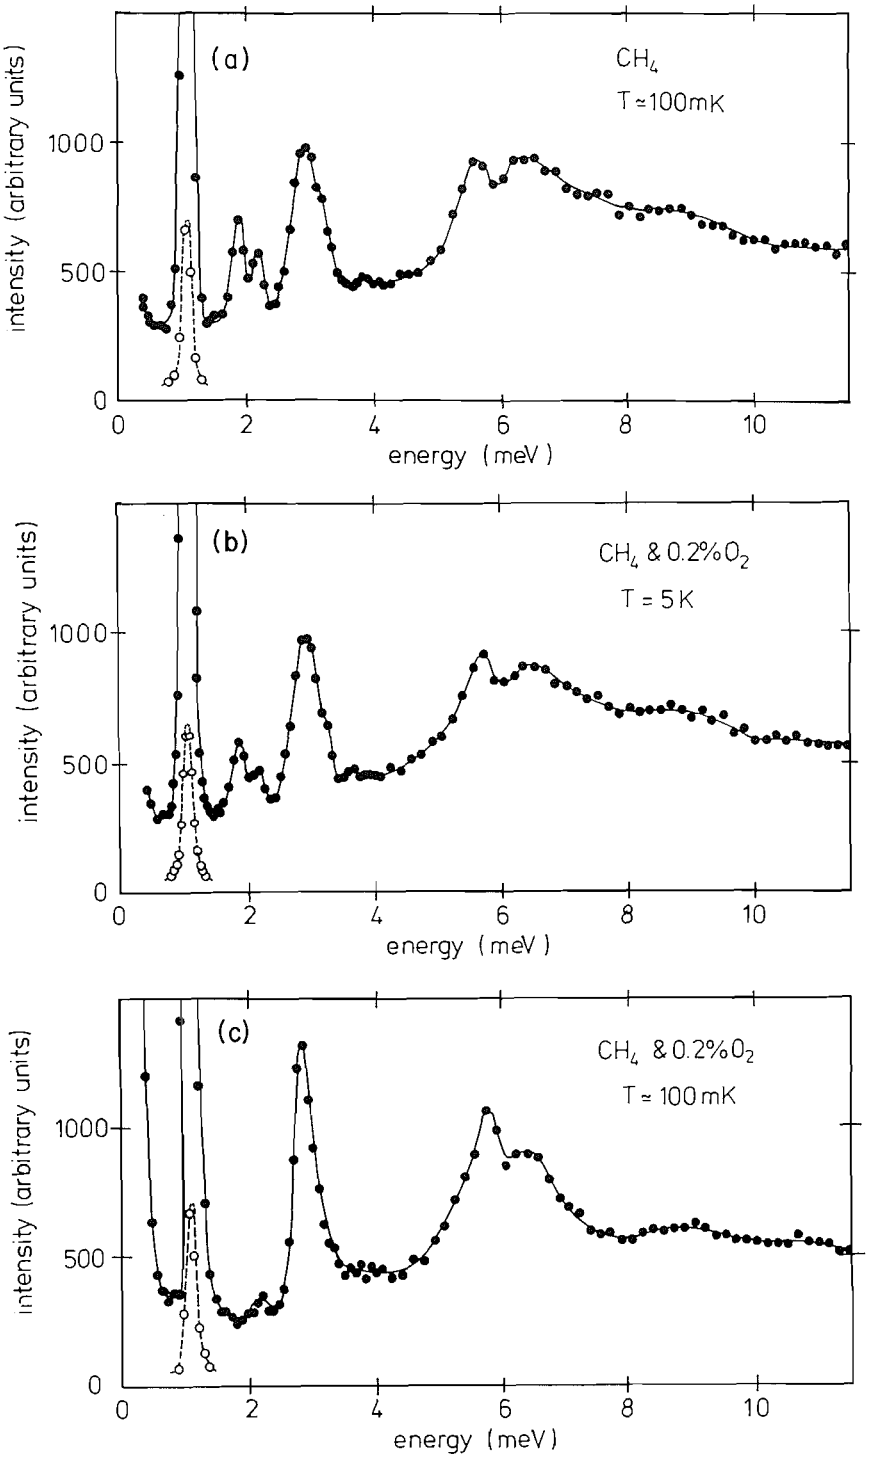

FIG. 2. Neutron scattering intensity from (*a*) pure CH_4 at a temperature of $T \lesssim 100$ mK, and CH_4 doped with 0.2% O_2 at (*b*) $T = 5$ K and (*c*) $T \lesssim 100$ mK. The measurements have been performed at $Q = 2.2$ Å^{-1} with $k_f = 1.4$ Å^{-1}; typical counting times were 12 min per data point. The solid lines are guides to the eye only. The dashed lines mark the 0 to 1 transition with the scale reduced by a factor of 5. The energy scale gives the energy of the excitations.

5 K, and (*c*) CH_4 with 0.2% O_2 at $T \lesssim 100$ mK. All these spectra are measured with neutron energy loss at $Q = 2.2$ Å^{-1}, and for reasons of the geometry of the instrument do not even include the elastic peak nor do they allow the extraction of detailed balance factors. Examples of measurements at $Q = 1.8$ Å^{-1} (CH_4 with 0.2% O_2, $T \lesssim 100$ mK) are shown in Fig. 3. In principle, measurements at $Q = 1.8$ Å^{-1} can be used to determine the position of the elastic peak and the energy resolution at the elastic position. In practice we have done that in an additional measurement at $T = 40$ K, when CH_4 is in its phase *I* and the rotational spectrum is very broad, which also could serve for a background determination including translational phonons in CH_4. The energy resolution was determined to be 0.21 meV ($Q = 1.8$ Å^{-1}) full width at half maximum; due to the horizontally curved analyser this value increases slightly with increasing momentum transfer. The energy resolution and

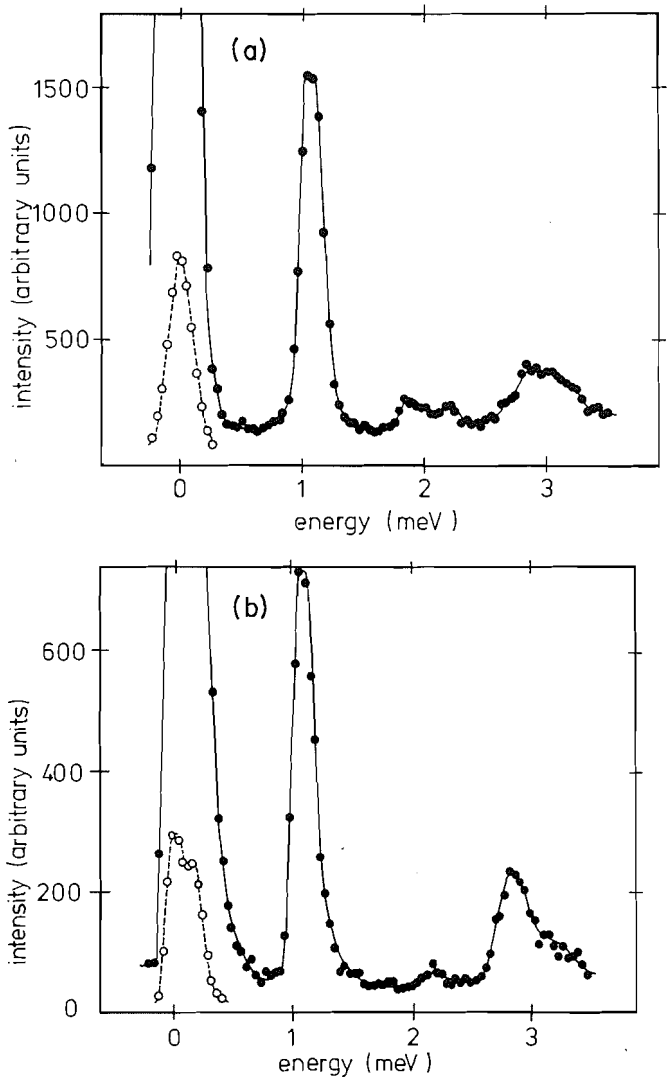

FIG. 3. Neutron scattering intensity from CH_4 doped with 0.2% O_2 measured with a momentum transfer at $Q = 1.8$ Å^{-1}. In (*a*) the temperature is $T = 5$ K; in (*b*) $T \lesssim 100$ mK. For $T = 5$ K and $T \lesssim 100$ mK the counting times were reduced by a factor of two and five, respectively, in comparison with the scans shown in Fig. 2. The scale of the elastic peak (open circles) is reduced by a factor of 10. All lines are guides to the eye only.

TABLE 1. Peak positions $\hbar\omega$ in meV as well as the integrated intensities I observed in the experiments (arbitrary units, normalized to the same monitor rate)

(*a*) $Q = 2.2$ Å^{-1}

3.12	14	0–2	3.16	15	0–2

*"Multi" denotes multiple scattering (2 excitations $J = 0 \rightarrow 1$); uncertainties concerning the assignment are discussed in the text.

thus the quality of the spectra is considerably better than that of earlier measurements. A quick inspection of Fig. 2*a–c* shows that all three spectra look rather similar.

In particular, there are only minor differences between Fig. 2*a* and Fig. 2*b*, which shows that for a similar population of the different spin species the excitation spectra are virtually identical. Differences concern the feature at 1.88 meV. The higher intensity at an energy transfer $\hbar\omega = 1.88$ meV for the sample with pure CH_4 (Fig. 2) indicates that the "rotational temperature" or "nuclear spin temperature" is greater than 5 K. Here we already use the assignment of the peaks given below. The sample with *A*-CH_4 II shows a more pronounced structure and the peak at 1.88 meV is absent.

For an assignment of the peaks, we compare our results with those published by Ozaki *et al.* (12). Obviously the well-defined peaks with energies below about 4 meV are related to the almost free rotations (perturbed by the cubic crystalline field of the neighbouring molecules) of the disordered molecules. Table 1 lists the energies deduced from the three spectra. The peak at about 1.08 meV is the well-known transition from the (perturbed) $J = 0$ to the $J = 1$ state (5, 6), while that at 3.0 meV is the $J = 0$ to $J = 2$ transition. The absence of the peak at 1.88 meV in *A*-CH_4 confirms that this is a transition from an excited state ($J = 1$ to $J = 2$), which disappears upon deexcitation of the $J = 1$ level. The conversion to the ground state also shows up in a 10% increase of the intensity of the $J = 0$ to $J = 1$ transition in *A*-CH_4: this agrees rather well with an increase of the population $P_{J=0}(5\text{ K}) = 0.875$ to $P_{J=0}(0\text{ K}) = 1.0$. The peak at 2.17 meV, which has twice the energy of the $J = 0$ to $J = 1$ transition, obviously is due to double inelastic scattering (intensity about 5% of the single inelastic scattering).

While the peaks do not shift in energy (contrary to the behaviour of the tunneling peaks in a converted sample (7)), all observed peaks are slightly narrower in the sample with *A*-CH_4. This is most pronounced for the structure centred at 3 meV, which becomes considerably narrower. As the larger width is observed both at $T = 5$ K (CH_4 with 0.2% O_2) and at $T \lesssim 100$ mK for pure CH_4, lifetime effects can be ruled out and the distribution of spin species seems to cause the observed width. Even the low temperature data for the oxygen-doped sample at $T \lesssim 100$ mK (Fig. 2*c*) seem to indicate either the presence of a shoulder on the high energy side or, rather, the presence of two peaks. This latter finding is corroborated when inspecting the data measured at $Q = 1.8$ Å^{-1} (with narrower steps in energy transfer); energies of about 2.84 meV and 3.12 meV are found (averaged values), with the first peak strongly temperature dependent and about twice as intense as that at 3.12 meV for *A*-CH_4 II. There seem to be two possible interpretations: (*i*) Either two of the perturbed $J = 2$ states (from three predicted ones (11)) have rather similar energies. This is not in agreement with the predicted separation of almost 1 meV ($E_{0-2A} = 2.65$ meV, $E_{0-2B} = 3.616$ meV (11, 12)). The calculation of

transition matrix element yields a $j_2^2(Q\rho)$ dependence (eq. [2]) of the leading term, and an intensity of the second peak that is about 60% of that of the first peak (12). These calculations also explain the absence of a second perturbed $J = 1$ to $J = 2$ transition, which is predicted to have only about 1/4 of the intensity. Nevertheless it remains to be explained why neither peak position is $E_{0-1} + E_{0-2} = 2.97$ meV, which is the mean value of the reported double peak. (*ii*) The other possibility is the presence of dispersion of the perturbed $J = 2$ state. Kobashi *et al.* (10) have included a coupling between ordered and disordered molecules and predict dispersion for modes that dominantly represent rotations of the disordered molecules. As their calculation is restricted to A-CH_4, both concerning ground and excited states, the dispersion reported by them is related to a perturbed $J = 3$ state, which is the lowest-lying excited state with A symmetry. Yet one may speculate that the introduction of a coupling between all neighbouring molecules introduces similar effects concerning the $J = 2$ levels. Then the two peaks may be identified with the density of states originating from the flat portions of a branch with dispersion. At present, however, no calculations are available. It may be noted that the restriction to A-CH_4 for ground and excited states is still very useful for comparison with optical experiments (16–19), which was the intention of the authors (10). For spin-incoherent neutron scattering cross sections, the inclusion of excited states with T symmetry is necessary and desirable. At least one open question remains: the strong increase of the intensity at $\hbar\omega = 2.84$ meV in A-CH_4 cannot simply be understood on the basis of the conversion of the disordered molecules. An assignment to librational excitations of the ordered molecules, however, needs to explain the low energy of the excitations.

For the above reasons we did not attempt to adjust potential parameters of the crystal field as, for example, done in connection with matrix isolated CH_4 molecules (20). As already pointed out by Ozaki *et al.* (12), the inclusion of both energies and Q-dependent intensities is most helpful for such an effort. We believe that a modification of the crystal field parameters has more severe effects on the transition matrix elements, i.e., on the intensities, than on the energy levels. Yet even for the latter there seem to be rather pronounced differences between theory and experiment. The measurement of Q-dependent intensities, therefore, provides the most direct way to the determination of improved eigenfunctions and the related crystal field parameters.

In the present experiment we only have data available for a fairly narrow range of momentum transfers and therefore only intensity ratios can be analysed (e.g., intensities normalized on that of the $J = 0$ to $J = 1$ transition). Here only coarse agreement is found; the $J = 1$ to $J = 2$ transition, e.g., has only about half of the predicted intensity. On the other hand the prediction of one perturbed $J = 0$ to $J = 3$ transition with high intensity may be a useful hint.

A quantitative comparison is even more difficult for excitations with energies larger than 3 meV. While there seems to be almost a "gap" at energies between 3 and 4.5 meV, we observed a broad band of intensity between about 4.5 and 12 meV, essentially in agreement with the results of Harker and Brugger (3). More or less well-defined peaks are observed at energies of about 5.7 and 6.5 meV with a much weaker maximum at 9.0 meV. A clear distinction between ordered and disordered molecules is difficult, and we must also not ignore the presence of translational phonons. We believe, however, that this band is largely due to the librations of the ordered molecules: (*a*) there are three times as many ordered molecules as disordered ones and also (*b*) Ozaki *et al.* (12) predict rather low intensity for transitions to the $J = 3$ and $J = 4$ sates, with the exception of one $J = 0$ to $J = 3$ transition. Within the single particle picture adopted by these authors, all librational excitations fall into the range between 6 and 7 meV (Fig. 1). Dispersion of the modes due to collective aspects clearly extends this range to values compatible with the observed band.

In an equilibrium sample at high temperatures all transitions between states with different spin symmetry contribute, except $A \leftrightarrow E$. The conversion of all molecules to the A state means that only excited A and T states are accessible in a neutron scattering experiment. As the intensity of inelastic A–A transitions is proportional to $j_3^2(Q\rho)$ (for the Q values of the present experiment this is $\sim Q^6$), this contribution is negligible for $Q = 1.8$ Å^{-1} and $Q = 2.2$ Å^{-1} (12, 21),[2] and hence only inelastic A–T transitions are important. This should result in a 30% overall decrease in intensity for the inelastic spectrum of the ordered molecules in A-CH_4 II as compared with a sample at $T = 5$ K. Inspection of the spectra from the doped sample at $T = 5$ K and $T \lesssim 100$ mK indeed yields a decrease of the overall inelastic intensity with the exception of the peak at 5.7 meV. This either could be due to the fact that there is a librational branch with T symmetry whose contribution gets much stronger upon conversion of the ground state to A (due to a favourable structure factor) or the peak at 5.7 meV could be an additional peak in the response of the disordered molecules, superimposed on a librational band. We note the fact that there is a $J = 0$ to $J = 3$ transition with fairly high calculated intensity. Comparison with the calculation of Kobashi *et al.* (11) cannot solve the problem, due to their general restriction to A symmetry. Optical data (16–19) yield peaks in the same energy range, but are restricted to $q = 0$ ($\boldsymbol{q}$ = wave vector in reduced zone-scheme).

When analysing the present data, one also should note that the oxygen impurities needed for enhanced conversion also mean a perturbation of the crystal. It has been suggested (7, 13) that some of the features observed may be due to such perturbations.

Conclusions

While the present experiment indeed provides additional insight into the rotational dynamics of the quantum molecular crystal CH_4, numerous questions remain. One of the ideas was to have a reduced number of transitions by converting all CH_4 molecules into their respective ground state with A symmetry. Here the preparation of A-methane was achieved by cooling an oxygen-doped sample to $T \lesssim 100$ mK. Yet again we found that, contrary to reports in the nmr literature, there is no fast conversion into the ground state for the disordered molecules. During times of the order of 1–2 days, only negligible conversion was observed in a sample with pure CH_4, similar to earlier observation of Kapulla and Gläser (5, 6). It appears that nuclear spin conversion in pure, O_2-doped or diluted samples (solid mixtures of CH_4 and Kr (22) is by no means satisfactorily explained at present (23). Obviously the conversion rate depends very strongly on the energy difference between the two states involved in the conversion process, on local surroundings and magnetic fields, as well as on temperature.[3]

How about the conclusions concerning the rotational states? Here we have to admit that not all assignment problems have been successfully overcome. Perhaps Q-dependent measurements over a wide range in Q could provide the necessary

[2]Also, D. Matuschek and A. Hüller, to be published.

[3]F. Guckelsberger and R. Scherm, unpublished.

solution (12, 21). On the other hand, calculations of the lattice dynamics have to be extended to include (*i*) all the spin states accessible in a neutron scattering experiment as well as (*ii*) the collective aspects due to the orientation–dependent coupling between neighbouring molecules.

As well, an incoherent neutron scattering experiment can only supply a density-of-state like result. Clearly, a direct coherent scattering experiment would yield more detailed information and a more serious test of lattice dynamical calculations. Such an experiment not only requires A-CH_4 II, but in addition a crystal with a sizable polarization with respect to the z-component of the nuclear spin, I_z (8). One could think of "brute force" methods to achieve this polarization (temperatures in the μK range and strong magnetic fields) but also of dynamical polarization (13). The alternative system, deuterated methane (CD_4), (*i*) means a rather dramatic step towards more classical properties and (*ii*) undergoes a phase transition to the more complicated phase III below $T = 22.1$ K. Therefore we suspect that many of the above-mentioned questions will remain open, at least for the near future.

NH_3 reorientation in phases I, II, and III of $Ni(NH_3)_6(NO_3)_2$

GORDON J. KEARLEY AND HERMA BLANK
Institut Max von Laue – Paul Langevin 156X, 38042 Grenoble CEDEX, France
Received September 28, 1987
This paper is dedicated to Professor James A. Morrison

GORDON J. KEARLEY and HERMA BLANK. Can. J. Chem. **66**, 692 (1988).

The inelastic neutron scattering (INS) spectra of rotational tunnelling and librations of NH_3 ligands in phase III of $Ni(NH_3)_6(NO_3)_2$ are not consistent with a rotational hindrance potential containing only cos $(3n\phi)$ terms owing to strong interaction between neighboring cations. This type of interaction, and motion of the whole cation, also influences the classical reorientational motions involving displacement of the H atoms, where the overall radius of rotation is consistently greater than the 0.9 Å expected for isolated NH_3 rotors. Quasielastic neutron scattering (QNS) suggests that in phase III there are two sublattices of cations, one of which becomes completely disordered (with respect to the NH_3 rotors) at the III–II phase transition. Disorder of the second sublattice marks the II–I transformation where only a single type of rotational motion is found.

GORDON J. KEARLEY et HERMA BLANK. Can. J. Chem. **66**, 692 (1988).

Les spectres de diffusion des neutrons inélastiques (DNI) de l'effet tunnel de rotation et des librations des ligands NH_3 dans le $Ni(NH_3)_6(NO_3)_2$ de phase III ne sont pas en accord avec un potentiel d'empêchement à la rotation ne contenant que des termes cos $(3n\phi)$ provenant d'une interaction forte entre les cations voisins. Ce type d'interaction, ainsi que le mouvement du cation dans son ensemble, influencent aussi les mouvements classiques de réorientation impliquant le déplacement des atomes H dans lesquels le rayon global de la rotation est toujours plus grand que le 0,9 Å attendu pour des rotors NH_3 isolés. La diffusion des neutrons quasi-élastiques (DNQ) suggère que, dans la phase III, il existe deux sous-réseaux de cations dont l'un devient complètement désordonné (par rapport aux rotors NH_3) lors de la transition phase III → II. Le désordre du deuxième sous-réseau marque la transformation II → I dans laquelle on ne trouve qu'un seul type de mouvement de rotation.

Introduction

The role played by disorder and reorientations of the ammine ligands in transition-metal hexammine salts has attracted the attention of several groups over the course of a number of years (see ref. 1 and references therein). The overall picture of six ammine groups, which undergo rotational diffusion at high temperature and then freeze into fixed orientations in the lowest-temperature phase transition, is generally accepted, but the details of the NH_3 orientations, particularly in the low-temperature phases, are largely unknown (2–5). In the present study we are concerned with motions not only of the NH_3 groups but also of the entire hexammine ion in three phases of nickel hexammine nitrate.

The sequence of phase transitions has been studied by ir (6), Raman (7), epr (8), and INS (9) spectroscopies, and by specific heat measurements (10, 11). For $Ni(NH_3)_6(NO_3)_2$, the transitions between the phases are usually quoted as (9):

$$\begin{array}{cccccccc} & \sim 180\,K & & 250\,K & & 250\,K & & \sim 90\,K \\ III & \rightarrow & II & \rightarrow & I & \rightarrow & II & \rightarrow & III \end{array}$$

Marked thermal hysteresis of the low-temperature transition is now well established for the nitrates, although it may well have been the source of confusion in the past (10) regarding the presence of an "extra" phase transformation at around 80 K. In the present work all temperature changes were made on heating to avoid ambiguity due to hysteresis. The III–II transition is usually attributed to disorder of the NH_3 ligands (6, 7, 9), while the onset of NO_3^- ion disorder is responsible for the II–I transformation (7).

Recently, neutron scattering spectroscopies have been used to study motions of the NH_3 groups in metal hexammine salts and have given a new insight into the potential energy surface of the NH_3 groups in the lowest-temperature phases (1, 12). Although the situation that emerges is complex, there is qualitative agreement with the idea that all NH_3 groups are essentially identical but that there is a disorder due to at least two energetically equivalent orientations (per cation) available to the ligands (13). The effect of this disorder on the NH_3 rotational potential seems to increase as the cation–cation separation decreases (12). In the present paper, we examine the rotational-tunnelling spectrum of the NH_3 ligands in the nitrate analogue, where the small anion leads to a reduced tunnel splitting and a greater sensitivity to the orientations of NH_3 groups on neighbouring cations compared with the iodide (12) or hexafluorophosphate (1) derivatives.

In many cases the tunnel splitting of the librational ground state can be compared with the energies of the librational modes, to deduce the form of the rotational hindrance potential and the barrier height (1, 12, 14–16). For phase III of $Ni(NH_3)_6(NO_3)_2$, however, the energy of the librational transitions of the NH_3 groups is too high to correlate with the tunnel splitting using a simple cosine potential form. Further, a multiplet of peaks has been reported in the librational region of the INS spectrum (9), which has been tentatively assigned to the presence of rather different barriers to rotation for the various NH_3 groups. This assignment gained support from the results of QNS spectra, which were interpreted as two of the six NH_3 groups on each cation undergoing reorientation on the time scale of this spectroscopy, while the remaining four groups are "stationary" (9). Tunnel splitting varies almost exponentially with the height of the barrier to reorientation, and if the above interpretation were valid, the effects of inequivalent NH_3 groups would be more manifest in the tunnelling spectrum.

In the present study we attempt to clarify the situation by a careful comparison of the tunnelling and librational INS spectra. We then present, and analyse, QNS spectra as a function of temperature in phases I, II, and III, going out to considerably higher momentum transfers than were previously available, to obtain a more accurate description of the reorientational processes.

Experimental

Samples were prepared by dissolving $Ni(H_2O)_6(OH)_2$ in concentrated ammonia solution, forming $Ni(NH_3)_6(OH)_2$. The nitrate ana-

logue was precipitated by the addition of ammonium nitrate solution, filtered, and recrystallized from dilute ammonia solution. The nitrate derivatives in particular lose ammonia rapidly and were handled and dried in an atmosphere with a small partial pressure of ammonia. Deuterated samples were prepared by the use of D_2O and deuterated ammonia solution.

Tunnelling spectra were collected using the IN5 multichopper time-of-flight spectrometer at the Institut Laue–Langevin (ILL), France. An incident neutron wavelength of 16 Å was used, giving an energy resolution (FWHM) of 3.3 μeV with a momentum transfer of 0.64 $Å^{-1}$. For the tunnelling spectrum detectors were grouped together at scattering angles between 90 and 130 degrees, with the final spectrum being obtained from the sum of these detectors. The IN5 spectrometer was also used for the quasielastic scattering experiments, using an incident neutron wavelength of 2.69 Å with detectors grouped to give a useful momentum-transfer range between 0.5 and 4.2 $Å^{-1}$. The resolution lost by the use of such short wavelengths was partly recovered by "squeezing" the neutron pulse length via a careful dephasing of the last two choppers. The measured energy resolution was 410 μeV in place of 700 μeV normally associated with a wavelength of 2.69 Å. Spectra collected at different scattering angles were normalized by comparison with a standard vanadium sample. Individual detector columns containing Bragg peaks were identified by inspection and removed from the data-treatment procedure.

High energy transfer spectra were collected using the IN4 double rotating-crystal time-of-flight spectrometer at the ILL. An incident neutron wavelength of 1.28 Å was used, giving an energy resolution of ca. 2.5 meV. Spectra recorded in all detectors between 100 and 140 degrees were summed together to produce the final spectrum. Standard liquid helium cryostats were used for all experiments, and changes to the sample temperature between quasielastic scattering measurements were made on heating.

Data-treatment routines were written locally using standard neutron-scattering algorithms. The fitting procedures, to extract peak positions and intensities, used a numerical convolution of the experimental resolution function with the calculated scattering functions. The calculated functions were then refined to minimize the difference between the observed and calculated spectra.

Results

Rotational tunnelling

When the tunnel splitting of rotational ground states is sufficiently large, INS provides a sensitive probe of the environments of the rotors, the subject having been reviewed by Press (17). Probably the most thoroughly studied example is that of methane, in which the spectra of protonated, deuterated, and partially deuterated species have been used to achieve a very complete description of the partially disordered structure of phase II of this compound (18). A similar situation appears to exist for the metal hexammines, and in the present case our concern is to distinguish the effects of disorder from those of crystal-field distortions.

Inspection of the tunnelling spectrum shown in Fig. 1 reveals the presence of at least two peaks in energy loss and in energy gain. These peaks arise from rotational tunnelling of the NH_3 ligands. Their positions provide information about the rotational hindrance potential while, in the simplest case, their intensities reflect the number of NH_3 groups experiencing these potentials, and hence provide a stringent test of the differing barrier heights alluded to above.

Peak positions and intensities, collected in Table 1, were estimated by fitting the spectrum with Gaussian functions convoluted with the instrumental resolution function, with the constraint that the spectrum be symmetric about the elastic peak. The fitted function is represented by the solid line in Fig. 1, with the component peaks below. Peak intensities, relative to the elastic peak, are 0.023 and 0.008 for the peaks at energy transfers of 5.5 and 18.9 μeV, respectively, the low intensities being due to the small momentum transfer, only 0.64 $Å^{-1}$. A comparison of the intensity of the 18.9-μeV peak, at higher momentum transfer, with the tunnelling spectrum of $Ni(NH_3)_6I_2$ (12) reveals that the *total* tunnelling intensity is very similar for the two salts, from which we conclude that for both salts the intensity accounts for essentially all NH_3 ligands.

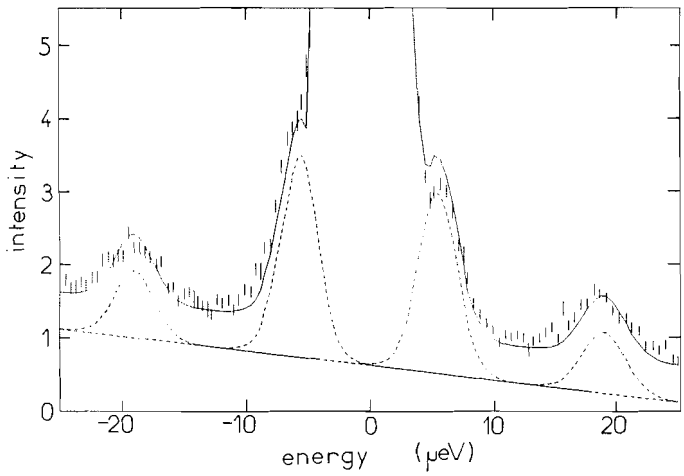

FIG. 1. Tunnelling spectrum of $Ni(NH_3)_6(NO_3)_2$ (1.8 K) obtained using the IN5 spectrometer. The solid line represents the fitted function, while the broken line shows the individual Gaussian components. The sloping background arises from the use of a high neutron pulse rate and was fitted using a single parameter.

TABLE 1. Positions and intensities of the INS peaks in the tunnelling and librational spectra regions. The intensities are quoted relative to the elastic peak intensity being unity

Assignment	Energy transfer	Relative intensity EPP = 1.000)
	(μeV)	
NH_3 tunnelling	5.56	0.008
NH_3 tunnelling	18.94	0.023
	(meV)	
NH_3 librations	20.5–37.9	
ND_3 librations	15.7–32.0	

The intensity ratio of the two tunnelling peaks in the present case, ca. 1:4, is not readily reconciled with crystallographic inequivalences of six NH_3 groups. While it could be argued that there may be a further unresolved peak of unit intensity that is missed due to inaccuracies in our intensity estimates, it is more likely that the observation of more than one peak is due to interaction between ligands, as described for the iodide analogue (12), and that static crystallographic inequivalences play only a minor part. In fact, a comparison of the librational spectrum (below) with the tunnelling spectrum suggests that, as expected, the NH_3–NH_3 interaction is stronger in the nitrate salt than in the iodide, *vide infra*. A study of the temperature dependence of the tunnelling spectrum would help clarify this point.

Librational motions

For $Ni(NH_3)_6(NO_3)_2$ at temperatures below ca. 5 K, the rotational motions are best described by tunnelling and librations rather than by almost free rotation. In principle, we may use the energy transfers of NH_3 tunnelling in this salt (above) to derive the energy transfers of the NH_3 librational modes if we ignore the effects of cation–cation interactions. Assuming that

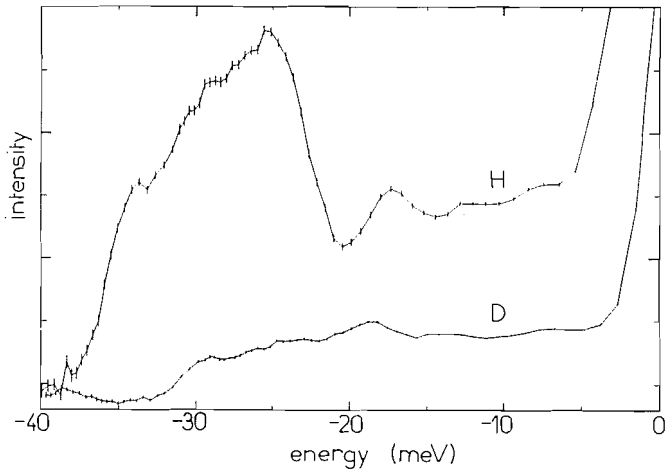

FIG. 2. INS spectra of $Ni(NH_3)_6(NO_3)_2$ and $Ni(ND_3)_6(NO_3)_2$ (5.0 K) in the librational spectral region obtained using the IN4 spectrometer. The low intensity of the peaks in the latter spectrum is due to the small incoherent scattering cross section of deuterium.

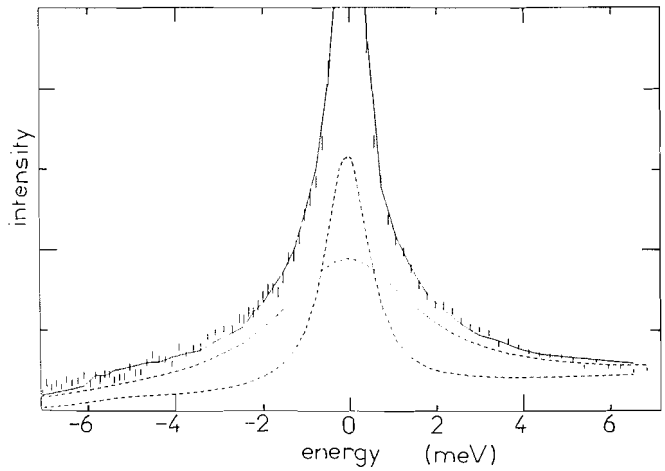

FIG. 3. Example of a QNS spectrum of phase II $Ni(NH_3)_6(NO_3)_2$ recorded at a scattering angle of 82.5 degrees ($Q = 3.1$ Å^{-1}). The solid line represents the calculated function and the broken lines represent the Lorentzian components.

the NH_3 groups retain their molecular C_{3v} symmetry, but occupy a site that has no symmetry on the time scale of the rotation, the hindrance potential, V, has the form cos (3ϕ). This potential can be included in the Schrödinger equation for a one-dimensional rotor:

$$[1] \quad (-\hbar^2 d^2/2I d\phi^2 + V(\phi))\Psi = E\Psi$$

to obtain the eigenvalues.

Attributing the tunnelling energies at 5.5 and 18.9 μeV to $J = 0 \rightarrow J = 1$ transitions gives rotational barrier heights of 38.0 and 27.5 meV, respectively. The corresponding librations ($J = 0 \rightarrow J = 2$) are calculated at 13.7 and 11.2 meV, respectively.

The INS spectra of $Ni(NH_3)_6(NO_3)_2$ and $Ni(ND_3)_6(NO_3)_2$ in the 5–40 meV region are shown in Fig. 2. The large amplitude of the librations, alongside the high scattering cross section of H atoms, strongly suggests that the dominant features, between 20 and 35 meV (Table 1), arise from librational modes, as proposed by ref. 9. This assignment is supported by the approximate $1/\sqrt{2}$ shift of these peaks and loss of intensity in the spectrum of the deuterated analogue. These librational features occur at energies more than twice the values calculated on the basis of a simple cos (3ϕ) potential using the barrier height calculated from the tunnel splitting. Cosine potentials of higher symmetry, cos (3$n\phi$) or combinations of such potentials including phase angles (16, 19), cannot reproduce the large separation between the tunnel-split ground state and the other librational levels. A detailed discussion of the potential form is beyond the scope of the present paper, since we have only two observations on which to base our arguments. We note, however, that the observed separation between the tunnel-split ground state and the librational levels can be produced by the use of a coupled potential (15).

The evidence for a coupled system is quite strong on the basis of both the tunnelling spectrum and the librational spectrum. It is conceivable that in such a coupled system, the multiplet peaks observed in the librational spectral region arise from a group of closely spaced energy levels, since it is clear that they do stem from crystallographically distinct ligands.

Quasielastic neutron scattering

Direct deduction of molecular motions from QNS spectroscopy of powdered samples is rarely feasible for systems of any complexity, but this spectroscopy is particularly useful for investigating the radius of rotational motions and the number density of species performing this rotation. For these purposes the most reliable measured quantity in QNS is the experimental elastic incoherent struture factor (EISF), which is the ratio of the elastic intensity to the elastic plus quasielastic intensity (see review article by Leadbetter and Lechner (20)). For the moment we will consider only the calculated EISF for motion on a circle,

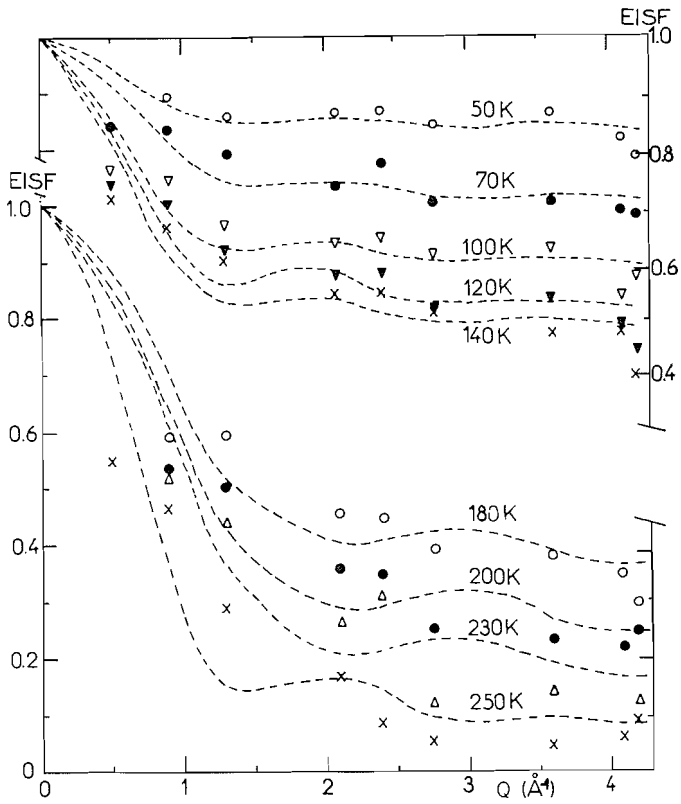

FIG. 4. Total EISFs of $Ni(NH_3)_6(NO_3)_2$ obtained by fitting the QNS spectra with one Lorentzian function (phase I, 250 K: phase III, 50–140 K) and two Lorentzians (phase II, 180–230 K). Broken lines show the best-fit calculated EISF using eq. [2] allowing only the radius, r, and the fraction, F, to refine. The number of sites on the circle, m, was set to 20.

FIG.. 5. Separated EISFs for the two Lorentzians fitted to the quasielastic spectra of phase II $Ni(NH_3)_6(NO_3)_2$. Calculated EISFs were obtained as described for Fig. 2.

which is given by:

$$[2] \quad 1 - F/\pi \sum_{l=1}^{m-1} m^{-1} \sum_{k=1}^{m} j_0(2Qr \sin \pi k/m) \cdot \cos(2\pi lk/m)$$

where j_0 is the zero-order Bessel function, m is the number of sites on the circle of radius, r, and Q is the momentum transfer. F is the fraction of protons in the system undergoing reorientation. If the elastic peak is readily separable from the quasielastic components, the overall experimental EISF is virtually independent of the detailed fitting of the quasielastic components.

In the present case, it transpired that elastic and quasielastic contributions are separable by fitting a single Lorentzian to the quasielastic scattering at sample temperatures below 180 K (phase III), and above 245 K (phase I). Between these temperatures (phase II), two Lorentzian functions were required to fit the data adequately. An example of a single spectrum with two fitted Lorentzian components is illustrated in Fig. 3. To maximize the significance of the fitted parameters, spectra collected at nine different scattering angles were refined simultaneously. Preliminary analyses revealed that the Lorentzian peak widths are Q dependent, from which we conclude that the overall process is of a diffusive nature, rather than jumps between a small number of sites. This conclusion is in good agreement with the mode of NH_3 motion reported for the iodide analogue (3) but in conflict with the instantaneous-jump process reported in previous studies of the nitrate and perchlorate salts (9, 21, 22). The Q dependence of the quasielastic width for diffusion on a circle was taken to be that of the sum of m Lorentzians with widths, τ, proportional to (23):

$$[3] \quad 1/2 \sin^2(\pi l/m)$$

weighted according to eq. [2]. Use of eqs. [2] and [3] with m, the number of sites on the circle, set to 20 gives a very close approximation to rotational diffusion. For motions on a radius of ca. 1 Å the quasielastic width is almost constant below a momentum transfer of 2.5 $Å^{-1}$.

In the event, spectra at nine scattering angles were refined using nine quasielastic intensity factors, an overall scale factor, and two width factors, for each of either one or two quasielastic components. The broken lines in Figs. 4 and 5 represent the best-fit calculated EISFs obtained using eq. [2] with $m = 20$, and allowing only the radius of rotation, r, and the fraction of protons in the system undergoing reorientation, F, to refine. We emphasize that the fitted EISFs are calculated using only rotation on a circle and, clearly, the actual reorientation process is more complicated than this, as evidenced by the systematic misfit of the calculated EISFs at around 1 $Å^{-1}$ (Figs. 4 and 5). We have obtained almost perfect fits to the EISFs by allowing two processes to occur: diffusion on a circle and spherical diffusion, refining the populations and radii of both processes. There is, however, a danger of overinterpretation of the results (the average error on the points of the EISFs (not shown) is about 12%) and we prefer to restrict our discussion to a more approximate overall process using only diffusion on a circle.

Two important results are derived from these EISFs. Firstly, on the timescale of this spectroscopy, the total fraction of

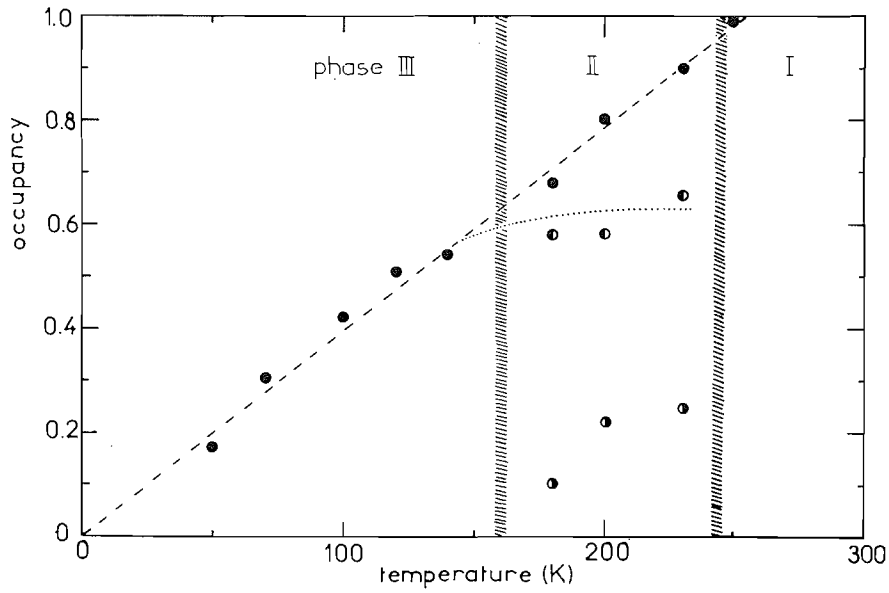

FIG. 6. Variation of the fraction of protons in the system contributing to the EISF with temperature. The filled circles represent the total occupancy; the left-filled and right-filled circles denote occupancies associated with peaks 1 and 2, respectively (Table 2). The dotted line is a guide to the continuity of peak 1 through the III–II phase transition.

TABLE 2. Radii and fraction of protons involved in motion (occupancy) for the *overall* reorientation processes (on the timescale of the spectroscopy) in $Ni(NH_3)_6(NO_3)_2$ at various temperatures in various phases. These values give the calculated EISFs shown in Figs. 4 and 5

Phase	Temperature (K)	Peak 1		Peak 2	
		Radius (Å)	Occupancy	Radius (Å)	Occupancy
III	50	2.07	0.17		
	70	1.99	0.30		
	100	2.16	0.42		
	120	2.12	0.51		
	140	2.16	0.54		
II	180	1.38	0.58	1.69	0.10
	200	1.44	0.58	1.53	0.22
	230	1.50	0.65	1.07	0.26
I	250	1.96	0.98		

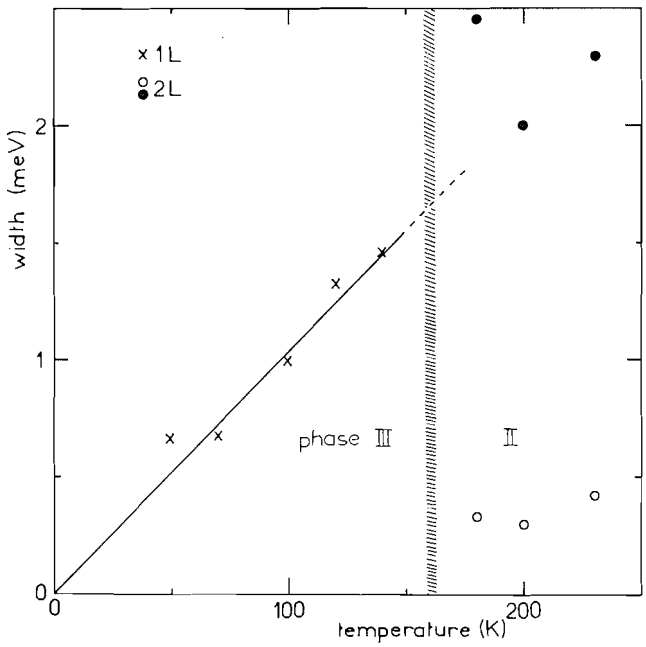

FIG. 7. Variation of peak width (diffusion constant) derived from the quasielastic components. The proportionality between the diffusion constant (HWHM) and temperature is consistent with Einstein behavior.

protons undergoing reorientation increases almost linearly with temperature up to the II–I transition, and is not simply related to crystallographically distinct NH_3 groups. This trend is shown graphically in Fig. 6. Secondly, the radius of rotation at all temperatures, including the two components above 180 K, is >1.0 Å (Table 2). A radius of rotation of ca. 1.5 Å resulted from the refinement of quasielastic peak widths (eq. [3]), and these radii are to be compared with simple NH_3 rotation (radius ca. 0.9 Å). A similar result has been obtained for NH_3 motions in $Ca(NH_3)_6$ (24) for which it was suggested that the NH_3 rotation occurs about a fluctuating axis. Clearly, in the present case there is some motion of the whole cation, but there is no unique interpretation of our results, and we must admit the possibility of tumbling motions, rotations of the octahedral cation around several axes, and simple precession of the Ni–N vectors.

Discussion

The spectra of both tunnelling and librational motions of the NH_3 ligands in this salt support the idea that the rotational potential is very sensitive to the orientation of the NH_3 ligands on the neighboring cation. This effect was predicted by Bates and Stevens (13) on the basis of a simple point-charge model. These authors also calculated that there are two energetically equivalent orientations of the NH_3 ligands on an isolated hexammine cluster, related by 60-degree rotation of all ligands. We denote these orientations A and B. For the isolated hexammine ion, a very low barrier separates the concerted interchange between A and B. The strong interaction between the cations, however, militates against the concerted process, and we are left with a situation in which various arrangements of A and B cations within the lattice must be considered.

It is interesting to note that at the III–II phase transition the population of H atoms involved in the reorientational processes giving the quasielastic scattering is around 50% (see Fig. 6). Further, comparison of the temperature dependence of the diffusion constants (Fig. 7) with the population of H atoms involved reveals that the III–II transition is marked by the onset of a second process rather than any stepwise change in the diffusion constant of the phase III process. This behavior suggests that there are two sublattices of cations (or groups of cations), one of which is ordered in phase III. This behavior could arise from the A and B orientations discussed above, and a crystallographic investigation of phases II and III would be most enlightening.

The trend of the total EISFs shown in Fig. 4 summarizes the nature of the phase transitions rather well. At a sample temperature of 250 K (phase I), the quasielastic scattering was fitted well with a single Lorentzian, as would be expected for the known crystallographic space group, $Fm3m$, of this phase. As with all the EISFs shown in the figures, the falloff with increasing Q is too rapid for simple reorientation of the NH_3 groups. The normal crystallographic description of the NH_3 groups in the cubic phases of these salts is that the three H atoms are disordered between 24 positions (3) (effectively rotational diffusion on a radius of ca. 0.9 Å). More recently, a phenomenological Frenkel model has been applied to describe the X-ray and neutron scattering from the NH_3 groups (25) but the physical meaning of this model is not clear.

Our results suggest that in *all* phases of $Ni(NH_3)_6(NO_3)_2$, NH_3 reorientations between neighboring cations are coupled to each other and to some form of whole-body "cation libration". The involvement of softening of the librational lattice mode in the phase transitions of these salts has already been suggested (5) and certainly merits further investigation.

Received August 28, 1987

This paper is dedicated to Professor J. A. Morrison

THOMAS BIRCHALL, CHRISTOPHER HALLETT, ANN VAILLANCOURT, and KRZYSZTOF RUEBENBAUER. Can. J. Chem. **66**, 698 (1988).

A ^{57}Fe Moessbauer study of the Fe_2O_3–WO_3 and Fe_2O_3–Cr_2O_3–WO_3 systems has been carried out. Single phase materials could be prepared having the composition $Fe_{2-x}WO_{6-3x/2}$ ($x = 0.28$), the stoichiometric Fe_2WO_6 always contained detectable amounts of α-Fe_2O_3. The iron tungstates are found to be unstable to prolonged heating at 1000°C. The $Cr_{2-y}Fe_yWO_6$ ($0 < y \leq 2$) system was shown to be of the trirutile type when $y \leq 1.7$ but multiphasic when $y > 1.7$, these latter phases have structures based upon the iron and chromium tungstate phases, respectively. The Moessbauer parameters for the $Cr_{2-y}Fe_yWO_6$ compositions do not appear to behave in the same fashion as the related $Fe_{2-x}Cr_xTeO_6$ system.

THOMAS BIRCHALL, CHRISTOPHER HALLETT, ANN VAILLANCOURT, etd KRZYSZTOF RUEBENBAUER. Can. J. Chem. **66**, 698 (1988).

On a réalisé une étude, par effet Moessbauer du ^{57}Fe, des systèmes Fe_2O_3–WO_3 et Fe_2O_3–Cr_2O_3–WO_3. On a pu préparer des produits en phase unique de composition $Fe_{2-x}WO_{6-3x/2}$ ($x = 0,28$) ; le produit de stoechiométrie Fe_2WO_6 contient toujours des quantités détectables d'α-Fe_2O_3. On a trouvé que les tungstates de fer sont instables si on les soumet à un chauffage prolongé à 1000°C. On a démontré que le système $Cr_{2-y}Fe_yWO_6$ ($0 < y \leq 2$) est du type de la trirutile lorsque $y \leq 1,7$, mais qu'il est multiphasique lorsque $y > 1,7$; ces dernières phases possèdent des structures qui sont basées sur des phases de tungstates respectivement de fer et de chrome. Le comportement des paramètres de Moessbauer pour les compositions $Cr_{2-y}Fe_yWO_6$ ne correspond pas à celui de système $Fe_{2-x}Cr_xTeO_6$ apparenté.

[Traduit par la revue]

Introduction

The iron–tungsten–oxygen and the iron–chromium–tungsten oxygen systems have been the subject of considerable interest in recent years (1–8). Senegas and Galy (4) determined the crystal structure of an iron(III) tungstate described as Fe_2WO_6. Subsequently, Leiva *et al.* (5–8) have investigated the properties of iron tungstates prepared as reported by Senegas and Galy (4) and reported that the material is best considered as a solid solution of $FeWO_4$ in Fe_2WO_6 (5, 6). The materials were described by the formula $Fe_{2-2x}W_{1+x}O_6$ (5). Given the sensitivity of Moessbauer spectroscopy (7) to the oxidation state of iron and the uncertainty (4–6) surrounding the oxidation state of iron in "Fe_2WO_6" it seemed surprising that no Moessbauer studies of iron tungstates prepared from Fe_2O_3 and WO_3 have been reported. Hence we have undertaken an iron-57 Moessbauer spectroscopic study of these materials in an attempt to clarify the nature of these materials.

It was also noted that studies of chromium-doped iron tungstates have been recently carried out (7, 8). It was reported that a solid solution series, $Cr_{2-y}Fe_yWO_6$, with the trirutile structure of Cr_2WO_6 could be prepared, although the series did not appear to extend across the composition range $0 \leq y \leq 2$ (7, 8). Given that other mixed metal oxide systems based on iron and chromium have been reported to show magnetic properties which were dependent on x in $Fe_{2-x}Cr_xO_3$ (9) and $Fe_{2-x}Cr_xTeO_6$ (10), and which were sensitive to detection by Moessbauer spectroscopy, the iron–tungsten system has also been examined by this technique.

[1]To whom all correspondence should be addressed.

Experimental

Preparation of materials

Iron tungstates were prepared by the calcination (2 × 30 h) in air of equimolar mixtures of α-Fe_2O_3 and WO_3 at 1000°C. "Iron-deficient" compounds were prepared by analogous methods. Some materials were heated at 1000°C for 3 weeks (see below).

