One significant difference between reaction in CTAOH and in DDAOH was observed at low surfactant concentrations for the hydrolysis of compounds **1***b–e*. Using nimetazepam **1***b* as an example, the rates at 3 m*M* surfactant are similar: 32.4×10^{-3} s^{-1} CTAOH and 31.0×10^{-3} s^{-1} for DDAOH. However, at 2 m*M* and 1 m*M* surfactant, the rate in CTAOH is lower, 9.8×10^{-3} s^{-1} (2 m*M*) than for reaction in DDAOH, 1.8×10^{-2} s^{-1} (2 m*M*) (see Table 2). This can be explained by assuming that the cmc of CTAOH is between 1 and 2 m*M*, so that at 1 m*M* no micelles are present. Vesicles, on the other hand, are not lost on dilution (2, 3) and reaction in DDAOH was not retarded to the same extent when the concentration was reduced in this concentration range. In fact, a more gradual decrease in rate of hydrolysis of **1***b* was observed down to as low as 0.1 m*M* DDAOH. Thus, compound **1***b* is incorporated into surfactant aggregates at quite low concentrations and the behaviour in CTAOH is not due to the lack of solubilization so much as to the lack of micelles.

[b]At 12 m*M* CTAB/100 m*M* NaOH, $k_1 = 9.69 \times 10^{-3}$ s^{-1}.

Reported values for the cmc of CTAOH vary considerably. Bunton and co-workers (8) comment that the cmc is not well defined but is approximately 10^{-3} M. Llamos and Zana quote a value of 1.8 m*M* obtained by a conductivity technique as being more reliable than the value of 0.8 m*M* obtained by the surface tension method (9). Furthermore, the 1.8 m*M* value from conductivity measurements obeys the logarithmic law usually found for the change of cmc with the number of carbon atoms (9). A value of 1.8 m*M* for the cmc of CTAOH fits in well with our observations, indicating differences in rates between CTAOH and DDAOH at 1 and 2 m*M* but not at 3 m*M* surfactant.

Comparison of CTAOH and CTAB/NaOH

For diazepam **1***a*, the rate of hydrolysis in 12 m*M* CTAOH and 88 m*M* NaOH (15.9×10^{-3} s^{-1}) was faster than in 12 m*M* CTAB and 0.1 *M* NaOH (9.69×10^{-3} s^{-1}) (same total concentration of hydroxide). The difference in rate is due to the combined effects of (*a*) the unfavourable exchange constants between hydroxide and bromide (not present in CTAOH) and (*b*) the different degrees of dissociation of micelles of CTAB ($\beta = 0.80$) and CTAOH ($\beta \approx 0.5$ between 4–10 m*M* CTAOH)

(10). In other words, the reaction in CTAB/NaOH is inhibited by the salt effect of 12 m*M* NaBr. It is of interest that this inhibition of the hydrolysis of diazepam (**1***a*) by 12 m*M* NaBr (40%) is less than that observed for compounds (**1***b–e*) (81–88% inhibition by 10 m*M* KBr). It would be of interest to determine whether this difference is a function of the different counterion (Na^+ versus K^+) or whether it is a function of different substituents on the compounds studied (e.g., for **1***a*, X = Cl, while for **1***b–e*, X = NO_2).

The other difference observed between reaction in CTAB and in CTAOH concerns the shape of the rate/surfactant profile in each case. Whereas reactions with NaOH in CTAB typically show a maximum corresponding to the complete solubilization of the substrate into the micelle (12 m*M* CTAB in the case of diazepam (1)), reactions in CTAOH continue to increase in rate even after all the substrate is completely solubilized. The rate of hydrolysis of diazepam in CTAOH increased up to 100 m*M* CTAOH.

This behaviour has been observed previously for other reactions in CTAOH and explained by the variation of the fraction of head groups neutralized as the surfactant concentration is changed (10).

Conclusions

Since similar mechanistic effects have been observed for the basic hydrolysis of benzodiazepinones in micelles (CTAB and CTAOH) in vesicles (DDAOH) and since vesicles are considered to be good membrane mimics (3), it seems reasonable to conclude that any mechanistic changes observed on transfer from water to micelles have relevance to the corresponding reactions in biological membranes.

Specifically, the basic hydrolysis of diazepam in the presence of biological membranes probably occurs via initial amide hydrolysis, whereas reaction in water involves initial azomethine hydrolysis. Thus, conclusions concerning the bioavailability of diazepam should not be based on studies of hydrolysis carried out in water.

Experimental

Materials

Substrates **1***a–e* were available from previous studies (1, 11).

Solutions of CTAOH were prepared from CTAB (8) by treatment with excess Ag_2SO_4 in methanolic solution. The mixture was sonicated for 2 h and then the solution was filtered, additional Ag_2SO_4 added, and the mixture resonicated. The solution was then filtered and the methanol removed *in vacuo*. The resulting cetyltrimethylammonium sulfate (CTAS) was recrystallized from MeOH/Et_2O. An aqueous solution of CTAS was treated with an equivalent amount of $Ba(OH)_2$ under N_2 gas. The $BaSO_4$ was removed by filtration and centrifugation. The resulting CTAOH was shown to be free of bromide, barium, and sulfate ions by standard methods. Solutions of CTAOH were stored at 0°C under N_2 gas.

Solutions of DDAOH were prepared from didodecyldimethylammonium bromide DDAB in an analogous way. In the hydroxy dechlorination of 1-chloro-2,4-dinitrobenzene, the kinetic behaviour of DDAOH, prepared as described above, was shown to be identical to that reported by Bunton and co-workers (6) for DDAOH prepared by an ion exchange resin technique. The hydroxide concentration of both CTAOH and DDAOH was determined by quenching an aliquot of the surfactant in excess standard dilute HCl followed by back titration of the excess HCl with standard NaOH solution using phenolphthalein indicator. Identical results were obtained whether the analysis was carried out in the presence or absence of methanol.

Rate constants were obtained as described previously (1), except that all manipulations with either CTAOH or DDAOH were carried out under a CO_2-free, N_2 atmosphere.

Cyclobutene photochemistry. Involvement of carbene intermediates in the photochemistry of alkylcyclobutenes

K. Brady Clark and William J. Leigh[1]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received September 30, 1987

K. Brady Clark and William J. Leigh. Can. J. Chem. **66**, 1571 (1988).

The photochemistry of 1,3,3,4- and 1,3,4,4-tetramethylcyclobutene has been investigated in pentane solution with monochromatic far ultraviolet (185, 193, and 214 nm) light sources, as well as in methanol solution with 214-nm excitation. Photolysis of each of the two isomeric cyclobutene derivatives results in competitive electrocyclic ring opening (yielding mixtures of stereoisomeric dienes in each case), fragmentation to yield propyne and methyl-2-butene, and isomerization to the other cyclobutene isomer. Quantum yields for product formation with 185-nm excitation have been measured in each case by cyclooctene actinometry. The occurrence of the interconversion process is offered as evidence for the intermediacy of cyclopropyl carbenes in the photochemistry of simple cyclobutenes in solution. On the basis of the known chemistry of carbenes of this type, their intermediacy in cyclobutene photochemistry may account at least partially for the formation of the formal ($2\pi + 2\pi$) cycloreversion products from photolysis of simple cyclobutene derivatives.

K. Brady Clark et William J. Leigh. Can. J. Chem. **66**, 1571 (1988).

On a étudié la photochimie des triméthyl-1,3,3,4 (et -1,3,4,4) cyclobutènes dans le pentane avec des sources de lumière ultraviolette liontaine (183, 194 et 214 nm) ainsi qui dans le méthanol avec une excitation à 214 nm. La photolyse de chacun des deux dérivés cyclobutènes isomères conduit à une ouverture de cycle électrocyclique (conduisant dans chaque cas à des mélanges de diènes stéréoisomères) qui est en compétition avec une fragmentation conduisant au propyne et au méthyl-2 butène-2 et avec une isomérisation conduisant à l'autre isomère cyclobutène. Utilisant l'actinométrie du cyclooctène et opérant à 185 nm, on a mesuré les rendements quantiques pour la formation des produits. Le fait que l'on observe le processus d'interconversion est proposé comme preuve de la présence de carbènes cyclopropyles comme intermédiaires dans la photochimie des cyclobutènes simples, en solution. En se basant sur la chimie connue des carbènes de ce type, on peut supposer que leur présence comme intermédiaires peut expliquer, au moins en partie, la formation des produits de la cycloréversion formelle ($2\pi + 2\pi$) de la photolyse de dérivés cyclobutènes simples.

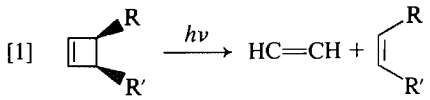
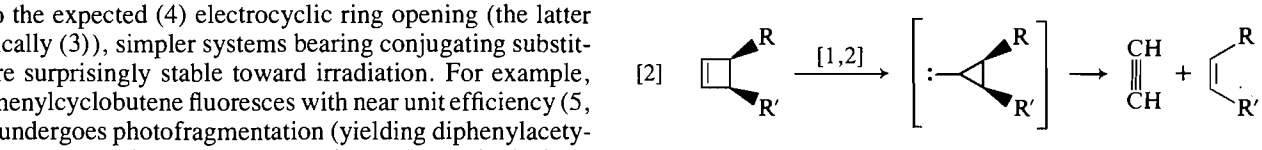
Introduction

The photochemistry of simple cyclobutenes has, until recently (1), defied thorough investigation. While strained systems such as benzocyclobutenes (2) and Dewar aromatics (3) undergo the expected (4) electrocyclic ring opening (the latter adiabatically (3)), simpler systems bearing conjugating substituents are surprisingly stable toward irradiation. For example, 1,2-diphenylcyclobutene fluoresces with near unit efficiency (5, 6), and undergoes photofragmentation (yielding diphenylacetylene and ethylene) in hydrocarbons (6) or photosolvolysis in protic solvents (7) in relatively low yields. Simple unsubstituted or alkyl-substituted systems, which absorb only in the far ultraviolet, are more reactive, undergoing electrocyclic ring opening and photofragmentation with similar efficiencies (1, 8–10). While the use of far-uv photochemical techniques does allow investigation of the photochemistry of these simple systems in solution, stringent precautions must be taken to avoid problems associated with secondary photolysis of the primary photoproducts (1).

The photofragmentation process, yielding the corresponding alkyne and alkene (eq. [1]) by formal retro ($2\pi + 2\pi$) cycloaddition, is known to occur stereospecifically (8) and with fairly high efficiency in simple, alkyl-substituted systems (1, 8–10). An alternative mechanism to the concerted cycloreversion pathway for the formation of these products has recently been proposed (9, 10), and involves fragmentation of carbene intermediates formed by [1,2]-alkyl migration (ring contraction) in the excited singlet state(s) of the cyclobutene (eq. [2]).





There is good precedent for such a suggestion. Cyclopropylmethylenes, generated by thermolysis or photolysis of the appropriate diazo compound or tosylhydrazone salt, are well known to undergo stereospecific fragmentation to the corresponding alkene and alkyne in high yield (11). Furthermore, the [1,2]-migration required for carbene formation from photolysis of cyclobutenes has ample precedent in alkene photochemistry (12), and this process has been attributed to the involvement of the $\pi,R(3s)$ Rydberg state. [1,2]-Hydrogen migrations are also common in alkene photochemistry (12, 13); in the case of cyclobutene, this would lead to cyclobutylidene, which is known to react predominantly by ring contraction to yield methylenecyclopropane (14; see also ref. 11*e*, pp. 42–44). Adam *et al.* have proposed the intermediacy of cyclobutylidene to explain the high yield of methylenecyclopropane observed from photolysis of cyclobutene itself in hydrocarbon solution with far-uv light (10).

We wish to report the results of a study that was designed to test for the involvement of cyclopropylmethylene intermediates in the direct photolysis of cyclobutenes by taking advantage of a second aspect of the known reactivity of these intermediates: ring expansion to cyclobutenes (11). We have investigated the photochemistry of two unsymmetrically substituted, isomeric

[1]Natural Sciences and Engineering Research Council of Canada University Research Fellow, 1983–1993. Author to whom correspondence may be addressed.

cyclobutene derivatives (**1** and **2**), on the premise that if ring contraction to cyclopropyl carbene intermediates occurs in these cases, it should be revealed by the interconversion of the two isomers (eq. [3]). Our results afford the first direct evidence for the formation of these intermediates in the photochemistry of simple cyclobutenes in solution.

[3] 
Results

The synthesis of 1,3,4,4- and 1,3,3,4-tetramethylcyclobutene (**1** and **2**, respectively) as a mixture of isomers was carried out by the route shown in eq. 4 (1). Compounds **1** and **2** were separated and purified by preparative gas chromatography (vpc), and their structures were assigned on the basis of their ir, mass, and 500-MHz ^1H and ^{13}C nmr spectra.

The isomers can be distinguished by the coupling between the two cyclobutene ring protons in the ^1H nmr spectra, since it is well established that in cyclobutene systems, vicinal (H1–H4 and H2–H3) interproton coupling is generally 1–2 Hz larger than allylic (H1–H3 and H2–H4) coupling (15). Thus, the isomer assigned as compound **1** has $J_{H2-H3} = 0.9$ Hz, while that assigned as **2** has $J_{H2-H4} < 0.2$ Hz (i.e., unresolvable).

[4] 
Further support for these structural assignments is obtained from the ^{13}C nmr spectra of the two isomers. First, the C2 chemical shift in **2** is shifted ca. 7 ppm downfield from its position in **1** due to the presence of the additional methyl group attached to C3 (16). Second, the undecoupled ^{13}C nmr spectra of the two isomers exhibit long-range $^{13}C-^1H$ coupling patterns that are also consistent with these assignments; the doublet splittings exhibited by the two highest field (quaternary) methyl groups in **1** and **2** as a result of long-range coupling with the ring hydrogens are particularly diagnostic. In the isomer assigned as **1**, only one of these carbons (that at 11.9 ppm) exhibits resolvable long-range coupling ($J \approx 1.3$ Hz), presumably with the ring hydrogen at C3. In the isomer assigned as **2**, the dominant quartet splittings of both of these carbons are further split into doublets, with $J \approx 1.0$ and 1.9 Hz, respectively. The assignment in this case is based upon the expectation that three-bond $^{13}C-^1H$ couplings (of which there should be three in **2** and one in **1**) should be better resolvable than four-bond couplings in compounds of this type (16).

Further corroborative attempts were made using proton nOe (nuclear Overhauser effect) difference spectroscopy, but these experiments were inconclusive; irradiation of only one of the methyl groups (that at 1.06 ppm in **1** and that at 1.08 ppm in **2**) resulted in significant nOe enhancement of any of the other proton resonances, and only the tertiary hydrogen (H3 in **1**; H4 in **2**) was affected.

The ultraviolet absorption spectra of **1** and **2** (not shown) in cyclohexane solution consist of single, featureless absorption bands with $\lambda_{max} = 192$ nm (ϵ 6700) in the case of **1**, and $\lambda_{max} = 193$ nm (ϵ 4960) in the case of **2**. In both spectra the absorption band tails out to ca. 215 nm and, while it is devoid of discernible fine structure, it is somewhat broader than the corresponding band in unsubstituted (at the double bond) homologs that we have studied (1, 17).[2]

Photolysis of **1** and **2** as deoxygenated, 0.02 M solutions in pentane or isopentane with a filtered (1, 18) low pressure mercury lamp (185 nm), the pulses of an argon fluoride excimer laser (193 nm), or an unfiltered Zn resonance lamp (214 nm) affords the product mixtures shown in eqs. [5] and [6], respectively. The dienes **3** and **4** were isolated by preparative vpc from 193-nm runs carried to ca. 40% conversion, and were identified on the basis of their ^1H nmr, ir, uv, and mass spectra, and by comparison to authentic samples (see experimental section). The formation of **3** from **1**, and **4** from **2**, affords

additional support for our structural assignments in the case of **1** and **2**.

The *E* and *Z* isomers of **3** were identified on the basis of their ^{1}H nmr spectra, and comparisons to the published spectra (19). Identification of *E*- and *Z*-**4** was not so straightforward. The ^{1}H nmr spectra of the two isomers exhibit substantially different chemical shifts for the four methyl groups; these allow a tentative assignment to be made on the basis of comparisons with the nmr spectra of the isomeric 3,4-dimethyl-2,4-hexadienes, whose identities have been previously assigned (20). The isomers have been more rigorously identified by uv photoelectron (pe) spectroscopy,[3] comparing the magnitude of the splitting between the two lowest energy bands in the pe spectra with calculated (MNDO) values. The magnitude of this splitting in simple cyclic and acyclic dienes varies dramatically with the dihedral angle defined by the four vinylogous carbons (ref. 22 and footnote 3). MNDO calculations carried out for *E*- and *Z*-**4** predict the most stable conformers to be twisted *s-cis* in both cases; the calculations for *E*-**4** predict a twist angle of 60.8° and a HOMO–SHOMO splitting of 1.1 eV, while those for *Z*-**4** predict a twist angle of 79° and a splitting of 0.5 eV. The uv photoelectron spectra of the two isomeric dienes from photolysis of **2** show splittings of ca. 0.7 and 1.3 eV, respectively, allowing the former to be identified as the *Z* isomer and the latter as the *E* isomer. The ultraviolet absorption spectra of the dienes thus identified as *E*-**4** (λ_{max} = 232 nm; ϵ 10 700) and *Z*-**4** (λ_{max} = 218 nm; ϵ 6300) are also consistent with their calculated geometries (23).

Propyne and methyl-2-butene were identified by gc–ms and by coinjection of authentic samples on at least two vpc columns.

Product yields were determined from the slopes of concentration vs. time plots, constructed for all products except propyne from vpc analyses of runs carried to <3% conversion. Figure 1 shows a typical plot, detailing the formation of **2**, *E*- and *Z*-**3**, and methyl-2-butene from 193-nm photolysis of **1**. Product quantum yields were determined by cyclooctene actinometry (24), using concentration vs. time plots from 185-nm runs (*n*-pentane solvent) carried to <3% conversion of starting material; these are collected in Table 1. No other products in addition to those shown in eq. [5] could be detected in the photolysate from **1** in yields greater than ca. 2% (our limits of detection). Photolysis of **2**, however, afforded three other minor products whose yields were too low (<5%) to enable isolation and identification.

Table 2 contains relative rates of diene and isomeric cyclobutene formation from photolysis of **1** and **2** in deoxygenated *n*-pentane or isopentane solution with the 185-, 193-, and 214-nm light sources, and in deoxygenated methanol solution with the 214-nm light source. No new products in addition to those observed in hydrocarbon solution with the 185-nm light source were found in any case. Photolyses of **1** and **2** were carried out in both *n*-pentane and isopentane solution with the 193-nm source, and yielded equivalent results for each compound in the two solvents.

We have demonstrated previously that the experimental conditions employed in these photolyses (monochromatic light sources, high substrate concentration, low conversion) are more than adequate to ensure that the products shown in eqs. [5] and [6] are indeed primary ones, and that secondary photolysis does not contribute to our results within our error limits. This can be considered rigorous in the case of the 185- and 193-nm photolyses, although in the 214-nm runs, it is likely that minor secondary photolysis of the diene products affects their relative (*E*/*Z*) yields to some extent (*vide supra*).

Methyl-2-butene	0.21 ± 0.02	0.092 ± 0.016

[a]Measured by cyclooctene actinometry (24), using a filtered (1, 18) low pressure mercury lamp.

Photostationary states for the direct *cis,trans*-photoisomerization of *E*- and *Z*-**3** were obtained by irradiation of deoxygenated, 0.003 M pentane solutions of the two diene isomers with 254-nm light until the compositions of the two solutions were identical. Similar experiments were carried out to determine photostationary states for isomerization of *E*- and *Z*-**4**. Quantum yield ratios, $\Phi_{Z\rightarrow E}/\Phi_{E\rightarrow Z}$, were then calculated for each isomeric diene pair from the photostationary state ratios and the extinction coefficients for absorption of the two diene isomers at the excitation wavelength (determined from the uv absorption spectra in pentane solution). These ratios are collected in Table 3.

Discussion

Direct photolysis of **1** and **2** in hydrocarbon solution with monochromatic far-ultraviolet light leads in both cases to fairly clean mixtures of five major products: the two geometric diene isomers from electrocyclic ring opening, methyl-2-butene and propyne from formal retrocycloaddition, and the other cyclobutene isomer resulting from **1**–**2** interconversion. The similari-

ties in the quantum yields for the ring-opening and fragmentation products (see Table 1) appear to be quite general in the photochemistry of simple cyclobutene derivatives, judging from the results of reported investigations of the photochemistry of bi- (1, 9) and tricyclic (8) systems, as well as those of other monocyclic derivatives (1, 10). Of special interest to this study, however, is the observation that interconversion of **1** and **2** occurs in significant amounts upon direct photolysis of either isomer in solution.

The formation of products consistent with the intermediacy of carbenes is a general feature of the photochemistry of simple alkenes in solution (12, 13). Generally, the intermediacy of carbenes in alkene photochemistry has been suggested by the similarities between the product mixtures obtained from alkene photolysis and those obtained when the carbenes are generated independently by photolysis or thermolysis of the corresponding diazo compound, diazirene, or tosylhydrazone salt. In addition, further support for carbene involvement has been provided by deuterium labelling studies (25) and intra- and intermolecular trapping with alcohols (13, 26). Usually, the distribution of carbene-derived products from alkene photolysis differs somewhat from that obtained when the carbene is generated by other means (13*a*,*b*), but it is well known that for a given multiplicity, carbene reactivity can vary markedly depending on the conditions of generation (11*e*, 14*a*).

The formation of carbene intermediates has been proposed to arise via [1,2]-alkyl or [1,2]-hydrogen migrations in the alkene $\pi,R(3s)$ Rydberg state (12), a species that presumably has some degree of radical cation character at the double bond. The Rydberg state assignment (as opposed to the π,π^* state, which leads to *cis*,*trans* isomerization, [1,3]-migrations, H_2 elimination (27), and hydrogen abstraction (12, 13)) has been made on the basis of several observations. P. J. Kropp and co-workers have shown that the yield of carbene-derived products from >200-nm photolysis of alkenes increases in importance with increasing alkyl substitution at the carbon–carbon bond (12), a trend that is mirrored in the progression to lower energy of the Rydberg state absorption (26) and fluorescence (29) bands in substituted alkenes in the gas phase. Related to this is the report that photolysis of 2,3-dimethyl-2-butene in hydrocarbon solution is strongly wavelength-dependent, with the yield of carbene-derived products increasing, at the expense of π,π^* derived products, with increasing excitation wavelength between 185 and 228 nm (30). The $\pi,R(3s)$ state is the lower energy one in this compound, according to gas phase uv absorption measurements (28). One question that remains to be answered in this area relates to the mechanism for population of the Rydberg state in solution phase photolyses, since the absorption coefficient for the $\pi,R(3s)$ transition is extremely weak in the condensed phase (27).

The photochemical interconversion of **1** and **2** observed in the present study, although it occurs in relatively minor amounts, provides convincing evidence for the formation of at least one common intermediate in the direct photolysis of these compounds. Other known alkene photoprocesses that could lead to cyclobutene products from **1** and **2**, such as [1,3]-hydrogen or -methyl migrations, clearly cannot interconvert the two isomers. For example, [1,3]-hydrogen migration (which might be considered the most likely alternative (12, 13)) is a degenerate rearrangement in the case of **1**, and [1,3]-methyl migration would afford the 1,2,3,4- (*cis* or *trans*) or 3,3,4,4-tetramethyl derivatives. While we cannot exclude the possibility that these products may indeed be formed in minor amounts, the main point to be made here is that single [1,3]-alkyl or -hydrogen migrations cannot account for the interconversion of **1** and **2**.

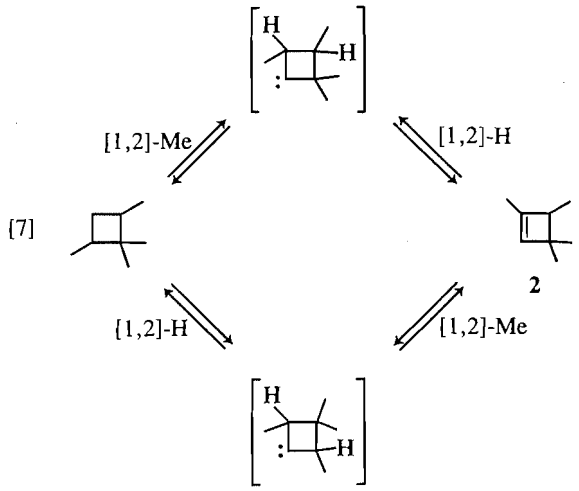
For personal use only.

The most reasonable pathways for interconversion of **1** and **2** involve the intermediacy of one or both of the cyclopropyl carbenes shown in eq. [3], or the cyclobutylidenes formed via [1,2]-methyl or [1,2]-hydrogen migration, as shown in eq. [7].



Cyclobutylidene has been proposed as an intermediate in the solution phase far-uv photochemistry of cyclobutene by Adam *et al.* (10), to explain the observed formation of methylcyclopropane in light yield. This carbene is indeed known to yield methylenecyclopropane, as well as minor amounts of cyclobutene, when it is generated independently from thermolysis or photolysis of diazo precursors (14). Several considerations lead us to favour the cyclopropylmethylene mechanism for the interconversion of **1** and **2**.

First, these intermediates may also account to some extent for the formation of propyne and methyl-2-butene (11), as was originally proposed (9, 10). It is clearly impossible to define this quantitatively since the extent to which the formally allowed, retro $(2\pi + 2\pi)$ cycloaddition pathway contributes to the formation of these products is indeterminable. In this regard, we note that fragmentation greatly outweighs isomer interconversion in the present cases, which is not the expected result if the behaviour of cyclopropyl carbenes generated from cyclobutene photolysis is assumed to be similar to that obtained when the carbene is generated directly from the diazo compound or diazo equivalent, unless fragmentation is derived largely from the $(2\pi + 2\pi)$ cycloreversion pathway. As noted above, however, the distribution of formally carbene-derived products from photolysis of alkenes in solution is usually quite different from that obtained when the carbenes are generated from other, more conventional, precursors.

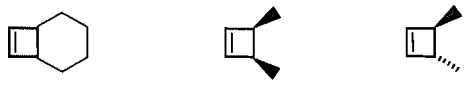
Second, the interconversion of **1** and **2** by the cyclobutylidene pathway requires sequential [1,2]-Me/[1,2]-H or [1,2]-H/[1,2]-Me migrations (see eq. [7]). These combinations can be expected to be highly inefficient, since [1,2]-hydrogen migration usually predominates over [1,2]-methyl migration (when both are possible) in both alkene photochemistry (12, 13) and carbene chemistry (11*e*, 14*a*). It is possible, however, that these unfavourable combinations may be occurring as minor reactions competing only marginally with [1,2]-H/[1,2]-H migrations, which are identity reactions and hence undetectable.

Finally, the intermediacy of cyclobutylidenes in the photochemistry of **1** and **2** should be signalled by the formation of methylenecyclopropane derivatives to at least some extent. In the case of **1** at least, we have not observed the formation of any products in addition to those shown in eq. [5] in greater than ca. 2% yield, using several different sets of analytical conditions. We have obtained similar results from far-uv photolysis of a number of other simple mono- and bicyclic alkylcyclobutenes (1, 17); of the compounds that we have studied, only **5** (*vide infra*) affords a photoproduct of this type, and in very low yield. This contrasts the reported behaviour of cyclobutene itself (10), for reasons that we do not yet understand.

Our attempts to provide more conclusive evidence for carbene involvement by trapping the suspected intermediates with methanol have been unsuccessful, but this may be the simple result of exceedingly fast rates of unimolecular carbene rearrangement and (or) fragmentation. While methanol trapping of carbenes of this type has apparently not been investigated, it has been reported that trapping of triplet cyclopropylmethylenes by alkenes is relatively inefficient (even with high alkene concentrations); the singlet carbene (the suspected multiplicity in the present cases) could not be trapped at all(11*i*). The use of alkenes as potential carbene trapping agents in the photolysis of **1** and **2** is impractical because of their own competing absorption in the wavelength range necessary for our photolyses, and this would be prohibitive with the high alkene concentrations necessary for the experiment's possible success.

Photochemical electrocyclic ring opening of **1** and **2** can in each case proceed to yield both geometric isomers of the corresponding dienes by symmetry-allowed, disrotatory pathways. However, since the two diene isomers are also obtainable, in principle, by conrotatory (symmetry-forbidden) ring-opening pathways, the present study can afford no information regarding the preferred pathway for the photochemical ring opening of cyclobutene. In both cases, the *E*-diene isomer is clearly favoured over the *Z*-isomer, perhaps indicating some common preference for the least sterically demanding ring-opening pathway; i.e., that which avoids buttressing the 3- and 4-methyl groups as ring opening proceeds.

The situation is almost certainly more complicated than this, however. Our recent investigations of the photochemistry of bicyclo[4.2.0]oct-6-ene (**5**) and *cis*- and *trans*-3,4-dimethylcyclobutene (*c*- and *t*-**6**, respectively) showed clearly that, in general, photochemical ring opening of simple cyclobutenes proceeds non-stereospecifically to yield mixtures of all possible diene geometric isomers (1). The 185-nm photolysis of **5** yields a mixture of *cis,cis*- and *cis,trans*-1,3-cyclooctadiene that is consistent with the purely disrotatory, *adiabatic* excited-state ring-opening mechanism that theory predicts should be possible (31). However, the results of 185-nm photolyses of *c*- and *t*-**6**



5 *c*-**6** *t*-**6**

(1), as well as more recent results (for other mono- and bicyclic derivatives and for **5** with longer wavelength excitation (17)), indicate that some portion of the formally forbidden diene isomer(s) *must* arise by the *conrotatory* ring-opening pathway. Whether this component is due to conrotatory opening on the same or a second excited-state surface, on the ground-state surface as a result of radiationless decay to hot vibrational levels, or some competition between (one or both of) these two pathways and adiabatic disrotatory ring opening remains to be determined. Comparison of the isomeric diene ratios obtained from photolysis of **1** and **2** (see Tables 1 and 2) with the quantum yield ratios for direct photoisomerization of the dienes (Table 3) verifies that the relative isomeric diene yields obtained from

cyclobutene photolysis are generally not defined by the decay characteristics of the diene singlet excited state (as obtained from the quantum yields for direct photoisomerization of the dienes).

The appearance of the solution phase uv absorption spectra of methyl-substituted monocyclic cyclobutenes (17) mirrors the trends found in substituted alkenes (28), suggesting that at least two excited states of similar energies are accessible in **1** and **2** under our conditions. Indeed, wavelength effects have been observed in the photochemistry of several of the simple cyclobutene derivatives that we have studied (1, 17). As the data in Table 2 show, however, the photochemistry of **1** and **2** is largely insensitive to changes in excitation wavelength. This might be expected if the various excited states accessible in the 185–214 nm region are approximately isoenergetic (21) or strongly coupled. While the *E*/*Z*-**4** ratio from photolysis of **2** does decrease significantly in the 214-nm photolysis compared to the shorter wavelength ones, it is likely that secondary diene photolysis affects the observed diene isomeric ratios to some degree at the longer wavelength. With cyclobutene absorption being fairly weak at 214 nm (while diene absorption is strong), secondary diene photolysis would probably not be discernible in the diene concentration vs. time plots.

Conclusions

In addition to undergoing electrocyclic ring opening and molecular fragmentation (formal retro $(2\pi + 2\pi)$ cycloaddition), the unsymmetrically substituted isomeric cyclobutene derivatives **1** and **2** are interconverted in low yields upon direct photolysis in solution with far-uv light. The photochemical interconversion of the two isomers provides direct evidence for the involvement of cyclopropyl carbene intermediates in the photochemistry of simple cyclobutenes in solution. These intermediates, formed by excited-state [1,2]-alkyl migration (ring contraction), might also account to some extent for the high yield of fragmentation products that is characteristic of the photochemistry of the chromophore.

Experimental

The ^{1}H nmr spectra were recorded on Varian EM390 (90 MHz) or Bruker AM500 (500 MHz) spectrometers in carbon tetrachloride (or deuteriochloroform where noted) and ^{13}C nmr spectra were recorded at 125.6 MHz on the Bruker AM500; all are reported in parts per million downfield from tetramethylsilane. Mass spectra were recorded on a VG7070 mass spectrometer interfaced with a Varian 3700 gas chromatograph, equipped with a 60 m × 0.25 mm DB-1 (Chromatograph Specialties, Inc.) fused silica capillary column. Exact masses were determined on a VGH ZABE mass spectrometer, and employed a mass of 12.000 000 for carbon. Ultraviolet absorption spectra were recorded in cyclohexane solution using a Perkin–Elmer Lambda 9 spectrometer equipped with a Model 3600 data station. Infrared spectra were recorded on a Perkin–Elmer 283 spectrometer as the neat liquids or in carbon tetrachloride or chloroform solution; spectra are reported in wavenumbers, calibrated using the 1601.9 cm^{-1} polystyrene absorption.

Analytical vpc separations were carried out using a Varian 3700 gas chromatograph (injector temperature = 80°C) equipped with a flame ionization detector, a Varian CDS101 or Hewlett–Packard HP-3393a integrator, and one of the following columns: (a) 1.0-μm SPB-1 wide-bore capillary (30 m × 0.75 mm i.d. borosilicate; Supelco, Inc.); or (b) 20% β,β-oxydipropionitrile (ODPN) on 80/100 Chromosorb PNAW (14 ft × 1/8 in. stainless steel; Supelco, Inc.). The detector response was calibrated for each photoproduct relative to an internal standard (*n*-octane or isooctane) by construction of working curves from a few standard solutions.

Semi-preparative vpc separations employed a Hewlett–Packard 5750B gas chromatograph equipped with a thermal conductivity detector (detector temperature = 160°C) and one of the following stainless steel columns: (c) 3.8% UC W892 on 80/100 Supelcoport (24 ft × 1/4 in.); or (d) 20% tris(cyanoethoxy)propane (TCEP) on Chromosorb 80/100 PNAW (12 ft × 1/4 in.).

n-Pentane (Baker Photrex), 2-methylbutane (Aldrich spectrophotometric), 2,2,4-trimethylpentane (isooctane; Baker Photrex), and *n*-octane (Polyscience, Quant grade) were used as received, as were citraconic anhydride, methyl-2-butene, 3-methyl-2-butanone; acetophenone, lead tetraacetate, and triphenylphosphine, all from Aldrich Chemical Co. Propyne was used as received from Canada Liquid Air, Inc. Methanol (Caledon HPLC) was distilled from magnesium methoxide. Mesityl oxide (Matheson, Coleman, and Bell) was bulb-to-bulb distilled and cyclooctene (Aldrich) was purified by vpc using column (c).

Compounds 1,3,4,4- (1) and 1,3,3,4-tetramethylcyclobutene (2)

Citraconic anhydride (15 g, 0.134 mol), methyl-2-butene (20.0 g, 0.286 mol), and acetophenone (5.15 g, 0.043 mol) were dissolved in ethyl acetate (500 mL) in a Pyrex immersion well equipped with a magnetic stirrer. The reaction mixture was cooled to ca. 5°C with an external ice–water bath and deoxygenated by bubbling dry nitrogen through the solution for approximately 30 min. The solution was then irradiated with a medium pressure mercury lamp (450 W, Hanovia), agitating constantly throughout the irradiation period with the magnetic stirrer as well as with a slow stream of dry nitrogen. After 11 h irradiation, nmr analysis of the crude photolysate revealed the disappearance of citraconic anhydride to be >95% complete. Evaporation of the solvent with a rotary evaporator afforded an orange-yellow oil, which was further distilled *in vacuo* (ca. 0.2 Torr; 1 Torr = 133.3 Pa) to remove acetophenone and unreacted anhydride.

A portion (12 g) of the orange, viscous oil that remained (17 g) was added to 12% aqueous hydrochloric acid (75 mL), stirred for ca. 10 h at room temperature, and then extracted with ether (3 × 50 mL). The extracts were washed with water (10 mL), saturated brine (10 mL), dried over anhydrous sodium sulfate, and then distilled to afford a light brown solid residue (11 g).

A portion (4.0 g, 0.019 mol) of the solid was added to pyridine (60 mL; distilled from barium oxide), the solution was placed in a 100-mL two-neck roundbottom flask connected to three sequential Dry Ice/acetone traps, and then saturated with oxygen. Lead tetraacetate (10.0 g, 0.023 mol) was added, a slight positive pressure of dry nitrogen was applied, and the mixture was placed in an oil bath (70°C). When gas evolution had subsided (ca. 10 min), the temperature of the oil bath was increased to 90°C and nitrogen was slowly bubbled through the reaction mixture over 24 h. The colourless liquid that had collected in the traps was dissolved in pentane (10 mL), washed with 5% aqueous hydrochloric acid (5 mL), water (5 mL), dried over anhydrous sodium sulfate, filtered, and concentrated by slow distillation. Vapor phase chromatographic analysis column (c) of the concentrated reaction mixure revealed the presence of two major products in a ca 1:1 ratio. These were collected by semipreparative vpc (column (c)); injector temperature = 120°C; detector temperature = 150°C; oven temperature = 70°C. Cyclobutenes **1** and **2** were obtained in >99% purity after further purification by vpc on column (d). Compound **1** eluted first from both vpc columns.

E-*2,3-dimethyl-2,4-hexadiene* (E-***3***)

Propyne (ca. 5 mL, 0.083 mol) was condensed in a Dry Ice/acetone trap and dissolved in anhydrous ether (70 mL) in a 100-mL three-neck roundbottom flask equipped with magnetic stirrer, Dry Ice condenser, addition funnel, thermometer, and gas inlet at −78°C. *n*-Butyllithium (36 mL of a 2 M hexane solution) was added dropwise with stirring under an argon atmosphere at a rate slow enough to ensure that the temperature of the reaction mixture did not rise above −50°C. The reaction mixture was stirred at −78°C for a further 1 h, and then neat 3-methyl-2-butanone (6.0 g, 0.071 mol) was added dropwise with stirring. The reaction mixture was allowed to warm to room temperature and then stirred for several hours. The mixture was then poured into a saturated aqueous ammonium chloride solution (30 mL) and extracted with ether (3 × 25 mL). The extracts were washed with water (10 mL), saturated brine (10 mL), and finally dried over anhydrous sodium sulfate. The filtered extracts were distilled to remove the solvent and then bulb-to-bulb distilled under vacuum (ca. 0.2 Torr) to yield a colourless liquid (5 g, 0.04 mol, 56%), identified as 4,5-dimethylhex-2-yn-4-ol (**7**) on the basis of its ^{1}H nmr, ir, and mass spectra, ir (neat): 3440(br s), 2970(s), 2920(s), 2880(s), 2250(w), 1460(m), 1445(m), 1365(s); ^{1}H nmr δ: 0.95 (dd, 6H), 1.35 (s, 3H), 1.80 (m, 4H); ms m/e(I) 126(1), 111(27), 108(13), 93(12), 84(31), 83(100), 82(17), 77(12), 67(15), 55(10). *Exact Mass* calcd. for $C_8H_{14}O$: 126.1045; found: 126.1038.

Alkynol **7** (2.7 g, 0.021 mol), Lindlar catalyst (0.08 g),and anhydrous ether (25 mL) were placed in a 100-mL two-neck roundbottom flask equipped with a reflux condenser and magnetic stirrer, and hydrogenated at 1 atm (101.3 kPa) for 7 h. The reaction mixture was filtered through Celite and the solvent was distilled, affording a colourless liquid that was identified at *Z*-4,5-dimethylhex-2-en-4-ol (**8**) on the basis of its ^{1}H nmr, ir, and mass spectra; ir (neat): 3480(br), 2960(s), 2932(m), 2870(m), 1610(w), 1460(m), 1368(m), 1258(m), 1089(m), 1016(m) 800(m); ^{1}H nmr (500 MHz) δ: 0.90 (d, 3H, J = 6.8 Hz), 0.91 (d, 3H, J = 6.9 Hz), 1.27 (s, 3H), 1.75 (septet, 1H, J = 6.9 Hz), 1.83 (dd, 3H, J = 7.2, 1.7 Hz), 5.37 (dq, 1H, J = 12.0, 1.7 Hz), 5.47 (dq, 1H, J = 12.0, 7.2 Hz). ms m/e(I): 128(1), 113(4), 111(15), 100(4), 87(17), 86(7), 85(100), 71(11), 69(47), 67(28), 65(4). *Exact Mass* calcd. for $C_8H_{16}O$: 128.1201; found: 128.1192.

Alkenol **8** (1.0 g, 0.0075 mmol), propionic anhydride (5 mL), and a small amount of iodine were placed in a 10 mL roundbottom flask equipped with a reflux condenser and magnetic stirrer (20). The mixture was stirred at ca. 120°C for 1 h. The flask was then cooled to room temperature, and the contents were poured into ether (ca. 15 mL). The solution was washed with saturated aqueous bicarbonate (3 × 25 mL), water (20 mL), dried over anhydrous sodium sulfate, and filtered. The solution was slowly distilled to remove the solvent, and the residue was then bulb-to-bulb distilled under vacuum (0.2 Torr) to yield a clear, colourless liquid. Vapor phase chromatographic analysis of the liquid (column (c)) showed it to contain one major product, which was separated with the same column by semi-preparative vpc (injector temperature = 120°C; detector temperature = 170°C; column temperature = 90°C). Diene *E*-**3** was obtained in >99% purity after further vpc purification (0.63 g, 70% yield from **9**); ir (neat): 3040(s), 2919(s), 2862(s), 1446(m), 1375(m), 1142(w), 1051(w), 1005(w), 956(s), 781(w); uv (cyclohexane) λ_{max}: 241 nm (ϵ = 21 250); ^{1}H nmr (500 MHz) δ: 1.69 (s, 3H), 1.74 (s, 3H), 1.77 (m, 6H) 5.47 (dq, 1H, J = 15.3, 6.8 Hz), 6.38 (d, 1H, J = 15.3 Hz); ms m/e(I): 110(58), 95(100), 81(13), 77(10), 67(49), 55(34), 53(16), 41(37), 39(28), 27(14). *Exact Mass* calcd. for C_8H_{14}: 110.1116; found: 110.1087.

Z-*2,3-Dimethyl-2,4-hexadiene* (Z-***3***) was synthesized by photolysis of a deoxygenated pentane (30 mL) solution of *E*-**3** (0.4 g, 0.0036 mol) in a Rayonet reactor fitted with 10 254-nm lamps. Irradiation of the solution for 5 h yielded a mixture of *E*- and *Z*-**3** along with one other minor product. The pentane was removed by slow distillation, and the photolysate was bulb-to-bulb distilled under vacuum (0.2 Torr). Diene *Z*-**3** was separated cleanly from the other components of the mixture by semi-preparative vpc (column (c)), and finally obtained in >99% purity after further vpc purification with the same column; ir (neat): 3004(s), 2920(s), 2863(s), 1444(m), 1405(w), 1372(m), 1156(w), 1124(w), 930(m), 735(m), 713(m); uv (cyclohexane) λ_{max}: 223 nm (ϵ 3500); ^{1}H nmr (500 MHz) δ: 1.52 (dd, 3H, J = 6.9, 11.8 Hz), 1.58 (s, 3H), 1.67 (s, 3H), 1.69 (s, 3H), 5.35 (dq, 1H, J = 11.1, 6.9 Hz), 5.80 (br d, 1H, J = 11.1 Hz); ms m/e(I): 110(75), 95(100), 81(14), 77(11), 67(55), 55(38), 53(20), 41(40), 39(28), 27(16). *Exact Mass* calcd. for C_8H_{14}: 110.1116; found: 110.1090.

E- *and* Z-*2,3-dimethyl-2,4-hexadiene* (***4***)

Sodium hydride (0.8 g, 0.033 mol) and dimethylsulfoxide (10 mL) were placed in a 100-mL, two-neck roundbottom flask equipped with a reflux condenser, magnetic stirrer, gas inlet, and addition funnel. The mixture was heated under a nitrogen atmosphere at 85°C until gas evolution ceased (ca. 45 min) and then cooled to room temperature. Ethyltriphenylphosphonium bromide (9.0 g, 0.023 mol) was dissolved in warm DMSO (30 mL) and added dropwise over 20 min. The orange-coloured mixture was stirred for a further 1 h at room temperature and neat mesityl oxide (2.3 g, 0.024 mol) was then added dropwise over 20 min. The resulting mixture was stirred for 15 h at room temperature, filtered through Celite, poured into water (50 mL), and extracted with pentane (5 × 25 mL). The extracts were washed with water (25 mL), saturated brine (15 mL), dried over anhydrous sodium sulfate, and filtered. Slow distillation to remove the solvent followed by bulb-to-bulb distillation of the residue at 0.2 Torr afforded a mixture of *E*- and *Z*-**4** as a colourless liquid. Dienes *E*- and *Z*-**4** (0.47 g, 0.0043 mol, 18%) were isolated as a mixture by semi-preparative vpc on column (c). Separation and further purification under the same conditions afforded the isomers in >99% purity.

E-*2,4-Dimethyl-2,4-hexadiene* (E-***4***): ir (neat): 3020(sh), 2967(s), 2922(s), 2862(s), 1656(w), 1445(s), 1374(m), 1182(w), 1052(w), 857(s), 772(w), 511(w); uv (cyclohexane) λ_{max}: 231 nm (ϵ 10 700); ^{1}H nmr (500 MHz, $CDCl_3$) δ: 1.65 (d, 3H, J = 6.9 Hz), 1.69 (s, 3H), 1.73 (s, 3H), 1.74 (s, 3H), 5.21 (q, 1H, J = 6.9 Hz), 5.61 (br s, 1H); ms m/e(I): 110(36), 95(100), 81(17), 77(13), 67(64), 55(59), 53(32), 41(53), 39(50), 27(34). *Exact Mass* calcd. for C_8H_{14}: 110.1116; found: 110.1088.

Z-*2,4-Dimethyl-2,4-hexadiene* (Z-***4***): ir (neat): 3020(sh), 2966(s), 2922(s), 2863(s), 2661(w), 1625(w), 1446(s), 1385(m), 1206(w), 1185(w), 1035(m), 824(m), 783(m), 554(w); uv (cyclohexane) λ_{max}: 217 nm (ϵ 6800); ^{1}H nmr (500 MHz, $CDCl_3$) δ: 1.48 (d, 3H, J = 6.8 Hz), 1.56 (s, 3H), 1.70 (br s, 3H), 1.76 (s, 3H), 5.26 (q,1H, J = 6.8 Hz), 5.54 (br s, 1H); ms m/e(I): 110(57), 95(100), 81(20), 77(21), 67(61), 55(43), 53(23), 41(35), 39(32), 27(19). *Exact Mass* calcd. for C_8H_{14}: 110.1116; found: 110.1087.

Photochemical experiments employed a 10-W Osram HNS 10W/U OZ low pressure mercury lamp in conjunction with a 25 × 3 mm LiF disc (Harshaw VUV) that had been irradiated with ca. 1.7 Mrad of γ-radiation from a ^{60}Co source (18), a 16-W Philips 93106E zinc resonance lamp, or the pulses (193 nm, ca. 10 ns, 20–100 mJ, 1-Hz repetition rate) from a Lumonics TE-861M excimer laser filled with an argon/fluorine/helium mixture. The low pressure mercury and Zn resonance lamps were surrounded by a metal case that incorporated a 1-in. port to contain the sample cell and filter (in the case of the Hg lamp). During 185-nm irradiations, the transmittance spectrum of the filter was monitored quite closely, as the transmittance at 254 nm tends to increase slowly with uv exposure (1, 18). A freshly prepared filter typically had an optical density of ca. 0.5 at 185-nm and ca. 5 at 254 nm. The lamps were given a 20-min warm-up period before each experiment and cooled with a stream of dry nitrogen.

Quantitative photolyses were carried out at ambient temperature (ca. 23°C) in 10 × 25 mm cylindrical Suprasil uv cells (Hellma). Preparative scale photolyses were carried out with the laser, in rectangular cells constructed from 10 × 20 mm rectangular Suprasil tubing (Vitro

Dynamics). In all cases, the sample was agitated during irradiation with a small magnetic stirrer. Solutions were deoxygenated before irradiation by bubbling dry nitrogen or argon through the cooled (to ca. 0°C) solutions for 5–15 min.

The products obtained from photolysis of **1** and **2** were identified by coinjecting photolysates carried to ca. 5% conversion with authentic samples on at least two vpc columns, and by comparison of the ^{1}H nmr spectra of isolated (from preparative runs carried to 30–40% conversion, by vpc with column (c), after concentration and bulb-to-bulb distillation) samples with those of the authentic samples.

Quantum yield determinations for 185-nm photolyses were carried out by cyclooctene actinometry (24), using approximately matched cells and alternately irradiating the substrate and actinometer solutions for identical, short periods of time.

Quantitative photolyses were monitored between 0.2 and 3% conversion, with aliquots being withdrawn at suitable time intervals for vpc analysis on columns (b) (for methyl-2-butene) and (a) (for all other products). Relative product yields were determined from the slopes of concentration versus time plots constructed for all components of the mixture relative to an internal standard. Relative detector responses were calibrated for all products using authentic samples. The concentration vs. time plots were linear in each case. Quantum yields were determined in similar fashion after calculating the light flux from the concentration vs. time plot for the formation of *trans*-cyclooctene from the *cis* isomer, whose photolysis was conducted concurrently with the substrate of interest as described above. A value of 0.32 was employed for the actinometric quantum yield (24).

The photostationary state for the direct photoisomerization of *E*- and *Z*-**3** at 254 nm was determined by irradiating deoxygenated, 0.003 M solutions of the two diene geometric isomers in 7 mm quartz tubes in a Rayonet reactor. Irradiation was continued, with periodic analysis by vpc (column (a)), until the photostationary state was reached. A similar procedure was employed for determination of the photostationary state for photoisomerization of *E*- and *Z*-**4**.

Surface photochemistry: Semiconductor mediated reactions of some saturated strained hydrocarbons[1]

N. Colin Baird, Anthony M. Draper, and Paul de Mayo

Photochemistry Unit, Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received October 23, 1987

N. Colin Baird, Anthony M. Draper, and Paul de Mayo. Can. J. Chem. **66**, 1579 (1988).

Quadricyclane (**1**) and 1,8-bishomocubane (**2**) have been found to undergo valence isomerization to norbornadiene and tricyclo[4.2.2.$0^{2,5}$]deca-3,7-diene, respectively, on illuminated CdS and ZnO. An electron transfer mechanism is proposed. Quantum yield, solvent effects, the role of oxygen, and the quenching of the reaction were investigated, and were consistent with this interpretation. The thermal reaction of **1** on CdS was also suggested to be an electron transfer process involving, in this case, defects or trapped holes on the surface of the semiconductor. An examination of a series of strained hydrocarbons structurally related to **1** (tetracyclo[3.3.0.$0^{2,8}$.$0^{4,6}$]octane **3**, pentacyclo[4.3.0.$0^{2,4}$.$0^{3,8}$.$0^{5,7}$]nonane **4** and pentacyclo[4.4.0.$0^{2,4}$.$0^{3,8}$.$0^{5,7}$]decane **5**) resulted, largely, in a demonstration of the resistance of their respective radical cations to rearrangement prior to back electron transfer. Calculations by MNDO, in combination with a modified version of MM2, were used to explore the differences in the reactivity of the radical cations of **1**, **3**, **4**, **5**, and an interpretation is presented.

N. Colin Baird, Anthony M. Draper et Paul de Mayo. Can. J. Chem. **66**, 1579 (1988).

On a observé que, placés sur du CdS et du ZnO illuminés, le quadricyclane (**1**) et le bishomo-1,8 cubane (**2**) subissent des isomérisations de valence conduisant respectivement au norbornadiène et au tricyclo[4.2.2.$0^{2,5}$]décadiène-3,7. On propose un mécanisme par transfert électronique. On a examiné les rendements quantiques, les effets de solvants, le rôle de l'oxygène et le piégeage des réactions et les résultats sont en accord avec cette interprétation. On a suggéré que la réaction thermique du composé **1** déposé sur du CdS se produit aussi par un processus de transfert électronique impliquant, dans ce cas, les défauts de la surface du semiconducteur. Lorsqu'on a examiné les résultats obtenus avec une série d'hydrocarbures tendus dont la structure est reliée à celle du composé **1**, comme le tétracyclo[3.3.0.$0^{2,8}$.$0^{4,6}$]octane **3**, le pentacyclo[4.3.0.$0^{2,4}$.$0^{3,8}$.$0^{5,7}$]nonane **4** et le pentacyclo[4.4.0.$0^{2,4}$.$0^{3,8}$.$0^{5,7}$]nonane **5**, on a mis en évidence le fait que leurs radicaux cations respectifs résistent à une transposition avant le transfert électronique en retour. On a utilisé des calculs effectués par la méthode des MNDO en conjonction avec une version modifiée de MM2 pour examiner les différences de réactivité des radicaux cations des composés **1**, **3**, **4**, et **5** et on présente une interprétation.

[Traduit par la revue]

Introduction

Photocatalysis on powdered semiconductors has been, in recent years, an area of intensive study. Much of the interest has been concentrated on the splitting of water with the object of developing a solar energy storage system. Of late, semiconductors have also been used as photocatalysts for electron transfer in organic reactions, and there have been several reports of semiconductor photoinduced organic electron transfer reactions involving both oxidative (e.g., addition of oxygen (1)) and non-oxidative (e.g., dimerization (2–4) and isomerization (5–9)) processes. We now wish to report our findings for the semiconductor mediated reactions of a series of strained hydrocarbons: tetracyclo[3.2.0.$0^{2,7}$.$0^{4,6}$]heptane (quadricyclane) **1**, pentacyclo[4.4.0.$0^{2,5}$.$0^{3,8}$.$0^{5,7}$]decane (1,8-bishomocubane) **2**, tetracyclo[3.3.0.$0^{2,8}$.$0^{4,6}$]octane **3**, pentacyclo[4.3.0.$0^{2,4}$.$0^{3,8}$.$0^{5,7}$]nonane (norsnoutane) **4**, and pentacyclo[4.3.0.$0^{2,4}$.$0^{3,8}$.$0^{5,7}$]decane (snoutane) **5**.

Initial interest in electron transfer reactions of strained saturated hydrocarbons was sparked by the finding that many of these compounds have exceedingly low oxidation potentials (Table 1) (10). This led to several studies of the radical cation rearrangements of such compounds. For example, the valence isomerization of $\mathbf{1}^+$ to the radical cation of norbornadiene **6** has been studied under many conditions. The electron transfer may be initiated by organic sensitizers (11) and transition metal complexes (12) and also electrochemically (13). Uncertainty as to whether or not the radical cations of **1** and **6** were distinct entities (14) was settled in an elegant study by Roth and Schilling (15). They were able to show that the radical cations are distinct species and that $\mathbf{1}^+$ has a lifetime of at least a few nanoseconds before irreversible rearrangement to $\mathbf{6}^+$. Later, these conclusions were supported by extensive theoretical calculations (16, 17).

The electron transfer induced rearrangement of **2** had never been previously reported. However, there was strong presumptive evidence suggesting that $\mathbf{2}^+$ would rearrange to $\mathbf{7}^+$. On Rh(I) and Pd(II) complexes **2** was shown to yield **7** as the major product (18). Furthermore, substituted derivatives of **2** were shown to rearrange to the corresponding tricyclo[4.2.2.$0^{2,5}$]deca-3,7-diene by an electron transfer mechanism (5, 19). Roth and Schilling (20) have applied the CIDNP technique to gain insight into the structures of the $\mathbf{2}^+$ deriva-

tives. They found that the rearrangement is, indeed, fast; however, they did observe an emission for one proton signal suggesting that this derivative of **7** has a discrete energy minimum.

The possible radical cation reactions of **3–5** had not yet been reported. Compounds **3–5** were known to quench the fluorescence of organic redox sensitizers (10, 12) through what is believed to be electron transfer to the fluorophore. If $\mathbf{3}^+$–$\mathbf{5}^+$ were to undergo an analogous rearrangement to that of $\mathbf{1}^+$, then the products would be **8–10**.

The semiconductors used in this work were ZnO and CdS, which have band gaps of 3.2 eV and 2.4 eV respectively. The positions of the valence bands, determined in acetonitrile (22), are 1.55 V for CdS and 2.4 V for ZnO. These values have been taken as being closest to those expected in the solvents used in experiments reported here. Thus, compounds **1–5**, having oxidation potentials less positive than the potential of the valence band of ZnO, fulfil the electrochemical requirements for electron transfer to illuminated ZnO. In the case of CdS, compound **1** has a suitable oxidation potential for electron donation to illuminated CdS while those of **2–5** are approximately isoenergetic with the photoinduced holes.[2]

By the virtue of these precedents, **1–5** seemed to be good candidates for electron transfer studies at illuminated semiconductors. Unanticipated results for the reactivity of $\mathbf{3}^+$–$\mathbf{5}^+$ led us to investigate these reactions further by calculations using MM2 and MNDO. A brief report of the conversion of **1** → **2** has been made (23).

Experimental

All solvents used for the semiconductor reactions were spec. grade from either Fisher, BDH, or Baker and were used as received. For the reaction of **1** on CdS, Aldrich Gold label 99.999% was used unless otherwise indicated. In all other reactions with CdS, "Fisher" CdS was used. The following saturated hydrocarbons were used as internal standards for gc analysis: *n*-heptane (Anachemia spectrograde C_7) for the reaction of **8**; cyclooctane (Aldrich, 99+% Gold Label, C_8) for the reactions of **1** and **2**; undecane (Aldrich, 99%, C_{11}) for the reactions of **9** and **10**. 1,2,4- and 1,3,5-trimethoxybenzene (Aldrich) were used as received: solutions were >99% pure as measured by analytical gc. 1,2,4,5-Tetramethoxybenzene was prepared as described by Bennington *et al.* (24) and was stored in the dark to prevent decomposition. Before a series of quenching experiments the 1,2,4,5-tetramethoxybenzene was sublimed. The material used in quenching experiments showed only one peak on analytical gc.

Procedure for irradiations

Two sizes of Pyrex vessels were used for semiconductor reactions: a 20 mm diameter base for 5-mL reaction volumes and a 11 mm diameter base for 1-mL reaction volumes. The base portion of the vessel was constructed from a test tube and was connected to either a B-10 joint (for reactions open to the atmosphere) or a 9-mm Fisher–Porter joint (for degassing).

All reaction vessels and magnetic stirbars were cleaned by sonication in an aqueous solution of Fisher FL-70 low foaming detergent. After sonication, the vessels were thoroughly rinsed with water followed by 1 × 10% NH_4OH; 5 × distilled H_2O; 2 × acetone; 2 × spec. grade CH_2Cl_2. The vessels were dried at 110°C overnight before use.

Semiconductor powders were weighed out and placed in a dry reaction vessel with a magnetic stirbar. The amount of semiconductor powder used was 10.0 ± 0.2 mg/mL of stock solution except in the reaction of **1** on CdS, where 10 mg/5 mL of stock solution was used: this was to maximize the difference between the thermal and light induced reactions. Stock solutions were prepared with known quantities of starting materials and internal standards. Reaction mixtures were sonicated for 4–5 min prior to, and stirred during, irradiation.

Degassed samples were evacuated prior to sonication to a residual pressure of $\leq 2 \times 10^{-5}$ Torr (1 Torr = 133.3 Pa) (three or more freeze/thaw cycles). Thermal reactions were wrapped in aluminium foil after sonication and stirred in a Braun Thermomix-1420 water bath at 40°C.

All irradiations, except for quantum yield determinations, were performed using a 1000-W Xenon lamp run at 880 W in either a PRA 301 or a PTI 02-A5001 lamp housing. A water-cooled water IR filter was used to remove infrared radiation. For all reactions an air-cooled Corning 0-52 filter was used to remove light ≤ 340 nm. The reaction vessel was held in the same position by a bracket to ensure reproducibility. The samples were cooled by compressed air and constantly stirred. The lamp output was periodically checked with a Scientech 364 power energy meter. However, for any given series of reactions a standard reaction was considered a more meaningful measure of the fluctuations in the light source. Irradiations of stock solution in the absence of semiconductor were performed to ensure that the semiconductor was required for reaction.

Reaction mixtures were open to the atmosphere via a condenser and were protected from atmospheric moisture by an anhydrous $CaSO_4$ drying tube. Unless specifically stated all samples were so treated except for the reaction of **1** on CdS where, contrariwise, all samples were degassed unless stated.

For the quantum yield determinations a PRA M303 150 W lamp was used with combined Corning 0-52 and 7-60 filters. This combination gave a window between 340 and 400 nm and transmitted light of energy

[2]The exact potentials of the holes or compounds are not known in the solvents used here. Furthermore, slightly endothermic electron transfers are known in homogeneous solution (22) and on CdS (7).

greater than the band gaps of both ZnO and CdS. Potassium ferrioxalate chemical actinometry was used to calibrate the light source. The reaction vessels were held in place using an aluminum block with a 1.0 × 1.5 cm window. All the light falling on the window was assumed to be adsorbed by the semiconductor.

All quantitative analysis of the semiconductor reactions was done on a Varian 3700 analytical gas chromatogram connected to a Hewlett Packard 3390A integrator. The semiconductor was removed by filtration through a short 1-cm Celite filter packed in a Pasteur pipette. Product analysis was based on the average of a minimum of two injections for each determination. For all reported yields the conservation of mass was > 95% relative to the internal standard.

Preparation of hydrocarbons

Quadricyclane (tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane) 1: Quadricyclane was prepared from freshly distilled **6** (Aldrich) by triplet sensitization by irradiated acetophenone (25).**1** was filtered through a short (2 cm) silica column prior to use and samples of **1** used in reactions were typically 98.5% **1** and 1.1% **6**.

1,8-Bishomocubane (pentacyclo[4.4.0.0^{2,5}.0^{3,8}.0^{4,7}]decane) 2: 1,8-Bishomocubane was prepared as previously described (26), and before use was sublimed very slowly onto a Dry Ice/acetone cold finger (100 mg, 1 h, 30–40°C at 1 Torr). Samples used in semiconductor reactions were 98% **2** and 1.5% **7**.

Snoutane (pentacyclo[4.4.0.0^{2,5}.0^{3,8}.0^{5,7}]decane 5: Snoutane was prepared by intramolecular rearrangement of **2** on Ag^+ (27). The sample purity was only 90%; however, this was sufficient to test if reaction occurred on illuminated semiconductors or with organic redox sensitizers.

Tetracyclo[4.3.0.0^{2,4}.0^{3,7}]non-8-ene 9: The preparation of **9** was that of Freeman and Balls (28). The purified **9** (94%) was used for the preparation of **4**.

Norsnoutane (pentacyclo[4.3.0.0^{2,4}.0^{3,8}.0^{5,7}]nonane) 4: Norsnoutane was prepared by direct irradiation of **9** (28). The purity of **4** used in semiconductor experiments was 95% **4** and 2% **9**.

exo-*Tricyclo[3.2.1.0^{2,4}]oct-6-ene 8*: A Simmonds–Smith reaction on norbornadiene gave **8** (29). The ZnCu couple was prepared by Le Goff's method (30).

Tetracyclo[3.3.0.0^{2,8}.0^{4,6}]octane 3: Intramolecular rearrangement of **8** on $[Rh(CO)_2Cl_2]_2$ gave **3** (31). The purity of **3** used in semiconductor irradiations was 97%.

Calculations

The molecular mechanics calculations were performed using Allinger's MM2 program (32). The program was modified to MM2' IVANOV by introducing the new parameters for strained hydrocarbons published by Ōsawa and co-workers and by Ivanov (33).

The semiempirical calculations were performed using Dewar and Thiel's MNDO method and program (34). The MNDO method has been successfully used by Bauld *et al.* to study the reactivity of radical cations (45). Initial geometries of the neutral compounds were those of the MM2'IVANOV minimum energy conformation. The only deviation from standard procedures occurred during the geometry optimizations of $\mathbf{3}^+$ and $\mathbf{5}^+$. In this case the program had not converged after 6000 CPU seconds on a Cybernex computer. The heat of formation had not changed by more than 0.5 kcal mol^{-1} after the first 1000 s because, we suspected, the calculated minimum was shallow. The conditions for convergence were thus relaxed in order to obtain a detailed orbital description of the radical cations of **3** and **4**.

The routine used to calculate the reaction coordinates was the same for all three pathways. The reaction coordinates in Figs. 5–7 are graphed with respect to the C2—C4 distance. The left-hand side of Fig. 5 (for example) starts with **1** having a C2—C4 bond of 1.54 Å and a ΔH_f of 83 kcal mol^{-1} calculated using the MM2 minimized geometry. Removal of an electron from **1** generates $\mathbf{1}^+$ with a ΔH_f of 298 kcal mol^{-1}. The dashed line represents a vertical transition, i.e., the radical cation here has the same geometry as the neutral parent compound. The same type of vertical ionization of **6** is plotted at C2—C4 separation of 2.42 Å, which is the optimum distance in **6**. The carbon skeleton of the vertically generated radical cation was then allowed to relax to an energy minimum. The whole carbon skeleton was not optimized, merely those bond distances, bond angles, and dihedral angles that changed significantly in the rearrangement. For example, in the isomerization of **1** to **6** the C2—C4 distance and the ∡C2C3C4 change from 1.54 Å and 60.1° in **1** to 2.42 Å and 105.5° in **6**, respectively. Since these changes are significant, the corresponding parameters were optimized. On the other hand, the changes in the C6—C7 distance and in ∡C1C2C5 were only 0.03 Å and 1.9°, respectively; hence these parameters were not optimized. At this stage in the calculation the geometric parameters describing the hydrogens were taken to be those for the neutral parent compounds.

To follow the remainder of the reaction the C2C3C4 angle was frozen at appropriate points to produce the C2—C4 distances that appear in the figures. The transition state was approached from both sides. The points near the transition state were then recalculated allowing the geometric variables associated with the hydrogens to be optimized. This optimization is represented on the figures by the vertical drop in energy from the squares near the transition state to the blank dots.

Results

The conversion of **1** to **6** and **2** to **7** on CdS and ZnO is summarized in Tables 2 and 3 respectively.[3] Both systems were not reactive in the absence of semiconductor. However, **1** (but not **2**) on CdS gave a "dark", thermal, reaction. Table 2 shows the results with two CdS samples but, in fact, all seven CdS samples examined gave some dark reaction (see below). The products (**6** and **7**) were identified by comparison of their ^{1}Hmr spectra with those of authentic samples. The mass balance for the reactions was greater than 95% (as determined by gc analysis with an internal standard), i.e., in 1 h no oxidation products could be detected in the presence of air. No new peaks were detectable by glc. In the absence of oxygen both reactions on ZnO showed a decreased yield. However, on CdS, degassed samples of **1** showed an increased yield[3] and those of **2** showed no change in yield. In addition, **2** showed rapid conversion to **7** in homogeneous solution with 9,10-dicyanoanthracene as an electron transfer sensitizer.

The results of quantum yield determinations for both reactions are presented in Table 4, but that for the rearrangement of **1** on CdS was not determined since it was impossible to separate the thermal and photochemical contributions to reaction. The errors associated with the quantum yields in Table 4 were quite large owing to the small values obtained for Φ and the length of time required to obtain reasonable conversion, and which permitted dark reaction.

The solvent effect on the isomerization of **1** and on ZnO and CdS is given in Table 5. Relative yields are given, compared to that for the reaction in CH_2Cl_2. The reaction on ZnO proceeds more efficiently in CH_2Cl_2 and somewhat less efficiently in CH_2CN. However, in solvents more polar than CH_3CN or less polar than CH_2Cl_2 no reaction is observed. On CdS there is virtually no reaction in CH_3CN whereas the reaction is quite efficient in hydrocarbon solvents that are less polar than CH_2Cl_2.

The results of an examination of the thermal (dark) reaction of **1** with several different samples of CdS are given in Table 6, which includes several properties of each sample: purity, as stated by the supplier; surface area; and structure. There appears to be no correlation between surface area and reactivity except possibly within the same structure type. The most efficient

[3]As noted, this transformation was reported in a preliminary form (23). Subsequently and independently, Ikezawa and Kutal confirmed our observations (35).

samples are those in the β (cubic) form, the slowest being in the α (hexagonal) form.

The quenching effects of added electron donors are shown in Figs. 1–4. The extent of quenching follows the oxidation potentials of the quencher, Table 1. The lines on the graphs are those obtained by curve fitting the data by a nonlinear least-squares treatment according to kinetics developed elsewhere (7, 36).

All attempts to rearrange **3–5** by photoinduced electron transfer using CdS, ZnO, TiO_2, and 9,10-dicyanoanthracene as sensitizers failed completely even when the reaction mixtures were irradiated for up to 20 h. Gas chromatographic (gc) analysis showed greater than 95% of the starting material remained.

The oxidation potentials of **3–5** are very close to that of bishomocubane, **2**. The values of k_q for the quenching of naphthalene for compounds **2**, **4**, and **5** is about the same (10). Both **1** and **2** have been shown to give radical cations that undergo subsequent reaction under conditions similar to those in which **3–5** were unchanged. It is not unreasonable to conclude,

therefore, that under the conditions described, the radical cations of **3–5** were indeed being formed but that back electron transfer successfully competed with chemcal transformation.

One possible explanation for such a situation could be that cycloaddition was thermodynamically favoured over cyclorever-sion. In the case of the **3**/**8** radical cation interconversion this appeared to be true. In a study (21) that examined the exciplex fluorescence quenching of typical organic redox sensitizers by **8**, **8** was observed to give **3**. In the same study **3** was observed to quench the fluorescence of the sensitizers; however, no subsequent rearrangement was observed. It is also interesting to note that **8** was a very efficient quencher, quenching with rates comparable to those of **1**; however, the quantum yield for isomerization was an order of magnitude lower.

In experiments on CdS, ZnO, and TiO_2 **8** isomerized to give a small amount (< 1%) of **3** in 4 h,when illuminated with light of energy greater than the band gap of the semiconductor. The isomerization was accompanied by the formation (~4%) of unidentified high molecular weight compounds, possibly dimers or oxidation products. On extended irradiation (10 h) with semiconductors or DCA as sensitizers, **9** showed no indication of isomerization to **4**. In the case of semiconductor sensitized reaction systems there was some loss (~5%) of **9** with the consequent formation of a number of high molecular weight compounds.

The experimental data obtained for the radical cations of **3–5**, **8**, and **9** were largely a demonstration of their resistance to rearrangement. It was these observations that led us to enquire further, with the aid of MM2 and MNDO, into the factors that govern the reactivity of a radical cation.

The calculated heats of isomerization (i.e., the relative energies) of the neutral "closed" dicyclopropanes and their

corresponding "open" olefins are listed in Table 7. The relative energy of **1** and **6** has been studied extensively, both theoretically and experimentally. The value of ΔH_r determined experimentally for **1** → **6** suggests that **1** lies at least 22 kcal mol^{-1} (37) above that of **6**. The theoretical values of ΔH_r closest to the experimental value were those obtained by higher level *ab initio* calculations, HF/6-31G* and MP2/6-31G* (17). MNDO (starting with MM2 minimum geometries) underestimates the difference in energy by 6 kcal mol^{-1}; however, its prediction is far superior to that of MINDO/3, which gives only a small difference in energy (16).

The relative energies calculated by MNDO suggest **3** is 28.1 kcal mol^{-1} more stable than **8**. There are no experimental values available for ΔH_r for the isomerization of **3** to **8**; however, thermolysis of **8** has been reported to give **3** at 200°C (38). This suggests that **3** may be thermodynamically more stable than **8** and supports the sign for the relative energy calculated by MNDO.

The relative energies of the radical cations are summarized in Table 8. Experimentally $\mathbf{6}^+$ is 9 kcal mol^{-1} lower in energy than is $\mathbf{1}^+$ (16, 17). The value calculated by MNDO is in the correct direction, but is 5 kcal mol^{-1} larger than the experimental value. This is quite acceptable considering that the MNDO calculation was not fully optimized (see above). The MNDO value is far superior to that of MINDO/3 which predicts $\mathbf{1}^+$ to be 12 kcal mol^{-1} more stable than $\mathbf{6}^+$. The calculated values of ΔH_r^+ closest to the experimental value are those obtained

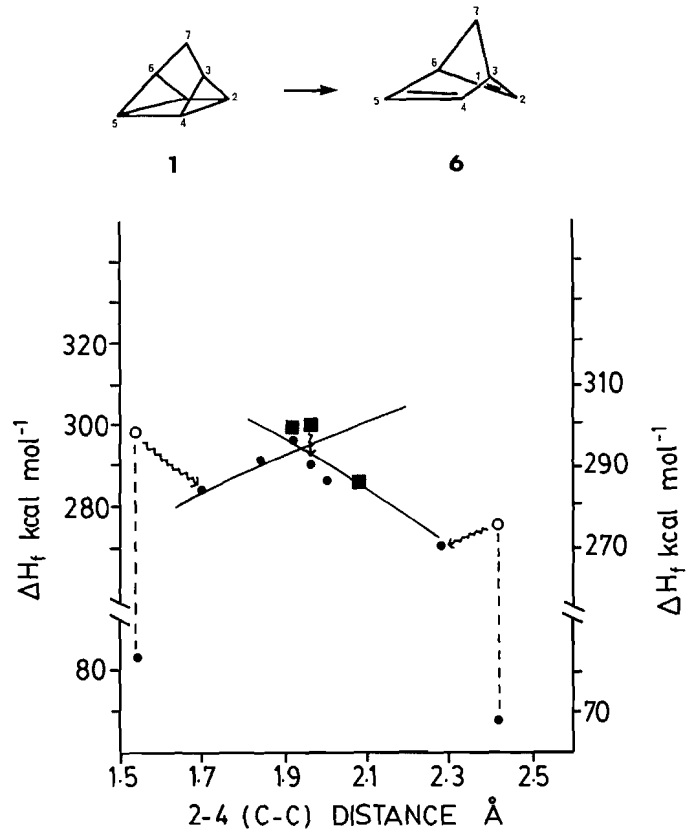

FIG. 5. Reaction coordinate for valence isomerization of **1**–**6**; (○) vertically generated radical cation, (■) hydrogens fixed.

using HF/6-31G* and MP2/6-31G* (17). The radical cation of **8** (MNDO) is 9 kcal mol^{-1} lower in energy than $\mathbf{3}^+$ (Table 8). The relative energy is in agreement with the experimentally observed direction of reaction. The calculated energy difference predicts $\mathbf{9}^+$ to be more stable than $\mathbf{4}^+$ by 17 kcal mol^{-1}. This suggests that if rearrangement were to occur it would be in the same direction as that of $\mathbf{1}^+$ to $\mathbf{6}^+$.

The reaction coordinates of the interconversions of $\mathbf{1}^+/\mathbf{6}^+$, $\mathbf{3}^+/\mathbf{8}^+$, and $\mathbf{4}^+/\mathbf{9}^+$ were investigated using MNDO (Figs. 5–7, respectively). Summarized in Table 9 are the activation energies for the reactions, calculated relative to the energy-minimized radical cations. The activation energies suggest that cycloreversion is favoured for $\mathbf{1}^+$ and $\mathbf{4}^+$. On the other hand, cycloaddition is favoured for $\mathbf{8}^+$ to give $\mathbf{3}^+$. Also listed in Table 10 is the approximate C2–C4 distance at the transition state. MNDO predicts the transition to be slightly on the side of the higher energy radical cation.

The calculated and experimental geometries of **1** and **6** are in good agreement with each other (Table 10). The structures are symmetric with respect to a plane that perpendicularly bisects the C1—C2 bond. This symmetry is also observed in the radical cations of **1** and **6** calculated by MNDO and *ab initio* methods. The agreement of the 6-31G (17) and MNDO geometries for the radical ion is very good, despite the approximations made in the MNDO calculation.

The geometries of **3**, **4**, **8**, and **9** calculated by MM2 also show symmetry with respect to a perpendicular plane that bisects the C1—C2 bond (Table 11). In radical cations $\mathbf{3}^+$ and $\mathbf{4}^+$ the symmetry with respect to this plane is lost according to MNDO calculations. The elongated C1—C7 bond of $\mathbf{3}^+$ was only obtained for the minimized radical cation.

[a]MM2IVANOV.
[b]MNDO.
[c]Bond lengths in Å and angles in degrees.

This may have been because ∡C2C3C4 was fixed in order to move through the reaction coordinate. However, this was not the case for $\mathbf{4}^+$, yet as the reaction coordinate was followed, there were a number of points where MNDO predicts an asymmetric minimum geometry, as indicated by a horizontal bar through the point (Fig. 7: the bar signifies the difference in the C2—C4 and C1—C6 distances).

Discussion

The role of oxygen

In most semiconductor photocatalyzed processes so far examined, it has been found that oxygen enhances the rate of reaction (see refs. 1, 3–5 for some examples). Only in the valence isomerizations of **1**, **2**, and some geometric isomerizations (6, 9) has the presence of oxygen produced the reverse effect.[3] Molecular oxygen is usually believed to play a role in the stabilization of the e^-/h^+ pair, possibly by trapping the electron from the semiconductor conduction band to form adsorbed superoxide. Superoxide formation on the surface of CdS has been confirmed by spin trapping techniques (39).

An alternative or, perhaps, an additional rationale for the normally observed phenomenon (40) is that strongly adsorbed oxygen acts as an electron acceptor, thus causing a greater polarization in the space charge layer of the semiconductor and the layer of adsorbate than in its absence. This increases the electric field and, in turn, increases band bending. The charge separation of the e^-/h^+ pair is accelerated and the potentials of the conduction and valence bands are lowered. The accelerated charge separation improves the migration of the holes to the surface, thereby facilitating their interception.

Both rationales for the role of oxygen give an explanation for the decreased rates of reactions of **1** and **2** on ZnO in the absence of oxygen. However, on CdS an *increased* rate is observed. For the stilbene isomerization (6) the explanation suggested for this phenomenon was that the beneficial effects of oxygen were outweighed by a competing quenching process: the quenching of the radical ion by superoxide. It was also observed that, in a series of substituted stilbenes, as the polarity of the compound increased the effect of oxygen diminished. This was tentatively explained in terms of increasing adsorptive ability with increasing polarity, thus competitively decreasing the amount of molecular oxygen on the surface.

Quantum yields

In both reactions (**1**→**6**, **2**→**7**) a chain mechanism is thermodynamically possible.[4] The radical cation rearrangement of **1** has been suggested to proceed through a chain mechanism when it is catalyzed electrochemically (catalytic factors as high as 11 have been reported (13)) and also when photosensitized by metal complexes ($\Phi > 200$) (12), but the rearrangement apparently does not proceed by a chain mechanism when sensitized by organic redox sensitizers in nonpolar solvents (41). Under the latter conditions it is believed that the reaction proceeds through an exciplex. Since the reaction of **2** itself has not been previously studied, the only comparison that can be made is with that of the substituted derivatives of **2**: these are believed to proceed by a chain mechanism (19).

The quantum yield values for the reactions on CdS of **1** and **2** were found to be very small indeed (10^{-3}–10^{-4}): a chain mechanism seems unlikely.

Solvent effects

The relative efficiencies found for the reaction of **1** in different solvents (Table 5) are largely consistent with findings from other studies. The most extensive examination of solvent effects previously reported concerned phenyl vinyl ether dimerization (3). No correlation could be found between rates of reaction and dielectric constants or solvent polarity, but there was a general indication that solvents of moderate polarity gave higher conversions. This was taken to suggest the results were a consequence of competitive adsorption phenomena: these observations have been noted in other systems examined (4, 6, 8). The reaction of certain stilbenes (6) and that of **1** on CdS proceed quite well in hydrocarbon solvents. The low polarity solvents may allow more successful competition by **1** for the surface, whereas the more polar CH_2Cl_2 would stabilize charge and elute products more efficiently. This suggestion is consistent with the observed increase in conversion for less polar reactants (stilbene, **1**, and **2**). For more polar reactants the effect may diminish as desorption of products becomes more important.

The dark reaction

Initially trace impurities were believed to be responsible for the thermal (dark) reactivity of CdS. However, the reaction was quenched by electron transfer quenchers, which would suggest that the reaction was proceeding through formation of a radical cation. The generation of radical cations in the dark on CdS has been previously proposed in the thermal dimerization of phenyl vinyl ether (2) where it was concluded that the rate of the dark reaction depended on defects in the CdS samples (42). Luminescence in colloidal CdS has been attributed to the formation of cadmium vacancies, and the presence of cadmium vacancies acting as electron acceptors had been reported earlier and assigned an energy level of 0.7 eV above the valence band (43). It is thus possible that the dark reaction of **1** is a result of interception of trapped holes either associated with cadmium vacancies or interstitial sulfur (for examples, see ref. 12). The very low oxidation potential of **1** (0.91 V) would make it possible for **1** to intercept centres that lie in the forbidden gap. This could account for the lack of dark reactivity of compounds such as **2** on CdS since the oxidation potential of **2** would be below that of such centres, so inhibiting reaction. In addition, low purity samples would be expected to give higher conversion (as observed) because impurities would increase the number of donor–acceptor centres.

Quenching studies

"Electronic quenching" decreases product formation by electron donation to the reactant radical cation, the photogenerated hole, and (or) the product radical cation, in the case of a chain mechanism. A good electronic quencher should have an oxidation potential above (less positive than) that of the photoinduced holes and (or) that of the reactant. 1,2,4,5-Tetramethoxybenzene, TEMB, (Table 1) is thermodynamically suitable to quench exothermically the photoinduced holes of ZnO and CdS as well as $\mathbf{1}^+$ and $\mathbf{2}^+$. The addition of TEMB to the reactions of **1** and **2** on either CdS or ZnO substantially reduces product formation (Figs. 1–4 respectively). Also Fig. 1 shows the effect of adding diglyme as a surface adsorbate to the reaction of **1** on ZnO. Diglyme is a very poor quencher whereas TEMB is very effective. Since diglyme's oxidation potential lies below the holes of ZnO, this suggests that TEMB is indeed quenching by electron transfer and not by competitive adsorption.

In the reactions mediated by ZnO (Figs. 1 and 3), 1,2,4-trimethoxybenzene, 1,2,4-TMB, only quenches the formation of **7**. The oxidation potential of 1,2,4-TMB (Table 1) lies between that of the holes and that of **1**, hence 1,2,4-TMB may quench the holes but not $\mathbf{1}^+$. When 1,2,4-TMB intercepts a hole it generates 1,2,4-TMB^+, but the latter is able, in turn, to accept an electron from **1** ($\Delta eV \simeq 0.2$). The net effect is no quenching. In the reaction of **2** on ZnO, 1,2,4-TMB can quench both $\mathbf{2}^+$ and the photoexcited holes, as with TEMB, and the curves are superimposable.

[4]The $E_{\frac{1}{2}}^{ox}$ of **2** is 1.56 V vs. SCE (10) and the $E_{\frac{1}{2}}^{ox}$ of **5** is estimated at 1.7 V vs. SCE by comparison with related compounds (5).

For personal use only.

The situation with CdS is a little more complex; here 1,2,4-TMB quenches both reactions. The quenching of the reaction of **1** is, however, considerably less than that of **2** and levels off at higher concentrations. The less efficient quenching and leveling off may be attributed to the interception of 1,2,4-TMB$^+$ by **1**, as on ZnO. The reason 1,2,4-TMB quenches **6** formation on CdS and not on ZnO is not fully understood. One possibility may be a shorter lifetime of the e^-/h^+ pair on CdS as compared to ZnO, and that quenching the hole on CdS by 1,2,4-TMB may be coupled to a fast electron recombination before interception by **1**.

Another substance was examined as a potential quencher: 1,3,5-trimethoxybenzene, 1,3,5-TMB. This showed virtually no quenching at those concentrations where the other quenchers were effective. In fact, 1,3,5-TMB has not yet displayed any significant quenching in CdS-mediated reactions This suggests that 1,3,5-TMB is a poor electron donor to the semiconductor and semiconductor generated radical cations. It is possible that the 0.2-eV difference between the holes and 1,3,5-TMB in CH_3CN solution may be significantly smaller in CH_2Cl_2 on the CdS surface.[2] However, the use of 1,3,5-TMB does demonstrate, because of its similar structure to the other methoxylated quenchers, that competitive adsorption plays a very minor role in quenching at these concentrations.

Calculations

Roth and Schilling have shown by the obtention of different nuclear spin polarization patterns for **1** and **6** that two different radical cations do, in fact, exist (15). This view is also supported by the photoelectron spectra (16, 44) and high level *ab initio* calculations (17). The electronic structures of the different radical ions are in agreement with expectations from simple molecular orbital models. The radical cation of **1** has one electron in a b_1 orbital and that of **6** has one electron in a b_2 orbital. The interconversion of $\mathbf{1}^+$ to $\mathbf{6}^+$ involves an orbital crossing as in the case of the neutral parent compound.

The results of the MNDO investigation reported here are in good agreement with these observations. Two distinct radical ions are predicted. The SOMO of $\mathbf{1}^+$ is a b_1 orbital and that of $\mathbf{6}^+$ is a b_2 orbital. The interconversion follows C_{2v} symmetry with orbital crossing of the SOMO and LUMO orbitals. Even if the initial geometry for $\mathbf{1}^+$ were given C_s symmetry, the MNDO program optimized the structure back to C_{2v} symmetry. This demonstrates that MNDO calculates a real minimum with C_{2v} symmetry and not just a shallow edge. Calculations at the STO-3G level predict a strongly distorted C_s symmetry structure for both radical cations; however, at the higher 6-31G level a symmetric structure is calculated for both radical cations (17). Removal of an electron from the b_1 orbital of **1** should result in the C1—C6 and C2—C4 bonds of **1** becoming less bonding (elongated) while the C1—C2 and C4—C6 bonds should become less antibonding (shorter). This idea suggests that $\mathbf{1}^+$ should relax to a geometry structurally closer to that of **6**, as suggested by Haselbach and co-workers for Type C radical cation rearrangements (44*b*). This process is predicted by MINDO/3 (16), 6-31G (17), and by the MNDO calculations reported here. The overall effect is to shorten the reaction coordinate. The same effect is observed from the other side of the reaction coordinate: $\mathbf{6}^+$ relaxes to a geometry structurally closer to **1**. MNDO calculates a shortening of the reaction coordinate from 0.89 to 0.58 Å due to this effect.

The relative energy of $\mathbf{1}^+$ and $\mathbf{6}^+$ is known experimentally to be approximately 9 kcal mol^{-1}. This energy difference is sufficient to account for the substantially different interconversion rates of $\mathbf{1}^+$ and $\mathbf{6}^+$, where, in fact, $\mathbf{1}^+$ is observed to rearrange irreversibly to $\mathbf{6}^+$. The MNDO calculated energy difference is in very good agreement with experiment considering that the structures could not be fully optimized. MNDO is superior to MINDO/3 in the treatment of such systems, since the latter failed to predict the correct order in energy for $\mathbf{1}^+$ and $\mathbf{6}^+$ (16).

The activation energy for the rearrangement of $\mathbf{1}^+$ and $\mathbf{6}^+$ was predicted to be approximately 10 kcal mol^{-1} by MNDO, which is considerably lower than the activation energy of 37.5 kcal mol^{-1} for the neutral parent compound. A value of 10 kcal mol^{-1} is still higher than expected for the reaction (4–5 kcal mol^{-1}) from the lifetime of only several nanoseconds predicted for $\mathbf{1}^+$ (16).

In summary, the MNDO calculations for the quadricyclane/norbornadiene system are in good agreement with the available experimental data and other theoretical calculations. Haselbach suggests the lowering of the activation energy for Type C processes can be attributed to: (*i*) the shorter reaction coordinate; (*ii*) involvement of only one electron; and (*iii*) the reduced energy gap between the SOMO and the LUMO as compared to that of the HOMO and LUMO of the parent compounds (45). The MNDO calculations show a reduction in the reaction coordinate of 40% for the reaction of the radical cations. Unfortunately no direct information about the relative energy levels of orbitals can be obtained for open shell molecules by MNDO. There is, however, an overall predicted 75% reduction in activation energy for the radical cation rearrangement.

The conversion of $\mathbf{8}^+ \rightarrow \mathbf{3}^+$ was observed to be approximately 10 times less efficient than that of $\mathbf{1}^+ \rightarrow \mathbf{6}^+$. The MNDO results are consistent with all the experimental information available. The observed direction of both the thermolysis and radical cation reactions can be attributed to overall exothermicity. The activation energy for the $\mathbf{8}^+ \rightarrow \mathbf{3}^+$ reaction is calculated to be 25 kcal mol^{-1} by MNDO. The MNDO calculations offer some explanation for the higher activation energy for the $\mathbf{8}^+ \rightarrow \mathbf{3}^+$ rearrangement compared to that of $\mathbf{1}^+ \rightarrow \mathbf{6}^+$. The shortening of the reaction coordinate for the radical cation reaction is only 16% for $\mathbf{8}^+ \rightarrow \mathbf{3}^+$ compared to the 40% for $\mathbf{1}^+ \rightarrow \mathbf{6}^+$. This is attributable to differences in the structures of the radical cations. MNDO calculates in the HOMO of **8** a contribution from both the double bond and the cyclopropane Walsh orbitals. This is very similar to the b_2 HOMO orbital of **6** where there are contributions from both double bonds. In **6**, these through-space interactions are maintained in the radical cation; however, in $\mathbf{8}^+$ the SOMO orbital is localized on the double bond.[5] As a result $\mathbf{8}^+$ shows virtually no relaxation toward $\mathbf{3}^+$. Furthermore, the structure of $\mathbf{3}^+$ is predicted to have an elongated C1—C7 bond. If this be the case, the correlation of the SOMO of $\mathbf{8}^+$ may be with a higher lying virtual orbital of $\mathbf{3}^+$. Correlation with higher orbitals leads to less stabilization and would result in a higher activation energy (46).

The last two compounds examined by MNDO calculations were **4** and **9**. MNDO predicts that $\mathbf{9}^+$ be more stable than $\mathbf{4}^+$ by 17 kcal mol^{-1}. This suggests that cycloreversion of $\mathbf{4}^+$ should proceed to $\mathbf{9}^+$. An activation energy of

[5]The disappearance of interactions between C1 and C2 and the Walsh orbitals is observed both in $\mathbf{8}^+$ and $\mathbf{9}^+$ and occurs even when the radical cations have the same geometry as the neutral parent compounds. The reason for this is not clear, however, since the through-space interactions for **2** are maintained in the radical cation of **6**.

33 kcal mol^{-1} was predicted for the interconversion of 4^+ to 9^+: this is 3.3 times that calculated for the isomerization of 1^+ to 6^+, and readily accounts for the lack of reaction observed. This high activation energy can be attributed to the nature of 4^+ and 9^+ as compared to 1^+ and 6^+. The overall picture for 4^+ and 9^+ is very similar to that for 3^+ and 8^+: the geometry of the minimized 9^+ is predicted to be similar to that of the neutral compound. The SOMO orbital is localized on C1 and C2 with no contributions from the Walsh orbitals of the cyclopropane. This leads to a slight elongation in the C1—C2 bond in 9^+ as compared to **9**; however, there is no shortening of the reaction coordinate along the C2—C4 distance, as occurs with the radical cations 6^+ and 8^+. An elongated C1—C6 bond is calculated for 4^+. The coefficients for the SOMO orbital localize the orbital on C1 and C6, unlike the SOMO of 1^+, which has b_2 symmetry. The predicted orbital correlation of the SOMO and LUMO orbitals may not be correct and higher virtual orbitals may be involved; this would also lead to a higher activation energy.

In-situ Fourier transform infrared spectroelectrochemical studies of the oxidation of some tetraphenylporphyrin complexes

A. Scott Hinman,[1] Brad J. Pavelich, and Karen McGarty

Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received August 10, 1987[2]

A. Scott Hinman, Brad J. Pavelich, and Karen McGarty. Can. J. Chem. **66**, 1589 (1988).

In-situ FTIR spectroelectrochemistry has been applied to determine difference spectra in the region 1800 to 1000 cm^{-1} associated with the oxidation of $TPPH_2$, TPPMg, TPPCu, TPPZn, TPPCo, TPPMnCl, and TPPFeCl. In all cases, formation of the π-cation radical results in two characteristic absorbance decreases near 1600 and 1485 cm^{-1}, and five characteristic absorbance increases near 1415, 1350, 1285, 1225, and 1005 cm^{-1}. Formation of the π-dication was observed for TPPZn, TPPMg, and TPPCo, and gave rise to a new absorbance increase near 1600 cm^{-1}, and a shift to higher frequency of bands in the 1200 to 1400 cm^{-1} region. Perchlorate coordination to oxidized TPPZn, TPPMg, and TPPCo gives rise to bands near 1140 and 1030 cm^{-1}.

A. Scott Hinman, Brad J. Pavelich, et Karen McGarty. Can. J. Chem. **66**, 1589 (1988).

On a utilisé la spectroélectrochimie FTIR *in situ* pour déterminer les différences spectrales, dans la région de 1800 à 1000 cm^{-1}, associées à l'oxydation des produits suivants: $TPPH_2$, TPPMg TPPCu, TPPCo, TPPMnCl, et TPPFeCl. Dans tous les cas, la formation du cation radical π provoque deux diminutions caractéristiques d'absorption près de 1600 et 1485 cm^{-1} ainsi que cinq augmentations caractéristiques d'absorption près de 1415, 1350, 1285, 1225 et 1005 cm^{-1}. On a observé la formation du dication π avec le TPPZn, le TPPMg et le TPPCo; elle donne lieu à une nouvelle augmentation de l'absorption près de 1600 cm^{-1} alors que les bandes de la région de 1200 à 1400 cm^{-1} sont déplacées vers des fréquences plus élevées. La coordination des TPPZn, TPPMg et TPPCo par le perchlorate donne lieu à l'apparition de nouvelles bandes près de 1140 et 1030 cm^{-1}.

[Traduit par la revue]

Introduction

In 1981, Goff, Reed, and co-workers (1) reported infrared spectra of a number of metallotetraphenylporphyrin π-cation radicals isolated from solution following one-electron oxidation of the neutral complexes. These all displayed strong absorbance in the vicinity of 1280 cm^{-1}. Since that time this band has been suggested (2) as the simplest of definitive criteria available for distinguishing between metal and porphyrin ring centered oxidation of tetraphenylporphyrin complexes. Other workers (3) have criticized the use of this band as a diagnostic criterion, and produced evidence suggesting that it could arise from occluded chlorocarbon solvent molecules in the crystalline cation radicals.

Our laboratory has recently reported (4, 5) the first applications of the recently developed (6) methodology of *in situ* Fourier transform infrared reflectance spectroelectrochemistry to studies of the anodic oxidation of metalloporphyrins. In this technique, infrared radiation passes through a thin layer of solution onto a polished electrode surface which reflects the incident beam back through the thin solution layer to a detector. Analysis of the energy spectra obtained prior to and following electrolysis affords a difference spectrum between oxidized and unoxidized forms of electroactive species within the thin layer cavity. Utilizing this technique, we were able to detect (4, 5), *in situ*, a strong absorbance at 1277 cm^{-1} due to the cation radical of tetraphenylporphinatozinc(II) (TPPZn) in 1,2-dichloroethane containing tetra-*n*-butylammonium perchlorate.

In the present study, we have extended our utilization of this technique to include a variety of other metal-TPP complexes as well as the free base, $TPPH_2$. Our intent was to provide further evidence concerning the validity of the 1280 cm^{-1} band as a diagnostic for identifying oxidation of the porphyrin ring as opposed to the metal center of the complex. Also, as the method is a difference technique, we anticipated that additional correlations, not readily apparent in comparisons of individual spectra of the oxidized and unoxidized complexes, might be observed. In a limited number of cases we have also been able to obtain spectral differences associated with two-electron oxidation of tetraphenylporphyrins to the π-dication. The discussions here are concerned with the use of *in situ* FTIR as an empirical tool for identifying the site of oxidation within the porphyrin complex, and no attempt has been made to interpret the data in terms of possible band assignments or structural differences between the porphyrin complexes.

Experimental

Porphyrins

The free-base tetraphenylporphine ($TPPH_2$) was used as received from Aldrich. TPPMg, TPPCu, TPPZn, TPPCo, and $TPPMnCH_3CO_2$ were prepared from the free base utilizing Adler's DMF method (7). TPPMnCl was prepared by dissolving 100 mg of $TPPMnCH_3CO_2$ in 150 mL of methanol to which 2 mL of 1 *M* aqueous HCl were then added. TPPMnCl was precipitated by the slow, dropwise addition of 200 mL of water, recovered by filtration, and dried *in vacuo* at 100°C. TPPFeCl was used as received from Porphyrin Products Inc., Logan, Utah.

Solvents and supporting electrolyte

Dibromomethane (Eastman) was shaken with activated alumina (Woelm N Super I) prior to use. Dichloromethane and 1,2-dichloroethane (Caledon D.I.G. grade) were purified as described in ref. 5. Tetra-*n*-butylammonium perchlorate (TBAP) from Fluka was recrystallized from an isopropanol/water mixture and dried *in vacuo* at 60°C.

Electrochemistry and in-situ *FTIR spectroelectrochemistry*

The cell and instrumentation employed for cyclic voltammetry were as described in ref. 5. The cell, optical arrangement, and instrumentation employed for *in situ* FTIR studies is described in detail in ref. 4. The cell utilizes a Pt mirror electrode and a CaF_2 window. The CaF_2 window allows observation of spectral features at frequencies higher than 980 cm^{-1}, although the signal-to-noise ratio is best above 1000 cm^{-1}.

Porphyrin concentrations in all experiments were approximately 2 m*M*. Supporting electrolyte concentration was 0.2 *M*. Prior to carrying out the infrared experiments, cyclic voltammetry was run on the porphyrin solutions to establish appropriate oxidation potentials. The solutions were then transferred to the thin layer reflectance cell mounted in a Nicolet 5DX FTIR spectrometer. The *in-situ* FTIR cell has previously been demonstrated (4) to possess excellent characteristics for both thin-layer and conventional cyclic voltammetry. The use of a different cell to determine oxidation potentials in these experiments was simply a matter of convenience. As the electrochemical equipment is situated in a different laboratory from the FTIR spectrometer, this procedure minimized the amount of equipment shuttling required (potentiostat only), and obviated the need for readjustment of the optical configuration which would have been required were the cell, instead of the solution, transferred between the laboratories.

After the solutions were transferred, a set of 128 energy spectra were collected and averaged with the electrode potential held at a value, E_1, approximately 100 mV cathodic of the half-wave potential for the first oxidation of the porphyrin complex. The potential was then increased to a value, E_2, which, as judged from the cyclic voltammetry, would facilitate the desired oxidation without interference from any process (e.g. dication formation) occurring at higher potentials. A second set of 128 spectra were then collected and averaged. The resulting averaged spectrum obtained at E_2 was then ratioed against the background spectrum obtained at the base potential E_1. Taking the log and multiplying by -1 then affords the difference in absorbance, $\Delta A = A(E_2) - A(E_1)$, between the oxidized and unoxidized solutions as a function of infrared frequency. In this mode of data presentation, negative absorbance bands indicate a loss of vibrational intensity associated with species in solution prior to electrolysis, and are referred to as disappearance bands. Positive absorbance indicates increased or new vibrational intensity associated with electrolysis products, and are referred to as appearance bands.

Results and discussion

Our initial report (4) of *in-situ* FTIR characterization of the one-electron oxidation of TPPZn utilized 1,2-dichloroethane as the solvent. This solvent displays strong absorbance bands at 1450, 1429, 1315, 1286, and 1233 cm^{-1} in the spectral region focused on in this study (1800 to 1000 cm^{-1}). The 1286 cm^{-1} band, in particular, limits the optical throughput in the region of the reported 1280 cm^{-1} diagnostic band of tetraphenylporphyrin cation radicals. Extremely small thin-layer thicknesses (< 10 μm) and high porphyrin concentrations are required to allow observation of spectral features due to the porphyrin oxidation in regions of solvent overlap. Dichloromethane possesses only a single strong absorbance, at 1269 cm^{-1}, in the wavelength region of interest, and would thus appear to be preferable to dichloroethane. We have, in fact, had some success with this solvent, but its volatility (bp 38°C) makes it difficult to work with. Prolonged exposure of the electrode to infrared radiation frequently leads to partial vaporization of the solvent within the thin-layer cavity, resulting in a broad, strong disappearance feature around 1270 cm^{-1} in the difference spectra obtained.

The results presented here utilized dibromomethane as solvent with TBAP as supporting electrolyte, except in a few cases noted differently. This solvent is superior to either dichloroethane or dichloromethane for infrared studies. It possesses a single strong absorbance, at 1192 cm^{-1}, in the 1800 to 1000 cm^{-1} region, and is less volatile (bp = 97°C) than either. The relatively clean infrared spectrum of the solvent allows the use of longer thin layer thicknesses (approximately 50 μm) than in dichloroethane. This increases the absorbance due to solvates and, consequently, the overall quality of the spectra obtained through most of the 1800 to 1000 cm^{-1} region. The tradeoff in utilizing the longer pathlength is that solvent absorbance at 1192 cm^{-1}, as well as that due to supporting electrolyte perchlorate, at 1089 cm^{-1}, are high enough that most of the detector signal in a 10 to 20 cm^{-1} region about these frequencies results from stray light reflected off the front surface of the window, precluding the observation of bands associated with porphyrin oxidation in these spectral regions.

TABLE 1. Cyclic voltammetric half-wave potentials[a] for oxidation of tetraphenylporphyrin complexes

Complex	Half-wave potential		
	Metal oxidation	1st ring oxidation	2nd ring oxidation
$TPPH_2$		1.06	Irreversible
TPPMg		0.66	0.94
TPPZn		0.78	1.08
TPPCu		1.04	1.26[b]
TPPCo	0.78	0.97	1.15
TPPMnCl		1.15	Irreversible
TPPFeCl		1.16	1.39[b]

[a]All potentials in volts vs. aqueous SCE as determined in 1,2-dichoroethane/0.2 *M* TBAP for TPPZn, and dibromomethane/0.2 *M* TBAP for all other complexes.

[b]Anodic to cathodic peak current ratio less than unity at sweep rates below 20 mV s^{-1}.

The characteristics of dibromomethane as a solvent for the electrochemical oxidation of metallotetraphenylporphyrins appear similar in most regards to those of dichloromethane. With TBAP as supporting electrolyte, both solvents allow access of potentials up to +1.8 V vs. SCE. Also, the half-wave potentials observed for metalloporphyrin oxidations in dibromomethane are generally very close to those reported in the literature for oxidations in dichloromethane. The first one electron oxidation of TPPMnCl occurs at $E_{1/2}$ = 1.15 V vs. SCE in CH_2Br_2/TBAP (0.2 *M*), as compared to a reported value of 1.14 V vs. SCE in CH_2Cl_2/TBAP (0.1 *M*) (8). TPPFeCl undergoes two oxidations at 1.16 and 1.39 vs. SCE in CH_2Br_2/TBAP (0.2 *M*), as compared to reported values of 1.11 and 1.38 V vs. SCE in CH_2Cl_2/TBAP (0.1 *M*) (9). TPPCo undergoes three oxidations at 0.78, 0.97, and 1.15 V vs. SCE in CH_2Br_2/TBAP (0.2. *M*) as compared to reported values of 0.78, 0.97, and 1.16 V vs. SCE in CH_2Cl_2/TBAP (0.1 *M*) (10). These data suggest that liquid junction potentials associated with the use of the aqueous SCE are similar for both solvents.

TPP complexes in nonaqueous solution frequently undergo two successive one-electron oxidations (11). While the cyclic voltammetric behaviour of TPP complexes in CH_2Br_2 and CH_2Cl_2 appear similar in many regards, the stability of the second one-electron oxidation products of some of the compounds investigated is lower in the former solvent. While we have been able to observe reversible behaviour for the second one-electron oxidation of $TPPH_2$ in dry dichloromethane, this process is irreversible in dibromomethane, with no cathodic peak coupled to the oxidation for sweep rates up to 300 mV s^{-1}. Similarly, the anodic-to-cathodic peak current ratios for the second oxidation of TPPFeCl and TPPCu become less than unity at sweep rates below 20 mV s^{-1}, while maintaining a value of unity for similar experiments in CH_2Cl_2. The nature of this irreversibility has not been investigated.

Table 1 summarizes the half-wave potentials, as observed by cyclic voltammetry, associated with oxidation of the porphyrin

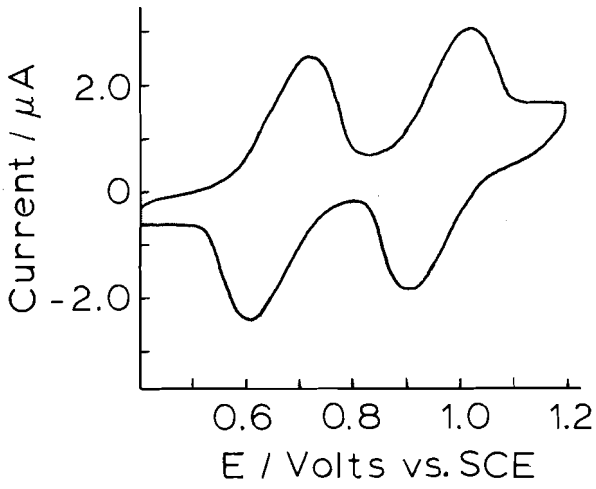

FIG. 1. Thin-layer voltammetry of 2.0 m*M* TPPMg in CH_2Br_2/TBAP (0.2 *M*) performed in the FTIR reflectance cell. Scan rate was 1.0 mV s^{-1}.

complexes utilized in this study. The oxidation products were stable ($i_{p,anodic}/i_{p,cathodic} = 1$) in all cases, except where noted otherwise. The assignment of the oxidation processes as ring centered in TPPMg, TPPZn, and $TPPH_2$ is unambiguous, as these complexes contain no oxidizable metal center. The assignment of oxidation site associated with the voltammetric waves for the other complexes is in accordance with their known behaviour in nonaqueous solution (11).

Figure 1 illustrates thin-layer voltammetry of TPPMg in CH_2Br_2/TBAP (0.2 *M*) in the same cell and under the same conditions used to collect the *in-situ* FTIR spectra reported below. The distortion from ideal symmetric thin layer behaviour is due to resistance-induced nonuniform potential distribution across the face of the working electrode (12). This distortion is more severe than we observed previously (4) for the oxidation of TPPZn in dichloroethane/TBAP, suggesting lower conductivity of the dibromomethane solutions. It is clearly not so severe, however, as to hinder our ability to carry out and resolve the successive oxidations of the complex. The resolution between successive oxidations associated with spectral data will, in fact, be better than that suggested by the voltammetry, as spectra are recorded after equilibrium conditions have been reached (ca. 90 s) at constant potential. Very little current flows and effects due to IR losses are minimized.

Figure 2*a* illustrates the difference spectrum associated with one-electron oxidation of TPPMg to the corresponding cation radical. The disappearance bands denoted 1D and 2D, and the appearance features denoted 1A–5A, are closely duplicated in difference spectra associated with cation radical formation in all complexes we have studied. The band positions and relative intensities, normalized to that of 3A, are summarized in Table 2. All of the bands reported in Table 2 were reproducibly observed in three successive experiments. Also, all bands are lost when the electrode potential is returned to the base value, indicating reversibility of the oxidations. Band 3A, occurring in the range 1276 to 1302 cm^{-1}, is always clearly evident as one of the strongest features in the spectrum, providing strong support for earlier reports (1, 2) of a 1280 cm^{-1} diagnostic band for TPP cation radicals.

Our results for TPPMnCl appear to contradict those of Spreer *et al.* (3). These workers reported that a band at 1280 cm^{-1} observed for the crystalline cation radical $TPPMnClSbCl_6 \cdot 4C_2H_2Cl_4$ was lost on prolonged exposure to vacuum, and suggested that the 1280 cm^{-1} band was due to the tetrachloroethane solvate molecules, rather than the cation radical. The *in-situ* difference spectrum in dibromomethane (Fig. 3) clearly shows the presence of a strong appearance band at 1286 cm^{-1}. CH_2Br_2 has no absorbance in this vicinity, so the band is not ascribable to solvent. This band was also clearly observable when dichloromethane or dichloroethane was the solvent.

The 1280 cm^{-1} band in the cation radicals occurs in a region where no significant absorbance due to the unoxidized porphyrin is observed. This facilitates its use as a diagnostic for ring oxidation in spectra of species isolated in the solid state. The additional bands observed in the difference spectra appear to provide a useful finger print for ring oxidation in *in-situ* studies, but are not likely to be as useful in interpreting single spectra of species isolated from solution. Bands 1D, 2D, 1A, 2A, and 5A all overlap with strong bands observed in the solid state spectra of the unoxidized porphyrins. Their observation in the difference spectra thus appears to result from a change in intensity of bands also present in the unoxidized species, rather from any new vibrational feature. Band 4A, in the region 1219 to 1239 cm^{-1}, occurs in a region where no major absorbance of the unoxidized porphyrins occur, and may be observable in solid state spectra of isolated cation radicals. Its intensity is much less than that of band 3A, however, and all of the unoxidized porphyrins examined display strong absorbance at approximately 1205 cm^{-1}, which could obscure this feature.

The difference spectrum associated with one-electron oxidation of TPPMg, Fig. 2*a*, also displays weak, broad appearance features at 1143 and 1034 cm^{-1}. Two such bands in the region above 1000 cm^{-1} are typical of coordinated perchlorate (13). We have previously shown (4, 5) that coordination of supporting electrolyte perchlorate accompanies the oxidation of TPPZn to the cation radical in dichloroethane, giving rise to appearance bands at 1137 and 1028 cm^{-1} in the *in-situ* difference spectrum. These bands were absent when the supporting electrolyte anion was tetrafluoroborate. Perchlorate coordination similarly appears to account for the 1143 and 1034 cm^{-1} bands accompanying the oxidation of TPPMg. Coordination of perchlorate is also indicated as accompanying the oxidation of the porphyrin ring in TPPCo (see below), but we were not able to reproducibly observe bands suggestive of perchlorate coordination to any of the other cation radicals investigated.

Figure 2*b* illustrates the difference spectrum observed on 2-electron oxidation of TPPMg to the π-dication. Not surprisingly, the bands due to coordinated perchlorate increase substantially, indicating that perchlorate complexation to the dication is more favourable than to the singly oxidized porphyrin. This increase in the extent of perchlorate complexation is also apparent when a second electron is removed from the porphyrin ring in TPPZn and TPPCo. With the π-dication species, in particular, it is possible that two perchlorate ions coordinate to yield a six-coordinate species. While the *in-situ* FTIR results do provide strong evidence that perchlorate complexation occurs, they do not provide unambiguous evidence as to the number of coordinating perchlorate ions involved.

In comparing Figs. 2*a* and 2*b*, it is evident that removal of a second electron from the porphyrin ring results in further changes in the vibrational spectrum of TPPMg. Appearance features at 1419, 1357, 1299, and 1226 cm^{-1} in Fig. 2*b* present a 4-band pattern reminiscent of that presented by bands 1A to

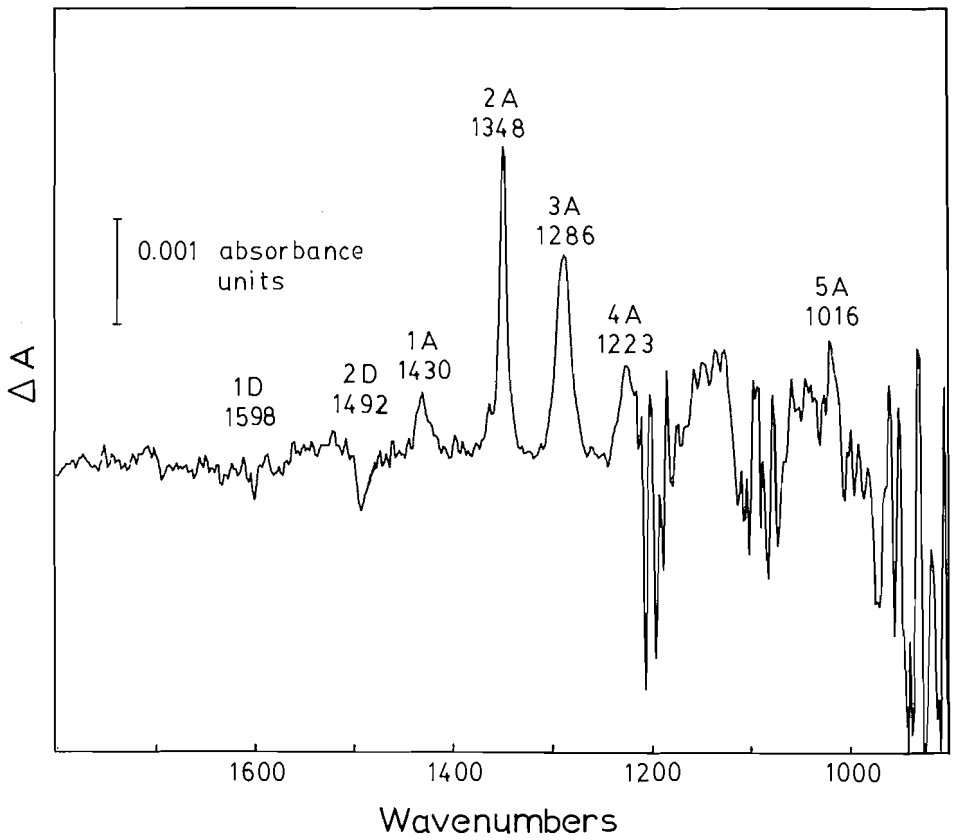

FIG. 3. *in-situ* FTIR difference spectrum for one-electron oxidation of TPPMnCl in CH_2Br_2/0.2 *M* TBAP. $E_1 = 0.95$ V; $E_2 = 1.20$ V vs. SCE. The lower absorbances in this figure as compared to figs. 2 and 5 should not be construed as an indication of lower molar absorptivity for bands of the TPPMnCl cation radical, as thin-layer cavity thickness and angle of incidence of the reflected infrared radiation were not rigorously controlled (see ref. 4).

For personal use only.

4A in the spectrum of the singly oxidized species, but shifted to higher frequency. Also, two closely spaced appearance peaks at 1569 and 1578 cm^{-1} are observed, although it is not clear whether these represent two new vibrational features, or a single appearance band split by a less intense disappearance band. In particular, a high frequency shift of bands 2A and 3A and a new appearance feature near 1600 cm^{-1} appear to be typical of π-dication formation, as similar changes are observed on loss of two electrons from the porphyrin ring of TPPCo and TPPZn. In TPPCo, the π-dication spectra shows a strong appearance band at 1606 cm^{-1}, and bands 1A to 4A are observed at 1434, 1376, 1315, and 1242, respectively, as compared to 1426, 1365, 1302, and 1241 for the π-cation radical. Similarly, the π-dication derived from TPPZn shows a strong appearance feature at 1588 cm^{-1}, and bands 1A to 4A are observed at 1409, 1360, 1300, and 1222 as compared to 1408, 1346, 1277, and 1222 cm^{-1} in the π-cation radical. We have not attempted to obtain dication spectra of the other complexes utilized, as the voltammetric studies indicated that these would not be stable on the longer time scale (approximately 3 min) required for FTIR characterization.

TPPCo in CH_2Br_2/TBAP undergoes three successive one-electron oxidations, as is evident in the cyclic voltammetry of Fig. 4. The voltammetry is very similar to that observed by Kadish (11) in CH_2Cl_2/TBAP, in accordance with the above noted similarity of CH_2Br_2 and CH_2Cl_2 as solvents for metalloporphyrin oxidations. In that report, the first of the three evident oxidation processes was ascribed to metal oxidation, while the remaining two processes were assigned to loss of

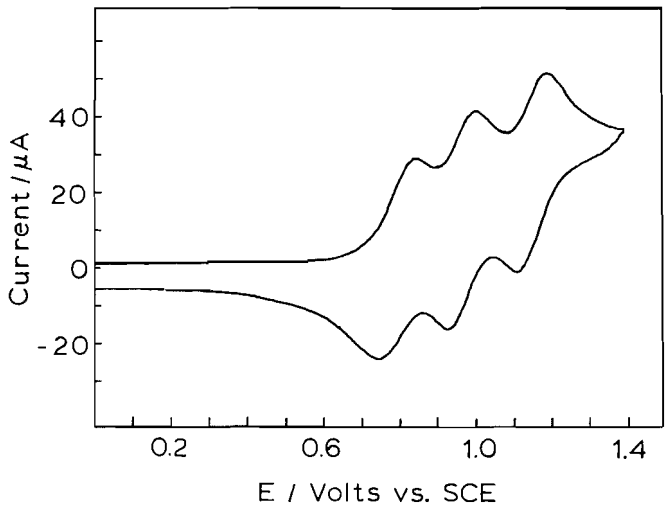

FIG. 4. Cyclic voltammetry of TPPCo in CH_2Br_2/0.2 *M* TBAP. Scan rate was 25 mV s^{-1}.

electrons from the porphyrin ring. Similarly, Gasyna *et al.* have considered that the first one-electron oxidation in CH_2Cl_2 is metal-centered based on magnetic circular dichroism measurements (14). The *in-situ* FTIR results confirm that this is also the correct assignment of the voltammetric waves in CH_2Br_2, and provide a comparison of vibrational changes due to oxidation of the metal center with those due to oxidation of the porphyrin ligand.

Figure 5 illustrates the *in-situ* FTIR spectroelectrochemistry

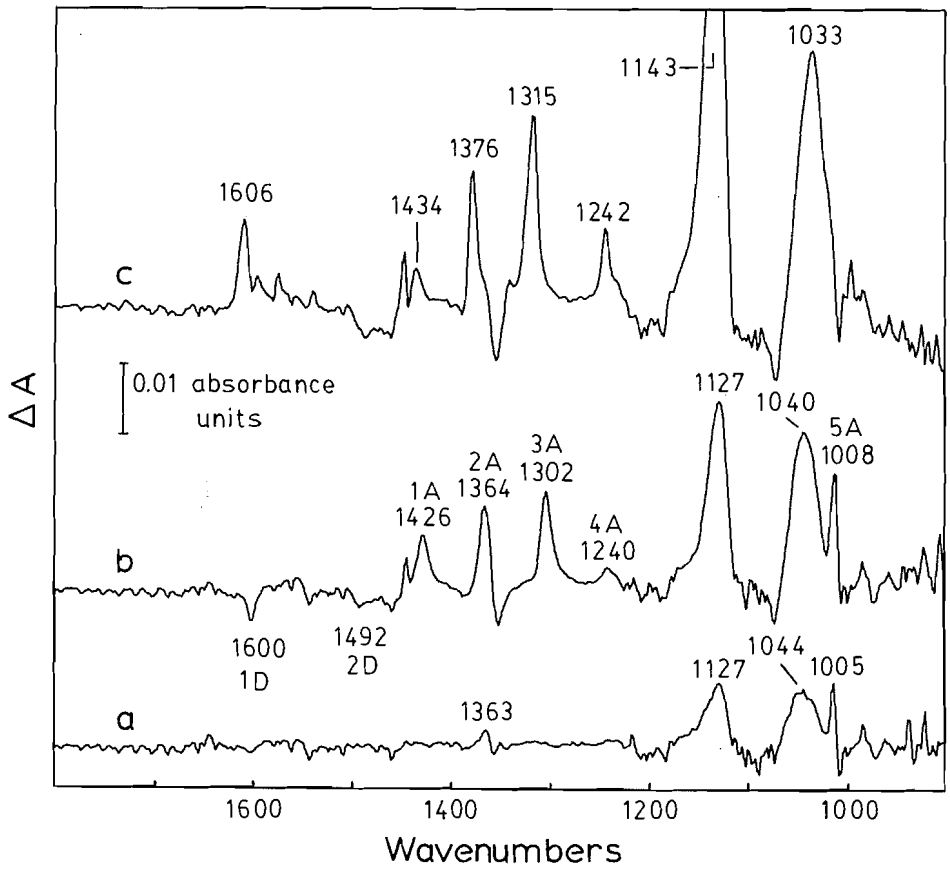

FIG. 5. *in-situ* FTIR difference spectra for **1** (*a*), **2** (*b*) and **3** (*c*) electron oxidation of TPPCo in CH_2Br_2/0.2 *M* TBAP. $E_1 = 0.65$ V vs. SCE for all spectra. $E_2 = 0.88$ (*a*); 1.08 (*b*); and 1.4 V vs. SCE (*c*).

associated with successive one-electron oxidation of TPPCo. In comparing Figs. 5*a* and *b* for one- and two-electron oxidation of TPPCo, it is evident that the porphyrin ligand vibrations in the region 1200 to 1700 cm^{-1} undergo very little perturbation on removal of one electron from the complex, while major perturbation of the ligand vibrations are observed on the loss of a second electron. It seems unreasonable to suggest that the porphyrin ligand vibrations would be more strongly affected by electron loss from the metal than from the ligand itself, and so these data force the conclusion that, at least under the conditions of these experiments, the first one-electron oxidation is metal-centered while the second electron derives from the porphyrin ring.

The difference spectrum associated with loss of the second electron from TPPCo, Fig. 5*b*, displays all of the appearance and disappearance bands which accompany the formation of the π-cation radicals of the other TPP complexes investigated. By way of contrast, the one-electron oxidation product, Fig. 5*a*, lacks any observable bands in the 1210 to 1310 cm^{-1} region where bands 3A and 4A would be anticipated for cation radical formation. The absence of any band near 1280 cm^{-1}, in particular, tends to confirm that the first oxidation of the Co(II) complex results in the formation of a Co(III) species.

The difference spectrum of Fig. 5*a* does indicate a sharp appearance feature at 1005 cm^{-1}, in the region where band 5A is anticipated for cation-radical formation, and a weaker appearance feature at 1363 cm^{-1}, in the region where band 2A is anticipated for ring oxidation. As was noted above, these bands are associated with an increase in the intensity of bands also present in the unoxidized complex. Increasing the charge on the metal center may thus result in the same type of perturbation responsible for the change in intensity of these bands as that due to removal of an electron from the porphyrin ring itself. The extent of the perturbation due to metal oxidation is much less than that due to ring oxidation, however, as evident in comparing Figs. 5*a* and 5*b*.

Also apparent in Fig. 5*a* are two strong bands at 1127 and 1044 cm^{-1}. As above, these are indicative of perchlorate coordination, and provide strong evidence that oxidation of the Co(II) center to Co(III) is accompanied by complexation of supporting electrolyte perchlorate.

The difference spectrum associated with removal of three electrons from TPPCo is illustrated in Fig. 5*c*. In comparing Fig. 5*b* and 5*c*, it is apparent that the third oxidation results in a shift of bands 2A and 3A to higher frequency and a new appearance band at 1606 cm^{-1}. As noted above, these changes are similar to those observed on formation of the π-dications of TPPMg and TPPZn, supporting the assignment of the third oxidation process as ring-centered.

It is also apparent in Fig. 5 that the extent of perchlorate complexation increases with the number of electrons removed from the porphyrin complex, as indicated by the increase in intensity of appearance bands near 1127 and 1040 cm^{-1}. TPPCo complexes with two axially bound ligands are well known. Thus, it is entirely feasible, particularly for the π-dication, that two perchlorates coordinate to yield an overall six-coordinate species. The splitting of these two bands also increases with oxidation state. The band positions are 1127 and 1044 cm^{-1} for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/07/12
For personal use only.

the Co(III) complex, 1127 and 1040 cm^{-1} for the π-cation radical, and 1131 and 1033 cm^{-1} for the π-dication. The extent of splitting may thus be correlated with the strength of perchlorate binding, although our data are as yet too limited to assess the usefulness of this criterion. The opposite trend, for instance, appears to hold for coordination of perchlorate to TPPMg cation-radical and dication, as evident in comparing Figs. 2*a* and 2*b*. The signal-to-noise ratio associated with the perchlorate bands at 1143 and 1034 cm^{-1} in Fig. 2*a* is too low to allow high precision in determination of the band positions, however.

It should be noted that, while the *in-situ* FTIR studies leave little doubt that the first oxidation of TPPCo under the conditions employed in this study is a metal-centered oxidation of Co(II) to Co(III), the one-electron oxidation product of TPPCo isolated with $SbCl_6^-$ as counterion has been characterized (15), on the basis of uv–vis and magnetic susceptibility data as well as an infrared band at 1290 cm^{-1}, as a π-cation radical containing Co(II). It has been demonstrated, however, that the site of oxidation in OEPCo(II) complexes (OEP = octaethylporphyrin) is highly dependent on the axial coordination environment of the metal center, and both OEPCo(III) and $OEP^{+\cdot}$Co(II) complexes are known (16). In the present case, the coordination of perchlorate, as clearly evident in the infrared data presented above, may be sufficiently more stabilizing to Co(III) than when $SbCl_6^-$ is present as counterion to direct loss of an electron from the metal center rather than the porphyrin ring. Coordination of trace water from the solvent is another possibility which, although there is no evidence to support it, cannot be ruled out as a contributing factor on the basis of our data. Coordination of water is believed to be important in determining the electron-transfer site in OEPCo(II) complexes (16).

Conclusions

The data presented above clearly supports previous workers' conclusions that infrared spectroscopy is a valuable tool for ascertaining the site of oxidation in TPP complexes (1, 2), and further demonstrate that such useful diagnostic evidence can be obtained *in situ* without isolation of the oxidized complexes. In addition to the obvious factor of convenience, *in-situ* characterization affords a difference spectrum in which small vibrational perturbations due to oxidation of the complexes are more likely to be observed than in single spectra of isolated species. The extra features observed in the difference spectra of this study indicate that the similarity of changes in vibrational structure accompanying oxidation of the porphyrin ring in TPP complexes goes beyond just the appearance of a band near 1280 cm^{-1}. Finally, *in-situ* FTIR spectroelectrochemistry provides evidence concerning coordination changes associated with the oxidation as they pertain in solution, rather than in the solid state. Such information cannot unambiguously be gleaned from spectra of isolated species.

Études des propriétés adsorbantes des fibres d'amiante modifiées et de fibres proposées comme substitut à l'amiante par chromatographie en phase gazeuse

YVES LEFEBVRE, MARYSE LAMBERT, JALEH KHORAMI ET HUGUES MÉNARD[1]

Département de chimie, Université de Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Reçu le 15 avril 1987[2]

YVES LEFEBVRE, MARYSE LAMBERT, JALEH KHORAMI et HUGUES MÉNARD. Can. J. Chem. **66**, 1596 (1988).

L'étude, par chromatographie en phase gazeuse, des tracés des isothermes d'adsorption du benzène sur les fibres d'amiante brutes et modifiées ainsi que sur des fibres proposées comme substitut à l'amiante, montre une différence marquée de comportement entre les différents adsorbants utilisés. La comparaison entre le pouvoir adsorbant des fibres d'amiante brutes, d'amiante phosphatées et d'amiante chauffées à 700°C, vis-à-vis de solutés ayant des groupements fonctionnels variables, a mis en évidence des phénomènes de physisorption et de chimisorption. La présence de groupements hydroxyles situés sur la surface des fibres d'amiante favorise l'adsorption de molécules organiques par la formation de liaisons hydrogènes.

YVES LEFEBVRE, MARYSE LAMBERT, JALEH KHORAMI, and HUGUES MÉNARD. Can. J. Chem. **66**, 1596 (1988).

A study, by vapor phase chromatography, of the adsorption isotherms of benzene on raw and modified asbestos fibers as well as on fibers proposed as substitutes for asbestos shows that there is a marked difference in the behaviour of the various fibers examined. A comparison of the adsorbing power of raw and phosphorylated asbestos fibers, as well as asbestos fibers heated to 700°C, has been made regarding their behaviour toward solutes bearing various functional groups, and it has shown the existence of physical adsorption as well as chemisorption. The presence of hydroxyl groups in the surface of the asbestos fibers favors the adsorption of organic molecules through hydrogen bonding.

Introduction

L'activité biologique des fibres d'amiante chrysotile est bien connue, et l'existence d'un effet synergique entre les fibres et les agents toxiques et (ou) cancérogènes a été démontrée par de nombreux chercheurs (1–3).

Parmi les facteurs responsables de l'activité biologique des fibres d'amiante chrysotile, la réactivité de la surface des fibres a été particulièrement soulignée. Plusieurs chercheurs ont entrepris leurs recherches dans le but de changer la composition chimique de la surface des fibres d'amiante (4, 5).

Parmi ces procédés, la phosphorylation des fibres, proposée et mise au point par Lalancette et Dunnigan (6), a connu beaucoup de succès. L'activité biologique de lamiante phosphaté est en effet diminuée de façon remarquable (7) et la réaction gaz–solide « $POCl_3$ vapeurs – amiante » permet la formation de polyphosphates qui encapsulent et obstruent les pores de ce minerai (8 et 9). Ménard *et al.* (10) ont également démontré que l'adsorption des hydrocarbures aromatiques polycycliques, en milieu liquide, sur l'amiante phosphaté est nettement diminuée.

Dans cette étude, nous présentons les mesures d'adsorption de différents hydrocarbures, avec groupements fonctionnels variables, sur l'amiante phosphaté, en utilisant la chromatographie en phase gazeuse. Ces résultats sont comparés avec ceux des fibres d'amiante brutes et chauffées à 700°C.

Nous avons aussi comparé les isothermes d'adsorption obtenus de l'amiante et de l'amiante modifié avec les isothermes de fibres synthétiques proposées comme substituts (par exemple Kevlar et carbone) (11) ainsi qu'avec un gel de silice utilisé comme support chromatographique de référence.

Partie expérimentale

Nous avons utilisé un chromatographe à gaz muni d'un détecteur à ionisation de flamme de la compagnie Perkin Elmer modèle 3920B pour mesurer les isothermes d'adsorption, en utilisant l'hélium comme gaz vecteur et nous avons éliminé les traces d'eau et le gaz carbonique avec un tamis moléculaire 13X.

Pour les injections, nous avons utilisé deux seringues Hamilton de 1 μL et de 10 μL. Le volume mort de la colonne est mesuré par injection de méthane.

Les tracés chromatographiques sont enregistrése via un intégrateur Hewlett Packard modèle 3390A.

Les isothermes d'adsorption sont mesurés à l'aide d'une série d'injections de benzène variant entre 0.1 et 5 μL, utilisant la méthode du maximum du pic. Les enthalpies isostériques d'adsorption sont obtenues en appliquant l'équation de Clausius–Clapeyron (12, 13) pour une série des isothermes obtenus à des températures variables.

Description des supports utilisés

1. L'amiante BC4-T provenant de la mine « British Canadian », a été défibrilé mécaniquement à l'aide d'un appareil B.O.P. (Ball Opener Penmen) et séché à 400°C.
2. L'amiante phosphaté a été préparé suivant les procédé de Lalancette et Dunnigan (6). Il faut noter que ces fibres ont été calcinées à 350°C après la réaction.
3. L'amiante traité thermiquement a été préparé par le chauffage de l'amiante à 700°C pendant 24 h.
4. Les fibres de carbone, Thornell grade VMA IIA. Ces fibres ont été broyées au mortier puis séchées à 400°C.
5. Les fibres de Kevlar, Dupont grade 6F-218, ont été séchées à 200°C, une température modérée pour éviter la décomposition thermique de ces fibres.
6. Le gel de silice, Merck, type 60, grade ART 9385, a été séchée à 300°C. La taille des particules se situe entre 40 et 63 μm.

Les traitements thermiques des supports entre 200 et 400°C éliminent les impuretés, comme l'eau sous forme moléculaire, éventuellement présentes sur la surface ou dans les pores des supports utilisés.

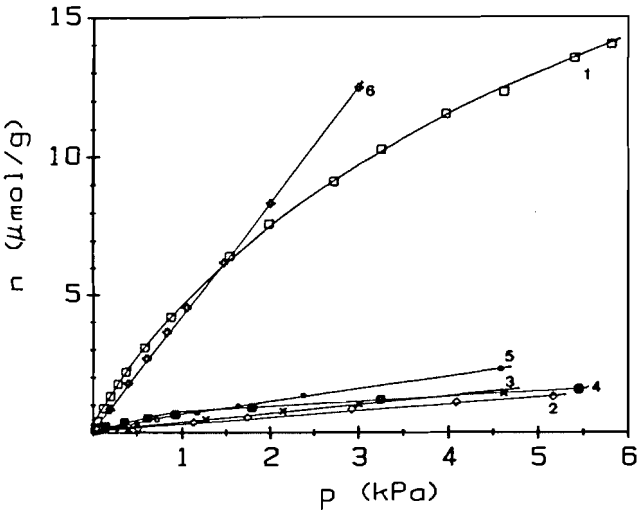

FIG. 1. Isotherme d'adsorption du benzène à 180°C exprimée avec la masse d'absorbant utilisée sur divers supports ; (1) amiante BC4-T, (2) amiante phosphaté, (3) amiante chauffé à 700°C, (4) fibre de carbone, (5) fibre Kevlar et (5) gel de silice.

Résultats et discussion

Isothermes d'adsorption du benzène

Les figures 1 et 2 représentent les isothermes d'adsorption du benzène sur les différents supports utilisés. Sur la figure 1, la quantité adsorbée *n* est exprimée par unité de poids de support utilisé, en fonction de la pression partielle de benzène en kPa. La quantité adsorbée peut être également exprimée par unité de surface de l'adsorbant (figure 2), en faisant intervenir les valeurs de surface spécifique mentionnées au tableau 1 ; cette représentation permet une meilleure interprétation de la réactivité de la surface ou des sites de surface. Nous pouvons observer sur la figure 2*a* que les fibres de carbone, qui sont actives biologiquement (14), possèdent la plus grande affinité pour le benzène.

L'adsorption du benzène sur les fibres de chrysotile brutes BC4-T est située en deuxième rang après les fibres de carbone ; cependant, les deux supports de l'amiante phosphaté et chauffé n'adsorbent que très peu de benzène et leurs isothermes d'adsorption sont situés dans le bas de l'échelle comme le Kevlar et la silice. La figure 2*b* montre une expansion sur l'axe *y* (ordonnée) pour mieux distinguer les isothermes d'adsorption des produits très peu adsorbants ; ce graphique nous montre aussi la linéarité de l'isotherme d'adsorption de la silice.

Pour obtenir la figure 3, nous avons appliqué le modèle de Langmuir (15) aux isothermes non-linéaires. Les tracés de p/Γ (ou Γ est la quantité adsorbée par unité de surface) en fonction de *p* montrent une adsorption en deux étapes mise en évidence par l'obtention de deux lignes brisées pour tous les adsorbants fibreux utilisés. Un isotherme de Langmuir typique ne donnerait qu'une seule droite. Un comportement similaire avait été observé par Contour *et al.* (16) dans le cas de l'adsorption de la diéthylaniline sur les fibres d'amiante chrysotile lors d'une étude par chromatographie en phase gazeuse. Dans un premier temps, l'adsorption se produit sur la surface externe des fibres. Un phénomène de condensation capillaire à l'intérieur des pores est reponsable de la deuxième étape de l'adsorption. Ce phénomène est souvent rencontré pour les adsorbants qui possèdent une large distribution de taille et de forme des pores.

L'isotherme d'adsorption de la silice étant linéaire (figures 1 et 2*b*), nous n'avons pas pu appliquer le modèle de Langmuir pour ce produit (14).

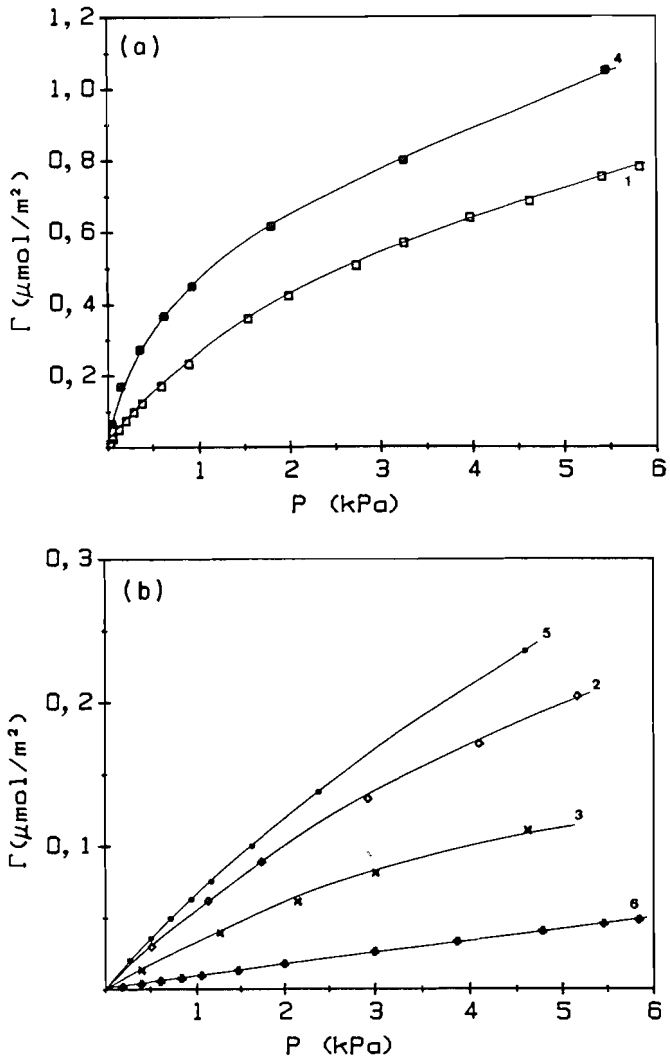

FIG. 2. Isotherme d'absorption du benzène à 180°C exprimée an excès de surface ; (1) amiante BC4-T et (4) fibre de carbone. (b) Isotherme d'absorption du benzène à 180°C exprimée en excès de surface, avec expansion en ordonnée ; (2) amiante phosphaté, (3) amiante chauffé à 700°C, (5) fibre Kevlar et (6) gel de silice.

TABLEAU 1. Surface spécifique (Σ) des adsorbants utilisés

Adsorbant	Σ (m^2/g)
Amiante BC4-T	18,0
Amiante phosphaté*	6,5
Amiante chauffé à 700°C	12,9
Silice	480
Fibre de carbone	1,5
Fibre Kevlar	9,8

*Contient 1,1% en poids de phosphore.

L'affinité de l'amiante chrysotile brut et modifié vis-à-vis les différents solutés

Dans un premier temps, les enthalpies isostériques moyennes d'adsorption (12) du benzène pour les trois échantillons de l'amiante BC4T brut, phosphaté et chauffé à 700°C, sont mesurées (tableau 2). Durant les expériences, nous avons constaté que nos mesures sont limitées en ce qui concerne les

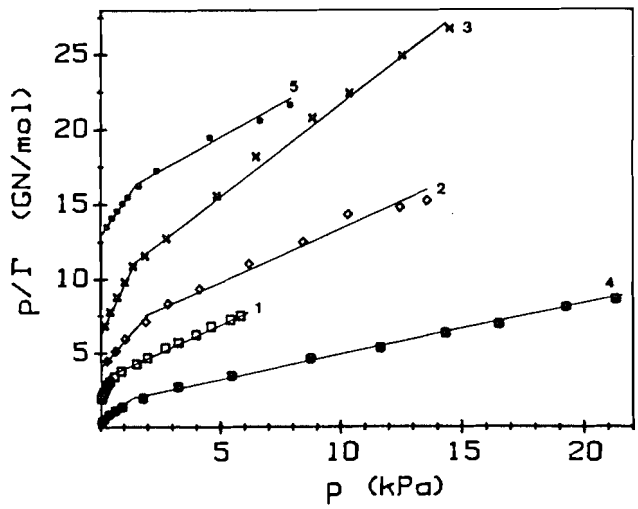

FIG. 3. Modèles théoretiques de Langmuir pour l'adsorption du benzène sur divers adsorbants; (1) amiante BC4-T (180°C), (2) amiante phosphaté (120°C), (3) amiante chauffé à 700°C (120°C), (4) fibre de carbone (180°C) et (5) fibre Kevlar (180°C).