The $Cr_{2-y}Fe_yWO_6$ compounds were prepared in the following manner. A standard solution of ferric nitrate was prepared by dissolving pure iron in concentrated nitric acid. A similar standard solution of Cr^{3+} was prepared by the reaction of $K_2Cr_2O_7$ with 30% H_2O_2 in acid solution. Appropriate quantities of these two solutions, to give the required Fe:Cr ratio, were mixed and aqueous NH_4OH added until complete precipitation of the iron and chromium hydroxides had occurred. The mixture was filtered, the filtrate was tested to ensure that precipitation was in fact complete, and the precipitate thoroughly washed with water and then dried for several hours at 120°C. This was followed by heating at 1000°C for 24 h, grinding the mixture, and reheating at 1000°C for a further period of 24 h. The mixed oxide $Cr_{2-y}Fe_yO_3$ thus formed was thoroughly mixed with the appropriate quantity of WO_3 and heated at 950°C for 24 h. The homogeneity was checked by X-ray powder diffraction. Powder X-ray data were recorded using a Philips horizontal goniometer and copper K_α radiation. Samples were mixed with an internal standard of KCl.

Moessbauer spectroscopy

Moessbauer spectra were recorded on apparatus described elsewhere (11). Samples were cooled to temperatures between 298 and 4.2 K in a "Technology Systems" cryostat while the ^{57}Co/Rh source was maintained at ambient temperature. The sample temperature was monitored by a "Thor" temperature controller. Absorbers were prepared by mixing the finely ground powders with Apiezon grease. The quantity of iron in each absorber (always < 10 mg Fe/cm^2) was calculated according to the method described by Long *et al.* (12) to minimize the effect of

γ-ray scattering by tungsten. The spectra were fitted using a modified version of the program developed by Ruebenbauer and Birchall (13) and all isomer shifts are relative to α-Fe as zero shift.

Results and Discussion

Iron–tungsten oxides

Calcining equimolar mixtures of α-Fe_2O_3 and WO_3 at 1000°C gave dark grey powders which were examined by Moessbauer spectroscopy and powder X-ray diffraction. Whilst PXRD gave little evidence for the presence of an impurity it was obvious from the Moessbauer spectrum that trace quantities of α-Fe_2O_3 were present, Fig. 1(*a*). Since the contribution of the impurity phase is small only the outer peaks of the sextet, which characterizes magnetically ordered α-Fe_2O_3, are visible above the baseline scatter. The Moessbauer data indicate that ca. 10% Fe is located in the haematite phase (Table 1). However, given the uncertainty in the relative recoil-free fractions of iron in Fe_2O_3 and "Fe_2WO_6," and the critical influence of the baseline position places an upper limit of contribution of a minor component at about 5 mol% Fe_2O_3. It is therefore interesting that this datum is consistent with the suggestions made by Leiva *et al.* (5, 6) that equimolar quantities of Fe_2O_3 and WO_3 react to give an iron tungstate together with some α-Fe_2O_3.

In addition Leiva *et al.* (5, 6) reported that iron-deficient mixtures of Fe_2O_3 and WO_3 react to give a monophasic, non-stoichiometric product, although no limits of nonstoichiometry were established. Hence iron-deficient mixtures of Fe_2O_3 and WO_3, with nominal compositions between Fe_2WO_6 and $Fe_{1.56}WO_{5.34}$, were calcined at 1000°C in an attempt to prepare monophasic materials and to investigate the limits of the iron-deficient-type nonstoichiometry. Solids prepared from reactants of nominal compositions from Fe_2WO_6 to $Fe_{1.92}WO_{5.88}$ gave Moessbauer spectra which retained evidence for the presence of α-Fe_2O_3. However, the material with a nominal composition $Fe_{1.88}WO_{5.82}$ gave a Moessbauer spectrum, Fig. 1(*b*), in which the baseline to each side of the doublet, arising from iron

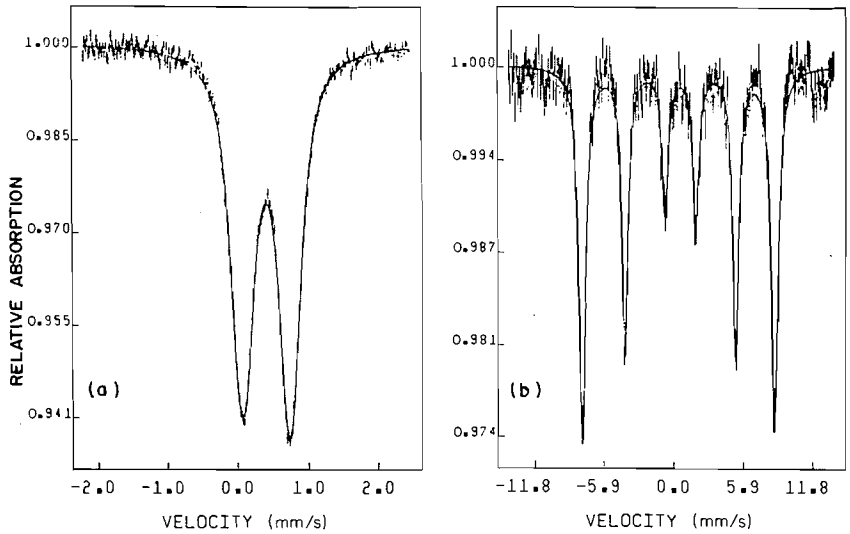

FIG. 2. ^{57}Fe Moessbauer spectra of (*a*) Fe_2WO_6 with a 6% Fe deficiency at 298 K fitted to two iron sites; (*b*) $Fe_{1.68}WO_{5.52}$ at 4.2 K.

tungstate, showed only normal statistical scatter with no evidence for a contribution from α-Fe_2O_3. It is also pertinent to note that materials with nominal composition of $Fe_{1.68}WO_{5.52}$ were found to be pure iron tungstates by both Moessbauer spectroscopy and powder X-ray diffraction. Examination, by powder X-ray diffraction, of solids which were more iron-deficient revealed trace quantities of WO_3. Since 2 mol% WO_3 was found to be readily detectable by X-ray diffraction it seems reasonable to conclude that solids with nominal compositions between $Fe_{1.88}WO_{5.82}$ and $Fe_{1.68}WO_{5.52}$ are monophasic materials which represent the approximate stoichiometry range in this form of iron tungstate. Reduction of the iron content beyond $Fe_{1.68}WO_{5.52}$ to $Fe_{1.64}WO_{5.48}$ reveals X-ray detectable traces of WO_3, whilst increasing the concentration of iron much above $Fe_{1.88}WO_{5.82}$ produces Moessbauer detectable Fe_2O_3.

Although these materials have been discussed in terms of iron and oxygen deficiency it should be noted that this represents the nominal compositions of the reactants. Since the solids were formed by calcination in air, the possible addition or loss of oxygen during the reaction cannot be discounted on the basis of X-ray diffraction or Moessbauer data. The reaction of a mixture of WO_3 and α-Fe_2O_3, which corresponded to a nominal composition of $Fe_{1.72}WO_{5.58}$ was therefore performed *in situ* whilst being monitored by thermal gravimetric analysis. No change in weight occurred during the course of the reaction (24 h). Powder X-ray data recorded from the product showed only lines reported as characteristic of "Fe_2WO_6" (4) with no evidence for WO_3. Taking the powder X-ray, Moessbauer and thermal gravimetric analysis data together, it seems reasonable to describe the iron tungstates prepared in ths work as $Fe_{2-x}WO_{6-3x/2}$.

It also appears worth noting the behaviour of these iron tungstates when subjected to prolonged calcination at 1000°C. The Moessbauer spectrum recorded from the iron tungstate prepared from an equimolar mixture of Fe_2O_3 and WO_3, and which was annealed for 3 weeks at 1000°C, is shown in Fig. 1(*c*). Similar spectra were obtained from an iron tungstate of nominal composition $Fe_{1.68}WO_{5.52}$. The contribution of iron in the form of α-Fe_2O_3 has increased from between 0 and 10% after short-term calcination, to 44% after heating for 3 weeks. Significant weight loss was also noted (ca. 25% of total sample). Hence it appears that iron tungstates decompose on the prolonged calcination at 1000°C with loss of tungsten as a volatile oxide.

Although the formula $Fe_{2-x}WO_{6-3x/2}$ does not require the presence of any Fe^{2+} to maintain charge-balance, the data presented so far have not unequivocally clarified the uncertainty concerning the oxidation states of iron present in iron tungstate (5, 6). It therefore seems pertinent to consider the Moessbauer spectra in more detail.

The Moessbauer spectra recorded for the iron tungstates at room temperature showed a quadrupole doublet, sometimes accompanied by a magnetic contribution from α-Fe_2O_3 (Table 1). While the doublet could be fitted to a model based on a single quadrupole-split resonance from an iron(III) species, the linewidths (0.36 mm s^{-1}) are larger than were observed (0.28 mm s^{-1}) from the room temperature spectra of iron-doped chromium tungstates, and that the fits are not completely satisfactory (Table 1). This would appear to indicate that the iron tungstate spectra reflect the contributions of more than one iron species having slightly different environments. It seems reasonable that these spectra could arise from two iron(III) sites characterized by different quadrupole splittings and similar isomer shifts and this alternate fit (Table 1) is shown in Fig. 2(*a*).

Perhaps a more realistic description would be of a number of slightly different Fe(III) sites and such a model would be consistent with the structure of iron tungstate. The material is composed of "zig-zag" chains of edge-sharing oxygen octahedra with one-third of the chains containing only iron whilst the remainder comprise alternating W- and Fe-centred octahedra (4, 7, 8). Hence it is possible that there might be slight differences between the electric field gradients at the iron nuclei in the two types of chains.

However, Leiva *et al.* (7, 8) suggest the presence of a partially reduced iron species with delocalization of the d^6 electron of the Fe(II) over all iron atoms. If hopping due to this delocalization is slow on the Moessbauer time scale, then a separate Fe^{2+} doublet should be observed. No such doublet was detected. Rapid averaging of electrons between Fe^{2+} and Fe^{3+} environments should result in increased isomer shifts and quadrupole splittings. The data are not abnormal for Fe^{3+} environments so this second possibility is also unlikely. Since magnetic field strengths are very dependent upon oxidation states, spectra were recorded from materials of composition $Fe_{1.84}WO_{5.76}$ and

$Fe_{1.68}WO_{5.52}$ at 4.2 K. The latter, depicted in Fig. 2(*b*) can clearly be described as comprising six well-resolved lines which are expected from a magnetically ordered Fe^{3+} material. It is interesting that the linewidths in the spectrum from $Fe_{1.68}WO_{5.52}$ are larger than those from $Fe_{1.84}WO_{5.76}$. This implies that the higher concentration of iron and oxygen vacancies, which might be expected in the more iron-deficient solid, induces a small magnetic field distribution. Since iron(II) species exhibit much smaller magnetic hyperfine fields than those of iron(III) species, it seems that the Moessbauer data obtained at 4.2 K, and being typical for Fe^{3+} argue against the presence of significant concentrations of reduced iron species in these materials.

Iron–chromium–tungsten oxides

Iron chromium tungstates with nominal compositions of $Cr_{2-y}Fe_yWO_6$ ($0 < y \leq 2$) were prepared, and the products were examined by powder X-ray diffraction. Materials in which $y \leq 1.7$ gave powder X-ray diffraction patterns similar to that reported (14) for Cr_2WO_6 and characteristic of a trirutile-type material. Leiva *et al.* (7, 8) have determined the lattice parameters of similar solids and reported that the materials were solid solutions of iron in chromium tungstate. Materials containing greater concentrations of iron were reportedly multiphasic. Our current data are consistent with those previous reports (7, 8), since powder X-ray diffraction patterns for samples of nominal compositions $1.7 < y < 1.9$ showed evidence for the presence of two phases with structures based on those of chromium tungstate (14) and iron tungstate (4). Although powder X-ray diffraction detected traces of $Fe_{1.95}Cr_{0.05}O_3$ in the solid, when $y = 1.95$, rather than a chromium tungstate-type phase, this does not necessarily imply that solid solution formation of Cr in iron tungstate has occurred. Indeed, given the poor sensitivity of powder X-ray diffraction to minor phases, it would be more reasonable to assume that the concentration of the Cr_2WO_6-type material detected in all other iron-rich solids has merely decreased beyond the detectability limit of the technique.

The Moessbauer data recorded at 298 and 4.2 K of the iron–chromium–tungsten oxides are summarized in Table 2. The chemical isomer shifts, δ, and quadrupole splittings, Δ, recorded at room temperature, are characteristic of iron(III) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

only slightly distorted octahedral environments. The first order approximation of the quadrupole splittings as defined in ref. 15 was used

$$[1] \quad \epsilon = \frac{e^2qQ}{4} \frac{(3\cos^2\theta - 1)}{2}$$

to determine θ, the angle between V_{ZZ} and the axis of magnetization. The quadrupole interaction (ϵ) was calculated from the line positions (x) in the liquid helium temperature spectra with the help of expression (16)

$$[2] \quad \epsilon = \tfrac{1}{8}[2(x_1 + x_6) - (x_2 + x_3 + x_4 + x_5)]$$

An inspection of the data in Table 2 indicates that both ϵ and θ are generally independent of y in $Cr_{2-y}Fe_yWO_6$ although it is apparent that θ is greater than zero, the value found for Cr_2WO_6 (17). However, it is notable that the quadrupole interaction (ϵ) is larger in the iron tungstates, containing no chromium, than in the series $Cr_{2-y}Fe_yWO_6$ and this is consistent with the room temperature quadrupole splitting data (Table 1). The independence of the Moessbauer parameters, ϵ and θ, from y in the iron–chromium tungstates might seem surprising given that Moessbauer studies of other mixed metal oxide systems, in which chromium may be replaced by iron (1, 10, 18), have revealed novel relationships between relative concentrations of iron and chromium and the Moessbauer parameters, especially ϵ, θ (10, 18), and in some cases T_N, H, and Δ (9). The quadrupole splittings and chemical isomer shifts of the $Cr_{2-y}Fe_yWO_6$ series are also largely independent of the concentrations of iron and chromium, although Δ does appear to undergo a generally decreasing trend with increasing Cr content. This may reflect the decreased lattice distortion as detected by diminishing lattice parameters (7, 8).

It is interesting, however, that an inspection of the data pertaining to the magnitude of the effective magnetic field at the iron nuclei (Table 2) reveals different behaviour. It appears that increasing iron content is accompanied by a concomitant increase in H until the magnitude of the magnetic field strength exceeds that in ternary iron tungstate. However, it should be pointed out that, for values of $2 - y < 0.8$, the ordering temperature might be such that a fully developed hyperfine field is not observed at 4.2 K. Thus the data from iron chromium tungstates contrast markedly with that from the $Fe_{2-x}Cr_xTeO_6$ system in which H is independent of the Fe:Cr ratio while ϵ and θ show strong correlations. The large linewidths observed in the spectra of some of the materials are perhaps not surprising in view of similar data elsewhere (10) and reflect a field distribution induced by imperfect ordering of Fe and Cr.

Molar entropies at 80 K of sub-monolayer nitrogen films adsorbed on graphite from heat capacity measurement[1]

AKIRA INABA AND HIDEAKI CHIHARA

Department of Chemistry and Chemical Thermodynamics Laboratory, Faculty of Science, Osaka University, Toyonaka, Osaka 560, Japan

Received August 25, 1987

This paper is dedicated to Professor James A. Morrison

AKIRA INABA and HIDEAKI CHIHARA. Can. J. Chem. **66**, 703 (1988).

The heat capacity of nitrogen adsorbed on an exfoliated graphite (Grafoil GTA) has been measured between 3 and 80 K at surface coverages of $\frac{1}{6}$, $\frac{1}{3}$, $\frac{1}{2}$, $\frac{2}{3}$, and $\frac{5}{6}$ layers. The molar entropies are determined at 80 K. The effect of energetic heterogeneity of the graphite surface seems to be much less than that expected from the measurements of heats of adsorption. The isosteric heat of adsorption at zero coverage $q_{st}(0)$, for a hypothetical homogeneous graphite surface is estimated to be 9.8 kJ mol^{-1} at 80 K, which is in good agreement with that obtained from simulations performed at 75 K, 9.9 kJ mol^{-1}.

AKIRA INABA et HIDEAKI CHIHARA. Can. J. Chem. **66**, 703 (1988).

Opérant entre 3 et 80 K, avec des couvertures de $\frac{1}{6}$, $\frac{1}{3}$, $\frac{1}{2}$, $\frac{2}{3}$ et $\frac{5}{6}$ de couche, on a mesuré la capacité calorifique de l'azote adsorbé sur un graphite exfolié (Grafoil GTA). On a déterminé les entropies molaires à 80 K. Il semble que l'effet de l'hétérogénéite énergétique de la surface de graphite soit beaucoup moindre que celle qu'on pourrait prévoir à partir de mesure des chaleurs d'absorption. À 80 K, on a évalué que la chaleur isostérique d'adsorption à une couverture nulle, $q_{st}(0)$, pour une surface de graphite hypothétique homogène, est égale à 9,8 kJ mol^{-1}; cette valeur est en bon accord avec celle (9,9 kJ mol^{-1}) qui a été obtenue grâce à des simulations effectuées à 75 K.

[Traduit par la revue]

Introduction

Over the past decade, exfoliated graphite has become popular in adsorption studies (1) as one of the most appropriate substrates to meet conflicting requirements: large specific surface area and small extent of surface heterogeneity. The former makes it easy to do a variety of experiments and the latter allows us to distinguish properties intrinsic to adsorption on perfect substrates from those due to substrate heterogeneity. While a number of structural and other investigations have been made of molecular films physically adsorbed on this kind of graphite, much less attention has been paid to the energetics of adsorption prior to recent extensive work by Morrison and co-workers (2–7). They developed an elaborate calorimetric technique to accurately measure differential (isosteric) and integral heats of adsorption, q_{st} and Q, over wide ranges of surface coverage and of temperature.

As a logical extension of their work, we recently developed a calorimeter to directly measure heat capacity of adsorbed films with requisite accuracy. Since a complete analysis of gross thermodynamic properties had been first made on the nitrogen-on-graphite system at 79.3 K (2), where the nitrogen film is in a fluid phase (8), our first investigation was to measure the heat capacity of that system between 3 and 80 K for sub-monolayer coverages. An ac technique developed by Chan and co-workers could resolve the heat capacity with a precision of ±0.2% in their measurements on nitrogen films between 18 and 70 K (9). However, it cannot determine the absolute value of the heat capacity or the molar entropy, as they pointed out.

In this paper we are mainly concerned with the molar entropies and compare those at 80 K determined from our heat capacity measurements with those derived from the measurements of heats of adsorption (2). Our calorimeter vessel and heat capacity data will be fully described elsewhere. It is suggested that such an examination of the thermodynamical consistency would lead us to a better understanding of intrinsic/equilibrium properties of the adsorbed films.

Experimental

The specimen of Grafoil GTA (6.21 g), which is commercially available (Union Carbide Corp.), was taken from the same roll that was used before for measurements of heats of adsorption (2). Its specific surface was determined to be 24 m^2 g^{-1} (2, 6). The sheets were packed tightly into the calorimeter vessel and heated under a vacuum better than 3×10^{-4} Pa at 400°C.

The calorimeter vessel used was constructed of copper, contained graphite adsorbent, and carried platinum and germanium resistance thermometers and a heater. A copper fine-tube attached to the calorimeter vessel was pinched off after introduction of the sample gas through it.

Nitrogen of special grade (minimum 99.9999%) was obtained from Takachiho Kagaku Co., Ltd. and was used without further purification. The amount of the gas to be introduced was determined by using a calibrated bulb (410 cm^3) and a Baratron gage (0–1000 Torr[2] type), both of which were connected to the filling system. The accuracy of the measurement of the amount of gas was better than ±0.2%. The monolayer capacity of the Grafoil for nitrogen as estimated by the B.E.T. method was $n_a = 0.25$ mmol g^{-1} (6).

Heat capacities were measured between 3 and 80 K for surface coverages of $\frac{1}{6}$, $\frac{1}{3}$, $\frac{1}{2}$, $\frac{2}{3}$, and $\frac{5}{6}$ layers. To prevent the films from forming any nonequilibrium/metastable phases prior to the measurements, the adsorbed system was held at 80 K overnight and then cooled down slowly, typically at 1 K min^{-1}. As indications of thermal relaxation or spontaneous release of energy could not be detected throughout the measurements, the films were assumed to be in their equilibrium state at each temperature. Some of the measurements were performed with the reheated graphite specimen to test whether the specimen had collected impurities. However, no significant effect could be seen in the molar entropies obtained. The heat capacity of the adsorbed films was determined from the difference between that of the calorimeter, adsorbent, and gas, and that of the calorimeter and adsorbent only. This difference was very small, for example amounting to 0.2% of the total heat capacity at 80 K in the case of $\frac{1}{6}$ monolayer coverage.

0.1665	81.5 ± 0.8
0.2051	74.5 ± 0.7

Results and discussion

Molar entropy determined from heat capacity measurement

The molar entropy S_a^C at 80 K was obtained from our experimental heat capacities and their extrapolation to below 3 K.

$$[1]\quad S_a^C(80\text{ K}) = \int_{3\text{K}}^{80\text{K}} (C/T)\,dT + S_a^C(3\text{ K})$$

where the heat capacity below 3 K was assumed to be represented by $C \propto T^2$. The results are summarized in Table 1 and plotted in Fig. 1 as a function of the coverage. An indication of the estimated error, which mainly came from the smallness of contribution to the overall heat capacity, is given by the vertical bars attached to specific plotted points. The initial decrease in entropy is usual and has been shown to be mostly due to the change in the configurational entropy S_c with coverage, which is represented by

$$[2]\quad S_c = R\left[-\ln\theta - \frac{1-\theta}{\theta}\ln(1-\theta)\right]$$

where θ is the surface coverage.

Molar entropy derived from heats of adsorption

From a knowledge of the free energy of adsorption (from the isotherm) and the heat of adsorption, the entropy S_a^Q of the adsorbed film can be readily calculated. The S_a^Q for nitrogen on Grafoil was calculated by Piper *et al.* (2) from their experimental data in the following way:

$$[3]\quad S_a^Q = S_g - \frac{Q}{T} - \frac{R}{V}\left(\int_0^V \ln p\,dV - V\ln p\right) - \frac{\alpha}{V}\int_0^V p\,dV$$

The entropy of the ideal gas, S_g, was calculated from the Sackur–Tetrode equation and the small corrections necessary for gaseous imperfection were made. Since their reference temperature of 79.3 K was chosen for convenience and has no particular meaning, the thermodynamic quantities that they obtained were converted to the values at 80 K to permit comparison between the two sets of values; their results at 80 K are also plotted in Fig. 1.

It is worth noting here that there are two factors involved in the evaluation of S_a^Q. One is that approach to equilibrium is a very slow process in adsorption experiments; in fact the slow temperature drift, either exothermic or endothermic, continues for hours, as reported for the ethylene/graphite system (7). The other factor is that if there is a hysteresis effect in the adsorption/desorption isotherm, the measurements of q_{st} would "see" only one branch of the hysteresis loop and would not correspond to the true equilibrium state.

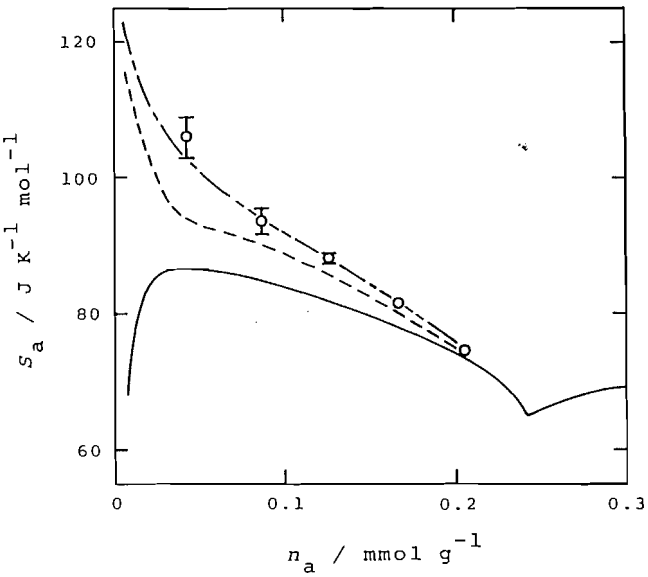

FIG. 1. Molar entropies of N_2 on Grafoil GTA at 80 K. ○, the present results; —, derived from experimental heats of adsorption (2); -------, estimate I; – – –, estimate II. See text for estimates I and II.

Comparison between the calorimetric and the isothermal entropies

It is evident that both the magnitude and the coverage dependence of the entropies S_a^Q of Piper *et al.* (2) are very different from S_a^C obtained from our heat capacity measurements, particularly at low coverages. In the case of bulk specimens, a difference between the calorimetric entropy and the statistical entropy, if any, is usually interpreted as indicating the presence of a zero-point entropy. In the present system, however, such an interpretation in terms of the existence of the zero-point entropy in the adsorbed nitrogen phase should be ruled out because $S_a^C > S_a^Q$.

It is evident from the initial decrease in q_{st} that there is some degree of surface heterogeneity. More active sites on the surface are therefore perferentially occupied by the adsorbed nitrogen, which may or may not be redistributed during the following equilibration process. The rationalization of the difference between the two entropies must be sought in the difference in state for which the entropy was measured and it could lead to better understanding of what is happening on the surface.

Thermodynamic consistency requires that the same value of the entropy should be obtained for the same state of aggregation of the same system. Therefore the fact that S_a^C is different from S_a^Q indicates that either the state or the system (or both) with which we are dealing in the two experiments must be different. With this in mind, there are several possibilities that need to be examined.

1. Surface conditions of graphite

The sample of graphite and its outgassing procedures were the same in both experiments. Furthermore, the results of the present experiment were completely reproducible. Even if there were some strategic impurities in the adsorbate gas that could be adsorbed preferentially on very active sites on the graphite surface, the discrepancy between S_a^C and S_a^Q cannot be explained because such impurities will be more strongly bound by the adsorbent, leading to a smaller heat capacity and therefore smaller S_a^C.

2. Lack of equilibrium

In the present experiment, almost all the nitrogen gas in the calorimeter was adsorbed at about 150 K during the cooling process and the calorimeter was aged at 80 K overnight; no appreciable heat effect was observed during the ageing process.

On the other hand, the "isothermal" adsorption at 80 K, as in the q_{st} measurements, is an extremely slow process with drifts of temperature and pressure continuing for hours. If the drift was not measured over a sufficiently long period, and if the exothermic drift was followed by an endothermic effect as was in fact observed in the case of ethylene on graphite, a possibility exists that the measured q_{st} was too large. A kind of ageing also took place in the q_{st} experiment because the calorimeter was cooled down to bring the temperature back to the predefined value. During such cooling the off-equilibrium could have been remedied but no monitoring was done. Lack of equilibrium at low coverages will have a persistent effect on S_a^Q for higher coverages becaue the q_{st} curve is integrated to obtain the integral heat of adsorption Q.

If the above hypothesis applies, it implies that the surface of the graphite has a much smaller degree of heterogeneity than one would assess from the coverage dependence of q_{st} (Fig. 2). We can then examine which q_{st}–coverage curve would reconcile the entropies S_a^C and S_a^Q.

Estimate I

A smooth extrapolation of q_{st}, which is illustrated by the dashed curve in Fig. 2, yields $q_{st}(0) = 10.4$ kJ mol^{-1}. In this estimate, the effect of too large q_{st} is assumed to become negligible beyond a surface coverage of $\frac{1}{6}$ layer. The corresponding integral heat of adsorption Q is plotted in Fig. 3. It should be noted that in the limit where $n_a = 0$, $q_{st}(0)$ and $Q(0)$ must be identical. We see that heats generated at low coverages are so large that their effect on Q makes a significant contribution even at higher coverages. It is evident from Fig. 1 that the S_a is even more sensitive.

Estimate II

Another estimate of $q_{st}(0)$ by a more or less linear extrapolation from higher coverages is possible, as illustrated by the dot-dashed curve in Fig. 2. Here the effect of off-equilibrium is supposed to remain up to $\frac{1}{3}$ layer. This estimate yields $q_{st}(0) = Q(0) = 9.8$ kJ mol^{-1} and reproduces our experimental molar entropies (Fig. 1) very well. As mentioned above, this behavior of the entropy is rather reasonable. Moreover, the estimated $q_{st}(0)$ at 80 K is in good agreement with that from the simulations performed at 75 K, 9.9 kJ mol^{-1} (10). Therefore estimate II gives a consistent overall picture of the properties of adsorbed nitrogen.

Although complete understanding of the behavior of the adsorbate at low coverages is still open to question, we believe that our values of molar entropies determined from the heat capacity measurements are acceptable for the intrinsic/equilibrium state of nitrogen films adsorbed on graphite.

Acknowledgments

This paper is dedicated to Professor James A. Morrison in appreciation of his friendship and of his distinguished contributions to science. We thank Mr. Tatsuya Shirakami for assistance with some of the experiments, and Professor J. A. Morrison and Professor M. L. Klein for helpful comments and guidance. Consideration of the influence of cholesterol on the physical properties of biological membranes leads to the conclusion that cholesterol increases the thickness of fluid membrane bilayers without appreciably increasing the microviscosity component of membrane fluidity. At sufficiently high cholesterol concentrations, the gel–liquid crystalline phase transition is completely eliminated in phospholipid–cholesterol mixtures and the system has the properties of a two-dimensional liquid over a wide range of temperatures. It is proposed that with the evolution of cholesterol and related sterols in an oxygen-rich atmosphere, the resulting modification of physical constraints on membrane properties made it possible for new evolutionary driving forces to manifest themselves leading to the peculiar properties of plasma membranes of eucaryotic cells.

MYER BLOOM et OLE G. MOURITSEN. Can. J. Chem. **66**, 706 (1988).

Si on examine l'influence du cholestérol sur les propriétés physiques des membranes biologiques, on est amené à conclure que le cholestérol augmente l'épaisseur des doubles couches des membranes fluides sans augmenter d'une façon appréciable la composante de la microviscosité de la fluidité de la membrane. A des concentrations de cholestérol suffisamment élevées, la transition de la phase cristalline gel–liquide est complètement éliminée des mélanges phospholipide–cholestérol et, pour un grand intervalle de températures, le système possède les propriétés d'une liquide bi-dimensionnel. On est amené à proposer que, avec l'évolution du cholestérol et des stérols apparentés dans un atmosphère riche en oxygène, la modification qui résulte de contraintes physiques sur les propriétés de la membrane fait qu'il est possible pour de nouvelles forces évolutionnaires de se manifester; ceci provoque l'apparition de propriétés particulières pour les membranes plasmatiques des cellules eucaryotices.

[Traduit par la revue]

Introduction

The nature of the three-dimensional structure of integral membrane proteins (1–3), the insights on the molecular evolution of cholesterol provided by Bloch (4–6), and the interpretation of deuterium nuclear magnetic resonance (^{2}H nmr) studies of the interaction between phospholipid molecules and integral membrane proteins (7–11) lead us to propose that the presence of cholesterol, or related sterols where appropriate,[1] modified the physical properties of membranes in a manner which was crucial to the evolution of eucaryotic cells into their present form.

At least two stages of membrane evolution have taken place. The *first stage* accounts for most natural membranes which do not contain cholesterol such as those of procaryotic cells and most organelles of eucaryotic cells. The *second stage* involves the evolution of eucaryotic cells or, at least, the plasma membranes of eucaryotic cells, upon the accumulation of oxygen in the atmosphere (12). The lipid composition of the plasma membranes of eucaryotic cells invariably includes a substantial fraction of cholesterol. Furthermore, Bloch (4, 5) has demonstrated that cholesterol evolved upon the appearance of oxygen in the atmosphere. He has speculated that the biological advantage associated with cholesterol may be due to the "reduced fluidity" or "increased microviscosity" which, it is claimed (13) the addition of cholesterol imparts to the liquid crystalline state of phospholipid bilayer membranes.[2] The discovery of hopanoid, triterpene derivatives in some procaryotic cells and in the form of "molecular fossils" of ancient times has led to the suggestion (14, 15) that these relatively rigid, anaerobically evolved, amphiphilic molecules play a similar "membrane reinforcement" role in some procaryotes to that played by aerobically evolved sterols such as cholesterol in eucaryotes.

In this paper, we propose that the biosynthesis of cholesterol in an aerobic atmosphere removed a bottleneck in the evolution of eucaryotic cells. Our proposal, which concerns a crucial evolutionary role played by the physical properties of membranes, can be related to the broad, phenomenological characterization of the evolution of eucaryotic cells given by Cavalier-Smith (16, 17). He identifies "twenty-two characters universally present in eucaryotes and universally absent from procaryotes" and presents detailed arguments that, of these, the advent of exocytosis (and endocytosis) is the most likely to have provided the driving force for the evolution of eucaryotic cells into their modern form. As described below, we have been led via an unconventional interpretation of measurements of physical properties of membranes to identify a possible physical bottleneck to cytosis which was removed by the appearance of cholesterol. We hypothesize that, in addition to influencing the cohesive strength of membranes, the main role of cholesterol in this evolutionary step was to relax an important constraint on

[1]The word "cholesterol" as used in this paper should sometimes be interpreted as "cholesterol or related sterols". The "related sterols" may be ergosterol in plants or precursors to cholesterol and ergosterol such as lanasterol or cycloartenol (5).

[2]Although we are concerned here with the influence of cholesterol on the physical properties of membranes, it should be noted that cholesterol may play a role in metabolic functions as well (5).

membrane thickness imposed by the biological necessity of membrane fluidity. In attempting to establish the validity of our hypothesis, we have been confronted with a remarkable lack of relevant information on basic physical properties of membranes. The filling of this information vacuum will lead to a better understanding of membrane properties in addition to checking our hypothesis.

Relationship between membrane evolution and cellular evolution

It is generally agreed that *procaryotic* cells came into existence almost 4×10^9 years = 4 GA ago (1 GA = 10^9 years). Procaryotic cells have only a single membrane and no nucleus. By contrast, most eucaryotic cells which exist today contain many organelles, each encapsulated within its own membrane. Our knowledge of the evolutionary relationship between procaryotic and eucaryotic cells is very fuzzy but it has advanced considerably during the past decade (18). Ten years ago, it was believed (19) that a procaryotic host cell spawned the first eucaryotic cell about 1.5 GA ago, approximately the time at which the earth's hydrosphere is thought to have become oxidizing (20). Cogent arguments have been made that the procaryotic to eucaryotic step occurred via a sub-line of wall-less anerobic procaryotes that gained the capacity for endocytosis (16, 17, 19). It is now known that there exist two distinct kingdoms of procaryotes called "eubacteria" and "archaebacteria" (18). These bacteria have quite different cytological and physiological properties from each other, operate optimally under different environmental conditions and have only distant and uncertain evolutionary linkages (18). If they do have a common ancestor, they parted in the early stages of cellular evolution. Furthermore, from an evolutionary standpoint, eucaryotic cells are as distant from eubacteria and archaebacteria as each of them is to the other.

The impetus to the more quantitative and searching examination of evolutionary connectivity at the cellular level that has taken place in recent years has been supplied by the development of new methods of quantitative analysis of sequences of nucleic acids. In particular, the nucleic acid sequencing of ribosomal RNA (rRNA) has proven to be an effective molecular chronometer over the time scales, of order GA, of importance in bacterial and cellular evolution. In a recent comprehensive review of the subject, Woese (18) predicts that nucleic acid sequencing will stimulate greatly expanded knowledge of cellular evolution in the near future.

A real understanding of the evolution of any biological system requires not only knowledge of changes in genetic characteristics but also insight into the interaction between the biological system and its surroundings. Whether or not a random change in the genes gives rise to a viable biological modification or not is determined by the environmental interactions. Contact between a cell and its surrounding environment is mediated by the plasma membrane, i.e. the outer membrane of the cell. Systematic differences exist between the composition of the plasma membranes of eubacteria, archaebacteria, and eucaryote cells (18, 21). We believe that these differences have an important evolutionary significance. We are now able to attempt an explanation of the relationship between membrane evolution and cellular evolution for eubacteria and eucaryote cells because of improvements in our understanding of the physical properties of biological membranes which have taken place during the past decade. We shall not discuss archaebacteria, partly because the characterization of the physical properties of their membranes has not yet been adequately developed (21). More important, the phospholipid composition of the plasma membranes of eucaryotic cells resembles that of eubacteria but not that of archaebacteria. Thus, if our proposals concerning the importance in the evolution of eucaryotic cells of the modification of the physical properties of their plasma membranes by sterols are confirmed, this would imply a closer evolutionary relationship between eucaryotic cells and eubacteria than archaebacteria.

Relationship between biological activity and membrane fluidity, microviscosity, segmental orientational order, rigidity, and thickness

It is now widely recognized and accepted that biological activity requires that membranes be in their fluid (liquid crystalline) state. When characterizing membrane fluidity, various authors sometimes use terms such as rigidity and microviscosity without adequately defining them, and often they are used in different senses. The confusion in describing the mechanical properties of membranes is caused by the conspicuous anisotropic nature of bimolecular fluid membrane sheet. To avoid ambiguities we shall here clarify the use of these terms and then review the influence of cholesterol on membrane fluidity.

Pure phospholipid bilayer membranes undergo a phase transition upon heating from a solid "gel" phase to a fluid "liquid crystalline" phase. The phase transition is accompanied by two major dramatic changes (7, 22): (*1*) increased conformational freedom and flexibility of the acyl chains leading to decreased segmental orientational order and decreased bilayer thickness, and (*2*) increased lateral diffusivity of the lipid molecules parallel to the plane of the membrane and onset of a more rapid rotational diffusion about the long molecular axis corresponding to decreased microviscosity. The higher *fluidity* of the high temperature phase is therefore caused by changes in two different components, namely orientational order and microviscosity.

In the case of pure phospholipid bilayer model membranes, there is a strong correlation between orientational order and microviscosity but this is not always the case. A prominent example central to our theme is that the introduction of cholesterol into phospholipid bilayer membranes increases the orientational order[3] but does not increase the microviscosity appreciably (24–26). The requirement of fluidity for biological activity should therefore be interpreted in terms of the microviscosity aspect of fluidity.

This interpretation of the influence of cholesterol is different from that given by Dahl *et al.* (13). They found a correlation between the biological viability of various sterols in the cholesterol evolutionary chain and increased "microviscosity". However, this correlation was made on the basis of steady state polarized fluorescence measurements. It is now known that such measurements on an anisotropic system do not actually measure microviscosity but rather a combination of microviscosity and the orientational order of the fluorescent probe (27, 28). A fluorescence depolarization study of membranes containing cholesterol has been carried out recently and the results analysed

[3]The associated decrease in the average membrane surface area per polar head is often called "condensation" in the literature (see, e.g. ref. 23).

with the anisotropic orienting potential included (29). In the light of these results, we can now re-interpret the earlier fluorescence measurements as indicating relatively little influence of cholesterol on the microviscosity component of the fluidity while giving a substantial increase in thickness as indicated by the orientational order of the lipid chains.

In some cases the words "increased rigidity" have been used to characterize increased "orientational order" or "microviscosity". It is clear that both cannot always be correct. We would prefer to reserve the word "rigidity" in membranes as a description of the resistance of the bilayer to shear. Since the hydrophobic interior of a fluid membrane is well approximated as an incompressible fluid, small values of "area compressibility" imply small fractional changes in membrane thickness under a given change in stress. Evans and Needham (30) have shown that the addition of cholesterol (CHOL) to a sample of dimyristoylphosphatidylcholine (DMPC) vesicles resulted in a greatly reduced membrane area compressibility. At the same time, the phase transition was eliminated for molar ratios CHOL:(CHOL + DMPC) > 0.125, while the vesicles behaved like liquids with zero surface shear restoring forces even at temperatures well below the phase transition for pure DMPC. The combination of decreased area compressibility and zero surface shear restoring forces is perfectly compatible with the two dimensional character of the membrane fluidity.

A close relationship exists between the average orientational order parameter of the acyl chains and the membrane thickness (7, 10, 31) which makes it possible to estimate the membrane thickness using ^{2}H nmr measurements. Such estimates should be reasonably good whenever the symmetry axis for orientational averaging is normal to the bilayer surface, i.e. they would not be reliable for the gel phase of pure phospholipid bilayers where the chains are tilted with respect to the bilayer normal, but the estimates would be good for the liquid–crystalline phase or for the gel phase close to the melting point for membranes with impurities such as cholesterol present which remove the chain tilt.

The indirect determination of membrane thickness using ^{2}H nmr is potentially very useful since there seems to be no reliable direct means of measuring membrane thickness for either synthetic membranes with impurities or biological membranes. Direct measurements using diffraction methods require that the membrane samples be prepared in the form of good quality smectic liquid crystals having long range order so that several orders of Bragg reflection may be obtained. This has been achieved for pure phospholipid bilayer systems (32, 33) but seems to be difficult for impure systems judging from the absence of good experimental data. Even in the pure systems, some differences of opinion exist on the interpretation of the diffraction data.

A lattice model has been used (31, 34) to derive a relationship between the separation, d, of the first carbon atoms in the acyl chains of the two leaflets, each acyl chain having n C—C bonds, in terms of the maximum separation, $d_{max} = 2.5n$ Å, and the magnitude of the average acyl chain orientational order parameter, $\langle S \rangle$,

$$[1] \quad d = d_{max}\,(0.5 + |\langle S \rangle|)$$

The quantity $|\langle S \rangle|$ is easily obtained from the average ^{2}H splitting of lipids with perdeuterated acyl chains, i.e. from the first moment of the distribution of quadrupolar splittings (35, 36).

Although the lattice model leading to eq. [1] is a simple one, its predictions are in agreement with neutron diffraction studies of ^{2}H-labelled phospholipid acyl chains in model membranes (37). Furthermore, the value of $|\langle S \rangle| = 0.164$ at 50°C for dipalmitoylphosphatidylcholine (DPPC) combined with the value of $d = 26$ Å at 44°C from the X-ray diffraction experiments of Lewis and Engelman (33) would require a value of $d_{max} = 39$ Å corresponding to $n = 39/2.5 = 15.6$, a very reasonable value for an acyl chain of 16 carbons. Reasonable results are also obtained using the measurements of Cornell and Separovic (32) for DPPC.

The most complete measurements of the influence of cholesterol on ^{2}H nmr splittings in a model membrane have been made by Vist (38). His measurements confirm those reported previously by Stockton and Smith (23) and Oldfield (8). For example, the average ^{2}H nmr splitting in DPPC increases by about 60% at 50°C when 25% cholesterol is added (38) so that $|\langle S \rangle|$ changes from about 0.16 to about 0.26. According to eq. [1], this corresponds to a change in d from 26 Å to about 30 Å. Even more striking is the behaviour of erythrocyte membranes where the influence of the large cholesterol concentration was found to give rise to a fluid membrane down to −5°C (39). The average quadrupolar splitting of DPPC in the erythrocyte membranes increased monotonically between 50°C and −5°C to an effective hydrophobic thickness of $d \simeq 35$ Å which is approximately 90% of the maximum value attainable with fully extended acyl chains. Yet, the lipid component of erythrocyte membranes is fluid as indicated by their ^{2}H nmr spectra (39) and measurements of the lateral mobility of lipid probes (25).

In summary, then, we list the effects of physiological concentrations of cholesterol on phospholipid bilayer model membranes.

1. The gel–liquid phase transition is eliminated.
2. No static surface rigidity is observed over a wide temperature range indicating fluid-like macroscopic properties.
3. Translational and rotational diffusion constants are not strongly affected in the high temperature region indicating a fluid-like microviscosity.
4. The area compressibility is greatly reduced leading to greater cohesion and reduced permeability.
5. The orientational order increases indicating greater membrane thickness and "condensation" of the membrane lipids.

Membranes in procaryotic cells – the first stage of membrane evolution

Most biological activity takes place at moderate temperatures and, in particular, not at temperatures well above 37°C. A consequence of this is that biological membranes must operate at moderate temperatures. When combined with the requirement of fluidity, this implies that the thickness of bilayers composed of lipids extracted from membranes which do not contain cholesterol must fall within a narrow range of values. For example, lipid molecules with longer saturated acyl chains lead to thicker bilayers (33) but also higher gel–liquid crystalline phase transition temperatures. Thus, membranes composed mainly of longer lipids would be in the gel phase at moderate temperatures. Shorter lipids would not form stable bilayers. Longer lipids having unsaturated bonds give rise to thinner bilayers than saturated chains of the same length (33) so that the thickness of fluid bilayers of such lipids is not so different at moderate temperatures from that due to shorter saturated chains.

The structure and amino acid sequence of integral membrane proteins indicate that they are predominantly made up of a number of α-helical segments which span the lipid bilayer. On

the basis of known primary sequences and diffraction studies, it has been demonstrated that the positions of the hydrophilic and hydrophobic parts of integral membrane proteins tend to be correlated with their counterparts in the lipid molecules comprising the membrane bilayer (1–3). In addition, ^{2}H nmr studies on a large number of bacterial and reconstituted membranes (see, e.g. Table 6 of ref. 9) all gave the unanticipated result that $<S>$ of the acyl chains in the fluid phase was unaffected by the presence of physiological concentrations of proteins. These results lead to the following hypothesis which, we suggest, governs some important aspects of the evolution of membranes in procaryotic cells.

Hypothesis 1. Integral membrane proteins operate in an optimum manner in membranes whose natural hydrophobic thickness matches the hydrophobic thickness of the protein.

We have pointed out in a theoretical analysis of the significance of the matching of the hydrophobic regions of lipids and proteins (10) that the ^{2}H nmr experiments were all carried out on lipids and proteins whose hydrophobic thickness were approximately matched. Thus the addition of such proteins would not modify bilayer thickness, and hence $<S>$, providing that Hypothesis 1 was correct. Strong support of Hypothesis 1 also comes from studies of the activity of a variety of membrane enzymes (40, 41) and ion-channels (42) as a function of membrane thickness. By manipulating the bilayer hydropobic thickness either by changing the lipid chain length or by incorporating alkanes and anaesthetics (43, 44) it is invariably found that the activity is optimized at a certain thickness. Perhaps the most striking confirmation of Hypothesis 1 comes from a systematic study of the influence of an integral membrane protein on the phase transition temperatures of phospholipid bilayer model membranes having different acyl chain lengths (45).

The evolutionary driving force which leads to the validity of this hypothesis presumably comes from the superiority of a strain-free membrane, under normal operating conditions, for survival under changes in environmental conditions, e.g. changes in stress, and for the optimum function of protein dynamics in analogy with cytoplasmic proteins (46).

Although we have emphasized that life at moderate temperatures would promote membranes having a relatively narrow range of thickness values, it is well known that some species of procaryotic cells are viable at abnormal temperatures and pressures (see, e.g. ref. 47). Hypothesis 1 also applies to such systems, of course. Lipids capable of being fluid under a certain range of external constraints can provide the basis of cellular membranes providing that appropriate integral membrane proteins can be evolved which match their thickness.

Whatever the cellular system, the capacity of most of the integral membrane proteins to function properly will be severely limited if the stresses on the membrane are extended beyond the range within which the membrane retains its fluid property. We believe that a sensitive parameter in relation to membrane fluidity is membrane thickness. Pure lipids undergo large discontinuous changes in membrane thickness as a result of the gel–liquid crystalline phase transition. Thus, some physical processes which require large excursions in membrane thickness may tend to stimulate a phase transition. This would be true of mixtures of phospholipids with short and long chains because of phase separation effects.

It is striking that, although procaryotic cells were present in an anaerobic atmosphere for more than 10^9 years they did not evolve any cells with organelles and/or compartmentalized nuclear material. Anaerobic molecular evolution did take place in procaryotic cells. We suggest that although the recently discovered triterpene derivatives evolved and are capable of replacing some aspects of cholesterol's influence on membrane properties (14, 15), they lacked the ability possessed by cholesterol to facilitate a crucial stage in the evolution of the type of internal structures associated with eucaryotic cells.

Plasma membranes in eucaryotic cells — the second stage of membrane evolution

In his review of the distinction between the properties of procaryotic and eucaryotic cells, Cavalier-Smith (17) identifies twenty-two universal eucaryotic characteristics which are universally absent from procaryotic cells. It is likely that a small number of these characteristics, possibly a single one, represent the driving force for the evolutionary development of eucaryotic cells as we see them today. We propose here that, with the appearance of large amounts of molecular oxygen in the earth's atmosphere between 2.3 and 1.5 GA ago (20), a bottleneck in the evolution of eucaryotic cells was removed by the resultant incorporation of sterols in the plasma membrane.

In an earlier paper, Cavalier-Smith (16) argued that the advent of exocytosis (and endocytosis) which makes it possible for a cell to export (or import) material at a much faster rate, could provide the "evolutionary driving force" to explain the development of the other universal eucaryotic characteristics. He suggested that cytosis would have been inhibited by the rigid peptidoglycan cell wall present in many procaryotic cells and universally absent in eucaryotic cells (17). This would require the replacement of cell walls by a still strong, but more flexible plasma membrane. We propose here that the development of a plasma membrane having suitable physical properties only became possible with the appearance of molecular oxygen, which gave rise to the evolution of sterols leading to cholesterol and related sterols (4, 5). We propose in a second hypothesis below that the crucial physical property imparted to membranes by cholesterol was its ability, described in an earlier part of this paper, to increase the thickness of fluid membrane bilayers by a large amount without appreciably increasing the microviscosity component of membrane fluidity.

Hypothesis 2. The evolution of eucaryotic cells required the evolution of plasma membranes containing cholesterol or related sterols and thus capable of maintaining their fluidity and integrity as membranes over a wide range of external constraints.

Implicit in this hypothesis is the idea that the process of cytosis requires membrane stretching and/or changes of local membrane curvature which would disrupt the integrity of the membrane in the absence of fluid-like microviscosity. Such fluid-like properties would allow large membrane curvature without abnormal increases in permeability. Presumably, this desirable property would be facilitated by rapid redistribution of molecular species in response to local stresses as discussed recently by Sackmann *et al.* (48).

Eucaryotic cells are on the average one order of magnitude larger in linear extension than procaryotic cells. The mechanical strength required for supporting larger cells could well be provided by cholesterol-containing plasma membranes. In fact, it has recently been demonstrated in model membranes that for a given fluidity, vesicle fusion is facilitated and larger vesicles are stabilized for increased acyl chain orientational order induced by cholesterol (49).

Experimental considerations

Further support or rejection of the conjectures concerning membrane evolution presented in this paper will require more information on the thermodynamic, mechanical, and dynamic properties of mixtures of lipids, sterols, and proteins as well as natural membranes. Here are a few useful questions and studies which could be approached in the laboratory.

It would be of interest to complement the study of fluorescence depolarization measurements in membranes containing a series of precursors of cholesterol (13) with other measurements of the type discussed earlier in this paper such as ^2H nmr calorimetry, and micromechanics, where possible. If the evolution of sterols in membranes to the biologically optimized forms of cholesterol and ergosterol took place for the type of physical reason we have postulated, it may be possible to identify the crucial physical parameters from a systematic study of model systems. In this respect, some triterpene derivatives such as the hopanoid molecules should be included in the study since these molecules would be expected to be further removed from cholesterol in their crucial physical properties. Some scattered measurements on such properties have been reported, but we make no attempt to review them here since none of them represent complete studies and they have not been focussed in relation to our hypotheses.

It would be highly desirable to carry out a comparative study of the phase diagrams of a mixture of phospholipids with a selected hopanoid and with a selected primitive sterol such as lanosterol. This might explain the observation (50) that, with the exception of tetrahymanol in a ciliate, hopanoids, or similar cyclization products of squalene do not occur as components in membranes of eucaryotic cells.

Experimental studies of the phase diagrams of lipid–cholesterol mixtures have been carried out using a variety of techniques, including ^2H nmr (38, 51), electron spin resonance (52), electron microscopy (53), and micromechanical measurements on individual vesicles (30). In the case of DPPC–cholesterol mixtures, a new fluid phase, sometimes called the "B phase" (51), has been shown to occur at concentrations of cholesterol above about 22%. Between about 8% and 20% cholesterol, the system consists of a mixture of the B phase and either the gel phase for $T < 41°C$ or the liquid crystalline phase for $T > 41°C$. A theoretical analysis of the cholesterol–DPPC system (54) has led to a phase diagram capable of fitting the available experimental observations on the DPPC–cholesterol system (38, 51–53) very well (see Fig. 1). Ipsen *et al.* (54) have characterized the gel phase of the pure lipid as a "solid-ordered phase" (so) and its liquid crystalline phase a "liquid-disordered (ld) phase". The B phase is described as a "liquid ordered (lo) phase" in which the acyl chains are ordered due to the lipid–cholesterol interaction while two dimensional fluidity is retained. This ordering gives a fluid phase of higher cohesive strength (30), presumably because of the increased effectiveness of the van der Waals interactions between neighbouring lipid molecules. The B phase seems, therefore, to have desirable properties for the plasma membranes of eucaryotic cells. The B-phase membranes are fluid over a wide temperature range, corresponding to a large change in membrane thickness, and have great cohesive strength. They have no phase transition corresponding to the gel–liquid crystalline (so–ld) transition which occurs in the absence of sterols.