TABLEAU 2. Enthalpies isostériques moyennes d'adsorption du benzène sur l'amiante et l'amiante modifié

Adsorbant	$-\Delta H$ (kJ/mol)	T (°C)
Amiante BC4-T	58 ± 1	210
Amiante phosphaté	50 ± 4	125
Amiante chauffé à 700°C	37 ± 2	150

échelles de température utilisées pour chaque support. Nous avons constaté que pour l'amiante BC4-T brut, le temps de retention mesurable se situe durant l'expérience entre 180 et 240°C, pour l'amiante phosphaté entre 90 et 140°C et pour l'amiante traité thermiquement entre 120 et 180°C. Le tableau 2 présente les isostériques moyennes d'adsorption du benzène sur les trois types d'amiante avant et après modification.

Néanmoins les enthalpies isostériques moyennes mesurées à la température moyenne pour chaque support, montrent une diminution de l'affinité de l'amiante après modification, surtout après traitement thermique à 700°C. Ceci provient probablement de la modification structurale intervenant à cette température (transformation chrysotile → forstérite).

Le tableau 3 illustre les volumes de rétention spécifiques mesurés sur l'amiante et l'amiante modifié, pour différents solutés ayant des groupements fonctionnels variables.

Nous pouvons constater que les volumes de retention spécifiques mesurés étant faibles pour le *n*-hexane et cyclohexane, nous n'avons pas pu observer une différence marquée entre les trois adsorbants. Cependant dans le cas du benzène et du toluène, une diminution marquée des volumes de rétention est observée. Pour les solutés ayant des groupements fonctionnels azotés et oxygénés, nous avons observé une adsorption significative pour les trois adsorbants de façon que dans plusieurs cas le pic chromatographique n'est même pas élué. Ce dernier peut être interprété comme une interaction très forte entre les trois supports et les groupements azotés et oxygénés des solutés et (ou) une chimisorption.

La diminution des volumes de rétention de l'amiante modifié

TABLEAU 3. Volumes de rétention spécifiques mesurés sur l'amiante et l'amiante modifié

	V(mL/g)		
	Support (température de la colonne)		
Soluté	Amiante BC4-T (180°C)	Amiante phosphaté (100°C)	Amiante chauffé à 700°C (100°C)
n-hexane	1,11	1,40	1,07
Cyclohexane	0,86	1,32	0,97
Dichlorométhane	1,89	0,64	0,95
Benzène	7,06	2,67	2,74
Toluène	19,44	5,85	6,67
Tétrahydrofuranne	11,47	N.E.*	N.E.*
Acétone	32,08	N.E.	N.E.
Méthanol	N.E.	N.E.	N.E.
Acétonitrile	N.E.	N.E.	N.E.

*Même résultat à 180°C.
N.E. Le pic chromatographique n'est pas élué.

(phosphaté et chauffé) vis-à-vis de benzène et toluène met en évidence l'intervention des groupements hydroxyles dans des liaisons hydrogènes par l'intermédiaire des électrons π de ces molécules. Il faut noter que dans le cas de l'amiante phosphaté, les groupements hydroxyles sont déjà engagés dans une intéraction entre $POCl_3$ et l'amiante et que la surface de l'amiante est encapsulée par les produits phosphatés formés. L'amiante chauffé à 700°C est presque complètement déhydroxylé et les groupements OH de la surface ont été expulsés sous forme d'eau à l'extérieur de la structure. L'interaction faible et la diminution légère de volumes de rétention dans le cas de dichlorométhane peut être reliée à la polarité de cette molécule. Pour le *n*-hexane et le cyclohexane l'absence des groupements fonctionnels et d'électrons π conduit à une affinité et une adsorption très faible entre ces solutés et les supports étudiés.

Conclusion

Les tracés des isothermes par chromatographie en phase gazeuse du benzène sur l'amiante brut et modifié montrent la grande affinité de l'amiante non traité pour le benzène et la probabilité de la formation des liaisons hydrogènes par l'intermédiaire des électrons π et les groupements hydroxyles. Nous avons aussi observé que les fibres de carbone actives biologiquement, adsorbent une quantité significative de benzène.

La comparaison des enthalpies isostériques moyennes d'adsorption du benzène sur l'amiante avant et après modification montre l'affinité accrue des fibres brutes pour le benzène et une diminution d'adsorption après modification surtout pour les fibres chauffées à 700°C.

La comparaison du pouvoir adsorbant des trois supports de l'amiante et l'amiante modifié vis-à-vis différents solutés organiques montre la possibilité de chimisorption par l'intermédiaire des groupements fonctionnels azotés ou oxygénés ainsi que la formation des liaisons hydrogènes entre les hydroxyles de l'amiante et les électrons π de ces molécules comme nous avons expliqué dans le cas de benzène.

X-Ray structure determination of 1,2-anhydro-3,4:5,6-di-*O*-isopropylidene-1-*C*-nitro-D-mannitol

WALTER A. SZAREK,[1] GEORGE W. HAY, RAMESH K. SOOD, KONIA TROUTON, AND SUZANNE FORTIER
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received October 13, 1987

WALTER A. SZAREK, GEORGE W. HAY, RAMESH K. SOOD, KONIA TROUTON, and SUZANNE FORTIER. Can. J. Chem. **66**, 1600 (1988).

The structure of the major product of the reaction of 1,2-dideoxy-3,4:5,6-di-*O*-isopropylidene-1-*C*-nitro-D-*arabino*-hex-1-enitol with 30% hydrogen peroxide and aqueous sodium hydrogencarbonate has been confirmed by X-ray crystallography to be that of 1,2-anhydro-3,4:5,6-di-*O*-isopropylidene-1-*C*-nitro-D-mannitol (*2*). The crystal structure of **2**, $C_{12}H_{19}NO_7$, is orthorhombic, $P2_12_12_1$, with cell dimensions $a = 10.269(3)$, $b = 15.115(7)$, $c = 9.295(8)$ Å, and $Z = 4$. The calculated density is $D_x = 1.336\ g\ cm^{-3}$. The structure was solved by direct methods and refined to a residual $R = 0.052$. The molecule has a $_2G^-$ conformation having bond lengths and angles in agreement with those observed in related structures, except for the C(1)—C(2), C(2)—C(3), and O(2N)—N bond distances which were found to be unusually small.

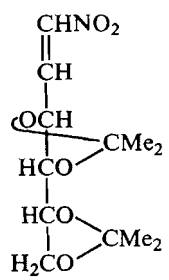
WALTER A. SZAREK, GEORGE W. HAY, RAMESH K. SOOD, KONIA TROUTON et SUZANNE FORTIER. Can. J. Chem. **66**, 1600 (1988).

Faisant appel à la diffraction des rayons-X, on a démontré que le produit principal de la réaction du didéoxy-1,3 di-*O*-isopropylidène-3,4:5,6 nitro-1-*C* D-*arabino*hexène-1 itol avec du peroxyde d'hydrogène à 30% et du carbonate acide de sodium aqueux est l'anhydro-1,2 di-*O*-isopropylidène-3,4:5,6 nitro-1-*C* D-mannitol (**2**). La structure cristalline du composé **2**, $C_{12}H_{19}NO_7$, est orthorhombique, $P2_12_12_1$, avec $a = 10{,}269(3)$, $b = 15{,}115(7)$ et $c = 9{,}295(8)$ Å et $Z = 4$. La densité calculée, D_x, est égale à $1{,}336\ g\ cm^{-3}$. On a résolu la structure par des méthodes directes et on l'a affinée jusqu'à une valeur résiduelle de $R = 0{,}052$. La molécule existe dans une conformation $_2G^-$ dont les longueurs des liaisons et les angles sont en accord avec ceux observés dans des structures semblables; on a toutefois observé que les longueurs des liaisons C(1)—C(2), C(2)—C(3) et O(2N)—N sont très courtes.

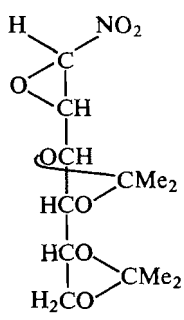
[Traduit par la revue]

Introduction

Syntheses of 2-deoxy-2-fluoro-D-glucose (1), or its ^{18}F-labeled analog (2), currently are of significant interest because of the application of the latter to the study of human metabolic processes by positron emission tomography (2). Recently, we reported (1) that 1,2-dideoxy-3,4:5,6-di-*O*-isopropylidene-1-*C*-nitro-D-*arabino*-hex-1-enitol (**1**) (3) reacted with 30% hydrogen peroxide and aqueous sodium hydrogencarbonate (4) to give a 1,2-anhydro derivative which, when treated with anhydrous potassium hydrogenfluoride, afforded a mixture of 2-deoxy-2-fluoro-3,4:5,6-di-*O*-isopropylidene-*aldehydo*-D-hexoses having the *gluco* and *manno* configurations in a ratio of approximately 4:1, respectively. Although this result, and other concurrent chemical evidence (1), strongly inferred that the 1,2-anhydro compound had the D-*manno* configuration (see **2**), there was some ambiguity[2] concerning the chirality of C(1) and C(2) which could not be resolved by the nmr data; the synthetic route, however, made the assignment of the absolute configurations of C(3)—C(5) completely unequivocal.



1



2

This problem has been solved by the determination of the crystal structure of the 1,2-anhydro compound described in ref. 1 by X-ray diffractometry. We present here the evidence which substantiates the structure of the 1,2-anhydro compound as **2**.

Results and discussion

The results of the X-ray diffraction studies (Tables 1–4) confirmed that the epoxidation (1, 4) of **1** afforded a product having a *manno* configuration. Although the X-ray data determined only the relative positions of the atoms, the certainty with respect to the chirality of C(3)—C(5) unambiguously established the absolute configuration as corresponding to D-*manno*, identical with that represented by structure **2** (see Fig. 1).

As expected, C(1) and C(2), which form part of an oxirane ring, have bond angles close to 60° and a bond distance (Table 3) similar to that reported (1.445(6) Å) (6) for the correspondent bond of 3,4-di-*O*-acetyl-1,2:5,6-dianhydrogalactitol. The remainder of the carbon atoms of the hexitol chain, each of which is involved in a 1,3-dioxolane ring, have bond angles (Table 3) which are nearly commensurate with those of DL (7), and the β (8) and K (9) forms of mannitol; the C(3)—C(4)—C(5) bond angle is ~1°[3] larger and the C(4)—C(5)—C(6) bond angle is ~1° smaller, relative to those compounds.

A salient feature of **2** in the crystalline state is the proximity of C(1), C(2), and C(3) (Table 3). The C(1)—C(2) bond distance (1.441(4) Å) is equal to that estimated (10) for tetrafluoroxirane. This is significantly shorter than the comparable bond of oxirane (1.462(3) Å) (11–13), (1*a*α, 2β, 2*a*β, 4α,

[a]$B_{eq} = (4/3)\Sigma_i\Sigma_j\beta_{ij}(\boldsymbol{a}_i \cdot \boldsymbol{a}_j)$.

7α, 7aβ, 8β, 8aα)-octahydro-4,7-epoxy-2,8-methanooxireno[*h*][3]benzoxepin-3(4*H*)-one (1.462 Å) (14), and 1,2:5,6-dianhydrogalactitol (1.453(5) Å) (6), and is similar to that of methyl 3,4-anhydro-1,6-bis-*O*-(*p*-toluenesulfonyl)-β-D-tagatofuranoside (1.45(1) Å) (15). The C(2)—C(3) bond distance (1.484(4) Å) is 0.02 Å shorter than even the correspondent bond of 1-*O*-acetyl-2,3:4,5-di-*O*-isopropylidene-D-*erythro*-pent-1-enitol (16) which incorporates a nominally sp^2-hybridized carbon atom. The bond is similar in length to (although shorter than) some C—C bonds of certain isopropylidene substituents of carbohydrates (16–19), and is commensurate with the C(2)—C(3) bond of one molecule of dimorphic 3,4-di-*O*-acetyl-1,2:5,6-dianhydrogalactitol (1.484(5) Å) (6). To our knowledge, the only C—C bonds of carbohydrate chains which are shorter than the C(2)—C(3) bond of **2** (oxirane rings excepted) are the singular C(3)—C(4) bond of 1,4:1′,4′:3,6:3′,6′-tetraanhydro-5,5′-*O*-oxydiethylene-2,2′-*O*-[pyridine-2,6-diylbis(methylene)]-di-D-mannitol (1.474(5) Å) (20), and the C(2)—C(3) (1.475(2) Å) (21) and C(4)—C(5) (1.480(2) Å) bonds of 1,2:3,4:5,6-trianhydro-D-iditol (21).

The usual value for the length of a paraffinic C—C bond is 1.537 Å (22), and in carbohydrate rings the C(sp^3)—C(sp^3) bonds exhibit a normal range of 1.516–1.540 Å (23). It is well known that macrocyclic and acyclic polyethers (24–29) and macrocyclic thioethers (30) possess C—C bonds which are much shorter than those expected with tetrahedral carbons. Uncomplexed tetrathia-12-crown-4, pentathia-15-crown-5, and hexathia-18-crown-6 have C—C bond distances in the range 1.440–1.528 Å (30), and uncomplexed 18-crown-6 has been reported to have a mean C—C bond distance of 1.507 (24) to 1.519 Å (31), depending on the corrections applied for internal molecular motions; complexation with alkali metals results in further diminution of the C—C bond distances (32, 33), yet, except for the cesium complex (33), even those atypical bonds exceed the length of the C(2)—C(3) bond of **2**. With respect to those polyethers, it has been noted (24, 26, 27, 31) that inadequate treatment of thermal motion may lead to spurious values for bond lengths. However, even critical assessment of such data (31) afforded unusually small bond distances, which may be attributed (27) to inductive effects originating at adjacent polarized bonds.

In pyranoid systems the diminution of some acetal C—O bond lengths has been associated (34–38) with increased effective electronegativity of the exocyclic oxygen, and stereoelectronic effects involving the donation of electrons by the endocyclic oxygen to the anomeric carbon atom (34–37), thereby shortening the O—C(1) bond of the ring and lengthening the exocyclic C(1)—O bond. As well, it has been proposed (39) that elongation of acetal C—O bonds by hydrogen bonding may result in contraction of adjacent C—O and C—C bonds.

The effect of unsaturated (40–46) and electronegative (10, 13, 40, 45–52) substituents on the bond lengths of three-membered rings has been investigated extensively. In alicyclic systems π-accepting substituents (40, 42, 46) tend to shorten the distal bond and lengthen the vicinal bonds of the ring whereas fluoro, oxo, and methylene groups (43, 46, 48, 51, 52) exert the opposite effect. In heterocyclic systems the ring C—C bond length diminishes as the electronegativity of the hetero atom increases (refs. 11, 13, 50, but see ref. 53), or as fluorine is introduced into the oxirane ring (10, 49); the replacement of H by methyl increases the C—C bond distance (47). In both cyclopropane (48, 51, 52) and oxirane (10, 49) the introduction of vicinal fluorine atoms entrains a stereochemical effect which results in the (F)C—C(F) bond being shorter in the *trans* isomer. These results have been interpreted (10, 52) as being a consequence of enhanced electron delocalization in the *trans* isomer, based on consideration of the contributing molecular orbitals. In the course of CNDO/2 investigations (44, 45) of a large number of derivatives of oxirane, calculations of orbital hybridization (44) in oxiranemethanol indicated that the exocyclic C—C bond had 32% *s*-character whereas the ring C—C bond had 23%. If this hybridization were applicable to the

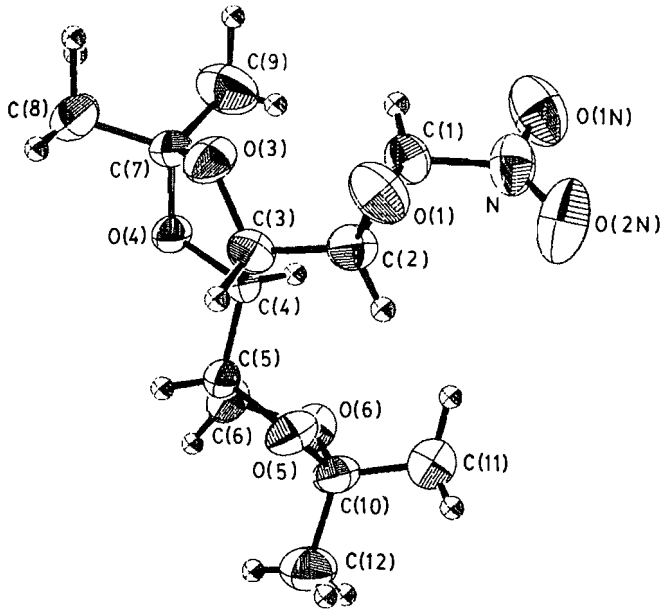

FIG. 1. The molecular structure of 1,2-anhydro-3,4:5,6-di-*O*-isopropylidene-1-*C*-nitro-D-mannitol (**2**).

C(2)—C(3) bond of **2** the contribution of such sp^2-hybridized atoms would afford a convenient explanation of its bond distance, which is intermediate to those of $\sigma(sp^2, sp^2)$ and $\sigma(sp^3, sp^3)$ molecular orbitals (22). However, in contrast to the cyclopropane ring (42), little conjugation has been detected (45) between the atoms of the oxirane ring and the π-electrons of substituents; with oxirane derivatives it was conjectured (45) that electron density distribution may be affected by intermolecular interactions. The ring C—C bond of tetracyanooxirane (41) is longer than that of oxirane and it was postulated (41) that this may be due to a weakening of the C—C bond by electron withdrawal. This may also be the case with nitrooxirane for which the C—C bond has been found (45) to be weaker than that of oxirane. Inasmuch as **2** incorporates an α-nitroepoxide and two 1,3-dioxolane rings, every carbon atom of the carbohydrate chain bears at least one strongly electronegative (54) substituent each of which possesses non-bonding or π-electrons, and the combination of factors contributing to the molecular dimensions may be very complex. Now that the molecular parameters of **2** have been established, the explanation for the proximity of C(1), C(2), and C(3) must await further theoretical studies.

The O(2N)—N bond distance (1.175(4) Å) is abnormally short and differs from the typical O(1N)—N bond distance (1.216(4) Å) by a factor greater than three times the estimated standard deviation. In an effort to explain this difference, a calculation of intermolecular atomic distances was performed; however, no close contact was evident.

The shape of **2** in the crystalline state (Fig. 1, Table 4) approximates the $_2G^-$ (55) sickle (56) conformation, although it is recognized that the carbon atoms of the sequence C(3)—C(4)—C(5)—C(6) are not coplanar: C(4) is +ac (57) with reference to C(1), C(5) is +ac to C(2), and C(6) is −ap to C(3); O(1) and O(3) are +sc (*gauche*), but O(4) and O(5) are −ap. The two acetal rings have very similar geometries, the O(3)—C(3)—C(4)—O(4) torsion angle being −25.6° (Table 4) and that for O(5)—C(5)—C(6)—O(6) being −24.5°; thus, each dioxolane ring is in a ^1E (58–60) conformation. This conformation of **2** agrees closely with that indicated by the ^{1}H-nmr data (1) for **2** in chloroform solution. It is noteworthy that, in the case of **2**, the value of $J_{1,2}$ (1) is not a useful criterion for determining the configurations of C(1) and C(2), although it is fully consistent with the assigned structure. The low (<1 Hz) value, which may be, in part, the consequence of the magnitude of the inductive effects, a phenomenon observed (61) with respect to ^3J values for *gauche* couplings in pyranoses, has been interpreted (5) as being indicative of a *trans* orientation. However, since both **2** and its *gluco* isomer exhibit the same value for $J_{1,2}$ (1), the configurations at those sites could be decided with certainty only on the basis of the X-ray data.

Experimental

Compound **2** was isolated (1) from ethyl acetate as colorless, orthorhombic crystals of space group $P2_12_12_1$. A single crystal, 0.40 × 0.10 × 0.10 mm, was selected for the collection of intensity data on an Enraf-Nonius CAD-4 diffractometer. The crystal data have been summarized in Table 1. The unit cell parameters were obtained by a least-squares analysis of 25-centered reflections in the range $22° < 2\theta < 38°$. The data were collected by the θ–2θ scan technique, with variable scanning rate, using graphite-monochromated MoK_α radiation. A total of 1483 unique reflections were measured in the range $1° < 2\theta < 50°$, of which 1110 having $I \geqq 3\sigma(I)$ were considered observed. Three standard reflections were measured every 7200 s of radiation time and showed no significant variation during the course of data collection. The intensities were corrected for Lorentz and polarization effects.

The structure was solved by direct methods using the program MULTAN80 (62). Difference Fourier map calculations revealed the positions of all hydrogen atoms (Table 2). Full-matrix, least-squares refinement was performed for a scale factor, and positional, and anisotropic thermal parameters of the non-hydrogen atoms. The hydrogen atoms were included in the calculations but were not refined; they were assigned isotropic thermal parameters equal in magnitude to those of the parent carbon atom. The function minimized was $\Sigma w||F_o| - |F_c||^2$ where $w = 1/\sigma^2(|F_o|)$. The refinement resulted in $R = 0.052$ and $R_w = 0.069$. The estimated standard deviation of an observation of unit weight was 2.589, the maximum shift to error ratio was 0.00, and the final difference Fourier synthesis was essentially featureless. The scattering factors used were those of Cromer and Waber (63). The anomalous dispersion coefficients were taken from the data of Cromer (64). The final atomic coordinates are given in Table 2. All calculations were performed on a PDP 11/23 computer using the structure determination package of Enraf-Nonius, SDP (65). The program ORTEP (66) was used for the preparation of the illustration (Fig. 1).[4]

Conductance behavior of some electrolytes in tetramethylurea

E. M. HANNA[1] AND A. A. TOSSONIAN
Department of Chemistry, University of Basrah, Basrah, Iraq

Received January 26, 1987[2]

E. M. HANNA and A. A. TOSSONIAN. Can. J. Chem. **66**, 1605 (1988).

Conductance investigations have been done at 25°C on tetramethylurea solutions containing NaI, KI, RbI, CsI, NH_4I, LiBr, NaBr, NH_4Br, or LiCl in the concentration range $2.0 \times 10^{-4} - 3.6 \times 10^{-3}$ *M*. The conductance data have been analyzed using the full equations of Pitts, Fuoss, and Lee–Wheaton for the conductivity of free ions. The best-fit values of Λ_0 are consistent with strong cation solvation and weak anion solvation by tetramethylurea. The K_A values indicate that these salts are associated electrolytes in this solvent.

E. M. HANNA et A. A. TOSSONIAN. Can. J. Chem. **66**, 1605 (1988).

Opérant à 25°C et à des concentrations allant de $2{,}0 \times 10^{-4}$ à $3{,}6 \times 10^{-3}$ *M*, on a déterminé la conductance de solutions de tétraméthylurée contenant les sels suivants : NaI, KI, RbI, CsI, NH_4I, LiBr, NH_4Br ou LiCl. On a analysé les données à l'aide des équations complètes de Pitts, Fuoss et Lee–Wheaton pour des ions libres. Les meilleurs ajustements de Λ_0 sont en accord avec une solvatation forte des cations et une solvatation faible des anions par la tétraméthylurée. Les valeurs des K_A indiquent que, dans ce solvant, ces sels sont des électrolytes associés.

[Traduit par la revue]

Introduction

Tetramethylurea (TMU) is a colourless mobile liquid, commercially available, and readily purified. It is a good solvent for a number of organic and inorganic compounds. Its physical properties at 25°C (mp, −1°C; bp, 176.5°C; density, 0.9616 g cm^{-3}; viscosity, 0.01402 P; and dielectric constant, 23.50) indicate it to be one of the interesting dipolar aprotic solvents. However, only a few studies have been done on the behavior and properties of salts in this solvent (1–6). Therefore, in this work conductance investigations were extended to more alkali metal salts to explore the influence of molecular structure, viscosity, and dielectric constant in determining properties of electrolytes in nonaqueous solvents.

Experimental

Solvent

The main impurity in nonaqueous solvents is water. Tetramethylurea purchased from Merck was purified by vacuum distillation at 0.4 mm Hg through a heated fractionating column. Only the middle 80% of the distillate was collected. Dry nitrogen was used in all transfers. The middle fraction from the first distillation was collected over 4A molecular sieves, decanted after 24 h, and then distilled over another quantity of molecular sieves from which the solvent was again freshly distilled before use. The specific conductivity of freshly distilled solvent was in the range $(2–4) \times 10^{-8}$ S cm^{-1}. Water content of the purified TMU by Karl Fischer titration was 0.001%.

A viscosity of 0.01402 ± 0.001 P was determined at 25°C with size 25 Ostwald type viscometer. With 50 cm^3 density bottle a density of 0.9616 ± 0.0002 g cm^{-3} was determined for TMU at 25°C. A dielectric constant of 23.50 ± 0.01 was determined for TMU with a Wissenschaftlich–Techniche–Workstalten dipole meter DMO1 using MFL3 cell. A Forma 2160 thermostat bath filled with water and maintained at 25.00 ± 0.01°C was used in the viscosity, density, and dielectric constant determinations. Our values of viscosity, 0.01402 P; density, 0.9616 g cm^{-3}; and dielectric constant, 23.50 are in good agreement with those reported by Barker and Caruso (1) (η, 0.01401; *d*, 0.9619; ϵ, 23.45) and Okpala *et al.* (7) (η, 0.01395; *d*, 0.9616; ϵ, 23.60).

Salts

Merck (proanalysis) potassium chloride was recrystallized three times from conductivity water, dried *in vacuo*, and fused in a platinum crucible. The sample was cooled and then grounded up into a fine powder. Immediately before use, samples were dried *in vacuo* at 120°C for 6 h. Merck (suprapur) lithium chloride; sodium, potassium, rubidium, cesium, and ammonium iodide; and lithium, sodium, and ammonium bromide were used as received. Before use, samples were heated *in vacuo* at 80°C for 8 h.

Apparatus

The same conductivity bridge, conductivity cell, oil bath, and dry box are described in detail elsewhere (8). As before, the conductivity cell was of the Marsh–Stokes type (9). Dry nitrogen was passed through a three-way tap to transfer the solution between vessel and storage flask. The cell was calibrated at 25°C using the Lind–Zwoleink–Fuoss (10) empirical equation for the molar conductivity of potassium chloride. The cell constant, obtained from three independent sets of measurements, was found to be 0.6554 ± 0.0003 cm^{-1}.

All transfers of solids and solutions were made inside the dry box. A 2% decone solution was used for cleaning. Apparatus were dried overnight at 120°C. The conductivity cell was dried with a stream of dry nitrogen while hot air was passed over its outside.

For each salt, two runs with different stock solutions were made. Successive additions of stock solution to the solvent in the conductivity cell were made using a 10 cm^3 syringe. It was found that 20 min were required to re-establish thermal equilibrium. All weights were corrected to vacuo.

Results and discussion

Table 1 gives the molar conductivities Λ in S cm^2 mol^{-1} and the molar concentrations *C* in mol dm^{-3} of the nine salts studied in TMU. The experimental results were analyzed with the computer programs used previously (8).

The equations used were in the form

$$[1] \quad \Lambda = \alpha[\Lambda_0 - f(\kappa,d)]$$

$$[2] \quad K_A = (1 - \alpha)/\alpha^2 C y^2$$

$$[3] \quad -\log y = A\alpha^{1/2}C^{1/2}/(1 + Bd\alpha^{1/2}C^{1/2})$$

The adjustable parameters were the molar conductivity at infinite dilution Λ_0, the association constant K_A, and the association distance *d* within which the oppositely charged ions are considered paired. The full equations of Pitts (11), Fuoss (12), and Lee–Wheaton (13) were used for the function $f(\kappa,d)$ in eq. [1]. The values of the best-fit parameters Λ_0, K_A, and *d*

as well as σ_Λ, the standard deviation of the individual points, are given in Table 2.

As previously observed (1, 3) the conductance of iodide solutions increased with time after the addition of iodide to solvent due to solute–solvent interactions. It was found that these solutions reached a maximum conductivity after about 20 min. Thus all conductance measurements were taken after 20 min after the addition of stock solution to the content of the cell. Similar conductivity–time behavior have been observed in acetonitrile (14), pyridine (15), benzonitrile (16), and phenol (17).

The data in Table 2 support previous observation (18) that Λ_0 values obtained from the three conductivity equations are in good agreement. As expected, the molar conductivity at infinite dilution of the cation increases as the size of the cation increases, which indicates that the effective size and cation–solvent interaction becomes smaller as the crystallographic radius increases.

[a]P, Pitts equation (1953); F, Fuoss equation (1978); LW, Lee–Wheaton equation (1978).

The calculated association constants in Table 2 show that all the salts studied to be associated in TMU at 25°C. With the exception of KI, the association constants of the alkali metal iodides and bromides increase as the cation size increases, consistent with the degree of solvation of cations by TMU.

For the sake of comparison, the conductivities of LiBr, NaBr, NaI, and RbI were measured in TMU at 25°C. Our best-fit values of Λ_0 and K_A are presented in Table 3 together with those obtained by Barker and Caruso (1, 3) so that a comparison between the two sets can be made. A perusal of Table 3 reveals that, with the exception of RbI, our values of Λ_0 are about one conductance unit lower than those obtained by Barker and Caruso (1, 3). This difference is probably due to the difference in the purity of the salts and the different methods of solvent purification used. It has been shown earlier (1, 3, 14–17) that the molar conductivity of iodine solutions increases with time as the solution ages. As can be seen from Table 3, there is a disagreement about the order of Λ_0. Our values of Λ_0 increase with increasing cationic size. Barker and Caruso found that $\Lambda_0(NaI) = \Lambda_0(RbI)$. However, there is an agreement about the order of K_A which increases with increasing size of the cation. This pattern of ionic association has also been reported in hexamethylphosphotriamide (8) and in propylene carbonate (18). A reverse order of association constants has been reported in other aprotic solvents (19, 20). Table 3 also shows that our K_A values are higher than those reported by Barker and Caruso, indicating that these salts are associated in TMU at 25°C. Barker and Caruso reported a negative K_A value for NaI and concluded that the salt is unassociated in this solvent. We believe that our K_A value is more reasonable and this salt, like other salts, is associated in TMU at 25°C.

Starting from $\lambda_0(Br^-) = 30.12$ S cm^2 mol^{-1} reported in the literature (2), as obtained from transference number measurements, the values of limiting molar ionic conductances of the ions listed in Table 4 were calculated. A perusal of Table 4 reveals that ammonium and alkali metal ions are arranged in the following order of their decreasing mobility $Cs^+ > Rb^+ > K^+ \sim NH_4^+ > Na^+ > Li^+$. Table 4 also shows that the observed order for anions $Br^- > I^- > Cl^-$ is in agreement with the previous observation (2) that solvation of anions by this solvent does not follow the general pattern.

Values of solvated radii r_s of the ions tabulated in Table 4 were calculated from the Stokes equation (21)

$$[4] \quad r_s = F^2/6\pi N\eta\lambda_0 = 0.82/\eta\lambda_0$$

Values of the effective ionic radii r_s^* listed in Table 4 were calculated replacing 6 by 4 in the denominator of eq. [4]. Table 4 shows that values of r_s^* are larger than r_s values for all the ions. For cations, values of λ_0 decrease as the crystallographic radii increase, indicating once again that solvation of the cations by negative and exposed end of the solvent dipole become less firm as cation size increases. It is clear from Table 4 that the differences between r_s^* and r_s for anions (except Cl^-) are less than those for cations, indicating that anion–solvent inter-

1. Introduction

Investigations on organic semiconductors continue with high activity in view of solar energy conversion. Metal-free phthalocyanine (Pc) and many of its metal derivatives have attracted attention mainly due to their stability and their high absorption in the visible region. They were used in Schottky barrier junctions with aluminum, chromium, or indium as rectifying contacts (1–10). Heterojunction photovoltaic cells of the type ZnO or CdS/Pc were shown to have efficiencies as high as 0.22% under AM2 illumination of 75 mW cm^{-2} (11–14). Phthalocyanines have also been studied in photoelectrochemical cells (15–17) and efficiencies of up to 7×10^{-2}% have been reported for *x*-Pc under white light irradiation (75 mW cm^{-2}) (18).

Phthalocyanines are known to exist in different polymorphic forms depending on their molecular stacking arrangements in the solid state (19). It has been shown that the strong interaction in structure has a remarkable influence on the crystal habits (20). In the case of the phthalocyanine compounds, the crystal habits are determined by π electronic interaction, which binds most strongly two neighbouring planar molecules in the crystal. The resulting intermolecular forces are relatively weak and slight differences in the way of superpositioning stacked molecules are possible. Many polymorphic forms are known; they are designated by the letters α, β, *x*, ϵ, and τ. The transformation of one form to an other one (dimorphic transformation) can be affected by several techniques including thermal (21) and organic solvent treatments (22–25), acid ball-milling (26), and inert solvent grinding (27). It has been shown that the metastable α-form of metal phthalocyanine is transformed into the stable β-form through various intermediate forms depending on the properties of organic solvents and that an *x*-form appears in the weak *n*-donor solvents such as ethanol, acetone, and carbon disulfide (22, 23). The dimorphic transformations have been studied by optical spectroscopy, X-ray and electron diffraction, and electron microscopy techniques (1–10, 28). It has been also demonstrated that the dimorphic transformation reorganizes the molecular arrangement within the solids and changes in the same time the optical, electrical, and photoconductivity properties of phthalocyanines (22–25). Thus the electrical conductivity of α-form phthalocyanine is three to five times higher than that of the β-form (29), and the *x*-form of phthalocyanine is substantially more photoactive than the α- and β-forms (30).

In this paper, we would like to report a new dimorphic transformation of hydroxyaluminum phthalocyanine which is induced by a treatment with aqueous acid solutions. The new polymorph, which is characterized by infrared, near-infrared, and visible absorption spectra and by X-ray diffraction, shows enhanced photoactivity in a photoelectrochemical solar cell device.

2. Experimental section

2.1 Materials

Hydroxyaluminum phthalocyanine (PcAlOH) was prepared as follows. Chloroaluminum phthalocyanine was first synthesized by heating *o*-phthalonitrile and aluminum chloride in quinoline (31). The product was filtered after cooling and washed with acetone and then ethanol in a Soxhlet extractor. The powder was heated in aqueous ammonia solution (30%) in the presence of pyridine for 12 h to give PcAlOH. The product was then washed by repeated solvent extraction techniques with acetone, ethanol, and chloroform (14).

The α-form PcAlOH powdered crystal can be obtained by vacuum sublimation (19) or by the following procedure, showing in both cases the same X-ray diffraction patterns. The blue solid compound was completely dissolved in concentrated sulfuric acid, resulting in a viscous dark-green paste. This paste was poured slowly into a large amount of ice cube and water, and vigorously stirred, yielding a blue precipitate of PcAlOH. After filtration and repeated washing with water, the blue solid was dispersed in a large volume of water, stirred for 3 h, and filtered. This treatment was repeated several times until the pH of the filtrate was neutral.

2.2 Procedure of treatment

The main process of the transformation of hydroxyaluminum phthalocyanine was investigated with thin films which were obtained by a vacuum-condensation method. A few milligrams of the pure α-PcAlOH solid were sublimed from a small crucible of boron nitride heated with a furnace of coiled tantalum and were condensed onto glass

For personal use only.

plates, quartz plates, CaF_2 plates, AgBr plates, or polished aluminum plates kept at room temperature. The pressure in the evaporator was about 5×10^{-6} Torr. The film thickness was determined by electronic absorption spectra and referred to a standard curve obtained by profilometry with a Sloan Dektak II. The film thickness was controlled in the range of 50–5000 Å (16). For the organic solvent treatment, thin films on glass plates were placed in the vapors of the liquids held at 60°C or directly dipped in the liquids for a few minutes at room temperature. For the acid treatment, the PcAlOH films on different substrates were dipped in a 2 wt.% aqueous solution of different acids (e.g. sulfuric acid, hydrochloric acid, trifluoroacetic acid, potassium hydrogen phthalic acid, and nitrophthalic acid) which was held at room temperature.

In order to trace the transformation of PcAlOH by the acid treatment, thin films on different substrates were successively taken out of the acid solutions, extensively washed with distilled water, dried in air at room temperature, and directly examined by different techniques. Absorption spectra were recorded with a LKB 4050 spectrometer, FT-IR spectra with a Nicolet 170SX and X-ray diffraction patterns with a Siemens diffractometer D500 using a CuK_α ($\lambda = 1.54$ Å) radiation.

The transformation of PcAlOH in organic solvents and aqueous acid solution was also followed by electronic absorption spectrometry. The films on glass plates were dipped in a solution hold inside the spectrometer and the absorption spectrum was recorded at different time intervals. For infrared measurements, PcAlOH was sublimed on CaF_2 and AgBr plates. The electronic absorption spectra were recorded first to determine the film thickness and the extent of the transformation. Then only the infrared spectra were recorded.

For X-ray diffraction measurements, PcAlOH was sublimed in the same time on polished aluminum plates and glass plates. The aluminum and glass plates were treated in the same condition. The glass plates were used as references for determining any transformation process of the film on the aluminum plates.

2.3 Electrochemical measurements

The tin oxide on glass (NESA) (PPG Industries, sheet resistance $r = 250\ \Omega$/square) electrodes were cleaned before sublimation by placing them in a detergent solution, followed by subsequent rinsing with water, distilled water, and methanol. An insulating polymer was used to define a 4-cm^2 surface area. The contact with the substrate electrode was made with a copper wire and silver conducting paint (GC Electronic). All chemicals and solvents used in this work were classified as high purity and used without further purification. They were dissolved in distilled water from a Corning Megapure water distillation system. All electrolytic solutions contained 0.1 *M* Na_2SO_4 and the pH was adjusted with hydrochloric acid. The optimized concentration (32) of the redox couple $[I_3^-] = 10^{-3}$, $[I^-] = 10^{-4}$ *M* was used.

A conventional three-electrode single-compartment cell was used for the electrochemical measurements, a saturated calomel electrode (SCE) as the reference and a platinum foil (8 cm^2) as the counter electrode. Electrolytic solutions were not deaerated and measurements were performed under ambient atmosphere. The working electrode was placed at about 2 mm from the cell window to minimize the light absorption by the solution. The organic film was always directly illuminated. The white light illumination source is a 300 W ELH tungsten halogen lamp of a Kodak Ektrographic slide projector, Model AF2. Monochromatic illumination was performed with a 650 W tungsten halogen and a Schoffel Instruments monochromator. All action spectra were converted for the same photon flux incident on the film at each wavelength (N_{max}), taking into account the measured light exponent, γ, at these energies. This parameter is found in eq. [1] (30):

$$[1] \quad J_\lambda = kI^\gamma$$

where k is a proportionality constant and I is the light intensity incident on the semiconductor. In the energy range used for the action spectra (from 30 to 260 mW cm^{-2}), γ was around 0.9 and did not depend on the wavelength. The corrected short-circuit photocurrent is then calculated using eq. [2]:

$$[2] \quad J_{\lambda\ \text{corrected}} = J_{\lambda\ \text{measured}}\left(\frac{N_{max}}{N_\lambda}\right)^\gamma$$

where N_{max} and N_λ are the numbers of maximum incident photons and incident photons for the considered wavelength, respectively ($N_{max} = 8.3 \times 10^{14}$ photons $cm^{-2}\ s^{-1}$). The light intensity was measured by a United Detector Technology detector equipped with a radiometric filter.

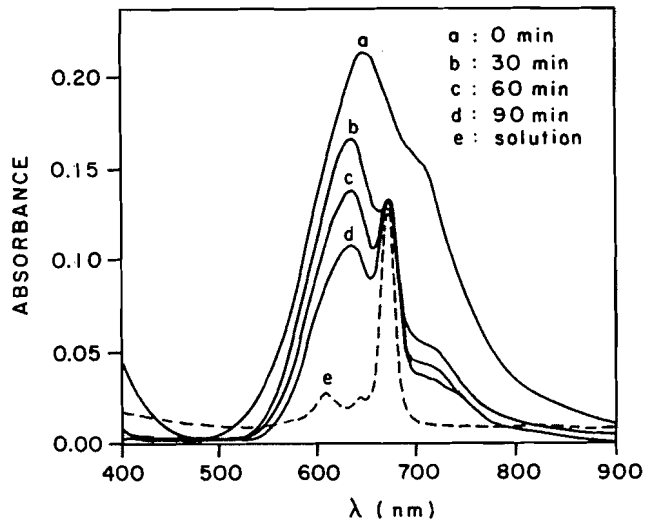

FIG. 1. Absorption spectra of PcAlOH: (*a*) solid thin film; (*b–d*) after different times of exposition to isopropanol vapour; and (*e*) solution in isopropanol.

All electrical measurements were performed in a Faraday cage. When used in the photogalvanic mode, the measurements were taken with a Keithley 616 electrometer; when used in the electrochemical and photoelectrochemical modes, the measurements were performed with a Model 362 potentiostat from Princeton Applied Research. The scanning rate was 2 mV s^{-1} for J–V measurements.

3. Results

3.1 Thin films absorption spectra

Visible absorption spectra were recorded for thin films of PcAlOH prepared by sublimation onto quartz and glass slides. Infrared spectra were recorded for similar films deposited onto calcium fluoride and silver bromide substrates.

The visible absorption spectra for thin films of PcAlOH on glass slide are shown in Figs. 1 and 2 (curve *a*). In the visible region the intense and broad Q band has a maximum at 640 nm with a shoulder at about 710 nm which are characteristic of the α-form. For comparison, the absorption spectra of PcAlOH dissolved in isopropanol is also shown in Fig. 1 (curve *e*). The relatively narrow Q band presented a maximum at 670 nm with shoulders at about 645 and 610 nm. When a thin film of PcAlOH (80 Å) was brought into contact with the isopropanol vapor at 55°C, a change of the absorption spectrum with time was observed (Fig. 1, curves *b* to *d*). A new absorption peak appears at 670 nm and increases with time, and this transformation is accompanied by the continual diminution of the 640 nm peak intensity. The variation is due probably to the transformation of the α-form to an amorphous phase and also to the slow dissolution of the solid film by the vapor of the alcohol. The observed spectrum could be, therefore, a combination of the PcAlOH solid thin film spectrum and the PcAlOH solution spectrum trapped in the thin film solid. Similar results were

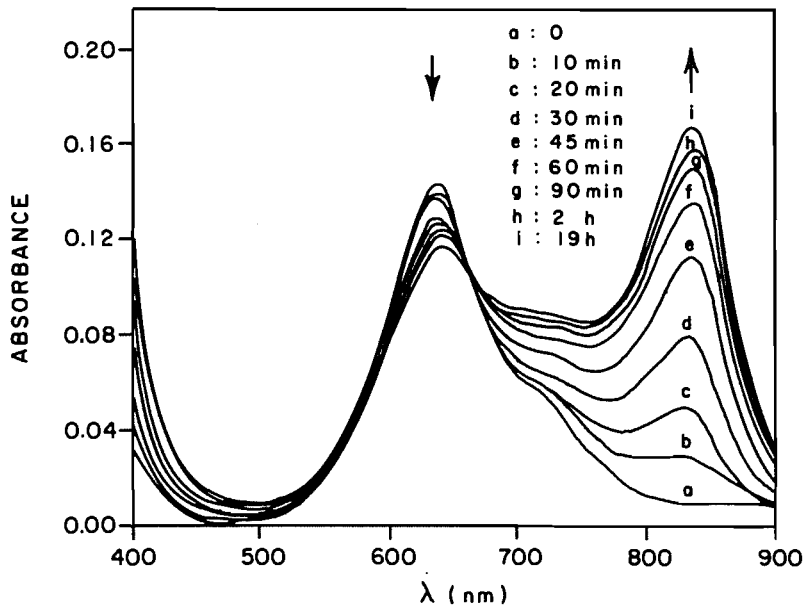

FIG. 2. Absorption spectra of PcAlOH thin film after different times of exposition to a 2 wt.% aqueous solution of potassium hydrogen phthalate.

observed when PcAlOH thin films on glass were dipped or exposed to the vapor of other organic solvents such as methanol, isopropanol, dichloromethane, and tetrahydrofuran. These results seem indicate that the α-form of PcAlOH is not transformed to an other polymorph form by a treatment with organic solvents as observed in the case of other metal phthalocyanines (22–25).

The absorption spectrum of PcAlOH thin films (60 Å) on a glass slide, when dipped in an aqueous potassium hydrogen phthalate (2 wt.%) at room temperature, changes drastically. A new and intense near-infrared absorption band appeared at 830 nm and this is accompanied by the diminution in the intensity of the peak absorption at 640 nm (Fig. 2). The visible spectra of the PcAlOH thin film dipped in a phthalate solution after various time at room temperature are depicted in Fig. 2. The new peak at 830 nm increased with time and this evolution is accompanied by a slow diminution of peak intensity at 640 nm. An isobestic point is observed at about 690 nm. The new peak at 830 nm is not due to the protonation of PcAlOH, because exhaustive washing of PcAlOH treated film with water showed the same absorption spectrum.

Similar results were observed when thin films of PcAlOH were dipped in other aqueous solutions of acids (Table 1).

The new form showing peak at 830 nm is tentatively called η-form.

The infrared absorption spectra of thin PcAlOH films (50 Å) evaporated on CaF_2 and AgBr substrates (showing only a Q-band at 640 nm, characteristic of the α-form) are shown in Figs. 3*a* and 4*a*, respectively. AgBr substrates were used to get information in the 1000–600 cm^{-1} region. After the samples have been dipped into a 2 wt.% aqueous solution of potassium hydrogen phthalate for 12 h, and the films extensively washed with water and allowed to dry in air, the infrared absorption spectra of the new form (showing absorption peak at 830 nm) changed drastically (Figs. 3*b* and 4*b*). Noticeable differences in the IR spectra were observed for the α-form and the η-form, particularly in the area of 1000 to 1200 cm^{-1}, where new peaks appeared at 1134, 1118, and 1065 cm^{-1} for the acid-treated films. A summary of the main absorption frequencies for the untreated (α-form) and acid-treated (η-form) films is given in Table 2.

TABLE 1. Effects of the acid treatment (12 h) on the absorption spectrum of PcAlOH films

Film thickness (Å)	Treatment by acids	Absorbance at 640 nm	Absorbance at 830 nm
140	(*1*) None	0.328	—
	(*2*) CF_3CO_2H	0.322	0.406
150	(*1*) None	0.341	—
	(*2*) 4-Nitrophthalic acid	0.241	0.300
130	(*1*) None	0.307	—
	(*2*) Potassium monophthalic acid	0.198	0.315
160	(*1*) None	0.353	—
	(*2*) HCl	0.300	0.855

3.2 X-ray diffraction

Figure 5 shows X-ray diffraction pattern for the sequential transformation of a thin PcAlOH film (50 Å). The α-form (Fig. 5*a*) was obtained by evaporation at 10^{-6} Torr on a polished aluminum plate. When exposed to an acid solution at room temperature, a new form η showing different X-ray diffraction pattern was obtained (Fig. 5*b*). These patterns show practically the same diffraction lines between $2\theta = 15$ to 30°. The main differences between *a* and *b* are the appearance of a new diffraction line at 12.1° and the disappearance of the line at 7.0°.

3.3 Photoactivity

The action spectra obtained for PcAlOH thin films (50 Å) with I_3^-/I^- redox couple before and after the treatment with trifluoroacetic acid are shown in Fig. 6. The photovoltaic effect occurs mainly at the interface PcAlOH and electrolyte. The photoresponse peaks coincide fairly well with the absorption

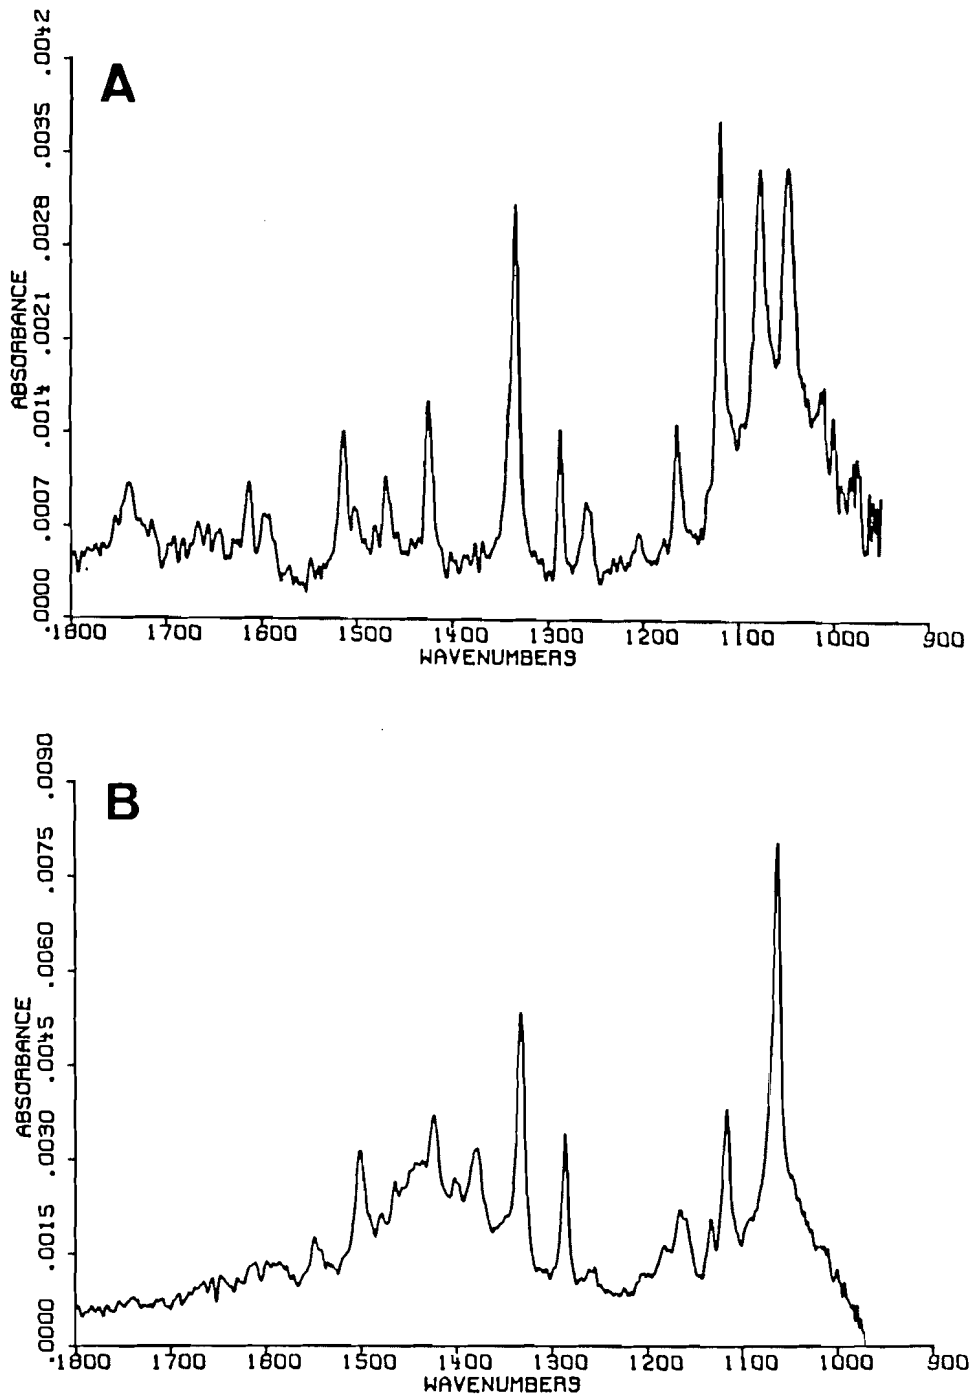

FIG. 3. Infrared spectra of PcAlOH thin film on CaF_2 plate before (*a*) and after (*b*) treatment with potassium hydrogen phthalate solution.

peaks (Fig. 7). The new polymorph which is very photoactive between 550–900 nm would permit the device to capture more light over a larger range of wavelengths and contributed to the improvement of its performance.

The current density – voltage (J–V) curves of a NESA/PcAlOH/I_3^-/I^-/Pt cell in the dark and under white light illumination of 10 mW cm^{-2} at pH = 1.0 are presented in Fig. 8. Curve *1* is for NESA in the dark, curves *2* and *3* are for untreated cells recorded in the dark and under illumination, respectively. (It took about 20 min to record curves *2* and *3*, so it is possible there are some dimorphic transformation induced by the electrolyte.) Curves *4* and *5* are for the trifluoroacetic acid treated cell in the dark and under illumination, respectively. Their photovoltaic properties are summarized in Table 3*A*. The acid-treated film shows an enhancement in the open-circuit voltage (V_{oc}) from 67 to 110 mV, the short-circuit photocurrent density (J) from 40 to 81 μA cm^{-2} and the fill factor (ff) from 0.41 to 0.58, resulting in an improvement of the conversion efficiency by a factor 5. The treatment by other acids gave similar results and for comparison, the photovoltaic

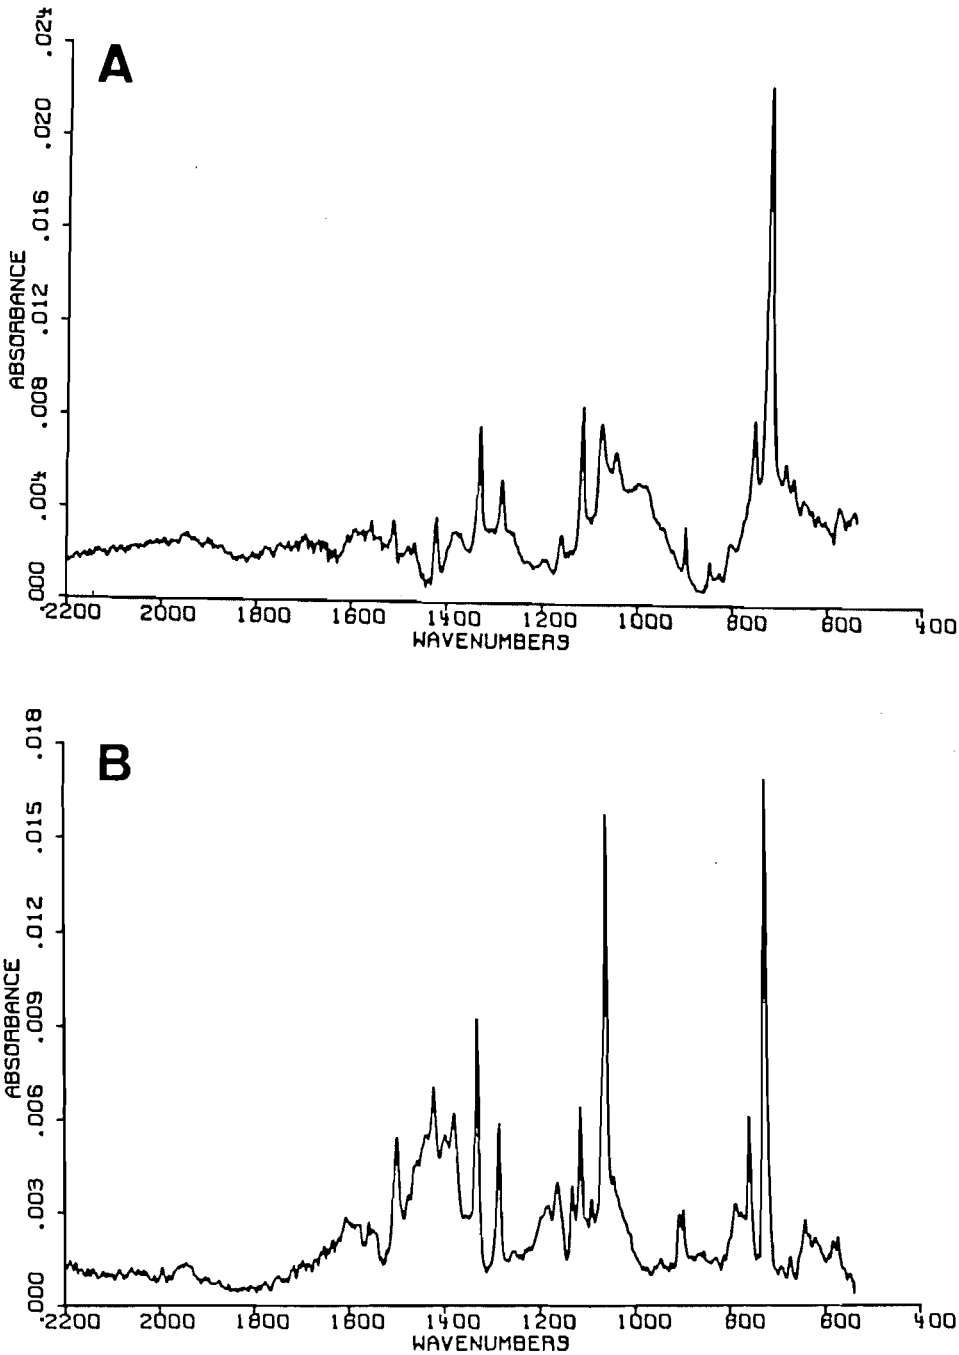

FIG. 4. Infrared spectra of PcAlOH thin film on AgBr plate before (*a*) and after (*b*) treatment with potassium hydrogen phthalate solution.

properties (15) of PcAlOH films treated with phthalic acid are shown in Table 3*B*. For I_3^-/I^- redox couple, lower pH usually gave higher conversion efficiency (32).

4. Discussion

Results of absorption spectra and X-ray diffraction indicate that the sublimed PcAlOH film exists in the α-form. Similar results are observed for ZnPc (23). Kobayashi *et al.* (22) have reported that the metastable α-form of metal phthalocyanine is transformed into the stable β-form through various intermediate forms (x, τ, ϵ) depending on the properties of the organic solvents and that an intermediate x-form appears in some solvents such as alcohols, acetone, ether, THF, $CHCl_3$. A schematic representation of the different molecular stacking for metallophthalocyanines can be found in reference (19). Hor and Loutfy (25) has observed a dimorphic transformation of PcMg (from the α-form to the x-form) induced by CH_2Cl_2 and THF, and an enhancement in photoactivity. No dimorphic transformation induced by organic solvents was observed for PcAlOH. But the metastable α-form of aluminum hydroxyphthalocyanine film can be transformed into a new form η by an acid treatment. The absorption spectrum of the new form is similar to the absorption spectra of the x-form of divalent metal phthalocyanine with absorption peaks at 640 and 830 nm. But the X-ray

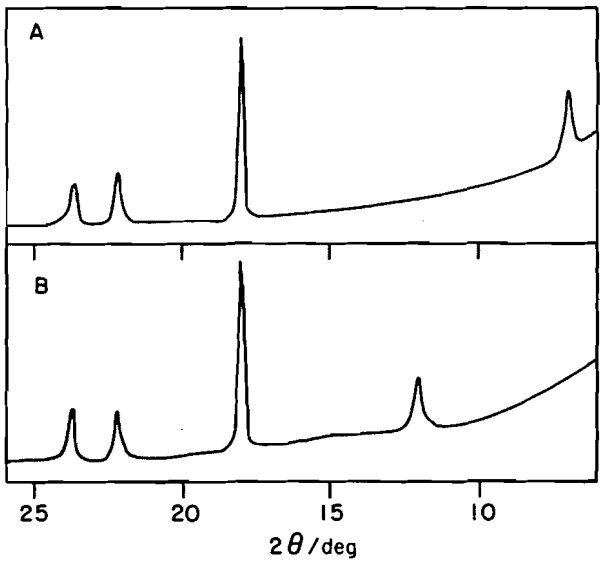

FIG. 5. X-ray diffraction patterns of PcAlOH thin film before (*a*) and after (*b*) treatment with potassium hydrogen phthalate solution.

diffraction pattern of the treated film is different from all X-ray diffractions of *x*-, τ-, or ϵ-forms described in the literature.

X-ray diffraction patterns of ZnPc films exposed to the vapor organic solvent show the transformation after 10 min of the α-form to the *x*-form which is completely transformed into the β-form after 120 min exposure (22). Based on the relation between the diffraction angle θ and the interplanetary distance *d*:

$$\sin\theta = \frac{\lambda}{2d}$$

with λ = 1.54 Å for Cu K_α, it was shown that the spacing *d* = 12.96 Å corresponds to the α-form, *d* = 12.54 and 9.48 Å to the β-forms and *d* = 11.4 Å to the *x*-form. For the untreated PcAlOH film, the spacing 12.78 Å corresponds probably to the α-form. For the treated films, the X-ray diffraction patterns show the spacing *d* = 7.31 Å for an unknown form η.

PcAlOH has a trivalent metal at centre and the OH group out of the macrocycle plane. Different dimeric structures are possible, with two Pc macrocycle planes parallel and the Al—OH oriented in the same direction (head-to-tail) or in the opposite direction (head-to-head or tail-to-tail). Similar results were observed for trivalent metal Pc's (21, 33–36). Thus, the X-ray structure determinations of single crystals of several vacuum-deposited thin film Pc's that have a trivalent or tetravalent metal at centre (e.g. PcGaCl, PcAlCl, PcInCl, PcVO) have shown that they have the tendency to aggregate in the solid state in either a cofacial stack (head-to-tail) or in various interleaved slipped stacks (head-to-head or tail-to-tail). It was proposed that the slipped configuration, in which the two Pc phases have more degree of movement than the α- or β-phases reported before for other Pc's (22, 23), is responsible for the strongly red-shifted visible absorbance spectra (33–36).

Infrared spectroscopy has been used by a number of authors as an indicator of crystallographic phase for phthalocyanines (23, 26, 37–40). The ir spectrum of the treated PcAlOH film

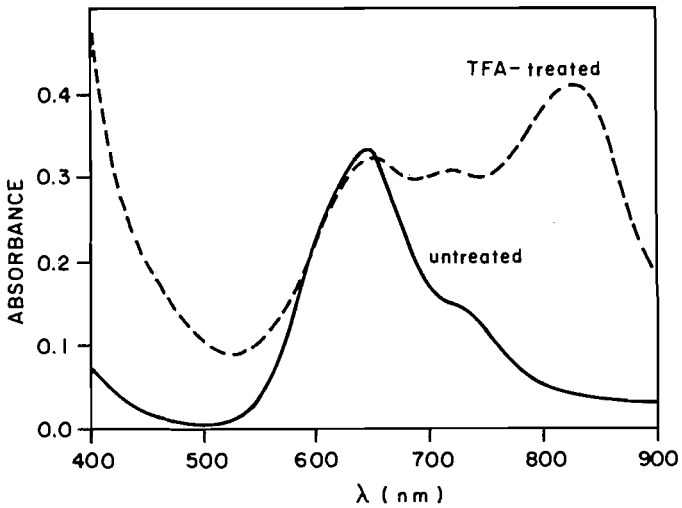

FIG. 7. Absorption spectra of PcAlOH thin film before (untreated) and after treatment with aqueous trifluoroacetic acid solution (TFA-treated).

is very different from that of the sublimed film. Besides the disappearance of peaks at 808, 852, 1261, 1471, 1514, 1596, 1613, and 1740 cm^{-1}, a change in the 1000–1100 cm^{-1} was observed, thus the two strong peaks at 1051 and 1080 cm^{-1} are replaced by a new peak at 1065 cm^{-1} for the treated PcAlOH film. The transformation from the α-form to the *x*-form for phthalocyanines induces modification principally in the absorption area of 700–800 cm^{-1} (37, 38), but rarely in the 1000–1100 cm^{-1} area.

It was also found that the treatment of other aluminum phthalocyanines such as chloroaluminum phthalocyanine or $PcAlOP(OH)_2OC_{16}H_{33}$ by acids gave the same effect, but free phthalocyanine is not converted. It seems that the aluminum metal has an effect on the transformation (32).

Spectroscopic studies and X-ray diffraction have shown the

transformation of α-PcAlOH to a new phase η by an acid treatment. The conversion mechanism and the crystallographic structure of the new form are not yet clear. One possible structure for η-form which collaborates well with spectroscopic and X-ray results is an interleaved arrangement involving four Pc planes with a tail-to-tail, head-to-head, tail-to-tail (PcAlOH..HOAlPc..PcAlOH..HOAlPc) stacking arrangement, slipping horizontally with respect to each other relatively to a *Z*-axis passing through the center of each Pc macrocycle in an *X*–*Y* parallel plane as suggested by Griffiths *et al.* for vanadyl phthalocyanine (21).

The enhancement of the photoactivity due to the dimorphic transformation of phthalocyanine films was already reported for

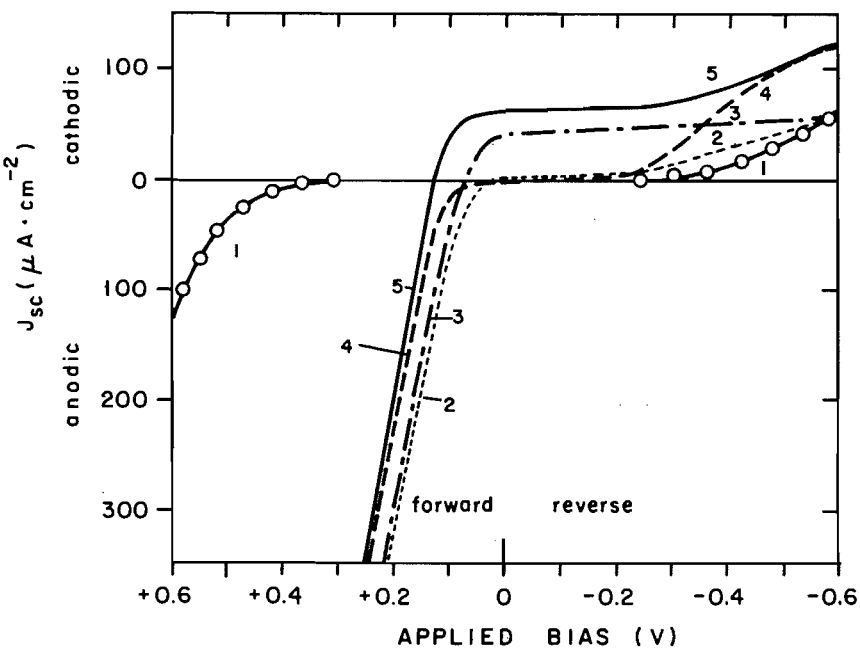

FIG. 8. *J*–*V* curves of a NESA/PcAlOH/I_3^-/I^-/Pt cell in the dark and under illumination (10 mW cm^{-2}): (*1*) NESA in the dark; (*2*) untreated in the dark; (*3*) untreated under illumination; (*4*) treated in the dark; (*5*) treated under illumination.

H_2Pc (20) and PcM (25) photovoltaic cells. In all cases, the improvement of the solar efficiency is only by a factor of 1.5. The enhancement in photoactivity of a PcAlOH treated with acid is more dramatic (factor up to 6) (Table 3). This is due mainly to a better quantum yield and an improvement of the junction rectifying behaviour of a NESA/PcAlOH/redox/Pt photoelectrochemical cells (15). The acid treatment broadens the absorption spectrum, modifies enormously the action spectra, and permits the device to capture more light over a larger range of wavelengths, contributing in part to the improvement of its performance. Better junction rectifying behavior was obtained for PcAlOH with the acid treatment. This is due to the decrease in the cell resistance by a factor of 4.2 (for I_3^-/I^-), an increase in J_{sc} and V_{oc}, and particularly an increase of ff (15). Values of ff up to 0.77 were obtained for a cell NESA/PcAlOH (600 Å)/I_3^-/I^-/Pt under 100 mW/cm^2 irradiation at pH 2.5 (15). This value is one of the highest observed for a photovoltaic organic cell.

5. Conclusion

A new polymorph η was obtained when thin films of the α-form of hydroxyaluminum phthalocyanine were dipped into aqueous acid solutions. The visible absorption spectrum of the new polymorph resembles that of the *x*-form for other metal phthalocyanines. However, the ir absorption spectrum and the X-ray diffraction patterns show absorption peaks and diffraction lines different from those observed for the middle energy polymorph (e.g. τ-, *x*-, or ϵ-forms). The structure of the *x*- or ϵ-forms has been assumed to have a dimeric structure of two neighboring, Pc macrocycle plane in a staggered configuration.

The new polymorph PcAlOH could have a similar structure but because of the trivalent nature of the Al metal, other configurations are possible as observed in the case of vanadyl phthalocyanine.

The photoactivity of the new PcAlOH polymorph induced by an acid treatment is substantially increased by a factor up to six. This is due mainly to a better quantum yield and an improvement of the function-rectifying behavior.

Received September 29, 1987

ALAN R. KATRITZKY, KATHLEEN S. LAURENZO, and DOUGLAS I. RELYEA. Can. J. Chem. **66**, 1617 (1988).

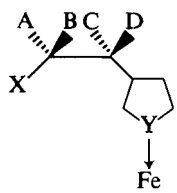
(Isothiazol-5-yl)diarylcarbinols were prepared from 5-lithioisothiazole. (Thiazol-5-yl)diarylcarbinols were obtained via 5-lithio-2-bromothiazole or 5-lithio-2-trimethylsilylthiazole with subsequent removal of the 2-substituent. Corresponding 2-aminothiazol-5-ylcarbinols were made by protecting 2-aminothiazole as its bis(trimethylsilyl) derivative. Biological activities were compared to the calculated electron densities at the heterocyclic N-atoms.

ALAN R. KATRITZKY, KATHLEEN S. LAURENZO et DOUGLAS I. RELYEA. Can. J. Chem. **66**, 1617 (1988).

Des isothiazolyl-5 diarylcarbinols ont été préparés à partir de lithio-5 isothiazole. Des thiazolyl-5 diarylcarbinols ont été obtenus soit du bromo-2 lithio-5 thiazole soit du lithio-5 triméthylsilyl-2 thiazole suivi du clivage du groupement-2. La synthèse des amino-2 thiazolyl-5 carbinols correspondants a été effectuée en protégeant l'amino-2 thiazole sous forme de dérivé bis(triméthylsilyle). L'activité fongicide des produits a été comparée avec la densité électronique calculée de l'atome d'azote hétérocyclique.

Introduction

Azole fungicides inhibit a cytochrome P450 enzyme in the ergosterol biosynthetic pathway (1), responsible for the 14α-demethylation of 24-methylene-24,25-dihydrolanosterol, a precursor to ergosterol, which is an essential component of the fungal cell wall (1*c*). The general structural requirements, cf. **1**,



1

A, B, C, D = lipophilic backbone
X = polar group

for these inhibitors (1*d*) include a lipophilic backbone and polar group necessary for recognition and binding at the active site. Critical for enzyme inactivation is a nitrogen β to the ring fusion point, the unshared pair of electrons of which complex with the Fe^{III} of the heme prosthetic group in the active site of the enzyme, preventing binding of the natural substrate.

Most of the azole fungicides on the market today are based on imidazole (e.g., **2**) or on 1,2,4-triazole (e.g., **3**, **4**). The Eli Lilly inhibitor Triarimol (**5**) is a pyrimidine with structural features similar to the model demethylase inhibitors **1**–**4**. The aim of the present work was to explore other heterocyclic ring systems with a nitrogen in the β-position for fungicidal activity. We chose Triarimol (**5**) as our model because two obvious disconnections suggested convenient synthetic routes: the addition of a heterocyclic anion to a substituted benzophenone, or the addition of two moles of a Grignard reagent to a heterocyclic carboxylic ester or acid chloride.

We now report the synthesis and fungicidal activity of a series of thiazolyl- and isothiazolyl-diarylcarbinols.

Results and discussion

Isothiazole compounds

Isothiazole is converted by *n*-butyllithium into isothiazol-5-yllithium (2), which has previously been added to various benzaldehydes affording secondary carbinols in low to moderate yields (3) and to one ketone (acetone) affording the corresponding tertiary carbinol in low yield (4).

In our hands, treatment of isothiazole with *n*-butyllithium at −78°C followed by benzophenone gave a trace of the desired product **6***a* (Table 1) (2%) but the major isolated product was benzhydrol. Addition of *n*-butyllithium to the isothiazole ring has been reported (2). We avoided this by using lithium diisopropylamide at ~ −70°C; reaction with 4,4′-dichlorobenzophenone then gave pure **6***b* in quantitative yield (Scheme 1).

This procedure was extended to a series of substituted benzophenones; reaction was sometimes complete after 2 h at −78°C; otherwise the temperature was allowed to rise to 0°C. After work-up, the products (Table 1) were purified by flash

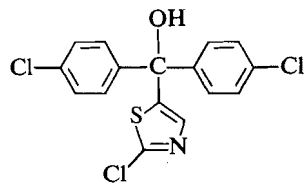
Thiazole compounds

A sub-structure search of Chemical Abstracts from 1927 to 1986 revealed no otherwise unsubstituted thiazoles with a tertiary carbinol group in the 5-position. Direct lithiation of the thiazole nucleus normally affords the corresponding 2-lithio derivative (5); if the 2-position is blocked, lithiation can occur at the 5-position (5, 6). Blocking the 2-position with a removable group was previously used by Noyce and Fike (6) to prepare a secondary 2-chlorothiazol-5-ylcarbinol; the chloro substituent was removed with zinc and acetic acid.

2-Chlorothiazole, treated successively with *n*-butyllithium and 4,4′-dichlorobenzophenone, gave carbinol **7** (52%). Simple dehalogenation of the thiazole ring with Zn and acetic acid (reflux, 4 h) was unsuccessful, presumably due to the sensitivity of the triarylcarbinol group to acidic conditions.



7

2-Halothiazoles are reported to undergo halogen–metal exchange with *n*-butyllithium (7). Carbinol **7**, on treatment with two equivalents of *n*-butyllithium at −78°C, followed by quenching with water, gave a mixture estimated by ^1H nmr to contain 50–60% of carbinol **9***b*. As 2-chlorothiazoles do not undergo this reaction as readily as 2-bromothiazoles (8), 2-bromo-5-lithiothiazole (unstable even in solution) was prepared by the controlled reaction of 2-bromothiazole and LDA (Scheme 2) and the benzophenone was added without delay. Complete reaction in about 15 min at −78°C gave diaryl-(2-bromothiazol-5-yl)carbinols (**8***a–f*) in good yields (Table 5), with structures confirmed by ^1H and ^{13}C nmr spectroscopy (Tables 6–8).

These yellow to light brown low-melting solids, though not analytically pure, were smoothly converted by treatment with two equivalents of *n*-butyllithium in THF at −78°C for 10–15 min, followed by water (Scheme 2), into the diaryl(thiazol-

5-yl)carbinols **9***a–f* (71–81%, Table 9). The structures of **9***a–f* were confirmed by ^1H and ^{13}C nmr spectroscopy (Tables 10–12).

Synthesis of 2-substituted thiazoles

Based on molecular orbital calculations and initial biological screening, we required thiazole compounds (**10**) with the 2,4-dichloro substitution pattern in the aryl rings, and electron-donating groups (e.g., methyl, methoxy, amino) at the 2-position of the thiazole ring. For the 2-amino compound **10***a*, 2-aminothiazole was protected as the *N,N*-bis(trimethylsilyl) derivative (9) by treating successively with two equivalents of *n*-butyllithium and two equivalents of trimethylsilyl chloride. Another equivalent of *n*-butyllithium, and then 2,4-dichlorobenzophenone, gave carbinol **10***a* (61%).

The reaction of 2-bromo-5-lithiothiazole with 2,4-dichlorobenzophenone failed, so carbinols **10***b* and *c* were prepared

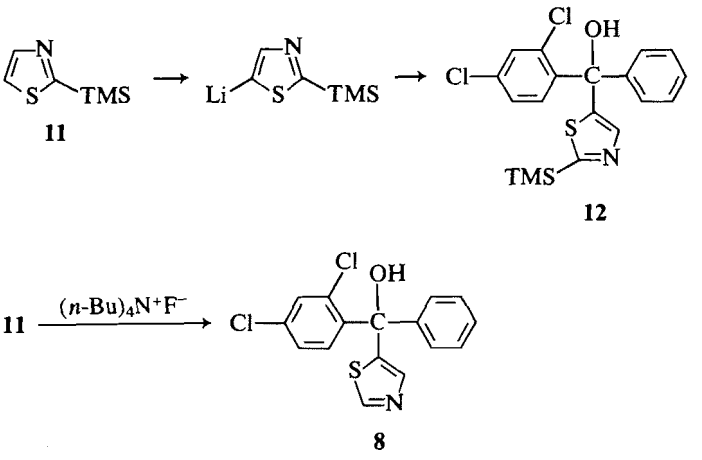

SCHEME 3

from 2-trimethylsilylthiazole (**11**) (10). Treatment of **11** with one equivalent of LDA followed by 2,4-dichlorobenzophenone gave the 2-trimethylsilyl-substituted carbinol **12** (Scheme 3) in which the thiazole ring is easily desilylated by silica gel (10). Tetrabutylammonium fluoride added directly to the ethereal solution of the crude product gave carbinol **10***b* (63%). Treatment of **10***b* with two equivalents of LDA followed by methyl iodide produced **10***c* (100%). The nmr spectral data for compounds **10***a–c* are included in Tables 9–12.

Chemical shift assignments

The ^{13}C chemical shifts of the heterocyclic ring carbons (Tables 2, 6, and 10) were assigned by comparison to literature values for the parent heterocycles (11, 12), and by APT (attached proton test) (13). An α,α-diarylcarbinol group substituted at C5 of isothiazole or 2-substituted thiazoles caused a downfield shift of ca. 28 ppm for C5. In the unsubstituted thiazole compounds (**9***b* and *f*) (Table 10), the signal for C5 was observed at δ 147.26 and 147.31, respectively, but for the other compounds **9** the signal for C5 is presumed to coincide with C1″ at δ 145–147; sometimes a shoulder can be detected.

The aryl ring carbons (Tables 3, 7, and 11) were assigned by APT and by comparison of shifts to those calculated by means of substituent parameters (11) using triphenylcarbinol as a model (14).

The ^1H nmr assignments (Tables 6, 9, and 12) are based on literature values for the ring protons in isothiazole (15) and thiazole (16); the ring protons in the 4-position were shielded by ca. 0.5 ppm compared to the parent heterocycles. For the unsubstituted thiazole compounds (**9**), this shift caused H4 (δ 7.9 in the parent ring) to be obscured by the aryl protons.

Biological evaluation

The compounds described in this paper were evaluated for control of the phytopathogenic fungi *Fusarium oxysporum*, *Botrytis cinerea*, *Alternaria solani*, *Cercospora arachidicola*, *Helminthosporium maydis*, *Sclerotinia sclerotiorum*, *Sclerotium rolfsii*, and *Phytophthora infestans* in in vitro tests at concentrations of 500 ppm and lower. In vivo tests were also conducted at 1000 ppm and lower with *Piricularia oryzae* on barley, *Erysiphe polygoni* on beans, *Erysiphe cichoracearum* on cucumber, *Erysiphe grammis* on barley, and *Uromyces phaseoli* on beans.

Control of phytopathogenic organisms is conveniently described by an efficacy value defined by

$$\text{efficacy} = \log\frac{\%\ \text{control}}{100} + \log\frac{10^6}{\text{concentration}}$$

[a]**9***b*, *d*, and *f* in DMSO; others in $CDCl_3$.
[b]2-CH_3: δ 19.20.

where concentration is measured in parts per million. Thus efficacy provides a single parameter in which large values reflect both high percent control and low concentration; for example, 90% control at 1000 ppm gives efficacy 2.95, 100% control at 50 ppm gives efficacy 4.30. Since control of less than 70% is generally not economically useful, efficacy is arbitrarily redefined as zero if percent control is less than 70% at the test concentration.

Certain members of both the isothiazole (**6**) and thiazole (**7**, **8**, **9**) series show significant fungicidal activity in both in vitro and in vivo testing (Table 13). For example, **6***c*, **6***g*, **8***e*, **9***a*, **9***b*, and **9***d* all control *Erysiphe polygoni* on beans at concentrations of 100 ppm or less. However, only compounds **6***g* and **9***d* might be described as having broad-spectrum activity and none are sufficiently potent for economic use.

In both the isothiazole and thiazole series there is no clearly evident effect on bioactivity by phenyl ring substituents that can be ascribed to electron release (**8***e* > **8***b*, but **9***e* ~ **9***b*) or lipophilicity (**6***b* < **6***c*, **8***b* ~ **8***c*, **9***b* > **9***c*). It does appear that the more active compounds from the standpoints of high activity and breadth of spectrum are the unsymmetrical dichloro analogs, perhaps because the molecular dipole promotes binding at the active site. Unsymmetric substitution is a frequent structural feature in fungicides of the ergosterol biosynthesis inhibitor class. Halogen at the 2-position of the thiazole ring appears to diminish activity (bromine, **8***b*) and narrow the spectrum (chlorine, **7**). This is consistent with expected steric and electronic effects on the heterocyclic nitrogen believed to bind with iron in the fungal enzyme.

Molecular orbital calculations

α,α-Diphenylmethyl substituted 5- and 6-membered nitrogen-containing heterocycles require a β-nitrogen for fungicidal activity (1*c*). A rough correlation exists[2] between biological activity and electron density at the β-nitrogen, calculated using the spectroscopic INDO program (17).

Thus, the 4-substituted pyridazine (activity = 4 on a 10-point scale) has a partial charge (−0.213) intermediate between those of the inactive 3-pyridazine compound (−0.060) and the compounds (pyridine, pyrimidine, pyrazine) with activity of 8–10 (−0.35 to −0.39). The five-membered rings (imidazole, 1,2,4-triazole) have slightly larger charges (−0.408, −0.411) than the six-membered rings though their activity is lower (activity = 6). Of the compounds in our synthetic program, the isothiazole and thiazole compounds had values in roughly the same range as the active six-membered ring compounds, but lower than the less active five-membered rings. The 1,2,3-thiadiazole compounds had far lower charges. In thiazole, the electron-withdrawing 2-chloro or 2-bromo substituent reduced the partial charge at the β-nitrogen relative to the unsubstituted ring, but thiazoles substituted with electron-releasing groups (amino, methyl, and methoxy) had enhanced partial charges at the β-nitrogen. These MO calculations suggest that thiadiazoles, oxazoles, and dioxazoles would not likely be active fungicides, and influenced our synthetic efforts.

Experimental

Melting points were determined on a Hoover capillary melting point apparatus and are uncorrected. The ^1H nmr spectra were obtained at 60 MHz on a Varian EM 360L nmr spectrometer, with TMS as internal standard. The ^{13}C nmr spectra were obtained on a JEOL FX-100 nmr spectrometer at 25 MHz, referenced to solvent (δ $CDCl_3$ = 77.0, δ DMSO-d_6 = 39.5). Low and high resolution mass spectra were obtained on an AEI MS30 mass spectrometer. Combustion analyses were performed on a Carlo Erba 1106 elemental analyzer.

Reagents were obtained from Aldrich with the exception of 2,4-dichlorobenzophenone, which was obtained from ICN Biochemicals.

THF and ether were distilled immediately before use from either CaH_2 or sodium/benzophenone under an argon atmosphere. Diisopropylamine was distilled from CaH_2 and stored over molecular sieves.

Geometric structures were obtained using the MNDO optimization procedure of Dewar and Thiel (18). At these geometries, wavefunctions and charge distributions were obtained using the INDO/S model of Zerner and others (17). Charge distributions were taken from a Mulliken population analysis using a deorthogonalized INDO wavefunction.

The following compounds were prepared by literature methods:

2-Propynal, 48% (crude), n_D = 1.4155 (lit. (19) 28–34% distilled, n_D = 1.4055); ^1H nmr ($CDCl_3$) δ: 3.63 (s, 1H, C≡C*H*), 9.37 (s, 1H, C(O)*H*); used without further purification.

cis-2-Propenal-3-thiosulfate, 48% (lit. (20) 65%); ^1H nmr (D_2O) δ: 6.5 (dd, 1H, H2), 7.85 (d, 1H, H3), 9.65 (bs, 1H, C(O)*H*).

Isothiazole, 41%, bp 113–114°C/760 Torr (1 Torr = 133.3 Pa) (lit. (20) 65%, bp 111–112°C/760 Torr); ^1H nmr ($CDCl_3$) δ: 7.4 (m, 1H, H4), 8.8 (m, 2H, H2 and H5); ^{13}C nmr ($CDCl_3$) δ: 156.34 (C3), 122.72 (C4), 147.08 (C5).

2-Chlorothiazole, 48%, bp 47°C/22 Torr (lit. (21) 70%, (22) bp 45°C/20 Torr); ^1H nmr ($CDCl_3$) δ: 7.4 (d, 1H, H5), 7.7 (d, 1H, H4); ^{13}C nmr ($CDCl_3$) δ: 151.32 (C2), 141.09 (C4), 121.01 (C5).

2-Bromothiazole, 65%, bp 65–68°C/20 Torr (lit. (21) 75%, (23) bp 70.5°C/20 Torr); ^1H nmr ($CDCl_3$) δ: 7.45 (m, 1H, H5), 7.6 (m, 1H, H4); ^{13}C nmr ($CDCl_3$) δ: 135.63 (C2), 142.60 (C4), 122.86 (C5).

2-Trimethylsilylthiazole, 55%, bp 70–72°C/22 Torr (lit. (10) 55%, bp 56–57°C/10 Torr); ^1H nmr ($CDCl_3$) δ: 8.25 (d, 1H, H4), 7.6 (d, 1H, H5), 0.45 (s, 9H, $(CH_3)_3$); ^{13}C nmr ($CDCl_3$) δ: 174.27 (C2), 145.66 (C4), 121.27 (C5), −1.04 ($(CH_3)_3$).

Bis(4-chlorophenyl)-(2-chlorothiazol-5-yl)carbinol

A solution of 2-chlorothiazole (3.0 g, 25.1 mmol) in ether (25 mL) and a solution of *n*-butyllithium (2.6 M, 10.6 mL, 27.6 mmol) were added simultaneously over a 45-min period to ether (30 mL) at −78°C. The somewhat brown solution was stirred an additional 2.5 h with gradual warming to −20°C. 4,4′-Dichlorobenzophenone (12.5 g, 50 mmol) in ether (50 mL) was added over 45 min. The temperature was allowed to rise to 0°C over 1 h, then held at room temperature an additional 30 min. Water (100 mL) was added and the aqueous phase was extracted with ether (2 × 100 mL). The combined organic phases were dried (Na_2SO_4) and the solvent was removed *in vacuo*. The crude product was purified by flash chromatography (230–400 mesh silica gel, 80:20 petroleum ether/diethyl ether) to give 4.85 g (52%) **7**, mp 122.5–123.5°C.

Diaryl(isothiazol-5-yl)carbinols: General synthetic procedure

Lithium diisopropylamide was prepared by the dropwise addition of *n*-butyllithium (2.6 M in hexanes, 1.27 mL, 3.3 mmol) to diisopropylamine (0.63 mL, 4.5 mmol) in THF (10 mL) at ≤ −70°C. The solution was allowed to warm gradually to 10°C, then cooled again to −78°C. Neat isothiazole (0.24 mL, 3.3 mmol) was added dropwise at such a rate that the temperature did not exceed −70°C. The resulting

flocculent white precipitate was stirred at −78°C for 2 h. A solution of the substituted benzophenone (3.0 mmol) in THF (10 mL) was added dropwise at ≤ −70°C, after which the reaction mixture was stirred at −78°C for 2 h. If the reaction was not complete (as evidenced by residual white precipitate and the presence of starting benzophenone in the tlc), the temperature was slowly allowed to rise to 0°C and held at this temperature until the reaction was complete. The clear light yellow solution was then poured into saturated NH_4Cl (50 mL) and extracted with ether (3 × 50 mL). The combined organic phases were dried (Na_2SO_4), filtered, and the solvent was evaporated *in vacuo*. The resulting yellow oil was placed under pump vacuum overnight, then purified by flash chromatography (230–400 mesh silica gel, 80:20 petroleum ether/diethyl ether). If necessary, the products were purified further by recrystallization from 2:1 hexane/ethanol (Table 1).

Diaryl-(2-bromothiazol-5-yl)carbinols: General synthetic procedure

Lithium diisopropylamide was prepared as described above from *n*-butyllithium (2.6 M in hexanes, 3.2 mL, 8.25 mmol) and diisopropylamine (1.59 mL, 11.25 mmol) in THF (20 mL). A solution of 2-bromothiazole (0.68 mL, 7.5 mmol) in THF (10 mL) was added dropwise without exceeding −75°C, as rapidly as possible at first, then more slowly toward the end of the addition. The total addition time was about 15–20 min. The rate of addition was critical; if too much time was taken or the temperature rose too high, considerable decomposition of the starting material occurred, as evidenced by the formation of a dark brown color. If all proceeded satisfactorily the reaction mixture at this point was yellow to light brown in color. After stirring 5 min at −78°C, a solution of the substituted benzophenone (7.5 mmol) in THF (10 mL) was added as rapidly as possible without exceeding −70°C. The light brown solution was stirred at −78°C for 15 min, then poured into saturated NH_4Cl (75 mL). The aqueous phase was extracted with ether (3 × 50 mL). The combined organic phases were dried over $MgSO_4$, filtered, and the solvent was removed *in vacuo*. The resulting brown oil was placed under pump vacuum overnight. The crude product was purified by flash chromatography (230–400 mesh silica gel, 80:20 petroleum ether/diethyl ether). The products are low-melting solids or semisolids (Table 2) that revert to oils on standing.

Diaryl(thiazol-5-yl)carbinols: General synthetic procedure

To a solution of the diaryl-(2-bromothiazol-5-yl)carbinol in THF (5–10 mL/mmol), was added dropwise a solution of *n*-butyllithium (2.6 M in hexanes, 2 equivalents plus a 10% excess) at ≤ −70°C. The reaction mixture was stirred at −78°C for 15 min, then poured into saturated NH_4Cl. The aqueous phase was extracted three times with an equal volume of ether. The combined organic phases were dried over $MgSO_4$, filtered, and the solvent was removed *in vacuo*. The crude products thus obtained were either solids or oils (Table 3). The solids were purified further by recrystallization from 2:1 hexane/chloroform, and the oils by flash chromatography (230–400 mesh silica gel, 1:1 petroleum ether/diethyl ether).

*(2,4-Dichlorophenyl)phenyl-(2-aminothiazol-5-yl)carbinol (**10**a)*

n-Butyllithium (3.2 mL, 2.5 M, 8 mmol) was added to a solution of 2-aminothiazole (0.40 g, 4 mmol) in THF (30 mL) at ≤ −70°C. The slightly cloudy light brown solution was stirred 1 h at −78°C, followed by the addition of chlorotrimethylsilane (1.01 mL, 8 mmol). The reaction mixture was allowed to slowly warm to −20°C, then cooled again to −78°C. *n*-Butyllithium (1.6 mL, 2.5 M, 4 mmol) was added at ≤ −70°C and the mixture was stirred for 15 min at −78°C. 2,4-Dichlorobenzophenone (1.0 g, 4 mmol) in THF (10 mL) was added at ≤ −65°C. The temperature was slowly allowed to warm to 0°C, then the mixture was stirred at room temperature overnight. The mixture was poured into saturated NH_4Cl (50 mL) and extracted with ether (3 × 50 mL). The combined ether phases were dried ($MgSO_4$), filtered, and evaporated to give 1.7 g brown oil. The crude product was purified by flash chromatography (230–400 mesh silica gel) using 50:50 petroleum ether/ethyl acetate (with 1% (v/v) triethylamine) until all other products were eluted, then pure ethyl acetate to elute the product (R_f = 0.41); yield 0.85 g (61%) **10***a*. The melting point (~87–115°C) was difficult to determine precisely due to the incorporation of air in the fluffy solid. The product could not be purified by recrystallization.

*(2,4-Dichlorophenyl)phenyl(thiazol-5-yl)carbinol (**10**b)*

A solution of lithium diisopropylamide was prepared from diisopropylamine (0.84 mL, 6 mmol) and *n*-butyllithium (2.0 mL, 2.5 M, 5 mmol) in THF (10 mL). The LDA solution was added to a solution of 2-trimethylsilylthiazole (**11**) (0.79 g, 5 mmol) in THF (40 mL) at $\leq -70°C$, then stirred at $-78°C$ for 2 h. A white precipitate formed. 2,4-Dichlorobenzophenone (1.26 g, 5 mmol) in THF (10 mL) was added and the temperature was slowly allowed to warm to 0°C, at which point the solution was clear. The reaction mixture was poured into saturated NH_4Cl (75 mL) and the aqueous phase was extracted with ether (3 × 50 mL). Tetrabutyl ammonium fluoride (5.5 mL, 1 M, 5.5 mmol) was added to the wet ether extract and the mixture was stirred overnight at room temperature. The ether phase was washed with water (50 mL), dried (Na_2SO_4), and evaporated to yield 1.7 g (100%) white solid. The crude product was purified by flash chromatography (230–400 mesh silica gel, 70:30 petroleum ether/ether) to give 1.05 g (63%) **10***b*, mp 149–150°C.

*(2,4-Dichlorophenyl)phenyl-(2-methylthiazol-5-yl)carbinol (**10**c)*

n-Butyllithium (1.2 mL, 2.5 M, 3 mmol) was added to a solution of (2,4-dichlorophenyl)phenyl(thiazol-5-yl)carbinol (**10***b*) (0.50 g, 1.5 mmol) in THF (15 mL) at $\leq -75°C$. The yellow solution was stirred 20 min at $-78°C$, followed by the addition of iodomethane (0.19 mL, 3 mmol). The reaction mixture was stirred for 45 min at $-78°C$; a white precipitate formed. The mixture was poured into saturated NH_4Cl (25 mL) and extracted with ether (3 × 25 mL). The combined ether phases were dried ($MgSO_4$), filtered, and evaporated to give 0.56 g yellowish solid. The crude product (0.42 g) was purified by flash chromatography (230–400 mesh silica gel, 50:50 petroleum ether/ether) to give 0.40 g (95% recovery, 100% overall yield) **10***c*, mp 164–166°C.

Heats of mixing of binary mixtures of pyridine base with *n*-alkane

TERESA KASPRZYCKA-GUTTMAN[1] AND JUAN H. VERA[2]
Department of Chemical Engineering, McGill University, Montreal, P.Q., Canada H3A 2A7

Received October 19, 1987

TERESA KASPRZYCKA-GUTTMAN and JUAN H. VERA. Can. J. Chem. **66**, 1625 (1988).

Heats of mixing of 2,4-lutidine and 2,4,6-collidine with *n*-alkanes were measured at 293.15 K using an isothermal dilution calorimeter. Experimental results were fitted with a Redlich–Kister polynomial. Experimental data and coefficients for the Redlich–Kister polynomials are reported.

TERESA KASPRZYCKA-GUTTMAN et JUAN H. VERA. Can. J. Chem. **66**, 1625 (1988).

Opérant à 293,15 K et utilisant un calorimètre à dilution isotherme, on a mesuré les chaleurs de mélange de la lutidine-2,4 et de la collidine-2,4,6 avec des *n*-alcanes. On a ajusté les résultats expérimentaux avec un polynôme de Redlich–Kister. On rapporte les données expérimentales et les coefficients des polynômes de Redlich–Kister.

[Traduit par la revue]

The literature provides no systematic studies of heats of mixing of binary systems comprising aromatic amines (pyridine bases) and *n*-alkanes. This study reports heats of mixing data for binary systems formed by 2,4-lutidine and 2,4,6-collidine with alkanes at 293.15 K.

Materials and apparatus

All the chemicals used in this work were 99 mol% pure as specified on their labels or certified by Aldrich Chemical Co. Their purity was verified by determinations of density and refractive indices, using a densimeter (Anton Paar K.G., Austria) and a precision refractometer (Bausch and Lomb Optical Company, USA), respectively. Their values are compared with literature data in Table 1 (1–3). All measurements of heats of mixing were carried out with a semicontinuous Van Ness type isothermal dilution calorimeter described in detail earlier (4, 5). The calorimeter was calibrated by determination of the excess heats of mixing of the system benzene–cyclohexane at 293.15 K. Our results were consistent with the literature data (6) within 1%. A maximum temperature deviation of 0.02 K with respect to the preset value may be present throughout the experiments.

Experimental results

The results of the measurements of heats of mixing for the systems: 2,4-lutidine + *n*-alkanes at 293.15 K are reported in Table 2, and those for the systems: 2,4,6-collidine + *n*-alkanes at the same temperature in Table 3. The data were fitted with the Redlich–Kister polynomial of the form:

$$[1] \quad H^M = x_1 x_2 [A + B(x_1 - x_2) + C(x_1 - x_2)^2]$$

TABLE 1. Densities and refractive indices component liquids at 293.15 K (1–3)

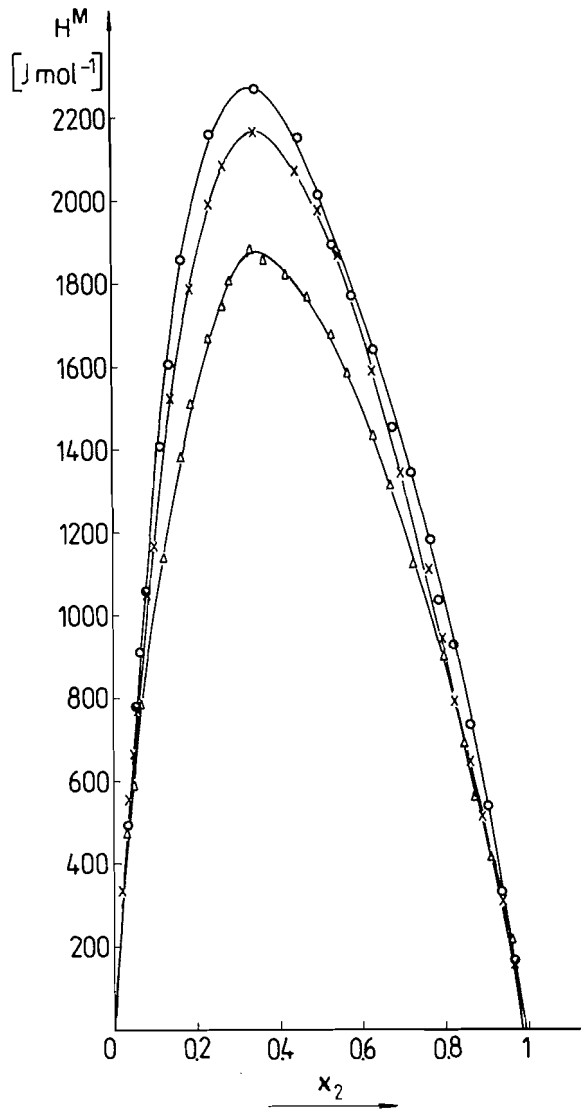

FIG. 2. Heats of mixing at 293.15 K for the binary systems: 2,4,6-collidine (2) + *n*-hexane (1), Δ; 2,4,6-collidine (2) + *n*-heptane (1), x; 2,4,6-collidine (2) + *n*-octane (1), o.

Discussion

Heats of mixing of the three binary systems 2,4-lutidine + *n*-hexane, + *n*-heptane, + *n*-octane, as a function of composition are shown in Fig. 1. Similarly, heats of mixing of the three binary mixtures 2,4,6-collidine + *n*-hexane, + *n*-heptane, + *n*-octane, as a function of composition, are shown in Fig. 2. All systems measured were found to be endothermal.

From the results of this work it is possible to see that in mixtures of pyridine bases with *n*-alkanes, it is the nature of the former that especially influences the heats of mixing values.

One of the factors responsible for the particular values of the heats of mixing seems to be the alkalinity of the pyridine base. According to Perrin (7), the pK_b values for pyridine bases are ($K_{b\ 2,4,6\text{-collidine}} = 7.5$) > ($K_{b\ 2,4\text{-lutidine}} = 6.7 = K_{b\ 2,6\text{-lutidine}}$) > ($K_{b\ \gamma\text{-picoline}} = 6$) > ($K_{b\ \alpha\text{-picoline}} = 5.9$) > ($K_{b\ \beta\text{-picoline}} = 5.7$) > ($K_{b\ \text{pyridine}} = 5.2$). At present we have not yet determined the heats of mixing for all mixtures of the above pyridine bases with hydrocarbons. However, the present results and previously reported values of heats of mixing for mixtures of pyridine with hydrocarbons (8–10), and of α-picoline with hydrocarbons (11) seem to indicate that the heats of mixing values at a given composition of the alkane increase with a rise of pK_b. However, in the case of 2,4- and 2,6-lutidine the pK_b values are virtually equal, whereas the respective values heats of mixing are different. This fact suggests that alkalinity is only one of the factors determining the heats of mixing values.

O^2-Isopropyl-2′-deoxythymidine (i^{2}dT) crystallizes in the tetragonal space group $P4_32_12$, and the cell dimensions are $a = b =$ 8.7667(2), c = 37.1943(12) Å. X-ray intensity data were measured with a diffractometer, and the structure was solved by direct methods. Least-squares refinement, which included all hydrogen atoms, converged at R = 0.036 for 1780 observed reflections. In analogy with other *O*-alkylated bases, the exocyclic O2—C8 bond is *syn-periplanar* to the C2—N3 bond in the pyrimidine ring. Angular distortions in the base can be correlated with those observed in O^4-alkylated pyrimidines and O^6-alkylated guanines. The conformation of the glycosyl bond is *anti* with χ_{CN} = 27.1°. The furanose ring adopts a C2′ *endo* pucker and the conformation about C4′—C5′ is *gauche*$^+$. ^{1}H nmr data show that these conformations are also preferred in solution.

GEORGE I. BIRNBAUM, KRISHAN L. SADANA, M. TAHIR RAZI, TERRY LEE, RUDY SEBASTIAN, GARRY W. BUCHKO, et FRANK E. HRUSKA. Can. J. Chem. **66**, 1628 (1988).

La O^2-isopropyl désoxy-2′ thymidine (i^{2}dT) cristallise dans le groupe d'espace tétragonal $P4_32_12$ avec $a = b$ = 8,7667(2) et c = 37,1943(12) Å. On a mesuré les données relatives aux intensités de la diffraction des rayons-X à l'aide d'un diffractomètre et on a résolu la structure à l'aide de méthodes directes. Un affinement par le méthode des moindres carrés, impliquant tous les atomes d'hydrogène, converge à R = 0,036 pour 1780 réflexions observées. Par analogie avec d'autres bases *O*-alkylées, la liaison exocyclique O2—C8 est *syn-périplanaire* par rapport à la liaison C2—N3 du cycle pyrimidine. On peut établir une corrélation entre les distorsions angulaires et celles observées dans des pyrimidines alkylées en O^4 et des guanines alkylées en O^6. La conformation de la liaison glycosyle est *anti* et le χ_{CN} = 27,1°. Le cycle furannose adopte une conformation C2′ *endo* plissée et la conformation autour de la liaison C4′—C5′ est *gauche*$^+$. Les données obtenues par rmn du ^{1}H indiquent que ces conformations sont aussi les conformations privilégiées en solution.

[Traduit par la revue]

Introduction

The mutagenic and carcinogenic consequences of the *O*-alkylation of nucleic acid bases have been the focus of numerous studies. Following the work of Loveless (1), research centered on O^6-alkylated guanine (r^{6}G), but considerable interest has shifted to the O^2- and O^4-alkylated thymines (r^{2}T and r^{4}T) following their identification in DNA treated with the potent carcinogen ethylnitrosourea (2). *O*-Alkylation of guanine and thymine effects a keto-to-enol tautomeric shift, and an alteration in their hydrogen-bonding capacity which forms the basis for interpretation of the misincorporations observed during transcription and replication (3, 4). The biological significance of *O*-alkylation is evidenced by the existence of enzyme repair systems for these lesions (5–7). Information about the electronic and geometrical changes resulting from *O*-alkylation has been provided by the X-ray crystallographic studies of O^4-methyluridine (m^{4}U) (8), O^4-methyl-2′-deoxythymidine (m^{4}dT) (9), and O^4-ethyl-2′-deoxythymidine (e^{4}dT) (10), as well as for several O^6-alkylated purine nucleosides and analogues (11–13) (Scheme 1). These studies have shown that the *O*-alkyl groups favor the *syn-periplanar* conformation relative to the N3 (pyrimidine) and N1 (purine) atoms which would hinder the approach of a second base. However, the accessibility of alternate conformations (e.g. *anti-periplanar*) which could also be suitable for base pair formation remains open to investigation (4, 9, 10, 14, 15). A review of the biological significance of *O*-alkyl pyrimidines was published very recently by Singer (16).

Though the promutagenic properties of O^2-alkylthymines are of considerable interest (2, 3), no crystallographic data are available for this modified base. In the present work we report our X-ray crystallographic results for O^2-isopropyl-2′-deoxythymidine (i^{2}dT) and a comparison with m^{4}dT (9) and e^{4}dT (10). For comparison with solution structures, ^{1}H and ^{13}C nmr data are provided for i^{2}dT, as well as for m^{2}dT, e^{2}dT, m^{4}dT, e^{4}dT, and i^{4}dT. A mass spectrometric study of several O^2- and O^4-alkylated 2′-deoxythymidines has been presented (17).

Experimental

To obtain i^{2}dT and e^{2}dT, dT was converted to its 3′-acyl derivative by standard procedures (18) and then to the 2,5′-anhydronucleoside following Secrist (19), as described in earlier work (20). Reflux of the latter derivative (1 mmol) in 20 mL of methanolic sodium isopropoxide or sodium ethoxide afforded the unprotected i^{2}dT or e^{2}dT. To obtain i^{4}dT and e^{4}dT, the procedure of Divakar and Reese (21) was used to prepare the 4-(1,2,4-triazol-1-yl) intermediate of 3′,5′-acetyl protected dT. This intermediate was converted to i^{4}dT and e^{4}dT by treatment with the appropriate alcoholic sodium alkoxide. Following neutralization with IRC-50 resin, the three nucleosides were purified by silica gel chromatography. Compounds m^{2}dT and m^{4}dT were prepared earlier as described (20).

^{1}H nmr spectra of the nucleosides were obtained at 300.13 MHz on a Bruker AM300 spectrometer. Aqueous solutions (1–2 mg/mL; pH ~7; 300 K) were prepared and purified of paramagnetic ions as described elsewhere (22). TSP was used as the internal reference. Spec-

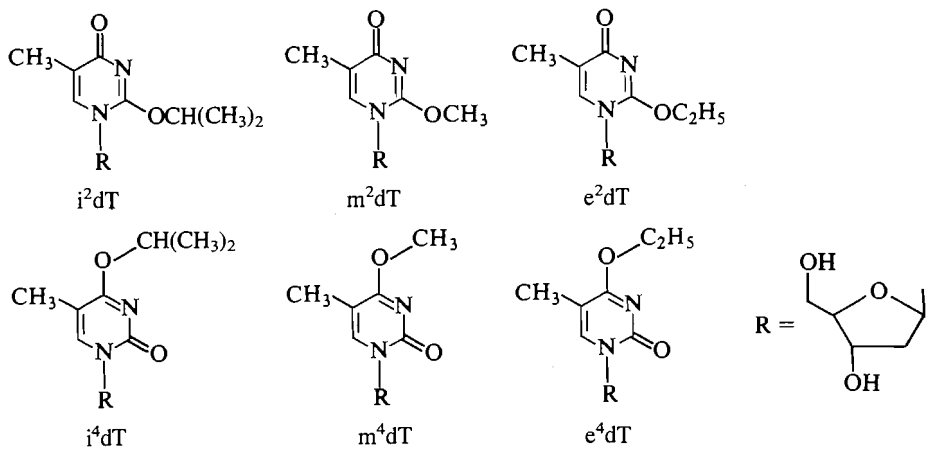

SCHEME 1

tral assignments followed earlier work (20, 22), and the analysis was carried out with NUMARIT (23). Proton decoupled ^{13}C nmr (75.5 MHz) spectra were obtained in 10 mm (od) tubes (5.5 mg/mL in D_2O; pH 5.4–8.0; 300 K; 1% dioxane for internal reference). Removal of paramagnetic ions and spectral assignments followed our earlier work (20, 22). Selective ^1H decoupling experiments confirmed our previous assignments (20) for the C1′ and C4′ atoms.

Colorless crystals were obtained from water. Precession photographs showed tetragonal symmetry and systematic absences corresponding to space groups $P4_12_12$ or $P4_32_12$. A crystal measuring 0.3 × 0.4 × 0.5 mm was mounted on an Enraf-Nonius CAD-4 diffractometer; it provided the following data:

$C_{13}H_{20}N_2O_5$ fw = 284.31

Tetragonal, $a = b = 8.7667(2)$, $c = 37.1943(12)$ Å, $V = 2858.53$ Å^3, $\rho_c = 1.32$ g cm^{-3}, $Z = 8$ (20°C; CuKα_1, $\lambda = 1.54056$ Å); $F(000) = 1216$, μ(CuKα) = 8.1 cm^{-1}.

The cell dimensions were determined from angular settings of 25 high-order ($47° < \theta < 59°$) reflections. Intensities were measured with Ni-filtered CuKα radiation, using $\omega/2\theta$ scans with variable ranges and speeds. Three standard reflections were monitored at frequent intervals; their intensities fluctuated by ±1%. A full octant with $2\theta \leq 152°$ was measured which included 3402 reflections. After averaging *hkl* and *khl* reflections, there were 1837 unique reflections of which 45 with $I < 3\sigma(I)$ were considered unobserved. The intensities were corrected for Lorentz and polarization factors; absorption corrections were considered unnecessary.

The structure was determined by direct methods with the aid of the computer program MULTAN78 (24). Assignment of the correct enantiomer established the space group as $P4_32_12$. Atomic parameters were refined by block-diagonal least squares. All 20 hydrogen atoms were refined with isotropic temperature parameters. The scattering factors were taken from the "International tables for X-ray crystallography" (25). Throughout the refinement the function $\Sigma w(|F_o| - |F_c|)^2$ was minimized and a factor of 0.8 was applied to all shifts. The following weighting scheme was used during the final stages: $w = w_1 \cdot w_2$, where $w_1 = 1$ for $|F_o| \leq 12$, $w_1 = 12/|F_o|$ for $|F_o| > 12$; and $w_2 = \sin^2\theta/0.7$ for $\sin^2\theta < 0.7$, $w_2 = 1$ for $\sin^2\theta \geq 0.7$. This scheme made the average value of $w(\Delta F^2)$ independent of $|F_o|$ and $\sin^2\theta$. The refinement converged to a conventional residual index $R = 0.036$ and a weighted index $R_w = 0.043$ for 1780 reflections (twelve strong, low-order reflections suffered from secondary extinction and were given zero weights). After the final least-squares cycle the average parameter shift equalled 0.1σ and the largest one 0.4σ. A final difference Fourier map showed no significant features. The atomic coordinates and equivalent isotropic temperature parameters of nonhydrogen atoms are listed in Table 1. Their anisotropic temperature parameters, hydrogen atom parameters, and a list of observed and calculated structure factors are available.[2]

[a]The z coordinates were multiplied by 10^5, the other parameters by 10^4.

Results and discussion

A stereoscopic view of i²dT, showing the overall conformation in the crystal and the atomic numbering scheme, is presented in Fig. 1. Note that the two methyl groups of the isopropyl group are diastereotopic due to the presence of the chiral centres in the sugar moiety; in Fig. 1, their carbon atoms are labelled C9*R* and C9*S* according to their *pro-R* or *pro-S* designation, respectively. Details of the conformation can be seen in the Newman projections (Fig. 2) and in Fig. 3 which also shows the bond lengths and bond angles.

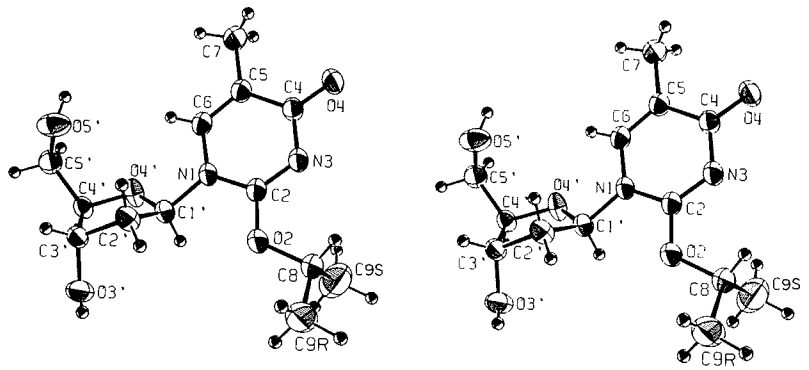

FIG. 1. Stereoscopic view of i^4dT; the ellipsoids correspond to 50% probability.

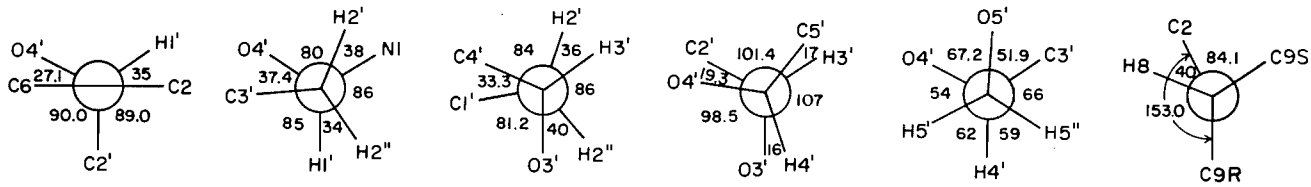

FIG. 2. Newman projections along (left to right) N1—C1′, C1′—C2′, C2′—C3′, C3′—C4′, C4′—C5′, and O2—C8.

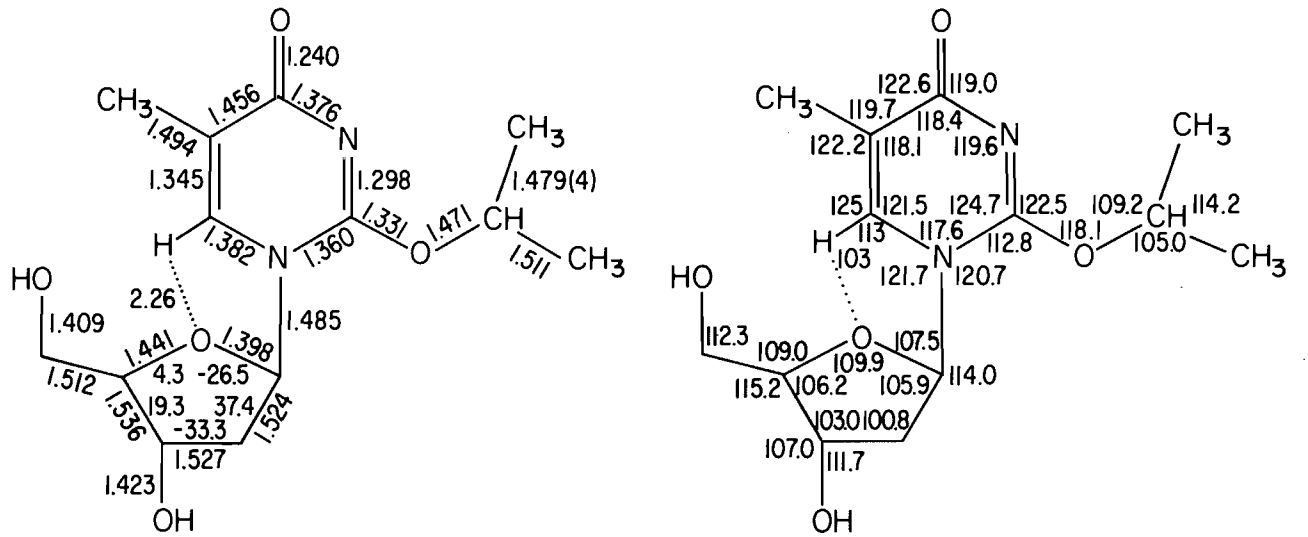

FIG. 3. Left, bond distances (Å) and endocyclic torsion angles (deg). Unless otherwise indicated, their estimated standard deviations (esd's) are 0.002–0.003 Å and 0.15–0.17°, respectively. Right, bond angles (deg); their esd's are 0.13–0.16°, except at C8 (0.2°).

Pyrimidine moiety

The pyrimidine ring is not exactly planar; N1 and C4 form the prows of a shallow boat. The absolute values of the endocyclic torsion angles are 0.4(3)° and 1.2(3)° at double bonds and 2.9(2)°–4.4(3)° at single bonds. While C8 is close to the mean plane of the ring, its methyl and hydrogen substituents are not.

As expected, the bond lengths differ significantly from average values in thymine residues (10). The conjugated system O2—C2=N3—C4=O4 created by O^2-alkylation can be compared to O4—C4=N3—C2=O2 in e^4dT, created by O^4-alkylation. We notice that C=N is 0.018 Å shorter in i^2dT, indicating a higher localization of electrons at this double bond. This can be explained by the cross-conjugated quinonoid system in i^2dT in which there is less delocalization than in the fully conjugated system in e^4dT.

Figure 4*a* facilitates further comparison of the effects of O^2- and O^4-alkylation on the bond angles of the pyrimidine ring; Fig. 4*b* provides similar data for the effect of O^6-alkylation on the bond angles of the guanine ring. In Fig. 4*a* the pyrimidine framework represents simultaneously an O^2-alkyl and O^4-alkyl thymine base. That is, we have rotated an i^2dT moiety about its N3—C6 axis and superimposed it on an r^4dT fragment so that their equivalent conjugated fragments, R(alkyl)—O4—C4—N3—C2=O2 and R—O2—C2—N3—C4=O4, are superimposed. (X represents the 5-methyl and sugar groups in r^4dT and i^2dT, respectively.) This approach facilitates comparison of corresponding positions in the ring, that is, those which are *ortho*, *meta*, and *para* to the *O*-alkylated carbon atom. The top number in Fig. 4*a* represents the difference in bond angle i^2dT − ⟨T⟩, where ⟨T⟩ is the average of six sets of literature values for the

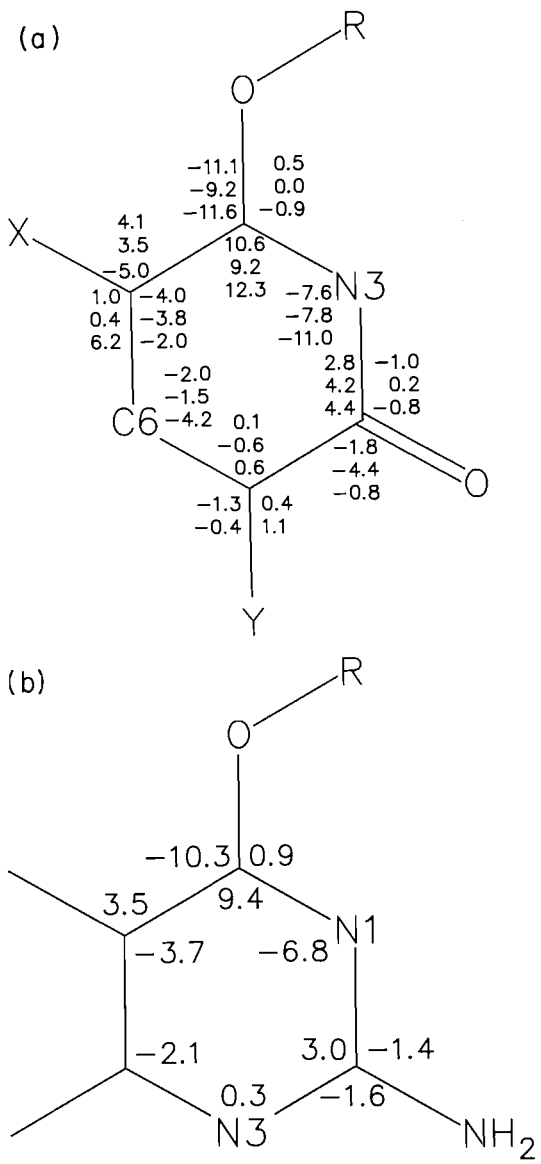

FIG. 4. Angular distortions caused by O^2- and O^4-alkylation of pyrimidine bases (*a*) and by O^6-alkylation of a guanine (*b*). The three values for each angle in (*a*) correspond to (top to bottom) $i^2dT - \langle T \rangle$, $r^4dT - \langle T \rangle$, and $\langle aU \rangle - \langle U \rangle$; the values in (*b*) correspond to $m^6G - \langle G \rangle$. See text for details.

thymine ring (10). The middle entry is $\langle r^4dT \rangle - \langle T \rangle$ where $\langle r^4dT \rangle$ is the average of the bond angles in m^4dT (9) and e^4dT (10). Since the formation of a 2,2′-anhydronucleoside mimics O^2-alkylation of a pyrimidine base, we also include $\langle aU \rangle - \langle U \rangle$ (lowest entry), where $\langle aU \rangle$ is the average of two sets of data for 2,2′-anhydrouridine (26, 27) and $\langle U \rangle$ the average of bond angles in a uracil base (28). Figure 4*b* provides $m^6G - \langle G \rangle$ data, the difference in bond angles for O^6-methylguanosine (12) and an average guanine base (28).

As can be seen, the distortions of the corresponding bond angles resulting from O^2- and O^4-alkylation are remarkably similar. For the most part, the bond angle changes effected by the formation of the 2,2′-anhydro link parallel those of O^2- and O^4-alkylation. Not surprisingly, the major differences are found at the exocyclic bond angles involving the N1—C1′ bond between sugar and base. Thus, in contrast with i^2dT and r^4dT, the C1′—N1—C2 angle of aU is compressed (−5.0°) whereas the C1′—N1—C6 angle is expanded (6.2°). These changes serve to diminish the C1′···O2 separation in aU relative to U.

The bond angle changes in the pyrimidine fragment of the guanine base produced by O^6-alkylation (Fig. 4*b*) are very similar to the changes at corresponding points of the thymine ring due to O^2- and O^4-alkylation. Thus the largest expansion (9.4°) occurs at the *O*-alkylated carbon (C6) whereas the largest compression (−10.3°) occurs at the exocyclic angle O6—C6—C5. This similarity is not unexpected since the tautomeric perturbations of the pyrimidine rings are identical for O^6- and O^4-alkylation.

Geometry of the isopropoxy group

The C2—O2—C8 bond angle is 118.8° which is similar to the magnitudes of the corresponding angle in m^2dT (9), e^4dT (10), and m^4U (8) (117.1°–118.4°); the corresponding angle in m^6G is smaller (116.4°) (12). The torsion angle in the N3—C2—O2—C8 fragment is −5.5°, placing the C8 atom in a *syn-periplanar* relation with the N3 atom. The C2—O2—C8—C9*R* and C2—O2—C8—C9*S* torsion angles are 153.0° and −84.1°, respectively. (C9*R* and C9*S* are the *pro-R* and *pro-S* methyl carbons of the isopropyl group.) The C9*S* methyl group flanks the pyrimidine on its 5′-face whereas the tertiary H8 hydrogen does so on its 3′-face. (We denote as 5′-, or 3′-, the face which points to the 5′-, or 3′-, end of a strand in a normal B–DNA molecule.) The C9*R* atom is directed away from the pyrimidine base, the situation which obtains for the methyl group of e^4dT. However, C9*R* is not coplanar with the base, but projects out slightly from the 3′-face. Relative to e^4dT, the O2—C8 bond of i^2dT has been rotated by 30° in order to avoid too short a contact between N3 and C9*S*. As it is, the distance between these atoms, 3.273(4) Å, is quite short.

Glycosyl bond

It has been known for some time that O^2-alkylation of pyrimidine nucleosides makes the glycosyl bond more susceptible to hydrolytic cleavage while O^4-alkylation has no measurable effect (20, 29). Therefore, it was of interest to determine whether the N1—C1′ bond in i^2dT is particularly weak (long). Our results show (Fig. 3) that this bond length (1.485 Å) is not significantly different from the corresponding one in m^4dT (1.478 Å) (9), e^4dT (1.493 Å) (10), and dT (1.480 Å) (30). Consequently, the relative facility with which the glycosyl bond is hydrolyzed must be due to the transition state rather than the ground state.

The conformation about the glycosyl bond is *anti* with χ_{CN} (C6—N1—C1′—O4′) = 27.1°, as it is m^4dT (40.6°), e^4dT (22.8°), and dT (39.1°).

Deoxyribose moiety

The bond lengths and bond angles of the sugar ring are normal (Fig. 3). The furanose ring adopts an *S*-type pucker (31) with a phase angle of pseudorotation (*P*) of 154.5° ($^2T_1$) and a maximum amplitude of pucker (τ_m) of 36.9°. *S*-Type puckers are also found in m^4dT (P = 133.8°; $_1T^2$; τ_m = 31.4°) (9) and the parent molecule dT (P = 187.5°; $_3T^2$; τ_m = 38.2°) (30). In contrast, e^4dT is in the *N*-range (P = 11.8°; $^3T_2$; τ_m = 36.5°) (10). The conformation about C4′—C5′ is *gauche*$^+$. This is also the case in m^4dT and e^4dT; in dT, on the other hand, it is *trans*.

Hydrogen bonding and packing

As shown in Fig. 3, there is an intramolecular C6—H···O4′ hydrogen bond. This unusual type of bond was first observed in 5-hydroxymethyl-2′-deoxyuridine (32). The H···O distance and C—H···O angle shown in the figure were calculated follow-

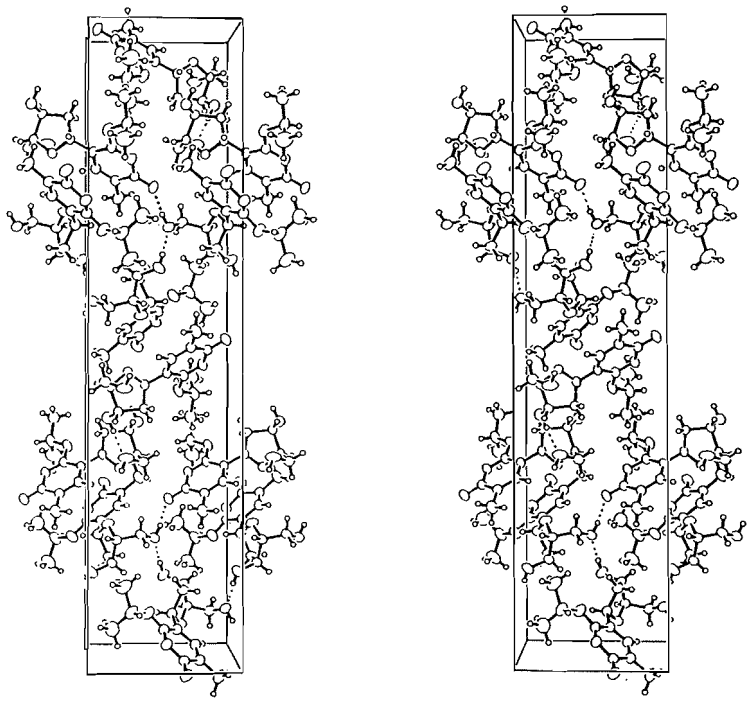

FIG. 5. Stereoscopic view of the molecular packing in the crystal. Dotted lines indicate hydrogen bonds.

ing the normalization of the C—H bond to its nominal value of 1.09 Å. They are well within the range of values previously observed in C—H···O bonds (33). In addition, there are two intermolecular hydrogen bonds: O3′—H···O5′ (at $1/2 + x$, $1/2 - y$, $5/4 - z$) and O5′—H···O4 (at y, x, $1 - z$). Their geometry is as follows: O3′···O5′ 2.742(2) Å, HO3′···O5′ 1.85(3) Å, HO3′···O5′$_{corr}$ 1.77Å (after normalizing O—H to 0.97 Å), O3′—H···O5′ 178(3)°; O5′···O4 2.652(2) Å, HO5′···O4 1.80(3) Å, HO5′···O4$_{corr}$ 1.70 Å, O5′—H···O4 168(3)°. The latter bond is quite strong, as one would expect on the basis of the "cooperative effect" (34). In contrast to the e^{4}dT structure, N3 does not act as a hydrogen bond acceptor. The packing of the molecules in the crystal is shown in Fig. 5. There are no significant stacking interactions.

^{1}H nmr analysis

With our previous studies (10, 20) we have a complete set of ^{1}H nmr data for the O^2- and O^4-methylated, -ethylated, and -isopropylated derivatives of dT. The sugar coupling constants (Table 2) are strikingly similar for the six molecules as well as for the parent dT, and indicate that these modifications have no significant influence on the sugar conformation in aqueous solution. Estimates based on $J(3'4')$ indicate a bias for the *S*-type pucker ($\%S = 60 \pm 4\%$) which is not unusual for pyrimidine 2′-deoxyribosides in solution. This is in line with the *S*-type pucker noted for m^{2}dT (9) and i^{2}dT, but contrasts with the $^3T_2$ pucker noted for e^{4}dT (10). The absence of any appreciable effect in solution of the bulky isopropyl group at the O2 position on the sugar ring is in line with a *syn-periplanar* conformation relative to N3.

The $J(4'5')$ and $J(4'5'')$ data (Table 2 and refs. 10 and 20) reveal little variation in the C4′—C5′ conformer distribution for dT and its *O*-alkyl derivatives, with average values of 49%, 38%, and 14% for the *gauche*$^+$, *trans*, and *gauche*$^-$ conformer populations, respectively. The overall similarity in the proton chemical shifts and coupling constants for the sugar protons suggests that O^2- and O^4-alkylation does not alter the *anti-syn* distribution of the *N*-glycosyl linkage.

[a]Data at 75.5 MHz measured relative to internal dioxane and converted to a TMS scale by addition of 67.86 ppm. The data for the r²dT and r⁴dT are relative to dT except for the *O*-alkyl carbons which are relative to TMS. A negative sign indicates a signal at high field of the reference.

[b]See footnote *d* in Table 2. The 9*R* and 9*S* assignment is arbitrary.

dT and its *O*-alkylated derivatives. Note that the δ values for dT are given relative to TMS, whereas those for the derivatives are given relative to dT (except for the *O*-alkyl carbons which are relative to TMS). Among the interesting trends are: (*1*) Corresponding δ values in the r²dT and r⁴dT series are similar, indicating that the tautomeric change effected by *O*-alkylation would account in each case for the δ changes relative to dT. (*2*) Alkylation at O2 and O4 causes a large deshielding of the alkoxylated carbon, C2 (3.7–4.7 ppm) and C4 (4.4–5.3 ppm), but the remaining carbonyl carbon, C4 or C2, is even more strongly deshielded. This is particularly evident in the r²dT series in which the effect at C4 is (on average) twice that at C2. (*3*) O^2-Alkylation causes a larger deshielding at the *para* C5 carbon than at C2. (*4*) In the r²dT and r⁴dT series, the alkoxylated carbon shifts upfield by about 0.4–0.5 ppm for each substitution of a methyl carbon at the C8 carbon; this can be attributed to a small γ-effect of methyl substitution (35).

Also interesting is the small chemical shift difference between C9*R* and C9*S* in i²dT (0.068 ppm; Table 3) which reflects the distereotopic relationship of the two methyl groups. (Distereotopic atoms will, in general, experience distinct magnetic shielding; see Jennings (36) and Tonelli *et al.* (37) for discussions of this phenomenon.) This relationship is also apparent in a small chemical shift difference of 0.9 Hz in their methyl protons (Table 2, footnote *e*). On the other hand, the two methyl groups in i⁴dT are also diastereotopic, but distinct resonances are not observed for them in either the ^{13}C or the ^1H nmr spectra. This is not surprising since the O^4-alkyl group is more distant from the chiral sugar moiety than the O^2-alkyl group; it is well known (36, 37) that the differential magnetic shielding of distereotopic atoms decreases rapidly with separation from chiral centres in a molecule.

Biological implications

In contrast to the e⁴dT structure (10), N3 does not act as a hydrogen bond acceptor. However, molecular models of i²dT suggest that the bulky isopropyl group may not prevent the base from pairing with either an adenine protonated at N1 (standard Watson–Crick geometry) or with a guanine (wobble base pair) (Fig. 6). With respect to the former we refer to the recent report by Hunter *et al.* (38), who found base pairing between a cytosine and an N1-protonated adenine in a double-helical dodecamer.

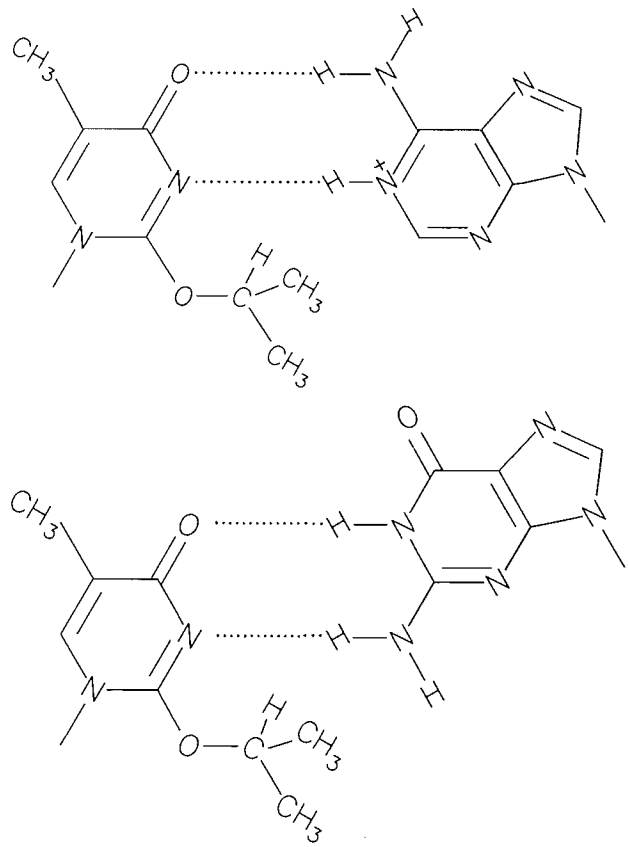

Fig. 6. Possible schemes of base pairing of i²dT with N1-protonated adenosine (top) and with guanosine (bottom).

The two schemes could account for the observed ambiguity of, for example, m²dT which can be incorporated opposite adenine by the Klenow fragment of DNA polymerase I, yet acts as dC upon replication (39). Analogous schemes could account for the recognition of O^2-ethyluridine as U or C in codon–anticodon binding (40).

Long-range $^{13}C,^{13}C$ spin–spin coupling constants in anisole and some derivatives

TED SCHAEFER AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received September 28, 1987

TED SCHAEFER and GLENN H. PENNER. Can. J. Chem. **66**, 1635 (1988).

^{13}C nuclear magnetic resonance chemical shifts and $^{n}J(^{13}C,^{13}C)$ are reported for anisole and 16 of its derivatives, all enriched with ^{13}C in the methoxyl group. $^{5}J(^{13}C,^{13}C)$ is directly proportional to $\sin^2\theta$, where θ is the angle by which the methoxy group twists about the C(1)—O bond. In acetone-d_6 solution, $^{5}J(C,C)$ is not observable for a number of 4-substituted anisoles, except for 1,4-dimethoxybenzene. For the latter, $^{5}J(C,C)$ is compatible with a twofold barrier of 19.3 ± 1.1 kJ/mol hindering rotation about the C(1)—O bond. However, it is unlikely that the barrier is purely twofold in nature. The observed $^{5}J(C,C)$ is also compatible with 10.5 and 6.0 kJ/mol for the twofold and fourfold components, respectively, implying a dynamical nuclear magnetic resonance barrier of less than 13 kJ/mol. While phase and solvent effects on the internal barrier in anisole are certainly substantial, it appears that a fourfold component must also be present. The apparent twofold barrier in 2,6-difluoroanisole is 5.4 ± 0.9 kJ/mol, based on $^{5}J(C,C)$ and $^{6}J(H\text{-}4,^{13}C)$. The latter coupling constant is also reported for 1,2,3-trimethoxybenzene and used to deduce its conformation. The θ dependence of $^{3}J(C,C)$ and $^{4}J(C,C)$ is briefly discussed for symmetrical anisole derivatives. Differential $^{13}C,^{13}C$ isotope shifts are reported for 1,4-dimethoxybenzene.

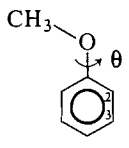
TED SCHAEFER et GLENN H. PENNER. Can. J. Chem. **66**, 1635 (1988).

On a déterminé les déplacements chimiques du ^{13}C ainsi que les constantes $^{n}J(^{13}C,^{13}C)$ pour l'anisole ainsi que 16 de ses dérivés, tous enrichis en ^{13}C dans le groupement méthoxyle. Les constantes de couplage $^{5}J(^{13}C,^{13}C)$ sont directement proportionnelles à $\sin^2\theta$, dans lequel θ est l'angle de torsion du groupement méthoxyle autour de la liaison C(1)—O. En solution dans l'acétone-d_6, on ne peut observer de constante $^{5}J(C,C)$ pour plusieurs dérivés de l'anisole substitués en position 4; la seule exception est le diméthoxy-1,4 benzène. Pour ce dernier, la valeur de la constante $^{5}J(C,C)$ suggère qu'il existe une barrière binaire à la rotation autour de la liaison C(1)—O de 19,3 ± 1,1 kJ/mol. Toutefois, il est peu probable que cette barrière soit uniquement de nature binaire. La valeur observée pour $^{5}J(C,C)$ est aussi compatible avec des composantes binaire et quaternaire respectivement de 10,5 et de 6,0 kJ/mol; ces données impliquent une barrière en résonance magnétique nucléaire dynamique inférieure à 13 kJ/mol. Alors que les effets de phase et de solvant sur la barrière interne de l'anisole sont certainement importants, il semble que la composante quaternaire doit certainement être présente. En se basant sur les constantes de $^{5}J(C,C)$ et $^{6}J(H\text{-}4,^{13}C)$, la barrière binaire apparente pour le difluoro-2,6 anisole est de 5,4 ± 0,9 kJ/mol. Cette dernière constante a aussi été observée avec le triméthoxy-1,2,3 benzène et on l'a utilisée pour déduire sa conformation. On discute brièvement du fait que, pour les dérivés symétriques de l'anisole, les constantes $^{3}J(C,C)$ et $^{4}J(C,C)$ varient avec θ. On rapporte aussi les déplacements isotopiques différentiels $^{13}C,^{13}C$ pour le diméthoxy-1,4 benzène.

[Traduit par la revue]

Introduction

The barrier to internal rotation about the C(1)—O bond in anisole in the liquid state is deduced from torsion frequencies as 25.3 kJ/mol and as 15.1 kJ/mol in the vapor on the assumption that it is twofold (1, 2). Because the conformation of lowest energy (3–5) has the carbon atom of the methyl group in the benzene plane, **1**, and because the ^{13}C nmr chemical shifts of



θ = 0° for planar anisole
θ = 180° for C-2, C-3
θ = 0° for C-5, C-6

1

C-2 and C-6 must differ by about 6 ppm (5–8), dynamic nmr measurements are indicated. At 120 K in dimethyl ether solution the resonance peaks of C-2 and C-6 are coincident and sharp, implying an internal rotational barrier of less than 19.7 kJ/mol (9). Spin-lattice relaxation measurements in the rotating frame suggest a barrier of less than 18.4 kJ/mol in the ether solution (9). Vibrational spectroscopy leads to a barrier of 48.1 kJ/mol in the solid anisole (10, 11). A recent exhaustive review is available (12).

The state dependence of the rotational motion about the C(1)—O bond is also suggested by *ab initio* molecular orbital calculations on the free molecule (13–18), which have the barrier as less than 8 kJ/mol, as do molecular mechanics computations (19). Microwave spectra (3) agree that **1** is the structure in the gas phase, while for 4-fluoroanisole such spectra (20) are consistent with a lower limit to the barrier of 4.6 kJ/mol. Photoelectron spectra of gaseous anisole imply an energy difference of 5.7 kJ/mol between planar and nonplanar forms of anisole (21). The long-range coupling constants between the ^{13}C nucleus in the methyl group and the ring protons of anisole in solution appear to be consistent with a relatively high barrier of more than 20 kJ/mol if it is assumed to be twofold (9). However, if a large fourfold component, V_4, is actually present, the long-range coupling constants are compatible with a smaller barrier. A V_2 of 11.0 kJ/mol and a V_4 of 10 kJ/mol, for example, yield a barrier of less than 16 kJ/mol and imply a $^{6}J(^{1}H,^{13}C)$ of 0.03 Hz, possibly compatible with a line width at half-height of 0.08 Hz in the ^{13}C multiplet (9). This negative evidence for a smaller barrier than 20 kJ/mol for anisole in solution is unsatisfactory.

It is conceivable that $^{6}J(^{1}H,^{13}C)$ is not simply proportional to $\sin^2\theta$ (see **1**), as has been assumed (9), although the methyl group replacement test (9, 22) does show $^{6}J(^{1}H,^{13}C)$ to be a σ–π coupling constant. Such a coupling mechanism is almost certainly consistent with a $\sin^2\theta$ behaviour (9, 23).