It is possible that the evolution of sterols in membranes was driven by the advantage of the B phase appearing at the lowest concentration of sterol. This conjecture should be easy to test

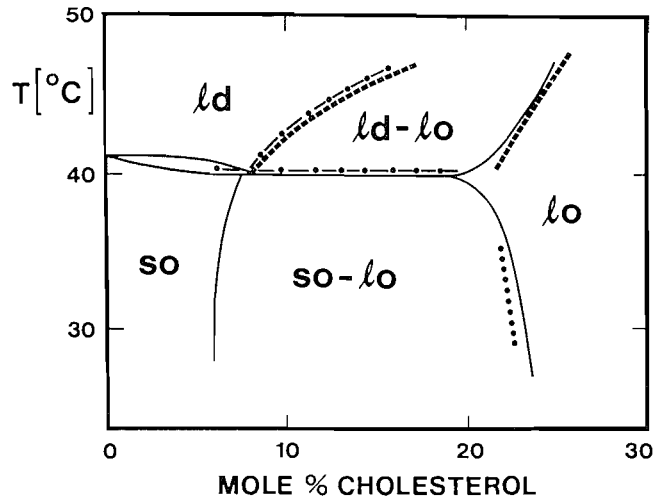

FIG. 1. Phase diagram for DPPC–cholesterol mixtures proposed by Vist (38) and Davis (51) and interpreted theoretically by Ipsen *et al.* (54). This diagram is based on a large number of experiments including several cited in this paper (30, 38, 51–53). The effect of the lipid–cholesterol interaction (54) is to stabilize, at high cholesterol concentrations, a "liquid-ordered" (lo) phase. At low cholesterol concentrations, the usually-discussed "solid-ordered" (so) (i.e. gel) and "liquid-disordered" (ld) (i.e. liquid crystalline) phases are obtained.

experimentally by carrying out careful measurements of the phase diagrams of mixtures of lipids and various sterols found on the evolutionary pathway to cholesterol and ergosterol (4, 5). For example, experiments are underway in the laboratory of one of us (M.B.) to compare the lowest concentration at which the B phase occurs with that of cholesterol in sterol–DPPC mixtures (Fig. 1). An interesting system to study in this way would be α-cholesterol–phospholipid mixtures. Dufourc *et al.* (55) have shown that the α-cholesterol molecule adopts a tilted conformation in phospholipid bilayer model membranes while the β-cholesterol ring structure lies with its plane parallel to the bilayer normal. They have speculated that this is why the β-cholesterol molecule occurs in natural systems while the α-cholesterol molecule does not. We ask here whether the tilt of α-cholesterol is less favourable to the stability of B phase and hence less favourable to the establishment of thermomechanical properties appropriate for plasma membranes of eucaryotic cells.

As described in various references cited in this paper, transient fluorescence depolarization and nmr relaxation measurements offer the possibility of determining the translational and rotational diffusion rates of lipid molecules and/or molecular probes in these same model systems. The relationship between such molecular dynamical properties and thermodynamic and mechanical properties is of great interest.

The methods described above can be applied to study some biological membranes though in some cases it will require the use of molecular probes in membrane extracts. It would be interesting to know whether there are systematic differences between the hydrophobic thickness of plasma membranes of eucaryotic cells and each of the membranes of organelles of the same cells and those of procaryotic cells. In the case of plasma membranes of eucaryotic cells, it would be highly desirable to also study the thickness of membranes formed from their separated lipids. Since plasma membranes have a large amount of polyunsaturated lipids (17), it may well be that the role of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

cholesterol is not to increase the membrane thickness, but rather to restore the thickness to values "normal" for saturated chains while imparting greater cohesive strength without changing the fluidity. Measurements of acyl chain orientational order carried out with perdeuterated fatty acid probes in erythrocytes (56) were in good agreement with those carried out later using perdeuterated phospholipid molecules. Such probes could be used in biological membranes in the experimental program outlined above.

It would also be of value to study cells which are abnormal in their cholesterol content. The cells of cancer tumours are an example (57).

Much insight into the structure of integral membrane proteins and how their geometry relates to membrane geometry is now obtained from the amino acid sequence, when available (1–3). It would be interesting to compare the amino acid sequences of membrane proteins of plasma membranes with those of the organelles of eucaryotic cells to check them as indicators of membrane hydrophobic thickness and/or variability of thickness.

Concluding remarks

As discussed near the beginning of this paper, the three known kingdoms of cells parted company early in the evolutionary history, as perceived via the rRNA molecular chronometer (18). The approximate dates at which eubacteria, archaebacteria, and eucaryotes diverged from each other are not known, however. Up to now, changes in nucleic acid sequences of rRNA have produced reliable information on the time-ordering of evolutionary events, but not on their tempo.

We can say, however, that procaryotic cells (eubacteria and archaebacteria) have existed for more than 3.5 GA, including the first GA in an anerobic atmosphere, without evolving any variants with internal compartments in the manner of what are now called eucaryotic cells. Furthermore, the plasma membranes in *all* eucaryotic cells characterized up to now contain sterols while essentially no procaryotic membranes contain sterols. Though the progenitor of eucaryotic cells may have evolved before the appearance of molecular oxygen in the atmosphere some 2.3 GA ago and the oxidation of the hydrosphere about 1.5 ago (20), the fact that the biosynthesis of sterols requires O_2 (4–6) implies unequivocally that the plasma membranes of eucaryotic cells evolved between 2.3 and 1.5 GA ago.

We have been led, following a detailed reconsideration of the striking effects of cholesterol on the physical properties of phospholipid bilayer model membranes, to postulate that these correlations and anti-correlations are no accident. We argue in this paper that prior to the appearance of cholesterol and related sterols, the available molecular building blocks for biological membranes were incapable of generating physical properties of a plasma membrane compatible with the evolution of modern eucaryotic cells.

The available data on physical properties of membranes are insufficient to test our argument adequately. It is not obvious at this time that molecules such as the cholesterol-resembling hopanoids, which evolved anaerobically in procaryotes and which are capable of replacing cholesterol in living systems under certain experimental conditions, were incapable of providing the physical properties necessary for facilitating special functions such as cytosis which could have provided the evolutionary driving force for eucaryotic cells. The subtle interplay between thermodynamic and micromechanical properties and rates of molecular motion which may be required to promote a process such as cytosis, while still maintaining membrane strength and permeability control, has not yet been examined carefully and exhaustively. When this is done, and it will require a considerable effort, it should be possible to demonstrate whether our hypothesis concerning eucaryotic evolution is correct or not. Whatever the outcome, the required experimental studies will generate considerable understanding concerning the systematics of the physical properties of membranes in relation to their biological function.

A few final words should be added about the relationship of our proposals to the well known and widely accepted symbiosis theory for the evolution of eucaryotic cells. We do not believe that our proposals are in disagreement with the symbiosis theory. On the contrary, it is unreasonable to expect cells to have evolved to the stage of being capable of swallowing an entire bacterium and allowing it to survive in its interior without having previously gone through a pre-bacterium-swallowing evolutionary phase, i.e. cells would first have had to develop and practice the swallowing facility on smaller objects. We have only dealt with this earlier stage in our paper. Whether subsequent internal incorporation of entire, smaller cells would *necessarily* follow such a development, and/or did actually follow it, must be settled by arguments and criteria other than those discussed here.

Acknowledgements

We thank Guy Cox, Ford Doolittle and Evan Evans for helpful discussions. We wish to dedicate this paper to Professor J.A. Morrison whose rigorous use of thermodynamics to characterize the physical and chemical properties of a variety of molecular systems is a model for the study of complex systems such as the biological membranes considered in this paper.

Molar excess volumes, isentropic compressions, and isobaric heat capacities of methanol – isomeric butanol systems at 298.15 K

TSUKASA OKANO, HIDEO OGAWA, AND SACHIO MURAKAMI[1]

Department of Chemistry, Faculty of Science, Osaka City University, 3-3-138 Sugimoto, Sumiyoshi-ku, Osaka 558, Japan

Received September 10, 1987

This paper is dedicated to Professor James A. Morrison

TSUKASA OKANO, HIDEO OGAWA, and SACHIO MURAKAMI. Can. J. Chem. **66**, 713 (1988).

Molar excess volumes, molar excess isentropic compressions, and molar excess isobaric heat capacities for binary liquid mixtures of methanol with 2-methylpropanol, 2-butanol, and 2-methyl-2-propanol have been determined at 298.15 K. The concentration dependence and magnitude of these thermodynamic functions are quite different from those of the methanol – 1-butanol system, which had been previously determined. Molar excess volumes for two of the present systems are positive over the whole concentration range, except for the 2-methyl-2-propanol system. For the latter system they are negative in the butanol-rich range. Molar excess isentropic compressions of these systems show slightly different concentration dependence from that of the excess volumes, but the order in magnitude resembles that of the excess volumes. Molar excess isobaric heat capacities for all systems are negative and show simple concentration dependence. The minimum values of excess heat capacities are correlated with the magnitude of molar isobaric heat capacities of the pure isomeric butanols. The behavior of these excess functions is discussed with reference to the differences in numbers and strength of hydrogen bonding between the pure liquid and the solution.

TSUKASA OKANO, HIDEO OGAWA et SACHIO MURAKAMI. Can. J. Chem. **66**, 713 (1988).

Opérant à 298,15 K, on a déterminé les volumes molaires en excès, les compressions molaires isentropiques en excès et les capacités calorifiques molaires isobares en excès des mélanges de liquides binaires formés d'une part de méthanol et d'autre part de méthyl-2 propanol, de butanol-2 ou de méthyl-2 propanol-2. La relation avec la concentration ainsi que l'amplitude de ces fonctions thermodynamiques sont très différentes de celles qu'on avait observées avec le système méthanol/butanol-1 qu'on avait étudié antérieurement. Les volumes molaires en excès de deux systèmes, excepté celui du méthyl-2 propanol-2, sont positifs à toutes les concentrations étudiées. Toutefois, avec ce dernier système, ils sont négatifs pour les concentrations riches en butanol. Par comparaison avec les volumes an excès, les compressions molaires isentropiques en excès de ces systèmes présentent des relations avec la concentration qui sont différentes; toutefois, l'ordre de grandeur resemble à celui des volumes en excès. Les capacités calorifiques molaires isobares en excès sont négatives pour tous les systèmes et la relation avec la concentration est simple. Il existe une corrélation entre les valeurs minimales des capacités calorifiques en excès et l'amplitude des capacités calorifiques molaires isobares des butanols isomères purs. On discute des comportements de ces fonctions en excès en fonction des différences dans les nombres et la force des liaisons hydrogènes entre le liquide pur et la solution.

[Traduit par la revue]

Introduction

Many years ago, various thermodynamic properties for mixtures composed of two different alcohols were reported in a series of papers (1–3) by Benson and co-workers. Recently, molar excess volumes, V^E, isentropic compressions, K_s^E, and isobaric heat capacities, C_p^E, for binary mixtures of methanol with ethanol, 1-propanol, and 1-butanol were measured at 298.15 K in our laboratory (4).

To discuss the thermodynamic behavior of mixtures composed of two different alcohols in further detail, the present paper reports the results of similar investigations of the binary liquid mixtures formed by mixing methanol (MeOH) with 2-methylpropanol (*i*-BuOH), 2-butanol (*s*-BuOH), and 2-methyl-2-propanol (*t*-BuOH).

Experimental

Materials

Special grade alcohols from Wako Pure Chemical Industries, Ltd. (Japan) were used as follows. MeOH, *i*-BuOH, and *s*-BuOH were stored over 3Å molecular sieves and fractionally distilled under a stream of N_2 gas. The *s*-BuOH was further vacuum distilled with 3Å molecular sieves. The *t*-BuOH was used without any purification, because no trace of impurities was detected by glc analysis. The water content in the pure samples used in this study was estimated to be less than 0.083 mol% in the same way as described in the previous paper (4).

[1]Author to whom correspondence may be addressed.

Apparatus and procedure

All measurements for systems of MeOH with *i*-BuOH and with *s*-BuOH were carried out at 298.15 K; those with *t*-BuOH were carried out at 299.15 K to avoid solidification of *t*-BuOH in the apparatus.

Excess volumes, V^E, and isentropic compressibilities, κ_s, for these mixtures were estimated from density, ρ, and speed of sound, u, measurements. Densities were measured by using a Picker vibrating densimeter (Sodev 01D, Canada) operated in the static mode. Speeds of sound were determined by means of a "Sing around" technique. All solutions were prepared in a specially devised bottle with same procedure as described previously (5). The error in the concentration of samples is estimated to be less than 3×10^{-5} in the mole fraction. Reproducibilities of ρ and u were better than 3×10^{-6} g cm^{-3} and 0.1 m s^{-1}, respectively.

Excess isobaric heat capacities, C_p^E, were measured by using a flow microcalorimeter constructed in our laboratory (6, 7), which can determine C_p^E accurately by the "direct mixing" method. The isobaric heat capacities C_p of pure component liquids were determined by a "delay loop" method at 298.15 or 299.15 K, in which the purified 1-propanol was used as a standard liquid and Kalinowska's C_p value was adopted at each temperature (8). The errors in C_p and C_p^E are estimated to be less than 0.2 and 0.05 J K^{-1} mol^{-1}, respectively.

The procedures followed in measurements have been described in detail in the previous paper (4). The physical properties of the pure component liquids determined in this study are listed in Table 1, with literature values of thermal expansion coefficients, α, used to calculate excess compressibilities, κ_s^E, of these mixtures.

Results

The experimental results for the present systems are summa-

rized in Tables 2 and 3. The results of u are listed in Table 2, in a form of Δu defined by

$$[1] \quad \Delta u = u - x_1 u_1^* - (1 - x_1) u_2^*$$

where x_i and u_i^* are the mole fraction and u of the pure component i, and subscripts 1 and 2 denote MeOH and isomeric butanol, respectively.

An excess thermodynamic function, X^E(V^E, K_s^E, and C_p^E) is defined by

$$[2] \quad X^E = X - X^{id}$$

where X is any thermodynamic function of solution and X^{id} is the ideal function, which obeys the ideal mixing law. Equations for calculation of these functions should be referred to in the previous paper (4).

Molar excess isothermal compressions, K_T^E, and molar excess isochoric heat capacities, C_V^E, for these mixtures were also calculated by combining the data of κ_s, C_p, V, and α for solution with those of the pure components. In these calculations, excess thermal expansion coefficients, α^E, for these systems were assumed to be zero because of the lack of α^E data, and the α values of solutions were approximated by using the α values of the pure components listed in Table 1. For ideal excess compressibilities, κ_T^{id} or κ_s^{id}, the rigorous definition was adopted, as recommended by Benson and Kiyohara (9) and Douheret *et al.* (10).

The excess functions X^E were fitted to the polynomial

$$[3] \quad X^E = x_1(1 - x_1) \sum_{i=1}^{n} A_i(1 - 2x_1)^{i-1}$$

by the least-squares method. The coefficients A_i are tabulated in Table 4 together with the standard deviations, s. V^E, K_s^E, K_T^E, and C_p^E are shown in Figs. 1–4, respectively. The curves in these figures were calculated from the A_i coefficients in Table 4. The difference in K_T^E calculated from the assumption of $\alpha^E = 0$ and $\alpha^E = -2\alpha^{id}V^E/V$ seems to be a little larger.[2]

The concentration dependence of C_V^E resembles that the C_p^E and the C_V^E value at equimolar concentration is less than the C_p^E value by 0.1 – 0.5 J K^{-1} mol^{-1} in magnitude; the difference in C_V^E from the values assumed for α^E as described above was also small.[3]

Discussion

A few thermodynamic studies of the methanol – isometric butanol systems have been carried out at 298.15 K. Murthy *et al.* (13) reported values of V^E for the *s*-BuOH system that are considerably larger than the present results. French and Criss (14) studied partial molar volumes and heat capacities of the *t*-BuOH system in the region of high dilution of *t*-BuOH, the signs of whose concentration dependence are in agreement with those of the excess partial molar quantities estimated from present results of V^E and C_p^E. However, it is not suitable to compare the magnitude of our results with their results because of a lack of data at high dilution. Our V^E results are in agreement with those of Polák *et al.* (1) within 0.005 cm^3 mol^{-1} at equimolar concentration. Polák *et al.* have determined excess Gibbs energies, G^E, excess enthalpies, H^E, and V^E for the present systems and discussed them in relation to the numbers and strength of intermolecular hydrogen bonding (1). Our V^E, K_T^E, and K_s^E results appear to support their thermodynamic discussion for these systems.

As shown in Figs. 1 and 2, V^E values in the isomeric butanol

[2][$\Delta K = K_T^E(\alpha^E = -2\alpha^{id}V^E/V) - K_T^E(\alpha^E = 0)$]
$\Delta K(x_1 = 0.5)$ is nearly −48 (*n*-BuOH), −68 (*i*-BuOH), −58 (*s*-BuOH), and −68 (*t*-BuOH) cm^3 TPa^{-1} mol^{-1}.

[3][$\Delta C = C_V^E(\alpha^E = -2\alpha^{id}V^E/V) - C_V^E(\alpha^E = 0)$]
$\Delta C(X_1 = 0.5) \simeq 0.1$ J K^{-1} mol^{-1} for all the systems.

systems are quite different from each other, and the concentration dependence of K_s^E and the order of the absolute values for these systems resemble those of V^E very well. Strictly speaking, K_T^E can be related to V^E as described previously (4).

Polák suggests that the thermodynamic properties for the *s*-BuOH system, ($H^E < 0$ and $V^E > 0$), are due to the geometrically worse packing of mixed associate species in solution. K_T^E for this system are larger positive values than those of the *i*-BuOH system, as shown in Fig. 3. The positive V^E and K_T^E values suggest loosely packed, easily compressible molecules in solution. This then indicates that by mixing MeOH with *s*-BuOH, there is formation of hydrogen bonds between unlike alcohol molecules ($H^E < 0$) and loosely packed associate spe-

cies ($V^E > 0$), and a decrease of volume expansion in mixing under higher pressure ($K_T^E > 0$).

A similar situation occurs at the MeOH-rich range of the *t*-BuOH system. When hydrogen bonding between unlike molecules takes place in this region, the bulky *tert*-butyl group in the *t*-BuOH molecule brings about the loose packing of molecules in solution and makes a positive contribution to V^E, as in the *s*-BuOH system. However, this contribution will weaken under higher pressure, resulting in a large positive contribution to K_T^E.

On the other hand, for the range rich in *t*-BuOH in this

system, the average molecular distance will be decreased on adding MeOH, because the MeOH molecule penetrates into the void space formed by bulky BuOH molecules and the molecules in solution will be closely packed ($V^E < 0$) by the formation of hydrogen bonding between unlike molecules ($H^E < 0$). Consequently, V^E could not decrease significantly with increasing pressure and this gives a large negative contribution to K_T^E.

H^E is positive for the *i*-BuOH system and negative for the *s*-BuOH and *t*-BuOH systems, respectively. On the other hand, the H^E is positive and C_p^E is negative for the MeOH + *n*-alcohol systems (1, 4). C_p^E indicates the temperature dependence of H^E. From these results, it is predicted $C_p^E < 0$ for the *i*-BuOH system ($H^E > 0$) and $C_p^E > 0$ for the *s*-BuOH and *t*-BuOH systems ($H^E < 0$). However, as shown in Fig. 4, C_p^E values for all the systems are negative and show simpler concentration dependence than those of H^E. Absolute magnitude of C_p^E is in the order *t*-BuOH > *s*-BuOH > *i*-BuOH > *n*-BuOH.

C_p^E should not be attributed to the difference in numbers of hydrogen bonds on mixing, but depends rather on the difference in numbers of hydrogen bonds broken, with increase of temperature, between the pure state and the solution state. The order of the absolute magnitude of C_p^E appears to be in agreement with that of the formation of the strong hydrogen bond and to be reciprocal to that of the steric effect, by which unstable associate species are formed in liquid. The more the steric effect exists in the pure alcohol, the more the hydrogen bond is broken down with increase of temperature. On the other hand, relatively more stable mixed associate species are formed in the solution state, resulting in $C_p^E < 0$. This leads to the conclusion that the absolute magnitude of C_p^E at equimolar concentration is closely correlated to the C_p value in the pure isomeric butanols. In Fig. 5, C_p^E at equimolar concentration is plotted against C_p of isomeric butanol. The linear correlation shown in this figure supports the above discussion and is a good source of information about the solution properties.

Summing up, we have presented information about the behavior of the component molecules in mixtures of two different alcohols. We intend to discuss the local concentration fluctuation in the MeOH + *n*-alcohol and isomeric butanol mixtures by use of the Kirkwood–Buff theory in a forthcoming communication.

With typical pair potentials, a bond is stretched by vibrations along the bond directions, while contraction is caused by the tension set up by vibrations normal to the bond direction. The rôle of these two effects is studied in calculations for parallel linear-chain and zigzag-chain models. For linear chains and rigid zigzag chains, expansion is positive in the plane normal to the chain direction, although it may be strongly anisotropic in this plane. Expansion along the chain direction is negative, and typically an order of magnitude less than that normal to the chain. For a flexible zigzag chain with bond angle 90°, expansion is positive in all directions; the Grüneisen tensor is approximately isotropic, but elastic anisotropy leads to smaller expansion coefficients in the molecular planes. The Reuss-averaged Grüneisen function derived from (6–12) pair potentials is about 3.5 for most of the models; this is higher than observed experimentally in polycrystalline polyethylene, indicating the need for more realistic models of organic polymers.

RUTH MARGARET BARRON, THOMAS HUGH KENNETH BARRON, PAUL MALCOLM MUMMERY et MICHAEL SHARKEY. Can. J. Chem. **66**, 718 (1988).

Avec des paires typiques de potentiel, une liaison est allongée par des vibrations le long des directions de la liaison, alors qu'une contraction résulte d'une tension causée par des vibrations normales à la direction de la liaison. On étudie le rôle de ces deux effets dans des calculs sur des modèles de chaînes parallèles, linéaires ou en zigzag. Pour les chaînes linéaires ou en zigzag rigides, l'expansion est positive dans le plan normal à la direction de la chaîne, même si cette expansion peut être fortement anisotrope dans ce plan. L'expansion le long de la direction de la chaîne est négative et, d'une façon générale, elle est d'un ordre de grandeur plus faible que celle qui est normale à la chaîne. Pour une chaîne en zigzag flexible avec un angle de liaison de 90°, l'expansion est positive dans toutes les directions; le tenseur de Grüneisen est approximativement isotrope, mais l'anisotropie élastique conduit à des coefficients d'expansion qui sont plus faibles dans les plans moléculaires. La fonction de Grüneisen moyenne selon Reuss, obtenue à partir de paires (6–12) de potentiels, est à peu près égale à 3,5 pour la plupart des modèles; cette valeur est plus élevée que celle observée expérimentalement dans le polyéthylène polycristallin et elle indique qu'il est nécessaire d'avoir des modèles plus réalistes pour les polymères organiques.

Introduction

Modelling the thermal expansion of polymeric solids presents formidable difficulties, for two reasons: (*i*) there is usually a strong dependence on morphology and crystal imperfections; (*ii*) the ideal perfect crystals usually have complex structures, in which both the elasticity and the vibrations depend on interatomic forces that are imperfectly understood. In the necessity of providing theories to discuss experimental results, many different ad hoc simplifications, assumptions, and approximations have been employed (see, for example, the brief review of Gibbons (1); also Engeln *et al.* (2), Choy *et al.* (3), and references therein). In an attempt to clear up one area of uncertainty, we have begun at Bristol to make a systematic study of the behaviour of ideal polymer crystals and its dependence both upon structure and upon the nature of the interatomic forces, starting from the simplest models and aiming towards models representing real polymers. In this we have two aims in view: (*i*) to test approximations and so find out under what circumstances they are reliable; (*ii*) to build up a detailed understanding of the underlying mechanism of the behaviour of polymeric crystals.

Theory

Grüneisen parameters and the thermodynamic Grüneisen function

We use the technique of quasi-harmonic lattice dynamics, in which the vibrations are treated as harmonic but with frequencies that depend on strain.[4] The application of this technique to crystals with varying internal strain has been illustrated by Gibbons (4) for tellurium and by Barron and Pasternak (5) for quartz. In lattice dynamics the vibrational modes are labelled by wave vector $\boldsymbol{q}$ and polarization index j. The strain derivatives of the vibrational frequencies $\nu(\boldsymbol{q},j)$ are conveniently described by dimensionless Grüneisen parameters for each mode $\boldsymbol{q},j$:

$$[1] \qquad \gamma_{\alpha\beta}(\mathbf{q},j) = -(\partial \ln \nu(\mathbf{q},j)/\partial \eta_{\alpha\beta})_{\eta'}$$

where $\eta_{\alpha\beta}$ is a component of the strain tensor and the subscript η' denotes that the other components are kept constant during differentiation. For an isotropic material we need consider only the volume dependence:

$$[2] \qquad \gamma(\mathbf{q},j) = -\mathrm{d} \ln \nu(\mathbf{q},j)/\mathrm{d} \ln V$$

These quantities arise in expressions for the thermal stress brought about by an increase of temperature, and the thermal expansion is then determined by the elastic response to this stress.

The thermal stress for an isotropic solid is $-(\partial P/\partial T)_V$. The change in stress is a response to the increase in energy density: $(\partial P/\partial T)_V$ is small at low temperatures, when the heat capacity is small, and varies by orders of magnitude as the temperature is increased. We therefore use the thermodynamic Grüneisen function $\gamma(T,V)$, which gives directly the change in thermal

[1]Now at Merton College, Oxford.

[2]Author to whom correspondence may be addressed.

[3]Now at Department of Metallurgy, Oxford.

[4]Choy *et al.* (3) give "quasiharmonic" a different meaning (see following page).

stress with internal energy density:

$$[3] \quad \gamma(T,V) = [\partial P/\partial(U/V]_V$$

The volumetric thermal expansion is then given by

$$[4] \quad \beta = \gamma C_V \chi_T / V$$

where χ_T is the isothermal compressibility.

For anisotropic solids the thermodynamic Grüneisen function becomes a tensor:

$$[5] \quad \gamma_{\alpha\beta} = -[\partial t_{\alpha\beta}/\partial(U/V)]_\eta$$

where $t_{\alpha\beta}$ is the stress tensor and the subscript η denotes constant strain. The response to the thermal stress is then determined by the elastic constants. In Voigt (single suffix) notation (see, e.g., ref. 6), the thermal expansion coefficients are given by

$$[6] \quad \alpha_\lambda = \sum_\mu s^T_{\lambda\mu}\gamma_\mu C_\eta / V$$

where C_η is the heat capacity at constant strain and the $s^T_{\lambda\mu}$ are elastic compliances. For example, a negative expansion in the z direction, α_3, may arise either from a negative γ_3 (s_{33} is always positive), or from negative cross compliances s_{13} and s_{23} (7).

The rôle of central forces

In quasi-harmonic theory the thermodynamic Grüneisen function is obtained as the average of the mode Grüneisen parameters weighted by the contributions of each mode to C_η:

$$[7] \quad \gamma_{\alpha\beta} = \sum_{\mathbf{q}} \sum_j \gamma_{\alpha\beta}(\mathbf{q}, j)\, c(\mathbf{q}, j; T)/C_\eta$$

Each vibrational mode can thus be considered as contributing separately to the thermal stress and hence to the thermal expansion. Its contribution depends not only on its degree of increased excitation but also on anharmonic terms in the crystal potential. For a pair (central force) interaction, thermal stress can arise in the following two ways (3, 8, 9):

1. *Bond-stretching effect.* When the vibration involves a component of relative motion along the bond, a negative cubic term in the pair potential will give rise to a thermal stress tending to extend the bond length. This effect has also been given the names *compression* (8), *bond anharmonicity* (9), and *intrinsic* (3); the second of these is misleading, since *all* effects in thermal expansion are anharmonic.

2. *Tension effect.* When the vibration involves relative motion perpendicular to the bond, the mean interatomic distance increases, and the resulting increase in bond tension causes a thermal stress tending to contract the bond and so restore the mean interatomic distance to its equilibrium value. This effect has also been given the names *shear* (8) and *quasi-harmonic* (3); the latter is misleading because the bond-stretching effect also is given by quasi-harmonic theory. When the relative motion also has a component along the bond there is an additional tension effect of *rotation* (9): the varying tension in the bond tends to rotate the direction of the bond away from the direction of the relative motion. However, different vibrations cause rotations in different directions: the net effect is identically zero in crystals of cubic symmetry, and is probably small in other crystals. In the present paper we derive only the total tension effect, without attempting to identify the rotation component separately.

The interatomic potentials used in our models are of the form

$$[8] \quad \phi(r) = \phi_0 + \frac{1}{2!}(r-r_0)^2\phi_0'' + \frac{1}{3!}(r-r_0)^3\phi_0'''$$

and are determined by the parameters ϕ_0'' and $r_0\phi_0'''$. The relative strength of the bond-stretching and tension effects is proportional to the ratio $r_0\phi_0'''/\phi_0''$. The Mie/Lennard-Jones 6–12 potential gives this ratio as -21, and not very different values are found for other short-range potentials in common use (10). An isotropic crystal with only one type of interacting pair gives a temperature independent bond-stretching contribution to $\gamma(T,V)$ of $-(r_0\phi'''/\phi_0'')/6$, and hence 3.5 for the 6–12 potential. This can be compared to a maximum contribution at low temperatures of -0.74 for the tension effect in close-packed crystals, decreasing in magnitude to -0.43 at higher temperatures when the vibrations are directed on average more along the bond directions. Tension effects can become larger and even dominant in crystals of open structure, where there are many vibrations polarized well away from any bond directions, and in crystals (such as polymers) where there are interactions of greatly differing magnitudes (1).

These points are conveniently illustrated by the work of Choy *et al.* (3) and Engeln *et al.* (2). To represent the thermal expansion of polymers, Choy *et al.* employed a model of parallel linear chains, in which central forces were supplemented by a bending force constant to keep the chains stiff; the intrachain bonds were stronger than the interchain bonds by about three orders of magnitude. By an appropriate choice of force constants, a fair fit was obtained to the anisotropic expansion of crystalline polyethylene as estimated from experimental data (11). Choy *et al.* concluded that the negative expansion along the chains was due solely to the tension effect; conversely, the positive expansion perpendicular to the chains was due to the bond-stretching effect, with a negligible contribution from the tension effect. This last conclusion is surprising, in view of the appreciable tension contribution to the expansion of close-packed isotropic crystals, and will be investigated further in the present paper.

Engeln *et al.* (2) made independent measurements of the thermal expansion of polyethylene. For a highly crystalline isotropic sample they obtained $\gamma(T,V)$ values of about 2 at low temperatures, falling off at higher temperatures when higher frequency modes were excited. This they compared with a much higher theoretical estimate obtained in the following way. It was assumed that at low temperatures the vibrations were perpendicular to the chain direction, and thus depended on weak intermolecular forces assumed to be derived from a 6–12 potential. An increase in volume was taken to be solely due to the increase in interchain distances, which was therefore given by $\delta r/r = \frac{1}{2}\,\delta V/V$, rather than by the expression $\frac{1}{3}\,\delta V/V$ for interatomic distances in an isotropic solid. $\gamma(T,V)$ was thus derived (from the bond-stretching contribution) as $-(r_0\phi_0'''/\phi_0'')/4 = 5.25$.

This derivation raises several important issues. We note in passing that the experimental value of $\gamma(T,V)$ at low temperatures is uncertain; the results of White and Choy (11) obtained by extrapolation from samples of varying crystallinity suggest a value of about 2.7. The theoretical argument tacitly makes the Reuss approximation (1), which neglects any local stresses that may develop in the material as the anisotropic crystallites expand. It also takes no account of the complex crystal structure of polyethylene, in which the interchain forces are between hydrogen atoms rather than the carbon skeletons, and in which also we have the possibility of changing orientation of the skeletal planes; nor does it consider noncentral forces. Finally, it neglects two effects that can be expected even with central forces between parallel skeletal chains: the tension effect, and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

effect of interchain interactions that are not perpendicular to the chain direction (thus giving a different value of $\delta r/r$). It is these last two effects we now investigate.

Flexible linear chain polymers

To obtain readily a stable structure, the model was developed from the highly stable face-centered cubic (fcc) lattice. The polymer crystal is obtained by strengthening all the bonds that run in one particular nearest neighbour direction. This destroys the cubic symmetry, and gives a body-centered orthorhombic crystal of parallel flexible chains linked by weaker interchain forces between the other nearest neighbours. With the *c*-axis in the chain direction, and the *b*-axis along an interchain bond perpendicular to the chain direction, the orthorhombic unit cell dimensions for the original fcc geometry are given by

$$[9] \quad a = \sqrt{2}, \qquad b = c = 1$$

where the unit of length is the nearest neighbour distance. Because the force constants no longer have cubic symmetry, thermal expansion will be anisotropic even when the starting configuration is cubic.

Besides the cell dimensions, the other input parameters of the model are the atomic mass, M, and two different sets of the force constants ϕ_0'' and $r_0\phi_0'''$ for the interchain and intrachain bonds. In all the present calculations M was taken to be 50 amu, and the ratio $r_0\phi_0'''/\phi_0''$ to be -21 as given by a 6–12 potential. The interchain force constants were taken to be

$$[10] \quad \phi_0''(\text{interchain}) = 3 \text{ N m}^{-1})$$

and the nearest neighbour distance to be 1 Å. The intrachain forces were varied between 3 N m^{-1} (giving cubic symmetry) and 30 000 N m^{-1} (giving an essentially rigid bond). The results for cubic symmetry gave isotropic behaviour in agreement with earlier work on the fcc lattice (see above). As ϕ_0'' (intrachain) was increased, behaviour became strongly anisotropic. Figure 1 shows the temperature dependence of the Grüneisen functions when ϕ_0'' (intrachain) = 30 000 N m^{-1}. Very large negative values are obtained for γ_3; they are due to the tension effect, the contribution of the bond-stretching terms (~2) being negligible by comparison, in agreement with the conclusion of Choy *et al.* (3). In contrast, γ_1 and γ_2 have increased only slightly from their values in the fcc lattice. As in the fcc lattice, their values are due mainly to the bond-stretching contributions, although the negative contributions of the tension effect remain appreciable. Anisotropy in the *xy* plane is weak.

Two other Grüneisen functions are shown in Fig. 1. γ_{REUSS} is the volumetric Grüneisen function under conditions of isotropic stress, and is an average of the γ_λ weighted by the compressibilities in each direction:

$$[11] \quad \gamma_{reuss} = (\chi_1\gamma_1 + \chi_2\gamma_2 + \chi_3\gamma_3)/(\chi_1+\chi_2+\chi_3)$$

The compressibilities for the model are given in $(TPa)^{-1}$ by

$$[12] \quad \chi_1 = 17.7, \qquad \chi_2 = 11.8, \qquad \chi_3 = 1.18 \times 10^{-3}$$

Despite the high values of γ_3, χ_3 is so small that the term $\chi_3\gamma_3$ is small compared with $\chi_1\gamma_1$ and $\chi_2\gamma_2$. γ_{VOIGT} is the volumetric Grüneisen function under conditions of isotropic strain, and is a simple arithmetic average:

$$[13] \quad \gamma_{VOIGT} = (\gamma_1 + \gamma_2 + \gamma_3)/3$$

It is dominated by γ_3, and hence by the tension effect.

The thermal expansion coefficients are shown in Fig. 2. They are derived by means of eq. [6], using the relevant compliances

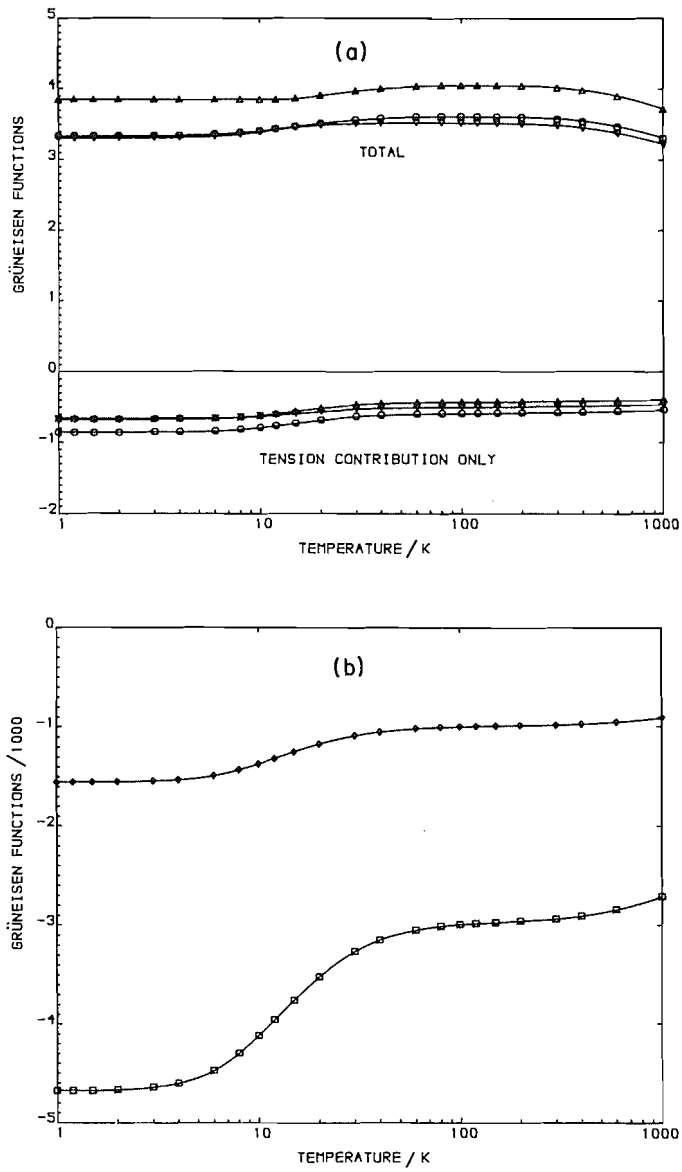

FIG. 1. Grüneisen functions for the linear chain model with cubic geometry and ϕ''(intrachain) = 30 000 N m^{-1}. (a) △, γ_1; △, γ_2; ○, γ_{REUSS}. (b) □, γ_3; ◇, γ_{VOIGT}.

of the static lattice; in Voigt notation, the compliances are given in $(TPa)^{-1}$ by

$$[14] \quad \begin{array}{ll} s_{11} = 29.4 & s_{12} = -11.8 \\ s_{22} = 23.6 & s_{23} = 0 \\ s_{33} = 2.36 \times 10^{-3} & s_{13} = -1.18 \times 10^{-3} \end{array}$$

The negative expansion in the chain direction is due to the tension effect. Despite the virtual incompressibility of the intrachain bonds, its magnitude is typically about 10% that of the expansion perpendicular to the bonds.

The negative values of γ_3 depend upon the magnitude of the tension produced by a given strain in the *c* direction, and hence are approximately proportional to the force constant ϕ_0''(intrachain). Reducing ϕ_0''(intrachain) to 300 N m^{-1}, we find γ_3 varying from about -44 at low temperatures to -26 at 200 K, with a further drop at higher temperatures as the intrachain modes become excited. However, until the intrachain modes are excited the values of γ_1 and γ_2 are very close to those given by ϕ_0''(intrachain) = 30 000 N m^{-1}; in each case the bonds

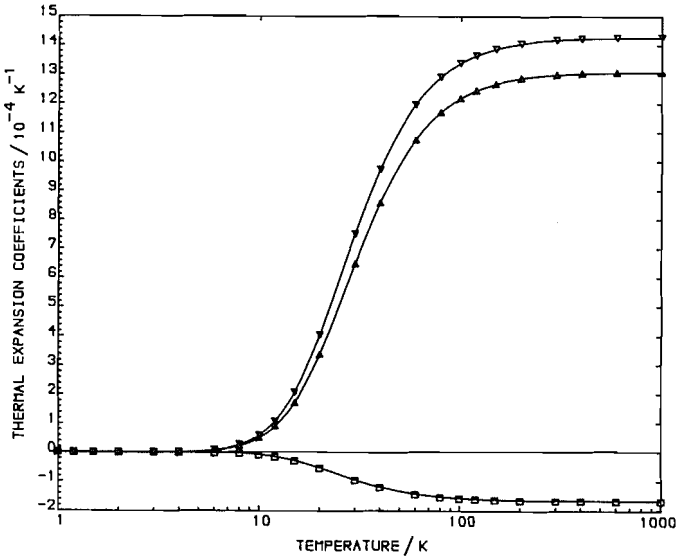

FIG. 2. Thermal expansion coefficients for the model of Fig. 1. ▽, α_1; Δ, α_2; □, α_3.

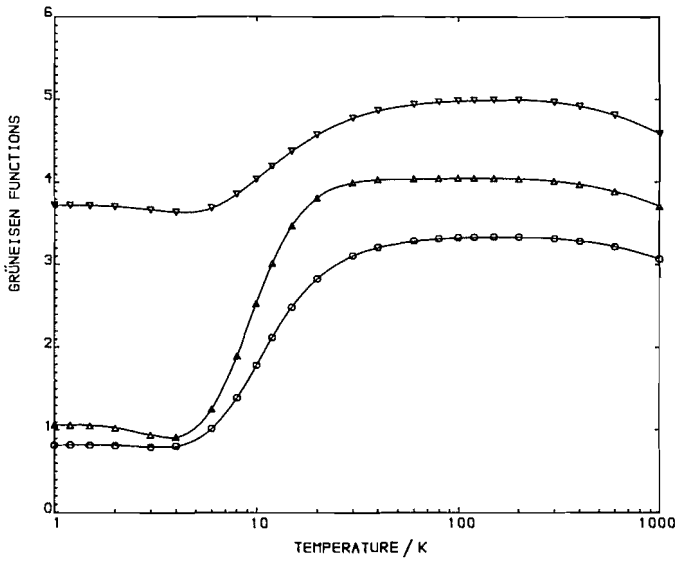

FIG. 3. Grüneisen functions for the linear chain model with the geometry of eqs. [16] and ϕ''(intrachain) = 30 000 N m^{-1}. ▽, γ_1; Δ, γ_2; ○, γ_{REUSS}.

are effectively rigid. We also see little change in the thermal expansion, even in the *c* direction, because although γ_3 is much smaller in magnitude and so gives rise to a lower thermal stress, the compressibility χ_3 is correspondingly larger. Each model corresponds closely to a system of light rigid rods freely jointed at their ends by massive bearings; the thermal motion causes the rods to librate as well as translate, so that the total length in the chain direction decreases.

We can now check whether the approximations used by Engeln *et al.* outlined above are valid for the present model. Since γ_{REUSS} is dominated by γ_1 and γ_2, it is a fair approximation to consider only those strains perpendicular to the polymer chains. But γ_1 and γ_2 are both considerably below the value of 5.25 assumed by Engeln *et al.* The tension effect contributes about −0.5 to the discrepancy. The remainder is chiefly due to the tacit assumption that the interchain interactions are perpendicular to the chain direction; in our model, four out of five bonds are at an angle of 60°, not 90°. A simple calculation shows that these bonds are longer than their interchain distance by a factor of 1/sin 60°, and also are stretched less by a factor sin 60°; allowing for this, the argument quoted by Engeln *et al.* would give a bond-stretching contribution to γ_{REUSS} of

[15] $5.25\,(\frac{4}{5}\sin^2 60° + \frac{1}{5}) = 4.20$

Adding the tension contributions gives an estimate for γ_{REUSS} of about 3.7, close to the computed value of about 3.6. There remains, however, an appreciable discrepancy between this value of 3.6 and experimental polycrystalline values of 2 and 2.7 (2, 11). One possible explanation is that local stresses are not wholly resolved in the experimental material, so that the relevant average of the γ_λ lies between γ_{REUSS} and γ_{VOIGT}.

To test these conclusions further, the geometry of the lattice was altered to make the interchain bonds more closely perpendicular to the chain direction. This was done by taking cell dimensions

[16] $a = 1.658$ Å, $b = 1$ Å, $c = 0.5$ Å

such that the intermolecular bond lengths all remained at 1 Å. Our expectation was that the values of γ_1, γ_2, and γ_{REUSS} would all increase from the values for cubic geometry, with little change in γ_3. In fact, the behaviour is more complicated (Fig. 3). γ_3 is indeed little altered and γ_1 is increased appreciably at high temperatures, and to a lesser extent at low temperatures, but γ_2 falls sharply at low temperatures. There is a large negative contribution from the tension effect to both γ_1 and γ_2 at very low temperatures, and γ_{REUSS} is decreased at all temperatures by appreciable weighting of γ_3 in the Reuss average, where the compressibilities in $(TPa)^{-1}$ differ markedly from those of eq. [12]:

[17] $\chi_1 = 4.11$, $\chi_2 = 8.79$, $\chi_3 = 5.03 \times 10^{-3}$

Admittedly, the model geometry is highly artificial, and possibly close to instability; it is unlikely to be realized by any real crystal. However, the results give warning that behaviour can be strongly dependent on structure, especially at low temperatures.

Parallel zigzag chain polymers

The crystal structure is shown in Fig. 4. The orthorhombic unit cell contains atoms at the points (0, 0, 0), $(ua, 0, \frac{1}{2}c)$, $(\frac{1}{2}a, \frac{1}{2}b, 0)$, $((\frac{1}{2} + u)a, \frac{1}{2}b, \frac{1}{2}c)$, and the geometry becomes face-centered cubic when $a = b = c$ and $u = \frac{1}{2}$. The parameter *u* is not determined by crystal symmetry, and so gives rise to an internal thermal expansion coefficient $\mathcal{A}_u = (\partial u/\partial T)_{\text{zero stress}}$.

In the cubic geometry, each atom has 12 equidistant nearest neighbours; two are in the same polymer chain, and interact strongly; the other 10 are in neighbouring chains. In place of angle forces, the bond angles are stiffened by second neighbour interactions ("struts") along the [001] direction. Calculations were also carried out with two geometries other than cubic, with bond angles of 109.5° (tetrahedral) and 120°, corresponding to ideal sp_3 and sp_2 hybridization in carbon chains. In these models the ratios *a:b:c* have been adjusted so that the interchain nearest neighbour distances remain equal to each other, although no longer equal to the intrachain bond length, which is held at 1.54 Å, a typical C—C bond length. The geometrical parameters of these models are given in Table 1.

In each model the atomic mass, *M*, has been taken to be 14 amu (the mass of a CH_2 group), $r_0\phi_0'''/\phi_0'' = -21$ for all interactions, and ϕ''(interchain) = 1 N m^{-1}. The other two force constants, ϕ''(intrachain) and ϕ''(strut), have been varied widely to give different types of polymeric behaviour. Face-centered

TABLE 1. Geometrical parameters of the zigzag chain models

Bond angle/degrees	u	a/Å	b/Å	c/Å
90.0	$\frac{1}{2}$	2.178	2.178	2.178
109.5	$\frac{1}{3}$	2.515	3.443	2.667
120.0	$\frac{1}{4}$	2.667	4.356	3.080

cubic symmetry is given by cubic geometry with

[18] $\phi''(\text{intrachain}) = 1\ \text{N m}^{-1}, \qquad \phi''(\text{strut}) = 0$

Flexible linear chains

Taking ϕ''(intrachain) = ϕ''(interchain), but making ϕ''(strut) much larger, gives parallel flexible linear chains with a different type of packing from the models of the preceding section. With cubic geometry the symmetry is tetragonal.

Results confirm our previous conclusions. At low and intermediate temperatures, γ_1 and γ_2 remain close to their fcc values, falling off at the highest temperatures when the strut vibrations become excited; γ_3 is strongly negative, due to the tension effect, and rises with temperature. The thermal expansion coefficients perpendicular to the chain, α_1 and α_2, are close to their fcc values at all temperatures down to 20°C, becoming smaller by some 20% at the lowest temperatures; α_3 is negative, in magnitude about 6% (high temperatures) to 15% (low temperatures) of α_1 and α_2.

Flexible zigzag chains

Taking ϕ''(intrachain) much greater than ϕ''(interchain), and ϕ''(strut) = 0, gives a polymeric crystal of flexible zigzag chains. At low temperatures the tension effect produces a large negative thermal stress along each strong bond, tending to decrease the distances between atomic sites along the chain. However, this need not lead to negative values of γ_3 or α_3, because almost all the stress can be relaxed by rearrangement within the unit cell.

Figure 5 shows the Grüneisen functions for a model with

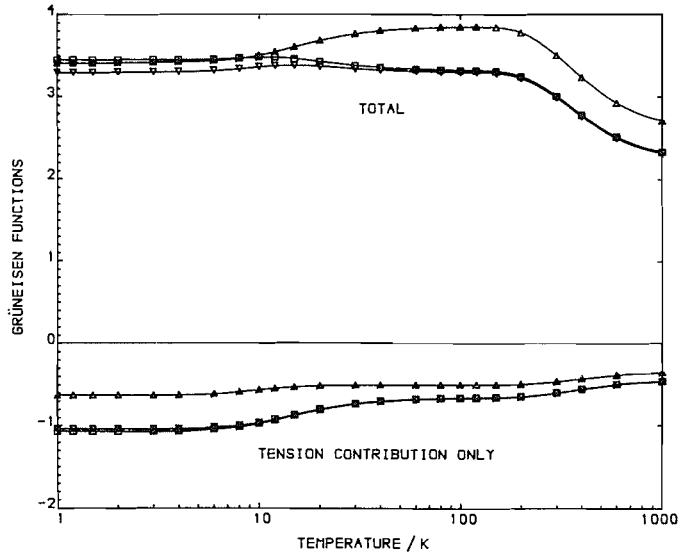

FIG. 5. Grüneisen functions for the flexible zigzag chains model with cubic geometry and ϕ''(intrachain) = 400 N m^{-1}. ▽, γ_1; Δ, γ_2; □, γ_3.

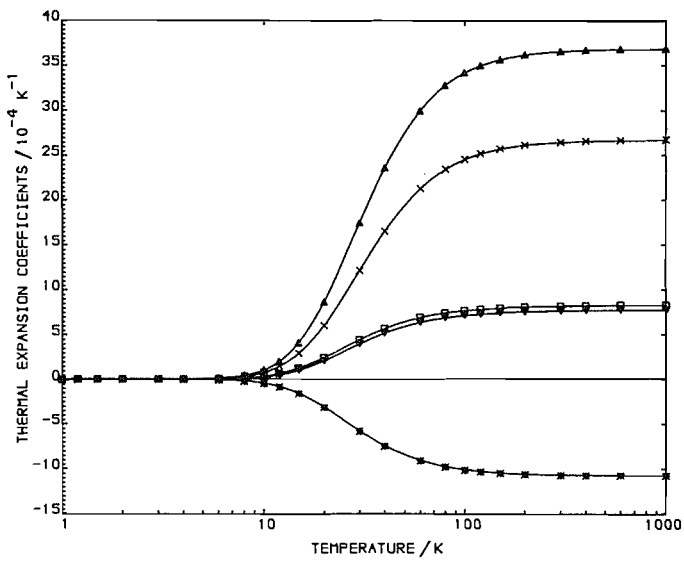

FIG. 6. Thermal expansion coefficients for the model of Fig. 5. ▽, α_1; Δ, α_2; □, α_3; ∗, $\mathcal{A}_u$; ×, α(fcc).

cubic geometry and ϕ''(intrachain) = 400 N m^{-1}. Differences from isotropic behaviour are fairly small; in detail, we note that it is the direction perpendicular to the planes of the molecules which is the odd one out, rather than the direction of the polymer chains. The decrease in the γ_λ at the highest temperatures is due to the excitation of intrachain bond-stretching modes.

Strong departures from isotropy are found for the thermal expansion (Fig. 6), with α_1 and α_3 reduced below fcc values and α_2 enhanced. This behaviour is associated with strong anisotropy in the cross compliances: in (TPa)$^{-1}$

[19] $s_{11} = s_{22} = s_{33} = 136.2$
$s_{23} = s_{12} = -27.3, \qquad s_{13} = -81.6$

Once again, it is the orientation of the molecular planes that appears to matter, and not the chain direction. The macroscopic behaviour would be little altered if the chain direction was taken along the *a*-direction.

The internal expansion coefficient $\mathcal{A}_u$ does, however, reveal

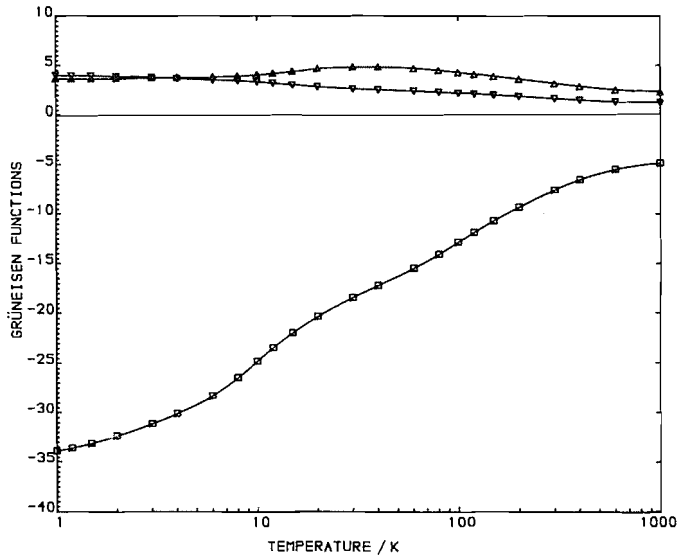

FIG. 7. Grüneisen functions for a stiffened zigzag chains model with tetrahedral bond angles and ϕ''(intrachain) = 400 N m^{-1}, ϕ''(strut) = 100 N m^{-1}. ▽, γ_1; △, γ_2; □, γ_3.