Another approach to the conformational behaviour of anisole involves the measurement of $^{n}J(^{13}C,^{13}C) \equiv {}^{n}J(C,C)$ in a set of compounds modelled to yield their θ dependence. Then, if the latter can be established, some independent conformational information may be accessible. This paper reports such measurements for a number of anisole derivatives, one of the ^{13}C nuclei in $^{n}J(C,C)$ being that at the methyl site.

Experimental

Enrichment of ^{13}C at the methyl site of the anisoles used 4.0 mmol of the corresponding phenol. This was dissolved in 5 mL of dry acetone, to which were added 0.8 g of dry K_2CO_3. The mixture was stirred and this was followed by addition of $^{13}CH_3I$ (95 at.% or higher isotopic purity, from MSD Istopes) in 5 mL of dry acetone. This mixture was stirred overnight. Addition of water gave a cloudy suspension that was extracted with ether. The extract was dried over anhydrous $MgSO_4$, filtered, and rotary evaporated. The ^1H and ^{13}C nmr spectra were indisputably those of the desired products.

Solutions of the anisole derivatives in acetone-d_6, containing small amounts of tetramethylsilane (TMS), were transferred to 10-mm od nmr tubes for ^{13}C nmr experiments (a few ^{13}C nmr measurements were later done on 5-mm tubes when a dual $^1H/^{13}C$ probe became available). Samples for ^1H nmr measurements employed 5-mm od nmr tubes. The sample tubes were degassed by the freeze–pump–thaw procedure and were then flame sealed to provide symmetrical tops.

All nmr spectra were accumulated on an AM300 Bruker spectrometer at a probe temperature of 300 K. For proton decoupled ^{13}C nmr spectra, some 128–256 free induction decays were acquired, while for proton coupled ^{13}C spectra these ranged from 400 to 2800. Acquisition times ranged from 20 to 30 s. For example, a spectral width of 100 Hz was assigned to a 4 K data region in the computer, to give an acquisition time of 20.5 s. The ^1H nmr spectra were the results of 8–32 induction decays with acquisition times of up to 40 s. Some zero-filling to twice the original data size was employed when desirable. Small amounts of Gaussian multiplication were employed before transformation to the frequency domain. Line widths at half-height were typically 0.05–0.25 Hz in the ^1H and ^{13}C nmr spectra.

Spectral analyses used the locally modified computer program NUMARIT (24), coupled to a plotting routine. INDO MO FPT computations (25, 26) utilized geometries optimized at the STO-3G level of molecular orbital theory, the latter computations employing MONSTERGAUSS, GAUSSIAN 80, and GAUSSIAN 82 packages (27–29). All computations, including those for spectral analysis, used Amdahl 470/V8, 580/5850, or 5870 systems. Statistical analyses used the SAS nonlinear regression procedure, NLIN.

Results and discussion

Table 1 contains ^{13}C nmr chemical shifts and $^nJ(^{13}C,^{13}C) \equiv {}^nJ(C,C)$ for anisole and 16 of its derivatives. Note that one ^{13}C nucleus in $^nJ(C,C)$ is always that of the methyl group (methylene for an ethoxy side chain). The signs of $^nJ(C,C,)$ are assumed on the basis of the computations below and because of the known signs for related coupling constants. $^2J(C,C)$ was determined to be negative in 3,5-dichlorothioanisole-α-^{13}C in an experiment in this laboratory, and $^3J(C,C)$ was found as positive. This experiment succeeded because the methyl protons coupled weakly to the ^{13}C nuclei and hence signs relative to $^1J(H,C)$ could be found by partial decoupling experiments. Similarly, $^4J(C,C)$ and $^5J(C,C)$ in 2,6-dichlorothioanisole were negative and positive, respectively. It is reasonable to expect the same signs of $^nJ(C,C)$ in anisole derivatives, particularly because $^6J(H\text{-}4,^{13}C)$ values have very similar magnitudes at the extrema in the conformational angle in anisoles and thioanisoles (see below and ref. 30), and because $^6J(H\text{-}4,^{13}C)$ is negative in both types of compounds (9, 30); it is also negative in benzyl cyanide-8-^{13}C (31). Therefore, since $^5J(C,C)$ and $^6J(H,C,)$ are both transmitted via a $\sigma-\pi$ coupling mechanism and since the hyperfine coupling parameters, Q^C_{CH} and Q^H_{CH}, are of opposite sign (32, 33), it appears certain that $^5J(C,C)$ in anisole derivatives is positive. $^5J(H,C)$ in anisole derivatives is positive for large θ values (15). Combined with eq. [2], this means that $^4J(C,C)$ is negative for such molecules. It then appears inevitable that $^4J(C,C)$ is positive for a small θ, for example, in anisole.

Figure 1 displays some proton decoupled and proton coupled ^{13}C nmr spectra, illustrating the extraction of small coupling constants.

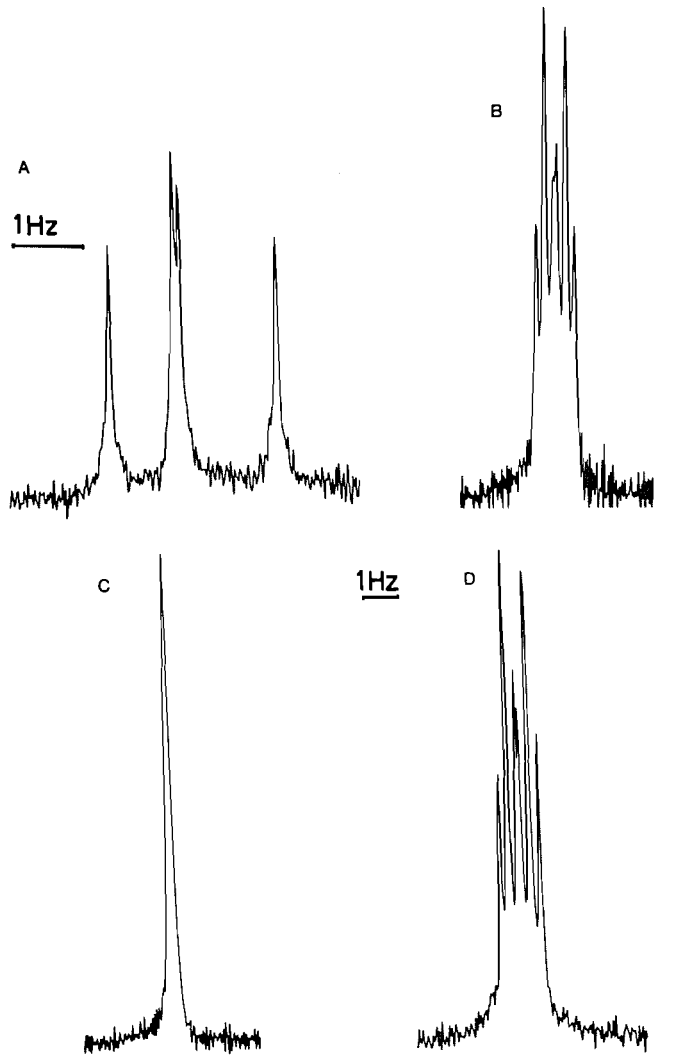

FIG. 1. In A the proton decoupled ^{13}C nmr spectrum of C-1 and C-4 is shown for 1,4-dimethoxybenzene as a 3.0 mol% solution in acetone-d_6 at 300 K and 75.486 MHz. One methoxy group is ^{13}C enriched. If it is attached at C-1, then the large splitting of 2.38 Hz is $^2J(C\text{-}1,C)$ and the small splitting of 0.065 Hz is $^5J(C\text{-}4,C)$. The latter splitting may be about 5% lower than the true $^5J(C\text{-}4,C)$ because of overlapping peaks. A differential isotope shift is present, the resonance frequency of C-1 being 0.23 Hz (3.0 ppb) lower than that of C-4. In B, part of the ^{13}C nmr spectrum of the 1-methoxy group in 2,6-dimethoxyanisole is shown at 300 K and as a 9.9 mol% solution in acetone-d_6. This natural abundance spectrum displays a $^5J(H\text{-}3,C)$ of 0.239(4) Hz and a $^6J(H\text{-}4,C)$ of (−)0.601(4) Hz. C displays the ^{13}C nmr spectrum of the flanking methoxy groups at positions C-2 and C-6. The single peak is not flat-topped, implying that coupling to the ring protons is rather small, probably less than 0.05 Hz. Note that the ^{13}C spectrum of the 1-methoxy group displays no evidence for coupling to methyl protons. In D, part of the ^{13}C nmr spectrum of the methoxy group in unenriched 2,6-dimethylanisole, as an 11 mol% solution in acetone-d_6 at 300 K, is shown under conditions in which the *ortho* methyl protons are being decoupled. The doublet of triplets arises from a $^5J(H\text{-}3,C) = {}^5J(H\text{-}5,C)$ of 0.263(7) Hz and a $^6J(H\text{-}4,C)$ of (−)0.622(4) Hz. In A the dispersion is greater than in B, C, and D, the lower scale being applicable to the latter.

INDO MO FPT computations

INDO MO FPT computations of $^nJ(C,C)$ in anisole as a function of the angle, θ, at intervals of 15°, gave numbers fitted

by eqs. [1]–[3]. The numbers in parentheses are standard deviations in the last significant figure. Equation [1] has the form of a Karplus relationship (34), although it is here written not in terms of cos θ and cos 2θ (trigonometric identities). While the actual values of the ^nJ(C,C) given by these equations are unlikely to be correct (9, 31, 35), the qualitative form is indicative of the empirical approach to follow in the use of ^nJ(C,C) for conformational deductions.

$$[1]\quad {}^3J(\mathrm{C,C})/\mathrm{Hz} = 1.92(3) - 0.76(4)\sin^2\theta + 1.47(4)\sin^2(\theta/2)$$

$$[2]\quad {}^4J(\mathrm{C,C})/\mathrm{Hz} = -0.15(1) - 1.45(2)\sin^2\theta + 0.36(2)\sin^2(\theta/2)$$

$$[3]\quad {}^5J(\mathrm{C,C})/\mathrm{Hz} = 0.00(0) + 1.53(1)\sin^2\theta$$

In an attempt to assess the intrinsic substituent effects on ^nJ(C,C), further computations were performed for the 4-fluoro, 2,6-difluoro, and 3,5-difluoro derivatives of anisole at intervales of 15° in θ. The STO-3G geometries were used as obtained by optimization procedures with the constraint that the carbon skeletons of the benzene rings remained as regular hexagons (our unpublished 6-31G MO geometry for anisole implies very small changes, less than 1°, in the internal ring angles). The fits to equations of the form $^nJ(\mathrm{C,C})/\mathrm{Hz} = A + B\sin^2\theta + C\sin^2(\theta/2)$ are summarized.

	^3J(C,C)	^4J(C,C)	^5J(C,C)
A: 4-F	1.86(4)	−0.17(2)	0.00(0)
3,5-diF	1.93(3)	−0.25(2)	−0.01(0)
2,6-diF	1.30(1)	−0.20(2)	0.00(1)
B: 4-F	−0.72(5)	−1.53(2)	1.61(1)
3,5-diF	−0.81(4)	−1.57(2)	1.49(1)
2,6-diF	−0.17(1)	−1.49(2)	1.51(1)
C: 4-F	1.59(5)	0.38(2)	—
3,5-diF	1.53(4)	0.63(2)	—
2,6-diF	1.66(2)	0.45(2)	—

Comparison with eqs. [1]–[3] indicates rather small intrinsic substituent effects except when the substituent is bonded to the carbon atom carrying the coupled nucleus.

^5J(C,C) as a conformational marker

^5J(C,C) is apparently a σ–π coupling, directly proportional to $\sin^2\theta$, just as ^6J(H,C) in anisole and involving the proton bonded to the *para* carbon nucleus of eq. [3] is very clearly a σ–π coupling (9).

The intrinsic perturbation of ^5J(C,C) by ring substituents, as distinct from their effect on $\langle\sin^2\theta\rangle$ and thereby on ^5J(C,C), is indicated as relatively small by the computations above. In 4-fluoroanisole, $^5J_{90}$ is computed to increase by 0.08 Hz or by 5.2% relative to anisole, whereas two *ortho* or *meta* fluorine substituents are calculated to decrease $^5J_{90}$ by only 0.02 Hz (1.3%) and 0.04 Hz (2.7%), respectively. Much of the increase in ^5J(C,C), from 0.94 Hz in 2,6-dibromoanisole to 1.02 Hz in 2,6-dibromo-4-fluoroanisole, is therefore plausibly attributable to an intrinsic perturbation by fluorine. However, fluorine is a weak π electron donor and is therefore expected also to cause a small increase in $\langle\sin^2\theta\rangle$. The apportionment of the 0.08 Hz between the two effects is problematical. The STO-3G MO barriers for anisole and 4-fluoroanisole imply an increase of 0.04 in $\langle\sin^2\theta\rangle$ for the latter, which would correspond to about 0.04 Hz in ^5J(C,C). However, the barriers in solution are certainly much larger than calculated for the free molecules and, of course, the change in $\langle\sin^2\theta\rangle$ caused by a 4-fluoro substituent in the presence of two *ortho* bromine substituents may well be different than in their absence.

Note, further, that ^5J(C,C) is 1.01 Hz in 2,6-dibromo-4-methylanisole. Because a methyl group is a weaker π electron donor than a fluorine substituent and because its intrinsic perturbation of $^6J_{90}$ is expected to be less than that by fluorine, this result emphasizes the difficulty of establishing an accurate value of $^5J_{90}$ in anisole itself and how it changes in the presence of ring substituents.

However, in the solid state, θ is given as 84° for 2,3,5,6-tetrachloro-1,4-dimethoxybenzene (36), corresponding to a $\sin^2\theta$ of 0.989. Kerr constants for solutions suggest θ as 90° when methyl, chlorine, or bromine substituents are placed in both *ortho* positions of anisole (37). For these substitution patterns, ^5J(C,C) lies between 0.92 and 0.98 Hz in Table 1. The latter value occurs for 2,6-dimethylanisole and the intrinsic perturbation of $^5J_{90}$ by the methyl groups is very likely rather small. It seems reasonable to write eq. [4] for anisole itself. Some of the other ^5J(C,C) values in Table 1 can then be discussed as follows.

$$[4]\quad {}^5J(\mathrm{C,C})/\mathrm{Hz} = (0.98 \pm 0.03)\langle\sin^2\theta\rangle$$

(i) 2,6-Difluoroanisole

The INDO MO FPT results imply a decrease of 1.3% in $^6J_{90}$ for this compound. Yet ^5J(C,C) is only 0.92 Hz in 2,6-dichloroanisole, so that $^6J_{90}$ could be as low as this in 2,6-difluoroanisole. For this value of $^6J_{90}$ and from the ^5J(C,C) of 0.69 Hz, there follow a $\langle\sin^2\theta\rangle$ of 0.75 and the conclusion that the perpendicular, with θ = 90°, is more stable than the planar conformation. The STO-3G MO computations, at 15° intervals of θ, agree with this conclusion and yield a twofold barrier of 6.9 ± 0.1 kJ/mol; a $\langle\sin^2\theta\rangle$ of 0.75 corresponds to one of 5.9 kJ/mol. If $^6J_{90}$ were as large as 0.98 Hz, then a twofold barrier of 4.5 kJ/mol would be deduced for the acetone-d_6 solution of 2,6-difluoroanisole. This value of $^6J_{90}$ cannot be unequivocally discarded but it should be noted that its use implies that the fluorine substituents do not intrinscally perturb $^6J_{90}$.

(ii) 1,4-Dimethoxybenzene

Of the *para* substituted anisoles in Table 1, only for 1,4-dimethoxybenzene is there a measurable value of ^5J(C,C). The methoxy group is a strong π electron donor and therefore the ^5J(C,C) of 0.07_4 Hz is consistent with the anticipated reduction of the barrier about the C_{sp^2}—O bond. Again, a $^6J_{90}$ is needed. In view of the INDO MO FPT calculations, an increase of less than 5% in $^6J_{90}$ from its value in eq. [4] can be assessed. A conservative estimate of 1.02 + 0.05 Hz leads to a $\langle\sin^2\theta\rangle$ of 0.072 ± 0.004 and thence to an apparent V_2 of 19.3 ± 1.1 kJ/mol. This result follows, as does that for 2,6-difluoroanisole above, from a hindered rotor model (38, 39) employing 31 free rotor basis functions.

Dielectric relaxation measurements on 1,4-dimethoxybenzene in tetrachloroethylene solution were compared with spin-lattice relaxation rates of the ^{13}C nuclei in the same solution (40). It was concluded that a twofold barrier of 22.2 ± 2.5 kJ/mol hindered the rotation about the C_{sp^2}—O bond. The following discussion of anisole shows the unlikelihood of a purely twofold barrier in both molecules.

(iii) Anisole

The ^5J(C,C) of less than 0.03 Hz strongly implies a $\langle\sin^2\theta\rangle$ of 0.03 or less. Were the internal barrier twofold, then its magnitude would be near 40 kJ/mol, easily ascertainable by previous experiments (9). The conclusion appears inescapable: a large fourfold component must be present in solution. For the free

For personal use only.

molecule, our STO-3G and 4-21G MO computations imply that V_4/V_2 is 0.38; a 4-31G calculation (14) gives this ratio as 0.5 ± 0.1. If the latter ratio holds in solution, then a V_2 of 16.5 and a V_4 of 9.5 kJ/mol are consistent with a $\langle \sin^2 \theta \rangle$ of less than 0.03 and with a dynamic nmr barrier of about 19 kJ/mol. It seems natural that V_4 should also be present in 1,4-dimethoxybenzene, as predicted by MO computations (18). The $\langle \sin^2 \theta \rangle$ of 0.07 for the latter is also compatible with a V_2 of 10.5 and a V_4 of 6.0 kJ/mol.

In summary, the barrier to rotation about the C(1)—O bond in anisole and its *meta* and *para* substituted derivatives in acetone-d_6 solution is too large to yield an observable ^5J(C,C), except for the 4-methoxy substituent. It appears that the barrier in all these molecules in Table 1 must have a substantial fourfold component.

Remarks on ^{4}J(C,C), ^{3}J(C,C), and ^{2}J(C,C)

The INDO MO FPT computations imply a large negative ^4J(C,C) for values near 90° and a positive ^4J(C,C) at a θ of zero. For evenfold barriers, $\langle \sin^2 (\theta/2) \rangle$ is 0.5, so that the data in Table 1 can only yield a relationship between $\langle \sin^2 \theta \rangle$ and ^4J(C,C). Comparison of ^4J(C,C) for different *para* substituted anisoles shows that ^4J(C,C) decreases in magnitude as the π donating ability of the substituent increases, as expected if the coefficient of $\sin^2 \theta$ in eq. [2] is negative.

The INDO MO FPT results imply a large perturbation of ^3J(C,C) for 2,6-difluoroanisole and relatively small perturbations for 4-fluoro and 3,5-difluoroanisole. The term in $\sin^2 \theta$ is calculated to decrease from about −0.8 Hz to −0.2 Hz in the presence of two *ortho* fluorine substituents. Experimentally, ^3J(C,C) decreases substantially for large θ values, that is, for all *diortho* substituted molecules in Table 1. The data are consistent with an intrinsic increase in ^3J(C,C) caused by electronegative *ortho* substituents; compare 2,6-dimethyl and 2,6-dibromoanisole, for example. Athough a number of ^3J(C,C) values have been reported for benzene derivatives in which one of the coupled nuclei resides in a side chain (41), few are available for the β-position. In acetophenone, ^3J(C,C) is 8.4 Hz for the ^{13}C nucleus in the methyl group (42), whereas in phenylacetic acid ^3J(C,C) is 1.9 Hz for the ^{13}C nucleus in the carboxyl group (43). The latter molecule has a large preference (44) for a conformation in which the carboxyl group lies in a plane perpendicular to that of the benzene ring. The data in Table 1 cannot be used to establish that ^3J obeys a Karplus relationship, as implied by the computations, but are consistent with a minimum near θ = 90° and maxima at θ = 0° and 180°. The largest ^3J in Table 1 occurs for 3,5-difluoroanisole, for which our STO-3G MO computations yield a V_2 component that is 3.7 kJ/mol larger than that in the computed barrier of anisole. It is therefore this compound which is expected to display the smallest deviations from planarity.

The ^2J(C,C) values increase from 2.3 Hz in anisole to 3.6 Hz for the derivatives with large *ortho* substituents. The INDO MO FPT values suggest small intrinsic substituent effects and yield ^2J(C,C) as −5.1 Hz at θ = 0° and −5.6 Hz at θ = 90°.

^{6}J(^1H,$^{13}CH_3$) as a conformational indicator

In previous work, $^6J(^1\text{H},^{13}\text{CH}_3) \equiv {}^6J$(H,C) was assessed as a σ−π coupling constant, proportional to $\sin^2 \theta$. $^6J_{90}$(H,C) was taken as −0.63 ± 0.01 Hz (19).

No ^6J(H,C) is observable for anisole in acetone-d_6 or in a CS_2/C_6D_{12} mixture (9). In 2,6-dimethylanisole, we measure ^6J(H,C) as -0.62_2 Hz, compared to −0.602 Hz in the 2,6-dichloro derivative, both in acetone-d_6 solution. A previous value for the latter molecule is −0.603(5) Hz in benzene-d_6 solution (9). For 2,6-difluoroanisole, the present ^6J(H,C) is -0.47_3 Hz, corresponding to an apparent V_2 of 5.9 ± 0.4 kJ/mol.

In 2,6-dimethoxyanisole, which could not be prepared with ^{13}C enrichment in the 1-methoxy group by our methods, ^6J(H,C) is −0.60 Hz. This result implies an arcsin $\langle \sin^2 \theta \rangle^{\frac{1}{2}}$ of about 80° for the central methoxy moiety. Its flanking methoxy groups display no observable ^6J(H,C) in Figure 1 and are therefore confined to small θ values (no ^5J(H,C) is observed either, implying (9) that the O—C bonds point away from the central methoxy entity). In such a situation, one might have expected an internal barrier to rotation about the C(1)—O bond similar to that in 2,6-difluoroanisole rather than, as suggested by ^6J(H,C), to that in 2,6-dichloroanisole. It follows that the π electron donating properties of the two, roughly in-plane, methoxy groups (maximum conjugation) decrease the mobile bond order of the C(1)—O bond substantially more than do two flanking fluorine substituents. This conclusion seems reasonable.

The arcsin $\langle \sin^2 \theta \rangle^{\frac{1}{2}}$ value of about 80° compares with 82 ± 7° reported for a 1,2,3 arrangement of methoxy substituents in some crystal structures (16). It is also compatible with qualitative conclusions based on ^{13}C nmr chemical shifts and ^{13}C spin-lattice relaxation times (45, 46), as well as with the observed dipole moment in solution (47, 48). The perpendicular orientation of the 1-methoxy group is assumed in the interpretation of the photoelectron spectrum in the vapor (16).

Differential isotope shifts in 1,4-dimethoxybenzene

If the methoxy group enriched in ^{13}C is attached at C-1, then, in Gombler's notation (51), $^2\Delta^{13}\text{C}(^{13/12}\text{C}) - {}^5\Delta^{13}\text{C}(^{13/12}\text{C})$ is −3.0 ± 0.3 ppb (see Fig. 1A, where the centers of gravity of the C-1 and C-4 doublets are clearly not coincident). In other words, C-1 is more shielded than C-4, resonating at a lower frequency of 0.23 Hz at 75.486 MHz than C-4. Very few $^{13/12}$C isotope shifts on ^{13}C are known (52). In some monosubstituted benzenes (53), $^2\Delta^{13}\text{C}(^{13/12}\text{C})$ within the ring is always less than 4 ppb and $^3\Delta^{13}\text{C}(^{13/12}\text{C})$ is less than 1.2 ppb, perhaps implying that the number above for 1,4-dimethoxybenzene is mainly $^2\Delta$. For C-2 and C-3 in this molecule, $^3\Delta - {}^4\Delta$ is 2.3 ± 0.3 ppb.

Long-range coupling constants for α-^{13}C nuclei in phenyl-X-R (X = O,S,Se,Te) derivatives. Internal rotational information

TED SCHAEFER AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received December 4, 1987

TED SCHAEFER and GLENN H. PENNER. Can. J. Chem. **66**, 1641 (1988).

The long-range spin–spin coupling constant over six bonds between the ^{19}F nucleus and the ^{13}C nucleus in the side chain, ^6J(C,F), is reported for 4—F—C_6H_4—X—R, where X = O, S and R = CH_3, CH_2CH_3, $CH(CH_3)_2$ and $C(CH_3)_3$. ^6J(C,F) depends on $\sin^2\theta$, where θ is the angle by which the side chain twists out-of-plane about the C_{sp^2}—X bond. Expectation values of $\sin^2\theta$ are obtained from ^6J(C,F), yielding magnitudes of the apparent twofold barrier to rotation about the C_{sp2}—X bond. In these terms, the most stable conformation is that for θ = 0° for all compounds, with the exception of R = $C(CH_3)_3$ and of X = S, R = $CH(CH_3)_2$; there is effectively free rotation about the C_{sp^2}—S bond in isopropyl 4-fluorophenyl sulfide in acetone-d_6 solution. Good correlations exist between ^6J(C,F) and a number of other molecular properties, including certain differences of ionization potentials of the molecular orbitals in the ethers. In particular, the chemical shifts of C-4 are correlated with ^6J(C,F). Because ^5J(C,C), the coupling constant involving C-4, also depends on $\sin^2\theta$, it is measured for the methyl and ethyl selenides and tellurides, as are other ^{13}C,^{13}C couplings involving a ^{13}C nucleus in the side chain. The literature values for the ^{13}C nuclear magnetic resonance chemical shifts in alkyl phenyl selenides and tellurides can be related to θ preferences and also allow estimates of the extrema in ^5J(C,C). The resultant values of $\arcsin\langle\sin^2\theta\rangle^{1/2}$ for R = CH_3 are in good agreement with estimates of θ obtained from electron diffraction patterns, photoelectron spectra, and nuclear magnetic resonance in the nematic phase.

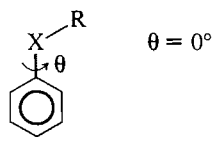
TED SCHAEFER et GLENN H. PENNER. Can. J. Chem. **66**, 1641 (1988).

On a déterminé les constantes de couplage spin–spin à longue distance, à travers six liaisons, entre le noyau de ^{19}F et le noyau de ^{13}C de la chaîne latérale, ^6J(C,F), des composés 4—F—C_6H_4—X—R, dans lesquels X = O ou S et R = CH_3, CH_2CH_3, $CH(CH_3)_2$ et $C(CH_3)_3$. Les valeurs des ^6J(C,F) varient avec le $\sin^2\theta$, dans lequel θ est l'angle entre le plan du noyau benzénique et la chaîne latérale. Les valeurs attendues de $\sin^2\theta$ sont obtenues à partir des valeurs des ^6J(C,F) et elles fournissent les amplitudes de la barrière binaire apparente pour la rotation autour de la liaison C_{sp^2}—X. Dans ces termes, la conformation la plus stable pour tous les composés, exceptés ceux pour lesquels R = $C(CH_3)_3$ ainsi que X = S et R = $CH(CH_3)_2$, est celle pour laquelle θ = 0°; en solution dans l'acétone-d_6, on observe de fait une rotation libre autour de la liaison C_{sp^2}—S du sulfure d'isopropyle et de fluoro-4 phényle. Il existe une bonne corrélation entre les valeurs de ^6J(C,F) et un certain nombre d'autres propriétés moléculaires, y compris certaines différences dans les potentiels d'ionisation des orbitales moléculaires des éthers. On peut établir, en particulier, une corrélation entre les déplacements chimiques en C-4 et les valeurs des ^6J(C,F). Puisque les valeurs de ^5J(C,C), les constantes de couplages impliquant le C-4, dépendent aussi de $\sin^2\theta$, on a mesuré cette constante pour les sélénures et les tellurures de méthyle ainsi que d'éthyle; on a aussi mesuré les constantes de couplage ^{13}C,^{13}C impliquant un noyau ^{13}C de la chaîne latérale. On peut établir une corrélation entre les préférences θ et les valeurs rapportées dans la littérature pour les déplacements chimiques en résonance moleculaire nucléaire du ^{13}C des sélénures et de tellurures d'alkyle et de phényle; à l'aide de ces déplacements chimiques, on peut aussi évaluer les extrêmes dans les valeurs des ^5J(C,C). Les valeurs résultantes pour $\arcsin\langle\sin^2\theta\rangle^{1/2}$, pour R = CH_3, sont en bon accord avec les évaluations obtenues pour θ à partir des patrons de diffraction, des spectres photoélectroniques et des spectres en résonance magnétique nucléaire dans une phase nématique.

[Traduit par la revue]

Introduction

The barriers to rotation about the C_{sp^2}—X bond in phenyl—X—R molecules (X = O, S, Se, Te; R = CH_3, CH_2CH_3, $CH(CH_3)_2$, $C(CH_3)_3$) are uncertain. The internal barrier in anisole is computed as consisting of twofold and fourfold components at the STO-3G level of *ab initio* molecular orbital theory, V_2 and V_4 being 5.6(4) and 2.1(4) kJ/mol, respectively (1, 2). A somewhat larger ratio of V_4/V_2 is approximated at the 4-31G level (3). A fully optimized STO-3G MO computation (4) has the planar conformer as 7.9 kJ/mol more stable than the orthogonal form. While microwave spectra (5) confirm the coplanar heavy atom conformation as the most stable (**1**, θ = 0°), they provide no information on the magnitude of the barrier; the microwave spectrum of 4-fluoroanisole places a lower limit of 4.5 kJ/mol on the height of the barrier (6). Molecular mechanics has this height as 7.9 kJ/mol (7) in anisole and the torsional frequency for motion about the C_{sp^2}—O bond yields 15.1 ± 0.3 kJ/mol on the assumption that the barrier is twofold in nature (8). The barrier height is phase dependent, reported as 48.2 ± 1.3 kJ/mol in the solid (9) and as 25.2 ± 0.3 kJ/mol (8) in the pure liquid (assumed twofold). Dynamic nmr experiments in ether solution imply a barrier height of less than 19.7 kJ/mol (10), while long-range coupling constants indicate the presence of a substantial fourfold component (10). Most experimental data (11–13) imply a rotational barrier in the gas phase of less than 10 kJ/mol.



θ = 0°

1

Much less work has been reported on the conformational properties of other phenyl alkyl ethers. Photoelectron spectra (14) in the gas phase are best interpreted in terms of planar conformations for the ethyl and isopropyl compounds, but for the *tert*-butyl phenyl ether a nonplanar conformation is found. Similar conclusions follow from infrared absorption intensities in CCl_4 solution (15). At high temperatures the presence of a nonplanar conformer is detected for anisole and ethyl phenyl ether (14).

In chloroform solution (16), the ^{1}H and ^{13}C nmr chemical shifts and some of the spin–spin coupling constants between

nuclei within the phenyl group of phenyl alkyl ethers are sensitive to the nature of the alkyl group. For example, ^1J(H-4,C-4), the coupling constant between the *para* ^{1}H and ^{13}C nuclei, is relatively insensitive to the substitution of an ethyl or an isopropyl for a methyl group; a relatively large change in ^1J(H-4,C-4) is observed in the presence of a *tert*-butyl group. These studies (16) show, in agreement with the gas phase photoelectron spectra, that in solution the $2p-\pi$ conjugation is much smaller for R = *tert*-butyl than for R = CH_3, CH_2CH_3, and $CH(CH_3)_2$.

^{13}C nuclear magnetic resonance and photoelectron studies (17, 18) of alkyl phenyl sulfides (R = CH_3, CH_2CH_3, $C(CH_3)_3$) demonstrate that the degree of nonplanarity increases monotonically as the size of the alkyl group increases (19). The degree of nonplanarity is a compromise between the effects of $3p....\pi$ conjugation, tending to decrease θ, and steric interference between the alkyl group and the *ortho* C—H bonds, tending to increase θ. The chemical shift of C-4 of the *tert*-butyl derivative is the same as in benzene, consistent with a large average θ in this compound. The Kerr constant in cyclohexane solution (20) indicates a θ of 82 ± 11°C. In the 4-fluorophenyl derivative (21) the C-4 and ^{19}F chemical shifts are almost identical with the corresponding shifts in fluorobenzene, in line with the conclusions above. Attempts have also been made to relate the ^{13}C nmr shifts to the populations of the planar conformers of the alkyl phenyl sulfides (22).

The ^{1}H and ^{2}H nmr spectra of 4-chlorophenyl methyl selenide-α-d_3 dissolved in a liquid crystal are consistent with a θ near 40°, implying only a small barrier to rotation about the C_{sp^2}—Se bond (23). An electron diffraction pattern in the gas phase suggests a θ of 40 ± 13° (24). The Kerr effect in solution has θ as 32° (25). The ^{13}C nmr chemical shifts of neat alkyl phenyl selenides (26, 27) bear out the intuition that $p...\pi$ conjugation decreases in the order O > S > Se. Hence nonplanar conformations will be increasingly favored in that order. Photoelectron spectra (28) and electric dipole moments (29) are in apparent agreement with such a conclusion, although it has been stated (30) that ^{1}H and ^{13}C nmr spectra of C_6H_5XR (X = O, S, Se, Te) in CCl_4 solution do not contradict the hypothesis of planar conformations.

The $p...\pi$ conjugation in methyl phenyl telluride is even weaker than for the selenium compound (29) and photoelectron spectra are consistent (31) with a θ of at least 60°, implying that the perpendicular is possibly more stable than the planar conformer.[1]

This paper reports on another approach to the estimation of the internal rotational potentials about the C_{sp^2}—X bonds in some phenyl-X-R derivatives. This approach utilizes long-range ^{13}C,^{13}C spin–spin coupling constants, ^nJ(C,C), where one ^{13}C nucleus is situated in R, for X = Se, Te and R = CH_3, CH_2CH_3. For 4-fluorophenyl-X-R, where R = CH_3, CH_2CH_3, $CH(CH_3)_2$, $C(CH_3)_3$ and X = O, S, the coupling constant over six formal bonds, $^6J(^{13}C,^{19}F)$, is used to assess the mobility about the C_{sp^2}—X bond. Both ^5J(C,C) and ^6J(C,F) depend on the angle θ in a simple way.

Experimental

The synthesis of selenoanisole-α-^{13}C (methyl phenyl selenide) went as follows. About 0.1 g of sodium was added to 10 mL of absolute methanol, followed by addition of 2 mmol of selenophenol (benzeneselenol). Then 2.3 mmol of $^{13}CH_3I$ (95 at.%) was added while stirring. The solution was stirred for 15 min, after which time water was added, giving a cloudy suspension. The mixture was extracted with ether, the ether layer was dried over anhydrous $MgSO_4$, filtered, and rotary evaporated. Ethylation to give ethyl phenyl selenide employed 2.3 mmol of $CH_3{}^{13}CH_2I$.

The methyl phenyl telluride, enriched with ^{13}C at the methyl site, was made from diphenyl ditelluride, which was added to 5 mL of absolute methanol and 2 mL of benzene (dissolution in this solvent mixture was not quite complete). To this mixture, 0.5 g of $NaBH_4$ in 5 mL of 1 N sodium hydroxide was added dropwise. The undissolved telluride went into solution, which first became colorless and then slightly cloudy. At this time, 0.5 g of $^{13}CH_3I$ in about 1 mL of methanol was added, and the solution was stirred for 0.5 h and then poured over crushed ice. After addition of 10% HCl, the mixture was extracted with methylene chloride, dried over anhydrous $MgSO_4$, filtered, and evaporated to give a light brown liquid. Ethyl phenyl telluride was prepared similarly, using $CH_3{}^{13}CH_2I$.

The ethers and sulfides with R = CH_3, CH_2CH_3, $CH(CH_3)_2$ can be obtained by the standard method of reacting the phenol or thiophenol derivatives with the appropriate alkyl iodide in dry acetone as the solvent and in the presence of dry sodium carbonate.

The *tert*-butyl-4-fluorophenyl ether was made from 4-fluorophenol, which was added to absolute methanol containing sodium. Alkylation under these basic conditions was obtained by the addition of *tert*-butyl bromide.

The preparation of *tert*-butyl-4-fluorophenyl sulfide proceeded according to the literature (32). Ten grams of 80% H_2SO_4 in a 50-mL beaker was cooled in an ice bath. Then 1.5 g of *tert*-butyl alcohol was added dropwise while stirring, holding the temperature below 10°C. 4-Fluorothiophenol (1.3 g) was then added dropwise, stirring the while. The mixture was stirred overnight at room temperature. Addition of crushed ice to the mixture was followed by extraction with ether and rotary evaporation to yield a viscous liquid.

Solutions for nmr spectral work were prepared in acetone-d_6 or benzene-d_6 (see tables) and were transferred to 10 mm od nmr sample tubes, together with 10 drops of tetramethylsilane (TMS). The sample tubes were degassed by the freeze–pump–thaw procedure and were then flame sealed.

Most ^{13}C nmr spectra were taken at 75.486 MHz on a Bruker AM300 spectrometer at a probe temperature of 300 K under conditions of proton decoupling. Those for the sulfides employed a WH90 instrument at 22.63 MHz and 305 K. Typically, 128–256 free induction decays were accumulated. For example, a spectral width of 100 Hz was assigned to a 4K data region, using acquisition times of 20.5 s. Zero-filling to twice the original data region before Fourier transformation, and using a small amount of Gaussian multiplication, resulted in acceptable line shapes and peak widths at half-height usually lying between 0.05 and 0.25 Hz.

STO-3G MO computations (33) employed the computer program GAUSSIAN 82 (34).

Results and discussion

Table 1 presents ^{13}C nmr chemical shifts and ^nJ(C,C) for the selenides and tellurides, one ^{13}C nucleus being that in the methyl or methylene groups of the side chain. When observable, ^nJ(C,C) values were typically reproducible to 0.01 Hz. The signs of ^nJ(C,C), n = 2–5, are assumed on the basis of those determined for thioanisole derivatives (35) and also computed semiempirically.

^6J(C,F) values in the ethers and sulfides are given in Table 2. Although they are almost certain to be positive (10, 36–38), their sign has previously not been determined. Figure 1 demonstrates the sign determination of ^6J(C,F) in 4-fluoroanisole-α-^{13}C. ^nJ(C,F) values for ^{13}C nuclei within the benzene ring are available, as are the ^{13}C chemical shifts for the sulfides (21), and

[1]In all these experiments, the derived angle of twist, θ, about the C_{sp^2}—X bond is an average value but it is often unclear what this average is. The distribution among θ values depends, of course, on the temperature and the internal rotational potential.

R/X	O[a]	S[b]	O[c]	S[d]	O[e]	S
CH_3	0.11	0.47	0.07_3	0.31_6	19.4	4.0
CH_2CH_3	0.12	0.74	0.08_0	0.49_1	17.3	0.2
$CH(CH_3)_2$	0.27	0.92	0.18_0	0.61_4	8.7	−2.4[f]
$C(CH_3)_3$	1.04	1.38	0.69_3	0.92_3	−4.2[f]	−18.3[f]

[a]All samples were 50 mol% in acetone-d_6, except for R = $C(CH_3)_3$, which was 5 mol%.
[b]50 mol% in acetone-d_6.
[c]Based on $^6J_{90}$(C,F) as 1.50 Hz; see text.
[d]Based on $^6J_{90}$(C,F) as 1.50 Hz.
[e]These are *apparent* V_2 values, in kJ/mol. It is unlikely, in the phenyl ethers, that a twofold component alone adequately describes the internal motion; see text.
[f]Negative numbers indicate the perpendicular conformer as most stable.

are not reported here. ^{13}C nuclear magnetic resonance studies of alkyl phenyl ethers are also available (16).

The dependence of $^6J(C,F)$ in the ethers and sulfides

Previous experimental and theoretical investigations (10, 36, 37) of ^6J(C,F) in a variety of benzene derivatives are all consistent with a simple dependence of the form $^6J(C,F) = {}^6J_{90}\sin^2\theta$, where $^6J_{90}$ is the value for the perpendicular conformation of the side chain. In 2,6-dibromo-4-fluoroanisole, ^6J(C,F) is 1.48 Hz (37). Judging by crystallographic diffraction data for an anisole derivative, in which two *ortho* chlorine substituents cause θ to be 84° (39), it seems most likely that $^6J_{90}$ is no greater than 1.50 Hz. If this number is used for $^6J_{90}$, the expectation values of $\sin^2\theta$ in Table 2 apply. Apparent V_2 values in this table then follow on the basis of a hindered rotor model (40). They are only apparent values because the $\langle\sin^2\theta\rangle$ values are also compatible with various ratios, V_2/V_4.

STO-3G MO computations on 4-fluoroanisole (2) yield V_2 and V_4 as 4.5 ± 0.4 and 2.2 ± 0.4 kJ/mol, respectively. There is no doubt that the barrier in anisole itself is highly state dependent, ranging from 48.2 kJ/mol in the solid (9) to an apparent V_2 of 25.2 kJ/mol in the pure liquid (8) and one of 15.1 kJ/mol in the gas phase (8). The apparent V_2 of 19.4 kJ/mol based on ^6J(C,F) for 4-fluoroanisole in acetone-d_6 solution (Table 2) is sensible in these terms because the fluorine substituent will act to decrease the mobile bond order of the C_{sp^2}—O bond. However, it is most unlkely that the internal rotational potential in anisole or its *para* fluoro derivative is purely twofold (1–4). In fact, a $\langle\sin^2\theta\rangle$ of 0.07_3 for the fluorine derivative is also found for a V_2 of 11.1 and a V_4 of 4.5 kJ/mol, taking the theoretical ratio of these components as a guide. Such a ratio corresponds to a barrier magnitude of less than 12 kJ/mol, as would be measured in principle by dynamic nmr procedures, for example.

One may identify another possible ambiguity concerning ^6J(C,F). The OR group is a strong π electron donor when θ is zero. The hyperfine coupling parameter of ^{19}F in the aromatic C—F bond is probably a function of the C—F mobile bond order (41–43) and, in the presence of a *para* OR group, might vary with θ. Because ^6J(C,F) may also reflect variations in the mobile bond order, it is possible that $^6J_{90}$ as used here is an underestimate in the sense that, for nearly planar conformations, $\langle\sin^2\theta\rangle$ is actually smaller than the value used in the discussion above. In a study of ^5J(C,C) in anisole derivatives (35), it is estimated that $^5J_{90}$(C,C) is 0.98 Hz. Hence ^5J(C,C) in 4-fluoroanisole should be ^6J(C,F) (0.98/1.50) or 0.07 Hz. This coupling has not been resolved (35), it being estimated that $^5J(C,C) < 0.05$ Hz. It therefore seems possible or even probable that the apparent V_2 in Table 2 is a lower limit.[2]

What is fairly certain from the data in Table 2, however, is the marked destabilization of the planar conformation in *tert*-butyl 4-fluorophenyl ether. The discussion above implies that a $^6J_{90}$ of 1.50 Hz is most reliable for this compound (θ nearer 90°). Therefore the $\langle\sin^2\theta\rangle$ of 0.69 demonstrates that the perpendicular conformer is more stable than the planar conformer (a vanishing barrier or a purely fourfold barrier entails a $\langle\sin^2\theta\rangle$ of 0.5). It also seems certain that the other ethers in Table 2 have a planar conformation as the most stable in acetone-d_6 solution.

Of course, the 4-fluoro substitutent will destabilize the planar conformation by π electron donation, so that the present conclusions do not directly apply to the alkyl phenyl ethers themselves. It is interesting, therefore, to note eq. [1], in which ΔI^{γ}_{31} is

[2]The intrinsic perturbation of ^6J(C,F) by other ring substituents may be inferable from extensive studies of, say, ^6J(H,F) and ^5J(C,F) in a variety of toluene derivatives; such studies are underway.

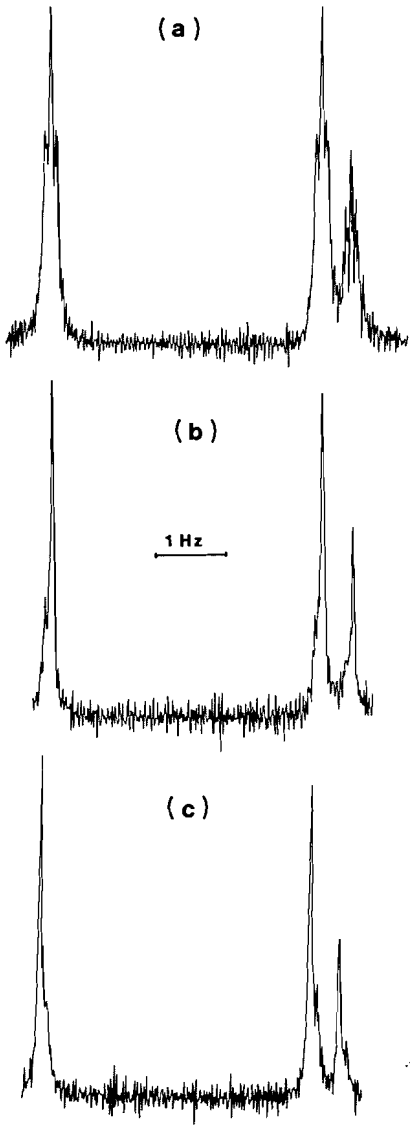

FIG. 1. In (a), part of the ^{19}F nmr spectrum of a 10 mol% solution of 4-fluoroanisole-α-^{13}C in acetone-d_6 is displayed at a probe temperature of 300 K and a spectrometer frequency of 282.363 MHz. The ^{19}F chemical shift is 38.45 ppm (deshielded) relative to internal C_6F_6. The digital resolution is 0.012 Hz/point. The ^{19}F spectrum evinces coupling interactions with all protons and with the ^{13}C nucleus of the methyl group. It is known that ^7J(H,F) is 0.083(1) Hz (46). The magnitude of ^6J(C,F) is 0.11 Hz, as measured from the proton decoupled ^{13}C nmr spectrum. These small coupling constants account for the fine structure of the bands in (a). In (b), the region of (a) is again displayed, but under conditions in which the low-frequency region of the methyl proton doublet is being irradiated. This irradiation causes partial decoupling (47) of the methyl protons, that is, for those molecules in which the ^{13}C nucleus has a given spin state, say $\frac{1}{2}$. A partial collapse of bands in (b) has occurred, so that intensity has accrued towards the right, that is, any quartet structure due to coupling with the methyl protons collapses in the low-frequency parts of the bands. In (c), the methyl protons are being irradiated at high frequency for the other spin state of ^{13}C, say $-\frac{1}{2}$. The high-frequency parts of the bands are collapsed. These $^{19}F\{^1H\}$ experiments show that ^1J(H,C)/^6J(C,F) is positive. It is known (48) that ^1J(H,C) is positive.

obtained from the photoelectron spectra of these ethers in the gas phase (14). ΔI^v_{31} represents the conjugative interaction between the oxygen lone pairs and the π electrons of the phenyl group. The correlation is significant at the 98% confidence level. It suggests that any perturbation of the conformational behaviour of the OR group by the fluorine substituent is proportional to the extent of $2p...\pi$ conjugation in the unsubstituted ethers and should therefore be least for the *tert*-butyl group. It also suggests that the qualitative nature of the internal rotational potential about the C_{sp^2}—O bond in the gas phase is not severely altered in solution, although, of course, the magnitudes of the *n*-fold components must increase in solution, as discussed above. Because ^6J(C,F) is proportional to $\sin^2\theta$, eq. [1] suggests that the conjugative interaction between the lone pairs on oxygen and the aromatic π orbitals also changes in this simple way with the conformational angle.

$$[1]\quad \Delta I^v_{31}/\text{eV} = 2.87 - 1.79\,{}^6J(\text{C,F}); \qquad r = 0.998$$

Equation [2] is also of some interest because it demonstrates a correlation between the one-bond $^1H,^{13}C$ coupling constant at C-4 in the phenyl groups of alkyl phenyl ethers as 1 molar solutions in $CDCl_3$ (16) and ^6J(C,F) in the corresponding 4-fluoro derivatives in acetone-d_6 solution. It is probable (44) that ^1J(H,C) is proportional to $-Q^H_{CH}$, a hyperfine interaction parameter that displays a much smaller variation (43) than that for ^{19}F in the C—F bond, possibly implying that ^6J(C,F) is a fairly reasonable indicator of the conformational properties of the OR group.

$$[2]\quad {}^1J(\text{H,C-4}) = 160.80 - 0.749\,{}^6J(\text{C,F}); \qquad r = 0.997$$

Turning to the sulfides in Table 2, it is noted that the SR is a much weaker π electron donor than the OR group. Consequently, it is likely that any intrinsic perturbation of ^6J(C,F) by conjugative interactions is much smaller for the sulfides. Furthermore, the barrier to internal rotation about the C_{sp^2}—S bond is therefore smaller than for the ethers; for thioanisole and 4-fluorothioanisole it is also computed as mainly twofold (2, 37).

In 2,6-dibromo-4-fluorothioanisole, ^6J(C,F) is 1.48 Hz (10), implying that $^6J_{90}$ is again about 1.50 Hz. On this basis, the $\langle\sin^2\theta\rangle$ and V_2 values follow as in Table 2. If the barriers for the larger alkyl groups are also mainly twofold, then there is essentially free rotation about the C_{sp^2}—S bond in the ethyl sulfide derivative, and for R = $CH(CH_3)_2$, $C(CH_3)_3$ the most stable conformation has θ as 90°. Our geometry-optimized STO-3G MO calculations on ethyl 4-fluorophenyl sulfide suggest that V_4 is about 10% of V_2, just as for the methyl compound (2), but essentially unaltered as to magnitudes: V_2 is calculated as 4.4(1) kJ/mol and V_4 as 0.5(1) kJ/mol. ^6J(C,F) is unequivocal in its indication of a much smaller barrier in the ethyl derivative in solution (Table 2).

A number of correlations between ^6J(C,F) and other conformationally dependent molecular properties exist for the sulfides. In eq. [3], σ°_R is related to the intensities of certain infrared bands (15) and is a measure of the resonance interaction between the substituent and the aromatic π system in CCl_4 solution. Again, in eq. [4] ^6J(C,F) correlates with the intensity of the ultraviolet band near 260 nm for these sulfides (18).

$$[3]\quad \sigma^\circ_R = -0.336 + 0.189\,{}^6J(\text{C,F})/\text{Hz}; \qquad r = 0.999$$

$$[4]\quad \varepsilon_{max} = (1.744 \times 10^4) - (1.143 - 10^4)\,{}^6J(\text{C,F})/\text{Hz}; \qquad r = 0.996$$

A very good correlation exists between the ^{13}C chemical shift of C-4 for the neat liquids (21) and ^6J(C,F) in acetone-d_6 solution for the four alkyl phenyl sulfides in Table 2, as in eq. [5]. This correlation is reasonable because δ(C-4) is most likely related to the electron density at C-4, and our computations of electron density, ρ, at C-4, using the STO-3G basis set on

TABLE 3. Conformational information about phenyl-X-R (X = S, Se, Te) derivatives from ^{13}C nmr chemical shifts and spin–spin coupling constants

[c]Based on eq. [7] of the text and δ(C-4).
[d]The alkyl-4-fluorophenyl sulfides, using ^6J(C,F) in Table 2.
[e]Based on δ(C-4) values for the alkyl phenyl selenides (26) and eq. [7].
[f]Based on δ(C-4) values (49) and eq. [7], the value for R = $C(CH_3)_3$ being unknown.
[g]In kJ/mol, *apparent* V_2 values.

4-fluoroanisole, suggest a $\sin^2\theta$ dependence, eq. [6]:

[5] $^6J(C,F)/Hz = -70.23 + 0.439\,\delta(C\text{-}4) \qquad r = 0.999$

[6] $\rho(C\text{-}4) = 5.871 - 0.01036\sin^2\theta$

^6J(C,F) and δ(C-4) therefore go as $\sin^2\theta$.[3]

The selenides and tellurides

The conjugative interactions tending to decrease the angle θ are clearly weaker in the sulfides than in the ethers. Intuitively the strength of such interactions should fall off as O > S > Se > Te, partly because of the increase in the C_{sp^2}—X bond length, but also because of the increasing mismatch in the energies of the relevant orbitals for the heavier chalcogens.

^5J(C,C) in thioanisole and its derivatives has a $\sin^2\theta$ dependence (35). Were $^5J_{90}$(C,C) available, $\langle\sin^2\theta\rangle$ would follow for the selenides and tellurides in Table 1. The synthesis of the appropriate 2,6-disubstituted derivatives has not been achieved and hence $^5J_{90}$(C,C) is not available. However, the correlation represented by eq. [6] suggests the following procedure. δ(C-4) for the alkyl phenyl sulfides (19) is written as eq. [7], where 128.5 is the ^{13}C chemical shift of benzene (26). For thioanisole in solution, $\langle\cos^2\theta\rangle$ is 0.74 (37), yielding A as 5.4_1. In 4-fluorothioansole, of course, $\langle\cos^2\theta\rangle$ will be smaller than in thioanisole because of the π electron donation by the fluorine substituent. Equation [7] and the δ(C-4) of 128.1 ppm for *tert*-butyl phenyl sulfide yield $\langle\cos^2\theta\rangle$ as 0.074 and imply (Table 2) that the barrier in this compound is little different from that of the 4-fluorophenyl derivative. This conclusion is sensible in that the $p\ldots\pi$ conjugation in the former is already almost completely broken; the fluorine substituent will therefore have only a slight influence. The apparent V_2 values for the alkyl phenyl sulfides and their 4-fluorophenyl derivatives are entered in Table 3. Those for the latter are based on ^6J(C,F), while those for the former are based on the value for thioanisole (37) derived from ^6J(H,C) and the δ(C-4) values (19) using eq. [7].

[7] $\delta(C\text{-}4) = 128.5 - A\langle\cos^2\theta\rangle$

Turning to the selenides, it is striking that δ(C-4) is the same in 4-*tert*-butyl phenyl selenide (26) as in the corresponding sulfide (19). Therefore eq. [7] is appropriate for the selenides, and their chemical shifts (26) then yield the $\langle\sin^2\theta\rangle$ values in Table 3. The apparent V_2 values seem reasonable by comparison with the sulfides. It follows that $^5J_{90}$(C,C) is 0.62 ± 0.03 Hz for the selenides as compared to 0.91 Hz determined for $^5J_{90}$(C,C) in the sulfides. A smaller number is expected for the selenides because of the smaller σ–π interactions anticipated for the Se—C bond.

For the tellurides, in which R = CH_3, CH_2CH_3, and $CH(CH_3)_2$, δ(C-4) is larger (49) than for the corresponding selenides, indicating less $p\ldots\pi$ conjugation for tellurium. A rough correlation exists between δ(C-4) for these two series (r = 0.979, significant at the 85% confidence level) and gives an estimate of 127.9 for *tert*-butyl phenyl telluride, which has not been made. Now, if eq. [7] holds, then the $\langle\sin^2\theta\rangle$ values in Table 3 follow and imply that the most stable conformation has θ as 90° for all R. It also follows that $^5J_{90}$(C,C) for the tellurides is 0.50 ± 0.02 Hz, as derived from the $\langle\sin^2\theta\rangle$ values and ^5J(C,C) in Table 1. Thus $^5J_{90}$(C,C) is smaller for the tellurides than for the selenides.

Table 3 also contains estimates of arcsin $\langle\sin^2\theta\rangle^{\frac{1}{2}}$. These numbers are not strictly comparable with estimates of θ obtained by other methods. Nevertheless, it is noted that the present value of 42° for methyl phenyl selenide is close to the 40 ± 5° obtained for the 4-chlorophenyl derivative in solution in a liquid crystal (23) and the 40 ± 13° determined in the gas phase by electron diffraction methods (24). A photoelectron pattern for methyl phenyl telluride has θ as near 60° (31), whereas arcsin $\langle\sin^2\theta\rangle^{1/2}$ in Table 3 is 53°.

^{3}J(C,C) and ^{4}J(C,C) in the selenides and tellurides

Vicinal coupling constants often obey a Karplus equation (50), $^3J = A + B\cos\theta + C\cos 2\theta$, equivalent to $^3J = C + D\sin^2\theta + E\sin^2(\theta/2)$. For evenfolded barriers, $\langle\sin^2(\theta/2)\rangle$ is 0.5. The $\langle\sin^2\theta\rangle$ values in Table 3 and the ^3J(C,C) values in Table 1 yield $^3J(C,C)/Hz = -4.2\sin^2\theta + 4.1$ for the selenides and $^3J(C,C)/Hz = -3.9\sin^2\theta + 3.9$ for the tellurides, to be regarded as indicative only, of course. If the indicated signs of ^4J(C,C) in Table 1 for the selenium compounds are correct, then $^4J(C,C)/Hz = -1.49\sin^2\theta + 0.75$; the reliability of this formulation cannot be judged at present. ^4J(C,C) for the tellurides was not observed.

Remarks on the internal motion in diphenyl ether. Fluorophenyl ethers

TED SCHAEFER, GLENN H. PENNER, CRAIG TAKEUCHI, AND POTLAKI TSEKI
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received January 13, 1988

TED SCHAEFER, GLENN H. PENNER, CRAIG TAKEUCHI, and POTLAKI TSEKI. Can. J. Chem. **66**, 1647 (1988).

The ^{13}C nuclear magnetic resonance chemical shifts and the $^{13}C,^{19}F$ spin–spin coupling constants are reported for 4,4′-difluorophenyl ether and 4-fluorophenyl phenyl ether in CS_2 and in acetone-d_6 solutions. An estimate of $^6J_{90}$, the extremum in the $\sigma-\pi$ coupling constant between the ^{19}F nucleus on one ring and the *ipso* ^{13}C nucleus on the other, is obtained from measurements on 2,6-dibromo-4-fluorophenyl phenyl ether. The ensuing estimates of $\langle\sin^2\theta\rangle$, the expectation values of $\sin^2\theta$ as obtained from $^6J(^{13}C,^{19}F)$, are compared with those obtained from STO-3G MO computations for diphenyl ether and its 4-fluoro derivatives. These computations give conformational energies at 30° intervals of the angles of twist about the two C—O bonds. In rough agreement with C-INDO computations, interconversion of the helical forms is calculated to occur most easily by the so-called one-ring flip mechanism; the barrier to interconversion is less than 1 kJ/mol in the ether and its 4-fluoro derivatives. It appears that the conformational behaviour of these derivatives is unaltered by passage from CS_2 to acetone solutions at 300 K. Furthermore, $\langle\sin^2\theta\rangle$ values from $^6J(^{13}C,^{19}F)$ in solution are very similar to those obtained from the computations on the free molecules. If this agreement is not accidental, then it may arise from a high degree of flexibility of the molecules in which, by a disrotatory or one-ring flip mechanism requiring a very low energy of activation, one helical or C_2 conformation can be converted to another. The other conformations have considerably higher energies and the solvents do not appear to lower these energies enough to favor their populations significantly at 300 K.

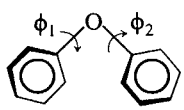
TED SCHAEFER, GLENN H. PENNER, CRAIG TAKEUCHI et POTLAKI TSEKI. Can. J. Chem. **66**, 1647 (1988).

Opérant en solutions dans le CS_2 ainsi que dans l'acétone-d_6, on a mesuré les déplacements chimiques en résonance magnétique nucléaire du ^{13}C ainsi que les constantes de couplage spin–spin $^{13}C,^{19}F$ de l'éther bis(difluoro-4,4′ phénylique) et de l'éther difluoro-4,4′ phényl phénylique. Utilisant des mesures effectuées sur l'éther dibromo-2,6 fluoro-4 phényl phénylique, on a évalué la constante $^6J_{90}$, l'extrême de la constante de couplage $\sigma-\pi$ entre le noyau de ^{19}F d'un cycle et le noyau ^{13}C *ipso* de l'autre. On a comparé les évaluations de $\langle\sin^2\theta\rangle$, les valeurs attendues pour $\sin^2\theta$ telles qu'obtenues à partir des constantes $^6J(^{13}C,^{19}F)$, avec celles obtenues à partir de calculs d'OM STO-3G effectués sur l'éther diphénylique ainsi que sur ses dérivés fluoro-4. Ces calculs conduisent à des énergies conformationnelles qui ont été évaluées à tous les 30° d'angle de torsion autour des deux liaisons C—O. En accord avec les résultats de calculs C-INDO, on a calculé que l'interconversion des formes hélicoïdales se produit principalement par le biais d'une mécanisme appelé inversion d'un cycle; dans le cas de l'ether et de ses dérivés fluoro-4, la barrière à l'interconversion est inférieure à 1 kJ/mol. Il semble que le comportement conformationnel de ces dérivés ne varie pas lorsque, à 300 K, on passe de solutions dans le CS_2 à des solutions dans l'acétone. De plus, les valeurs de $\langle\sin^2\theta\rangle$, obtenues à partir des constantes $^6J(^{13}C,^{19}F)$ en solution, ressemblent beaucoup à celles obtenues à partir de calculs sur des molécules libres. Si cet accord n'est pas accidentel, il pourrait alors découler d'un degré élevé de flexibilité des molécules qui, par un mécanisme disrotatoire ou un par un mécanisme d'inversion de cycle n'impliquant qu'une faible énergie d'activation, permettrait des conversions rapides entre les conformations hélicoïdales et C_2. Les énergies des autres conformations sont beaucoup plus élevées et les solvants ne semblent pas les abaisser suffisamment pour que, à 300 K, leurs populations soient importantes.

[Traduit par la revue]

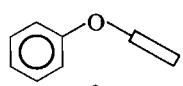
Introduction

With some exceptions, a variety of experimental and theoretical approaches to the internal dynamics in diphenyl ether suggest that the molecule adopts a helical conformation in which ϕ_1 and ϕ_2 lie in the vicinity of 25–50°. These approaches have recently been reviewed (1, 2), so that a detailed recapitulation is not necessary here. The potential surface described by ϕ_1 and ϕ_2 is not available experimentally, although ^{13}C nmr spin-lattice relaxation times for a chloroform solution have been interpreted to mean that the barrier to internal rotation is 10.2 kJ/mol for the phenyl groups (2). This number is similar to the 10 kJ/mol estimated for the enthalpy of activation from dielectric relaxation studies on diphenyl ether dispersed in a polystyrene matrix (3). *Ab initio* computations of this surface seem not to be available. The semiempirical C-INDO method (4) appears to overcome the defects of the usual CNDO–INDO approaches to internal barriers in conjugated systems. Its recent application to diphenyl ether gave energies at 30° intervals for both ϕ_1 and ϕ_2 (1). So-called standard structural parameters were used in these calculations and a fixed C—O—C angle of 123° was assumed (1). The ensuing energy contours implied that **2** and not **3** was



1

$\phi_1 = \phi_2 = 0°$
when phenyl groups are in the COC plane.



$\phi_1 = 0°$

$\phi_1 = \phi_2 = 90°$ **3**

the transition state for interconversion of the helical forms **1**, the highest stability being calculated for $\phi_1 = \phi_2 = 35°$. Conformation **2** is reached by a disrotatory mechanism, the so-called one-ring flip (5, 6), while **3** is attained by a conrotatory mechanism or two-ring flip. A planar transition state would have a very high energy because of repulsive forces between *ortho* C—H bonds on neighbouring rings.

The C-INDO results indicated that **2** is only 1.4 kJ/mol less stable than **1**. In other words, the helical enantiomers can interconvert rather freely at ambient temperatures. Conformation **3** was computed as 8.0 kJ/mol less stable than **1**.

In Table 1 the computed STO-3G MO energies are presented. In our opinion this method of presentation is more easily com-

[a]See structure **1** for definitions of the angle ϕ. If the COC plane lies in the plane of the page, then, as ϕ_1 and ϕ_2 increase somewhat from zero, the proximate *ortho* C—H bonds of the two rings have moved so that one lies above (ϕ_2), and one below (ϕ_1), the COC plane.

[b]The pathway for the high-energy, so-called zero-ring flip beginning at $\phi_1 = \phi_2 = 45°$.

[c]The pathway for the low-energy, so-called one-ring flip beginning at $\phi_1 = \phi_2 = 45°$ and having a barrier of 0.69 kJ/mol for interconversion.

[d]The pathway for the intermediate-energy, so-called two-ring flip having a barrier of 11.3 kJ/mol for interconversion.

prehended quantitatively than a contour diagram. The numbers were obtained by a geometry-optimization procedure in which all bond angles and lengths were allowed to vary, except that the carbon frameworks of the phenyl groups were constrained to remain as regular hexagons. At $\phi_1 = \phi_2 = 45°$, the energy is 42.08 kJ/mol lower than that of the planar form **1**. In qualitative agreement with the C-INDO computations, the $\phi_1 = 0°$, $\phi_2 = 90°$ conformer is found to be the transition state, calculated as only 0.7 kJ/mol above the minimum. The activation energy for interconversion via **3** is computed to be 11.3 kJ/mol, while that via the planar form is 42.1 kJ/mol. The one-ring flip is strongly favored over the two-ring flip mechanism for interconversion. Figure 1 gives the STO-3G MO structure at $\phi_1 = \phi_2 = 45°$.

No gas-phase experimental determinations of the conformational properties of diphenyl ether appear to be available. The C-INDO (1) and STO-3G MO computations both imply large amplitude motions about the C—O bonds at ambient temperatures. Apparently such motions are carried over into the liquid state, diphenyl ether displaying very short intramolecular dielectric relaxation times (3, 7); these are rather insensitive to the viscosity of the solution (8). Vibrational spectra in the solid and liquid phases are consistent with a helical (C_2) structure of diphenyl ether (1). The optical anisotropy (9) and the Kerr constant (10) of diphenyl ether are consistent with $\phi_1 = \phi_2 = 34–37°$. The large amplitudes of internal motion in diphenyl ether, indicated by the calculations and by the very short dielectric relaxation times, imply rather weak conjugation in this molecule (1). This suggestion is borne out by the ^{13}C chemical shifts of the *para* carbon-13 nuclei, which are sensitive to π electron density at the *para* site. The observed shifts (11, 12) imply an electron density much smaller than that in phenol or anisole and rather similar to that in fluorobenzene. In other words, the mobile bond order in the C—O bonds of diphenyl ether is much smaller than in phenol, leading to greater internal motional freedom.

Because of the paucity of experimental data on the internal motion in diphenyl ether, it seems worthwhile to add to these data. One conformational indicator, an angle dependent long-range nuclear spin–spin coupling constant, has not yet been used for diphenyl ether or its derivatives. By analogy to anisole

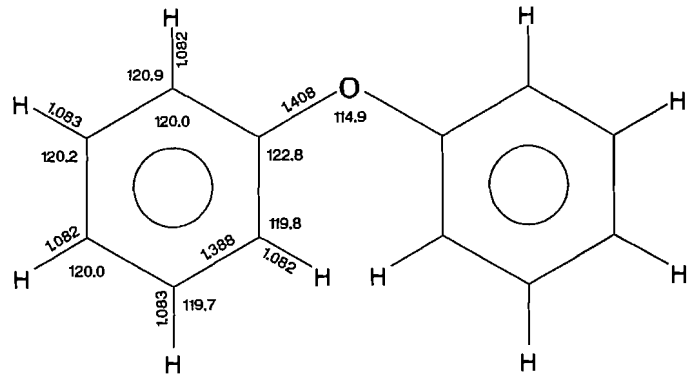

FIG. 1. The bond lengths and angles are given for the STO-3G MO structure of diphenyl ether at $\phi_1 = \phi_2 = 45°$ (see **1** in text). The geometry optimization procedure constrained the carbon skeletons of the phenyl groups to regular hexagons. This computed structure can serve as a basis for future computations with larger basis sets and for comparison with as yet unperformed experimental work on the structure of the free molecule. The COC angle seems particularly small in view of the 123° assumed in the C-INDO computations (1) and the values near 120° found from X-ray diffraction results (25, 26).

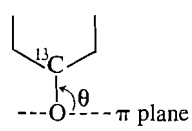
and its derivatives (13), a useful coupling constant would be $^6J_p(^1H,^{13}C) \equiv {}^6J(H,C)$ in diphenyl ether. This coupling constant is expected to be mediated by a $\sigma-\pi$ mechanism and to be proportional to $\sin^2\theta$ (see **4**). Its reliable measurement would



4

require ^{13}C enrichment at the C-1 site and the latter is beyond our resources. However, the corresponding $^6J(^{13}C, ^{19}F) \equiv {}^6J$ is also dependent on $\sin^2\theta$ in a variety of molecules, such as 4-fluoroanisole (13), 4-fluoroethylbenzene (14), and 4-fluorobiphenyl (15). In 4-fluorodiphenyl ether, for example, a fairly rigid planar conformation would then display a ^6J very near zero, while a rigid **3** should have the maximum coupling

[a]For a 10 mol% solution in CS_2, containing also 10 mol% C_6D_{12} and 0.5 mol% TMS.
[b]For a 10 mol% solution in acetone-d_6, containing 0.5 mol% TMS.
[c]The $^{13}C,^{19}F$ coupling constants are reproducible to within ±0.02 Hz.
[d]For 10 mol% solutions in CS_2(acetone-d_6) solutions, δ_1, δ_2, δ_3, and δ_4 for diphenyl ether are 157.31 (157.97), 118.86 (119.36), 129.55 (130.44). and 122.98 (123.87), respectively.

constant because $\sin^2\theta$ is near unity. At $\phi_1 = \phi_2 = 45°$, $\sin^2\theta$ is 0.5. If the maximum value of ^6J (that is, $^6J_{90}$) can be ascertained, then the measurement of ^6J in 4-fluorophenyl phenyl ether and in 4-fluorophenyl ether may well provide conformational insight.[1]

The presence of fluorine substituents can, in principle, alter the internal dynamics of the ether. Because fluorine is a weak π electron donor, it might be expected that the mobile bond orders at the C—O bonds will decrease further and hence that the internal motional freedom will increase beyond that in diphenyl ether itself. However, such an increase may be small because the conjugational extent in diphenyl ether is already rather small and because fluorine is not a strong donor. The variation of ^6J between the 4-fluorophenyl phenyl ether and the 4-fluorophenyl ether will proably indicate such conformational perturbations. The polarity of the solvent may alter the conformational equilibria.

Experimental

Diphenyl ether and 4-fluorophenyl ether came from Aldrich. The 2,6-dibromo-4-fluorophenyl phenyl ether was prepared as follows (16). A mixture of 4 g of diphenyl iodonium bromide (Aldrich), 0.44 g of NaOH, 60 mL of H_2O, and 2,6-dibromo-4-fluorophenol (Aldrich) was heated under reflux for 24 h. The extracted (ether) solution was washed with aqueous NaOH, dried with $MgSO_4$, and evaporated to yield a mixture of the desired product and iodobenzene (^1H nmr spectrum). The mixture was left open to the air for 3 days, after which a slightly yellow crystalline solid remained. It gave the correct molecular mass peak and a satisfactory ^1H nmr spectrum. The 4-fluorophenyl phenyl ether was prepared in a similar fashion.

The compounds were dissolved in acetone-d_6 or in a CS_2/C_6D_{12} solvent mixture to form approximately 10 mol% solutions. These were transferred to 5 mm od nmr sample tubes and were degassed by several freeze–pump–thaw cycles before flame sealing.

The ^{13}C nmr spectra were accumulated on a Bruker AM-300 FFT spectrometer at a probe temperature of 300 K by methods described previously (17).

[1]Note that it is the twist angle, ϕ, about the C—O bond belonging to the ring containing the fluorine nucleus, that defines the θ in $\sin^2\theta$. Thus, in 4-fluorophenyl phenyl ether, $\sin^2\theta$ is independent of the angle of twist about the C—O bond belonging to the phenyl group.

The STO-3G MO computations (18) utilized the computer program GAUSSIAN 82 (19) and were performed on an Amdahl 5870.

Results and discussion

Table 2 presents the ^{13}C nmr chemical shifts for diphenyl ether and three of its derivatives. For the latter, the $^{13}C,^{19}F$ spin–spin coupling constants are also given.

$^6J(^{13}C,^{19}F) \equiv {}^6J$ and $\langle\sin^2\theta\rangle$

In 2,6-dibromo-4-fluorophenyl phenyl ether, ^6J is 1.25(2) Hz (Table 2). This coupling constant arises from a $\sigma-\pi$ mechanism, going as $\sin^2\theta$, and is analogous to ^6J in 4-fluoroanisole (13). In the latter, two bromine substituents placed *ortho* to the methoxy group provide a measure of $^6J_{90}$. Now, in the diphenyl ether derivative above, both conformations **2** and **3** have θ as 90° if, in **2**, ϕ_2 defines the angle by which the $C_6H_2Br_2F$ group is rotated out of the COC plane (see **1**). In view of the computations for diphenyl ether, it appears sensible that this compound has its most stable conformation as **2**, in which the phenyl group lies in a plane perpendicular to the plane of the other, heavily substituted, phenyl group. Torsion about its own C—O bond by this phenyl group, that is, movement towards conformation **3**, does not cause θ to deviate from 90°. However, torsion about the other C—O bond decreases the value of θ. How large this reduction is, on average, is unknown. In the *ortho* dichloro and dibromo derivatives of anisole, the $\sigma-\pi$ couplings, $^6J(^1H,^{13}C)$, are very nearly equal (13), implying an average very near 90° at 300 K. Noting that the planar form of anisole, with θ as 0°, is very stable (13), it seems a reasonable surmise that $^6J_{90}$ in the phenyl ethers is very near 1.25 Hz.

It is also of interest that, in the crystal, 2-(3′-methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene has a conformation analogous to **2** with θ being about 80° for the phenyl group bearing the isopropyl substituents (20), the latter having the methine C—H bonds pointing in the direction of the ether oxygen atom. Furthermore, rotation about the C—O bond of the isopropyl-substituted ring apparently has a free energy of activation at 203 K of 44.8 kJ/mol (21).

These data are consistent with the arguments above for the low-energy conformer as **2** in the dibromofluorophenyl phenyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/07/12
For personal use only.

ether. In summary, torsion of the phenyl group about its own C—O axis to produce **3** is hindered by conjugational interactions of about 11 kJ/mol (Table 1), while torsion about the other C—O is opposed by steric repulsions between *ortho* C—H and C—Br bonds of the two phenyl groups. $^6J_{90}$ will be assumed to be 1.25(2) Hz (even a θ of 80° has $\sin^2\theta$ as 0.97).

On this assumption, the ^6J of 0.57(2) Hz in 4,4′-difluorophenyl ether in CS_2, as well as in acetone-d_6, solution implies a $\langle\sin^2\theta\rangle$ of 0.46 ± 0.02 at 300 K. At this temperature, the energies given in Table 1 for biphenyl yield $\langle\sin^2\theta\rangle$ as 0.49. Repetition of the STO-3G MO calculations for the same grid of θ values, but now for the difluorophenyl ether, yields a very similar set of conformational energies. The conformation with $\phi_1 = \phi_2 = 45°$ is now 42.8$_5$ kJ/mol more stable than the planar molecule, and the one-ring flip mechanism has a barrier of 0.9 kJ/mol. The expectation value of $\sin^2\theta$ is calculated as 0.50 at 300 K. The experimental results imply that the polar solvent, acetone-d_6, has not altered the conformational behaviour displayed in the nonpolar solvent, CS_2. Furthermore, these results are consistent with very small solvent effect on the conformational properties of the difluorophenyl ether, assuming that the STO-3G MO energies are reliable. Alternatively, the reasonable agreement between computation and experiment may be accidental.

Turning to 4-fluorophenyl phenyl ether, ^6J is 0.62(2) Hz in both solvent systems (Table 2), corresponding to a $\langle\sin^2\theta\rangle$ of 0.50 ± 0.02 at 300 K.

The STO-3G MO optimizations on this molecule have the barrier to interconversion by the one-ring flip mechanism as 0.6 kJ/mol, implying slightly larger torsion angles in the most stable conformation than in diphenyl ether or in 4,4′-difluorophenyl ether. The averaging procedure appropriate to the estimation of ^6J(C,F), which depends on rotations about only one C—O bond, yields the relevant $\langle\sin^2\theta\rangle$ as 0.494 at 300 K. Again, the computations for the free molecule agree with the experimental test in CS_2 and in acetone solutions.

The ^{13}C nmr chemical shifts

The solvent dependence of the ^{13}C nuclear screening for the fluorine derivatives of diphenyl ether is shared by the parent compound (footnote to Table 2). In view of the previous discussion, it is therefore reasonable that the decreased screening in the more polar solvent is attributable to a general solvent effect and not to conformational changes (the solvent dependence of ^nJ(C,F), $n = 1$–4, is reminiscent of that for ^3J(H,F) and ^4J(H,F) in other fluorobenzene derivatives (22); ^6J(C,F), in contrast, is solvent independent).

For a given solvent, the ^{13}C nmr chemical shifts of the unsubstituted phenyl groups in 4-fluorophenyl phenyl ether and in the bromine derivative are of some interest. Relative to diphenyl ether, $\delta_{4'}$ in the 4-fluorophenyl phenyl ether indicates a decreased screening of near 4 ppm, whereas the screening variations of the other ^{13}C nuclei in the phenyl moiety are very much smaller. It is commonly assumed that the nuclear screening at the *para* position is dominated by π electron (resonance) effects in benzene derivatives. Comparison of the chemical shifts for the 4,4′-difluorophenyl ether with those for the monofluoro compound suggests that the influence of the 4-fluoro substituent nine bonds removed in the latter arises mainly from a relay effect and not by a transfer of electron density between the two benzene rings. This suggestion was originally made on the basis of ^{19}F nmr chemical shifts (23).

The shielding of the ^{13}C nuclei in the phenyl group of 2,6-dibromo-4-fluorophenyl phenyl ether is consistent ($\delta_{4'}$ and $\delta_{1'}$) with somewhat increased electron donation from the oxygen atom, as expected for the conformation discussed above. The increase in shielding of nearly 4 ppm at C-2 and C-6 in the unsubstituted phenyl group has a precedent in 2,3,5,6-tetrachlorophenyl phenyl ether (12) and a similar deshielding occurs in 2,6-dimethylphenyl phenyl ether (24). These shift perturbations are intriguing because they are not understood.

Received December 8, 1987

HÉLÈNE AMMANN and GILLES DUPUIS. Can. J. Chem. **66**, 1651 (1988).

We describe the synthesis of a D-lactosamine-type trisaccharide, 6-(bromoacetamido)hexyl 2-*O*-(4-*O*-β-D-galactopyranosyl-2-acetamido-2-(deoxy-β-D-glucopyranosyl)-α-D-mannopyranoside (**18**), designed for affinity labeling the *Phaseolus vulgaris* leukoagglutinin sugar binding site. The trisaccharide derivative was obtained by condensation of 4-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-3,6-di-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl trichloroacetimidate (**8**) with 6-(*N*-benzyloxycarbonylamino)-hexyl 3,4,6-tri-*O*-benzyl-α-D-mannopyranoside (**13**). Removal of the protecting groups afforded 6-aminohexyl 2-*O*-(4-*O*-β-D-galactopyranosyl-2-acetamido-2-deoxy-β-D-glucopyranosyl)-α-D-mannopyranoside (**17**), which was converted into the corresponding bromoacetamido derivative by reaction with *N*-hydroxysuccinimido bromoacetate.

HÉLÈNE AMMANN et GILLES DUPUIS. Can. J. Chem. **66**, 1651 (1988).

Nous décrivons la synthèse d'un trisaccharide de type D-lactosamine, soit le *N*-bromométhylcarboxyamino-6 hexyl *O*-2-(*O*-4-β-D-galactopyranosyl acétamido-2 désoxy-2 β-D-glucopyranosyl)-α-D-mannopyranoside (**18**) qui est conçu pour marquer le site de reconnaissance des glucides chez la leucoagglutinine de *Phaseolus vulgaris*. Le trisaccharide a été obtenu par condensation du disaccharide trichloroacétimidate de *O*-4-(tétra-*O*-acétyl-2,3,4,6 β-D-galactopyranosyl) di-*O*-acétyl-3,6 désoxy-2 phtalimido-2 β-D-glucopyranosyle (**8**) avec le *N*-benzyloxycarbonylamino-6 hexyl tri-*O*-benzyl-3,4,6 α-D-mannopyranoside (**13**). L'enlèvement des groupements protecteurs a donné l'amino-6 hexyl *O*-2-(*O*-4-β-D-galactopyranosyl acétamido-2 désoxy-2 β-D-glucopyranosyl) α-D-mannopyranoside (**17**) qui a été converti en dérivé *N*-bromoacétamido par réaction avec le bromoacétate de *N*-hydroxysuccinimidyle.

Mammalian glycoproteins can be classified into two major categories according to the nature of the glycosidic bond involved in protein–carbohydrate linkage (1–3). For instance, the "mucin-type" glycoproteins are characterized by the presence of an *O*-glycosidic bond between the carbohydrate chain and serine or threonine residues of the polypeptide backbone. In the case of *N*-linked "serum-" and "surface-type" glycoproteins, the carbohydrate chains are covalently bound to asparagine residues located in the -Asn-X-Ser(Thr)- sequence (4, 5). These glycoproteins can be further divided into "high mannose" type (oligomannosidic type) and the "complex" and "hybrid" types (*N*-acetyl-D-lactosamine type) in accordance with the structure of the carbohydrate moiety.

Previous work by Cummings and Kornfeld (6), Kaifu and Osawa (7), and by Hammarström *et al.* (8) has established that leukoagglutinin, a mitogenic isolectin isolated from *Phaseolus vulgaris* (9), specifically recognizes the minimal trisaccharidic sequence 2-*O*-(4-*O*-β-D-galactopyranosyl-2-acetamido-2-deoxy -β-D-glucopyranosyl)-D-mannopyranose that is found in some *N*-type glycoproteins. The synthesis of this trisaccharide has previously been reported (7, 10). In addition, various saccharide derivatives substituted with a reactive alkyl or acyl chain designed to serve as photoaffinity labeling reagents or to establish covalent bonds with protein carriers have been prepared by a number of investigators (11–25). It was therefore of interest to prepare the trisaccharide **17** modified in a manner that allows its use as an affinity labeling reagent to probe the nature of the sugar binding site of leukoagglutinin.

We report the synthesis of the trisaccharide 2-*O*-(4-*O*-β-D-galactopyranosyl-2-acetamido-2-deoxy-β-D-glucopyranosyl)-α-D-mannopyranosyl derivative, modified at the C-1 position of the mannose moiety with an amino group-bearing side chain, which can be modified further in a number of ways to prepare various derivatives suitable for affinity labeling studies. We show one example of such a modification, by reporting the synthesis of the bromoacetyl derivative of trisaccharide **17**.

Results and discussion

The key intermediate in the synthesis of modified trisaccharide **18** was the known (26) D-lactosamine derivative 4-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-3,6-di-*O*-acetyl-2-deoxy-2-phthalimido-D-glucopyranose **7**. Grundler and Schmidt (26) have shown that conversion of **7** into the corresponding trichloroacetimidate **8** and reaction with suitably protected D-galactose derivatives possessing a free hydroxyl group at position C-3 give a high yield of the β-anomer, and it was anticipated that such a scheme could be applied for reaction of **8** with the D-mannose derivative **13**.

Compound **7** was prepared by Grundler and Schmidt (26) by selective deprotection of the C-1 position of *tert*-butyldimethylsilyl-4-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-3,6-di-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranoside. We hypothesized that compound **7** could be obtained by a shorter route using a modification of the procedure described by Arnarp and Lönngren (10). Thus, peracetylated lactal **1** was obtained according to the procedure described by Haworth *et al.* (27), by reaction of 1-bromo peracetylated lactose with zinc in acetic acid. Azidonitration of **1** gave the same ratio of mixed crystalline azidonitrates **2**, **3**, and **4**, as described (10). The mixture was hydrogenated in the presence of a palladium catalyst, at atmospheric pressure. Anomers **5** and **6** (10) were converted into crystalline[1] **7**, by reaction with *N*-carbo-

[1]Compound **7** has been described by Grundler and Schmidt (26) as an amorphous powder. However, we succeeded in obtaining this intermediate as a crystalline product that possessed an ^{1}Hmr spectrum similar to that of the reported compound, except in the case of assignment of the aromatic protons. Grundler and Schmidt (26) reported values of 8.9–8.7 ppm, whereas we observed values of 7.9–7.7 ppm. This discrepancy between our findings and those reported may result from a typographical mistake, since our data are consistent with assignment values (9.7–7.7 ppm) reported by Grundler and Schmidt for other phthalimide derivatives of protected D-lactosamine.

FIG. 1. Synthetic scheme for the preparation of the lactose derivatives used as intermediates for the synthesis of the trisaccharide described in this study. Lactal **1** was converted into the mixture of compounds **2**–**4** by azidonitration and the mixture of anomeric compounds **3** and **4** was hydrogenated to give **5** and **6**. Reaction with *N*-carboethoxyphthalimide gave **7**, which was converted into **8** by reaction with trichloroacetonitrile.

ethoxyphthalimide, under reflux of the solvent in the presence of a catalytic amount of triethylamine. We found these conditions to be superior to those described by Arnarp and Lönngren (10) for the protection of the primary amino group. At the same time, a free hydroxyl group at the C-1 position of the D-lactosamine derivative is obtained, and that allows for the planned conversion of **7** into the corresponding β-trichloroacetimidate derivative **8**.

Key intermediate **8** was essentially obtained as described (26). The D-lactosamine derivative **8** showed an ^{1}Hmr spectrum identical to that reported, but we observed a melting point of 174–175°C, as opposed to the reported 128°C (26).

Bundle and Josephson (28) have described the synthesis of a protected L-rhamnose derivative possessing a "linking arm" in the aglycon portion of the molecule. When one compares the structure of D-mannose to L-rhamnose, it is obvious that the two molecules possess identical equatorial/axial relative orientations of the substituents. It was thus expected that the sequence of reactions published by Bundle and Josephson could be applied to the synthesis of compound **13**. Furthermore, it was also expected that protection of the primary (C-6) alcohol of D-mannose by benzylation would not affect the general outline of the synthesis.

2,3,4,6-Tetra-*O*-acetyl-D-mannopyranosyl bromide **9** (29) was converted into 3,4,6-tri-*O*-acetyl-1,2-*O*-(methoxyethylidene)-β-D-mannopyranose **10** (30) by reaction of **9** with methanol using 2,6-lutidine as solvent. Compound **10** was crystalline and homogeneous by the usual criteria. Deacetylation of **10** by ammonolysis followed by treatment with benzyl bromide in the presence of sodium hydride afforded crystalline **11**, which was allowed to react with 6-(*N*-benzyloxycarbonyl)-aminohexanol to yield homogeneous compound **12**, after purification. It was found essential to use 1.1 equivalents of $HgBr_2$ instead of a catalytic amount of the mercuric salt to complete reaction of **11**. We consistently obtained a low yield of **12** (~30%). It is presumed that this results, in part, from the fact that methanol liberated during the reaction competes with the protected amino alcohol for reaction with **11**. Evidence for this side reaction was obtained by allowing **11** to react with methanol and analyzing the product of the reaction by tlc.

Selective removal of the acetyl protecting group at the C-2 position of intermediate **12** by treatment with a catalytic amount of sodium methoxide in methanol afforded D-mannose derivative **13** as an oil. Reaction of D-lactosamine derivative **8** with protected D-mannopyranoside intermediate **13** in the presence of one equivalent of boron trifluoroetherate (26) gave homogeneous protected trisaccharide **14**, with a 69% yield. Evidence that the glycosylation reaction gave the expected anomer is based on the work of Grundler and Schmidt (26) and on the characteristic signal of the anomeric proton (5.51 ppm, J = 8.5 Hz) observed by ^{1}Hmr.

Compound **14** was readily deacetylated by treatment with an ammonia-saturated methanol solution to give **15**, while treatment with hydrazine removed the phthalimido protecting group. The partially protected trisaccharide derivative was then *N*-acetylated, following the conditions described by Arnarp and Lönngren (10), to trisaccharide **16**. Product **16** was hydrogenated in the presence of colloidal palladium to give desired trisaccharide **17**.

Trisaccharide **17** possesses a versatile amino group that can be converted into a variety of derivatives, which in turn can serve for covalent modifications of *Phaseolus vulgaris* leukoagglutinin. For instance, acylation with a suitable aryl azido moiety will yield derivatives that can be used as probes for photoaffinity labeling studies (31). Alternatively, acylation by reaction with selected cyclic anhydrides affords derivatives that can be utilized as ligands for affinity chromatography purification of this lectin. Such compounds can further be converted into hydrazides that, in turn, can serve to generate the corresponding azides for affinity labeling studies. Leukoagglutinin affinity labeling reagents can also be obtained directly by conversion of the amino group of trisacharide **17** into a bromoacetamido derivative. Bromoacetamido compounds are highly reactive and have been used by Schoellman and Shaw (32) and by Ong *et al.* (33) to specifically inactivate proteolytic enzymes and by Givol and co-workers (34–36) to label the antigenic binding site of antibodies.

We therefore prepared the bromoacetyl derivative of trisaccharide **17** by reaction with *N*-oxysuccinimidyl 2-bromoacetate (37) in an aqueous tetrahydrofuran milieu. The desired sugar derivative **18** was obtained after purification by gel filtration. The ^{1}Hmr and ^{80}Br nmr analyses were consistent with the structure required. Further work is in progress to use derivative **18** for affinity labeling studies of the leukoagglutinin sugar binding site.

Materials and methods

Melting points were determined on a Büchi apparatus and are not corrected. Optical rotations were measured with a OLD 5 Carl Zeiss polarimeter. The nmr spectra were recorded at 250.13 MHz in the pulse Fourier-transformed mode on a Bruker WM-250 instrument. Unless otherwise indicated, samples were dissolved in deuterated chloroform. Chemical shifts are reported in ppm (δ) of the field relative to tetramethylsilane. Tentative signal assignments are based on values re-

FIG. 2. Synthetic scheme to prepare the mannopyranosyl derivative intermediates used for the synthesis of the trisaccharide described in this study. Acetobromomannose **9** was converted into **10** by reaction with methanol in the presence of 2,6-lutidine. Deacetylation and treatment with benzyl bromide afforded **11**, which was allowed to react with 6-(*N*-benzyloxycarbonylamino)-hexanol to give **12**. Compound **13** was obtained by treatment of **12** with sodium methoxide.

ported in the literature (7, 10, 26, 28).[2] Thin-layer chromatographic analyses were performed on 0.5-mm-thick silica gel G (Sigma Chemical Co., St Louis, MO) coated plates. The systems used were I, ethyl acetate – petroleum ether (3:2); II: ethyl acetate – petroleum ether (1:1); III: ethyl acetate – light petroleum ether (2:1); IV: chloroform–methanol (7:1); V: 1-butanol – acetic acid – water (3:1:1). Sugar derivatives were detected by spraying 0.02 M ammonium molybdate and 0.025 M ceric(IV) sulfate in 10% sulfuric acid (38) and heating at 120°C. Column chromatography of intermediates was done by using silicic acid (Kieselgel 60 F_{254}, 70–230 mesh). Petroleum ether refers to the fraction boiling at 60–110°C, whereas light petroleum ether was the fraction boiling at 30–60°C. *N*-Carboethoxyphthalimide was recrystallized from ethanol. Zinc was activated by a 2-min treatment in 10% aqueous hydrogen chloride, washed with water to neutrality, and then with acetone (39). Sodium hydride was obtained as a 60% suspension in mineral oil. Prior to use, it was washed with the appropriate reaction solvent for 20 min, filtered, and resuspended in the same solvent. Evaporations were done with a rotary evaporator, at temperatures below 40°C.

6-(N-Benzyloxycarbonylamino)-hexanol)

The title compound was prepared by treating 6-aminohexanol (15 g, 128 mmol), dissolved in a mixture of tetrahydrofuran (150 mL) and water (45 mL), with benzylchloroformate (24 g, 141 mmol), which was added by portions at 4°C under vigorous stirring. The pH was maintained at 8–9 by addition of 1 N NaOH. After 30 min, the mixture was further stirred at room temperature for 30 min, while maintaining pH. The reaction mixture was extracted with diethyl ether and the organic phase was dried (Na_2SO_4) and evaporated. The desired compound was crystallized from diethyl ether – ethyl acetate – petroleum ether. Yield, 30.3 g (94%); mp 80–81°C. *Anal.* calcd. for $C_{14}H_{21}NO_3$ (251.3): C 66.91, H 8.42, N 5.57; found: C 66.21, H 8.56, N 5.42.

FIG. 3. Synthetic route used for the synthesis of the trisaccharide **18**. Intermediate **14** was obtained by condensation of disaccharide **8** with protected mannose derivative **13**. Treatment of **14** with ammonia in methanol gave **15**, which was allowed to react with hydrazine and then acetylated to afford **16**. Hydrogenation gave **17**, which was converted into **18** by reaction with *N*-oxysuccinimidyl bromoacetate.

4-O-(2,3,4,6-Tetra-O-acetyl-β-D-galactopyranosyl)-3,6-di-O-acetyl-2-deoxy-2-phthalimido-D-glucopyranose (7)

The mixture of compounds **5** and **6** (10) (25 g) and *N*-carboethoxyphthalimide (19 g, 85 mmol) was dissolved in absolute ethanol (200 mL) and the solution was dried for a few minutes over molecular sieves. After 3 h of reflux of the solvent, no further change (tlc) was observed unless a few drops of triethylamine were added. Completion of the reaction occurred after 1.5 h. The solution was cooled at room temperature, filtered, and concentrated to dryness *in vacuo*. Purification by chromatography on silicic acid using ethyl acetate – petroleum ether – methanol (30:20:0.5) as eluent gave the desired product, which crystallized from methanol. Yield, 6 g; mp 138.5–140°C; R_f^{III}: 0.56; $[\alpha]_D^{24}$ +34° (*c* 1.1, chloroform) (lit. (26) $[\alpha]_D^{25}$

+39 (*c* 1.0, chloroform); ^{1}Hmr: 7.86–7.82 and 7.75–7.70 m (4H, Pht); 5.75 dd (1H, H-3); 5.64 dd (1H, H-1); 5.33 dd (1H, H-4′); 5.12 dd (1H, H-2′); 4.96 dd (1H, H-3′); 4.54 m ($2H_{pyr}$); 4.19–3.83 m ($7H_{pyr}$); 2.13, 2.12, 2.06, 2.03, 1.96, 1.90 s (18H, 6 CH_3-CO).

4-O-(2,3,4,6-Tetra-O-acetyl-β-D-galactopyranosyl)-3,6-di-O-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl trichloroacetimidate (8)

A solution of compound **7** (26) (2.0 g, 2.76 mmol) in distilled dichloromethane (15 mL) was added to a suspension of sodium hydride (70 mg, 1.75 mmol) in dichloromethane (20 mL). Trichloroacetonitrile (5.5 mL, 54.8 mmol) was added and the solution was stirred for 20 min at room temperature. The mixture was added at the top of a silicic acid column and elution was carried out with ethyl acetate – light petroleum ether (3:2). Compound **8** crystallized from ethyl acetate – light petroleum ether. Yield, 1.7 g (71%); mp 174.5–175°C; R_f^{III}: 0.80; ^{1}Hmr: 8.65 s (1H, NH); 7.84–7.81 and 7.72–7.69 m (4H, Pht); 6.61 d ($J_{1,2}$ = 7.8 Hz, 1H, H-1); 5.86 dd ($J_{3,2}$ = 10.6 Hz, $J_{3,4}$ = 8.5 Hz, 1H, H-3); 5.34 dd ($J_{4',3'}$ = 3.4 Hz, $J_{4',5'}$ = 1 Hz, 1H, H-4′); 5.13 dd ($J_{2',1'}$ = 7.8 Hz, $J_{2',3'}$ = 10.4 Hz, 1H, H-2′); 4.95 dd (1H, H-3′); 4.56–4.47 m ($3H_{pyr}$); 4.25–3.87 m ($6H_{pyr}$); 2.15, 2.14, 2.06, 2.05, 1.96, 1.93 s (18H, 6 CH_3-CO).

3,4,6-Tri-O-benzyl 1,2-O-(methoxyethylidene)-β-D-mannopyranose (11)

Compound **10** (30) (22 g, 61 mmol) dissolved in dry methanol (88 mL) and chloroform (0.5 mL) was treated with ammonia-saturated methanol (44 mL). The solution was stirred for 48 h at room temperature under an anhydrous atmosphere. After evaporation of the solvent, the residue was dried under high vacuum (P_2O_5) for 1 h. The oil (15 g) was dissolved in distilled *N,N*-dimethylformamide (90 mL) and added to a suspension of sodium hydride (9 g, 375 mmol) in *N,N*-dimethylformamide (145 mL). Benzyl bromide (33 mL, 286 mmol) was added dropwise over a 15-min period while maintaining the mixture at room temperature by cooling with a water bath. The mixture was stirred under anhydrous conditions for 18 h at which time dry methanol (30 mL) was added dropwise. After 1 h of stirring, the suspension was poured into water (300 mL) and the pH was brought to 8 with 1 N hydrogen chloride. The oil was extracted with ethyl acetate (4 × 100 mL), and the organic phase was washed with water (3 × 100 mL), dried (Na_2SO_4), and concentrated to dryness *in vacuo*. Crystallization from diethyl ether – petroleum ether gave compound **11**. Yield, 16 g (52%); mp 78–78.5°C; R_f^{II}: 0.79; $[\alpha]_D^{24}$: +26° (*c* 1.1, chloroform); ^{1}Hmr: 7.39–7.29 m (15H, 3Ph); 5.35 d ($J_{1,2}$ = 2.5 Hz, 1H, H-1); 4.92–4.57 m (7H, 3CH_2-Ph, H-3); 4.40 dd ($J_{2,3}$ = 4.0 Hz, 1H, H-2); 3.93 t ($J_{4,3}$ = $J_{4,5}$ = 9.4 Hz, 1H, H-4); 3.75–3.70 m (2H, H-6); 3.45 m (1H, H-5); 3.29 s (3H, CH_3-O); 1.74 s (3H, CH_3-C). *Anal.* calcd. for $C_{30}H_{34}O_7$ (506.6): C 71.13, H 6.76; found: C 70.47, H 6.76.

6-(N-Benzyloxycarbonylamino)-hexyl 2-O-acetyl-3,4,6-tri-O-benzyl-α-D-mannopyranoside (12)

Compound **11** (2 g, 3.95 mmol) was dissolved in dry distilled acetonitrile (22 mL), and 6-(*N*-benzyloxycarbonylamino)-hexanol (9.92 g, 39.5 mmol) and mercuric bromide (1.42 g, 3.95 mmol) were added simultaneously. After 70 min of reflux of the solvent, the mixture was filtered and evaporated. The residue was dissolved in chloroform (75 mL) and washed with water (2 × 25 mL). After drying (Na_2SO_4) and concentration, compound **12** was purified by chromatography on silicic acid using ethyl acetate – petroleum ether (9:41) as eluent. The product was obtained as an oil. Yield, 1.3 g (45%); R_f^{II}: 0.71; ^{1}Hmr: 7.38–7.25 and 7.18–7.13 m (20H, 4Ph); 5.36 dd (1H, $J_{2,1}$ = 1.8 Hz, $J_{2,3}$ = 3.3 Hz, H-2); 5.10 s (2H, COO-CH_2-Ph); 4.88–4.45 m (8H, H-1, H-3, 3CH_2Ph); 4.01–3.64 m (5H, $3H_{pyr}$, CH_2-O); 3.41–3.27 m (1H, H-5); 3.17 q (2H, CH_2-NH); 2.19 s (3H, CH_3-CO); 1.65–1.31 m (8H, $4CH_2$).

6-(N-Benzyloxycarbonylamino)-hexyl 3,4,6-tri-O-benzyl-α-D-mannopyranoside (13)

Compound **12** (1.3 g, 1.79 mmol) was treated with a catalytic amount of sodium in dry methanol (40 ml) for 4 h at room temperature. The pH was brought to 6 with acetic acid – methanol (1:1) and the mixture was filtered and concentrated to dryness *in vacuo*. The residue was dissolved in chloroform (50 mL) and washed with water (25 mL). The aqueous phase was extracted with chloroform (50 mL) and the combined organic phases were washed with water (25 mL). Evaporation of the dried (Na_2SO_4) chloroform solution gave an oil. Yield, 1.04 g (85%), R_f^{II}: 0.59; $[\alpha]_D^{24}$ +34° (*c* 1.1, chloroform); ^{1}Hmr: 7.34–7.21 and 7.15–7.12 m (20H, 4Ph); 5.06 s (2H, COOCH_2-Ph); 4.85 dd (1H, OH); 4.81–4.48 m (8H, $2H_{pyr}$, 3CH_2-Ph); 3.99 t (1H, H-2); 3.83–3.51 m (5H, $3H_{pyr}$, O-CH_2); 3.41–3.32 m (1H, H-5); 3.13 q (2H, CH_2-N); 1.48–1.29 m (8H, $4CH_2$). *Anal.* calcd. for $C_{41}H_{49}NO_8$ (683.8): C 72.01, H 7.22, N 2.05; found: C 72.09, H 7.37, N 1.98.

6-(N-Benzyloxycarbonylamino)-hexyl 2-O-[4-O-(2, 3, 4, 6-tetra-O-acetyl)-β-D-galactopyranosyl-(3, 6-di-O-acetyl)-2-deoxy-2-phthalimido-β-D-glucopyranosyl]-(3,4,6-tri-O-benyzl)-α-D-mannopyranoside (14)

Compounds **13** (730 mg, 1.067 mmol) and **8** (1.02 g, 1.175 mmol) were dissolved in distilled dichloromethane (36 mL). The solution was dried over molecular sieves for 10 min, cooled at −8°C, and boron trifluoride etherate was added (131 μL, 1.07 mmol). After 3.5 h under stirring, the mixture was washed with water (5 mL), 1 N sodium bicarbonate (3 × 5 mL), and water (2 × 5 mL). The organic phase was dried (Na_2SO_4), evaporated to dryness, and purified by chromatography on silicic acid using ethyl acetate – petroleum ether (15:35) as eluent. The product was obtained as an oil. Yield, 1.03 g (69% based on **13**); R_f^I: 0.57; $[\alpha]_D^{24}$ +3.4° (*c* 1.1, chloroform); ^{1}Hmr: 7.62–7.54 m (4H, Pht); 7.37–7.23 and 7.15–7.11 m (20H, 4Ph); 5.78 dd (1H, H-3_{glc}); 5.51 d ($J_{1,2}$ = 8.5 Hz; 1H, H-1_{glc}); 5.34 dd ($J_{4,3}$ = 3.8 Hz, $J_{4,5}$ = 1.2 Hz, 1H, H-4_{gal}); 5.14 dd ($J_{2,3}$ = 10.5 Hz, $J_{2,1}$ = 7 Hz, 1H, H-2_{gal}); 5.08 s (2H, COO-CH_2-Ph); 4.97 dd (1H, H-3_{gal}); 4.78–4.25 m (10H, $4H_{pyr}$, 3CH_2-Ph); 4.22–3.79 m (10H, $8H_{pyr}$, O-CH_2); 3.55–3.04 m (6H, $4H_{pyr}$, CH_2NH); 2.14, 2.07, 2.06, 2.03, 1.97, 1.91 s (18H, 6CH_3-CO); 1.48–1.19 m (8H, $4CH_2$). *Anal.* calcd. for $C_{73}H_{84}N_2O_{25}$ (1389.5): C 63.10, H 6.09, N 2.02; found: C 63.33, H 6.65, N 1.91.

6-(N-Benzyloxycarbonylamino)-hexyl 2-O-(4-O-β-D-galactopyranosyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl)-3,4,6-tri-O-benzyl-α-D-mannopyranoside (15)

Compound **14** (1.00 g, 720 μmol) was dissolved in anhydrous methanol (15 mL). Deacetylation was accomplished in the presence of 15 mL of ammonia-saturated methanol for 40 h at room temperature. The mixture was concentrated to dryness. The residue (1.2 g) was purified by chromatography on silicic acid using chloroform–methanol (14:1) as eluent. The oil obtained consisted of two products. Yield, 0.57 g (70%); R_f^{IV}: 0.37 and 0.47; ^{1}Hmr (CD_3OD and DMSO-d_6): 7.83–7.75 m (4H, Pht); 7.39–7.20 and 7.13–7.06 m (20H, 4Ph); 5.22 d ($1H_{pyr}$); 4.96 s (2H, COO-CH_2-Ph); 4.74–3.18 m (28H, $20H_{pyr}$, 3CH_2Ph, O-CH_2); 2.93 m (2H, CH_2-N); 1.37–1.15 m (8H, $4CH_2$).

6-(N-Benzyloxycarbonylamino)-hexyl 2-O-(4-O-β-D-galactopyranosyl-2-acetamido-2-deoxy-β-D-glucopyranosyl)-3,4,6-tri-O-benzyl-α-D-mannopyranoside (16)

Compound **15** (0.32 g, 283 μmol) was dissolved in ethanol (30 mL) and 59.3 μL of hydrazine (1.7 mmol) was added. The solution was heated under reflux under a nitrogen atmosphere for 3 h. After cooling, the hydrazine was neutralized with glacial acetic acid (97.2 μL, 1.7 mmol). The mixture was concentrated and the residue was acetylated by treatment with 4 mL of acetic anhydride – pyridine (1:1) for 10 h at room temperature. The solution was then evaporated to dryness. Hydrazine by-products were eliminated by chromatography of the reaction mixture on a silicic acid column that was eluted with chloroform–methanol (7:1). Removal of the *O*-acetyl residues was accomplished by allowing the mixture of partially acetylated compounds, in methanol (10 mL), to react with ammonia-saturated methanol for 44 h at room temperature. After concentration to dryness *in vacuo*, the mixture (0.44 g) was purified by chromatography on a silicic acid column that was eluted with chloroform–methanol (14:1). Yield, 320 mg (92%); R_f^V: 0.24. The ^{1}Hmr (D_2O) spectrum of the crude product showed the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/07/12
For personal use only.

absence of signals corresponding to the phthalimido protons (7.9–7.8 ppm). A singlet at 1.83 ppm was attributed to CH_3-CO-NH.

6-Aminohexyl 2-O-(4-O-β-D-galactopyranosyl-2-acetamido-2-deoxy-β-D-glucopyranosyl)-α-D-mannopyranoside (17)

Compound **16** (320 mg, 306 μmol) was dissolved in 90% aqueous acetic acid (30 mL) and hydrogenated at 570 kPa over colloidal palladium (prepared by reduction of $PdCl_2$ with formic acid) for 26 h at room temperature. The catalyst was removed and the solution was lyophilized. The residue was purified on a Mono S column (Pharmacia Fine Chemicals, Montreal) using an hplc system (Waters Associates Inc., Milford, MA) in the following way. The trisaccharide derivative was dissolved in 2 mM acetic acid and injected at the top of the column equilibrated in water. Elution was done using triethylamine gradient concentrations of 1–100 mM. The desired product was located in the 55 mM triethylamine eluate (ninhydrin spot test). Yield, 183 mg (93%); R_f^V: 0.16; $[\alpha]_D^{24}$ −5.8° (*c* 1.0, H_2O); ^{1}Hmr (D_2O): 4.69 d ($J_{1,2}$ = 5.2 Hz, 1H, H-1_{man}); 4.38 dd ($J_{2,3}$ = 2.8 Hz, 1H, H-2_{man}); 4.26 d ($J_{1,2}$ = 7.9 Hz, 1H, H-1_{gal}); 3.85–3.29 m (19H, OCH_2, 17H_{pyr}); 2.79–2.71 m (2H, CH_2-N); 1.85 s (3H, CH_3-CO); 1.44–1.39 and 1.24–1.15 (8H, 4CH_2). The signal corresponding to H-1_{glc} was not observable due to interference of the HOD peak.

6-(Bromoacetamido)-hexyl 2-O-(4-O-β-D-galactopyranosyl-2-acetamido-2-deoxy-β-D-glucopyranosyl)-α-D-mannopyranoside (18)

Trisaccharide **17** (51 mg, 79 μmol) was dissolved in water (0.5 mL) and the pH was adjusted to 7–8 by addition of triethylamine (10% in tetrahydrofuran). *N*-Oxysuccinimidyl 2-bromoacetate (prepared by reaction with *N*-hydroxysuccinimide and 2-bromoacetic acid in the presence of *N*,*N*′-dicyclohexylcarbodiimide, mp 109–110°C) (23 mg, 99 μmol), dissolved in tetrahydrofuran (156 μL), was added in three portions. The pH was maintained at 7–8 by addition of dilute triethylamine. After 23 min, the reaction gave a negative ninhydrin test. The mixture was filtered and lyophilized. The dried powder was purified by gel filtration on a Bio Gel P-2 (Bio Rad, Richmond, CA) column equilibrated in water. Column elution was done with water. Lyophilization of the desired fractions afforded a white powder. Yield, 24.3 mg (62%); R_f^{IV}: 0.62; $[\alpha]_D^{24}$ +2.2° (*c* 1.0, H_2O); ^{1}Hmr (D_2O): 4.67 d ($J_{1,2}$ = 7.0 Hz, 1H, H-1_{man}); 4.41 s (2H, −CO-CH_2Br); 4.25 d ($J_{1,2}$ = 7.7 Hz, 1H, H-1_{gal}); 3.71–3.30 m (19H, 17H_{pyr}, OCH_2); 3.06 m (2H, CH_2-NH-$COCH_2$Br); 1.83 s (3H, CH_3-CO); 1.69–1.10 m (8H, 4CH_2). The presence of the bromide group was assessed by ^{80}Br nmr spectroscopy (67.55 MHz; reference, NaBr in D_2O), which showed a broad signal centred at 2.5 ppm.

The photochemistry of 8-cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene

CHRISTOPHER OWEN BENDER,[1] DOUGLAS DOLMAN, AND GAETANNE KATHRYN MURPHY[2]
Department of Chemistry, University of Lethbridge, Lethbridge, Alta., Canada T1K 3M4

Received January 15, 1988

CHRISTOPHER OWEN BENDER, DOUGLAS DOLMAN, and GAETANNE KATHRYN MURPHY. Can. J. Chem. **66**, 1656 (1988).

The direct irradiation of 6-cyanobenzocyclooctatetraene (**7**) led to 5- and 8-cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene (**9** and **8**), isolated in 21 and 63% yields, respectively. On triplet sensitized irradiation **8** gave 1- and 6-cyanobenzosemibullvalenes (**4** and **12**; Φ = 0.006 and 0.088, respectively) and naphthalene (Φ = 0.012). The direct irradiation of **8** yielded **12** (Φ = 0.050), naphthalene (Φ = 0.015), **7** (Φ = 0.007), 7-cyanobenzocyclooctatetraene (**13**; Φ = 0.007), and 5-cyano-7,8-benzotetracyclo[3.3.0.$0^{2,4}$.$0^{3,6}$]oct-7-ene (**14**; Φ = 0.004). Deuterium labelling studies suggest that **12** derives from Zimmerman di-π-methane rearrangement of **8**, and that photoproduct cyclooctatetraene **7** is not formed by simple electrocyclic opening of the cyclobutene ring of **8**.

CHRISTOPHER OWEN BENDER, DOUGLAS DOLMAN et GAETANNE KATHRYN MURPHY. Can. J. Chem. **66**, 1656 (1988).

La photolyse directe du cyano-6 benzocyclooctatetraène (**7**) conduit aux cyano-5 et -8 benzo-2,3 bicyclo[4.2.0]octatriènes-2,4,7 (**9** et **8**), avec des rendements de 21 and 63%, respectivement. Par irradiation sensibilizée, **8** conduit aux cyano-1 et -6 benzo semi-bullvalènes (**4** et **12**; Φ = 0,006 et 0,088, respectivement) et au naphtalène (Φ = 0,012). Par irradiation directe, **8** conduit à **12** (Φ = 0,050), au naphtalène (Φ = 0,015), à **7** (Φ = 0,007), au cyano-7 benzocyclooctatetraène (**13**; Φ = 0,007), et au cyano-5 benzo-7,8 tetracyclo[3.3.0.$0^{2,4}$.$0^{3,6}$]octène-7 (**14**; Φ = 0,004). Des études de marquages au deuterium suggèrent que **12** dérive d'une transposition di-π-méthane de Zimmerman, et que **7** ne se produit pas par un mécanisme qui comporte l'ouverture électrocyclique de l'anneau du cyclobutène de **8**.

Introduction

Semibullvalene derivatives are effective building blocks in the synthesis of a variety of cyclopentanoid natural products (1). Recently, we reported a new route to the semibullvalene (SB) ring system from the triplet sensitized photoisomerization of some 2,3-benzobicyclo[4.2.0]octa-2,4,7-trienes (viz., dienes **1** (2), **3**, and **5** (3)). A potential drawback to the general utility of this ring interconversion is a concurrent fragmentation process that produces naphthalene (and presumably acetylene) derivatives. Competition between these two reaction types is strongly dependent on the substituent location, and near extremes of the partitioning were found for the cyanolated derivatives **3** and **5**; **3** gave mostly SB **4**, while **5** yielded mainly naphthalene (note Scheme 1).

We have continued our studies aimed at delineating the product controlling features in 2,3-benzobicyclo[4.2.0]octa-2,4,7-trienes, and now report on the photochemistry of the 8-cyano derivative **8**. Diene **8** was selected for study since operation of the cleavage reaction would produce the same fragments (naphthalene and cyanoacetylene) found in the case of **5**. This study would therefore test the notion, discussed in our earlier paper (3), of correlation between the stability of the acetylene unit expelled and the preference for the fragmentation process in the reaction bifurcation.

Results

The desired diene **8** was obtained as the major (63%) product from the direct irradiation ($\lambda > 310$ nm) of the tail of the absorption band of the known 6-cyanobenzocyclooctatetraene (6-CN-BCOT; **7**) (cf. the preparation of dienes **1** (2), **3**, and **5** (3) from the corresponding BCOT's); the diene isomer **9** was the only other observable (gc and nmr monitoring) product (21%).

The structure of **8** was assigned on the basis of spectral data (see Experimental) and chemical evidence. Catalytic hydrogenation gave the tetrahydro derivative **10**, which was identical to the unique product from the hydrogenation of the known compound **11** (4). Additionally, it was found that **8** reverted almost quantitatively to BCOT **7** on heating (ca. 150°C for 3 h). Here we note that **1** (2), **3**, and **5** (3) also rearrange thermally to the corresponding BCOT's without fragmentation.

In contrast to the simplicity of the thermal behaviour of **8**, photolysis gave more complex reaction mixtures. Product structures, chemical yields (gc analysis), and quantum yields (Φ's) for the direct and sensitized irradiations of **8** are given in Scheme 2.

Of the photoproducts, only 5-cyano-7,8-benzotetracyclo-[3.3.0.$0^{2,4}$.$0^{3,6}$]oct-7-ene (**14**) and 6-cyanobenzotricyclo-[3.3.0.$0^{2,8}$]octa-3,6-diene (SB **12**) are new compounds. The structure of **14** was derived from spectral data alone. The mass spectrum is similar to that of **15** (3), and shows a strong molecular peak at *m/e* 179, and a major fragmentation peak at *m/e* 128, corresponding to naphthalene ion. In the ^{1}H nmr spectrum, the signals due to the non-aromatic protons approximate an AA'MXX' spin system (cf. **15** (3)), and the chemical shifts (δ 4.47 (H-1,6), δ 3.36 (H-4), and δ 2.25 (H-2,3)) are similar to those of the corresponding protons in **16** (5) (δ 3.85 (H-1,6), δ 2.94 (H-4), and δ 2.07 (H-2,3)); H-4 in both **14** and **16** occurs as a triplet, with $J_{4,2(3)}$ = 3.5 Hz. Finally, the plane of symmetry in **14** was confirmed by the proton decoupled ^{13}C nmr spectrum, which contained only eight resonances; the chemical shifts of the aliphatic ring carbons (δ 55.48 (C-1,6), δ 20.26 (C-2,3), δ 27.67 (C-4), and δ 55.48 (C-5)) correlate well with those reported (5) for **16** (δ 53.2 (C-1,6), δ 20.1 (C-2,3), δ 24.9 (C-4), and δ 64.5 (C-5)).

In the case of photoproduct **12**, the physical characterization was compromised by the facile polymerization of the semibullvalene upon solvent removal. Similar behaviour was observed with the isomeric vinyl cyano-substituted semibullvalene **6** (3). Persuasive evidence for structure **12** was, however, provided by nmr data and hydrogenation results. Details of the ^{1}H nmr spectrum of **12** are given in Table 1, along with those of the related semibullvalenes **6** (3) and **17** (6). Inspection of the data reveals that the proton chemical shifts for **12** fall within

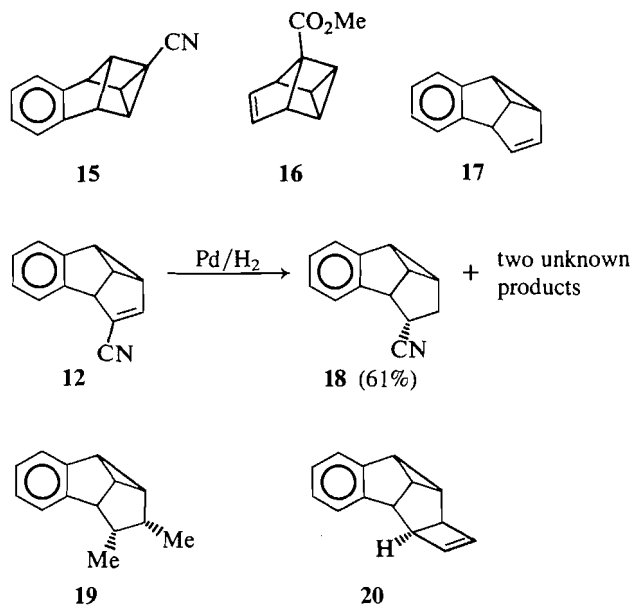
SCHEME 2

expected values; the 0.9-ppm downfield shift of H-7 in **12** relative to H-17 in **17** compares well with the reported chemical shift substituent constant of 0.8 ppm for the *cis* proton of acrylonitrile (7). Also, the coupling constants observed for **12** (see Table 1) are characteristic of the rigid benzosemibullvalene system (6).

Further support for structure **12** was provided by catalytic hydrogenation, which yielded three main products (4:1:1) by gc. The major product was isolated and identified as 6-cyano-3,4-benzotricyclo[3.3.0.$0^{2,8}$]oct-3-ene (**18**), a stable crystalline dihydro derivative of **12**. The characterization of **18** rests on comparison of its ^{1}H nmr spectrum with that of the closely related dihydro semibullvalene **19** (2). Details of the spectra are given in Table 2. Since $J_{5,6}$ = 5.0 Hz in **18** and **19**, the stereochemistry at C-6 is probably the same in both compounds, and opposite to that assigned to **20**, where $J_{5,6}$ = 0 Hz (8). Also in both **18** and **19**, $J_{5,7}$ = 1.5 Hz. This small coupling, previously overlooked by us in the case of **19** (2), is attributed to "W" coupling (9), which operates through the saturated and approximately coplanar H5—C5—C6—C7—H7 portion of the molecule (Dreiding Model).

Next, attention was turned to the possible involvement of



SCHEME 3

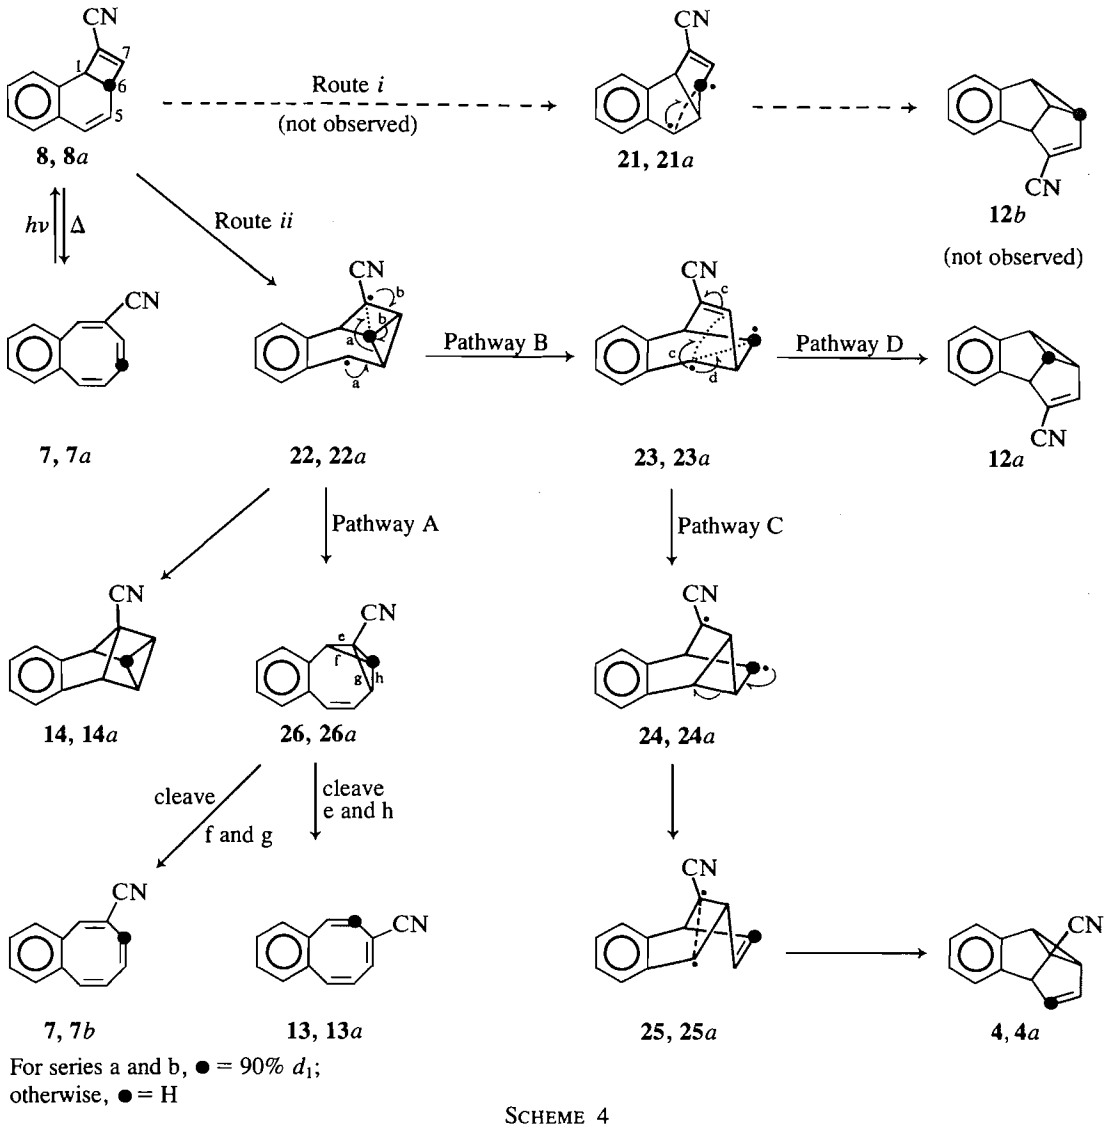

SCHEME 4

secondary photochemistry in the formation of the photoproducts given in Scheme 2. Separate irradiations of the product isomers **4**, **7**, **12**, and **14**, under the conditions employed for the starting diene **8**, showed that all were essentially unreactive on exposure to Pyrex filtered light, and were similarly resistant to photoisomerization on attempts at sensitization with Michler's ketone. In the case of photoproduct **13**, the absence of dienes **3** and **5** in photolysates of **8** indicate that COT **13** (3) also plays no part in secondary interconversions in the present study at the conversion levels used.

Mechanistic considerations

Although the formation of the major product, SB **12**, from the direct and sensitized irradiations of **8** can be readily interpreted in terms of a Zimmerman di-π-methane (DPM) rearrangement (10) with initial bridging between C-5 and C-7 (Scheme 4, route *ii*), there exists an attractive alternative mechanism which involves cleavage of the cyclobutene C1—C6 bond (Scheme 4, route *i*). This latter mechanism is appealing since it engenders immediate relief of ring strain (note structure **21**) while providing extensive stabilization of the radical centres. To distinguish between operation of these two possible mechanisms, irradiations of the deuterium labelled compound **8***a* were undertaken. Labelled diene **8***a* was obtained from the direct irradiation of the known (11) deuterated COT **7***a* (ca. 90% d_1 at C-8).

H-2	3.29 t	3.15 t	2.86 t
H-5	4.06 d	4.02 dd	3.81 dd
H-6	—	6.24 d	5.47 dd
H-7	6.01 d	—	5.08 dd
H-8	2.82 ddd	2.90 t	2.60 dt

[a]Run in $CDCl_3$ (**12**) or CCl_4 (**6** and **17**) solvent with TMS as internal standard.

[b]Coupling constants for **12** are: $J_{1,2} = J_{1,5} = J_{1,8} = 6$; $J_{2,8} = 7$, and $J_{7,8} = 2.5$ Hz; corresponding coupling constants for **6** and **17** are within 0.5 Hz.

The direct and sensitized photolysis of **8***a* led to SB product **12***a* with deuterium located exclusively at C-1, as determined by ^{1}H nmr analysis (integration results for **12***a* and for all subsequent labelled compounds are given in the Experimental).

TABLE 2. The ^{1}H nmr data of the ring-attached protons of the dihydrosemibullvalenes **18** and **19**

Assignment	Description and signal positions, $\delta^{a,b}$	
	18	**19**
Aromatics	7.17–7.30 m	6.90–7.21 m
H-1	2.90 br q	2.98 q
H-2	2.40 dd	2.25 d
H-5	3.73 dt	3.34 bt
H-6	3.32 ddd	2.83 m
H-7	2.27 m	2.52 m
H-7′	1.40 ddd	—
H-8	1.95 dq	2.01 q

[a]Run in $CDCl_3$ solvent with TMS as internal standard.
[b]Coupling constants for **18** are: $J_{1,2} = J_{1,8} = 6.5$; $J_{1,5} = J_{5,6} = 5.0$; $J_{2,8} = 7.5$; $J_{5,7} = 1.5$; $J_{6,7} = 8.5$; $J_{6,7'} = 10.5$; $J_{7,7'} = 13.5$; $J_{7,8} = 7$; and $J_{7',8'} = 2$ Hz; corresponding coupling constants for **19** are within 1.0 Hz.

Thus the DPM rearrangement (Scheme 4, route *ii*) alone accounts for the conversion of diene **8** to SB **12**.

The label locations in the other photoproducts derived from **8***a* were also examined, and proved to be intriguing in the cases of **4**, **7**, and **13**. Firstly, **4***a* is the minor SB product obtained from sensitization. A mechanism consistent with this observation is given in Scheme 4 (pathway C), and can be seen to involve a novel cyclopropyl ring closure of diradical **23***a*, to give the rearranged diradical **24***a*.

The second and by far the more surprising finding is that the 6-CN-BCOT product isolated from the direct irradiation of **8***a* is **7***b*, and not the label-isomer **7***a*. A possible rationale for the formation of COT **7***b* is given in Scheme 4 (pathway A), where the intermediacy of octavalene **26***a* is called upon. Here it is assumed that **26***a*, a member of the little known tricyclo[5.1.0.0^{2,8}]octa-3,5-diene ring system (12, 13), is thermally unstable under the photolysis conditions used. Operation of this mechanism not only accounts for the production of **7***b*, but also provides a convenient explanation for the formation of COT **13**, and it predicts the observed location of the deuterium label at C-6 in **13***a*. Furthermore, one would anticipate that intermediate **26** should generate more or less equal quantities of the COT's **7** and **13** by cleavage of alternate pairs of allylic (g or h) and benzylic (e or f) bonds. Inspection of the yields in Scheme 2 shows that the product ratio (**7**:**13**) is indeed 1:1.

Lastly with respect to the labelling studies, the thermolysis of **8***a* was carried out. This led to regeneration of the starting COT (**7***a*); no **7***b* could be detected by nmr integration.

Discussion

Diene **8** follows the general trend observed for derivatives **1**, **3**, and **5** of producing SB and naphthalene products upon triplet excitation. Unlike **5** (3), however, cleavage into the same fragments (naphthalene and cyanoacetylene) is seen to be a minor pathway (ca. <15%) in the case of **8**. Thus contrary to our previous suggestion (3), we now conclude that the stability of the acetylene unit expelled is not the controlling feature of the SB/naphthalene product bifurcation.

In the present case, the predominance of the SB **12** formation is attributed to the favorable stabilization (benzylic and cyano) afforded the radical centres in the initial DPM rearrangement intermediate **22** (see Scheme 4). The rearrangement is both singlet and triplet derived. Sensitization of **8** led to naphthalene and the SB's **4** and **12**, and is attributed to triplet (T_1) processes. The absence of SB **4** in direct irradiations of diene **8** implies that SB **12**, and its companion products formed from this mode of excitation, originate from S_1 alone. Thus **8** provides the second example of a 2,3-benzobicyclo[4.2.0]octa-2,4,7-triene that undergoes DPM rearrangement from both singlet and triplet excited states; diene **5** was the first (3). These observations are of interest, since DPM rearrangements in rigid systems show a general preference of triplet initiation (10).

Further to SB's **4** and **12**, it appears that their formation depends on the spin multiplicity of diradical **23**. For the singlet, it is assumed that the radical centres close to give SB **12**, while for the triplet, intersystem crossing and closure (→SB **12**) compete with rearrangement to the cyclopropyldicarbinyl diradical **24** and thence SB **4** formation. Precedence for this latter pathway (i.e., **24** → **25** → **4**) exists. Species like **24** are commonly invoked in barrelene photochemistry, and Zimmerman has studied product formations from the corresponding prototype diradical of **24** (i.e., **24** less the CN group). It was found that generation of the triplet species did indeed lead predominantly to benzosemibullvalene (14).

The tetracyclic compound **14** arises only from the S_1 state of **8**. Analogous $2\pi + 2\pi$ cycloaddition reactions occur in related dienes when the cyclobutenyl double bond is substituted with at least one good electron acceptor group. Thus the reaction is observed with **5** (3), 4,5-diphenyl-2,3-benzo- and 7-*tert*-butyl-8-methoxycarbonyl-bicyclo[4.2.0]octa-2,4,7-triene (15, 16), but not with **1** (2) nor with **3** (3).

The remaining minor singlet rearrangement products of **8** are the COT's **7** and **13**. Our interpretation of the coformation of these COT's via octavalene **26** (Scheme 4, pathway A) is tentative, but the recent observation of isomerization of parent octavalene to cyclooctatetraene in the ground state is consistent with the mechanism proposed here (12, 13). That COT **7** does not result from electrocyclic opening of the cyclobutene ring is noteworthy since such a process is formally allowed in the excited state. Evidently channelling of the excitation energy to the C1—C6 bond is avoided, as a consequence of the substitution pattern in **8**.

In conclusion, we note that all the photoisomerization products (from S_1 or T_1) of **8** can be accounted for by mechanisms involving the initial formation of the "Zimmerman-type" DPM diradical **22**. The present findings, together with those from our previous studies (2, 3), suggest that promotion of the SB formation in the triplet SB/naphthalene product bifurcation of 2,3-benzobicyclo[4.2.0]octa-2,4,7-trienes correlates with factors that generally enhance DPM reactivity, i.e., attachment of delocalizing substituents to the methane carbon (17) or the terminal vinyl carbons of the DPM moiety (11, 18).

Experimental

The nmr spectra were recorded on a Bruker 400-MHz or a Varian 60-MHz instrument, with TMS as internal standard. The chemical shifts are in δ units and the coupling constants (J) in Hz. The abbreviations br, s, d, t, q, and m refer to broad, singlet, doublet, triplet, quartet, and multiplet, respectively. The ir spectra were recorded on a Perkin–Elmer 337 spectrometer. The uv spectra were measured on either a Cary 15 or a Varian DMS 100S spectrometer; maxima are given in nm, with ε_{max} values in parentheses; sh = shoulder. Melting points are uncorrected. Elemental analyses were performed either by Galbraith Labs, Inc., Knoxville, TN, or by the

Analytical Services Lab, Department of Chemistry, the University of Alberta. Unless stated otherwise, column chromatography was carried out on Silica Gel 60 (Merck; 230–400 mesh) mixed with Sylvania 2282 phosphor and slurry packed into quartz columns permitting monitoring by a hand uv lamp, or on Lobar columns (Merck; size B, LiChroprep Si 60). Rotating (i.e., centrifugally accelerated) tlc separations were done on a Model 7924 Chromatotron (Harrison Research). The gc analyses were made on a Varian 3700 instrument (FID), coupled to a Varian CDS 111 computing integrator, and fitted with, unless otherwise stated, an SE-30 glass capillary column 30 m × 0.32 mm. For preparative gc separations, a Varian AP-90 instrument was used (0.25 in. × 8 ft of 7.5% SE-30 on DMCS 45/50; helium gas; 190°C). Cyclohexane solvent for photolyses was prepared by scrubbing with 20% fuming sulfuric acid, followed by washing with 10% aqueous sodium hydroxide, drying ($MgSO_4$), and finally distilling from calcium hydride. Michler's ketone sensitizer was crystallized and vacuum sublimed prior to use.

General procedures for preparative photolyses

The apparatus consisted of a 450-W Hanovia medium pressure mercury arc surrounded by a water-cooled quartz immersion well. The light was filtered through either a cylindrical Pyrex sleeve or an aqueous copper sulfate solution (250 g $CuSO_4$ in 1 L water; cut-off λ was 310 nm) contained in a concentric filter jacket (10-mm path length). Two types of sample cell were used. Cell A (200-mL sample volume) consisted of a cylindrical collar (Pyrex), which surrounded the aqueous filter jacket. The cell was fitted with gas inlet and exit ports, and sample solutions were purged with argon prior to, and during, irradiations. Cell B (35-mL sample volume) was a test-tube-like vessel (quartz), and sample solutions contained therein were deoxygenated, by flushing with argon, and sealed under a positive pressure; the solutions were magnetically stirred throughout the course of the irradiations.

Direct irradiation of cyclooctatetraene 7

A solution of 140.1 mg (0.78 mmol) of **7** (11) in 200 mL of cyclohexane was photolyzed at >310 nm for 20.5 h in Cell A. The photolysate analysed (nmr) for a diene photoproduct ratio (**8**:**9**) of 2.3:1. The photolysate was concentrated and the residue crystallized from 3 mL of hexane to give 98.3 mg (70%) of recovered COT **7**. The mother liquors were column chromatographed on Silica Gel 60 (2 cm × 45 cm; 2.5% ethyl acetate – cyclohexane) into two bands. The second band contained 17.7 mg (13%) of diene **8**, mp 69–71°C (from hexane); ir (KBr): 2220 (C≡N) cm^{-1}; uv (hexane): 261 sh (5 040), 267 (5 780), 274 sh (5 370), 290 sh (2 850), and 301 sh (730); nmr (400 MHz; $CDCl_3$): 7.17–7.28 (m, 3H, aromatics), 7.08 (m, 1H, aromatic), 6.77 (d, 1H, H-7, $J_{7,6}$ = 1.1), 6.37 (br d, 1H, H-4, $J_{4,5}$ = 10, $J_{4,6}$ = 1.5), 5.80 (dd, 1H, H-5, $J_{5,4}$ = 10, $J_{5,6}$ = 4.5), 4.37 (d, 1H, H-1, $J_{1,6}$ = 4.5), and 3.75 (br tt, 1H, H-6, $J_{6,1}$ = $J_{6,5}$ = 4.5, $J_{6,4}$ = $J_{6,7}$ = 1.3); spin decoupling experiments: irradiation of H-7 collapsed H-6 to a dt ($J_{6,1}$ = $J_{6,5}$ = 4.5, $J_{6,4}$ = 1.5); irradiation of H-4 collapsed H-5 to a d ($J_{5,6}$ = 4.5) and H-6 to a dt ($J_{6,1}$ = $J_{6,5}$ = 4.5, $J_{6,7}$ = 1.1); irradiation of H-5 modified H-6 and collapsed H-4 to a d ($J_{4,6}$ = 1.5); irradiation of H-1 modified H-6; irradiation of H-6 collapsed H-1 to an s, H-7 to an s, H-5 to a d ($J_{5,4}$ = 10). Mass spectrum showed molecular ion at m/e = 179.0733 (83%), 128 (base peak); $C_{13}H_9N$ requires 179.0734. *Anal.* calcd. for $C_{13}H_9N$: C 87.12, H 5.06, N 7.82; found: C 86.81, H 5.25, N 7.72.

The first band was rechromatographed three times on Silica Gel 60 (2 cm × 45 cm; 2% ether–cyclohexane); COT **7** was eluted first, followed by diene **9**. This procedure led to the isolation of 13.9 mg (10%) of COT **7** and 5.8 mg (4%) of diene **9**, mp 75–77°C (from hexane); ir (KBr): 2200 (C≡N) cm^{-1}; uv (hexane): 276 sh (8 500), 286.5 (12 200), 296.5 (12 600), 304 sh (9 400), and 318.5 (5 700); nmr (400 MHz; $CDCl_3$): 7.15–7.35 (m, 4H, aromatics), 6.99 (br s, 1H, H-4), 6.25 (br d, 1H, H-7, $J_{8,7}$ = 2.8), 6.13 (dd, 1H, H-8, $J_{8,1}$ = 1, $J_{7,8}$ = 2.8), 4.27 (d, 1H, H-1, $J_{1,6}$ = 4.5), and 3.82 (br d, 1H, H-6, $J_{6,1}$ = 4.5, $J_{6,4}$ = $J_{6,7}$ = 1); spin decoupling experiments: irradiation of H-4 modified H-6 to a dd ($J_{6,1}$ = 4.5, $J_{6,7}$ = 1); irradiation of H-7 collapsed H-8 to a d ($J_{8,1}$ = 1); irradiation of H-8 collapsed H-7 to a br s; irradiation of H-1 modified H-7 to a dd ($J_{7,6}$ = 1, $J_{8,7}$ = 2.8) and collapsed H-6 to a br s and H-8 to a d ($J_{7,8}$ = 2.8); irradiation of H-6 sharpened H-4 and H-7, and collapsed H-1 to a br s. Mass spectrum showed molecular ion at m/e = 179.0731 (93%), 153 (base peak).

Catalytic reduction of endo*-8-cyano-2,3-benzobicyclo[4.2.0]octa-2,4-diene (**11**)*

A stirred mixture of 41.8 mg (0.23 mmol) of **11** (4) and 6.0 mg of 10% Pd on C in 8 mL of ethyl acetate was hydrogenated at room temperature and pressure during 20 min. The catalyst was removed by filtration through Celite, and the solution concentrated. The residue was subjected to rotating tlc (silica gel; 2 mm thickness; 10% ethyl acetate – cyclohexane). Short path distillation (70°C/0.1 Torr; 1 Torr = 133.3 Pa) of the main band gave 32.4 mg (77%) of *endo*-8-cyano-2,3-benzobicyclo[4.2.0]oct-2-ene (**10**; gc purity >99%) as a colourless oil; ir (neat liquid): 2230 (C≡N) cm^{-1}; uv (hexane): 249 sh (120), 253 sh (175), 261 sh (280), 266 (375), and 273 (380); nmr (400 MHz; $CDCl_3$): 7.07–7.26 (m, 4H, aromatics), 3.82 (br t, 1H, H-1, $J_{1,6}$ ~ $J_{1,8}$ ~ 9, $J_{1,7'}$ ~ 2), 3.61 (dt, 1H, H-8, $J_{8,1}$ = 8, $J_{8,7}$ = $J_{8,7'}$ = 9), 2.92–3.03 (m, 2H, H-4′ and H-6), 2.76 (dt, 1H, H-4, $J_{4,5}$ = $J_{4,5'}$ = 4.5, $J_{4,4'}$ = 16), 2.53 (sym m, 1H, H-7′), 2.20 (dt, 1H, H-7, $J_{7,6}$ = $J_{7,8}$ = 8, $J_{7,7'}$ = 12), 1.79–1.86 and 1.66–1.75 (m and m, 2H, C-5 methylenes); spin decoupling experiments: irradiation of H-1 modified H-8 and the 2.92–3.03 m, and collapsed H-7′ to a dt ($J_{7,7'}$ = 12, $J_{7',6}$ = $J_{7',8}$ = 10.5); other decouplings confirmed the above assignments and coupling constants. Mass spectrum showed molecular ion at m/e = 183.1048 (6.5%), 130 (base peak); $C_{13}H_{13}N$ requires 183.1048.