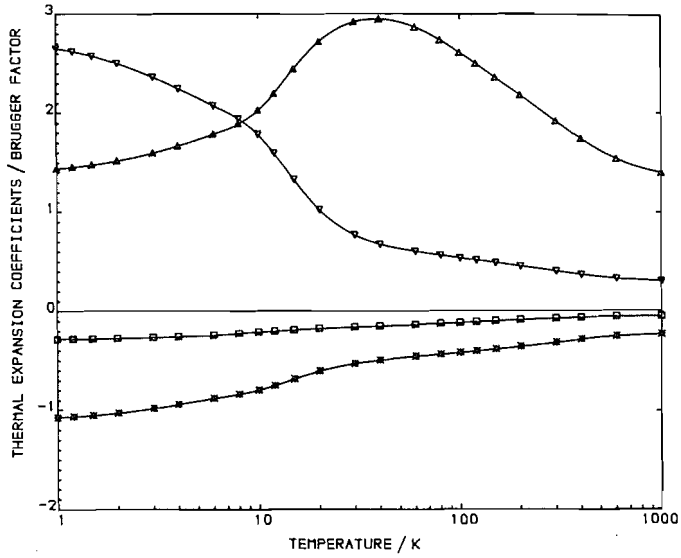

FIG. 8. Thermal expansion coefficients divided by the Brugger factor ($C_V\chi/V$), for the model of Fig. 7. ▽, α_1; △, α_2; □, α_3; ∗, $\mathcal{A}_u$.

dependence on the polymer chain direction. Its strong negative value is evidence of the opening of the angles in the polymer chain and the decrease in the chain width.

Calculations were also made for a model with the same force constants but with tetrahedral bond angles (Table 1). One effect is to enhance the difference between the values of γ_2 and the values of γ_1 and γ_3; at 150 K, $\gamma_1 = 3.2$, $\gamma_2 = 4.5$, $\gamma_3 = 3.0$. The main effect, however, is in the compliances and consequent thermal expansion. The compliances in (TPa)$^{-1}$ are now

$$\begin{array}{llll} & s_{11} = 270.6 & s_{23} = -16.3 \\ [20] & s_{22} = 97.4 & s_{31} = -189.2 \\ & s_{33} = 230.2 & s_{12} = -32.5 \end{array}$$

The balancing of terms of opposite sign in eq. [6] leads now to very small expansion in the chain direction; at 150 K,

$$\begin{aligned} &\alpha_1 = 6.8 \times 10^{-4}\,\mathrm{K}^{-1}, \\ [21]\quad &\alpha_2 = 13.2 \times 10^{-4}\,\mathrm{K}^{-1}, \\ &\alpha_3 = 0.8 \times 10^{-4}\,\mathrm{K}^{-1} \end{aligned}$$

Stiff zigzag chains

Taking both ϕ''(intrachain) and ϕ''(strut) much greater than ϕ''(interchain) gives a model of stiff polymer chains that might be expected to combine features of both the previous models. At low and intermediate temperatures the tension effect now produces negative thermal stresses along both the intrachain bonds and the struts. Stresses along the intrachain bonds can be relaxed as for the flexible chain by internal rearrangement within the unit cell, but those along the struts give rise to large negative values for γ_3.

Figure 7 shows Grüneisen functions for a model with tetrahedral bond angles and

$$\begin{aligned} [22]\quad &\phi''(\text{intrachain}) = 400\ \mathrm{N\ m^{-1}}, \\ &\phi''(\text{strut}) = 100\ \mathrm{N\ m^{-1}} \end{aligned}$$

The behaviour is broadly similar to that of the linear chain models, but with an increased anisotropy in the *ab* plane, due entirely to the bond-stretching contribution.

The elastic compliances are strongly anisotropic: in (TPa)$^{-1}$

$$\begin{array}{llll} & s_{11} = 115.7 & s_{12} = -45.9 \\ [23] & s_{22} = 96.3 & s_{23} = -0.064 \\ & s_{33} = 0.910 & s_{13} = -0.748 \end{array}$$

Combined with the anisotropy in the γ_λ and its variation with temperature, they give rise to a marked anisotropy in the thermal expansion coefficients. These are shown in Fig. 8, divided by the Brugger[5] factor $\chi C_\eta/V$ to reveal details of the low temperature behaviour. The magnitude of the expansion coefficients is markedly lower than for the fcc model.

The internal expansion coefficient $\mathcal{A}_u$ is again negative. At low and intermediate temperatures both the intrachain bond lengths and the strut length decrease with increasing temperature, due to the tension effect; since the bond length is shorter, its relative contraction is greater, so that the bond angle increases with temperature.

Calculations were also undertaken for two other models with the same values for the force constants but with bond angles of 90° (cubic geometry) and 120°. Broadly similar results were obtained, except that the expansion coefficients were lower for the model with the bond angle of 120°, and higher for that with the bond angle of 90°; probably this is because the crystal dimensions increase as the angle increases (Table 1), but the vibrations keep roughly the same amplitudes. The high temperature ratio α_2/α_1 was greatest for the model with bond angle 90°, for which α_2 remained greater than α_1 down to $T = 0$.

The stiffened zigzag chain thus behaves similarly to the flexible linear chain, except that there is greater anisotropy in the plane perpendicular to the chain direction.

Summary and conclusions

With linear chain polymers, and also with rigid zigzag chains, bond stretching causes a positive expansion in the intermolecular bonds; the negative tension effect is appreciable but smaller, so that the Grüneisen functions perpendicular to the chain direction have positive values of about 3.5; this is larger than for isotropic crystals, but considerably smaller than the value of

[5]The ratio $\alpha_\lambda V/\chi C_\eta$ is sometimes called the Brugger Grüneisen function (6, 12).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

5.25 sometimes quoted for a "bundle of tubes" model. Along the chain direction the Grüneisen function is dominated by the tension effect and is large and negative, giving rise to a negative expansion of typically an order of magnitude less than that in the perpendicular directions. This negative expansion persists even when the intramolecular bonding becomes infinitely strong, since it is due not to changes in bond lengths, but to the librations of the rigid bonds. In the present central force models, the tension effect also causes a contraction in the zigzag chain widths and an increase in the bond angle.

The behaviour of a flexible zigzag polymer is radically different, because the tension-induced thermal stresses can be largely relieved by adjusting the bond angle. In the model of Figs. 5 and 6, the Grüneisen tensor is almost isotropic, and the thermal expansion positive in all directions.

The model of Fig. 3 provides a warning against sweeping generalizations, especially when the geometry is unusual. Nevertheless, because central forces play an important rôle in all crystals, the general conclusions outlined above give a valid, if partial, interpretation of observed polymeric behaviour. To go further, we need to take account of noncentral forces, and of internal degrees of freedom due to chain substituents and polymer plane reorientation. A full interpretation will also have to consider the effects of morphology.

Models of picosecond-scale mobilities in glassy and polycrystalline quinoline

WALTER G. ROTHSCHILD

Physical and Chemical Sciences Laboratories, Ford Motor Co., Dearborn, MI 48121-2053, U.S.A.

Received September 28, 1987

This paper is dedicated to Professor J. A. Morrison

WALTER G. ROTHSCHILD. Can. J. Chem. **66**, 725 (1988).

The observed inhomogeneous band broadening of the 1033-cm^{-1} ir C—H in-plane deformation fundamental of quinoline in a glassy state and a polycrystal at 115 K was related to the theoretical concepts of the underlying vibrational T_2 processes. The motional narrowing model that fits best the spectral data and reflects the particular physical nature of the locally-ordered glass is the recently introduced stretched ("extended", "fractional") exponential $\exp[-(t/\tau)^{\alpha}]$. Extension of the model to shorter time regimes is discussed. The modulation model which simulates the corresponding spectral data and describes the longer-range order of the polycrystal is the damped oscillator $\exp(-t\gamma/2)[\cos\theta t + (\gamma/2\theta)\sin\theta t]$, previously proposed for oscillator – lattice mode coupling.

WALTER G. ROTHSCHILD. Can. J. Chem. **66**, 725 (1988).

La relaxation de phase de la vibration de déformation C—H à 1033 cm^{-1} observée en absorption infrarouge pour la quinoline à l'état vitreux et polycristallin (115 K) est analysée selon les concepts théoriques d'un processus de déphasage vibrationnel. L'exponentielle "étendue" $\exp[-(t/\tau)^{\alpha}]$ que nous avons récemment introduite comme fonction de modulation pour les corps amorphes localement structurés simule bien les données spectrales et rend compte du caractère particulier de l'état vitreux; nous discutons ici son application au régime des temps courts. L'oscillateur amorti $\exp(-t\gamma/2)[\cos\theta t + (\gamma/2\theta)\sin\theta t]$, connu depuis longtemps comme fonction de modulation en présence d'un couplage entre l'oscillateur et les vibrations du reseau, prédit le rétrécissement dynamique du spectre en relation avec l'ordre à longue distance de l'état polycristallin.

Introduction

The inhomogeneous broadening of spontaneous vibrational band contours, the so-called vibrational dephasing or T_2 process, is one of the few mechanisms that can be employed to give quantitative information on the fast dynamics of a "bath" or lattice surrounding a convenient probe oscillator. Briefly, the theory is set up in terms of the equation of motion of the stochastic oscillator amplitude $m(t)$ moving under a perturbation potential $H_1(t)$ that accounts for the elastic interaction between the bath coordinates and the ground and excited vibrational levels of the probe oscillator (1–3). Since phonon depopulation of the excited oscillator level is relatively slow, only the diagonal elements in the bath–oscillator interaction matrix are retained (4). The most convenient approach then resolves, to all practical purposes, to a judicious and problem-related choice of the autocorrelation function of the fluctuation $\Delta V(t)$ of the intermolecular potential $V(t)$ at the oscillator displacement coordinate (3, 5–7). In turn, $\Delta V(t)$ is considered to be proportional to $H_1(t)$ and, hence, to the shift of the stochastic transition frequency $\hbar^{-1}H_1(t) = \omega_1(t)$ (counted from the band center, ω_c, $\omega_1 \equiv \omega - \omega_c$) (8). Consequently, the problem of having to write out the physical model of the particular form of the amplitude autocorrelation

$$[1] \quad C(t) = \langle m(t)m(0)\rangle\langle|m(0)|^2\rangle^{-1}$$

is then reduced to that of formulating a relevant and physically sound correlation function ("modulation function") of $\omega_1(t)$ (2),

$$[2] \quad F(t) = \langle\omega_1(t)\omega_1(0)\rangle\langle|\omega_1(0)|^2\rangle^{-1}$$

with

$$C(t) = \exp\left\{-\langle|\omega_1(0)|^2\rangle\int_0^t dt'(t-t')F(t')\right\}$$

In the following, we shall discuss previously published vibrational dephasing data of the C—H in-plane deformation fundamental of quinoline (a', 1033 cm^{-1}) in a glassy and a polycrystalline phase, using a new model of non-Markovian modulation quite recently introduced by us and a well-known damped-oscillatory modulation function, respectively. It will be seen that the data simulation as well as the expected physics of the static-dynamic properties of the respective systems are considerably better mirrored by these models than by the usual Gauss–Markov mechanism (exponential modulation). Finally, we draw comparisons with other models.

Experimental

The material, the experimental spectral procedures as well as the method of numerical Fourier inversion have been described previously (9, 10). We merely recall that the band of the polycrystal is, as expected, blue-shifted (by 1 cm^{-1}) from that of the glass (quenched liquid, 115 K). The respective (full) halfwidths are 2.5 and 9 cm^{-1}. The oscillator profile of the glass is asymmetric (10); however, the perturbing effect is not serious within the range of the experimental correlation data. Furthermore, the baselines of the profiles are flat and overlap with adjacent bands is minimal or easily corrected (10). Therefore, the correlation data are not disturbed by sinc-type oscillations within the time domain considered here.

The data fit of the theory for the glassy state (see eq. [3]) was performed by using standard integration subroutines and judging the best-fit to the data by eye. The glassy quinoline is in a slow modulation regime; this, as we have discussed previously (11), means that it is not possible to identify a unique set of α, τ but that its most reasonable range must be obtained from considerations of the physics of the system (see also below).

Data fit of the theory for the polycrystal is straightforward; it has been described previously (12).

Results and discussion

Glassy state

The theoretical vibrational amplitude correlation function that is expected to respond well to the complex static and the convoluted dynamics of the vibrational dephasing process of glassy systems is given by (13)

$$[3] \quad C(t) = \exp\{-\langle|\omega_1(0)|^2\rangle(\tau^2/\alpha)[(t/\tau)\gamma(1/\alpha, (t/\tau)^{\alpha}) - \gamma(2/\alpha, (t/\tau)^{\alpha})]\}$$

where $0 < \alpha \leq 1$ is the so-called dispersion or shape parameter

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

and τ a time constant, γ denotes the incomplete γ function, and $\langle|\omega_1(0)|^2\rangle$ is the vibrational second spectral moment of the profile $I(\omega)$. Equation [3] is computer-fitted, as described in the previous section, to the experimental $C(t)$ and $\langle|\omega_1(0)|^2\rangle$,

$$[4] \quad C(t) = \text{F.T.}\{I(\omega)\}$$

$$\langle|\omega_1(0)|^2\rangle = \int_{-\infty}^{\infty} d\omega I(\omega)(\omega - \omega_c)^2$$

where F.T. designates Fourier transform and ω_c is set equal to the first moment of the profile.

It is easy to see that setting $\alpha = 1$ in eq. [3] yields the relation (10)

$$[5] \quad C(t) = \exp\{-\langle|\omega_1(0)|^2\rangle[\tau^2(\exp(-t/\tau) - 1) + \tau t]\}$$

that has been so useful to describe vibrational dephasing in nonassociated, mobile liquids (14).

For short t, eq. [3] approximates a Gaussian (leaving the first correction term)

$$[6] \quad C(t) = \exp\{-\langle|\omega_1(0)|^2\rangle t^2[(1/2) - (t/\tau)^\alpha/(\alpha + 2)(\alpha + 1)]\}$$

whereas for long t it approximates an exponential,

$$[7] \quad C(t) = \exp\{-\langle|\omega_1(0)|^2\rangle \tau\Gamma(1 + 1/\alpha)t\}$$

where Γ is the Euler γ function (13).

The modulation function $F(t)$ (see eq. [2]) inherent in eq. [3] is the stretched ("fractional", "extended") exponential

$$[8] \quad F(t) = \exp[-(t/\tau)^\alpha]$$

a formulation that has been shown to describe a wide range of diverse non-Markovian relaxation processes (15). (For a detailed description of its properties within the relaxation scheme of vibrational modes of amorphous systems ref. 13 should be consulted.)

Equation [6] demonstrates that for $t/\tau \equiv t^* \ll 1$, the smaller is α, the shorter is the time domain of pure Gaussian decay. In fact, for times beyond and up to a crossover time, it is easily seen from eq. [6] that $C(t^*, \alpha < 1) > C(t^*, \alpha = 1)$. In other words, for $t^* \lesssim 1$, $C(t^*, \alpha)$ decays the slower the smaller is α, whereas for $t^* \gtrsim 1$, $C(t^*, \alpha)$ decays the faster the smaller is α. The value t_c^* at the crossover point (where all $C(t^*, \alpha)$ intersect) must be calculated from eq. [3]. Comparison of the series development of the latter (13) with that of eq. [5] shows readily that $t_c^* > 1$. Note that the crossover point may not be reached within the experimental range of $C(t)$ if the system is in a slow modulation regime (see below). The crossover point of $F(t^*, \alpha)$ is, of course, at $t_c^* = 1$.

Application of eq. [3] to the spectral profile $I(\omega)$ of the C—H in-plane deformation oscillator of quinoline quenched rapidly from the liquid to 115 K is shown in the left portion of Fig. 1. The system is in a slow modulation regime (13),

$$[9] \quad \sigma = \langle|\omega_1(0)|^2\rangle^{1/2}\Gamma(1 + 1/\alpha)\tau \gtrsim 2$$

with $\langle|\omega_1(0)|^2\rangle = 0.6 \times 10^{24}$ (radian/s)^2.

Therefore, dispersion parameter α and time constant τ cannot be uniquely determined within a desired, narrow range in this system here since, as already mentioned above, the constant factor in the exponent of eq. [3] is so large (τ is so long) that $C(t)$ has dropped below its experimentally known range at a time point still within the condition $t^* \lesssim 1$. (See also Fig. 2 of ref. 11.) In other words, least-squares minimization methods for optimizing the fit of eq. [3] to the data (16) would not converge here to *one* set of α, τ. For instance, the sets α, τ = 1.0, 3 ps; 0.60, 7 ps; and 0.30, 40 ps fit the data about equally well.

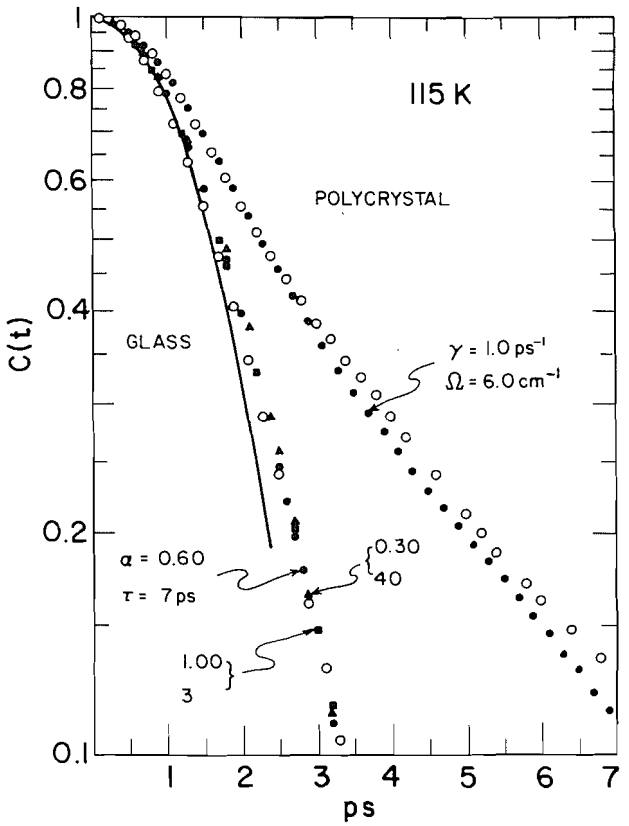

FIG. 1. Vibrational amplitude autocorrelation for the C—H in-plane (a') infrared oscillator of quinoline at 1033 cm^{-1}. The open circles are the data (via eq. [4]), the solid points are calculated with eq. [3] (glass) and eq. [14] (polycrystal).

Yet, it is clear that correlation decay for an assumed static regime ($t \sim 0$), namely the pure Gaussian decay of $C(t)$ (see eq. [6]), is definitely too rapid (see the curve in Fig. 1). Consequently, the particular glassy state of quinoline observed here is not devoid of some type of *relatively rapid* motion which effectively modulates the oscillator frequency. However, we propose that those sets of α associated with longer τ, say $5 < \tau < 40$ ps, render a more plausible picture of the physical dynamical situation in low-temperature glassy quinoline than the shorter τ (at $\alpha \sim 1$). In this respect, consider that modulation time τ for liquid quinoline at 303 K amounts to 0.3 ps (10); using the small, average activation factor of 1 kcal/mol, this would lengthen τ already to ~5 ps at 115 K — all other conditions remaining the same. Notice that $\tau \sim 40$ ps is, in principle, an observable upper limit under optimal accuracy $\Delta\nu = \pm 0.2$ cm^{-1} of a bandwidth measurement.

$$[10] \quad \tau \sim (\pi c \Delta\nu)^{-1} \sim 50 \text{ ps}$$

Values of dispersion parameter α, in the lower ranges of the order of 0.3–0.6, have been established for other relaxation phenomena in amorphous states (17). However, it is difficult to be confident in singling out one of the fundamental physical processes that have been shown to lead to a relaxation function of the type of eq. [8] (15) such as defect diffusion or hierarchically-constrained dynamics. First, it seems that these physical models are only valid for long t, a situation that is not satisfied by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

the observable dynamics of the glassy quinoline system ($\sigma \gg 1$, see eq. [9]). Second, these particular models rest on rather specific boundary conditions (15) such as form of intermolecular potential and dimensionality of the lattice, a situation which has been criticized (18) (it appears rightly) as going against the *universal* experimental applicability of eq. [8] as well as its worthiness at "shorter t". Third, eq. [8] can also result from a model of many, parallel and *independent* relaxation pathways, each of which is governed by pure exponential decay,

$$[11] \quad F(t) = \exp[-(t/\tau)^{\alpha}] = \int_0^{\infty} d\tau p_{\alpha}(\tau) \exp(-t/\tau)$$

where $p_{\alpha}(\tau)$ is the continuous probability density of the τ's (19). The parallel-independent relaxation pathway model has been termed "microscopically arbitrary" (20) as regards $p_{\alpha}(\tau)$ since any reasonable function $F(t)$ should be expressible in terms of its inverse Laplace transform (eq. [11]). Yet, there is no proof against the parallel-independent relaxation model and it has shown its worthiness in many relevant situations (21, 22).

Therefore, under these presently unresolved circumstances, it appears wise to propose a general, less model-dependent basis for the success of eq. [8] in the system investigated here; after all, the ubiquitous pure-exponential modulation model ($\alpha = 1$) is also, fundamentally, an (convenient) assumption. In this frame of mind, it is useful to recall that the age-specific failure rate $h(t)$ associated with $F(t)$ of eq. [8] (23),

$$[12] \quad h(t) = (\alpha/\tau)(t/\tau)^{\alpha-1}$$

decreases hyperbolically with t for $0 < \alpha < 1$. Without attempting to define any *specific* modulation process for a glass, this, at least, gives a useful hint to the effect that the dynamics of the glassy quinoline which lead to a modulation event at the active oscillator site are far removed from a chain of uncorrelated random steps ($\alpha = 1$, $h(t)$ = constant). Equation [12] shows that the later is the time instant of observation, the smaller is the rate $h(t) = f(t)/F(t)$; in other words, the later is t, the smaller is the probability density $f(t)$ that the autocorrelation of the random oscillator frequency $\omega_1(t)$ changes at t relative to the probability $F(t)$ (survivor probability (24))

$$[13] \quad F(t) = \int_t^{\infty} dt\, f(t)$$

that it has *not yet changed* at times $t_i \leq t$. The effect of the sets of α, τ (ps) = 1.00, 3; 0.60, 7; 0.30, 40 on $h(t)$ are shown in Fig. 2, which also contains the (near-identical) associated $F(t)$: the increased drop of $h(t)$ with decreasing α is evident.

We then picture the dynamical events that lead to a modulation step of the oscillator state in the glassy phase of quinoline to arise from motions within large, frozen-in "faults" that suddenly cause a "catastrophic" potential fluctuation in the immediate neighborhood of the probe oscillator *after an initial period of completely randomly-distributed* (Poisson) *modulation events*. Such initial, pure-exponential modulated decay (eq. [5]) has also been observed in other amorphous, locally-structured systems (11, 13, 16). Thus, it appears that the picosecond dynamics of a quenched glassy phase, as they are exhibited here in their effects on motional band narrowing of an internal probe oscillator in quinoline, arise from "liquid-like", completely randomly-occurring fluctuations in the environment of the probe oscillator ($h(t)$ = constant) that are superposed by early, singular (non-Markovian) and more extensive potential excursions ($\alpha < 1$), conceivably due to relaxation of frozen-in structure faults. In this context, it is useful to recall that this particular glassy state was generated by cooling the compound in its absorption cell from its liquid (at 303 K) to 115 K at an approximate cooling rate of 40 deg/min. Also, with respect to the following discussion of the polycrystalline phase, the latter was prepared by gradual cooling to 115 K (mp 258 K).

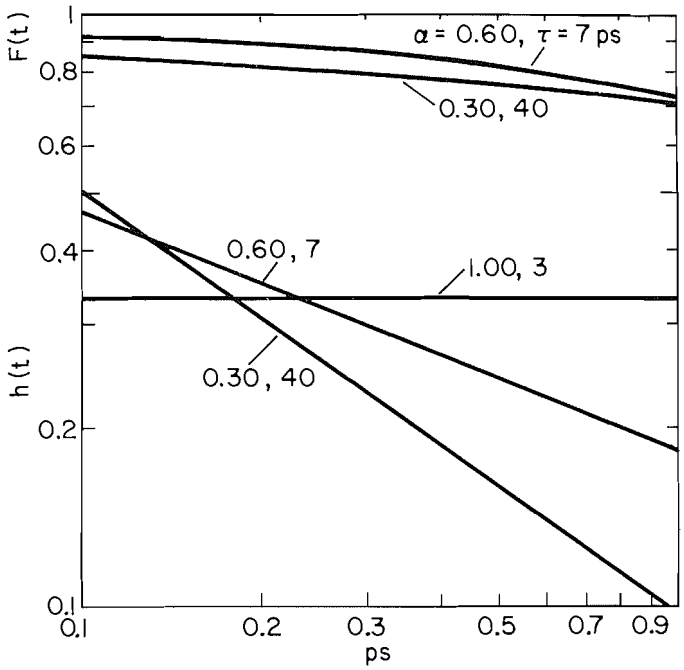

FIG. 2. Survivor functions $F(t)$ (eq. [8]) and age-specific failure rates $h(t)$ (eq. [12]) for the C—H in-plane oscillator of the glassy state of quinoline. For instance, at t = 1 ps, $h \sim 0.1$ for the set α, τ (ps) = 0.30; 40, $h \sim 0.2$ for 0.60; 7, and $h \sim 0.3$ for 1.00; 3 at essentially identical F's.

Polycrystal

The characteristics of the vibrational amplitude correlation of the C—H deformation of quinoline in its polycrystalline phase, shown in the right portion of Fig. 1, are entirely different from those of its glass. First, the vibrational correlation decay of $C(t)$ is slower than in the glass. Second, the experimental $C(t)$ shows a "dip" in the time domain between 2–4 ps, an effect that can be reproduced by the theoretical amplitude correlation function (12, 25)

$$[14] \quad C(t) = \exp(-\langle|\omega_1(0)|^2\rangle\Omega^{-2}[t\gamma + \Omega^{-2}\{(\gamma^2 - \Omega^2) \times [\exp(-t\gamma/2)\cos\theta t - 1] + (\gamma/2\theta)(\gamma^2 - 3\Omega^2)\exp(-t\gamma/2)\sin\theta t\}])$$

where $\theta = (\Omega^2 - \gamma^2/4)^{1/2}$. Equation [14] is based on modulation function

$$[15] \quad F(t) = \exp(-t\gamma/2)[\cos\theta t + (\gamma/2\theta)\sin\theta t]$$

the well-known harmonic librational oscillator, and is proposed to describe coupling of the internal probe oscillator coordinate to lattice phonons of mean frequency Ω (25); γ is here the damping constant of the autocorrelation of the (instantaneously acting) random force of the bath. Notice that eq. [14] has as many adjustable parameters (two) as eq. [3].

The plot of the autocorrelation data and best-fit values of γ and Ω from eq. [14] are displayed in the right-side portion of Fig. 1; Ω corresponds here to a frequency distribution that is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

peaked in the far-infrared. We have not succeeded in finding data on lattice mode distributions of crystalline quinoline which could be used to verify whether $\Omega = 6\ cm^{-1}$ is a reasonable value. On the other hand, such a low frequency would indicate whole-molecule displacements or libratory motion about center-of-mass equilibrium positions (rather than some internal motion). It is also interesting to note that the time scale τ corresponding to $\Omega = 6\ cm^{-1}$ falls near the lower limit of the range of the τ's for the glassy state of quinoline. The motional narrowing effect in the polycrystal is therefore considerably greater than that in the glass. For the latter (eq. [9]), $\sigma = 8$ with the set $\alpha, \tau = 0.6, 7$ ps. For the former, $\sigma = \langle|\omega_1(0)|^2\rangle^{1/2}(\theta + \gamma/2)/\Omega^2 = 0.8$, $\langle|\omega_1(0)|^2\rangle = 11\ cm^{-2}$.

Finally, we note that $F(t)$ of eq. [15] cannot be considered here as proper survivor function (eq. [13]) per se since its derivative (24),

$$[16] \quad -(d/dt)F(t) = f(t) = (\Omega^2/\theta)\exp(-t\gamma/2)\sin\theta t$$

is not a true probability density function ($f(t) < 0$ for $n(\pi/\theta) < t < (n + 1)(\pi/\theta)$, n odd). In fact, $F(t)$ passes first into a negative region at $t = 2.05$ ps. However, $F(t)$ may be artificially truncated to zero for $t > 2$ ps by a step function. The visible perturbation on $C(t)$ by this operation would be small since $C(t)$ becomes essentially exponential (Markovian) for $t \gtrsim 2$ ps.

Comparison with other models

Whereas the inhomogeneous vibrational dephasing process as understood here (that is to say, the scattering of bath excitations by the probe oscillator coordinate without exchange of energy) is by all accepted notions the singly prevalent vibrational relaxation mechanism in amorphous substances, there is no guarantee that this must always be so. There are documented cases of a concurrent, extraordinarily rapid phonon population relaxation by quasi-resonant (intramolecular) energy transfer (26). Yet, it appears that this phenomenon is restricted to C—H valence stretches in near-resonance with a C—H deformation overtone. Therefore, we shall not consider an appropriate two-process vibrational relaxation model, suggested by Guillaume *et al.* (27), since there is no independent data base to verify its contribution to phonon depopulation in the type of systems considered here. Furthermore, the model displays unphysical behavior at $t \rightarrow 0$. Similarly, the two-process relaxation model by Katō and Takenaka (28), which essentially separates the purely static contribution in the exponent of eq. [5], the second-order term, into two portions of which one is factored out into a pure Gaussian ("inhomogeneous" contribution) and the remainder left as leading term of the series in t^* ("homogeneous", rapidly-modulated contribution), is not useful here. It appears futile to establish a countable number of sufficiently different, quasi-static environments in the quenched quinoline without detailed structural information. The modulation function contains an additive, constant term (29): it therefore lacks all finite moments and the corresponding $C(t)$ is unphysical in not attaining exponential decay at long times.

The thermodynamics of orientational disorder in a molecular solid: $(CH_3)_3CCHO$

MARY ANNE WHITE[1] AND ALLYSON PERROTT
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3
Received September 8, 1987

This paper is dedicated to Professor James A. Morrison

MARY ANNE WHITE and ALLYSON PERROTT. Can J. Chem. **66**, 729 (1988)

The heat capacity of *tert*-butylaldehyde, $(CH_3)_3CCHO$, has been measured as a function of temperature from 29 to 298 K, to investigate solid-state polymorphism. There are two solid–solid phase transitions in this material, T_{tr} = 158.5 and 183.9 K, $\Delta S_{tr} = 0.402R$ and $3.153R$ respectively. The thermodynamic parameters for the transitions are consistent with mechanisms proposed on the basis of recent nuclear magnetic resonance investigations of this material.

MARY ANNE WHITE et ALLYSON PERROTT. Can J. Chem. **66**, 729 (1988)

Afin d'étudier le polymorphisme à l'état solide, on a mesuré la capacité calorifique du *tert*-butylaldéhyde, $(CH_3)_3CCHO$, en fonction de la température de 29 à 298 K. Avec ce produit, on a observé deux transitions de phase solide–solide, T_{tr} = 158,5 et 183,9 K, $\Delta S_{tr} = 0{,}402R$ et $3{,}153R$. Les paramètres thermodynamiques pour les transitions sont en accord avec les mécanismes proposés en se basant sur des études récentes en résonance magnétique nucléaire de ce composé.

Introduction

The possibility of relatively free reorientational motion in a solid was first proposed by Pauling in 1930 (1), and the study of orientation disorder in crystals (ODIC) has been fruitful in recent years, both experimentally and theoretically. The archetypal example of restricted rotation or reorientation in the solid phase that exists just below the melting point is, of course, solid methane (2, 3), and the title compound can be considered to be *spiritus paludis ornatum*. $(CH_3)_3CCHO$ (2,2-dimethylpropanal, also known as *tert*-butylaldehyde, pivalaldehyde, pivaldehyde, and trimethylacetaldehyde), like many other substances with roughly spherical molecules, including the *tert*-butylhalides and methyl chloroform, exhibits a solid rotator phase (4–6). This orientationally disordered phase has been confirmed by measurements of dielectric constant and proton magnetic resonance linewidth of $(CH_3)_3CCHO$ (5), and by studies of the ^2H nmr lineshapes for $(CD_3)_3CCHO$ (7).

Since other compounds similar to $(CH_3)_3CCHO$, such as trimethylchlorosilane, 3,3-dimethyl-2-butanone, and 2,2-dimethylpropane nitrile, do not possess solid rotator phases (5), several criteria to predict the presence of rotator phases have been suggested. These criteria include consideration of bond lengths and deviations from spherical symmetry (8); the volume required for dipole rotation (6); the ratio of molecular interaction energies for the dipolar relaxation process and the viscosity process (4). Unfortunately, none of these approaches has proven to be reliable, as can be seen in the compilations of Krishnaji and Mansingh (4) and Segel and Mansingh (5).

Several works (9–11) summarize the observed properties of rotator phases. Although the lattice is crystalline in the rotator phase, rotational freedom of the molecules makes the properties of the rotator phase intermediate between those of the liquid and "normal" solid phases. In some of these properties the rotator phase may actually be closer to the liquid phase. Solids in the rotator phase tend to be soft and waxy, while the non-rotator phases tend to be harder and brittle. Because solids in the rotator phase can be extruded by relatively low pressures, they are often referred to as "plastic" crystals. The X-ray diffraction pattern of a rotator phase is diffuse, with a good deal of background scattering. Although the dielectric constant of an orientationally ordered solid drops dramatically on cooling through the freezing point, the dielectric constant of a substance possessing a solid rotator phase increases slightly on freezing (9, 10).

The heat capacities of two substances possessing solid rotator phases, *tert*-butylchloride (2-chloro-2-methylpropane) and *tert*-butylbromide (2-bromo-2-methylpropane), were investigated by Kushner, Crowe, and Smyth (12). The results showed two solid–solid phase transitions for each compound. For *tert*-butylchloride, the enthalpy and entropy of the lower-temperature transition were found to be substantially lower than those for the higher-temperature transition. It was concluded therefore that most of the rotational freedom does not set in until the higher-temperature transition is reached. For *tert*-butylbromide, the enthalpy and entropy of the lower-temperature transition are greater than those for the higher-temperature transition. In this case, most of the rotational freedom sets in at the lower transition. In both compounds, the entropy of fusion is low ($<0.95R$) indicating that nearly all of the discontinuous increase in entropy taking the ordered solid to the liquid is obtained over the two transitions. This is typical for compounds possessing solid rotator phases, and Timmermans' early criterion (13) for orientational disorder in the solid was based on the value of the entropy of fusion ($<2.5R$).

The aim of the present work was to measure the heat capacity of *tert*-butylaldehyde and determine the enthalpy and entropy of its solid–solid transitions, to clarify the nature of its phase transitions. Discrepancies between the literature values of the melting point of $(CH_3)_3CCHO$ (*vide infra*) and the question of the effect of impurity on the phase transitions led us to measure the heat capacities of both a commercial and a purified (distilled) sample of $(CH_3)_3CCHO$.

Experimental

The heat capacities were measured in an adiabatic heat-pulse calorimeter. The calorimeter, which is described in detail elsewhere (14), is known to have an accuracy of ±0.5% from our measurement of the heat capacity of Calorimetry Conference (NBS-49) benzoic acid. The temperature (resistance of the Pt thermometer) and heat input were measured with a Hewlett–Packard 3456A digital multimeter, interfaced with a Hewlett–Packard HP87A personal computer (14).

As there has been some discrepancy in the literature concerning the purity of *tert*-butylaldehyde (see Results and discussion), two samples were used. The first of these was a commercial sample (Aldrich,

TABLE 1 (*concluded*)

nominally 97%), the same as was used for the protonated-sample measurements in the recent nmr investigations (7). The heat capacity of 2.2969 g of this sample was measured from $T = 28$ to 298 K.

The second sample was prepared from the first by distillation. The fraction collected boiled at 74°C at a pressure of 760.5 Torr (1 Torr = 1.33.3 Pa). The heat capacity of 2.6328 g of this sample was measured from $T = 113$ to 296 K.

Gas chromatographic/mass spectroscopic checks of the two samples revealed that the commercial sample was 95% pure, with nine detectable impurity peaks. The distilled sample was considerably cleaner, 99% pure, with only one detectable impurity. The mass spectrum of the impurity and the infrared spectrum of the distilled sample indicated that the impurity is likely 2,2-dimethylpropanol.

Results and discussion

The experimental values of the molar heat capacity, C_p, of the commercial and distilled samples of *tert*-butylaldehyde are given in Tables 1 and 2, respectively. Neither sample showed any thermal history effects in the heat capacity results, and the relaxation times following heating were relatively short (generally <5 min, but up to 20 min in the region of the higher-temperature solid–solid transition), consistent with rapid attainment of thermal equilibrium.

The only literature value of the heat capacity of $(CH_3)_3CCHO$ available for comparison with the present measurements is one measurement, in the liquid state, at $T = 298$ K (15), and our measurements for the distilled sample are 1.4% higher at this temperature.

The results of the measurements on both samples are illustrated in Fig. 1. The overall features are very similar for both samples, showing the presence of two solid–solid phase transitions prior to melting. At low temperatures, $T < 150$ K, the heat capacity curves merge, but at higher temperatures there are some differences.

The earliest report of the synthesis of $(CH_3)_3CCHO$ gave its melting point as 276 K (16). A slightly later synthesis gave $(CH_3)_3CCHO$ with melting point of 279 K (17). We find the melting point of our commercial sample to be 270.3 ± 0.2 K, and that of the distilled sample to be 272.1 ± 0.3 K. If the highest literature value for the melting point, 279 K, is correct, the two present measurements of the melting point as a function of purity must reflect a steep change in melting point at low impurity levels in $(CH_3)_3CCHO$, and a leveling off at slightly higher impurity levels. Our attempts to determine the true melting point of $(CH_3)_3CCHO$ by extrapolation of the plot of the reciprocal of the fraction melted (1 / F) as a function of temperature to F = 1 yielded a value of 277 ± 2 K; the large uncertainty is due to the high curvature of the plot, which indicates that the *tert*-butylaldehyde and its impurity form a solid solution (18). It is interesting to note that the early investigation of the dielectric constant (5) was carried out on a sample with a boiling point that matched that of the literature (17) value, 348 K, but with an exceptionally low melting point, 228 K, yet the dielectric measurements showed clearly the existence of the higher-temperature phase transition.

Two solid–solid phase transitions are seen in the commercial and the distilled sample of $(CH_3)_3CCHO$. A summary of the transition temperatures (determined from the maxima in C_p), enthalpies (determined from the "long heat" method (19)), and entropies is given in Table 3. The transformations overlap somewhat and, for the purpose of assessing the relative contributions of each to the enthalpy and entropy, the solid–solid transitions were partitioned at the minimum between them. Although this division is necessarily arbitrary, it does not affect the total transition entropy or enthalpy. In the distilled sample, 2% of the total entropy occurs within 3.4 K of the lower-temperature maximum in C_p, and 56% of the total transition entropy occurs within 3.8 K of the higher-temperature maximum in C_p, and similar values were obtained for the commercial sample. Therefore, there is no doubt that most of the entropy change is associated with the higher-temperature transformation.

Despite the broadening of the higher-temperature solid–solid transition in the purer sample (see Fig. 1) and its slightly lower transition temperature, the entropy and enthalpy changes of this transition are substantially unchanged with level of purity. The temperature, enthalpy, and entropy of the lower-temperature transformation differ somewhat more between the two samples (Table 3). One curious finding is the slight thermal anomaly at about 220 K in the distilled sample that is absent in the commercial sample. In general, we believe that the purer sample reflects more accurately the true thermodynamic properties of $(CH_3)_3CCHO$, and we will base our further discussion on the results obtained with the sample that was prepared by distillation.

It is useful to compare the transition entropies with those of other *tert*-butyl compounds that also exhibit polymorphism; these values are given in Table 4 for $(CH_3)_3CX$ for X = Cl, Br, SH, CHO. It is striking that each of these compounds has one transition with ΔS_{tr} ca. $3.2R$, and one or more smaller transitions, most often of ΔS_{tr} ca. $0.5R$. The order of these transitions is not the same in each compound; the lowest-temperature transition has the smallest entropy in X = CHO and Cl, while in X = Br and SH it has the highest entropy.

Although these entropy arguments hint that these compounds fall into two categories (CHO and Cl; Br and SH), nmr results show that this view is too simplistic. In particular, ^2H lineshapes

have shown that the onset of the rotations of the methyl groups (C_3 rotations) and the rotations about the C—X axis (C_3' rotations) is strongly dependent on X, from stepwise onset for *tert*-butylchloride (21) to C_3 and C_3' motions commencing at about the same temperature in *tert*-butylaldehyde (7).

From the nmr study of *tert*-butylaldehyde (7), it is known that the rigid ^2H nmr lineshape for *tert*-butylaldehyde begins its collapse at a temperature of about 100 K, close to the temperature at which the heat capacity begins to rise appreciably from the baseline. It should be emphasized that there is no transition per se at 100 K, but that this serves as a well-documented example of the *initiation* of a phase transition commensurate with changes in the nmr lineshape.

The nmr experiments on *tert*-butylaldehyde have shown that at $T = 153$ K the "fingerprint" of rapid C_3 and C_3' motions, a 12–14 kHz splitting in the ^2H powder spectrum, is observed. Slightly beyond that temperature additional motion sets in, and from the nmr experiments and information known from early dielectric work (5), it has been proposed (7) that rotations about the C_2' axis (the axis passing through the center of mass and parallel to the dipole moment) set in. Although this motion does not give rise to a discontinuity in $^2H(T_1)$, the nmr experiment does show unusual behaviour of the ^2H quadrupole coupling tensor in this temperature region (7). It is now apparent from the calorimetric experiment that C_2' rotations are responsible for the lower-temperature phase transformation. The entropy change associated with this transition can be reconciled with a twofold increase in accessible positions, as $R \ln 2$ ($0.69R$) is quite close to the observed entropy change ($0.53R$), especially considering the error involved in partitioning the total entropy change between the two transitions. It should be noted that this transition has virtually no first-order character.

As the temperature is increased further, the molecular reorientations in *tert*-butylaldehyde become faster, resulting finally in the transformation at $T = 184$ K to the "plastic crystalline" (rotator) phase. This is the transformation that is associated with the larger entropy change, consistent with overall molecular tumbling in the highest-temperature solid phase of *tert*-butylaldehyde. The entropy change is close to that seen in the transformation to the rotator phase in *tert*-butylchloride, which has been attributed to an increase from two orientations in the solid to 40 ($R \ln 40/2 = 3.00R$); the small additional entropy change ($0.22R$ for X = Cl, $0.15R$ for X = CHO) is likely due to slight structural rearrangement of the lattice.

It is interesting to note that replacement of the aldehydic proton of *tert*-butylaldehyde with a methyl group (to give 3,3-dimethyl-2-butanone) apparently prevents the occurrence of an orientationally disordered solid phase (5). Both compounds are predicted to have solid rotator phases on the basis of the Smyth (bond lengths) and the Clemett (dipole–dipole interaction compared to the thermal energy at the freezing point) criteria. It seems likely that the predictive powers of these simple criteria are limited by the assumption of single-particle motions in these solids; reorientational motions in globular molecular solids are more likely to involve intermolecular cooperation.

Finally, we should like to comment that the simplicity of the atomic composition of *tert*-butylaldehyde, and the availability of reliable C,H,O interatomic potentials, make $(CH_3)_3CCHO$ an excellent candidate for Monte Carlo and (or) molecular dynamical simulation calculations.

Deuterium nuclear magnetic resonance lineshapes for polycrystalline $(CD_3)_3CCHO$ and $(CD_3)_3CI$ have been investigated between 100 K and the melting point of each sample. As in other *tert*-butyl compounds, rotational motion of methyl and *tert*-butyl groups occurs in the lowest temperature phase, while the solid phase just below the melting point is characterized by overall molecular rotations in both *tert*-butylaldehyde and *tert*-butyliodide. The "rotator" phase is observed in *tert*-butyliodide-d_9 between 239 and 212 K only upon cooling; no solid–solid phase transition is observed upon heating. In $(CD_3)_3CCHO$, two solid–solid phase transitions are observed at 165 ± 5 K and 190 ± 2 K. Deuterium nuclear magnetic resonance lineshapes in the solid II phase are consistent with rapid 180° flips about a pseudo-C_2 axis. Deuterium spin-lattice relaxation times were measured in the liquid, solid I, and solid II phases of $(CD_3)_3CCHO$, and in the liquid and rotator phases of $(CD_3)_3CI$ and $(CD_3)_3CCl$. The data for both the chloride and the iodide compounds indicate a discontinuous increase in the rotational correlation time upon melting, similar to that observed in $(CD_3)_3CBr$ and $(CD_3)_3CSH$. However, neither ^2H nor ^{13}C T_1's of the methyls indicate that a discontinuity occurs at the melting point for *tert*-butylaldehyde. Carbon-13 and ^{17}O relaxation times of the aldehyde substituent support this result.

SANDRA MOOIBROEK, RODERICK E. WASYLISHEN, J. B. MACDONALD, CHRISTOPHER I. RATCLIFFE et JOHN A. RIPMEESTER. Can. J. Chem. **66**, 734 (1988).

Opérant entre 100 K et le point de fusion de chaque échantillon, on a étudié les formes des raies en résonance magnétique nucléaire du deutérium du $(CD_3)_3CCHO$ et du $(CD_3)_3CI$ polycristallins. Comme il a été observé avec d'autres composés *tert*-butylés, le mouvement de rotation des groupements méthyles et *tert*-butyles se produisent à la température la plus basse; par ailleurs, la phase solide, juste au-dessous du point de fusion, est caractérisée par des rotations moléculaires globales tant dans le *tert*-butylaldehyde que dans l'iodure de *tert*-butyle. Pour l'iodure de *tert*-butyle-d_9, on n'a pu observer la phase "rotator" que lors du chauffage entre 239 et 212 K. Dans le $(CD_3)_3CCHO$, on a observé les deux phases de transition solide–solide à 165 ± 5 K et à 190 ± 2 K. Les formes des raies en résonance magnétique nucléaire du deutérium de la phase solide II sont en accord avec des inversions rapides de 180° autour du pseudo-axe C_2. On a mesuré les temps de relaxation spin-réseau du deutérium dans les phases liquide, solide I et solide II du $(CD_3)_3CCHO$ et dans les phases liquide et rotator du $(CD_3)_3CI$ et $(CD_3)_3CCl$. Les données tant pour le dérivé chloré que pour le dérivé iodé indiquent qu'il existe une augmentation discontinue du temps de corrélation rotationnel au point de fusion et ce comportement est semblable à celui observé avec le $(CD_3)_3CBr$ et le $(CD_3)_3CSH$. Toutefois, les T_1 des groupements méthyles tant du ^2H que du ^{13}C n'indiquent pas la présence d'une discontinuité au point de fusion du *tert*-butylaldéhyde. Les temps de relaxation du ^{13}C et du ^{17}O du substituant aldéhyde supportent ce résultat.

[Traduit par la revue]

Introduction

tert-Butyl-X compounds (X = CH_3, Cl, Br, SH, etc.) have generated considerable interest over the past few years (1–3) due to their solid–solid phase transitions and characteristic orientational disorder in crystal (ODIC) properties. Typically, these compounds have a "rotator" phase (solid I) just below the melting point, in which the molecules undergo rapid, liquid-like reorientation, and a low temperature phase (solid II or III, etc.) in which reorientation is restricted to rotations or $2\pi/3$ jumps of the methyl groups (C_3) and the *tert*-butyl group (C_3') (4, 5). Other types of reorientation may occur in the intermediate phase(s), but these appear to be highly dependent on the substituent X (6).

Relatively little is known about the X = aldehyde or iodide derivatives in the solid state. Early dielectric measurements on *tert*-butyliodide (7) indicated a phase change at 198 K, while a later study (8) found no evidence for a solid–solid phase change in DTA or X-ray diffraction data, nor any abrupt changes or discontinuities in the temperature dependence of either the dielectric constant or the ^1H nmr second moment below the melting point of 236 K. A smooth decrease in the proton second moment between 115 and 170 K was interpreted as increasingly rapid C_3 and C_3' rotations. However, a more recent ^1H nmr study (9) found a large discontinuity in the temperature dependence of the spin-lattice relaxation time, T_1, at 222 K. A minimum in the lowest temperature phase was attributed to methyl reorientations, while molecular tumbling and translational motions were thought to contribute to T_1 in the 222–236 K interval.

Measurements of the dielectric constant and ^1H nmr linewidth as a function of temperature have also been performed on *tert*-butylaldehyde (pivaldehyde) (10). The dielectric constant abruptly changes from a value of 2–3 below 186 K to ~9 above this temperature, while the ^1H nmr linewidth decreases (*i*) between 90 and 100 K, (*ii*) at 180 K, and (*iii*) again at the melting point. The transition temperature of 180 or 186 K is suspect, however: the melting point of the sample used in the study was 228 K; the literature value is 279 K (11). Again, the large change in the nmr linewidth at 90–100 K is attributed to C_3

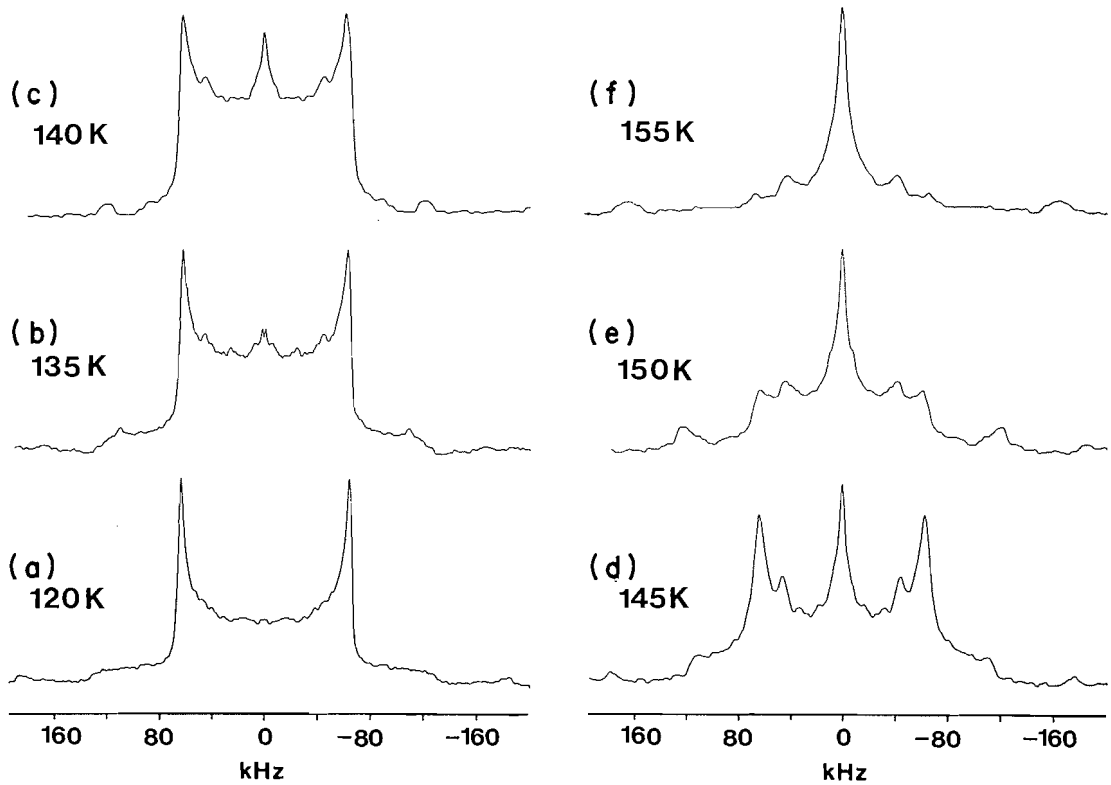

FIG. 1. Deuterium nmr spectra of *tert*-butyliodide-d_9 (solid II): (a) 120 K, (b) 135 K, (c) 140 K, (d) 145 K, (e) 150 K, and (f) 155 K. The quadrupolar splitting in the spectrum recorded at 120 K is 130 ± 2 kHz, corresponding to χ = 174 kHz.

motions, while overall molecular rotations occur in phase I (above 186 K).

The present study of $(CD_3)_3CCHO$ and $(CD_3)_3CI$ was undertaken to determine the type of reorientations present in the solid state, and whether phase transitions similar to those observed in other *tert*-butyl compounds occur here as well. Deuterium nmr has proved to be particularly useful for investigations of this nature (5) since the quadrupolar lineshape of powdered samples can, in favorable cases, distinguish what type of motion is occurring, and ^2H T_1's can provide rotational correlation times free from intermolecular or translational effects over a wide range of reorientational rates. Carbon-13 and ^{17}O spin-lattice relaxation times of the aldehyde group of $(CH_3)_3CCHO$ also provide some insight into the motion of this substituent in the liquid and solid I phases.