Catalytic reduction of diene 8

A stirred mixture of 6.0 mg (0.034 mmol) of **8** and 2.1 mg of 10% Pd on C in 4 mL of ethyl acetate was hydrogenated at room temperature and pressure during 25 min. The catalyst was removed by filtration through Celite, and the solution concentrated. The residue was subjected to rotating tlc (silica gel; 2 mm thickness; 10% ethyl acetate – cyclohexane). Short path distillation (65°C/0.1 Torr) of the main band gave 5.4 mg (88%) of colourless oil identical (gc, ir, nmr) to **10**.

Thermolysis of diene 8

A solution of 15.2 mg (0.085 mmol) of **8** in 2 mL of *n*-nonane was refluxed (ca. 150°C) during 3 h. The thermolysis product (no naphthalene by gc) was column chromatographed on Silica Gel 60 (1 cm × 35 cm; 2% ether–cyclohexane). Crystallization of the main band from hexane gave 13.8 mg (91%) of COT **7**, mp 72–74°C (lit. (11) mp 73–74°C).

Direct irradiation of diene 8

A solution of 78.0 mg (0.44 mmol) of diene **8** and 6.7 mg of tetradecane (gc standard) in 35 mL of cyclohexane was photolyzed (Pyrex filter) for 12 h in cell B (45% conversion by gc). The photolysate composition analysed (gc and nmr) for 3.9 mg (7%) naphthalene, 1.6 mg (2%) tetracyclic **14**, 2.7 mg (3%) COT **13**, 2.7 mg (3%) COT **7**, 42.9 mg (55%) diene **8**, and 19.4 mg (25%) SB **12**. The photolysate was concentrated and the residue chromatographed on a Lobar column (4% ethyl acetate – cyclohexane). The first band eluted was naphthalene (identified by gc and nmr). The second band gave 2.2 mg (3%) of COT **7**, and the third band gave 2.1 mg (3%) of COT **13**, mp 100–102°C (from hexane; lit. (11) mp 102–103°C), identified by gc and nmr comparison with an authentic sample (11). The fourth band gave 39.7 mg (51%) of recovered diene **8**. The fifth band contained 1.2 mg (1.5%) of tetracyclic **14**, mp 95–97°C (from hexane); ir (KBr): 2230 (C≡N) cm^{-1}; uv (hexane): 253 (135), 258 (210), 264 (280), 266 (270), 271 (165), and 273 (250); ^1H nmr (400 MHz; $CDCl_3$): 7.20–7.25 (sym m, 4H, aromatics), 4.45–4.48 (sym m, 2H, H-1 and H-6), 3.36 (br t, 1H, H-4, $J_{4,2(3)}$ = 3.5, $J_{4,1(6)} \leq 0.3$), 2.24–2.27 (sym m, 2H, H-2 and H-3); spin decoupling experiments: irradiation of H-1,6 collapsed H-2,3 to a d ($J_{2(3),4}$ = 3.5) and H-4 to a sharp t ($J_{4,2(3)}$ = 3.5); irradiation of H-4 modified both H-1,6 and H-2,3; irradiation of H-2,3 collapsed both H-1,6 and H-4 to br singlets; ^{13}C nmr (100 MHz; ^1H decoupled; $CDCl_3$): 144.07 (C7 and C8), 127.24 and 122.04 (α- and β-aromatics), 117.63 (C≡N), 55.48 (C1 and C6), 50.99 (C5), 27.67 (C4), and 20.26 (C2 and C3) ppm. Mass spectrum showed molecular

For personal use only.

ion at m/e = 179.0726 (69%), 128 (base peak); $C_{13}H_9N$ requires 179.0734. *Anal.* calcd. for $C_{13}H_9N$: C 87.12, H 5.06, N 7.82; found: C 87.24, H 5.17, N 7.63.

The seventh, and last, band contained SB **12** of gc purity >98% (note: SB **12** rapidly polymerizes when solvent free); details of the nmr data are given in Table 1; spin decoupling experiments: irradiation of H-7 collapsed H-8 to a dd ($J_{8,1}$ = 6, $J_{8,2}$ = 7); irradiation of H-5 collapsed H-1 to a t ($J_{1,2} = J_{1,8}$ = 6); irradiation of H-1 collapsed H-5 to an s, H-2 to a d ($J_{2,8}$ = 7), and H-8 to a dd ($J_{8,2}$ = 7, $J_{8,7}$ = 2.5); irradiation of H-2 modified H-1 and H-8; irradiation of H-8 collapsed H-7 to an s, H-1 to a t ($J_{1,2} = J_{1,5}$ = 6), and H-2 to a d ($J_{2,8}$ = 7).

Catalytic reduction of SB ***12***

A stirred mixture of ca. 49 mg (0.27 mmol) of **12**, 8.1 mg of 10% Pd on C, and 8.6 mg of tetradecane (gc standard) in 10 mL of ethyl acetate was hydrogenated at room temperature and pressure during 40 min (complete loss of starting material). The catalyst was removed by filtration through Celite, and the resulting solution, when analysed by gc, showed three major peaks of relative area 4(**18**):1(unknown):1(unknown). The solution was concentrated and the residue was chromatographed on a column of Silica Gel 60 (2 cm × 45 cm; 2% ether–cyclohexane). Crystallization of the main band from hexane gave 29.8 mg (61%) of colourless **18**, mp 106–108°C; ir (KBr): 2225 (C≡N) cm^{-1}; uv (hexane): 223 sh (4 600), 258 sh (240), 264 (400), 269 sh (550), 270 (600), and 278 (720); ^1H nmr (400 MHz; $CDCl_3$), see Table 2; spin decoupling experiments: irradiation of H-5 collapsed H-6 to a dd ($J_{6,7}$ = 8.5, $J_{6',7}$ = 10.5), H-1 to a br t ($J_{1,2} \sim J_{1,8} \sim$ 6.5), and H-7 to a ddd ($J_{7,6}$ = 8.5, $J_{7',7}$ = 13.5, $J_{7,8}$ = 7); irradiation of H-6 collapsed H-5 to a dd ($J_{5,1}$ = 5.0, $J_{5,7}$ = 1.5), H-7′ to a dd ($J_{7',7}$ = 13.5, $J_{7',8}$ = 2), and modified H-7; irradiation of H-1 collapsed H-5 to a d ($J_{5,6}$ = 5.0), H-2 to a d ($J_{2,8}$ = 7.5), and H-8 to a br dt ($J_{8,2} \sim J_{8,7} \sim$ 7.5, $J_{8,7'}$ = 2); irradiation of H-2 modified H-1 and H-8; irradiation of H-7 collapsed H-5 to a t ($J_{5,1} = J_{5,6}$ = 5.0), and modified H-6, H-8, and H-7′; irradiation of H-8 modified H-1, and collapsed H-2 to a d ($J_{2,1}$ = 6.5), H-7 to a ddd ($J_{7,6}$ = 8.5, $J_{7,7'}$ = 13.5, $J_{7,5}$ = 1.5), and H-7′ to a dd ($J_{7',6}$ = 10.5, $J_{7',7}$ = 13.5); irradiation of H-7′ modified H-6 and H-7, and collapsed H-8 to a br q ($J_{8,1} \sim J_{8,2} \sim J_{8,7} \sim$ 7). Mass spectrum showed molecular ion at m/e = 181.0890 (69%), 128 (base peak); $C_{13}H_{11}N$ requires 181.0892. *Anal.* calcd. for $C_{13}H_{11}N$: C 86.15, H 6.12, N 7.73; found: C 86.33, H 6.13, N 7.74.

Sensitized irradiation of diene ***8***

A solution of 38.2 mg (0.21 mmol) of diene **8**, 4.3 mg (0.02 mmol) of Michler's ketone, and 5.2 mg of tetradecane (gc standard) in 35 mL of cyclohexane was photolyzed (uranium glass filter) for 1.5 h in cell B (74% conversion by gc). The photolysate composition analysed (gc) for 2.3 mg (8%) naphthalene, 2.0 mg (6%) SB **4**, 9.9 mg (26%) diene **8**, and 22.1 mg (58%) SB **12**. The photolysate was concentrated and the residue chromatographed on Silica Gel 60 (2 cm × 45 cm; 4% ether–cyclohexane). The first band eluted was naphthalene (identified by gc and nmr) and the second band contained 8.6 mg (23%) of recovered diene **8**. The third band contained a mixture of SB **4** and SB **12**; a small sample of pure SB **12** (>98% by gc) was obtained from the tail end of the band. Preparative gc of the bulk of the third band on an S.E. 30 column eluted, firstly, 0.9 mg (2%) of SB **4**, identified by gc and nmr comparison with an authentic sample (11), followed by SB **12**, much of which polymerized in the collector. We have subsequently found that SB's **4** and **12** can be completely separated by column chromatography on silica gel impregnated with silver nitrate.

Quantum yield determinations

Quantum yields were performed on an apparatus previously described (19), which includes an optical bench arranged for beam splitting into ferrioxalate actinometer (20). Cyclohexane solutions (3 mL) of reactants (ca. (5–6.5) × 10^{-3} M) and sensitizer, if any (Michler's ketone, 0.57 × 10^{-3} M), were deoxygenated prior to irradiation by flushing with argon. A positive pressure of argon was maintained over the stirred solutions throughout the course of the irradiations. The quantum yields, given in Scheme 2, were obtained from several runs extrapolated to zero conversion. Product analyses were determined by gc (internal tetradecane standard) and by nmr. For the direct irradiations, light of wavelength 280 nm was used. For sensitized runs, the sensitizer absorbed >95% of the incident light (334 nm) employed.

Labelled COT ***7****a*

Deuterated COT ***7a*** (90% d_1 at C-8) was prepared as previously described (11); nmr (400 MHz; $CDCl_3$): 7.22–7.28 (m, 3.51H, H-5 + 2 aromatics + residual $CHCl_3$), 6.95–7.00 (m, 2.00H, 2 aromatics), 6.55 (d, 1.02H, H-10, $J_{10,9}$ = 11.5), 6.08 (dd, 0.07H, H-8, $J_{8,7}$ = 11, $J_{8,9}$ = 4), 6.04 (d, 1.00H, H-9, $J_{9,10}$ = 11.5), and 5.76 (br s, 0.97H, H-7). Integrations for ***7a*** and for all subsequent deuterium labelled compounds were normalized by assigning integer values to one or more aromatic proton signals, unless otherwise indicated; integration errors due to baseline undulations are estimated to be within ca. ±0.05H.

Labelled diene ***8****a from COT* ***7****a*

A solution of 238.9 mg (1.33 mmol) of COT ***7a*** (ca. 90% d_1 at C-8) in 200 mL of cyclohexane was photolyzed directly at >310 nm for 21 h in Cell A. The photolysate was worked up as in the case of the direct irradiation of COT **7** to give 33.3 mg (14%) of diene ***8a***; nmr (400 MHz; $CDCl_3$): 7.18–7.27 (m, 3.72H, 3 aromatics + residual $CHCl_3$), 7.08 (m, 1.00H, 1 aromatic), 6.78 (s, 0.98H, H-7), 6.38 (d, 1.00H, H-4, $J_{4,5}$ = 10), 5.80 (d, 1.00H, H-5, $J_{5,4}$ = 10), 4.36 (s, 1.00H, H-1), and 3.76 (m, 0.07H, H-6).

Thermolysis of labelled diene ***8****a*

A solution of 9.5 mg (0.053 mmol) of ***8a*** in 1 mL of *n*-nonane was refluxed (ca. 151°C) during 2.25 h. The thermolysis product was worked up as in the case of the thermolysis of nondeuterated diene to give 8.3 mg (87%) of COT ***7a***; nmr (400 MHz; $CDCl_3$): 7.22–7.28 (m, 3.53H, H-5 + 2 aromatics + residual $CHCl_3$), 6.95–7.00 (m, 2.00H, 2 aromatics), 6.55 (d, 1.00H, $J_{10,9}$ = 11.5), 6.08 (dd, 0.09H, H-8, $J_{8,7}$ = 11, $J_{8,9}$ = 4), 6.04 (d, 1.00H, H-9, $J_{9,10}$ = 11.5), and 5.76 (br s, 0.98H, H-7).

Direct irradiation of labelled diene ***8****a*

A solution of 30.3 mg (0.17 mmol) of diene ***8a*** and 6.0 mg of tetradecane (gc standard) in 35 mL of cyclohexane was photolyzed (Pyrex filter) for 10.3 h in cell B (46% conversion by gc). The photolysate, when worked up as in the case of the direct irradiation of unlabelled **8**, gave: 0.8 mg (3%) COT ***7b***, nmr (400 MHz; $CDCl_3$): 7.22–7.28 (m, 5.47H, H-5 + 2 aromatics + residual $CHCl_3$), 6.95–7.00 (m, 2.00H, 2 aromatics), 6.55 (d, 1.04H, H-10, $J_{10,9}$ = 11.5), 6.08 (m, 0.98H, H-8), 6.04 (dd, 1.00H, H-9, $J_{9,8}$ = 4, $J_{9,10}$ = 11.5), and 5.76 (d, 0.09H, H-7, $J_{7,8}$ = 11); 0.9 mg (3%) COT ***13a***, nmr (400 MHz; $CDCl_3$): 7.21–7.31 (m, 3.58H, 2 aromatics + residual $CHCl_3$), 6.95–7.05 (m, 2.00H, 2 aromatics), 6.75 and 6.73 (s and d, 1.99H, H-5 and H-10, $J_{10,9}$ = 11.5), 6.67 (d, 0.96H, H-8, $J_{8,9}$ = 4), 6.07 (dd, 1.00H, H-9, $J_{9,8}$ = 4, $J_{9,10}$ = 11.5), and 5.95 (d, 0.10H, H-6, $J_{6,5}$ = 11.5); 13.9 mg (46%) of recovered diene ***8a***, nmr (60 MHz; CCl_4): 6.93–7.48 (m, 4.00H, 4 aromatics), 6.77 (s, 0.95H, H-7), 6.43 (d, 0.95H, H-4, $J_{4,5}$ = 10), 5.83 (d, 1.00H, H-5, $J_{5,4}$ = 10), 4.46 (s, 1.03H, H-1), and 3.83 (m, 0.09H, H-6); ca. 0.5 mg (2%) of tetracyclic **14**-d_1, nmr (400 MHz; $CDCl_3$): 7.20–7.25 (m, 4.55H, 4 aromatics + residual $CHCl_3$), 4.45–4.48 (m, 2.00H, H-1 and H-6), 3.36 (d, 0.99H, H-4, $J_{4,3}$ = 3.5), 2.24–2.27 (t, 1.05H, H-2 and H-3, $J_{3,4} = J_{3,6}$ = 3.5); and 6.4 mg (21%, estimated by gc) of SB ***12a***, nmr (400 MHz; $CDCl_3$): 7.33 (m, 1.00H, 1 aromatic), 7.18–7.28 (m, 3.66H, 3 aromatics + residual $CHCl_3$), 6.01 (d, 0.98H, H-7, $J_{7,8}$ = 2.5), 4.06 (s, 1.03H, H-5), 3.49 (q, 0.08H, H-1, $J_{1,2} = J_{1,5} = J_{1,8}$ = 6), 3.29 (d, 1.03H, H-2, $J_{2,8}$ = 7), and 2.79 (dd, 0.98H, H-8, $J_{8,2}$ = 7, $J_{8,7}$ = 2.5).

Sensitized irradiation of labelled diene ***8****a*

A solution of 39.6 mg (0.22 mmol) of diene ***8a***, 4.3 mg (0.02 mmol) of Michler's ketone, and 5.4 mg of tetradecane (gc standard) in 35 mL of cyclohexane was photolyzed (uranium glass filter) for 1.5 h in cell B (76% conversion by gc). The photolysate, when worked up as in the case of the direct irradiation of unlabelled **8**, gave: 8.1 mg (20%) of recovered diene ***8a***, nmr (60 MHz; CCl_4): 6.77–7.48 (m, 4.00H, 4 aromatics), 6.77 (s, 1.01H, H-7), 6.43 (d, 1.06H, H-4, $J_{4,5}$ = 10),

5.83 (d, 0.99H, H-5, $J_{5,4}$ = 10), 4.46 (s, 0.97H, H-1), and 3.83 (m, 0.10H, H-6); 0.9 mg (2%) of SB **4***a*, nmr (400 MHz; $CDCl_3$): 7.38 (m, 1.05H, 1 aromatic), 7.20 (m, 2.01H, 2 aromatics), 7.10 (m, 0.94H, aromatic), 5.72 (m, 0.07H, H-6), 5.20 (d, 1.00H, H-7, $J_{7,8}$ = 2.5), 4.20 (s, 0.95H, H-5), 3.68 (d, 0.95H, H-2, $J_{2,8}$ = 7.5), 3.36 (dd, 0.99H, H-8, $J_{8,2}$ = 7.5, $J_{8,7}$ = 2.5); and SB **12***a*, nmr (400 MHz; $CDCl_3$): 7.33 (m, 1.00H, 1 aromatic), 7.18–7.28 (m, 3.20H, 3 aromatics + residual $CHCl_3$), 6.01 (d, 0.99H, H-7, $J_{7,8}$ = 2.5), 4.06 (s, 1.00H, H-5), 3.49 (q, 0.09H, H-1, $J_{1,2}$ = $J_{1,5}$ = $J_{1,8}$ = 6), 3.29 (d, 1.04H, H-2, $J_{2,8}$ = 7), and 2.79 (dd, 1.03H, H-8, $J_{8,2}$ = 7, $J_{8,7}$ = 2.5).

Influence of alkylation of the amino group on the reactions of adenine with the methylmercury(II) cation

LUCIE GRENIER, JEAN-PIERRE CHARLAND, AND ANDRÉ L. BEAUCHAMP[1]

Département de Chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Qué.), Canada H3C 3J7

Received December 24, 1987

LUCIE GRENIER, JEAN-PIERRE CHARLAND, and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **66**, 1663 (1988).

Reaction of the CH_3Hg^+ cation with 6-dimethylamino- and 6-diethylaminopurine (HL) yielded compounds of the types $[(CH_3Hg)L]$, $[(CH_3Hg)_2L]X$ (X = NO_3, ClO_4), and $[(CH_3Hg)_2(HL)](NO_3)_2$. Metal binding to N(9) in $[(CH_3Hg)L]$ was deduced from the nmr spectra. The coordination sites in the other types of compounds were determined from X-ray diffraction studies on two complexes of 6-dimethylaminopurine. Crystals of $[(CH_3Hg)_2L]ClO_4$ are monoclinic, space group $P2_1/c$, a = 9.319(3) Å, b = 9.581(8) Å, c = 19.624(8) Å, β = 118.23(3)°, and Z = 4. The structure was refined on 1521 nonzero MoKα reflections to R = 0.040. $[(CH_3Hg)_2(HL)](NO_3)_2.H_2O$ belongs to the same space group, a = 11.012(3) Å, b = 23.669(7) Å, c = 6.748(4) Å, β = 95.25(4)°, Z = 4, 1781 MoKα reflections, R = 0.053. In both complexes, the CH_3Hg^+ groups are bound to the N(9) and N(3) sites of the purine ring. In the $[(CH_3Hg)_2L]^+$ cation, the lone pair of N(7) is free, whereas it is occupied by a proton in $[(CH_3Hg)_2(HL)]^{2+}$. The ^1H and ^{13}C nmr spectra show that the solid state structures are retained in DMSO solutions. The $^2J(^{199}Hg—^1H)$ coupling constants suggest that protonation on N(7) produces for N(9) and N(3) average decreases of basicity corresponding to ~3 pK units.

LUCIE GRENIER, JEAN-PIERRE CHARLAND et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **66**, 1663 (1988).

La réaction du cation CH_3Hg^+ avec la diméthylamino-6 et la diéthylamino-6 purine (HL) conduit à des composés de type $[(CH_3Hg)L]$, $[(CH_3Hg)_2L]X$ (X = NO_3, ClO_4) et $[(CH_3Hg)_2(HL)](NO_3)_2$. Les spectres rmn indiquent que le métal se lie au site N(9) dans $[(CH_3Hg)L]$. Les sites de coordination dans les deux autres cas ont été déterminés par diffraction des rayons-X sur des composés de la diméthylamino-6 purine. Les cristaux de $[(CH_3Hg)_2L]ClO_4$ sont monocliniques, groupe spatial $P2_1/c$, a = 9,319(3) Å, b = 9,581(8) Å, c = 19,624(8) Å, β = 118,23(3)° et Z = 4. La structure a été affinée au moyen de 1521 réflexions MoKα observées, jusqu'à un facteur R de 0,040. $[(CH_3Hg)_2(HL)](NO_3)_2.H_2O$ appartient au même groupe spatial, a = 11,012(3) Å, b = 23,669(7) Å, c = 6,748(4) Å, β = 95,25(4)°, Z = 4, 1781 réflexions MoKα, R = 0,053. Dans les deux complexes, les groupes CH_3Hg^+ sont liés aux sites N(9) et N(3) du noyau purinique. Dans le cation $[(CH_3Hg)_2L]^+$, le doublet de N(7) est libre, tandis qu'il est occupé par un proton dans $[(CH_3Hg)_2(HL)]^{2+}$. Les résultats de rmn ^1H et ^{13}C montrent que les structures observées à l'état solide sont retenues en solution dans DMSO. Les constantes de couplage $^2J(^{199}Hg—^1H)$ indiquent que la protonation de N(7) entraîne pour N(9) et N(3) un abaissement moyen de basicité correspondant à ~3 unités de pK.

Introduction

Over the past few years, we have been conducting an in-depth study of the coordination of the uniligating CH_3Hg^+ cation with adenine and some of its derivatives, both in the solid state and in solution (1–3). It was found that CH_3Hg^+ and the proton are not introduced onto the adenine ring following the same order. Indeed, protons bind to the adeninate monoanion in the sequence N(9)—N(1)—N(7)—N(3) (4), whereas only three CH_3Hg^+ cations could be introduced, in the order N(9)—N(7)—N(3). Binding to N(1) was not observed with adenine.

We recently became interested in developing multidentate ligands that could induce the formation of metal–metal bonds, while retaining available coordination sites to accept other types of electrophilic moieties. Since ^1H and ^{13}C nmr results had revealed that the N(9)/N(7)-bonded $[(CH_3Hg)_2(adeninate)]^+$ cation is probably involved in a tautomeric equilibrium with an N(9)/N(3) form in DMSO (5), we felt that mild steric hindrance in the neighborhood of N(7) might cleanly displace reactivity to the N(9)/N(3) side of the ring. To test this assumption, adenine was dialkylated at the amino group and allowed to react with CH_3Hg^+. The marked differences displayed by these dialkylated ligands are discussed in the present paper.

Experimental

Preparation

6-Dimethylaminopurine (HDMAd) and 6-diethylaminopurine (HDEAd) were prepared from 6-chloropurine (Aldrich) according to Itaya, Matsumoto, and Ogawa (6). The aqueous CH_3HgOH (1 *M*) solutions were used as received from Aldrich. Solutions of CH_3HgClO_4 and CH_3HgNO_3 were prepared in our laboratory as described earlier (7). The microanalyses were carried out by Schwarzkopf Microanalytical Laboratories, New York.

The ^1H nmr spectra were obtained at ambient probe temperature with a Bruker WH-90 instrument. The ^{13}C spectra were recorded at 100.62 MHz with the Bruker WH-400 instrument of the Centre Régional de RMN Haut Champ located at the Université de Montréal. The solvent was DMSO-d_6 ("Silanor", Merck, Sharp & Dohme Canada) containing TMS as internal reference.

$[(CH_3Hg)(DMAd)]$

The ligand (164 mg, 1 mmol) was dissolved in boiling water (19 mL) and CH_3HgOH 1 *M* (1.0 mL, 1 mmol) was added. The mixture was left at room temperature for 2 days and a white powder was obtained. It was quickly washed with small amounts of cold water. Yield: 290 mg, 78%. *Anal.* calcd. for $C_8H_{11}HgN_5$: C 25.43, H 2.93, N 18.54, Hg 53.09; found: C 25.38, N 2.90, N 18.49, Hg 53.02.

$[(CH_3Hg)_2(DMAd)]ClO_4$

The ligand (164 mg, 1 mmol) was dissolved in boiling water (18 mL). To the hot solution were added 1.0 mL (1 mmol) 1 *M* CH_3HgClO_4 and 1.0 mL (1 mmol) 1 *M* CH_3HgOH. After 2 days at room temperature, colorless crystals were filtered and quickly washed with small amounts of cold water. Yield: 410 mg, 63%. The same compound was obtained in lower yield (42%) when 1 mmol of CH_3HgClO_4 was used without hydroxide. The crystalline sample was morphologically homogeneous and the structure analysis described hereafter was done on a crystal from this batch.

$[(CH_3Hg)_2(DMAd)]NO_3.H_2O$

The method above was used, replacing CH_3HgClO_4 by CH_3HgNO_3. Yield: 41%. *Anal.* calcd. for $C_9H_{16}Hg_2N_6O_4$: C 16.05, H 2.39, N 12.48, Hg 59.57; found: C 16.17, H 2.31, N 12.70, Hg 60.19.

[(CH$_3$Hg)$_2$(HDMAd)](NO$_3$)$_2$.H$_2$O

To a suspension of 163 mg (1 mmol) of ligand in acetonitrile (30 mL) were added 2.0 mL (2 mmol) of aqueous 1 *M* CH_3HgNO_3, whereupon a clear solution was obtained. After spontaneous evaporation of two thirds of the solvent at room temperature, a white precipitate was collected and quickly washed with cold acetonitrile. Yield: 450 mg, 63%. *Anal.* calcd. for $C_9H_{15}Hg_2N_7O_6$: C 15.05, H 2.10, N 13.65, Hg 55.84; found: C 15.48, H 2.26, N 13.53, Hg 55.37. The same compound was obtained in low yield (11%) from a mixture of 1 mmol (163 mg) of ligand dissolved in 30 mL of water, with 1.0 mL of concentrated HNO_3 and 2.0 mL (2 mmol) of 1 *M* CH_3HgNO_3. After spontaneous evaporation of 20 mL of solvent at room temperature, a fine colorless powder was obtained.

With 6-diethylaminopurine, similar compounds were obtained by starting with 1 mmol (191 mg). Yields and microanalytical results are given below.

[(CH$_3$Hg)(DEAd)]

Yield: 270 mg, 67%. *Anal.* calcd. for $C_{10}H_{15}HgN_5$: C 29.59, H 3.73, N 17.26, Hg 49.42; found: C 29.67, H 3.88, N 17.33, Hg 49.53.

[(CH$_3$Hg)$_2$(DEAd)]NO$_3$

Yield: 220 mg, 33%. *Anal.* calcd. for $C_{11}H_{18}Hg_2N_6O_3$: C 19.33, H 2.65, N 12.30, Hg 58.70; found: C 19.28, H 2.86, N 12.21, Hg 58.58.

[(CH$_3$Hg)$_2$(DEAd)]ClO$_4$

Yield: 297 mg, 39%. *Anal.* calcd. for $C_{11}H_{18}ClHg_2N_5O_4$: C 18.33, H 2.52, N 9.71, Cl 4.92, Hg 55.65; found: C 18.41, H 2.67, N 9.39, Cl 4.68, Hg 55.18.

[(CH$_3$Hg)$_2$(HDEAd)](NO$_3$)$_2$

Yield: 192 mg, 62%. *Anal.* calcd. for $C_{11}H_{19}Hg_2N_7O_6$: C 17.70, H 2.57, N 13.13, Hg 53.74; found: C 17.55, H 2.62, N 13.06, Hg 53.46.

X-ray diffraction work

Space group and initial cell dimensions for both compounds were determined from precession and cone-axis photographs. The $2/m$ Laue symmetry and systematic absences ($0k0$, $k \neq 2n$; $h0l$, $l \neq 2n$) uniquely defined space group $P2_1/c$. The intensity data were collected with an Enraf-Nonius CAD4 diffractometer, following the procedure described elsewhere (8). The data were corrected for the Lorentz effect, polarization, and absorption (Gaussian integration, grid 8 × 8 × 8). The structures were solved by the heavy-atom method and refined on $|F_o|$ by least-squares procedures. The mercury atoms were located from Patterson maps and the non-hydrogen atoms were subsequently found from difference Fourier (ΔF) maps phased on Hg. The non-hydrogen atoms were isotropically refined by full-matrix squares. The ring hydrogen atoms were fixed at idealized positions (C(N)—H = 0.95 Å, sp^2 hybridization, isotropic B = 4.0 Å^2). Their parameters were not refined, but the coordinates were recalculated after each least-squares cycle. The methyl hydrogens were not visible on the ΔF maps. In the last cycles, the non-hdyrogen atoms were anisotropically refined by block-diagonal least squares. Details for each structure are given below. The scattering curves used were from standard sources (9). The f' and f'' contributions to anomalous dispersion for Hg and Cl (10) were included in structure factor calculations.

[(CH$_3$Hg)$_2$(DMAd)]ClO$_4$

$C_9H_{14}ClHg_2N_5O_4$ fw = 692.88

Monoclinic, $P2_1/c$, a = 9.319(3) Å, b = 9.581(8) Å, c = 19.624(8) Å, β = 118.23(3)°, V = 1544 Å^3, D_{calcd} = 2.981 g cm^{-3}, D_{obs} (in $C_2H_2Br_4/CH_3I$) = 2.88(3) g cm^{-3}, Z = 4, λ(MoKα) = 0.71069 Å, μ(MoKα) = 200.6 cm^{-1}, crystal dimensions (0.54 × 0.26 × 0.15 mm), transmission range = 0.021–0.096, T = 293 K.

A set of 2020 independent hkl and $hk\bar{l}$ reflections within a sphere limited by 2θ = 45° was collected. The three standard reflections fluctuated within ±4.0% during data collection. On the basis of the criterion $I > 3\sigma(I)$, a set of 1521 reflections was retained for structure determination. Isotropic refinement of all non-hydrogen atoms converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.101$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.112$. Anisotropic refinement of the non-hydrogen atoms with hydrogens fixed converged at $R = 0.040$, $R_w = 0.050$, and a goodness-of-fit ratio of 1.97 and 190 parameters varied. The general background in the final ΔF map was lower than ±0.70 e Å^{-3}, and a few peaks in the range ±|0.7–1.3| e Å^{-3} were found near Hg.

[(CH$_3$Hg)$_2$(HDMAd)](NO$_3$)$_2$.H$_2$O

$C_9H_{17}Hg_2N_7O_7$ fw = 736.46

Monoclinic, $P2_1/c$, a = 11.012(3) Å, b = 23.669(7) Å, c = 6.748(4) Å, β = 95.25(4)°, V = 1751 Å^3, D_{calcd} = 2.793 g cm^{-3},

D_{obs} (in $C_2H_2Br_4$–CH_3I) = 2.84(2) g cm^{-3}, Z = 4, λ(MoKα) = 0.71069 Å, μ(MoKα) = 175.5 cm^{-1}, crystal dimensions: 0.60 × 0.03 × 0.17 mm, transmission range: 0.040–0.596, T = 293 K.

A total of 3069 independent hkl and $hk\bar{l}$ reflections was collected ($2\theta_{max}$ = 50°), of which 1781 were above background ($I > 3.0\sigma(I)$). The standard reflections fluctuated within ±2.0% during data collection. Isotropic refinement led to R = 0.109 and R_w = 0.115. Anisotropic refinement converged for R = 0.053, R_w = 0.060 and a goodness-of-fit ratio of 2.11 for 226 parameters varied. The general background on the final ΔF map was below ±0.9 e Å^{-3}, and a few peaks in the range ± |0.9–1.9| e Å^{-3} were found near Hg.

The refined coordinates for both structures are listed in Table 1. The anisotropic temperature factors are provided in the supplementary material.[2]

Results and discussion

Reactions

The reaction of CH_3HgOH with the dialkylaminopurines (HL) yielded as the only product the neutral [(CH_3Hg)L] complex, in which the N(9)—H proton has been displaced by the CH_3Hg^+ cation and neutralized by the OH^- group. As in the case of adenine (2), all attempts to obtain 1:1 complexes without loss of the imidazole proton were unsuccessful. Adding HNO_3 or $HClO_4$ to a 1:1 mixture of the ligands with the corresponding CH_3Hg^+ salt led to the purinium salt [H_2L]X. When the reaction was conducted with CH_3HgNO_3 or CH_3HgClO_4 without adding acid, the 2:1 [$(CH_3Hg)_2$L]X compounds were obtained, one half of the ligand being used to accept the proton displaced by the methylmercury cation (equation [1]):

[1] $2CH_3HgX + 2HL \rightleftharpoons [(CH_3Hg)_2L]X + [H_2L]X$

Better yields were obtained from equimolar amounts of ligand, CH_3HgOH and CH_3HgX. In this respect, the dialkylaminopurines react like adenine (2).

Various attempts were made to prepare higher complexes, by using CH_3HgX:ligand ratios as high as 8. These mixtures invariably yielded the [$(CH_3Hg)_2$L]X complexes as the major products, indicating that in contrast with adenine, introducing a third CH_3Hg^+ group onto the ligand is difficult. With high metal-to-ligand ratios, a small amount of a compound whose analog with adenine had not been obtained, appeared in crystalline form and could be separated from the major powdery material. This compound was subsequently shown to be a 2:1 complex [$(CH_3Hg)_2$(HL)]$(NO_3)_2$ in which the ligand retained the imidazole proton, its formation being favored by the excess of acidic $CH_3HgOH_2^+$ ions ($pk_a \sim 4.6$) (11). The same compound was obtained in high yields by adding HNO_3 to a 2:1 CH_3HgX:ligand mixture in acetonitrile–water.

The structures of the two cationic compounds of dimethylaminopurine were determined by X-ray diffraction.

Crystal structures

The numbering scheme used for the complex cations in [$(CH_3Hg)_2$(DMAd)]ClO_4 and [$(CH_3Hg)_2$(HDMAd)]$(NO_3)_2.H_2O$ is shown in Fig. 1. In both compounds, the CH_3Hg^+ groups are bonded to the N(9) and N(3) sites of dimethylaminopurine. In the [$(CH_3Hg)_2$(DMAd)]$^+$ ion, the ligand is formally anionic, since the N(9)—H proton has been substituted by the metal. The N(7) position in [$(CH_3Hg)_2$(HDMAd)]$^{2+}$ is occupied by a proton, which can be regarded as having been transferred from N(9) to N(7) in a formally neutral purine ligand.

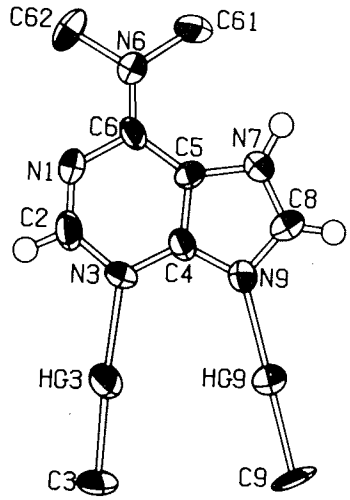

FIG. 1. ORTEP drawing of the complex cation in [$(CH_3Hg)_2$(HDMAd)]$(NO_3)_2.H_2O$. Ellipsoids correspond to 50% probability. The hydrogens are shown as spheres of arbitrary size. The same numbering scheme is used for [$(CH_3Hg)_2$(DMAd)]ClO_4, whose ORTEP drawing is given in the supplementary material.

Interatomic distances and bond angles are listed in Table 2. The four Hg—N and Hg—C distances, averaging 2.11 and 2.06 Å (σ = 0.02 Å), respectively, do not significantly differ from those reported for similar systems (2, 3). These two primary bonds define a roughly linear coordination about mercury: departure from the ideal 180° angle (≤3.7(8)°) is significant, but common for such compounds. The Hg...Hg separation is 3.315(1) Å for [$(CH_3Hg)_2$(DMAd)]$^+$ and 3.253(1) Å for [$(CH_3Hg)_2$(HDMAd)]$^{2+}$. This is higher than the sum of the van der Waals radii (3.0 Å) (12) and Hg...Hg contacts as short as 3.06 Å have been observed in cytosine complexes (7, 13). Positioning two CH_3Hg^+ groups side-by-side did not introduce severe constraints in normal coordination geometry, since the two Hg—N—C angles show no dramatic differences for any of the coordination sites. The greatest difference occurs for the N(9)-bound metal in [$(CH_3Hg)_2$(HDMAd)]$^{2+}$, where the C—N(9)—Hg(9) angles (123.5(11) and 132.7(13)°) indicate that binding is achieved in a direction only 5° off the normal lone pair orientation.

The bond lengths in the ligands are listed in Table 2. The large standard deviations in these heavy-atom structures mask any significant changes in distances that might result from complexation. For the [$(CH_3Hg)_2$(HDMAd)]$^{2+}$ ion, the C(5)—N(7)—C(8) and C(4)—C(5)—N(7) angles are respectively 4° greater and 7° smaller than those of a neutral adenine ring (14) and of the [$(CH_3Hg)_2$(DMAd)]$^+$ cation (Table 2). Taylor and Kennard (15) have shown for a broad sample of purines that protonation on a ring nitrogen produces on the internal C—N—C angle an increase of 4–6°, balanced by opposite changes on one or both adjacent N—C—C angles to keep the ring planar. The observed variations follow the pattern expected for N(7)-protonation, which has also been found for the

[2]The supplementary material includes lists of observed and calculated structure factor amplitudes, anisotropic temperature factors, fixed hydrogen coordinates, distances and angles in the anions, and details on the geometry of intermolecular interactions and on least-squares planes calculations for both structures. Complete set of data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

adeninate ligand in the N(3)/N(9)-coordinated N(7)-protonated $Cu_2(adeninate)_4(ClO_4)_4.4H_2O$ compound (16). These angles, together with hydrogen-bonding (see packing pattern below), provide unambiguous proof for the presence of an acidic proton at N(7).

The purine system can be described as two planar units rings bent by 2° about the C(4)—C(5) bond. Maximum deviation of any ring atom from its own plane is 2σ (0.04 Å). Packing forces produce greater distortion in the substituents mainly for the CH_3Hg^+ groups. The NO_3^- ion is trigonal planar and the ClO_4^- ions is tetrahedral as expected. The mean distances are 1.23 Å (σ = 0.03 Å) for N—O and 1.37 Å (σ = 0.04 Å) for Cl—O. More details are given in the supplementary material.

The unit cell of $[(CH_3Hg)_2(DMAd)]ClO_4$ is shown in Fig. 2. Pairs of complex cations and ClO_4^- ions are clustered about crystallographic inversion centres and held together by eight Hg...O contacts. The six Hg(9)...O contacts are shorter than 3.07 Å (Table 3). Each Hg(3) atom participates in rather long 3.11(2) Å interactions with O(3). There are no particular contacts involving N(1) or N(7).

The packing pattern for $[(CH_3Hg)_2(HDMAd)](NO_3)_2.H_2O$ is shown in Fig. 3. The structure is stabilized by various Hg(9)–nitrate contacts (Table 3). Water molecule O(30), tightly held by Hg(3) at 2.74(1) Å, forms hydrogen bonds with two nitrate ions. O(11) is suitably oriented to be hydrogen-bonded with N(7)—H. The N(7)...O(11) distance of 2.77(2) Å

is much shorter than the sum of the van der Waals radii (3.05 Å) (12) and consistent only with strong hydrogen-bonding, thereby confirming that N(7) is protonated.

Nuclear magnetic resonance spectroscopy

The ^1H and ^{13}C nmr data for the two ligands and their three types of complexes are given in Tables 4 and 5, respectively. Our results for the free ligands are similar to those already reported (17–19).

Substitution of H(9) to yield the neutral $[(CH_3Hg)L]$ compounds induces upfield shifts of 0.28 ppm for H8 and 0.10 ppm for H2. In the ^{13}C spectrum, large downfield shifts are observed for C4 (5.7 ppm) and C8 (7.8 ppm). These displacements are similar to those observed upon formation of the corresponding adenine complex (1) and indicate that the neutral complex is N(9)-bonded here as well. The dialkylamino resonances are not appreciably affected in this case, but introducing a second CH_3Hg^+ group onto the ring generates a cationic species and induces downfield shifts of 0.1 ppm for the ^1H signals of the methyl protons in the dimethylamino compound and for the methylene protons in the other ligand. This second CH_3Hg^+ group shifts the H2 resonance by +0.31 ppm and the H8 resonance by +0.17 ppm from their respective positions for $[(CH_3Hg)L]$. This is consistent with coordination to N(3) for this second metal atom. In the ^{13}C spectra, the signal of the C(4) atom, adjacent to N(3), is shifted 5.8 ppm upfield, but the C(2) resonance does not move.

The $[(CH_3Hg)_2(HL)]^{2+}$ cations can be regarded as resulting from the protonation of $[(CH_3Hg)_2L]^+$. This proton does not greatly affect the dialkylamino resonances, but produces downfield shifts of 0.30 ppm for H8 and 0.10 ppm for H2. The ^{13}C signals appreciably displaced by protonation are those of the carbons adjacent to N(7), namely C(5) ($\Delta\delta \sim 2.5$ ppm) and C(8) ($\Delta\delta \sim 2$ ppm) (Table 5). This provides support for the presence of the acidic proton at the N(7) site as observed in the crystal structure. This proton does not produce independent ^1H signals, but broad peaks are found at ~6.7 ppm for the N(7)—H proton in exchange with those of the small amount of water present in the solvent.

The spectra of the complexes also contain a high-field signal for the mercury-bound methyl protons. Only one signal is observed for the 2:1 complexes, because these groups are in fast exchange. The ^1H signals undergo small downfield shifts as the number of CH_3Hg^+ groups increases, but they are not very informative. The ^2J coupling constants between the methyl

protons and ^{199}Hg are more interesting, as they provide information on the nucleophilic character of the coordination site. Rabenstein (11) has noted that the $^2J(^1H—^{199}Hg)$ coupling constants and the formation constants K for a series of [(CH_3Hg)L] complexes obey the approximate equation $^2J = 249 - 5.09 \log K$. It happens that the [(CH_3Hg)L] formation constants and the protonation constants of the same ligands are not numerically very different for oxygen and nitrogen ligands, so that a similar relationship is loosely applicable to pK_a. This relationship is found to be surprisingly well followed in the present case. The neutral compound shows a ^2J value of 200 Hz, the same as the adenine analogue (1). When this ^2J value is placed into the above equation, a value of 9.2 is predicted for the pK_a of the site occupied by mercury. The pK_a of the imidazole proton of 6-dimethylaminopurine is 10.5 (20, 21). For the $[(CH_3Hg)_2L]^+$ cations, an average coupling constant of 217 Hz is obtained for the two CH_3Hg^+ groups. It corresponds to an average pK_a of 6.3. If the value of 9.2 is assumed for one of the CH_3Hg^+ groups, this would lead to a pK_a 3.4 for the other site. This is about 1 pK_a unit less basic than found for the formation of the H_2L^+ cations, which are however known to be protonated at the N(1) site (4). It is reasonable that N(3) be less nucleophilic than N(1).

For the protonated $[(CH_3Hg)_2(HL)]^{2+}$ ions, the coupling constant of 232 Hz corresponds to an average pK_a of 3.3 for the N(3) and N(9) sites of an N(7)-protonated molecule. This corresponds to a decrease of nucleophilicity of 3 pK_a units compared to the non-protonated form. Fast exchange of the

CH_3Hg^+ groups leading to averaged ^2J constants does not allow to determine whether this change of basicity is equally shared by the two coordination sites.

Conclusion

The reaction occurring in the first place between the CH_3Hg^+ ion and adenine is a substitution of the N(9)—H proton. The present work shows that alkylation of the 6-amino group does not affect this behavior. However, the second coordination takes place only at N(3) with the dialkylated derivatives, whereas for adenine, the N(9)/N(7) species is present in the solid state and represents the major tautomer in solution. Displacement of the reaction to the N(9)/N(3) region must be ascribed to the steric effect of the alkyl groups: not enough room is left for a CH_3Hg^+ ion to bind in a normal way to the N(7) lone pair, but the smaller H^+ ion can fit in this region without drastic steric hindrance.

Cerium(IV)-induced nitration of cinnamic acids. Novel remote electrophilic substitution

JOHN R. PETERSON,[1] HOANG D. DO, AND ANDREW J. DUNHAM
The Michael Faraday Laboratories, Department of Chemistry, Northern Illinois University, DeKalb, IL 60115, U.S.A.

Received July 24, 1987[2]

JOHN R. PETERSON, HOANG D. DO, and ANDREW J. DUNHAM. Can. J. Chem. **66**, 1670 (1988).

The treatment of (*E*)-3,4-dimethoxycinnamic acid with ceric ammonium nitrate in trifluoroacetic acid afforded (*E*)-1,2-dimethoxy-4-nitro-5-(2-nitroethenyl)benzene in 79% yield. The unusual ipso substitution of the carboxylic acid moiety by a nitro functional center illustrated a new reaction manifold of cerium(IV). Six cinnamic acids were examined to ascertain the generality of the transformation. The bidentate nitrato structure of the metal salt is believed to account for the nitrating ability of this system.

JOHN R. PETERSON, HOANG D. DO et ANDREW J. DUNHAM. Can. J. Chem. **66**, 1670 (1988).

La réaction de l'acide diméthoxy-3,4 cinnamique-(*E*) avec le nitrate d'ammonium cérique dans l'acide trifluoroacétique conduit au diméthoxy-1,2 nitro-4 (nitro-2 éthènyl)-4 benzène-(*E*), avec un rendement de 79%. La réaction ipso inhabituelle qui conduit à un remplacement de la portion acide carboxylique par un groupement nitro est une illustration d'un nouvel aspect des réactions variées du cérium(IV). Dans le but d'évaluer la généralité de cette réaction, on l'a appliqué à six acides cinnamiques. On croit que la structure bidentate du nitrato peut expliquer les qualités nitratantes de ce système.

[Traduit par la revue]

Introduction

The nitration of aromatic compounds has been an area of extensive investigation, and the nitronium ion (NO_2^+) has been well established as an electrophile for this reaction (1). Standard procedures for NO_2^+ generation have employed nitric acid directly or have produced nitric acid *in situ* by means of nitrate salts in protic media (2). Although transition metal salts could provide a synthetically attractive alternative to conventional procedures for benzenoid compound nitration, only a few reports describing the use of these reagents have appeared in the literature. Palladium(II) (3), zirconium(IV) (4), iron(III) (4), titanium(IV) (5), and most recently cerium(IV) nitrate (6) have effected nitration of aromatic compounds. The nature of the electrophilic agent in a metal induced nitration would be of interest, as the intermediacy of NO_2^+ would not be mandated. In conjunction with studies focused at the projected synthesis of podophyllotoxin, the reaction of methoxy substituted cinnamic acids with ceric ammonium nitrate (CAN) was investigated. We report herein the results obtained with this metal system, which led not only to nitration of the aromatic nucleus, but to novel ipso substitution of the carboxylic acid group by a nitro functional center as well.

Results and discussion

Attention will be first directed to the reaction of (*E*)-3,4-dimethoxycinnamic acid (**1**) with CAN, eq. [1]. This reaction,

[1] 
as well as the other discussed below, was conducted by magnetically stirring a mixture of CAN and the cinnamic acid in trifluoroacetic acid (TFA) for 1 h at 23°C. Product isolation was accomplished by medium pressure liquid chromatography (mplc) after esterification of the acidic product fraction. (*E*)-1,2-Dimethoxy-4-nitro-5-(2-nitroethenyl)benzene (**2**) and the methyl ester of (*E*)-4,5-dimethoxy-2-nitrocinnamic acid (**3**) were thereby obtained from **1** in 79 and 4% yields, respectively. The infrared spectrum of **2** was characterized by strong absorptions at 1570 and 1321 cm^{-1} for the nitro groups and a lack of absorption in the carbonyl region.

The formation of **2** provided incentive for further exploration of this novel remote and nuclear electrophilic substitution reaction. Dinitrostyrenes are synthetically versatile compounds, having been transformed into cinnolines (7), indoles (8), benzodiazepines (9), and amino substituted mescaline congeners (10). In addition, various analogues of **2** have been reported to exhibit fungicidal activity (11). A standard route to the dinitrostyrenes has been the condensation of nitromethane with nitrobenzaldehydes, with the latter prepared by an aromatic nitration reaction (7, 8). The procedure described in this paper provides a unique entry into this class of compounds, as both nitro groups are introduced into the molecule simultaneously.

Our results with other cinnamic acids are shown in Table 1. Nitrobenzaldehydes and nitrobenzoic acids were sometimes obtained in addition to the dinitrostyrene and nitrocinnamic acid (entries 2–4). The side-chain double-bond cleavage products were formed in the course of the reaction, rather than during the work-up or isolation steps, and could not be avoided. The regioselectivity of nuclear ring nitration could be rationalized for all of the products from the well-known *ortho,para*-directing effects of a methoxy substituent (12). Remote ipso substitution of a carboxylic acid moiety by a nitro group occurred when an electron-donating substituent was present at the 2- or 4-position of the aromatic ring with regard to the propenoic acid side chain (entries 1–4). Even (*E*)-3-methoxycinnamic acid (**18**) afforded a dinitrostyrene (**19**), albeit in low yield. In this case, electron donation by the methoxy group to the position α to the carboxylic acid was not possible through conjugation, and the major product isolated was (*E*)-3-methoxy-4-nitrocinnamic acid (**20**). Our efforts to achieve a material balance in the latter reaction were unsuccessful. Cinnamic acid (**21**) presented a limit to the nitrating ability of

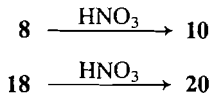
TABLE 1. Cerium(IV)-induced nitration of cinnamic acids[a]

Entry	Cinnamic acid	Products (% yield)			
1	**1**	**2** (79)	**3** (4)		
2	 **4**	 **5** (18)	 **6** (44)	 **7** (20)	
3	 **8**	 **9** (39)	 **10** (20)	 **11** (29)	 **12** (4)
4	 **13**	 **14** (4)	 **15** (20)	 **16** (8)	 **17** (68)
5	 **18**	 **19** (3)	 **20** (35)		
6	 **21**	No reaction; 100% recovery			

[a]All experiments employed a trifluoroacetic acid solution of the cinnamic acid (0.33 M) and ceric ammonium nitrate (0.42 M). The reactions were stirred for 1 h at 23°C.



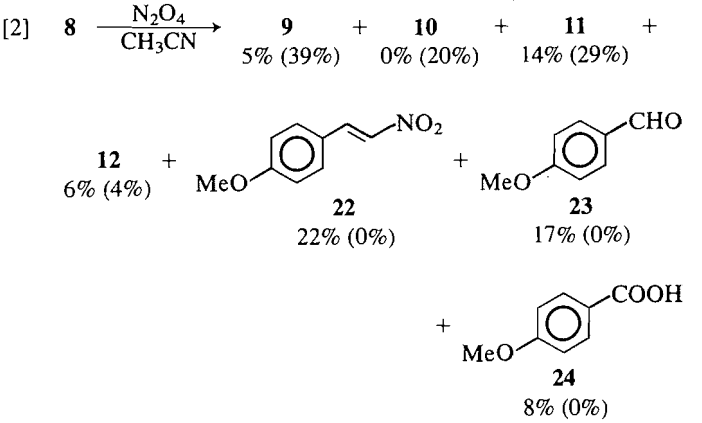
SCHEME 1

the CAN system with quantitative recovery of starting material realized. The electron-withdrawing character of the propenoic acid side chain in **21** even circumvented aromatic ring nitration.

Four experimental facts must be accounted for when the mechanism of remote ipso substitution of a carboxylic acid group by a nitro substituent is considered. First, Luff (13), Chakravarti *et al.* (14), and Rubenstein (15) have examined the reaction of nitric acid with methoxy substituted cinnamic acids, Scheme 1. The failure of NO_2^+ to produce a dinitrostyrene in their studies would only be consistent with the presence of a different nitrating species in the CAN system. Second, the CAN reaction was found to be very electrophilic in character; the reaction viability depended upon the presence of *ortho,para*-directing and ring-activating substituents on the cinnamic acid. Next, products that would be anticipated from solvolysis or nucleophilic capture of a carbocationic intermediate were not found in the CAN nitrations. Finally, the yield of dinitrostyrene was not improved when greater than 1.25 mole equivalents of CAN were employed in the reaction.

Sodium nitrate/TFA mixtures have found synthetic utility for the nitration of aromatic compounds (2). We have established that CAN was not serving simply as another nitrate anion source in the remote ipso substitution reaction. The key significance of the Ce(IV) ion in this system was demonstrated by the substitution of acetonitrile for TFA as the reaction medium. No reaction was observed when a cinnamic acid was subjected to powdered ammonium nitrate in acetonitrile; however, the inclusion of CAN in the reaction quickly afforded a nitrostyrene.

Aromatic compound nitration by nitrogen dioxide (NO_2) has been well documented (16). Two sets of experiments have demonstrated that NO_2 was not the electrophilic agent responsible for the chemistry reported in Table 1, even though NO_2 was occasionally liberated during the CAN nitrations. Very different results from those reported in Table 1 were obtained when the cinnamic acids were treated with dinitrogen tetroxide.[3] The reaction of **8** with dinitrogen tetroxide yielded not only **9**, **11**, and **12**, but in addition a similar product series, **22–24**, lacking a nitro substituent on the aromatic ring, eq. [2].



[3]The oxides of NO_2 and N_2O_4 exist in equilibrium (see ref. 17).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/07/12
For personal use only.

The latter were not observed when the TFA/CAN system was employed (product % yields for this system in parentheses). The absence of **10** in the product mixture of the dinitrogen tetroxide experiment and the large product composition variations between the two systems led to the conclusion that NO_2 was not the electrophilic species of the CAN/TFA system. Further evidence for this conclusion was obtained when the behavior of **21** with CAN in TFA and with dinitrogen tetroxide in acetonitrile was compared, eq. [3]. In CAN/TFA system, the

[3] **21** $\xrightarrow[CH_3CN]{N_2O_4}$ 
25

usual dark color of the reaction failed to develop even after 4 h at 23°C, and neither the evolution of NO_2 nor any exothermicity was observed over the course of the experiment. In contrast, the subjection of **21** to dinitrogen tetroxide in acetonitrile resulted in a vigorous reaction, raising the temperature to the boiling point of acetonitrile. 4-Nitrobenzoic acid (**25**) was isolated in 7% yield after esterification of the acidic fraction. Although unreacted **21** was not present in the product mixture, we were unsuccessful in isolating any other products in reasonably pure form.

Our proposed mechanism for a remote ipso substitution reaction utilizing **8** as the substrate and a simplified structure for CAN is shown in Scheme 2. Cerium(IV) nitrate serves as the electrophile for this transformation, obviating NO_2^+ or NO_2 generation. We suggest that the bidentate nitrato structure of this metal salt is fundamental to its nitrating ability (18). The nitrating capacity of isostructural metal nitrates has been noted by Addison and others (4, 5). The first step of the mechanism would be facilitated by methoxy substitution on the aromatic nucleus. In this regard, the failure of **21** to provide a nitrostyrene in the presence of CAN suggested that the first step of the mechanism could be rate determining. An electronic reorganization of zwitterion **26** would afford a Ce(IV) alkoxide and carbocation **27**. Decarboxylation of the latter would then deliver nitrostyrene **22**.

An alternative mechanism in which an aromatic radical cation would be formed by Ce(IV) oxidation of the cinnamic acid appears less likely to us.[4] Such a process would require the radical cation to selectively capture NO_2 or NO_2^- for dinitrostyrene formation. Our strongest evidence against an oxidative mechanism comes from an examination of the product composition for reactions in which a high material balance was achieved (Table 1, entries 3 and 4). The oxidation of certain aromatic substrates with CAN has been shown to yield side-chain and nuclear substitution products that arose by nucleophilic capture (benzyl nitrates) or solvolysis (benzyl and aryl acetates) of a carbocationic intermediate (19). Kochi *et al.* have likewise reported the formation of trifluoroacetoxylated products from aromatic substrates when the oxidation reaction was conducted in TFA (20). The absence of nitrate and trifluoroacetic containing products in our reaction mixtures makes an oxidative mechanism seem unreasonable. Dinctürk and Ridd previously put forth similar arguments against the generation of an aromatic radical cation in their nitrations of aromatic compounds with CAN (6*c*). As an additional point, the stoichiometry associated with remote ipso substitution of a nitro group for a carboxylic acid by an oxidative mechanism would require two cerium(IV) ions per aromatic molecule (6*b*). Our observation of optimal dinitrostyrene formation with 1.25 equivalents of CAN per equivalent of aromatic substrate would be consistent with the mechanism proposed in Scheme 2, but not with an oxidative process.[5]

Aromatic ring nitration with CAN in acetonitrile is likely to proceed by a mechanism similar to that shown in Scheme 2 (6). In the present studies, however, we are unable to ascribe a particular mechanism to the formation of the ring nitrated products. Nuclear ring nitration in TFA could have resulted either from electrophilic attack by CAN or NO_2^+.

In conclusion, the reaction of methoxy substituted cinnamic acids with CAN afforded dinitrostyrenes. A mechanism for the remote ipso substitution of a carboxylic acid group by a nitro substituent was presented where CAN served as the electrophilic agent. The bidentate nitrato structure of CAN is felt to be responsible for the nitrating ability of this system.

Experimental

Melting points were determined with a Mel-Temp apparatus and are uncorrected. Infrared spectra were recorded on a Sargent Welch 3-200 spectrophotometer employing either a thin film or KBr pellet technique. The nmr spectra were accumulated on an IBM WP-200 instrument at 200 MHz for proton and at 50 MHz for carbon. Chemical shifts were reported as parts per million downfield relative to tetramethylsilane in chloroform-*d*. Products were isolated by medium-pressure liquid chromatography (FMI pump, silica gel column, and a Gilson model 131 refractive index detector) utilizing ethyl acetate/hexane mixtures as eluents.

CAN, TFA, and **21** were obtained from Aldrich Chemical Co. and used without further purification. Cinnamic acids **1**, **4**, **8**, **13**, and **18** were prepared by the literature method (21). References after a compound name refer to literature physical data that matched the present values.

General procedure for cinnamic acid nitration by CAN in TFA

A 50-mL, round-bottomed flask equipped with a nitrogen inlet was charged with a cinnamic acid (1.68 mmol), TFA (6 mL), and CAN (1.16 g, 2.11 mmol). The reaction was magnetically stirred for 1 h at 23°C before diluting the dark brown mixture with water (25 mL). The aqueous mixture was extracted with chloroform (3 × 25 mL), and the combined extracts washed with saturated sodium bicarbonate solution (2 × 25 mL), dried (magnesium sulfate), and concentrated. Chromatography afforded the dinitrostyrenes and nitrobenzaldehydes.

Acidification (37% hydrochloric acid) of the sodium bicarbonate washes to approximately pH 1 and extraction with chloroform (3 × 20 mL) provided the acidic coproducts after solvent removal. Esterification was effected by refluxing a methanol (25 mL) solution of the carboxylic acids in the presence of 98% sulfuric acid (0.5 mL) for 3 h. The reaction mixture was cooled, diluted with water (30 mL), and extracted with chloroform (3 × 20 mL). The combined organic extracts were washed with saturated sodium bicarbonate solution (20 mL), dried (magnesium sulfate), concentrated, and chromatographed to deliver the methyl cinnamates and benzoates.

*2,4-Dimethoxy-5-nitrobenzaldehyde (**6**) (24)*

Yield: 44%; mp 182–185°C (not recrystallized) (lit. mp 188–189°C); ir: 3140, 1680, 1615, 1400, 1310, 1295, 1220, 1075, 1010, 925, 880, 840 cm^{-1}; ^{1}H nmr δ: 10.28 (s, 1H), 8.50 (s, 1H), 6.54 (s, 1H), 4.07 (s, 3H), 4.05 (s, 3H).

*Methyl 2,4-dimethoxy-5-nitrobenzoate (**7**-Me ester) (25)*

Yield: 20%; mp 145–147°C (lit. mp 147°C); ir: 3140, 2925, 2855, 1700, 1620, 1570, 1560, 1530, 1440, 1400, 1350, 1290, 1280, 1220, 1015, 825 cm^{-1}; ^{1}H nmr δ: 8.63 (s, 1H), 6.54 (s, 1H), 4.05 (s, 3H), 4.02 (s, 3H), 3.89 (s, 3H).

*(E)-1-Methoxy-2-nitro-4-(2-nitroethenyl)benzene (**9**) (26)*

Yield: 39%; mp 163–165°C (lit. mp 166°C); ir: 3109, 2920, 2847, 1688, 1611, 1534, 1454, 1437, 1348, 1279, 1184, 1088, 1009, 972, 822, 760, 675 cm^{-1}; ^{1}H nmr δ: 8.06 (d, 1H, J = 2.22 Hz), 7.96 (d, 1H, J = 13.68 Hz), 7.74 (dd, 1H, J = 8.79, 2.22 Hz), 7.55 (d, 1H, J = 13.68 Hz), 7.18 (d, 1H, J = 8.79 Hz), 4.04 (s, 3H); ^{13}C nmr δ: 160.32, 137.42, 136.16, 134.35, 126.06, 122.66, 116.11, 114.48, 56.96.

*Methyl (E)-3-(4-methoxy-3-nitrophenyl)propenoate (**10**-Me ester) (27)*

Yield: 20%; mp 128–130°C (lit. mp 130.0–130.5°C); ir: 2950, 1717, 1616, 1533, 1439, 1344, 1273, 1177, 1088, 1013, 822, 760, 673 cm^{-1}; ^{1}H nmr δ: 8.01 (d, 1H, J = 2.25 Hz), 7.83 (dd, 1H, J = 8.76, 2.25 Hz), 7.62 (d, 1H, J = 16.26 Hz), 7.12 (d, 1H, J = 8.76 Hz), 6.40 (d, 1H, J = 16.26 Hz), 4.00 (s, 3H), 3.82 (s, 3H).

*4-Methoxy-3-nitrobenzaldehyde (**11**) (28)*

Yield: 29%; mp 81–83°C (lit. 82–84°C); ir: 3117, 3069, 2997, 2922, 2853, 1690, 1611, 1528, 1446, 1354, 1279, 1206, 1159, 1080, 1007, 930, 820, 764, 719, 690, 598 cm^{-1}; ^{1}H nmr δ: 9.95 (s, 1H), 8.36 (d, 1H, J = 2.04 Hz), 8.10 (dd, 1H, J = 8.76, 2.04 Hz), 7.24 (d, 1H, J = 8.76 Hz), 4.08 (s, 3H).

*Methyl 4-methoxy-3-nitrobenzoate (**12**-Me ester) (29)*

Yield: 4%; mp 106–108°C (lit. mp 107.5–108.5°C); ir: 2920, 1715, 1616, 1526, 1435, 1341, 1277, 1186, 1011, 816, 754, 675 cm^{-1}; ^{1}H nmr δ: 8.55 (d, 1H, J = 2.20 Hz), 8.20 (dd, 1H, J = 8.76, 2.20 Hz), 7.16 (d, 1H, J = 8.76 Hz), 4.15 (s, 3H), 3.90 (s, 3H).

*(E)-2-Methoxy-1-nitro-3-(2-nitroethenyl)benzene (**14**) (11)*

Yield: 14%; mp 152–154°C (lit. mp 154°C) ir: 2920, 1692, 1636, 1603, 1528, 1424, 1346, 1277, 1250, 1088, 988, 847, 814, 754 cm^{-1}; ^{1}H nmr δ: 8.19 (d, 1H, J = 13.89 Hz), 7.95 (dd, 1H, J = 8.12, 1.60 Hz), 7.75 (d, 1H, J = 13.89 Hz), 7.74 (dd, 1H, J = 8.73, 1.60 Hz), 7.33 (t, 1H, J = 7.97 Hz), 3.99 (s, 3H); ^{13}C nmr δ: 157.62, 140.13, 133.82, 132.09, 128.82, 124.52, 123.80, 106.99, 63.52.

*(E)-1-Methoxy-4-nitro-2-(2-nitroethenyl)benzene (**15**) (30)*

Yield: 20%; mp 172–174°C (lit. mp 174–176°C); ir: 1600, 1570, 1480, 1325, 1275, 1190, 1140, 1095, 1000, 985, 960, 830, 780, 740, 620 cm^{-1}; ^{1}H nmr δ: 8.39 (br s, 1H), 8.36 (dd, 1H, J = 8.88, 2.84 Hz), 8.14 (d, 1H, J = 13.75 Hz), 7.87 (d, 1H, J = 13.75 Hz), 7.10 (d, 1H, J = 8.88 Hz), 4.10 (s, 3H); ^{13}C nmr δ: 163.33, 140.21, 132.64, 128.30, 127.12, 120.00, 111.57, 56.84.

*2-Methoxy-5-nitrobenzaldehyde (**16**) (31)*

Yield: 8%; mp 88–89°C (lit. mp 89–90°C); ir: 3075, 2922, 1686, 1609, 1586, 1522, 1487, 1429, 1398, 1341, 1275, 1176, 1074, 1015, 943, 916, 829, 750, 633 cm^{-1}; ^{1}H nmr δ: 10.46 (s, 1H), 8.71 (d, 1H, J = 2.91 Hz), 8.44 (dd, 1H, J = 9.19, 2.91 Hz), 7.12 (d, 1H, J = 9.19 Hz), 4.08 (s, 3H).

*Methyl (E)-3-(2-methoxy-5-nitrophenyl)propenoate (**17**-Me ester) (32)*

Yield: 68%; mp 159–161°C (lit. mp 163°C); ir: 1700, 1570, 1480, 1435, 1300, 1250, 1170, 1080, 1005, 915, 865, 820, 740 cm^{-1}; ^{1}H nmr δ: 8.41 (d, 1H, J = 2.75 Hz), 8.25 (dd, 1H, J = 9.18, 2.75 Hz), 7.95 (d, 1H, J = 16.21 Hz), 6.95 (d, 1H, J = 9.18 Hz), 6.61 (d, 1H, J = 16.21 Hz), 4.02 (s, 3H), 3.83 (s, 3H).

*(E)-2-Methoxy-1-nitro-4-(2-nitroethenyl)benzene (**19**)*[6]

Yield: 3%; mp 234–235°C; ir: 1591, 1549, 1485, 1443, 1341, 1273, 1123, 1042, 1018, 932, 883, 798, 777, 692 cm^{-1}; ^{1}H nmr δ: 8.60 (d, 1H, J = 13.27 Hz), 8.27 (d, 1H, J = 8.95 Hz), 7.83 (d, 1H, J = 2.62 Hz), 7.54 (dd, 1H, J = 8.95, 2.62 Hz), 7.35 (d, 1H, J = 13.27 Hz), 3.91 (s, 3H). *Anal.* calcd. for $C_9H_8N_2O_5$: C 48.22, H 3.60, N 12.50; found: C 48.54, H 3.75, N 12.47.

[6]Dinitrostyrene **19** was identified by spectral analysis and comparison of its melting point with that of the known other possible isomers, (*E*)-1-methoxy-2-nitro-3-(2-nitroethenyl)benzene (lit. (33) mp 155–157°C) and (*E*)-4-methoxy-1-nitro-2-(2-nitroethenyl)benzene (lit. (11) mp 103°C).

*(E)-Methyl 3-(3-methoxy-4-nitrophenyl)propenoate (**20**-Me ester) (13, 14)*

Yield: 35%; ir: 1711, 1587, 1506, 1435, 1337, 1271, 1233, 1084, 1036, 966, 847 cm^{-1}; ^1H nmr δ: 8.21 (d, 1H, J = 15.82 Hz), 8.14 (d, 1H, J = 10.01 Hz), 7.04–6.93 (m, 2H), 6.29 (d, 1H, J = 15.82 Hz), 3.92 (s, 3H), 3.83 (s, 3H). The product was further characterized by melting point of the acid (**20**), mp 218°C (lit. mp 218°C).

Nitration with dinitrogen tetroxide in acetonitrile

Dinitrogen tetroxide (2 mL) was added to a solution of **8** or **21** (5 mmol) in acetonitrile (30 mL). The reaction, which immediately evolved heat and became dark brown, was stirred for 1 h before work-up as described in the general synthetic procedure. Product isolation by mplc afforded **9** (5%), **11** (14%), **12** (6%), **22** (22%), **23** (17%), and **24** (8%) from the reaction of **8**. Similarly, **25** (7%) was obtained from the reaction of **21** with dinitrogen tetroxide.

The transformation of levopimaric acid into warburganal

WILLIAM A. AYER AND FRANCISCO X. TALAMAS
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received January 8, 1988

WILLIAM A. AYER and FRANCISCO X. TALAMAS. Can. J. Chem. **66**, 1675 (1988).

The chiral resin acid levopimaric acid (**1**), isolated from pine oleoresin, is used as a starting material for the synthesis of (−)-warburganal (**2**). The synthesis proceeds via the endoperoxide of methyl levopimarate, which after ozonolysis, protection of the resulting aldehyde function, reduction, and treatment with sodium methoxide provides the tetranorditerpenoid **12***a*. The hemiacetal **12***a* is then transformed to a mixture of hemithioacetals. At this point the carbomethoxyl group at C-4 is reduced to a methyl group, and then a C-11, C-12 double bond is introduced. Ozonolysis followed by elimination of formic acid provides a mixture of olefins (**27**) that is hydroxylated at C-9. Removal of the protecting group then gives (−)-warburganal (**2**). The sequence requires 15 steps and the overall yield from levopimaric acid to warburganal is 2.7%.

WILLIAM A. AYER et FRANCISCO X. TALAMAS. Can. J. Chem. **66**, 1675 (1988).

L'acide lévopimarique (**1**), la résine chirale extraite de l'oléorésine du pin, est utilisé comme produit de départ pour la synthèse du (−)-warburganal (**2**). La synthèse implique la formation de l'endoperoxyde du lévopimarate de méthyle et son ozonolyse, la protection de l'aldéhyde qui en résulte, une réduction et un traitement par le méthylate de sodium qui fournit le tétranorditerpénoïde **12***a*. Cet hémiacétal **12***a* est ensuite transformé en un mélange d'hémithioacétals. À ce point, le groupement carbométhoxyle en C-4 est réduit en groupement méthyle et la double liaison en C-11, C-12 est alors introduite. Une ozonolyse, suivie d'une élimination d'acide formique, fournit un mélange des oléfines **27** qui est hydrolyse en C-9. L'élimination du groupement protecteur fournit alors le (−)-warburganal (**2**). La série de réactions implique 15 étapes et le rendement global de l'acide lévopimarique au warburganal est de 2,7%.

[Traduit par la revue]

The exudate of pine trees, called oleoresin, is rich in the so-called resin acids, one of the major acids being levopimaric acid (**1**). The isolation of levopimaric acid from the inexpensive oleoresin is straightforward (1) and thus **1** is an attractive chiral starting material for organic synthesis. In this report we describe the transformation of levopimaric acid into (−)-warburganal (**2**), a drimane class sesquiterpene that acts as an antifeedant towards both the African army worm (2) and certain fish (3). Warburganal, which has a hot taste to the human tongue (3, 4), also shows strong molluscicidial activity (5). The transformation of the resin acid abietic acid (**3**) to (−)-warburganal has been described previously (6), as have several total synthesis of (±)-warburganal (ref. 7 and references therein).

The first stage in the transformation was the removal of the five extra carbon atoms (C-12, C-13, and the isopropyl group) contained in the diterpene framework of levopimaric acid (**1**). Methyl levopimarate (**1***a*), prepared by treating **1** with diazomethane, was photooxygenated to give the known (8) crystalline endoperoxide **4** in 76% yield. The appearance of a high field methyl signal (δ 0.57) in the ^{1}H nmr spectrum of **4** is consistent with the α-orientation of the peroxide, since now the methyl group at C-10 is shielded by the C-13, C-14 double bond (9). Ozonolysis of **4**, followed by reductive work-up ($(CH_3)_2S$), provided the oily ketoaldehyde **5**, which was transformed to the crystalline dimethyl acetal **6** by treatment with trimethyl orthoformate in the presence of acid. The electron impact mass spectrum (eims) of **6** does not show a molecular ion, but the chemical ionization mass spectrum (cims) shows a prominent $(M + NH_4)^+$ peak and the ^{1}H nmr spectrum shows three methoxyl peaks and an acetal methine singlet δ 4.64.

Endoperoxides may be cleaved to γ-hydroxyketones by treatment with base (10). Since the hydrogen at C-12 is activated by the adjacent carbonyl group, compound **6** was smoothly transformed to oily yellow α-diketone **7** by treatment with triethylamine. The ir spectrum of **7** shows hydroxyl (3456 cm^{-1}) and carbonyl (1725 cm^{-1}) absorption. The ^{1}H nmr spectrum (most signals are doubled) indicates that **7** exists as a tautomeric mixture of the diketone (yellow color) and cyclic hemiacetal(s). Treatment of **7** with trimethyl orthoformate under acid catalysis gave the crystalline cyclic acetal **8**. The ^{1}H nmr spectrum of **8** shows an apparent quintet at δ 3.34 for the isopropyl methine (assignment confirmed by decoupling the methyl doublets at δ 1.09 and 1.14). The chemical shift of the methine proton is appropriate for a hydrogen α to a ketone rather than α to an acetal, indicating the formation of the five-membered cyclic acetal. Treatment of **8** with sodium methoxide in methanol-d_1 caused exchange of the methine hydrogen. The deuterated compound does not show the δ 3.34 signal in the ^{1}H nmr spectrum and shows the isopropyl methyls as singlets at δ 1.12 and 1.08, confirming structure **8**. Attempts to introduce an 11,12-double bond by elimination of the elements of methanol from **8** were unsuccessful.

Treatment of diketone **7** with acetic anhydride – triethylamine provided a mixture of enol acetates **9** and **10** in a ratio of about 1:1 (as determined by nmr). When diisopropylethylamine was used as the base (and solvent), **9** was the major component of the enol acetate mixture (ratio ca. 12:1). The enol acetates were separated by flash chromatography over silica gel. Compound **9** displays an alkenic hydrogen (doublet, J = 11 Hz, δ 6.45) and an isopropyl methine (δ 3.06). The stereochemistry of the double bond (Z) was assigned on the basis of the low field shift (δ 6.45) of the alkenic hydrogen in the nmr (11). Enol acetate **10** does not show an alkenic hydrogen in the nmr, but does show alkenic methyls (d 2.17 and d 1.76). With compound **9** in hand, we set out to remove the unneeded five carbons from the diterpene skeleton. However, the compound was resistant to oxidative cleavage (ozone, osmium tetroxide – sodium periodate (12, 13), potassium permanganate (14), ruthenium tetraoxide (15)) of the C—C double bond. In all cases **9** was recovered from the reaction mixture. This lack of reactivity is attributed to the conjugated nature of the double bond and to its hindered nature.

10

At this point we discovered a very useful reaction, which led to the removal of four of the unwanted carbon atoms. Reduction of the ketone function in the peroxide **6** provided a mixture of C-13 epimeric alcohols **11**. Treatment of the mixture **11** with sodium methoxide in methanol at room temperature brought about the fragmentation reaction, indicated by the arrows in **11**, to furnish the C-12 aldehyde, which was isolated as a mixture consisting mainly of the epimeric hemiacetals **12**. The ir spectrum of **12** shows hydroxyl (3480 cm^{-1}) and ester (1725 cm^{-1}) absorption. The ^1H nmr spectrum shows two hemiacetal methine hydrogens (δ 5.64 and 5.43) as well as a small signal for the aldehyde tautomer (δ 9.70). Acetylation of **12** gave a separable mixture of the acetal acetates **13***a* and **13***b*. The stereochemical assignments are made on the basis of ^1H nmr measurements. In one epimer (**13***a*) the C-12 hydrogen appears as a doublet (J = 5.5 Hz) while in the other (**13***b*), this signal is an apparent triplet (J's 5.5 Hz). Inspection of molecular models suggests that these observations are best accommodated as illustrated in Fig. 1. In **13***a* the dihedral angles are ca. 30° and 90° (J's 5.5 and 0 Hz) whereas in **13***b* they are ca. 30° and 150° (J's each 5.5 Hz). The base-catalyzed cleavage of **11** to give **12** finds analogy in the known reaction of epoxides with alkaline hydrogen peroxide (16).

The carbon skeleton of **12** closely resembles that of the drimanes except for the extra carbon at C-11. We felt that this carbon could be removed by oxidation of enol ether **14**, since the carbon–carbon double bond in **14** should be much more reactive than that in the enol acetate **9**. Attempts to dehydrate hemiacetal **12** under a variety of conditions ($POCl_3$, $SOCl_2$, tosyl isocyanate) gave complex mixtures of products. Attempted mesylation of **12** gave an unexpected result. The product was a separable mixture of the epimeric methyl acetals **15** containing a free C-14 aldehyde group. A similar result was obtained when **12** was treated with iodine in refluxing toluene or with *p*-toluenesulfonic acid in benzene at room temperature. The mass spectra of **15***a* and **15***b* both show base peaks at m/z 295 corresponding to $M^+ - CHO$. The ^1H nmr spectrum of **15***a* reveals the presence of only two methoxyl groups (δ 3.64 (ester), δ 3.39 (acetal)) and of aldehydic hydrogen (δ 9.82). The methine hydrogen at C-12 appears as an apparent triplet (δ 5.24, J's 5.0 Hz). The ^1H nmr spectrum of **15***b* gives a similar spectrum except that the C-12 methine hydrogen appears as a doublet (δ 5.31, J = 5.5 Hz). In both **15***a* and **15***b*, nuclear Overhauser enhancement (nOe) experiments confirmed the proximity of the aldehyde function to the angular methyl group. The formation of **15***a* may be rationalized as depicted in Scheme 1. Formation of ion **A** is followed by a methoxyl shift to give **B**. Ion **B** is then captured by a nucleophile (chloride ion in

the case of the mesyl chloride reaction) to give an intermediate **C**, which is hydrolyzed to the aldehyde by traces of water or during work-up. The more stable cyclic acetal **15***b* is formed by acid-catalyzed epimerization of **15***a*.

At this stage we decided to protect the C-14 aldehyde function as the dioxolane derivative since we felt this would not interfere with operations at the cyclic hemiacetal center. It proved most convenient to introduce the dioxolane protecting group directly into the ozonolysis product **5**. The resulting **6***a* was then reduced with $NaBH_4$ and the resulting mixture of epimeric alcohols treated with sodium methoxide to give **12***a*. Treatment of **12***a* with methanesulfonyl chloride in the presence of triethylamine gave the mesylate **16**. The ^1H nmr spectrum shows only one methylsulfonate peak (δ 3.37) and the C-12 hydrogen appears as a doublet (δ 5.06, J = 5.8 Hz), indicating that only the α isomer is present. Attempts to form the enol ether **14***a* by treatment of **16** with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in refluxing toluene were unsuccessful.

The desired enol ether **14***a* was prepared in the following way. Treatment of hemiacetal **12***a* with thiophenol in the presence of trifluoroacetic acid (TFA) gave a mixture of the hemithioacetals **17***a* and **17***b* along with small amounts of the thioacetal **18**. The latter compound could be transformed into a mixture of **17***a* and **17***b* under acidic conditions (TFA–CH_2Cl_2). The epimeric hemithioacetals are separable by flash chromatography and are distinguished by their ^1H nmr spectra. The minor component **17***a* shows the signal for H-12 as a doublet of doublets (J's 9.0 and 6.5 Hz) at δ 5.54. Epimer **17***b* also shows this signal as a double doublet, but with smaller J values (8.0 and 1.5 Hz). In **17***a* one of the hydrogens of the dioxolane ring appears at especially low field (δ 4.31), presumably deshielded by the β substituent at C-12. The mixture of **17***a* and **17***b* was oxidized with one equivalent of *m*-chloroperbenzoic acid (*m*-CPBA) to yield the corresponding sulfoxides, which were heated in xylene in the presence of triethylphosphite (17) to give the acid-sensitive enol ether **14***a* in 65% yield from the hemithioacetals. The nmr spectra of **14***a* show olefinic hydrogens at δ 6.40 (H-12) and δ 5.17 (H-11) and olefinic carbons at δ 147.8 (C-12) and δ 101.7 (C-11), the remainder of the signals being consistent with the assigned structure.

Ozonolysis of **14***a* in dichloromethane–methanol and reductive work-up (dimethyl sulfide) gave the aldehyde **19** containing the desired drimane sesquiterpene skeleton. The ^1H nmr spectrum of **19** shows an aldehydic hydrogen as a doublet at δ 9.92 coupled (3 Hz) to another doublet at δ 2.17 (H-9).

With the desired carbon skeleton of warburganal in hand we were left with the problems of adjusting the ring B functionality and of transforming the C-4 carbomethoxyl into a methyl group. Since compound **19** would require protection of the aldehyde functionality, we decided to backtrack somewhat and use the mixture of hemithioacetals **17***a* and **17***b* as the point of introduction of the C-4 methyl group, since in these the projected ring B functionality is in a protected form. Most methods for the transformation of an ester group to a methyl group proceed through the intermediate alcohol or aldehyde. Reduction of the mixture **17** with lithium aluminum hydride gave the corresponding alcohols **20** in over 90% yield.

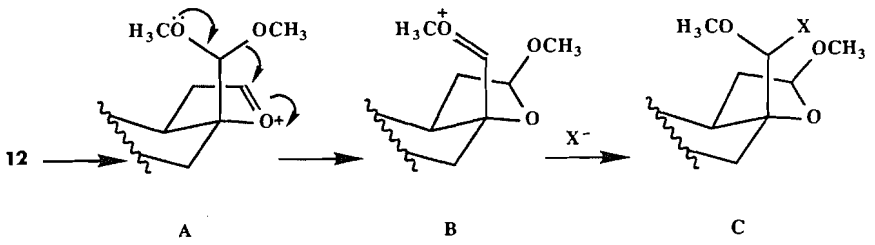

SCHEME 1

Oxidation of **20** with pyridinium chlorochromate (PCC) (18) gave the aldehydes **21**, which show aldehydic hydrogen singlets at δ 9.22 and 9.17 in the nmr. Treatment of the aldehydes under the conditions of the Huang-Minlon modification of the Wolff–Kishner reaction (19) gave a mixture of products in which alcohol **22** was the major component. The ir spectrum of **22** shows hydroxyl absorption (3565 cm^{-1}) and a characteristic (20) *gem*-dimethyl doublet (1387 and 1364 cm^{-1}). The ^1H nmr spectrum displays three quarternary methyl singlets and a methyl triplet. Presumably the thiophenol group is displaced by hydroxyl (or hydrazine) under the forcing conditions of this reaction, leading to reduction of the masked aldehyde at C-12 as well as the aldehyde at C-4. Aldehyde **21** was treated with *p*-toluenesulfonyl hydrazine (tosyl hydrazine) in refluxing ethanol to afford the tosylhydrazones **23**. Reduction of **23** with sodium borohydride gave a complex mixture of products, but treatment with bis(benzyloxy)borane followed by addition of sodium acetate (21) gave a separable mixture of the desired 4α-methyl compounds **24***a* and **24***b* in about 50% overall yield from the aldehydes **21**. The use of tetrabutylammonium acetate in place of sodium acetate (22) did not improve the yield. Similar results were obtained when catecholborane (23) was used instead of bis(benzoyloxy)borane. The ^1H nmr spectrum of **24***a* displays signals for three quaternary methyls and shows H-12 as a doublet of doublets at δ 5.56 (*J*'s 9.0 and 6.0 Hz). The ^{13}C nmr spectrum shows methyl signals at δ 33.4, 20.9, and 15.9. The chemical shift of the methyls is similar to those reported for natural products with the 4α,4β,10-trimethyldecalin system (24). The hemithioacetal **24***b* has spectroscopic (ir, ms, nmr) properties similar to those of **24***a* except that the coupling constants for H-12 are smaller (8.0 and 1.5 Hz). Because of the poor yields in the reduction step, other methods for effecting the carbomethoxyl to methyl transformation were investigated. Alcohols **20** were mesylated and the mesylates reduced with lithium triethylborohydride (superhydride) (25). The only products obtained were the alcohols **20**, the result of S—O cleavage. Similar results were obtained when the tosylates of **20** were reduced with superhydride, except that in this case about 25% of the product resulted from C—O cleavage. Recently it has been reported that 2-propanesulfonates of hindered alcohols give better yields of C—O cleavage than the corresponding mesylates or tosylates (26). Indeed, preparation of the 2-propanesulfonyl derivatives of **20** and reduction with superhydride in toluene (90°C) gave **24***a* and **24***b* in about 65% yield, a modest improvement over the tosylhydrazone route.

The hemithioacetals **24***a* and **24***b* were oxidized with *m*-CPBA to give the corresponding sulfoxides, which were heated in refluxing xylenes to afford the enol ether **25** in 65% yield. The ^{1}H nmr spectrum of **25** shows signals for three quaternary methyls and for enol ether hydrogens at δ 6.47 (H-11) and δ 5.39 (H-12). Earlier we had encountered difficulties in dehydrating alcohol **19** and had found that introduction of the ring B double bond was best achieved using the *O*-formyl derivative **19***a*, obtained when the ozonolysis of **14***a* was carried out in a nonprotic solvent. Accordingly, enol ether **25** was treated with ozone in ethyl acetate (−78°C), followed by trimethylphosphite, to give the *O*-formyl aldehyde **26**. The crude reaction product, which shows signals at δ 9.88 (aldehydic hydrogen) and δ 8.24 (*O*-formyl hydrogen), was treated with DBU in refluxing benzene to provide a mixture of unsaturated aldehydes **27**. The mixture **27** was not characterized but was immediately treated with potassium hydride in tetrahydrofuran followed by addition of the molybdenum peroxide reagent MoO_5·pyridine·HMPA (MoOPH) (27). The product, formed in about 60% yield from **25**, was compound **28**, the monoethylene acetal of warburganal (**2**). Compound **28** shows hydroxyl (3460 cm^{-1}) and aldehyde carbonyl (1724 cm^{-1}) absorption in the ir, and its ^{1}H nmr spectrum displays an aldehydic hydrogen (δ 9.85) and an alkenic hydrogen (δ 6.36, dd, *J*'s 5.0, 2.5 Hz). Removal of the dioxolane protecting group (*p*-TsOH–acetone) gave (−)-warburganal (**2**). The melting point (6, 28), specific rotation (6), and spectroscopic data (ir, nmr, ms (5, 7)) obtained for the synthetic material agree well with those reported.

During the course of our studies, the 4-carbomethoxy analog of warburganal, compound **29**, was prepared from the aldehyde **19***a* using the same sequence of reactions as for the transformation of aldehyde **26** to warburganal. The experimental details for this process have been recorded (33). Compound **29** has previously been prepared from abietic acid (6).

Experimental

All reactions were carried out under a positive pressure of an inert gas unless otherwise noted. Reactions requiring anhydrous conditions were performed in oven-dried glassware (115°C, 2 h), which was cooled in a desiccator, assembled, sealed with a rubber septum, and purged with an inert gas. Solvents were distilled before use for chromatography or extraction. Anhydrous solvents were distilled from appropriate drying agents: diethyl ether by distillation from a blue solution of sodium benzophenone ketyl; tetrahydrofuran (THF) by distillation from a blue solution of potassium benzophenone ketyl; dichloromethane, chloroform, toluene, pyridine, triethylamine, diisopropylamine, diisopropylethylamine, benzyl alcohol, oxalyl chloride, dimethyl sulfoxide (DMSO), dimethylformamide (DMF), and hexamethylphosphoric triamide (HMPA) by distillation from calcium hydride (the latter three under reduced pressure and stored over molecular sieves (3A) under nitrogen). Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C. The commercial solutions (Aldrich) of methyllithium in ether, *n*-butyllithium in THF, and phenyllithium in ether were titrated before use by the diphenylacetic acid method (29).

Flash chromatography was performed by using E. Merck silica gel 60 (230–400 ASTM mesh) according to the procedure of Still *et al.* (30). Analytical thin-layer chromatography (tlc) was carried out on aluminum sheets precoated (0.2-mm layer thickness) with silica gel 60 F_{254} (E. Merck, Darmstadt).

Melting points were recorded on a Fisher–Johns melting point apparatus and are uncorrected. Fourier transform infrared spectra were recorded on a Nicolet 7199 FT interferometer. Films for ir are "cast" by placing a drop of solution onto KBr plates and then allowing the solvent to evaporate. Ultraviolet spectra were recorded on a Hewlett Packard HP8450A diode array spectrometer coupled to a 7470A plotter.

Hydrogen nuclear magnetic resonance (^{1}H nmr) spectra were recorded on Bruker WP-80 (at 80 MHz), Varian HA-100 (at 100 MHz), Bruker WH-200 (at 200 MHz), Bruker WM-360 (at 360t MHz), or Bruker WH-400 (at 400 MHz) spectrometers in the specified deuterated solvent with tetramethylsilane (TMS) as an internal standard and measurements are reported in ppm downfield from TMS (δ). ^{13}C nuclear magnetic resonance (^{13}C nmr) spectra were measured on Bruker WH-200 (at 50.3 MHz) or Bruker WH-400 (at 100.6 MHz) spectrometers. For ^{13}C nmr, deuterochloroform ($CDCl_3$) was employed as the internal standard (assigned as 77.0 ppm downfield from TMS) and measurements are reported in ppm downfield from TMS (δ). Carbon-13 multiplicities were derived from gate decoupling spin echo experiments (31). In the assignments quoted terpenoid numbering, as in **1** and **5**, is used throughout.

High resolution electron impact mass spectra (hrms) were recorded on an A.E.I. MS-50 mass spectrometer coupled to a DS50 computer. Chemical ionization (ammonia as reagent gas) mass spectra (cims) and low resolution electron impact mass spectra (lrms) were obtained using an A.E.I. MS-9 mass spectrometer. Data are reported as *m/z* (relative intensity). Unless diagnostically significant, peaks with intensities less than 20% of the base peak are omitted. Optical rotations were determined on a Perkin Elmer model 141 polarimeter with a sodium lamp (589 nm) at room temperature. Combustion analyses were performed by the Microanalytical Laboratory of the University of Alberta.

*Levopimaric acid (**1**)*

Levopimaric acid was isolated from pine oleoresin (Naval Stores and Timber Production Laboratory, Olustee, Florida, U.S.A.) as described (1); mp 128°C; $[\alpha]_D$ −265° (*c* 6.6, MeOH).

*Methyl levopimarate (**1**a)*

An ethereal solution of diazomethane was added dropwise with stirring to a solution of levopimaric acid (5.092 g) in ether (200 mL) at 0°C until the yellow color persisted. The reaction mixture was dried (Na_2SO_4), and concentrated *in vacuo* to give **1***a* as a solid (5.230 g, 98%); mp 60–62°C; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 5.5 (1H, d, 1.5 Hz, H-14), 5.11 (1H, t, 4 Hz, H-12), 3.65 (3H, s, C-18 OCH_3), 2.38–2.0 (5H, m), 1.91 (1H, dd, 12.75, 2.75 Hz, H-5), 1.84–1.38 (9H, m), 1.17 (3H, s, C-4 CH_3), 0.95 (6H, d, 7 Hz, CH_3-16,17), 0.89 (3H, s, C-10 CH_3); hrms, *m/z* calcd. for $C_{21}H_{32}O_2$ (M^+): 316.2394; found: 316.2402.

*Methyl 8α,12α-epidioxyabiet-13-enate (**4**) (8)*

A solution of methyl levopimarate (4.040 g) and rose bengal (50 mg) in 95% ethanol (240 mL) was irradiated with a 40-watt Luminate lamp while oxygen was bubbled through the solution. After 9 h the solvent was removed *in vacuo*. The residue was dissolved in ether (300 mL), washed with saturated $NaHCO_3$, water, brine, dried (Na_2SO_4), and concentrated to give a pink solid (4.350 g). Purification by flash chromatography, eluant Skellysolve B – ethyl acetate (85:15) gave the endoperoxide **4** as a solid (3.360 g, 76%). An analytical sample of the endoperoxide was obtained by recrystallization from Skellysolve B; mp 102°C (lit. (8) mp 100–101°C); $[\alpha]_D$ +82.6° (*c* 1.4, $CHCl_3$) (lit. (8) $[\alpha]_D$ +93.5°); ^{1}H nmr (400 MHz, $CDCl_3$) δ: 5.88 (1H, t, 1.5 Hz, H-14), 4.63 (1H, dt, 4.5, 1.5 Hz, H-12), 3.69 (3H, s), 2.51 (1H, quintet d, 7, 1.5 Hz, H-15), 2.25 (1H, ddd, 14, 9.5, 4.5 Hz, H-11α), 1.98 (1H, dd, 9, 5.5 Hz, H-9), 1.94–1.02 (12H, m), 1.14 (3H, s, C-4 CH_3), 1.12 (3H, d, 7 Hz, CH_3-16), 1.08 (3H, d, 7 Hz, CH_3-17), 0.57 (3H, s, C-10 CH_3); ^{13}C nmr ($CDCl_3$) δ: 178.8 (s, C-18), 149.1 (s, C-13), 124.7 (d, C-4), 76.9 (s, C-8), 74.7 (d, C-12), 51.9 (q, C-18 OCH_3), 50.2 (d), 49.3 (d), 47.1 (s, C-4), 36.9 (t), 36.8 (t), 36.3 (s), 32.2 (t), 31.1 (d, C-15), 25.1 (t), 21.7 (t), 20.4 (q, C-16), 20.2 (q, C-17), 17.1 (t), 16.6 (q), 15.2 (q); hrms, *m/z* calcd. for $C_{21}H_{32}O_4$ (M^+): 348.2292; found: 348.2300 (5), 316 (67), 146 (34), 121 (100), 105 (30).

*(1S,5R,6R,9R,12S,14R)-1,5-Dimethyl-10,11-dioxa-12-isopropylcarbonyl-9-formyl-5-methoxycarbonyltricyclo[8.4.0.0^{9,14}]tetradecane (**5**)*

A solution of the endoperoxide **4** (820 mg, 2.3 mmol) in dichloromethane–methanol (9:1, 100 mL) was cooled in a Dry Ice – acetone bath. Ozone was bubbled through the solution until the solution remained pale blue. Excess ozone was removed with N_2, then methyl sulfide (0.4 mL) was added to the solution. The reaction mixture was allowed to warm to room temperature and the solvent was removed. The residue was dissolved in ether, washed with water (2×), brine, dried (Na_2SO_4), and the solvent removed to give the ketoaldehyde **5** as an oil (860 mg, 98%). A sample was purified by flash chromatography (CH_2Cl_2–EtOAc, 98:2); $[\alpha]_D$ −183.5° (*c* 0.2, $CHCl_3$); ir ($CHCl_3$, cast): 2750, 1723 (br, vs), 1248 cm^{-1}; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 9.77 (1H, s), 4.85 (1H, dd, 9, 4.5 Hz, H-12), 3.67 (3H, s), 2.85 (1H, quintet, 7 Hz, H-15), 2.13–1.21 (14H, m), 1.17 (3H, s, C-4 CH_3), 1.14 (3H, d, 7 Hz, CH_3-16), 1.07 (3H, d, 6.5 Hz, CH_3-17), 0.95 (3H, s, C-10 CH_3)); hrms, *m/z* calcd. for $C_{21}H_{32}O_6$ (M^+): 380.2190; found: 380.2199 (0.3), 352 (13), 281 (16), 164 (16), 263 (22), 203 (10), 121 (34), 71 (100). *Anal.* calcd. for $C_{21}H_{32}O_6$: C 66.33, H 8.48; found: C 66.35, H 8.59.

*(1S,5R,6R,9R,12S,14R)-1,5-Dimethyl-9-(dimethoxymethyl)-10,11-dioxa-12-isobutyryl-5-methoxycarbonyltricyclo[8.4.0.0^{9,14}]-tetradecane (**6**)*

A solution of the ketoaldehyde **5** (860 mg, 2.26 mmol) and *p*-toluenesulfonic acid (catalytic amount) in trimethyl orthoformate (10 mL) was stirred at room temperature for 20 h. The solution was diluted with ether, washed with saturated $NaHCO_3$, H_2O, brine, dried (Na_2SO_4), and evaporated to give **6** as a solid (930 mg). The crude product was recrystallized from ether to yield colorless needles (665 mg, 69%); mp 167–168°C; $[\alpha]_D$ −119° (*c* 0.75, $CHCl_3$); ir ($CHCl_3$, cast): 1722, 1248, 1128, 1068 cm^{-1}; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 4.72 (1H, dd, 11, 3 Hz, H-12), 4.64 (1H, s, H-14), 3.67 (3H, s, C-18 OCH_3), 3.60 (3H, s, C-14 OCH_3), 3.46 (3H, s, C-14 OCH_3), 2.96 (1H, quintet, 7 Hz, H-15), 2.20–0.95 (14H, m), 1.17 (3H, s, C-4 CH_3), 1.10 (3H, d, 7 Hz, C-16), 1.08 (3H, d, 7 Hz, CH_3-17), 0.91 (3H, s, C-10 CH_3); hrms, *m/z* calcd. for $C_{19}H_{31}O_6$ ($M^+ - C_4H_7O$): 355.2112; found: 355.2121 (0.3), 263 (1.6), 121 (3), 81 (2), 75 (100); cims (NH_3): 444 (M^+ − 18, 100). *Anal.* calcd. for $C_{23}H_{38}O_7$: C 64.76, H 8.98; found: C 64.95, H 9.08.

*(1S,2R,3R,6R,7R)-1,7-Dimethyl-3-(dimethoxymethyl)-2-(2,3-dioxo-4-methylpentyl)-3-hydroxy-7-methoxycarbonylbicyclo[4.4.0]-decane (**7**)*

A solution of the peroxide **6** (107 mg, 0.25 mmol) and triethylamine (0.04 mL, 0.28 mmol) in chloroform (5 mL) was stirred for 48 h at room temperature. The resulting yellow solution was concentrated *in vacuo* to give **7** as an oil. The crude product was purified by flash column chromatography (Skellysolve B – acetone, 3:1) to give pure α-diketone **7** (103 mg, 96%); ir ($CHCl_3$, cast): 3456 (br), 1725, 1245, 1119, 1070 cm^{-1}; cims: 444 (M^+ + 18, 19), 426 (M^+, 10), 412 (100).

*(1S,5R,6R,9R,13R)-1,5-Dimethyl-9-(dimethoxymethyl)-11-isobutyryl-11-methoxy-5-methoxycarbonyl-10-oxatricyclo[7.4.0.0^{9,13}]-tetradecane (**8**)*

α-Diketone **7** (199.4 mg, 0.47 mmol), *d,l*-camphorsulfonic acid (catalytic amount), and trimethyl orthoformate (5 mL) were stirred for 12 h at room temperature. The solution was diluted with ether, washed with saturated $NaHCO_3$, H_2O, brine, dried (Na_2SO_4), and the solvent removed *in vacuo* to give a solid (179.5 mg). The solid was recrystallized from Skellysolve B to afford **8** as colorless needles (102 mg, 49%); mp 180–182°C; ir (CH_2Cl_2, cast): 1726, 1247, 1119, 1067, 1008, 955 cm^{-1}; ^{1}H nmr (400 MHz, $CDCl_3$) δ: 4.49 (1H, s, H-14), 3.70 (3H, s, C-18 OCH_3), 3.56 (3H, s), 3.34 (1H, quintet, 7 Hz, H-15), 3.26 (3H, s), 3.25 (3H, s), 2.46 (1H, dd, 15, 12 Hz, H-11β), 2.35 (1H, dt, 12, 3 Hz, H-7β), 2.07 (1H, dd, 15, 7 Hz, H-11α), 1.90 (1H, dd, 10, 3.5 Hz, H-5), 1.83 (1H, dd, 11, 5 Hz), 1.74 (1H, dd, 12, 7 Hz, H-9), 1.7–1.01 (8H, m), 1.19 (3H, s, C-4 CH_3), 1.14 (3H, d, 7 Hz, CH_3-16), 1.09 (3H, d, 7 Hz, CH_3-17), 0.92 (3H, s, C-10 CH_3); hrms, *m/z* calcd. for $C_{20}H_{33}O_6$ ($M^+ - C_4H_7O$): 369.2268; found: 369.2277 (37), 365 (18), 337 (23), 305 (20), 273 (27), 263 (32), 245 (53), 171 (15), 121 (15), 75 (100); cims (NH_3): 458 (M^+ + 18, 43), 426 (35), 409 (100). *Anal.* calcd. for $C_{24}H_{40}O_7$: C 65.43, H 9.15; found: C 65.34, H 9.20.

*(1S,5R,6R,9R,13R)-1,5-Dimethyl-9-(dimethoxymethyl)-11-(2-^{2}H)-isobutyryl-11-methoxy-5-methoxycarbonyl-10-oxatricyclo-[7.4.0.0^{9,13}]tetradecane (**8**-d$_1$)*

A small piece of metallic sodium was dissolved in methanol-d_1 (1 mL), then ketone **8** (8 mg) was added to the solution. After 12 h at room temperature the reaction was quenched with 1 drop H_2O, the solvent removed, and the residue dissolved in CH_2Cl_2. The organic extract was dried (Na_2SO_4), filtered, and evaporated under reduced pressure to yield a solid (7.5 mg). The solid was crystallized from Skellysolve B to give **8**-d_1 as white crystals; mp 179–180°C; ^{1}H nmr (400 MHz, $CDCl_3$) δ: 4.48 (1H, s, H-14), 3.68 (3H, s, C-18 OCH_3), 3.54 (3H, s), 3.25 (3H, s), 3.24 (3H, s), 2.45 (1H, dd, 14.5, 11.5 Hz, H-11β), 2.34 (1H, dt, 12.3 Hz, H-7β), 2.06 (1H, dd, 14.5, 7 Hz, H-11α), 1.89 (1H, dd, 10, 3.5 Hz, H-5), 1.82 (1H, dd, 11, 5 Hz), 1.73 (1H, dd, 11.5, 7 Hz, H-9), 1.70–1.20 (8H, m), 1.19 (3H, s, C-4 CH_3), 1.12 (3H, s, CH_3-16), 1.08 (3H, s, CH_3-17), 0.92 (3H, s, C-10 CH_3); cims (NH_3): 459 (M^+ + 18, 12), 427 (13), 410 (100).

*(1S,2R,3R,6R,7R)-2-Acetoxy-3-oxo-4-methylpent-1-enyl)-1,7-dimethyl-3-(dimethoxymethyl)-3-hydroxy-7-methoxycarbonylbicyclo[4.4.0]decane (**9**) and (1S,2R,3R,6R,7R)-1,7-dimethyl-3-(dimethoxymethyl)-3-hydroxy-7-methoxycarbonyl-2-(4-oxo-3-acetoxy-2-methylpent-2-enyl)-bicyclo[4.4.0]decane (**10**)*

The α-diketone **7** (187 mg), acetic anhydride (2 mL), and diisopropylethylamine (4 mL) were placed in a round-bottom flask fitted with a condenser. The two-phase reaction was refluxed under N_2 for 1.5 h. The reaction mixture was poured on ice and saturated $NaHCO_3$ and extracted with ether (3×). The organic extracts were combined, washed with 10% HCl (3×), saturated $NaHCO_3$ (2×), brine (2×), dried (Na_2SO_4), and concentrated *in vacuo* to give a dark yellow oil (198 mg). The crude product was purified by flash column chromatography (Skellysolve B – acetone, 4:1) to give **9** (145 mg), then **10** (11 mg). Compound **9**: ir ($CHCl_3$, cast): 3550, 1759, 1725, 1686, 1640, 1250, 1212 cm^{-1}; uv (MeOH) λ_{max}: 235 nm (ε 10 702); ^{1}H nmr (400 MHz, $CDCl_3$) δ: 6.45 (1H, d, 11 Hz, H-11), 4.48 (1H, s, H-14), 3.63 (3H, s, C-18 OCH_3), 3.43 (3H, s, C-14 OCH_3), 3.40 (3H, s, C-14 OCH_3), 3.06 (1H, quintet, 7 Hz, H-15), 2.58 (1H, br s, D_2O exchangeable), 2.56 (1H, d, 11 Hz, H-9), 2.22 (3H, s, $OCOCH_3$), 2.13 (1H, m), 1.86 (1H, m), 1.76–1.20 (9H, m), 1.16 (3H, d, 7 Hz, CH_3-16), 1.15 (3H, s, C-4 CH_3), 1.12 (3H, d, 7 Hz, CH_3-17), 1.01 (3H, s, C-10 CH_3); hrms, *m/z* calcd. for $C_{24}H_{36}O_7$ ($M^+ - CH_4O$): 436.2461; found: 436.2461 (2), 394 (36), 351 (4), 333 (3), 291 (6), 273 (7), 121 (100), 75 (10); cims (NH_3): 486 (M^+ + 18, 100). *Anal.* calcd. for $C_{25}H_{40}O_8$: C 64.08, H 8.60; found: C 64.37, H 8.63.

Compound **10**: ir ($CHCl_3$, cast): 3544 (br), 1754, 1723, 1695, 1625, 1249, 1211, 1128, 1068, 750 cm^{-1}; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 4.36 (1H, s, H-14), 3.67 (3H, s, C-18 OCH_3), 3.60 (3H, s, C-14 OCH_3), 3.45 (3H, s, C-14 OCH_3), 3.06 (1H, dd, 20, 5 Hz), 2.41 (2H, m), 2.28 (3H, s, $OCOCH_3$), 2.17 (3H, s, CH_3-16), 2.12–1.96 (2H, m), 1.76 (3H, s, CH_3-17), 1.58–0.9 (10H, m), 1.12 (3H, s, C-4 CH_3), 0.84 (3H, s, C-10 CH_3); hrms, *m/z* calcd. for $C_{24}H_{36}O_7$ ($M^+ - CH_4O$): 436.2461; found: 436.2460 (7), 393 (37), 376 (22), 375 (11), 333 (25), 315 (34), 273 (18), 263 (21), 141 (15), 121 (23), 75 (100); cims (NH_3): 486 (M^+ + 18, 8), 437 (29), 405 (100).

*(1S,5R,6R,9R,12S,14R)-1,5-Dimethyl-9-(dimethoxymethyl)-10,11-dioxa-12-(1-hydroxy-2-methylpropyl)-5-methoxycarbonyltricyclo[8.4.6.0^{9,14}]tetradecane (**11**)*

Sodium borohydride (9.1 mg, 0.24 mmol) was added slowly over 15 min to a solution of the ketoperoxide **6** (102 mg, 0.24 mmol) in methanol–dichloromethane (4:1). After addition was completed, 1 drop of acetic acid was added, the reaction mixture stirred for 5 min, then the solvent removed *in vacuo*. The residue was partitioned between ether and water. The organic layer was washed with saturated

$NaHCO_3$ (2×), brine (2×), dried (Na_2SO_4), and concentrated to yield **11** as a solid (94 mg, 92%). A portion of the product was recrystallized from ether – Skellysolve B to give colorless needles, mp 134–135°C. The following data were obtained for the mixture of epimers **11**; ir (CH_2Cl_2, cast): 3537 (br), 1724, 1250, 1192, 1170, 1153, 1125, 1089 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 4.61 (0.6H, s, H-14), 4.59 (0.4H, s, H-14), 4.36 (1H, m, H-12), 3.67 (3H, s, C-18 OCH_3), 3.62 (3H, s, C-14 OCH_3), 3.48 and 3.47 (3H, s, C-14 OCH_3), 3.35 (0.6H, dd, 11.5, 3 Hz, H-13), 3.12 (0.4H, dd, 8.5, 4.5 Hz, H-13), 2.66 (0.6H, br s, D_2O exchangeable), 2.41 (0.4H, br s, D_2O exchangeable), 2.41–2.17 (1H, m), 1.98–1.24 (14H, m), 1.18 (3H, s, C-4 CH_3), 1.03 (3H, d, 7 Hz, CH_3-16), 0.94 (3H, s, C-10 CH_3), 0.85 (3H, d, 7 Hz, CH_3-17); cims (NH_3): 446 (M^+ + 18, 53), 382 (100).

Hemiacetals ***12***

Metallic sodium (5 mg) was added to methanol (2 mL) and when the sodium was consumed the solution was added to compound **11** (20 mg) in methanol (2 mL). After 12 h at room temperature one drop of water was added, the solvent evaporated, and the residue dissolved in CH_2Cl_2. The organic layer was washed with H_2O, brine, dried (Na_2SO_4), and the solvent removed *in vacuo* to yield a solid (13.5 mg). A pure sample was obtained by recrystallization from Skellysolve B; mp 99–100°C; ir (CH_2Cl_2, cast): 3480 (br), 2760, 1725, 1248, 1121, 1070 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 9.7 (0.15H, t, 2.5 Hz, H-12), 5.64 (0.15H, m, H-12), 5.43 (0.7H, m, H-12); cims (NH_3): 374 (M^+ + 18, 17), 356 (18), 310 (100).

*(1S,5R,6R,9R,11S,13R)-11-Acetoxy-1,5-dimethyl-9-(dimethoxymethyl)-5-methoxycarbonyl-10-oxatricyclo[7.4.0.0^{9,13}]tridecane (**13**a) and (1S,5R,6R,9R,11R,13R)-11-acetoxy-1,5-dimethyl-9-(dimethoxymethyl)-5-methoxycarbonyl-10-oxatricyclo[7.4.0.0^{9,13}]tridecane (**13**b)*

The hemiacetals **12** (10.8 mg) and acetic anhydride (10 drops) in triethylamine (2 mL) were stirred at room temperature for 36 h. The solution was poured into cold saturated $NaHCO_3$ and extracted with ether. The ether extract was washed with 10% HCl, saturated $NaHCO_3$, H_2O, brine, dried (Na_2SO_4), and evaporated to give a yellow oil. Purification by flash chromatography (Skellysolve B – ethyl acetate, 55:45) furnished the acetate **13***a* (6.8 mg, 57%) and the acetate **13***b* (1.6 mg, 14%), each as a colorless oil.

The acetone **13***a* has the following properties: ir (CH_2Cl_2, cast): 1744, 1729, 1241 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 6.37 (1H, d, 5.5 Hz, H-12), 4.55 (1H, s, H-14), 3.7 (3H, s, C-18 OCH_3), 3.51 (3H, s, C-14 OCH_3), 3.38 (3H, s, C-14 OCH_3), 2.46 (1H, ddd, 14, 11.5, 5.5 Hz, H-11β), 2.35 (1H, m, H-7β), 2.07 (3H, s, $OCOCH_3$), 1.95 (1H, dd, 14, 7 Hz, H-11α), 1.54 (1H, dd, 11.5, 7 Hz, H-9), 1.91–1.21 (10H, m), 1.19 (3H, s, C-4 CH_3), 0.93 (3H, s, C-10 CH_3); cims (NH_3): 416 (M^+ + 18, 87).

The acetate **13***b* has the following properties: ir (CH_2Cl_2, cast): 1744, 1727, 1239, 1127, 1070, 969 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 6.16 (1H, t, 5.5 Hz, H-12), 4.5 (1H, s, H-14), 3.65 (3H, s, C-18 OCH_3), 3.43 (3H, s, C-14 OCH_3), 3.37 (3H, s, C-14 OCH_3), 2.26 (1H, brd, 12, 3 Hz, H-7β), 2.20 (1H, ddd, 17, 11, 5.5 Hz, H-11β), 2.06 (3H, s, CH_3COO), 2.0 (1H, dt, 17, 5.5 Hz, H-11α), 1.85–1.18 (11H, m), 1.16 (3H, s, C-4 CH_3), 0.94 (3H, s, C-10 CH_3); cims (NH_3): 416 (M^+ + 18, 2).

*(1S,5R,6R,9R,11S,13R)-1,5-Dimethyl-9-formyl-5-methoxycarbonyl-11-methoxy-10-oxatricyclo[7.4.0.0.^{9,13}]tridecane (**15**a) and(1S,5R,6R,9R,11R,13R)-1,5-dimethyl-9-formyl-5-methoxycarbonyl-11-methoxy-10-oxatricyclo[7.4.0.0^{9,13}]tridecane (**15**b)*

Methanesulfonyl chloride (0.05 mL) was added to a solution of hemiacetal **12** (14.8 mg), triethylamine (0.1 mL), and CH_2Cl_2 (2 mL) at 0°C. After 4 h at 0°C the solution was warmed to room temperature and 1 drop of H_2O was added. The solution was stirred for 2 h, then poured onto H_2O and extracted with CH_2Cl_2 (2×). The extract was washed with H_2O, brine, dried (Na_2SO_4), and evaporated *in vacuo* to give a yellow oil. Purification by flash chromatography (Skellysolve B – ethyl acetate, 3:1) afforded the aldehyde **15***a* (6.2 mg), mp 109°C (from Skellysolve B); $[\alpha]_D$ −54.9° (*c* 0.41, $CHCl_3$); ir (CH_2Cl_2, cast): 2760, 1723, 1248 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 9.82 (1H, d, 1.5 Hz, H-14), 5.24 (1H, t, 5 Hz, H-12 X portion of an ABCX system), 3.64 (3H, s, C-18 OCH_3), 3.39 (3H, s, C-12 OCH_3), 2.44 (1H, dt, 12, 3 Hz, H-7β), 2.24 (1H, complex, C portion of an ABCX system), 1.96 (2H, complex, AB portion of an ABCX system), 1.81 (1H, dd, 12.75, 2.75 Hz, H-5), 1.78–1.12 (9H, m), 1.1 (3H, s, C-4 CH_3), 0.82 (3H, s, C-10 CH_3); ^{13}C nmr ($CDCl_3$) δ: 198.1 (d, C-14), 178.7 (s, C-18), 107.0 (d, C-12), 85.3 (s, C-8), 61.1 (d, C-9), 56.2 (q, C-12 OCH_3), 51.9 (q, C-18 OCH_3), 50.9 (d, C-5), 46.8 (s, C-4), 38.2, 37.1, 36.1 (s, C-16), 31.2, 31.0, 22.5, 17.3 (t, C-2), 15.9 (q, CH_3), 15.4 (q, CH_3); hrms, *m/z* calcd. for $C_{17}H_{27}O_4$ (M^+ − CHO): 295.1902; found: 295.1910 (100), 231 (4), 203 (23), 121 (12); cims (NH_3): 342 (M^+ − 18, 20), 310 (100), 292 (10).

Nuclear Overhauser enhancement difference spectroscopy (nOeds) on the aldehyde gave the following results: presaturation of H-14 (δ 9.82): 7% (H-11β), 7% (C-4 CH_3), 17% (C-10 CH_3); presaturation of C-10 CH_3 (δ 0.82): 15% (H-14), 9.5% (H-11β), 20% (C-4 CH_3).

In some cases the aldehyde **15***b* was present as a minor component in the crude product. A pure sample was obtained by recrystallization from Skellysolve B; mp 90–91°C; ir (CH_2Cl_2, cast): 2740, 1725, 1247, 1172, 1102, 1002 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 9.61 (1H, s, H-14), 5.31 (1H, d, 5.5 Hz, H-12), 3.67 (3H, s, C-18 OCH_3), 3.39 (3H, s, C-12 OCH_3), 2.37 (1H, complex, H-7β), 2.18 (1H, dd, 14, 6 Hz, H-11α), 2.06 (1H, ddd, 14.5, 12, 5.5 Hz, H-11β), 1.91 (1H, dd, 12.5, 3 Hz, H-5), 1.78 (1H, dd, 12, 6 Hz, H-9), 1.82–1.73 (1H, m), 1.69–1.21 (8H, m), 1.13 (3H, s, C-4 CH_3), 0.76 (3H, s, C-10 CH_3); ^{13}C nmr ($CDCl_3$) δ: 198.3 (d, C-14), 178.6 (s, C-18), 105.5 (d, C-12), 86.5 (s, C-8), 58.7 (d, C-9), 55.3 (q, C-12 OCH_3), 51.9 (q, C-18 OCH_3), 50.6 (d, C-5), 46.8 (s, C-4), 38.1 (t), 37.1 (t), 35.8 (s, C-10), 32.6 (t), 30.4 (t), 22.7 (t), 17.4 (t, C-2), 16.3 (q), 15.9 (q); hrms, *m/z* calcd. for $C_{17}H_{27}O_4$ (M^+ − CHO): 295.1902; found: 295.1911 (100), 265 (3), 203 (24), 185 (7), 159 (8), 121 (21).

Nuclear Overhauser enhancement difference spectroscopy gave the following results: presaturation of C-10 CH_3 (δ 0.76): 12% (H-14), 7.5% (H-11β), 15% (C-4 CH_3).

*(1S,5R,6R,9R,12S,14R)-1,5-Dimethyl-10,11-dioxa-9-ethylenedioxymethyl-12-isobutyryl-5-methoxycarbonyltricyclo[8.4.0.0.^{9,14}]tetradecane (**6**a)*

A solution of the crude aldehyde **5** (543 mg, 1.43 mmol), ethylene glycol (0.4 mL, 7.15 mmol), trimethyl orthoformate (0.78 mL, 7.15 mmol), and *p*-toluenesulfonic acid (40 mg) in dry benzene (6 mL) was stirred in an oil bath at 45°C under reduced pressure (160 Torr; 1 Torr = 133.3 Pa) for 10 h. The dimethyl acetal formed in the reaction was converted to the dioxolane by adding ethylene glycol (0.4 mL) and heating the solution at 80°C for 10 min at atmospheric pressure. The reaction mixture was diluted with CH_2Cl_2, washed with 10% HCl (2×), saturated $NaHCO_3$ (2×), brine, dried ($MgSO_4$), and concentrated *in vacuo* to yield an oil. Recrystallization from ether afforded the ketone **6***a* as white crystals (239 mg) and purification of the mother liquors by flash chromatography (dichloromethane – ethyl acetate, 9:1) gave further **6***a* (121 mg). The overall yield of the ketone from levopimaric acid is 49% when the reaction sequence is carried out without purification. Ketone **6***a* shows the following properties: $[\alpha]_D$ −133.3° (*c* 0.15, $CHCl_3$); ir (CH_2Cl_2, cast): 1722, 1713, 1245, 1171, 1147, 1042 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 5.37 (1H, s, H-14), 4.80 (1H, dd, 11.5, 2.5 Hz, H-12), 4.20–3.84 (4H, complex), 3.68 (3H, s), 2.88 (1H, quintet, 7 Hz, H-15), 2.21 (1H, complex), 1.94 (1H, dt, 12.5, 3 Hz, H-7β), 1.9–0.83 (12H, m), 1.18 (3H, s, C-4 CH_3), 1.12 (3H, d, 7 Hz, CH_3-16), 1.06 (3H, d, 7 Hz, CH_3-17), 1.01 (3H, s, C-10 CH_3); ^{13}C nmr ($CDCl_3$) δ: 210.5 (s, C-13), 178.7 (s, C-18), 105.5 (d, C-14), 86.3 (d, C-12), 81.4 (s, C-8), 65.2 (t), 57.4 (d, C-9), 51.9 (q, C-18 OCH_3), 50.9 (d, C-5), 47.4 (s, C-4), 38.1 (t), 36.9 (t), 35.9 (s, C-10), 32.7 (t), 22.3 (t), 22.0 (t), 18.1 (q), 17.6 (t), 17.5 (q), 16.0 (q, two carbons); hrms, *m/z* calcd. for $C_{19}H_{29}O_6$ (M^+ − C_4H_7O): 353.1956; found: 353.1965 (1), 281 (1), 203 (1), 121 (3), 73 (100); cims (NH_3): 442 (M^+ + 18, 24), 424 (M^+, 3), 337 (100). *Anal.* calcd. for $C_{23}H_{36}O_7$: C 65.03, H 8.55; found: C 65.03, H 8.50.

*(1S,5R,6R,9R,12S,14R)-1,5-Dimethyl-10,11-dioxa-9-ethylenedioxymethyl-12-(1-hydroxy-2-methylpropyl)-5-methoxycarbonyltricyclo[8.4.0.0.^{9,14}]tetradecane (**11**a)*

Sodium borohydride (225 mg, 5.94 mmol) was added slowly to a stirred solution of ketone **6***a* (2.52 g, 5.94 mmol) in CH_2Cl_2–MeOH (20 mL, 1:1). After 15 min, addition was complete and the reaction was quenched by adding 3 drops of acetic acid. The solvent was removed under vacuum and the residue partitioned between ether and water. The ethereal layer was separated and washed with saturated $NaHCO_3$, H_2O, brine, dried ($MgSO_4$), and evaporated *in vacuo* to yield the epimeric alcohols **11***a* (2.40 g) as a solid. An analytical sample was obtained by recrystallization from Skellysolve B; mp 163.5–164.5°C; ir ($CHCl_3$, cast): 3520 (br), 1724, 1249, 1170, 1150, 1106, 1008 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 5.28 (0.3H, s, H-14), 5.22 (0.7H, s, H-14), 4.34 (0.7H, dt, 11, 3 Hz, H-12), 4.29 (0.3H, ddd, 11, 5.5, 3 Hz, H-12), 3.3 (0.7H, dd, 8, 3 Hz, H-13), 3.18 (0.3H, t, 5.5 Hz, H-13), 2.31 (0.7H, s, D_2O exchangeable), 2.13 (0.3H, s, D_2O exchangeable); hrms, *m/z* calcd. for $C_{19}H_{29}O_6$ ($M^+ - C_4H_9O$): 353.1956; found: 353.1964 (0.3), 321 (1), 281 (2), 121 (3), 73 (100); cims (NH_3): 444 (M^+ + 18, 25), 426 (M^+, 1), 337 (100). *Anal.* calcd. for $C_{23}H_{38}O_7$: C 64.75, H 8.98; found: C 65.11, H 8.93.

*Hemiacetals **12**a*

A solution of the crude alcohols **11***a* (2.40 g) and sodium methoxide (321 mg) in methanol (30 mL) was stirred for 12 h at room temperature. Water (0.1 mL) was added and the solvent removed *in vacuo*. The residue was dissolved in CH_2Cl_2 and washed with H_2O, brine, dried ($MgSO_4$), and evaporated *in vacuo* to give the hemiacetals **12***a* (1.94 g) as a solid. An analytical sample was prepared by recrystallization from Skellysolve B – diisopropyl ether; mp 122–123°C; ir ($CHCl_3$, cast): 3428 (br), 2720, 1726 (br), 1249, 1172, 1142, 1119, 1070 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 9.74 (0.2H, t, 2.5 Hz, H-12), 5.56 (0.4H, d, 6 Hz, H-12), 5.44 (0.4H, m, H-12), 5.19, 5.11, and 5.06 (1H, s, H-14); hrms, *m/z* calcd. for $C_{19}H_{30}O_6$: 354.2034; found: 354.2042 (3), 281 (66), 221 (27), 203 (21), 121 (26), 73 (100). *Anal.* calcd. for $C_{19}H_{30}O_6$: C 64.38, H 8.53; found: C 64.61, H 8.62.

*(1S,5R,6R,9R,11S,13R)-1,5-Dimethyl-9-ethylenedioxymethyl-11-methanesulfonyl-5-methoxycarbonyl-10-oxatricyclo[7.4.0.0.^{9,13}]tridecane (**16**)*

To a solution of hemiacetal **12***a* (10 mg, 0.028 mmol) and triethylamine (0.1 mL, 1.36 mmol) in CH_2Cl_2 in an ice-water bath (5°C) was added methanesulfonyl chloride (0.05 mL, 0.29 mmol). The solution was stirred for 2 h at 5°C, then poured onto cold H_2O and extracted twice with ether. The organic layer was washed with cold 10% HCl, saturated $NaHCO_3$, H_2O, brine, dried ($MgSO_4$), and evaporated *in vacuo* to give a yellow oil (8.9 mg). Purification by flash chromatography (Skellysolve B – acetone, 3:1) yielded **16** as a colorless oil (6 mg); ir (CH_2Cl_2, cast): 1726, 1358, 1335, 1247, 1150, 1143, 1122, 1100, 945 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 5.18 (1H, s, H-14), 5.06 (1H, d, 5.75 Hz, H-12), 4.02–3.94 (2H, m), 3.9–3.78 (2H, m), 3.65 (3H, s, C-18 OCH_3), 3.37 (3H, s, C-12 OSO_2CH_3), 2.38 (1H, dt, 12, 3 Hz, H-7β), 2.34 (1H, ddd, 14.5, 11.5, 5.75 Hz, H-11β), 2.02 (1H, dd, 14.5, 6.75 Hz, H-11α), 1.92 (1H, dd, 11.5, 3 Hz, H-5), 1.81 (1H, dt, 13.5, 5 Hz), 1.94 (1H, dd, 11.5, 6.75 Hz, H-9), 1.78–1.21 (8H, m), 1.16 (3H, s, C-4 CH_3), 0.95 (3H, s, C-10 CH_3).

*(1S,5R,6R,9R,11R,13R)-1,5-Dimethyl-9-ethylenedioxymethyl-5-methoxycarbonyl-10-oxa-11-phenylthiotricyclo[7.4.0.0.^{9,13}]tridecane (**17**a), (1S,5R,6R,9R,11S,13R)-1,5-dimethyl-9-ethylenedioxymethyl-5-methoxycarbonyl-10-oxa-11-phenylthiotricyclo[7.4.0.0^{9,13}]tridecane (**17**b) and (1S,2R,3R,6R,7R)-1,7-dimethyl-2-[2,2′-bis(phenylthio)-ethyl]-3-ethylenedioxymethyl-3-hydroxy-7-methoxycarbonylbicyclo[4.4.0]decane (**18**)*

A solution of the crude hemiacetal **12***a* (2.04 g), thiophenol (1.22 mL), and trifluoroacetic acid (3 drops) in CH_2Cl_2 (25 mL) was stirred for 38 h at room temperature. The solution was diluted with CH_2Cl_2 and washed with 5% Na_2CO_3 (4×), brine, dried ($MgSO_4$), and evaporated *in vacuo* to yield the mixture of thioacetals as an oil. Purification by flash chromatography (Skellysolve B – acetone, 3:1) gave the hemithioacetals **17***a* and **17***b* (1.93 g, 72%) as an oil and the thioacetal **18** (0.19 g, 6%) as an oil.

Compounds **17***a* and **17***b* were separated by flash chromatography (Skellysolve B – ethyl acetate, 7:3). Compound **17***a*, obtained as an oil, shows the following properties: $[\alpha]_D$ +80.3° (*c* 0.11, $CHCl_3$), ir (CH_2Cl_2, cast): 3045, 1725, 1580 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 7.48 (2H, dd, 8.5, 1.5 Hz, Ar-H), 7.32–7.12 (3H, m, Ar-H), 5.54 (1H, dd, 9, 6.5 Hz, H-12), 5.28 (1H, s, H-14), 4.39 (1H, complex), 4.10–3.71 (3H, complex), 3.67 (3H, s, C-18 OCH_3), 2.39 (1H, dd, 14.5, 11.5, 9 Hz, H-11β), 2.38 (1H, m, H-7β), 2.12 (1H, dt, 11.5, 6.5 Hz, H-11α), 1.91–1.28 (11H, m), 1.16 (3H, s, C-4 OCH_3), 1.02 (3H, s, C-10 CH_3); ^{13}C nmr ($CDCl_3$) δ: 178.7 (s, C-18), 138.1 (s), 129.7 (d, 2×), 128.8 (d, 2×), 126.0 (d), 105.3 (d, C-14), 89.3 (s, C-12), 84.2 (s, C-8), 66.5 (t), 64.9 (t), 61.8 (d, C-9), 51.9 (q, C-18 OCH_3), 51.8 (d, C-5), 47.0 (s, C-4), 39.1 (t), 37.2 (t), 36.3 (t), 35.8 (s, C-10), 31.3 (t), 23.2 (t), 17.5 (t), 16.2 (q), 15.8 (q); hrms, *m/z* calcd. for $C_{25}H_{34}O_5S$ (M^+): 446.2117; found: 446.2127 (2), 373 (51), 337 (100), 293 (21), 263 (39), 215 (18), 121 (17), 73 (85); cims (NH_3): 464 (M^+ + 18, 0.6), 354 (4), 337 (3). *Anal.* calcd. for $C_{25}H_{34}O_5S$: C 67.23, H 7.67; found: C 67.23, H 7.58.

Compound **17***b*, obtained as an oil, shows the following properties: $[\alpha]_D$ −81.3° (*c* 0.16, $CHCl_3$); ir (CH_2Cl_2, cast): 3045, 1725, 1580 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 7.61–7.5 (2H, m, Ar-H), 7.42–7.28 (3H, m, Ar-H), 5.63 (1H, dd, 8, 1.5 Hz, H-12), 5.22 (1H, s, H-14), 4.08–3.80 (4H, m), 3.67 (3H, s, C-18 OCH_3), 2.72 (1H, ddd, 14.5, 11.5, 8 Hz, H-11β), 2.38 (1H, m, H-7β), 1.84 (1H, ddd, 11.5, 7, 1.5 Hz, H-11α), 1.76–1.22 (11H, m), 1.12 (3H, s, C-4 CH_3), 0.93 (3H, s, C-10 CH_3); ^{13}C nmr ($CDCl_3$) δ: 178.7 (s, C-18), 134.5 (s, Ar), 132.0 (d, Ar, 2×), 128.7 (d, Ar, 2×), 127.0 (d, Ar), 105.5 (d, C-14), 86.8 (d, C-12), 85.0 (s, C-8), 66.2 (t), 64.7 (t), 60.0 (d, C-9), 51.9 (q, C-18 OCH_3), 51.6 (d, C-5), 46.9 (s, C-4), 39.0 (t), 37.1 (t), 35.8 (t), 35.5 (s, C-10), 31.8 (t), 22.9 (t), 17.5 (t), 16.0 (q), 15.8 (q); hrms, *m/z* calcd. for $C_{25}H_{34}O_5S$ (M^+): 446.2117; found: 446.2127 (1), 373 (37), 337 (100), 293 (16), 263 (26), 215 (15), 121 (14), 73 (78); cims (NH_3): 464 (M^+ + 18, 8), 354 (15). *Anal.* calcd. for $C_{25}H_{34}O_5S$: C 67.23, H 7.67; found: C 67.14, H 7.74.

The thioacetal **18** shows the following properties: ir ($CHCl_3$, cast): 3512 (br), 3056, 1723, 1582 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 7.54 (2H, dd, 8, 1.5 Hz, Ar-H), 7.46 (2H, dd, 8, 1.5 Hz, Ar-H), 7.36–7.19 (6H, m, Ar-H), 4.99 (1H, s, H-14), 4.96 (1H, dd, 9.5, 5.75 Hz, H-12), 3.87–3.66 (4H, m), 3.66 (3H, s, C-18 OCH_3), 2.83 (1H, ddd, 15.5, 6.75, 5.5 Hz, H-11), 2.51 (1H, s, D_2O exchangeable), 2.1 (1H, dd, 10, 3 Hz, H-5), 2.05 (1H, dd, 7, 2.75 Hz, H-9), 1.82 (1H, ddd, 15.5, 9.5, 2.75 Hz, H-11), 1.95–1.16 (10H, m), 1.1 (3H, s, C-4 CH_3), 0.83 (3H, s, C-10 CH_3).

A solution of the thioacetal **18** (189 mg) and trifluoroacetic acid (1 drop) in CH_2Cl_2 (2 mL) was stirred at room temperature for 78 h. The reaction was worked up and purified as described above to yield the hemithioacetals **17***a* and **17***b* (172 mg) as an oil. The overall yield from the ketoperoxide **6***a* is 75%.

*(1S,5R,6R,9R,13R)-1,5-Dimethyl-9-ethylenedioxymethyl-5-methoxycarbonyl-10-oxatricyclo[7.4.0.0.^{9,13}]tridec-11-ene (**14**a)*

A solution of *m*-chloroperbenzoic acid (188 mg) in CH_2Cl_2 (3 mL) was added to a cooled solution (ice bath) of hemithioacetals **17** (468 mg) in CH_2Cl_2 (8 mL). The solution was stirred for 15 min, then diluted with CH_2Cl_2, and washed with saturated $NaHCO_3$, brine, dried ($MgSO_4$), and evaporated *in vacuo* to give the corresponding sulfoxides (462 mg) as an oil.

A solution of the sulfoxides (462 mg) and triethylphosphite (0.89 mL) in 10 mL of xylenes was refluxed for 2½ h under nitrogen. The solvent was removed azeotropically with benzene in the rotary evaporator. The residue was purified by flash chromatography (Skellysolve B – ethyl acetate, 65:35) to give the enol ether **14***a* (225 mg, 65% overall yield) from the hemithioacetals) as a solid. An analytical sample was obtained by recrystallization from Skellysolve B – diisopropyl ether; mp 93–95°C; ir (CH_2Cl_2, cast): 3080, 1723, 1585, 1246 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 6.4 (1H, t, 3.25 Hz, H-12), 5.31 (1H, s, H-14), 5.17 (1H, t, 2.5 Hz, H-11), 4.06–3.76 (4H, m), 3.67 (3H, s, C-18 OCH_3), 3.06 (1H, br s, H-9), 2.42 (1H, dt, 12,

3.25 Hz, H-7β), 1.91–1.18 (10H, m), 1.17 (3H, s, C-4 CH_3), 1.08 (3H, s, C-10 CH_3); ^{13}C nmr ($CDCl_3$) δ: 178.7 (s, C-18), 147.8 (d, C-12), 104.9 (d, C-14), 101.7 (d, C-11), 88.9 (s, C-8), 65.5 (t), 65.0 (t), 64.5 (d, C-9), 51.9 (q, C-18 OCH_3), 51.4 (d, C-5), 46.9 (s, C-4), 39.3 (t), 37.2 (t), 36.2 (s, C-10), 34.6 (t), 23.6 (t), 17.7 (t), 17.5 (q), 15.5 (q); hrms, *m/z* calcd. for $C_{19}H_{28}O_5$ (M^+): 336.1929; found: 336.1936 (0.2), 263 (22), 262 (12), 203 (30), 121 (11), 95 (10), 81 (39), 73 (100); cims (NH_3): 354 (M^+ + 18, 24), 337 (100). *Anal.* calcd. for $C_{19}H_{28}O_5$: C 67.83, H 8.39; found: C 67.55, H 8.28.

*12,12-Ethylenedioxy-8α-hydroxy-4α-methoxycarbonyldriman-11-al (**19**)*

A solution of the enol ether **14***a* (125 mg) in dichloromethane–methanol (10 mL, 1:1) was cooled in a Dry Ice – acetone bath. Ozone was bubbled through the solution until a pale blue color appeared. Excess ozone was removed with nitrogen. Methyl sulfide (0.06 mL) was added and the reaction mixture was allowed to warm to room temperature. The solvent was evaporated and the residue dissolved in CH_2Cl_2, washed with H_2O, brine, dried ($MgSO_4$), and evaporated *in vacuo* to give the β-hydroxyaldehyde **19** (124 mg, 98%) as a solid. An analytical sample was obtained by recrystallization from Skellysolve B – ethyl acetate; mp 120–121°C; $[\alpha]_D$ −52.8° (*c* 0.13, $CHCl_3$); ir (CH_2Cl_2, cast): 3505 (br), 2755, 1720, 1253 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 9.92 (1H, d, 3 Hz, H-11), 5.26 (1H, s, H-12), 4.08–3.86 (4H, m), 3.68 (3H, s, C-13 OCH_3), 2.97 (1H, s, D_2O exchangeable), 2.17 (1H, d, 3 Hz, H-9), 2.15 (1H, dd, 10, 3 Hz, H-5), 1.99 (1H, br d, 13 Hz), 1.82–1.10 (9H, m), 1.29 (3H, s, C-10 CH_3), 1.19 (3H, s, C-4 CH_3); hrms, *m/z* calcd. for $C_{18}H_{18}O_6$ (M^+): 340.1878; found: 340.1885 (2), 322 (2), 295 (14), 267 (9), 207 (10), 121 (8), 73 (100); cims (NH_3): 358 (M^+ + 18, 100), 341 (M^+ + 1, 11). *Anal.* calcd. for $C_{18}H_{28}O_6$: C 63.51, H 8.29; found: C 63.13, H 8.27.

*(1S,5R,6R,9R,13R)-1,5-Dimethyl-9-ethylenedioxymethyl-5-hydroxymethyl-10-oxa-11-phenylthiotricyclo[7.4.0.0.^{9,13}]tridecane (**20**)*

A solution of **17***a* and **17***b* (849 mg) in THF (4 mL) was added slowly to a suspension of $LiAlH_4$ (144 mg) in THF (2 mL) cooled in an ice bath. The suspension was stirred for ½h at 5°C, then 1 h at room temperature. The excess $LiAlH_4$ was destroyed by careful addition of H_2O (0.15 mL), 15% NaOH (0.15 mL), H_2O (0.45 mL). The slurry was vigorously stirred until a fine solid formed, dried ($MgSO_4$), and filtered. The white solid was washed with ether (3×), and the solvent removed *in vacuo* to yield the epimeric mixture of alcohols **20** (730 mg, 92%) as a colorless oil; ir (CH_2Cl_2, cast): 3436 (br), 3050, 1580 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 5.34 (0.2H, s, H-14), 5.25 (0.8H, s, H-14), 3.37 (1H, br d, 11 Hz, H-18), 3.11 (1H, br d, 11 Hz, H-18), 1.04 (0.6H, s, C-10 CH_3), 0.93 (2.4H, s, C-10 CH_3), 0.80 (0.6H, s, C-4 CH_3), 0.77 (2.4H, s, C-4 CH_3); hrms, *m/z* calcd. for $C_{24}H_{34}O_4S$ (M^+): 418.2168; found: 418.2177 (1), 345 (44), 309 (98), 265 (19), 247 (21), 235 (35), 217 (26), 110 (15), 73 (100).

*(1S,5R,6R,9R,13R)-1,5-Dimethyl-9-ethylenedioxymethyl-5-formyl-10-oxa-11-phenylthiotricyclo[7.4.0.0.^{9,13}]tridecane (**21**)*

A solution of the epimeric mixture of alcohols **20** (414 mg) in CH_2Cl_2 (5 mL) was added to a suspension of pyridinium chlorochromate (18) (373 mg) in CH_2Cl_2 (10 mL). The suspension was stirred for 1½h at room temperature, then diluted with ether (30 mL). The reaction mixture was decanted and the sticky oil washed with ether (3×) until it turned solid. The combined organic extracts were filtered through a pad of Florisil and evaporated to give aldehyde **21** (373 mg, 90%) as an oil. The ^1H nmr spectrum of the product shows signals for two epimers in a ratio of about 4:1. The mixture shows the following properties: ir (CH_2Cl_2, cast): 3050, 2680, 1723, 1580 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 9.22, 9.17 (1H, s, H-18), 5.29, 5.19 (1H, s, H-14), 1.09, 1.05, 1.03, 0.94 (6H, s, C-4 and C-10 CH_3); hrms, *m/z* calcd. for $C_{24}H_{32}O_4S$ (M^+): 416.2012; found: 416.2021 (2), 343 (30), 307 (100), 233 (29), 73 (77).

*(1S,2R,3R,6S)-1,7,7-Trimethyl-2-ethyl-3-ethylenedioxymethyl-3-hydroxybicyclo[4.4.0]decane (**22**)*

A mixture of the aldehydes **21** (20 mg), ethanol (0.1 mL), 95% hydrazine (0.1 mL), and KOH (0.2 g) in ethylene glycol (2 mL) was placed in an oil bath and warmed slowly to 150°C under nitrogen. After 3 h at 150°C the condenser was replaced with a short distillation column and the temperature was increased to 210°C. The reaction mixture was stirred for 5 h at this temperature during which time a few drops of colorless liquid distilled off. The solution was cooled, diluted with H_2O, and extracted with ether. The combined extracts were washed with H_2O, brine, dried ($MgSO_4$), and evaporated *in vacuo* to give a complex mixture (12.8 mg) as an oil. Purification by flash chromatography (Skellysolve B – ethyl acetate 7:3) gave the alcohol **22** (1.2 mg) as an oil; ir (CH_2Cl_2, cast): 3565 (Br), 1387, 1364, 1340, 1118, 1059, 1045, 1020, 963, 947 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 5.1 (1H, s, H-14), 4.13–3.85 (4H, m), 2.67 (1H, s, D_2O exchangeable), 2.23 (1H, dt, 11.5, 3 Hz, H-7β), 1.99 (1H, complex), 1.78–1.16 (12H, m), 1.01 (3H, t, 7.5 Hz, CH_3-12), 0.87 (6H, s), 0.81 (3H, s); hrms, *m/z* calcd. for $C_{15}H_{27}O$ (M^+ − $C_3H_5O_2$): 223.2055; found: 223.2062 (100), 205 (86), 137 (40), 123 (15), 109 (13), 99 (15), 95 (17), 83 (11), 73 (96); cims (NH_3): 314 (M^+ + 18, 100), 296 (M^+, 2), 279 (95), 235 (15), 217 (59).