In addition, we have reexamined the ^2H T_1's in the liquid and rotator phases of $(CD_3)_3CCl$ (12) in light of the recent results for $(CD_3)_3CSH$ (6) and $(CD_3)_3CBr$ (13), in which small discontinuities were found in T_1 at the melting point.

Experimental

Samples of $(CD_3)_3CCHO$, $(CD_3)_3CI$, and $(CD_3)_3CCl$ were purchased from Merck, Sharp & Dohme Co.; $(CH_3)_3CCHO$ (97%) was obtained from Aldrich Chemical Co. Both labelled and unlabelled *tert*-butylaldehyde had melting points of 270–271 K, and were used without further purification. The samples were transferred to 1-cm cylindrical microcells of 9 mm outer diameter, then degassed using repetitive freeze–pump–thaw cycles before sealing.

All experiments were performed on a Nicolet 360-MHz (^1H) spectrometer, with the following exceptions: ^{17}O T_1 measurements of *tert*-butylaldehyde and ^2H T_1 measurements of $(CD_3)_3CCHO$ in solid II and $(CD_3)_3CI$ in solid I were carried out on a Bruker MSL 200; also low temperature ^2H spectra were obtained on a Bruker CXP 180-MHz instrument.

The probes used for relaxation measurements were calibrated using a copper–constantan thermocouple; temperature regulation is estimated to be within ±2 K. T_1's were obtained with the standard inversion–recovery experiment, typically using 12 values of τ and recycle delays of $\geq 5T_1$. Ninety-degree pulse widths are between 16 and 20 μs for ^{13}C, and 25–35 μs for ^2H on the Nicolet, approximately 18 μs for ^{17}O and 14 μs for ^2H on the MSL high resolution probe, and 7.5–8 μs for ^2H on the MSL broadband probe operating at low power. This latter probe was used to obtain ^2H T_1's of $(CD_3)_3CCHO$ in solid II.

During the ^{13}C T_1 experiments on unlabelled *tert*-butylaldehyde, two-level decoupling was carried out to obtain decoupled spectra with nuclear Overhauser enhancement. To measure the nOe, four (single scan) spectra were collected with the nOe, then four without the enhancement, using recycle delays of >10 T_1. The nOe is calculated from the ratio of the average signal intensity of the first set of four spectra to the average intensity of the second set.

To obtain the low temperature ^2H spectra shown in Figs. 1 and 2, a phase alternated quadrupole echo technique (14) was employed on the Bruker CXP spectrometer. For these spectra, the echo–pulse spacing was ~40 μs with 90-degree pulse widths of 3 μs. Dwell times of 0.5 μs were used to record 512-point quadrupole echoes, which were zero-filled to 4 K before Fourier transformation. The echo sequence was also incorporated into the T_1 experiments on $(CD_3)_3CCHO$ in solid II, in which 1 K points were collected and the echo–pulse spacing was ~30 μs. In this case, similar results were obtained when the echo sequence was not used, since the linewidth is less than 10 kHz.

Results and discussion

A. Lowest temperature phases

In contrast to the process of motional averaging upon warming rigid $(CD_3)_3CCl$ or $(CD_3)_3CBr$, stepwise onset of first C_3', then C_3, motions (5) does not occur in either $(CD_3)_3CI$ or $(CD_3)_3CCHO$. Both of these latter molecules, however, have similar ^2H spectra in the motional averaging temperature range.

When *tert*-butyliodide is warmed above 130 K, some distor-

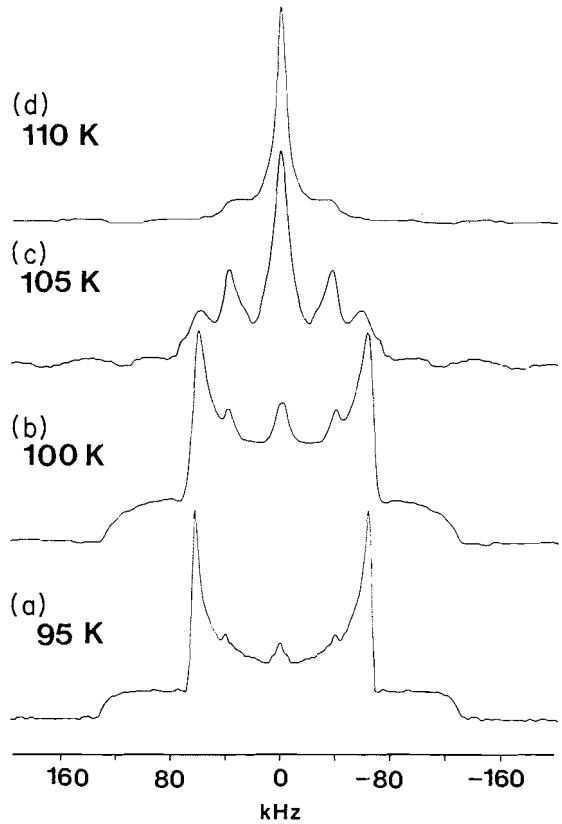

FIG. 2. Low temperature deuterium nmr spectra of *tert*-butylaldehyde-d_9, $(CD_3)_3CCHO$, at (a) 95 K, (b) 100 K, (c) 105 K, and (d) 110 K. The quadrupolar splitting in (a) is 129 ± 2 kHz, corresponding to $\chi = 172$ kHz.

tions occur in the "rigid" lineshape ($\chi = e^2qQ/h = 174$ kHz, $\eta = 0$), with additional peaks, symmetrically placed at + and −45 kHz from the centre of the Pake-like doublet, appearing between 140 and 150 K (Fig. 1). In *tert*-butylaldehyde, a similar rigid lineshape begins to collapse at ~100 K, with a splitting of approximately 80 kHz apparent in the ^2H spectrum (Fig. 2). These spectra are the result of both C_3 and C_3' motions occurring at rates of 10^4–10^6 s^{-1} (15). In *tert*-butyliodide, the persistence of the rigid lineshape singularities up to ~155 K suggests that the rate of C_3' motions is greater than C_3 rotations. The ^2H spectrum at 150 K resembles a simulation of the lineshape with rates of about 10^6 s^{-1} (C_3') and 10^4 s^{-1} (C_3) (15). In *tert*-butylaldehyde, the rapid loss of intensity in the outer wings and relatively high intensity in the central and ±40 kHz peaks suggest that in this case C_3 motions are more rapid than C_3'. The ^2H spectrum of *tert*-butylaldehyde-d_9 at 110 K resembles a C_3' ~10^4 s^{-1}, C_3 ~10^6 s^{-1} lineshape simulation (15). It is of interest to point out that in the gas phase, the barrier to methyl group rotation is approximately three times larger than the barrier for internal rotation about the C—C bond connecting the *tert*-butyl and aldehyde groups (16).

Upon warming *tert*-butyliodide above 150 K, the wings and shoulders of the ^2H spectrum collapse and a featureless lineshape, characteristic of 10^5–10^6 s^{-1} C_3 motion along with 10^5–10^7 s^{-1} C_3' motion (15), is observed. Above 200 K, an axially symmetric 14-kHz Pake doublet becomes apparent and persists up to the melting point of 237 K. The 14-kHz splitting and symmetric lineshape is consistent with rapid ($\geq 10^7$ s^{-1}) C_3 and C_3' motions, as occur in the solid III of *tert*-butylchloride (12, 5) and *tert*-butylbromide (13, 5).

Similarly, the deuterium spectrum of $(CD_3)_3CCHO$ indicates 10^5–10^7 s^{-1} C_3 and C_3' motion at 115 K, and the 12–14 kHz splitting is observed at 153 K (Fig. 3). However, further motional averaging occurs in *tert*-butylaldehyde at temperatures below the transition to the plastic phase, which occurs at 190 ± 2 K. Since rapid C_3 and C_3' motions are already occurring, the additional motion, which narrows the width of the powder spectrum (Fig. 3) to approximately 8 kHz and increases η to ~0.6, must involve whole molecule motion, possibly C_2' flips (*vide infra*).

The observation of whole molecule reorientation in solid II was unexpected, since dielectric data (10) taken at 100 kHz did not indicate any motion of the dipole moment in this phase. The dielectric results might be consistent with the ^2H nmr observations, however, if 2-site exchange is occurring between aldehyde sites oriented such that the molecular dipole moments in each site are approximately parallel. This is not an impossible requirement: the dipole moment of pivaldehyde is oriented about 11° away from the C_2' axis shown in Fig. 4 (16). If this geometry holds for the solid state, the dielectric constant will not be affected significantly by 180° flips about this axis.

The ^2H lineshapes above 167 K are also consistent with a 180° flip motion. Note that if the C—C—C angle in Fig. 4 is tetrahedral, the C_2' axis is oriented approximately 54.7 degrees from the C_3 and C_3' averaged principal axes of the methyl deuterons, and also that the splitting in the 153 K spectrum, approximately 12.5 kHz, corresponds to $\chi \simeq 16.7$ kHz. Numerical simulation of the effect of fast C_2' flips (Fig. 5) shows good agreement with the experimental spectrum at 168 K when χ is assumed to be 15.2 kHz, and the angle between the flip axis and the principal efg axis is taken as 51.5 degrees. The simulation is based on the formalism described by Becker (17), and includes Gaussian linebroadening equivalent to $\frac{1}{10}$ the spectral width.

Onset of motional averaging beyond C_3 and C_3' in the *tert*-butyl-X compounds (e.g., X = Cl, Br, I, SH) is typically accompanied by a phase transition (prior to the plastic phase); thus the observation of whole molecule reorientations in *tert*-butylaldehyde led us to suspect that a phase change occurs in the 152–188 K temperature range. There is no apparent discontinuity in the plots of dielectric constant vs. T (10) or in the plot of ln T_1 (^2H) vs. T^{-1} (Fig. 6) at temperatures *below* the phase transition to the plastic phase; however, the ^2H lineshapes in the 153–188 K range exhibit some very unusual behaviour. Plots of the components of the deuterium quadrupole coupling tensor versus temperature (Fig. 7) indicate that there is an abrupt change at about 165 ± 5 K. From 153 to 165 K the q_{yy} component is almost constant, while the q_{zz} and q_{xx} components decrease rapidly in frequency (i.e., η increases rapidly, Fig. 8), and it is clear that this does not reflect an activated process. From 168 K to temperatures just below the transition to the plastic phase there are only small changes in the frequencies of the ^2H quadrupolar tensor components and, as demonstrated above, the ^2H nmr lineshape can be interpreted in terms of 2-fold flips. The rapid changes occurring in the 153–165 K range might possibly be associated with 2-fold flips between sites having different statistical populations (i.e., an asymmetric double-well potential) (18). Such a model could explain the rapid increase in η between 153 K and 165 K.

The obvious inference from the abrupt changes in the ^2H nmr lineshapes at 165 K (Figs. 7 and 8) is that there is a second solid–solid phase transition, and this has in fact been confirmed from the results of a calorimetric study (19). In the ln T_1(^2H) vs. T^{-1} plot (Fig. 6), 165 K is the temperature at which there appears to be a broad T_1 minimum. Phase transitions without abrupt changes in T_1 are not unknown (20). The minimum in Fig. 6

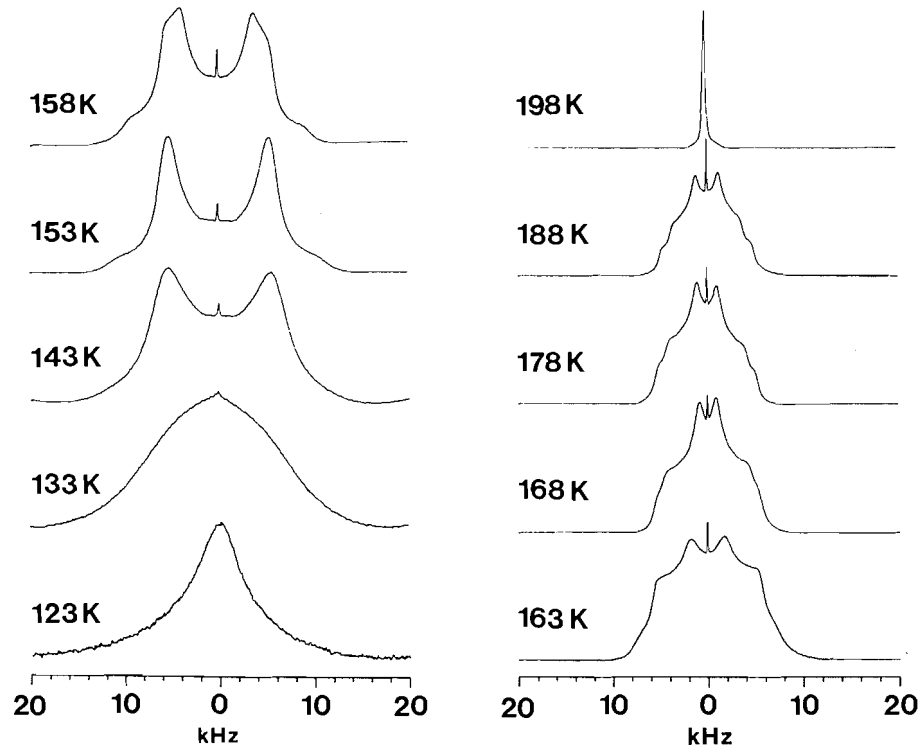

FIG. 3. Deuterium nmr spectra of $(CD_3)_3CCHO$ between 123 and 198 K.

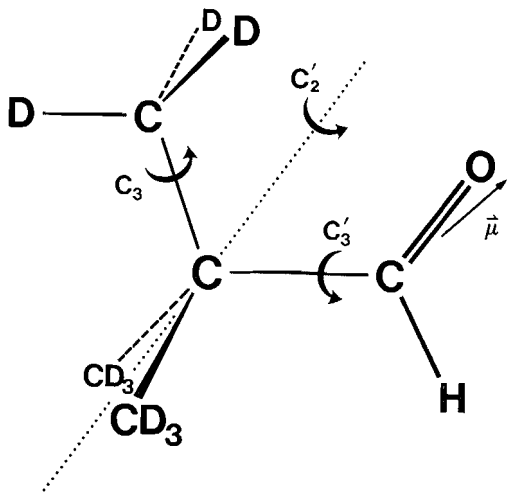

FIG. 4. Illustration of an approximate C_2' axis and the direction of the dipole moment in *tert*-butylaldehyde.

occurs at $T_1 = 2.0$ ms, corresponding to $\tau_{eff} = 0.6158\ \omega_0^{-1} = 3.2 \times 10^{-9}$ s. Assuming that only C_3 and C_3' motions are effective for relaxation near ω_0^{-1}, $T_{1\,min}$ is calculated as 1.7 ms (21) when the rates of both motions are equal and have a value of 8.4×10^7. If the rates of the two motions differ (as expected), the calculated T_1 minimum increases; thus this model can account for the observed value. The E_a from the slope above 165 K is about 15 kJ mol^{-1}.

There is no evidence to suggest that hydrogen bonding plays a role in the reorientational motion of *tert*-butylaldehyde in solid II or solid III. If hydrogen bonding occurred, as in pivalic acid (22), we would expect an activation energy of approximately 50–60 kJ mol^{-1}. By contrast, *tert*-butylaldehyde between 130 and 190 K behaves very much the same as solids II–IV of the thiol analog (6), in which hydrogen bonding does not occur.

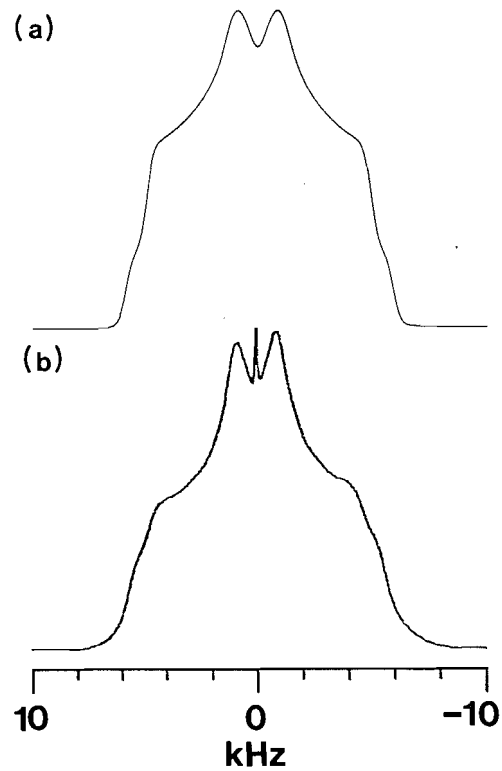

FIG. 5 Experimental ^2H nmr spectrum of $(CD_3)_3CCHO$ at 168 K (bottom) and simulated spectrum (top), assuming fast C_2' flips about an axis oriented 51.5 degrees from the principal axis of the field gradient, a quadrupolar coupling constant of 15.2 kHz, and $\eta = 0$.

B. Rotator phase: Solid I

In a rotator or "plastic" phase, molecular reorientation is rapid enough in all directions to completely average the quadrupolar interaction and only a single line is observed in the ^2H spectrum.

As noted above and by Chihara *et al.* (8), no solid–solid

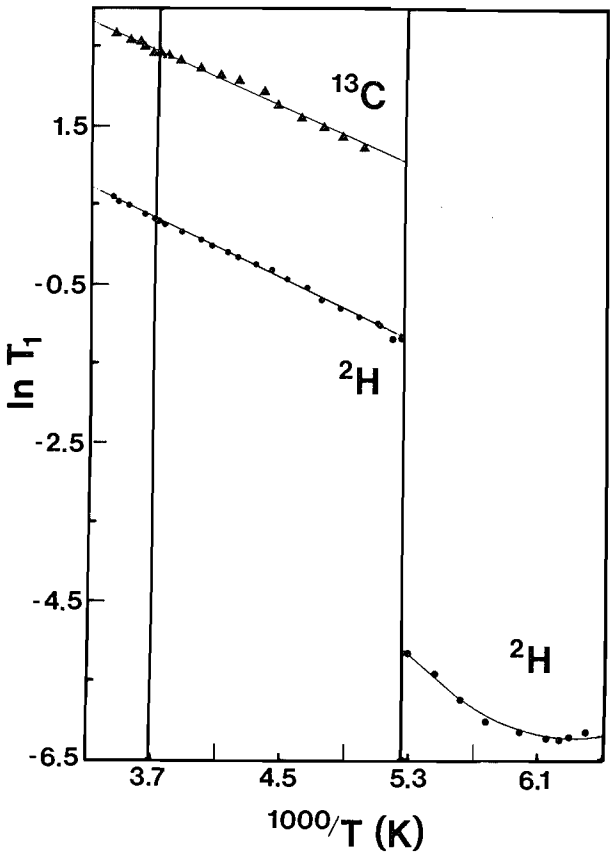

FIG. 6. The temperature dependence of ^{2}H and ^{13}C T_1 values in *tert*-butylaldehyde. The ^{2}H T_1's were obtained for $(CD_3)_3CCHO$ while the methyl ^{13}C T_1 measurements were made on an unlabelled sample of $(CH_3)_3CCHO$. The vertical lines represent the liquid ↔ solid I and solid I ↔ solid II phase transitions.

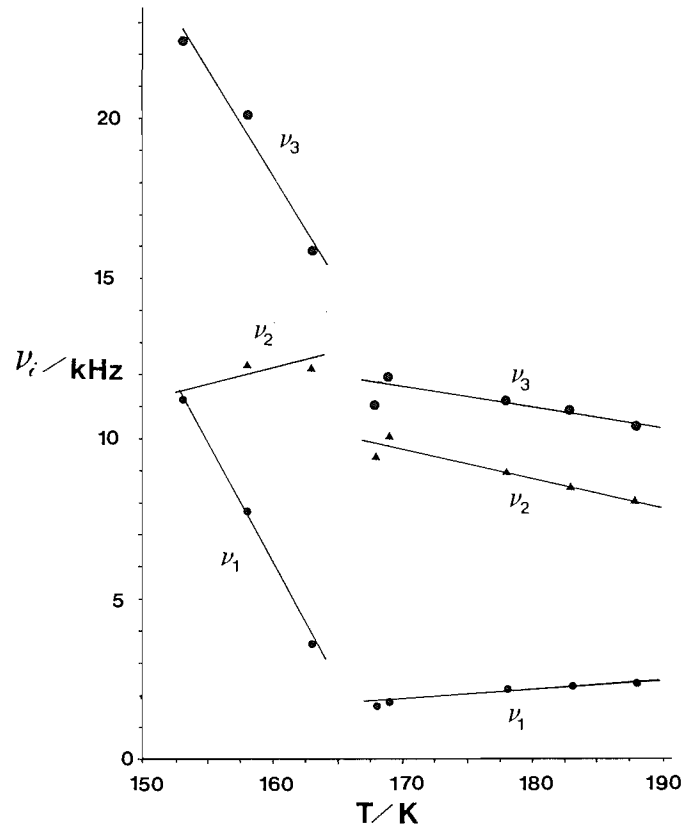

FIG. 7. Plot of the principal components of the quadrupolar coupling tensor vs. temperature for $(CD_3)_3CCHO$ between 150 and 190 K.

phase transitions are observed in *tert*-butyliodide upon warming. However, when the sample is cooled sufficiently slowly, a rotator phase forms at 239 K and is stable down to 212 K where solid II, characterized by the 14 kHz splitting, is observed. Rapid cooling results in formation of solid II at temperatures above the 212 K transition point, hence the transition at 222 K noted by Köksal (9) is not surprising. The equilibrium transition temperature may be even lower than 212 K, which we achieved by cooling at a rate of 2° per hour.

The rotator phase of $(CD_3)_3CI$ can be distinguished from the liquid by both the Arrhenius behaviour and the discontinuity in the ^{2}H T_1 at the freezing point (Fig. 9). The activation energies and effective rotational correlation times obtained from least-square fits of the ln T_1 vs. T^{-1} plots are compared with data from other *tert*-butyl-X compounds in Tables 1 and 2 respectively.

As noted above, spin-lattice relaxation data for the methyl group of *tert*-butylaldehyde are plotted in Fig. 6. Carbon-13 and ^{17}O T_1 measurements were also performed on the aldehyde moiety. The nOe of the methyl carbon is full in both liquid and solid I phases, but the nOe of the aldehyde carbon gradually decreases from the full value of 2.988 at 216 K to 1.95 near the melting point. Both T_1 (observed) and the nOe were thus measured at various temperatures to calculate

$$T_{1dd} = 1.988(T_{1,obs})/(\text{nOe} - 1)$$

and effective rotational correlation times from refs. 23 and 24:

$$[1] \quad (T_{1dd})^{-1} = \left(\frac{\mu_0}{4\pi}\right)^2 n_H \frac{\hbar^2 \gamma_H{}^2 \gamma_C{}^2}{r_{CH}^6} \tau_{eff}$$

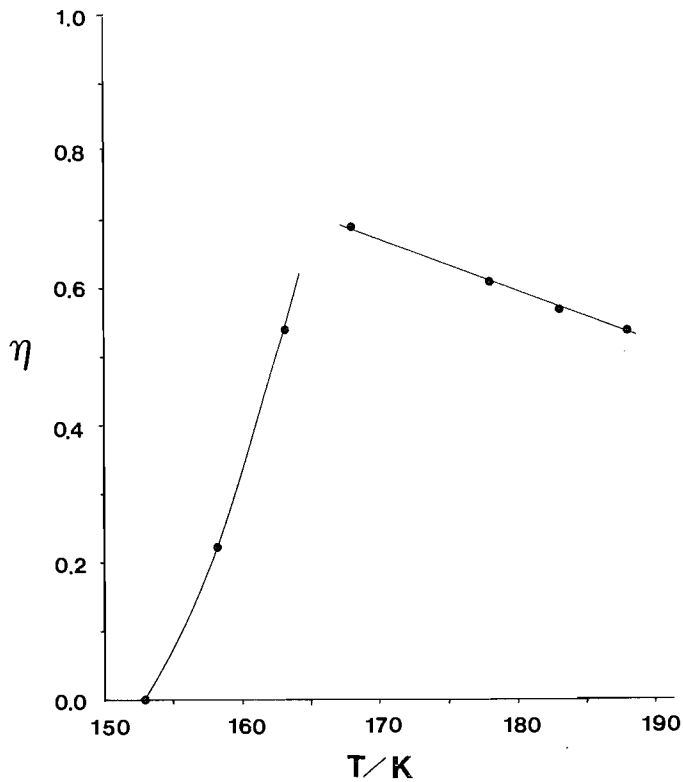

FIG. 8. Plot of the asymmetry parameter, η, vs. temperature for $(CD_3)_3CCHO$ between 150 and 190 K.

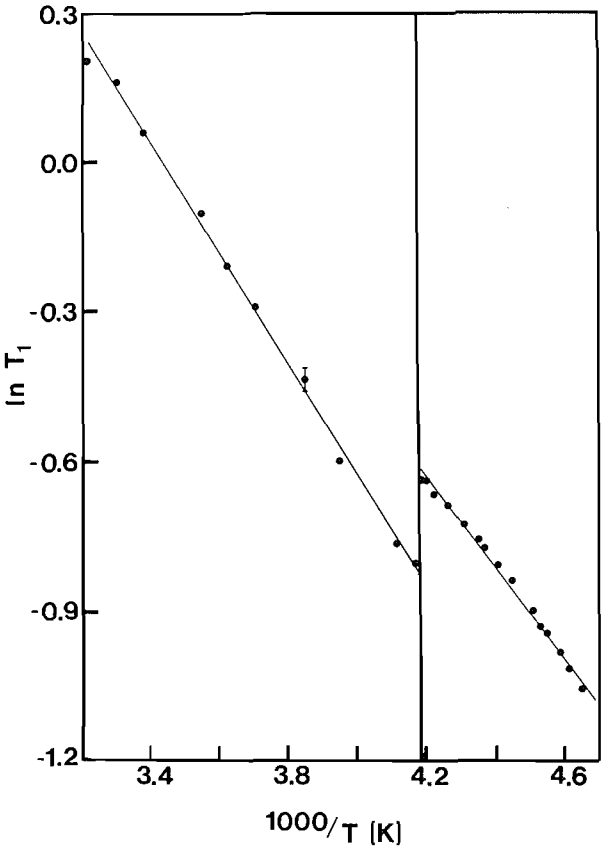

FIG. 9. The temperature dependence of ^2H T_1 values in *tert*-butyliodide. The values obtained in solid II were obtained upon slowly cooling the sample from the liquid.

TABLE 1. Activation energies from the temperature dependence of ^2H T_1's in several *tert*-butyl-X compounds, in kJ mol^{-1}

X	E_a, liquid	E_a, solid I	Reference
CH_3	4.1	4.1	31
Cl	7.0	5.8	Present
SH	7.1	7.1	6
Br	7.9	7.2	13
CHO	7.8	7.8	Present
I	9.1	7.6	Present

Using r = 109 pm for the methyl carbon/hydrogen bond length, and r = 111.4 pm for the C—H of the aldehyde group (as in acetaldehyde (25)), the simple relationships τ_{eff} (methyl) = 15.6 ps/T_{1dd} (in s), and τ_{eff} (aldehyde) = 53.0 ps/T_{1dd}(s) are obtained. The six closest methyl protons (at approximately 272 pm, (25)) contribute less than 3% to T_{1dd} of the aldehyde carbon.

Both ^2H and ^{17}O relax solely by the quadrupolar mechanism, for which (23, 26)

$$[2]\quad (T_1)^{-1} = \frac{3}{10}\,\pi^2\chi^2\,\frac{2I+3}{I^2(2I-1)}\left(1+\frac{\eta^2}{3}\right)\tau_{eff}$$

when $(\tau_{eff}\omega_0)^2 \ll 1$. The quadrupolar coupling constant and asymmetry parameter of ^2H in *tert*-butylaldehyde is 172 ± 2 kHz, η = 0 (see Fig. 2, 95 K), thus $\tau_{eff}(^2H)$ = 2.28 ± 0.05 ps/T_1(s). For the ^{17}O data, χ and η are estimated from the experimental values for formaldehyde (27) and the calculated values for acetaldehyde (28) as 11.8 ± 1 MHz and 0.55 ± 0.1, respectively. Using these values, $\tau_{eff}(^{17}O)$ = 6.8 ± 1.4 ps/T_1 (ms).

TABLE 2. Effective correlation times at the melting point (in ps), determined from ^2H T_1 data of labelled methyl groups in several *tert*-butyl-X compounds

X	τ_{eff}, liquid	τ_{eff}, solid I	Reference
CH_3	0.9	0.9	31
Cl	2.0	1.8	Present
SH	1.5	1.3	6
Br	2.5	2.2	13
CHO	1.6	1.6	Present
I	5.3	4.2	Present

Methyl ^{13}C and ^2H T_1 data for *tert*-butylaldehyde are in good agreement, as shown in Fig. 6. From these data we obtain an activation energy E_a of 7.8 ± 0.5 kJ mol^{-1} for overall molecular tumbling in both solid I and liquid phases. The effective rotational correlation time at the melting point (mp) is 1.5 ± 0.1 ps.

Due to the near-zero slope of T_1 (observed) and errors in the measurements of the nOe, there is considerable scatter in the ln T_{1dd} versus T^{-1} data for the aldehyde carbon. Least-squares fit of the data yields ln T_1/s = $-1.06(10^3)/T + 7.71$, from which E_a is calculated as 9 ± 2 kJ mol^{-1}, and τ_{eff}(mp) = 1.2 ± 0.3 ps. Rapid relaxation and broad lines in the ^{17}O spectrum also result in poor reproducibility of the T_1 data, and make T_1 measurements below 240 K impractical. Despite these difficulties, the least-squares fit of the data over the temperature range 241–292 K, ln T_1/ms = $-1.30(10^3)/T$ + 6.74, yields an E_a for the aldehyde group of 11 ± 2 kJ mol^{-1} and τ_{eff}(mp) = 1.0 ± 0.3 ps, in reasonable agreement with the ^{13}C data. The shorter effective correlation times obtained for the aldehyde substituent relative to that of the methyl groups may indicate independent internal rotation of the aldehyde moiety in solid I, but the uncertainty of the data does not allow us to state this with confidence. Internal rotation would, however, result in differences in the ^{17}O and ^{13}C T_1 data, due to the different orientation of the respective principal axes (28, 17). Microwave data have determined a value of 4.9 kJ mol^{-1} for reorientation of the *tert*-butyl group (V_3) in pivaldehyde (16).

Again, note the striking similarity between pivaldehyde and *tert*-butylthiol; the latter has a melting point of 274 K (29), and an internal barrier V_3 = 7.1 kJ mol^{-1} (30). The correlation times at the melting point of *tert*-butylthiol are 1.5 ± 0.1 ps from the methyl data and 1.1 ± 0.1 ps for the deuterated thiol substituent (6). Overall anisotropic rotational diffusion cannot account for the shorter rotational correlation time of the thiol group.

C. Discontinuity of τ_{eff} at the melting point

In *tert*-butyliodide, an increase in T_1 upon decreasing the temperature from 243 to 241 K (liquid → solid I) indicates a decrease in τ_{eff}, i.e., faster reorientation immediately upon entering solid I. This result has also been observed in *tert*-butylbromide (13), *tert*-butylthiol (6), and, although not previously reported for *tert*-butylchloride (12), more accurate ^2H T_1 data (Fig. 10) confirm that a discontinuous decrease in τ_{eff} upon freezing occurs in this compound as well.

Within experimental error, however, we cannot claim such a discontinuity in the *tert*-butylaldehyde data, although in light of the observation of this result in all other *tert*-butyl-X samples that we have studied, it is somewhat surprising that it is not observed for X = CHO.

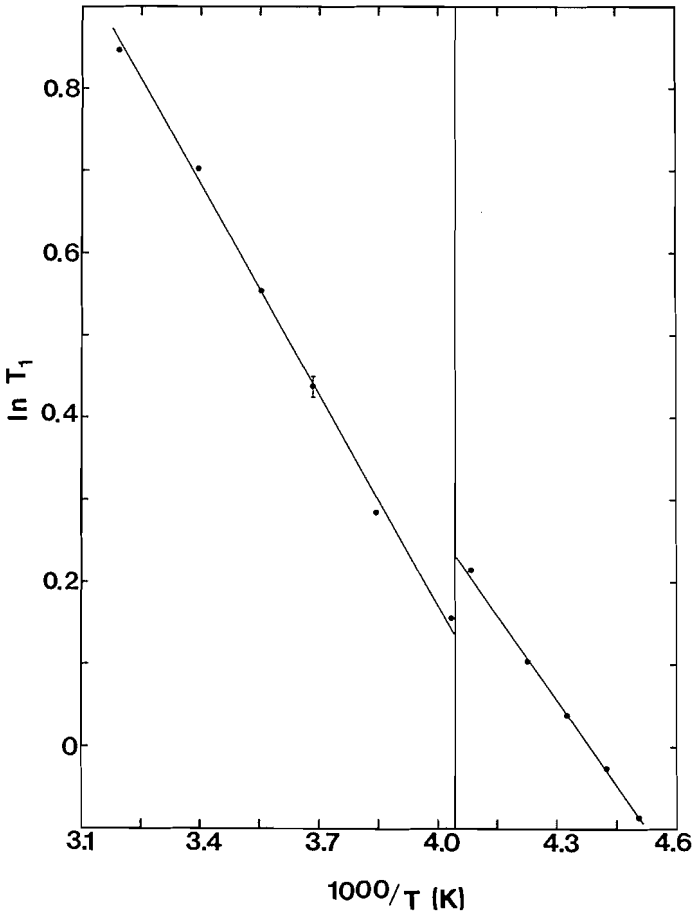

FIG. 10. Deuterium T_1's in the liquid and solid I phases of *tert*-butylchloride.

D. Liquid

The activation energy obtained for $(CD_3)_3CI$ in the liquid phase is 9.1 kJ mol^{-1}, somewhat higher than usual (Table 1). Effective correlation times calculated for *tert*-butyliodide at the melting point, using $\tau_{eff} = 2.23$ ps/T_1 (s), are also 2 to 3 times longer than for the other *tert*-butyl-X compounds. This no doubt reflects the severe departure from tetrahedral symmetry introduced by the large iodine atom, which is likely to be the bulkiest *tert*-butyl substituent for which a plastic phase is observed.

Within experimental error, activation energies calculated for liquid *tert*-butylaldehyde are the same as in solid I. With reference to Table 1, it is interesting to note that the activation energies obtained in solid I of the *tert*-butyl-X compounds are, in all cases, either less than or equal to the activation energies obtained in the liquid.

Received September 2, 1987

This paper is dedicated to Professor J. A. Morrison

CONSTANTINE MAVROYANNIS. Can. J. Chem. **66**, 741 (1988).

The optical excitation spectra of neutral rare-gas atoms physisorbed on metal surfaces have been considered. Emphasis has been given to the dynamic effects of the surface plasmons on the lifetimes of the adsorbed atoms. At low coverage and when the damping of the surface plasmons is much greater than the effective radiative damping, the spectral functions of the symmetric and antisymmetric modes consist of asymmetric Lorentzian lines, whose asymmetry depends on the strength of the surface plasmons. At this limit the relative intensities of the symmetric and antisymmetric modes take positive and negative values describing the physical processes of absorption (attenuation) and stimulated emission (amplification), respectively. Hence, the occasional disappearance of the spectral lines of the optical absorption is due to a cancellation process, which takes place between the frequency profiles arising from two nearby excited states of the adsorbed atom. The red shifted peak of the symmetric mode of the higher excited state and the blue shifted peak of the antisymmetric mode of the lower excited state of the atom cancel each other out provided that their frequency profiles nearly coincide. This may be a possible explanation of the persistence-extinction phenomenon that has been observed for a number of rare-gas substrate systems in the low coverage limit, where it has been proposed that a charge-transfer instability exists. Numerical results indicate that the peaks of excited Xe on Al and excited Kr on Au vanish in the low coverage limit.

CONSTANTINE MAVROYANNIS. Can. J. Chem. **66**, 741 (1988).

On a étudié les spectres d'excitation optique d'atomes de gaz rares neutres adsorbés physiquement sur des surfaces métalliques. On considère principalement les effets dynamiques des plasmons de surface sur les temps de vie des atomes adsorbés. Lorsque la couverture est faible et que le ralentissement des plasmons de surface est beaucoup plus grand que le ralentissement radiatif effectif, les fonctions spectrales des modes symétriques et antisymétriques consistent en des raies asymétriques de Lorentz dont l'asymétrie dépend de la force des plasmons de surface. A cette limite, les intensités relatives des modes symétriques et antisymétriques prennent des valeurs positive et négative en décrivant respectivement les processus physiques d'adsorption (atténuation) et d'émission stimulées (amplification). Il s'en suit que la disparition occasionnelle des lignes du spectre d'absorption optique est due à une processus d'annulation qui prend place entre les profils de fréquence qui proviennent de deux états excités adjacents de l'atome adsorbé. La raie déplacée vers le rouge du mode symétrique de l'état excité le plus élevé de l'atome et la raie déplacée vers le bleu du mode antisymétrique de l'état excité le plus bas de l'atome s'annulent lorsque leurs profils de fréquence coïncident. Ceci est une explication possible du phénomène de persistance–extinction qui a été observé pour un certain nombre de systèmes de substrats de gaz rares à la limite d'une couverture faible et pour lesquels il a été proposé qu'il existe une instabilité de transfert de charge. Les résultats numériques indiquent que les raies dûes au Xe excité sur Al et au Kr excité sur Au disparaissent à la limite d'une couverture faible.

I. Introduction

There has been an accumulation of experimental data concerning the optical spectra of rare-gas atoms physisorbed on metal surfaces. The differential reflectivity experiments were conducted by Flynn and co-workers (1–10) by means of synchrotron radiation. They measured the optical spectra of the adsorbate atoms on metal surfaces as a function of coverage. In the high coverage limit, the observed spectra were found to be similar to comparable excitations in the gas phase and condensed rare gases. Striking changes in the optical spectra have been found (1–4) in the limit of low coverage as should be expected since at this limit, participation of the surface excitations is anticipated to take place. At low coverage the optical spectra disappear on some surfaces but persist on others. For instance, the adsorbed spectra of Xe on Ti, Al and Au and Kr on Au vanish while those of Xe and Ar on Mg, Kr on Al, and Ar on Au persist (1–4).

The dependence of the optical absorption data on the quantity $\phi - I^*$, where ϕ is the metal work function and I^* is the energy required to ionize the rare-gas atom in its lowest excited state, led the authors (3–6) to propose the existence of a "charge-transfer instability" for rare-gas–metal–substrate systems. Briefly, if $I^* > \phi$, the adsorbate level lies well below the Fermi level of the metal substrate, the excited electron cannot enter the metal but is localized on the excited atom; with the result that the final-state adsorbate configuration is neutral. If $\phi > I^*$, the excited state lies above the Fermi level and is unstable against charge-transfer to the metal. The observed spectra led the authors (2, 3, 8) to suggest that the "switch" to blue shifts for $\phi > I^*$ occurs when the excitation causes the rare-gas atom to become ionized. Arguments against the foregoing interpretation of the optical data have been made by Lang and co-workers (11, 12). No theoretical explanation has been developed (11, 13) for the occasional disappearance of the excitonic component of the optical-absorption spectra at low coverage.

Since then, the spectra of the rare-gas adsorbates on metal surfaces have been studied by a number of methods such as Auger electron yield (14), electron-energy-loss spectroscopy (15), and photoemission methods (16). The results derived by these methods differ among themselves and with the optical data obtained by the use of the differential reflectance technique (1–3). Photoemission experiments (12, 16) have suggested adsorbate energy-level configurations, which agree with density-functional calculations (11, 12) but which disagree with the interpretation of the optical data. A recent review on the subject has been written by Flynn (10) to whom we refer for further details and literature. We shall describe here our recent work

(17) concerning the optical excitation spectra of neutral rare-gas atoms physisorbed on metal surfaces. The model Hamiltonian, which is used to derive the expressions of the appropriate Green functions of the system is developed in Section II. The excitation spectra of the symmetric and antisymmetric modes of the system have been considered in Sections III and IV, respectively. The computed spectra of Xe, Kr, and Ar on various metal surfaces are graphically presented and discussed. Concluding remarks are presented in Section V.

II. The model Hamiltonian

We take a simple model (17–19), which consists of a plane boundary separating an empty space and a homogeneous isotropic metallic medium having a dielectric function

$$[1] \quad \epsilon(\omega) = 1 - \frac{\omega_p^2}{\omega^2 + i\omega\gamma_{sp}}$$

where ω_p is the plasma frequency of the metallic electrons and γ_{sp} ($\gamma_{sp} \ll \omega$) is the intrinsic damping of surface plasmons due to the decay processes arising from the interactions with electron-hole pairs (20), phonons (21), impurities (22), etc. A neutral atom A is fixed at (0, 0, R) with z-axis taken perpendicular to the plane $z = 0$. The image of the atom A, which is designated by B, will be situated at (0, 0, $-R$) from the plane in the metallic medium described by the dielectric function $\epsilon(\omega)$. Each electron $(x_i, y_i, R - z_i)$ of the atom A with charge e will have an image $(x_i, y_i, R + z_i)$ having a fictitious charge $-e\epsilon_1$, where

$$[2] \quad \epsilon_1 \equiv \epsilon_1(\omega) = \frac{\epsilon(\omega) - 1}{\epsilon(\omega) + 1}$$

The existence of the screening factor $\epsilon_1(\omega)$ is due to boundary conditions at the plane separating the empty space and the homogeneous isotropic metallic medium for distances of the atomic electrons from the plane at which retardation effects can be discarded (18, 19). The limit of either $\omega \to 0$ or $\omega_p \to \infty$ leads to $\epsilon(\omega) \to \infty$ and $\epsilon_1(\omega) = 1$; this limit exists for the so called "perfect conductor", where the medium excludes the field completely.

The atom A is assumed to have nondegenerate electronic states, the ground and excited states denoted by $|0\rangle$ and $|\nu\rangle$ with frequencies E_0 and E_ν, respectively. The electronic transitions $|0\rangle \leftrightarrow |\nu\rangle$ are electric dipole allowed and the transition frequencies are denoted by $E_{\nu 0} = E_\nu - E_0$; units in which $\hbar = 1$ are used throughout. The distance $2R$ between the atom A and its image B is taken such that the inequality $(2RE_{\nu 0}/c) < 1$ is satisfied and retardation effects are unimportant. The distance $2R$ is also taken such that the overlap between the wavefunctions is very small and may be neglected and the interaction between the physisorbed atom A and its image B is of the dipole–dipole type (18); effects associated with the translational motion of the atom A and its image such as recoil, etc., are ignored. The Hamiltonian describing the system consisting of the atom A interacting with its image B at a distance $2R$ apart may be taken to be (17, 19)

$$[3] \quad H = \sum_\nu E_{\nu 0}(b_{A\nu}^\dagger b_{A\nu} + b_{B\nu}^\dagger b_{B\nu}) + \sum_\nu V_{AB}^\nu \bar{b}_{A\nu}\bar{b}_{B\nu} + \sum_{k,\lambda} ck\beta_{k\lambda}^\dagger\beta_{k\lambda} + \frac{\bar{\omega}_p^2}{4}\sum_{k,\lambda}\frac{1}{ck}\bar{\beta}_{k\lambda}^\dagger\bar{\beta}_{k\lambda} + \frac{i\bar{\omega}_p}{2}\sum_{k,\lambda,\nu}\left[f_{0\nu}(\boldsymbol{k},\lambda)\frac{E_{\nu 0}}{ck}\right]^{1/2} \times (e^{-i\boldsymbol{k}\cdot\boldsymbol{R}}\bar{b}_{A\nu} + \epsilon_1 e^{i\boldsymbol{k}\cdot\boldsymbol{R}}\bar{b}_{B\nu})\bar{\beta}_{k\lambda}$$

where $f_{0\nu}(\boldsymbol{k}, \lambda)$ is the oscillator strength of the electronic transition $|0\rangle \leftrightarrow |\nu\rangle$ and $\bar{\omega}_p$ is the plasma frequency of the atomic electrons defined by $\bar{\omega}_p^2 = 4\pi e^2 S/mV$, where S is the number of all optically active electrons of the neutral atom A; and m and V are the electron mass and the volume of the sample container, respectively. The operators $\beta_{k\lambda}^\dagger$ and $\beta_{k\lambda}$ are the boson creation and annihilation operators describing the electromagnetic field with wavevector $\boldsymbol{k}$, frequency ck and transverse polarization $\lambda = 1, 2$, and $\bar{\beta}_{k\lambda} = \beta_{k\lambda} + \beta_{k\lambda}^\dagger$. The atomic excitation operators $b_{A\nu}^\dagger, b_{A\nu}$ and $b_{B\nu}^\dagger, b_{B\nu}$ are defined as

$$[4] \quad b_{A\nu}^\dagger = \alpha_{A\nu}^\dagger\alpha_{A0}, \quad b_{A\nu} = \alpha_{A0}^\dagger\alpha_{A\nu}, \quad b_{B\nu}^\dagger = \alpha_{B\nu}^\dagger\alpha_{B0}, \quad b_{B\nu} = \alpha_{B0}^\dagger\alpha_{B\nu}, \quad \bar{b}_{A\nu} \equiv b_{A\nu} + b_{A\nu}^\dagger, \quad \tilde{b}_{A\nu} \equiv b_{A\nu} - b_{A\nu}^\dagger$$

where $\alpha_{Ai}^\dagger, \alpha_{Bi}^\dagger$ and α_{Ai}, α_{Bi} are the Fermi creation and annihilation operators describing the electron states $i = |0\rangle$ and $i = |\nu\rangle$ of the atom A and image B, respectively; and the corresponding electron number operators are defined as $n_{Ai} = \alpha_{Ai}^\dagger\alpha_{Ai}$ and $n_{Bi} = \alpha_{Bi}^\dagger\alpha_{Bi}$.

The atomic excitation operators $b_{A\nu}^\dagger, b_{A\nu}$ and $b_{B\nu}^\dagger, b_{B\nu}$ satisfy the following commutation relations

$$[5] \quad [b_{A\nu}, b_{A\nu}^\dagger]_- = n_{A0} - n_{A\nu} = 1 - 2n_{A\nu}, \quad [b_{A\nu}^\dagger, b_{B\nu}]_- = [b_{B\nu}^\dagger, b_{A\nu}]_- = 0, \quad [b_{B\nu}, b_{B\nu}^\dagger]_- = n_{B0} - n_{B\nu} = 1 - 2n_{B\nu}, \quad [b_{A\nu}, b_{B\nu}]_- = [b_{A\nu}^\dagger, b_{B\nu}^\dagger]_- = 0$$

where

$$[6] \quad \sum_\nu n_{A\nu} = \sum_\nu n_{B\nu} = 1$$

When the average value of the number operators $n_{A\nu}$ and $n_{B\nu}$ are much smaller than unity, i.e., when

$$\bar{n}_{A\nu} \equiv \langle n_{A\nu}\rangle \ll 1, \quad \bar{n}_{B\nu} \equiv \langle n_{B\nu}\rangle \ll 1,$$

then the excitation operators $b_{A\nu}^\dagger, b_{A\nu}$ and $b_{B\nu}^\dagger, b_{B\nu}$ satisfy approximately Bose statistics.

The first term on the right-hand side (rhs) of eq. [3] represents the free atomic fields while the second term describes the Coulomb interaction between the atom A and its image B; the coupling function $V_{AB}^\nu = \bar{V}\epsilon_1$, where $\bar{V} = \Sigma U_{0\nu}^{AB}(\boldsymbol{R})$ is the Coulomb interaction, which in the dipole–dipole approximation, is the Lennard–Jones energy of interaction (18, 23–25). The third and fourth terms represent the free electromagnetic field and the contribution arising from the square of the vector potential term of the electromagnetic field, respectively. The last term describes the interaction of the electromagnetic field with the electron states of the atoms A and B.

For a perfect conductor $\epsilon(\omega) = \infty$ and $\epsilon_1 = 1$ the Hamiltonian [3] describes the interaction between the atom A and a perfectly conducting plane of distance R apart or the interaction between the atom A and its image B, which is equivalent to that describing the interaction between two identical atoms in the gas phase at a distance $2R$ apart (26–29). All the interactions involved in the Hamiltonian [3] are weak perturbations and, therefore, any time-dependent perturbation method when appropriately chosen is suitable to study the required excitation spectra arising from radiative and nonradiative decay mechanisms. We shall make use of the retarded double-time Green functions whose properties as well as whose use in statistical physics can be found elsewhere (30).

The atom A and its image B interact through their dipole–dipole interactions and radiate to each other as well and, hence, due to the cooperative radiative interaction between the atom A and its image B two new states, the symmetric and antisym-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

metric (with respect to interchange between the atoms), are generated (31). The excitation spectra due to the process $|0\rangle \leftrightarrow |\nu\rangle$ for the symmetric and antisymmetric modes are determined by the imaginary parts of the Green functions $-2\mathrm{Im}G_{AB}^{(\pm)}(\omega)$, where the Green functions $G_{AB}^{(\pm)}(\omega)$ are defined as

$$[7] \quad G_{AB}^{(\pm)}(\omega) = \langle\langle b_{A\nu} \pm b_{B\nu}; b_{A\nu}^{\dagger} \pm b_{B\nu}^{\dagger}\rangle\rangle$$

The plus (+) and (−) signs refer to the symmetric and antisymmetric combination with respect to the interchange between the atom A and its image B. $G_{AB}^{(\pm)}(\omega)$ are Fourier transforms of the corresponding Green functions (30). The expressions for the absorption coefficient describing the transition $|0\rangle \leftrightarrow |\nu\rangle$ for the symmetric and antisymmetric modes of the system consisting of the atom A interacting with its image B are determined by the spectral functions which are obtained from the imaginary parts of the Green functions $G_{AB}^{(\pm)}(\omega)$, namely $-2\mathrm{Im}G_{AB}^{(\pm)}(\omega)$.

Using the Hamiltonian [3] we derive the following equations of motion for the Green functions

$$[8] \quad G_{AB}^{(\pm)}(\omega) = \frac{2(\bar{n}_0 - \bar{n}_\nu)(E_{\nu 0} \pm 2V_{AB}^{\nu})}{\pi(\omega^2 - \omega_{\pm}^2)}$$

where $\bar{n}_0 = \langle\alpha_{A0}^{\dagger}\alpha_{A0}\rangle = \langle\alpha_{B0}^{\dagger}\alpha_{B0}\rangle$ and $\bar{n}_\nu = \langle\alpha_{A\nu}^{\dagger}\alpha_{A\nu}\rangle = \langle\alpha_{B\nu}^{\dagger}\alpha_{B\nu}\rangle$ are the average values of the electron number operators describing the electron population of the states $|0\rangle$ and $|\nu\rangle$ at $t = t'$, respectively. The energies of excitation ω_+ and ω_- are defined as

$$[9] \quad \omega_{\pm}^2 = (E_{\nu 0} \pm 2V_{AB}^{\nu})(E_{\nu 0} \pm \gamma_{\pm})$$

where $\gamma_\pm$ denote scattering functions, which are determined by

$$[10] \quad \gamma_{\pm} \equiv \gamma_{\pm}(\omega) = \tfrac{1}{2}\gamma[1 + \epsilon_1^2(\omega)] \pm \epsilon_1(\omega)\gamma_{AB}$$

with

$$[11] \quad \gamma_{AB} \equiv \gamma_{AB}(\omega) = \bar{\omega}_p^2 \sum_{k,\lambda,\nu} \frac{f_{0\nu}(k,\lambda)E_{\nu 0}}{(\omega^2 - c^2k^2 - \omega_p^2)} \exp 2i(\boldsymbol{k}.\boldsymbol{R})$$

The scattering function $\gamma \equiv \gamma(\omega) \equiv \gamma_{AA}(\omega) \equiv \gamma_{BB}(\omega)$ is derived from the expression $\gamma_{AB}(\omega)$, eq. [11], if the exponential $\exp 2i(\boldsymbol{k}.\boldsymbol{R})$ is replaced by unity. The Green functions $G_{AB}^{(\pm)}(\omega)$ given by eq. [8] will be used to describe the excitation spectrum of the symmetric and antisymmetric modes, which for the sake of convenience, will be discussed separately.

III. Excitation spectra of the symmetric modes

To discuss the excitation spectrum, we consider the case of short distances of separation between the atom and the metal surface, i.e., where the inequality $(2RE_{\nu 0}/c) < 1$ is satisfied and retardation effects are unimportant (17–19, 26–29). In this case, the expressions for $\gamma_\pm(\omega)$ can be calculated from eqs. [10] and [11]; the results of such a calculation are known in the literature (26–29, 32–34). For $(2RE_{\nu 0}/c) < 1$ an expansion in powers of $2RE_{\nu 0}/c$ yields $\mathrm{Re}\gamma_{AB}(\omega) \approx 0$. The imaginary part of $\gamma_{AB}(\omega)$ depends on the distance R through the $\exp 2i(\boldsymbol{k}.\boldsymbol{R})$ in eq. [11]. The dependence of the lifetime of the physisorbed atom on the distance from the surface has been extensively discussed in the literature (35–39) and has been verified experimentally as well (40, 41). In the present study, we confine ourselves only to the case of short distances for which $(2RE_{\nu 0}/c) < 1$, and we are mainly concerned with the effects of surface plasmons on the lifetime of the physisorbed atoms and, hence, variations of the decay process with the distance will be completely ignored. Then the imaginary part of $\gamma_{AB}(\omega)$ is determined by (26–29)

$$[12] \quad \mathrm{Im}\gamma_{AB}(\omega) \approx \mathrm{Im}\gamma(\omega) \approx \gamma_0 = \tfrac{4}{3}(E_{\nu 0}/c)^3|P_{0\nu}|^2$$

and describes the spontaneous emission probability for the transition $|\nu\rangle \rightarrow |0\rangle$, where $\boldsymbol{P}_{0\nu}$ is the matrix element of the transition dipole moment and is assumed to be real. Then from eq. [10], we have

$$[13] \quad \mathrm{Im}\gamma_{\pm} \equiv \mathrm{Im}\gamma_{\pm}(\omega) \approx \tfrac{1}{2}\gamma_0[1 \pm \epsilon_1(\omega)]^2$$

Inspection of eq. [13] reveals that for a perfectly conducting surface for which $\epsilon_1 = 1$, the imaginary part of $\frac{1}{2}\gamma_\pm$ becomes equal to $\frac{1}{2}\mathrm{Im}\gamma_+ \approx \gamma_0$ and $\frac{1}{2}\mathrm{Im}\gamma_- \approx 0$, which coincide with the Dicke result (31, 39) describing the radiative decay of the symmetric and antisymmetric modes arising from the cooperative radiative interaction of two identical atoms in the gas phase, respectively (26–29).

Substituting into eq. [8] the expressions for $\epsilon_1(\omega)$ and $\epsilon(\omega)$ and the Lennard–Jones energy of interaction (17–19, 23) $\boldsymbol{V} = (1/12R^3)\Sigma_\nu|\boldsymbol{P}_{0\nu}|^2$, where only the term proportional for R^{-3} is retained, we derive from eq. [8] the following expression

$$[14] \quad G_{AB}^{(+)}(\omega) = \left(\frac{\bar{n}_0 - \bar{n}_\nu}{\pi}\right) 2E_{\nu 0}[\omega^2 - \omega_{sp}^2(1-\alpha) + i\omega\gamma_{sp}] \times \{(\omega^2 - \omega_{s+}^2)(\omega^2 - \omega_{s-}^2) + i\omega\gamma_{sp}(\omega^2 - E_{\nu 0}^2) + \frac{i\gamma_0}{2}[1 + \epsilon_1(\omega)]^2[\omega^2 - \omega_{sp}^2(1-\alpha) + i\omega\gamma_{sp}]E_{\nu 0}\}^{-1}$$

which describes the Green function of the symmetric modes of the system. The energies of excitation $\omega_{s\pm}$ are determined by

$$[15] \quad \omega_{s\pm}^2 = \tfrac{1}{2}\{E_{\nu 0}^2 + \omega_{sp}^2 \pm [(E_{\nu 0}^2 - \omega_{sp}^2)^2 + 4E_{\nu 0}^2\omega_{sp}^2\alpha]^{1/2}\}$$

where ω_{sp} is the frequency of the surface plasmons defined as $\omega_{sp} = \omega_p/\sqrt{2}$ and the coupling function $\alpha \equiv \alpha(\boldsymbol{R}) = \alpha_s/2R^3$ with α_s being the static polarizability (25) of the atom $\alpha_s = (2/3)\Sigma_\nu|\boldsymbol{P}_{0\nu}|^2/E_{\nu 0}$. The expression [14] describes the Green function of the symmetric modes, where the effects of the damping for the surface plasmons are fully included. Then if energy shifts proportional to $\gamma_0\gamma_{sp}$ are neglected, as being very small, the excitation spectrum of the symmetric modes is determined by

$$[16] \quad J_{AB}^{(+)}(\omega) = -2\mathrm{Im}G_{AB}^{(+)}(\omega) = \frac{(\bar{n}_0 - \bar{n}_\nu)}{\pi}[\bar{I}_s(\omega) + \bar{I}_s(-\omega)]$$

where the spectral functions $\bar{I}_s(\pm\omega)$ are defined as

$$[17] \quad \bar{I}_s(\omega) = \frac{N_s(\omega_{s+})\Gamma_+(\omega_{s+}) - (\omega - \omega_{s+})M_s\gamma_{sp}}{(\omega - \omega_{s+})^2 + \Gamma_+^2(\omega_{s+})} + \frac{N_s(\omega_{s-})\Gamma_+(\omega_{s-}) + (\omega - \omega_{s-})M_s\gamma_{sp}}{(\omega - \omega_{s-})^2 + \Gamma^2(\omega_{s-})}$$

$$[18] \quad N_s(\omega_{s\pm}) = \pm\left(\frac{2E_{\nu 0}}{\omega_{s\pm}}\right)\frac{[\omega_{s\pm}^2 - \omega_{sp}^2(1-\alpha)]}{(\omega_{s+}^2 - \omega_{s-}^2)}, \qquad M_s = \frac{2E_{\nu 0}}{(\omega_{s+}^2 - \omega_{s-}^2)}$$

$$[19] \quad \Gamma_+(\omega_{s\pm}) = \gamma_+(\omega_{s\pm}) + \Gamma_{sp}(\omega_{s\pm})$$

$$[20] \quad \gamma_+(\gamma_{s\pm}) = \frac{\gamma_0}{8}N_s(\omega_{s\pm})[1 + \epsilon_1(\omega_{s\pm})]^2$$

$$[21] \quad \lambda_{sp}(\omega_{s\pm}) = \Gamma_{sp}(\omega_{s\pm})/\gamma_{sp} = \pm\tfrac{1}{2}\frac{(\omega_{s\pm}^2 - E_{\nu 0}^2)}{(\omega_{s+}^2 - \omega_{s-}^2)}$$

The spectral function $\bar{I}_s(\omega)$ describes asymmetric Lorentzian lines, which are peaked at the frequencies $\omega = \omega_{s\pm}$ having spectral widths of the order of $\Gamma_+(\omega_{s\pm})$; the extent of the asymmetry at $\omega \neq \omega_{s\pm}$ depends on the strength of the damping of the surface plasmons γ_{sp}. Inspection of eq. [15] reveals that one of the energies of excitations is close to the value of the atomic frequency $E_{\nu 0}$ while the other is close to the value of the surface plasmon frequency ω_{sp}. Thus, when $E_{\nu 0}$ is greater than ω_{sp}, $E_{\nu 0} > \omega_{sp}$, then the excitations at $\omega = \omega_{s+}$ ($E_{\nu 0} < \omega_{s+}$) and $\omega = \omega_{s-}$ ($\omega_{sp} > \omega_{s-}$) may be referred to as the atomic and surface plasmon-like excitations, respectively. The reverse is true for $E_{\nu 0} < \omega_{sp}$. The splitting of the excitation spectrum into the frequencies ω_{s+} and ω_{s-} is due to the dipole–dipole interaction between the atom A and its image B. Because of this interaction, $N_s(\omega_{s\pm})$ is given by eq. [18] for $\alpha \neq 0$ while for $\alpha = 0$, which occurs in the limit for $R \rightarrow \infty$, $N_s(E_{\nu 0}) = 2$ and $N_s(\omega_{sp}) = 0$. Hence, for $\alpha \neq 0$, $N_s(\omega_{s\pm})$ takes values less than 2, i.e., $0 < N_s(\omega_{s\pm}) < 2$.

The expressions [16]–[21] imply that the damping of the surface plasmons, which is of a nonradiative nature, contributes in the same way as does that damping arising from radiative decay processes and, hence, should be included for quantitative comparisons with the observed data. The first term in the expression [19] describes the radiative damping, and the second term represents the damping of the surface plasmons, while terms proportional to $\gamma_0\gamma_{sp}$ have been neglected. The expression [20] for $\gamma_+(\omega_{s\pm})$ indicates that the radiative damping at the corresponding frequencies $\omega = \omega_{s\pm}$ is influenced by two effects: firstly, the factor $N_s(\omega_{s\pm})$ describing the effects of the dipole–dipole interaction between the atom and its image for $\alpha \neq 0$ and, secondly, the factor $[1 + \epsilon_1(\omega_{s\pm})]^2$, which describes the cooperative radiative interaction between the atom and its image. For a perfect conductor $\epsilon_1 = 1$ while for a metal surface $\epsilon_1(\omega_{s\pm}) \neq 1$. The deviation of $\epsilon_1(\omega_{s\pm})$ from unity, $\epsilon_1(\omega_{s\pm}) \neq 1$, is due to the screening of the image charge of the atom by the metallic electrons of the surface and describes the dynamic effect arising from the surface plasmons at the frequencies $\omega = \omega_{s\pm}$. For a perfect conductor $\epsilon_1 = 1$ and $N_s \rightarrow 2$ then $\gamma_+ \approx \gamma_0$, which is the Dicke result (31, 36, 39) and which is twice that of the isolated atom. However, in the presence of plasmon damping, since γ_{sp} is always[2] much greater than γ_0, $\gamma_{sp} \gg \gamma_0$ (or the corresponding lifetimes $\tau_0 \gg \tau_{sp}$), the radiative one-atom-image process is erased by the nonradiative process. Hence, the radiative and nonradiative processes compete with each other only when the radiative processes arise from cooperative effects of an assembly of N identical atoms adsorbed on the metal surface. In this case, the effective radiative damping (31, 42) is equal to $N\gamma_0$ for large N and may be in a position to compete with γ_{sp}.

1. Nonradiative excitation spectra

In the case where the surface plasmon mode is heavily damped, namely, when $\gamma_{sp} \gg \gamma_0$, which is always valid, the radiative contributions to the damping can be neglected, and $\Gamma_+(\omega_{s\pm}) \approx \Gamma_{sp}(\omega_{s\pm})$ defined by eq. [21]. In this case nonradiative energy transfer of the excitation energy of the atom to the metal takes place, and in this limit the spectral function [17] is reduced to

$$[22] \quad \gamma_{sp}\bar{I}_s(\omega) = \frac{N_s(\omega_{s+})\lambda_{sp}(\omega_{s+}) - X^{sp}_{s+}M_s}{[X^{sp}_{s+}]^2 + \lambda^2_{sp}(\omega_{s+})} + \frac{N_s(\omega_{s-})\lambda_{sp}(\omega_{s-}) + X^{sp}_{s-}M_s}{[X^{sp}_{s-}]^2 + \lambda^2_{sp}(\omega_{s-})}$$

where

$$[23] \quad X^{sp}_{s\pm} = (\omega - \omega_{s\pm})/\gamma_{sp}$$

defines the reduced frequency. The relative intensity per atom at the frequencies $\omega = \omega_{s\pm}$ in units of γ_{sp} is determined by

$$[24] \quad \gamma_{sp}\bar{I}_s(\omega_{s\pm}) = \frac{N_s(\omega_{s\pm})}{\lambda_{sp}(\omega_{s\pm})}$$

which defines the maximum height of the peak in question. In the absence of interaction between the atom and its image, i.e., when $\alpha \rightarrow 0$ then $\omega_{s+} \rightarrow E_{\nu 0}$, $\omega_{s-} \rightarrow \omega_{sp}$, $\lambda_{sp}(E_{\nu 0}) \rightarrow 0$ while $\lambda_{sp}(\omega_{sp})$ takes its largest value, $\lambda_{sp}(\omega_{sp}) = 0.5$, but in this limit, $N_s(E_{\nu 0}) = 2$ and $N_s(\omega_{sp}) = 0$. On the other hand, at resonance, i.e, when $E_{\nu 0} = \omega_{sp}$ then $\omega^2_{s\pm} = E^2_{\nu 0}(1 \pm \sqrt{\alpha})$, $N_s(\omega_{s\pm}) = (1 \pm \sqrt{\alpha})^{1/2}$ and $\lambda_{sp}(\omega_{s\pm}) = 0.25$, which implies that both modes, the atomic and the surface plasmon-like modes, have equal lifetimes of the order of $4/\gamma_{sp}$.

Using values of α obtained from Table 2 of ref. 25 and eqs. [15], [18], [21], and [23] we derive numerical values for $\omega_{s\pm}$, $N_s(\omega_{s\pm})$, M_s, $\lambda_{sp}(\omega_{s\pm})$, and $\gamma_{sp}\bar{I}_s(\omega_{s\pm})$, respectively. The numerical results are tabulated in Table 1 for the symmetric modes of the excited rare-gas atoms Xe, Kr, and Ar, which are physisorbed on the metal surfaces of Mg, Al, and Au, respectively. For the numerical applications, we have examined two different excited states of Xe, three of Kr, and only one of Ar, respectively. The observed values for the frequencies of the surface plasmons, which have been obtained from ref. 43, have been used for the metals in question. The computed energies of excitation $\omega_{s\pm}$ in eV are shown in the third column of Table 1, which imply that the excitation energies for the atomic-like excitations of the excited rare-gas atoms physisorbed on Mg are blue shifted while those on the metal surfaces of Al and Au are red shifted in comparison with the values of the gas phase excitations of the single isolated atoms in question. Inspection of Table 1 indicates that for the atomic-like excitations, the numerical values of $N_s(\omega_{s\pm})$ are less but near 2, while the corresponding ones for the surface plasmon-like excitations are much less than 1, but the sum $N_s(\omega_{s+}) + N_s(\omega_{s-}) \approx 2$, which is the numerical value for the single isolated atom case for which $\alpha = 0$.

The data in the fifth column of Table 1 for $\lambda_{sp}(\omega_{s\pm})$ indicate that for the surface plasmon-like excitations, $\lambda_{sp}(\omega_{s\pm})$ takes values near but always less than 0.5, while for the atomic-like excitations $\lambda_{sp}(\omega_{s\pm}) \ll 1$. Since $\lambda^{-1}_{sp}(\omega_{s\pm})$ describes the lifetime of the excitations involved in units of γ_{sp}, eq. [21] for values of $\lambda_{sp}(\omega_{s\pm}) \ll 1$ implies that there is a large enhancement of the lifetimes of the atomic-like excitations. Considering that for the atomic-like excitations $N_s(\omega_{s\pm})$ takes values near 2, the expression $\gamma_{sp}\bar{I}_s(\omega_{s\pm})$ given by eq. [24] and the numerical data in the sixth column of Table 1 indicate twice the lifetimes of the excitations in question in units of γ_{sp}.

Using the data from Table 1 the computed spectra from eq. [22] of the atomic-like excitations are illustrated in Figs. 1–4, where the relative intensity per atom $\bar{I}_s(\omega)$ in units of γ_{sp}, $\gamma_{sp}\bar{I}_s(\omega)$, is plotted versus the relative frequency $X^{sp}_{s\pm} = (\omega - \omega_{s\pm})/\gamma_{sp}$ in units of eV/γ_{sp}; the numbering on the abscissa refers to the frequency ω in eV. The data in Table 1 and Figs.

[2]Radiative and nonradiative lifetimes τ_0 and τ_{sp} are of the order of 10^{-7}–10^{-9} s and 10^{-14}–10^{-15} s, respectively; hence, adsorbate excitations on metals are characterized by extremely short nonradiative lifetimes, which are 10^5–10^6 times shorter than the free atom lifetimes (15, 20–22).

TABLE 1. Calculated energies of excitation $\omega_{s\pm}$, probability amplitudes $N_s(\omega_{s\pm})$, spectral widths $\lambda_{sp}(\omega_{s\pm})$ in units of γ_{sp}, relative intensities per atom $\gamma_{sp}\tilde{I}_s(\omega_{s\pm})$ in units of γ_{sp} and asymmetries of M_s in $(eV)^{-1}$ for the *symmetric modes* of excited Xe, Kr, and Ar atoms, which are physisorbed on the metal surfaces of Mg, Al, and Au, respectively; the metallic surfaces have the corresponding surface plasmon frequencies (43) $\omega_{sp} = \omega_p/\sqrt{2} = 7.4953$, 10.8187, and 17.1827 eV

1–4 indicate that the relative intensities per atom, $\gamma_{sp}\tilde{I}_s(\omega)$, of the symmetric modes take positive values implying that the physical process of absorption (attenuation) take place at the corresponding frequencies. The height of each peak, $\gamma_{sp}\tilde{I}_s(\omega_{s\pm})$, in Figs. 1–4 determines the total enhancement, which occurs for the atomic-like excitations of the physisorbed excited atoms in question in the limit when the nonradiative lifetimes of the surface plasmons are very much shorter than the corresponding atomic lifetimes, i.e., when $\tau_0 \gg \tau_{sp}$ ($\gamma_{sp} \gg \gamma_0$). It should be emphasized that the spectra in Figs. 1–4 of the atomic-like excitations are due entirely to the interaction of the atom A with its image B, namely, they exist only for values of $\alpha \neq 0$. This implies that the presence of the surface plasmons results in the splitting of their spectrum into surface plasmon-like and atomic-like excitations, whose spectral widths are of the order of magnitude $\lambda_{sp}(\omega_{s-})\gamma_{sp}$ and $\lambda_{sp}(\omega_{s+})\gamma_{sp}$, respectively, and vice versa. Small values of α produce small values of $\lambda_{sp}(\omega_{s\pm})$, which in turn enhance the lifetimes or, equivalently, diminish the damping of the atomic-like excitations. In Figs. 1–4, the spectra have asymmetric Lorentzian lineshapes; they have a sharp cutoff on the high-frequency side and a low-frequency tail; and the extent of the asymmetry depends on the numerical values of M_s. The center of each peak in Figs. 1–4 is depicted at the excitation frequency $\omega = \omega_{s\pm}$ in eV.

IV. Excitation spectra of the antisymmetric modes

Considering the limit of short distances, where $(2RE_{v0}/c) < 1$, we derive from eq. [8] the following expression

$$[25]\quad G^{(-)}_{AB}(\omega) = \frac{(\bar{n}_0 - \bar{n}_v)}{\pi} 2E_{v0}[\omega^2 - \omega_{sp}^2(1+\alpha) + i\omega\gamma_{sp}]\{(\omega^2 - \omega_{a+}^2)(\omega^2 - \omega_{a-}^2) + i\omega\gamma_{sp}(\omega^2 - E_{v0}^2) + \frac{i\gamma_0}{2}[1 - \epsilon_1(\omega)^2][\omega^2 - \omega_{sp}^2(1+\alpha) + i\omega\gamma_{sp}]E_{v0}\}^{-1}$$

which describes the Green function of the antisymmetric modes with the energies of excitation ω_{a+} and ω_{a-} determined by

$$[26]\quad \omega_{a\pm}^2 = \tfrac{1}{2}\{E_{v0}^2 + \omega_{sp}^2 \pm [(E_{v0}^2 - \omega_{sp}^2)^2 - 4E_{v0}^2\omega_{sp}^2\alpha]^{1/2}\}$$

The expressions [25] and [26] can be derived from the corresponding eqs. [14] and [15] if α is replaced everywhere by $-\alpha$ and $[1 + \epsilon_1(\omega)]^2$ in the denominator of [14] is replaced by $[1 - \epsilon_1(\omega)]^2$. Equation [26] implies that the energies of excitation $\omega_{a\pm}$ are real and well separated provided that the inequality

$$[27]\quad (E_{v0}^2 - \omega_{sp}^2)^2 > 4E_{v0}^2\omega_{sp}^2\alpha$$

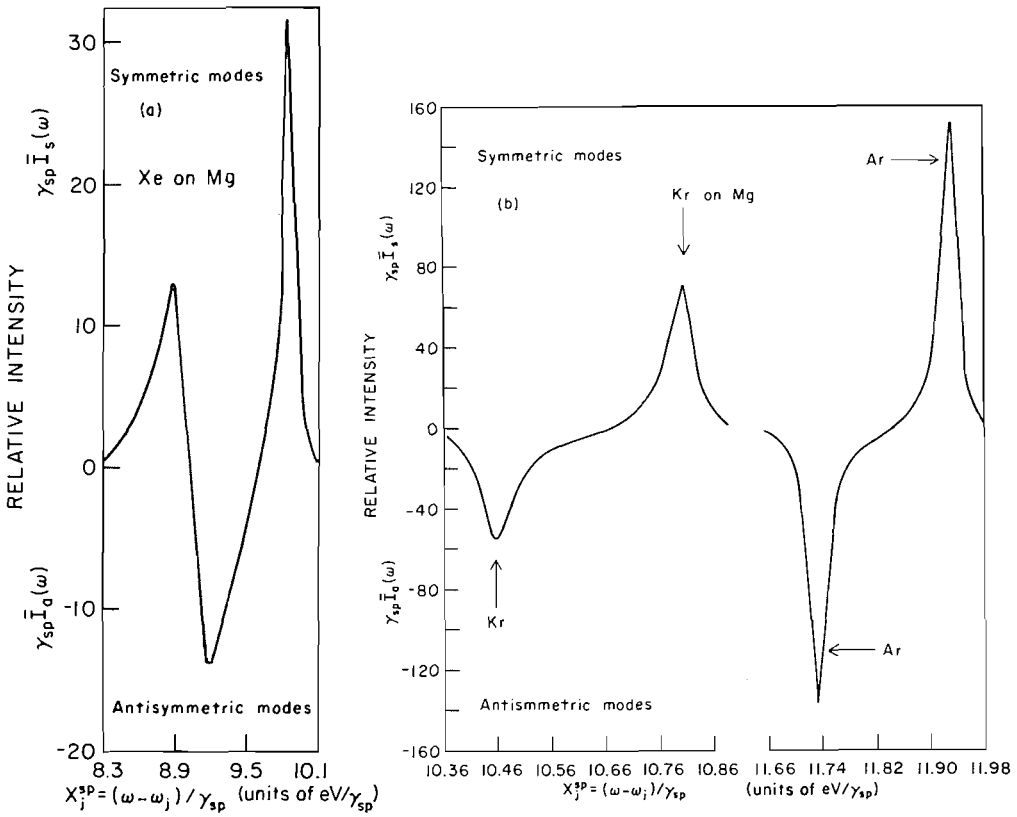

FIG. 1. Spectra of the atomic-like excitations of excited rare-gas atoms physisorbed on the surface of Mg. The relative intensities per atom $\gamma_{sp}\bar{I}_j(\omega)$ in units of γ_{sp} are computed from eqs. [22] and [40], and are plotted versus the relative frequencies $X_j^{sp} = (\omega - \omega_j)/\gamma_{sp}$ in units of eV/γ_{sp}, where $j = s\pm$ and $a\pm$ for the symmetric (positive intensities) and antisymmetric (negative intensities) modes, respectively. The numbering on the abscissa refers to the frequency ω in eV. The center of each asymmetric Lorentzian line is depicted at the excitation frequency $\omega = \omega_j$: (*a*) excited Xe at the frequencies $E_{\nu 0} = 8.437$ and 9.57 eV, respectively; (*b*) excited Kr and Ar at the frequencies $E_{\nu 0} = 10.64$ and 11.83, respectively.

is satisfied. In the opposite limit, i.e., when the inequality

[28] $(E_{\nu 0}^2 - \omega_{sp}^2)^2 < 4E_{\nu 0}^2\omega_{sp}^2\alpha$

is satisfied then eq. [26] becomes

[29] $\omega_{a\pm}^2 = \bar{\omega}_a^2(1 \pm i\gamma_a)$

where

[30] $\bar{\omega}_a^2 = \frac{1}{2}(E_{\nu 0}^2 + \omega_{sp}^2); \quad \gamma_a = \left\{ \frac{E_{\nu 0}^2\omega_{sp}^2(1+\alpha)}{\bar{\omega}_a^4} - 1 \right\}^{1/2}$

The inequality [28] refers to the physical process which occurs whenever the system is close to resonance conditions, where the frequency $E_{\nu 0}$ is very close to the surface plasmon frequency. Hence, when $E_{\nu 0} = \omega_{sp}$, $\gamma_a = \sqrt{\alpha}$ and $\bar{\omega}_a\gamma_a/2$ describes the nonradiative damping of the antisymmetric mode at the frequency $\omega = \bar{\omega}_a$. This situation has been discussed for a number of systems in refs. 24, 25, 44 to which the reader is referred for details. The inequality [28] is satisfied from the data listed in Table 2 for excited Xe at the frequencies $E_{\nu 0} =$ 8.437 and 9.57 eV physisorbed on Mg and Al, respectively; such cases have been discussed elsewhere (17).

In the limiting case where the inequality [27] is satisfied, and energy shifts of the order of $\gamma_0\gamma_{sp}$ are neglected, then following the expansion of the expression [25] about the poles at $\omega^2 = \omega_{a+}^2$ and $\omega^2 = \omega_{a-}^2$, we derive the imaginary part of the Green function as

[31] $\bar{J}_{AB}(\omega) = -2\mathrm{Im}\bar{G}_{AB}(\omega) = \dfrac{(\bar{n}_0 - \bar{n}_\nu)}{\pi}[\bar{I}_a(\omega) + \bar{I}_a(-\omega)]$

where the spectral functions $\bar{I}_a(\pm\omega)$ are defined by

[32] $\bar{I}_a(\omega) = \dfrac{N_a(\omega_{a+})\Gamma_-(\omega_{a+}) - (\omega - \omega_{a+})M_a\gamma_{sp}}{(\omega - \omega_{a+})^2 + \Gamma_-^2(\omega_{a+})} + \dfrac{N_a(\omega_{a-})\Gamma_-(\omega_{a-}) + (\omega - \omega_{a-})M_a\gamma_{sp}}{(\omega - \omega_{a-})^2 + \Gamma_-^2(\omega_{a-})}$

[33] $N_a(\omega_{a\pm}) = \pm\left(\dfrac{2E_{\nu 0}}{\omega_{a\pm}}\right)\dfrac{[\omega_{a\pm}^2 - \omega_{sp}^2(1+\alpha)]}{(\omega_{a+}^2 - \omega_{a-}^2)}$

[34] $M_a = \dfrac{2E_{\nu 0}}{(\omega_{a+}^2 - \omega_{a-}^2)}$

[35] $\Gamma_-(\omega_{a\pm}) = \gamma_-(\omega_{a\pm}) + \Gamma_{sp}(\omega_{a\pm})$

[36] $\gamma_-(\omega_{a\pm}) = \dfrac{\gamma_0}{8}N_a(\omega_{a\pm})[1 - \epsilon_1(\omega_{a\pm})]^2$

[37] $\lambda_{sp}(\omega_{a\pm}) = \Gamma_{sp}(\omega_{a\pm})/\gamma_{sp} = \pm\dfrac{1}{2}\dfrac{(\omega_{a\pm}^2 - E_{\nu 0}^2)}{(\omega_{a+}^2 - \omega_{a-}^2)}$

[38] $\lambda_{sp}(\omega_{a+}) + \lambda_{sp}(\omega_{a-}) = 0.5$

[39] $[1 - \epsilon_1(\omega)]^2 = [1 - \mathrm{Re}\epsilon_1(\omega)]^2 - [\mathrm{Im}\epsilon_1(\omega)]^2$

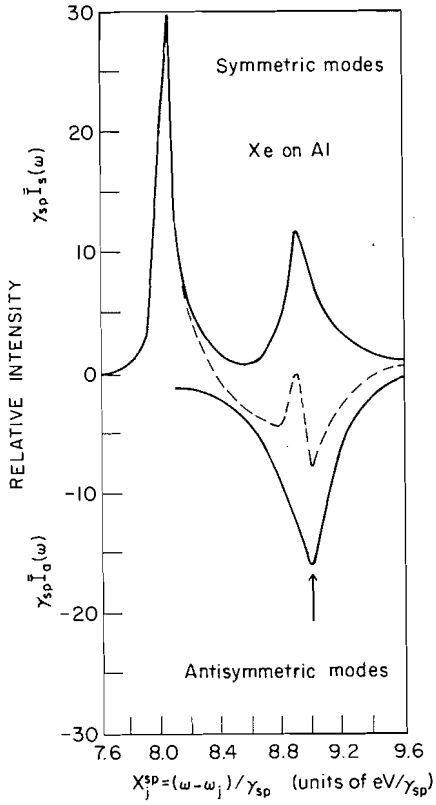

FIG. 2. As in Fig. 1 but on the surface of Al. The dashed line indicates the net lineshape of excited Xe on Al, which results from the combination of the red shifted peak of the symmetric mode at ω_{s-} = 8.9178 eV (atomic excitation 9.57 eV) and the blue shifted peak of the antisymmetric mode at ω_{a-} = 8.9952 eV (atomic excitation 8.437 eV).

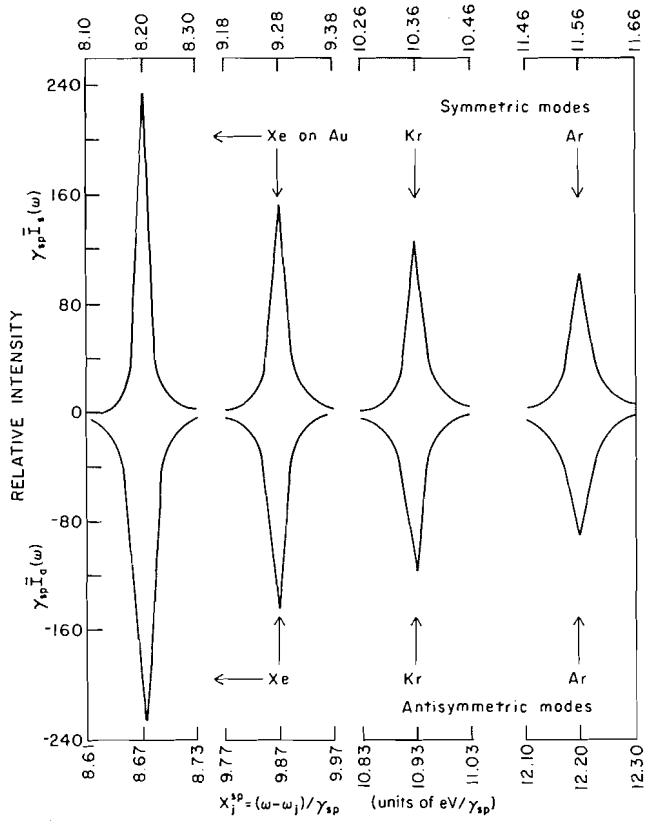

FIG. 3. As in Fig. 1 but on the surface of Au.

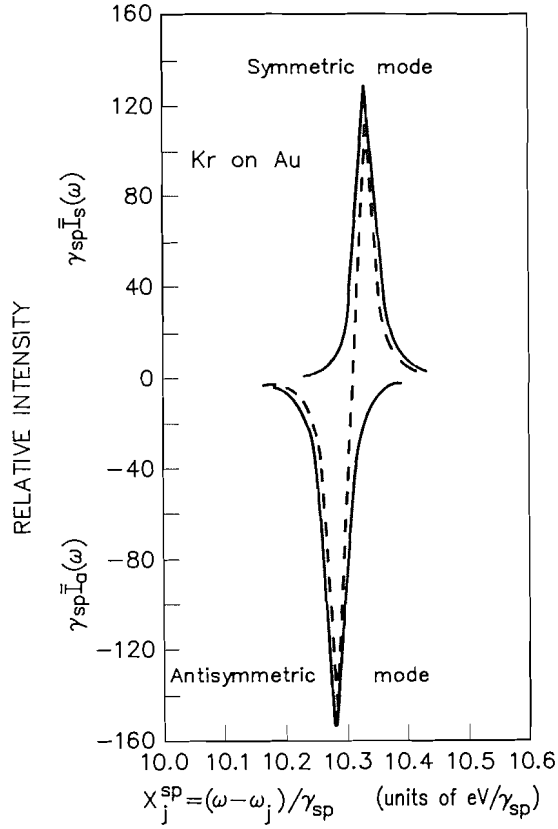

FIG. 4. As in Fig. 1 but for excited Kr at the frequencies E_{v0} = 10.03 and 10.60 eV, respectively, physisorbed on the surface of Au. The dashed line illustrates the net lineshape arising from the combination of the red shifted peak of the symmetric mode at ω_{s-} = 10.326 eV (atomic excitation 10.6 eV) and the blue shifted peak of the antisymmetric mode at ω_{a-} = 10.2815 eV (atomic excitation 10.03 eV).

The expression [31] is analogous to eq. [16] and represents the excitation spectrum of the antisymmetric modes arising from the interaction between the adsorbed atom and its image. Hence, the discussion of the spectrum of the antisymmetric mode is similar to that of the symmetric modes. For a perfect conductor $\epsilon_1(\omega) = 1$, $\omega_a = E_{v0} - \bar{V}$, and $\gamma_-(\omega_a) \rightarrow 0$. This is the Dicke result (29, 31, 39, 45) for the radiative spectra of the antisymmetric modes of two identical atoms in the gas phase, where the photon is trapped between the two atoms. Hence, for perfectly conducting surfaces for which $\epsilon_1(\omega_a) = 1$, the radiative antisymmetric modes describe stationary states, $\gamma_-(\omega_a) = 0$, while for metal and dielectric surfaces where $\epsilon_1(\omega_{a\pm}) \neq 1$, they represent states having radiative lifetimes $1/\gamma_-(\omega_{a\pm})$ arising from radiative decay processes. However, in the presence of the surface plasmon damping, the radiative processes are completely erased since γ_{sp} is always very much larger than γ_0, $\gamma_{sp} \gg \gamma_0$ and, therefore, the nonradiative process dominates.

1. Nonradiative excitation spectra

When $\gamma_{sp} \gg \gamma_0$, which is always applicable, the radiative damping effects are unimportant and can be neglected, and $\Gamma_-(\omega_{a\pm}) \approx \Gamma_{sp}(\omega_{a\pm})$, which is determined by eq. [37]. In this case the spectral function [32] can be written as

$$[40]\quad \gamma_{sp}\bar{I}_a(\omega) = \frac{N_a(\omega_{a+})\lambda_{sp}(\omega_{a+}) - X_{a+}^{sp}M_a}{[X_{a+}^{sp}]^2 + \lambda_{sp}^2(\omega_{a+})} + \frac{N_a(\omega_{a-})\lambda_{sp}(\omega_{a-}) + X_{a-}^{sp}M_a}{[X_{a-}^{sp}]^2 + \lambda_{sp}^2(\omega_{a-})}$$

where

[41] $X_{a\pm}^{sp} = (\omega - \omega_{a\pm})/\gamma_{sp}$

is the reduced frequency. The relative intensity per atom at the frequencies $\omega = \omega_{a\pm}$ in units of γ_{sp} is determined by

[42] $$\gamma_{sp}\bar{I}_a(\omega_{a\pm}) = \frac{N_a(\omega_{a\pm})}{\lambda_{sp}(\omega_{a\pm})}$$

which is the maximum height of the peaks in question at the frequencies $\omega = \omega_{a\pm}$. The expressions [40]–[42] are analogous to eqs. [22]–[24] for the symmetric modes. Hence, the discussion of the spectra of the symmetric modes is applicable to the spectra of the antisymmetric modes.

In the limit when the inequality [27] is satisfied the computed data for $\omega_{a\pm}$, $N_a(\omega_{a\pm})$, $\lambda_{sp}(\omega_{a\pm})$, $\gamma_{sp}\bar{I}_a(\omega_{a\pm})$, and M_a, are listed in Table 2 and are analogous to those for the symmetric modes given in Table 1. The computed values for $N_a(\omega_{a\pm})$ and $\lambda_{sp}(\omega_{a\pm})$ listed in Table 2 indicate that when $N_a(\omega_{a\pm})$ takes a positive value the corresponding value for $\lambda_{sp}(\omega_{a\pm})$ is negative and vice versa. This implies that the relative intensities of the peaks always take negative values indicating that the physical process of stimulated emission (amplification) occurs at the corresponding frequencies. The data of the sixth column in Tables 1 and 2 imply that for the atomic-like excitations the relative intensities per atom $\gamma_{sp}\bar{I}_s(\omega_{s\pm})$ of the symmetric modes are slightly larger or smaller in magnitude than the corresponding values of the antisymmetric modes $\gamma_{sp}\bar{I}_a(\omega_{a\pm})$; but they always have opposite signs and, hence, can cancel each other out whenever the corresponding frequencies coincide.

As can be verified from the data in the Tables 1 and 2, when the frequencies of the symmetric modes are *blue* shifted, the corresponding ones of the antisymmetric modes are *red* shifted and vice versa. Therefore, the spectral peaks of the symmetric and antisymmetric modes may cancel each other out either when they belong to the same atomic excitation frequency $E_{\nu 0}$, in which case the energy shift must be extremely small, or when they belong to two different nearby excited states of the atom. The latter case may occur when the atomic-like excitation frequency of the symmetric mode of the higher excited state of the atom is red shifted, while the corresponding one of the antisymmetric mode of the lower excited state of the atom in blue shifted to the extent that the atomic-like excitation frequency of the modes in question nearly coincide. The data in Tables 1 and 2 indicate that such a case has materialized; for instance, for the $P_{1/2}$ excitation (46, 47) of Xe at the frequency $E_{\nu 0} = 9.57$ eV physisorbed on Al, the atomic-like excitation of the symmetric mode at $\omega_{s-} = 8.9178$ eV is red shifted and the relative intensity of the peak is $\bar{I}_s(\omega_{s-}) = 11.60/\gamma_{sp}$. Conversely, for the $P_{3/2}$ excitation (46, 47) of Xe at the frequency $E_{\nu 0} = 8.437$ eV on Al, the atomic-like excitation of the antisymmetric mode at $\omega_{a-} = 8.9952$ eV is blue shifted and the relative intensity of the peak is equal to $\bar{I}_a(\omega_{a-}) = -15.84/\gamma_{sp}$. Hence, the peaks of the symmetric and antisymmetric modes have similar positive and negative profiles, and then may cancel each other out either completely or partially. Because of the large values of $\lambda_{sp}(\omega_{s\pm})$ and $\lambda_{sp}(\omega_{a\pm})$ and the small values of $N_s(\omega_{s\pm})$ and $N_a(\omega_{a\pm})$, the spectra of the surface plasmon-like excitations of the symmetric and antisymmetric modes are broadened to the extent that it is impossible to present them graphically.

Using the data from Table 2, the computed spectra from eq. [40] of the antisymmetric modes are illustrated in Figs. 1–4, where the relative frequency $X_{a\pm}^{sp} = (\omega - \omega_{a\pm})/\gamma_{sp}$ is plotted versus the relative intensity per atom $\gamma_{sp}\bar{I}_a(\omega)$ in units of γ_{sp}. Since the relative intensities $\gamma_{sp}\bar{I}_a(\omega)$ take negative values, the spectra of the antisymmetric modes in Figs. 1–4 occupy the negative axis while the corresponding spectra of the symmetric

modes occupy the positive axis. Peaks having positive and negative intensities describe physical processes, where absorption (attenuation) and stimulated emission (amplification) take place at the corresponding frequencies, respectively. Figures 1*a* and 1*b* indicate that for Xe, Kr, and Ar on Mg, respectively, the peaks of the symmetric modes are blue shifted while the corresponding ones of the antisymmetric modes are red shifted relative to the atomic frequencies $E_{\nu 0}$. The opposite shifts occur for Xe, Kr, and Ar on the surfaces of Al and Au, respectively, where the peaks of the symmetric and antisymmetric modes are red and blue shifted, respectively, as depicted in Figs. 2–4.

Inspection of Figs. 1*a* and 1*b* implies that there is no overlap between the frequencies of the spectral profiles of the symmetric and anti-symmetric modes, which originate either from the same atomic excitation $E_{\nu 0}$ like the case of Kr and Ar or from two different atomic excitations as in the case of Xe. Figure 1*a* illustrates the spectra of the atomic-like excitations of Xe on Mg, where the symmetric modes consist of two blue shifted peaks at $\omega_{s+} = 8.8694$ eV (atomic excitation $E_{\nu 0} = 8.437$ eV) and $\omega_{s+} = 9.8445$ eV (atomic excitation $E_{\nu 0} = 9.57$ eV), while the antisymmetric mode consists only of the red shifted peak at $\omega_{a+} = 9.1484$ eV (atomic excitation $E_{\nu 0} = 9.57$ eV), because, as mentioned previously, the other peak at the atomic excitation $E_{\nu 0} = 8.437$ eV satisfies the inequality [28]. The frequencies of the peaks in question are such that they behave as if they had absorption–amplification and amplification–absorption lineshapes, respectively; however, the frequencies of the peaks are well separated such that there is no cancellation of intensities.

Figure 2 illustrates the spectra of the atomic-like excitations of the symmetric modes of Xe, on Al as well as one peak of the antisymmetric mode for Xe on Al. The dashed line in Fig. 2 indicates the net lineshape of excited Xe on Al, which originates from the combination of two lineshapes: the red shifted peak of the symmetric mode at $\omega_{s-} = 8.9178$ eV (atomic excitation $E_{\nu 0} = 9.57$ eV) and the blue shifted peak of the antisymmetric mode at $\omega_{a-} = 8.9952$ eV (atomic excitation $E_{\nu 0} = 8.437$ eV). These two peaks, whose frequency profiles are nearly overlapping, cancel each other out with the result that the peak at the atomic frequency $E_{\nu 0} = 9.57$ eV vanishes. A peak or a shoulder having a small negative intensity appears on each side of the vanished peak at $\omega_{s-} = 8.9178$ eV as indicated by the dashed line in Fig. 2.

Figure 3 illustrates the spectra of the atomic-like excitations of the symmetric and antisymmetric modes of Xe, Kr, and Ar physisorbed on Au, respectively. Inspection of the spectra in Fig. 3 reveals that the numerical value of the sum of the heights of the peaks $\bar{I}_s(\omega_{s-}) + \bar{I}_a(\omega_{a-})$ for the symmetric and antisymmetric modes occurring at the same atomic excitation $E_{\nu 0}$ takes the lowest value, which is of the order of $7/\gamma_{sp}$ for Xe and Kr adsorbed on Au. However, this cancellation between the positive and negative heights of the peaks never materializes as there is a large frequency shift between the peaks of the modes in question. For instance, in the two excited states of Xe (atomic excitations $E_{\nu 0} = 8.437$ and 9.57 eV) and for Kr (atomic excitation $E_{\nu 0} = 10.64$ eV) on Au, the frequency shifts are equal to $\omega_{a-} - \omega_{s-} = 0.4694$, 0.5862, and 0.5635 eV, respectively. Cancellation between the positive and negative heights of the peaks arising from the symmetric and the antisymmetric modes, respectively, occurs whenever there is an overlap between the frequency profiles of the peaks in question. Hence, there is no cancellation among the two positive peaks of the symmetric modes and the corresponding negative peaks of the antisymmetric modes of Xe on Au, whose lineshapes are shown in Fig. 3. The same argument applies for the peak of

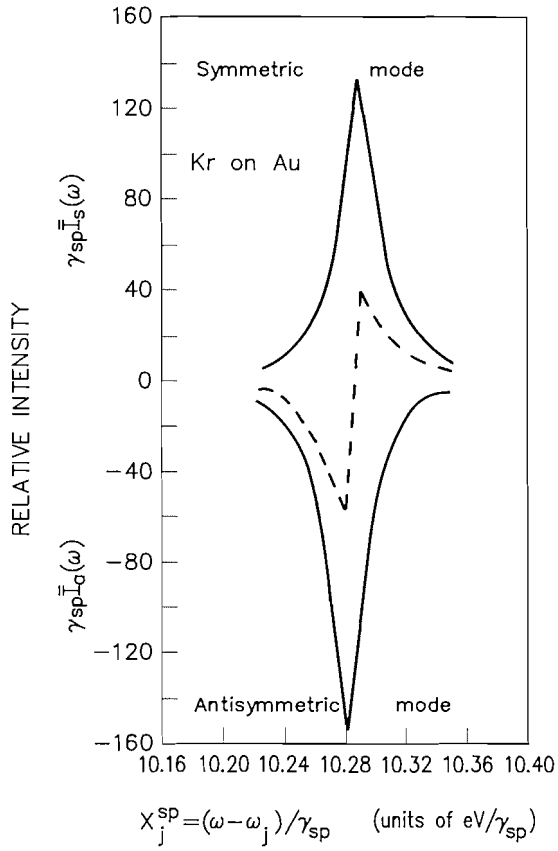

FIG. 5. As in Fig. 4 but for excited Kr at the frequencies $E_{\nu 0} = 10.03$ and 10.56 eV, respectively, physisorbed on the surface of Au. The dashed line illustrates the net lineshape arising from the combination of the red shifted peak of the symmetric mode at $\omega_{s-} = 10.2882$ eV (atomic excitation 10.56 eV) and the blue shifted peak of the antisymmetric mode at $\omega_{a-} = 10.2815$ eV (atomic excitation 10.03 eV).

the symmetric and the corresponding one of the antisymmetric mode of Kr on Au at the atomic frequency $E_{\nu 0} = 10.64$ eV, which are depicted in Fig. 3.

To examine two excited states of Kr adsorbed on Au simultaneously, we consider the two free atom excitations $P_{3/2}$ and $P_{1/2}$ of Kr, which according to Moore's (47) tables occur at the frequencies $E_{\nu 0} = 10.03$ and 10.6 eV, respectively. The computed values for the parameters of the symmetric and antisymmetric modes are listed in Tables 1 and 2, respectively. There are very small differences in the numerical values of the computed parameters when the values of $E_{\nu 0} = 10.60$ and 10.64 eV are used in the calculation. Using the data from Tables 1 and 2, the spectra of Kr on Au are illustrated by solid lines in Fig. 4 for the atomic-like excitations of the two symmetric and two antisymmetric modes, respectively. There is an overlap of the frequency profiles between the red shifted peak at $\omega_{s-} = 10.33$ eV (atomic excitation $E_{\nu 0} = 10.60$ eV) of the symmetric mode and the blue shifted peak at $\omega_{a-} = 10.28$ eV (atomic excitation $E_{\nu 0} = 10.03$ eV) of the antisymmetric mode. The net result of the two lineshapes is illustrated by the dashed line in Fig. 4, which is of the absorption–amplification type, where the system absorbs and amplifies at the frequencies $\omega_{s-} = 10.33$ eV and $\omega_{a-} = 10.28$ eV, respectively.

Inspection of the lineshape of the dashed line in Fig. 4 reveals that the system at this condition is very unstable so that an infinitesimal frequency shift or a very small disturbance in the right direction either on the symmetric or on the antisymmetric mode will stabilize the system, where the positive and negative

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

peaks will cancel each other out; the result will be the disappearance of the peak arising at the atomic excitation $E_{\nu 0} = 10.6$ eV. For the remaining peaks at the frequencies $\omega_{s-} = 9.78$ eV and $\omega_{a-} = 10.88$ eV of the symmetric and antisymmetric modes, respectively, other nearby excited states of the atom must be taken into consideration. These nearby states may be vibrationally or rotationally excited, which differ by very small amounts from the pure electronic excited states in question.

Another illuminating example is that of the two excited states of Kr at the frequencies $E_{\nu 0} = 10.03$ and 10.56 eV (47), respectively, which are supposed to be physisorbed on Au. Using the data listed in Tables 1 and 2, the computed spectra of the symmetric and antisymmetric modes are illustrated in Fig. 5. The net result of the two lineshapes is illustrated by the dashed line in Fig. 5, which indicates that the overlap of the frequency profiles between the red shifted peak at $\omega_{s-} = 10.2882$ eV (atomic excitation $E_{\nu 0} = 10.56$ eV) of the symmetric mode and the blue shifted peak at $\omega_{a-} = 10.2815$ eV (atomic excitation $E_{\nu 0} = 10.03$ eV) of the antisymmetric mode is much greater than the corresponding one in Fig. 4. Hence, the net spectrum illustrated in Fig. 5 is much more unstable from that in Fig. 4 and an infinitesimal disturbance in the right direction will stabilize the system by cancelling out the positive and negative components of the symmetric and antisymmetric modes, respectively.

Closing this section, we may conclude that the occasional disappearance of the spectral lines of the optical absorption at low coverages may be attributed to a cancellation process, which occurs between the frequency profiles arising from two nearby excited states of the atom. The red shifted peak of the symmetric mode of the higher excited state and the blue shifted peak of the antisymmetric mode of the lower excited state of the atom cancel each other out provided that their frequency profiles nearly coincide. Thus, in order to perform a thorough investigation, all the closely lying excited states of the free atom must be considered in the calculation.

When there are N excited atoms A physisorbed on the metal surface, the effective lifetime of a system of N excited identical atoms is shortened (31, 42) by a factor proportional to $1/N$ compared with the lifetime of a single isolated atom provided that the excited atoms interact with their common radiation field and decay cooperatively (superradiance). This radiative cooperative effect of the atoms on the metal surface has been considered in ref. 17, where the dipole–dipole interaction between the absorbate atoms on the surface of the metal has been neglected so that the derived results are applicable in the low coverage limit. It is shown (17) that at low coverage the height of the peaks of the spectral lines is proportional to N, while the total spectral function varies as N^2, a fact which is compatible with the experiment (3, 7, 8); the reader is referred to ref. 17 for details.

V. Concluding remarks

We have considered the excitation spectra of neutral rare-gas atoms physisorbed on metal surfaces. It is shown that at low coverage the occasional disappearance of the peaks of the spectral lines is due to the existence of the symmetric and antisymmetric states, whose relative intensities take positive and negative values, respectively. Hence, they may have the opportunity to cancel each other out whenever the frequency profiles on the peaks in question coincide. The relative intensities of the antisymmetric modes become negative only, at least for the cases under investigation, when the damping of the surface plasmons is much greater than the damping due to the radiative decay processes. This implies that the occasional disappearance of the peaks of the spectral lines should be only observed in optical experiments provided that the appropriate conditions are fulfilled; this is compatible with the experimental observations.

The disappearance of the optical spectra of Xe on Al and of Kr on Au is compatible with the observed ones (2, 3, 7, 8). Contrary to the experimental data (1–10), the optical spectrum of Xe on Au failed to disappear because of the existence of large frequency shifts, which occur between the peaks of the symmetric and antisymmetric modes arising from nearby excited states of the free Xe atom. However, the frequency shifts can be reduced through internal or external perturbations (17). We believe that the cancellation of the proper lineshapes between the peaks of the symmetric and antisymmetric modes may be a possible explanation of the persistence-extinction phenomenon that has been observed (1–10) for a number of rare-gas metal substrate systems in the low coverage limit.

It should be mentioned that in deriving the expression for the Green function [8] only linear effects have been taken into consideration and, therefore, the derived spectra of the symmetric and antisymmetric modes are independent of each other. Considering that the experiment yields the overall lineshapes of the spectral lines in question, any improvement of the theory should produce coupling between the symmetric and antisymmetric modes under investigation. The first of such improvements is to consider coupling between nearby excited states of the physisorbed atom. Such couplings are important because, although small, they are of the same order of magnitude as the coupling between the atom and its image.

This paper is dedicated to Professor J. A. Morrison

HIDEO YASUDA and JOHN C. RAICH. Can. J. Chem. **66**, 752 (1988).

The dynamic susceptibility of a one-dimensional rotor in crystal fields of various symmetry is calculated within the framework of classical mechanics. The contributions from oscillatory and rotary motions are treatable separately. This approach serves to clarify the structure of the spectrum. The nature and magnitude of the quantum effect are investigated and a comparison with earlier quantum mechanical calculations is made.

HIDEO YASUDA et JOHN C. RAICH. Can. J. Chem. **66**, 752 (1988).

Utilisant les principes de la mécanique classique, on a calculé la susceptibilité dynamique d'un rotor unidimensionnel dans des champs cristallins de diverses symétries. Les contributions dûes aux mouvements oscillatoires et rotatoires ont été traités séparément. Cette méthode permet de clarifier la structure du spectre. On a étudié la nature et l'amplitude de l'effet quantique et on a fait une comparaison avec des calculs de mécanique quantique qui ont été effectués antérieurement.

I. Introduction

Molecular crystals and liquid crystals are made up, at least in part, of molecules or molecular ions with angular degrees of freedom. When these molecules are incorporated into a crystal lattice, their angular motions are strongly affected by the presence of neighboring molecules or ions. The environment of the neighboring molecules is represented by an orientational potential (molecular field or crystal field) for a specific molecule. When the temperature is low compared with the barrier height of the orientational potential, molecules are captured in the potential minima and perform small angular oscillations or librations. In addition to these librational modes, quantum mechanical tunnelling between equivalent molecular orientations corresponding to neighboring potential wells can occur. On the other hand, if the temperature is of the order of the orientational potential, the molecule can jump over the barriers and perform continuous rotational diffusion.

An understanding of these different types of rotational excitations is important for the interpretation of experimental observations in terms of intermolecular potentials. To help us understand the spectra of rotational excitations we have studied the susceptibility for single particle excitations quantum mechanically (1). It seems unlikely that one can directly relate the susceptibility of a one-dimensional hindered rotor to experimental observations for three-dimensional crystals. However, we successfully applied a one-dimensional model to describe order–disorder phase transitions in ammonium halide crystals (2) where the susceptibilities for the coupled orientational and translational degrees of freedom were constructed from single particle susceptibilities using mean field treatments (3–5). This limited success provides justification for further study of one-dimensional rotors.