(1S,5R,6R,9R,13R)-1,5-Dimethyl-9-ethylenedioxymethyl-5-formyl-10-oxa-11-phenylthiotricyclo[7.4.0.0.^{9,13}]tridecane p*-toluenesulfonyl hydrazone (**23**)*

A solution of the mixture of aldehydes **21** (96 mg) and *p*-tosylhydrazine (48 mg) in 98% ethanol (0.5 mL) was refluxed for 1 h under a nitrogen atmosphere. The reaction mixture was diluted with methanol and the solvent removed *in vacuo* to yield **23** (4:1 mixture of epimers) as a white solid showing the following properties: ir (CH_2Cl_2, cast): 3195, 3058, 1597, 1584, 1359, 1169, 1120, 1022, 814, 738, 696, 579, 549 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 6.85, 6.81 (1H, s, H-18), 5.25, 5.16 (1H, s, H-14), 2.44 (3H, s, Ar-CH_3), 1.0, 0.97 (3H, s), 0.98, 0.89 (3H, s); hrms, *m/z* calcd. for $C_{28}H_{35}N_2O_3S_2$ (M^+ − $C_3H_5O_2$): 511.2079; found: 511.2089 (1), 327 (25), 291 (89), 217 (28), 109 (20), 91 (52), 73 (100).

*(1S,6S,9R,11R,13R)-9-Ethylenedioxymethyl-10-oxa-11-phenylthiotricyclo[7.4.0.0.^{9,13}]tridecane (**24**a) and (1S,6S,9R,11S,13R)-9-ethylenedioxymethyl-10-oxa-11-phenylthiotricyclo[7.4.0.0.^{9,13}]-tridecane (**24**b)*

A. From the tosylhydrazone 23

A flamed three-necked round-bottom flask was charged with benzoic acid (115.3 mg, 9.44 mmol) and chloroform (1.5 mL) in a nitrogen atmosphere. The solution was cooled in an ice bath. A 1 M BH_3–THF solution (0.47 mL, 0.47 mmol) was added slowly by syringe to the cool solution, and the mixture was stirred for ½h. A solution of the tosylhydrazone **23** (135 mg, 0.231 mmol) in chloroform (2.5 mL) was added to the hydride reagent and stirred for 1 h in the ice bath, then $NaOAc \cdot 3H_2O$ (64 mg, 0.47 mmol) was added and the ice bath removed. The solution was diluted with DMSO (2 mL), then refluxed for 1 h under a nitrogen atmosphere. The reaction mixture was diluted with CH_2Cl_2, washed with 5% Na_2CO_3 (3×), brine, dried ($MgSO_4$), and evaporated in the rotavaporator to yield an oil. Purification by flash chromatography (Skellysolve B – ethyl acetate, 85:15) afforded the β-hemithioacetal **24***a* and α-hemithioacetal **24***b* (43 mg, 46% from the aldehyde), each as an oil that solidified in the refrigerator.

The β-hemithioacetal **24***a* was recrystallized from methanol–acetone; mp 98.5–99.5°C; $[\alpha]_D$ +65° (*c* 0.21, $CHCl_3$); ir (CH_2Cl_2, cast): 3045, 1583, 1390, 1380 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 7.5 (2H, dd, 8, 1.5 Hz, Ar-H), 7.34–7.26 (2H, m, Ar-H), 7.19 (1H, tt, 7.5, 1.5 Hz, Ar-H), 5.56 (1H, dd, 9, 6 Hz, H-12), 5.35 (1H, s, H-14), 4.40 (1H, complex), 4.08–3.76 (1H, complex), 2.44 (1H, m), 2.37 (1H, ddd, 14, 11.5, 9 Hz, H-11β), 2.15 (1H, dt, 11, 6 Hz, H-11α), 1.73 (1H, dd, 14, 6 Hz, H-9), 1.84–0.98 (10H, m), 0.98 (3H, s), 0.87 (3H, s), 0.84 (3H, s); ^{13}C nmr (100 MHz, $CDCl_3$) δ: 138.2 (s, Ar), 129.8 (d, Ar, 2×), 128.8 (d, Ar, 2×), 126.0 (d, Ar-C), 105.5 (d, C-14), 89.4 (d, C-12), 84.3 (s, C-8), 66.5 (t), 64.8 (t), 62.1 (d, C-9), 57.5 (d, C-5), 42.5 (t), 40.1 (t), 36.8 (t), 36.4 (s, C-10), 33.4 (q, C-18), 33.2 (s, C-4), 31.5 (t), 20.9 (q, C-19), 20.8 (t), 18.6 (t, C-2), 15.9 (q, C-20); hrms, *m/z* calcd. for $C_{24}H_{34}O_3S$ (M^+): 402.2219; found: 402.2228 (2), 329 (40), 293 (100), 219 (31), 149 (38), 73 (72). *Anal.* calcd. for $C_{24}H_{34}O_3S$: C 71.60, H 8.51; found: C 71.48, H 8.39.

A pure sample of the α-hemiacetal **24***b* was obtained by recrystallization from acetone; mp 123–124°C; $[\alpha]_D$ −96°C (*c* 0.32, $CHCl_3$);

ir (CH_2Cl_2, cast): 3045, 1580, 1396, 1379 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 7.54 (2H, dd, 8, 1.5 Hz, Ar-H), 7.36–7.24 (3H, m, Ar-H), 5.6 (1H, dd, 8, 1.5 Hz, H-12), 5.26 (1H, s, H-14), 4.07–3.80 (4H, complex), 2.68 (1H, ddd, 14.5, 11.75, 8.5 Hz, H-11β), 2.4 (1H, dt, 12, 3 Hz, H-7β), 1.79 (1H, ddd, 12, 7, 1.5 Hz, H-11α), 1.74 (1H, ddd, 14, 6.5, 3 Hz), 1.48 (1H, dd, 14.5, 7 Hz, H-9), 1.67–0.78 (3H, m), 0.89 (3H, s), 0.84 (3H, s), 0.8 (3H, s); ^{13}C nmr ($CDCl_3$) δ: 132.7 (s, Ar), 132.5 (d, Ar, 2×), 128.6 (d, Ar, 2×), 127.0 (d, Ar), 105.7 (d, C-14), 86.5 (d, C-12), 85.2 (s, C-8), 66.2 (t), 64.7 (t), 60.2 (d, C-9), 56.3 (d, C-5), 42.5 (t), 39.9 (t), 36.2 (t), 36.2 (s, C-10), 33.4 (q, C-18), 33.1 (s, C-4), 32.1 (t), 20.9 (q, C-19), 20.7 (t), 18.5 (t, C-2), 15.8 (q, C-20); hrms, *m/z* calcd. for $C_{24}H_{34}O_3S$ (M^+): 402.2219; found: 402.2228 (1), 329 (24), 293 (100), 219 (20), 73 (69). *Anal.* calcd. for $C_{24}H_{34}O_3S$: C 71.60, H 8.51; found: C 71.44, H 8.45.

In a separate experiment, catecholborane (1 mL, 9 mmol) was added to a solution of the tosylhydrazone **23** (prepared as described above from the aldehyde **21** (110 mg) and tosylhydrazine (501 mg)) in $CHCl_3$ (7 mL) cooled in an ice bath. The solution was stirred for 1½ h at 5°C, quenched with $NaOAc \cdot 3H_2O$ (2.34 g), then warmed to room temperature. The slurry was diluted with DMSO (2 mL) and refluxed for 2 h under a nitrogen atmosphere. Work-up and purification as described above gave the epimeric mixture of hemithioacetals **24***a* and **24***b* (355 mg, 36% from the aldehyde) as an oil.

*B. From the isopropylsulfonates of **20***

2-Propanesulfonyl chloride (0.14 mL, prepared as described (31)) was added to a solution of the epimeric mixture of alcohols **20** (105 mg) and triethylamine (0.43 mL) in ether (4 mL), cooled in a Dry Ice – CCl_4 bath. The reaction mixture was kept at −20°C for 2 h, then poured onto a cool solution of $NaHCO_3$. The oily product was extracted with CH_2Cl_2, washed with 10% HCl, saturated $NaHCO_3$, brine, dried ($MgSO_4$), and evaporated to give an oil. Purification by flash chromatography (Skellysolve B – ethyl acetate, 3:2) afforded the isopropylsulfonates of alcohols **20** (112 mg) as a separable mixture of the C-12 epimers.

A 0.4 M solution of $LiEt_3BH$–THF (1.3 mL) was added to a solution of the isopropylsulfonates (68 mg) in toluene (1.5 mL). The reaction mixture was stirred in an oil bath (90°C) for 6 h, then cooled and a drop of H_2O added. The reaction mixture was diluted with ether, washed with $NaHCO_3$, H_2O, brine, dried ($MgSO_4$), and the solvent removed to give an oil (45 mg). Purification by flash chromatography (Skellysolve B – ethyl acetate, 85:15) afforded the hemithioacetals **24***a* and **24***b* (33.6 mg, 64%) as an oil that shows the same spectroscopic properties as above.

*(1S,6S,9R,13R)-9-Ethylenedioxymethyl-10-oxa-1,5,5-trimethyltricyclo[7.4.0.0.^{9,13}]tridec-11-ene (**25**)*

A solution of *m*-chloroperbenzoic acid (260 mg, 1.5 mmol) in CH_2Cl_2 (10 mL) was added to a cooled solution (ice bath) of the hemithioacetals **24***a* and **24***b* (606 mg, 1.5 mmol) in CH_2Cl_2 (10 mL). The reaction mixture was stirred for 15 min at 5°C, diluted with CH_2Cl_2, washed with saturated $NaHCO_3$, brine, dried, and the solvent evaporated *in vacuo* to give the sulfoxides (611 mg) as an oil. A solution of the crude sulfoxides and triethylphosphite (0.75 mL) in xylene (10 mL) was refluxed for 4 h under nitrogen. The solvent was removed azeotropically with benzene. The residue was purified by flash chromatography (Skellysolve B – ethyl acetate, 3:1) to give the enol ether **25** (287 mg, 65%) as a solid; ir (KBr): 3089, 1592, 1387, 1369 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 6.47 (1H, t, 3.5 Hz, H-12), 5.39 (1H, s, H-14), 5.23 (1H, m, H-11), 4.12–3.82 (4H, complex), 3.02 (1H, br s, H-9), 2.51 (1H, dt, 12, 3 Hz, H-7β), 1.91–1.0 (10H, m), 1.05 (3H, s), 0.89 (3H, s), 0.84 (3H, s); ^{13}C nmr ($CDCl_3$) δ: 147.7 (d, C-11), 105.3 (d, C-14), 102.2 (d, C-12), 89.2 (s, C-8), 65.5 (t), 65.0 (t), 64.8 (d, C-9), 57.1 (d, C-5), 42.8 (t), 40.3 (t), 36.8 (s, C-10), 35.3 (t), 33.5 (q, CH_3-18), 33.2 (s, C-4), 21.4 (t), 20.7 (q, CH_3-19), 18.6 (t, C-2), 17.5 (q, CH_3-30); hrms, *m/z* calcd. for $C_{18}H_{28}O_3$ (M^+): 292.2031; found: 292.2038 (2), 219 (30), 125 (14), 81 (46), 73 (100).

*12,12-Ethylenedioxy-9α-hydroxydrim-7-en-11-al (**28**)*

A solution of the enol ether **25** (62.3 mg) in ethyl acetate (6 mL) was cooled in a Dry Ice – acetone bath. Ozone was bubbled through the solution until a pale blue color appeared. Excess ozone was removed with nitrogen. Triethylphosphite (0.1 mL) was added and the reaction mixture allowed to reach room temperature. The solvent was evaporated *in vacuo* and the residue left under vacuum for 2 h. The formate **26** was identified by its ^1H nmr spectrum (100 MHz, $CDCl_3$) δ: 9.88 (1H, d, 3 Hz, H-11), 8.24 (1H, s, OCHO), 5.51 (1H, s, H-14), 2.83 (1H, d, 3 Hz, H-9), 1.29 (3H, s, CH_3-15), 0.9 (3H, s), 0.85 (3H, s).

A solution of the crude formate **26** and DBU (0.063 mL) in dry benzene (3 mL) was refluxed under argon for 1½ h. The reaction mixture was diluted with ether, washed with 10% HCl, $NaHCO_3$, brine, dried ($MgSO_4$), and the ether evaporated *in vacuo* to give a mixture of unsaturated aldehydes **27** (50.4 mg). In a flame-dried three-neck, round-bottom flask, fitted with an L-shaped tube, a nitrogen line, and a septum, was placed a 35% KH emulsion (50 mg). The oil was removed with Skellysolve B, and THF (1 mL) was added. The flask was cooled in an ice bath, then the crude aldehydes in THF (1 mL) were added slowly to the slurry and the mixture stirred for 2 h at 5°C. Oxodiperoxymolybdenum(pyridine)-hexamethylphosphoramide (MoOPH, 118 mg, Aldrich Chemicals) was placed in the L-shaped tube and the flask was cooled in a Dry Ice – acetone bath. The MoOPH was added all at once, and the suspension stirred vigorously, then warmed slowly to −55°C (Dry Ice – acetonitrile) and stirred for 1 h. The bath was removed and the reaction was quenched with 10% Na_2SO_3 (1 mL) at 0°C. The two-phase solution was stirred until no change in color in the organic layer was observed. The two phases were separated and the aqueous layer was extracted with ether, washed with H_2O, brine, and dried ($MgSO_4$). The ether solution was filtered and evaporated *in vacuo* to yield the crude hydroxyaldehyde **28** (37.5 mg). Purification by flash chromatography (dichloromethane–acetone, 97:3) gave the hydroxyaldehyde **28** as a solid: ir (CH_2Cl_2, cast): 3460, 1713, 1387, 1362, 1111 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 9.85 (1H, d, 1 Hz, H-11), 6.36 (1H, dd, 5, 2.5 Hz, H-7), 5.22 (1H, s, H-12), 3.9 (1H, d, 1 Hz, D_2O exchangeable), 3.99–3.85 (4H, m), 2.28 (1H, dt, 19, 5 Hz, H-6α), 2.11 (1H, ddd, 19, 12, 2.5 Hz, H-6β), 1.89 (1H, dd, 12, 4 Hz, H-5), 1.77 (1H, td, 13, 4.5 Hz), 1.53 (1H, dt, 13.5, 3 Hz), 1.49–1.0 (4H, m), 1.22 (3H, s), 0.97 (3H, s), 0.91 (3H, s); ^{13}C nmr ($CDCl_3$) δ: 203.5 (d, C-11), 136.6 (d, C-7), 134.2 (s, C-8), 106.1 (d, C-12), 77.9 (s, C-9), 64.8 (t), 64.5 (t), 41.6 (d, C-5), 41.5 (t), 41.4 (s, C-10), 33.1 (q, C-13), 33.0 (s, C-4), 31.9 (t), 24.3 (t), 22.2 (q, C-14), 18.0 (t, C-2), 17.2 (q, C-15); hrms, *m/z* calcd. for $C_{17}H_{26}O_4$ (M^+): 294.1824; found: 294.1831 (6), 276 (2), 266 (11), 265 (58), 221 (10), 109 (23), 73 (100).

*Warburganal (**2**)*

A solution of the crude hydroxyaldehyde **28** (37.5 mg) and a catalytic amount of *p*-toluenesulfonic acid in acetone (4 mL) was stirred at room temperature for 1 h. The reaction was quenched with saturated $NaHCO_3$ (1 drop), the solvent removed, and the residue diluted with CH_2Cl_2. The organic solution was washed with saturated $NaHCO_3$, brine, dried ($MgSO_4$), and evaporated *in vacuo* to give the crude product (30.4 mg) as an oil. Purification by flash chromatography (CH_2Cl_2–acetone, 97:3) gave an impure sample of polygodial (3.9 mg) and warburganal (**2**) (7.5 mg, 14% overall yield from the enol ether **25**) as a solid. Recrystallization from Skellysolve B provided material, mp 106–107°C (lit. (6) mp 107–108°C, (28) mp 106–107°C); $[\alpha]_D$ −243° (*c* 0.037, $CHCl_3$); (lit. (6) $[\alpha]_D$ −263°); ir (CH_2Cl_2, cast): 3479, 1720, 1682, 1638, 1360, 1357, 1129, 803 cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 9.76 (1H, d, 1 Hz, H-11), 9.43 (1H, s, H-12), 7.28 (1H, dd, 5, 2.5 Hz, H-7), 4.09 (1H, d, 1 Hz, D_2O exchangeable), 2.59 (1H, dt, 21.5, 5 Hz, H-6α), 2.35 (1H, ddd, 21.5, 12, 2.5 Hz, H-6β), 1.9 (1H, dd, 12, 5 Hz, H-5), 1.75–1.22 (6H, m), 1.1 (3H, s), 1.0 (3H, s), 0.95 (3H, s); ^{13}C nmr ($CDCl_3$) δ: 202.0 (d, C-12), 192.5 (d, C-11), 157.2 (d, C-7), 140.5 (s, C-8), 77.1 (s, C-9), 41.7 (d, C-5), 41.4 (s, C-10), 41.3 (t, C-3), 33.0 (s, C-4), 33.0 (q, C-13), 31.2 (t, C-1), 25.9 (t, C-6), 22.0 (q, C-14), 17.7 (t, C-2), 17.0 (q, C-15); hrms, *m/z* calcd. for $C_{15}H_{22}O_3$ (M^+): 250.1563; found: 250.1569 (8), 232 (7), 222 (31), 221 (92), 189 (18), 124 (43), 123 (20), 109 (100), 104 (41), 91 (26), 69 (42).

The reactions of simple dimethylallylamines with dimethyl acetylenedicarboxylate. Formation of 1-dimethylamino-2-allylmaleates via formal allyl transfer[1]

ADRIAN L. SCHWAN[2] AND JOHN WARKENTIN[3]

Department of Chemistry, McMaster University, 1280 Main Street West, Hamilton, Ont., Canada L8S 4M1

Received January 13, 1988

ADRIAN L. SCHWAN and JOHN WARKENTIN. Can. J. Chem. **66**, 1686 (1988).

Tertiary amines bearing two methyl groups and an allylic substituent (X) react with dimethyl acetylenedicarboxylate (DMAD) to afford the corresponding 1-dimethylamino-2-X′ maleates, in which X′ is the allylic isomer of X. The mechanism postulated involves reversible formation of a zwitterion by attack of the amine at an *sp*-carbon of DMAD. The zwitterion then undergoes intramolecular allyl transfer, through a 6-membered transition state. Evidence for a zwitterionic intermediate (quaternary ammonium allenolate) includes capture of the allenolate centre by intramolecular addition to a carbonyl group and by proton transfer from chloroform.

ADRIAN L. SCHWAN et JOHN WARKENTIN. Can. J. Chem. **66**, 1686 (1988).

Les amines tertiaires qui portent deux groupements méthyles et un substituant allylique (X) réagissent avec l'acétylènedicarboxylate de diméthyle (ADDM) pour fournir les maléates correspondants, diméthylamino-1 X′-2 maléates, dans lesquels le groupement X′ est l'isomère allylique de X. Le mécanisme postulé implique la formation réversible d'un zwitterion par l'attaque de l'amine sur le carbone-*sp* de l'ADDM. Le zwitterion subit alors un transfert allylique intramoléculaire par le biais d'un état de transition à six chaînons. Les données supportant l'hypothèse de l'existence d'un zwitterion comme intermédiaire (allènolate d'ammonium quaternaire) comportent la capture du centre allènolate par une addition intramoléculaire sur un groupement carbonyle ainsi qu'un transfert de proton à partir du chloroforme.

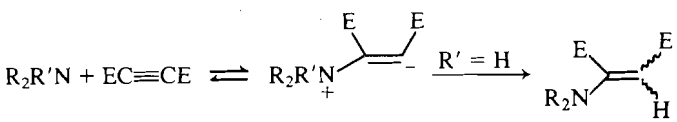
[Traduit par la revue]

Introduction

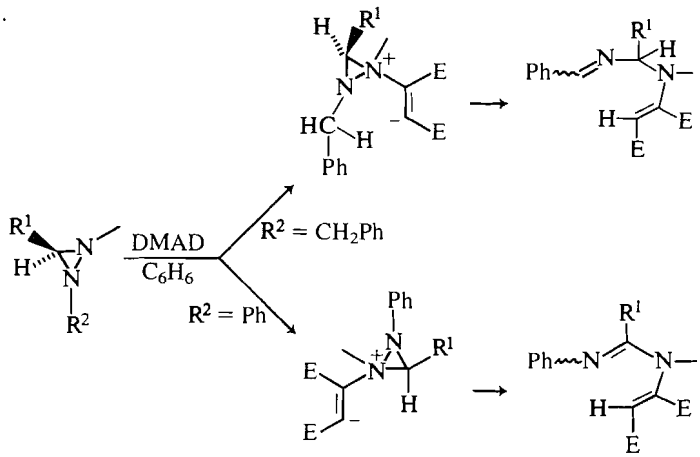
There are few publications concerning the reactions of tertiary amines with dimethyl acetylenedicarboxylate (DMAD), but those reports that do exist are rather interesting (1, 2). Whereas DMAD and primary or secondary amines usually give Michael adducts via a series of proton transfers after initial encounter, this possibility is precluded with tertiary amines, and other transformations must take place to give non-ionic products. Scheme 1 suggests that, in all cases, products result from initial formation of a zwitterion such as **1**.

Two main types of reactions are known to take place when **1** results from a tertiary amine. One involves the intramolecular abstraction of a proton by the anionic end of the zwitterion with subsequent migration of one or more bonds to restore the nitrogen atom to neutrality. Carrié and co-workers (3) used that chemistry in ring-opening reactions of diaziridines (Scheme 2). Other authors have suggested a similar deprotonation step to account for their observed products (4–8).

The second major reaction available to **1** is the intramolecular

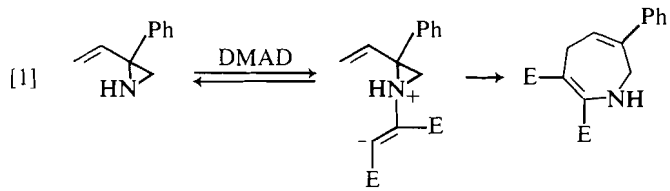


SCHEME 1



SCHEME 2

attack of the anionic end on a suitably situated electrophilic centre on one of the other groups attached to the nitrogen. Carbonyl groups have been shown to be appropriate electrophiles (7, 10).[4] The work of Hassner and co-workers (reaction [1]) provides an illustration of the attack on another



functionality (11). One of their proposals is that the ring opening depicted in reaction [1] is fast enough to preclude Michael adduct formation by proton transfer (11). Similar rearrangements have been demonstrated using propiolate esters (8, 12–15).

The double bond migrations exemplified by reaction [1] are accompanied by a second simultaneous transformation that makes the overall rearrangement energetically favourable (8, 11–15). In some cases there is release of ring strain accompanying the double bond migration (11, 14, 15), while in other instances a suitably disposed methoxy group aids in the migration of the double bond and in the overall neutralization of the nucleophilic nitrogen (8, 12, 13) (reaction [2]).

[2] 
These transformations caught our attention and we wondered if the structurally specialized systems are necessary for the success of the reaction. This curiosity led us to investigate the chemistry of DMAD and simple dimethylallyl amines.

Results

Several dimethylallyl amines of the general structure **1** were synthesized. Refluxing these amines with one equivalent of DMAD in CH_3CN gave a series of 1-dimethylamino-2-allyl maleates **2** in all but two cases (**2***e*, **2***f*) (reaction [3]). These

products were identified from their proton and carbon nmr data as well as from infrared and mass spectra. The maleate geometry was assigned with the aid of mechanistic arguments (see Discussion).

The geometry of the 2-butenyl moiety of **2***b* could not be assigned readily by measuring the coupling constants of the vinyl protons because a 500-MHz nmr instrument was incapable of separating the vinyl proton signals. Therefore a different criterion had to be employed. The ^{13}C nmr chemical shift of the methyl group of the 2-butenyl side chain was found to be 18.6 ppm. This correlates well with *trans*-2-butene and *trans*-2-octene whose sp^2-bonded methyl carbons resonate at 17.3 and 19 ppm respectively (16). The methyl signals of the *cis* analogs appear at 10.6 ppm (*cis*-2-butene) and 13 ppm (*cis*-2-octene) (16). Comparison to these data allowed us to assign the geometry of the 2-butenyl portion of **2***b* as *trans*.

Product **2***g* was obtained as an inseparable mixture of fumarate and maleate isomers. The ^1H nmr spectrometry indicated that the ratio was 3:1. The major isomer was assigned the fumarate geometry on the following basis. Dimethylamino groups have been shown to shield protons on substituents *cis* to them. That is, in instances where geometric isomers have been obtained and their ^1H nmr spectra have been recorded, the protons on substituents *cis* to the dimethylamino moiety resonated at higher field than those *trans* to the dimethylamino group (17, 18). The methine proton of the major isomer of the mixture (**2***g*) resonated at 3.47 ppm while the signal from the analogous proton of the minor isomer was found at 2.92 ppm. This is consistent with the dimethylamino group situated *cis* to the butenyl function of the minor isomer of **2***g*.

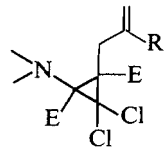
The other criterion for differentiating between the two isomers is the chemical shifts of the methoxyl protons of butenedioic esters. The signals of the methoxyl protons of methyl maleates are found slightly downfield from those of the fumarates (19–21). The methoxyl peaks in the ^1H nmr spectrum of the minor isomer of **2***g* were found at 3.61 and 3.72 ppm while those of the major isomer appeared at 3.56 and 3.69 ppm. These two criteria allow confident assignments to be made of the identities of the geometric isomers **2***g*.

A product common to all of the reaction mixtures is the previously synthesized dimethylamino maleate **3** (21). Facile separation of reaction components by column chromatography permitted determination of the yields of products **2** and **3** in each reaction (Table 1). The aminoallylation products **2**, obtained as oils, are all new compounds. A significant amount of coloured by-product remained at the top of the chromatography column in each case.

Benzyldimethylamine (**4**) was also treated with DMAD in CH_3CN but only dimethylamino maleate **3** and starting amine **4** were among the non-polar products recovered.

Some of the amines (**1***a–d*) were also treated with 1 equivalent of DMAD in $CHCl_3$ at room temperature. Reaction times extended from 1 day to 6 weeks. Yields from reactions in $CHCl_3$ were very dependent upon initial concentrations. More concentrated solutions gave increased yields of **3**, in most cases, and lower yields of **2** (Table 2).

Amines **1***a* and **1***c* reacted with DMAD in $CHCl_3$ to afford **5***a* and **5***c*, respectively, as additional non-polar products. Both were isolated in low yields. In both solvents, DMAD was usually the limiting reagent and yields were therefore based on the amount of amine consumed. Amines **1***c* and **1***d* were also treated with DMAD in CH_2Cl_2 but lower yields of **2** were obtained in these cases (15% **2***c*, 10% **2***d*).



5*a* R = H
5*b* R = CH_3

Treatment of α-(dimethylaminomethyl)-isobutyrophenone (**6**) with DMAD in $CHCl_3$ gave heterocyclic alcohol **7** in 42% yield (reaction [4]). In deuteriochloroform, **7** (O—D) was

formed. The rate of formation of the hydroxylated product in $CHCl_3$ was 1.9 times the rate of formation of the deuterated analog in $CDCl_3$.

Discussion

We believe that the double bond migration or allyl transfer proceeds via a zwitterionic intermediate (e.g., **8**) as proposed by several other authors (1, 2, 8, 11–15). We choose to depict the anionic end of **8** as an allenolate anion rather than a vinyl anion in accord with results of recent calculations by Grein and co-workers (reaction [5]) (22).[5]

[5] **1** + DMAD 
→ **2**

8

[5]Also F. Grein, personal communication.

Strong evidence for the intramolecularity of this reaction lies in the fact that more dilute chloroform solutions lead to cleaner reaction mixtures (Table 1). If **8** were to lead to **2** via an intermolecular route (i.e., bimolecular in **8**), then the yield of **2** would be expected to be lowered significantly by dilution due to the greater likelihood of competitive side reactions such as proton abstraction from chloroform. Amine **1***b* gave solely allyl transfer product **2***b* and none of its *cis* isomer **12**. This result also lends credence to the proposed intramolecular mechanism (Scheme 3). Scheme 3 shows conformations **8***b* and **8***b*′ leading to **2***b* and to **12** by intramolecular transfer. Both must be viewed as having the N—C (allyl) bond approximately eclipsing the allyl π orbital, to permit good overlap for formation of the new π bond that develops in the allyl fragment during its transfer. Examination of models suggests that **8***b* is less congested that **8***b*′ and that **2***b* should therefore be the preferred product. Bimolecular self-reaction of zwitterion **8***b* could also lead to **2***b*, after deallylation of intermediate **9**, or to **12** after deallylation of **10**. Models for the intermolecular transfer suggest a preference for **9** rather than **10** and therefore for product **2** rather than **12**. However, the geometric requirements for bimolecular reactions are more relaxed with respect to the preference for **9** over **10**. Moreover, it is highly unlikely that intermediate **9** is dequaternized efficiently to **2** whereas the isomeric **10** is not dequaternized efficiently to **12**. Since **12** is not formed, the suggested

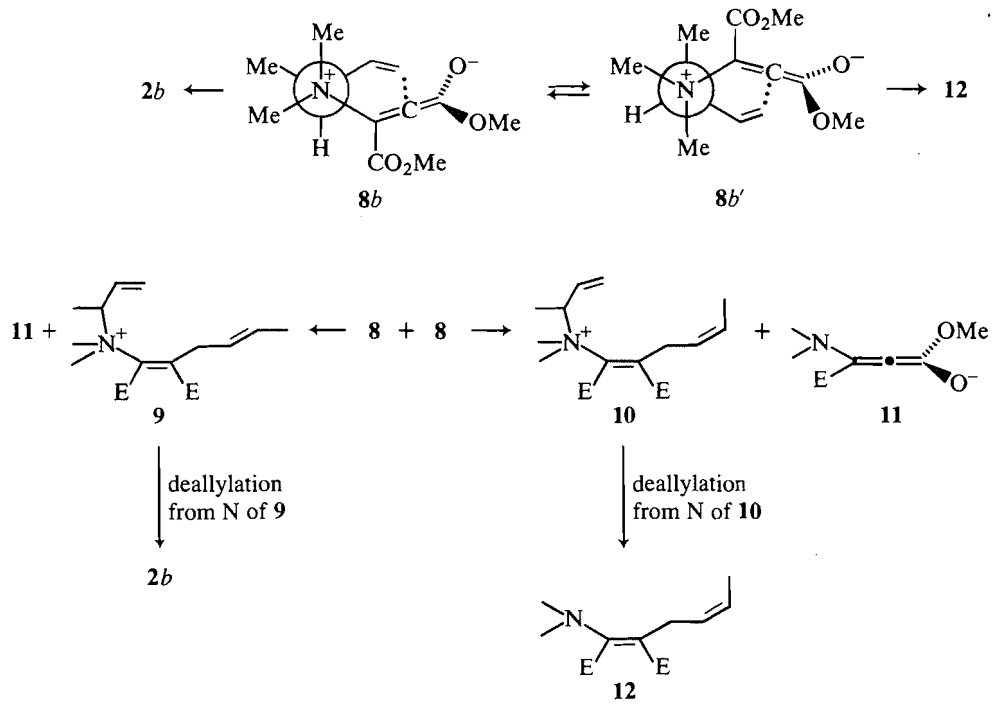
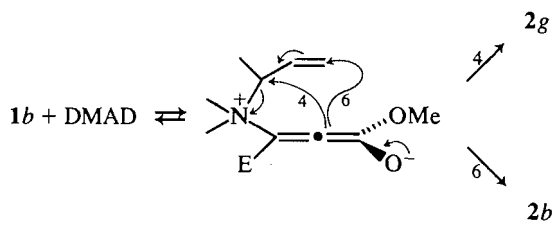
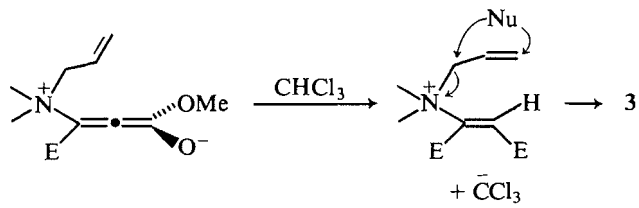


SCHEME 3



SCHEME 4



SCHEME 5

conclusion is that most (or all) of the allylic transfer occurs by an intramolecular mechanism. The only indication that intermolecular reactions, whatever they are, compete with intramolecular allyl transfer is the concentration dependence of the yields of **2** (Table 2).

The question as to whether there is a six-membered transition state or a four-membered transition state (Scheme 4) during the allyl transfer is also answered by analysis of the reaction products of amine **1***b* and DMAD. Maleate **2***b* was isolated whereas maleate **2***g* should have been the product of the allyl transfer if a four-membered transition state were involved. Also consistent with the proposed mechanism is the fact that **2***g* rather than **2***b* is the product when **1***g* is treated with DMAD.

Isomers **2***g* are the only allyl transfer products obtained as a mixture of fumarate and maleate esters. Presumably the additional steric bulk of the *sec*-butenyl substituent of **2***g* aids in the facile isomerization of the initial maleate product. The 3:1 isomer ratio was consistently present after work-up whether the reaction was carried out in CH_3CN for 1, 2, or 5.5 h, or in $CHCl_3$. The 3:1 ratio is probably the equilibrium composition.

The reaction proceeds more readily in CH_3CN than in $CHCl_3$ and the best conditions for the allyl transfer in $CHCl_3$ are dilute solution and low temperature. Consumption of starting materials may therefore take extended periods of time. A competing reaction in this solvent is deprotonation of $CHCl_3$ by the anionic end of the zwitterion (Scheme 5). The cation may then lose its allyl group to a nucleophile in solution, such as starting amine, via an S_N2 or S_N2' substitution with the aminomaleate as the leaving group. This would account for the significant amounts of **3** observed.

The lower average yields of **3** produced in CH_3CN as compared to those in $CHCl_3$ are probably attributable to the lower pK_a of $CHCl_3$ (24 (ref. 23)), compared to that of CH_3CN (31 (ref. 24)). We assume that the kinetic acidities of these solvents, which would be more suitable data for comparison, are different in the same sense.

The observation that the product resulting from deprotonation from the solvent (**3**) is the maleate rather than the fumarate deserves discussion. The maleate is more often obtained in a non-protic than in a protic solvent (25–27). Despite early recognition of this phenomenon, a satisfactory explanation has not been published. One theory is that the fumarate anion is formed initially and if there is no good proton transfer agent available (e.g., alcohol) it then inverts to the maleate anion, which undergoes subsequent reaction that may include deprotonation from $CHCl_3$ or CH_3CN (27, 28).

We postulate that the anion is allenic and has the option of adding an electrophile from either face of the enolate plane to give the maleate or the fumarate. A structure such as **13** depicts how maleate formation is preferred in $CHCl_3$. If the molecule of $CHCl_3$ to be deprotonated is situated "inside" the zwitterion, then it is between the ammonium and the allenyl moieties. This proximity to the ammonium nitrogen allows for a favourable coulombic interaction, which lowers the energy of the proton transfer transition state. The maleate geometry is a necessary result from alignment as in **13**. Formation of the fumarate ester

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12

13

has no such intramolecular stabilizing effect available. A similar explanation can be involved for deprotonation from CH_3CN. This explanation for maleate formation is similar to that proposed when the two addends deposited across the acetylene originate from one molecule (26).

In alcohols, which have pK_a values much lower than that of $CHCl_3$, as well as better H-bonding ability, the deprotonation is presumably very fast and the need for minimizing the separation of paired ions is much reduced. Consequently the protonation step in alcohols is governed, at least in part, by thermodynamics, and the fumarate product predominates.

The presence of trichloromethyl anion accounts for the formation of cyclopropanes **5***a* and **5***c*. The anion loses chloride ion to generate dichlorocarbene, which adds to the more nucleophilic double bond of maleates **2***a* and **2***c* (29). The stereochemistry of **5***a* and **5***c* in assigned as *cis* (diester), based on the geometries of the precursors **2***a* and **2***c*. We are unsure of the reason why similar cyclopropanes, derived from **2***b* and **2***d*, were not obtained. The greater efficiency of allyl transfer in the phenyl-substituted case and the lower amount of **3** formed in the case of **2***b* suggest that deprotonation of $CHCl_3$, and hence formation of dichlorocarbene, is less important in cases **2***b* and **2***d* than it is in cases **2***a* and **2***c*.

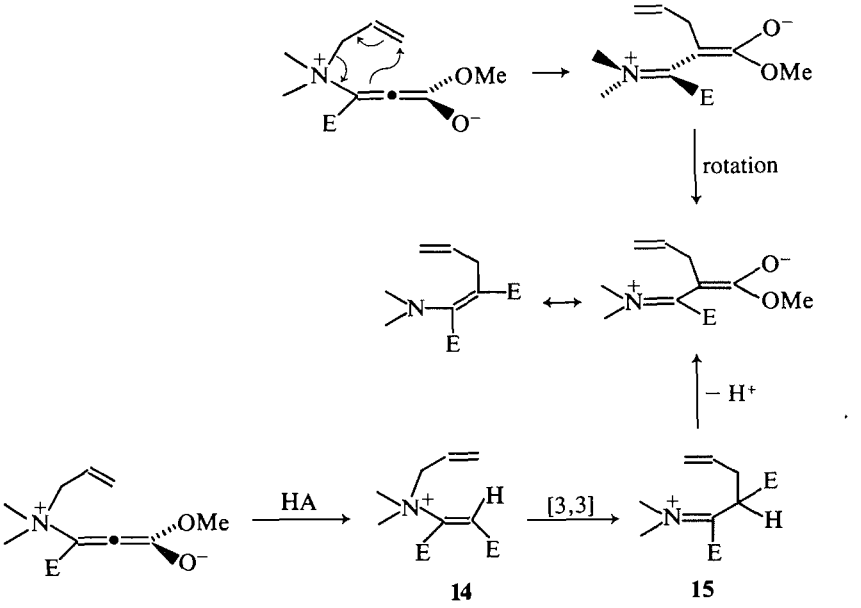
Amines **1***e* and **1***f* did not undergo the allyl transfer reaction on treatment with DMAD. Their failure to do so cannot be attributed to steric effects because steric hindrance cannot be larger in those cases than it is in the case of **1***c*. Electronic effects of the halogen substituents (in **1***e*, **1***f*) should not be very important either, because those substituents are effectively at the centre of an allylic fragment in the transition structure. The failure of **2***b* and **2***d* to react with DMAD in the expected way is surprising.

The allyl transfer reaction of **8** may be a [3,3]-sigmatropic rearrangement to a new zwitterion with orthogonal π-systems, followed by rotation (Scheme 6). Some heteroatomic species that are known to undergo [3,3]-sigmatropic rearrangement are zwitterions (8, 11–15), ammonium ions (30), and neutral maleates (31, 32).

In our cases, since the solvent was obviously being deprotonated, as indicated by the products derived from dichlorocarbene, the reaction environment is probably of an alkaline nature. This does not, however, eliminate the possibility that a species such as **14** (formed by deprotonation of $CHCl_3$) is doing the [3,3]-sigmatropic rearrangement (Scheme 6). Deprotonation of **15** would then produce **2**. It follows that the addition of a weak acid such as benzoic acid to the reaction mixture should enhance the yield of allyl transfer product if the mechanism of Scheme 6 were correct. The presence of benzoic acid (0.05 equiv.) led to a reduced rather than enhanced yield of **2***a* from **1***a*. The benzoic acid experiment therefore does not support the mechanism in which [3,3]-sigmatropic rearrangement of ammonium ion **14** plays a major role. On the other hand, the much lower yields of **2***c* and **2***d* obtained when CH_2Cl_2 was substituted for $CHCl_3$ as the solvent suggests that proton transfer from the solvent *is* important. As it is, we can offer no explanation for the $CHCl_3$–CH_2Cl_2 solvent dependence.

Benzyldimethylamine (**4**) did not undergo the rearrangement. Presumably the disruption of aromaticity requires too much energy, although neutral maleates have been shown to overcome similar barriers and to undergo [3,3]-sigmatropic rearrangements (26, 27).

The formation of alcohol **7** during the treatment of **6** with DMAD is another example demonstrating the nucleophilicity of the anionic portion of zwitterions such as **1**. Scheme 7 illustrates a mechanism that fits the evidence acquired. As in the other cases, formation of zwitterion **16** should be reversible. The next steps, to form **17** and **18**, are also best described as reversible for the following reason. The observed isotope effect on the rate of formation of **7** in $CHCl_3$ ($CDCl_3$) is 1.9. If the step **17** → **18** were rate determining and irreversible then the isotope effect at room temperature would be expected to be considerably larger, be-



14 15

SCHEME 6

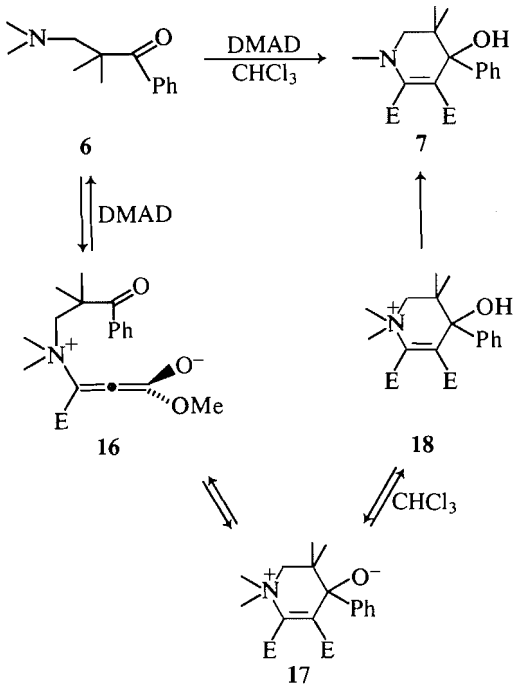

SCHEME 7

cause it would represent the primary kinetic isotope effect for proton transfer from carbon to oxygen. If that step is reversible, however, then the observed isotope effect represents an equilibrium isotope effect or a composite of kinetic and equilibrium isotope effects. If partial or total equilibration of **17** and **18** is granted, then the more likely equilibration of **17** with **16** follows.

Once ammonium ion **18** is formed, it can either be demethylated to give **7** or remain as a polar by-product. Trichloromethyl anion is not the demethylating agent since CH_3CCl_3 was not found in the reaction mixture. It is expected that chloride is not the demethylating agent either since ammonium chloride salts remain as such at room temperature rather than equilibrating with alkyl chlorides and amines. Therefore, the demethylating agent is probably starting amine and this would help to account for the low yield of non-polar products.

In summary, we have shown that a reaction that was previously applied to specialized systems can also be achieved in simple systems. The new products have potential in synthesis as highly functionalized dienophiles and dipolarophiles, either directly or after facile conversion to their respective *N*-phenylmaleimides (33). The formation of **7** illustrates the potential of the procedure for the synthesis of heterocycles.

Experimental

Melting points were determined on a Thomas Hoover capillary melting point apparatus and are uncorrected.

The ^1H nmr spectra were recorded on a Varian EM 390 or a Bruker AM 500 spectrometer. The ^{13}C nmr spectra were recorded on a Bruker WP 80/90, WH 250, or AM 500 spectrometer. Infrared spectra were obtained with a Perkin–Elmer model 283 instrument and were calibrated against the 1601.4 cm^{-1} band of polystyrene. Ultraviolet spectra were taken with a Hewlett–Packard model 8451/A diode array spectrophotometer. Analytical thin-layer chromatography was performed with plastic backed thin-layer neutral alumina plates (Merck Aluminiumoxid 60 F_{254}) of 0.2 mm thickness.

Chloroform was washed with H_2SO_4 and distilled from P_2O_5 before use. Methylene chloride was distilled from P_2O_5. Acetonitrile was dried by elution through a neutral Al_2O_3(I) column.

Allylamine, methallylamine, 40% aqueous dimethylamine, benzylamine, 3-chloro-1-butene, crotyl chloride, 2,3-dibromopropene, and 2,3-dichloropropene are all commercially available and were used as received. DMAD (Aldrich) was distilled under reduced pressure before use.

Amines **1***a* (34) and **1***f* (35) were prepared according to published procedures. Amines **1***c*, bp 81–83°C (lit. (36) bp 82–83.5°C), and **4**, bp 85°C (27 Torr; 1 Torr = 133.3 Pa), (lit. (36) bp 72–78°C (8 Torr)), were prepared from methallylamine and benzylamine, respectively, by using the Eschweiler–Clarke methodology employed for **1***a* (34).

1-Amino-2-butene and 3-amino-1-butene were prepared from their respective chlorides via the Gabriel synthesis (37). Amine **1***b* was then synthesized from 3-amino-1-butene via the Eschweiler–Clarke method (34), bp 87–88°C (lit. (38) bp 91°C). Similarly, **1***g* (90–95% pure) was prepared from 1-amino-2-butene, bp 95–96°C (lit. (39) bp 93°C). The impurity was found to be inert to DMAD.

Synthesis of amine ***1****c*

A 100-mL flask was charged with 8.92 g (0.080 mol) of 2,3-dichloropropene, 30 mL of 40% Me_2NH/H_2O, and 20 mL of MeOH. The solution was warmed at 60°C for 15 h. After cooling, 50 mL of 50% aqueous KOH was added and the solution was extracted with 2 × 40 mL of ether. The organic phases were combined and dried over KOH. After concentration (aspirator), the residue was dried once more over KOH and then distilled from KOH. The yield of **1***c* was 3.56 g (37%), bp 113–114°C (lit. (40) bp 119–120°C (755 Torr)).

Synthesis of amine ***1****d*

A 250-mL flask was charged with 100 mL of α-methylstyrene and 13.6 g (0.11 mol) of *tert*-butyl hypochlorite (Frinton). AIBN (0.25 g, 1.8 mmol) was added and the contents were warmed to 80°C for 4 h. After cooling, the contents were distilled under reduced pressure. The fractions collected above 70°C (6.5 Torr) were combined (≅ 20 mL) and dissolved in 170 mL of MeOH. The solution was stirred with ice cooling while 70 mL of 40% Me_2NH/H_2O was added dropwise over a period of 20 min. The ice bath was then removed and the contents were allowed to stir at room temperature for 16 h. The solution was then carefully added to 200 mL of ice-cooled aqueous HCl (6%). The aqueous solution was washed (3 × 70 mL) with ether and was then added dropwise to ice-cooled aqueous Na_2CO_3 (5%). After addition was complete, the solution was saturated with Na_2CO_3 and extracted (3 × 100 mL) with ether. The combined organic extracts were washed with brine and dried over $MgSO_4$.

After filtration and concentration, the residue was applied to an Al_2O_3(II) column and eluted with 10% ether in light petroleum. The only compound that was eluted was amine **1***d* (4.60 g, 27% yield overall); ^1H nmr (90 MHz, $CDCl_3$) δ: 2.24 (s, 6H), 3.27 (s, br, 2H), 5.19 (s, br, 1H), 5.42 (s, br, 1H), 7.24–7.60 (m, 5H); ^{13}C nmr (22.62 MHz, $CDCl_3$ at 77.20) δ: 145.35, 140.21, 128.27, 127.55, 126.27, 115.18, 64.52, 45.28; ms(ei) *m/z* (%): 161(30), 118(16), 115(15), 59(13), 58(100).

Reactions of DMAD with amines

In the general procedure the appropriate amine and one equivalent of DMAD were mixed together in a volume of solvent chosen to give the concentrations indicated in Tables 1 and 2. Air above the chloroform solutions was displaced with N_2 and the solutions were allowed to stand protected from light. The CH_3CN solutions were refluxed with a $CaCl_2$ drying tube attached to the condenser. When periodic ^1H nmr spectra of the mixtures indicated complete consumption of either reactant, the mixtures were worked up. Mixtures were separated as described below. Spectral data of all products of allyl transfer are in Tables 3–5.

Amine ***1****a and DMAD*

After removal of solvent (aspirator), the residue was applied to a column containing basic Al_2O_3(II). Elution with 50% ether in light petroleum provided three components from reactions with $CHCl_3$ as solvent and two components from reactions with CH_3CN as solvent. Product **5***a* was eluted first (R_f 0.79, 50:50 ether:petroleum) followed by **2***a* (R_f 0.41) and **3** (R_f 0.26), mp 80–80.5°C (petroleum ether –

Amine ***1***b *and DMAD*

After removal of solvent, the residue was applied to a column containing basic Al_2O_3(II). Elution with 20% ether in petroleum provided first **2***b* (R_f 0.53, 50:50 ether–petroleum) followed by **3**.

Amine ***1***c *and DMAD*

After removal of solvent and application of the residue to a basic Al_2O_3(II) column, elution with 20% ether in light petroleum yielded **5***c* (from reaction in $CHCl_3$ solution only) (R_f 0.31, 20% ether). Increasing the ether component to 50% gave **2***c* (R_f 0.44, 50%) followed by **3**. Elution of the product mixture from reaction in CH_3CN was begun with 50% ether in light petroleum. Spectra of **5***c*: uv ($CHCl_3$) λ_{max} (log ε): 240 nm (3.14); ir (neat film), cm^{-1}: 1741, 1735, 1646, 1603; ^{1}H nmr (90 MHz, $CDCl_3$) δ: 1.81 (s, 3H), 2.42 (s, 6H), 2.91(ab q, J = 13.5 Hz, 2H), 3.76 (s, 3H), 3.82 (s, 3H), 4.96 (s, br, 2H); ^{13}C nmr (62.90 MHz, $CDCl_3$ at 77.20) δ: 24.26, 40.67, 41.26, 51.41, 52.61, 74.36, 117.32, 126.63, 135.40, 140.89, 166.44, 167.31; ms (ci, CH_4) m/z: 328(4), 326(10), 324(22), 322(12), 272(12), 270(60), 268(100), 266(28), 264(38), 170(58); ms (ei, 70 eV) m/z: 272(10), 270(65), 268(100), 266(40), 264(65), 170(18), 150(23); ms (ei, high resolution) m/z calcd. for $C_9H_{12}NO_4{}^{35}Cl^{37}Cl$: 270.0114; found: 270.0113; calcd. for $C_9H_{12}NO_4{}^{35}Cl_2$: 268.0143; found: 268.0132.

Amine ***1***d *and DMAD*

After removal of solvent and application of the residue to a basic Al_2O_3(II) column, elution with 40% ether in light petroleum gave **2***d* (R_f 0.43, 50% ether) followed by **3**.

Amines ***1***e *and* ***1***f *and DMAD*

Chromatography of the residue after concentration of the reaction mixture gave only **3**.

Amine ***1***g *and DMAD*

After concentration of the solution and application of the residue onto Al_2O_3(II), elution with 33% ether in light petroleum provided *cis* and *trans* **2***g* as an inseparable mixture (R_f 0.40, 33%) followed by **3**.

Amine ***4*** *and DMAD*

After complete consumption of DMAD, as revealed by ^{1}H nmr spectroscopy, chromatography yielded only **3** and starting amine **4**.

Reaction of ***6*** *with DMAD*

A reaction vessel was charged with 5 mL of dry $CHCl_3$, 0.341 g (1.66 mmol) of **6** (ref. 9), and 0.235 g (1.65 mmol) of DMAD. Air was displaced by passing N_2 briefly over the solution, which was allowed to

stand in the dark. After 21 days at room temperature the solution was concentrated and applied to a basic Al_2O_3(II) column. Elution with 10% ether in petroleum afforded unreacted amine (41 mg). By increasing the polarity gradually, **7** (mp 126–127°C, petroleum) was eluted (R_f 0.24, 25% EtOAc in petroleum). The yield was 42%, based on the amount of **6** consumed. Spectral data for **7**: uv (CH_3OH), λ_{max} (log ε): 292 nm (4.18); ir (neat film), cm^{-1}: 3402 (v br), 1746, 1696, 1652; ^1H nmr (90 MHZ, $CDCl_3$) δ: 0.67 (s, 3H), 1.20 (s, 3H), 2.93 (ab q, J = 13 Hz, 2H), 2.99 (s, 3H), 3.53 (s, 3H), 3.94 (s, 3H), 4.81 (s, br, 1H), 7.26–7.58 (m, 5H); ^{13}C nmr (22.62 MHz, $CDCl_3$ at 77.20) δ: 21.88, 22.77, 35.22, 40.27, 51.93, 52.75, 59.51, 77.37, 98.46, 127.31, 146.21, 149.78, 166.02, 167.74; ms (ei, 70 eV) m/z (%): 333(12), 302(14), 300(14), 276(25), 244(32), 218(22), 198(49), 186(40), 105(100), 77(23); ms (high resolution) m/z calcd. for $C_{18}H_{23}NO_5$: 333.1576; found: 333.1576.

Relative rates of reactions of ***6*** *with DMAD in $CHCl_3$ and in $CDCl_3$*

Solutions of DMAD and **6** (each 0.33 M) in $CHCl_3$ ($CDCl_3$) were degassed by means of three freeze–pump–thaw cycles at 0.05 Torr and sealed into nmr tubes. The tubes were kept at room temperature for 6 days, during which time changes were monitored by ^1H nmr spectroscopy. Product **7** was formed 1.9 times faster in $CHCl_3$ than in $CDCl_3$. Examination of the contents of the $CDCl_3$-containing tube by ^2H nmr spectroscopy (76.75 MHz) revealed a strong broad signal at δ 4.81, as well as the ^2H signal from the solvent. Addition of CH_3CCl_3 to the $CHCl_3$-containing tube led to a new singlet in the ^1H nmr spectrum.

NOTE ADDED IN PROOF: After this paper was accepted we became aware of recent, closely related work by Kandeel and Vernon (41).

Acknowledgements

This work was financed from a grant provided by the Natural Sciences and Engineering Research Council of Canada. The authors thank Dr. D. Hughes and Mr. B. Sayer for some of the nmr data and Dr. R. Smith and Messrs J. Capron and F. Ramelan for the mass spectra. They are indebted also to Professor F. Grein for information concerning the energy/geometry relationships of alleneolate anion systems.

JERZY STRZELBICKI, WITOLD CHAREWICZ, JORG BEGER, and LUTZ HINZ. Can. J. Chem. **66**, 1695 (1988).

The synthesis of a series of *n*-dodecyloligo(oxyethylene) carboxylic acids of general formula $C_{12}H_{25}(OCH_2CH_2)_nOCH_2COOH$ ($n = 0$ to 5) and application of these compounds for the separation of Zn(II), Cd(II), and Hg(II) in extraction are reported. Negligible extractability of the metal ions investigated was found using dodecyloxyacetic acid ($n = 0$) which indicated that complexation resulted from metal–cation interaction with oxygen atoms of the polyoxyethylene chain incorporated into the molecule of complexon. In extractions from aqueous solutions containing $ZnCl_2$, $CdCl_2$, $HgCl_2$, and NaOH (pH regulator), loading of the organic phases increased for extractants with more oxyethylene units. In particular, Hg(II) extractability and molecular structure of the extractant are related. The selectivity of extraction increased drastically if NaCl was added to the initial aqueous phase, as the extractabilities of Cd(II) and, particularly, Hg(II) declined while the extractability of Zn(II) remained high. Selectivity of extraction is produced by the complex chemical equilibria resulted from complexation of the metal cation by an alkyloligoether carboxylic acid in the organic phase and by Cl^- and OH^- anions in the aqueous phase. Thus, aqueous solution parameters greatly influence the efficiency and the selectivity of the extraction process and suitable experimental conditions are very important.

JERZY STRZELBICKI, WITOLD CHAREWICZ, JORG BEGER, et LUTZ HINZ. Can. J. Chem. **66**, 1695 (1988).

On a réalisé la synthèse d'une série d'acides *n*-dodécyloligo(oxyéthylène)carboxyliques de formule générale $C_{12}H_{25}(OCH_2CH_2)_nOCH_2COOH$ ($n = 0$ à 5) et on a examiné l'utilité de ces composés pour séparer et extraire les ions Zn(II), Cd(II) et Hg(II). La quantité d'ions métalliques extraite par l'acide dodécyloxyacétique ($n = 0$) est négligeable; ce résultat indique que la complexation est dûe aux interactions des ions métalliques avec les atomes d'oxygène de la chaîne polyoxyéthylène incorporée dans la molécule complexante. Lors d'extractions effectuées à partir de solutions aqueuses contenant du $ZnCl_2$, du $CdCl_2$, du $HgCl_2$ et du NaOH (pour régulariser le pH), les molécules complexantes contenant le plus grand nombre d'unités oxyméthylènes provoquent une augmentation de la concentration des ions extraits dans les phases organiques; on a pu mettre en évidence une relation entre la facilité d'extraction du Hg(II) et la structure moléculaire des molécules complexantes. La sélectivité des extractions augmente d'une façon drastique lorsqu'on ajoute du NaCl à la phase aqueuse initiale; dans ces conditions, la facilité d'extraction du Cd(II) et, en particulier, celle du Hg(II) diminuent alors que celle du Zn(II) demeure élevée. La sélectivité des extractions est le reflet d'équilibres chimiques complexes qui proviennent de la complexation des cations métalliques par un acide alkyloligoéther carboxylique dans la phase organique et par les anions Cl^- et OH^- dans la phase aqueuse. Ainsi, les paramètres de la solution aqueuse influencent beaucoup l'efficacité et la sélectivité du processus d'extraction; des conditions expérimentales appropriées sont donc très importantes.

[Traduit par la revue]

Introduction

Previously, single ion and competitive extraction of Co(II) and Ni(II) ions from ammonia–chloride aqueous solutions by highly lipophilic crown carboxylic acids was reported (1), and separation of Co(II) ammine cations from Ni(II) ammine cations was found possible. "Sandwich" type of extraction complexes of stoichiometry $M(CE)_2$ were postulated in which the metal ammine cation is located between two polyether rings of crown carboxylate anions (CE). The metal ammine cation interacts with the crown carboxylic acid forming hydrogen bonds between oxygen atoms of the polyether rings and hydrogen atoms of the ammine ligands. On the other hand, no detectable extraction of Co(II) and Ni(II) cations from their chloride solutions was found using these highly lipophilic crown carboxylic acids (1).

Further studies on Co(II) and Ni(II) ion extraction, using the highly lipophilic oligoether carboxylic acid $C_{12}H_{25}O(CH_2CH_2O)_4CH_2CO_2H$ (2), showed that the ligand exhibited higher selectivity toward Co(II) and Ni(II) ammine cations than crown carboxylic acids. Moreover, acyclic polyether carboxylic acid extracted Co(II) and Ni(II) cations efficiently from aqueous chloride solutions but selectivity of the process was low. This low selectivity could be explained in terms of similar physicochemical properties and sizes of Co(II) and Ni(II) cations.

To determine the relationship between the size of the extracted ion and the number of oxyethylene units incorporated into a molecule of an alkyloligo(oxyethylene) carboxylic acid, experiments were performed on competitive extraction of Zn(II), Cd(II), and Hg(II) by a series of dodecyloligo(oxyethylene) carboxylic acids **1**–**6** of the general formula $C_{12}H_{25}(OCH_2CH_2)_nOCH_2COOH$ ($n = 0$ to 5). Zn(II), Cd(II), and Hg(II) were chosen because their ionic diameters change gradually (3). Only competitive extraction experiments were conducted as it was found previously (4, 5) that results from single cation extractions often do not agree with results obtained in a competitive extraction in compatible systems.

The results of this investigation are reported in this paper.

Experimental

Apparatus

Concentrations of metals in aqueous and organic phases were determined radiometrically (^{65}Zn, ^{115m}Cd, and ^{203}Hg) with a Nuclear Data Inc. (Model 1200) multichannel gamma radiation spectrometer and a

Canberra Industries (Model 7228) Ge/Li semiconductor probe. Measurements of the equilibrium pH in the aqueous phases were made with an ELPO (Model N-512) pH-meter and an Energopomiar (Model SAgP-209W) glass body combination electrode. ^{1}H nmr spectra were determined with a Tesla BC 487 nuclear magnetic resonance spectrometer. Melting points, which were corrected, were determined using a Carl Zeiss Jena micromelting point Boethius apparatus.

Reagents

Radioisotopes were from the Isotope Production and Reactor Center of the Institute of Atomic Energy, Swierk, Poland (^{65}Zn, ^{115m}Cd), and from the Central Institute of Nuclear Research, Dresden, GDR (^{203}Hg). Reagent grade sodium, hydrochloric acid, sulphuric acid, zinc chloride, cadmium chloride, mercury(II) chloride, sodium chloride, sodium hydroxide, sodium chloroacetate, diethylether, *n*-hexane, xylene, and chloroform were obtained from POCh (Gliwice, Poland). $ZnCl_2$, $CdCl_2$, and $HgCl_2$ were additionally dried at 120°C and then kept in a desiccator containing drying agent. 1-Dodecanol, 1-bromododecane, ethylene, diethylene, triethylene, and tetraethylene glycols were obtained from Fluka (GFR). Pentaethylene glycol was obtained from Aldrich (Milwaukee, WI, U.S.A.). The glycols were converted into the corresponding α-*n*-dodecyl-ω-hydroxy-oligo(oxyethylene)s according to published procedures (6–9).

Synthesis of n*-dodecyloligo(oxyethylene) carboxylic acids* ***1–6***

Xylene (500 mL) was heated over 1 mol (23 g) of metallic sodium until the mixture came to a boil. Thereafter, the mixture was slowly heated while being stirred vigorously and a white–grey suspension of sodium was obtained. The corresponding α-*n*-dodecyl-ω-hydroxy-oligo(oxyethylene) $C_{12}H_{25}$ $(OCH_2CH_2)_nOH$ (1 mol) was added dropwise to the suspension until a clear solution was obtained. Fine powdered sodium chloroacetate (1.1 mol = 128 g, 10% excess) was added in small portions to the solution. The reaction mixture was stirred at reflux for 16 h at a temperature of 110–130°C. After the reaction mixture cooled to room temperature, 100 mL of water and 100 mL of diethylether were added. The mixture was acidified with concentrated HCl (12 *M*) or H_2SO_4 (9 *M*). Phases were separated and the solvents (xylene and diethylether) were evaporated from the organic phase. The residue was dissolved in 100 mL of *n*-hexane and then the product, dodecyloligo(oxyethylene) carboxylic acid, was crystallized in a re-

$n = 1$, **2**;
$n = 2$, **3**;
$n = 3$, **4**;
$n = 4$, **5**;
$n = 5$, **6**.

Procedure

The extraction experiments were conducted at room temperature (19–21°C). The organic phase (5 mL) was a 0.010 M solution of an oligoether carboxylic acid in chloroform and the aqueous phase (5 mL) was a 0.00167 M solution of zinc, cadmium, and mercury chlorides (each) (labelled with ^{65}Zn, ^{115m}Cd, and ^{203}Hg radioisotopes) and NaOH (pH regulator). In the series of experiments, NaCl (at a concentration of 2.34 M) was added to the aqueous phases. Furthermore, a few experiments were done with each divalent metal chloride at a concentration of 0.000835 M and a NaCl concentration of 1.17 M in the initial aqueous phase.

Both organic and aqueous phases were placed in a separatory funnel and shaken vigorously for 15 min. Usually, the phases separated just after shaking was stopped (in particular, in the systems with acidic or neutral aqueous solution) or they could be separated by centrifuging for several minutes (15–20 min) if an emulsion appeared (usually in the systems with basic aqueous solution). However, most often with emulsions the phases were left in the separatory funnel for 18 h to allow them to separate. Samples (1.0 mL or 2.0 mL) of each phase were removed for the γ-spectrometric determination of metal concentrations. The metal concentrations were determined only in the clear organic and aqueous phases. Finally, the equilibrium pH of the aqueous phase was measured.

At the high equilibrium pH of the aqueous phase (usually a pH higher than 9), the emulsion formed was often so stable that the separation of the phases was impossible even by centrifuging. The results of the extraction experiments were presented only for those regions of equilibrium pH of the aqueous phase in which the organic and aqueous phases were separated and clear before metal concentrations were determined. Therefore the end of the extraction curves in the figures indicates pH values for which the emulsification process was too strong to continue the extraction experiments. Emulsions did not appear in the extraction systems with 0.000835 M solutions of divalent metal chlorides without NaCl addition.

In a few experiments, in the basic region of equilibrium pH, Zn(II) and/or Cd(II) hydroxide precipitation appeared in the systems. Because the metal concentrations were determined in the clear organic phase and the systems were fully equilibrated, the experimental data are included in the paper and they indicate concentrations of the metal complex soluble in chloroform.

Results and discussion

No divalent metal ions were transferred from the aqueous solutions containing NaCl at a concentration of 2.34 M into a chloroform solution of **1**. In the systems with an aqueous phase containing no addition of NaCl, tracer amounts of divalent metal

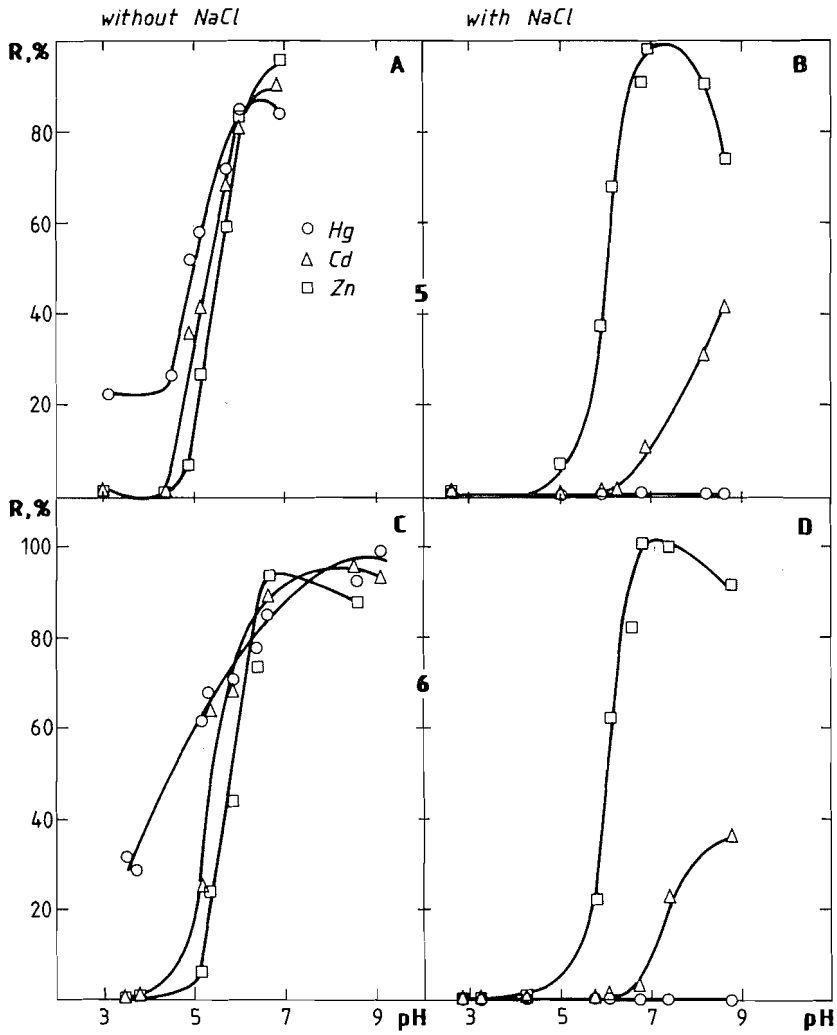

FIG. 2. Fraction of metals extracted (R) from aqueous solutions of 0.00167 M Zn(II), Cd(II), and Hg(II) chlorides (each) (A, C) and from aqueous solutions of 0.00167 M Zn(II), Cd(II), and Hg(II) chlorides (each) and 2.34 M NaCl (B, D) into 0.010 M solutions of *n*-dodecyloligo(oxyethylene) carboxylic acid in chloroform vs. equilibrium pH of the aqueous phase.

cations were extracted by **1** at the equilibrium pH of the aqueous phase above 9 (2% of Hg(II), 2.5% of Cd(II), and 1.2% of Zn(II)).

The results from the competitive extraction of Zn(II), Cd(II), and Hg(II) from 0.00167 M aqueous solutions of metal chlorides (each) into a 0.010 M solution of oligoether carboxylic acids **2**–**6** in chloroform are presented in Figs. 1 and 2. Two series of experiments were done. In the first one, the aqueous phase contained zinc, cadmium, and mercury chlorides and sodium hydroxide (the pH regulator) (Figs. 1*A*, *C*, *E* and 2*A*, *C*) while in the second one, sodium chloride was added to the initial aqueous phase at a concentration of 2.34 M (Figs. 1*B*, *D*, *F* and 2*B*, *D*). The sodium concentration in the initial aqueous solutions, which resulted from pH regulation using a NaOH solution, did not exceed 0.02 M (for the highest pH values).

Between the pH values 5 to 7, the extractability of divalent metal cations increased sharply with increasing equilibrium pH of the aqueous phase. A further increasing of the pH usually did not produce remarkable changes in the divalent metal cation extractability, but in some systems (Figs. 1*F* and 3*A*, *C*, *D*) extractability decreased sharply at pH > 8 and simultaneously the precipitation of Zn(II) and/or Cd(II) hydroxides appeared.

Extraction from a 0.00167 M *solution of divalent metal chlorides*

From solutions containing no addition of NaCl, extraction of Zn(II) and Cd(II) ions was very high and usually more than 90% of those cations were transported into the chloroform phase from the neutral and basic aqueous phase (Figs. 1*A*, *C*, *E*, and 2*A*, *C*). The extractability of Hg(II) increased with the increasing number of oxyethylene units incorporated into the molecule of extractant. The highest Hg(II) extractabilities were as follows: 33% using **2** (in the pH region 6.9 to 7.8), 57% using **3** (at pH 7.25), 60% using **4** (at pH 8.1), 85% using **5** (at pH 6.0), and 99.6% using **6** (at pH 9.2).

The correlation between the number of oxyethylene units incorporated into the molecule of an extractant and the extractability of Hg(II) indicates that an enlargement of the polyether portion in the acyclic polyether carboxylic acid may improve metal cation extractability. It seems that Hg(II) ions are too large (ionic diameters of Zn(II), Cd(II), and Hg(II) are 1.48, 1.94, and 2.20 Å, respectively (3)) to be strongly complexed by the short oligo(oxyethylene) portion of **2**–**4**. On the other hand, the interaction of the oxygens of the oxyethylene chain with Zn(II) ion was evidently very strong, because Zn(II) was extracted

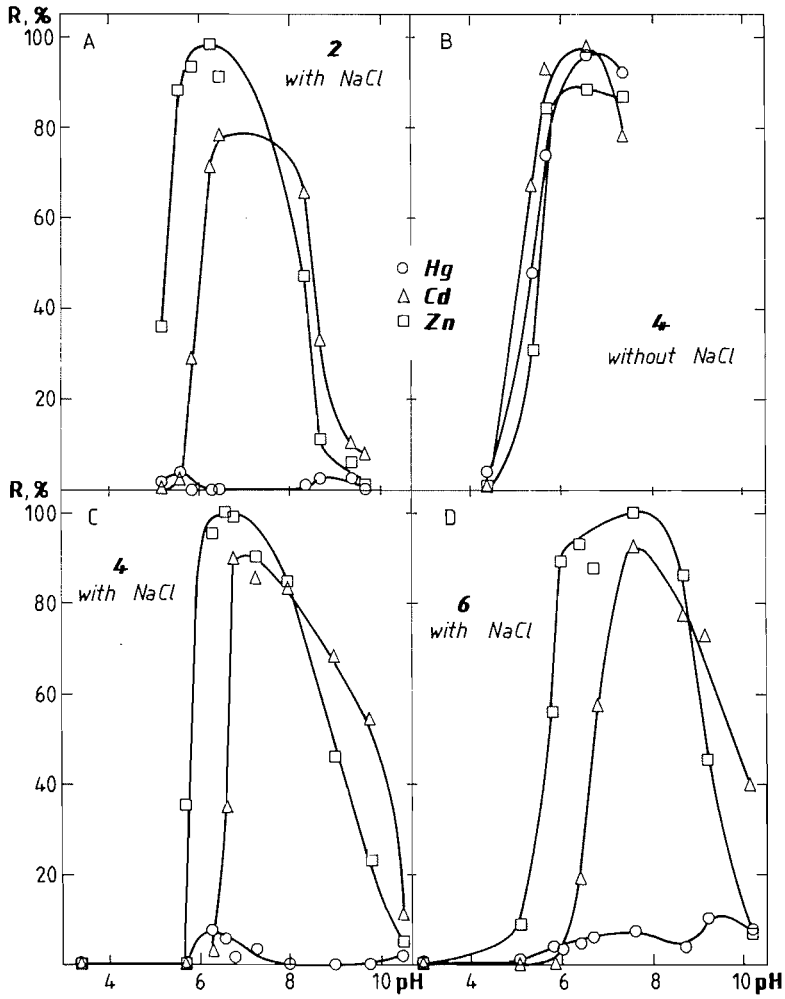

FIG. 3. Fraction of metals extracted (R) from aqueous solutions of 0.000835 M Zn(II), Cd(II), and Hg(II) chlorides (each) (B) and from aqueous solutions of 0.000835 M Zn(II), Cd(II), and Hg(II) chlorides (each) and 1.17 M NaCl (A, C, D) into 0.010 M solutions of n-dodecyloligo(oxyethylene) carboxylic acid in chloroform vs. equilibrium pH of the aqueous phase.

efficiently also by **2** (with only one oxyethylene unit incorporated into the molecule). The complexation of Zn(II), Cd(II), and Hg(II) ions are associated with the oxyethylene portion of the molecule because no extractability of the divalent cations by alkyloxyacetic acid **1** was observed. The interaction between a metal cation and a carboxylate anion is evidently not strong enough to produce metal extractability by itself. Thus, the carboxylic group is important mainly because after its deprotonization, an electroneutral metal extraction complex can be transferred into the organic phase without simultaneous transfer of an inorganic anion.

From the total divalent metal concentration in the best loaded organic phases (Table 2) it turns out that the most probable stoichiometry of the extraction complex is $M(II)(OE)_2$ (OE = an oligo(oxyethylene) carboxylate anion). This stoichiometry is anticipated also from electroneutrality of the complexes transferred into chloroform phase, taking into account that transfer of strongly hydrated Cl^- and OH^- anions into the low polar organic phase has low probability (5).

The stoichiometry of the extraction complexes was confirmed by additional experiments in which a 0.01 M chloroform solution of **5** was contacted with a 0.01 M aqueous solution of $ZnCl_2$, $CdCl_2$, or $HgCl_2$ in the single cation extraction. The metal concentrations in the organic phase after equilibration (pH 6.9) did not exceed 0.005 M (0.0047 M, 0.0044 M, and 0.0040 M for Zn(II), Cd(II), and Hg(II), respectively).

Extraction from a 0.00167 M *solution of divalent metal chlorides and 2.34* M *NaCl*

The selectivity of extraction of the divalent cations from a 2.34 M solution of NaCl improved remarkably. The extractability of Zn(II) remained very high (usually up to 100% of extraction from the neutral solution) but extractability of Cd(II) and, particularly, Hg(II) decreased sharply. The decrease of the extractability of Cd(II) and Hg(II) from a 2.34 M solution of NaCl resulted clearly from the formation of divalent metal chloride complexes. It is known that the stability of chloride complexes decreases in the order Hg(II) > Cd(II) > Zn(II) (11, 12). Under experimental conditions, the chloride complexes of Hg(II) are thermodynamically more stable than complexes of Hg(II) with oligoether carboxylic acids.

In some cases Zn(II) was efficiently separated from Cd(II) and Hg(II) in the systems with 2.34 M solutions of NaCl. Cd(II) and Hg(II) were not extracted by **3** in the pH region 2.5 to 6.6 while extractability of Zn(II) in that system at pH 6.6 was 93.5% (Fig. 1D). Cd(II) and Hg(II) were not extracted by **5** in the pH

TABLE 2. Total concentration of divalent metals in the highest loaded organic phases after extraction

Polyether carboxylic acid	Data taken from	Total M(II) concentration in organic phase, $M \times 10^3$
2	Fig. 1*A* at pH 6.9	3.88
3	Fig. 1*C* at pH 7.25	4.19
4	Fig. 1*E* at pH 8.1	4.29
5	Fig. 2*A* at pH 6.9	4.50
6	Fig. 2*C* at pH 9.1	4.86

region 2.6 to 6.8 while Zn(II) extractability at pH 6.8 was 92% (Fig. 2*B*). Similarly, neither Cd(II) nor Hg(II) were extracted by **6** in the pH region 2.95 to 6.6 while 82.5% of Zn(II) at pH 6.6 was extracted in that system.

Extraction from a 0.000835 M *solution of divalent metal chlorides*

The selectivity of extraction decreased markedly when the divalent metal chloride concentration in the initial aqueous phase was 0.000835 *M* (each). All three divalent cations were similarly extracted and almost no separation was achieved in the system containing no addition of NaCl (Fig. 3*B*). After NaCl was added into the aqueous phase at a concentration of 1.17 *M*, separation was somewhat improved, because extractability of Hg(II) decreased sharply. Moreover, due to the shift of the Cd(II) extraction curves into the more basic region than those of Zn(II), separation of those cations in the pH region from about 5 to 7 was also possible (Figs. 3*A*, *C*, *D*).

Above pH 8 in the systems with NaCl (Figs. 3*A*, *C*, *D*), the metal concentrations in the organic phase decreased sharply and precipitation of Zn(II) and/or Cd(II) hydroxide appeared. This phenomenon indicates that, under experimental conditions, metal hydroxides are more stable than metal – alkyloligo(oxyethylene) carboxylic acid complexes. It also indicates that the interaction of an alkyloligo(oxyethylene) carboxylic acid with Zn(II) and Cd(II) is very different from that with Co(II) and Ni(II). It has been reported previously (2) that in the system with **5**, the extractability of Co(II) and Ni(II) from their chloride aqueous solution increased with increasing pH, also in the basic region of pH. The different complexation of Zn(II), Cd(II), Co(II), and Ni(II) by alkyloligo(oxyethylene) carboxylic acids in the basic region of pH cannot be explained in terms of the different stability of metal hydroxides (stability of $M(OH)_2$ decreases in the order Zn(II) > Ni(II) > Co(II) > Cd(II) (13)) or the different ionic diameter of the metal ions (ionic diameter for Zn(II), Cd(II), Co(II), and Ni(II) is 1.48, 1.96, 1.48, and 1.44 Å, respectively (3)). Apparently, the accommodation of the ligand field of a polyether carboxylate and oxygen donor atoms of the polyoxyethylene chain to the field imposed by Ni(II) and Co(II) is much better than to the field imposed by Zn(II) and Cd(II).

A novel method of complete activation by carbonyldiimidazole: application to ester synthesis

ROBERT C. MORTON, DEV MANGROO, AND GERHARD E. GERBER[1]
Department of Biochemistry, McMaster University, Hamilton, Ont., Canada L8N 3Z5

Received October 13, 1987

ROBERT C. MORTON, DEV MANGROO, and GERHARD E. GERBER. Can. J. Chem. **66**, 1701 (1988).

The activation of carboxylic groups by carbonyldiimidazole (CDI) results in the presence of excess CDI; it is shown that this reacts rapidly with the target hydroxyl groups under acylation conditions, thus preventing the desired acylation even when an excess of reagent is present and resulting in poor yields. The methods described result in rapid, complete, and convenient removal of the excess CDI. This procedure thus permits the use of sufficient excess of CDI to effect complete activation of the acid to the imidazolide. The imidazolides prepared in this manner, when used in limiting amounts, can be quantitatively converted to esters or amides; when used in slight excess, these imidazolides result in the quantitative acylation of target groups.

ROBERT C. MORTON, DEV MANGROO et GERHARD E. GERBER. Can. J. Chem. **66**, 1701 (1988).

L'activation des groupements carboxyliques par le carbonyldiimidazole (CDI) fait qu'on se trouve toujours en présence d'un excès de CDI; on démontre que, dans des conditions conduisant à une acylation, celui-ci réagit rapidement avec les groupements hydroxyles des molécules cibles et que l'acylation désirée est empêchée, même lorsqu'un excès du réactif est présent, et que les rendements obtenus sont faibles. Les méthodes proposées permettent d'enlever rapidement, complètement et d'une façon simple l'excès de CDI. Ces méthodes permettent donc d'utiliser un excès suffisant de CDI pour effectuer une activation complète de l'acide en imidazolide. Lorsqu'on utilise des quantités limitantes des imidazolides ainsi préparés, on peut les transformer quantitativement en esters ou en amides; lorsqu'on les utilise avec un léger excès, ces imidazolides conduisent à une acylation complète des groupements cibles.

Introduction

Carbonyldiimidazole (CDI), is a commonly used reagent for the activation of carboxylic acid groups and has been used for the preparation of affinity columns (1–5), the attachment of *t*-BOC amino acids to solid supports (6, 7), and in the preparation of fatty acyl CoA thioesters (8), phospholipids (9–16), and simple peptides (17–21). In general, the activation reaction consists of reacting the carboxylic acid with an excess of CDI in an anhydrous solvent such as tetrahydrofuran, chloroform, benzene, or dimethylformamide and the resulting activated acid is used as the acylating reagent without further purification.

We have adopted this method of activation for the preparation of esters of coenzyme A, phospholipids, and polar derivatives of hydrophobic proteins (23). However, in each case the reaction was variable and the yield of the desired products was often low. High performance liquid chromatographic (hplc) analysis of the acylation reaction, using DNP-prolylserinamide as a model compound, indicated that this was related to the presence of CDI during the acylation reaction.

Activation of the acid by one equivalent or only a slight excess of CDI results in a slow and incomplete reaction, leaving a residual amount of free CDI unless very long activation times are used. Activation by a substantial excess of CDI results in faster and complete activation but the excess CDI is still present. The activated acyl imidazolide is normally used directly without purification due to its sensitivity to hydrolysis, and thus the excess of CDI still present reacts with the target groups and thereby prevents their acylation.

We have developed a method of complete activation of the carboxylic acid by a substantial excess of CDI, which is subsequently removed selectively by incubation of the activation mixture with Sephadex LH-20 in dry benzene. The described activation procedure completely eliminates the side reaction with the activating agent and affords the desired acylation in excellent yield.

Experimental

General

Trimesic acid (1,3,5-benzenetricarboxylic acid), 1,1-carbonyldiimidazole (CDI), and ninhydrin were purchased from Sigma Chemical Co. Sephadex LH-20 was purchased from Pharmacia and triethylamine from Pierce.

Reagent grade dimethylformamide (DMF) was dried by the addition of 0.1 volume of dry benzene, removal of 0.2 volume under reduced pressure, and storage over 4 A molecular sieve and under nitrogen. All distillation was performed under nitrogen. Benzene was dried by refluxing for 4 h over calcium hydride, distilled, and stored over 4 A molecular sieve under nitrogen. Triethylamine was distilled from ninhydrin and stored over 4 A molecular sieve, under nitrogen and at 4°C in the dark.

Synthesis of DNP-prolylserinamide

DNP-proline was activated by the addition of 1.1 equivalents of CDI in dry THF as a 60 mM solution and incubated at room temperature for 1 h under nitrogen. To the reactive imidazolide derivative, 3 equivalents of the hydrochloride salt of serinamide were added as a freshly prepared 1.54 M aqueous solution in the presence of 1 equivalent of Bu_4NOH. After 12 h at room temperature, the reaction was diluted with a 0.5 volume of water and the DNP-peptide extracted into ethyl acetate. The peptide product was purified by preparative hplc on a reversed phase μ Bondapak C_{18} column, which was equilibrated and run isocratically with 1% aqueous acetic acid containing 10% methanol. The DNP-peptide was dried several times from anhydrous pyridine and then stored as a 25 mM solution in dry pyridine over molecular sieve and under nitrogen.

Synthesis of di(trimethylsilylethyl)trimesic acid (DT-TM acid)

All steps in the synthesis of the diprotected trimesic acid (DT-TM acid) were performed in a closed vessel under nitrogen and at room temperature. The triimidazolide derivative of trimesic acid was generated by the addition of 4.8 mmol of trimesic acid in 6 mL of anhydrous DMF, in approximately 1-mL aliquots, to a screw cap tube containing

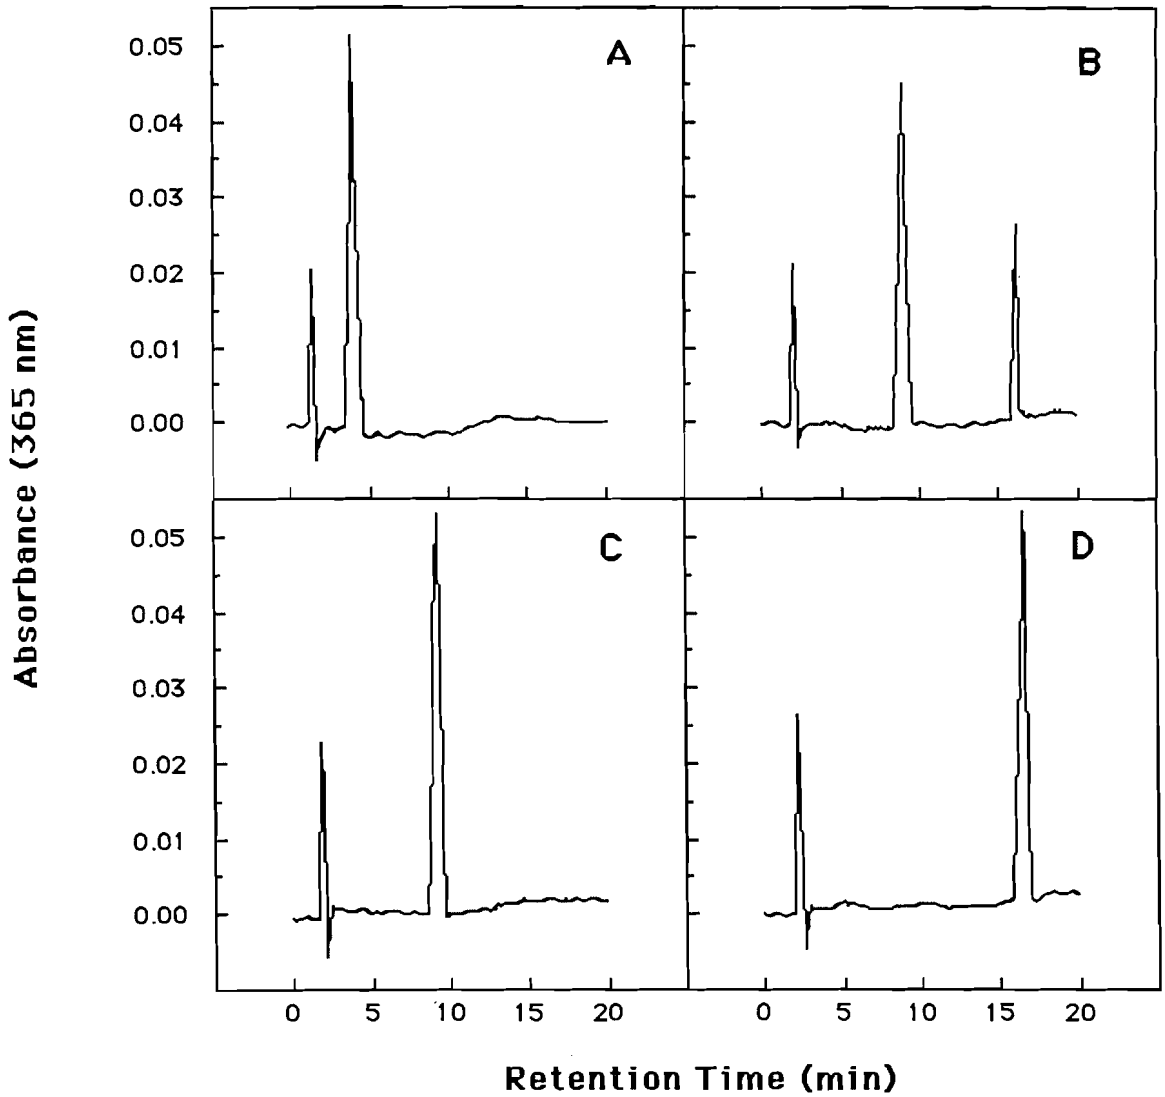

FIG. 1. Analysis of the reaction products by hplc. DT-TM imidazolide was prepared using 1.5 equiv. of CDI and incubated for 1 h with or without 4 equiv. of Sephadex LH-20 in dry benzene as described in the experimental section. The peptide DNP-prolylserinamide was subjected to standard acylation conditions using the following reagents: A. No reagent; B. 200 mM DT-TM imidazolide without Sephadex LH-20 pretreatment; C. 50 mM CDI; D. 200 mM DT-TM imidazolide pretreated with Sephadex LH-20. After 1 h, aliquots were diluted into aqueous DMF and subjected to hplc analysis as described in the experimental section.

2.33 g CDI (3 equivalents) in 4 mL of dry DMF. During the addition, the mixture was continuously vortexed. After 1 h, two equivalents of $Me_3SiCH_2CH_2OH$ were added and the reaction allowed to proceed overnight. Following dilution with an equal volume of dry DMF, the remaining imidazolides were hydrolyzed by the addition of 2 mL of 2.5 M aqueous NaOH. Three petroleum ether extractions completely removed the triester of TM acid. Acidification with HCl to pH 1 allowed the desired product, DT-TM acid, to be selectively extracted into diethyl ether/petroleum ether (1:9, v/v). The monoester of TM acid remained in the aqueous phase. The extracts containing DT-TM acid were pooled, and washed once with 0.1 N HCl and then once with 4 M NaCl. The solvent was evaporated under a stream of nitrogen and the product was repeatedly (3 times) dissolved in dry benzene and the solvent removed under reduced pressure. The DT-TM acid was a single peak on hplc analysis and had the expected nmr spectrum. The dried DT-TM acid was stored as a 0.2 M solution in dry benzene, over molecular sieve (4 A) and under nitrogen.

Determination of the capacity of Sephadex LH-20 for CDI

To a flamed Pyrex screw cap tube (13 × 100 mm) containing 40 mg of dry Sephadex LH-20 in 1.0 mL of dry benzene was added 6.9×10^{-4} mol of CDI (1.5 M in dry DMF). The tube was flushed with nitrogen, then mixed continuously at room temperature for 1 h. An aliquot (10 μL) of the reaction was diluted to 2 mL with dry benzene and the absorbance at 290 nm was measured to assess the extent of CDI removal. The extinction coefficient of CDI at 290 nm in benzene is 210. After maximal removal of CDI (66.6%) the capacity of Sephadex LH-20 for CDI was calculated to be 1.15×10^{-5} mol of hydroxyl groups per mg of dry Sephadex LH-20.

Preparation of acid imidazolides

The DT-TM acid (1 M in dry DMF) was transferred to a flamed Pyrex screw cap tube (10 × 100 mm) containing 1.5 equivalents of CDI (0.2 M) in 15% DMF/85% benzene under nitrogen. The reaction was allowed to proceed for 1 h; the imidazolide was then diluted with dry benzene to 40 mM, and transferred to another flamed Pyrex screw cap tube containing 4 equivalents of dry Sephadex LH-20. The tube was flushed with nitrogen and mixed continuously for 1 h; centrifugation removed the Sephadex LH-20 and removal of the solvent under reduced pressure afforded the imidazolide free of excess CDI.

Standard peptide acylation

DNP-prolylserinamide was routinely acylated at room temperature,

under nitrogen, as a 1 mM solution in anhydrous DMF in the presence of 200 mM DT-TM imidazolide and 1 M triethylamine. The extent of acylation of the DNP-peptide was determined by reverse phase hplc by diluting an aliquot of the reaction into aqueous DMF (10% water; v/v) and analyzing a portion using a 4.6 × 250 mm μBondapak C_{18} column equilibrated with 35% methanol in 10 mM sodium acetate, pH 4.4. The column was developed at 1 mL/min, while the methanol content of the eluent was increased to 100% over 15 min to afford a 10-min separation between the retention times of the starting peptide and the trimesylated product.

Results and discussion

Carbonyldiimidazole (CDI) has been used extensively (22) for the activation of carboxylic acid groups since it reacts quantitatively to produce the acid imidazolide. An excess of CDI is used to ensure complete activation of the acid since the purity of the commercially available CDI is variable due to its extreme sensitivity to water, and since any residual water in the solvents would result in some loss of CDI. It has been reported (8, 9–16) and we confirmed that the yields of desired acylation products is often poor. Consequently, we studied the acylation of the peptide DNP-prolylserinamide by an acid imidazolide: the dinitrophenyl group allows detection (365 nm) of peptide-related products produced during the acylation; the acid chosen for this study was the diprotected derivative of trimesic acid (DT-TM acid) developed by us for derivatization of proteins (23), since it could readily be detected spectrally during hplc analysis, as well as being available to us in tritiated form.

The products of the reaction of DT-TM imidazolide with DNP-prolylserinamide were analyzed by hplc as shown in Fig. 1. The peptide is essentially pure and runs as a single peak at 4.0 min (panel A), the peak observed at 1.2 min being due to solvent. Reaction of the peptide with acid activated with 1.5 equivalents of CDI resulted in complete loss of starting material and formation of two new products. The minor product (10%) eluting at 16.6 min (Fig. 1B) was determined to be the desired trimesylated peptide since it contained the DNP chromophore and the tritiated form of the DT-TM acid; the major product (90%) eluting at 9.1 min did not contain DT-TM acid (data not shown). A product eluting at the latter position is also generated when the peptide is incubated with CDI under acylation conditions (Fig. 1C) in the absence of DT-TM imidazolide. This product is presumed to be the imidazole-*N*-carboxylic ester of the peptide since the reaction between an alcohol and CDI to produce imidazole-*N*-carboxylic ester has been previously described (22) and since it contains the peptide but not the DT-TM acid. Although the imidazolide is present in twice the concentration of the excess CDI, the trimesylated product is obtained only in about 10% yield; this indicates that the CDI must react considerably faster than does the imidazolide under these conditions. It was therefore concluded that this side reaction with CDI was responsible for the poor yields of the desired acylated peptide.

The effect of excess CDI on the rate of acylation was assessed quantitatively using this system and the results are shown in Fig. 2. Acylation with DT-TM acid, that had been activated with 1.0 or 1.5 equivalents of CDI resulted in 60 and 10% acylation of the peptide respectively. Addition of freshly activated reagent to these samples resulted in no increase in the amount of acylated peptide formed; this is consistent with the observed loss (Fig. 1B) of starting peptide under these conditions and the excess CDI thus had irreversibly blocked the hydroxyl group of the peptide.

The acylation reaction must therefore be performed in the absence of CDI. The obvious route of activation of the carboxylic acid with only one equivalent of CDI still produced unsatisfactory results since this required exact titration of the reagents and anhydrous conditions; in addition, as the CDI is consumed, the activation becomes slow, resulting in incomplete activation and the resulting presence of residual CDI. A better alternative would be the complete activation of the acid with an excess of CDI followed by removal of the unreacted CDI. This selective removal of CDI without significant loss of the activated acid should be possible since the reactivity of the CDI seemed to be much higher. This was confirmed by determining the reactivities of CDI and DT-TM imidazolide towards methanol in benzene or DMF, as shown in Fig. 3. The extent of reaction of CDI and DT-TM imidazolide under these conditions was determined by monitoring the absorbance at 290 nm (CDI) and at 310 nm (DT-TM imidazolide) at the specified times. The reactivities of the two reactive compounds towards methanol were similar in DMF while in benzene the rate of reaction of CDI was approximately 175 times faster than that of the imidazolide. This higher reactivity of CDI in benzene should allow its selective reaction with hydroxyl groups without significant loss of the imidazolide. The reaction of the excess CDI with the solid phase hydroxylic support Sephadex LH-20 (3-hydroxypropyl derivative of Sephadex G-25) in benzene resulted in the removal of the generated reactive by-product, imidazolide-*N*-carboxylic ester, which became attached to the Sephadex LH-20. The time course of removal of CDI from solution is shown in Fig. 4. Complete removal of the excess CDI was achieved within 1 h after incubation with a 4-fold excess of Sephadex LH-20 per mole equiv-

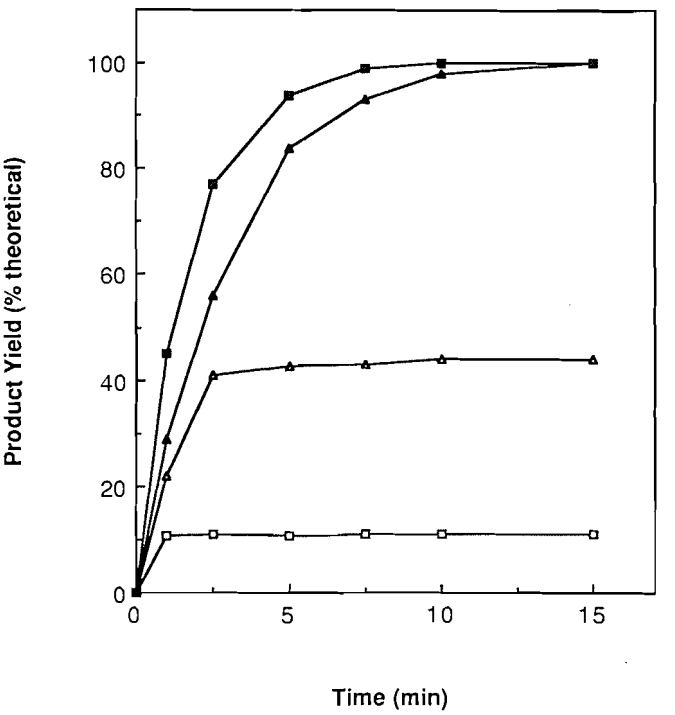

FIG. 2. Trimesylation time course for DNP-prolylserinamide with Sephadex LH-20 treated or untreated DT-TM imidazolide. DT-TM imidazolide was generated by activation with 1.5 equiv. (square) or 1.0 equiv. (triangle) of CDI and then incubated for 1 h with (■, ▲) or without (□, △) 4 equiv. of Sephadex LH-20 in dry benzene. The resulting reagents were then used to trimesylate DNP-prolylserinamide under the standard reaction conditions. At the times indicated, an aliquot was withdrawn, diluted into aqueous DMF, and subjected to hplc analysis as described in the experimental section.

TABLE 1. Formation of DT-TM imidazolide

Solvent	Molar ratio CDI to DT-TM acid	Molar ratio Et_3N to DT-TM acid	Number of equal portions of DT-TM acid	DT-TM anhydride (% theor)	DT-TM imidazolide (% theor)
DMF	1.5	0	1	8	84
	1.5	0	4	10	80
	1.5	2	1	20	60
	1.5	2	4	28	44
	3.0	0	2	6	88
	3.0	2	2	10	80
Benzene:DMF (3: 1)	1.5	0	1	0	100
	1.5	0	4	0	100

Diprotected trimesic (DT-TM) acid was activated by its addition to a solution of CDI under the conditions specified in the table. The activation was allowed to proceed at room temperature for a period of 1 h after the last addition of reagent. Cyclohexylamine (10 molar excess to CDI) was added and left for an additional 0.5 h. Aliquots of 100 nmol were analyzed by hplc at 280 nm on a Waters Bondpak C_{18} reversed phase column (0.46 × 25 cm) eluted with a methanol gradient from 20% to 100% over 10 min. The amount of DT-TM anhydride generated was determined from the amount of DT-TM acid formed due to addition of the cyclohexylamine; the amount of DT-TM imidazolide was calculated from the amount of DT-TM cyclohexylamide, corrected for the amount derived from the DT-TM anhydride.

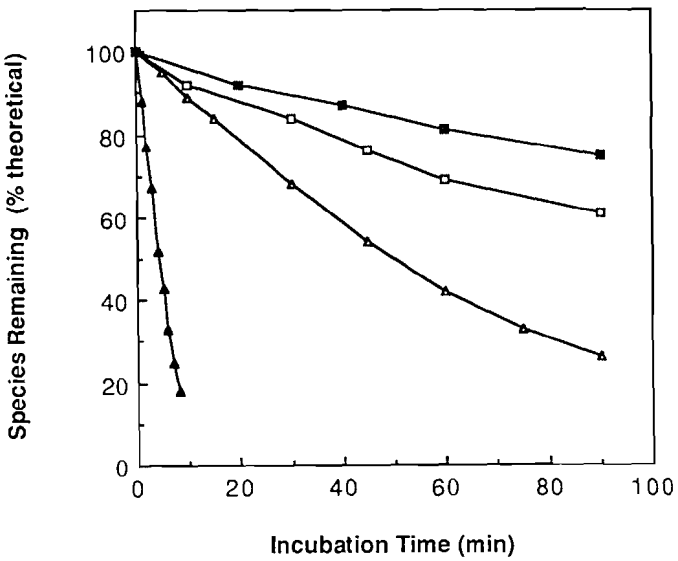

FIG. 3. Solvent effect on the reactivity of CDI and DT-TM imidazolide. Methanol was added to 6.7 mM solutions of CDI (triangle) and DT-TM imidazolide (square) to give a final methanol concentration of 100 mM. These reactions were performed in anhydrous DMF (△, □) or benzene (▲, ■) and the concentration of the activated species was monitored spectrally using a Varian Cary 210 spectrophotometer; a wavelength of 290 nm was used for CDI (ϵ_{290} = 210 M^{-1} cm^{-1}) and 310 nm for DT-TM imidazolide (ϵ_{310} = 280 M^{-1} cm^{-1}).

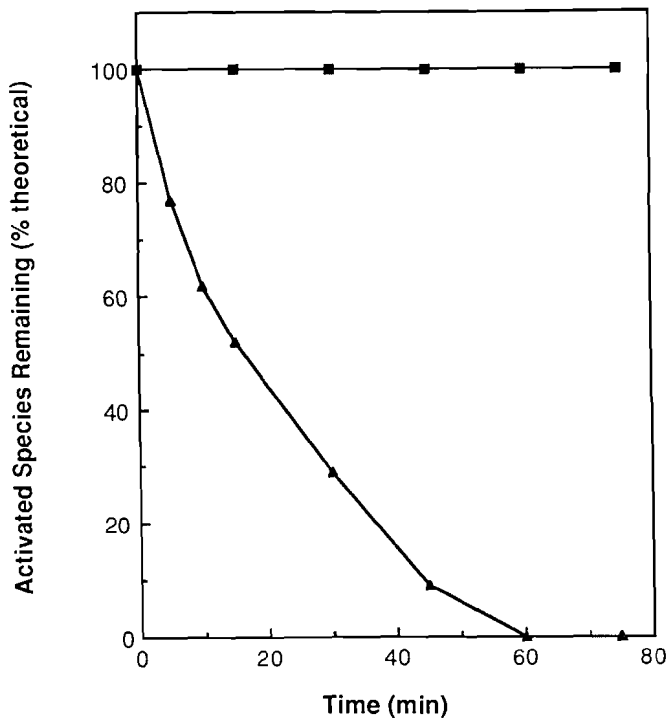

FIG. 4. Reaction of CDI and DT-TM imidazolide with Sephadex LH-20. Four equivalents of Sephadex LH-20 were added to a 20 mM solution of CDI (▲) and a 40 mM solution of DT-TM imidazolide (■) in anhydrous benzene. At the times indicated, an aliquot of the solution was diluted 20-fold with dry benzene and the activated species quantitated spectrally at 290 nm for CDI and 310 nm for DT-TM imidazolide.

alent of residual CDI, in the absence of base; under these conditions no loss of radioactive DT-TM imidazolide was observed. The capacity of Sephadex LH-20 for CDI was determined to be 1.15 × 10^{-5} mol/mg as described in the experimental section.

The time course of acylation of the peptide after removal of the excess CDI using this procedure is shown in Fig. 2. The reactions with DT-TM acid that had been activated with 1.0 or 1.5 equivalents CDI now both resulted in 100% reaction whereas in the absence of the LH-20 treatment this reagent had produced yields of 60 and 10% respectively. Analysis of the final product of this reaction by hplc is shown in Fig. 1D; a single product corresponding to the DT-TM peptide was observed, while the product corresponding to the CDI adduct was absent. It is thus clear that the treatment with Sephadex LH-20 completely removes the CDI, resulting in faster acylation rates, more complete reactions, and purer products.

In those cases where availability of the acylating agent is limiting, a side reaction that may account for low yields is the formation of anhydride during activation, since the maximum yield via the anhydride based on acid is reduced to one half of that via the imidazolide. Th extent of anhydride formation during the preparation of the DT-TM imidazolide derivative was determined by hplc. This analysis involved an indirect assay in

For personal use only.

which DT-TM acid was activated as described in Table 1, followed by the addition of 10 equivalents of cyclohexylamine. Reaction of cyclohexylamine with DT-TM imidazolide formed the corresponding amide derivative, while reaction with DT-TM anhydride resulted in the formation of one equivalent of the amide derivative and one equivalent of DT-TM acid. This reaction mixture was analyzed by hplc, as described in the legend to Table 1, and monitored at 280 nm; the amount of free DT-TM acid generated afforded a quantitative assay of the amount of anhydride that had been formed.

The results in Table 1 clearly show that DMF is a relatively poor solvent for CDI activation of DT-TM acid, in all cases resulting in substantial formation of DT-TM anhydride. The presence of Et_3N during the activation was found to double the amount of DT-TM anhydride formed. Apparently the generation of the DT-TM carboxylate ion results in the nucleophilic attack on the DT-TM imidazolide, thereby forming the anhydride. Increasing the amount of CDI or the number of additions of DT-TM acid, in equal portions, was found to make little difference in reducing the anhydride formation. In the benzene/DMF mixture, the formation of DT-TM imidazolide was 100%, irrespective of the method of addition of the DT-TM acid (all at once or in four equal aliquots), and the activation reaction was found to be complete within 0.5 h. The activation of acids by CDI is thus best done in nonpolar solvents such as benzene in the absence of base, since more polar solvents or the presence of base result in anhydride formation.

We have systematically assessed the imidazolide approach of carboxylic acid activation and have solved several problems associated with this procedure: activation of the acid is best achieved in a nonpolar solvent in the absence of any base. Complete formation of the imidazolide is ensured by an excess of CDI with respect to the carboxylic acid. Any residual CDI can be entirely eliminated by a brief incubation with Sephadex LH-20 in dry benzene without any loss of the acid imidazolide. The resulting imidazolide can be quantitatively converted to an ester or amide without any side reactions.

Effect of solvent structure on electron reactivity: 2-propanol/water mixtures

YADOLLAH MAHAM AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 2, 1988

YADOLLAH MAHAM and GORDON R. FREEMAN. Can. J. Chem. **66**, 1706 (1988).

The reactivity of solvated electrons (e_s^-) with efficient (nitrobenzene, acetone) and inefficient (phenol, toluene) scavengers is affected greatly by the solvent composition in 2-propanol/water mixed solvents. 2-Propanol is the only secondary alcohol that is completely miscible with water. The variation of the nitrobenzene rate constant k_2 with solvent composition displays four viscosity zones, as in primary and tertiary alcohol/water mixtures. In zone (*c*), where the Stokes–Smoluchowski equation applies, the nitrobenzene k_2 values in the secondary alcohol/water mixtures are situated between those in the primary and tertiary alcohols, due to the relative values of the dielectric permittivity ϵ. The charge–dipole attraction energy varies as ϵ^{-1}.

The two water-rich zones (*c*) and (*d*) are characterized by a large change of viscosity η and a small change in e_s^- solvation energy (trap depth) E_r; here k_2 for all the scavengers correlates with the inverse of the viscosity. In the two alcohol-rich zones (*a*) and (*b*) the change of η is small but that of E_r is large; here k_2 of inefficient scavengers correlates with the inverse of E_r, due to the difficulty of electron transfer out of deeper traps. Activation energies E_2 and entropies $\Delta S_2^{\ddagger}$ also show composition zone behaviour. The value of $\Delta S_2^{\ddagger}$ is more negative for less efficient scavengers; E_2 varies less and does not correlate with reactivity or E_r. Electron transfer from solvent to inefficient scavenger is driven by solvent rearrangement around the reaction center, reflected in $\Delta S_2^{\ddagger}$.

YADOLLAH MAHAM et GORDON R. FREEMAN. Can. J. Chem. **66**, 1706 (1988).

La réactivité des électrons solvatés (e_s^-) avec des pièges efficaces (nitrobenzène ou acétone) ou inefficaces (phénol ou toluène) est fortement affectée par la composition des solvants mixtes propanol-2/eau. Le propanol-2 est le seul alcool secondaire qui soit complètement miscible avec l'eau. La variation de la constante de vitesse, k_2, du nitrobenzène en fonction de la composition du solvant présente quatre zones de viscosité, comme dans le cas des mélanges eau/alcools primaire ou tertiaire. Dans la zone (*c*), où l'équation de Stokes–Smoluchowski s'applique, les valeurs k_2 du nitrobenzène dans les mélanges alcool secondaire/eau se situent entre celles des alcools primaire et tertiaire; cette situation resulte des valeurs relatives des permitivités diélectriques ϵ. L'énergie d'attraction charge–dipôle varie en fonction de ϵ^{-1}.

Les zones (*c*) et (*d*), qui sont riches en eau, sont caractérisées par un changement important de la viscosité η et de faibles changements dans l'énergie de solvatation des e_s^- (profondeur de la trappe) E_r; dans ce cas, il existe une corrélation entre la valeur de k_2 pour tous les pièges et l'inverse de la viscosité. Dans les zones (*a*) et (*b*) riches en alcools, le changement dans la valeur de η est faible alors que celui de E_r est grand; dans ce cas, il existe une corrélation entre la valeur de k_2 pour les pièges inefficaces et l'inverse de E_r; cette corrélation est dûe à la difficulté d'effectuer une transfert d'électrons pour sortir des trappes plus profondes. Il existe aussi une corrélation entre les énergies (E_2) et les entropie $\Delta S_2^{\ddagger}$ d'activation et le comportement de la zone de composition. La valeur de $\Delta S_2^{\ddagger}$ est plus négative pour les pièges les moins efficaces; les valeurs de E_2 varient moins et elles ne présentent pas de corrélation avec la réactivité ou E_r. Le transfert d'électron du solvant vers un piège inefficace est facilité par une transposition du solvant autour du centre réactionnel et celui-ci se réflète dans la valeur du $\Delta S_2^{\ddagger}$.

Introduction

The reactivities of solvated electrons with neutral solutes in primary (1, 2) and tertiary (3) alcohol/water mixed solvents are strongly dependent on solvent composition. Aqueous mixtures of the secondary alcohol 2-butanol have also been studied (4), but the alcohol is not completely miscible with water. A preliminary study with the completely miscible secondary alcohol, 2-propanol/water mixtures (5), had displayed complex behavior, but subsequent studies with other alcohols (1–4) indicated that a further study of 2-propanol/water was needed.

The static dielectric permittivity of the solvent has been shown to affect the rate of a nearly diffusion-controlled reaction of solvated electrons with a neutral, polar solute (4, 6). The same effect has now been observed in 2-propanol/water mixed solvents.

Experimental

Materials

2-Propanol (2-PrOH) was obtained from Aldrich Chemical Co. (99+%, spectroscopic grade, Gold Label). Nitrobenzene (99+%) and phenol (99+%) were from Aldrich. Acetone (99.9%) and toluene (99.8+%) were from Burdick and Jackson Labs.

Purification of 2-PrOH was as described in ref. 5. The water content was 0.2 mol% (Karl Fischer titration). The half-life of e_s^- after a 100-ns pulse of 1.9 MeV electrons ($\sim 2 \times 10^{16}$ eV/g) at 298 K was 15–17 μs.

The water was passed through a Nanopure II Barnstead ion exchanger. The half-life of e_s^- after a 100-ns pulse at 298 K was ~25 μs. In the mixed pure solvents the half-lives were as follows (mole fraction H_2O, μs): 0.10, 18 ± 3; 0.50, 30 ± 6; 0.74, 30 ± 5; 0.90, 37 ± 3; 0.97, 27 ± 3. The half-lives depend on solvent structure in a manner not yet determined.

Techniques

The methods of sample preparation (1) and irradiation (7, 8) were essentially the same as in the indicated references.

Results and discussion

Four solutes, with e_s^- rate constants in the range 10^7–10^4 m^3/mol s, were studied as a function of temperature. First-order decay constants k_1 were measured at four or five different scavenger concentrations in a given solvent. Second-order rate constants k_2 were obtained from the slopes of plots of k_1 against concentration (1). Arrhenius plots of k_2 for nitrobenzene, acetone, phenol, and toluene are given in Figs. 1–4, respectively.

The Arrhenius parameters A_2 (m^3/mol s) and E_2 (kJ/mol) are listed in Table 1, along with the entropy of activation $\Delta S_2^{\ddagger}$ (J/mol K).

[1] $k_2 = A_2 \exp(-E_2/RT)$

[2] $\Delta S_2^{\ddagger} = 19(\log A_2 - 9.8)$ at 298 K

The four solutes are discussed in two categories.

1. Efficient scavengers

The reaction of solvated electrons with nitrobenzene is nearly diffusion-controlled (4, 9). However, a plot of k_2(nitrobenzene) against solvent viscosity (10) at 298 K displays four zones of behaviour (Fig. 5), as did similar plots in other alcohol/water mixed solvents (3). The values from 1-PrOH/water (1) and *t*-BuOH/water (3) are included in Fig. 5 for comparison.

In the 2-PrOH/water mixtures the mole fractions of water in the four zones are (*a*) $0 \leq x_{H_2O} \leq 0.10$; (*b*) $0.10 \leq x_{H_2O} \leq 0.74$ (mixture with maximum viscosity η_{max}); (*c*) $0.74 \leq x_{H_2O} \leq 0.97$; (*d*) $0.97 \leq x_{H_2O} \leq 1.00$.

If the effective radii of e_s^- and nitrobenzene for diffusion (r_e and r_S, respectively) and for reaction (R_e and R_S) were constant in a given zone, one would expect to find $k_2 \propto \eta^{-1.0}$. This only occurs in zone (*c*). In the mixtures of each of the different alcohols with water, zone (*c*) extends from the mole fraction of maximum viscosity $x_{\eta_{max}}$ to $x_{H_2O} \approx 0.97$. The structure of the solvent about the reactants therefore remains relatively constant in zone (*c*). The values of k_2 in the secondary alcohol mixtures lie between those for the primary and tertiary alcohol/water mixtures. The values of ηk_2(nitrobenzene) in zone (*c*) at 298 K are 4.0, 4.2, and 4.7 (10^4 m^3 Pa/mol) for primary, secondary, and tertiary alcohol/water mixed solvents, respectively. This means that the Stokes–Smoluchowski term $(1/r_e + 1/r_s)(R_e +$

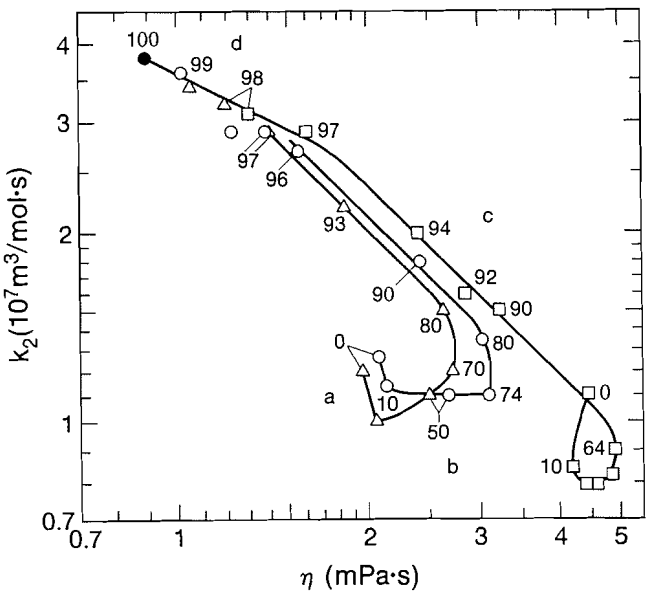

FIG. 5. k_2(nitrobenzene) at 298 K against viscosity of alcohol/water mixed solvents. ●, pure water; ○, 2-PrOH/water; △, 1-PrOH/water (1); □, *t*-BuOH/water (4). Numbers beside the points indicate mol% water. Zone (*c*) lines are drawn with slope −1.0.

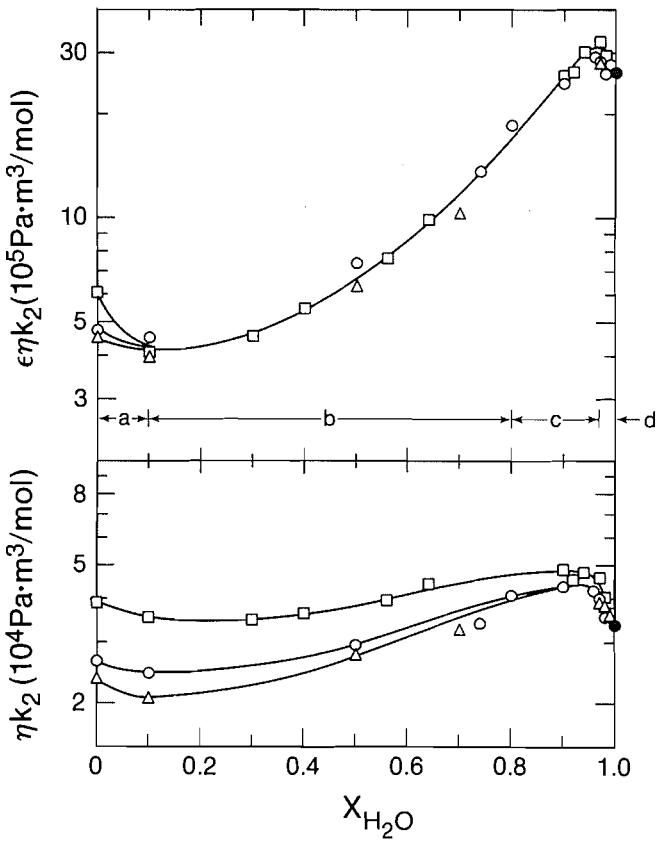

FIG. 6. Nitrobenzene rate constant normalized for viscosity, ηk_2, and for static dielectric permittivity and viscosity, $\epsilon\eta k_2$, at 298 K as a function of solvent composition. ○, 2-PrOH/water; △, 1-PrOH/water (ref. 1); □, *t*-BuOH/water (ref. 4); ●, pure water.

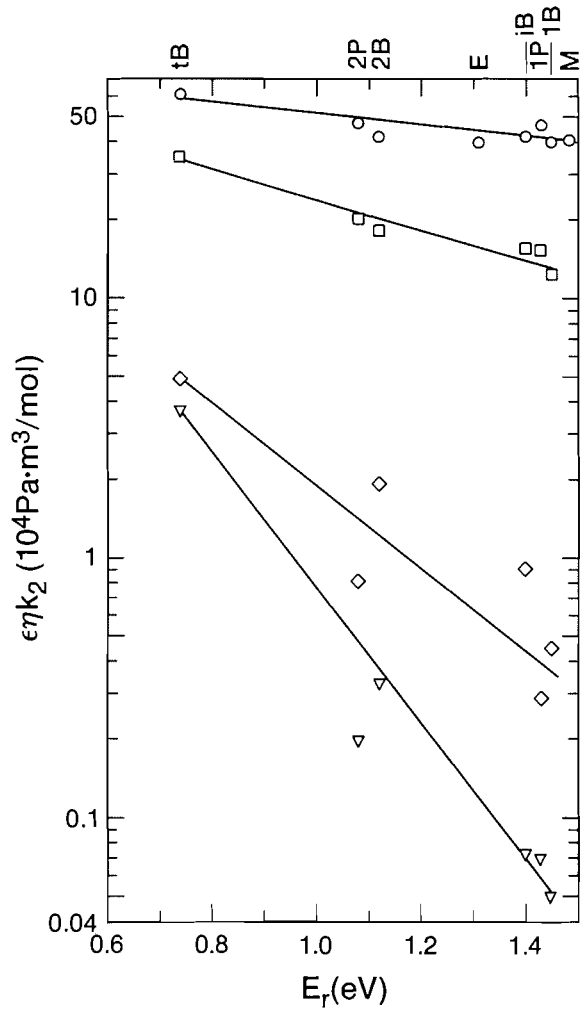

FIG. 7. Rate constant normalized for viscosity and static dielectric permittivity, $\epsilon\eta k_2$, as a function of trap depth E_r of e_s^- in pure alcohols at 298 K. Solutes: ○, nitrobenzene; □, acetone; ◇, phenol; and ▽, toluene. E_r values are from ref. 11; ϵ and η from ref. 10; k_2 in methanol (M) from ref. 12 at 292 K; k_2 in ethanol (E) from ref. 13; k_2 in 1-PrOH from ref. 1; k_2 in 1-BuOH from ref. 2; k_2 in *i*-BuOH and 2-BuOH from ref. 4.

R_s) increases in that order. The increase is partly attributed to an effective increase of $R = (R_e + R_S)$, due to the decreasing static dielectric permittivity ϵ of the solvents (10) and the attendant increase of charge–dipole attraction energy $U(R)$. This introduces a Debye factor f into the equation for a diffusion-controlled reaction (4, 6):

$$[3] \quad k_2 = 4\pi N_A(D_e + D_S)(R_e + R_S)f$$

where

$$[4] \quad f = \frac{U(R)}{k_B T} (\exp [U(R)/k_B T] - 1)^{-1}$$

and

$$[5] \quad U(R) = -M\xi/4\pi\epsilon_0\epsilon R^2$$

were $M = 1.4 \times 10^{-29}$ C m is the dipole amount of nitrobenzene, $\xi = 1.6 \times 10^{-19}$ C is the electron charge, and ϵ_0 is the permittivity of vacuum. The value of f increases with decreasing ϵ (Table 10).

In zone (*d*) k_2 decreases approximately as $\eta^{-0.5}$, so r or R does not remain constant. The behavior is similar for all of the alcohols.

On the lower-water-content side of the viscosity maximum, zones (*a*) and (*b*), there is no simple correlation between k_2 and viscosity (Fig. 5).

The dependence of k_2(nitrobenzene) on the static dielectric permittivity is demonstrated in Fig. 6. When the viscosity normalized ηk_2 is plotted against mole fraction of water in 1-PrOH, 2-PrOH, and *t*-BuOH, a separate curve is obtained for each alcohol. However, when normalized for static dielectric permittivity $\epsilon\eta k_2$, the data for the three alcohols fall on the same curve, except in zone (*a*).

The electron trap depth is for kinetic purposes represented by the optical absorption energy E_r, on the low energy side of the absorption maximum:

$$[6] \quad E_r = E_{Amax} - W_r$$

where E_{Amax} is the energy at maximum absorption and W_r is the width of the low energy side of the band at half height (11).

The electron trap depth changes greatly across zone (*a*), and the $\epsilon\eta k_2$ differences are attributed to that. The values of E_r in pure 1-PrOH, 2-PrOH, and *t*-BuOH are 1.43, 1.08, and 0.82 eV, respectively (11). The slight dependence of k_2 on E_r means that the reaction of e_s^- with nitrobenzene is not quite diffusion-controlled.

The dependence of $\epsilon\eta k_2$ on E_r in pure alcohol solvents (1, 4, 12, 13) is displayed in Fig 7 for solutes of different reactivity

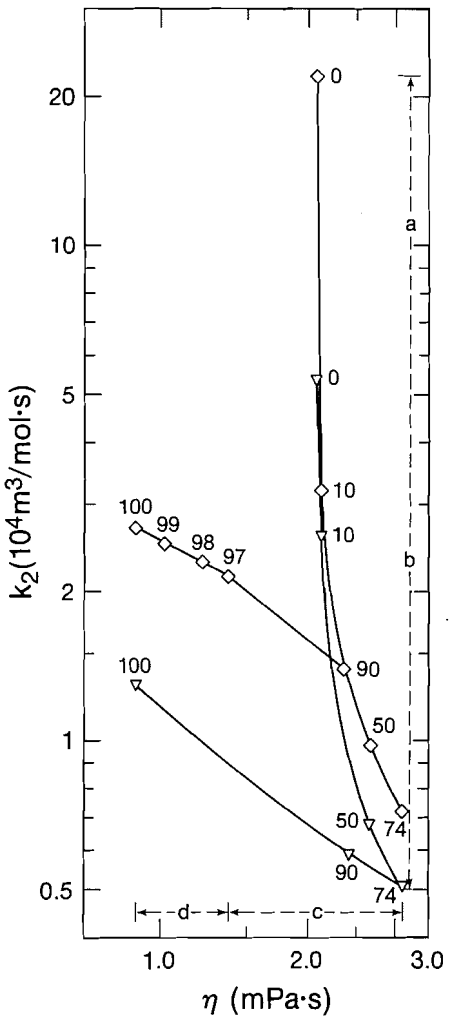

FIG. 8. Plot of k_2 vs. η for inefficient scavengers in 2-PrOH/water mixtures at 298 K. Solute: ◇, phenol; ▽, toluene.

with e_s^-. The slope of the line becomes more negative with decreasing reactivity. The limiting slope for a diffusion controlled reaction is presumed to be zero. Thus the nitrobenzene reaction is not quite diffusion controlled.

2. Inefficient scavengers

In zones (*a*) and (*b*), on the higher alcohol side of the composition of maximum viscosity, the values of k_2 for phenol and toluene decrease with increasing water content and do not correlate with solvent viscosity (Fig. 8). On the higher water side of the viscosity maximum the values of k_2 increase with water content and do correlate with viscosity (Fig. 8).

The decrease of k_2 in zones (*a*) and (*b*) for inefficient scavengers is caused by the increasing trap depth of the electrons, which makes it more difficult for the electron to jump from the solvent trap onto the solute molecule (1, 3, 14).

The encounter efficiency of the reaction is approximated by the ratio of k_2 for the inefficient scavenger to that for nitrobenzene, k_2/k_N. Semilog plots of k_2/k_N against E_r are shown in Fig. 9. The negative slopes reflect the increasing free energy of activation of the electron capture reactions as E_r increases (4).

E_η (○) is the Arrhenius temperature coefficient for shear viscosity, calculated from data in ref. 15. E_r (△), ref. 11.

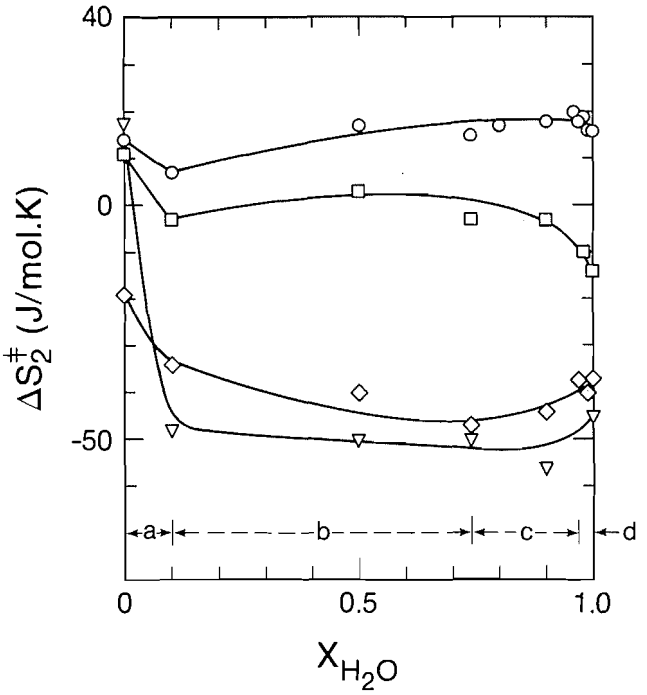

FIG. 11. Entroy of activation $\Delta S_2^{\ddagger}$ at 298 K for (e_s^- + S) against mol fraction water in 2-PrOH/water mixtures. Solute: ○, nitrobenzene; □, acetone; ◇, phenol; ▽, toluene.

[9] $$\ln (k_2/k_N) \approx -\Delta G_5^{\ddagger} 4 /RT$$

for inefficient scavengers.

3. Energies and entropies of activation

The activation energies E_2 of the e_s^- reactions in zones (*b*) – (*d*) follow trends similar to that of viscous flow E_η (15) (Fig. 10). In zone (*a*) the behavior of E_2 is different, as was that of $\epsilon\eta k_2$ (Fig. 6). The entropies of activation $\Delta S_2^{\ddagger}$ also indicate special behavior in zone (*a*) (Fig. 11).

Although there are not many points on the E_η curve in Fig. 10, the behavior is similar to that for 1-PrOH/water mixtures (10, 16). There is no special behavior of E_η in zone (*a*). The rapid decreases of E_2 and $\Delta S_2^{\ddagger}$ in zone (*a*) must be due to the changing solvation of the reactant pair.

The decrease of reactivity in the series nitrobenzene, acetone, phenol, toluene is associated mainly with a decrease in $\Delta S_2^{\ddagger}$ (Fig. 11). It does not correlate with E_2 (Fig. 10). Nor does E_2 correlate with E_r (Fig. 10). The entropy of activation is associated with rearrangement of solvent molecules around the reactant pair.

Ambident reactivity in the reaction of phenoxide ion with 2-*N*-(2′,4′-dinitrophenyl)- and 2-*N*-(4′-nitrophenyl)-4,6-dinitrobenzotriazole 1-oxides, new superelectrophiles[1]

ERWIN BUNCEL[2] AND JULIAN M. DUST[3]

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received October 20, 1987

ERWIN BUNCEL and JULIAN M. DUST. Can. J. Chem. **66**, 1712 (1988).

Reaction of the novel superelectrophiles 2-*N*-(2′,4′-dinitrophenyl)- and 2-*N*-(4′-nitrophenyl)-4,6-dinitrobenzotriazole 1-oxides, **3**, and **4**, possessing two electrophilic centres, with the ambident nucleophile potassium phenoxide in $(CD_3)_2SO$ was followed by 400 MHz ^1H nuclear magnetic resonance spectroscopy. A dichotomy in the reaction pathways has been observed. With MeO^-, attack at C-7 leads to reversible adduct formation, while attack at C-1′ results in irreversible N-2:C-1′ bond scission via the metastable C-1′ adduct. In contrast, the reaction of **3** and **4** with PhO^- proceeds by a two-pronged attack: formation of C-7 carbon-bonded phenoxide adducts via the *ortho* and *para* carbon sites, and oxygen-based cleavage products by attack at the C-1′ position, accompanied by N-2:C-1′ bond scission, in accord with the ambident reactivity of PhO^-. Significantly, in this case reaction of both C-7 and C-1′ is effectively irreversible. Moreover, the reaction of phenoxide with either **3** or **4** shows striking differences compared to the reaction of PhO^- with 2-*N*-(picryl)-4,6-dinitrobenzotriazole 1-oxide, **1**. Reaction of PhO^- with **1** resulted only in O-attack at C-1′ and N-2:C-1′ bond scission; there was no evidence for C-7 adduct formation via O- or C-attack. This marked difference in behaviour can be attributed to the decreased susceptibility to C-1′ attack exhibited by **3** and **4** as compared to **1** and arises from the successive removal of electron-withdrawing nitro groups from the 2-*N*-nitroaryl moiety in the series **1** → **3** → **4**. The reactions are discussed on the basis of selectivity considerations and an activation energy/reaction coordinate profile comparing the pathways for both C-attack at C-7 and O-attack at C-1′ as electrophilicity (delocalizability) is progressively modulated in the reaction series.

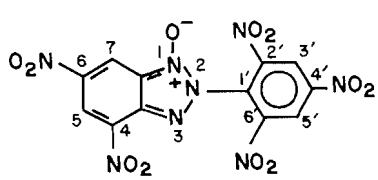
ERWIN BUNCEL et JULIAN M. DUST. Can. J. Chem. **66**, 1712 (1988).

Opérant dans le $(CD_3)_2SO$ et faisant appel à la résonance magnétique nucléaire du ^1H à 400 MHz, on a suivi l'évolution de la réaction des nouveaux super-électrophiles possédant deux sites de réaction, les oxydes-1 des *N*-2-(dinitro-2′,4′ phényl) et N-2-(nitro-4′ phényl) dinitro-4,6 benzotriazoles (**3** et **4**), avec le phénolate de potassium, un nucléophile possédant deux sites de réaction. On a observé une dichotomie dans les voies réactionnelles. Avec le MeO^-, l'attaque en C-7 conduit à la formation réversible d'un adduit alors que l'attaque en C-1′ conduit à une scission irréversible de la liaison N-2:C-1′ par le biais de l'adduit métastable C-1′. Par ailleurs, la réaction des composés **3** et **4** avec le PhO^- procède par une attaque sur deux fronts : la formation d'adduits phénolates liés en C-7 par le biais des sites carbonés en *ortho* et en *para* ainsi que la formation de produits de clivage contenant de l'oxygène, qui proviennent d'une attaque en position C-1′ accompagnée d'une scission de la liaison N-2:C-1′; ces résultats sont en accord avec la réactivité ambivalente du PhO^-. Il est important de noter que, dans ce cas, les réactions tant en C-7 qu'en C-1′ sont de fait irréversibles. De plus, la réaction du phénolate avec les composés soit **3** ou **4** présente des différences marquées par rapport à ce qui est observé lors de la réaction du PhO^- avec l'oxyde-1 du *N*-2-(picryl) dinitro-4,6 benzotriazole, **1**. La réaction du PhO^- avec le composé **1** ne conduit qu'à une attaque sur l'oxygène en C-1′ et à une scission de la liaison N-2:C-1′; on n'a pas obtenu de résultats suggérant qu'il y a formation d'un adduit en C-7 par le biais d'une attaque du O ou du C. Cette différence marquée de comportement peut être attribuée à une diminution de la susceptibilité à l'attaque en C-1′ qui est observée avec les composés **3** et **4**, par rapport au composé **1**, et qui provient de l'élimination successive (dans la portion *N*-2 nitroaryl de la série **1** → **3** → **4**) des groupements nitro qui possèdent un effet électro-attracteur. On discute des réactions en fonction de considérations de sélectivité et d'un profil d'énergie d'activation vs. les coordonnées de la réaction comparant les voies réactionnelles tant de l'attaque du C en C-7 que de l'attaque du O en C-1′ lorsque le caractère électrophile (possibilité de délocalisation) est progressivement modulé dans les séries de réactions.

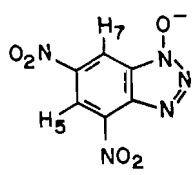
[Traduit par la revue]

As part of our ongoing program of study concerning the interactions of normal and ambident nucleophiles with electron-deficient aromatic and heteroaromatic series (1–5), we have previously investigated the reactions of a wide variety of nucleophiles with 2-*N*-(picryl)-4,6-dinitrobenzotriazole 1-oxide (Pi-DNBT, **1**). Pi-DNBT was found to be a superelectrophile; on the basis of its reactivity with ethanethiol, **1** has been ranked between the conventional electrophile, 1,3,5-trinitrobenzene (TNB), and the superelectrophile, 4,6-dinitrobenzofuroxan (DNBF) (6), on a scale of increasing electrophilicity in Meisenheimer complex (anionic σ-adduct) formation (3).

Reaction of **1** with a wide range of nucleophiles results in



1



2

partition of the attack (Scheme 1): at C-7 (Path a) reaction generally yields an observable Meisenheimer adduct, or at C-1′ (Path b) forms a metastable adduct that rapidly decomposes to give displacement products (3–5).

Interestingly, while reaction of **1** with methoxide, for example, follows the two-pronged attack outlined in Scheme 1, the reaction with phenoxide is observed to occur solely at C-1′ to give rise to picryl phenyl ether (TNP) and the 4,6-dinitrobenzotriazole 1-oxyanion ($DNBT^-$, **2**) (3–5). This is

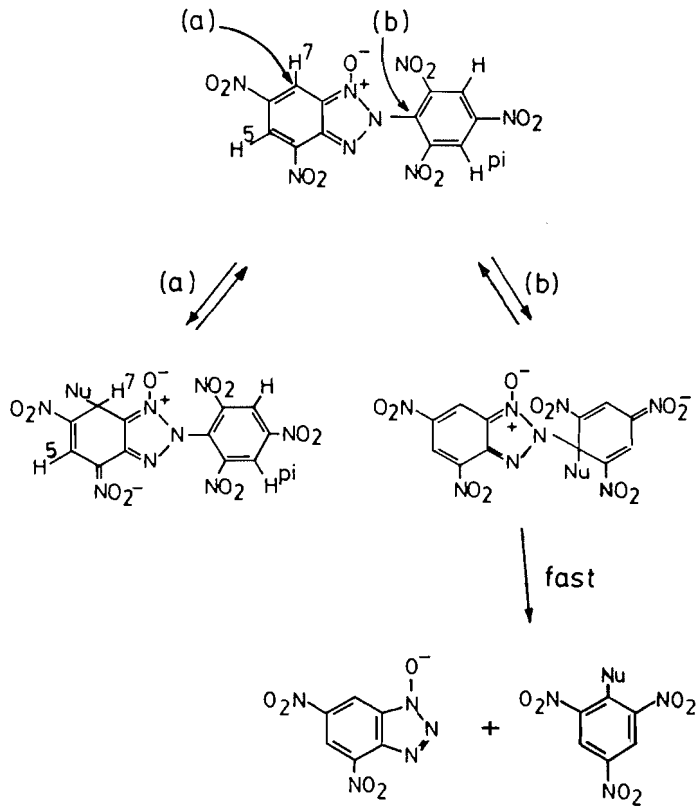


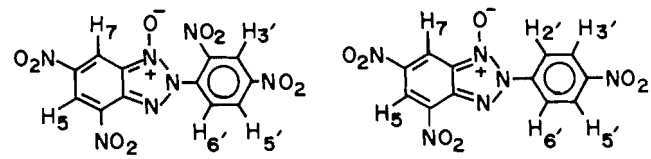
SCHEME 1

presumably the result of both facile formation of the metastable C-1′ oxygen-centered adduct and its rapid irreversible decomposition. The relative importance of these two factors depends upon the comparison made, i.e., O- versus C-attack, and C-7 versus C-1′ attack.

It is pertinent to the study that reaction of phenoxide with TNB (1, 2) or with DNBF (4) yields carbon-centered Meisenheimer adducts as the only spectrally observable species in these systems. In contrast, reaction of the sterically hindered 2,4,6-trimethylphenoxide with TNB leads to formation of a spectrally observable oxygen-centered Meisenheimer complex that eventually decomposes in favour of formation of 2,4,6-trimethylphenyl 3′,5′-dinitrophenyl ether, through loss of nitrite ion in a displacement (S_NAr) process involving free TNB present in the system at equilibrium (7).

Most recently we have examined the reaction of dopamine (3,4-dihydroxyphenylethylamine) with TNB (8). Dopamine is an interesting ambident nucleophile that may react via oxygen, carbon, or nitrogen centres, depending, at least partially, on the degree of ionization of the nucleophile. We have found, however, that reaction occurs to form initially a kinetically preferred nitrogen adduct, followed by formation of a thermodynamically more stable carbon-centered complex. No oxygen-centered complex was noted. Clearly, there is an order of thermodynamic stability of these complexes; carbon adducts are generally the most stable, oxygen adducts the least stable, and nitrogen-based complexes are of intermediate stability. Recent work by Terrier and co-workers (9), concerning the reactions of imidazolide and pyrrolide anions with TNB, confirms the relative order of stability of N- and C-bonded Meisenheimer complexes.

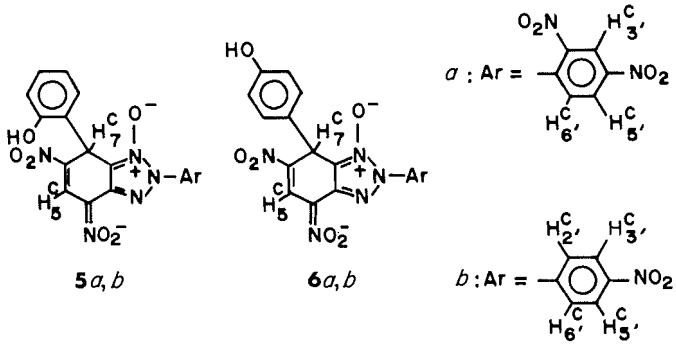
As part of our studies to delineate the stabilities of oxygen-centered Meisenheimer complexes formed by phenoxide ions relative to carbon-bonded adducts (1, 7, 8, 10), we have extended the study to the reactions of PhO^- with the newly prepared members of the 2-*N*-(nitroaryl)-4,6-dinitrobenzotriazole 1-oxide series of compounds: 2-*N*-(2′,4′-dinitrophenyl)-4,6-dinitrobenzotriazole 1-oxide and 2-*N*-(4′-nitrophenyl)-4,6-dinitrobenzotriazole 1-oxide (DNP-DNBT and NP-DNBT, **3** and **4**, respectively). Compounds **1**, **3**, and **4** represent a decreasing order of electron deficiency in the 2-*N*-nitroaryl ring, and consequently we expected that C-1′ attack (Scheme 1) would become increasingly disfavoured and, as a result, C-7 attack increasingly favoured in going from **1** → **3** → **4**. In turn, this would provide the opportunity for PhO^- to react at the anticipated superelectrophilic centre, C-7, via O- or C-attack, contrasting with the situation as regards **1**, where PhO^- reacts only at C-1′ as an O-nucleophile.



3 **4**

Results

The salient features of the reaction of potassium phenoxide with **3** and **4** in $(CD_3)_2SO$ solution are (*a*) formation of C-7 carbon-centered complexes, i.e., the C-7 *ortho* and *para* complexes, **5** and **6**, and (*b*) simultaneous formation of **2** and the respective nitroaryl phenyl ether. Moreover, there is evidence for the formation of a C-7 hydroxide adduct in the reaction with **3**.



5*a*,*b* **6***a*,*b*

Thus, the reaction pathways comprise both O- and C-attack. O-attack is restricted to the C-1′ position and C-attack is restricted to the C-7 position; both are effectively irreversible processes.

The reactions were followed by 400 MHz ^1H nmr spectroscopy. All chemical shifts are listed in parts per million (ppm) and all coupling constants are given in units of hertz (Hz). $(CD_3)_2SO$ served as the solvent. To obtain quantitative information, a known amount of 1,4-dibromobenzene was added to each sample; integration of the dibromobenzene singlet and the peaks of the complexes permitted estimation of the concentrations of all identifiable species.

Reactions were undertaken with equimolar or excess (3 equiv.) KOPh. The potassium phenoxide was prepared separately and dissolved in $(CD)_3)_2SO$; the relevant quantity could be readily injected into the nmr tube to initiate the reaction.

Reaction of DNP-DNBT (3) with KOPh

The initial spectrum in the reaction of 1 equivalent of PhO^-

4	**6***b*	5.330 (s)	8.748 (s)	[d]	[d]	[d]	[d]	9.321 (s, OH)

[a]The phenyl ring is not observed for any of the adducts.
[b]Partly obscured by peaks due to **2**.
[c]Superscript "c" refers to σ complex.
[d]Not observed, obscured by peaks due to phenoxide, **2**, and other species.

with **3** (initial concentration: ca. 0.020 M) contains broad signals for **3** with somewhat sharper resonances for the various reaction products. Even from this first spectrum (acquired within 3 min) peaks can be noted that are attributable to **2** and, by comparison with the authentic ether, to the 2,4-dinitrophenyl phenyl ether (DNP). The DNP peaks occur at 7.542 (2H, t, *meta*), 7.368 (1H, t, *para*), and 7.269 (2H, d, *ortho*) for the phenyl moiety of the ether, and at 7.146 (1H, d, J = 9.31, H_6), 8.463, 8.438 (1H, d,d, J = 9.31, 2.75, H_5), and 8.892 (1H, d, J = 2.75, H_3) for the 2,4-dinitrophenyl portion of the ether. Examination of the phenolic region also reveals resonances due to phenol at 7.149 (1H, t, *para*) and 6.740 (4H, m, *meta* and *ortho*), while a singlet at 9.335 ppm is ascribed to the phenolic hydroxyl.

With time the spectrum resolved further to reveal signals assignable to two separate carbon-centered phenoxide adducts of **3**. The larger set of signals appears at 5.575 (s), 8.723 (s), and 8.793 (d, J = 2.28), with an apparent doublet of doublets centered at 8.665 (d,d, J = 8.91, 2.28), as well as a doublet at 8.033 (J = 8.91). These resonances are ascribed to H_7^c, H_5^c, $H_{3'}^c$, $H_{5'}^c$, and $H_{6'}^c$, of a C-7 (*ortho*) DNP-DNBT·PhOH$^-$ adduct, formulated as **5***a*. The smaller set of signals is found at 5.294 (s), 8.748 (s), 8.808 (d, J = 2.25), and 8.066 (d, J = 9.04), and ascribed to H_7^c, H_5^c, $H_{3'}^c$, and $H_{6'}^c$, of another C-7 C-centered (*para*) DNP-DNBT·PhOH$^-$ adduct, **6***a*. (Superscript "c" indicates "complex".)

Several pertinent comments must be made concerning the assignment of the nmr spectra. First, in no spectrum could protons of the various phenyl moieties of the carbon adducts **5***a* and **6***a* be discerned, as a result of overlap of the signals with those due to phenol/phenoxide, **2**, etc. In fact, the spectrum is complex and, consequently, in the case of **5***a*, the doublet of doublets due to $H_{5'}^c$ is partially obscured by the resonances which correspond to **2** at 8.719 (d, J = 2.00, H_7) and 8.697 (d, J = 2.00, H_5). The assignment, therefore, partially rests upon the fact that the sp^3-bound protons of anionic σ-complexes are very sensitive to the nature of the attached group (11). Thus, the sp^3-bound protons of the *ortho* and *para* C-adducts of TNB are separated by 0.34 ppm, with the *ortho* C-adduct proton found farthest downfield (1, 2). In the present system ΔH_7^c for the **5***a*/**6***a* pair is 0.281 ppm. Furthermore, acidification does not affect the resonances due to **5***a* or **6***a*, in accord with the known stability of phenoxide-type carbon-bonded Meisenheimer adducts in mildly acidic media (1, 2).[4]

Equally important to the assignment is the presence of two singlets downfield at 9.419 and 9.311. The proximity of these singlets to that at 9.335, which was previously assigned to the OH of phenol, as well as the observed disappearance of the signals upon treatment with D_2O indicates that these peaks are also due to phenolic OH groups. The 9.419 peak has an integral equivalent to that for the H_7^c peak of the complex **5***a*, while the integral of the 9.311 peak corresponds to that for the H_7^c resonance of the complex **6***a*. Note that in structure **5***a* the phenolic OH group must be close to either the 6-NO_2 or the *N*-oxide function of the complex; internal hydrogen bonding could cause the 0.1-ppm downfield shift of the OH peak of the *ortho* C-bonded phenoxide complex, **5***a*, relative to the position of the OH peak of the *para* DNP-DNBT·PhOH$^-$ adduct, **6***a*.

Therefore, the chemical shifts of the H_7^c protons, the observed acid stability, and the presence of the phenolic OH groups all combine to confirm the assignment of the foregoing signals (Table 1) to the carbon-centered C-7 DNP-DNBT·PhOH$^-$ adducts, **5***a* and **6***a*. It is also significant to note that the ratio of the *ortho* adduct, **5***a*, to the *para* adduct, **6***a*, is 2:1.

Simultaneous with identification of the resonances due to the C-7 DNP-DNBT·PhOH$^-$ adducts, **5***a* and **6***a*, another set of signals is noted at 5.958 (d, J = 7.39), 6.079 (d, J = 7.00), and 8.131 (d, J = 7.00). Significantly, all of these signals disappear upon acidification of the solution. Although the chemical shift data are limited, it would appear that the signals are attributable to an O-centered adduct, since such adducts are known to be acid labile (13, 14). Comparison with the reaction of hydroxide with **3**[5] suggests that these signals belong to the C-7 DNP-DNBT·OH$^-$ adduct, formed by attack of hydroxide on the C-7 position. (Hydroxide would be generated by the equilibration of phenoxide with traces of water present in the $(CD_3)_2SO$ solvent.)

The behaviour of the DNP-DNBT/PhO$^-$ system under the condition of 3 equivalents of added phenoxide is very similar to that of the 1 equivalent case. Addition of KOPh results in an initial very broad, unresolved ^{1}H nmr spectrum. The first well-resolved spectrum is recorded after 1.5 h. This spectrum displays the signals for the DNP ether, **2**, PhO$^-$, and the two C-bonded phenoxide adducts, **5***a* and **6***a*. The signals for the substrate, **3**, are not observable. The C-7 bonded H_7^c peaks of **5***a* and **6***a* now appear at 5.644 and 5.331 ppm, respectively. The positions of the other signals of these complexes are unchanged by the modification of the medium. Such behaviour with

varying concentration ratios of PhO^- to substrate has been observed previously in related systems (*1b*). No evidence for formation of the C-7 DNP-DNBT·OH^- adduct is found in this case, which may be a result of the relatively long period of time required before a well-resolved nmr spectrum can be recorded. It is interesting to note that the integral ratio of the *ortho*-bonded carbon-based DNP-DNBT·$PhOH^-$ adduct, **5***a*, to the *para*-bonded counterpart, **6***a*, is almost 1:1 in this reaction system.

Reaction of NP-DNBT (4) with KOPh

The course followed in the reaction of **4** with PhO^- is superficially similar to that observed in the DNP-DNBT/PhO^- system. The initial spectrum (5 min) consists of broad resonances that resolve in later spectra. A resolved spectrum includes peaks for **4**, as well as resonances attributable to the C-7 *para* and *ortho*-C-bonded adducts of **4**, i.e., **6***b* and **5***b*, in the 1 equivalent reaction.

Thus, the more intense peaks of **5***b* appear at 5.603 (s, H_7^{ς}), with a pair of doublets at 8.253 and 8.453 (d,d, J = 8.98, $H_{2',6'}^{\varsigma}$, $H_{3',5'}^{\varsigma}$) and a singlet at 8.716 ppm (H_5^{ς}) with the phenolic OH resonance at 9.377 ppm. Note the similarity of the H_7^{ς} chemical shift of **5***b* as compared to **5***a*; given the known sensitivity of the sp^3-bound proton to the nature of the attached group (11), it is reasonable that H_7^{ς} for **5***a* appears at 5.575 while H_7^{ς} due to **5***b* appears at 5.603, a difference of only 0.028 ppm. This comparison demonstrates the internal consistency of the assignments in that the chemical shift of H_7^{ς} for the *ortho*-C-bonded adducts formed at C-7 of either substrate, **3** or **4**, should be similar.

The *para*-C-bonded NP-DNBT·$PhOH^-$ adduct, **6***b*, displays weaker bands situated at 5.330 (s, H_7^{ς}), 8.748 (s, H_5^{ς}), with the phenolic OH at 9.321 ppm. Although $H_{2',6'}^{\varsigma}$ and $H_{3',5'}^{\varsigma}$ are hidden from view, a doublet centered at 6.639 (J = 7.91 Hz) may be part of the A_2B_2 (or A_2X_2) spin system of the *para*-C phenoxy moiety.

Once again, the similarity in the chemical shifts for H_7^{ς} of **6***b* versus its analogue **6***a* is striking: 5.330 for the former as compared to 5.294 for the latter, a difference of only 0.036 ppm. The assignment is also confirmed by the ΔH_7^{ς} value for **6***b* as compared to **5***b*: 0.333 ppm. In the TNB/PhO^- system the corresponding difference in chemical shift was found to be 0.34 ppm (1, 2).

In accord with the results of the DNP-DNBT/PhO^- reaction, the integral ratio of **5***b* compared to **6***b* is almost exactly 2:1. Also in agreement with the assignments made, acidification does not diminish the signals attributed to **5***b* or **6***b* other than would be expected as a result of dilution, and addition of D_2O results in the disappearance of the singlets due to the phenolic hydroxyls.

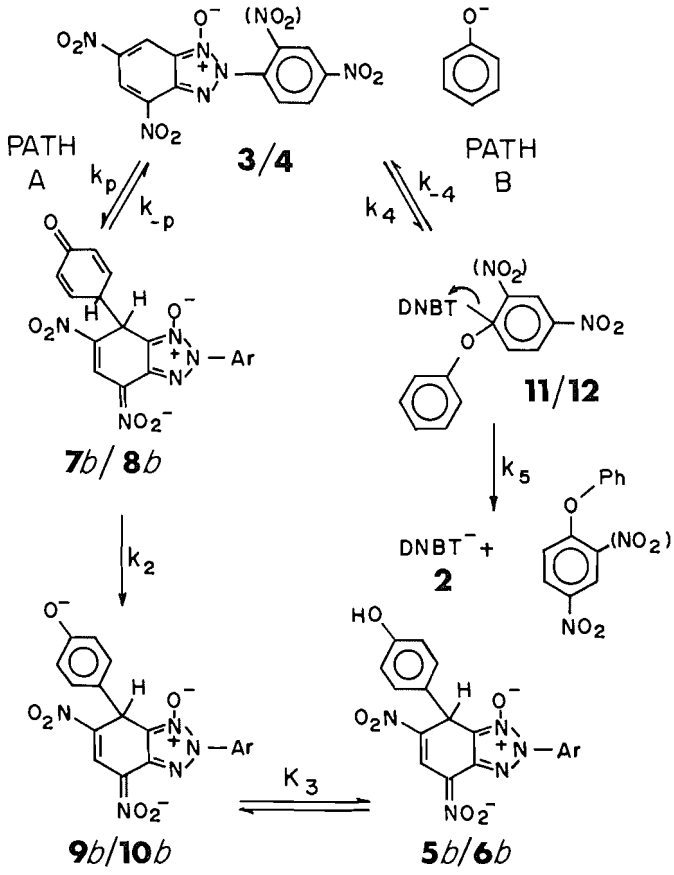
The presence of the other product of N-2:C-1′ bond scission, the 4-nitrophenyl phenyl ether (PN), is inferred from the observation of **2** in the reaction mixture; the ether signals are presumably hidden by those of other species, such as phenoxide.

The results in the 3 equivalent experiment are comparable to the above. The starting material, **4**, is wholly consumed by the added KOPh but otherwise the course of the reaction is unchanged.

Discussion

Reaction pathways

The course of the reaction of phenoxide with either **3** or **4** shows striking differences compared to the reaction of PhO^- with Pi-DNBT, **1**. Reaction at C-1′ of either **3** or **4** occurs via the oxygen centre of the attacking PhO^- and leads to formation of



SCHEME 2

the N-2:C-1′ cleavage products: the nitroaryl phenyl ether and **2**. This behaviour is strictly comparable to that found for methoxide reacting with Pi-DNBT (Scheme 1). However, the nitroaryl phenyl ether does not react further with the added KOPh, contrasting with the Pi-DNBT/MeO^- system.

Concurrently, there is reaction of PhO^- at C-7 with both **3** and **4**, in which PhO^- behaves only as a C-nucleophile (Scheme 2). This contrasts with the behaviour observed in the Pi-DNBT/PhO^- system where reaction of PhO^- at C-7 is not detectable, either by C- or O-attack (4, 5).

In addition, **3** reacts with hydroxide, generated through equilibration of the added KOPh with water present in the solvent, to form the C-7 DNP-DNBT·OH^- adduct.[5]

Thus, the dichotomy inherent in the present results is clear: in attack at C-1′ PhO^- behaves solely as an oxygen-centered nucleophile, whereas in attack at C-7 PhO^- acts only as a carbon-centered nucleophile.

Selectivity considerations

It has previously been found useful to consider the reactions of **1** from a reactivity–selectivity point of view (4, 5). Since semiquantitative data could be obtained for these reactions from the comparative integrals for the internal standard, 1,4-dibromobenzene, and the species of interest, the percentage of each complex formed can be estimated for the 1 equivalent experiments (Table 2).

Before considering the selectivity of each of the substrates (**1**, **3**, **4**) with respect to the reaction with PhO^-, it is necessary first to consider the overall kinetics involved in these reactions.

Unlike the reaction of methoxide with **1**, reaction of PhO^- at C-7 of **3** or **4** occurs by an effectively irreversible process. Thus,

TABLE 2. The extent of adduct formation with **1**, **3**, and **4** (1 equiv. PhO^-)

Substrate	Time (min)[a]	% Adducts (total)	%C-7	%C-1′[b]	%C-7/%C-1′[c]
1	2.5	100	—	100	0
3	74	52.7[d]	33.9[e]	18.8	1.80
4	200	28.8	21.6[f]	7.2	3.00

[a]Broadness prevents an earlier estimate.
[b]% C-1′ = % **2** = % nitroaryl phenyl ether.
[c]Related to k_1/k_4.
[d]Percentage excludes the C-7 DNP-DNBT·OH^- adduct (7.5%).
[e]***5a*** makes up 22.6% of the 33.9%; ***5b*** makes up the remaining 11.3%.
[f]***6a*** makes up 14.4% of the 21.6%; ***6b*** makes up the remaining 7.2%.

reaction of PhO^- as a carbon-centered nucleophile would involve initial formation of a quinoidal intermediate, ***7b*** or ***7a***, which, in a second step, would undergo rearomatization with protonation to yield the observed C-adduct, ***5b*** or ***5a*** (Scheme 2). The presence of the hydroxyl groups of the attached phenoxyls of each adduct (***5a/5b***, ***6a/6b***) confirms the aromatic nature of the final, observed C-adduct.

The process may be written as occurring in three steps (Scheme 2). In the first step the quinoidal adduct is formed; this is characterized by a forward rate constant (k_p for the *para* adduct, ***7b***, and k_o for the *ortho* adduct, ***7a*** (not shown in Scheme 2)). The rearomatization step is associated with a forward rate constant k_2, and the protonation step is described by an equilibrium constant, K_3. The observations suggest that K_3 is large (as befits protonation of what is essentially a substituted phenoxide ion, i.e., $K_3 = 1/K_a$ (15)),[6] and that k_2 is larger than $k_p(k_o)$. The last conclusion follows from the lack of observation of the quinoidal adduct in this or in previous studies (1, 2, 4). It is possible that the reverse rate coefficients (k_{-p} and k_{-o}) may also be ignored, i.e., $k_2 \gg k_{-p}$. Under these circumstances the rate-determining step for this process would be characterized by the rate constant $k_p(k_o)$.

On the other hand, reaction at C-1′ via the oxygen centre of PhO^- also leads to formation of a metastable intermediate, in this case the C-1′ adduct. If formation of this species is assigned a rate constant k_4, and the rapid decomposition of the adduct a rate constant k_5, then the lack of observation of a C-1′ adduct in this and related systems (4, 5) suggests that k_4 should be viewed as the effective overall rate-determining rate constant for this process. Once again this derivation requires the assumption that $k_5 \gg k_{-4}$.

Thus, the overall rate expression is given by eq. [1]:

$$[1] \quad -d[\mathbf{3}]/dt = (k_p + k_o + k_4)[\mathbf{3}][PhO^-]$$

The derivation of eq. [1] ignores the process of C-7 adduct formation by HO^-.[5] A comparable equation can be derived for the reaction of **4** with PhO^- through replacement of [**3**] with [**4**] in eq. [1].

It is interesting to note that the 2:1 statistical ratio found for the C-adduct pairs ***5a/6a***, as well as ***5b/6b*** (Table 2), suggests that $k_p = k_o$ for **3** and **4**; i.e., the activation barrier associated with formation of ***7a*** and ***8a*** is equivalent to that for ***7b*** and ***8b*** formation, respectively.

To compare the overall tendencies for attack at C-7 as compared to C-1′ in both substrates, it is useful to substitute an overall C-7 rate constant, k_1, for the quantity ($k_p + k_o$) and replace [**3**] (or [**4**]) by the concentration of substrate, S, i.e.:

$$[2] \quad -d[S]/dt = (k_1 + k_4)[S][PhO^-]$$

The form of eq. [2] is that of competing second-order reactions (16) and comparison of the competing rate constants k_1 and k_4 gives insight into the relative electrophilicity and selectivity of C-7 versus C-1′.

In related systems (4, 5) it has been noted that the hallmark of a selective reaction is the observation of the C-7 adduct. Clearly, this will only be true in the case where the quantity of nucleophile is limited. Therefore, selectivity may be defined as the ratio of the rate constants for attack at C-7 and C-1′, i.e., k_1/k_4, where k_1 represents C-attack at C-7 by both the *para* and *ortho* positions of PhO^-, for the 1 equivalent reactions.

The data shown in Table 2 were obtained at somewhat different reaction times, owing to the initial broadness encountered in the reactions of **3** and **4** with PhO^-. However, the percentages of complexes formed may be used as a guide to the selectivities since the ratio of the products formed must be a reflection of the magnitudes of the ratio constants (k_1, k_4) involved.

In this regard, it is clear that **1** is a less selective electrophile than **3**, in the reaction with PhO^-. In the case of **1**, 100% of the reaction proceeds via Path B (Scheme 2) to yield the products derived solely from C-1′ O-attack, while in the case of the **3**, reaction is partitioned between C-7 attack via carbon (33.9%, both *para* and *ortho* adducts) and C-1′ attack via oxygen (18.8%). To the extent that the percentages of complexes formed reflect the magnitudes of the rate constants, the ratio k_1/k_4 would be 33.9/18.8 = 1.80.

Proceeding from **3** to **4**, the ratio of C-7 versus C-1′ attack increases; now the ratio (k_1/k_4) is 3.0. Thus by our definition **3** would be more selective than **4** and even more selective than **1**.

It is interesting to consider, as well, the overall reactivity of the substrates towards PhO^-. **1** reacts completely while for **3** the total percentage of complexes formed is only 52.7% (excluding the C-7 HO^- adduct). The percentage drops further for **4**, which, even after 200 min reaction time, yields only 28.8% of all complexes formed.

Equally interesting is the fact that the ratio of the *ortho* to the *para* C-adduct is 2:1 for both **3** and **4**, contrasting with the situation for TNB (1). This is the ratio predicted purely on a statistical basis. Clearly C-7 is a highly reactive and relatively unselective position in these systems.

Comparative energy profiles

While the trend in selectivity discussed above (see also Table 2) is a function of an increase in the relative magnitude of k_1, it is even more a result of a significant decrease in k_4. Hence, even though the percentage of the C-7 adduct formed increases from nil to 33.9% in going from **1** to **3** as substrate, the absolute percentage of C-7 complex formed actually drops to 21.6% for

[6]pK_a of PhOH in DMSO = 16.4; $1/K_a = 2.5 \times 10^{16}$ (ref. 15).

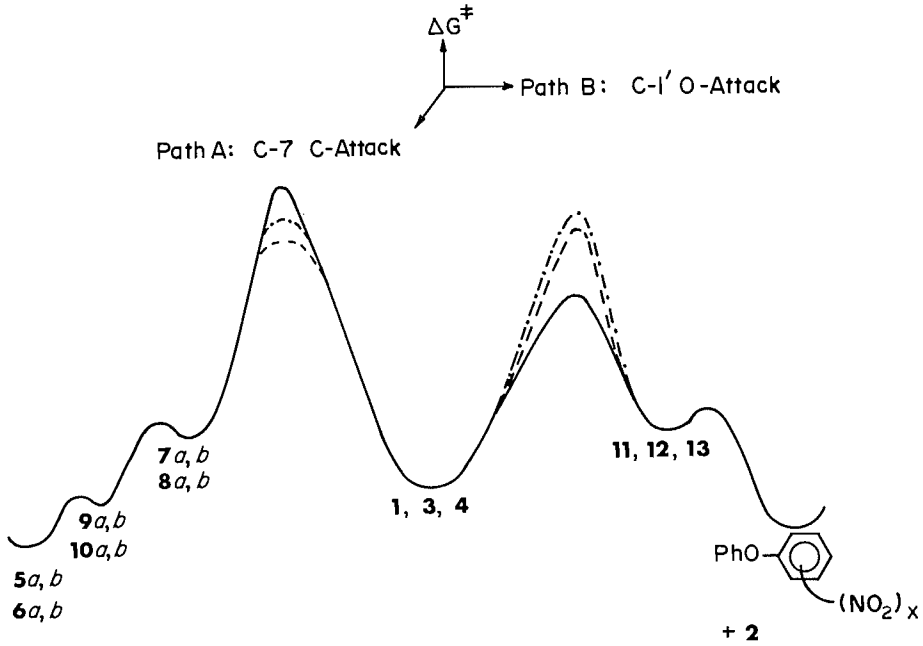

FIG. 1. Comparative activation energy – reaction coordinate profile: left-hand branch represents Path A (Scheme 2) and the right-hand branch represents Path B (Scheme 2). The energy profile for **1** (solid line) is compared with those for **3** (dashed line) and **4** (dot and dash line) in reaction with PhO^-. The C-1′ O-adducts formed from **1**, **3**, and **4** are labelled **13**, **11**, and **12** respectively; the other adducts are labelled as in the text.

4. This decrease in the actual percentage of C-7 NP-DBNT·$PhOH^-$ adduct(s) formed is offset by a larger decrease in the percentage of C-1′ adduct formation in going from **3** to **4** (18.8 to 7.2%, respectively).

These results can be illustrated by the energy/reaction coordinate profile shown in Fig. 1. The profile shows both Path A (left-hand branch), which involves C-attack at the C-7 position, and Path B (right-hand branch), which involves O-attack at the C-1′ position (Scheme 2). The requirement (17, 18) that reactivity–selectivity considerations apply to reactions that can be compared on the same energy profile is, therefore, met in the present system.

Path B shows that the activation barrier associated with O-attack at C-1′ increases substantially between **1** and **3** and less significantly between **3** and **4**. This is consistent with the semi-quantitative results (Table 2). The second activation barrier illustrated in Path B represents the decomposition of the C-1′ O-adduct to **2** and the nitroaryl phenyl ether. Since this step is not rate-determining it is not possible to ascertain any modification in the energetics involved as the substrate is changed from **1** to **3** and to **4**.

The increase in the activation barrier for rate-determining formation of the C-1′ adduct along the series (Path B) must be linked to the decrease in the nitro functions attached to the 2-*N*-nitroaryl ring. As the nitro groups are progressively removed the 2-*N*-nitroaryl ring becomes successively less able to delocalize the charge acquired upon formation of the C-1′ adduct. If the transition state associated with attack at C-1′ in Path B is relatively late (19), then the kinetic barrier for attack at C-1′ would change as shown in Fig. 1 as the substrate is changed. In other words, the factors that stabilize the C-1′ adducts would also be expected to stabilize a late, adduct-like transition state and, therefore, the rate of formation of the N-2:C-1′ cleavage products would decrease as the nitro groups attached to the 2-*N*-nitroaryl function are removed.

An alternative view would hold that reaction of PhO^- via oxygen at C-1′ proceeds through a relatively early transition state. If this is the case, then the decrease in reaction at C-1′ that accompanies removal of the nitro groups of the 2-*N*-nitroaryl moieties of the substrates may simply indicate a decrease in the positive charge density (and attendant electrophilicity) of the C-1′ position. We have previously pointed out that σ-complex formation may proceed through an early transition state (10) where the overall S_NAr process (20) involves reaction of a 1-X-2,4,6-trinitrobenzene in which X is a bulky substituent. This description may also apply to **3** and **4**, where DNBT is the bulky substituent.

Proceeding to Path A, the results listed in Table 2 also allow one to compare the energetics involved. While the kinetic barrier is shown to decrease for C-7 C-attack on **3** as compared to **1**, the barrier increases again for **4** as compared to **3**.

Apparently, removal of the nitro groups from the 2-*N*-nitroaryl ring leads to decreased reactivity at the C-7 position for **4** as compared to **3**. The effect of the distant 2-*N*-nitroaryl ring is likely to be inductive in nature and, therefore, dependent upon the proximity of the substituents to the C-7 reactive centre. Whether the 2-*N*-nitroaryl ring influences reactivity at the C-7 centre by modifying the electrophilicity (positive charge density) at the position (in an early transition state) or by modifying the ability to stabilize the final C-7 complex (in a late transition state) is not clear from the present results. In either case, a nitro group in the *para* position of the 2-*N*-nitroaryl moiety is not as effective as an *ortho* nitro group in affecting the reactivity of the C-7 position.

Electron transfer on the reaction pathway?

The broadness noted in the initial ^1H nmr spectrum is interesting, in light of the recent suggestion (21) that the reaction of picryl chloride with hydroxide proceeds via electron transfer. The central intermediate in the reaction is then a radical anion-radical pair. Such paramagnetic species are known to cause ^1H nmr spectral broadening (22) and such broadening has been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/07/12
For personal use only.

observed in other systems involving Meisenheimer adducts (23).

However, although the spectra are generally broad in the early stages of the reaction, the signals due to the substrates are broad even after the peaks due to the complexes have resolved. Furthermore, the C-7 HO^- adduct declines with time in favour of the cleavage products. It is noteworthy that the spectrum is sharp and well resolved at this point in the reaction. If the C-7 HO^- adduct or the other C-7 adducts result from an electron transfer process, then their decomposition should also proceed via an electron transfer process; the spectrum should hence remain broad until the C-7 HO^- adduct has decomposed.

These observations suggest that the initial broadness noted in the ^1H nmr spectra in the reactions is a consequence of a side reaction, probably involving free radicals, but is not the main pathway for formation of the Meisenheimer complexes reported here.

Conclusions

The present results represent the first comparison of irreversible oxygen- and carbon-centered attack involving Meisenheimer complex formation. Thus, C-attack by PhO^- at C-7 of the substrates **3** and **4** leads to initial formation of a quinoidal adduct; rearomatization to give adducts such as **5** and **6** is an effectively irreversible process. Similarly, O-attack at C-1′ is an effectively irreversible process in the systems since the C-1′ O-adduct decomposes rapidly and irreversibly to products of N-2:C-1′ bond scission.

The decrease in intrinsic stability of the C-1′ adducts and the transition state leading to them (or, alternatively, the decrease in electrophilicity of the C-1′ positions), for **3** and **4**, accounts for the observation of the C-7 adducts in these two cases. This result is in marked contrast to the reaction of **1** with PhO^- where neither O- nor C-bonded C-7 adducts are observed.

The statistical concentration ratio of the C-7 *ortho* and *para* C-adducts of both **3** and **4** emphasizes the highly electrophilic and relatively unselective nature of the C-7 site. Clearly **3** and **4** are superelectrophiles.

Experimental

Materials

$(CD_3)_2SO$ (Merck) was treated thrice sequentially with 4A molecular sieves prior to use. 1,4-Dibromobenzene (Eastman) was recrystallized twice from ethanol and dried *in vacuo* (<1 Torr; 1 Torr = 133.3 Pa). 2,4-Dinitrophenylhydrazine (BDH), 4-nitrophenylhydrazine (Aldrich), 2,4-dinitrochlorobenzene (Eastman), and tris(hydroxymethyl)aminoethane (Tris; Aldrich) were dried but otherwise used without purification. Nitration of 2,4-dinitrochlorobenzene afforded the picryl chloride used in the preparations below (24), mp 83°C (lit. (24) mp 83°C). Methanol was purified by reflux with and distillation from Mg turnings (25). Phenol was purified by recrystallization from petroleum ether. Potassium methoxide (ca. 4 M) was prepared from freshly cut potassium metal and dry methanol in a nitrogen-filled dry box. The potassium methoxide solution was then standardized against standard HCl, which had been standardized against weighed quantities of Tris (26). Potassium phenoxide was prepared from the purified phenol and standardized KOMe in MeOH in a dry box; excess MeOH was evaporated under a stream of nitrogen and the solid dried under vacuum, mp > 220°C (lit. (27) mp 285–289°C). The 400 MHz ^1H nmr spectrum displayed the following resonances (δ, ppm, $(CD_3)_2SO$): 5.910 (1H, t, *para*), 6.123 (2H, d, *ortho*), and 6.706 (2H, t, *meta*).

Preparation of 2-N-(2′,4′-dinitrophenyl)-4,6-dinitrobenzotriazole 1-oxide, 3

2,2′,4,4′,6-Pentanitrohydrazobenzene (PNH) was synthesized from picryl chloride and 2,4-dinitrophenylhydrazine by the procedure of Leeman and Grandmougin (28) in 88.6% yield, mp 220–223°C (lit. (28) mp 225°C (dec.)). The PNH (2.00 g, 0.0049 mol) was dissolved in concentrated H_2SO_4 (100 mL) in a beaker, and the solution was heated to 40°C and allowed to stir until a thin-layer chromatogram (silica, THF eluant) of the reaction mixture showed no remaining PNH (ca. 1.5 h). The mixture was cooled in ice and then poured into ice water. The yellow precipitate was collected by vacuum filtration and recrystallized from benzene and then from acetonitrile. Yield: 0.930 g, 48.6%; R_f (silica, THF eluant): 0.69; mp 254–256°C (dec.); uv–vis (CH_2Cl_2): 420.0 nm (log ε: 3.85), 340 (sh), 296.0 (log ε: 519); ^1H nmr (δ, ppm, $(CD_3)_2SO$; coupling constants are given in hertz): 8.368 (1H, d, $J_{5',6'}$ = 8.71, $H_{6'}$), 8.950 (1H, d,d, $J_{6',5'}$ = 8.71, $J_{3',5'}$ = 2.30, $H_{5'}$), 9.072 (1H, d, $J_{5',3'}$ = 2.30, $H_{3'}$), 9.091 (1H, d, $J_{5,7}$ = 1.90, H_5) and 9.363 (1H, d, $J_{7,5}$ = 1.90, H_7). *Anal.* calcd. for $C_{12}H_5N_7O_9$ (%): C 36.84, H 1.29, N 25.06; found (%): C 37.32, H 1.47, N 24.76.

Preparation of 2-N-(4′-nitrophenyl)-4,6-dinitrobenzotriazole 1-oxide, 4

2,4,4′,6-Tetranitrohydrazobenzene (TNH) was prepared from picryl chloride and 4-nitrophenylhydrazine (29) in quantitative yield, mp 213–215°C (lit. (12) mp 214–215°C). In the best of several attempts to cyclize the TNH, the hydrazobenzene (3.0 g; 0.0082 mol) was added to concentrated H_2SO_4 (100 mL) in a beaker at room temperature and the TNH solution was stirred for no more than 7 min and then poured into ice water. The tarry residue was collected by vacuum filtration. When crystallized (twice) from acetonitrile it yielded 0.307 g, 10.4%; R_f (silica, CH_2Cl_2 eluant): 0.57; (THF eluant): 0.72 (with streaking); mp 225–226°C; uv–vis (CH_2Cl_2): 424.0 nm (log ε: 3.85), 340 (sh), 316 (log ε: 4.41), 260 (log ε: 4.14); ^1H nmr (δ(ppm), $(CD_3)_2SO$): 8.489 (2H, d, $J_{2',6'-3',5'}$ = 9.18, $H_{2',6'}$), 8.591 (2H, d, $J_{3',5'-2',6'}$ = 9.18, $H_{3',5'}$), 9.059 (1H, d, $J_{5,7}$ = 1.90, H_5) and 9.293 (1H, d, $J_{7,5}$ = 1.90, H_7). *Anal.* calcd. for $C_{12}H_6N_6O_7$ (%): C 41.63, H 1.75, N 24.27; found (%): C 41.49, H 1.85, N 23.94.

^1H nuclear magnetic resonance experiments

The ^1H nmr experiments were carried out on a Bruker AM-400 spectrometer, operating at 400 MHz. Wilmad PP-507 nmr tubes were used in all experiments. The spectrometer was adjusted routinely as follows: spin rate, 25 rps; relaxation delay, 2.0 s; acquisition time, 2.982 s; pulse width, 5 μs (with a pulse angle of 45°); sweep width, 5500 Hz; 32 000 data points; temperature, ambient (21 ± 2°C). All stock solutions and the nmr tubes were capped with rubber septa and all tubes were swept out with N_2 prior to the injection of the reactants. All tubes were injected with a known volume of a stock 1,4-dibromobenzene (DBB) solution in $(CD_3)_2SO$, which acted as an internal integration standard. DMSO-d_5H served as the chemical shift standard.

A representative experiment: the reaction of DNP-DNBT (3) with equimolar KOPh

The DNP-DNBT stock solution (0.1329 M) was prepared by dissolution of a weighed quantity of **3** (0.2601 g, 6.649×10^{-5} mol) in $(CD_3)_2SO$ (0.50 mL). Dissolution of KOPh (0.1347 g, 0.001019 mol) in $(CD_3)_2SO$ (1.0 mL) afforded the phenoxide stock solution used (1.019 M). The initial spectrum was measured using an nmr tube that contained the substrate, 1,4-dibromobenzene, and $(CD_3)_2SO$ (75, 5, and 400 μL of the solutions, respectively). After the injection of 1 equiv. of KOPh (10 μL) to the substrate sample, the FID (16 transients) was collected within 3 min of the mixing of the reactants. In later spectra 64 transients per FID sufficed to obtain the spectra reported here. Final concentration of both reagents was ca. 0.020 M. Spectra were recorded at the following time intervals: 3, 20, 140, 232, 313, 386, 429, and finally 2730 min.

In a separate experiment, D_2O (2 drops) was added to the sample tube after the reaction was well advanced and the spectrum was acquired. Finally TFA (3 μL) was injected into the nmr tube and the spectrum again obtained.

Spectra were plotted from 4200 to 0 Hz and replotted from 3850 to 2050 Hz at a higher peak amplitude. Computer printouts of the chemical shifts (5 places) were obtained. The spectra were integrated.

Received December 15, 1987

AIJAZ AHMAD ANSARI and M. R. ISLAM. Can. J. Chem. **66**, 1720 (1988).

Electrical conductivities of Me_4NBr, Et_4NBr, Pr_4NBr, Bu_4NBr, and Bu_4PBr have been measured in isopropanol + water (2-PrOH + H_2O) mixtures covering the approximate range of dielectric constant ($71.40 \geq D \geq 19.40$) at 25°C. The conductance data have been analysed by using the Fuoss-1978 (F78) conductance equation and the results compared with those obtained from the Fuoss–Onsager–Skinner (FOS) equation. The values of the limiting equivalent conductance, Λ_0, the association constant, K_A, and the distance of ion-size parameter (R or a_K^0) are computed from these data. A better fit of the conductance data was provided by the F78 equation. Ion–solvent interactions and effective sizes of tetraalkylammonium ions are also discussed in order to understand the magnitude of the ionic association. The overall association behaviour of these salts has been found to increase with decrease in dielectric constant of the medium.

AIJAZ AHMAD ANSARI et M. R. ISLAM. Can. J. Chem. **66**, 1720 (1988).

Opérant à 25°C, on a mesuré les conductivités électriques du Me_4NBr, du Et_4NBr, du Pr_4NBr, du Bu_4NBr et du Bu_4PBr dans des mélanges d'isopropanol/eau (PrOH-2 + H_2O) couvrant des constantes diélectriques de $71{,}40 \geq D \geq 19{,}40$. On a analysé les données de conductivité à l'aide de l'équation de conductance de Fuoss-1978 (F78) et on a comparé les résultats obtenus avec ceux auxquels conduit l'équation de Fuoss–Onsager–Skinner (FOS). Utilisant ces données, on a calculé les valeurs limites de la conductance équivalente, Λ_0, la constante d'association, K_A, ainsi que la distance ou le paramètre de la grosseur de l'ion (R ou a_K^0). Les données de conductance donnent un meilleur accord avec l'équation F78. Afin de comprendre l'amplitude de l'association ionique de ces sels, on discute aussi des interactions ion–solvant et des grosseurs effectives des ions tétraalkylammonium. On a trouvé que le comportement global de l'association de ces sels augmente avec une diminution de la constante diélectrique du milieu.

[Traduit par la revue]

Introduction

Extensive studies (1–6) on the electrical conductance of dilute electrolytic solutions have been made in aqueous, non-aqueous, and mixed organic solvents to examine the influence of dielectric constant on ionic-association and solute–solvent interactions. In addition, the anomalous physical proties of isopropanol + water mixtures have enabled several workers (7, 8) to interpret the unique structure of that solvent. Recently, it has been reported (9) that the isomeric isopropanol (2-PrOH) differs considerably from normal alcohols in undergoing protonation by solvated proton (H_3O^+) in water either as $(R'OH)_2^+H$ or as $(R'OH)_3^+H$, where R′ is an alkyl group. Conway and Bockris (10) have also proposed that in the tetrahedral structure of protonated alcohol, i.e. $(R'OH)_3^+H$, the alcohol chain becomes more bulky in the presence of water and thus the mobility of the alcohol-solvated proton becomes normal due to alignment of solvent molecules. Therefore, 2-PrOH appears to be a stronger base as well as a stronger hydrogen bond acceptor than any other lower alcohols. Furthermore, the conductance studies (6, 7) of alkali and tetraalkylammonium halides in various mixed solvent systems reveal that the association behaviour of specific ion–solvent interactions mainly depends on the nature, composition variation, and the structure of the solvents. It has been found that the association of electrolytes in solvents containing hydroxyl groups appears to increase with increasing proportion of alcohol and ionic size (2, 3) contrary to the predictions in the electrolytic theory. This has, however, been explained in terms of the multiple-step association process (11–13), i.e., the formation of solvent-separated ion-pairs, SSIP, and the formation of contact ion-pairs, CIP. Therefore, it would be of great interest to undertake the measurement of electrical conductances of tetramethyl-, tetraethyl-, tetrapropyl-, tetrabutyl-ammonium bromides (Me_4NBr, Et_4NBr, Pr_4NBr, and Bu_4NBr) and tetrabutylphosphonium bromide (Bu_4PBr) in 2-PrOH + H_2O mixtures in comparison with those in 1-PrOH + H_2O mixtures (14).

Experimental

Purified (7) and redistilled reagent grade 2-PrOH (BDH) with specific conductance, $(2–7) \times 10^{-8}\ \Omega^{-1}\ cm^{-1}$ was used immediately for the preparation of solvent mixtures with triply distilled water (specific conductance = $2.3 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$). The density and viscosity measurements of pure 2-PrOH and those of its aqueous mixtures (2-PrOH + H_2O) have been reported earlier (15). The dielectric constants of solvent mixtures used for analysis were taken from the literature (16). Me_4NBr, Et_4NBr, Pr_4NBr (Fluka, AG), Bu_4NBr (Estman, AG), and Bu_4PBr (Alfa, inorganic) were used as solute.

The conductivity measurements were done using an impedence bridge, 1608-A (General Radio & Co., USA), at a constant frequency of 1 kHz with an accuracy of ±0.05 to ±0.005%. The conductivity cell used was a four-necked flask with a 250 cm^3 capacity, and was equipped with a nitrogen inlet, a magnetic stirrer, and two platinized platinum electrodes. The cell (cell constant 0.995 cm^{-1}) was calibrated with aqueous KCl solution.

The solvent mixtures and solutions were prepared by weight under nitrogen atmosphere in a dry box just before conductivity measurements. Initially a known volume of concentrated electrolytic solution,

$C_{max} = 2 \times D^3 \times 10^{-7}$ (17), was taken in the conductivity cell which was immersed in a thermostated liquid paraffin bath maintained at 25 ± 0.01°C. The solutions of desired concentrations were obtained by dilution and the conductance values recorded after attainment of thermal equilibrium. All the conductivity measurements were made in an atmosphere of pure and dry nitrogen. The reproducibility of the conductivity measurements was better than 0.05%.

Results and discussion

Analysis of conductance data

The molar conductivities, Λ (S cm^2 mol^{-1}), for dilute solutions of Me_4NBr, Et_4NBr, Pr_4NBr, Bu_4NBr, and Bu_4PBr in 2-PrOH + H_2O mixtures as a function of concentration, C (mol dm^{-3}), at 25°C are given in Table 1.

The concentration dependence of conductance data for all the salts have been first analysed in terms of F78 conductance equation (18, 19) based on the concept of diffusion-controlled steady state approach. The conductance equation used is of the form,

$$[1] \quad \Lambda = [1 - \alpha(1 - \gamma)][\Lambda_0(1 + \Delta X/X) + \Delta\Lambda_e]$$

where Λ_0 is the limiting equivalent conductance, the term $\Delta X/X$ represents the relaxation effect, $\Delta\Lambda_e$ the electrophoretic effect, γ denotes the fraction of solute present as free ions, and α is the contact pair parameter. Both ΔX and $\Delta\Lambda_e$ depend on the values of the diameter of Gurney cosphere, R, dielectric constant, and viscosity. The parameters and auxilliary variables are related by the following set of equations,

$$[2] \quad K_R = (1 - \alpha)(1 - \gamma)/C\gamma^2 f^2 = (4\pi NR^3/3000) \exp(\beta/R)$$

and

$$[3] \quad K_S = \alpha/(1 - \alpha) = \exp(-E_s/kT)$$

where K_R and K_S refer to the SSIP and CIP formation constants, respectively. The activity coefficient, f, and the difference in energy, E_s, between a pair in the states $r = R$ and $r = a$, where r is the centre-to-centre distance in the case of paired ions and α is the ionic diameter. On rearranging eq. [3] we get

$$[4] \quad (1 - \alpha) = 1/(1 + K_S)$$

Substitution of eq. [4] in eq. [2] gives the conductometric association constant, K_A

$$[5] \quad K_A = (1 - \gamma)/C\gamma^2 f^2 = K_R/(1 - \alpha) = K_R(1 + K_S)$$

The activity coefficient is given by

$$[6] \quad -\ln f = \beta\kappa/2(1 + \kappa R)$$

where $\beta = e^2/DkT$ and $\kappa^2 = 8\pi\beta\gamma n = \pi\beta NC\gamma/125$.

For this purpose the specially designed PARACOND (17) computer programme for the PARAmetric analysis of CONDuctance data for the symmetrical electrolytes have been used. Equations [1]–[6] have been used to find the values of conductance parameters, Λ_0, K_A, and R where $\gamma < 1$ and $K_A > 0.0$ which minimize the standard deviation, σ_Λ, calculated from the relation

$$[7] \quad \sigma_\Lambda = [\Sigma(\Lambda(obs) - \Lambda(cal))^2/N - 3]^{1/2}$$

Similarly, each set of conductance data was then analysed using the FOS equation (20).

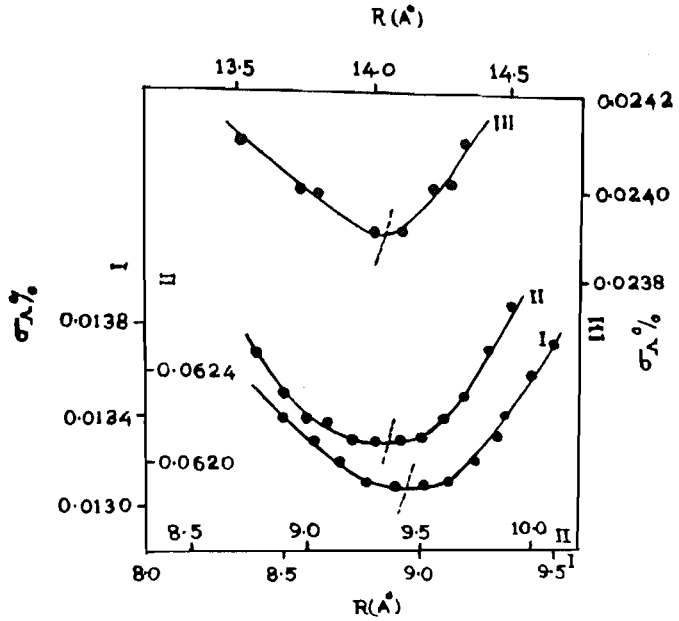

FIG. 1. Plots of σ_Λ% vs. R for Me_4NBr (*I*) in 20 wt.% Bu_4NBr (*II*) in 30 wt.% and Bu_4NBr (*III*) in 80 wt.% 2-PrOH.

$$[8] \quad \Lambda = \Lambda_0 - SC^{1/2} + EC \log(6E_1'C) + LC$$

for unassociated electrolyte while

$$[9] \quad \Lambda = \Lambda_0 - S(C\gamma)^{1/2} + EC\gamma \log(6E_1'C\gamma) + LC\gamma - K_A C\gamma f^2 \Lambda$$

for associated electrolyte. The terms appearing in eq. [8] and eq. [9] are those given by Fuoss (21). To solve eqs. [8] and [9] a similar computer programme developed by Kay *et al.* (2) was used.

The initial values of limiting equivalent conductance used in the Fuoss method of analysis have been obtained using the Shedlovsky's (22) method of extrapolation of the conductance data. The values of Λ_0 have been computed for each of the sequence of R values by minimizing the standard deviation, σ_Λ. The computed values of R depend on the dielectric constant of the medium (19). It is initially set equal to $a + d_s$ where a is sum of crystallographic radii and d_s is the diameter of a solvent molecule, when $a + d_s$ is greater than $\beta/2$. When $\beta/2$ is greater than $(a + d_s)$, R is set equal to $\beta/2$, and $\beta/2$ are used to find the value of R_{min} for each salt in order to obtain the final value of R. For mixture of higher dielectric constant ($D > 30$) the plots of σ_Λ% vs. R usually show a shallow minimum with R_{min} values ranging from 4 to 10 Å and for $D < 30$ rather sharp minimum is found in σ_Λ% vs. R plots (Fig. 1).

The computed values of the adjustable parameters Λ_0, K_A, K_R, K_S, and R from F78 and Λ_0, K_A, and a_K^0 from FOS conductance equations along with σ_Λ% (i.e. $\sigma_{min} \times 100/\Lambda_0$) which correspond to minimum standard deviations are listed in Tables 2 and 3, respectively. All calculations have been carried out on an VAX-11/780 computer.

Limiting equivalent conductance

The values of Λ_0 (Tables 2 and 3) obtained for all salts through the F78 equation are found to be almost close to those obtained by using the FOS equation within the limits of errors. An inspection of Tables 2 and 3 reveal an apparently normal behaviour of tetraalkylammonium salts in various solvent

mixtures, i.e., Λ_0 decreases with increasing size of the tetraalkylammonium ions in the order $Me_4N^+ > Et_4N^+ > Pr_4N^+ > Bu_4N^+ \approx Bu_4P^+$ and with decreasing dielectric constant of the solvent mixtures. This is in agreement with the earlier findings (1–8, 11–14) in several pure and mixed solvents. However, the decrease in Λ_0 values with increasing proportion of 2-PrOH can also be explained on the basis of ion–solvent interactions, which increase with the increase in ionic size and hydrophobic solvation of cations following the order $Me_4N^+ < Et_4N^+ < Pr_4N^+ < Bu_4N^+ \approx Bu_4P^+$. As a result the mobilities of respective ions decrease in the reverse order. However, in any given solvent mixture the limiting equivalent conductance decreases in the order $Me_4NBr > Et_4NBr > Pr_4NBr > Bu_4NBr \approx Bu_4PBr$. It may also be noted that in the case of high dielectric medium ($71.40 \geq D \geq 49.70$) the extent of decrease in the Λ_0 values are significant due to higher mobility as compared to those in low dielectric constant medium ($42.50 \geq D \geq 20.30$).

Association constant and distance parameter

The values of K_A (Tables 2 and 3) for all the salts in 2-PrOH + H_2O mixtures computed through F78 equation are found to be larger than those obtained using the FOS equation. On the other hand, the K_A values obtained from FOS equation are negative or less than ten in the dielectric range ($71.40 \geq D \geq 49.70$) and it has been considered as non-associated but in the dielectric range

(42.50 ≥ D ≥ 19.41) gives appreciably large values for those electrolytes which are associated. The overall values of association constant increase with a decrease in the solvent dielectric constant. However, the association constant obtained from F78 and FOS equations are an exponential function of the dielectric constant of the medium as is evident from the linear plots of log K_A vs. $1/D$ (Fig. 2). Therefore, this linearity of the plots suggest the applicability of the Bjerrum theories of ion association (28–30).

Further, the K_A values for all the salts in a given dielectric medium increases with increasing size of the ions in the dielectric range (71.40 ≥ D ≥ 28.70) in the order $Me_4N^+ < Et_4N^+ < Pr_4N^+ < Bu_4N^+ \approx Bu_4P^+$ as expected (23–27). However, this order does not carry over in the dielectric range (23.70 ≥ D ≥ 19.40), it becomes $Me_4N^+ > Et_4N^+ > Pr_4N^+ > Bu_4N^+ \approx Bu_4P^+$. This anomalous behaviour of K_A in the low dielectric medium may be ascribed to the predominant solvation of cations due to increasing the charge density with decreasing size. Consequently, it is evident from Table 2 that the overall values of the solvent-separated ion-pair (SSIP) formation constant, K_R, increases with a decrease in the dielectric constant of the medium as is the case with K_A but the contact

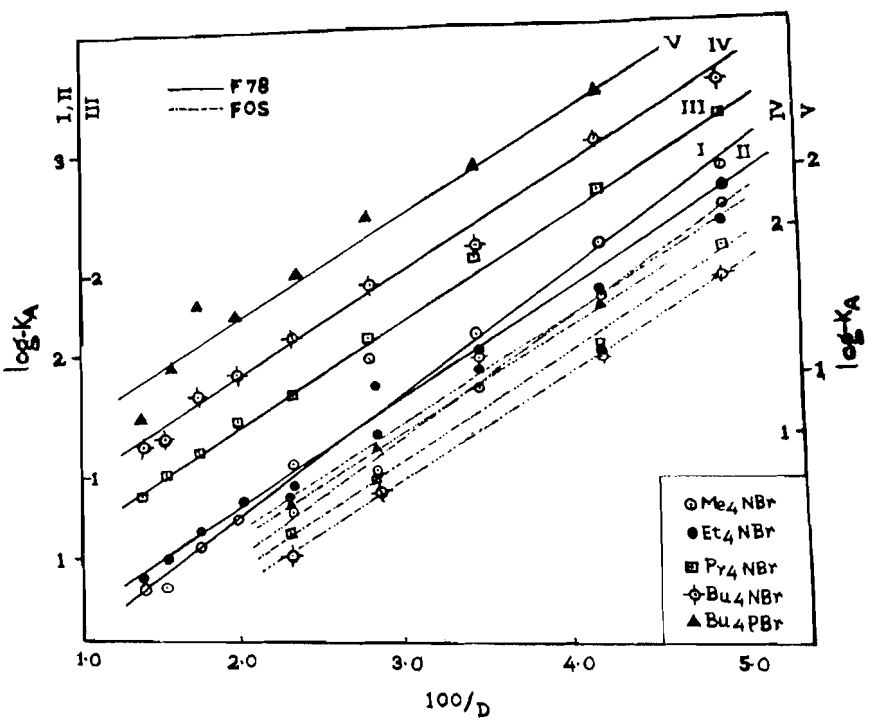

FIG. 2. Plots of log K_A vs. $100/D$.

ion-pair (CIP) formation constant K_S seems to be independent of such effects.

The values of distance or ion-size parameters (R or a_K^0), obtained from different theories of ion-association to predict the K_A values, are compared with the crystallographic radii of the salts under study. The values of a_K^0 (Table 3) obtained from the FOS equation in the dielectric range ($71.4 \geq D \geq 35.5$) are smaller than the crystallographic radii of the ion. We find the results difficult to understand. However, the F78 equation predicts meaningful values of R (Table 2), which are greater (31, 32) than the Bjerrum critical distance, q ($= e^2/2DkT$) while the a_K^0 is less than q. However, an increase in R with a decrease in the dielectric constant of the medium also indicates an increase in ionic association (18, 19), a behaviour that can be explained by the formation of the solvent-separated ion-pair (SSIP) and the contact ion-pair (CIP). For a contact ion-pair, $R = a$; and for SSIP, $R = a + d_s$, where d_s is the diameter of the solvent molecule and is equal to 3.20 to 4.60 Å. Therefore, the values of R show that the tetraalkylammonium halides do not form SSIP or CIP in 10 and 20 wt.% 2-PrOH. In the dielectric range ($56.90 \geq D \geq 19.40$), ion-pairs are formed, and are mostly SSIP. Consequently, it is difficult to draw any definite conclusion from the best-fit R values as they are particularly susceptible to the choice of conductance equation.

Some generalizations, however, have been made about the R value obtained from the F78 equation as discussed.

Thus, in view of the above facts, it can be concluded that the F78 conductance equation gives significantly better fit parameters than the FOS equation; it also appears to be better suited for explaining all respects of conductance behaviour because it includes the solvated radii of the ions present in the solution.

Acknowledgements

We thank Professor R. M. Fuoss, Professor R. L. Kay for invaluable help in making his computer programmes available, and Professor M. T. Ahmad and Z. H. Engg. College, A.M.U., Aligarh, for providing the impedence bridge. We would also like to thank Professor N. Islam for his helpful discussion and the Chairman of the Department of Chemistry for providing the necessary facilities.

Molecular emission and electronic structure of associated chlorophyll *a*

N. E. BINNIE, L. V. HALEY, T. A. MATTIOLI, D. L. THIBODEAU, W. WANG, AND J. A. KONINGSTEIN[1]
Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received February 5, 1987[2]

N. E. BINNIE, L. V. HALEY, T. A. MATTIOLI, D. L. THIBODEAU, W. WANG, and J. A. KONINGSTEIN. Can. J. Chem. **66**, 1728 (1988).

We report the wavelength-selective Raman and fluorescence spectra of monomeric and aggregate species of chlorophyll *a* in solution. The excitation profile for the molecular emission of the various chlorophyll complexes permit the construction of part of the electronic energy level diagram. For a T-shaped dimeric chlorophyll *a*, pseudo-exciton splittings of 667 cm^{-1} in the Soret and 397 cm^{-1} in the Q_y bands are obtained.

N. E. BINNIE, L. V. HALEY, T. A. MATTIOLI, D. L. THIBODEAU, W. WANG et J. A. KONINGSTEIN. Can. J. Chem. **66**, 1728 (1988).

On a déterminé les spectres Raman et de fluorescence à longueurs d'onde sélective d'espèces monomères et sous forme d'agrégats de chlorophylle *a* en solution. A l'aide des profils d'excitation de l'émission moléculaire des complexes de diverses chlorophylles, on peut construire une partie du diagramme des niveaux d'énergie électronique. Pour une chlorophylle *a* dimère en forme de T, on a obtenu des séparations de 667 et de 397 cm^{-1} respectivement pour les bandes de Soret et de Q_y.

[Traduit par la revue]

1. Introduction

There are numerous reports in the literature which deal with spectroscopic and other properties of solutions which contain chlorophyll *a* (Chl*a*). Much attention has been paid to the interpretation of the absorption (1–4) and fluorescence (5–13) spectrum of this biologically interesting molecule. It is well known that monomers and aggregates of this and the bacteriochlorophyll molecule play an important role in the photophysical process in plants and bacteria. We discuss here spectral properties of the model compound Chl*a* *in vitro*. In particular, the spectra of aggregates of this compound could be of importance in the identification of the spectra of chlorophyll *in vivo* (14).

The principal features of the absorption spectrum of Chl*a* are the $Q_{y,x}$ ($S_{1,2} \leftarrow S_0$) and Soret bands ($S_{3,4} \leftarrow S_0$). They occur in the spectral regions of 600–720 nm and 400–450 nm, respectively. Compared to the position of these bands of the less concentrated solutions in non-polar solvents like carbon tetrachloride, benzene, or hexane, the positions are red-shifted in the more concentrated solutions. Furthermore, the bands broaden and the Q_y absorption band is split into two components. These spectral features in combination with thermodynamic data, have in the past been interpreted (1, 11–15, 35) in terms of the contribution to the absorption spectra of the aggregates. Also, large changes in the concentration of Chl*a* result in minor changes in the absorption spectrum (11, 16, 17). In addition, the absorption spectrum of some of the monomeric species is known but not that of the aggregates.

In recent publications (11–13) from this laboratory, information was presented leading to the assignment of the fluorescence spectrum of monomeric and aggregated Chl*a* in hexane. In dry hexane the fluorescence of the penta-coordinated monohydrate dominates over that of any other species in highly diluted solutions ($<10^{-6}$ *M*). For more concentrated solutions the fluorescence spectrum reveals the presence of an approximately T-shaped dimer (hereafter referred to as the dimer) where bonding occurs (16–20, 25, 26) between the keto group on ring V of one Chl*a* molecule (donor) to the Mg atom of another (acceptor). The macrocycles of the chlorophyll molecules are thought to be approximately perpendicular to each other, contrary to the geometry for another dimer (21) where the rings are parallel but translated with respect to each other. This dimer, composed of bacteriochlorophyll molecules, is found in the reaction center of certain bacteria (21). The structure of this dimer is stabilized through linkages of the cluster with a protein molecule. In contrast, such co-facial dimers are less stable in solution. They are thought to be a minority species in our solutions.

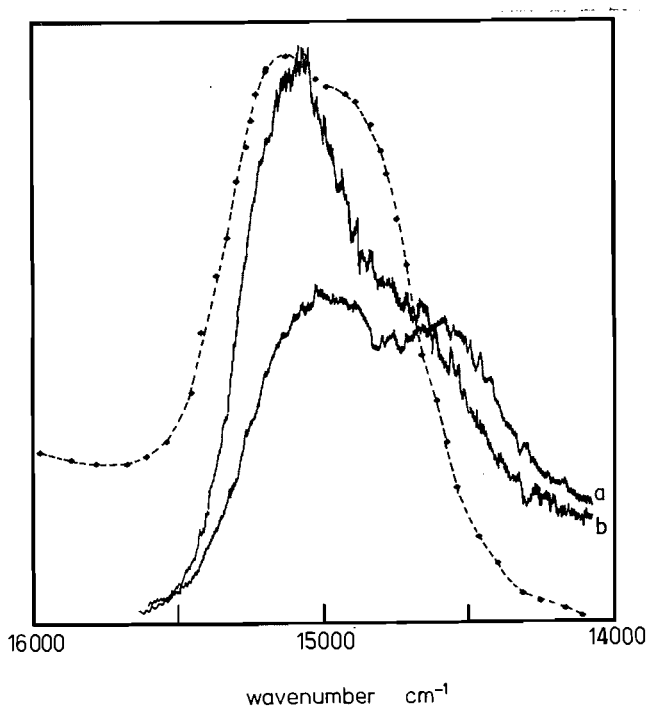

FIG. 1. Fluorescence of a 1×10^{-4} *M* solution of Chl*a* in hexane. (*a*) Cell thickness is 10 mm. (*b*) Same solution as in (*a*) with a cell thickness of 1 mm. Absorption spectrum (·-·-·-·) of this solution.

In the present work we report the results of fluorescence excitation and nanosecond resonance Raman measurements of solutions containing monomeric Chl*a* and the dimer. In addition to information which can be obtained from the absorption spectrum, the fluorescence excitation profiles for specific species

and the resonance Raman excitation profiles can provide one with sufficient data to obtain the positions of energy levels lying in the Q and Soret bands of the species in solution.

II. Experimental

Chl*a* was extracted from fresh spinach according to the method of Omata and Murata (22) and purity established by standard techniques (23, 24). The pure Chl*a* wa stored in the dark in a nitrogen-purged dry box. Chl*a* was dried by codistillation sequentially three times with dry carbon tetrachloride (Baker Photorex) and two times with dry hexane (Caledon Labs. Inc., spectral grace) prior to preparation of a concentrated stock solution. All solvents were dried by passing through a column of neutral aluminum oxide (Woelm Activity 1, carried out in the nitrogen-purged dry box) and were then degassed.

Samples for fluorescence and Raman measurements were contained in either air-tight quartz optical cells fitted with Teflon stopcocks (fluorescence measurements) or a flowing cell technique was used ensuring that neither oxygen or water would enter the solutions (Raman measurements). The dilute 10^{-7}–10^{-6} *M* Chl*a* hexane solutions were prepared by dilution of the stock solution with degassed solvents of dried hexane (hereafter referred to only as hexane) or undried hexane (used as received) as specified in the text. The samples were equilibrated for a minimum of 1 h before use. The 10^{-5} and 10^{-4} *M* solutions were prepared using dried hexane.

Molecular emissions from solutions of chlorophyll dissolved in 2,4-lutidine were also studied. The solvent lutidine (Aldrich 97% pure) was successively distilled over KOH and BaO under reduced pressure. The dried solvents were kept over molecular sieves and purged with N_2 before use.

Pulsed laser fluorescence and Raman spectroscopy experiments were performed using a tunable dye laser pumped with a Nitrogen or Excimer laser (Lambda Physik Fl 2000 and M2000 or Lumonics models TE 430 and EPD 330), pulse FWHM of 5 and 10 ns, respectively. The emitted light was observed in the back scattering or reflection techniques in order to minimize self-absorption. Because both the incident light and emitted light were absorbed, the depth of the sample illumination was a critical parameter in the experiments. If the width of the sample was not adjusted with respect to increasing sample concentration, then reabsorption effects distorted the spectra. In Fig. 1 we show the fluorescence spectra of a 10^{-4} *M* Chl*a* solution in hexane where the sample was placd in a 10 mm cell (Fig. 1*a*) and a 1 mm cell (Fig. 1*b*). Superimposed on the data is the absorption spectrum of this solution. Self absorption is evident across the entire fluorescence spectrum. As a result of this observation, we chose a 1 mm cell for the 10^{-4} *M* solution, therefore minimizing the spectral distortion due to self absorption.

The light was dispersed by a Jobin-Yvon Ramanor HG2 spectrometer equipped with curved holographic ruled gratings. Spectra were recorded with a slit of 3–7 cm^{-1} and the radiation emerging frm the exit slit was detected by a RCA 31034 cooled photomultiplier tube. The pulsed signals were fed into a gated detection system (Stanford Research Associates) and the spectra were recorded on a stripchart recorder or processed with a computer. If not stated differently, fluorescence spectra were recorded with a gate of 3 ns at a point in time at which the intensity of the fluorescence signal has reached its maximum intensity. The Raman spectra were recorded with a similar gate but at a point in time (t_0) at which the laser pulse has reached its maximum intensity. Lifetimes were computer-calculated with a modified phase-plane method, and are estimated to contain an uncertainty of 0.5 ns.

Our spectroscopic studies in the past and present point to the fact that for equal concentration of dry Chl*a* in the solvents hexane, carbon tetrachloride, or benzene, the concentration of aggregates is higher in hexane. Hence, we chose to use hexane as the solvent to investigate the emission spectra of aggregates of Chl*a*.

III. Results and discussion

A. Fluorescence excitation spectra

Monomer

It is well known that fluorescence from monomeric species of Chl*a* is most conveniently studied if the large molecule is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

dissolved in polar solvents. However, if dissolved in non-polar solvents the fluorescence as well as the absorption spectrum cannot be interpreted in terms of properties of a single species. We have shown in an earlier publication (13) that for solutions which are $<10^{-6}$ *M* Chl*a* in hexane, the fluorescence spectrum of the monohydrate which has a maximum intensity at 664 nm exceeds that of any other species. Shown in Figs. 2*a* and *b* are the excitation profiles of the Soret and Q_y absorption band systems which are characterized by maxima at 426 nm and 660–662 nm. The positions of these maxima coincide with the maxima of the Soret and Q_y absorption bands of the monohydrate in solution (13). Therefore there exists a correlation between the absorption spectrum and the fluorescence excitation profile for the red emission of the monohydrate. The observed decay time of this emission if excited at 436 nm is 6.2 ns.

Dimer

The results of a wavelength-selective fluorescence study of Chl*a* for concentrations $>10^{-6}$ *M* in hexane are presented in Figs. 3 and 4. These solutions contain, besides the monohydrate, various aggregates of Chl*a*. It is known that a chemical equilibrium exists between the species in solution (16, 17) as is evident by the appearance of red-shifted absorption features in both the Soret and Q_y spectral regions. In the solvents CCl_4 and hexane, vapour phase osmometry (35) data were directly attributed to species having an average aggregation number of approximately 2. Therefore we assume that in our hexane solutions, upon an increase in concentration of Chl*a*, the first species to exhibit fluorescence besides the monohydrate should be the dimer. Some information on the spectroscopic properties of this dimer has been discussed in earlier work (13). In the following discussion we present a comparison of molecular emission (fluorescence and Raman) and other data. These results, in particular the resonance Raman spectra, strongly support the existing picture of the chemical link betwen the two Chl*a* molecules of the dimer.

In Fig. 3 we show the wavelength-dependent fluorescence spectra of a solution which is 5×10^{-6} *M* and contains monohydrate species as well as dimers. If the solution is excited at 422 nm the emission of the monohydrate at 664 nm is clearly observed. The apparent shift in the 664 nm emission is due to the effect of reabsorption caused by an increase in the illuminated sample volume as the wavelength of the laser is scanned away from the intensity maximum of the Soret absorption band. Upon excitation between 430 and 457 nm the intensity of an emission at 686 ± 1 nm is detectable. Relative to the excitation profile of the monomer (Fig. 2*a*), that for the band at 686 nm has a maximum between 440 and 448 nm (Fig. 5) and we assign this fluorescence (13) to that of the dimer. The increase in concentration of the dimer with respect to that of the monomer is evident if the results in Figs. 3 and 4 are compared. The spectra shown in Fig. 4 of solutions which are 10^{-5} and 10^{-4} *M* are recorded from cells which are, respectively, 10 mm and 1 mm thick, therefore minimizing the relative effect of reabsorption of the fluorescences. The result of mimimizing the effect of reabsorption has permitted us to increase our accuracy so as to establish a reliable emission wavelength for each of the species. Preliminary experimental data for a 10^{-3} *M* solution suggest that the 686 nm emission band still dominates the spectra, indicating that the concentration of the dimer is still high in comparison to that of other species. In an earlier publication (13), a dicussion was given of the emission band assignments in the spectral region of 668–688 nm in terms of fluorescences originating in the acceptor and donor molecules of the dimer. In the present study we conclude that the donor emits at 686 ± 1 nm, and further evidence for this assignment will be given in section B.

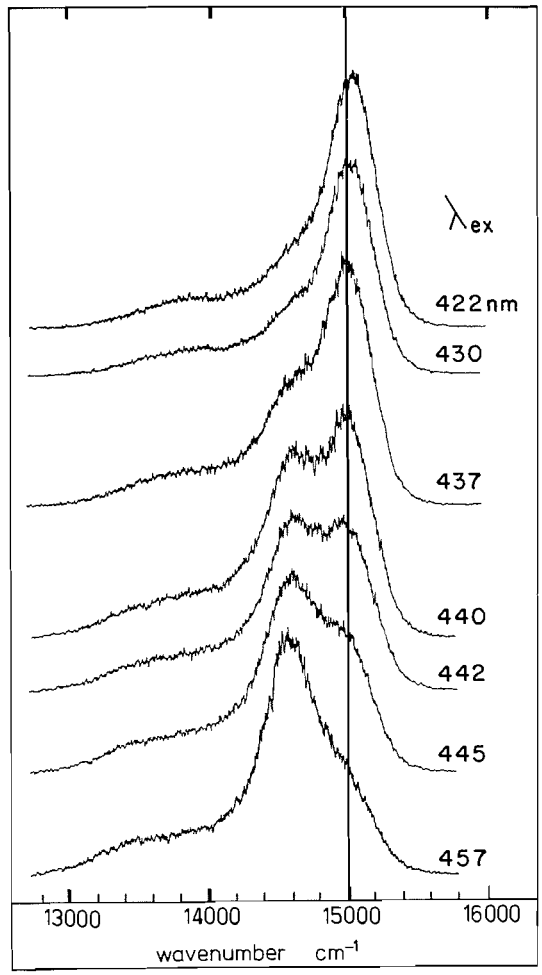

FIG. 3. Wavelength-selective fluorescence spectrum of a solution of 5×10^{-6} *M* Chl*a* Chl*a* in dry hexane. The vertical bar denotes the position of the fluorescence of the chlorophyll monohydrate molecule at 664 nm. Fluorescence from the donor at 686 nm (14577 cm^{-1}) is selectively excited with the laser wavelength of 457 nm.

B. Nanosecond resonance Raman spectra and excitation profiles

Raman spectra of Chl*a* in hexane, excited with pulsed (27–29) and cw laser radiation (30–32) have been reported in the literature. If excited with laser radiation tuned to the spectral region of the Soret band of Chl*a*, the intensity of the Raman spectrum is resonance enhanced. Spectra from solutions which are $>10^{-5}$ *M* in chlorophyll can be recorded with good signal/noise ratios. The solutions contain more than one species with overlapping Soret bands. The vibrational frequencies of normal modes of the different Chl*a* species are not far apart because the width and the shift of the Raman bands are similar. Hence, the resonance Raman excitation profile for the intensity of Raman bands may contain useful information on the position of electronic excited states. Of relevance here is the experimental result that the width of these profiles at resonance is ~ 100 cm^{-1} as compared to a ~ 1000 cm^{-1} width for absorption bands of the solutions.

In the present work we are mainly interested in the excitation spectra (see Fig. 5) of one of the most intense Raman bands of

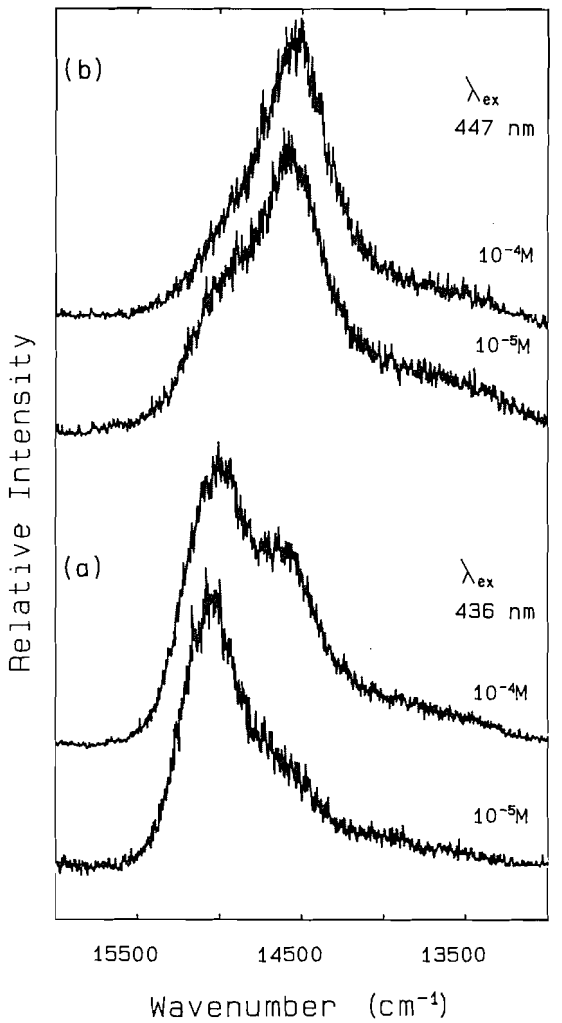

FIG. 4. Pulsed laser fluorescence excitation of Chl*a* in hexane. The spectra of the 10^{-5} *M* solution are obtained from a 10 mm cell, and those from the 10^{-4} *M* solution from a 1 mm cell.

Chl*a* in solution. The excitation profile was obtained by plotting the intensity ratio of the intense Raman band at approximately 1550 cm^{-1} of Chl*a* to that of a band of the solvent as a function of the wavelength of the pulsed laser radiation that induces the spectra. This Raman shift is primarily due to C—C stretching modes of the Chl*a* molecule and its position changes from species to species.

Monomer

When the Chl*a* is dissolved in lutidine, aggregation does not occur (32) and the penta-coordinated Chl*a* complex is the species present in a 10^{-4} *M* solution. The resonance Raman profile (not shown) for the intensity of the 1550 cm^{-1} band has a maximum between 430 and 445 nm which is close to the cross-over point of the Soret absorption band at 433 nm and the two-photon induced Stokes shifted fluorescence at 444 nm, see Fig. 6. The maximum at 439 nm is assigned to the position of the electronic origin for transitions between the S_3 and S_0 electronic surfaces of the chlorophyll–lutidine complex.

Dimer

The excitation profile for the Raman band at 1550 cm^{-1} in the spectral interval of 430–450 nm for 1×10^{-4} *M* Chl*a* in hexane is shown in Fig. 5. The main components in this solution are the monohydrate and the donor–acceptor dimer complex. In order to record these spectra, the intensity of the laser radiation at 435.2 nm was sufficiently high to produce effective population saturation of lower-lying nanosecond-lived excited states (S_1) of the monohydrate, and donor molecule as judged from Q_y fluorescence of these entities. From the pulsed laser intensity-dependent value of the sample transmission, it follows that the intensity of the $S_n \leftarrow S_1$ absorption at 435.5 nm is smaller than that of the transition at that wavelength which originates in the ground state (34). Hence we predict a smaller intensity enhancement for vibrational scattering in the electronic excited state at the ground state resonant wavelengths.

Also shown in Fig. 5 is the two-photon induced blue fluorescence from the 1×10^{-4} *M* solution and the excitation profile of the dimer fluorescence band at 686 nm. The width of the fluorescence band is ~2000 cm^{-1} as compared to 1000 cm^{-1} for the emission in the blue for monomeric chlorophyll in lutidine, see Fig. 6. The large width of the blue fluorescence band is due to contributions of emissions from the monohydrate, dimer, and perhaps even higher aggregates. The maximum intensity of the blue emission is at 455 nm and is assigned to emission of the dimer. This fluorescence originates in the S_3 level of the donor molecule. From the Raman excitation spectra we find that resonance with this state occurs if the laser is tuned to 448.2 nm, hence the S_3 state of the donor is near 22 300 cm^{-1}. This position is within experimental error equal to the cross-over point of the two-photon induced blue fluorescence and the contour of the excitation profile for the emission at 686 nm, see Fig. 5.

In order to assign the S_3 position of the acceptor molecule the following arguments are pertinent. The position of the Soret band for the monohydrate complex is at 426 nm. Although two-photon induced blue fluorescence from solutions containing this complex could not be detected, the Stokes shift for the penta-coordinated lutidine (see above) and other complexes (33, 34) is between 11 and 14 nm. We predict for the monohydrate complex an electronic orgin between 431 and 433 nm. The excitation profile of Fig. 5 shows maxima at 435.2 and 448.2 nm. However, a search for intensity increases in the excitation profile between 426 and 435.2 nm for a 10^{-4} *M* solution of Chl*a* in hexane was negative. The position of the Soret absorption band of this solution, which yields the excitation profile of Fig. 5 is at 430 nm, and the Soret band of the monohydrate was not detected. Assuming a Stokes shift similar to that of the monomer, an electronic origin of the acceptor would then be expected between 435 and 437 nm. Hence we assign the maximum of the profile at 435.2 nm to the position of an electronic origin (S_3) of the acceptor molecule, and that at 448.2 nm to an origin (S_3) of the donor. At the resonating wavelengths, the degree of enhancement of the Raman band intensities of the dimer is in agreement with the difference of the intensity of the absorption bands at 430 and 444 nm.

For the acceptor molecule, the assignment of the electronic origin is supported by wavelength-dependent intensity measurements of Raman bands at 1705 and 1655 cm^{-1}. The band at 1655 cm^{-1} is due to scattering from the Mg-bound C—O group on ring V of the donor chlorophyll molecule, while the band at 1705 cm^{-1} is the frequency of this mode for the free keto group of the acceptor molecule (30). Compared to the intensity of the band at 1655 cm^{-1} that of the band at 1705 cm^{-1} goes through a maximum if the wavelength of the laser is tuned to 404.9 nm. At this wavelength, resonance occurs with the vibronic side band due to the C=O vibration at 1705 cm^{-1} of the non-ligated keto group on ring V of the electronic surface having its origin at

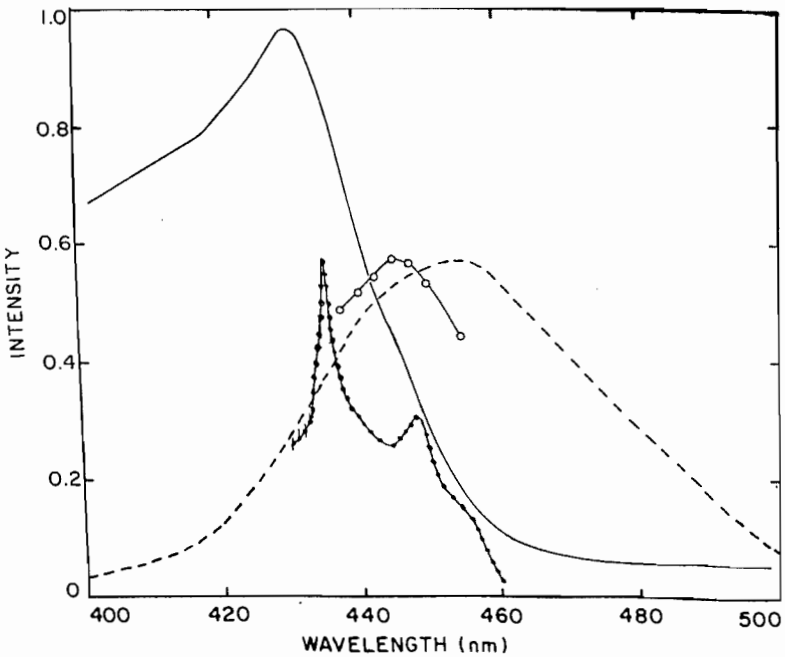

FIG. 5. Absorption (—) and two-photon induced fluorescence (----) of a solution in which the concentration of the dimeric complex dominates over that of other species. Also indicated is the excitation profile (-○-○) for the donor emission at 686 nm. The resonance Raman excitation profile (-●-●-●-) peaks at the position of electronic origins of the donor (448.2 nm) and acceptor molecule (435.2 nm).

435.2 nm (22 978 cm^{-1}). Furthermore, the intensity of the 1705 cm^{-1} band is higher than that of the band at 1655 cm^{-1} if the spectrum is excited with radiation at 435.2 nm while the reverse occurs for radiation tuned to 448.2 nm. The spectral results and assignments are summarized in Table 1.

Finally, the spectral results presented above are used to determine the pseudo-exciton splitting in both the Q_y and Soret band systems. In the absence of resonance Raman data from the Q_y band system, the band origins were estimated from absorption and fluorescence measurements of the donor, and for the acceptor, we used the absorption data and an estimated Stokes shift for the fluorescence maximum (based on a similar Stokes shift as in lutidine). Origins are located at 664 and 682.5 nm for the acceptor and donor molecules, respectively. The splitting of the pseudo-exciton components is 397 cm^{-1}. As mentioned above, the resonance Raman excitation profile in the Soret band region yields the S_3 electronic origins of the donor and acceptor molecules directly. Here, the pseudo-exciton splitting is 667 cm^{-1}. For the complex mentioned above (T-shaped dimer in hexane), calculations utilizing an exciton formalism which includes the environmental effects (36) on the electronic states of the donor–acceptor complex revealed the fact that the contribution of the transition density – transition density interaction energy to the total splitting is small. This result is to be expected if the angle

Biosynthesis of the lupine alkaloids. II. Sparteine and lupanine

W. MAREK GOLEBIEWSKI[1] AND IAN D. SPENSER
Department of Chemistry, McMaster University, Hamilton, Ont., Canada, L8S 4M1

Received December 8, 1987

W. MAREK GOLEBIEWSKI and IAN D. SPENSER. Can. J. Chem. **66**, 1734 (1988).

Contrary to predictions based on earlier observations, it is now found that label from DL-[6-^{14}C]lysine and from [6-^{14}C]-Δ^1-piperideine does not enter the three C_5 segments of lupanine with equal efficiency. One of the C_5 segments is labelled at a significantly higher level than the other two C_5 segments, which show identical levels of labelling. A new biogenetic model is proposed, which is consistent with these new findings as well as with all other regio- and stereochemical evidence on the mode of incorporation of precursors that is available.

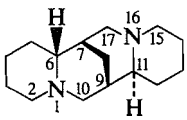
W. MAREK GOLEBIEWSKI et IAN D. SPENSER. Can. J. Chem. **66**, 1734 (1988).

Contrairement à ce qui a été prédit en se basant sur des observations antérieures, on a maintenant trouvé que le marqueur de la DL-[^{14}C-6]-lysine et celui e la [^{14}C-6]-Δ^1-pipéridéine ne sont pas incorporés des les trois segments en C_5 de la lupanine avec des efficacités identiques. L'un des segments en C_5 porte un taux de marquage beaucoup plus élevé que celui des deux autres segments en C_5 dont les niveaux de marquage sont identiques. On propose donc un nouveau modèle biogénétique qui est en accord avec ces nouvelles données ainsi qu'avec d'autres données disponibles sur les régio- ou stéréochimies du mode d'incorporation.

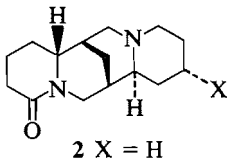
[Traduit par la revue]

Introduction

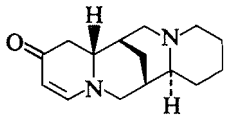
Recent investigations (1–5) employing ^{13}C- and ^{13}C,^{15}N-labelled substrates have confirmed and extended earlier results obtained with ^{14}C-labelled tracers (6–16) on the biosynthesis of the tetracyclic bisquinolizidine-type lupine alkaloids (e.g., (−)sparteine (1, 2, 5, 7, 9, 12) (**1**), (+)lupanine (3–6, 8, 10, 11, 13, 16) (**2**), (+)-13α-hydroxylupanine (4, 5, 8, 13, 14) (**3**), (−)multiflorine (12, 15) (**4**)), and have firmly established that



1

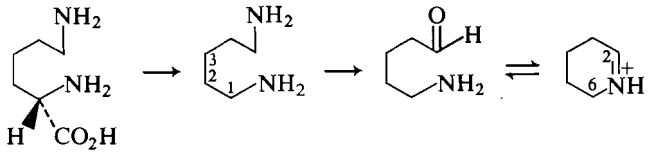


2 X = H
3 X = OH



4

these alkaloids originate from three C_5 chains derived from lysine (9–13, 15) or, more specifically, from L-lysine (**5**) (16). Cadaverine (1–9, 11, 14, 15) (**6**), the decarboxylation product of lysine, is also a precursor and is, presumably, an intermediate (17) between lysine and the alkaloids.



5 **6** **7** **8**

It is likely that the intact C_5 chain of cadaverine is utilized in the generation of a C_5 intermediate and that three molecules of this C_5 intermediate supply the three C_5 units, C-2,-3,-4,-5,-6, C-10,-9,-8,-7,-17, and C-15,-14,-13,-12,-11, of the alkaloids.

The two nitrogen atoms of the $C_{15}N_2$ skeleton of the alkaloids are also derived from lysine (9, 15) or cadaverine (1–4). Two C—N units, C-2,N-1 and C-15,N-16, of the alkaloids are derived from the NH_2CH_2- group of cadaverine, whereas the other four C—N bonds of the alkaloids are formed in the course of biosynthesis.

The evidence suggests that lysine, C_6N_2, via cadaverine, C_5N_2, supplies a C_5N intermediate from which the two C_5N chains of the alkaloids, N-1,C-2,-3,-4,-5,-6 and N-16,C-15,-14,-13,-12,-11, are derived *in toto*, and that the central C_5 unit of the alkaloids, C-10,-9,-8,-7,-17, is derived from the same C_5N intermediate with loss of nitrogen.

Incorporation studies with deuterium-labelled samples of lysine (3) and cadaverine (3, 18–21) into (−)sparteine (3, 18, 21) (**1**), (+)sparteine (19) (the enantiomer of **1**), (+)lupanine (3, 18, 20, 21) (**2**), and (+)-13α-hydroxylupanine (20, 21) (**3**) throw light on the mode of incorporation of the C_5N unit and define the stereochemistry of some of the steps in the biosynthetic sequence from lysine into cadaverine and thence into the alkaloids.

It is observed that deuterium is retained, *inter alia*, at C-2, C-10, and C-17 of sparteine, derived from one or the other of the enantiomers of [1-^{2}H]cadaverine (3, 18). 17-Oxosparteine (22, 23), 10-oxosparteine (23), lupanine (24, 25), or 1,2-dehydrosparteinium ion (26) cannot therefore be intermediates between cadaverine and sparteine, contrary to what had variously been suggested (22–26). Retention of deuterium at C-8 of lupanine (20, 21), 13α-hydroxylupanine (20, 21), and sparteine (21), derived from [3,3-$^2H_2$]cadaverine, disposes of a hypothetical biosynthetic sequence (22) that requires loss of hydrogen from C-8 of the alkaloids.

From the experiments with deuteriated cadaverine (3, 18, 19) it can be inferred that, on the route to the alkaloids, loss of one of the two amino groups of cadaverine is accompanied by removal of the *si*-hydrogen atom from the adjacent enantiotopic -CH_2- group. This is the hydrogen atom that is known to be lost in the course of the conversion of cadaverine into the corresponding aldehyde, 5-aminopentanal (**7**) (or rather the corresponding Schiff base, Δ^1-piperideine (**8**), into which 5-aminopentanal is spontaneously transformed (27)),[2] by oxidative deamination, catalyzed by diamine oxidase (27, 31) (EC 1.4.3.6), or by

[1]On leave from the Department of Chemistry, University of Warsaw, 02-093 Warsaw, Poland.

[2]The spontaneous pH-dependent conversion of 5-aminopentanal into Δ^1-piperideine, and thence into the corresponding dimer and trimers, has been the subject of detailed investigations (28, 29). These spontaneous conversions were not taken into account in a proposed biosynthetic model (22, 30), which has now been disproved (20, 21).

transamination, catalyzed by diamine aminotransferase (32–34) (EC 2.6.1.29).

The evidence would appear to point to 5-aminopentanal (**7**), or rather its cyclic Schiff base, Δ^1-piperideine (**8**), as the cadaverine-derived C_5N unit that serves as the intermediate in the biosynthesis of the lupine alkaloids and supplies the two C_5N chains that yield the C_5N units N-1,C-2,-3,-4,-5,-6 and N-16,C-15,-14,-13,-12,-11, as well as the C_5 chain that yields the central C_5 unit, C-10,-9,-8,-7,-17, of the alkaloids.

Indeed, label from [2-^{14}C]- and [6-^{14}C]-Δ^1-piperideine is incorporated into lupanine (23). Moreover, entry of label from these two tracers is regiospecific: Approximately one third of the activity of the intact lupanine from [6-^{14}C]-Δ^1-piperideine is located at each of C-2 and C-15, whereas C-11 and C-17 each bear ca. one third of the total label of the alkaloid when [2-^{14}C]-Δ^1-piperideine serves as the substrate. Furthermore, deuterium from [2-^{2}H]-Δ^1-piperideine is located at C-6, C-11, and at the α-site of C-17 of lupanine (3), and at no other carbon atom. This regiospecific incorporation of labelled Δ^1-piperideine into the C_5 unit, C-10,-9,-8,-7,-17, proves that derivation of this segment from the cadaverine-derived C_5N unit cannot proceed via a later intermediate with C_{2v} symmetry (such as glutardialdehyde (35)). Furthermore, the observed (3, 23) regiochemistry of the incorporation of label from [2-^{2}H]-, [2-^{14}C]-, and [6-^{14}C]-Δ^1-piperideine into the carbon atoms, C-10 and C-17, of the central C_5 unit disproves a biosynthetic model (36) that predicts a result opposite to that actually observed.

The alkaloids, derived from tracer experiments carried out over the past 25 years, show a consistent labelling pattern: Without exception, incorporation of label from the ^{14}C-labelled substrates, [2-^{14}C]lysine (9–13, 15) and [1-^{14}C]cadaverine (6–9, 11, 14, 15), led to $C_{15}N_2$ alkaloids that contained approximately one sixth of their total specific activity at each of the labelled carbon atoms that were assayed individually. [2-^{14}C]- and [6-^{14}C]-Δ^1-piperideine gave alkaloids containing approximately one third of their activity at such carbons (23). Similarly, without exception, incorporation of label from ^{13}C-labelled substrates, [1-^{13}C,1-^{15}N]cadaverine (1–4) and [1,2-$^{13}C_2$]cadaverine (5), yielded alkaloids approximately equally enriched at each of six sites. Correspondingly, equal enrichments were observed at the various ^{2}H-labelled sites within alkaloids derived from deuterium labelled substrates (3, 18).

Thus, in every case, precursor entered each of the three C_5 segments of the $C_{15}N_2$ alkaloids simultaneously, suggesting that elaboration of the $C_{15}N_2$ skeleton takes place either by modification of a trimeric intermediate formed in one step from the C_5N monomer, or by a multistep process in a closed system (e.g., on an enzyme surface) that does not permit exchange of intermediates. Either way, the experimental results do not yield information on the steps of the process from C_5N monomer to $C_{15}N_2$ product.

The tracer results now reported indicate that the equal distribution over six (or three) sites, hitherto observed, must have been the result of fortuitous experimental conditions.

The characteristic distribution of incorporation of label from DL-[6-^{14}C]lysine and [6-^{14}C]-Δ^1-piperideine, now observed, opens the way to the study of the intermediate steps between the C_5N monomer and the $C_{15}N_2$ alkaloids.

Methods and results

In 11 tracer experiments (expts. 7–17) samples of lysine, cadaverine, and Δ^1-piperideine, specifically labelled with radioactive (expts. 7–12) or stable isotopes (expts. 13–17) were administered by wick to intact plants of *Lupinus angustifolius*. The plants were kept in contact with tracer solution for 3–9 days and lupanine was then isolated. Details of these experiments are summarized in Table 1.

In six further experiments (expts. 1–6), details of which have been reported (37), samples of the same three substrates, labelled with radioactive (expt. 6) or stable isotopes (expts. 1–5), were administered to *Lupinus luteus*, from which labelled samples of lupinine and sparteine were isolated. These experiments have been fully described in the first paper of this series (37), which dealt with the biosynthesis of lupinine. The incorporation of label into samples of sparteine obtained in these experiments will be discussed in the present context.

The labelled compounds employed in the tracer experiments were obtained as follows: DL-[6-^{14}C]Lysine monohydrochloride (expts. 7–9) was a commercial product (CEA France); [2-^{14}C]-Δ^1-piperideine (expt. 10) and [6-^{14}C]-Δ^1-piperideine (expts. 11, 12) were prepared by oxidation of the correspondingly labelled DL-lysine (see Experimental).

DL-[6-^{13}C]Lysine (expt. 17) was synthesized by adaptation of a known method (38), in five steps from diethyl acetamidomalonate, acrolein, and potassium [^{13}C]cyanide (99 at .% ^{13}C) (see Experimental). The preparation of samples of DL-[2-^{2}H]lysine (27) (expts. 3, 16), [1-^{13}C,1-^{15}N]cadaverine (37) (expts. 5, 13), (*R*)-[1-^{2}H]cadaverine (27) (expts. 1, 14), and (*S*)-[1-^{2}H]-cadaverine (27) (expts. 2, 15) has been described.

After being kept in contact with tracer solution for several days, the plants were harvested and alkaloids were extracted by standard methods. *Lupinus luteus* yielded lupinine and (−)sparteine (37), *L. angustifolius* gave (+)lupanine and (+)-13α-hydroxylupanine (see Experimental).

The labelling pattern within the samples of lupanine (**2**) derived from the experiments with ^{14}C-labelled lysine (expts. 7–9, Table 2) and Δ^1-piperideine (expts. 10–12, Table 3) was determined by the degradation sequence shown in Scheme 1. Radioactivity at C-2 and C-17 of lupanine (**2**) was assayed directly (benzoic acid). Radioactivity at C-15 was determined as β-alanine (**17**) (C-15,14,13) and as γ-aminobutyric acid (**16**) (C-15,14,13,12), on the assumption that label from the precursors that were employed would be confined to carbon atoms of lupanine that are adjacent to nitrogen, and that other carbons would be unlabelled. Radioactivity at C-15 together with C-11 was determined as pipecolic acid (**15**) (C-9,11,12,13,14,15), on the basis of the same assumption. Thus, four of the six carbon atoms adjacent to nitrogen became accessible.

Lupanine derived from [6-^{14}C]lysine contained approximately one half of its label within pipecolic acid (C-11 plus C-15), and approximately one quarter of its label within β-alanine and γ-aminobutyrate (C-15). One eighth of the label was recovered from each of C-2 and C-17 (expts. 7–9, Table 2; Scheme 2).

Lupanine derived from [2-^{14}C]-Δ^1-piperideine contained approximately one third of its label (33%) within pipecolic acid (C-11 plus C-15) whereas β-alanine and γ-aminobutyrate (C-15) were essentially inactive. Somewhat less than one third (27%) was present at C-17, whereas C-2 was not labelled (expt. 10, Table 3; Scheme 2).

Lupanine derived from [6-^{14}C]-Δ^1-piperideine again contained one third or more of its label (32%, 42%) within pipecolic acid (C-11 plus C-15) as well as within β-alanine (33%, 39%) and γ-aminobutyrate (32%) (C-15) (expts. 11, 12, Table 3; Scheme 2).

The labelling pattern within the sample of lupanine derived from DL-[6-^{13}C]lysine (expt. 17, Fig. 1) and within the samples

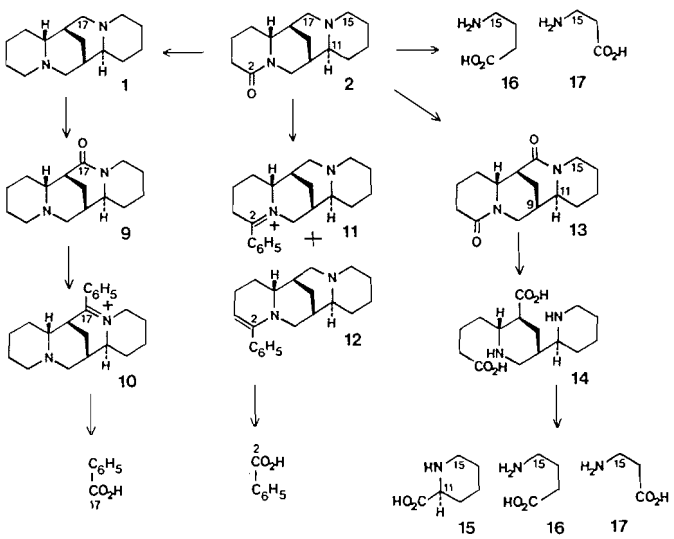
[d]This sample was obtained by further dilution of the 17-oxosparteine with non-radioactive carrier.
[e]RSA = relative specific activity (percent) (17-oxosparteine = 100%).



SCHEME. 1. Degradation of lupanine to determine labelling at C-2, C-11, C-15, and C-17.

of lupanine (expt. 13, Fig. 2), 13-hydroxylupanine (expt. 13, Fig. 3), and sparteine (expt. 5, Fig. 4) derived from [1-^{13}C, 1-^{15}N]cadaverine was determined by ^{13}C nmr spectroscopy. Spectra were recorded in the Fourier mode, at 20.15 MHz on a Bruker WP 80 spectrometer and at 125.8 MHz on a Bruker AM 500 spectrometer. Spectral assignments for sparteine, lupanine, and hydroxylupanine have been reported (39) [3].

The ^{13}C nmr spectrum of the sample of lupanine derived from DL-[6-^{13}C]lysine (Fig. 1) shows that the six carbon atoms adjacent to nitrogen, C-2, C-6, C-10, C-11, C-15, and C-17, but none of the other carbon atoms, are enriched in ^{13}C. Within experimental error the six carbon atoms are enriched to an equal extent. Similarly, the ^{13}C nmr spectra of the samples of lupanine (Fig. 2), 13α-hydroxylupanine (Fig. 3), and sparteine (Fig. 4), derived from [1-^{13}C,1-^{15}N]cadaverine, show enrichment at the same six carbon atoms. The enrichment at each of the six carbon atoms, calculated from the signal areas, was 1.9 ± 0.1% for the lupanine from DL-[6-^{13}C]lysine and 9.7 ± 0.5% for the lupa-

[3]The assignment of the two signals, C-5 and C-8, in the spectrum of lupanine, reported in ref. 39, must be reversed (5).

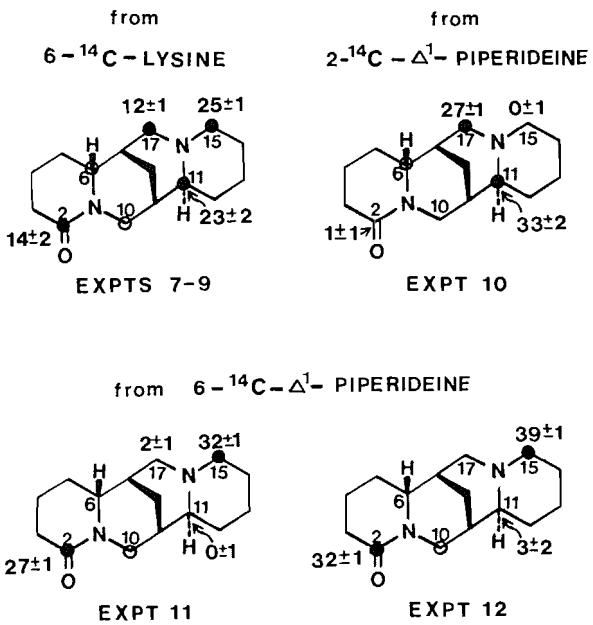

SCHEME. 2. Incorporation of label from [6-^{14}C]lysine and from [2-^{14}C]- and [6-^{14}C]-Δ^1-piperideine into lupanine.

nine, 3.2 ± 0.2% for the 13α-hydroxylupanine, and 50 ± 3% for the sparteine from [1-^{13}C,1-^{15}N]cadaverine.

In the spectrum of each of the three alkaloids, derived from [1-^{13}C,1-^{15}N]cadaverine, each of the signals due to two of the carbon atoms, C-6 and C-11, appears as a singlet, whereas each of the signals due to two carbon atoms, C-2 and C-15, appears as a doublet associated with a singlet of lower intensity, and each of the signals due to C-10 appears as a singlet associated with a well-resolved but much less intense doublet. The signals due to C-17 vary in appearance: In the spectra of lupanine (Fig. 2) and hydroxylupanine (Fig. 3), C-17 appears as a singlet whereas it appears as a singlet associated with a less intense doublet in the spectrum of sparteine (Fig. 4).

The distribution of deuterium within the samples of sparteine (expts. 1–4) and lupanine (expts. 14–16) derived from DL-[2-^{2}H]lysine (expts. 3, 16), from (*R*)-[1-^{2}H]cadaverine (expts. 1, 14), and (*S*)-[1-^{2}H]cadaverine (expts. 2, 15) and from [2-^{2}H]-Δ^1-piperideine (expt. 4) was determined by ^{2}H nmr spectroscopy. Spectral details and results of these experiments have been published (3).

Discussion

Feeding experiments with ^{13}C-labelled samples of lysine (see Fig. 1) and cadaverine (1–5), bearing enriched ^{13}C at one of the carbon atoms adjacent to nitrogen (Figs. 2–4), yielded ^{13}C-enriched $C_{15}N_2$ lupine alkaloids. The distribution of ^{13}C within these alkaloids, established by ^{13}C nmr spectroscopy, substantiates the inferences drawn from the results of the tracer experiments with correspondingly ^{14}C-labelled substrates (6–15), that label is evenly distributed over the six carbon atoms adjacent to the nitrogen atoms of the $C_{15}N_2$ lupine alkaloids.

Thus, each of carbon atoms C-2, C-6, C-10, C-11, C-15, and C-17 within lupanine derived from DL-[6-^{13}C]lysine (Fig. 1), from [1-^{13}C,1-^{15}N]cadaverine (3, 4), from [1,2-$^{13}C_2$]-cadaverine (5), and within 13α-hydroxylupanine (4, 5) and sparteine (1, 2, 5) derived from the latter two substrates, show equal ^{13}C enrichment (1–5), within the limits of detection.

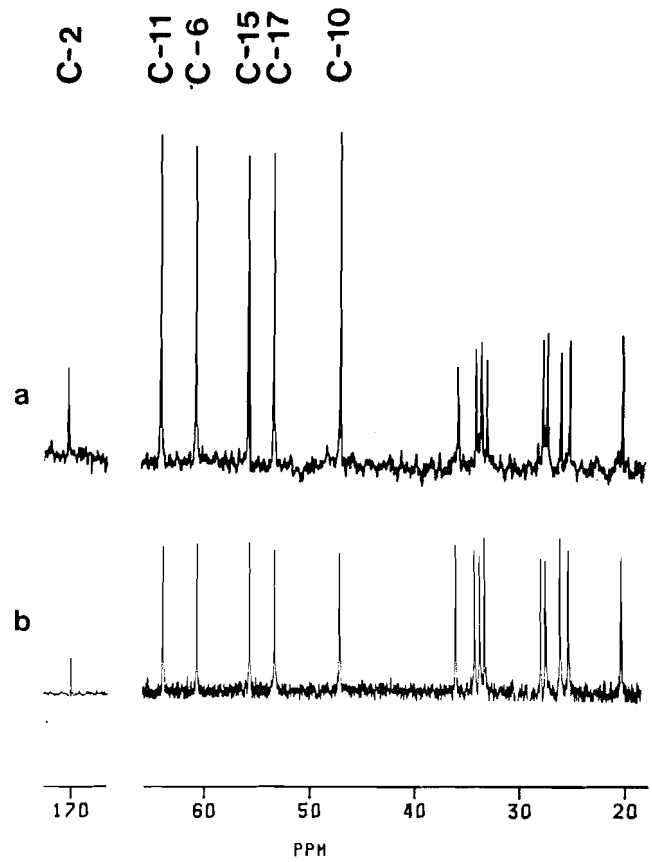

FIG. 1. (a) The 125.8-MHz ^{13}C nmr spectrum of (+)lupanine (**2**) derived from DL-[6-^{13}C]lysine; (b) natural abundance spectrum of (+)lupanine.

This distribution of label together with the evidence, presented in the introduction, on the retention of an intact C—N bond of cadaverine at N-1,C-2 and at N-16,C-15 of the alkaloids (1–4) and on the regiospecificity of entry of label from ^{14}C-labelled Δ^1-piperideine (23) leads to the inference that the $C_{15}N_2$ skeleton of the alkaloids is generated from three identical cadaverine-derived C_5N units, as shown in Scheme 3.

On the basis of the tracer evidence that was available 10 years ago we suggested (23) that equal distribution of label over the three C_5 segments of the $C_{15}N_2$ skeleton might be explained if the $C_{15}N_2$ alkaloids were derived from a trimer of Δ^1-piperideine. This biogenetic model also accounts for the stereochemistry of the alkaloids. The model is entirely consistent with the more recent results on the incorporation of ^{13}C and ^{13}C,^{15}N-labelled (1–5) and ^{2}H-labelled (3, 18–21) substrates, which are summarized in the introduction. These results define the regiochemistry and the prochirality of biosynthesis. Scheme 4 presents an updated version of the piperideine trimer model of biosynthesis. A cornerstone of this model is the equal incorporation of ^{14}C- or ^{13}C-label into the three C_5 segments of the alkaloids.

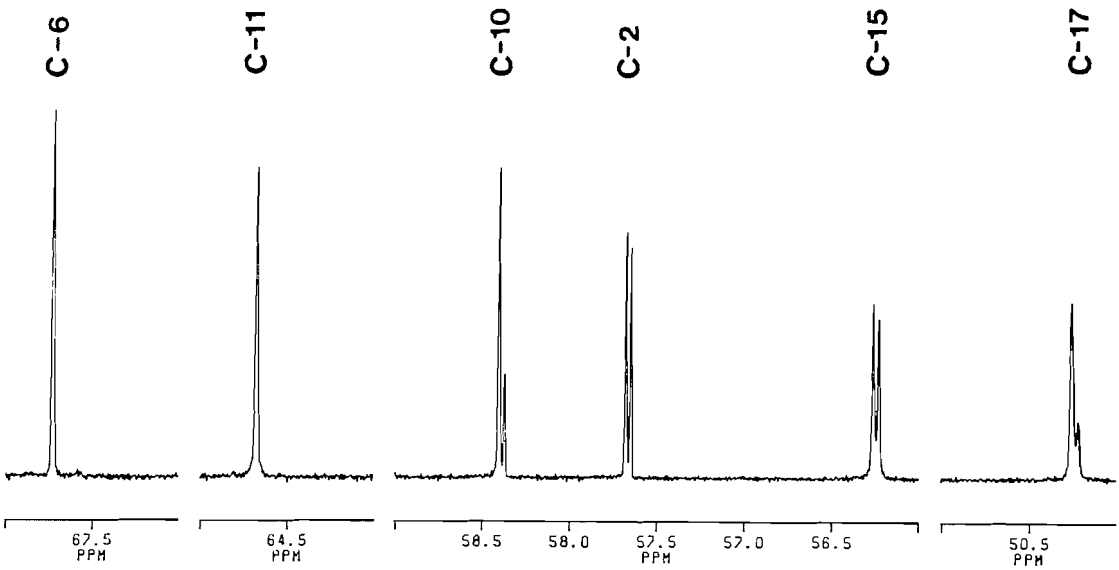

FIG. 4. Signals due to the ^{13}C-enriched carbon atoms in the 125.8-MHz ^{13}C nmr spectrum of (−)sparteine (**1**) derived from [1-^{13}C, 1-^{15}N]cadaverine.

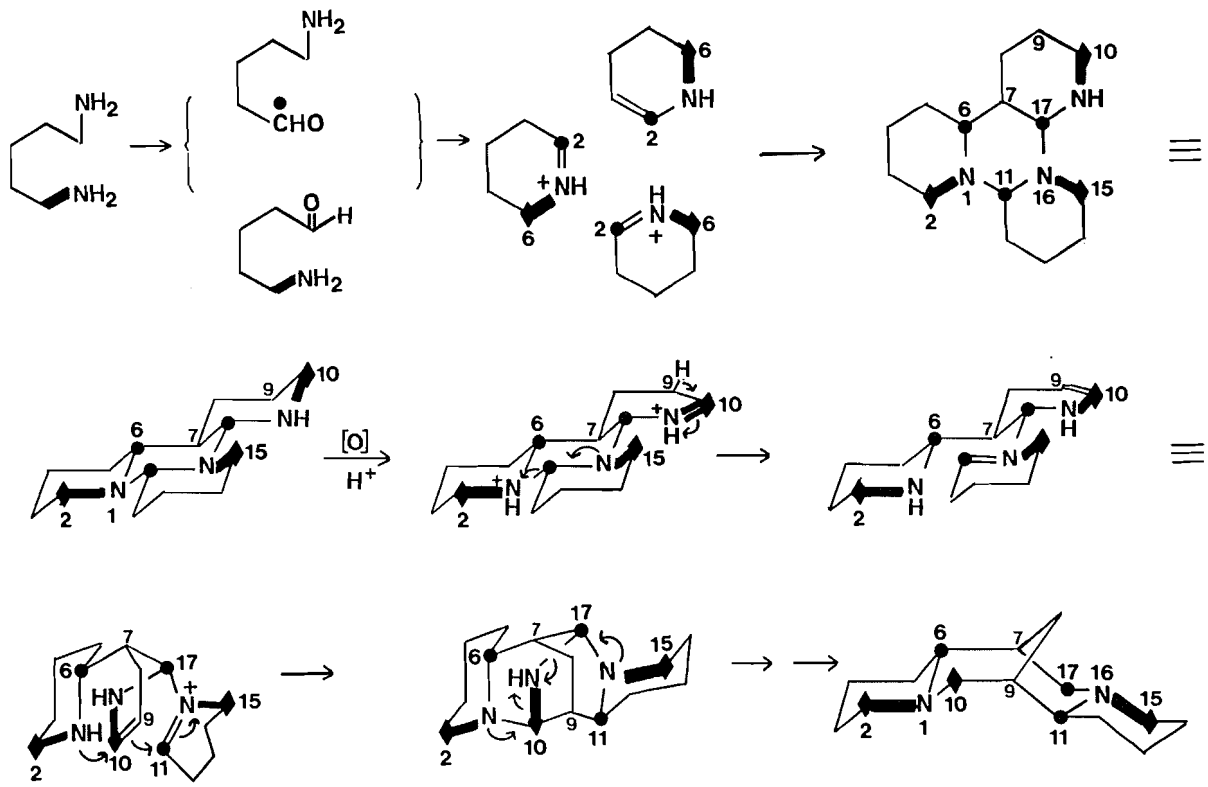

SCHEME. 4. The Δ^1-piperideine trimer model of sparteine biosynthesis, showing the predicted distribution of label from [1-^{13}C,1-^{15}N]cadaverine (■, ●) and from [2-^{14}C]- and [6-^{14}C]-Δ^1-piperideine (2 = ●, 6 = ◆).

The 20.15-MHz ^{13}C nmr spectrum (2) of the sample of sparteine, derived from [1-^{13}C,1-^{15}N]cadaverine, showed six signals that indicated ^{13}C enrichment. Two of these signals, those due to C-2 and C-15, appeared as doublets ($J_{^{13}C\text{-}2,^{15}N\text{-}1}$ 3.6 Hz, $J_{^{13}C\text{-}15,^{15}N\text{-}16}$ 3.9 Hz), proving intact incorporation of the ^{13}C–^{15}N moiety of the precursor into the two C—N units, C-2,N-1 and C-15,N-16 of the alkaloid. Central singlets were not detectable in these signals. This showed that every molecule containing ^{13}C at either of these sites also contains ^{15}N at the position adjacent to ^{13}C, and that in no case is ^{13}C, at either of these sites, contiguous with ^{14}N.

Two other signals, due to C-6 and C-11, appeared as singlets. This proved that ^{13}C at these sites is not intramolecularly contiguous with ^{15}N. This is as would be predicted if each of the

C_5N units of the alkaloids, N-1,C-2,-3,-4,-5,-6 and N-16,C-15,-14,-13,-12,-11, originated *in toto* from a cadaverine-derived C_5N unit, NH_2—CH_2—CH_2—CH_2—CH_2—CHO. [1-^{13}C,1-^{15}N]Cadaverine would yield either $^{15}NH_2$—$^{13}CH_2$—CH_2—CH_2—CH_2—CHO or NH_2—CH_2—CH_2—CH_2—CH_2—^{13}CHO. Thus, C-6 cannot be enriched in ^{13}C, in molecules in which N-1 is enriched in ^{15}N; and C-11 cannot be enriched in ^{13}C if N-16 is enriched in ^{15}N. The ^{13}C-enriched signals due to C-6 and C-11 must therefore appear as singlets, as was indeed observed. The last two ^{13}C-enriched signals, due to C-10 and C-17, were unresolved in the 20.15-MHz ^{13}C nmr spectrum (2). At 125.8 MHz (Fig. 4) each of these two signals is resolved into a pair of lines of relative signal area 3:1.

Each of these signals represents a singlet, relative area 1, due to ^{13}C adjacent to ^{14}N, superimposed on a doublet, relative area 1, due to ^{13}C adjacent to ^{15}N ($J_{^{13}C\text{-}10,^{15}N\text{-}1}$ 4.0 Hz, isotope shift −0.015 ppm; $J_{^{13}C\text{-}17,^{15}N\text{-}16}$ 4.4 Hz, isotope shift −0.015 ppm). This is the result that would be expected if sparteine were generated from a 1:1 mixture of natural abundance and highly ^{13}C,^{15}N-enriched C_5N precursor, and if a C_5N unit from this mix, destined to lose ^{15}N to become the central C_5 chain, C-10,-9,-8,-7,-17, of the alkaloid were to couple with each of the two other units from this mix that yield the two outer rings of the sparteine system.

The incorporation pattern of [1-^{13}C,1-^{15}N]cadaverine into sparteine, as revealed by high resolution nmr, is entirely consistent with and supports the Δ^1-piperideine trimer model of biosynthesis.

Close scrutiny of the ^{13}C nmr spectra of lupanine (Fig. 2) and 13α-hydroxylupanine (Fig. 3) reveals a somewhat different picture.

As in the case of sparteine (2) (Fig. 4), the signals due to C-6 and C-11 in the spectra of lupanine (3) (Fig. 2) and 13α-hydroxylupanine (Fig. 3) appear as enriched singlets. As in the case of sparteine, the signals due to C-2 and C-15 show that an intact ^{15}N–^{13}C unit of the precursor had entered the two sites, N-1,C-2 and N-16,C-15, of the alkaloids. However, whereas in the case of sparteine these two signals appeared as doublets (2), due to the high specific incorporation (ca. 50% per C_5 unit), in the present cases each of these signals appears as a doublet associated with a singlet (lupanine $J_{^{13}C\text{-}2,^{15}N\text{-}1}$ 11.9 Hz, isotope shift −0.02 ppm; $J_{^{13}C\text{-}15,^{15}N\text{-}16}$ 3.6 Hz, isotope shift −0.02 ppm; 13α-hydroxylupanine $J_{^{13}C\text{-}2,^{15}N\text{-}1}$ 12.7 Hz, isotope shift −0.02 ppm; $J_{^{13}C\text{-}15,^{15}N\text{-}16}$ 3.5 Hz, isotope shift −0.01 ppm). The doublet/singlet ratios (lupanine C-2 3.3; C-15 3.1; 13α-hydroxylupanine C-2 2.0; C-15 2.1) are consistent with the lower specific incorporation of enriched substrate into the products (9.7% and 3.2% per C_5 unit, respectively). It is important to note that, in each of the alkaloids, the doublet/singlet ratio at the two sites is equal within experimental error, as expected. This shows that the two outer rings originate from the same doubly enriched precursor. Yet, the spectrum indicates that there is an important difference between the interactions of the two outer rings with the central C_5 unit: Whereas the signal due to C-10 appears as a singlet associated with a doublet due to ^{13}C-10, ^{15}N-1 coupling (lupanine singlet/doublet ratio 2.4, $J_{^{13}C\text{-}10,^{15}N\text{-}1}$ 9.0 Hz, isotope shift −0.02 ppm; 13α-hydroxylupanine singlet/doublet ratio 2.5, $J_{^{13}C\text{-}10,^{15}N\text{-}1}$ 3.2 Hz, isotope shift −0.02 ppm), the signal due to C-17 appears, in each case, as a broad-based (4 Hz) singlet and does not show a resolved doublet. Similar observations have been reported by Rana and Robins (4). The differences in the appearance of the signals due to C-10 and C-17 may be due to differences in the coupling constants around N-1 and N-16 (ca. 12 and 3.5 Hz, respectively). However, it is conceivable that, since the enrichment within C-10 and C-17 is equal, the observed differences in the signals may indicate that N-16 is less enriched in ^{15}N than N-1.

It should be noted that in the sparteine, from the same substrate (1, 2) (Fig. 4), the observed singlet/doublet ratios shown by the signals due to C-10 and C-17 were identical (see above), indicating equal ^{15}N enrichment at N-1 and N-16.

It would thus appear that, whereas under the conditions of the sparteine experiments (1, 2) the efficiency of entry of label from [1-^{13}C,1-^{15}N]cadaverine into each of the two C_5N units and into the central C_5 unit of the alkaloid was the same, in the other experiments (3, 4) the efficiency of entry of label from the precursor into the C_5N unit, N-16,C-15,-14,-13,-12,-11, may not have been the same as that of its entry into the other two units.

As a corollary of unequal enrichment in ^{15}N at N-1 and N-16, one would expect to find that enrichment at C-2(≡ C-6) would be different from enrichment at C-15(≡ C-11). This prediction cannot be conclusively confirmed or controverted on the basis of the spectra that are at hand, because of the difficulties of obtaining accurate and reproducible quantitative values for the signal areas of the different signals in the ^{13}C nmr spectrum of a minute sample of compound containing enrichment at individual carbon atoms. At best, it can be said that the spectra that are available (3, 4) suggest the possibility that the $C_{15}N_2$ alkaloids that were generated in some of the experiments with [1-^{13}C,1-^{15}N]cadaverine contained different levels of isotopic enrichment in the two C_5N segments, N-1,C-2,-3,-4,-5,-6 and N-16,C-15,-14,-13,-12,-11.

Since other evidence, reviewed earlier, led to the inference that these two moieties, as well as the central C_5 chain of the alkaloids, originate from one and the same C_5N precursor, it follows that, in the course of construction of the $C_{15}N_2$ skeleton, at least one of the C_5N precursor units may have undergone endogenous carrier dilution at a level different from that suffered by the other two C_5N precursor units.

The suspicion, aroused on the basis of the ^{13}C nmr spectra, that one of the C_5 segments of the $C_{15}N_2$ alkaloids may contain isotopic enrichment at a level different from that of the other two C_5 segments, became certainty, on the basis of the results of tracer experiments with ^{14}C-labelled substrates. The distribution of label, established by controlled chemical degradations of lupanine samples derived from DL-[6-^{14}C]lysine in three separate experiments (expts. 7–9, Table 2, Scheme 2), differed dramatically from the equal labelling at six sites adjacent to nitrogen, expected on the basis of published work with DL-[2-^{14}C]lysine (10, 11, 13). One quarter of the total activity of the alkaloid was located at each of C-15 and C-11, so that the C_5N unit, N-16,C-15,-14,-13,-12,-11, accounted for half the activity within the lupanine molecule. The other half was distributed over the rest of the molecule, C-2 and C-17 each containing one eighth of the activity, with the other two eighths presumably distributed over C-6 and C-10 (Scheme 2).

Degradation of the samples of lupanine derived from [2-^{14}C]- and [6-^{14}C]-Δ^1-piperideine showed similar trends, in that in each case the C_5N moiety, N-16,C-15,-14,-13,-12,-11, contained somewhat higher labelling than the other two C_5 moieties. In one case (expt. 12, Table 3), approximately 40% of label was located at C-15, whereas C-2 and, presumably, C-10 each contained approximately 30% of label (Scheme 2).

Such a distribution of label can arise only if one of the three identical C_5N units, namely that which serves as the precursor of

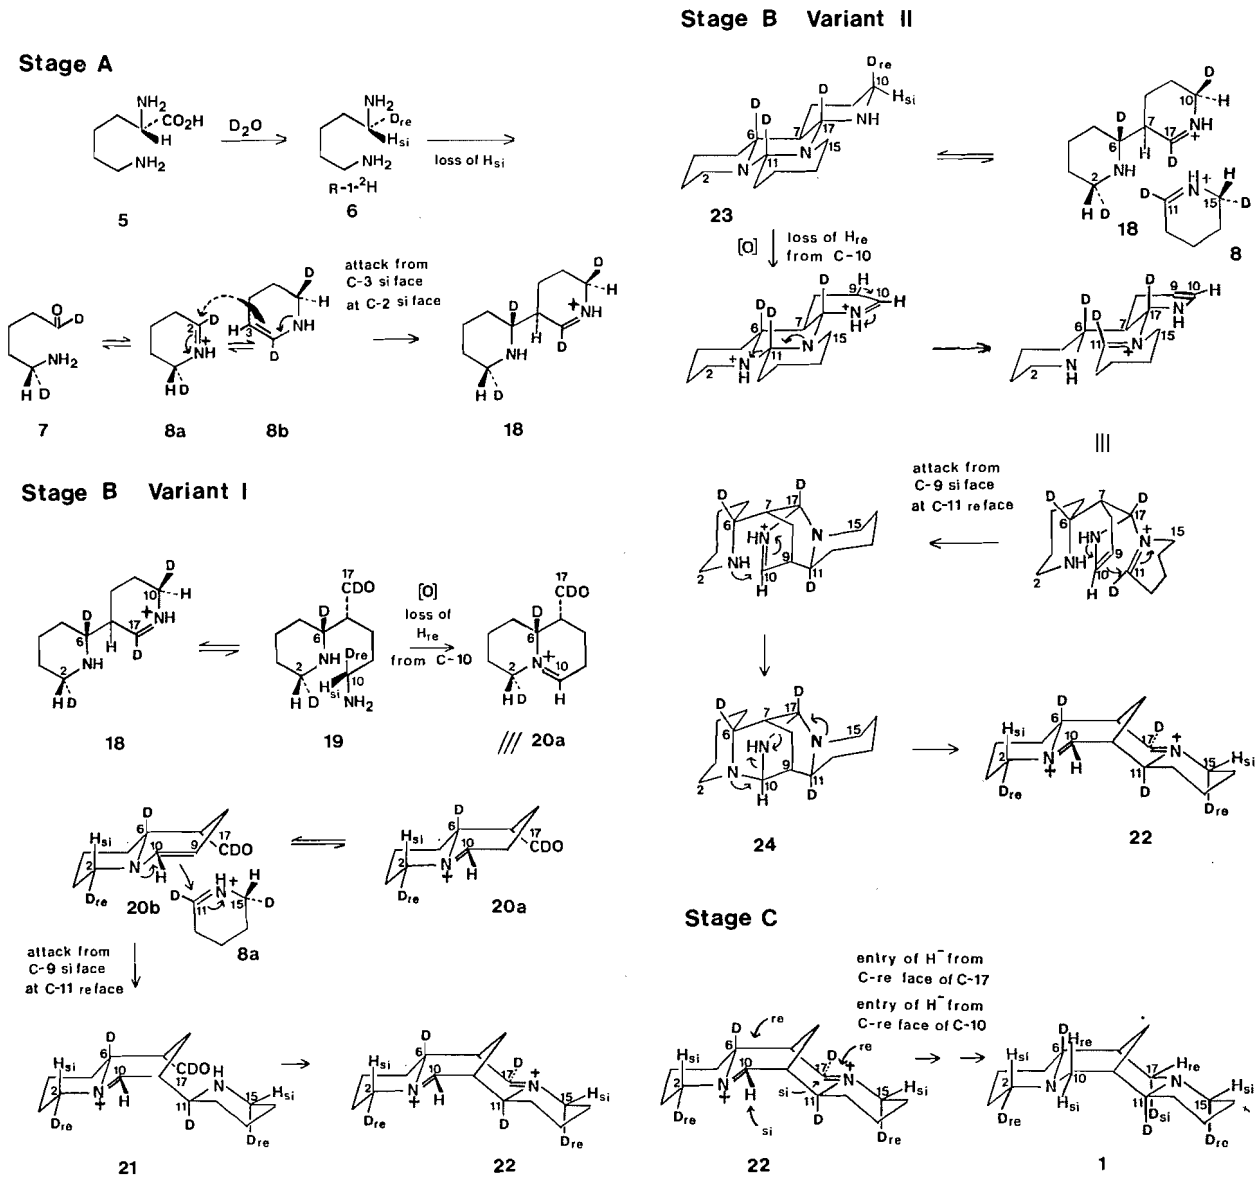

SCHEME. 5. Biosynthesis of sparteine from (*R*)-[1-^{2}H]cadaverine. Stage A: The initial steps. Stage B: Two variants, I and II, of the intermediate steps. Stage C: The final step. (a = acid, b = base).

the C_5N moiety N-16,C-15,-14,-13,-12,-11 of the alkaloids, suffers less endogenous carrier dilution on the route to the product than the two units that give rise to the rest of the bisquinolizidine system.

Clearly, a bisquinolizidine skeleton showing this distribution of label cannot be derived from a trimer of the C_5N precursor since trimerization of a labelled monomer would deliver equimolar quantities of label into each of the three subunits of the trimer.

Evidently the Δ^1-piperideine trimer model (23) of the biosynthesis of the $C_{15}N_2$ lupine alkaloids, as it stands (Scheme 4), cannot accommodate these new experimental findings, which indicate that two of the three C_5 units of the bisquinolizidine skeleton, C-2,-3,-4,-5,-6 and C-10,-9,-8,-7,-17, are invariably labelled at the same level, while the third C_5 unit, C-11,-12,-13,-14,-15, can carry label at a lower level (as may have been the case in some of the experiments with [^{13}C,^{15}N]cadaverine (3, 4)), at the same level (as in all the experiments with ^{14}C-labelled lysine and cadaverine, hitherto reported (6–15)) or at a higher level (as now observed with ^{14}C-labelled lysine and Δ^1-piperideine).

A modified biosynthetic model, which is consistent with the new findings and also accounts for the earlier observations on the regiospecificity of entry of label from ^{14}C-, ^{13}C-, ^{13}C,^{15}N-, and ^{2}H-labelled substrates (1–21, 23) and accommodates the evidence on the stereochemistry of biosynthesis derived from the incorporation of label from deuteriated substrates (3, 18–21), is presented in Schemes 5 and 6.

The two key intermediates of this model are the Δ^1-piperideine dimer, tetrahydroanabasine (**18**), and the bisquinolizidine derivative, 1,10;16,17-didehydrosparteinium ion (**22**).

The initial steps of the model (Stage A, Schemes 5 and 6), conversion of L-lysine (**5**) into tetrahydroanabasine (**18**) via cadaverine (**6**) and Δ^1-piperideine (**8**), in four stereochemically defined reactions, are identical with those of the route from L-lysine into the $C_{10}N$ lupine alkaloid lupinine, whose biosynthesis has been discussed in detail in the first paper of this series (37). The suggestion that tetrahydroanabasine may be an in-

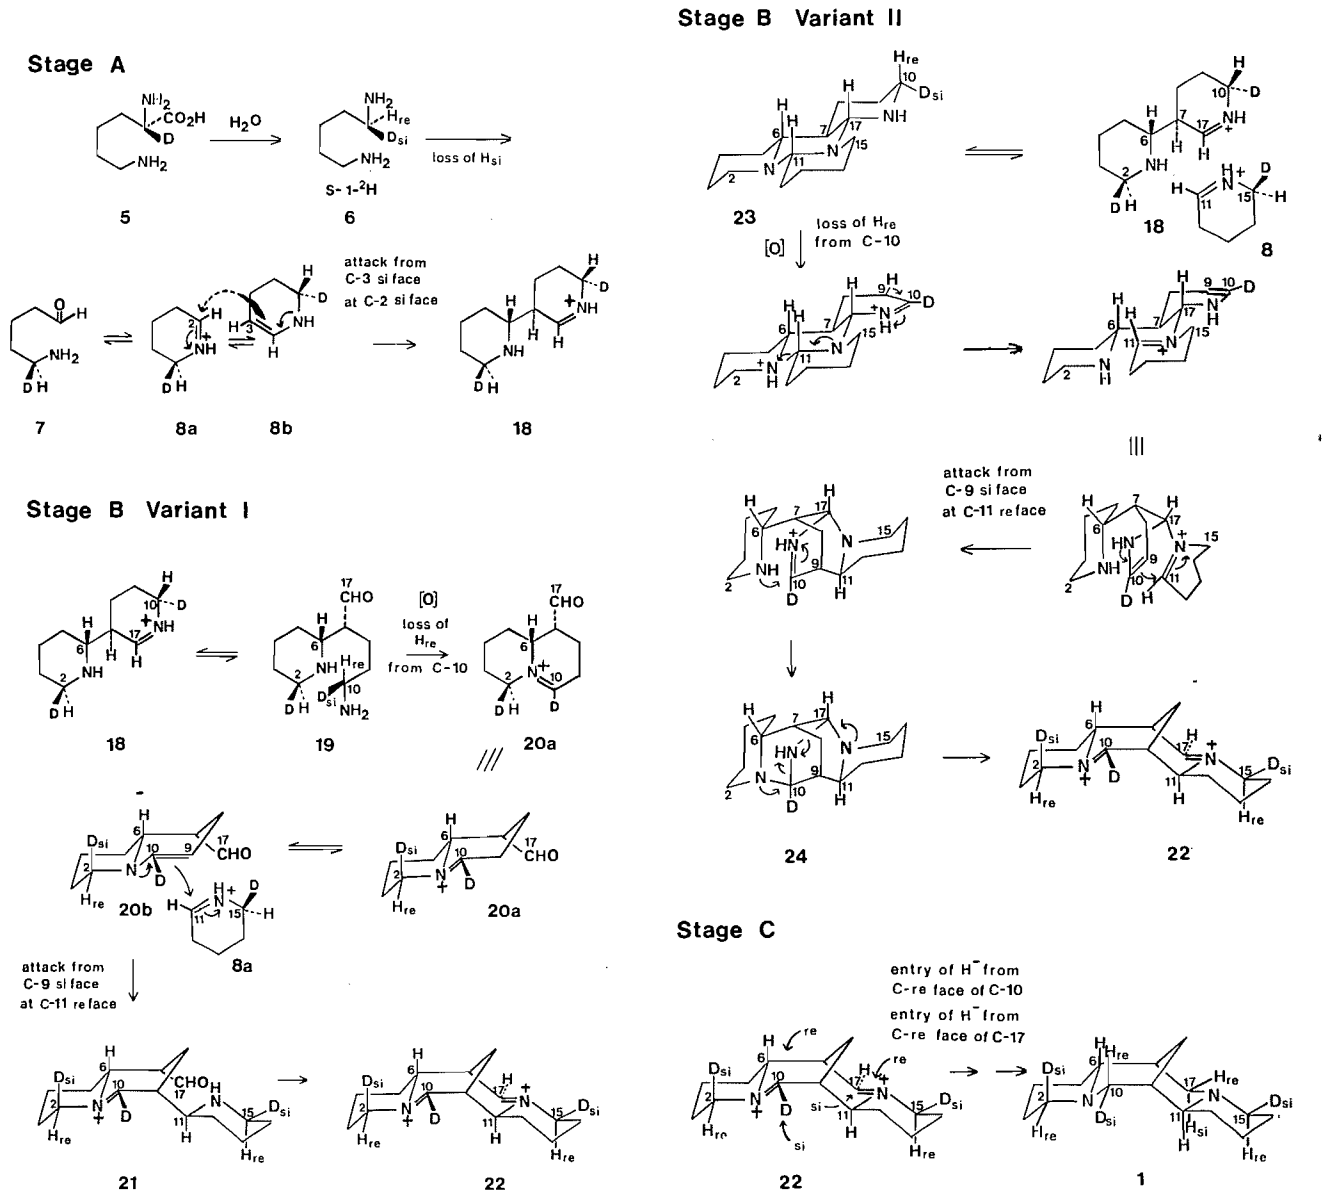

SCHEME. 6. Biosynthesis of sparteine from (*S*)-[1-^{2}H]cadaverine. Stage A: The initial steps. Stage B: Two variants, I and II, of the intermediate steps. Stage C: The final step. (a = acid, b = base).

termediate on the pathway to lupinine was first made by Schütte (40).

In the final steps of the proposed sequence (Stage C, Schemes 5 and 6) sparteine (**1**), lupanine (**2**), and other bisquinolizidine lupine alkaloids are generated from 1,10;16,17-didehydrosparteinium ion (**22**). This is the entity that we regard as the first intermediate containing the complete $C_{15}N_2$ skeleton.

The intermediate steps of the model (Stage B, Schemes 5 and 6) lead from tetrahydroanabasine (**18**) into the didehydrosparteinium ion (**22**). Two routes for this transformation must be considered. The major difference between these routes is the timing of the loss of nitrogen from the C_5N precursor unit that is destined to yield the central C_5 chain, C-10,-9,-8,-7,-17, of the bisquinolizidine skeleton.

In one case (variant I) nitrogen is eliminated from a tetrahydroanabasine-derived $C_{10}N_2$ intermediate (**19**). Further condensation with the additional C_5N unit takes place after nitrogen loss. Generation of the didehydrosparteinium ion (**22**) by this route can be schematically represented by the reaction sequence (*i*) $C_{10}N_2$ minus $N \rightarrow C_{10}N$; (*ii*) $C_{10}N$ plus $C_5N \rightarrow C_{15}N_2$. The key $C_{10}N$ intermediate (**20**) of this sequence not only serves as one of the building blocks of the bisquinolizidine lupine alkaloids but is also a precursor of the $C_{10}N$ lupine alkaloid, lupinine (37). The possible involvement of this key intermediate in the elaboration of the $C_{15}N_2$ lupine alkaloids was first suggested by Leete (41) (see ref. 23).

In the other case (variant II) the didehydrosparteinium ion (**22**) is generated by elimination of nitrogen from a $C_{15}N_3$ intermediate (**24**) that is formed after condensation of tetrahydroanabasine (**18**) with Δ^1-piperideine (**8**). This reaction sequence is schematically represented by (*i*) $C_{10}N_2$ plus $C_5N \rightarrow C_{15}N_3$; (*ii*) $C_{15}N_3$ minus $N \rightarrow C_{15}N_2$. This pathway implicates the conformationally favoured stereoisomer (**23**) of isotripiperideine (42) and is a modification of the Δ^1-piperideine trimer model (23) of lupine alkaloid biosynthesis (Scheme 4).

Both variants predict that the two C_5 chains, C-2,-3,-4,-5,-6 and C-10,-9,-8,-7,-17, of the alkaloids are derived from the two C_5 chains of tetrahydroanabasine (**18**). Since tetrahydroanaba-

sine is formed by dimerization of Δ^1-piperideine (**8**) it is a necessary consequence of its mode of formation that the two C_5 chains contain equimolar amounts of label, if generated from labelled Δ^1-piperideine, and that the four carbon atoms, C-2, -6, -10, and -17, of sparteine or lupanine are invariably equally labelled with ^{14}C or equally enriched in ^{13}C, when derived from appropriately ^{14}C- or ^{13}C-labelled lysine or cadaverine.

Both variants of Stage B, Schemes 5 and 6, predict that the C_5 chain, C-11,-12,-13,-14,-15, of the alkaloids is derived from the C_5 chain of a third Δ^1-piperideine unit that condenses with the previously formed C_{10} intermediate in a later separate step. Since, in the intact plant, the pool sizes of the C_{10} and the C_5 intermediates are not necessarily the same at the time of their condensation, conditions can therefore exist, in an experiment with labelled substrates, that can lead to the delivery into the C_5 chain, C-11,-12,-13,-14,-15, of a different concentration of label, higher or lower, than into the C_{10} unit, C-2,-3,-4,-5,-6;C-10,-9,-8,-7,-17.

In experiments with intact plants it would appear to be almost impossible to control the conditions that might lead to predictably different levels of enrichment in the C_{10} and C_5 segments of the product. It is likely, however, that in the case of the experiments with DL-[6-^{14}C]lysine (expts. 7–9) the high specific activity (48 mCi/mmol) and thus the minute quantity of the precursor that was administered (ca. 0.03, 0.07, 0.04 mg labelled lysine per plant administered in a single dose, then allowed to metabolize for 4 days) favoured discrimination of labelling in the two segments of lupanine. This must be compared with the results obtained when a much larger amount of precursor was administered, as in the experiment with DL-[6-^{13}C]lysine (expt. 17) (9 mg enriched lysine per plant, administered in 5 equal portions daily for 5 days, then allowed to metabolize for 4 more days) and in the experiments with DL-[2-^{14}C]lysine reported in the literature (9, 13, 15) (ca. 1–2 mg labelled lysine per plant, then incubated over 4 days). In these experiments equimolar labelling or enrichment was observed at each of the six labelled sites, presumably because the endogenous pools of the C_{10} and C_5 intermediates were swamped by the large amount of exogenous substrate that had been administered. On the other hand, in the experiments with [6-^{14}C]lysine (expts. 7–9) the tracer amounts of exogenous substrate that were administered evidently did not obliterate the differences in the pool sizes, of the C_{10} and the C_5 precursor, that existed endogenously. As a consequence, different levels of labelling at the sites of the C_{10} unit and those of the C_5 unit resulted.

This serendipitous observation opens the way to the next stage of the investigation of the biosynthesis of the $C_{15}N_2$ lupine alkaloids, a critical examination of the intermediate steps of the biosynthetic route.

Even though we currently tend to favour variant I of the model outlined in Stage B of Schemes 5 and 6, both variants, I and II, are consistent with the regiochemical and stereochemical evidence derived from incorporation experiments with intact plants, and must be tested. This work is in progress.

Experimental

Radioactive materials

DL-[2-^{14}C]Lysine and DL-[6-^{14}C]lysine were obtained from commercial sources (see Table 1).

Δ^1-Piperideine was obtained from DL-lysine by oxidation with *N*-bromosuccinimide (cf. ref. 43). *N*-Bromosuccinimide (40 mg, 0.22 mM) was added to a solution containing the radioactive lysine together with carrier DL-lysine monohydrochloride to make a total of 20 mg (0.11 mM) lysine monohydrochloride in 3 mL of water. The flask was rotated on a rotary evaporator under mild suction while immersed in a water bath at 40–50°C. When the solution had become colorless (ca. 20 min) it was basified with potassium carbonate (20% w/v, 2 mL) and extracted with chloroform (6 × 5 mL). The chloroform extract was washed with water, filtered, and evaporated to dryness. The oily residue (30 mg) was dissolved in dilute hydrochloric acid (0.25 M, 1 mL). Thin-layer chromatography (silica gel, 1-butanol:acetic acid:water, 2:1:1) showed the presence of Δ^1-piperideine (R_f 0.6) as the major component, together with traces of unchanged lysine (R_f 0.23). The radiochemical yield was approximately 50%.