In the present paper we provide a classical calculation of the single-particle orientational susceptibility for a one-dimensional rotor in crystal fields of various symmetry. The desired susceptibility is defined as

$$[1] \qquad \chi_\alpha(\omega) = \phi^q_\alpha(0) + z\int_0^\infty e^{zt}\phi^q_\alpha(t)\,dt \qquad (z = i\omega - \lambda,\ \lambda \to 0_+)$$

with the quasi-relaxational function

$$[2] \qquad \phi^q_\alpha(t) = \beta\langle Q_\alpha(0)Q_\alpha(t)\rangle$$

where $Q_\alpha(t)$ denotes a rotational coordinate at time t.[1]

The main motivation for the present work is to clarify the structure of the spectrum for a one-dimensional hindered rotor and to identify contributions from motions that can be classified as either oscillatory or rotatory. The present calculation can not explain the central peak in the spectrum, which is due to quantum tunnelling. However, one can estimate such quantum effects by comparing the present calculations with previous quantum mechanical results (1). In addition, the present study is expected to provide insight into the theoretical treatment of non-linear rotational modes in molecular crystals.

II. Classical mechanical mode

The hamiltonian for one-dimensional hindered rotor is

$$[3] \qquad H = Bp^2 + V_0 \cos M\phi$$

where B is the rotational constant and $M = 2$, 3, 4, and 6 indicates the symmetry of the crystal field. Considering that the crystal field has potential minima for values of the rotation coordinate $\phi = (2n + V_0/V + 1/2)\pi/M$ with $V = |V_0|$ and $n = 0, 1, 2, \ldots, M - 1$, we make the following variable transformation:

$$[4] \qquad M\phi = (2n + V_0/V + 1/2)\pi + \phi'$$

The new variable is limited to the range $-\pi \leqq \phi' \leqq \pi$. Then the equation of motion is given as

$$[5] \qquad 2MBp = \dot{\phi}', \quad MV \sin\phi' = -\dot{p}$$

This equation suggests that the introduction of dimensionless

[1] The exact definition of the relaxation function is

$$\phi_\alpha(t) = \beta\langle Q_\alpha(0)Q_\alpha(t)\rangle - \beta\langle Q^0_\alpha Q^0_\alpha\rangle$$

where Q^0_α is the invariant part of $Q_\alpha(t)$ with respect to the natural motion (6). One can confirm that the susceptibility [1] remains unchanged when one replaces $\phi^q_\alpha(t)$ with $\phi_\alpha(t)$, that is, one can add an arbitrary constant to $\phi^q_\alpha(t)$ in eq. [1].

time τ defined as

$$[6] \qquad \rho = M(2BV)^{1/2}t$$

simplifies the problem. Let us suppose $\phi' = 0$ and $p = p_0$ at $\tau = 0$; then we have the following solution for ϕ'_τ, which defines ϕ' at time τ:

$$[7] \qquad \sin(\phi'_\tau/2) = \begin{cases} k\,\mathrm{sn}(\mathrm{sign}(p_0)\tau,k) & \text{for } k<1 \\ \mathrm{sn}(\mathrm{sign}(p_0)k_\tau,1/k) & \text{for } k>1 \end{cases}$$

with $k = |p_0|(B/2V)^{1/2}$ and the Jacobi's sn function (7). It follows from eqs. [5], [6], and [7] that the angular momentum p at time τ which is denoted by p_τ, is given as

$$[8] \qquad |p|/(2V/B)^{1/2} = \begin{cases} k\,\mathrm{cn}(\mathrm{sign}(p_0)\tau,k) & \text{for } k<1 \\ k\,\mathrm{dn}(\mathrm{sign}(p_0)k_\tau,1/k) & \text{for } k>1 \end{cases}$$

with Jacobi's cn and dn functions. Equation [8] is essentially same as the well-known solution for a simple pendulum. The expressions for $k < 1$ and $k > 1$ represent oscillatory and rotatory motion, respectively.

In order to treat the quasi-relaxation function defined in eq. [2], we need the solution for eq. [5] which has arbitrary ϕ' and p as the initial condition. This solution is obtained by replacing $\mathrm{sign}(p_0)\tau$ by $u + \mathrm{sign}(p_0)\tau$ in eqs. [7] and [8]. Because of the range of ϕ', we have the limitation $-K(k) \leqq u \leqq K(k)$ for $k<1$ and $-K(1/k) \leqq ku \leqq K(1/k)$ for $k > 1$, where $K(k)$ is the complete elliptic integral of the first kind (7). We also have $\mathrm{sign}(p_0) = \mathrm{sign}(p)$. Then the solution of the equation of motion is rewritten

$$[9] \qquad \sin(\phi'_\tau/2) = \begin{cases} k\,\mathrm{sn}(u + \mathrm{sign}(p)\tau,k) & \text{for } k<1 \\ \mathrm{sn}(ku + \mathrm{sign}(p)k_\tau,1/k) & \text{for } k>1 \end{cases}$$

and

$$[10] \qquad |p|/(2V/B)^{1/2} = \begin{cases} k\,\mathrm{cn}(u + \mathrm{sign}(p)\tau,k) & \text{for } k<1 \\ k\,\mathrm{dn}(ku + \mathrm{sign}(p)k_\tau,1/k) & \text{for } k>1 \end{cases}$$

The variables p and ϕ', which are values of p_τ and ϕ'_τ in eqs. [9] and [10] at $\tau = 0$, appear in the calculation of the average in eq. [2]. Equations [9] and [10] suggest a transformation from the variables p and ϕ' to the set (k,u). Since the Jacobian has the same value $2\,\mathrm{sign}(p)(2V/B)^{1/2}k$ for both $k<1$ and $k>1$, we have

$$[11] \qquad \mathrm{sign}(p)\mathrm{d}p\mathrm{d}\phi' = 2(2V/B)^{1/2}k\mathrm{d}k\mathrm{d}u$$

In terms of the new variables the following hamiltonian results

$$[12] \qquad H = 2Vk^2 - V$$

We choose $Q_C(t) = \cos m\phi_t$ or $Q_S(t) = \sin m\phi_t$ as the rotational variables or coordinates in eq. [2], where ϕ_t indicates a rotational angle ϕ at time t (1, 2). In terms of the dimensionless time τ these rotational coordinates are expressed as

$$[13a] \qquad Q_C(\tau) = [Q_+(\tau) + Q_-(\tau)]/2$$

$$[13b] \qquad Q_S(\tau) = [Q_+(\tau) - Q_-(\tau)]/2i$$

and

$$[14] \qquad Q_\pm(\tau) = \exp\left[\pm i\frac{m}{M}\left(2n + \frac{V_0}{V} + \frac{1}{2}\right)\pi + \phi'_\tau\right]$$

The product $Q_\alpha(0)Q_\alpha(\tau)$, where α = C or S, which is the important quantity appearing in the relaxation function, is a function of the variables m/M, n, V_0/V, k, u, and τ. To illustrate this dependence explicitly we write the product as

$$[15] \qquad Q_\alpha(0)Q_\alpha(\tau) \equiv F_\alpha(m/M,n,V_0/V,k,u,\tau)$$

Next we consider the integral $\int_{-\infty}^{\infty}\mathrm{d}p\int_0^{2\pi}\mathrm{d}\phi f(p,\phi)$ of an arbitrary function $f(p,\phi)$. Using eq. [4], one can reduce this integral to the following form:

$$[16] \qquad \int_{-\infty}^{\infty}\mathrm{d}p\int_0^{2\pi}\mathrm{d}\phi f(p,\phi) = \int_0^{\infty}\mathrm{d}p\int_0^{\pi}\mathrm{d}\phi'\ \frac{1}{M}\sum_{n=0}^{M-1}[f(p,g/M + \phi'/M) + f(p,g/M - \phi'/M) + f(-p,g/M + \phi'/M) + f(-p,g/M - \phi'/M)]$$

with $g = (2n + V_0/V + 1/2)\pi$. Using eqs. [9], [10], and [11], a change of the variables of integration to k and u is easily accomplished.

Applying these methods to the calculation of the quasi-relaxation function [2] at the dimensionless time τ yields

$$[17] \qquad \phi^q_\alpha(\tau) = \beta\int_0^1\mathrm{d}k\int_0^{K(k)}\mathrm{d}u\ kh_\alpha(k,u,\tau)P(k) + \beta\int_1^{\infty}\mathrm{d}k\int_0^{K(1/k)}\mathrm{d}(ku)\ h_\alpha(k,u,\tau)P(k)$$

where

$$[18] \qquad h_\alpha(k,u,\tau) = \frac{1}{M}\sum_{n=0}^{M-1}[F_\alpha(m/M,n,V_0/V,k,u,\tau) + F_\alpha(m/M,n,V_0/V,k,-u,\tau) + F_\alpha(m/M,n,V_0/V,k,u,-\tau) + F_\alpha(m/M,n,V_0/V,k,-u,-\tau)]$$

and

$$[19] \qquad P(k) = 2(2V/B)^{1/2}\exp(-\beta H)/\int_{-\infty}^{\infty}\mathrm{d}p\int_0^{2\pi}\mathrm{d}\phi\exp(-\beta H) = \exp(-2\beta Vk^2)/(Z_1 + Z_2)$$

with

$$[20] \qquad Z_1 = 4\int_0^1\mathrm{d}k\,kK(k)\exp(-2\beta Vk^2)$$

and

$$[21] \qquad Z_2 = 4\int_1^{\infty}\mathrm{d}k\,K(1/k)\exp(-2\beta Vk^2)$$

Using eqs. [13] through [15], expression [18] is straightforwardly reduced to the following:

$$[22] \qquad h_\alpha(k,u,\tau) = \left\{\cos\frac{m}{M}\left(\phi'_\tau - \phi'_0\right) + \cos\frac{m}{M}\left(\phi'_\tau - \phi'_0\right) + \delta(\alpha)f(2m/M,V_0/V) \times\left[\cos\frac{m}{M}\left(\phi'_\tau + \phi'_0\right) + \cos\frac{m}{M}\left(\phi'_\tau + \phi'_0\right)\right]\right\}$$

with

$$[23] \qquad \sin(\phi'_\tau/2) = \begin{cases} k\,\mathrm{sn}(u + \tau,k) & \text{for } k<1 \\ \mathrm{sn}(ku + k_\tau,1/k) & \text{for } k>1 \end{cases}$$

Here the quantities $\delta(\alpha)$ and $f(2m/M,V_0/V)$ denotes

$$[24] \qquad \delta(\mathrm{C}) = 1, \quad \delta(\mathrm{S}) = -1$$

and

$$[25] \qquad f(2m/M,V_0/V) = \begin{cases} 0 & \text{for } 2m/M \neq \text{an integer} \\ (-1)^{m(V_0/V+1)/M} & \text{for } 2m/M = \text{an integer} \end{cases}$$

respectively. Before going to the next step, we must keep in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

mind that ϕ'_τ which appears in eq. [22] and is a function of k, u, and τ is the principal value of the arcsin of the right hand side of eq. [23] for $k < 1$, but not for $k > 1$.

Using eq. [17], one can formally calculate the desired susceptibility [1]. Equation [1] for the case of the present dimensionless time τ can be rewritten as

$$[26] \quad \chi_\alpha(\omega_0) = \phi^q_\alpha(0) + z\int e^{z\tau}\phi^q_\alpha(\tau)d\tau \qquad (z = i\omega_0 - \lambda,\ \lambda \to 0_+)$$

where $\omega_0 = \omega/M(2BV)^{1/2}$. Here, ω is measured in units of $M(2BV)^{1/2}$ with ω_0 a dimensionless frequency.

III. Fourier approximation for the susceptibility

Although the calculation of the rotational susceptibility follows in principle from eq. [26], its calculation in practice is complicated by unknown singularities. This difficulty may be surmounted using a Fourier approximation for expression [22]. Such an approach is reasonable because of the periodic nature of eq. [22].

In the Fourier approximation one expresses eq. [22] as

$$[27] \quad h_\alpha(k,u,\tau) = \sum_{l=0}^{n} A_{\alpha l}(k,u,\tau_0)\cos(2\pi l\tau/\tau_0)$$

where τ_0 is the period of $h_\alpha(k,u,\tau)$ and $n \leqq N$. The meaning of the integer N is explained below. The coefficients $A_{\alpha l}(k,u,\tau_0)$ are determined by the method of least squares as

$$A_{\alpha 0}(k,u,\tau_0) = \frac{1}{2N}\sum_r h_\alpha(k,u,\tau_r)$$

$$[28] \quad A_{\alpha l}(k,u,\tau_0) = \frac{1}{N}\sum_r h_\alpha(k,u,\tau_r)\cos(\pi lr/N) \qquad (l \neq 0,N)$$

$$A_{\alpha N}(k,u,\tau_0) = \frac{1}{2N}\sum_r (-1)^r h_\alpha(k,u,\tau_r)$$

Here $\tau_r = \tau_0 r/2N$ and the summations with respect to r run from $-N + 1$ to N. Equations [22] and [23] imply the period:

$$[29] \quad \begin{aligned} \tau_0 &\equiv \tau_{\mathrm{I}} = 4K(k) && \text{for } k < 1 \\ \tau_0 &\equiv \tau_{\mathrm{II}} = 2MK(1/k)/mk && \text{for } k > 1 \end{aligned}$$

Substituting [19] and [27] in the quasi-relaxation function [17] yields the following expression:

$$[30] \quad \phi^q_\alpha(\tau) = \sum_{l=0}^{n}[\phi_{\mathrm{I}\alpha l}(\tau) + \phi_{\mathrm{II}\alpha l}(\tau)]$$

with

$$[31a] \quad \phi_{\mathrm{I}\alpha l}(\tau) = \beta\int_0^1 dk\, kK(k)A_{\mathrm{I}\alpha l}(k)\cos(2\pi l\tau/\tau_{\mathrm{I}})\,P(k)$$

and

$$[31b] \quad \phi_{\mathrm{II}\alpha l}(\tau) = \beta\int_1^\infty dk\, K(1/k)A_{\mathrm{II}\alpha l}(k)\cos(2\pi l\tau/\tau_{\mathrm{II}})\,P(k)$$

Here the following notation has been employed:

$$[32a] \quad A_{\mathrm{I}\alpha l}(k) = \int_0^1 du\, A_{\alpha l}(k,K(k)u,\tau_{\mathrm{I}})$$

and

$$[32c] \quad A_{\mathrm{II}\alpha l}(k) = \int_0^1 du\, A_{\alpha l}(k,K(1/k)u/k,\tau_{\mathrm{II}})$$

It is apparent from eqs. [30] and [31] that the time-independent part of the quasi-relaxation function, which is just the quantity $\beta\langle Q^0_\alpha Q^0_\alpha\rangle$ on ref. 6 and is denoted by the same symbol, is

$$[33] \quad \beta\langle Q^0_\alpha Q^0_\alpha\rangle = \phi_{\mathrm{I}\alpha 0}(0) + \phi_{\mathrm{II}\alpha 0}(0)$$

Thus we find that the exact relaxation function is given by

$$[34] \quad \phi_\alpha(\tau) = \sum_{l=1}^{n}[\phi_{\mathrm{I}\alpha l}(\tau) + \phi_{\mathrm{II}\alpha l}(\tau)]$$

As pointed out in ref. 6, we may use this relaxation function instead of the quasi-relaxation function $\phi^q_\alpha(\tau)$ in the calculation of the susceptibility [26].

When expressions [34] and [31] are substituted in the susceptibility [26], we obtain

$$[35] \quad \chi_\alpha(\omega_0) = \sum_{l=1}^{n}[\chi_{\mathrm{I}\alpha l}(\omega_0/l) + \chi_{\mathrm{II}\alpha l}(M\omega_0/2ml)]$$

with

$$[36] \quad \chi_{\mathrm{G}\alpha l}(X) = \chi'_{\mathrm{G}\alpha l}(X) + iX''_{\mathrm{G}\alpha l}(X) \quad \mathrm{G} = \mathrm{I}\text{ or }\mathrm{II}$$

where χ' and χ'' represent the real and imaginary parts of χ, respectively. Here

$$[37a] \quad \chi'_{\mathrm{I}\alpha l}(X) = \beta\int_0^1 dk\, kK(k)A_{\mathrm{I}\alpha l}(k)P(k) \times\left[1 - \frac{X}{2}P\left(\frac{1}{X + 2\pi/\tau_{\mathrm{I}}} + \frac{1}{X - 2\pi/\tau_{\mathrm{I}}}\right)\right]$$

$$[37b] \quad \chi'_{\mathrm{II}\alpha l}(X) = \beta\int_1^\infty dk\, K(1/k)A_{\mathrm{II}\alpha l}(k)P(k) \times\left[1 - \frac{X}{2}P\left(\frac{1}{X + M\pi/m\tau_{\mathrm{II}}} + \frac{1}{X - M\pi/m\tau_{\mathrm{II}}}\right)\right]$$

$$[38a] \quad \chi''_{\mathrm{I}\alpha l}(X) = \beta\int_0^1 dk\, kK(k)A_{\mathrm{I}\alpha l}(k)P(k) \times\frac{\pi X}{2}[\delta(X + 2\pi/\tau_{\mathrm{I}}) + \delta(X - 2\pi/\tau_{\mathrm{I}})]$$

$$[38b] \quad \chi''_{\mathrm{II}\alpha l}(X) = \beta\int_1^\infty dk\, K(1/k)A_{\mathrm{II}\alpha l}(k)P(k) \times\frac{\pi X}{2}[\delta(X + M\pi/m\tau_{\mathrm{II}}) + \delta(X - M\pi/m\tau_{\mathrm{II}})]$$

The formula $\lim_{\lambda\to 0_+}(x + i\lambda)^{-1} = P(1/x) - i\pi\delta(x)$ has been used in the above derivations.

We can obtain in principle the analytic functional form for the susceptibility [35] by using eqs. [37] and [38]. Exact calculations are hopelessly difficult in the present form because of the complicated functional forms of τ_{I} and τ_{II} as given by [29]. However, we can derive the following approximations:

$$[39a] \quad 2\pi/\tau_{\mathrm{I}} = \pi/2K(k) \simeq (1 - k^2)^{1/4}$$

$$[39b] \quad M\pi/m\tau_{\mathrm{II}} = \pi k/2K(1/k) \simeq k^{1/2}(k^2 - 1)^{1/4}$$

The derivations of the above approximations are given in the Appendix, where a high precision approximation for the Jacobi sn (u,k) function, utilized in the present work, is also given.

We now adopt the variable transformations $(1 - k^2)^{1/4} = x$ and $k^{1/2}(k^2 - 1)^{1/4} = y$. Then we obtain the relations

$$[40a] \quad kK(k)\,dk = -\pi x^2\,dx$$

$$[40b] \quad K(1/k)\,dk = -\pi y^2(1 + 4y^4)^{-1/2}dy$$

In regard to the approximations [39a] and [39b], the reader is referred to the Appendix which contains a discussion of the adequacy of the present approximations in the vicinity of $k = 1$, where $K(k)$ diverges. Using these approximations we rewrite the imaginary parts of the susceptibilities [38a] and [38b] as

follows:

$$[41a]\quad \chi''_{\mathrm{I}\alpha l}(X) = \begin{cases} \beta\pi X^3 A_{\mathrm{I}\alpha l}([1 - X^4]^{1/2}) P_{\mathrm{I}}(X) \\ 0 \qquad \text{for } |X| > 1 \end{cases}$$

for $|X| < 1$

$$[41b]\quad \chi''_{\mathrm{II}\alpha l}(X) = \frac{\beta\pi}{2} X^3 (1 + 4X^4)^{-1/2} \times A_{\mathrm{II}\alpha l}(\{[1 + (1 + 4X^4)^{1/2}]/2\}^{1/2}) P_{\mathrm{II}}(X)$$

Here the quantities $P_{\mathrm{I}}(X)$ and $P_{\mathrm{II}}(X)$ denote

$$[42a]\quad P_{\mathrm{I}}(X) = \exp(2\beta V X^4)/Z_{12}$$

and

$$[42b]\quad P_{\mathrm{II}}(X) = \exp(\beta V[1 - (1 + 4X^4)^{1/2}])/Z_{12}$$

with

$$[43]\quad Z_{12} = 4\int_0^1 dx\, x^2 \exp(2\beta V x^4) + 4\int_0^\infty dy\, y^2 (1 + 4y^4)^{-1/2} \exp(\beta V[1 - (1 + 4y^4)^{1/2}])$$

Here we have used eq. [19] through [21], [38], and the variable transformations.

Using the same approximations as above, we can reduce each component of the real part of the susceptibility [37] to a tractable expression. The Kramers–Kronig relation

$$[44]\quad \chi'_{\mathrm{G}\alpha l}(X) = \frac{1}{\pi} \fint_{-\infty}^{\infty} \frac{\chi''_{\mathrm{G}\alpha l}(\xi)}{\xi - X} d\xi$$

where $\fint$ denotes the principal value of the integral, is satisfied for each component of the susceptibility defined by eq. [36].

The representation [35] together with [41] and [44] is our final result for the susceptibility of a one-dimensional hindered rotor. Numerical calculation for various cases show that the terms with $l = 1$, $\chi \mathrm{G}\alpha 1$, are dominant.[2] This seems to indicate that the function [22] is reasonably well approximated, except for a constant term, by use of only one cos term, that is, $\cos(2\pi l\tau/\tau_0)$.

IV. Spectrum of a classical hindered rotor

In the preceding section, we derived the desired susceptibility in a tractably analytic form. A reasonably accurate approximation to its imaginary part, which consists of two types I (oscillatory motion) and II (rotatory motion) has been obtained. The real part can in principle be evaluated from the Kramers–Kronig relation [44]. However, we discuss only the imaginary part of the susceptibility in the present paper.

It is well known that the imaginary part of the susceptibility is related to the spectral function, which is, in the present case, the spectrum of the spontaneous fluctuations in the $\cos(m\phi)$ or $\sin(m\phi)$ or the Fourier transform of the correlation $\langle Q_\alpha(0) Q_\alpha(t)\rangle$. This quantity can be related to the results of scattering experiments. In our model the spectral function of the dimensionless frequency ω_0 is expressed as

$$[45]\quad S_\alpha(\omega_0) = S_{\mathrm{I}\alpha}(\omega_0) + S_{\mathrm{II}\alpha}(\omega_0)$$

with

$$[46a]\quad S_{\mathrm{I}\alpha}(\omega_0) = f(\omega_0) \sum_{l=1}^{n} \chi''_{\mathrm{I}\alpha l}(\omega_0/l)$$

[2] If $\chi \mathrm{G}\alpha 1$ is zero, the next non-vanishing term $\chi \mathrm{G}\alpha l$ is dominant as discussed in Fig. 5.

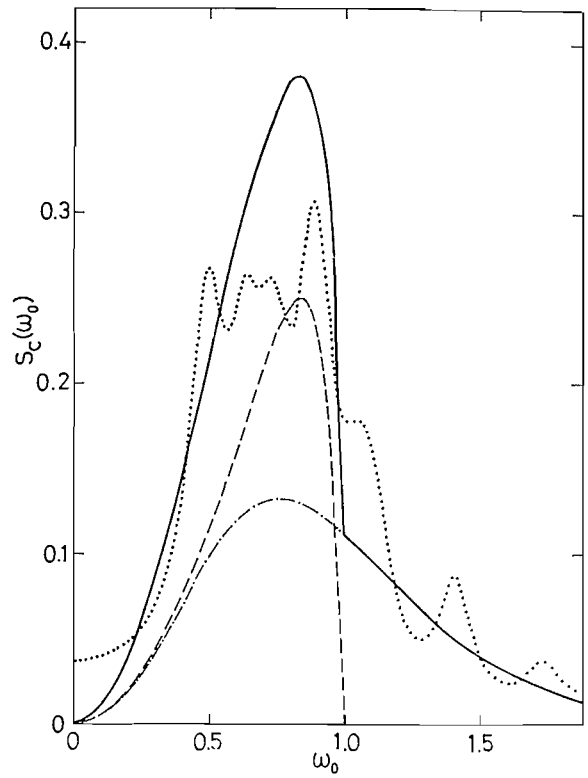

FIG. 1. The spectrum $S_{\mathrm{C}}(\omega_0)$ for the case $m = 1$, $M = 2$, $V_0 = 5B$, and $T = 10B$, where ω_0 is the dimensionless frequency related to frequency ω by $\omega = M(2BV)^{1/2}\omega_0$ as described in the text. Here the index M indicates the symmetry of the crystal field and m is the index for the coordinate in question. The spectrum obtained by the exact quantum mechanical calculation is shown by the dotted curve, where damping constant $\lambda = 0.5$ (in units of B). The oscillatory spectrum $S_{\mathrm{IC}}(\omega_0)$ and the rotatory spectrum $S_{\mathrm{IIC}}(\omega_0)$ calculated classically are given by the dashed and dot–dashed curves, respectively. The solid curve corresponds to the total classical spectrum $S_{\mathrm{C}}(\omega_0)$ $(= S_{\mathrm{IC}}(\omega_0) + S_{\mathrm{IIC}}(\omega_0))$.

and

$$[46b]\quad S_{\mathrm{II}\alpha}(\omega_0) = f(\omega_0) \sum_{l=1}^{n} \chi''_{\mathrm{II}\alpha l}(M\omega_0/2ml)$$

where the factor $f(\omega_0)$ is given by

$$[47]\quad f(\omega_0) = 2/[M(2BV)^{1/2}\beta\omega_0]$$

Equation [47] is obtained from comparison of the definitions of the spectral function and the susceptibility. For a quantum mechanical deviation the factor $f(\omega_0)$ has the form (1, 5)

$$[48]\quad f(\omega_0) = 2/[1 - \exp(-M(2BV)^{1/2}\beta\omega_0)]$$

Because we are considering the classical model we should use eq. [47] for the form of $f(\omega_0)$. When we compare the present results, written in the form of the spectral function, with the previous quantum mechanical results (1) represented in the spectral form we prefer to use eq. [48] rather than eq. [47] for the form of $f(\omega_0)$. The spectral functions derived using the different factors, defined by either eq. [47] or eq. [48], will differ from one another, even if the imaginary parts of the susceptibility are the same. To avoid differentiation just on the basis of the factors, we use eq. [48] for our definition of $f(\omega_0)$ for all calculations. In practice, the difference between [47] and [48] is small when

$$M(2BV)^{1/2}\beta\omega_0 \sim \omega_0 \lesssim 1$$

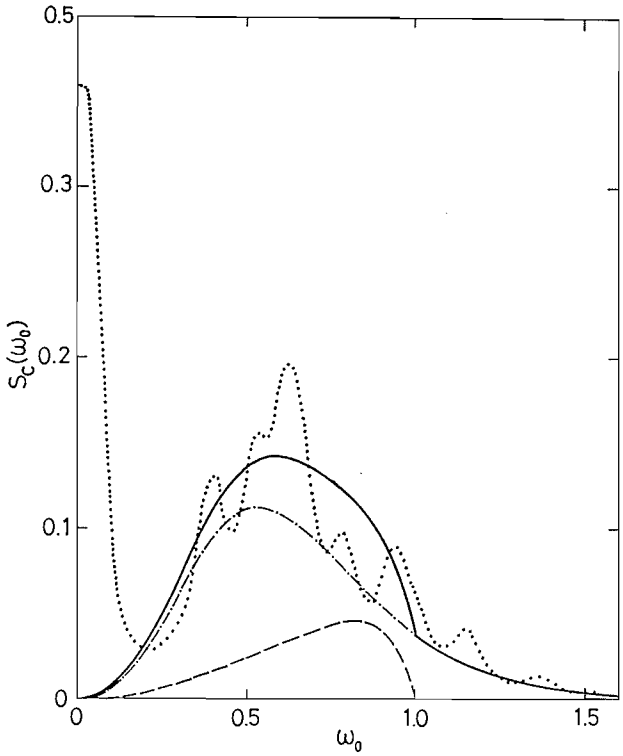

FIG. 2. The spectrum $S_C(\omega_0)$ for the case $m = 1$, $M = 3$, $V_0 = \pm 5B$, and $T = 10B$ ($\lambda = 0.5$). The notation is the same as for Fig. 1.

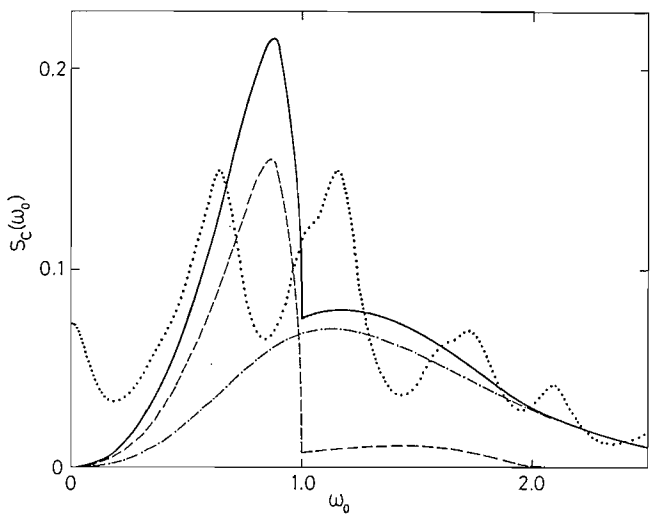

FIG. 3. The spectrum $S_C(\omega_0)$ in the case $m = 2$, $M = 3$, $V_0 = \pm 5B$, and $T = 10B$ ($\lambda = 1.0$). The notation is the same as for Fig. 1.

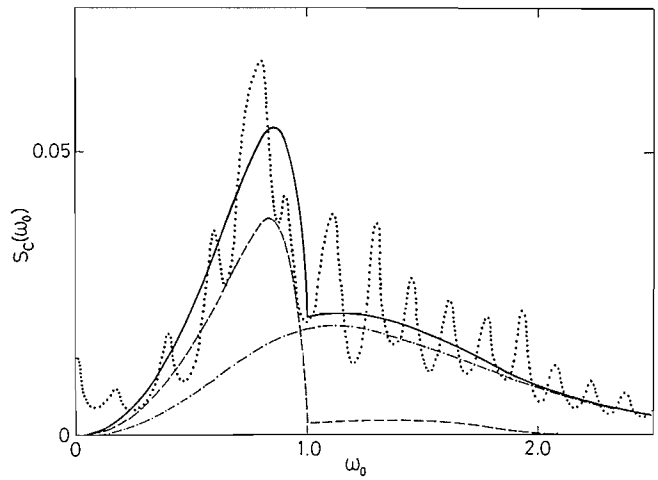

FIG. 4. The spectrum $S_C(\omega_0)$ in the case $m = 2$, $M = 3$, $V_0 = \pm 40B$, and $T = 100B$ ($\lambda = 1.0$). The notation is the same as for Fig. 1.

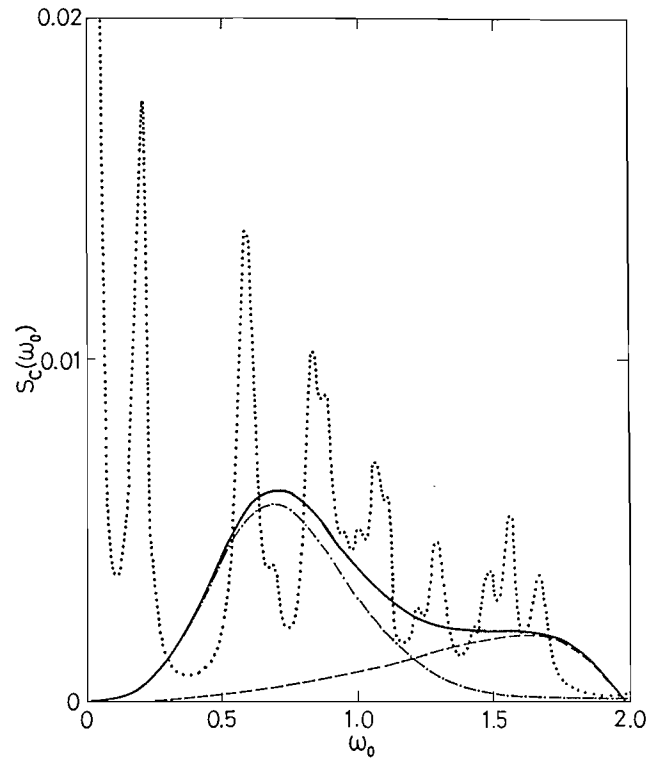

FIG. 5. The spectrum $S_C(\omega_0)$ in the case $m = 2$, $M = 4$, $V_0 = -40B$, and $T = 28B$ ($\lambda = 1.0$). The notation is the same as for Fig. 1.

The methods described above allow us to evaluate the classical spectral functions of the rotational coordinates $\cos m\phi$ and $\sin m\phi$ for a one-dimensional hindered rotor. The spectrum is naturally separated into two parts, those representing the oscillatory and the rotatory motions of the rotor. The imaginary part of the oscillatory susceptibility and that of the rotatory one are easily evaluated using eq. [41*a*] and eq. [41*b*], respectively. Below we describe the numerical calculations of spectral functions for various cases of interest and compare the present classical spectra with previous quantum mechanical results (1).

The value of the integer N defines the number of divisions of the period in the calculation of the coefficients, given by eq. [20], of the Fourier expansion [27]. For the present calculations we choose $N = 20$. The number of terms in the summation over the index in eqs. [46*a*] and [46*b*] is determined by a requirement to include at least 99% of the susceptibility at a given frequency ω_0. One finds that the $l = 1$ term is dominant for those values of ω_0 where the susceptibility is relatively large, the $l = 2$ term is important in the vicinity of $\omega_0 = 0$ and the $l = 4$ term contributes in the region of large ω_0. For the present calculation terms with $l > 5$ are excluded.

First we discuss the spectra for the case where the temperature is of the order of the orientational potential barrier height. The same case has been treated in the previous quantum mechanical paper (1). The results are shown in Figs. 1 through 4 together along with those of the previous quantum mechanical calculation. For Figs. 1 through 3 the relationship between the

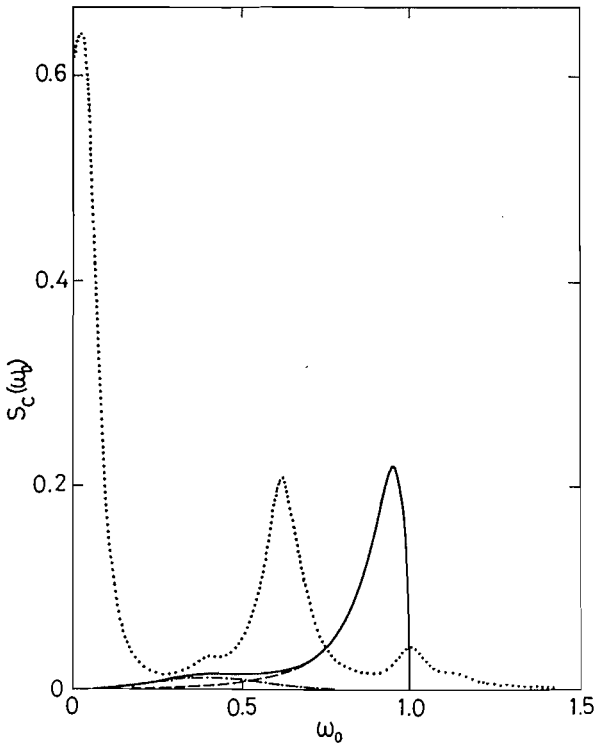

FIG. 6. The spectrum $S_C(\omega_0)$ in the case $m = 1$, $M = 3$, $V_0 = \pm 5B$, and $T = 2B$, where light molecules are postulated ($\lambda = 0.5$). The notation is the same as for Fig. 1.

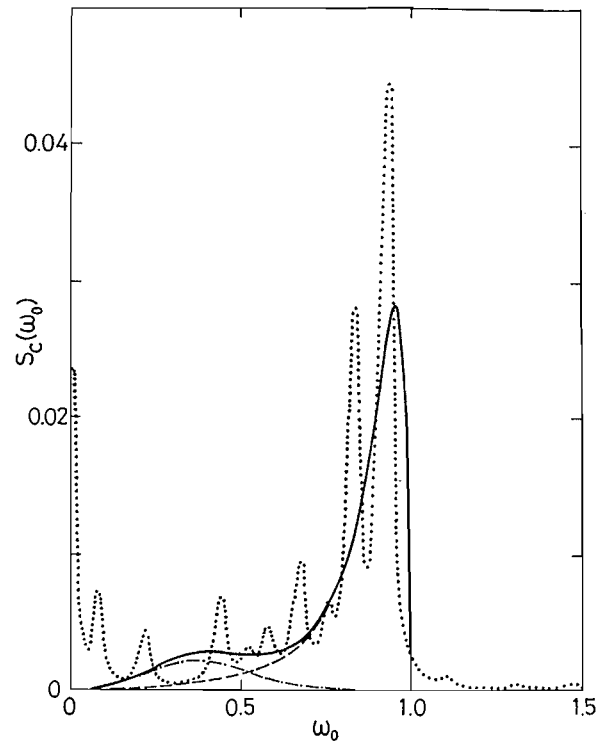

FIG. 7. The spectrum $S_C(\omega_0)$ in the case $m = 1$, $M = 3$, $V_0 = \pm 50B$, and $T = 20B$, where intermediate molecules are postulated ($\lambda = 0.5$). The notation is the same as for Fig. 1.

temperature, T, and the barrier height, V_0 is $V_0 = \pm 2T$; for Fig. 4 the corresponding relation is $V_0 = \pm 0.4T$. We note that the agreement between the quantum mechanical spectra and the classical mechanical one is quite good except in the vicinity of $\omega_0 = 0$. This observation suggests that the spectrum in the vicinity of $\omega_0 = 0$ arises from quantum mechanical tunnelling between equivalent molecular orientations. The figures show that the present classical calculation leads to a significant clarification of the structure of the spectrum. The present calculation allows us to distinguish between the rotational and vibrational contribution to the spectrum. Each of the spectra considered is decomposed into two separate components, one due to periodic angular oscillation and the other due to hindered continuous rotation. These different types of motion correspond to the spectral functions $S_{IC}(\omega_0)$ and $S_{IIC}(\omega_0)$ and are represented by the dashed and dot–dashed curves, respectively, in all figures. For cases when the temperature is comparable to the barrier height one finds roughly equal contributions from rotational and vibrational modes. In cases where the temperature is much less than the barrier height, as discussed below, the vibrational component of the spectrum dominates.

One would expect better agreement between classical and quantum treatments as the mass of the rotor is increased. This is indeed the case, as is evident from a comparison of Figs. 3 and 4 with Figs. 1 and 2.

As another example we consider the case pertinent to an earlier study of phase transitions in ammonium halide crystals (2). For this example the imaginary part of the susceptibility contains only the $l = 2$ term, that is $S_{IC}(\omega_0) = f(\omega_0)\chi''_{IC2}(\omega_0/2)$. The results of the classical and quantum calculations are shown in Fig. 5. In this case there is an appreciable difference between the classical and quantum results.

Finally we examine the spectra for the ordered phase of a molecular or ionic crystal, where molecules are captured in potential minima and perform angular oscillations (about an axis in our model). To illustrate the three cases of interest, we will use $T = 2B$, $V = 5B$ for light rotors (Fig. 6), $T = 20B$, $V = 50B$ for moderately heavy rotors (Fig. 7) and $T = 200B$, $V = 500B$ for massive rotors (Fig. 8) as the relevant relationships between temperature, potential barrier height, and rotational constant. These figures clearly show that the classical and quantum spectra for moderately heavy and heavy molecules (rotors to be exact) are very similar except in the vicinity of zero frequency, where we have central peaks due to quantum tunnelling. As one would expect, in the case of light molecules the agreement between the classical and quantum spectra is poor because of large quantum effects.

One can also observe that the classical calculations for coordinates $\cos m\phi_t$ with $m = 1$ agree better with the quantum results than those with $m = 2$. The effect of temperature in approaching the classical limit is more difficult to discern. The classical spectra of Fig. 3 ($V_0 = \pm 2T$) and Fig. 4 ($V_0 = \pm 0.4T$) are quite similar. The quantum spectrum of Fig. 4, with a higher temperature, has many more oscillations than the spectrum of Fig. 3. At the higher temperatures, the classical spectra appear to average out the oscillations of the quantum spectra.

The previous quantum mechanical treatment which employed methods developed by DeRaedt and DeRaedt (8) evaluated the quantity $\beta\langle Q^0_\alpha Q^0_\alpha\rangle$ in an approximate manner. As we could not calculate this quantity in the classical limit, we replaced it by $\langle Q_\alpha(0)\rangle^2$ under the assumption of ergodicity. At this time we are able to check the validity of this approximation for one dimensional rotational modes. The use of eq. [33] together with eq. [34] allows us to evaluate $\beta\langle Q_\alpha(0)Q_\alpha(0)\rangle$ and $\beta\langle Q^0_\alpha Q^0_\alpha\rangle$ simultaneously. The numerical classical and quantum values for these quantities for the cases corresponding to Figs. 1 through 8 are listed in Table 1.

8	Quantum	0.00249	0.00135	0.392
	Classical	0.00250	0.00233	

*The numbers 1 through 8 correspond to the one-dimensional hindered rotors of the figures with the same numbers. The last column represents the difference in $\beta\langle Q_C^0 Q_C^0\rangle$ between the classical and quantum values, divided by $\beta\langle Q_C(0)Q_C(0)\rangle$ in the classical case.

For the examples examined in the present paper, this table shows that the classical values of $\beta\langle Q_\alpha^0 Q_\alpha^0\rangle$ are always larger than the quantum values while the values $\beta\langle Q_C(0)Q_C(0)\rangle$ are almost same in both the classical and quantum cases. This implies that the invariant part of Q_α^0 of the rotational coordinate $Q_\alpha(t)$ with respect to the natural motion decreases by an amount corresponding to quantum tunnelling when one passes from the classical limit to the quantum case. Thus we might expect that the difference between the classical $\beta\langle Q_\alpha^0 Q_\alpha^0\rangle$ and the quantum $\beta\langle Q_\alpha^0 Q_\alpha^0\rangle$ divided by $\beta\langle Q_\alpha(0)Q_\alpha(0)\rangle$ to be a measure for the relative contribution of the central peak to the spectrum. We can confirm this conclusion by a rough comparison of the values in the last column of the table with the corresponding figure.

Appendix

Approximate expressions for the Jacobian elliptic function sn (u,k) and the complete elliptic integral of the first kind (7)

The Jacobian elliptic function sn (u,k) can be expressed in terms of θ functions, with a parameter q which may be computed from

[A1] $$q = \epsilon + 2\epsilon^5 + 15\epsilon^9 + 150\epsilon^{13} (+ \cdots)$$

with

[A2] $$2\epsilon = (1 - k'^{1/2})/(1 + k'^{1/2}), \qquad k' = (1 - k^2)^{1/2}$$

Using θ functions expressed in the form of expansions, we obtain the following approximate expression for sn (u,k):

[A3] $$\mathrm{sn}\,(u,k) = \frac{(1 + 2q + 2q^4)(\sin \pi z - q^2 \sin 3\pi z + q^6 \sin 5\pi z)}{(1 + q^2 + q^6)(1 - 2q \cos 2\pi z + 2q^4 \cos 4\pi z)}$$

with $z = u/2K(k)$, where $K(k)$ is the complete elliptic integral of the first kind. This expression is adequate for our purpose, because, as explained below, there is no need to represent the detailed behaviour of the function sn for k extremely close to 1.

Next we derive the approximations [39*a*] and [39*b*]. As a first approximation we have

[A4] $$\pi/2K(k) \simeq [1 + (1 - k^2)^{1/4}]^2/4$$

For the right hand side of the above, the following is permitted:

[A5] $$[1 - \{1 - (1 - k^2)^{1/4}\}/2]^2 \simeq 1 - \{1 - (1 - k^2)^{1/4}\} = (1 - k^2)^{1/4}$$

Here we have

[A6] $$\pi/2K(k) \simeq (1 - k^2)^{1/4}$$

This appears to be an excellent approximation although it is obtained from two successive rough approximations. Using the same method we can obtain the approximation [39*b*].

We have no problems so long as the approximations [39*a*] and [39*b*] are used for $1/K(k)$ or $1/K(1/k)$. However, when we rewrite them as

[A7] $$2K(k) \simeq \pi(1 - k^2)^{-1/4}$$

and

[A8] $$2K(1/k) \simeq \pi k^{1/2}(k^2 - 1)^{-1/4}$$

we have a problem with respect to the convergence of $K(k)$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

or $K(1/k)$ in the vicinity of $k = 1$. The following limit is well-known:

[A9] $$\lim_{k \to 1-0} 2K(k) = -\ln (1 - k)$$

We then have

[A10] $$\lim_{k \to 1-0} [-\ln (1 - k)]/[\pi(1 - k^2)^{-1/4}] = 0$$

and

[A11] $$\lim_{k \to 1+0} [-\ln (1 - 1/k)]/[\pi k^{1/2}(k^2 - 1)^{-1/4}] = 0$$

Equations [A10] and [A11] indicate that the convergences of the approximate expressions for $K(k)$ and $K(1/k)$, as given by [A7] and [A8], are stronger than the exact ones. The susceptibility is calculated in this paper by use of the approximate expressions. Results such as [41*a*], [41*b*], and [43] show that there is almost no contribution from $k = 1$; $k = 1$ corresponds to $X = 0$ in eq. [41]. Hence, we expect no problems in regard to convergence for the present calculations.

The critical temperature, the critical pressure, and the dependence of vapour pressure on temperature for dodecafluorocyclohexane and hexafluorobenzene

D. R. DAVIES, M. B. EWING, J. A. HUGILL, AND M. L. MCGLASHAN
Department of Chemistry, University College London, 20 Gordon Street, London WC1H 0AJ, England

Received September 2, 1987

This paper is dedicated to Professor J. A. Morrison

D. R. DAVIES, M. B. EWING, J. A. HUGILL, and M. L. MCGLASHAN. Can. J. Chem. **66**, 760 (1988).

The critical temperature T^c, the critical pressure p^c, and the dependence of the vapour pressure p on the temperature T, have been measured for dodecafluorocyclohexane and hexafluorobenzene. For the first substance, little had previously been known. For the second substance, previous measurements have been confirmed and extended. The results have been analysed by means of Wagner's equation: $\ln(p/p^c) = (T^c/T)(A_2\tau + A_3\tau^{1.5} + A_4\tau^{2.5} + A_5\tau^5)$ where $\tau = (1 - T/T^c)$.

D. R. DAVIES, M. B. EWING, J. A. HUGILL et M. L. MCGLASHAN. Can. J. Chem. **66**, 760 (1988).

Opérant avec du dodécafluorocyclohexane et de l'hexafluorobenzène, on a mesuré la température critique, T^c, la pression critique, p^c, ainsi que la relation qui existe entre ces valeurs et la pression de vapeur p et la température T. Au sujet du premier composé, on connaissait peu de choses. Dans le cas du deuxième produit, on a confirmé et étendu les études qui avaient été réalisées antérieurement. On a analysé les résultats à l'aide de l'équation de Wagner : $\ln(p/p^c) = (T^c/T)(A_2\tau + A_3\tau^{1.5} + A_4\tau^{2.5} + A_5\tau^5)$ dans laquelle $\tau = (1 - T/T^c)$.

[Traduit par la revue]

Introduction

We have taken the opportunity, belatedly, to present the results of measurements of the critical temperature T^c, the critical pressure p^c, and the dependence of vapour pressure p on temperature T, for dodecafluorocyclohexane and hexafluorobenzene. For dodecafluorocyclohexane only two values of the vapour pressure at temperatures above 370 K, and the critical temperature, had previously been measured (1). For hexafluorobenzene both our vapour pressures and our critical temperature and critical pressure confirm previous results (2–8).

Experimental

Dodecafluorocyclohexane and hexafluorobenzene were gifts from the Imperial Smelting Company (now ISC Chemicals plc). The mole-fraction purities determined by glc were 0.94 of c-C_6F_{12} and 0.999 of C_6F_6. The dodecafluorocyclohexane was purified by slow sublimation at atmospheric pressure until its mole-fraction purity was 0.997 of c-C_6F_{12}; we were unable to purify it further. The relative difference $(p^b - p^d)/p^d$ between the bubble pressure p^b and the dew pressure p^d was 0.0017, just a little less than the upper bound allowed by Timmermans (9) for samples intended for accurate physical measurements. The hexafluorobenzene was used without further purification except for drying and degassing; its value for $(p^b - p^d)/p^d$ was 0.0005.

The apparatus and method were the same as those previously described: for dodecafluorocyclohexane and for the earlier measurements on hexafluorobenzene in refs. 10 and 11, and for the later measurements on hexafluorobenzene in ref. 12. Temperatures are all expressed in terms of the IPTS-68 and are denoted by T_{68}.

Results

Our vapour pressures p at temperatures T_{68} are given for dodecafluorocyclohexane in Table 1 and for hexafluorobenzene in Table 2. Our values of the critical constants of each fluid are given and compared with literature values in Table 3. We estimated the critical molar volume V_m^c of c-C_6F_{12} from the dimensions of the tube in which fluid at its critical point was enclosed by mercury and the amount of substance of c-C_6F_{12} in the tube. For hexafluorobenzene the critical pressure obtained by analysing only our own vapour pressures was 3275.2 kPa, by analysing them together with the measurements of Ambrose (2) was 3274.7 kPa, and by analysing all of those together with the measurements of Douslin *et al.* (3) and Counsell *et al.* (4)

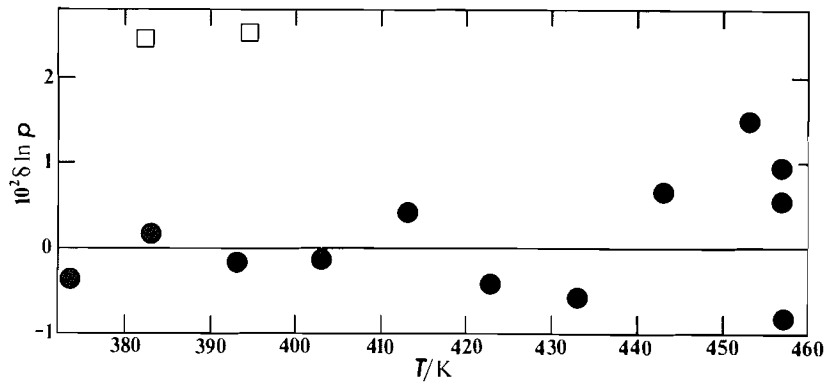

FIG. 1. For dodecafluorocyclohexane, a plot of the deviations $\delta \ln p = \ln(p/p^c) - (T^c/T)(A_2\tau + A_3\tau^{1.5} + A_4\tau^{2.5} + A_5\tau^5)$ from the equation due to Wagner (13) where p denotes the vapour pressure, T the temperature, T^c the critical temperature, and $\tau = (1 - T/T^c)$, with the critical pressure p^c treated as an adjustable parameter, against the temperature T. ●, This work; □, Rowlinson and Thacker (1).

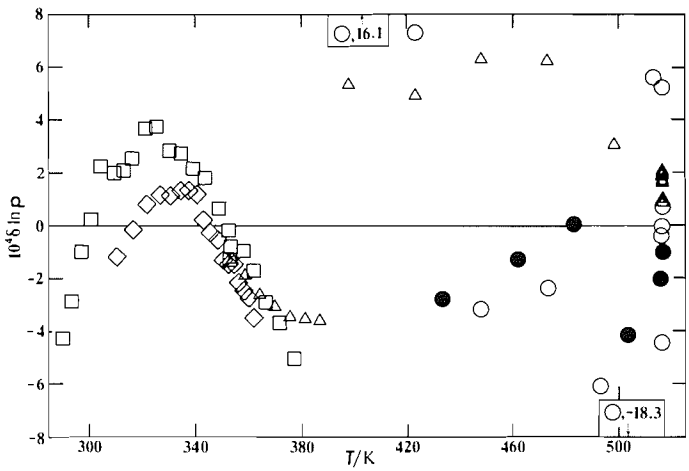

FIG. 2. For hexafluorobenzene, a plot of the deviations $\delta \ln p = \ln(p/p^c) - (T^c/T)(A_2\tau + A_3\tau^{1.5} + A_4\tau^{2.5} + A_5\tau^5)$ from the equation due to Wagner (13) where p denotes the vapour pressure, T the temperature, T^c the critical temperature, and $\tau = (1 - T/T^c)$, with the critical pressure p^c treated as an adjustable parameter, against the temperature T. ●, This work (later measurements); ○, this work (earlier measurements); □, Ambrose (2); △, Douslin *et al.* (3); ◇, Counsell *et al.* (4).

was 3275.0 kPa. To four significant figures all these values are identical.

Discussion

The vapour pressures of each liquid were analysed in terms of the deviations $\delta \ln p$:

$$[1]\quad \delta \ln p = \ln(p/p^c) - (T^c/T)(A_2\tau + A_3\tau^{1.5} + A_4\tau^{2.5} + A_5\tau^5)$$

from the equation of Wagner (13, 14), where $\tau = (1 - T/T^c)$, with the critical pressure p^c treated as an adjustable parameter. For dodecafluorocyclohexane we obtained with $T_{68}^c = 457.290$ K: $p^c = 2241.7$ kPa, $A_2 = -11.82$, $A_3 = 20.10$, $A_4 = -65.2$, and $A_5 = 840$. For hexafluorobenzene we obtained with $T_{68}^c = 516.710$ K: $p^c = 3275.0$ kPa, $A_2 = -8.0657$, $A_3 = 2.0297$, $A_4 = -3.1301$, and $A_5 = -4.080$.