In this manner DL-[6-^{14}C]lysine (total activity 0.1 mCi, specific activity 48 mCi/mmol, CEA France) was converted into [6-^{14}C]-Δ^1-piperideine (specific activity 0.9 mCi/mmol) (expts. 11, 12), and DL-[2-^{14}C]lysine (total activity 0.1 mCi, specific activity 4.7 mCi/mmol, New England Nuclear) was converted into [2-^{14}C]-Δ^1-piperideine (specific activity 0.8 mCi/mmol) (expt. 10).

Administration of radioactive tracers to L. angustifolius *and* L. luteus

Plants were grown from seed and used for tracer experiments 3–6 weeks after germination. Experiments with *L. angustifolius* were carried out in the greenhouse (expts. 7–11) or in the growth chambers (expt. 13). The tracer experiment with *L. luteus* (expt. 6) has been described (37). Tracer solution was administered to 12–30 plants by wick in a single dose. The plants were allowed to grow 3–5 days in contact with tracer. Details of the experiments with *L. angustifolius* are summarized in Table 1. Details of the experiments with *L. luteus* were reported previously (37).

^{13}C- and ^{2}H-enriched compounds

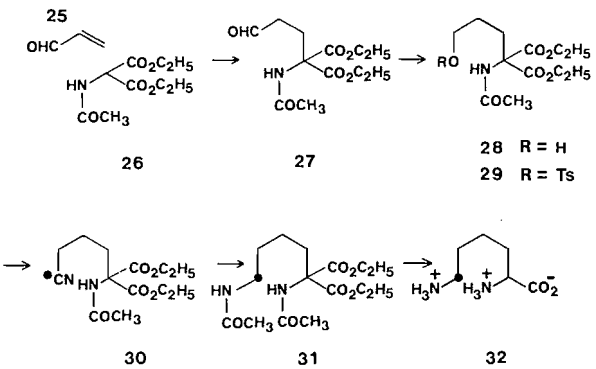
The preparation of [1-^{13}C,1-^{15}N]cadaverine (37) and of the ^{2}H-enriched samples of cadaverine (27), lysine (27), and Δ^1-piperideine (27) has been reported previously.

DL-*[6-^{13}C]Lysine monohydrochloride* (Scheme 7)

*Ethyl 2-acetylamino-2-ethoxycarbonyl-5-hydroxypentanoate (ref. 44) (**28**).* Diethyl acetamidomalonate (**26**) (10.9 g) was added to a suspension of freshly prepared sodium methoxide (from 18 mg sodium metal) in dry benzene (17 mL). The mixture was cooled and freshly distilled acrolein (**25**) (2.9 g) in dry benzene (4 mL) was added dropwise with stirring over 15 min. Stirring was continued for 2 h at room temperature. The mixture was then filtered and the filtrate evaporated. The crude aldehyde (**27**) so obtained was dissolved in ethanol (5 mL), triethylamine (5 mL) and freshly prepared Raney nickel catalyst (1 g) were added, and the mixture was shaken 24 h in a Parr hydrogenator (40–50 psi, 75°C; 1 psi = 6.9 kPa). The catalyst was centrifuged off, the supernatant solution was concentrated, and the oily residue was dissolved in ether (40 mL) and cooled (−5°C). The product (**28**) that separated was filtered off, washed with cold ether, and recrystallized from acetone/ether. Yield 5.5 g, mp. 80°C (lit. (44) mp 80–81°C); ^{1}H nmr ($CDCl_3$) δ: 7.1 (1H, s, NH), 4.2 (4H, q, *J* 7.5 Hz, CH_2CH_3), 3.6 (2H, t, *J* 6.9 Hz, H-5), 3.3 (1H, s, OH), 2.5–2.3 (2H, m, H-4), 1.5–1.2 (2H, m, H-3), 2.0 (3H, s, CH_3CO), 1.3 (6H, t, *J* 7.5 Hz, CH_3CH_2) ppm.

Ethyl O-p-*toluenesulfonyl-2-acetylamino-2-ethoxycarbonyl-5-hydroxypentanoate (**29**).* Tosyl chloride (6.42 g) was added in small portions to a solution of the alcohol (**28**) (4.63 g) in anhydrous pyridine (70 mL) at 0°C. The mixture was kept 20 h at 5°C and was then poured into a water/ice mixture, which was stirred 2 h. The white precipitate was filtered off, washed with water (3 × 50 mL), and dried *in vacuo* over anhydrous potassium hydroxide. The product (**29**) was recrystallized from methanol and was filtered off at 0°C. Yield 5.34 g, mp. 106.5–107°C; ^{1}H nmr (C_6D_6) δ: 7.7 (2H, d, *J* 8.4 Hz, H-2′,6′), 7.1 (2H, d, *J* 8.4 Hz, H-3′,5′), 6.7 (1H, s, NH), 4.1 (4H, q, *J* 7.2 Hz, -CH_2CH_3), 3.9 (2H, t, *J* 6.3 Hz, H-5), 2.5–2.3 (2H, m, H-4), 2.2 (3H, s, CH_3Ph), 1.7 (3H, s, CH_3CO), 1.7–1.4 (2H, m, H-3), 1.1 (6H, t, *J* 7.2 Hz, CH_2CH_3) ppm.

*Ethyl 2-acetylamino-2-ethoxycarbonyl-5-[^{13}C-cyano]pentanoate (**30**)* (cf. ref. 38). A solution of the above tosylate (**29**) (4.23 g) in

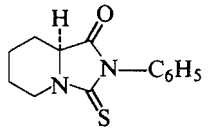


SCHEME. 7. Synthesis of [6-^{13}C]lysine (● denotes ^{13}C).

dimethyl sulfoxide (11 mL) was added dropwise at room temperature over 2 h to a stirred solution of potassium [^{13}C]cyanide (99 at.% ^{13}C, MSD Isotopes, Montreal) (680 mg) in dimethyl sulfoxide (15 mL) and water (2 mL). Stirring was continued for a further 21 h, at which time starting material was no longer present (tlc). The yellow solution was poured into water (150 mL) and the product was extracted into benzene (5 × 50 mL). The benzene extract was washed with saturated sodium chloride solution (6 × 50 mL), dried, and evaporated *in vacuo* to yield the nitrile (**30**) as a yellowish oil that crystallized on cooling (2.75 g). An analytical sample was obtained by recrystallization from ethanol/hexane at −44°C; mp 47–48°C. In an earlier report the substance failed to crystallize (38). Infrared (liquid film): 3360 (NH), 2220 (CN), 1742, 1190 (CO_2Et), 1665 (NCO) cm^{-1}; ^{1}H nmr $CDCl_3$) δ: 6.9 (1H, s, NH), 4.1 (4H, q, *J* 7.5 Hz, CH_2CH_3), 2.6–2.2 (4H, m, H-3,-5), 2.0 (3H, s, CH_3CO), 1.5 (2H, m, H-4), 1.3 (6H, t, *J* 7.5 Hz, CH_2CH_3); ^{13}C nmr δ; 169.5 ($COCH_3$), 167.7 (-CO_2-), 119.1 (CN), 66.1 (-OCH_2-), 58.3 (C-2), 31.7 (d, *J* 3.6 Hz, C-3), 23.0 (CH_3-CO), 19.5 (d, *J* 42 Hz, C-5), 15.6 (C-4), 14.0 (CH_3CH_2) ppm.

*Ethyl N,N′-diacetyl-2,6-diamino-2-ethoxycarbonyl[6-^{13}C]hexanoate (**31**).* Freshly prepared Raney-nickel catalyst (0.5 g) was added to a solution of the above nitrile (**30**) (2.68 g) in ethanol (absolute, 20 mL) and the mixture stirred 2 h at room temperature. The mixture was then centrifuged, the supernatant solution decanted, and the residue washed twice with ethanol. Solvent was removed *in vacuo*, and the residue dissolved in acetic anhydride (5 mL) and mixed with a suspension of Raney nickel (0.8 g) in acetic anhydride (15 mL). The mixture was shaken 3 h in a Parr hydrogenator (45–50 psi, 68°C internal temperature). The catalyst was centrifuged off and the supernatant solution evaporated to dryness. The product (**31**) was obtained as a yellow solid, which was recrystallized from ethanol. Yield 2.15 g, mp 133–135°C; ^{1}H nmr ($CDCl_3$) δ: 6.9 (1H, s, NH-2), 6.1 (1H, br, NH-6), 4.3 (4H, q, *J* 7 Hz), 3.1 (2H, dq, $J_{^{13}C,H-6}$ 147 Hz, $J_{H-5,H-6} = J_{H-6,NH}$ 6.6 Hz), 2.5–2.3 (2H, m, H-5), 2.0, 1.9 (2 × 3H, 2 × s, CH_3CON-2, CH_3CON-6), 1.5 (4H, m, H-3,-4), 1.3 (6H, t, *J* 7 Hz); ^{13}C nmr ($CDCl_3$) δ: 170.1, 169.1 (CON-6, CON-2), 168.0 (-CO_2-), 66.4 (-OCH_2-), 63.9 (C-2), 42.8 (C-3), 39.2 (C-6), 31.9 (d, *J* 4.1 Hz, C-4), 29.1 (d, *J* 36.3 Hz, C-5), 22.9, 21.0 (CH_3CON-2, CH_3CON-6), 13.5 (CH_3CH_2) ppm.

DL-*[6-^{13}C]Lysine monohydrochloride (**32**).* The diacetamide (**31**) (1.36 g) was refluxed 20 h in hydrochloric acid (4.8 M, 11.3 mL). The solution was evaporated to dryness, water was added, and the solution again evaporated and the residue dried *in vacuo*, yielding crystalline dihydrochloride of [6-^{13}C]lysine (0.88 g). This was dissolved in hot ethanol (10 mL) and the mixture was filtered. Pyridine (0.5 mL) in ethanol (1 mL) was added dropwise to the stirred solution. The monohydrochloride of [6-^{13}C]lysine crystallized and was washed with cold ethanol (absolute, 2 × 1 mL). Yield 0.66 g; ^{1}H nmr (D_2O) δ: 3.8 (1H, t, *J* 5.7 Hz, H-2), 3.2 (2H, dt, $J_{^{13}C,H-6}$ 127.8 Hz, $J_{H-6,H-5}$ 7.2 Hz), 2.1–1.4 (6H, m); ^{13}C nmr (D_2O) δ: 175.3 (C-1), 55.3 (C-2), 40.0 (C-6), 30.7 (d, *J* 4.9 Hz, C-3), 27.2 (d, *J* 35.5 Hz, C-5), 22.3 (C-4) ppm. For assignments see ref. 45.



33

Administration of ^{13}C- and ^{2}H-enriched substrates to L. angustifolius *and* L. luteus

The plants used in these experiments were grown from seed and were used in feeding experiments 3–6 weeks after germination. The feeding experiments with *L. angustifolius* were carried out in the greenhouse (summer months, expts. 13, 16) or in the growth chambers (winter months, expts. 14, 15, 17). The experiments with *L. luteus* (expts. 1–5) have been described (37). Tracer solution was administered by wick over a period of 5 days, and the plants were then grown for a further period of 3–4 days before being harvested. Details of the experiments with *L. angustifolius* are summarized in Table 1. The experiments with *L. luteus* have been reported (37).

*Extraction of (+)sparteine (**1**) from* Lupinus luteus

This procedure has been described previously (37).

*Extraction of (+)lupanine (**2**) and (+)-13-hydroxylupanine (**3**) from* Lupinus angustifolius (cf. ref. 46)

In the experiments with radioactive substrates (expts. 7–12) the plant material was dried (2 days, 50°C) and ground. In a typical procedure (expt. 11) the ground plant material (16 g) was moistened with potassium carbonate solution (25% w/v, 25 mL); the mixture was allowed to stand 20 min and was then mixed with Kieselguhr G (Stahl) (16 g) and continuously extracted 5 h with methylene chloride. (In the experiments with substrates enriched with stable isotopes (expts. 13–17), the fresh plant material was macerated with methanol and extracted continuously for 7 h). The extract was evaporated to dryness, hydrochloric acid (1 M, 3 mL) was added, the mixture was shaken with ether (5 × 3 mL), and the extract discarded. The aqueous layer was filtered through Celite and the filtrate was further extracted with chloroform (4 × 3 mL), neutralized with potassium carbonate, made alkaline with potassium hydroxide solution (50% w/v, 1 mL), and extracted with methylene chloride (3 × 5 mL). The chloroform extract, containing acylated alkaloids, was dried over sodium sulfate and evaporated. The residue was dissolved in hydrochloric acid (4%, 3 mL), and reextracted with chloroform (3 × 2 mL). The aqueous layer was basified, and extracted with methylene chloride (3 × 2 mL).

The two methylene chloride extracts were combined, dried over sodium sulfate, and evaporated. The residue (50 mg) was dissolved in dilute hydrochloric acid (1 M, 4 mL). The solution was neutralized with potassium carbonate, basified with potassium hydroxide solution (50% w/v, 2 mL), and mixed with Kieselguhr G (Stahl) (7 g). The mixture was placed on a column (1.5 cm diameter) containing Kieselguhr (7 g) that had been mixed with potassium hydroxide solution (50% w/v, 2 mL). The column was washed with petroleum ether (30–60°C, 150 mL), which eluted the lupanine fraction (15 mg), then with ether (50 mL), which yielded the angustifoline fraction (1 mg), and finally with methylene chloride (150 mL), which yielded pure 13-hydroxylupanine (32 mg). Thin-layer chromatography (silica, hexane:ethyl acetate:diethylamine, 17.5:77.5:5) of the lupanine fraction showed that all radioactivity was present at the R_f value (0.65) corresponding to lupanine.

(+)Lupanine perchlorate

Crude lupanine from the radioactive feeding experiments was mixed with a solution of perchloric acid in methanol (10% v/v, 3 drops) yielding an immediate precipitate of the perchlorate. The radioactive product was diluted with inactive lupanine perchlorate as carrier and recrystallized from methanol. Melting point 213°C (lit. (47) mp. 211–212°C; (48) mp 209°C).

(+)Lupanine methiodide

Lupanine (23 mg) was dissolved in benzene (1 mL). Methyl iodide (0.5 mL) was added, and the solution was refluxed for 1 h and kept

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

overnight. The solution was evaporated and the residue triturated with benzene, filtered, and washed with benzene. The product was recrystallized from 2-propanol, yielding lupanine methiodide, melting point 274–275°C (lit. (48) mp 274°C for (−)lupanine methiodide).

Degradation of lupanine (Scheme 1)

Carbon-17 as benzoic acid (cf. refs. 13, 49)

Conversion of lupanine (2) perchlorate into sparteine (1) (cf. ref. 50). Lupanine perchlorate (128 mg) was dissolved in dilute hydrochloric acid (1.3 M, 8 mL); platinum oxide (140 mg) was added and the mixture shaken in a Parr hydrogenator for 15 h at 20 psi. The solution was filtered, the precipitate washed with water (3 × 1 mL), the aqueous filtrate basified with aqueous sodium hydroxide (10% w/v), and product extracted into ether (4 × 4 mL). The ether solution was dried (anhydrous potassium carbonate) and evaporated, yielding sparteine as a colorless oil whose ir spectrum was identical with that of an authentic specimen of sparteine.

Conversion of sparteine (1) into 17-oxosparteine (9) (cf. refs. 7, 50). Sparteine (64 mg) was dissolved in dilute hydrochloric acid (0.4 M, 1.2 mL); the solution was basified with diluted sodium hydroxide (10% w/v, 1.8 mL) and an aqueous solution of potassium ferricyanide (0.4 g in 1.5 mL) was added. The mixture was vigorously shaken for 40 min, acidified with dilute hydrochloric acid (4 M, 1 mL), and extracted with ether (3 × 3 mL). The ether extract was washed with dilute hydrochloric acid (1 M, 2 × 3 mL); the aqueous extract was basified with dilute sodium hydroxide (10% w/v, 3 mL) and extracted with ether (3 × 3 mL). The ether extract was dried (anhydrous potassium carbonate) and evaporated, yielding 17-oxosparteine (**9**) (60 mg) as an oil that crystallized on standing, and was recrystallized from petroleum ether (30–60°C). Melting point 83–84°C (lit. (7) mp 86–87°C; (50) mp 87°C).

Phenylation of 17-oxosparteine (9) (cf. refs. 13, 49). 17-Oxosparteine (55 mg) in anhydrous ether (1 mL) was added to a stirred suspension of phenyllithium in anhydrous ether, prepared from lithium (0.14 g) and bromobenzene (0.6 mL) in anhydrous ether (10 mL) in a nitrogen atmosphere. The mixture was refluxed 30 min, dry toluene (3 mL) was added, and the temperature of the oil bath was slowly raised to 100°C and so maintained for 1 h. The mixture was allowed to cool to room temperature overnight, anhydrous ether (5 mL) was added, unreacted lithium removed with a spatula, and the solution poured into dilute hydrochloric acid (4 M, 2 mL) and crushed ice. After being stirred for 15 min the solution was extracted with ether (3 × 5 mL), and the ether extract washed with dilute hydrochloric acid (M, 2 × 3 mL). The combined acid fractions were basified with solid sodium carbonate and extracted with chloroform (3 × 5 mL). The chloroform extract was washed with saturated sodium chloride solution, filtered, dried (anhydrous sodium carbonate), and evaporated. The product, presumably 17-phenyl-16,17-dehydrosparteinium hydroxide (**10**), was obtained as a yellow oil (53 mg); ir: 3070, 3030, 1675 (C=N$^+$), 1600, 1500, 750, 700 (phenyl) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 8.0 (m, 1H (*para* H)), 7.5 (m, 2H (2 × *ortho* H)), 7.2 (m, 2H (2 × *meta* H)) ppm.

Benzoic acid from 17-phenyl-16,17-dehydrosparteinium hydroxide (10). Crude 17-phenyl-16,17-dehydrosparteinium hydroxide (53 mg) was dissolved in acetone (1 mL), water (8 mL) was added, the mixture was heated to remove acetone, and finely powdered potassium permanganate (0.4 g) was then added in small portions to the stirred suspension. The mixture was refluxed for 3 h with vigorous stirring, more potassium permanganate (0.4 g) was added, and refluxing continued for 3 h. Manganese dioxide was filtered off, the precipitate washed with water (3 × 1 mL), the filtrate extracted with ether, and the extract discarded. The aqueous layer was acidified with dilute sulfuric acid (1 M, 3 mL), decolorized by addition of sodium bisulfite, and extracted with ether (3 × 10 mL). Evaporation of the ether extract gave benzoic acid (13 mg), which was purified by sublimation at 40°C and 5 × 10^{-2} Torr (1 Torr = 133.3 Pa). Yield 7 mg, mp 121–121.5°C.

Carbon-2 as benzoic acid (cf. refs. 8, 13, 49)

Phenylation of lupanine (2) (cf. ref. 49). Lupanine perchlorate (95 mg) was dissolved in aqueous ammonia (0.880 ammonia:water, 1:2, 5 mL), and the solution stirred with benzene (5 mL) at room temperature. The benzene layer was separated, the aqueous layer extracted with chloroform (3 × 5 mL), and the combined chloroform solution was washed with sodium chloride solution, dried, and evaporated, yielding lupanine (65 mg) as a colorless oil. Phenylation was performed by a procedure similar to that described above for the phenylation of 17-oxosparteine. The product (73 mg), presumably 2-phenyl-1,2-dehydrosparteinium hydroxide (**11**) together with a little 2-phenyl-2,3-dehydrosparteine (**12**), was obtained as a glass; ir: 3070, 3030, 2820, 2775, 2740 (Bohlmann bands), 1680 (C=N$^+$), 1640 (HC=C), 1605, 1495, 750, 700 (phenyl) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.4 (m, 5H) ppm.

Benzoic acid from 2-phenyl-1,2-dehydrosparteinium hydroxide (11). Benzoic acid (9 mg), mp 122°C, was obtained by permanganate oxidation of crude 2-phenyldehydrosparteinium hydroxide (73 mg) by a method similar to that described above for the oxidation of 17-phenyl-16,17-dehydrosparteinium hydroxide.

Carbon-15 (together with carbon-14,13 (and 12)) as β-alanine (17) and γ-aminobutyric acid (16) (by direct oxidation of lupanine (**2**))

Oxidation of lupanine perchlorate (cf. ref. 13). Lupanine perchlorate (200 mg) was dissolved in an ice-cooled mixture of concentrated sulfuric acid (1 mL) and water (1.6 mL). A solution of chromic oxide (1.2 g) in water (1 mL) was added with stirring. The mixture was heated (100°C) for 72 h with continuous stirring. Excess chromic acid was decomposed by addition of 2-propanol, water was added, and the solution continuously extracted for 20 h with ether to remove succinic acid and small amounts of other oxidation products. The acid layer was neutralized by addition of an excess of a hot saturated solution of barium hydroxide followed by solid carbon dioxide. The precipitate of barium sulfate and carbonate was centrifuged off and washed with hot water. The combined aqueous solution was filtered and evaporated. The residue was dissolved in water and applied to a column (1.2 × 10 cm) of Dowex 50 × 4 (H$^+$ form). Inorganic salts were eluted with water (100 mL), and the mixture of amino acids (mainly β-alanine and γ-aminobutyric acid) with pyridine (1 M, 100 mL). The pyridine eluate was evaporated to dryness, and the residue dissolved in water and applied to a second column (1.4 × 15 cm) of Dowex 50 × 4 (pyridinium form). The column was washed with water (100 mL) followed by pyridine (0.025 M, 150 mL and 0.050 M, 100 mL). Fractions of 3 mL were collected. β-Alanine (2 mg) emerged first, followed by γ-aminobutyric acid (0.4 mg). The amino acids were converted into the hydrochloride salts, which were then purified by sublimation at 90–100°C and 3 × 10^{-2} Torr. The sublimed salts were recrystallized from methanol–ether, yielding β-alanine hydrochloride, mp 120–121°C (lit. (51*a*) mp 123°C) and γ-aminobutyric acid hydrochloride, mp 133–135°C (lit. (51*b*) mp 135–136°C).

Carbons-11 and -15 (together with carbons-9, -12, -13, and -14) as pipecolic acid (15) (by stepwise oxidation of lupanine)

Conversion of lupanine (2) into 17-oxolupanine (13) (cf. ref. 50). Lupanine (150 mg) obtained from lupanine perchlorate (see above) was dissolved in dilute acetic acid (50% w/v, 3 mL). A solution of potassium permanganate (267 mg) in acetone (25 mL) was added dropwise over 30 min to the stirred solution and stirring continued 30 min. Manganese dioxide was filtered off, the precipitate washed with acetone, the acetone was evaporated, and the residue decolorized with a dilute solution of sodium bisulfite (5 mL). The product was extracted into chloroform (3 × 5 mL), the chloroform extract was washed first with cold dilute hydrochloric acid (1 M, 1 × 5 mL), then with sodium carbonate solution, and finally with water, and was then evaporated. 17-Oxolupanine (**13**) was obtained as a colorless oil (155 mg), which crystallized on standing and was recrystallized from acetone-ether; mp 153–155°C (lit. (52) mp 154°C).

Hydrolysis of 17-oxolupanine (13) (cf. ref. 53). 17-Oxolupanine (90 mg) was dissolved in concentrated hydrochloric acid (2 mL) and heated for 20 h in a sealed tube at 180°C. The solution was then extracted with benzene to remove traces of starting material. The solution was concentrated *in vacuo*, water was added, and the pH of the solution adjusted to pH 6.5 by addition of dilute sodium hydroxide. The solution was applied to a column (1.2 × 10 cm) of Dowex 50 × 4 (H$^+$ form).

The column was eluted with water, followed by 1 M ammonia. Evaporation of the ammonia solution gave the product, presumably **14**, as a slightly colored amorphous solid (50 mg) that was oxidized without further purification.

Oxidation of the hydrolysis product. The crude product (**14**) (40 mg) was dissolved in dilute sulfuric acid (20% v/v, 2 mL), the solution was cooled to 0°C and stirred, and chromium trioxide (200 mg) was added in small portions with vigorous stirring. The solution was then heated to 100°C and stirring was continued for 6 h. Excess chromic acid was decomposed by addition of 2-propanol, and the solution was diluted and extracted with ether (3 × 10 mL). The aqueous layer was neutralized by addition of saturated barium hydroxide solution, followed by solid carbon dioxide. The precipitate was centrifuged off and washed, the aqueous layer was filtered and concentrated, and the crude amino acid mixture, so obtained, was applied to a column (1.2 × 10 cm) of Dowex 50 × 4 (H^+ form). The column was washed with water, and pipecolic acid, together with a little starting material, was eluted with 1 M ammonia. The ammoniacal eluate was evaporated, yielding a residue (12 mg) that contained five components, including β-alanine, γ-aminobutyric acid, pipecolic acid, and some unchanged starting material. The residue was dissolved in methanol. The methanol solution was filtered and evaporated to dryness. The residue was sublimed at 2×10^{-2} Torr. β-Alanine and γ-aminobutyric acid both sublimed at approximately 150°C in low yield. Pipecolic acid sublimed at 200°C. The pipecolic acid, presumably *S*-pipecolic acid, was resublimed. Yield 1.5 mg (9%), mp 269–270°C (dec.) (lit. (51*c*) mp 270°C for (±) and *R*-; 259–260°C for *S*-pipecolic acid (*sic*!)).

To increase the yields of β-alanine and of γ-aminobutyric acid an improved separation procedure was devised. The crude amino acid mixture (70 mg) obtained by oxidation of the diamino acid (**14**) (200 mg) was applied to a column (1.2 × 12 cm) of Dowex 50 × 4 (pyridinium form). The column was washed with water and amino acids were then eluted with pyridine (0.025 M). The early fractions yielded a mixture of β-alanine and pipecolic acid (20.7 mg). Later fractions contained γ-aminobutyric acid (2.4 mg). β-Alanine and pipecolic acid were dissolved in aqueous pyridine (2:3 v/v, 2 mL) and the pH of the mixture was adjusted to pH 8.5 with potassium carbonate. Freshly distilled phenylisothiocyanate (0.25 mL) was added and the mixture heated for 3 h at 45°C and kept overnight at room temperature. The mixture was acidified with dilute hydrochloric acid with cooling and extracted with chloroform (3 × 2 mL). The extract was concentrated and the residue shaken with dilute sodium hydroxide. The aqueous layer containing the phenylthiourea derivatives was acidified with dilute hydrochloric acid and extracted with chloroform. The solvent was removed *in vacuo* and the oily residue was heated for 2 h at 40°C with methanolic hydrochloric acid (1.2 M, 2 mL) and left overnight at room temperature. Solvent was evaporated and the residue was diluted with water and extracted with chloroform. The solution was concentrated to dryness and the residue (21 mg) was applied to a silica gel column (2 g, 230–400 mesh BDH). The column was washed with hexane (4 mL) and then with a mixture of hexane:diethyl ether (2:1, 10 mL). The methyl ester of the phenylthiourea derivative of β-alanine ($PhNHC(=S)NHCH_2CH_2CO_2CH_3$) was eluted with hexane:diethyl ether (1:1); yield 7.9 mg, mp 54°C (after recrystallization from diethyl ether:hexane) (lit. (54) mp 66.5–67°C; ir: 1732, 1180 (-CO_2-), 3100–3000, 1600, 1530 (phenyl), 1500 (C=S), 3210–3320 (NH) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 8.0 (bs, 1H, NH—Ph), 7.1–7.5 (m, 5H), 6.7 (1H, NH), 3.9 (m, 2H, CH_2—N, collapsed to a t, *J* 5.7 Hz, on shaking with D_2O), 3.6 (3H, s) 2.8 (2H, t, CH_2CO) ppm; ms *m/z*: 238 (36%, molecular ion), 207(9) 131(17), 93(100), 87(9). *Exact Mass* calcd. for $C_{11}H_{14}N_2O_2S$: 238.0776; found: 238.0779 (±0.0003).

A further elution with the same solvent system afforded the pipecolic acid condensation product (**33**) (5.8 mg), mp 161°C (from methanol) (lit. (55) mp 162–163°C); ms *m/z*: 246 (100%, molecular ion), 217(15), 135(46), 83(90), 81(58), 77(62), 55(56).

Acknowledgments

We are grateful to Professor Dr. M. Wiewiórowski, University of Poznan, for a gift of seeds of *Lupinus luteus* and *L. angustifolius*, to Thelma Leech, Greenhouse Supervisor, McMaster University, for providing facilities for our experiments, and to Brian G. Sayer, Department of Chemistry, for recording nmr spectra. This investigation was supported by a grant from the Natural Sciences and Engineering Research Council of Canada.

Received December 9, 1987

C. T. YIM and D. F. R. GILSON. Can. J. Chem. **66**, 1749 (1988).

The solute orientation parameters for benzene, trichloro-, and tribromobenzene have been measured, as functions of temperature, in the nematic solvents EBBA and ZLI-1132. The potential functions for orientation were derived for the model based on short and long-range contributions to the potential, with the former dependent on either a function of molecular shape or of molecular volume. There is reasonable agreement between calculated and experimental solute order parameters in both cases, and the difference in solute order parameter in the two solvents arises mainly from the difference in solvent electric field gradient.

C. T. YIM et D. F. R. GILSON. Can. J. Chem. **66**, 1749 (1988).

Utilisant les solvants nématiques EBBA et ZLI-1132, on a mesuré les paramètres d'orientation de soluté du benzène et des trichloro- et tribromo-benzènes, en fonction de la température. On a obtenu les fonctions de potentiel du modèle en se basant sur les contributions au potentiel à courte ainsi qu'à longue distance; les premières dépendent soit de la forme soit du volume moléculaire. Dans chacun de ces cas, on observe une bonne concordance entre les paramètres calculés et les paramètres expérimentaux pour l'ordre des solutés; dans ces deux solvants, la différence dans le paramètre d'ordre du soluté provient principalement de la différence dans le gradient du champ électrique.

Introduction

There have been numerous attempts to extend the original Maier–Saupe theory of nematic liquid crystals (1) to account for the orientation of a solute molecule dissolved in a nematic solvent, and, in particular, to relate this orientation to some molecular property of the solute. Recently, Burnell and co-workers (2–4) have proposed two approaches to this problem. The first is that the intermolecular forces responsible for the orientation of the solute arise from both short-range and long-range interactions, which depend upon the solute molecular size and shape and on the interaction of the solute molecular quadrupole moment with the electric field gradient in the solvent, respectively. The second theory (4) requires that a plot of the solute order parameter, S_2, versus that of the solvent, S_1, should yield a universal curve independent of concentration and temperature and related to the ratio of the magnitudes of the ordering potentials, which is interpreted in terms of a virtual transition temperature for the non-mesogenic solute.

As part of a program of studying the orientation of substituted benzene derivatives (5), we have measured the solute order parameters as functions of temperature in dilute solutions of benzene, 1,3,5-trichlorobenzene, and 1,3,5-tribromobenzene in the solvents EBBA and 1132, and these results have been used to examine factors affecting the short-range interactions.

Experimental

Solutes were obtained from commercial sources and used without further purification. EBBA was prepared by literature methods (6) and 1132 obtained from BDH Chemicals. Solutions were prepared at concentrations of 1 mol% for the trihalobenzenes and 2 mol% for benzene. Spectra were recorded on Varian XL-200 or XL-300 spectrometers without deuterium lock, and the temperatures were measured by the ethylene glycol shift. The molecular geometry for benzene was taken from the work of Lounila and Diehl (7), and for trichlorobenzene from ref. 8; the same structure was also adopted for the tribromo derivative. The solvent order parameters were obtained from dipolar splittings in the nmr spectrum of the pure solvent for EBBA (5), and from refractive index data for 1132 (9).

Results and discussion

For all three solutes, at similar reduced temperature, the solute orientation is always greater in 1132 than in EBBA, Fig. 1.

The orientation parameters can be calculated by solving integrals of the type

$$[1] \quad S_{ij} = \int (3 \cos\theta_i \cos\theta_j - \delta_{ij}) \exp(-U/k_B T)\, d\Omega/2Z$$

where $Z = \int \exp(-U/k_B T)\, d\Omega$.

For molecules with 3-fold (or higher) symmetry only one order parameter is required to describe the orientation, and the potential function, $U(\cos\theta)$, is given by eq. [2];

$$[2] \quad U(\cos\theta) = (3/2)\, A_{12} S_1 \cdot \cos^2\theta$$

where S_1 is the solvent order parameter and A_{12} describes the strength of the solute–solvent interaction. In dilute solution the solute–solute interaction can be ignored and A_{12} is assumed to contain the two contributions due to short and long-range interactions. For each solute/solvent pair, the constants can be determined by interpolation for the same temperatures at which the electric field gradients were measured (11, 12) and the short-range term can be obtained by subtracting the calculated long-range contribution from the experimental value for that temperature, and averaging the results.

To determine the long-range forces, which are given by $-(1/3)\,\Sigma Q_{ii} F_{ii}$, it is necessary to know the molecular quadrupole tensors and the electric field gradients. The molecular quadrupole moment is not a commonly available parameter, but values have been reported for these three compounds (13–16). In the case of benzene the values range from -18 to -33×10^{-40} C m^2, and the average of these has been used in the present work. The electric field gradients in EBBA and 1132 have been measured by Burnell and co-workers (11, 12) from an analysis of the quadrupole splittings in the deuterium nmr spectra of HD and D_2 dissolved in these two solvents. An interesting result of these studies is that the field gradients are of opposite sign, and,

therefore, for a common solute molecule there should be an enhanced orientation in one solvent and a diminished orientation in the other, as observed in the present study. A consideration of the errors in the reported values of the quadrupole moment and the field gradients suggests that the uncertainty in both quantities may be 10%.

For the three solutes used in this study, the parameter A_{12} is not entirely independent of temperature and (or) the solvent order parameter, as it should be from eq. [2]. This can be seen in the plots, Fig. 2, of $A_{12}S_1/k_BT$ versus S_1/T, which should be straight lines with slopes A_{12}/k_B, but show a curvature as the temperature increases, with a downward deviation in EBBA and an upward deviation in 1132. It is assumed that the short-range interaction is given by a solvent dependent constant multiplied by some molecular property. Burnell and co-workers have proposed (2, 3) that it is linked to a function of the perimeter length of the molecule and a restoring force constant that results from the displacement of the liquid crystal molecules by the solute. In the present work we have examined two other functions. The first is based on molecular shape anisotropy, similar to eq. [3], and which has been used for molecules of lower symmetry (5).

$$[3] \quad A_{SR} = A_L(L_2 - (L_1 + L_3)/2)$$

where L_i is the molecular dimension, including the van der Waals radii,[1] along the ith axis.[2] The constant A_L has the dimension of force. The second approach assumes a short-range force dependent on molar volume, eq. [4],

$$[4] \quad A_{SR} = A_V V$$

[1]The van der Waals radii were taken from ref. 17.

[2]The axis system is chosen such that the 3-axis is perpendicular to the ring plane of the solute molecule.

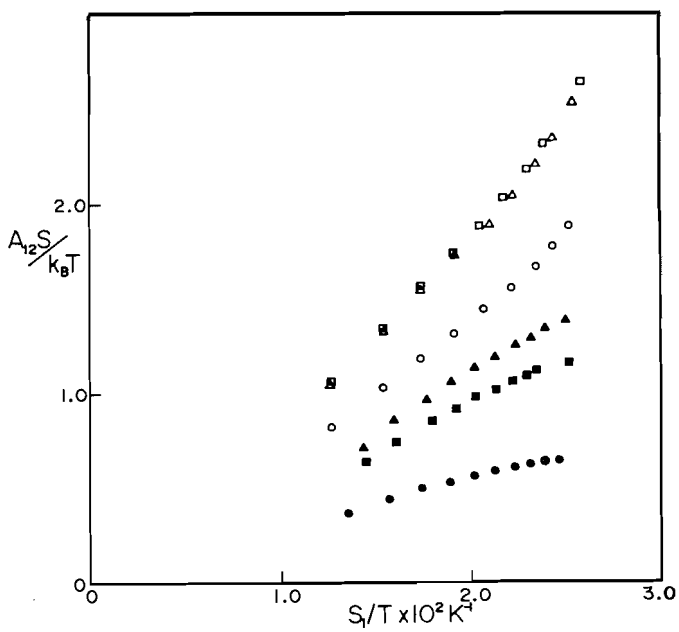

FIG. 2. Plots of $\{A_{12}S_1/k_BT\}$ versus S_1/T. Symbols as in Fig. 1.

and gives a constant, A_V, with dimensions of pressure, but, since the molecules have approximately the same thickness, this might be better interpreted as a function of cross-sectional area in the present case. Since the ratios of A_L or A_V for the same solute in different liquid crystal solvents should be independent of the solute, they have been constrained so that their ratio is constant. The calculated A_{12} values for the length, volume, and circumference models are compared with the experimental re-

TABLE 1. Potential constants for different models.[a] L, C, and V refer to the length, circumference, and volume[b] models, respectively

		A_{exp}	A_L	A_V	A_C
Benzene	1132	9.63	10.42	10.64	10.46
Trichlorobenzene	1132	12.61	11.51	11.23	11.37
Tribromobenzene	1132	12.73	12.67	12.71	12.79
Benzene	EBBA	3.84	3.06	3.24	3.09
Trichlorobenzene	EBBA	7.74	7.89	7.60	7.75
Tribromobenzene	EBBA	6.60	7.65	7.66	7.75
Root-mean-square error			0.77	0.86	0.83

[a] $\times 10^{21}$ J molecule^{-1}.
[b] The molar volume data, ref. 18, were measured for solutions in carbon tetrachloride at 25°C.

sults in Table 1. The rms errors between the calculated and experimental A_{12} values favour the model based upon the anisotropy in the molecular length, but the uncertainties in the various quantities are large, and there is not really any difference between any treatment. The calculated order parameters for the length model are compared with the experimental values in Fig. 1.

An obvious deficiency in all these models is that they do not explain the non-linearity of the plots in Fig. 2. This could be an indication that the two different contributions have a different temperature dependence, or it may be due to an incomplete function for the pseudopotential, the omission of higher rank terms (10) for instance, the assumption of constant volume, or it could be attributed to difficulties over the choice of values for the solvent order parameter, which were measured by different experimental methods and may not be comparable. It is possible that different solutes occupy, on the average, different regions of the liquid crystal solvent and are exposed to different order parameters.

The potential function in eq. [2] applies to the solvent itself (assuming uniaxial symmetry) and, according to the mean field approach of Maier and Saupe (1), the transition from the nematic to the isotropic phase occurs when the term $A_{11}/k_BTV = 4.54$, where V is the molar volume. This proportionality between A_{ii} and the transition temperature was used by Burnell and co-workers (4) to derive a virtual transition temperature at which the solute would exhibit a nematic-to-isotropic transition. Using the present results, although there was quite good agreement between the experimental points and theoretical curves in plots of solute versus solvent order parameters, there was little agreement between the virtual transition temperatures for the three solvents 1132, EBBA, and 5CB.

Azapropellanes 5.[1] Synthesis of chiral (non-racemic) 2-methyl azapropellanes

JOHN M. MCINTOSH AND SAMUEL O. ACQUAAH[2]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received January 29, 1988

JOHN M. MCINTOSH and SAMUEL O. ACQUAAH. Can. J. Chem. **66**, 1752 (1988).

The preparation of *S*-(−)-6-methyl-2-piperidinone from *S*-alanine and *R*-(−)-5-methyl-2-pyrrolidinone from *S*-glutamic acid and their conversion into *S*-2-methyl-1-azoniatricyclo[4.4.4.$0^{1,6}$]tetradecane (**2***a*) and *R*-2-methyl-1-azoniatricyclo-[4.4.3.$0^{1,6}$]tridecane (**2***b*) with enantiomeric excesses of 95 and 92% respectively are described. The use of these compounds as phase-transfer catalysts did not lead to significant asymmetric induction.

JOHN M. MCINTOSH et SAMUEL O. ACQUAAH. Can. J. Chem. **66**, 1752 (1988).

On décrit la préparation de la *S*-(−)-méthyl-6 pipéridone-2 à partir de la *S*-alanine et de la *R*-(+)-méthyl-5 pyrrolidinone-2 à partir de l'acide *S*-glutamique ainsi que leur conversion en *S*-méthyl-2 azonia-1 tricyclo[4.4.4.$0^{1,6}$]tétradécane (**2***a*) et *R*-méthyl-2 azonia-1 tricyclo[4.4.3.$0^{1,6}$]tridécane (**2***b*) avec des excès d'énantiomères qui sont respectivement de 95 et 92%. Lorsqu'on a utilisé ces composés comme catalyseurs de transfert de phase, on n'a pas obtenu de quantités importantes d'induction asymétrique.

[Traduit par la revue]

The use of chiral catalysts in phase-transfer reactions for the preparation of enantiomerically enriched products has attracted continuing attention by many groups, With some very notable exceptions (1, 2), the results obtained have been disappointing. In most cases, the catalysts utilized have been derived by quaternization of readily available chiral amines. In general, catalysts derived by quaternization of amines such as norephedrine, in which the chirality resides exclusively in the carbon skeleton, have proven to be ineffective in inducing asymmetry whereas the use of quaternary derivatives of tertiary amines such as quinine, cinchonidine, etc. (2) has been much more successful. Some time ago we noted (3) that the latter type of catalyst possesses a chiral nitrogen atom in addition to asymmetry in the carbon skeleton, and we postulated a set of criteria for the structure of chiral phase-transfer catalysts that led to the selection of compounds of type **1** (azapropellanes) (Fig. 1) as possible candidates for investigation. The reasons for the choice of this type of molecule have been given elsewhere (3).

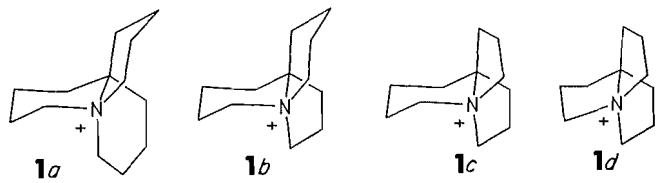

FIG. 1

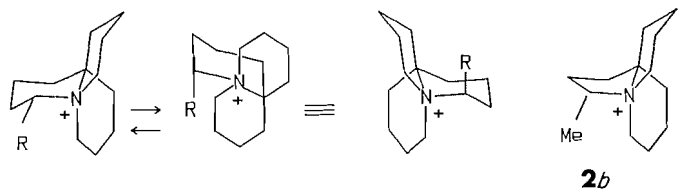

1*a* (R=H) **2***a* (R=Me)

FIG. 2

The use of synthetic materials as catalysts has the advantage that one can choose specific structures designed to demonstrate the result of structural changes and thus allow the correlation of structure with the extent of asymmetric induction. The disadvantage lies in the inability to use the chiral molecules provided by nature. Thus the synthesis of **1***a–d* was carried out and nmr experiments allowed the unambiguous conclusion that, while **1***a* is a chiral (C_3) molecule, the rapid rate of the chair–chair interconversion of all three rings, a process which converts **1***a* into its enantiomer (Fig. 2 R = H), does not give rise to an optically stable catalyst (4). This conclusion was independently reached by Alder and Arrowsmith (5). The rate of inversion of **1***b* and **1***c* is even faster, while the geometry of **1***d* does not render it chiral.

If one considers the geometry of **1***a* as it should influence the transition state of a phase-transfer reaction, the following points emerge. The anion X^- of the quaternary salt must, by virtue of the structure of **1***a*, be associated with *only one face* of the tetrahedral nitrogen atom. The choice of **1***a* was made to ensure this fact. This face of the nitrogen atom is surrounded by the three α-equatorial protons. The discrimination between the relative topicity relies on the very small hydrogen atoms. If one of these atoms is replaced by a larger group, two effects should be evident. First, the steric discrimination on the chiral face should be larger, and, more importantly, the rate of ring inversion should be dramatically reduced and the bias to the conformational equilibrium between the two (now diastereomeric) forms should be large, since one conformation must have an axial substituent that, models suggest, would be impossibly hindered (Fig. 2. R ≠ H).

In support of these ideas, the synthesis of **2***a* in racemic form was carried out (6) and nmr experiments indicated that the presence of the α-methyl group had indeed rendered **2***a* both conformationally stable and apparently existing in only one conformational form. The single substituent had frozen the conformation of not only the substituted ring, but the other two rings as well. Unfortunately, all attempts at resolving **2***a* into its optical antipodes failed. For this reason, the absolute asymmetric synthesis of **2***a* was attempted. This synthesis and the synthesis of **2***b* in a chiral form are the subject of this report.

Results and discussion

The syntheses of **2***a* and **2***b* were planned around one central point. It has been shown that pyrolysis of *N*-ω-carboxyalkyllactams with soda lime affords bicyclic iminium

SCHEME 2

salts in which the stereochemistry of the α-carbon is not disturbed (7). Since these iminium salts were the central intermediates in our synthesis of **1**, the preparation of **2***a* and **2***b* simplified to the preparation of lactams **3***a* (Scheme 1) and **3***b* (Scheme 2) in enantiomerically pure form. Lactam **3***b* is a known compound (8*a*), but its reported synthesis was not amenable to preparation on the scale we required and the absolute configuration of the (+) isomer has been the subject of conflicting reports (8). To establish the configuration unambiguously and provide amounts suitable for further synthetic operations, lactam **3***b* was prepared by reduction of the known (14) bromomethyl lactam **10** derived from *S*-glutamic acid. The sign of rotation of **4** was identical to that originally reported for the *S* isomer by Cervinka *et al.* (8*a*) and the *R*-isomer by Cervinka and others (8*b*, *c*). This synthesis confirms that the (+) isomer must have the *R* configuration. Using the highest rotation reported for **3***b*, the calculated enantiomeric excess for our preparation is 95%.

The synthesis of **3***a* (8*a*) was not as straightforward since chiral α-aminoadipic acid is not easily available (9). Attempts at homologating **3***b* or asymmetrically reducing the imine derived from (+) α-methylbenzyl amine and 5-oxohexanoic acid failed. The successful synthesis of **3***a* from *S*-alanine is outlined in Scheme 1. The overall yield was approximately 40% and the enantiomeric excess calculated on the basis of the highest previously reported rotation for **3***a* (8*a*) was 92%.

Alkylation of **3***a* or **3***b* with ethyl 5-bromopentanoate using potassium hydride (10) afforded **5***a* or **5***b*, which on pyrolysis over soda lime in the published manner (11) and treatment of the distillate with 70% perchloric acid gave **6***a* or **6***b*. Completion of the synthesis of **2***a* and **2***b* was achieved using the methodology applied to the synthesis of **1***a* (Scheme 3) (3*a*). The iminium perchlorate was alkylated using 4-phenoxybutylmagnesium bromide (3*a*) and the product was cleaved to the bromoamine hydrobromide with concentrated hydrobromic acid. Cyclization to the azapropellane was achieved by treating this material with an excess of silver oxide.

The yields of the Grignard products **8** were quite low and they appeared to be a mixture of stereoisomers based upon nmr data. However, the synthetic route was planned in such a way that the distinction between the stereoisomers is lost in the final cyclization. The physical and spectroscopic data for **2***a* are identical to those previously reported for the racemic material (6).

The molecular weight (FI ms), elemental analysis, and nmr data for **2***b* are fully consistent with the assigned structure. DEPT editing of the ^{13}C nmr spectrum confirms the presence of one CH_3, one CH, and one quaternary carbon. The normal ^{13}C nmr spectrum shows only nine resonances whose chemical shifts are consistent with those expected from a comparison with **1***b* (4). Either average values for the carbons in the two six-membered rings are being observed, or the difference between them is insufficient to be resolved at 75 MHz.

The conversion of lactams **3***a* and **3***b* to **2***a* and **2***b* respectively is expected to proceed without loss of optical integrity based on literature precedents (7). In an attempt to demonstrate this fact, the nmr of salt **2***b* was run in the presence of *S* (+)camphor-10-sulfonic acid. Although the methyl region was severely complicated by the presence of the signals due to the camphor moiety, no signals could be seen that could be attributed to a second diastereomer of **2***b*. The use of other chiral anions (e.g., mandelate) also failed to demonstrate the presence of a second diastereomer. Therefore, the best estimates of the optical purity of **2***a* and **2***b* are based on the known purity of lactams **3***a* and **3***b*

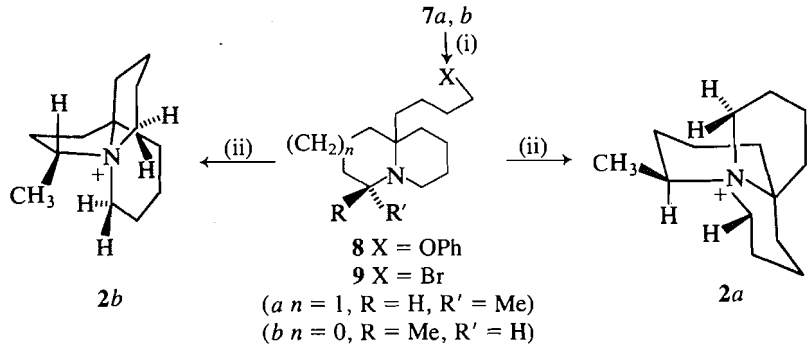

SCHEME 3

and are 92 and 95% respectively. Salts **1***a* and **1***b* have previously been shown to be effective phase-transfer catalysts (3*a*). To determine the effect of the asymmetry in the catalysts on phase-transfer reactions, two test reactions were performed. In both cyclopropanation of 2-chloroacrylonitrile (12) with diethylbromomalonate and allylation of 2-carbethoxycyclohexanone (13), excellent chemical yields of adducts were obtained. However, in each case, as measured by 300-MHz nmr in the presence of the chiral lanthanide shift reagent $Eu(hfc)_3$, the maximum amount of asymmetric induction that could be measured was <2%. In the case of the alkylation product, the reported optical rotation of the material with 6% e.e. was −8.2° and the induction in our reaction calculated on this basis is of similar magnitude.

The instances of high stereoselectivity in phase-transfer reactions reported to date have demonstrated the apparent desirability of a second, polar group critically situated to allow a coordinating group in the catalytic site. The high enantiomeric excesses obtained in the epoxidations using cinchona alkaloid-derived catalysts is lost upon acetylation (2*c*, *d*) and Colonna and co-workers have demonstrated the requirement for a β-hydroxy group in the catalyst for an asymmetric Darzen's condensation (1*c*). In addition, Dolling *et al.* (1*b*) have demonstrated the effect on asymmetric induction of changing a benzyl group to the more coordinatively unsaturated *p*-CF_3benzyl group. If molecules of the azapropellane type are to exhibit more stereoselective results, they should be modified to place such a coordinating group on the face of the nitrogen atom. However, we have no plans to pursue this avenue any further.

Experimental

All melting points and boiling points are uncorrected. Infrared spectra were run on a Perkin–Elmer model 180 instrument in chloroform solution or in the FT mode on a Nicolet 5 DX spectrometer as neat samples. The ^{1}H nmr spectra were run at 60 MHz on a Varian EM 360 spectrometer in chloroform-*d* with tetramethylsilane (TMS) as the internal standard. The data are presented in the format: chemical shift (multiplicity, number of protons, coupling constant). The ^{13}C nmr spectra were recorded at 22.64 MHz on a Bruker CXP 100 spectrometer. Gas chromatographic analyses were performed on a Varian model 3700 instrument using a 1.5 ft × 1/8 in. column packed with 5% OV-101 on Chromosorb W or a column packed with 20% SE30 on Chromosorb W. Mass spectra were run on a Varian MAT CH5 instrument in the field ionization (FI), field desorption (FD), or electron impact (EI) mode. Optical rotations were measured on a Perkin–Elmer model 241 polarimeter. Concentrations in g/100 mL of solvent are included following the measured optical rotations.

Microanalyses were done by Guelph Chemical Laboratories, Guelph, Ontario, and Galbraith Laboratories, Knoxville, Tennessee. For column chromatography, silica gel (Merck silica gel 60) 70–230 mesh was used. Reagent grade chemicals were used without further purification unless otherwise specified. Tetrahydrofuran or dimethoxyethane were dried with potassium and benzophenone and distilled under nitrogen. Diisopropyl amine was stored over potassium hydroxide. Methylene chloride, chloroform, and carbon tetrachloride were distilled from calcium hydride. Dimethyl formamide was distilled over barium oxide and stored over molecular sieves. For reactions that involved aqueous work-up, the drying agent was magnesium sulfate.

S-(+)-*6-Methyl-2-piperidinone* (*3*a)

L-Alanine was protected as the N-^{t}BOC derivative and converted via the mixed anhydride with ethyl chloroformate to the diazoketone by treatment with diazomethane (14*a*, *b*). The diazoketone (16 g, 0.08 mol) was dissolved in dry methanol (120 mL) and treated with a few drops of a solution of silver benzoate (1 g) in triethyl amine (11.6 mL). A vigorous reaction occurred with the evolution of nitrogen. When the reaction had subsided, the mixture was treated with charcoal, boiled for a few minutes, and then filtered. The solvent was removed and ether (150 mL) was added and the mixture was washed with dilute HCl, saturated $NaHCO_3$, and then brine. The solution was dried, the ether evaporated, and the residue chromatographed over silica gel using petroleum ether – ether (3:1) and crystallized in pentane to give the N-^{t}BOC derivative of (*S*)-3-aminobutanoic acid methyl ester in 75% yield, mp 42°C; $[\alpha]_D^{25}$ −24.4° (*c* 0.54, chloroform) (lit. (14*c*) mp 42°C; $[\alpha]_D^{25}$ −20.0° (*c* 0.54 chloroform)).

The ester (10 g, 0.046 mol) in ether (100 mL) was cooled to −78°C and reduced with DIBAL (90 mL of 1.5 M solution in toluene). The reaction was quenched at the same temperature by adding 6.5 mL of methanol. The solution was poured into a saturated solution of sodium potassium tartrate (Rochelle salt) (65 mL) and water (400 mL) at 0°C. After stirring for 1 h at this temperature, the mixture was filtered, the filtrate extracted with ether (2 × 100 mL), and the residue also extracted with ether (4 × 75 mL). The combined filtrates were dried and evaporated to give the aldehyde, which was used directly as follows. The residue in THF solution (50 mL) was added under nitrogen to a −78°C solution of the Wittig reagent prepared from *n*-BuLi (28.6 mL of 2.5 M solution in hexane) and triethyl phosphonoacetate (13.6 g, 0.06 mol) in THF (250 mL). After stirring for 2 h at −78°C, the reaction was quenched with water, extracted with ethyl acetate (3 × 100 mL), and dried. The solvents were removed and the residue chromatographed on silica gel using petroleum ether – ethyl acetate (9:1) as eluant to give the homologated olefinic ester, which was immediately dissolved in ethanol and reduced to **3***b* with hydrogen in the presence of 10% palladium on carbon. Filtration and evaporation of the solvent was followed by treatment of the residue with 1:1 trifluoroacetic acid in methylene chloride at 0°C for 30 min to remove the ^{t}BOC protecting group. Triethyl amine (1.1 equiv.) in methylene chloride was added and, after removal of the solvent, the residue was heated at 180°C for 1 h. Distillation at approximately 1 Torr pressure (1 Torr = 133.3 Pa) gave the lactam **3***a*, which immediately solidified; mp 80–81°C; $[\alpha]_D^{25}$ +25.6° (*c* 2.04, water) (lit. (8*a*) $[\alpha]_D^{25}$ +27.8° (*c* 2.03, water)); ^{1}H nmr: 7.30–6.80 (bs, 1H), 3.67–3.05 (m, 1H), 2.40–2.05 (m, 2H), 2.00–1.25 (m, 4H), 1.20–1.15 (d, 3H, J = 8 Hz).

(R)-*(+)-5-Methyl-2-pyrrolidinone* **3**b)

(*S*)-5-Bromomethyl-2-pyrrolidinone (**10**) (15) (8.8 g, 0.05 mol) in ethanol (150 mL) and triethylamine (5.06 g, 0.05 mol) was reduced with hydrogen in the presence of a catalytic amount of 10% palladium on carbon for 36 h at 1 atmosphere pressure (1 atm = 101.3 kPa) and ambient temperature. The mixture was filtered through Celite and the solvent evaporated. The residue was extracted with ether (3 × 100 mL), the ether evaporated, and the residue was distilled under reduced pressure to give 4.1 g (85%) of **3***b* as a colorless oil, bp 90°C (1.8 Torr); $[\alpha]_D^{25}$ +24.8 (*c* 0.9, water) (lit. (8*a*) $[\alpha]_D^{25}$ +26.6 (*c* 0.9, water)); ir: 3240, 2967, 2931, 1690, 1423, 1378, 1277 cm^{-1}; ^1H nmr: 1.17 (d, 3H, J = 7 Hz), 1.67 (m, 1H), 2.27 (m, 3H), 3.76 (m, 1H), 7.76 (bs, 1H); ^{13}C nmr: 178.4, 50.1, 30.6, 29.0, 22.0; ms (FI), m/z: 99.

(S)-N-*(4-Carbethoxybutyl)-6-methyl-2-piperidinone (5*a)

Potassium hydride (20 g of 35% by weight in mineral oil (0.16 mol)) was washed three times with pentane and dried under nitrogen. Dry 1,2-dimethoxyethane (DME) (100 mL) was added, followed by the dropwise addition of **3***a* (17 g, 0.15 mol) in 50 mL of DME. The mixture was stirred at room temperature for about 3 h. Ethyl 5-bromovalerate (17 g, 0.15 mol) in 50 mL of DME was added slowly and the mixture was stirred at room temperature for 8 h. The reaction was quenched with ethanol followed by a small amount of water and then filtered. The filtrate was concentrated and methylene chloride (100 mL) and water (50 mL) were added. The aqueous layer was separated and the organic layer washed with brine and dried. Removal of the solvent and distillation gave **5***a* as a colorless oil; ir: 3048, 2943, 2872, 1733, 1634, 1472, 1375, 1248, 1182 cm^{-1}; ^1H nmr: 1.20 (d, 3H, J = 7 Hz), 1.23 (t, 3H, J = 7 Hz), 1.43–2.10 (m, 8H), 2.10–2.53 (m, 4H), 2.67–3.17 (m, 1H), 3.27–3.57 (m, 2H), 4.13 (q, 2H, J = 7 Hz); ^{13}C nmr: 178.2, 169.5, 59.9, 51.8, 44.3, 33.7, 30.1, 27.0, 22.2, 19.8, 17.3, 14.0.

(R)-N-*(4-Carbethoxybutyl)-5-methyl-2-pyrrolidinone (5*b)

This compound was prepared in the same manner as described for **5***a* using (*R*)-5-methyl-2-pyrrolidinone (**3***b*). A colorless oil was obtained in 70% yield, bp 140–142°C (1 Torr); $[\alpha]_D^{25}$ +6.5° (*c* 2.0, ethanol); ir: 2967, 2934, 2870, 1733, 1687, 1417, 1375, 1251, 1184, 1156, 1098 cm^{-1}; ^1H nmr: 1.20 (d, 3H J = 7 Hz), 1.26 (t, 3H, J = 7 Hz), 1.56 (m, 5H), 2.23 (m, 5H), 2.93 (m, 1H), 3.60 (m, 2H), 4.13 (q, 2H, J = 7 Hz). *Anal.* calcd. for $C_{12}H_{21}NO_3$: C 63.39, H 9.31, N 6.16; found: C 63.65, H 9.68, N 6.35.

(S)-*4-Methyl-*$\Delta^{4,10}$*-dehydroquinolizidinium perchlorate (6*a)

Ester **5***a* (5 g, 0.02 mol) was mixed thoroughly with 10 g of soda lime and transferred to a flask that was fitted with a short-path distillation head. The system was purged with nitrogen and heated with a free flame until all the volatile material had distilled (head temperature ca. 180°C). The two-phase distillate was diluted with ether, the phases separated, and the aqueous phase extracted with ether. The combined ethereal phases were dried and evaporated to give the crude enamine, which was treated with sufficient 1:1 70% perchloric acid in ethanol to just render the solution acidic. The dried precipitated crystalline product (2.35 g, 45%) had mp 249–250°C (dec.). The racemic form has previously been reported (16). *Anal.* calcd. for $C_{10}H_{18}ClNO_4$: C 47.70, H 7.21, N 5.56; found: C 48.02, H 6.98, N 5.39.

*(3*R*)-3-Methyl-*$\Delta^{4,9}$*-dehydroindolizidinium perchlorate (6*b)

Using the procedure described for **6***a*, the enamine derived from **5***b* was obtained as a colorless oil in 65% yield. The perchlorate was obtained by treatment of a freshly prepared sample of the enamine in ethanol (20 mL) at 0°C with cold 70% perchloric acid. The precipitated salt was filtered and recrystallized from ethanol to give **6***b* in 45% overall yield from the lactam ester **5***b*, mp 215–218°C; ir: 1700 cm^{-1}; ^1H nmr: 1.46 (d, 3H, J = 7 Hz), 1.50–1.99 (m, 2H), 2.46–2.49 (m, 2H), 2.51–2.84 (m, 2H), 2.85–3.14 (m, 2H), 3.60 (m, 2H), 4.50 (m, 2H); ^{13}C nmr: 190.4, 68.9, 45.7, 37.4, 27.8, 26.5, 20.0, 17.8, 16.3. *Anal.* calcd. for $C_9H_{16}ClNO_4$: C 45.47, H 6.78, N 5.89; found: C 45.62, H 6.62, N 6.27.

*(4*S*,9a*R*) and (4*S*,9a*S*)-9a-(4-phenoxybutyl)-4-methylquinolizidine (8*a)

This was prepared from **6***a* as follows. The perchlorate was converted to the nitrile (**7***a*) in 70% yield using saturated sodium cyanide solution according to Leonard's procedure (17); ir (neat): 2360 cm^{-1}; ^1H nmr: 1.05 (d, 3H, J = 7 Hz), 1.0–1.80 (m, 12H), 2.15 (t, 1H), 2.35 (m, 1H), 3.12 (bd, 1H). The nitrile gave **8***a* in 40% yield upon refluxing with a THF solution of the Grignard reagent derived from 4-phenoxybutyl bromide (3*a*), followed by chromatography of the crude material on silica gel with ether as the eluant; ^1H nmr: 7.50–6.75 (m, 5H), 3.50 (t, 2H, J = 6 Hz), 2.75–2.05 (m, 4H), 2.10–1.00 (m, 20H).

This material was not purified further but carried on directly to the cyclization reaction.

*(3*R*,9*S*)/(3*R*,9*R*)-(4-Phenoxybutyl)-3-methylindolizidine (8*b)

In the same manner as described for **8***a*, nitrile **7***b* was prepared from perchlorate **6***b* in 78% yield, bp 80–84°C (4.5 Torr); $[\alpha]_D^{25}$ −62.3 (*c* 1.06, chloroform); ir: 2200 cm^{-1}; ^1H nmr: 1.12 (d, 3H, J = 6.1 Hz), 1.2–1.8 (m, 8H), 1.95–2.20 (m, 4H), 2.62 (m, 1H), 3.15 (bd, 1H, J = 10.5 Hz); ^{13}C nmr: 99.7, 98.0, 57.0, 45.7, 35.3, 34.6, 34.5, 28.9, 24.6, 21.4.

The Grignard product **8***b* was obtained from **7***b* in 45% yield, $[\alpha]_D^{25}$ −39.5° (*c* 1.5, chloroform); ir: 3010, 2930, 1600, 1585, 1490, 1465, 1450, 1290 cm^{-1}; ^1H nmr: 1.00–2.00 (m, 18H), 2.74–2.77 (m, 4H), 3.48 (t, 2H, J = 6 Hz), 6.71–7.42 (m, 5H); ^{13}C nmr: 160.3, 129.5, 120.7, 114.8, 67.9, 49.2, 35.5, 26.0, 20.5, 20.2. *Anal.* calcd. for $C_{19}H_{29}NO$: C 79.39, H 10.16, N 4.88; found: C 80.12, H 11.09, N 5.03.

2-Methyl-1-azoniatricyclo[4.4.4.$0^{1,6}$*]tetradecane iodide (2*a)

Using the procedure described below for the preparation of **2***b*, iodide **2***a* (X = I^-) was obtained in 20% yield from **8***a*: mp >300°C, $[\alpha]_D^{25}$ −14.9° (*c* 0.5, methanol). Spectroscopic data for the hydroxide salt were identical to the previously prepared racemic material (6) and the fdms gave a single peak at m/z = 208.

(R)-*2-Methyl-1-azoniatricyclo[4.4.3.*$0^{1,6}$*]tridecane bromide (2*b)

This was prepared by the procedure described in the literature (3*a*, 6). The ether **8***b* (0.25 g) was converted to the bromide **9***b* using concentrated hydrobromic acid, and the crude material, without any purification, was cyclized using silver oxide in water to give the hydroxide salt, which was neutralized with hydrobromic acid to give pure product (0.085 g) after recrystallization from methanol; mp >300°C; $[\alpha]_D^{25}$ −22.5° (*c* 1.0, methanol). Spectroscopic data were acquired on the trifluoroacetate salt. Although acceptable carbon analysis could not be obtained, the field desorption mass spectrum gave a single peak at the expected m/z = 194, the ^{13}C nmr showed the correct number of absorptions, and the ^1H nmr was entirely consistent with the assigned structure; ^1H nmr (D_2O): 1.35 (d, 3H, J = 6.5 Hz), 1.5–2.1 (m, 13H), 2.3–2.6 (m, 3H), 3.07 (m, 2H), 3.22 (ddd, 1H, J = 13.0, 13.0, 3.7 Hz), 3.78 (ddd, 1H, J = 13.4, 13.4, 3.5 Hz), 4.57 (m, 1H); ^{13}C nmr (D_2O): 73.5, 63.3, 52.5, 29.9, 26.8, 25.0, 19.1, 17.4, 12.1. *Anal.* calcd. for $C_{13}H_{24}NBr$: C 56.93, H 8.82, N 5.11; found: C 55.70, H 9.02, N 4.93.

General procedure for the phase-transfer cyclopropanation reactions (ref. 12)

To a mixture of toluene (20 mL) and 1 mL of 9.5 M aqueous sodium hydroxide was added the catalyst **2***a* or **2***b* (20 mg). The system was purged with nitrogen and cooled to 0°C in an ice bath. To this solution was added 0.01 mol of the α,β-unsaturated carbonyl compound (2-chloroacrylonitrile, acrolein, or methyl vinyl ketone) at 0°C with good stirring. The addition required 10 min and stirring was continued for 1 h at 0°C and a further 2 h at ambient temperature. The solution was diluted with water (20 mL), the layers separated, and the organic phase dried. The mixture was filtered, the solvent evaporated, and the catalyst removed by the addition of anhydrous ether and filtration of the turbid solution. The ether was evaporated and the residue chromatographed on silica gel with ether–hexane as eluant. The products were obtained in 60–75% yields and had spectra identical to those of authentic

material (12), and the specific rotations in various runs varied between 0.7 and 1.6°.

General procedure for phase-transfer alkylation reactions

A solution of ethyl 2-oxocyclohexanecarboxylate (0.005 mol) in toluene (20 mL), which contained 0.005 mol of the alkylating agent and the catalyst **2***a* or **2***b* (15 mg), was stirred vigorously in the presence of 4.5 mL of aqueous 2.5 M sodium hydroxide solution at room temperature overnight. The organic phase was separated and washed with water, and then with brine. The dried solution was filtered, evaporated, and the residue chromatographed over silica gel using ether–hexane as eluant. The products were obtained in 60–80% yields, showed specific rotations varying between 0.8 and 1.3°, and had spectra identical to those of authentic material (13).

J. A. CARAM, M. E. MARTINS, E. G. GROS, and C. M. MARSCHOFF. Can. J. Chem. **66**, 1757 (1988).

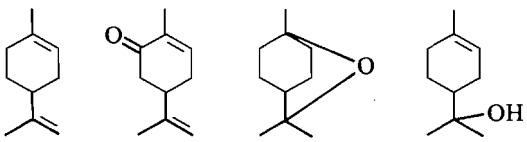
The anodic behaviour of limonene on Pt electrodes was studied in LiCl solutions in acetonitrile with low water content. It was found that *cis*-6-acetamido-*p*-menth-1,8-diene is formed with acceptable yields. This compound is of interest as a potential intermediate for obtaining oxidation derivatives of limonene. Other products, among them the new compound 8-acetamido-2,4,8-trimethyl-4-chloromethyl-3-*aza*-bicyclo[3.3.1]non-2-ene, were identified. Reaction routes are proposed.

J. A. CARAM, M. E. MARTINS, E. G. GROS et C. M. MARSCHOFF. Can. J. Chem. **66**, 1757 (1988).

Le comportement anodique du limonène est étudié dans solutions de LiCl en acétonitrile avec minces quantités d'eau en employant électrodes de Pt. Le produit principal est le *cis*-6-acétamide-*p*-menth-1,8-diène, qui s'obtient spécifiquement. Ce dérivé peut etre utilisé pour la préparation de produits d'oxidation du limonène. D'autres produits, parmi lesquels le nouveau composé 8-acétamide-2,4,8-triméthyl-4-chlorométhyl-3-*aza*-bicycle[3.3.1]non-2-ène, ont été identifiés et les chemins de reaction qui abutissent a sa formation sont proposés.

Introduction

Some of the most valuable essential oils of monoterpenoid structure are those which have at least one oxygen-containing group in the otherwise unmodified hydrocarbon molecule. Examples of this are fairly abundant and, for reagent grade compounds, it can be mentioned that limonene (**1**) is priced at 0.61 dollars (U.S.) per g, while carvone (**2**), cineol (**3**), and *p*-menth-1-en-8-ol (**4**) costs are, respectively, 1.39, 1.04, and



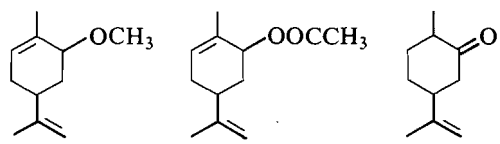
1 **2** **3** **4**

6.40 dollars per g (1). Consequently, significant efforts have been devoted to find synthetic paths for preparing derivatives of this type from the naturally abundant hydrocarbons on a cost-effective basis.

It is noteworthy that, in spite of a theoretically favourable scenario (high specificity needs for the oxidation reaction and relatively low production volume requirements), electrochemical processes have not been frequently considered as candidates to intervene in these syntheses. In fact, there are only a few published papers dealing with the electrochemical behaviour of terpenes and related molecules, and almost all of them correspond to different attempts at directly obtaining oxidation products.

Early work has shown (2–4) that anodic oxidation of monoterpenes in aqueous solutions is not very promising as a preparative technique because of the tendency of monoterpenes to polymerize on the electrode surface, a feature which comes from the fact that two independent double bonds are present in the hydrocarbon molecule. As a consequence of this limitation, some studies have been carried out on terpene oxidation in non-aqueous media, since it is expected that competition for electrode sites by the organic solvent might reduce the tendency to polymerization.

Thus, Shono and co-workers (5, 6) have studied the anodic behaviour of limonene and the pinenes in methanol and acetic acid, employing carbon electrodes, and Montiel *et al* (7) have recently worked on the oxidation of limonene in tetrahydrofurane–water mixtures. In the first case, methyl ethers (**5**) and acetates (**6**) were obtained with yields of *ca.* 30%, while the latter workers were able to produce dihydrocarvone (**7**) as well



5 **6** **7**

as other ring oxidation products in unknown yields, but always at the expense of losing one of the double bonds.

In our laboratory, limonene oxidation on Pt electrodes in acetonitrile (AN) solutions has been studied (8) and, although potentiodynamic measurements led to the conclusion that anodic oxidation of the organic molecule takes place after homogeneous hydration of the double bonds, the existence of other, simultaneous, chemical reactions made the mixtures

resulting from potentiostatic experiments too complex to be adequately resolved. Further work on the chemistry of limonene in AN acid solutions (9) showed that a completely non-electrochemical reaction also takes place, yielding a new type of iminium salt, 8-acetamido-2,4,4,8-tetramethyl-3-azaniumbicyclo[3.3.1]non-2-ene perchlorate (ATABNEP), which displays quite an unusual chemical behaviour for compounds of this kind (10). In this case, ATABNEP is very stable and does not undergo hydrolysis in acid media.

Taking into account the above-mentioned difficulties encountered in direct anodic oxidation efforts, it was thought worthwhile to explore the possibilities of electrochemically preparing molecules with other functional groups in the hydrocarbon ring which might serve as intermediates for obtaining the desired compounds. With this goal in mind, we decided to investigate the anodic behaviour of limonene in acetonitrile solutions containing Cl^- ions.

Experimental

AN (Carlo Erba p.a.) was purified as previously described (8) and *d*-limonene (Fluka, purum) was distilled under reduced pressure yielding a 98% purity compound. LiCl (Riedel de Haen p.a.) and $LiClO_4$ (Fluka, p.a.) were dried under vacuum at 100°C prior to use. Water content of the solvent was always below 0.05%.

Two types of electrochemical cell were employed depending on the kind of experiment performed. Thus, potentiodynamic measurements were carried out in a one-compartment cell, while preparative electrolyses at controlled potential conditions were done in a three-body cell of the type used before (8). In the latter case, the working electrode compartment included an auxiliary Pt wire electrode which was employed for obtaining voltammograms of the working solution at different times during electrolysis. The working electrode was, in all cases, a Pt wire (Johnson Mattey, Specpur) and the counterelectrode as well as the auxiliary electrode were made of platinized Pt. The reference electrode was Ag/Ag^+ 0.01 *M* in AN, with respect to which all potential data are referred. Purified nitrogen was bubbled into the cell prior to each experiment.

After every preparative electrolysis, the central compartment was drained and the solution transferred to an adequate vessel, where the solvent was evaporated at 25°C under vacuum. The resulting mixture was extracted with chloroform and the remaining solution dissolved in water. The organic phase was then washed with water and dried with anhydrous Na_2SO_4 and concentrated in 3–5 mL. The aqueous phase was treated with NaOH (0.5 *M*) and the resulting mixture extracted with chloroform.

Product analysis was performed by gas chromatography (GC) with a Hewlett-Packard 5830A gas chromatograph equipped with a FID detector and Hewlett-Packard 18850A terminal using glass columns (1.80 m × 2 mm i.d.) packed with 3% OV-225 on Chromosorb W-AW-DMCS. Gas chromatography – mass spectrometry (GC–MS) analyses were conducted with a Varian 1440 gas chromatograph coupled to a Varian-MAT CH7-A mass spectrometer interfaced to a Varian-MAT Data System 166 computer. Separation of compound **10** for ^{1}H-NMR analysis was achieved by high performance liquid chromatography (HPCL) employing reverse phase operation with a 10 micron silica-gel column (Altech C-18; 250 × 10 mm) and methanol–water (90:10) as developing solvent. Flow rate was 6 mL/min.

Results

Current–potential plots obtained with repetitive triangular potential sweeps for blank solutions and for one of the reaction media are shown in Fig. 1. It is seen from these data that the response of the AN–$LiClO_4$ and AN–$LiClO_4$–limonene systems are in good agreement with previous data (8, 11–14).

Preparative electrolysis was carried out with 0.02 *M* LiCl, 0.02 *M* limonene solutions in AN (0.1 *M* $LiClO_4$) at the

observed potential peaks, i.e., 0.95 and 1.10 V. The current–potential plots resulting under repetitive triangular potential sweeps at different times are shown in Fig. 2 for one of the experiments at 1.10 V. Very similar responses were obtained when the electrolysis potential was fixed at 0.95 V.

The chromatograms obtained are summarized in Tables 1–3.

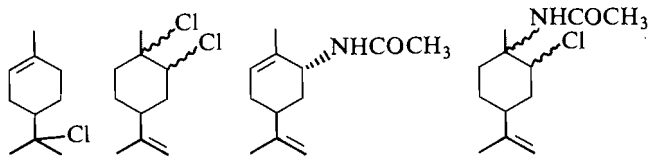
It must be mentioned that the chromatogram for the alkali extract of the electrolysis at 0.95 V is essentially the same than that shown in Table 3. Taking into account the results of mass spectroscopy experiments and, in some cases, ^{1}H-NMR spectra, chromatographic peaks were assigned as shown in Table 4.

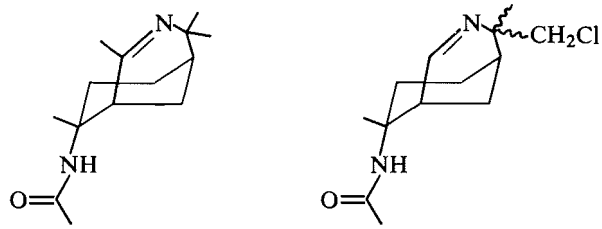
Stereospecificity in the formation of **10** is confirmed by



8 **9** **10** **11**

analysis of the ^{1}H-NMR spectrum, which is in good agreement with published data for the *cis*-form (15). The formation of this isomer is an interesting result, since chemical production of compound **10** leads, according to the reagent employed, either to specific production of the *trans* form or to a mixture of both isomers (15).

It must also be mentioned that compound **13** has not been



12 **13**

previously reported and, as far as we are aware, this is the first time it has been prepared.

An estimation of the different product yields was carried out by chromatographic analysis, using benzyl chloride as internal standard for the chloroformic extract and compound **12**, chemically prepared (10), for the alkaline extract. Faradic yields thus obtained are shown in Tables 5 and 6.

Also, repetitive triangular potential sweep experiment were performed at different reactant concentrations and varying sweep rates. Thus, Fig. 3 shows the voltammograms obtained when limonene concentration (C_L) is varied from 0 to 0.02 *M* at LiCl concentration (C_{Cl^-}) of 0.02 *M*. Figure 4 gives the resulting curves when C_{Cl^-} is varied at $C_L = 0.01$ *M*. Finally, experiments performed at different scan rates are shown in Fig. 5.

Discussion

When the above results are considered, the main product to be stressed is the quite high yield of compound **10**, which is just the limonene molecule with both double bonds preserved and an acetamido group in position 6. This product seems promising for further chemical attack to yield carvone or other oxidation derivatives of limonene, and work in this direction is being presently pursued.

From another point of view, it is of some interest to analyze the possible reaction paths and other characteristics of the processes taking place in the system under study. In this connection, the first consideration to be made regards the voltammograms in Fig. 1. It seems clear from these voltammograms that, in agreement with published data (11) and taking into account the results in Figs. 3 and 4, the peak at *ca.* 0.95 V can be assigned to the oxidation of Cl^-, with the reduction peak completely inhibited by further reaction with limonene. Also

1-Acetamido-2-chloro-*p*-menth-8-ene	4
8-Acetamido-2,4,8-trimethyl-4-chloromethyl-3-*aza*-bicyclo[3.3.1]non-2-ene	1

the large peak at 1.6 V must be assigned to limonene oxidation, with no direct bearing of the halogen on its behaviour (8, 14). The curves in Figs. 3 and 4 also show that the potential of the first peak is almost independent of limonene concentration in the anodic scan, while the cathodic peak potential varies with C_L and is rapidly inhibited by increasing concentration of the hydrocarbon. These figures also show that the peak at 1.1–1.15 V is only seen when both species, limonene and Cl^-, are present at significant concentrations and its potential depends on both C_L and C_{Cl^-}. Finally, Fig. 5 shows that the potential value for the first peak is very sensitive to scan rate, while the potential value for the second peak is almost independent of this parameter.

These results strongly suggest that the electrochemical step involved in the second peak occurs via an intermediate which is formed by a surface reaction between an oxidized halogen atom and a limonene-derived species, a proposal that is further supported by the fact that the potential of this peak is almost independent of scan rate.

This behaviour, and the necessity of having both species at significant concentrations, are understandable in terms of the well known fact that limonene, because of its two double bonds, is strongly adsorbed on Pt and shows a definite tendency to polymerize on the electrode surface. Thus, for low Cl^- ion concentration, adsorbed limonene molecules are stabilized, and attack by an adsorbed Cl· radical is difficult, while for larger anion concentrations, competition for the adsorption sites takes place and, hence, limonene is more prone to react.

On account of all this, and taking note of the nature of the obtained products, the following reaction paths, which because of the vicinity of both peaks are to some extent operative during electrolyses at 0.95 V and at 1.10 V, are proposed, with the common initial step:

[1] $Cl^- = Cl\cdot + e^-$

(a) Reaction route for compound ***10***

As it has been mentioned, the second peak observed in the cyclic voltammograms should be assigned to an anodic process

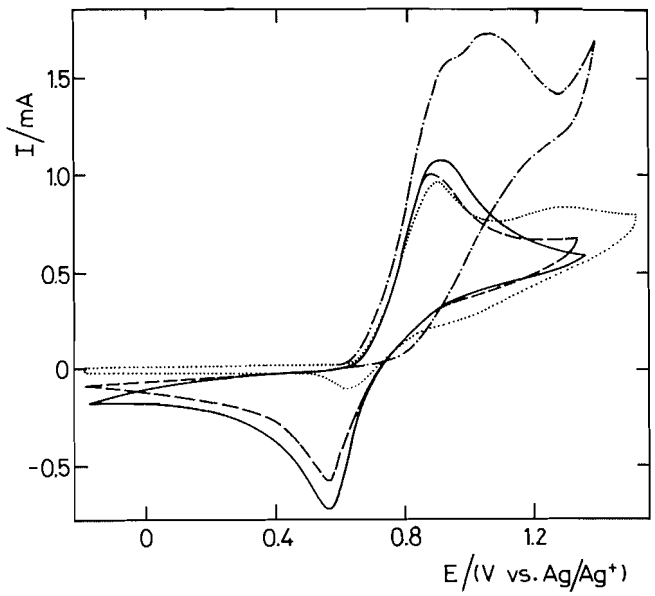

FIG. 3. Voltammetric response to varying limonene concentration. $LiClO_4$ 0.1 *M*, LiCl 0.02 *M*, limonene (—) = 0; (----) = 0.000425 *M*; (····) = 0.0018 *M*; (-.-.-.) = 0.0238 *M*. Scan rate 0.150 V/s.

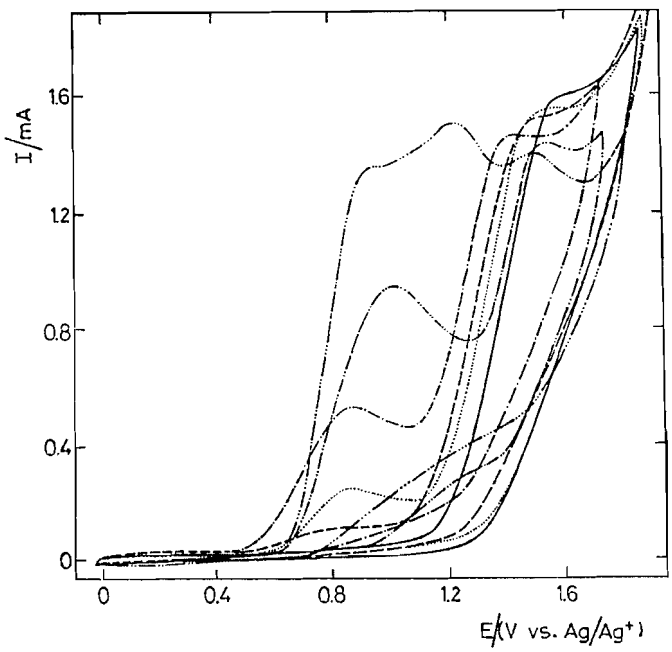

FIG. 4. Voltammetric response to varying Cl^- concentration. $LiClO_4$ 0.1 *M*, limonene 0.01 *M*, LiCl (—) = 0; (----) = 0.000395 *M*; (····) = 0.0018 *M*; (-.-.-.) = 0.0050 *M*; (-...-..) = 0.010 *M*; (-...-...) = 0.020 *M*. Scan rate 0.150 V/s.

involving a surface species formed from halogen atoms and limonene-derived species. Also, since **10** is the principal product, its formation should account for most of the charge involved in the process and for the fact that only rather small amounts of molecular chlorine are formed, thus giving a rationale to the low yields observed for products **8**, **9**, and **11**. These low yields should be compared with the rather high quantities obtained for equivalent compounds in the electrochemical chlorination of cyclohexene (16).

Thus, it is proposed that on the electrode surface an adsorbed Cl· radical produces the abstraction of an allylic proton from a

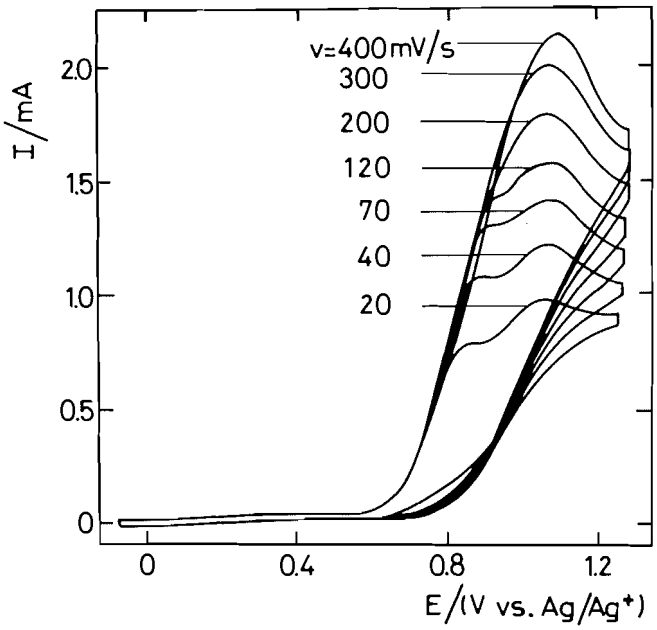

FIG. 5. Scan rate dependence of the voltammograms of the working solution.

neighbouring adsorbed limonene molecule:

[2] $Cl\cdot(ads) + (ads) = Cl^- + (ads) = Cl^- + H^+$

$+ (ads)$

followed by the electrochemical step:

[3] $(ads) = + e^-$

Finally, nucleophilic attack of the solvent gives the main product:

[4] $CH_3CN + H_2O +$ $= NHCOCH_3 + H^+$

(b) Reaction route for compounds ***9***, ***11***, *and* ***13***

It is generally admitted that electrochemical chlorination usually occurs by homogeneous reaction of molecular chlorine, generated *in situ*, with double bonds through formation of an halonium ion (16). In our case, however, the fact that the limonene molecule has two double bonds and the nature and yield of the resulting products points to a different path.

In this respect, it is to be first considered which are the steps leading from Cl^- ions in solution to molecular chlorine. Although the detailed mechanisms which operate in electrochemical generation of molecular chlorine continue to be an open field for basic research and depend on the nature of the electrode material as well as on the characteristics of the electrochemical medium, it seems safe (17) to state that the first process is the formation of adsorbed Cl· radicals, as indicated in eq. [1], followed by surface reactions involving one or two of these radicals and, perhaps, Cl^- ions or oxidized species which give adsorbed molecular chlorine:

[5] nCl·(ads) + X = Cl_2(ads) (n = 1,2)

which finally desorbs to give molecular chlorine in solution:

[6] $Cl_2(ads) = Cl_2(sol)$

However, if this sequence were completed in our case, and the halogenated derivatives formed by homogeneous reaction via halonium intermediates, products resulting from attack on both double bonds should be obtained with similar yields. This is not the case and, thus, it seems reasonable to propose that halonium ion formation takes place on the electrode surface, before molecular chlorine is desorbed:

[7] $Cl_2(ads) +$ $(ads) =$ $+ Cl^-$

or

[8] $Cl_2(ads) +$ $(ads) =$ $+ Cl^-$

Desorption of these ions is strongly favoured by the anodic potential and, hence, for the halonium ion generated on position 1 we have:

[9] $+ Cl^- =$

9

or

[10] $+ CH_3CN =$

followed by:

[11] $+ H_2O =$

11

By its hand, the halonium ion resulting from eq. [8] when reacting with the solvent follows the Ritter mechanism and yields an iminium salt (9):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

[12] 
[13] 
which is dissolved in water and, when treated with alkali gives the corresponding imine (10):

[14] 
which is extracted by chloroform.

The absence of 8,9-dichloro compounds and the lower yields observed for compound **13** when compared to products **9** and **11** indicate that the concentration of halonium ions on position 1,2 is far larger than that of those obtained on position 8,9. This fact agrees well with our proposal since, for steric reasons, limonene adsorption should preferentially occur through the exocyclic double bond.

(c) Reaction routes for compounds 8 and 12

Formation of **8** can be explained in terms of the generation of a positive center in the limonene molecule, at position 8, due to the acidification produced when compound **10** is formed:

[15] 
8

When the solvent is the nucleophile, ATABNEP is formed (9):

[16] 
which, under alkali attack in the water phase, gives the imine, **12**, which is extracted in chloroform.

Mass spectra of the identified peaks were as follows:

Peak 1 (compound **8**): m/z (%) 174(2.2), 172 (7.8), 136(44.9), 121(62.7), 95(60.1), 93(100), 81(33), 79(37), 77(26), 67(69), 68(63), 41(60).

Peak 2 (compound **9**): m/z (%) 173(0.7), 172 (4.1), 171(1.3), 170(9.6), 137(2.0), 136(8.1), 135(14.6), 134(16.4), 129(9.8), 127(30.4), 121(16.2), 119(29.1), 93(100), 91(51.5), 83(63.6), 79(30.0), 77(24.4), 68(29.0), 67(36.3), 41(80.3).

Peak 4 (compound **10**): m/z (%) 193(41.3), 178(4.2), 151(3.7), 150(9.4), 136(14.9), 134(33.1), 119(100), 110(21.5), 93(13.5), 81(22.1), 67(31.1), 43(36.3), 42(59.2), 41(53.8).

Peaks 6, 7, and 8 yield the same mass spectra which correspond to compound **11**: m/z (%) 229(1.5), 194(9.3), 193(15.9), 178(7.8), 172(4.8), 170(1.3), 150(20.4), 135(16.4), 134(44), 110(43.7), 93(49.4), 70(59.7), 60(100), 43(34.0).

Peak 9 (compound **12**) m/z (%) 236(37.0), 221(12.2), 177(35.3), 162(25.8), 150(29.1), 136(37.7), 122(82.4), 43(56.0), 42(100).

Peaks 10 and 11 yield the same mass spectra which correspond to compound **13**: m/z (%) 236(17.4), 235(100), 221(7.6), 213(4.3), 211(13.1), 176(39.4), 162(15.7), 136(42.7), 135(12.6), 134(22.5), 122(29.2), 43(39.4), 42(61.3), 41(28.0).

^{1}H-NMR spectrum of compound **10**:

Chemical shifts ($CDCl_3$, TMS): 1.65 (m, CH_3-1), 1.74 (m, CH_3-10), 1.97 (s, $COCH_3$), 4.72–4.76 (m, H-6 and CH_2-9), 5.4 (m, H-2).

ANDRÉ G. MICHEL, GUY EVRARD, BERNADETTE NORBERG, and EUGÈNE MILCHERT. Can. J. Chem. **66**, 1763 (1988).

The two title compounds belong to the family homobenzomorphans. Their analgesic properties are comparable to morphine but without inducing physical dependence. This work presents the results of X-ray diffraction and NMR studies to elucidate the conformational properties particular to this class of compounds. More specifically, the spatial orientation of the nitrogen lone-pair are compared to those observed for other related molecules. The two molecules adopt the same L-shaped structure and the 16β-methyl substituent present in the second molecule does not modify this structure. Although very different in both structures, the intermolecular interactions do not alter the molecular conformation. The nitrogen lone pair is oriented away from the benzene ring and its orientation is conserved in solution, as proven by nmr studies. The main conclusions are that the seven-membered ring shows very specific conformational properties and that the lone-pair orientation is predictable, according to the position of the nitrogen in the ring. Finally, it is concluded that correlations between the nitrogen lone-pair orientation and the analgesic activity have to be reconsidered.

ANDRÉ G. MICHEL, GUY EVRARD, BERNADETTE NORBERG et EUGÈNE MILCHERT. Can. J. Chem. **66**, 1763 (1988).

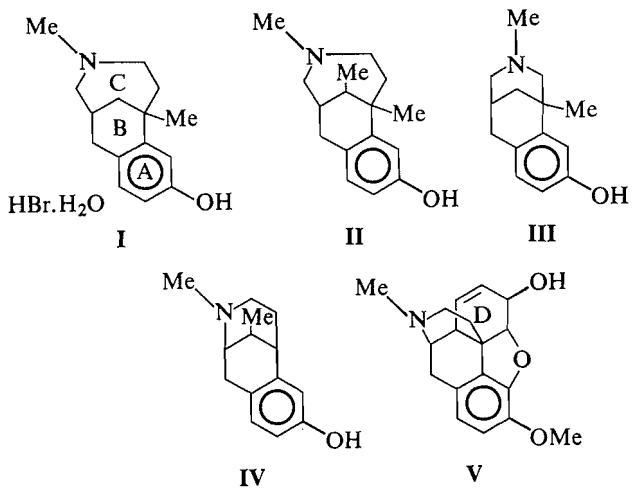
Les deux composés faisant l'objet de cette étude, appartiennent à la famille des homobenzomorphanes. Leurs propriétés analgésiques se sont avérées très intéressantes sous deux aspects : ils conservent une activité proche de la morphine et d'autre part ne provoquent pas de dépendance physique. Le présent travail vise à mettre en évidence les propriétés conformationnelles caractéristiques de ces composés, en vue d'en expliquer les propriétés typiques en terme de conformations. Plus particulièrement, l'orientation de la paire libre de l'azote est comparée à celle que l'on observe dans d'autres composés analgésiques. Il apparaît que les deux molécules adoptent la forme en L caractéristique et que le groupe 16β-méthyl présent dans le composé **II**, n'induit aucune modification conformationnelle importante. Les interactions intermoléculaires sont également décrites; quoique très différentes d'une molécule à l'autre, elles n'induisent pas non plus de modification conformationnelle notoire. Le comportement de ces molécules en solution est aussi étudié. Il s'avère que ce type de molécule possédant un cycle C à 7 membres oriente la paire libre de l'azote de façon spécifique selon la position de l'atome d'azote dans le cycle. On doit également conclure que la corrélation entre cette orientation et l'activité analgésique de ces molécules doit être reconsidérée.

Introduction

The present work is part of a more general crystal and molecular structure study of opiate alkaloids. The first part was published earlier (1) and reported oripavine and thebaine structure determinations in order to analyse the geometrical properties of narcotic opioids; the influence of the 16β-aryl substitution adjacent to the N atom in the piperidinyl ring was also discussed.

The present paper deals with opiate alkaloids where the classical C ring has been changed for a seven-membered ring with the N atom at the second position. These compounds have been found to be very active as opioids: analgesic activity of title compounds were determined using optically resolved stereoisomers (2, 3). Surprisingly, it was reported that the optical resolution gave no effect on the analgesic activity of compound **I**. Nevertheless, the *levo* isomer of compound **II** was analgesically much more potent than the *dextro* isomer and equipotent with morphine (3).

In light of X-ray structure determination, we describe the configuration of the seven-membered ring integrated into the



I, 1,4-dimethyl-11-hydroxy-2,3,4,5,6,7-hexahydro-1,6-1*H*-4-benzazonine hydrobromide
II, 1,4,14β-trimethyl-11-hydroxy-2,3,4,5,6,7-hexahydro-1,6-methano-1*H*-4-benzazonine
III, 1,3-dimethyl-1,2,3,4,5,6-hexahydro-1,5-methano-3-benzazocin-9-ol (10)
IV, 2,9β-dimethyl-6,7-benzomorphan (8)
V, codeine (7)

[1]Homobenzomorphan is a conventional designation for 10-hydroxy-4-methyl-2,3,4,5,6,7-hexahydro-1,6-methano-1*H*-4-benzazonine.

multi-ring system of homobenzomorphans. The nmr results suggest that the same conformations are also present in solution. After earlier statements on the importance of the nitrogen lone-pair orientation in the stereospecific opiate receptor (12), it was interesting to have an insight into the particular configuration of the seven-membered ring integrated into the multi-ring system of compounds **I** and **II**. It was hoped to correlate the above-mentioned differences in the analgesic activity with the presence of 12β-methyl group (C18 in the crystal numbering) in compound **II**.

Experimental

X-ray diffraction

The compounds have been synthesized (2) and supplied as racemic mixtures. Recrystallisation of compound **I** from MeOH–H_2O gave a crystalline mixture. On the basis of ref. 3, this mixture was expected to be the (+) and (+/−) bases. The crystal used for the X-ray analysis was from the (+) component. Subsequent photographic oscillation and Weissenberg films confirmed the assumption of a single stereoisomer, and a non-centrosymmetric space group was determined.

In case of compound **II**, the recrystallisation from MeOH–H_2O gave needles of the racemic mixture, confirmed by the determination of a centrosymmetric space group. For both compounds, the cell dimensions were refined with 25 reflections measured on the diffractometer. Independent reflections were collected on a Nonius, CAD-4 automatic diffractometer system. Table 1 gives the experimental conditions of the X-ray experiments.

Intensity data were corrected for Lorentz-polarization effects. No corrections were made for absorption or dispersion effects. Direct methods were applied to solve the structures using a MULTAN80 system of programs (4). The coordinates of all non-hydrogen atoms in the two compounds were determined from the best E-map. Further calculations were performed using SHELX (5). The positions of all hydrogen atoms were determined on an electron density difference Fourier map after initial refinement of non-hydrogen atoms. The final structures were refined by using full-matrix least squares with anisotropic temperature factors for non-hydrogen atoms and isotropic temperature factors for hydrogen atoms. The weighting scheme used in the least-squares refinement was $w = 1/[\sigma^2(F) + 0.001F^2]$. Table 2 gives the parameters concerning the refinements. Atomic parameters are given in Table 3.[4]

The high negative residual on the last difference Fourier synthesis for compound **I** appears in a region close to the water O(18) atom. This observation is to be correlated with a high equivalent B for this atom, reflecting an important level of disorder for the solvent molecule.

[4]Tables of anisotropic temperature factor tables, the structure factor tables, the atomic coordinates of the hydrogen atoms nmr ^{13}C chemical shifts may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Nuclear magnetic resonance

Proton decoupled carbon-13 nuclear magnetic resonance measurements were performed on a BRUKER CXP200/ASPECT 2000 spectrometer. Chemical shift assignments were facilitated by T_1 measurements and selective decoupling experiments. Compound **II** was studied in $CDCl_3$ from 223 to 323 K and in DMSO-d_6 at 323 K whereas compound **I** was studied from 300 to 373 K in DMSO-d_6 and in D_2O/CD_3OH (1:3 v/v) at 273 K.

Results

Molecular structures

Figure 1 shows the stereoscopic view of the molecular structures for compounds **I** and **II**. The characteristic L-shape is clearly observable, and the methylation at C(10) does not induce significant changes in compound **II**. In both compounds, the N-methyl group is pseudo-equatorial with respect to the seven-membered ring C: as a consequence the nitrogen hydrogen in compound **I** and the nitrogen lone pair in compound **II** are oriented away from cycle A. In Fig. 1*a*, this orientation has been visualized by placing the proton on the nitrogen pointing towards the bromide ion. In the case of compound **II** represented in Fig. 1*b*, a symmetry-related O(1) atom has been used to illustrate the nitrogen lone pair orientation, involved in an intermolecular hydrogen bond in the crystal.

Figure 2 gives the numbering scheme used. Bond lengths, valence, and torsional angles are given in Tables 4, 5, and 6, respectively. Significant differences in bond lengths and angles are only observed for the seven-membered ring and especially the region of the N(14) atom. Nevertheless, in both compounds, the C ring appears to adopt a "crown" conformation. This can be quantitatively realised examining the seven torsional angles indicated in Table 6.

Crystal packing

In the crystal of compound **I**, the packing of the molecules is achieved by hydrogen bonds between atoms of Br, O, and N. Each water oxygen O(18) is bonded to two symmetry-related bromide ions. The water–bromide system constitutes endless

chains oriented along the (b,c) diagonal. The molecules are connected to the water–bromide chains by two hydrogen bonds. The first one is formed between the phenolic O(1) as donor and O(18) water atom as acceptor. The second one involves a bromide ion as acceptor, sharing a proton with the basic nitrogen N(14) atom. The resulting extensive network of hydrogen bonds is shown in Fig. 3.

The packing in the crystal of compound **II** is mainly achieved by hydrogen bondings between the phenolic oxygen O(1) and a nitrogen atom N(15). The resulting head-to-tail system gives rise to infinite chains of molecules shown in Fig. 4. Hydroxyl hydrogen atoms H(1) have been included in the packing diagram. Van der Waals interactions assume the cohesion between the chains. Table 7 gives the hydrogen-bond distances and angles obtained for both compounds. The values obtained

for compound **I** may be compared to those of related 6,7-benzomorphan compounds published earlier (6). It is interesting to observe that the benzomorphan hydrobromide (6) and compound **I** of the present study adopt similar crystal packing. Values obtained for hydrogen-bond geometries (Table 7) are also very similar.

Molecular comparisons

Comparisons of the molecular conformations of compounds **I**, **II**, **III**, and **V** have been made using the molecular modelling system SYBYL (11). After introduction of the experimental atom coordinates of two molecules into the program, one molecule is subjected to translation and rigid rotation so that the homologous series of atoms of ring A coincide for the two molecules (FIT subprogram of SYBYL). The stereoviews of the resultant pairs of molecules are given in Fig. 5. As can be seen in Fig. 5(*a*), although packed in very different ways, molecular conformations of compounds **I** and **II** are very similar. Also, the presence of a 12β-methyl substituent in compound **II** does not induce important modifications on the molecular conformation. Significant differences may be observed on intramolecular bonds C(15)—N(14) and C(13)—N(14): see Table 4. The most different valence angles are C(8)—C(9)—C(15), C(10)—C(9)—C(15), C(6)—C(11)—C(12), C(10)—C(11)—C(12), and C(15)—N(14)—C(17) as can be seen in Table 5. Meanwhile, it must be pointed out that the nitrogen atom region of the molecule is mostly affected, as seen from the selected torsional angles given in Table 6.

Dynamic nuclear magnetic resonance analysis (DNMR)

The ^{13}C nmr chemical shifts of compound **I** (in $CDCl_3$) and compound **II** (in DMSO-d_6) have been recorded as a function of temperature. The small chemical shift changes are entirely consistent with solvent effects and within the temperature range studied show no evidence of conformational changes.

Discussion

Examining the stereoviews of molecular superpositions of various six-membered piperidyl and seven-membered C ring structures of opiates, it appears that several rules are emerging.

In the case of a piperidyl C ring, the conformation is always "chair". As a consequence and assuming that the N—CH_3 group will always be pseudo equatorial, the N lone pair will point away from the A ring if the N is in first position adjacent to the tertiary carbon. This was observed in compound **IV** (8) and can be seen for compound **V** in Fig. 5*c* and has been observed for all known morphine-like molecules (6, 9). If the nitrogen is moved to the second position, for the same chair conformations and the N—CH_3 equatorial, the lone-pair will point towards the A ring: see compound **III** (10) on Fig. 5*b*.

The same rules apply in the case of seven-membered C rings. In compounds **I** and **II**, the complete multi-ring structure adapts itself by modifying the B ring to accommodate the special C ring. This can be seen on superpositions 5*b* and 5*c*. For these structures, the "crown" conformation of the seven-membered ring observed in the present study for compounds **I** and **II**, appears to be very rigid and changes very little in solution. The

examination of this C ring shows that a nitrogen atom in a position adjacent to the tertiary carbon, would have its lone pair pointing towards the A ring in order to place the N—CH_3 in an equatorial position. If the nitrogen atom is moved to the second position, the lone pair will point away from the A ring, as shown by the structures of **I** and **II** and as observed in Fig. 5*a*.

From the present study it follows that the direction (away or toward the A ring) of the electron lone pair of the nitrogen atom in 6-piperidyl and seven-membered C-ring opioids is completely predictable: it depends on the position of the nitrogen atom in the C ring. For the wide variety of modified benzomorphanes synthesized (2), all compounds were shown to be active (2, 3) at various levels, regardless of the nitrogen atom position and hence lone pair orientation. Although a "black or white" answer was not observed, minor structural variations in benzomorphan opiates have been associated with drastic changes in the relative agonist or antagonist properties (14). Following these observations, in the particular case of compounds **I** and **II** the minor distortions observed in the C ring (Table 5 and Fig. 5*a*) have to be considered to account for different activities, the differentiation in the analgesic activity and stereospecificity could also be associated with the presence of the 12β-methyl (C18) group and the steric hindrance of a particular region of space, as invoked in the case of compound **IV** (8) and other benzomorphans.

DAVID J. ELLIOT, SANNA HAUKILAHTI, DAVID G. HOLAH, ALAN N. HUGHES, STANISLAW MACIASZEK, RICHARD J. BARTON, YAOGUANG LUO, and BEVERLY E. ROBERTSON. Can. J. Chem. **66**, 1770 (1988).

Reactions between Co(II), Diphos, and $NaBH_3CN$ lead to $Co(BH_3CN)_2(Diphos)_2$, **1**, or $[Co(BH_3CN)(Diphos)_2]X$, **2** (X = ClO_4 or BPh_4), and, in certain solvents, **2** reacts to produce $[Co(CN)(Diphos)_2](ClO_4)$. Compound **1** can be reversibly converted to $Co(BH_3CN)_2(DMF)_4$, **4**, via $Co(BH_3CN)_2(Diphos)(DMF)$. In addition, **1** reacts with CO to form the Co(I) and Co(III) compounds $[Co(Diphos)_2](CO)]X$ and $[Co(Diphos)_2(CN)_2]X$ (X = BH_3CN or BPh_4). Single crystal X-ray diffraction studies of **4** show that the compound crystallizes in the triclinic space group $P\bar{1}$, with unit cell parameters $a = 7.572(6)$, $b = 9.695(6)$, $c = 9.395(6)$ Å, $\alpha = 81.06(4)$, $\beta = 68.46(5)$, $\gamma = 68.19(5)°$, $V = 595.5$ Å^3, $Z = 1$, and $d_{calcd} = 1.202$ g cm^{-3}. The structure converged to a conventional *R* factor of 0.040 for 2841 observations and showed an octahedral arrangement of four O atoms from DMF molecules and two *trans* N-bound BH_3CN groups around the Co(II) center.

DAVID J. ELLIOT, SANNA HAUKILAHTI, DAVID G. HOLAH, ALAN N. HUGHES, STANISLAW MACIASZEK, RICHARD J. BARTON, YAOGUANG LUO et BEVERLY E. ROBERTSON. Can. J. Chem. **66**, 1770 (1988).

Les réactions de Co(II) avec le Diphos et le $NaBH_3CN$ conduisent aux composés $Co(BH_3CN)_2(Diphos)_2$, (**1**) ou $[Co(BH_3CN)(Diphos)_2]X$ (**2**) (X = ClO_4 ou BPh_4) et, dans certains solvants, le composé **2** réagit pour conduire à la formation de $[Co(CN)(Diphos)_2)](ClO_4)$. On peut transformer le composé **1** en composé **4** (le $Co(BH_3CN)_2(DMF)_4$) par le biais du $Co(BH_3CN)_2(Diphos)(DMF)$. De plus, le composé **1** réagit avec le CO pour conduire à la formation des composés Co(I) et Co(III) $[Co(Diphos)_2](CO)]X$ et $[Co(Diphos)_2(CN_2]X$ (X = BH_3CN ou BPh_4). Des études par diffraction des rayons-X sur des cristaux uniques du composé **4** démontrent qu'ils cristallisent dans le groupe d'espace triclinique $P\bar{1}$, avec des dimensions de maille de $a = 7{,}572(6)$, $b = 9{,}695(6)$, et $c = 9{,}395(6)$ Å, $\alpha = 81{,}06(4)$, $\beta = 68{,}46(5)$, et $\gamma = 68{,}19(5)°$, $V = 595{,}5$ Å^3, $Z = 1$ et $d_{calc} = 1{,}202$ g cm^{-3}. La structure converge vers un facteur *R* conventionnel de 0,040 pour 2841 observations et elle présente un arrangement octaédrique pour les quatre atomes d'oxygène des molécules de DMF alors que les deux groupements BH_3CN sont liés par l'azote dans des arrangements *trans* par rapport au Co(II) qui se trouve au centre.

[Traduit par la revue]

Introduction

We have been interested for some time in reactions between $NaBH_4$ (1), $NaBH_3CN$ (2,3) (or $NaBH_2(CN)_2$ (4)), and metal ions in the presence of phosphines, particularly with respect to the extent to which metal ion reduction occurs, the sequence of steps in the reduction, and the mode of coordination of the hydroborate grouping in those products in which it is present. Reactions involving $NaBH_4$ are often very fast and can lead to a very complex series of intermediates and products (1). We therefore felt that the introduction of a second π acceptor molecule, like CO, into these systems may significantly modify the course of events (5). This paper reports on reactions between (Co(II), $NaBH_3CN$, and $Ph_2PCH_2CH_2PPh_2$ (Diphos) in the presence of CO; the results obtained prompted a reinvestigation of the same system in the absence of CO (6).

Experimental

Materials

The hydrates of cobalt perchlorate, chloride, and bromide, and $NaBPh_4$ were obtained from Alfa Products; 1,2-bis(diphenylphosphino)ethane, Diphos, from Strem Chemicals, Inc.; $NaBH_3CN$ from Aldrich; and CO from Canadian Liquid Air.

All solvents were reagent grade and were purified by distillation before being degassed with oxygen-free, dry nitrogen and stored in a glove box.

Analyses and physical measurements

These were carried out as previously described (3).

Synthesis of the compounds

Unless otherwise specified, all synthetic work was carried out under nitrogen in a glove box. Yields were generally in the range of 50–80%. Although the $NaBH_3CN$ was stored under dry conditions, its reactivity was found to vary from sample to sample, especially with age. This did not, in general, change the outcome of the reactions.

Bis(cyanotrihydroborato)[1,2-bis(diphenylphosphino)ethane]-cobalt(II), $Co(BH_3CN)_2(Diphos)_2$ (1)

$Co(ClO_4)_2 \cdot 6H_2O$ (2.0 g, 5.5 mmol), dissolved in ethanol (15 mL), was mixed with Diphos (4.3 g, 10.8 mmol) in benzene (20 mL) to produce a bright yellow solid. A solution of $NaBH_3CN$ (1.7 g, 27 mmol) in ethanol (≈10 mL) was added dropwise, with stirring, over a 10-min period, and the stirring was continued for ≈3 h. The resulting yellow-orange solid was filtered off, washed with EtOH and benzene, and dried. It was recrystallized by dissolving it in the minimum amount of DMF, which produces a red solution, and adding ethanol. Crystallization took place overnight. Yield = 75%. μ_{eff}: 1.82 BM at 22°C; ir, ν_{BH}: 2310(s), 2250(sh); ν_{CN}: 2190 cm^{-1}; $^{31}P-\{^1H\}$ nmr (DMF), δ: −9.1(vb, see discussion). *Anal.* calcd. for $Co(BH_3CN)_2(Diphos)_2$: C 69.32, H 5.82, N 3.00; found: C 70.68, H 6.02, N 2.99.

The complex is much less soluble in CH_2Cl_2 than in DMF, but small amounts can be recrystallized from the former. *Anal.* calcd. for

$Co(BH_3CN)_2(Diphos)_2 \cdot CH_2Cl_2$: C 64.74, H 5.53, N 2.75; found: C 65.02, H 5.46, N 2.78.

The compound is unstable if left in solvents for long periods. For example, in acetone, orange, green, and, finally, blue solutions are observed in sequence over a period of several days at room temperature. In DMF, unstable, blue crystals were isolated after several days. These showed the presence of Co—CN groups.

Bis(cyanotrihydroborato)tetrakis(N,N-dimethylformamide)cobalt(II), $Co(BH_3CN)_2(DMF)_4$ (4)

$Co(ClO_4)_2 \cdot 6H_2O$ (0.55 g, 1.5 mmol) in DMF (10 mL) was reacted with $NaBH_3CN$ (0.5 g, 8 mmol) in ethanol (10 mL). The reaction mixture turned pink and crystals were produced in high yield within 2–3 h on cooling. These were filtered off, washed with ether and dried under reduced pressure. The product is both soluble and stable in DMF. It slowly dissolves in CH_3CN to give a blue-violet solution, and turns violet immediately in CH_2Cl_2 and acetone. μ_{eff}: 5.10 BM at 22°C; ir, ν_{DMF}: 1650(vs. b), 1500(s), 1250(s), 1120(s), 860(s); ν_{BH}: 2370(sh), 2330(s), 2290(m), 2275(m); ν_{CN}: 2200(s), 2220(w); other peaks at 2150(w), 2100(w), 2030(w) 2010(w), 1985(w) cm^{-1}. Reflectance spectrum $^4T_{1g}(F) \rightarrow {}^4T_{2g}$ at 8330 cm^{-1}, $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ at 19 230 cm^{-1}. *Anal.* calcd. for $Co(BH_3CN)_2(DMF)_4$: C 39.01, H 7.95, N 19.50; found: C 38.92, H 7.95, N 19.65.

The same product is also formed by crystallizing **1** from DMF/ether over a period of ≈3 days at room temperature.

$Co(BD_3CN)_2(DMF)_4$

$CoCl_2 \cdot 6H_2O$[2] (0.12 g, 0.50 mmol) in DMF (5 mL) was treated with $NaBD_3CN$ (0.16 g, 2.5 mmol) in EtOH (5 mL). Et_2O (5 mL) was added and the solution produced crystals in ≈2 h when cooled; ir, ν_{BH}: 2330(w, residual); ν_{CN}: 2200(vs); ν_{BD}: 1760(s), 1775(sh), 1730(vw,sh); $\nu_{CO(DMF)}$: 1650(vs,b); other peaks at 2155(vw), 2100(vw), 2030(w), and 1970(vw) cm^{-1}.

Bis(cyanotrihydroborato)N,N-dimethylformamide-1,2-bis(diphenyl phosphino)ethanecobalt(II), $Co(BH_3CN)_2(Diphos)(DMF)$ (5)

$Co(BH_3CN)_2(Diphos)_2$ (0.19 g, 0.2 mmol) and $Co(BH_3CN)_2(DMF)_4$ (0.076 g, 0.18 mmol) were mixed in CH_3CN (≈20 mL). The reaction produced a clear red solution within a few minutes and this was stirred for ≈4 h. Concentration of this solution by a slow N_2 flow produced red crystals of the product in high yield. This product is soluble in DMF and CH_3CN, but turns green instantly in $CHCl_3$. μ_{eff}: 1.93 BM at 22°C; ir, ν_{BH}: 2330(s), 2280(m), 2255(m); ν_{CN}: 2200(s); ν_{CO}: 1650(s). *Anal.* calcd. for $Co(BH_3CN)_2(Diphos)(DMF)$: C 60.98, H 6.07, N 6.88; found: C 60.91, H 5.92, N 6.90.

Reactions of $Co(BH_3CN)_2(Diphos)(DMF)$, (5)

(i) With Diphos

Compound **5** was dissolved in DMF to which was added a slight excess of Diphos. Addition of ethanol produced yellow crystals of $Co(BH_3CN)_2(Diphos)_2$ over a 2-day period in the refrigerator. The composition of the product was confirmed by ir and CHN analyses.

(ii) With DMF

$Co(BH_3CN)_2(Diphos)(DMF)$ was dissolved in DMF. Addition of ether produced crystals of $Co(BH_3CN)_2(DMF)_4$.

Cyanotrihydroboratobis[1,2-bis(diphenylphosphino)ethane]cobalt(II) perchlorate or tetraphenylborate, $[Co(BH_3CN)(Diphos)_2]X$, $X = ClO_4$ or BPh_4 (2)

(a) $X = ClO_4$

A solution of $NaBH_3CN$ (0.31 g, 4.9 mmol) in ethanol (≈10 mL) was added dropwise over a 10-min period to a stirred mixture of $Co(ClO_4)_2 \cdot 6H_2O$ (0.90 g, ≈2.5 mmol) and Diphos (3.0 g, 7.5 mmol) in ethanol/toluene 6:1 (≈10 mL). The solution was stirred for 3 h after which an orange solid was filtered off, and recrystallized from a deep red CH_2Cl_2 solution by the addition of hexane. The complex may also be recrystallized from DMF/EtOH.

[2]It was found that when $Co(ClO_4)_2 \cdot 6H_2O$ was used in this reaction, more rapid D–H exchange took place and the resulting crystals contained little B–D.

Decomposition occurs if samples are left for long periods in solvents (see later); the compound is stable in air.

Other reaction conditions also lead to the same product. For example, reactions in which ratios of $Co(ClO_4)_2 \cdot 6H_2O$/Diphos/$NaBH_3CN$ of 1:3:6 or 1:2:5 are used, and which are filtered after ≈10 min of reaction time, also lead to this product, although some contamination with $Co(BH_3CN)_2(Diphos)_2$ may occur. The ready solubility of $[Co(BH_3CN)(Diphos)_2](ClO_4)$ in CH_2Cl_2 allows for its easy separation from the latter. μ_{eff}: 1.94 BM; ir, ν_{BH}: 2270(w,sh), 2310(s), 2360(w,sh); ν_{CN}: 2180(s); ν_{ClO_4}: 1100(vs,b). *Anal.* calcd. for $[Co(BH_3CN)(Diphos)_2](ClO_4)$: C 63.97, H 5.17, N 1.41; found: C 64.02, H 5.29, N 1.42.

(b) $X = BPh_4$

A slight excess of $NaBPh_4$ in ethanol was added to a solution of **2** ($X = ClO_4$) in acetone. An orange microcrystalline product was precipitated by the addition of ether or hexane. The complex was identified from its reflectance spectrum, which is identical with that of **2** ($X = ClO_4$), as is its ir spectrum (with the exception of ν_{ClO_4} at 1100 cm^{-1}).

Cyanobis[1,2-bis(diphenylphosphino)ethane]cobalt(II) perchlorate, $[Co(CN)(Diphos)_2](ClO_4)$ (3)

$[Co(BH_3CN)(Diphos)_2](ClO_4)$ was dissolved in acetone, producing a brown solution from which a dark brown crystalline solid was obtained by the addition of a small amount of hexane. The product was filtered off, washed with hexane, and dried under reduced pressure. The crystals do not redissolve completely in acetone. They are soluble in methylene chloride, but decomposition occurs within ≈20 min. μ_{eff} 1.80 BM; ir, ν_{CN}: 2098(s); ν_{ClO_4}: 1100(vs, vb). *Anal.* calcd. for $[Co(CN)(Diphos)_2](ClO_4)$: C 64.87, H 4.93, N 1.43; found: C 65.24, H 5.09, N 1.31.

The same product is formed when CH_2Cl_2 solutions of $[Co(BH_3CN)(Diphos)_2](ClO_4)$ are left for 3–4 days.

Carbonylbis[1,2-bis(diphenylphosphino)ethane]cobalt(I) cyanotrihydroborate or tetraphenylborate, $[Co(CO)(Diphos)_2]X$, $X = BH_3CN$ or BPh_4 (6)

(a) $X = BH_3CN$

CO was passed for 10 min into a green solution of $CoBr_2 \cdot 6H_2O$ (0.43 g, 1.3 mmol) and Diphos (1.0 g, 2.5 mmol) in EtOH/benzene (1:1, 15 mL) to which $NaBH_3CN$ (0.23 g, 3.7 mmol) in EtOH (5 mL) had been added over a 15-min period. The solution turned red and the small amount of a green solid that precipitated out was filtered off. Concentration of the filtrate by a slow N_2 stream produced yellow-orange crystals, which were filtered off, washed with hexane, and dried under vacuum; ir, ν_{BH}: 2310(s), 2280(sh); ν_{CN}: 2160; ν_{CO}: 1918 cm^{-1}; $^{31}P-\{^1H\}$ nmr (CH_2Cl_2), δ: 69.7(s). *Anal.* calcd. for $[Co(CO)(Diphos)_2](BH_3CN)$: C 70.22, H 5.57, N 1.52; found: C 70.10, H 5.63, N 1.65.

In an alternative synthesis, a solution of $Co(BH_3CN)_2(Diphos)_2$ in DMF/EtOH (1:1) was filtered after CO had been passed for 20 min. Addition of ether or hexane to the red filtrate produced orange crystals after several days at ≈0°C. The ^{31}P nmr and ir spectra were found to be the same as above, except that the presence of ethanol in the lattice is revealed by ν_{OH} 3350(w), 1670(m) cm^{-1} and by the ^1H nmr spectrum ($CDCl_3$) (EtOH at δ 1.25(t), 3.75(q); integration EtOH:Diphos ≈1:1).

(b) $X = BPh_4$

A slight excess of $NaBPh_4$ in ethanol was added to a solution of **6** ($X = BH_3CN$) in CH_2Cl_2. Addition of hexane produced a crystalline solid that exhibited ^{31}P nmr and ir spectra identical (with the exception of the BH_3CN ir absorptions) with those shown by **6** ($X = BH_3CN$).

Dicyanobis[1,2-bis(diphenylphosphino)ethane]cobalt(III) cyanotrihydroborate or tetraphenylborate, $[Co(CN)_2(Diphos)_2]X$, $X = BH_3CN$ or BPh_4 (7)

(a) $X = BH_3CN$

A suspension of $Co(BH_3CN)_2(Diphos)_2$ in CH_2Cl_2 was saturated with CO for ≈20 min. The undissolved starting material slowly dissolved over 24–48 h. Ether was added and the solution produced

For personal use only.

yellow crystals. Similarly, a solution of $Co(BH_3CH)_2(Diphos)_2$ in DMF/EtOH (or the filtrate after this compound was recrystallized from DMF/EtOH) was saturated with CO for ≈40 min, filtered, and ether added to the filtrate. Several weeks in the freezer produced yellow crystals, which were filtered off, washed with ether, and dried under reduced pressure; ir, ν_{CN}: 2100(s); ν_{CN} (from BH_3CN): 2160(s); ν_{BH}: 2305(s), 2270(sh); ν_{OH} (from EtOH): 3300(b), 1665(m) cm^{-1}; $^{31}P-\{^1H\}$ nmr (DMF), δ: 55.8(s); ^1H nmr ($CDCl_3$) EtOH at δ: 1.25(t), 3.75(q); integration EtOH:Diphos 1:1. *Anal.* calcd. for $[Co(CN)_2(Diphos)_2](BH_3CN)\cdot 2EtOH$: C 66.86, H 5.95, N 3.97; found: C 66.50, H 5.79, N 4.00. The amount of ethanol varies from sample to sample. For example, good chemical analyses have also been obtained for this compound with only one EtOH molecule per Co atom.

(b) X = BPh_4

The yellow crystals obtained by the method described above were dissolved in $EtOH/CH_2Cl_2$ (1:1) to which an equal molar quantity of $NaBPh_4$ in EtOH was added. The bright yellow crystalline product that formed was filtered off, washed with EtOH, and dried under reduced pressure; ir, ν_{CN}: 2110 cm^{-1}. *Anal.* calcd. for $[Co(CN)_2(Diphos)_2](BPh_4)$: C 76.35, H 5.59, N 2.28; found: C 75.49, H 5.52, N 2.20.

X-ray structure determination of $Co(BH_3CN)_2(DMF)_4$

$C_{14}H_{34}CoN_6O_4$ fw = 431.02

Triclinic, space group $P\bar{1}$, $a = 7.572(6)$, $b = 9.695(6)$, $c = 9.395(6)$ Å, $\alpha = 81.06(4)$, $\beta = 68.46(5)$, $\gamma = 68.19(5)°$, $V = 595.5(6)$ Å^3, $T = 293(2)$ K, $Z = 1$, $D_x = 1.202$ g cm^{-3}, F(000) = 227, μ(MoKα) = 14.1 cm^{-1}, λ(MoKα) = 0.71069 Å.

A crystal with irregular shape, and dimension approximately 0.4 mm on a side, was mounted and sealed in a quartz capillary.

Unit-cell parameters were determined by least-square refinement on the positions of 72 reflections with $30 \leq 2\theta \leq 39°$. The density of the crystal was not determined. Intensities were measured with graphite-monochromated MoKα radiation on a modified Picker FACS-1 diffractometer, using the NRCC diffractometer control system (7). The θ–2θ scan technique, with profile analysis, was employed. Data were measured in the range of $3 \leq 2\theta \leq 60°$, using a scan speed of 2°/min and a scan width of $(0.7 + 0.692 \tan\theta)$ degrees. The intensities of three reference reflections, measured after every 47 reflections throughout the data collection, did not change significantly. A total of 3414 independent reflections were collected, of which 2841 were considered as observed with $I/\sigma(I) \geq 2.0$, and were used in the structure determination.

The data were corrected for the Lorentz effect and polarization. All calculations were carried out with the XTAL system of crystallographic programs (8). Scattering factors were taken from the XTAL system. A dispersion correction, taken from International Tables for X-ray Crystallography Vol. 4 (9), was applied to the scattering factor of the cobalt atom.

The average values of $|E|$, $|E^2-1|$, $|E^2-1|^2$, and $|E^2-1|^3$ were 0.879, 0.744, 0.961, and 2.212 respectively, clearly indicating a noncentrosymmetric space group. The structure was then solved by direct methods. An *E*-map gave 23 out of 27 non-hydrogen atoms. Subsequent electron density Fourier syntheses revealed all non-hydrogen atoms and the structure was refined on *F*. However, examination of the structure showed that it contained a center of symmetry at the Co atom.[3] The space group was changed to $P\bar{1}$ and refinement proceeded. All hydrogen atoms were found from a difference map. The non-hydrogen atoms were refined with anisotropic temperature factors and the hydrogen atoms with isotropic temperature factors. Weights were calculated as $\sigma^2(F)$ where $\sigma(F)$ is based on counting statistics and the excess of scatter in the standard reflections. The structure was refined using data not corrected for absorption, using data corrected for absorption based on a single psi scan assuming absorption in the quartz capillary, and using data corrected for absorption by the Gaussian integration method (10).[4] All three refinements gave identical coordinates and temperature factors within the esd's and nearly identical estimated standard deviations. The results reported here are for the final refinement. The absorption corrections (*A*) ranged from 0.823 to 0.865. Convergence was reached at $R = 0.036$, $R_w = 0.039$, and $S = 2.87$. The maximum residual electron density was 0.31 e Å^{-3}. The average and maximum shift/error were 0.004 and 0.070.[5]

Results and discussion

One of the first products obtained from $Co(II)/NaBH_3CN$/Diphos/CO reactions is a yellow-brown crystalline product, $Co(BH_3CN)_2(Diphos)_2$, **1**. This surprised us, since we had previously reported (6) that reactions between Co(II) (as the chloride), $NaBH_3CN$, and Diphos lead to the formation of Co(I), and it prompted us to reexamine the latter type of reaction using both $CoCl_2\cdot 6H_2O$ (6) and $Co(ClO_4)_2\cdot 6H_2O$ as the source of cobalt(II). In fact, starting with $Co(ClO_4)_2\cdot 6H_2O$, the product depends on the Co(II) : $NaBH_3CN$ ratio and the time of the reaction as outlined in Scheme 1. Thus, short reaction times and (or) smaller amounts of $NaBH_3CN$ lead to the formation of the dark brown $[Co(BH_3CN)(Diphos)_2]X$, **2** (X = ClO_4), which readily forms **2** (X = BPh_4) on addition of $NaBPh_4$ in ethanol. Solutions of **2** (X = ClO_4) in acetone or methylene chloride produce $[Co(CN)(Diphos)_2](ClO_4)$ **3**. The ir spectral data (see Experimental) support the presence of ionic ClO_4^-, N-bound BH_3CN^- in **2**, and the Co—CN group in **3**. No meaningful nmr data were obtained since the complexes are paramagnetic, $\mu_{eff} \approx 2.1$ BM, i.e., low spin d^7 systems.

Reflectance spectra of **2** and **3** are shown in Fig. 1. In CH_2Cl_2 solution, the peaks are in almost the same positions, i.e., ≈8500 cm^{-1}, ε 130 L M^{-1} cm^{-1} (with a shoulder at ≈6900 cm^{-1}) and 14 900, ε = 33 L M^{-1} cm^{-1}. Included in Fig. 1 for comparison is the reflectance spectrum of the low-spin distorted 5-coordinated species $CoH(BH_3CN)(PPh_3)_3$ (11). There are several published spectral studies on other closely related low-spin Co(II) compounds of the type $[CoX(P\cap P)_2]Y$. Representative examples are X = Br, P∩P = *cis*-1,2-bis-(diphenylphosphino)ethylene, Y = BPh_4 (12); P∩P = Diphos, X = Y = halide, X = halide, Y = BPh_4, ClO_4 (13); and P∩P = bis(diphenylphosphino)methane, X = halide, Y = ClO_4 (14). While there are some similarities between the spectra of all of these compounds, the agreement is not good and the differences may well reflect varying distortions in the molecules.

The same reactants under different conditions (Scheme 1), or reactions using $CoCl_2\cdot 6H_2O$ as the Co(II) source, all produce **1**, which was recrystallized from DMF–ethanol.

In the solid state, **1** has a magnetic moment of 1.82 BM. When freshly dissolved in DMF (i.e., such that there is insufficient time for the formation of **4**, see later) the ^{31}P nmr spectrum of **1** shows only an extremely broad (peak base from approximately δ −5 to δ +10) low intensity signal at δ −9.1. This is probably due to paramagnetically shifted and broadened ^{31}P resonances from coordinated Diphos since the signals for

[3]The realization that the structure was centrosymmetric occurred after the original manuscript was submitted. We wish to acknowledge that this most serious error was also noted by one of the referees.

[4]Absorption corrections were suggested by a referee.

[5]Supplementary material deposited: tables of atomic coordinates and temperature factors, bond lengths and angles, anisotropic temperature factors, and observed and calculated structure factors (24 pages). SCHEME 1

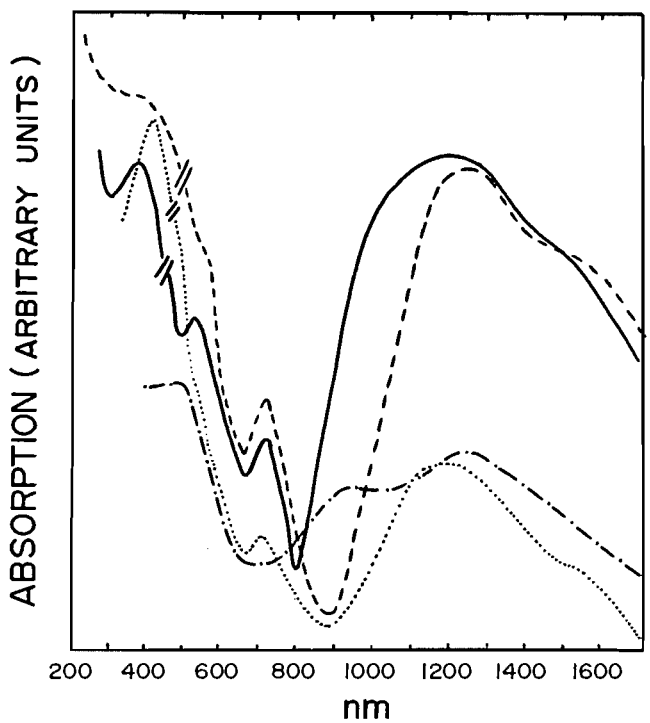

FIG. 1. Reflectance spectra. —— $[Co(CN)(Diphos)_2](ClO_4)$, **3**; ---- $[Co(BH_3CN)(Diphos)_2](ClO_4)$, **2**; ..... $[Co(BH_3CN)_2(Diphos)(DMF)$ **5**; —·— $[CoH(BH_3CN)(PPh_3)_3$.

free Diphos in these and solutions of other paramagnetic species, while shifted somewhat, remain comparatively sharp. The ir spectrum of **1** shows only a single ν_{CN} at 2190 cm^{-1}, which is close to ν_{CN} (2179 cm^{-1}) for $NaBH_3CN$. We have observed no reaction between solutions of **1** in DMF and $NaBPh_4$ in ethanol and, therefore, the two (ir-equivalent) BH_3CN groups appear to be coordinated to the cobalt. It therefore appears that **1** may be a low-spin 6-coordinated Co(II) compound of which very few examples have been characterized (15).

The reflectance spectrum of **1** shows a broad peak at ≈10 000 cm^{-1} with a shoulder at ≈18 000 cm^{-1}. In DMF, the main peak is at ≈8250 cm^{-1} ($\epsilon \approx 30\ L\ M\ cm^{-1}$) with the shoulder at ≈13 300 cm^{-1}. In CH_2Cl_2, the spectrum is essentially the same except that the additional peak occurs at 15 400 cm^{-1} ($\epsilon \approx 60\ L\ M^{-1}\ cm^{-1}$). There are some similarities between these spectra and those already reported for compounds believed to contain low-spin 6-coordinated Co(II), which have bands in the 7500–8000 cm^{-1} and 15 000–16 000 cm^{-1} regions.[6] Tentative assignments have been made.

Because of the potential importance of **1**, many (unsuccessful) attempts were made to grow crystals suitable for X-ray diffraction studies. Data were collected on a crystal obtained by the diffusion of ether into dilute solutions of **1** in DMF at 0°C. However, even though the yellow-brown colour of **1** persists for long periods in such solutions, the crystal was later shown to be **4**, $Co(BH_3CN)_2(DMF)_4$. The ir spectrum of **4** shows a strong peak at 2000 cm^{-1}, due to the coordinated CN group of BH_3CN, and a series of weak, but sharp, peaks of unknown origin at 2150, 2100, 2030, 2010, and 1985 cm^{-1}, which do not change significantly in the spectrum of the deuterated complex. There are also strong peaks, due to DMF, at 1650, 1500, 1250, 1120, and 860 cm^{-1}. Compound **4** is readily prepared in high yield simply by treating Co(II) perchlorate in DMF with $NaBH_3CN$. It reacts with Diphos to produce **1**. As expected, changing the four P atoms of **1** to four O atoms in **4** results in a spin state change, **4** having a magnetic moment of 5.1 BM, and an electronic spectrum typical of octahedral Co(II) compounds (see Experimental).

There is also a reaction between **1** and **4** that produces **5** according to:

$$Co(BH_3CN)_2(Diphos)_2 + Co(BH_3CN)_2(DMF)_4 \rightarrow 2\ Co(BH_3CN)_2(Diphos)(DMF) + 3\ DMF$$

Compound **5** is soluble in DMF (producing **4** over several days)

and in CH_3CN but turns green instantly in $CHCl_3$. The ir spectrum clearly shows ν_{CN} at 2200 cm^{-1} and ν_{CO} of DMF at 1650 cm^{-1}. The single Diphos molecule in **5** is sufficient to cause a low-spin configuration, ($\mu_{eff} = 1.93$ BM) and the reflectance spectrum of **5** is identical with those of **2** and **3**. (Fig. 1).

X-ray crystallography shows that the Co(II) ion, which is

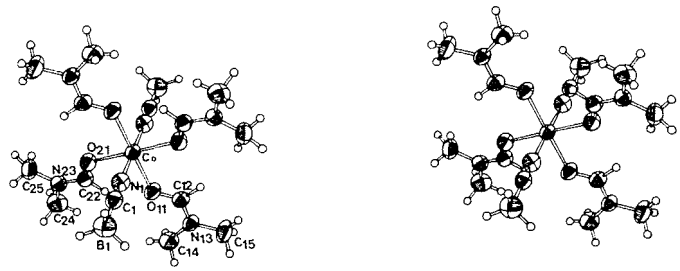

FIG. 2. Stereogram showing the molecular structure and labelling scheme for $Co(BH_3CN)_2(DMF)_4$.

located on a center of symmetry, is surrounded by two *trans*, N-bound BH_3CN groups and four O-bound DMF molecules in an almost perfect octahedron. Tables 1 and 2 list atomic coordinates and bond lengths and angles, and the stereogram in Fig. 2 shows the molecular structure with the atom labelling scheme. The two essentially identical Co—O bond lengths are almost equal to the Co—N bond length. The bond angles about the Co atom are very close to 90°.

The metal—N—C bond angles in coordinated BH_3CN complexes have been related to the positions of the ν_{CN} in ir spectra (16). In **4** the C—N bond length of 1.138(3) Å and the Co—N—C bond angle of 177.6(2)° account for the single ν_{CN} absorption at 2200 cm^{-1} and compare favourably with, for example, a ν_{CN} at 2210 cm^{-1} for a Cu—N—C angle of 175.6° in $(Me_2dien)Cu(BH_3CN)_2$ (16). The bond lengths and angles of the coordinated DMF molecules are similar to those found in other structures (17).

Since, as outlined in the above discussion, $NaBH_3CN$ alone seems unable to reduce Co(II)-Diphos mixtures, as observed with analogous Ni(II) systems (3), we have introduced CO into these reactions. This will increase the reductive nature of the conditions and the excellent π bonding properties of CO should help stabilize the resulting products. Two approaches have been followed: (*i*) saturating solutions of Co(II)-Diphos mixtures with CO before and after the addition of $NaBH_4$ or $NaBH_3CN$ and (*ii*) reactions of **1** with CO. The former has produced several new Co(O) complexes (18) along with $[Co(CO)(Diphos)_2]X$ ($X = BH_3CN$, BPh_4) **6**. This compound, **6** ($X = ClO_4$) has previously been characterized (5, 19), as have related Rh (20) and Ir (21) complexes. Compound **6** has also been obtained from reactions of **1** with CO, but what is perhaps more interesting is that when CO and solutions of **1** in either DMF–ethanol of CH_2Cl_2 are left for longer periods of time, the Co(III) complex **7**, $[Co(CN)_2(Diphos)_2](BH_3CN)$ is formed as the ethanol solvate (Scheme 1). This reacts with $NaBPh_4$ to form **7** ($X = BPh_4$).

The coordinated CN groups appear in ir spectra of **7** as a sharp signal at 2100 cm^{-1}, as observed previously in this cation (22) (prepared by the interaction of $Co(CN)_2(Diphos)_2$ with O_2). The ν_{CN} of BH_3CN^- occurs at 2160 cm^{-1}, i.e., at slightly lower energy than in $NaBH_3CN$, and this seems to be a general observation for a number of coordination compounds with ionic BH_3CN groups. In the ^{31}P nmr spectra of these complexes, a singlet at δ 55, consistent with chelating Diphos, is observed. Formation of Co(III) by oxidative addition of HX (X = H, halogens, etc.) is well known and the resulting Co(III) hydrido species have been extensively studied (2). However, it seems more likely in this case that disproportionation of a Co(II)-CO-Diphos species occurs to produce the Co(III) and Co(I)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12

compounds, which, overall, may be represented as:

$$2\,Co(BH_3CN)_2(Diphos)_2 \xrightarrow{CO} [Co(CN)_2(Diphos)_2]^+ + [Co(CO)(Diphos)_2](BH_3CN) + \text{borane (?)}$$

The effect of (mostly monodentate) phosphines on Co(II) disproportionation has been extensively discussed recently, and it is significant that all four of the bidentate phosphines included in this study (23) resulted in disproportionation. However, CO is clearly needed in the above reaction, as the available evidence suggests that **1** produces paramagnetic blue Co(II)—CN compounds when left in DMF (Experimental).

ED AWERE, JACK PASSMORE, KEITH F. PRESTON, and LESLIE H. SUTCLIFFE. Can. J. Chem. **66**, 1776 (1988).

Electron spin resonance spectra observed in dilute solutions of the hexafluoroarsenate salts of selenothiadiazolylium cations in polar solvents are ascribed to the parent cation radicals $\overline{SeNSeSeN}^+$, $\overline{SNSeSeN}^+$, $\overline{SNSeSN}^+$, and $\overline{SNSSN}^+$. The **g**- and nitrogen hyperfine tensors for the three selenium-containing species are entirely in line with the planar π-radical description deduced in earlier studies of trithiadiazolylium. Substantial increases in the *g*-shifts on substitution of sulphur by selenium result in broadening of the solution spectra and concomitant loss of nitrogen hyperfine structure. From measurements made in solid SO_2, the following principal tensor components were deduced for the new, Se-containing radicals: $\overline{SeNSeSeN}^+$: **g** = (1.9930, 2.0108, 2.1379), $\mathbf{a}_N(2)$ = (7.4, ≈0, ≈0) gauss, $\mathbf{a}_{Se}(2)$ = (180, 70, 43) gauss; $\overline{SNSeSeN}^+$: **g** = (1.9941, 2.0108, 2.1355), $\mathbf{a}_N(2)$ = (6.9, ≈0, ≈0) gauss, $\mathbf{a}_{Se}(2)$ = (180, 70, 45) gauss; $\overline{SNSeSN}^+$: **g** = (1.9957, 2.0086, 2.0736), $\mathbf{a}_N(2)$ = (8.3, ≈0, ≈0) gauss, $\mathbf{a}_{Se}$ = (198, 78, 75) gauss, where the values are given in the order *x*, *y*, *z*, *x* being the direction perpendicular to the radical plane.