As shown in Fig. 1 for dodecafluorocyclohexane, all our 12 points, except one which was excluded from the regression, give values of $\delta \ln p$ lying within ± 0.01. The two values of Rowlinson and Thacker (1) give values lying a little more than twice as far from zero, both in the same direction. As shown in Fig. 2 for hexafluorobenzene, only two (and those are two of our earlier, and admittedly less accurate, measurements) of the 78 points from this work, and from the work of Ambrose (2), Douslin *et al.* (3), and Counsell *et al.* (4), give values of $\delta \ln p$ lying outside $\pm 8 \times 10^{-4}$. The older measurements, not included in Fig. 2, give deviations $\delta \ln p$ from Wagner's equation [1] ranging for those of Patrick and Prosser (6) from 65×10^{-4} at 312.99 K to -54×10^{-4} at 358.12 K; and for those of Evans and Tiley (7) from 355×10^{-4} at 381.51 K to -254×10^{-4} at 515.61 K.

Approximations for the inner branch of potential curves of diatomic molecules

Y. P. VARSHNI

Ottawa–Carleton Institute for Physics, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received August 17, 1987

This paper is dedicated to Professor James A. Morrison

Y. P. VARSHNI. Can. J. Chem. **66**, 763 (1988).

Three potential energy functions are examined with respect to their ability to reproduce the inner branch of the potential curve for 43 molecular states. Two of the states turn out to be unusual. In the remaining 41 cases, it is found that a potential proposed by the author gives the least error in 28 cases and is close to the least error in another six. The potential curves of NaAr(X) and XeCl(X) are very different from those of the other 41 states considered in this paper. The Born–Mayer potential appears to provide a reasonable representation of the inner branch of the potential curve for XeCl(X).

Y. P. VARSHNI. Can. J. Chem. **66**, 763 (1988).

On a examiné les trois potentiels d'énergie par rapport à leur habilité à reproduire les branches internes de la courbe de potentiel de 43 états moléculaires. Il en ressort que deux de ces états sont inhabituels. Les 41 autres cas se divisent comme suit : pour 28 cas, on a trouvé que le potentiel proposé par l'auteur conduit à une erreur minimale alors que, pour six autres cas, il conduit pratiquement à l'erreur minimale. Les courbes de potentiel du NaAr(X) et du XeCl(X) sont très différentes de celles des 41 autres états considérés dans notre travail. Le potentiel de Born–Mayer semble fournir une représentation raisonnable de la branche interne de la courbe de potentiel du XeCl(X).

Introduction

It is usually difficult to obtain the RKR (Rydberg–Klein–Rees) curves for heavy diatomic molecules. The difficulty stems from the fact that while it may be possible to carry out a reliable vibrational analysis for a particular electronic transition for such a molecule, it is very difficult to achieve a rotational analysis because the spectral lines are so congested. As pointed out by Tellinghuisen and Henderson (1) (TH), in the absence of rotational constants the RKR method can yield only the width of the potential curve, $R_+ - R_-$, as a function of v and G_v. Thus to obtain the potential curve, one must guess the equilibrium internuclear distance and the shape of either the inner or outer branch of the potential curve.

Tellinghuisen and co-workers (2–5) have approximated the unknown repulsive or inner branch (R_-) by a variety of methods, e.g., representing it by an inverse power potential (4) or by a Morse potential (3), then simply adding the RKR width as a function of energy to obtain the outer branch (R_+). TH have tested the approximation of representing the inner branch by a Morse potential (6) approximation on 25 molecular states for which the RKR curves are known. The errors show a whole spectrum of values, from quite small to quite large. The question naturally arises whether better results are possible by the use of other potential functions. There are two other three-parameter functions, the Rydberg potential (7) and a potential proposed by the author (8), which are able to predict $\omega_e x_e$ values better (8, 9) than the Morse curve in many cases. Thus it was of interest to examine the applicability of these two potentials to approximate the inner branch of potential curves. We have considered 18 states in addition to those considered by TH and, also, some of the data that we use are different from those used by TH; in view of these factors we have also included the Morse potential in our investigation. We use the usual symbols for the molecular constants (10).

The three potentials are as follows.

Morse (6):

$$[1] \quad U = D_e[1 - e^{-a(r-r_e)}]^2$$

Rydberg (7):

$$[2] \quad U = D_e[1 + b(r - r_e)]e^{-b(r-r_e)}$$

Varshni III (8, 9):

$$[3] \quad U = D_e\left\{1 - \frac{r_e}{r}\exp\left[-\beta(r^2 - r_e^2)\right]\right\}^2$$

Potential [3] has been found to give quite good results for several molecular properties (11–14). Each of the three potentials has three parameters and these can be readily determined in terms of k_e, r_e, and D_e. The expressions for a, b, and β are as follows:

$$[4] \quad a = (k_e/2D_e)^{1/2}$$

$$[5] \quad b = (k_e/D_e)^{1/2}$$

and

$$[6] \quad \beta = \frac{1}{2r_e^2}[\Delta^{1/2} - 1]$$

where

$$\Delta = k_e r_e^2/2D_e$$

Data

We have considered here a total of 43 states. The data employed by us are shown in Table 1. The 18 states that are in addition to those considered by TH are identified by an asterisk in column 1 of Table 1. The references in column 5 are for RKR curves and for most of the molecular data. Such molecular data that are not from the given references are from TH and from Huber and Herzberg (22). For those states also considered by TH, for the most part our data are the same as those used by TH, except for the following differences.

$K_2(X)$ and $K_2(B)$: Very recently Heinze *et al.* (26) investigated the B–X band system of the K_2 molecule by Doppler-free polarization spectroscopy in a heat-pipe oven. New molecular constants were given as well as the RKR curves for the X and B states. We have used these data. (TH had considered only the $K_2(X)$ state.) Ross *et al.* (38) have also given the RKR curve for the ground state of K_2.

$S_2(X)$: TH used the RKR curve that was calculated by them. We have used the RKR curve from Bradson and Volkmar (31).

$I_2(X)$: Recently Martin *et al.* (33) presented an accurate

RKR curve for $^{127}I_2(X)$ from data obtained from an extensive analysis of the $BO_u^+ \rightarrow XO_f^+$ fluorescence spectrum of $^{127}I_2$. We have used this RKR curve.

$I_2(A)$ and $I_2(A')$: We have used the r_e values given in the original references. TH used slightly different values.

$SiO(X)$, $Se_2(X)$, $I_2(B)$, $Mg_2(X)$, and $NaAr(X)$: TH used RKR curves calculated by themselves (unpublished). We have used the RKR curves calculated by us using the program of Tellinghuisen (39).

For all the states marked by an asterisk, except $K_2(B)$, the RKR curves were also calculated by us using the program of Tellinghuisen (39). Where the range of applicability of the $G(v)$ series was not known, the RKR curve was cut off at about 80% of D_e.

Results and discussion

The calculated parameters for the three potentials are shown in the last three columns of Table 1.

For the Morse potential, R_- is calculated from

$$[7] \quad R_- = r_e - \ln [1 + (U/D_e)^{1/2}]/a$$

For the other two potentials an iterative method was used, on a computer.

It is convenient (1) to discuss the results in terms of the dimensionless variables,

$$[8] \quad \delta = \frac{R_-(\text{calcd. from the potential}) - R_-(\text{RKR})}{r_e}$$

and

$$[9] \quad u = U/D_e$$

Generally speaking, for all the three potentials, δ increases with u. A sample illustration is shown in Fig. 1. Sometimes there is a slight reversal of the curvature near the end. The curves for the different potentials do not cross each other. Under the circumstances, for comparison purposes, the maximum

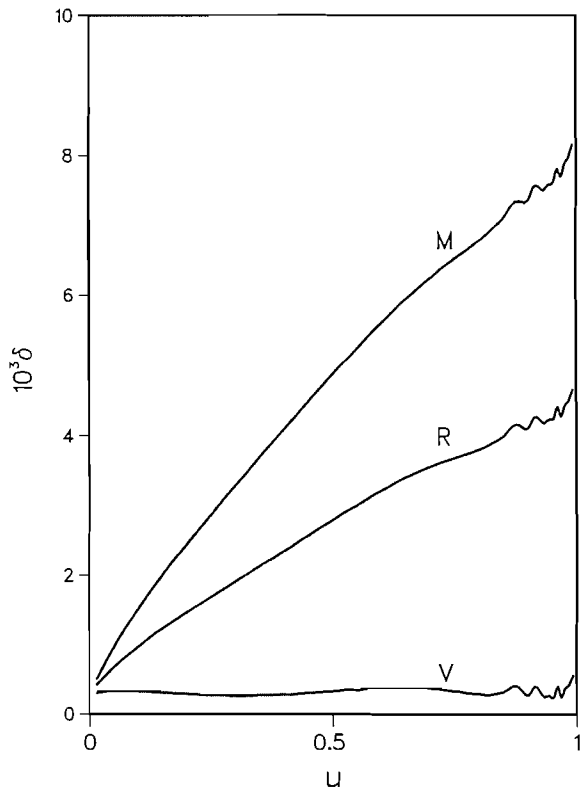

FIG. 1. $10^3\delta$ versus u for $Cl_2(X)$ by the three potentials. M, Morse; R, Rydberg; V, Varshni III. The ripples toward the end are due to slight inaccuracies in the RKR curve.

value of δ is a good measure of the error from the function. In Table 2 we show the δ_{max} values ($\times 10^3$) for the three potentials. The maximum value of u for which the RKR curve was available is also shown.

It will be noticed from Table 2 that the results for NaAr and XeCl are very poor for all three potentials. We shall consider these two molecules later. In the remaining 41 cases, potential [3] gives the best results in 28 cases, the Morse potential in 9, and the Rydberg potential in 4. In the 4 cases for which the results from the Rydberg potential are better than those from [3], the difference is only marginal. A similar remark applies for RbH, where the Morse potential gives the least error, but the difference from the results of eq. [3] is only marginal. For $Ar_2(X)$ the Morse potential gives the smallest error but the results from the other two potentials are pretty close to it.

For all except two of the states that are "common" with TH, there is good agreement between our results and those of TH. The two exceptions are $I_2(A)$ and NaAr(X). In the case of $I_2(A)$ the difference appears to stem from the different r_e values used by us and by TH. As noted earlier we have followed the r_e value given in the quoted reference. For NaAr(X), our value for $10^3\delta_{max}$ is 135.6, while TH give a value of 6. This discrepancy is very large. In the paper by Tellinghuisen *et al.* (37) from which the data were taken, there occurs the following sentence: "However, the initial calculations indicated clearly that a Morse curve rises too rapidly with decreasing R....". Our findings are in agreement with this sentence. Subsequently, in ref. 37, a modified Morse curve was used. It is possible that the value 6 quoted by TH refers to the modified Morse curve and not to the Morse curve. The other two potentials also give large errors for this state. NaAr is a van der Waals molecule and the nature of its potential curve is expected to be much different from most of the other molecules considered in this paper.

TABLE 2. Comparison of δ_{max} for the three potentials

State	u_{max}	$10^3\delta_{max}$ Morse	Rydberg	Equation [3]
$H_2(X)$	0.98	−34.1	−43.7	24.8

$CO(X)$	0.57	−3.5	−7.0	−7.4
$SiO(X)$	0.56	−3.8	−7.0	−8.5
$O_2(X)$	0.71	1.3	−2.1	−5.1
$O_2(A)$	0.98	13.3	10.7	7.6
$O_2(B)$	0.90	14.1	11.1	7.5
$S_2(X)$	0.61	4.4	1.8	1.9
$Se_2(X)$	0.39	3.2	1.4	−0.6
$^{19}F_2$	0.79	7.1	4.5	1.5
$Cl_2(X)$	0.99	8.2	4.7	0.6
$^{79}Br_2$	0.78	9.2	6.6	3.4
$I_2(X)$	1.00	9.2	6.4	3.1
$I_2(A)$	0.95	−11.1	−13.0	−14.7
$I_2(A')$	0.83	8.9	7.0	5.2
$I_2(B)$	0.98	7.3	4.8	2.2
$^{39}Cl^{19}F$	0.77	24.4	21.3	17.9
$^{79}Br^{19}F$	0.80	14.0	10.9	7.4
$^{79}Br^{35}Cl$	0.78	8.5	5.7	2.4
$^{127}I^{19}F$	0.79	5.8	2.7	2.3
$^{127}I^{35}Cl$	0.80	10.9	8.2	4.8
$^{127}I^{79}Br$	0.78	11.3	8.8	5.8
$Ar_2(X)$	0.71	1.3	−1.4	−3.0
$Mg_2(X)$	0.99	−7.9	−11.3	−15.4
NaAr(X)	0.98	135.6	132.8	129.5
XeCl(X)	0.95	−76.4	−80.5	−84.2

For molecules for which D_e is poorly known (or not known at all), but $\omega_e x_e$ is known and is positive, D_e can be estimated (9) from

$$[10] \quad D_e = \frac{5Wk_e r_e^2}{2(\omega_e x_e r_e^2 \mu_A - 9W)}$$

where $W = 2.1072 \times 10^{-16}$, and then potential [3] can be applied.

We then consider XeCl(X). The shape of the potential curve for this state is known only approximately, having been obtained through trial and error Franck–Condon calculations (1, 3). The following discussion is subject to this caveat. The nature of the potential curve depends on the nature of the binding. It is reasonable to expect that XeCl binding should have an appreciable ionic component. We have tried the Born–Mayer potential

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

$$[11] \quad V = \frac{A}{r} + Be^{-r/\sigma}$$

for this molecule. Using the conditions [8a, b, c] of ref. 8, the three parameters were determined to be: $\sigma = 0.14699$ Å, $A = 950.9\,\text{cm}^{-1}$ Å, and $B = 4.6792 \times 10^{10}\,\text{cm}^{-1}$. A comparison of the resulting curve with the RKR curve showed that the value of $10^3\delta_{max}$ was only -12.0, a considerable improvement on the previous results. We may note here two differences between our application of the Born–Mayer potential and the customary application (40) of this potential to ionic molecules. First, the coefficient of the first term has been taken to be a parameter A, rather than e^2, and second, we have assumed $U(r_e) - U(\infty) = -D_e$, rather than $-D_i$.

The performance of a potential energy function depends on its analytical form and the number of parameters involved in it. For a fixed number of parameters one tries to select the potential that gives the fewest errors. Our aim in this paper has been to focus on such potential functions that can be used when only limited data are available, as in the situation outlined in the opening paragraph. One can obviously expect to improve the agreement with a greater number of parameters. Several potential functions with more than three parameters are available (8, 11, 41–43).

In conclusion we find that for most molecules whose binding is mostly covalent, potential [3] provides a good description of the inner branch of the RKR curve. For XeCl type of molecules, the Born–Mayer potential deserves further exploration.

The effect of an additive on a water–surfactant system can be studied through thermodynamic functions of transfer of the additive from water to aqueous solutions of the surfactant. These thermodynamic functions often go through extrema in the region of the critical micellar concentration (cmc) of the surfactant. As it can be shown with a simple chemical equilibrium model, the general shape of the transfer functions is primarily related to the pair-wise hydrophobic interactions between the additive and the surfactant monomers, to a shift in the monomer–micelle equilibrium and to the distribution of the additive between the aqueous phase and the micelles. Medium and electrostatic effects are also possible, especially with ionic systems. To separate these effects and identify the salts which distribute themselves in the micelles, the volumes and heat capacities of transfer of hydrophobic ammonium salts from water to aqueous solutions of dimethyloctylamine oxide have been investigated. The short chain salts have only a small effect on monomer–micelle equilibrium by salting out the monomers, whereas the more hydrophobic ones participate also to the micellization process, shifting more strongly the surfactant monomer–micelle equilibrium.

DANIEL HÉTU et JACQUES E. DESNOYERS. Can. J. Chem. **66**, 767 (1988).

L'effet d'un additif sur un système eau–tensioactif peut être étudié par le biais des fonctions de transfert de l'additif de l'eau aux solutions aqueuses du tensioactif. Ces fonctions thermodynamiques passent souvent par un extremum dans la région de la concentration micellaire critique (cmc) du tensioactif. Comme il peut être démontré à l'aide d'un modèle simple d'équilibre chimique, l'allure générale des fonctions de transfert est principalement reliée aux interactions hydrophobes par paires entre les monomères de l'additif et du tensioactif, au déplacement de l'équilibre monomères–micelles du tensioactif, ainsi qu'à la distribution de l'additif entre la phase aqueuse et les micelles. Des effets de milieu ainsi qu'électrostatiques peuvent aussi jouer un rôle important, particulièrement dans le cas de systèmes ioniques. Afin de séparer ces effets et d'identifier les sels qui participent à la micellisation, les volumes et capacités calorifiques de transfert de sels hydrophobes d'ammonium de l'eau aux solutions aqueuses d'oxyde d'octyldiméthylamine ont été investigués. Les sels à courtes chaînes ont seulement un petit effet sur l'équilibre monomères–micelles du tensioactif, dû à un effet de relargage, alors que les sels à plus longues chaînes participent en plus à la micellisation, déplaçant davantage l'équilibre du tensioactif.

Introduction

Electrolytes have an important effect on the properties of aqueous micellar solutions. Inorganic electrolytes generally lower the critical micellar concentration (cmc) of surfactants by salting out the monomers (1, 2), they modify the shape and size of the micelles (2–4) and they lower the interfacial tension between microemulsions and an aqueous or oil phase (5, 6). As the hydrophobic character of the electrolyte increases, hydrophobic interactions with the surfactant become increasingly important and with long-chain electrolytes, mixed micelles are formed (7). Similar effects are also observed for electrolytes in some hydro-organic mixtures.

One of the best ways of studying the effect of an additive on micellar systems is through thermodynamic functions of transfer of the additive from water to aqueous solutions of surfactants (8). Incidentally, in recent years, the amount of reliable data on such functions has increased remarkably (9–22). At the same time, theoretical models have been developed to simulate the trends in the transfer functions and extract, from the data, fundamental thermodynamic parameters for the mixed micelles (18–27). In this respect, much work has been done to understand the role of alcohols and light oils on micellar systems, but less is known on the transfer of electrolytes to such systems.

The chemical equilibrium model for the formation of mixed micelles introduced by Roux *et al.* (26, 27) assumes that the general trends in the transfer functions of non-electrolytes are mainly due to the pair-wise hydrophobic interactions between the additive and surfactant monomers, to a shift in the monomer–micelle equilibrium of the surfactant induced by the solute and to the distribution of the additive between the aqueous phase and the micelles. With simple electrolytes, no mixed micelles are formed, and the shift in cmc is therefore simply due to the interactions between monomers and to medium effects. In order to verify the importance of each effect and to distinguish between the additives which participate to the micellization from those which simply act on the aqueous medium, a systematic study was made of the functions of transfer of ammonium salts from water to aqueous solutions of a non-ionic surfactant, octyldimethylamine oxide (C_8DAO). Two approaches were adopted. In the first, the transfers of ammonium salts of the homologous series RNH_3Br were investigated. This series starts from an ionic surfactant, octylammonium hydrobromide (OctNH_3Br or OABr), to, decreasing gradually the chain length, finish with a simple salt effect. In the second, the symmetrical quaternary ammonium salts (R_4NBr) were chosen, since the more hydrophobic R_4NBr salts are known to salt in non-electrolytes in water (28).

The two thermodynamic properties that will be reported here are the volumes and the heat capacities. These two properties are easily measured concurrently and the data for the binary system water–C_8DAO are already available (29). Some cmc measurements were also made as a function of the concentration

[1]Paper written in the honour of J. A. Morrison who introduced J. E. Desnoyers to the field of calorimetry and thermodynamics.

of electrolytes or alcohols, such data being useful for the interpretation.

Experimental

The flow techniques used for volumes and heat capacities have been well described elsewhere (30–32). The densities and volumetric heat capacities of the ternary system were measured using the binary system (surfactant 2 in water W) as reference liquid, and the apparent molar quantities $V_{\phi,3}$ and $C_{p,\phi,3}$ of the additive 3 were calculated from these measurements (31). Any functions of transfer Y can then be obtained from these data by

$$[1] \quad \Delta Y_3(\mathrm{W} \rightarrow \mathrm{W} + 2) = Y_{\phi,3}(\mathrm{W} + 2) - Y_{\phi,3}(\mathrm{W})$$

This is a good approximation of the standard transfer functions, when the concentration of the additive is sufficiently close to the infinite dilution.

The ternary system solutions were prepared using the corresponding binary solutions of C_8DAO as solvent and the electrolytes added were held at a constant concentration of 0.05 mol kg^{-1} in all cases. This concentration represents a good compromise between a measurable quantity and a good approximation of infinite dilution.

For the cmc measurements, the surfactant solutions were initially prepared and diluted for each measurement using aqueous solutions of the additives as solvent. The data (densities for the added salts and conductivities for the alcohols) were plotted against the surfactant concentration. Assuming a linear behavior of the property studied on both sides of the cmc, the cmc values were taken as the intercept of the two linear sections.

The water used to prepare the solutions and as a reference liquid has been distilled, filtered, deionized, and degassed. Its specific conductivity was always lower than $2 \times 10^{-7}\ \Omega^{-1}$. The alcohols, 2-propanol (2-PrOH), *n*-butanol (BuOH), and *n*-pentanol (PenOH), from Fisher, were of ACS quality. They have been dried over molecular sieves and filtered.

C_8DAO (27) and OABr (33) have been prepared following methods described elsewhere.

Sodium chloride (NaBr), of ACS quality, was purchased from Fisher. It was dried 24 h under vacuum at 200°C and kept, also under vacuum, in the presence of P_2O_5.

With the exception of OABr, the primary ammonium salts of the series RNH_3Br, where R stand for methyl (Me), butyl (Bu), hexyl (Hex), and octyl (Oct), have been prepared and purified following methods described elsewhere (34).

Except for propyl (R = Pr), which comes from Pfaltz & Bauer, all the quaternary symmetric ammonium salts of the series R_4NBr have been purchased from Eastman Kodak. Their purification has been done according to methods described elsewhere (28).

The dibutylammonium bromide (Bu_2NH_2Br) has been synthesized in the same way as OABr, starting with dibutylamine purchased from J. T. Baker Chemical. The purity of the final product was checked by nmr spectroscopy.

The trimethylbutylammonium bromide was prepared by the action of 1-bromobutane, purchased from J. T. Baker Chemical, on trimethylamine provided by Aldrich Chemical in a 25% by weight aqueous solution. For the reaction, the amine was extracted and transferred with dried nitrogen to a solution of 1-bromobutane in benzene, in a reflux apparatus held at 65°C. The solution was stirred. After three recrystallizations in a 5/1 mixture of benzene – absolute ethanol, it was found by nmr spectroscopy that the product contained about 3% of impurities. After five more recrystallizations in the same mixture of solvents and a last one in a mixture of 20% absolute ethanol, 20% diethylether, and 60% acetone, the impurity peak was still present, but at a much smaller level.

Results and discussion

The electrolytes investigated in the present transfer functions to micellar systems vary significantly in nature: they go from simple electrolytes (NaBr) that remain essentially in the aqueous phase, to real surfactants (OABr) which form mixed micelles and bulky hydrophobic electrolytes (Pen_4NBr) which certainly have an affinity for the surfactants, but whose structures are not easily compatible with mixed micellar state. No simple model should therefore account for all of them. The model of Roux *et al.* (26, 27), based on the formation of mixed micelles, will be used as a starting point to see if it is possible through this model to distinguish between solutes that distribute themselves in the micelles and others where other types of interactions are responsible for the observed trends in the transfer functions.

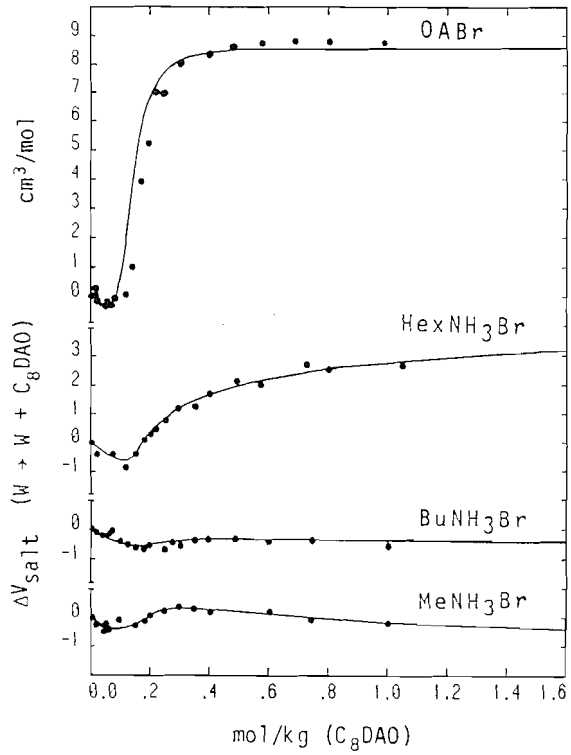

FIG. 1. Volumes of transfer of the salts of the series RNH_3Br from water to aqueous solutions of C_8DAO at 25°C; — simulations.

The original data for all the transfer functions are available elsewhere (38). Only trends will therefore be reported in graphical form and parameters derived from the data will be tabulated.

Homologous series RNH_3Br

The volumes and heat capacities of transfer of the salts of the homologous series RNH_3Br are shown, respectively, in Figs. 1 and 2. The lines represent the simulations using the model of Roux *et al.* (26, 27) with adjustment of K_D, the distribution constant, ΔY_3^M, the change in partial molar quantity Y of the electrolyte between its micellar and aqueous standard states, and $B_{Y,AB}$, the initial slope for pair-wise hydrophobic interactions between the monomers of the solute 2 (A) and those of the electrolyte 3 (B). The values obtained for these parameters are presented in Table 1, where are also given, m_3, the experimental molality of the electrolyte, and ΔH_3^M, the enthalpy change used in the expression of the relaxation term which is responsible for the maximum. The parameters for the binary system water–C_8DAO, for instance m_1 (cmc), n (aggregation number), and the various micellization functions ΔY_2^M, were taken from Desnoyers *et al.* (29).

The functions of transfer of OABr are qualitatively similar to those of alcohols (27) to the same surfactant. In Fig. 1, the

TABLE 1. Parameters used for the adjusted simulations of the volumes and heat capacities of transfer of the salts of the series RNH_3Br from water to aqueous solutions of C_8DAO at 25°C

Parameters	Value			
	$MeNH_3Br$	$BuNH_3Br$	$HexNH_3Br$	OABr
m_3 (mol kg^{-1})	0.05	0.05	0.05	0.05
ΔV_3^M (cm^3 mol^{-1})	−1.8	−0.75	4.0	8.3
K_D[a]	1.5	1.3	4.2	19.5
$B_{V,AB}$ (cm^3 mol^{-2} kg)	−1.0	−4.6	−5.2	−7.6
$\Delta C_{p,3}^M$ (J K^{-1} mol^{-1})	225	225	5.0	−245
ΔH_3^M (J mol^{-1})	0	0	1000[c]	1975[d]
K_D[b]	1.7	2.4	3.8	18.5
$B_{C,AB}$ (J K^{-1} mol^{-1} kg)	0.0	0.0	0.0	0.0

[a]Value obtained by adjustment of the volumes.
[b]Value obtained by adjustment of heat capacities; K_D is dimensionless but is here defined as the inverse of the molality and must be multiplied by 55.51 to be compared on a mole fraction scale (see ref. 27).
[c]Reference 33.
[d]Reference 35.

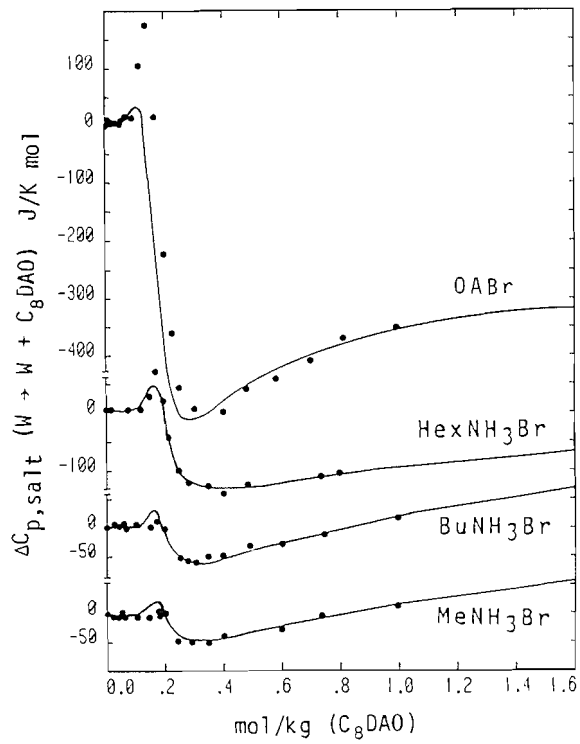

FIG. 2. Heat capacities of transfer of the salts of the series RNH_3Br from water to aqueous solutions of C_8DAO at 25°C; — simulations.

volumes present a small minimum due to the hydrophobic interactions between the monomers of C_8DAO and OABr in the pre-micellar region and a large positive ΔV_3^M which corresponds to the loss of hydrophobic hydration in the post-micellar region. Similarly, a typical large and negative $\Delta C_{p,3}^M$ is observed in Fig. 2. As the chain length of the amine salt decreases, the general trends of the transfer functions remain the same, but the change ΔY_3^M decreases significantly in magnitude. So, if, as expected, OABr participates in the micellization process, such a behaviour does not seem to exist for the two shorter electrolytes of the series.

An analysis of the parameters of Table 1 also leads to interesting conclusions. It is first worth noting that the distribution constants obtained either by the simulation of volumes or heat capacities are generally very close together, as it was the case for the transfer of alcohols (27). In the model of Roux *et al.*, K_D is ideally related to the inverse of the maximum solubility of monomers in water, which is, for a surfactant, given approximately by the cmc. As given by Desnoyers and co-workers (35), the cmc of OABr is 0.22 mol kg^{-1}. This would give a K_D value of 4.5, which is four times lower than the average value in Table 1. This implies that OABr monomers have more affinity for C_8DAO micelles than for their own micelles, which is however not really unexpected, since the electrostatic repulsion between the ionic heads are probably lower in mixed micelles OABr–C_8DAO than in OABr micelles. Also, the volume of transfer of OABr, 8.3 cm^3 mol^{-1}, is of the same magnitude as the volume of micellization of OABr, 8.1 cm^3 mol^{-1} (35). Therefore, the volume occupied by OABr in the micellar and mixed micellar states is the same, which is also expected, since the chain length of the two surfactants involved are the same. On the other hand, the heat capacity of transfer, −245 J K^{-1} mol^{-1}, is less negative than the heat capacity of micellization, −332 J K^{-1} mol^{-1} (35), probably as a result of the difference in the repulsion energies. This difference, which is important for heat capacities but not for the volumes, accounts for the large minimum in the heat capacities of transfer observed with OABr in Fig. 2 and not with the volumes in Fig. 1.

In the case of $HexNH_3Br$, the initial slope for the volumes is less pronounced, which indicates weaker hydrophobic interactions. The K_D and ΔY_3^M values are also smaller in magnitude, which indicates that $HexNH_3Br$ participates to the micellization, but less easily than OABr.

In the case of the two last electrolytes, ΔY_3^M are close to zero or even of opposite sign. This suggests that these electrolytes simply shift the monomer–micelle equilibrium, but do not form mixed micelles. The parameters extracted from the model have therefore little physical meaning in these cases, but it is nevertheless interesting to note that the model can be used to fit the data.

To give an overall view, the parameters obtained with the simulations were plotted, in Fig. 3, as a function of the number of carbon atoms of the hydrophobic chain of the electrolytes transfered. As expected, the initial slopes $B_{V,AB}$ increase in magnitude with the chain length, since the hydrophobic character of the amine salts increases with chain length.

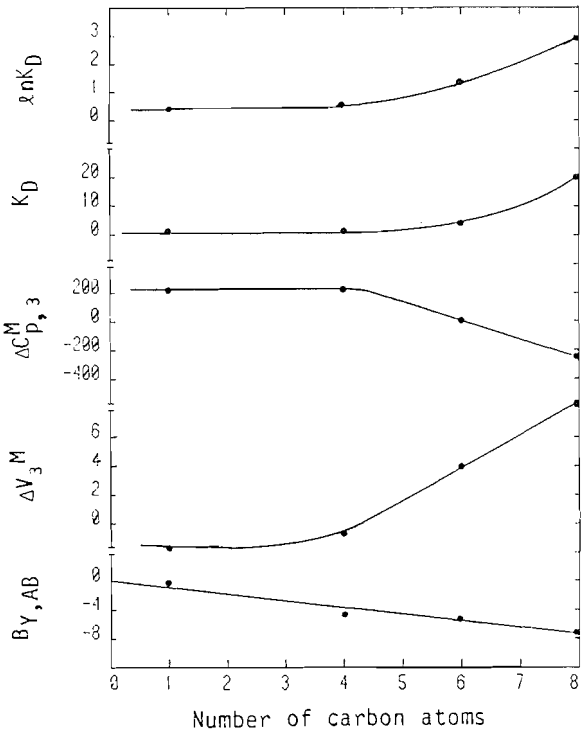

FIG. 3. Parameters obtained with the adjusted simulations of the functions of transfer of the salts of the series RNH_3Br at 25°C.

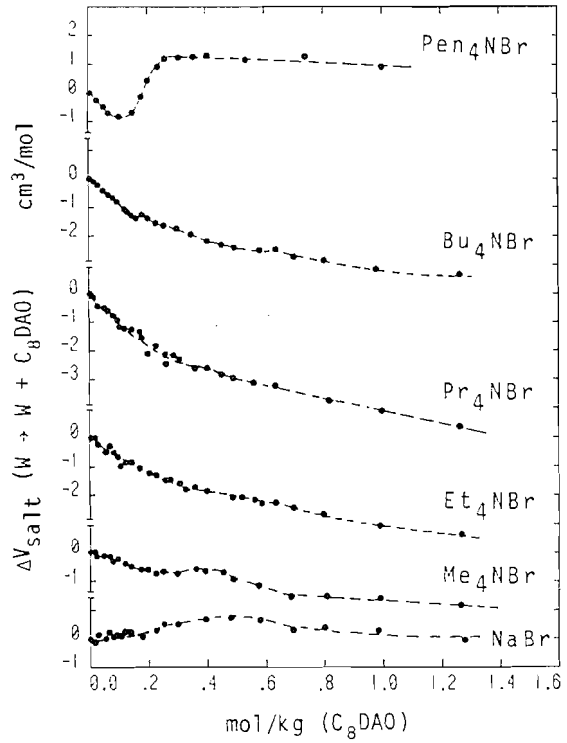

FIG. 4. Volumes of transfer of the salts of the series R_4NBr from water to aqueous solutions of C_8DAO at 25°C.

However, rather than to tend slowly to zero as the chain length decreases, the distribution constant values seem to level off to a small positive value. This is enhanced by the values of ln K_D which should rapidly tend to negative values when K_D tends to zero. This clearly shows that the model cannot be applied significantly to the salts of less than five carbon atoms, the residual value on K_D simply expressing the small electrostatic contributions for the monomer–micelle equilibrium displacement due for example to a salting-out effect. It is also apparent that ΔY_3^M of the short-chain electrolytes is not reflecting any more the change in property of the electrolyte when going from an aqueous medium to a condensed state in mixed micelles.

Symmetric salts R_4NBr

The volumes and heat capacities of transfer of NaBr and of the symmetric tetraalkylammonium salts from water to aqueous C_8DAO are respectively presented in Figs. 4 and 5. No simulation of the data with the mixed micelles model of Roux *et al.* were attempted with this series.

It can be seen that NaBr, which can only have a simple salt effect, behaves greatly like $MeNH_3Br$ in Figs. 1 and 2. The transfer functions simply go through an extremum around the cmc of C_8DAO, essentially due to electrostatic contributions to the monomer–micelle equilibrium displacement, to gradually come back around zero in higher concentration region.

For the ammonium salts, a maximum is also clearly defined in the volumes of Me_4NBr, but for the others, the hydrophobic interactions between R_4N^+ and the surfactant mask nearly completely any contribution due to the shift in monomer–micelle equilibrium. Also, it is only in the case of Pen_4NBr that evidence is seen in the volumes for the formation of mixed micelles. With heat capacities, as seen from the initial slopes close to zero, the contribution of hydrophobic interactions is much smaller. The influence of R_4NBr in shifting the monomer–micelle equilibrium is then more apparent, but as for the volumes, the formation of mixed micelles is strongly

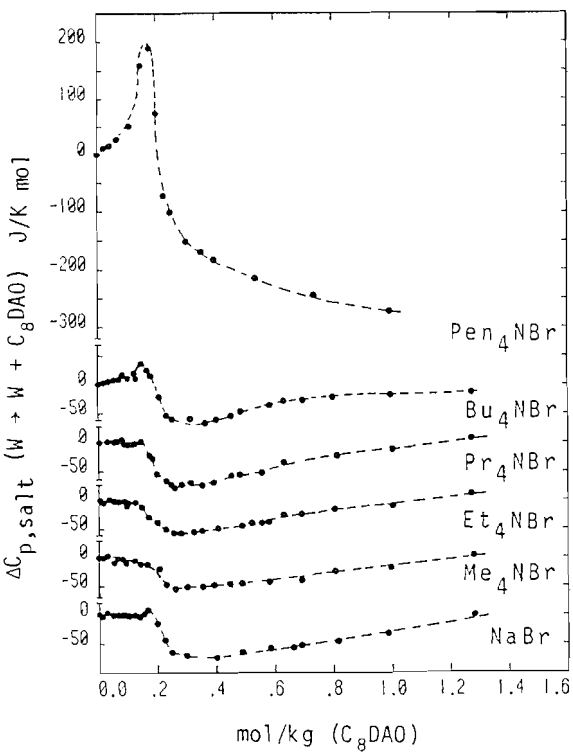

FIG. 5. Heat capacities of transfer of the salts of the series R_4NBr from water to aqueous solutions of C_8DAO at 25°C.

suggested only in the case of Pen_4NBr. It is interesting to note that the shift in equilibrium appears to vary little with hydrophobic character of the electrolytes when no mixed micelles are formed, which tends to confirm that the minimum is essentially due to electrostatic contributions.

In Fig. 6, the transfer volumes of Me_4NBr, Et_4NBr, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12

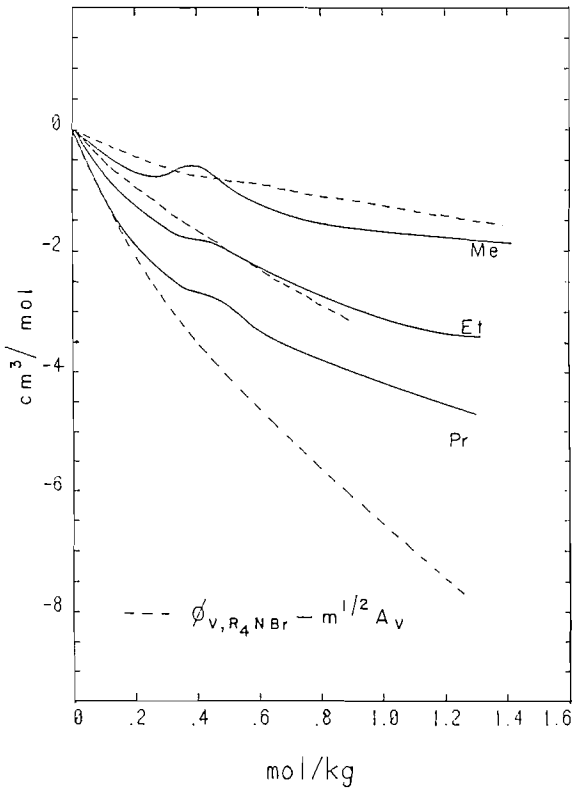

FIG. 6. Comparison of the volumes of transfer of Me_4NBr, Et_4NBr, and Pr_4NBr from water to aqueous C_8DAO with their partial molar volumes in water without Debye–Hückel contributions at 25°C. --- apparent molar volumes, from ref. 40; — volumes of transfer.

Pr_4NBr are compared to their apparent molar volumes in water (40) from which the Debye–Hückel contributions ($m^{1/2}A_V$) were substracted. For Me_4NBr and Et_4NBr, the behaviour in a micellar solution is not much different from the one in water, but it differs in an important way in the case of Pr_4NBr for which the transfer volumes tend to a less negative value than apparent molar volumes. This would mean that Pr_4N^+ is more affected by the presence of C_8DAO micelles than Me_4N^+ and Et_4N^+ and that Pr_4NBr probably participates to a small extent to the micellization process, which was not really apparent in Figs. 4 and 5.

If the extrema are related to the equilibrium displacement, there should be a relationship with the cmc displacements. In order to verify this, the values of d ln cmc/dm_3 of C_8DAO by R_4NBr salts and, for sake of comparison, those of OABr by the alcohols (ROH) were measured. These results are respectively given in Tables 2 and 3. For NaBr and most ammonium salts, there is a nearly constant displacement, which does not seem to exist in the case of alcohols, while with Pen_4NBr, the displacement is large and in the same direction as the effect of alcohols. From these results, we can therefore state that there are two kinds of equilibrium displacements: the first one, which would be very weak in the case of non-ionic polar solute such as alcohols, would be due to a medium or salting effect and the other to the participation of the additive to the micellization process. Also, since the model used for the simulations of the RNH_3Br salts does not take the salting effect explicitly into account, it is not surprising that a clear difference between the short chain salts and the longer ones seems to exist. Incidentally, this was not the case for the transfers of alcohols (27) where the progression of the parameters seemed to be continuous when the chain length was gradually increased.

TABLE 2. cmc displacements of C_8DAO by NaBr and the salts of the series R_4NBr at 25°C

Salt	Radius (Å)	d ln cmc/dm_3	σ
NaBr	1.0[a]	−0.72	0.02

[b]Reference 37.

An approach similar to the one of Roux *et al.* (26) for mixed micelles can be used to simulate the salting effect on the transfer functions of electrolytes to micellar solutions. This model is based on the mass-action model of Desnoyers *et al.* (29) for the binary systems of non-ionic surfactants, where a one-step process for the micellization is assumed. Then, if α_0 represents the fraction of surfactant molecules A which stay in free monomer form and if m_2 is the molality (mol kg^{-1}) of the surfactant, the concentration of the monomers A is $\alpha_0 m_2$ and that of the micelles M is $(1 - \alpha_0)m_2/n$, n being the aggregation number. The equilibrium constant is therefore given as:

$$[2] \quad K_M = \frac{[M]}{[A]^n} = \frac{(1 - \alpha_0)}{\alpha_0{}^n n m_2{}^{n-1}}$$

where the activity coefficients of species are all neglected. This equation can be expressed in the logarithmic form as:

$$[3] \quad -\frac{1}{n} \ln K_M = \ln \alpha_0 m_2 - \frac{1}{n} \ln [(1 - \alpha_0)m_2/n]$$

When K_M and n are known, this equation can be solved, by a successive approximation method, to find α_0 for any given m_2. The value for K_M is obtained from the inflexion point in α_0 as a function of m_2. This point is defined as $(\partial^2\alpha_0/\partial m_2{}^2)_{m_1} = 0$, which allows to find α_1, α_0 at the inflexion concentration m_1, and to relate α_1 to the aggregation number by the equation:

$$[4] \quad \alpha_1 = \frac{n}{n-1}[1 - (1/2n)^{1/2}]$$

In the mixed micelles model, the equilibrium eq. [3] was modified, to account for the shift in K_M induced by the presence of the additive in the micelles. Similarly, eq. [3] should be modified in the presence of an electrolyte to account for the salting effect on the surfactant monomers. By analogy with the salting effects on alcohols (39), the activity coefficient of the monomers A is related to the concentration of the electrolyte B through a Setchenov constant $B_{G,AB}$ and the final equation for the ternary system has therefore the form:

$$[5] \quad -\frac{1}{n} \ln K_M = \ln \alpha m_2 - \frac{1}{n} \ln [(1 - \alpha)m_2/n] + 2B_{G,AB}m_3$$

where the lack of subscript 0 on α indicates that it is a ternary system. Assuming that K_M is the same as for the binary system, eq. [5] can be solved in the same way as eq. [3]. Because of the last term, the values for α are different from α_0, the difference $(\alpha_0 - \alpha)$ expressing the surfactant monomer-micelles equilibrium displacement.

The expression for the volumes of transfer would now have

PenOH	5	−3.0	0.7
HexOH	6	−6.1	2.0

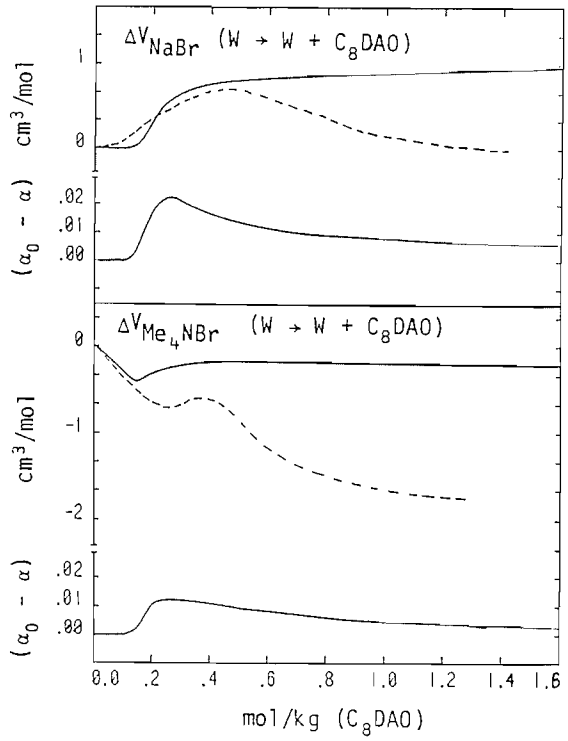

FIG. 7. Simulations of the volumes of transfer of NaBr and Me_4NBr from water to aqueous solutions of C_8DAO at 25°C; --- experimental data; — simulations.

the form:

$$[6]\quad \Delta V_3(\mathrm{W} \rightarrow \mathrm{W}+2) = 2\alpha m_2 B_{V,\mathrm{AB}} + (\alpha_0 - \alpha) m_2 \Delta V_2^M / m_3$$

where $B_{V,\mathrm{AB}}$, the initial slope related to the interactions between the surfactant monomers A and the salt B, is essentially the pressure derivative of $B_{\mathrm{G,AB}}$ and ΔV_2^M, the micellization volume of the surfactant expressing the change between the micellar and aqueous monomer standard states.

The Setchenov constant is directly related to the variation of the cmc with m_3 (25):

$$[7]\quad 2B_{\mathrm{G,AB}} = \mathrm{d}\ln \mathrm{cmc}/\mathrm{d}m_3$$

Therefore, using the experimental values for $B_{\mathrm{G,AB}}$, α can be calculated from eq. [5] and α_0 from eq. [3]. The difference $(\alpha_0 - \alpha)$ and the simulated volumes of transfer of NaBr and Me_4NBr are shown in Fig. 7 and compared with the experimental data. While, as expected, $(\alpha_0 - \alpha)$ goes through a maximum in the micellization region, the simulated volumes of transfer do not go through a maximum, but essentially level off beyond the cmc region. A maximum could of course be generated by introducing an interaction term between the electrolyte and the micelles, but as more adjustable parameters are added the model becomes more empirical. Therefore, although the present simple approach does indicate that the

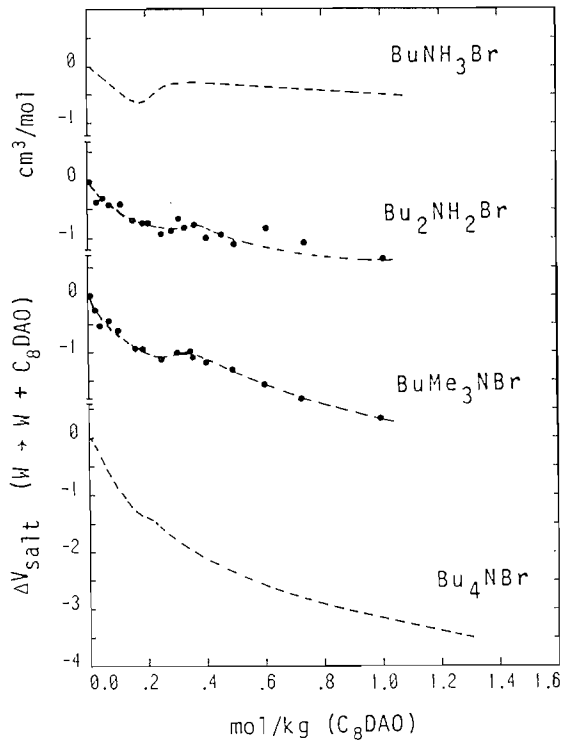

FIG. 8. Volumes of transfer of ammonium salts from water to aqueous solutions of C_8DAO at 25°C.

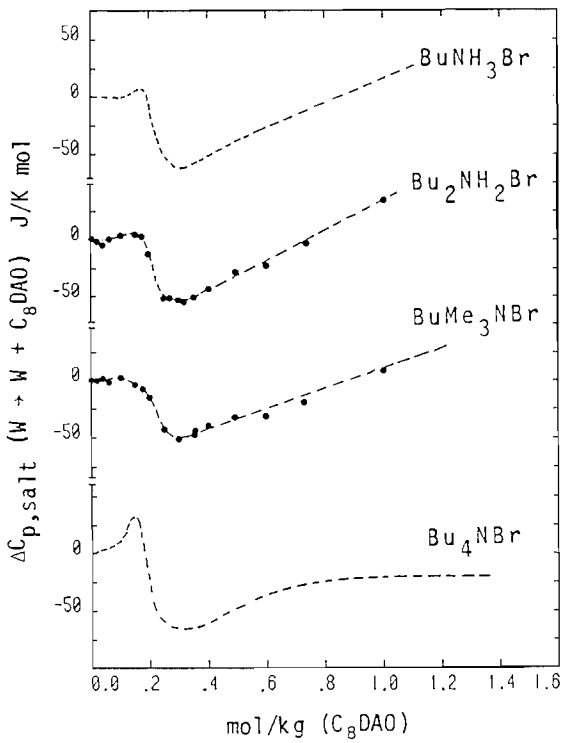

FIG. 9. Heat capacities of transfer of ammonium salts from water to aqueous solutions of C_8DAO at 25°C.

observed trends for the transfer of electrolytes to micellar systems are related to the salting out of surfactant monomers, the theory, at present, is only of qualitative value. It can, however, be mentioned that for the salts which do not form mixed micelles, the change in the micellar region of transfer functions could be interpreted as a modification of the solvent in the presence of the micelles, this contribution being probably

always present, but masked when mixed micelles are formed. This idea is supported by the constant residual values on ΔY_3^M for the two shorter electrolytes in Fig. 3.

Steric hindrance effect

In Figs. 8 and 9 are shown respectively the volumes and heat capacities of transfer of Bu_2NH_2Br and $BuMe_3NBr$ from water to aqueous C_8DAO. For the sake of comparison, the curves of $BuNH_3Br$ and Bu_4NBr have also been reproduced from previous figures.

The dependance of ΔY_3 ($W \rightarrow W + C_8DAO$) on surfactant concentration are similar for $BuNH_3Br$, Bu_2NH_2Br, and $BuMe_3NBr$ and slightly different for Bu_4NBr in the post-micellar region. On the other hand, Bu_2NH_2Br has the same number of carbon atoms as OABr and half as many as Bu_4NBr. This confirms that symmetry plays a very important role in micelle formation. OABr is a true surfactant which readily forms mixed micelles, Bu_4NBr barely shows tendencies to associate with the micelles and the three other electrolytes in Figs. 8 and 9 primarily have a medium effect on the transfer functions.

Conclusion

The transfer of electrolytes from water to micellar systems fall into three categories. Long-chain ionic surfactants readily form mixed micelles with non-ionic surfactants. The critical chain length for the formation of mixed micelles of course depends on the nature of the non-ionic surfactant, but is of the order of 5 to 6 carbon atoms. Inorganic electrolytes primarily shift the cmc of the micellar system by salting out the monomers. This salting-out effect seems, as a first approximation, to be independent of chain length. Hydrophobic electrolytes, which have chain lengths too short to form mixed micelles or which are bulky, do interact with the surfactant monomers (hydrophobic interactions), but do not show tendencies to associate with the surfactant monomers, until the cations become very hydrophobic (Pen_4N^+). See Denoyers and Arel (34) for a discussion of these effects. Bu_4NBr, and possibly Pr_4NBr, are borderline electrolytes in that they are quite hydrophobic, but show only a small tendency to associate with C_8DAO.

A complete theory for the transfer of organic electrolytes from water to micellar systems would have to include terms for the formation of mixed micelles, for the salting out of monomers by the ionic head, for hydrophobic interactions between the hydrophobic tail of the electrolyte and the surfactant monomers and possibly for the interaction between the electrolyte and the neutral micelles or a change in the solvent in the presence of micelles.