ED AWERE, JACK PASSMORE, KEITH F. PRESTON et LESLIE H. SUTCLIFFE. Can. J. Chem. **66**, 1776 (1988).

Les spectres de résonance paramagnétique électronique de solutions diluées d'hexafluoroarsénates de cations sélénothiazolylium, dans des solvants polaires, sont attribués aux cations radicaux $\overline{SeNSeSeN}^+$, $\overline{SNSeSeN}^+$, $\overline{SNSeSN}^+$ et $\overline{SNSSN}^+$. Les tenseurs hyperfins-**g** et de l'azote des trois espèces contenant du sélénium correspondent complètement avec la description planaire d'un radical π qui a été déduite sur la base d'études antérieures sur le trithiadiazolylium. Les augmentations importantes des déplacements-*g* qui se produisent lors de la substitution du soufre par du sélénium conduisent à un élargissement des spectres en solution et à une perte concomitante de la structure hyperfine de l'azote. À l'aide de mesures faites dans du SO_2 à l'état solide, on a déduit les composantes principales des tenseurs pour les nouveaux radicaux contenant du Se : $\overline{SeNSeSeN}^+$: **g** = (1,9930; 2,0108 et 2,1379), $\mathbf{a}_N(2)$ = (7,4; ≈0; ≈0) gauss, $\mathbf{a}_{Se}(2)$ = (180; 70; 43) gauss; $\overline{SNSeSeN}^+$: **g** = (1,9941; 2,0108 et 2,1355), $\mathbf{a}_N(2)$ = (6,9; ≈0; ≈0) gauss, $\mathbf{a}_{Se}(2)$ = (180; 70; 45) gauss; $\overline{SNSeSN}^+$: **g** = (1,9957; 2,0086 et 2,0736), $\mathbf{a}_N(2)$ = (8,3; ≈0; ≈0) gauss, $\mathbf{a}_{Se}$ = (198; 78; 75) gauss dans lesquels les valeurs sont données dans l'ordre *x*, *y* et *z* et *x* est dans la direction perpendiculaire au plan du radical.

[Traduit par la revue]

Introduction

As an unsurpassed probe of unpaired electron spin density, the electron spin resonance spectrometer has provided a unique link between experimentalist and theoretician in the study of free-radical structures. Nowhere has this been more evident than in the interpretation of hyperfine splittings in conjugated organic π-radicals, and in particular, carbocyclic radicals (1). Delocalization of the unpaired electron confers stability upon many annulene radicals, and they are often "persistent" species. There is, of course, no a priori reason why resonance stabilization should be restricted to carbocyclics, although relatively few persistent inorganic cyclic radicals are known. Notable exceptions are provided by the cyclic sulphur and sulphur–nitrogen radicals (2). This dearth of persistent inorganic cyclic radicals is all the more surprising in view of the considerable number of known stable inorganic radicals, such as O_2, NO, NO_2, ClO_2, etc. A particularly simple and remarkably persistent inorganic radical, which is often a by-product of reactions of sulphur–nitrogen compounds in polar solvents, is the sulphur nitride cation $S_3N_2^+$ (3–8). Recent crystallographic and esr spectroscopic studies (6–9) have shown that this species is a planar π-radical having the structure shown in Fig. 1. As part of a programme of studies of this prototypal free radical and its derivatives, we report here the results of an esr investigation of certain selenium analogues.

Experimental

$Se_4(AsF_6)_2$ was prepared by the reaction of elemental selenium with an excess of AsF_5 containing a trace of bromine (10, 11).[2] S_4N_4 was prepared by a modification[3] of an established procedure (14). $Se_8(AsF_6)_2$ was obtained by a modification of the recipe of Gillespie and Ummat (15), and $SNAsF_6$ by the reaction of $S_3N_3Cl_3$ with three equivalents of $AgAsF_6$ (16). Deuteriosulphuric acid (99.5% isotopically pure), purchased from Aldrich, and sulphur dioxide from Matheson were used as received.

The reaction between $Se_4(AsF_6)_2$ and S_4N_4 was used to generate (17) the compound $(Se_2N_2S)_2(AsF_6)_2$. Although the portion of the products least soluble in SO_2 gave an elemental analysis appropriate for that formulation, esr spectra (see below) cast some doubt on the purity of the product. Accordingly, the product was treated further by

oxidation with AsF_5 and a trace of bromine as a "facilitating agent" (10, 11).[2] The weights of products and reactants were consistent with a new formulation $(Se_2N_2S)(AsF_6)_2$, and an X-ray crystallographic structural determination confirmed the formation of the $Se_2N_2S^{2+}$ 6π doubly charged cation.[4] This compound $(Se_2N_2S)(AsF_6)_2$ constitutes sample A for the purposes of further discussion.

A solid sample containing crystals of $(Se/SSN_2S)_2(AsF_6)_2$, where Se/S denotes 50% occupancy by Se and S, was prepared from a reaction of $Se_8(AsF_6)_2$ and four equivalents of $NSAsF_6$ in SO_2 solution. The less soluble $Se_4(AsF_6)_2$ was precipitated from a supernatant liquid that yielded a mixture of yellow and black crystals upon removal of solvent. One of the black crystals was shown to be $(Se/SSeN_2S)_2(AsF_6)_2$ by single-crystal X-ray crystallography.[4] The black crystals were sorted from the yellow by hand in a dry-box, and these constituted sample B.

Minute quantities ($\approx$1 mg) of each of compounds A and B were transferred in turn to a 3-mm borosilicate esr tube under an atmosphere of dry nitrogen in a standard dry-box. Deuteriosulphuric acid was added at this stage or, alternatively, the tubes were capped and attached to a vacuum line for the addition of SO_2. After the addition of sufficient solvent to ensure complete dissolution of all the solid, the tubes were sealed under vacuum and transferred to the resonant microwave cavity of a Varian E-12 or a Bruker ESP 300 spectrometer. Temperature control in the esr cavity was achieved with liquid nitrogen, with a regulated flow of cold nitrogen, or with an Oxford Instruments' liquid helium cryostat. Microwave frequencies were measured with a Systron–Donner frequency counter and dc magnetic fields with a Cyclotron Corporation gaussmeter.

Results

Single, broad, featureless absorptions were the dominant features of the esr spectra (Fig. 2) of both A and B in liquid SO_2 or liquid D_2SO_4. The isotropic g-factor of A was larger than that of B, as was its linewidth. An additional weak feature of the solution spectra (Fig. 2) consisted of a 1:2:3:2:1 quintet with isotropic g, ^{14}N hyperfine coupling, and linewidth parameters characteristic of the radical $S_3N_2^+$ (7, 8). This radical was clearly present in traces only and its spectral intensity varied from sample to sample.

To minimize the extent of decomposition of the selenium-containing cations and reduce the complexity of the powder spectra, samples were dissolved in solvent in as short a time as possible, then frozen and kept in liquid nitrogen. In this manner, interference from the purely sulphur-containing species was essentially eliminated, and the powder spectra (Figs. 3, 4) are those of the selenium-containing radicals. Both powder spectra bear a close resemblance to the known spectrum of $S_3N_2^+$ (7, 8) with three distinct g-features, only one of which displayed a resolved hyperfine manifold due to interaction with two equivalent ^{14}N ($I = 1$) nuclei (Figs. 3, 4). For the purposes of comparison, a spectrum of $S_3N_2^+$ was generated by the reaction of $NS_2^+AsF_6^-$ with tetrahydrofuran vapour (19), followed by

dissolution in SO_2 or D_2SO_4. g-factors and ^{14}N hyperfine interactions were determined from the turning points of the powder spectra, and their values (Tables 1, 2) were confirmed by spectral simulation (20). Spectra in D_2SO_4 were considerably weaker than in SO_2, and a number of features, particularly those of $Se_3N_2^+$, were only detectable in the latter matrix.

The esr spectra were obtained in similar fashion from the portion of products of the reaction (17) between $Se_4(AsF_6)_2$ and S_4N_4 that was least soluble in SO_2 (see experimental section). However, these spectra were more complex than those obtained from either A or B, and closer inspection showed that they were due to a mixture of all four title radicals.

Discussion

The striking similarity of the powder spectra of A and B to that of 1,2,4,3,5-trithiadiazolyl (7, 8) leaves little doubt that the carriers are all closely related free radicals. The spectra of A and B (Figs. 3, 4) were readily simulated (20) using parameters, given in Table 1, that closely resemble those of $S_3N_2^+$.

Simulation did not, however, reproduce the "doublet" structure apparent in the g_{zz} and g_{xx} features of A (Fig. 3). This doubling of lines in the spectrum of A is due, we believe, to the presence of two very similar radicals, $\overline{SNSeSeN}^+$ and $\overline{SeNSeSeN}^+$, rather than to the occurrence of two distinct trapping sites for the same species. The formation of both radicals from A was somewhat surprising, and must be the result of complex reactions following the initial reduction of the dication $\overline{SNSeSeN}^{2+}$ in solution. Examination of crystals of A indicated the complete absence of paramagnetic impurities. The g-factors, discussed below, support our contention that the spectra obtained from A arose from a mixture of the two radicals. Furthermore, we note that the same doubling of lines occurred in D_2SO_4, and that multiple trapping sites were not observed for either $\overline{SNSSN}^+$ or $\overline{SNSeSN}^+$. We have considerable confidence, therefore, in our assignment of the spectrum of B to $\overline{SNSeSN}^+$ and that of A to a mixture of $\overline{SeNSeSeN}^+$ and $\overline{SNSeSeN}^+$. Trace amounts of $S_3N_2^+$ were also present (Fig. 2) in both cases. It should also be pointed out that one crystal of B was shown by X-ray crystallography[4] to be $\overline{SNSe/SSeN}^+$, with one position occupied by 50% Se and 50% S atoms. It is conceivable that the Se/S ratio is variable, and that the particular samples chosen for esr study had a larger percentage content of S than the crystal used for the X-ray structure determination.

The esr measurements on $S_3N_2^+$ in liquid, polycrystalline, and single-crystal samples have shown beyond any doubt that it has the planar C_{2v} geometry of Fig. 1 and an $^2A_2$ ground state (7–9). Experiment has shown that the two equivalent sulphur nuclei in that species make important $3p_x$ contributions to the SOMO, whereas the unique sulphur nucleus makes only a small, indirect contribution through spin polarization (7–9). Theoretical calculations at the Hückel level, summarized in Fig. 5 and Table 3, agree extremely well with the experimental findings, whereas INDO calculations overemphasize the polarization contribution at the unique atom (7). Accordingly, one would expect substitution of selenium for sulphur at the equivalent positions to exert a considerable influence on the electronic parameters, but much less so at the unique position.

[a]Half-filled orbital.
[b]Energy in hartrees.

This expectation is realized, for example, in the effect of selenium substitution on the principal g-values, particularly g_{zz} (Table 1).

The displacement of g from the free-spin value are determined by the relative disposition of ground and excited electronic states that are connected by the spin-orbit interaction operator, and by the size of the atomic spin-orbit coupling parameters. Δg values in the present instance are given by a simplification of the Stone formula (21):

$$\Delta g = \frac{2}{(E_0 - E_n)} \cdot (\Sigma \lambda_i c_{gi} c_{ei})(\Sigma c_{gi} c_{ei})$$

where c_{gi} and c_{ei} are p-atomic orbital coefficients of atom i in the ground- and excited-state wavefunctions connected by spin-orbit interaction, and E_0 and E_n are the energies of the ground and excited SOMOs. As we have shown elsewhere (9), the application of this formula to the Hückel molecular orbitals of $S_3N_2^+$ readily accounts for the observed ordering of the principal g-values with respect to the free-spin value, viz. $g_{zz} \gg g_{yy} > g_e > g_{xx}$. Since the spin-orbit coupling constants of ^{77}Se, ^{33}S, and ^{14}N are in the ratio of 22:5:1 (12), we may justifiably ignore the contributions of the nitrogen nuclei to the g-shifts of these radicals. If we furthermore assume that the excitation energy does not change significantly in the series of radicals, $\overline{SNSSN}^+$, $\overline{SNSeSN}^+$, $\overline{SNSeSeN}^+$, and ignore contributions from the unique S nucleus, we predict from the simplified Stone expression g-shifts in the ratio 1:2.7:4.4. For $H_0 /\!/ z$, the axis of greatest g-shift, the ratio of experimental shifts, 1:3.0:5.7, is in fair accord with this prediction. Along the other axes, the agreement with prediction is poor, but the anticipated trend is correct, i.e., increasing departure of g from the free-spin value with increasing selenium substitution. The substitution of the unique sulphur nucleus by selenium has very little effect on the spectral parameters of the radical, as shown by the comparison of the data for $\overline{SNSeSeN}^+$ and $\overline{SeNSeSeN}^+$ (Tables 1, 2). This weak influence is due to the absence of direct contributions from the unique atom to the SOMO. Nevertheless, further small increases in both Δg_{xx} and Δg_{zz} are observed upon replacement of the last sulphur atom by selenium.

TABLE 4. Estimated unpaired spin populations[a] of valence atomic s and p orbitals in selenothiadiazolyl radicals

	p_x	45.1	45.3	52.3	
S_4	s				0.2
	p_x				(−)13.8

[a]Percentage unpaired spin populations estimated using parameters of ref. 13 and experimental hyperfine tensors of Table 1 and ref. 8.

Turning now to the nuclear hyperfine interactions (Tables 1, 2), we note firstly the decrease in a_{xx} for the two equivalent ^{14}N nuclei as sulphur is replaced by selenium. This drift of unpaired spin away from the nitrogens is the anticipated result of replacing sulphur by the more electropositive selenium in an *antibonding* (Fig. 1) orbital. To place the effect on a more quantitative basis, we have converted (Table 4) the hyperfine couplings of Table 1 into unpaired spin populations of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/07/12
For personal use only.

atomic s and p orbitals using theoretical one-electron parameters (13). In so doing, we have assumed that, as found experimentally for ^{33}S (8, 9), the signs of a_{yy} and a_{zz} for ^{77}Se are opposite to that of a_{xx}. Since the summed spin populations then exceed unity, we assume that the excess represents negative spin density on the unique S (or Se) nucleus, for which a coupling has not been observed or measured in this work. In the case of the $S_3N_2^+$ radical, hyperfine coupling to the unique sulphur nucleus has been measured (7–9), and the assumption of a negative spin density leads (Table 4) to an excellent spin count. With these assumptions, we see that the shift of unpaired spin indicated by the nitrogen hyperfine couplings is confirmed by the increased spin density at the equivalent selenium positions. In the case of the monoselenium radical, the lone selenium nucleus apparently gains spin at the expense of the nitrogen and remaining sulphur nuclei. Strictly speaking, this radical has lower symmetry (C_s) than the others and has geometrically inequivalent nitrogen nuclei. The ^{14}N manifold of $\overline{SNSeSN}^+$ did in fact differ from those of the other three radicals (Fig. 3), in that the inner three lines of the quintet had a width and asymmetry suggestive of an incompletely resolved hyperfine manifold due to inequivalent ^{14}N nuclei.

The disparity in linewidths of the liquid-phase spectra (Table 1) is a direct consequence of the increased g-anisotropy occasioned by selenium substitution. In the McConnell expression (18) for epr spectral linewidths in solution,

$$[T_2(m_I)]^{-1} = A + Bm_I + Cm_I^2$$

the coefficients A, B, C are proportional to the inner products of the anisotropic **g**- and hyperfine tensors, **g**:**g**, **g**:**a**, and **a**:**a**, respectively. The variation in linewidth across the ^{14}N manifold of $\overline{SNSSN}^+$ (7, 8) clearly indicates that the second term in this expression is an important one. If, in fact, it is the dominant term, we would anticipate a ratio of linewidths of 1:3:4:4 for the four species. If, on the other hand, the first term is dominant, we would expect a ratio of 1:11:39:41, which is very much in line with the observed ratio of linewidths (Tables 1, 2). We conclude, therefore, that the m_I-independent term makes the major contribution to the isotropic spectral linewidth. It is, of course, this strong dependence of linewidth on g-anisotropy which unfortunately obliterates the ^{14}N hyperfine structure of the selenium-containing radicals in solution.

All of the data presented here reinforce our original assignments of a C_{2v} geometry and an $^2A_2$ ground state (Fig. 1) to trithiadiazolyl. Furthermore, the trends observed in the spectral parameters upon substitution of sulphur by selenium conform very well to quantum theoretical expectations. The structure of this important class of simple inorganic cyclic free radicals is now firmly established.

Received August 12, 1987

EDOUARD C. VAUTHIER, MICHEL COMEAU, SIMONE ODIOT, and SANDOR FLISZAR. Can. J. Chem. **66**, 1781 (1988).

Dia- and paramagnetic shielding constants of HF, NH_3, N_2, H_2O, and CO were calculated in the 4-31G, 4-31G*, and 6-31G** bases, using gauge-invariant atomic orbitals. Correlation effects were evaluated by 2nd-order perturbation theory: while the diamagnetic contributions are virtually unaffected by correlation, the paramagnetic parts (σ_p) are modified by ~10 ppm in the 6-31G** basis. With or without correlation, calculated σ_p values differ significantly from results obtained from measured spin-rotation constants. However, improvements in the basis set descriptions and inclusion of correlation yield chemical shift values for ^{15}N and ^{17}O converging toward their experimental counterparts obtained from conventional nuclear magnetic resonance spectroscopy.

EDOUARD C. VAUTHIER, MICHEL COMEAU, SIMONE ODIOT et SANDOR FLISZAR. Can. J. Chem. **66**, 1781 (1988).

Des orbitales atomiques gauge invariantes sont utilisées pour le calcul des constantes d'écran dia- et paramagnétiques des molécules HF, NH_3, N_2, H_2O et CO dans les bases 4-31G, 4-31G* et 6-31G**. L'effet de la corrélation électronique est évalué par perturbation au 2e ordre : celle-ci est pratiquement sans effet sur la partie diamagnétique mais modifie la partie paramagnétique (σ_p) d'environ 10 ppm dans la base 6-31G**. Les valeurs de σ_p avec et sans corrélation diffèrent sensiblement des valeurs déduites à partir de mesures de constantes spin-rotation. Par contre, une augmentation de base avec corrélation électronique fait converger les déplacements chimiques calculés pour ^{15}N et ^{17}O vers les valeurs expérimentales mesurées par voie traditionnelle.

Introduction

Ab initio calculations of magnetic shielding constants have been carried out using (*i*) the finite perturbation method (1–3), (*ii*) the coupled Hartree–Fock (CHF) approach (4–6), (*iii*) the IGLO formalism (7, 8), or (*iv*) a variant thereof (9). The first method has been applied either without (2) or with consideration of GIAO's (3, 10, 11), while the CHF approach has involved GIAO's (4, 5, 12–14) or GTO bases without gauge factors (15–17). The use of the latter in methods (*i*) and (*ii*) may be criticized since the vector potential, from which the magnetic field is derived, is determined only to within an arbitrary gradient; hence, an infinite basis is required to satisfy the special gauge invariance with respect to choice of the origin of the vector potential (18). In contrast, a gauge factor associated with each atomic orbital (GIAO) ensures this invariance with atomic orbital bases which are necessarily limited: the price to be paid is an increase in computer time because the presence of gauge factors requires evaluation of non-classical bielectronic integrals. Unfortunately, the use of GIAO's is not a panacea. Average deviations between calculated and experimental ^{13}C chemical shifts in alkanes and alkenes are ~8 ppm in the IGLO method (19) and ~5 ppm in semi-empirical (20, 21) and *ab initio* calculations (12). In short, there is room for improvement.

In order to improve numerical results, to save computer time, and to achieve an acceptable gauge invariance, GTO wave functions are expanded via configuration interaction (16, 17, 22) or a gauge factor is used with each molecular orbital. In the latter approach, the evaluation of non-classical bielectronic integrals is avoided by insertion of a completeness relation (8). The first alternative (16, 17, 22), however, leads to numerical results which are not entirely gauge invariant. In the HF molecule, for example, a translation of its molecular axes affects the calculated shielding of ^{19}F by 2 ppm (22). On the other hand, in comparison with calculations involving single determinants, the role of electron correlation appears to be important.

On these grounds it seems appropriate to ensure translational invariance with the use of gauge invariant (GIAO) orbitals and to consider correlation as well. To our knowledge, no formalism has yet been developed which would allow to retain correlation effects in gauge invariant calculations. In the present approach, electron correlation is treated by second-order perturbation theory (23), as indicated below.

Theory

The expression derived below for σ without correlation differs from that obtained in the traditional way using the GIAO basis. In the latter, $\vec{\sigma}$ is obtained by a double differentiation of $E(\vec{B},\vec{\mu}_M)$ after that a transformation $h|f_\nu\chi_\nu^0\rangle = f_\nu h_\nu|\chi_\nu^0\rangle$ is done leading to a diamagnetic term involving $\vec{r}_\nu\vec{r}_M/r_M^3$. It is possible to get the same diamagnetic term as Ramsey by following the Musher's approach (24) and developing the energy and ψ in term of $\vec{B}$ and $\vec{\mu}_M$. Let us shortly introduce our notations to go toward correlation, and improve the computation of bielectronic integrals with gauge factors in traditional CHF.

In the presence of a magnetic field $\vec{B}$ and a magnetic moment $\vec{\mu}_M$, the appropriate hamiltonian is

$$H_0(\vec{B},\vec{\mu}_M) = \sum_k \left[(1/2)(-i\hbar\vec{\nabla}_k + \frac{e}{c}\vec{A}_k)^2 + V_k \right]$$

$$\vec{A}_k = \frac{1}{2}\vec{B}\wedge\vec{r}_k + \frac{\vec{\mu}_M\wedge\vec{r}_{Mk}}{r_{Mk}^3}$$

Separating now the orders in $\vec{B}$ and $\vec{\mu}_M$, it follows that

$$H_0(\vec{B},\vec{\mu}_M) = H_0^0 + \vec{B}\sum_k\vec{h}^{10}(k) + \vec{\mu}_M\sum_k\vec{h}^{01}(k) + \vec{\mu}_M\sum_k\vec{\vec{h}}^{11}(k)\vec{B}$$

$$H_0(\vec{B},\vec{\mu}_M) = H_0^0 + \vec{B}\vec{H}_0^{10} + \vec{\mu}_M\vec{H}_0^{01} + \vec{\mu}_M\vec{\vec{H}}_0^{11}\vec{B}$$

with

[1]Visiting scientists. Permanent address: Département de Recherches Physiques, Université Pierre et Marie Curie (Paris V9), 4 place Jussieu, Tour 22, 75252 Paris Cedex 05, France.

$$\vec{H}_0^{10} = \sum_k \vec{h}^{10}(k) = \sum_k -\frac{ie\hbar}{2mc}\vec{r}_k \wedge \vec{\nabla}_k$$

$$\vec{H}_0^{01} = \sum_k \vec{h}^{01}(k) = \sum_k -\frac{ie\hbar}{mc}\frac{\vec{r}_{Mk} \wedge \vec{\nabla}_k}{r_{Mk}^3}$$

$$\vec{\vec{H}}_0^{11} = \sum_k \vec{\vec{h}}^{11}(k) = \sum_k \frac{e^2}{2c^2}\frac{\vec{r}_k\vec{r}_{Mk}\vec{\vec{1}} - r_k r_{Mk}}{r_{Mk}^3}$$

The wave function $\Psi_0(\vec{B},\vec{\mu}_M)$ of the ground state is described by a Slater determinant constructed from molecular orbitals having the form

$$\Phi_i(\vec{B},\vec{\mu}_M) = \sum_\mu C_{\mu i}(\vec{B},\vec{\mu}_M)\chi_\mu(\vec{B})$$

$$\chi_\mu(\vec{B}) = \chi_\mu^0 \exp\left(-\frac{ie}{\hbar c}\vec{A}_\mu.\vec{r}\right)$$

$$\vec{A}_\mu = \frac{1}{2}\vec{B} \wedge \vec{R}_\mu$$

Defining here

$$c_{\mu i}(\vec{B},\vec{\mu}_M) = c_{\mu i}^0 + i\vec{B}\ \mathrm{Im}\ \vec{x}_{\mu i}^{10} \ldots$$

$$\chi_\mu(\vec{B}) = \chi_\mu^0 - \frac{ie}{2\hbar c}\chi_\mu^0\vec{B}.\overrightarrow{R_\mu \wedge r}$$

we obtain the following expression for the molecular orbitals

$$\Phi_i(\vec{B},\vec{\mu}_M) = \Phi_i^0 + i\vec{B}\sum_\mu \vec{x}_{\mu i}^{10}\chi_\mu^0 - \frac{ie}{2\hbar c}\vec{B}\sum_\mu c_{\mu i}^0\overrightarrow{(R_\mu \wedge r)}\chi_\mu^0$$

The latter equation is conveniently rewritten in the following manner

$$\Phi_i(\vec{B},\vec{\mu}_M) = \Phi_i^0 + \vec{B}\vec{\Phi}_i^{10} + \vec{B}\vec{\Phi}_i^{10}(0)$$

where

$$\vec{\Phi}_i^{10} = i\sum_\mu \vec{x}_{\mu i}^{10}\chi_\mu^0$$

$$\vec{\Phi}_i^{10}(0) = -\frac{ie}{2\hbar c}\sum_\mu c_{\mu i}^0\overrightarrow{(R_\mu \wedge r)}\chi_\mu^0$$

At this point we turn our attention to the Schrödinger equation

$$H_0(\vec{B},\vec{\mu}_M)\Psi_0(\vec{B},\vec{\mu}_M) = E_0(\vec{B},\vec{\mu}_M)\Psi_0(\vec{B},\vec{\mu}_M)$$

and expand the wave function in terms of $\vec{B}$ and $\vec{\mu}$, i.e.,

$$\Psi_0(\vec{B},\vec{\mu}_M) = \Psi_0^0 + \vec{B}\vec{\Psi}_0^{10} + \vec{\mu}_M\vec{\Psi}_0^{01}$$

with energy

$$E_0(\vec{B},\vec{\mu}_M) = E_0^0 + \vec{B}\vec{E}_0^{10} + \vec{\mu}_M\vec{E}_0^{01} + \vec{\mu}_M\vec{\vec{E}}_0^{11}\vec{B}$$

Thus we arrive at Musher's formula

$$\vec{\vec{E}}_0^{11} = \langle\Psi_0^0|\vec{\vec{H}}_0^{11}|\Psi_0^0\rangle + 2\,\mathrm{Re}\langle\Psi_0^0|\vec{H}_0^{01}|\vec{\Psi}_0^{10}\rangle$$

which is instrumental in the derivation of the shielding tensor $\vec{\vec{\sigma}}$. Indeed, the second-order energy $\vec{\vec{E}}_0^{11}$ given in terms of molecular orbitals

$$\vec{\vec{E}}_0^{11} = 2\sum_{i=1}^n \langle\Phi_i^0|\vec{\vec{h}}^{11}|\Phi_i^0\rangle + 4\,\mathrm{Re}\sum_{i=1}^n \langle\Phi_i^0|\vec{h}^{01}|\vec{\Phi}_i^{10}\rangle + 4\,\mathrm{Re}\sum_{i=1}^n \langle\vec{\Phi}_i^0|\vec{h}^{01}|\vec{\Phi}_i^{10}(0)\rangle$$

leads directly to $\vec{\vec{\sigma}}$ in terms of atomic orbitals, i.e.,

$$[1]\quad {}^M\sigma_{\alpha\beta} = \frac{e^2}{2c^2}\sum_{\mu,\nu} P_{\mu\nu}^0\langle\chi_\mu^0\left|\frac{\vec{r}.\vec{r}_M\delta_{\alpha\beta} - r_\alpha r_{M\beta}}{r_M^3}\right|\chi_\nu^0\rangle + \frac{4}{c}\sum_{i=1}^{occ}\sum_{\mu,\nu}\mathrm{Im}\ x_{\nu i}^{10}(\beta)\, c_{\mu i}^0\langle\chi_\mu^0\left|\frac{l_{M\alpha}}{r_M^3}\right|\chi_\nu^0\rangle + \frac{e^2}{c^2}\sum_{\mu,\nu}P_{\mu\nu}^0\langle\chi_\mu^0\left|(R_\mu \wedge r)_\beta\frac{l_{M\alpha}}{r_M^3}\right|\chi_\nu^0\rangle$$

with $l_{M\alpha} = \overrightarrow{(r_M \wedge \nabla)}_\alpha$.

The imaginary coefficients, Im $x_{\nu i}^{10}(\beta)$, appearing in eq. [1] are calculated following the traditional coupled Hartree–Fock method with a separation of the orders in $\vec{B}$ and $\vec{\mu}_M$, and their projection, i.e.,

$$\mathrm{Im}\ \vec{x}_\nu^{10} = \sum_{l\neq i}^{basis}\vec{a}_{il}c_{\nu l}^0$$

The $\vec{a}_{il}$ coefficients are obtained by solving iteratively the equation

$$\vec{a}_{ji} = (\epsilon_j^0 - \epsilon_i^0)^{-1}\sum_{\mu,\nu} c_{\mu i}^0 c_{\nu j}^0(\vec{F}_{\mu\nu}^{10} - \epsilon_j^0\vec{S}_{\mu\nu}^{10})$$

for all i and j's. Moreover, letting

$$\sum_{\mu,\nu} c_{\mu i}^0 c_{\nu j}^0\vec{G}_{\mu\nu}^{10} = \sum_{\mu,\nu,\eta,\sigma}(\mu^0\nu^0|\eta^0\sigma^0)(c_{\mu i}^0 c_{\nu j}^0\vec{P}_{\eta\sigma}^{10} - \frac{1}{2}c_{\mu i}^0 c_{\sigma j}^0\vec{P}_{\eta\nu}^{10}) + \frac{e}{2hc}\sum_{\mu,\nu,\eta,\sigma}\left(\mu^0\nu^0\left|\frac{\overrightarrow{(R_\eta - R_\sigma)\wedge r_2}}{r_{12}}\right|\eta^0\sigma^0\right)\left(c_{\eta i}^0 c_{\sigma j}^0 P_{\mu\nu}^0 + c_{\mu i}^0 c_{\nu j}^0 P_{\eta\sigma}^0 - \frac{1}{2}\left(c_{\eta i}^0 c_{\nu j}^0 P_{\mu\sigma}^0 + c_{\mu i}^0 c_{\sigma j}^0 P_{\eta\nu}^0\right)\right)$$

where

$$\vec{P}_{\eta\sigma}^{10} = 2\sum_l^{occ}\sum_{i\neq l}^{basis}\vec{a}_{li}(c_{\sigma l}^0 c_{\eta i}^0 - c_{\eta l}^0 c_{\sigma i}^0)$$

calculations are *significantly simplified* because they involve evaluation of *only one type* of bielectronic integrals.

So far we have dealt exclusively with single determinantal wave functions. Consider now the second-order electronic correlation energy

$$E^{(2)}(\vec{B},\vec{\mu}_M) = \sum_{i\neq 0}\frac{\langle\Psi_0(\vec{B},\vec{\mu}_M)|H(\vec{B},\vec{\mu}_M)|\Psi_i(\vec{B},\vec{\mu}_M)\rangle^*\langle\Psi_0(\vec{B},\vec{\mu}_M)|H(\vec{B},\vec{\mu}_M)|\Psi_i(\vec{B},\vec{\mu}_M)\rangle}{W_0(\vec{B},\vec{\mu}_M) - W_i(\vec{B},\vec{\mu}_M)}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 61.7.252.67 on 09/07/12
For personal use only.

where the singlet diexcited states leading to 4,2,0 open shells are represented by $\Psi_i(\vec{B},\vec{\mu}_M)$. The corresponding Hartree–Fock energies are $W_i(\vec{B},\vec{\mu}_M)$. This correlation energy, expanded in terms of S^2 eigenfunctions, i.e.,

$$E^{(2)}(\vec{B},\vec{\mu}_M) = -2\sum_{i<j}\sum_{a<b}\frac{2(ib|ja)^*(ib|ja) + 2(ia|jb)^*(ia|jb) - (ia|jb)^*(ib|ja)}{\epsilon_a + \epsilon_b - \epsilon_i - \epsilon_j} - \frac{(ib|ja)^*(ia|jb)}{\epsilon_a + \epsilon_b - \epsilon_i - \epsilon_j}$$
$$- \sum_i\sum_{a<b}\frac{2(ia|ib)^*(ia|ib)}{\epsilon_a + \epsilon_b - \epsilon_i - \epsilon_i} - \sum_{i<j}\sum_a\frac{2(ia|ja)^*(ia|ja)}{\epsilon_a + \epsilon_a - \epsilon_i - \epsilon_j} - \sum_i\sum_a\frac{(ia|ia)^*(ia|ia)}{\epsilon_a + \epsilon_a - \epsilon_i - \epsilon_i}$$

is differentiated with respect to both $\vec{B}$ and $\vec{\mu}_M$. Thus we obtain the second-order Möller–Plesset correction, ${}^M\sigma_{\alpha\beta}(MP2)$, for the shielding tensor. The final result is

$${}^M\sigma_{\alpha\beta}(MP2) =$$
$$4\sum_{i<j}\sum_{a<b}(\epsilon_a^0 + \epsilon_b^0 - \epsilon_i^0 - \epsilon_j^0)^{-2}({}^M\epsilon_{a\alpha\beta}^{11} + {}^M\epsilon_{b\alpha\beta}^{11} - {}^M\epsilon_{i\alpha\beta}^{11} - {}^M\epsilon_{j\alpha\beta}^{11})((i^0b^0|j^0a^0)^2 + (i^0a^0|j^0b^0)^2 - (i^0a^0|j^0b^0)(i^0b^0|j^0a^0))$$
$$+ 2\sum_i\sum_{a<b}(\epsilon_a^0 + \epsilon_b^0 - \epsilon_i^0 - \epsilon_i^0)^{-2}({}^M\epsilon_{a\alpha\beta}^{11} + {}^M\epsilon_{b\alpha\beta}^{11} - {}^M\epsilon_{i\alpha\beta}^{11} - {}^M\epsilon_{i\alpha\beta}^{11})(i^0a^0|i^0b^0)^2$$
$$+ 2\sum_{i<j}\sum_a(\epsilon_a^0 + \epsilon_a^0 - \epsilon_i^0 - \epsilon_j^0)^{-2}({}^M\epsilon_{a\alpha\beta}^{11} + {}^M\epsilon_{a\alpha\beta}^{11} - {}^M\epsilon_{i\alpha\beta}^{11} - {}^M\epsilon_{j\alpha\beta}^{11})(i^0a^0|j^0a^0)^2$$
$$+ \sum_i\sum_a(\epsilon_a^0 + \epsilon_a^0 - \epsilon_i^0 - \epsilon_i^0)^{-2}({}^M\epsilon_{a\alpha\beta}^{11} + {}^M\epsilon_{a\alpha\beta}^{11} - {}^M\epsilon_{i\alpha\beta}^{11} - {}^M\epsilon_{i\alpha\beta}^{11})(i^0a^0|i^0a^0)^2$$

In this equation, it is

$${}^M\epsilon_{a\alpha\beta}^{11} = \left(\frac{\partial^2\epsilon_a(\vec{B},\vec{\mu}_M)}{\partial B_\beta\partial\mu_{M\alpha}}\right)_{\mu_{M\alpha}=B_\beta=0}$$

and, therefore,

$$\epsilon_{a\alpha\beta}^{11} = \frac{e^2}{2c^2}\sum_{\mu,\nu}c_{\mu a}^0c_{\nu a}^0\langle\chi_\mu^0\left|\frac{\vec{r}_\nu.\vec{r}_M\delta_{\alpha\beta} - r_{\nu\alpha}r_{M\beta}}{r_M^3}\right|\chi_\nu^0\rangle + \frac{e^2}{2c^2}\sum_{\mu,\nu}c_{\mu a}^0c_{\nu a}^0\langle\chi_\mu^0\left|((R_\mu - R_\nu)\wedge r)_\beta\frac{l_{M\alpha}}{r_M^3}\right|\chi_\nu^0\rangle$$
$$+ \frac{1}{c}\sum_{\mu,\nu}(c_{\mu a}^0\,\mathrm{Im}\,x_{\nu a}^{10}(\beta) - c_{\nu a}^0\,\mathrm{Im}\,x_{\mu a}^{10}(\beta))\langle\chi_\mu^0\left|\frac{l_{M\alpha}}{r_M^3}\right|\chi_\nu^0\rangle$$

Using here the equation

$$\langle\chi_\mu^0\left|\frac{\vec{R}_\nu.\vec{r}_M\delta_{\alpha\beta} - R_{\nu\alpha}r_{M\beta}}{r_M^3}\right|\chi_\nu^0\rangle = -\langle\chi_\nu^0\left|(R_\nu\wedge r)_\beta\frac{l_{M\alpha}}{r_M^3}\right|\chi_\mu^0\rangle - \langle\chi_\mu^0\left|(R_\nu\wedge r)_\beta\frac{l_{M\alpha}}{r_M^3}\right|\chi_\nu^0\rangle$$

which follows from the Hermitian property of the operator $l_{M\alpha}$, we deduce the final result given in eq. [2]

$$[2]\quad {}^M\epsilon_{a\alpha\beta}^{11} = \frac{e^2}{2c^2}\sum_{\mu,\nu}c_{\mu a}^0c_{\nu a}^0\langle\chi_\mu^0\left|\frac{\vec{r}.\vec{r}_M\delta_{\alpha\beta} - r_\alpha r_{M\beta}}{r_M^3}\right|\chi_\nu^0\rangle + \frac{e^2}{c^2}\sum_{\mu,\nu}c_{\mu a}^0c_{\nu a}^0\langle\chi_\mu^0\left|(R_\mu\wedge r)_\beta\frac{l_{M\alpha}}{r_M^3}\right|\chi_\nu^0\rangle$$
$$+ \frac{1}{c}\sum_{\mu,\nu}(c_{\mu a}^0\,\mathrm{Im}\,x_{\nu a}^{10}(\beta) - c_{\nu a}^0\,\mathrm{Im}\,x_{\mu a}^{10}(\beta))\langle\chi_\mu^0\left|\frac{l_{M\alpha}}{r_M^3}\right|\chi_\nu^0\rangle$$

Our diamagnetic term involving $1/c^2$ in eqs. [1] and [2] is the same as that obtained from a theory using a basis set without gauge factors and *thus depends on the origin defined for the molecular axes*. The other two terms in eqs. [1] and [2] represent the paramagnetic contribution. They differ, of course, from what would be obtained from a basis set without gauge factors. This is due to the presence in front of each AO of a gauge factor which introduces continually (i.e., for each AO) a gradient in the vector potential. As a consequence, we cannot compare our paramagnetic term to that determined from spin-rotation experiments, first because the latter corresponds to a fixed origin of the vector potential, defined either at the center of mass of the molecule or at the atom M of interest (25*b*) and, second, because our calculations involve a finite basis set. The use of an infinite basis set, of course, would lead to the paramagnetic term given by spin-rotation experiments whether or not we use gauge factors. Hence, tentatively we are inclined to judge the quality of our basis sets and of the correlation effects from a comparison between our calculated paramagnetic terms and those given by experiment.

Results

Using this approach, we have now calculated the average dia- and paramagnetic shielding constants of F, N, O in HF, NH_3, N_2, H_2O, and CO, locating the origin at the atom of interest. In each case, both the geometry and the basis sets (4-31G, 4-31G*, and 6-31G**) were carefully optimized. Our calculations are reported in Table 1 along with experimental results obtained from spin-rotation experiments. The agreement is only moderate for the reasons given earlier: while basis set and correlation effects, as revealed by second-order Möller–Plesset perturbation theory, are visibly significant in the evaluation of the paramagnetic terms, improvement in the basis sets and inclusion of correlation cannot be claimed to yield

Shift	Value							
	4-31G	4-31G MP2	4-31G*	4-31G* MP2	6-31G**	6-31G** MP2	Expl. *a*	Expl. *b*
$\delta_{N_2}^{NH_3}$	385.6	380.2	346.9	339.5	344.8	343.6	326.16 ± 0.08	330.9 ± 0.08
$\delta_{H_2O}^{CO}$	435.6	496.0	383.2	422.8	378.1	382.5	386.3 ± 1	394.4 ± 1

[a]The experimental values follow from conventional nmr measurements, in the gas phase at 300 K, reported in ref. 32 for NH_3/N_2 and in ref. 31 for CO/H_2O. In the liquid phase, at 300 K, the results are 307.0 for $\delta_{N_2}^{NH_3}$ (35) and 353.3 ppm for $\delta_{H_2O}^{CO}$ (31). For a discussion of the difference between gas phase and liquid phase results, see ref. 32.
[b]Experimental shift corrected of rovibronic effects. See text.

results converging toward their experimental counterparts. The most striking effects appear with a change of basis, and the best results are with the 6-31G** basis set. In this basis, inclusion of correlation worsens the calculation in nearly all cases. Our calculated values for the total shielding tensor $\bar{\sigma} = \sigma^d + \sigma^p$ at 0 K without MP2 at the 6-31G** level are only respectable in comparison with experimental values at 300 K, provided that these latter are carefully selected. A word of caution is in order, however, regarding this type of assessment involving data derived from spin-rotation experiments; a problem discussed in detail by Jameson and co-workers (32), and in our case for $\bar{\sigma}$ of N_2: for this molecule an old spin-rotation measurement gives $\sigma^p(N_2) = -485.8 \pm 20$ ppm leading to $\bar{\sigma}(N_2) = 384.5 - 485.8 = -101.3 \pm 20$ ppm, but Jameson gives $\bar{\sigma}(N_2) = -61.6$ ppm from an nmr measurement of the chemical shift between NH_3 and N_2 (32). On the other hand, using Huzinaga's extended basis Schindler and Kutzelnigg calculate a total shielding of nitrogen, namely, −108.4 ppm in N_2 (33) supporting the spin-rotation experimental value, but in contrast our computed $\bar{\sigma}$ value for N_2, namely, −72.2 ppm supports the value −61.6 ppm of Jameson and not the spin-rotation value -101.3 ± 20 ppm. Later we shall see also that our computed chemical shift $\delta_{N_2}^{NH_3}$ agrees with Jameson's experimental shift 326.16 ppm supporting also the experimental $\sigma^p(NH_3) = -90.06$ ppm.

Temporarily leaving the problems regarding the nitrogen shielding constants, let us briefly examine the results deduced for oxygen. For H_2O no direct spin-rotation data are available, but from nmr measurement of $\delta_{H_2O}^{CO} = 386.3 \pm 1$ ppm and assuming $\bar{\sigma} = -42.3 \pm 17.2$ for CO (31), a total shielding of 344.0 ± 17.2 ppm is deduced for H_2O at 300 K and finally 357.6 ± 17.2 ppm at 0 K (with the value 13.6 ppm for rovibronic corrections). Our computed 6-31G** values for $\sigma(H_2O) = 341.4$ ppm and $\sigma(CO) = -36.6$ ppm are in reasonable agreement with experimental values 357.6 ± 17.2 and -42.3 ± 17.2 ppm, respectively. For H_2O the total

For personal use only.

shielding calculated by Schindler and Kutzelnigg is 327.4 (7) and −84.1 ppm for CO (33). As a consequence the difference between the CO and H_2O oxygen calculated in the Schindler approach amounts to 411.5 ppm, a value differing significantly from its nmr experimental counterpart 386.3 ± 1 (Table 2).

Inspection of Table 2 suggests that our calculated shift for NH_3 (from N_2), namely, 343.6 converges toward its experimental counterpart obtained from conventional gas phase nmr measurement; 326.16 (32) and not toward the shift deduced from spin-rotation data; 375 ± 25 and seems to confirm the conclusion of Jameson (32) concerning the imprecision for $\sigma^p(N_2)$ issued from spin rotation. Going from 4-31G to 6-31G** MP2 we gain 42 ppm toward the experimental shift for $\delta_{N_2}^{NH_3}$ and 53 ppm in the same direction for $\delta_{H_2O}^{CO}$. Admittedly the improvement appears to be relatively small for $\delta_{N_2}^{NH_3}$ since we are, still, 17 ppm removed from the experimental shift at 300 K. In fact we must take into account rovibronic corrections in comparing our computed chemical shift at the equilibrium geometry with the experimental counterpart at 300 K; recently Jameson and Osten have reported values for $\sigma(300\,K) - \sigma_e$ for a set of molecules: with Table 13 of ref. 36 and experimental values at 300 K (Table 2) we deduce $\delta_{H_2O}^{CO}(r_e) = \delta_{H_2O}^{CO}(300\,K) + 13.0 - 4.88 = 394.4 \pm 1$ and our computed 6-31G** MP2 value (382.5) is in disagreement by ≃11.9 ppm. For N_2 and NH_3 we get from the same reference $\delta_{N_2}^{NH_3}(r_e) = \delta_{N_2}^{NH_3}(300\,K) - 3.49 + 8.3 = 330.9$ ppm and our 6-31G** MP2 value (343.6) is imprecise by 12.6 ppm. Indeed Table 2 confirms the important roles of correlation and *basis set* in reproducing the nmr shift.

Nevertheless, no definite statement can be made as to how important correlation effects of nmr shielding constants in HF, NH_3, H_2O, N_2, CO may be. For theoretical reasons explained earlier concerning the use of an infinite basis set when gauge factors occur, it would become necessary to perform computations with a nearly saturated basis set: the 6-31G** basis is far from saturated and MP2 is partly compensating, in the wrong direction, for inadequacy of the basis: MP2 is not worth doing at this level. This conclusion is itself a worthwhile thing for other workers to know about. Improvement of the calculations start, *first*, with a search of a better basis set and secondly with higher corrections in the correlation: the theory outlined above can be extended to give MP4 corrections for the shielding tensor. Another way to improve numerical results would be to use the Xα theory without gauge factors reviewed in ref. 37 by incorporating an appropriate α.

Long-range formyl proton coupling constants of 4-X-phenyl formates (X = H,F,CH_3,NO_2) and 2,6-dichlorophenyl formate. Conformations in solution

TED SCHAEFER, RUDY SEBASTIAN, AND GLENN H. PENNER
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received November 9, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

TED SCHAEFER, RUDY SEBASTIAN, and GLENN H. PENNER. Can. J. Chem. **66**, 1787 (1988).

The signs and magnitudes of the long-range coupling constants between the formyl and ring protons over five, six, seven, and eight bonds in phenyl formate and its 4-fluoro, 4-methyl, and 4-nitro derivatives are reported. These numbers are combined with CNDO/2 and INDO MO FPT computations of their conformational dependence and with STO-3G MO populational distributions to provide a description of the conformational behaviour of these molecules. The *Z* conformers, predominantly nonplanar and having the carbonyl group pointing towards the ring, appear to account for more than 95% of the molecules in CS_2 solution at 300 K. In polar solvents, significant populations of the *E* conformers are indicated by the long-range coupling constants. The long-range coupling constants for the formyl proton in 2,6-dichlorophenyl formate are consistent with geometry-optimized STO-3G MO computations, which imply that the *Z* conformation, with the aldehyde group lying near the plane perpendicular to the benzene plane, is again at least 95% abundant at 300 K. The proton chemical shifts are also consistent with these conclusions.

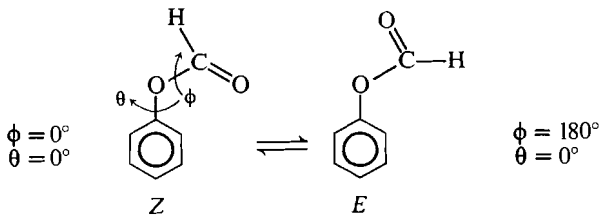
TED SCHAEFER, RUDY SEBASTIAN et GLENN H. PENNER. Can. J. Chem. **66**, 1787 (1988).

On a déterminé les signes et les amplitudes des constantes de couplage à longue distance entre les protons du groupement formyle et ceux du cycle à travers cinq, six, sept et huit liaisons du formate de phényle et de ses dérivés fluoro-4, méthyl-4 et nitro-4. On a combiné ces valeurs avec celles obtenues à l'aide de calculs d'OM CNDO/2 et INDO sur leur dépendance conformationnelle ainsi qu'avec celles de distributions de populations évaluées par des calculs d'OM STO-3G pour obtenir une description du comportement conformationnel de ces molécules. En solution dans le CS_2, à 300 K, il semble que 95% des molécules existent comme conformères *Z*, qui sont principalement non-planaires et dans lesquels le groupement carbonyle est orienté vers le cycle. Dans les solvants polaires, les constantes de couplage à longue distance indiquent qu'il existe une proportion importante de conformères *E*. Les constantes de couplage à longue distance pour le proton formyle du formate de dichloro-2,6 phényle sont en accord avec les calculs d'OM STO-3G optimisés pour la géométrie: ils indiquent que, à 300 K, la conformation *Z*, dans laquelle le groupement aldéhyde est pratiquement perpendiculaire au plan du benzéne, correspond à au moins 95% des molécules. Les déplacements chimiques du proton sont aussi en accord avec ces conclusions.

[Traduit par la revue]

Introduction

An early discussion of the conformational behaviour of phenyl formate suggested a nearly planar *Z* form, planar because of resonance stabilization, *Z* because of a favorable interaction between the C═O and O—C(1) dipoles and because of a



minimal repulsion between the lone-pair electrons on the two oxygen atoms (1). Consistent with the existence of only one conformer is the presence of only one carbonyl stretching band in both CS_2 and CH_3CN solutions (1).

A recent study of spin–spin coupling constants over six bonds between ^{19}F and ^{13}C nuclei in 4-F-phenyl esters concluded that ^6J(C,F) is consistent with severely nonplanar *Z* conformations (2*a*). Geometry-optimized STO-3G MO computations for a grid of θ and ϕ values implied that less than 3% of the most stable *E* conformer (at θ = 60°) would be present at 300 K. Rotation about the O—C(1) bond was computed to have a relatively low barrier and the expectation value of θ was predicted as 58° at 300 K and that of $\sin^2\theta$ as 0.68, in excellent agreement with the value (2*a*) obtained from ^6J(C,F).

Although ^6J(C,F) was consistent with a nonplanar *Z* conformer, it could not be shown that ^6J(C,F) would not also agree with a nonplanar *E* conformer (ϕ near 180° instead of 0°). A referee of that paper (2*a*) suggested the measurement of ^7J(H,F) in 4-fluorophenyl formate because this coupling constant might well be sensitive to the orientation of the aldehyde group.

It turns out that ^7J(H,F) is very small indeed. However, the coupling constants over five and six bonds between the aldehydic proton and the *ortho* and *meta* ring protons, when combined with CNDO/2 and INDO MO FPT computations, are informative about the nonplanarity of the molecule and appear to distinguish between *Z* and *E* conformers. This paper reports on the measurement of these parameters under very high resolution in phenyl formate and its 4-fluoro, 4-methyl, 4-nitro, and 2,6-dichloro derivatives.

Experimental

Phenyl formate and 4-nitrophenyl formate came from Aldrich, while the 4-fluorophenyl formate was synthesized in this laboratory (2*a*). The 4-methylphenyl formate and 2,6-dichlorophenyl formate were obtained in small amounts from the corresponding phenols by the procedure in the literature (2*b*), but reaction times were increased to 33 days. Samples for nmr analysis were prepared in a CS_2/C_6D_{12}/TMS mixture, containing 10 mol% of the deuterated cyclohexane and 0.5 mol% of tetramethylsilane. The phenyl formate sample had a concentration of 0.7 mol% and the sample containing the 4-nitro derivative was very dilute, certainly less than 0.7 mol%. A 5.0 mol% solution of 4-fluorophenyl formate in the solvent mixture above, containing a tiny amount of C_6F_6, was transferred to a 5 mm o.d. sample tube via a pipette containing a wad of cotton wool; the other samples were treated similarly. Degassing of the sample tubes by the freeze–

pump–thaw technique was followed by flame sealing to produce a symmetrical closure. Samples in other solvents were prepared in the same way.

The ^{1}H nmr spectra were accumulated at a probe temperature of 300 K on a Bruker AM300 spectrometer. The general procedure necessary to produce narrow peaks has been described previously (3). Peak widths at half-height of as little as 0.03 Hz or less were attainable.

The signs of the coupling constants between the aldehydic and ring protons in phenyl formate were found by weak irradiation (4) experiments. Simulations of double resonance spectra with the computer program DOR (5), as modified in this laboratory, confirmed the signs of the long-range coupling constants deduced by visual inspection.

Results and discussion

Spectral analyses and sign determinations

The ^{1}H nmr spectra were analyzed with the computer program NUMARIT (6), as reworked in this laboratory, and some of the ensuing spectral parameters appear in Table 1. There exist no significant correlations of those of the aldehyde proton with other spectral parameters. Figure 1 illustrates the sign determinations of ^5J, ^6J, and ^7J, the coupling constants between the aldehydic proton and the ring protons in phenyl formate. The aldehydic proton nmr spectrum is also shown for 4-fluorophenyl formate.

The long-range couplings to the aldehyde proton

One striking aspect of $^{5,6,7}J$ is their positive sign. Anisole, for example (7), displays alternating signs for $^{5,6,7}J$, as does thioanisole (8). In anisole, ^5J is negative as a consequence of a through-space or proximate interaction of the orbitals in the *ortho* C—H bond with those in the methyl group (9) in the stable planar form of this molecule. In phenyl formate, ^5J is +0.41 Hz, an immediate indication that the planar *E* form is not the predominant conformer. This indication is supported by our CNDO/2 and INDO MO FPT (10, 11) computations, which do predict a negative ^5J for the planar *E* conformation. These computations were performed for a grid of θ and φ values, namely, $0° \leq \theta \leq 90°$ in steps of 15°, together with $0° \leq \phi \leq 180°$ in steps of 30°. Note that $\theta = 0°$, $\phi = 0°$ defines the planar *Z* conformer, while $\theta = 0°$, $\phi° = 180°$ defines the planar *E* conformer.

Rather than tabulate some 500 computed coupling constants, Figs. 2 and 3 display the computed θ dependence of ^5J and ^6J. The curves are only drawn for the extremes of φ, that is, for $\phi = 0°$ (*Z* conformer) and $\phi = 180°$ (*E* conformer). Intermediate values of φ produce plots lying between these extremes.

The θ dependence of ^5J in Fig. 2 is perhaps unanticipated. Thus, in the *Z* conformation the largest value is calculated for an "anti-zigzag" arrangement of the intervening bonds at $\theta = 0°$. In the *E* conformation large and negative ^5J values occur at $\theta = 0°$, perhaps as anticipated because of probable through-space or proximate interactions between the orbitals in the *ortho* and aldehydic C—H bonds. Note also that for this conformation the CNDO/2 values for ^5J go effectively to zero at large values of θ, while the INDO numbers remain significantly negative throughout the range of θ.

Now, the geometry-optimized STO-3G MO energies of phenyl formate (2*a*) allow a calculation of the population distribution at 300 K, the temperature of the nmr experiments. It appears that 93.4% of the free molecules should exist in the *Z* conformation ($\phi = 0°$), another 4.2% in the conformation with $\phi = 30°$, and 2.1% as the pure *E* conformers ($\phi = 180°$). Combination of these populations and their θ distributions with the theoretical coupling constants yields ^5J as 0.374 and 0.286

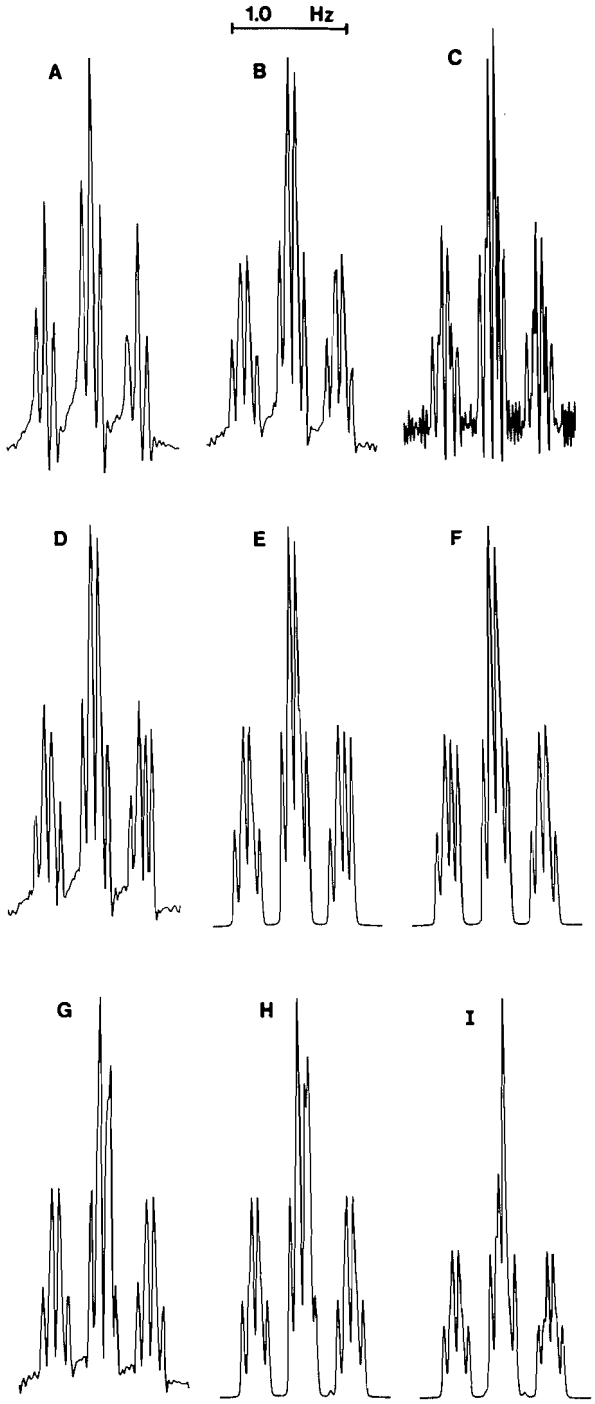

FIG. 1. In A the aldehydic proton nmr spectrum of 4-fluorophenyl formate is shown at 300 MHz and 300 K for a 5.0 mol% solution in a CS_2 solvent mixture (see Experimental). The linewidth at half-height is less than 0.03 Hz and no evidence for a coupling interaction with ^{19}F is present. In B the aldehyde proton of a 0.7 mol% solution of phenyl formate displays coupling interactions with all ring protons. In C severe resolution enhancement procedures show that the inner peaks of the apparent quartets in B can be further resolved. Of course, the ring proton nmr spectrum displays all the expected doublets and with clean resolution. In D the *para* ring protons are being weakly irradiated (low frequency region), demonstrating that ^5J(H-2,HCO) $\equiv$ ^5J, and ^6J(H-3,CHO) $\equiv$ ^6J are positive with respect to the positive coupling constants within the ring. In E the computed double resonance spectrum is displayed, assuming a B_2 field of 0.20 Hz and positive signs for ^5J and ^6J. The computed spectrum assumes peak widths of 0.025 Hz, causing fine structure of the inner bands (compare C). The important comparison with D should be made at the right of the spectra. In F the computed spectrum assumes a negative ^5J for the irradiation conditions in D. In G the *meta* proton region is being irradiated (low frequency region). The computed spectrum in H assumes ^5J and ^7J as positive, that in I has ^7J as negative. A complete series of experiments and simulations leaves no doubt that all couplings to the aldehyde proton are positive.

Hz with the INDO and CNDO/2 approaches, respectively. The populations with $\phi > 0°$ contribute -0.011 Hz to the value for the INDO numbers. According to Fig. 2, large populations of the *E* conformer would give rise to a negative ^5J, the observed value, however, being $+0.41$ Hz (Table 1) in the nonpolar solvent, CS_2. Because the conformational dependence of long-range coupling constants between side-chain nuclei and ring protons is usually computed correctly qualitatively and often quantitatively (9, 12–14), it is likely that the present results do indeed exclude significant populations of the *E* conformer. Previously, the ^6J(C,F) values in 4-fluorophenyl formate (2*a*) gave information about the θ but not the ϕ preferences.

Turning to ^6J, its computed dependence for the *Z* and *E* conformers is shown in Fig. 3. For the *Z* conformer, the INDO values are described by $^6J/\text{Hz} = -0.03 + 0.52 \sin^2(\theta/2)$ to within an average deviation of less than 0.005 Hz. This dependence is reminiscent of the σ electron component of $^5J(H,CH_3)$, involving the *meta* protons, in toluene (15, 16). It may also be noted that INDO values for coupling interactions of side chain nuclei with *meta* protons are usually overestimated (12, 17) although their conformational dependence is given correctly qualitatively. For example, in benzaldehyde the aldehyde proton coupling constant with the *meta* protons is computed as 0.90 Hz, whereas the CNDO/2 value is 0.46 Hz (17), much closer to the experimental value of 0.43 Hz (18). It is therefore not surprising that the INDO values of ^6J for phenyl formate correspond to a population-weighted average of 0.22_3 Hz, rather larger than the measured 0.08_1 Hz, but that the CNDO/2 numbers yield 0.10_5 Hz, perhaps in acceptable agreement with observation. Further, noting that the *E* conformer has computed ^6J values lying between -0.08 and $+0.04$ Hz (Fig. 3) for $0° \leq \theta \leq 180°$, it again appears that the observed ^6J in phenyl formate is consistent with the conformational conclusions above.

The theoretical values of ^7J are also most consistent with a *Z* conformation for phenyl formate in that they are computed as <-0.01 Hz in any *E* conformer. See a later section for a discussion.

According to the ^5J of 0.41_7 Hz for 4-fluorophenyl formate, the conformational distribution of phenyl formate is not significantly perturbed by the fluorine substituent. This indication is reasonable in view of the ^{13}C nmr chemical shifts of a series of 1,4-disubstituted benzene derivatives (19), from which it was concluded that the $OCOCH_3$ group (and presumably also the OCOH group) does not interact strongly with a *para* substituent. The reduction of ^6J by almost 0.02 Hz in 4-fluorophenyl formate (Table 1) is then attributable to an intrinsic perturbation by the nearby fluorine substituent.

This perturbation is slightly larger than in the 4-nitrophenyl formate,[1] in which, however, ^5J has increased to 0.43_3 Hz. The small increase (Table 1 and Fig. 2) is consistent with a small decrease of θ relative to the parent compound. In turn, this decrease would correspond to a small increase in the conjugative interaction of the OCOH moiety with the phenyl ring in the nitro derivative.

The OCOH group is expected to be a weak π electron donor

[1]A recent reference (28) to an unpublished X-ray structure of 4-nitrophenyl chloroformate has θ as 61° for the *Z* conformer.

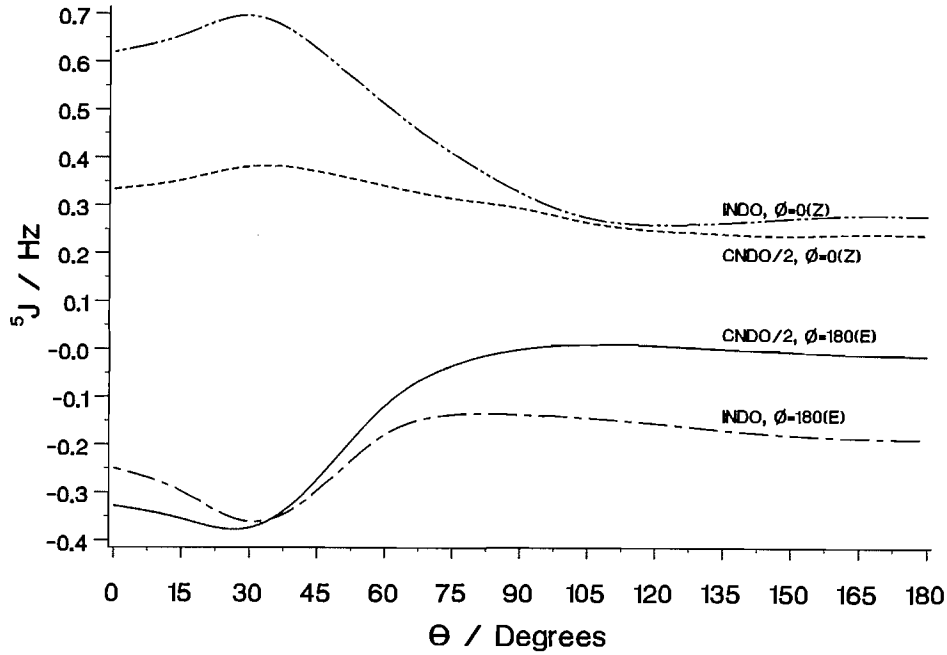

FIG. 2. The CNDO/2 and INDO MO FPT values of ^5J(aldehydic and *ortho* ring protons) are plotted as a function of θ for the *Z* and *E* conformations (see structural diagrams in the text) of phenyl formate. Note that $\theta = 0°$, $\phi = 0°$ defines the planar *Z* conformation. Rotation about the C(1)—O bond is described by θ. The planar *E* conformation has θ as 0° and φ as 180°. The computed numbers for $0° \leq \phi \leq 180°$ fall between the curves for $\phi = 0°$ and 180° shown in the figure.

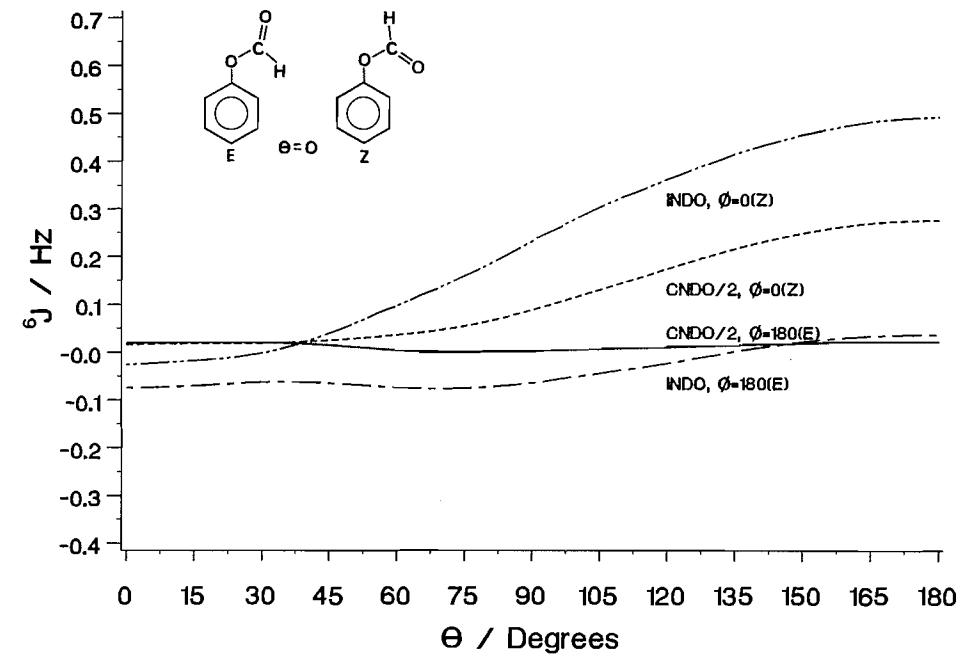

FIG. 3. Plots of the computed ^6J(aldehydic and ring protons) values are shown for the *E* and *Z* conformations of phenyl formate. See the structural diagrams in the text and the caption of Fig. 2 for further description. The top curve is described by the equation $^6J/\text{Hz} = -0.03 + 0.52 \sin^2(\theta/2)$.

(19), as is also suggested by the chemical shift of H-4 in phenyl formate in Table 1. In the same solvent system, the protons of benzene are less shielded by 0.06 ppm (16) than H-4 in phenyl formate. Comparison with the increased shielding of 0.21 ppm of H-4 in toluene (16), relative to benzene, indicates the weakness of the π electron donating abilities of the OCOH grouping in the neutral molecule.

Solvent effect on the conformational equilibrium

Apparently the dipole moment of phenyl formate is unavailable. The CNDO/2 values are 1.1 D for the planar *Z* conformer and 0.9 D if $\theta = 90°$. The STO-3G value is 0.8 D for both of these *Z* conformers. Theory therefore indicates a dipole moment of approximately 1 D for the *Z* form of phenyl formate. For the *E* conformer, the computed dipole moments are again roughly independent of θ, but are large, 3.7 D from the semiempirical computation and near 3 D from the *ab initio* calculation. Accordingly, a solvent perturbation of the gas phase conformational distribution is possible, particularly for a polar solvent, which should favor the *E* conformers as judged by an electrosta-

TABLE 2. Long-range coupling constants in Hz for the formyl proton in different solvents at 300 K

Solvent	^5J	^6J	^7J	Solvent	^5J	^6J	^7J
CS_2[a]	0.413(1)	0.081(1)	0.051(1)	CS_2[b]	0.404(1)	0.074(1)	—[c]
CD_2Cl_2[a]	0.373(0)	0.072(0)	0.045(1)	CD_3CN[b]	0.344(1)	0.061(1)	—[c]
$(CD_3)_2CO$[a]	0.349(1)	0.067(1)	0.041(1)	CS_2[d]	—	0.136(1)	−0.002(1)
CD_3CN[a]	0.349(1)	0.069(1)	0.041(1)	CD_3CN[d]	—	0.129(0)	−0.001(1)

[a]These numbers refer to phenyl formate. The concentrations were 1.0 mol% in CD_2Cl_2, $(CD_3)_2CO$, and CD_3CN, all containing also 0.5 mol% TMS. The rms deviations in the analyses of the ^1H nmr spectra in these three solvents were 0.002, 0.004, and 0.004, respectively.

[b]These numbers refer to 4-methylphenyl formate at 1.25 mol% in concentration.

[c]$^8J(OCH,CH_3)$ is ±0.030 Hz in CS_2 and ±0.020 Hz in CD_3CN.

[d]These numbers refer to 2,6-dichlorophenyl formate. $^7J(OCH,H)$ is unobservable, the formyl ^1H nmr peak widths at half-height being 0.014 Hz in CD_3CN and 0.025 Hz in CS_2 (the formyl proton is relatively far from other nuclear dipoles). The numbers given for ^7J come from the analytical fitting procedure and probably indicate rounding off results. The rms deviations in the analyses were 0.001 for both solutions.

tic model (20*a*). For alkyl formates there exists evidence for a solvent dependence of the energy difference between *Z* and *E* conformers (20*b*, 20*c*).

In Table 2 the long-range coupling constants for the formyl proton in phenyl formate are given for solutions in CD_2Cl_2, acetone-d_6, and CD_3CN. The dielectric constants of these solvents are near 9, 21, and 39, respectively. ^5J decreases from 0.413 Hz in CS_2 solution to 0.373 Hz in CD_2Cl_2 and then to 0.349 Hz in acetone-d_6 and CD_3CN. The plots in Fig. 1 imply increased populations of the *E* conformer in the more polar solutions. An approximate estimate of these populations can be had as follows. The population distribution obtained from the molecular orbital computations (2*a*) implies that 97.6% of the phenyl formate molecules effectively exist in the *Z* conformation at 300 K. On the assumption that this distribution holds in the nonpolar CS_2 solution and that ^5J_Z is 0.43 Hz while ^5J_E is −0.20 Hz (these ^5J values are the averages of the INDO MO FPT numbers at θ equal to 45° and 60°, such θ values representing almost isoenergetic conformers), it follows that the *Z* conformers constitute 91% of the total population in CD_2Cl_2 solution and 87% in acetone-d_6 and CD_3CN solutions. The above values of ^5J_Z and ^5J_E also reproduce the larger ^5J in CS_2 solution. Note, however, that these estimates of the conformer populations must be treated with circumspection; it is probably safe to conclude that significant amounts of the *E* conformer are present in the more polar solvents at 300 K. Confirmation of this conclusion by other methods would be useful.

^6J also decreases in the polar solvents (Tables 1 and 2), although the decrease is rather small. Nevertheless, the CNDO/2 computations, as used above in the discussion of ^6J in the CS_2 solution, agree that ^6J should decrease as the population of the *E* conformer rises. Thus, at θ > 45° the computed ^6J becomes less than 0.01 Hz for the *E* form of phenyl formate compared to about 0.1 Hz for the *Z* form. Decreases in ^5J and ^6J on passing from CS_2 to CD_3CN solutions also occur for 4-methylphenyl formate, the magnitudes of these decreases being the same as for phenyl formate.

The coupling constants, $^7J(H,H)$, $^8J(H,H)$, and $^7J(H,F)$

The INDO MO FPT values for $^7J(H,H)$ in the *Z* conformation of phenyl formate are reproduced precisely (to within an average deviation of 0.001 Hz for seven values) by $^7J(H,H)/Hz = -0.043 \sin^2\theta + 0.119 \cos^2\theta$. For the *E* conformation, the theoretical values are independent of θ to within 0.003 Hz and do not rise above 0.009 Hz. In the *Z* conformation, the C=O bond pointing towards the phenyl group, the theory therefore suggests a σ–π electron mechanism, going as $\sin^2\theta$ and involving subtle exchange interactions at the ester site, as well as a possible π electron mechanism, varying as $\cos^2\theta$. The latter mode of transmission of spin state information could conceivably involve the 2*p*...π conjugation at the C(1)—O bond, which would be most effective for θ = 0°. In that event, the mechanism would include the aromatic π electron system and transmission at the *para* C—H bond would depend on the usual spin polarization at that end of the coupling pathway. In toluene and *p*-xylene, $^6J(H,H) = -^7J(H,H)$ to within experimental error, consistent with the assumption that, for these molecules, the σ–π parameters of the aromatic C—H and the C—CH_3 bonds are equal in magnitude. It would follow that, in 4-methylphenyl formate, $^8J(H,H)$ should be equal to $-^7J(H,H)$ in phenyl formate (12, 18, 21, 22), assuming that the methyl substituent did not alter significantly the conformational behaviour of the ester linkage. This latter assumption is supported by the near equality of ^5J for the two compounds (Table 2), ^5J apparently being sensitive to conformation.

In fact, $^8J(H,H)$ is $\pm 0.03_0$ Hz in CS_2 solution, compared to 0.05_1 Hz for $^7J(H,H)$. This result implies that the term in $\cos^2\theta$ does not involve 2*p*...π conjugation at the C(1)—O bond. On the contrary, this term may represent a coupling via the σ electrons of the phenyl group and, in particular, probably does not involve π electron spin polarization at the *para* C—H bond. An approximate prediction of the σ–π electron component of $^7J(H,H)$, proportional to $\sin^2\theta$, can be had from the expectation value of $\sin^2\theta$ obtained from the MO computations. This value is 0.680 and yields −0.029 Hz for the σ–π component of $^7J(H,H)$, using the equation above, perhaps in fortuitous agreement with the measured value of $\pm 0.03_0$ Hz for $^8J(H,H)$ (footnote in Table 2). The $^8J(H,H)$ of $\pm 0.02_0$ Hz in CD_3CN solution is consistent with an increase in the *E* population, as deduced on the basis of ^5J and ^6J in a previous section.

The vanishing $^7J(H,F)$ in 4-fluorophenyl formate is now understandable. The ratio of the hyperfine parameters of the *para* C—H and C—F bonds is available from $^6J(H,H)$ and $^6J(H,F)$ in toluene (16) and 4-fluorotoluene (23). It is −1.92, the hyperfine parameters being of opposite sign for the two bonds and larger in magnitude for fluorine. The σ–π component of $^7J(H,F)$ is therefore -0.03_0 (−1.92) or 0.05_8 Hz. It follows that a σ electron component of near −0.06 Hz may exist for $^7J(H,F)$. Its existence could be tested if the carbonyl group could be held in the aromatic plane.

The discussion in the preceding paragraphs suggests that the theoretical value of the σ–π coupling magnitude in ^7J is correct. However, it does not follow that the theoretical coefficient of $\cos^2\theta$ is valid. In fact, the $^7J(H,H)$ of +0.05 Hz for phenyl formate in CS_2 solution indicates, together with the above expectation value of $\sin^2\theta$, that the multiplier of $\cos^2\theta$ should be 0.24_8 Hz.

It is interesting, therefore, that $^7J(H,H)$ in 2,6-dichlorophenyl

formate apparently vanishes (Table 2) in both CS_2 and CD_3CN solutions (the formyl ^1H nmr spectrum is a triplet with a linewidth of half-height of 0.014 Hz in the CD_3CN solution and is probably so small because there are no proximate magnetic dipoles of substantial magnitude). The modified relationship between $^7J(H,H)$ and $\sin^2\theta$, $^7J(H,H)/Hz = -0.04 \sin^2\theta + 0.25\cos^2\theta$, predicts $\langle\sin^2\theta\rangle$ as 0.85, which might, however, be as large as 0.90 in view of experimental error. This conclusion assumes the *Z* conformer as stable.

Our geometry-optimized STO 3G MO computations (24, 25), retaining the carbon atoms of the phenyl group in a plane but not as a regular hexagon, confirm the stability of the *Z* conformer. At $\theta = 90°$, this conformer is computed as 15.4 kJ/mol more stable than the *E* conformer. This stability is 4.5 kJ/mol larger than for phenyl formate at $\theta = 90°$. At a θ of 75°, the most stable computed conformer is twisted by 5.9° away from the pure *Z* form and is 0.96 kJ/mol less stable than the pure *Z* form for $\theta = 90°$. At a θ of 60°, the corresponding twist is 16.2° and this conformer, effectively *Z*, is 7.1 kJ/mol less stable than the pure *Z* conformer at a θ of 90°. At lower θ values the energy of the *Z* conformer rises rapidly and all *E* conformers are computed as not less than 15.3 kJ/mol higher in energy than the most stable *Z* conformer. Accordingly, the computations imply a $\langle\sin^2\theta\rangle$ of about 0.96 at 300 K, corresponding to a $^7J(H,H)$ of −0.03 Hz. This value does not agree with experiment, although it is indeed smaller in magnitude than measured in phenyl formate and has therefore changed in the qualitatively correct way. However, the INDO MO values of $^7J(H,H)$ are quite sensitive to the angle ϕ at θ values between 75° and 60°, dropping to −0.01 Hz at $\theta = 75°$, $\phi = 30°$ and becoming +0.02 Hz at $\theta = 60°$, $\phi = 30°$. In other words, not very large changes of the computed ϕ values for the stable conformers of 2,6-dichlorophenyl formate might well lead to the vanishing $^7J(H,H)$.

It is possible that intrinsic perturbations of $^7J(H,H)$ by the chlorine substituents are present, although $\sigma-\pi$ interactions involving the *para* proton and side-chain nuclei are insensitive to such perturbations in other systems (26). For θ near 90°, of course, $^7J(H,H)$ is indicated as a $\sigma-\pi$ coupling.

By way of contrast, $^6J(H,H)$ is probably significantly perturbed by the *ortho* chlorine substituents, judging by other systems. Thus, in toluene (15, 16) the coupling constant between the *meta* protons and those in the side chain increases significantly in the presence of two *ortho* fluorine substituents. The increase has been attributed to the perturbation of the electron component (16). A similar increase also appears to occur in benzaldehyde and its derivatives, as another example (18). The measured value of 0.13 Hz for $^6J(H,H)$ in 2,6-dichlorophenyl formate can be attributed partly to a substituent perturbation. Furthermore, the computed $^6J(H,H)$ for the *E* conformer of phenyl formate is always less than 0.01 Hz in magnitude (Fig. 2), so that $^6J(H,H)$ is consistent with a *Z* conformation for the 2,6-dichloro derivative, in agreement with the STO-3G MO computations.

The chemical shifts

The value of δ for the *para* proton of phenyl formate in the CS_2 solution mixture is 0.06 smaller than that of benzene under the same conditions. In 2,6-dichlorophenyl formate in this solvent mixture, δ_p is 7.11. Assuming additivity of substituent shifts, in the absence of two *meta* chlorine atoms δ_p would be 7.23 ppm. Comparison with the δ of 7.22 for benzene suggests, first, that conjugative π electron release by the ester group is effectively absent and, second, that the *Z* conformation is predominant in the dichloro derivative given that this is true for the parent molecule. However, this suggestion is plausible only, since the carbonyl group is known to possess a substantial diamagnetic anisotropy, which is ignored in this interpretation. Correction for shifts caused by the two chlorine substituents yields a δ of 7.28 for H-3 and H-5 in 2,6-dichloro phenyl formate, very near the 7.29 measured for phenyl formate (correction for an *ortho* chlorine is only 0.02 and for a *para* chlorine is −0.04). It is again plausible that the *Z* conformer is the stable one in 2,6-dichlorophenyl formate.

Perhaps more convincing, the δ values of the formyl proton in the two molecules differ by only 0.017 in the CS_2 solutions. The *E* conformer brings the formyl proton into the shielding region of the benzene magnetic dipole for $\theta > 60°$. From the model of Haigh and Mallion (27) it might be estimated that, at $\theta = 90°$, the formyl proton in the *E* conformer would be shielded by at least 0.25 ppm relative to the *Z* conformer. Large amounts of the *E* conformer are therefore contraindicated for the 2,6-dichloro derivative in CS_2 solution. In CD_3CN solution, the formyl proton in the latter molecule is more shielded, by 0.042 ppm, than in phenyl formate, again suggesting little difference in *Z*/*E* ratios for the two molecules. In summary, the proton chemical shifts are consistent with the arguments concerning the long-range coupling constants in previous sections.

In conclusion, a word of caution is in order. The minimal basis set used in the present work may turn out to be inadequate, although it is noted that substantially larger basis sets are sometimes in substantially poorer agreement with experimental internal barriers for benzene derivatives, for example, for benzaldehyde (29). On the other hand, for methyl formate surprisingly large basis sets and even corrections for electron correlation are necessary for a correct description of its conformational behaviour (30).

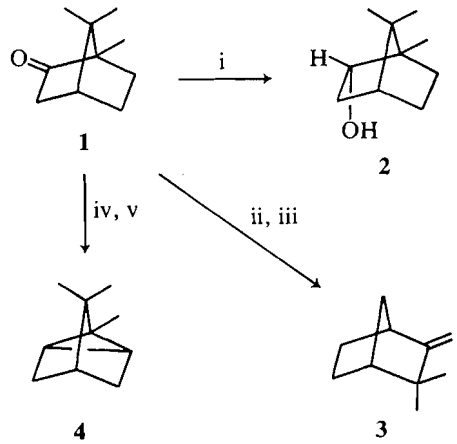
(+)-Camphor (**1**), (+)-borneol (**2**), (+)-camphene (**3**) and tricyclene (**4**) (Scheme 1) represent a quartet of monoterpenoid compounds that are synthetically and, perhaps, biosynthetically related to each other. From a synthetic viewpoint (+)-camphor (**1**) can be regarded as the parent compound, which is readily converted to the other three members of the quartet by reduction, dehydration, and rearrangement reactions (cf. Scheme 1). As indicated in previous reports (1), a structural survey of sesquiterpenoids reveals the possibility of similar structural quartets in which each individual sesquiterpenoid can be regarded as the isoprenylog of camphor, borneol, camphene, or tricyclene. In this way one can recognise the possible occurrence of at least five structural quartets (Scheme 2) with (−)-campherenone (**6**), (+)-epicampherenone (**7**), (+)-copacamphor (**8**), (+)-ylangocamphor (**9**), and (+)-longicamphor (**10**) having the same synthetic relationship with other members of the quartet as camphor has with borneol, camphene, and tricyclene.

The synthetic strategy (Scheme 2) revealed by this structural analysis involves the initial conversion of (+)-camphor (**1**) or (−)-camphor (**5**) to the appropriate enantiomer of the "parent" sesquiterpenoid ketones, i.e., campherenone (**6**), epicampherenone (**7**), copacamphor (**8**), ylangocamphor (**9**), and longicamphor (**10**). The subsequent conversion of these compounds to other members of the quartet would then involve reduction, rearrangement, and cyclization reactions analogous to those used for the conversion of camphor to borneol, camphene, and tricyclene (cf. Scheme 1). On the basis of these speculative proposals previous investigations in our laboratory (1) established camphor as a chiral starting material in the enantiospecific synthesis of campherenone, campherenol, β-santalene, α-santalene, epicampherenone, isoepicampherenol, epi-β-santalene, sativene,[3] copaborneol, and copacamphene (cf. Scheme 2).

The use of this strategy for the synthesis of (+)-longiborneol (**11**),[3,4] (+)-longifolene (**12**),[3,4] and (+)-longicyclene (**13**)[4]



Reagents and conditions: i, Ca/NH_3; ii, $LiAH(OBu^t)_3$/THF; iii, TsCl/C_5H_5N; iv, NH_2NH_2/H^+; v, HgO/heat

SCHEME 1

(Scheme 2) requires a method for converting (+)-camphor (**1**) to (+)-longicamphor (**10**), and in our initial investigations we assumed that this could be accomplished by cyclization of (+)-campherenone (**20**) or an enol derivative of this compound. (+)-Campherenone (**20**) was synthesized from (+)-8-bromocamphor (**14**) (4)[5] by a reaction sequence (Scheme 3) that is less hazardous and more convenient than the one previously reported by us (1*b*). However, all our attempts to construct the longicamphor framework by cyclization of (+)-campherenone (**20**), campherenone hydrochloride (**21**), campherenone hydrochloride trimethylsilyl enol ether (**22**), or campherenone hydrochloride enol acetate (**23**) were unsuccessful (5) (cf. Experimental) and the only product isolated was dimer **24**. As a result, we turned our attention to the possibility of employing an intramolecular Mukaiyama reaction (6) to construct the longibornane framework. The bicyclic trimethylsilyl enol ether (**34**) required in this approach was synthesized from (+)-8-cyanocamphor ethylene ketal (**17**) (7) by the reaction sequence outlined in Scheme 4 and subsequently treated with titanium tetrachloride at −78°C for ~45 min to provide a mixture (~3:1) of diastereomeric tricyclic methoxyketones (**36***a*,*b*)[6] in ~85%

[1]Preliminary communication: ref. 8.

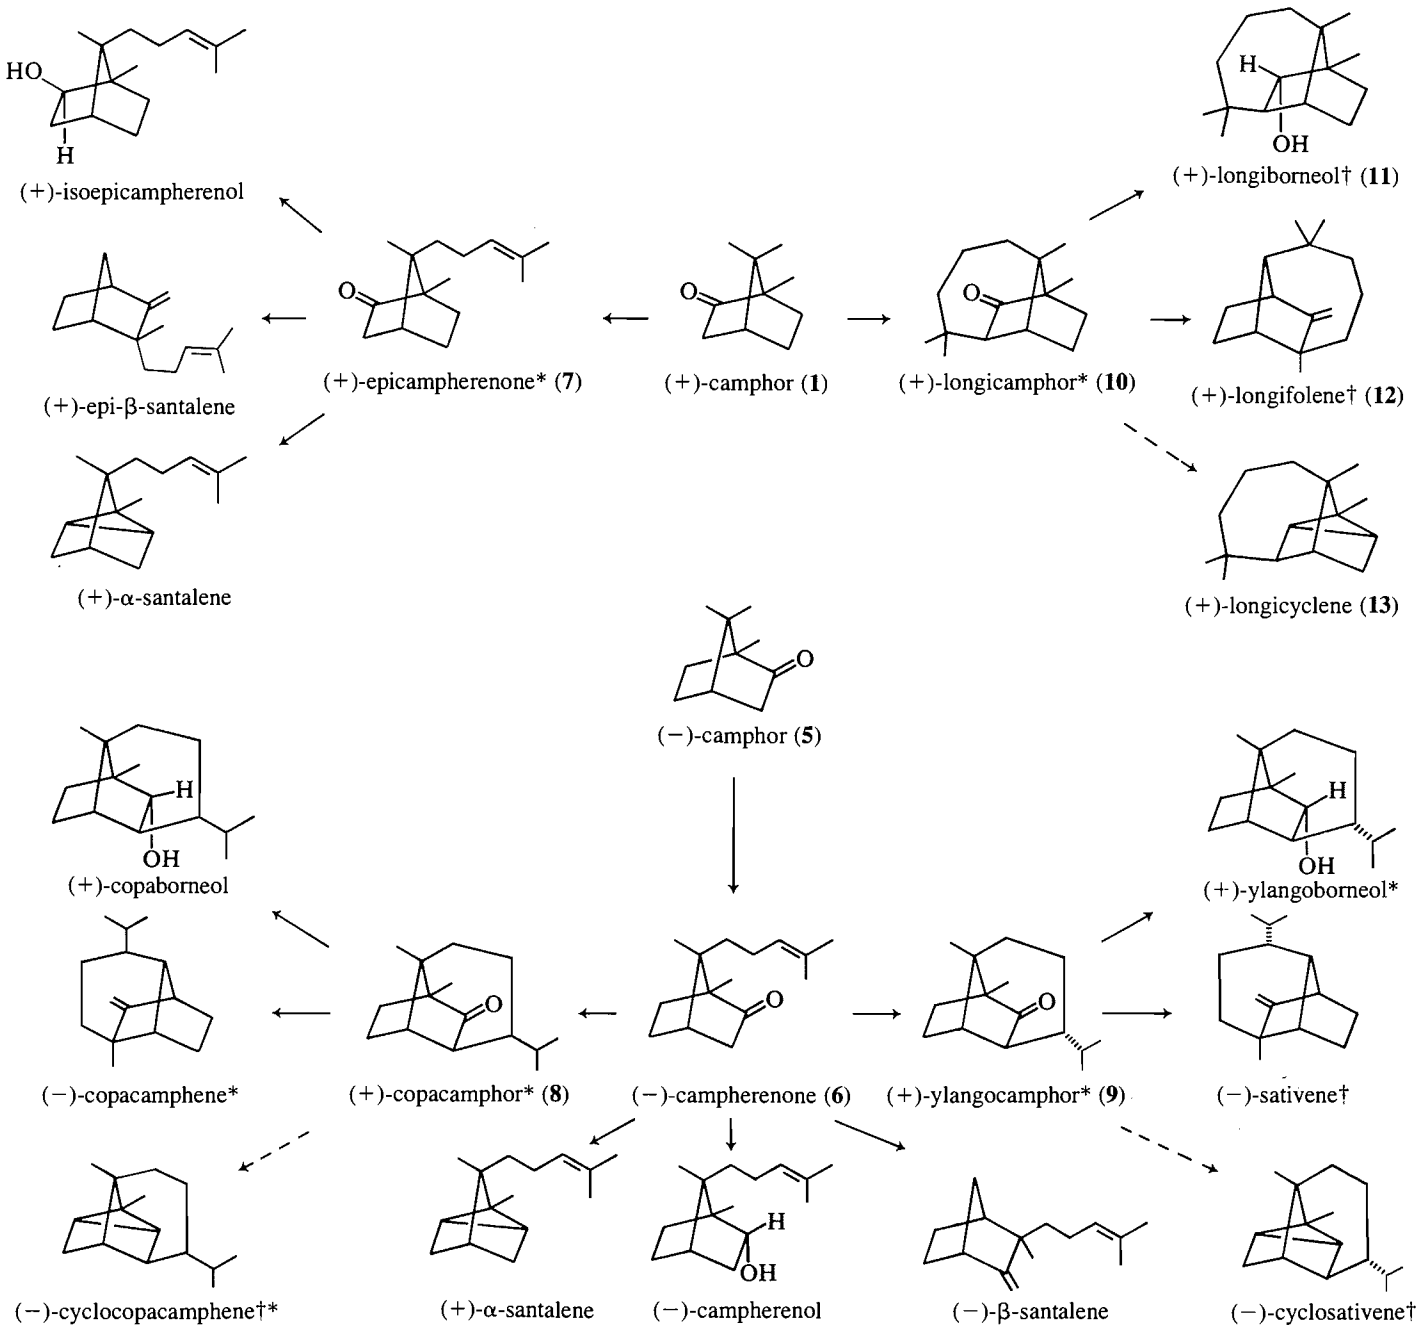
[2]An outline of this research was previewed at the 70th Canadian Chemical Conference, Quebec City, June 1987, and the 42nd ACS Northwest Regional Meeting, Western Washington University, Bellingham, WA, U.S.A., June 1987.

[3]Both enantiomers occur in nature and their synthesis would involve commercially available (+)- or (−)-camphor as a starting material.

[4]Several synthetic routes to racemic or optically active forms of longicamphor (2), longiborneol (2), longifolene (3), and longicyclene (2) have previously been reported.

[5]We have not been able to repeat the yield quoted in our original paper (4*a*), and now find that (+)-8-bromocamphor (**7**) can be prepared from (+)-camphor (**1**) in ~35% overall yield.

[6]Diastereomeric hydroxyethoxyketones (**35***a*, *b*) were obtained in ~75% yield when the enol trimethylsilyl ether (**33**) derived from **31** was treated in a similar way (cf. Scheme 5).



SCHEME 2

yield. The structure (**36***a*) of the major diastereomer produced in this intramolecular Mukaiyama reaction was subsequently confirmed by X-ray crystallographic analysis.[7]

At this stage in our investigations we considered the possibility of synthesizing isolongiborneol (**47**) from methoxy ketones **36***a*,*b* by a series of simple functional group transformations. For this purpose methoxyketones **36***a*,*b* were converted, in 91% yield, to the corresponding *exo*-alcohols **37***a*,*b* (Scheme 5) by reduction with lithium aluminum hydride. However, acetylation of **37***a*, *b* was only partially successful since the product was a mixture (~3:1) of (*R*)-methoxyalcohol **37***a* and (*S*)-methoxyacetate **38** (Scheme 5). The initial assignment of configuration to **37***a* was based on this acetylation experiment since a molecular model of **37***a* clearly indicates that the hydroxyl group in this compound is sterically hindered by the methoxyl group.

The difficulties encountered above prompted us to use an alternative approach, which involved initial reduction (Ca/NH_3) of methoxy ketones **36***a*,*b* to *endo*-alcohols **39***a*,*b* (Scheme 4). Subsequent acetylation, demethylation, and oxidation provided keto-acetates (**42**) in ~75% overall yield. Construction of the *gem*-dimethyl group was then accomplished by an efficient 3-step procedure (9) (methylenation, cyclopropanation, and hydrogenolysis) and, when this was coupled with reductive removal of the acetyl group, (+)-longiborneol (**11**) ($[\alpha]_D$ +15.8; *c* 0.54, $CHCl_3$) was obtained in ~70% overall yield. The capillary glc retention time and 400-MHz ^1H nmr spectrum of our synthetic material were identical with those of authentic longiborneol (11). In addition, the optical purity of synthetic

SCHEME 3

(+)-longiborneol (**11**) was supported by the absence of diastereomeric signals in the ^1H nmr ^{19}F nmr, and ^{13}C nmr spectra of the corresponding MTPA ester (**46**) (12). Oxidation of (+)-longiborneol (**11**) with PCC in CH_2Cl_2 (13) gave (+)-longicamphor (**10**) (2), which was reduced with $LiAlH_4$ in THF to provide (+)-isolongiborneol (**45**). Subsequent treatment of (+)-isolongiborneol (**47**) with methanesulphonyl chloride in DMAP/pyridine at ~100°C resulted in Wagner–Meerwein rearrangement and formation of (+)-longifolene (**12**) (3*d*) ($[\alpha]_D$ +51.78; *c* 0.89, $CHCl_3$) in ~65% yield.

Experimental

Melting points (mp) were determined on a Kofler micro heating stage and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 137 spectrophotometer and optical rotations were made on a Perkin–Elmer 141 polarimeter. The ^1H nmr spectra were recorded on Bruker WH-400, Bruker WP-80, or Nicolet–Oxford H-270 instruments. Signal positions are given in delta (δ) with tetramethylsilane (TMS) as internal reference. The integrated areas and signal multiplicities are indicated in parentheses. Low resolution mass spectra were determined on a MAT CH-4 spectrometer and high resolution spectra were recorded on a Kratos MS-50 spectrometer. Gas–liquid chromatography was performed on a Hewlett–Packard model 5830A gas chromatograph with a 6 ft × 1/8 in. column (3% OV-17) or a Hewlett–Packard model 5830A gas chromatograph with a 12 m × 0.2 mm column (OV-1). Column chromatography was done using Merck silica gel 60 (230–400 mesh), and thin-layer chromatography (tlc) utilizing silica gel 1 B2-F (Baker-flex) sheets. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia.

All reactions involving moisture sensitive reagents were performed under an atmosphere of dry argon using either oven or flame dried glassware. All reaction products were dried by allowing the solutions to stand over anhydrous magnesium sulphate. The solvents and reagents used were purified as follows: tetrahydrofuran was distilled from calcium hydride and then from lithium aluminum hydride (LAH). Diethyl ether was distilled from LAH and hexamethylphosphoramide (HMPA), benzene, methylene chloride, diisopropylamine, dimethyl sulphoxide (DMSO), and pyridine were distilled from calcium hydride. Methanol was obtained by distillation from magnesium methoxide. Petroleum ether (the hydrocarbon fraction of boiling range 30–60°C) was distilled prior to use.

(+)-3,3-Dibromocamphor

Bromine (292 mL, 5.7 mol) was added to (+)-camphor (**26**) (102 g, 0.67 mmol; Aldrich Chemical Co.) dissolved in glacial acetic acid (326

mL, 5.7 mol) and hydrogen bromide gas was bubbled through the reaction mixture for 1 h at 110°C. Stirring was continued at 110°C for 16 h in the dark and the reaction mixture was then poured into water and excess bromine destroyed with sodium bisulphite. The aqueous layer was extracted with ether and the combined organic extracts were washed with water, saturated sodium bicarbonate, saturated brine, and dried over $MgSO_4$. Removal of solvent gave a pale yellow oil, which solidified upon cooling in an ice bath. Crystallization from petroleum ether provided (+)-3,3-dibromocamphor (205 g, 99%); mp 60°C; $[\alpha]_D^{25}$ 37.1° (*c* 1.67, C_2H_5OH); ν_{max} (CCl_4): 2950, 1770 cm^{-1}; δ ($CDCl_3$, 80 MHz): 1.05 (s, 3H), 1.15 (s, 3H), 1.27 (s, 3H), 2.82 (d, 1H, J = 4 Hz, C_4H); *m/e* (relative intensity): 308/310/312(0.59/1.15/0.66, $M/M+2/M+4$), 284(1.43), 282(2.92), 280(1.09), 232(8.28), 230(7.97), 203(11.30), 201(11.73), 123(66.82), 107(44.10), 95(28.80), 91(32.45), 83(100.00). *Mol. Wt.* calcd. for $C_{10}H_{14}OBr_2$: 307.9411/309.9391/311.9370; found (high resolution mass spectrometry): 307.9418/309.9397/311.9375. *Anal.* calcd. for $C_{10}H_{14}OBr_2$: C 38.74, H 4.55; found: C 38.63, H 4.58.

*(+)-8-Bromocamphor (**14**) (4)*

A solution of (+)-3,3-dibromocamphor (19.7 g, 63.5 mmol) in bromine (3,3 mL, 63.5 mmol) was cooled in an ice-water bath while chlorosulphonic acid (25 mL, 372.7 mmol) was added dropwise. The ice bath was then removed and stirring was continued for 3.5 h before the reaction mixture was carefully poured into ice. Excess bromine was destroyed with sodium bisulphite and the aqueous solution was extracted with ether and worked up in the usual way to provide crude 3,3,8-tribromocamphor (24.2 g) as a viscous brown oil that was used in the next step without further purification.

Crude 3,3,8-tribromocamphor (300 g, 0.771 mol) was dissolved in glacial acetic acid (450 mL) and cooled by an ice-water bath. Zinc dust (75 g, 1.15 mol), was slowly added with *vigorous stirring*. The ice-water bath was then removed and stirring was continued for 4.5 h at room temperature. The reaction mixture was poured into ice-water containing sodium bicarbonate, and extracted with ether. The combined organic extract was washed with saturated sodium bicarbonate solution until neutral, then with water, and dried ($MgSO_4$). Removal of solvent gave a brown oil (190 g) that upon fractional distillation provided (+)-8-bromocamphor (**14**) (107 g, 60%) (4) as a colorless crystalline solid; bp 70–110°C (0.005 Torr; 1 Torr = 133.3 Pa). Sublimation followed by crystallization from petroleum ether (30–60°C) provided colorless crystals; mp 83–85°C; $[\alpha]_D^{25}$ +73.1° (*c* 1.17, C_2H_5OH); $[\alpha]_D^{25}$ +76.7° (*c* 1.24, $CHCl_3$); R_f 0.39 (petroleum ether:ether, 9:1); ν_{max} ($CHCl_3$): 2975, 1751 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.93 (s, 3H), 1.15 (s, 3H), 3.10, 3.17 (AB quartet, 2H, J_{AB} = 10 Hz); *m/e* (relative intensity): 230/232(3.57/2.79, $M/M+2$), 205(1.18), 188(1.93), 186(2.05), 175(1.07), 159(1.45), 151(5.36), 149(15.07), 109(28.36), 108(42.74), 107(46.55), 95(10.13). *Mol. Wt.* calcd. for $C_{10}H_{15}OBr$: 230.0306/232.0286; found: 230.0308/232.0290. *Anal.* calcd. for $C_{10}H_{15}OBr$: C 38.74, H 4.55; found: C 38.63, H 4.58.

(+)-8-Bromocamphor ethylene ketal

To a solution of (+)-8-bromocamphor (**14**) (9.8 g, 4.3 mmol) in dry ethylene glycol (140 mL, 354 mmol) under an argon atmosphere was added chlorotrimethylsilane (31 mL, 244 mmol) (18) and the reaction mixture stirred for 6 h at room temperature. Water (50 mL) was then added and work-up by extraction with ether gave a crude product that was purified by chromatography on silica gel (petroleum ether:ether, 15:1) to afford (+)-8-bromocamphor ethylene ketal (10.34 g, 88%) as a colorless oil; $[\alpha]_D^{25}$ +12.06° (*c* 1.02, $CHCl_3$); ν_{max} (film): 2981 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.82 (s, 3H), 1.06 (s, 3H), 3.70–4.00 (m, 4H, $ROCH_2CH_2OR$), 3.24, 4.22 (AB quartet, 2H, J_{AB} = 10 Hz); *m/e* (relative intensity): 275(1.59, M^+), 273(1.72), 197(1.27), 196(13.56), 195(100.00). *Mol. Wt.* calcd. for $C_{12}H_{19}O_2Br$: 275.0568; found: 275.0468. *Anal.* calcd. for $C_{12}H_{19}O_2Br$: C 52.38, H 6.96; found: C 52.60, H 6.93.

*(+)-8-Iodocamphor (**15**)*

Dry potassium iodide (31.2 g, 188 mmol) was added to a stirred solution of (+)-8-bromocamphor (**14**) (14.48 g, 63 mmol) in dry dimethyl sulphoxide (60 mL) and stirring continued at 110°C under an argon atmosphere for 40 h. The cooled reaction mixture was added to water (200 mL), extracted with ether, and worked up in the usual way to provide a crude product that was purified by column chromatography (silica gel, petroleum ether:ether, 15:1) to afford (+)-8-iodocamphor (**15**) (16.8 g, 95%) as a colorless oil; R_f 0.30 (pet. ether:ether, 9:1); $[\alpha]_D^{25}$ +72.14° (*c* 14.5, $CHCl_3$); ν_{max} (film): 2981, 1741 cm^{-1}; δ ($CDCl_3$, 270 MHz): 0.94 (s, 3H, CH_3), 1.12 (s, 3H, CH_3), 2.91, 3.00 (AB quartet, 2H, RCH_2I, J_{AB} = 10 Hz); *m/e* (relative intensity): 278(23.10, M^+), 277(1.90), 223(1.90), 182(3.3), 1.52(7.30), 151(50.00), 123(28.00), 109(69.40), 107(100.00). *Mol. Wt.* calcd. for $C_{10}H_{15}OI$: 278.0167; found: 278.0169. *Anal.* calcd. for $C_{10}H_{15}OI$: C 43.18, H 5.44, I 45.63; found: C 43.30, H 5.43, I 45.45.

*(+)-8-Iodocamphor ethylene ketal (**16**)*

Chlorotrimethylsilane (31 mL, 242 mmol) was added to a solution of (+)-8-iodocamphor (**15**) (16.8 g, 60.4 mmol) in dry ethylene glycol (80 mL) under an argon atmosphere and the reaction mixture stirred for 6 h at room temperature (18). Water (50 mL) was added and the mixture was extracted with ether and worked up in the usual way to provide, after column chromatography (silica gel, pet. ether:ether, 15:1), (+)-8-iodocamphor ethylene ketal (**16**) (18.2 g, 94%) as a colorless oil; R_f 0.63 (pet. ether:ether, 9:1); $[\alpha]_D^{25}$ +34.32° (*c* 0.7, $CHCl_3$); ν_{max} (film): 2973 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.82 (s, 3H, CH_3), 1.05 (s, 3H, CH_3), 3.04, 4.07 (AB quartet, 2H, ICH_2R, J_{AB} = 10 Hz), 3.74–3.98 (m, 4H, $ROCH_2CH_2OR$); *m/e* (relative intensity): 321(0.27, M^+-1), 304(0.22), 262(0.29), 221(0.59), 197(1.38), 196(13.41), 195(100.00). *Mol. Wt.* calcd. for $C_{12}H_{18}IO_2$ 321.0350; found: 321.0350. *Anal.* calcd. for $C_{12}H_{19}IO_2$: C 44.74, H 5.94; found: C 45.03, H 6.10.

*(+)-8-Cyanocamphor ethylene ketal (**17**) (7)*

(*a*) Dry sodium cyanide (9.0 g, 184 mmol) was added to a stirred solution of (+)-8-bromocamphor ethylene ketal (10.34 g, 37.6 mmol) in dry dimethyl sulphoxide (150 mL) and stirring continued at 60°C under an argon atmosphere for 7 days. After cooling, the reaction mixture was added to water (200 mL), extracted with ether, and worked up in the usual way. Column chromatography (silica gel, pet. ether: ether, 6:1) of the crude product gave (+)-8-cyanocamphor ethylene ketal (**17**) (4.5 g, 54%) as a colorless oil; R_f 0.48 (pet. ether:ether, 4:1); $[\alpha]_D^{25}$ +5.06° (*c* 2.35, C_2H_5OH); ν_{max} (film): 2950, 2250 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.85 (s, 3H, CH_3), 1.09 (s, 3H, CH_3), 2.30, 2.98 (AB quartet, 2H, $NCCH_2R$, J_{AB} = 16 Hz), 3.70–4.00 (m, 4H, $ROCH_2CH_2OR$); *m/e* (relative intensity): 221(1.07, M^+), 182(3.14), 181(24.80), 166(1.94), 140(1.30), 133(1.01), 127(1.76), 125(3.87), 113(11.7), 95(100.00). *Mol. Wt.* calcd. for $C_{13}H_{19}O_2N$: 221.1416; found: 221.1416. *Anal.* calcd. for $C_{13}H_{19}O_2N$: C 70.56, H 8.65, N 6.33; found: C 70.72, H 8.80, N 6.22.

(*b*) Dry sodium cyanide (1.46 g, 29.8 mmol) was added to a stirred solution of (+)-8-iodocamphor ethylene ketal (**16**) (2.4 g, 7.5 mmol) in dry dimethyl sulphoxide (35 mL) and stirring continued at 60°C under an argon atmosphere for 3 days. After cooling, the reaction mixture was poured onto water (50 mL), extracted with ether, and worked up in the usual way. Column chromatography (silica gel, pet. ether: ether, 6:1) of the crude product gave (+)-8-cyanocamphor ethylene ketal (**17**) (1.53 g, 92%) as a colorless oil.

*Cyanoketal (**18**)*

n-Butyllithium (1.6 M; hexane) (3.6 mL, 5.7 mmol) was added to a stirred solution of diisopropylamine (0.8 mL, 5.7 mmol) in dry tetrahydrofuran (8 mL) under an argon atmosphere at 0°C, and stirring was continued for 30 min. (+)-8-Cyanocamphor ethylene ketal (**17**) (1.0 g, 4.7 mmol) in dry tetrahydrofuran (23 mL) was added to this cooled solution at −78°C. Stirring was continued for 2 h before prenyl bromide (0.82 mL, 7.1 mmol) was introduced at −78°C. The reaction mixture was stirred for 10 h and worked up by adding water (10 mL) and extracting with ether. The combined organic layer was washed with saturated ammonium chloride solution, brine solution, and dried ($MgSO_4$). Removal of solvent followed by column chromatography (silica gel, pet. ether:ether, 10:1) provided a mixture of epimers of cyanoketal (**18**) (1.28 g, 95%) as a colorless oil; the ratio (6:1) of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12

epimers was determined from the proton integrations in the nmr spectrum; R_f 0.22 (pet. ether:ether, 9:1); ν_{max} (film): 2975, 2250 cm^{-1}; δ ($CDCl_3$ 400 MHz), ^1H nmr of the major diastereomer: 1.03 (s, 3H, CH_3), 1.1 (s, 3H, CH_3), 1.65 (s, 3H, CH_3), 1.75 (s, 3H, CH_3), 3.38 (dd, 1H, R^1R^2CHCN, J = 4 Hz, 12 Hz), 3.70–4.00 (m, 4H, ROC_2H_4OR), 5.24 (t, 1H, $(CH_3)_2C{:}CHR$, J = 8 Hz); *m/e* (relative intensity): 289(4.62, M^+), 181(17.79), 125(15.64), 107(1.10), 99(1.32), 96(7.46), 95(100.00). *Mol. Wt.* calcd. for $C_{18}H_{27}O_2N$: 289.2024; found: 289.2045. *Anal.* calcd. for $C_{18}H_{27}O_2H$: C 74.70, H 9.40, N 4.84; found: C 74.39, H 9.55, N 4.90.

(−)-Campherenone ethylene ketal (19)

To a solution of potassium (0.36 g, 92 mmol) in dry hexamethylphosphoramide (7 mL) (14) under an argon atmosphere at 25°C was added a solution of cyanoketal (**18**) epimers (1.33 g, 4.59 mmol) in anhydrous ether (7 mL), followed by *tert*-butanol (0.65 mL, 6.9 mmol). Stirring was continued for 12 h and the reaction mixture worked up by adding brine solution (10 mL) and extracting with ether. The combined organic extract was washed with brine solution and dried ($MgSO_4$). Removal of solvent gave a crude product that was purified by column chromatography (silica gel, pet. ether:ether, 10:1 to give (−)-campherenone ethylene ketal (**19**) (0.716 g, 78%) as a colorless oil; R_f 0.89 (pet. ether:ether, 9:1); $[\alpha]_D^{25}$ −14.48° (*c* 0.58, $CHCl_3$); ν_{max} (film): 2776, 1661 (weak) cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.80 (s, 3H, CH_3), 0.88 (s, 3H, CH_3), 1.62 (s, 3H, CH_3), 1.69 (s, 3H, CH_3), 3.7–4.0 (m, 4H, ROC_2H_4OR). 5.15 (t, 1H, R, J = 8 Hz); *m/e* (relative intensity): 264(10.96, M^+), 221(2.67), 195(2.16), 187(2.74), 180(6.82), 165(4.44), 159(2.10), 155(2.29), 153(7.49), 149(2.00), 140(3.57), 135(6.66), 133(4.02), 125(100.00). *Mol. Wt.* calcd. for $C_{17}H_{28}O_2$: 264.2089; found: 264.2086. *Anal.* calcd. for $C_{17}H_{28}O_2$: C 77.22, H 10.67; found: C 77.50, H 10.70.

(+)-Campherenone (20)

(−)-Campherenone ethylene ketal (**19**) (0.52 g, 2.0 mmol) was dissolved in acetone (5 mL) and treated with hydrochloric acid solution (1 N, 3 mL) for 3 h at 25°C. Work-up in the usual way provided a crude product that was purified by column chromatography (silica gel, pet. ether:ether, 10:1) to provide (+)-campherenone (**20**) (0.42 g, 96%) as a colorless oil; R_f 0.50 (pet. ether:ether, 9:1); $[\alpha]_D^{25}$ +30.77° (*c* 2.78, $CHCl_3$) (lit. (1*a*) for (−)-campherenone, $[\alpha]_D^{23}$ −30.6° (*c* 10.7, $CHCl_3$)); ν_{max} (film): 2979, 1748 cm^{-1}, δ ($CDCl_3$, 400 MHz): 0.90 (s, 3H, CH_3), 0.98 (s, 3H, CH_3), 1.59 (s, 3H, CH_3), 1.67 (s, 3H, CH_3), 5.05 (t, 1H, $(CH_3)_2C{:}CHR$, J = 8 Hz); *m/e* (relative intensity): 220(19.06, M^+), 163(3.98), 137(6.83), 135(12.72), 121(12.77), 109(34.25), 95(29.54), 69(45.85). *Mol. Wt.* calcd. for $C_{15}H_{24}O$: 220.1827; found: 220.1827. *Anal.* calcd. for $C_{15}H_{24}O$: C 81.76, H 10.98; found: C 82.00, H 11.00.

(+)-Campherenone hydrochloride (21)

(+)-Campherenone (**20**) (0.29 g, 1.3 mmol) was dissolved in anhydrous ether (8 mL) and concentrated hydrochloric acid (3 mL, 13.0 mmol) was added slowly at 25°C. Stirring was continued for 8 h before water (10 mL) was added; the reaction mixture was extracted with ether and the combined organic layer washed with saturated sodium bicarbonate solution, water, and then dried ($MgSO_4$). Removal of solvent followed by chromatography of the crude product on silica gel (pet. ether:ether, 10:1) afforded (+)-campherenone hydrochloride (**21**) (0.32 g, 96%) as a colorless oil; R_f 0.38 (pet. ether:ether, 9:1); $[\alpha]_D^{25}$ +37.89° (*c* 0.47, $CHCl_3$); ν_{max} (film): 1741, 2964 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.9 (s, 3H, CH_3), 0.93 (s, 3H, CH_3), 1.55 (s, 6H, $R'RC{:}C(CH_3)_2$); *m/e* (relative intensity): 256(9.92, M^+), 221(10.05), 220(23.28), 177(8.38), 163(17.64), 151(10.79), 137(15.12), 135(19.63), 123(15.13), 111(39.54), 109(84.16), 108(26.88), 95(68.77), 81(100.00). *Mol. Wt.* calcd. for $C_{15}H_{25}OCl$: 256.1594; found: 256.1596. *Anal.* calcd. for $C_{15}H_{25}OCl$: C 70.15, H 9.81; found: C 69.90, H 10.09.

Campherenone hydrochloride enol trimethylsilylether (22)

Lithium diisopropylamide was generated by reacting *n*-butyllithium (1.6 M; hexane) (0.29 mL, 0.43 mmol) with diisopropylamine (0.06 mL, 0.43 mmol) in dry tetrahydrofuran (4 mL) at 0°C under an argon atmosphere for 30 min. A solution of (+)-campherenone hydrochloride (**21**) (91 mg, 0.36 mmol) in dry tetrahydrofuran (2 mL) was added to the reaction mixture at −78°C. After 2 h, freshly distilled chlorotrimethylsilane (0.067 mL, 0.53 mmol) was added and stirring was continued for 1 h at room temperature. The solvent was filtered through a column of Celite and evaporated to provide campherenone hydrochloride enol trimethylsilylether (**22**) (110 mg, 97%) as a colorless oil; ν_{max} (film): 2977, 1618 cm^{-1}; δ ($CDCl_3$, 80 MHz): 0.2 (s, 9H, $RSi(CH_3)_3$), 0.7 (s, 3H, CH_3), 0.85 (s, 3H, CH_3), 1.55 (s, 6H, $(CH_3)_2CClR$), 4.58 (d, 1H (TMSO)$RC{:}CHR'$, J = 4 Hz).

Campherenone hydrochloride enol acetate (23)

A solution of (+)-campherenone hydrochloride (**21**) (89 mg, 0.35 mmol) in dry tetrahydrofuran (5 mL) was treated at 25°C with *n*-butyllithium (1.6 M;hexane) (0.3 mL, 0.4 mmol) for 15 min. The enolate anion thus generated was cooled to −50°C and treated with dry acetic anhydride (0.06 mL, 0.6 mmol). After 15 min, the reaction mixture was warmed to 25°C and saturated sodium bicarbonate solution (5 mL) was added to quench excess acetic anhydride. The mixture was then extracted with pet. ether and the combined organic extracts washed with brine solution and dried ($MgSO_4$). After removal of solvent, the crude product was purified by column chromatography (silica gel, pet. ether:ether, 6:1) to provide campherenone hydrochloride enol acetate (**23**) (92 mg, 95%) as a colorless oil; R_f 0.65 (pet. ether:ether, 4:1); ν_{max} (film): 2980, 1760 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.78 (s, 3H, CH_3), 0.92 (s, 3H, CH_3), 1.56 (s, 3H, CH_3), 1.57 (s, 3H, CH_3), 2.15 (s, 3H, CH_3), 5.53 (d, 1H, (AcO)RC: CHR', J = 4 Hz); *m/e* (relative intensity): 298(3.20, M^+), 258(18.24), 256(54.65), 220(72.17), 192(16.48), 179(55.87), 177(21.46), 161(20.67), 149(16.13), 137(77.71), 135(75.24), 123(25.51), 110(100.00). *Mol Wt.* calcd. for $C_{17}H_{27}O_2Cl$: 298.1699; found: 298.1700.

Attempted cyclization of campherenone derivatives[8] *(5)*

(*a*) To a cooled (0°C), well-stirred solution of (+)-campherenone (**20**) (25 mg, 0.11 mmol) in dry methylene chloride (2 mL) under an argon atmosphere was added dropwise stannic chloride (0.003 mL, 0.02 mmol). After 24 h the reaction mixture was diluted with water (10 mL) and extracted with ether. The combined organic extract was washed with saturated sodium bicarbonate solution, water, and dried ($MgSO_4$). After removal of solvent, the crude product was purified by column chromatography (silica gel, pet. ether:ether, 5:1) to give campherenone dimer (**24**) (13 mg) as a colorless oil; R_f 0.1 (pet. ether:ether, 9:1); ν_{max} (film): 2986, 1736 cm^{-1}; δ ($CDCl_3$, 400 MHz), ^1H nmr of the major diastereomer: 0.81 (s, 6H, $(CH_3)_2$), 0.90 (s, 6H, $(CH_3)_2$), 0.93, 0.98 (s, s, 6H, $(CH_3)_2$), 162 (s, 3H, CH_3), 1.86 (s, 3H, CH_3), 5.00 (t, 1H, $(CH_3)_2C{:}CHR$, J = 8 Hz); *m/e* (relative intensity): 440(8.45, M^+), 277(5.94), 262(3.45), 233(3.16), 222(13.29), 220(16.75), 177(8.11), 149(11.70), 138(10.59), 135(13.10), 121(12.92), 109(41.22), 95(50.84). *Mol. Wt.* calcd. for $C_{30}H_{48}O_2$: 440.3654; found: 440.3650.

(*b*) Titanium tetrachloride (0.055mL, 0.50 mmol) was added dropwise to a cooled (−78°C), well-stirred solution of campherenone hydrochloride trimethylsilyl enol ether (**22**) (140 mg, 0.42 mmol) in dry methylene chloride (26 mL) under an argon atmosphere. After 12 h, the reaction mixture was diluted with water (10 mL) and extracted with ether. The combined organic extract was washed with saturated sodium bicarbonate solution, water, and dried ($MgSO_4$). After removal of solvent, the crude product was purified by column chromatography (silica gel, pet. ether:ether, 5:1) to give a mixture of epimers of campherenone dimer (**24**) (47 mg) and (+)-campherenone hydrochloride (**21**) (49 mg).

(*c*) To a cooled (0°C), well-stirred solution of dry stannic chloride (6.4 μL, 5.4×10^{-2} mmol) in dry methylene chloride (6 mL) was added dropwise a solution of (+)-campherenone hydrochloride (**21**) (68 mg, 0.27 mmol) in methylene chloride (8 mL), under an argon atmosphere. After 2 days, the reaction mixture was diluted with water (10 mL) and extracted with ether. The combined organic extract was

[8]We are grateful to Dr. Susan Piper for preliminary investigations in this area.

For personal use only.

washed with saturated sodium bicarbonate solution, water, and dried ($MgSO_4$). After removal of solvent, the crude product was purified by column chromatography (silica gel, pet. ether:ether, 5:1) to give a mixture (3.5:1 by nmr) of epimers of campherenone dimer (**24**) (57 mg) as a colorless oil.

(*d*) To a cooled (0°C), well-stirred solution of campherenone hydrochloride enol acetate (**23**) (76 mg, 0.27 mmol) in dry methylene chloride (5 mL) under an argon atmosphere was added stannic chloride (6.4 μL, 5.4×10^{-2} mmol). After 16 h, the reaction mixture was diluted with water (10 mL) and extracted with ether. The combined organic extract was washed with saturated sodium bicarbonate solution, water, and dried ($MgSO_4$). After removal of solvent, the crude product was purified by column chromatography (silica gel; pet. ether:ether, 5:1) to give campherenone dimer (**24**) (20 mg) as a colorless oil.

tert-*Butyldimethylsilyltrifluoromethanesulfonate (TBDMS-triflate)*

Triflic acid (20.5 mL, 232 mmol) was added dropwise to freshly sublimed *tert*-butyldimethylsilyl chloride (35.0 g, 232 mmol) at room temperature and the resulting mixture heated at 60°C for 16 h. The product was then distilled from the reaction flask to afford TBDMS-triflate (56.0 g, 91%) as a colorless liquid (bp 65–67°C; 12 Torr).

3-Bromo-1-tert-*butyldimethylsilyloxypropane*

Freshly distilled TBDMS-triflate (13 g, 49 mmol) was added dropwise to a solution of 3-bromo-1-propanol (6.8 g, 49 mmol) and 2,6-lutidine (5.3 g, 49 mmol) in dry methylene chloride (35 mL) at 0°C under an argon atmosphere and stirring was continued for 4 h. The reaction mixture was added to water (50 mL) and extracted with methylene chloride. The combined organic extract was washed with hydrochloric acid (1 N), saturated ammonium chloride solution, water, and dried ($MgSO_4$). Upon removal of solvent under vacuum, the crude product was subjected to column chromatography (silica gel, pet. ether:ether, 9:1) to afford the 3-bromo-*tert*-butyldimethylsilyloxypropane (10 g, 85%) as a colorless oil; R_f 0.95 (pet. ether:ether, 9:1); ν_{max} (film): 2940 cm^{-1}; δ ($CDCl_3$, 270 MHz): 0.08 (s, 6H, $RSi(CH_3)_2$), 0.91 (s, 9H, $(CH_3)_3C$-SiR), 1.96–2.08 (m, 2H, $ROCH_2CH_2CH_2Br$), 3.5 (t, 2H, RCH_2OSi, J = 6 Hz), 3.72 (t, 2H, RCH_2Br, J = 6 Hz); *m/e* (relative intensity): 253/255(7.04/6.69, $M/M+2$), 213(1.38), 207(1.04), 205(1.02), 197(52.07), 195(53.40), 169(63.49), 167(66.12), 139(90.35), 137(89.69), 115(100.00).

*Ketal-nitrile (25*a,b*)*

n-Butyllithium (1.6 M; hexane) (31 mL, 31 mmol) was added to a stirred solution of diisopropylamine (4.4 mL, 31 mmol) in dry tetrahydrofuran (50 mL) under an argon atmosphere at 0°C and stirring was continued for 30 min. (+)-8-Cyanocamphor ethylene ketal (**17**) (5.7 g, 26 mmol) in dry tetrahydrofuran (20 mL) was added to this cooled solution at −78°C and stirring was continued for 2 h before a solution of 3-bromo-*tert*-butyldimethylsilyloxypropane (9.3 g, 39 mmol) in tetrahydrofuran (20 mL) was introduced at −78°C. The reaction mixture was stirred for 10 h and worked up by adding water (10 mL) and extracting with ether. The combined organic extract was washed with saturated ammonium chloride solution, brine solution, and dried ($MgSO_4$). After removal of solvent and column chromatography (silica gel, pet. ether:ether, 5:1) a mixture of (*R*)-ketal-nitrile (**25***a*)[9] and its epimer (**25***b*) (9.5 g, 94%) was obtained as a colorless oil. The ratio (6:1) of epimers (**25***a*:**25***b*) was determined by proton integrations in nmr; R_f 0.85 (pet. ether:ether, 1:1); ν_{max} (film): 2980, 2257 cm^{-1}; δ ($CDCl_3$, 400 MHz) (**25***a*): 0.55 (s, 6H, $RSi(CH_3)_2$), 0.89 (s, 9H, $(CH_3)_3CSiR$), 1.25 (s, 3H, CH_3), 1.75 (s, 3H, CH_3), 3.48 (m, 1H, R^1CHCNR^2), 3.58–3.98 (m, 6H, $ROCH_2CH_2OR$, and RCH_2OSi); *m/e* (relative intensity): 393(0.41, M^+), 378(1.14), 338(1.64), 336(26.30), 293(2.10), 292(9.14), 274(2.63), 265(1.35), 255(1.09), 181(39.71), 113(15.15), 95(100.00). *Mol. Wt.* calcd. for $C_{22}H_{39}O_3SiN$: 393.2699; found: 393.2707. *Anal.* calcd. for $C_{22}H_{39}O_3SiN$: C 67.13, H 10.00, N 3.56; found: C 67.10, H 10.12, N 3.78.

(−)-Hydroxy-ketal (26)

Potassium (0.14 g, 3.6 mmol) was added to dry hexamethylphosphoramide (6 mL) (14) under an argon atmosphere at 25°C and to the dark blue solution was added a solution of nitrile (**25***a*, *b*) (0.71 g, 1.8 mmol) in anhydrous ether (5 mL) and *tert*-butanol (0.25 mL, 2.7 mmol). Stirring was continued for 10 h and the reaction was worked up in the usual way after extraction with ether. The crude product was purified by column chromatography (silica gel, pet. ether:ether, 5:1) to afford (−)-hydroxy-ketal (**26**) (0.36 g, 83%) as a colorless oil; R_f 0.32 (pet. ether:ether, 1:1); $[\alpha]_D^{25}$ −14.67° (*c* 0.45, $CHCl_3$); ν_{max} (film); 2964, 3407 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.80 (s, 3H, CH_3), 0.85 (s, 3H, CH_3), 3.70–4.00 (m, 4H, $ROCH_2CH_2OR$), 3.66 (t, 2H, RCH_2OH, J = 6 Hz); *m/e* (relative intensity): 254(6.48 M^+), 224(1.79), 223(1.73), 199(2.26), 195(1.19), 181(11.72), 143(36.53), 135(13.37), 125(99.91), 99(40.70), 95(100.00). *Mol. Wt.* calcd. for $C_{15}H_{26}O_3$: 254.1882; found: 254.1879. *Anal.* calcd. for $C_{15}H_{26}O_3$: C 70.83, H 10.30; found: C 70.56, H 10.41.

A later fraction provided silyloxy-ketal (**27**) (11 mg) as a colorless oil; R_f 0.81 (pet. ether:ether, 1:1; $[\alpha]_D^{25}$ −6.88° (*c* 0.77, $CHCl_3$); ν_{max} (film): 2986 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.60 (s, 6H, $RSi(CH_3)_2$), 0.79 (s, 3H, CH_3), 0.84 (s, 3H, CH_3), 0.91 (s, 9H, $RSiC(CH_3)_3$), 3.62 (t, 2H, RCH_2OSi, J = 6 Hz), 3.71–3.96 (m, 4H, $ROCH_2CH_2OR$); *m/e* (relative intensity): 368(4.43, M^+), 353(2.31), 311(20.75), 268(11.83), 267(54.66), 257(24.87), 193(53.78), 181(14.99), 175(29.49), 125(74.92), 119(33.90), 95(100.00). *Mol. Wt.* calcd. for $C_{21}H_{40}O_3Si$: 368.2746; found: 368.2737. *Anal.* calcd. for $C_{21}H_{40}O_3Si$: C 68.42, H 10.94; found: C 68.71, H 10.88.

A final fraction provided a mixture of epimers of hydroxyketal-nitrile (**28***a*, *b*) (89 mg) as a colorless oil; R_f 0.26 (pet. ether:ether, 2:3); ν_{max} (film): 3420, 2970, 2248 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.03 (s, 3H, CH_3), 1.08 (s, 3H, CH_3), 3.46 (dd, 1H, R^1R^2CHCN, J = 10 Hz, 4 Hz), 3.70–4.00 (m, 6H, $ROCH_2CH_2OR$, and RCH_2OH); *m/e* (relative intensity): 279(0.48, M^+), 239(0.79), 182(4.47), 181(35.86), 144(2.02), 113(11.66), 95(100.00). *Mol. Wt.* calcd. for $C_{16}H_{25}O_3N$: 279.1834; found: 279.1819. *Anal.* calcd. for $C_{16}H_{25}O_3N$: C 68.79, H 9.02, N 5.01; found: C 68.70, H 9.00, N 4.90.

A further quantity of hydroxy-ketal (**26**) was obtained when tetra-*n*-butyl ammonium fluoride (100 mL, 1 M solution in tetrahydrofuran) was added to (−)-silyloxy-ketal (**27**) (10.5 g, 28.5 mmol) at 25°C under an argon atmosphere. Stirring was continued for 6 h before water (50 mL) was added. The reaction mixture was extracted with ether and the combined organic layer was washed with saturated sodium bicarbonate solution, brine solution, water, and dried ($MgSO_4$). Upon removal of solvent under vacuum, the crude product was purified by column chromatography (silica gel, pet. ether:ether, 5:1) to give the (−)-hydroxyketal (**26**) (7.0 g, 97%) as a colorless oil.

(+)-Hydroxyketone (29)

Hydroxyketal (**26**) (1.0 g, 3.9 mmol) was dissolved in acetone (20 mL), hydrochloric acid (1 N, 12 mL) was added dropwise, and the reaction mixture stirred at 25°C for 2 h. The reaction mixture was added to water (20 mL) and, following extraction with ether, was worked up in the usual way. The crude product was purified by column chromatography (silica gel, pet. ether:ether, 10:1) to afford (+)-hydroxyketone (**29**) (0.81 g, 99%) as a colorless oil; R_f 0.30 (pet. ether:ether, 7:2); $[\alpha]_D^{25}$ +41.88° (*c* 0.16, $CHCl_3$); ν_{max} (film): 3340, 2980, 1745 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.91 (s, 3H, CH_3), 0.97 (s, 3H, CH_3), 3.64 (t, 2H, RCH_2OH, J = 6 Hz); *m/e* (relative intensity): 210(22.98 M^+), 192(1.59), 177(1.63), 168(1.31), 167(2.08), 153(3.85), 151(9.99), 149(5.32), 138(18.55), 137(25.14), 135(17.70), 111(14.27), 110(15.16), 109(100.00). *Mol. Wt.* calcd. for $C_{13}H_{22}O_2$: 210.1620; found: 210.1615. *Anal.* calcd. for $C_{13}H_{22}O_2$: C 74.24, H 10.54; found: C 73.96, H 10.80.

[9]The (*R*)-stereoselectivity of this reaction was determined by X-ray crystallographic analysis[7] of the *p*-bromobenzoate derivative of hydroxyketalnitrile (**28***a*) derived from the major epimer (**25***a*). Stereoselective reactions at the C(8) or C(9) neopentyl position in camphor derivatives (15; also S. E. Piper, unpublished observations) and norcamphor derivatives (16) have been observed previously.

*(+)-Ketoaldehyde (**30**)*

A solution of (+)-hydroxyketone (**29**) (0.76 g, 3.6 mmol) and pyridinium dichromate (17) (2.7 g, 7.2 mmol) in dry methylene chloride (25 mL) was stirred at 25°C under an argon atmosphere for 10 h. The reaction mixture was then diluted with ether and filtered through a pad of silica gel. Removal of solvent gave a crude product that was purified by column chromatography (silica gel, pet. ether:ether, 4:1) to afford (+)-ketoaldehyde (**30**) (0.72 g, 96%) as a colorless oil; R_f 0.49 (pet. ether:ether, 2:7); $[\alpha]_D^{25}$ +27.46° (*c* 1.18, $CHCl_3$); ν_{max} (film): 2735 cm^{-1}; δ ($CDCl_3$; 400 MHz): 0.91 (s, 3H, CH_3), 0.98 (s, 3H, CH_3), 9.76 (t, 1H, RC*H*O, *J* = 1.5 Hz); *m/e* (relative intensity): 208(14.19, M^+), 180(6.03), 175(9.95), 162(6.56), 147(14.42), 137(24.96), 136(14.72), 135(24.90), 133(21.93), 109(57.16), 95(80.99), 81(100.00). *Mol. Wt.* calcd. for $C_{13}H_{20}O_2$: 208.1463; found: 208.1467. *Anal.* calcd. for $C_{13}H_{20}O_2$: C 74.96, H 9.68; found: C 74.89, H 9.73.

*Keto-acetal (**31**)*

A solution of (+)-keto-aldehyde (**30**) (38 mg, 0.18 mmol), ethylene glycol (0.013 mL, 0.23 mmol), and *p*-toluenesulfonic acid (catalytic amount) in benzene (5 mL) was refluxed in a Dean–Stark apparatus for 1.25 h. Water (20 mL) was added and the reaction mixture was extracted with ether and worked up in the usual way. Removal of solvent gave a crude product that was purified by column chromatography (silica gel, pet. ether:ether, 5:1) to provide keto-acetal (**31**) (40 mg, 89%) as a colorless oil; R_f 0.41 (pet. ether:ether, 1:1); ν_{max} (film): 1740, 2979 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.91 (s, 3H, CH_3), 0.97 (s, 3H, CH_3), 3.80–4.00 (m, 4H, ROCH_2CH_2OR), 4.84 (t, 1H, RC*H*(OR^1)$_2$, *J* = 4.5 Hz); *m/e* (relative intensity): 252(4.52, M^+), 238(1.24), 191(2.90), 190(6.89), 176(2.09), 175(7.39), 167(1.45), 164(1.18), 148(6.24), 99 (22.90), 95(15.37), 73(100.00). *Mol. Wt.* calcd. for $C_{15}H_{24}O_3$: 252.1725; found: 252.1722. *Anal.* calcd. for $C_{15}H_{24}O_3$: C 71.39, H 9.59; found: C 71.12, H 9.55.

*Trimethylsilyl enol ether (**33**)*

Lithium diisopropylamide was generated by reacting *n*-butyllithium (1.6 M; hexane) (1.35 mL, 2.03 mmol) with diisopropylamine (0.28 mL, 2.0 mmol) in dry tetrahydrofuran (5 mL) at 0°C under an argon atmosphere for 30 min. A solution of keto-acetal (**31**) (0.42 g, 1.7 mmol) in dry tetrahydrofuran (5 mL) was then added to this cooled reaction mixture at −78°C and, after 2 h, dry chlorotrimethylsilane (0.37 mL, 2.6 mmol) was introduced. Stirring was continued for 1 h while the temperature reached 25°C. The solvent was removed and a solution of the residue in ether was filtered through a pad of Celite and sand. Removal of ether provided trimethylsilyl enol ether (**33**) (0.54 g, 98%) as a colorless oil; ν_{max} (film): 2951, 1616 cm^{-1}; δ ($CDCl_3$, 80 MHz): 0.13 (s, 9H, RSi(CH_3)$_3$), 0.67 (s, 3H, CH_3), 0.81 (s, 3H, CH_3), 3.50–4.00 (m, 4H, ROCH_2CH_2OR), 4.54 (d, 1H, R^1C*H*:C(OR^2)R^3, *J* = 4 Hz), 4.79 (t, 1H, RC*H*(OR)$_2$, *J* = 4.5 Hz); *m/e* (relative intensity): 324(4.57, M^+), 281(1.22), 253(3.11), 252(5.29), 251(16.01), 209(8.96), 183(15.62), 99(9.51), 95(7.19), 73(100.00). *Anal.* calcd. for $C_{18}H_{32}O_3Si$: C 66.62, H 9.94; found: C 66.68, H 9.88.

*Hydroxyethoxy-ketones (**35**a,b)*

To a solution of trimethylsilyl enol ether (**33**) (0.13 g, 0.41 mmol) in dry methylene chloride (25 mL) under an argon atmosphere was added titanium tetrachloride (0.050 mL, 0.48 mmol) at −78°C and stirring continued for 20 min. Saturated sodium bicarbonate solution (10 mL) was added at −78°C and, after warming, the reaction mixture was extracted with ether, and the combined organic layer was washed with saturated sodium bicarbonate solution, brine solution, water, and dried ($MgSO_4$). Removal of solvent gave a crude product that was purified by column chromatography (silica gel, pet. ether:ether, 4:1) to afford a mixture of epimers of hydroxyethoxy-ketones (**35***a,b*) (78 mg, 78%) as a colorless oil. The ratio (1.2:1) of epimers (**35***a*:**35***b*) was determined from proton integration in the nmr spectrum.

35*a*: R_f 0.22 (pet. ether:ether, 3:7), ν_{max} (film): 3457, 1734, 2950 cm^{-1}; δ ($CDCl_3$, 270 MHz): 0.92 (s, 3H, CH_3), 0.97 (s, 3H, CH_3), 2.48 (d, 1H, α*H*, *J* = 6 Hz), 3.60–3.70 (m, 4H, ROCH_2CH_2OR), 3.70–3.80 (m, 1H, R^2C*H*OR); *m/e* (relative intensity): 252(2.83, M^+), 234(1.16), 222(3.18), 209(2.27), 207(3.44), 192(3.38), 191(6.92), 190(9.91), 179(1.99), 177(1.36), 175(6.70), 173(6.07), 164(3.60), 163(18.33), 147(59.08), 137(10.70), 135(29.86), 134(26.63), 132(23.22), 107(22.40), 95(27.14). *Mol. Wt.* calcd. for $C_{15}H_{24}O_3$: 252.1725; found: 252.1725.

35*b*: R_f 0.28 (pet. ether:ether, 3:7); ν_{max} (film): 3457, 2950, 1734, cm^{-1}; δ ($CDCl_3$, 270 MHz); 0.92 (s, 3H, CH_3), 2.30–2.40 (m, 2H, C-3H, C-4H). 3.50–3.75 (m, 4H, ROCH_2CH_2OR), 3.76–3.86 (m, 1H, R^2C*H*OR); *m/e* (relative intensity): 252(35.14, M^+), 234(3.92), 224(1.18), 222(6.04), 209(4.46), 208(5.97), 107(31.69), 191(22.41), 190(70.93), 175(40.28), 163(47.37), 162(41.74), 161(19.93), 149(13.83), 148(27.41), 147(100.00). *Mol. Wt.* calcd. for $C_{15}H_{24}O_3$: 252.1725; found: 252.1721.

*(+)-Dimethoxyketone (**32**)*

(+)-Ketoaldehyde (**30**) (0.64 g, 3.1 mmol) was treated with a methanolic solution of cerium trichloride heptahydrate (0.4 M, 6.7 mL) and trimethyl orthoformate (2.3 mL, 21 mmol) (19). Stirring was continued at 25°C for 2 h before sodium bicarbonate solution (5%, 20 mL) was added and the reaction mixture extracted with ether and worked up as usual. The crude product was purified by column chromatography (silica gel, pet. ether:ether, 1:1) to give (+)-dimethoxyketone (**32**) (0.63 g, 83%) as a colorless oil; R_f 0.72 (pet. ether:ether, 2:7); $[\alpha]_D^{25}$ +32.14° (*c* 0.98, $CHCl_3$); ν_{max} (film): 2960, 1742, 1121 cm^{-1}; δ ($CDCl_3$, 270 MHz): 0.90 (s, 3H, CH_3), 0.95 (s, 3H, CH_3), 3.30 (s, 6H, RCH(OCH_3)$_2$), 4.33 (t, 1H, RC*H*(OCH_3)$_2$, *J* = 4 Hz); *m/e* (relative intensity): 254(0.98, M^+), 224(2.28), 223(13.72), 222(19.48), 207(3.88), 191(15.27), 190(22.66), 175(14.94), 162(10.42), 149(11.38), 148(16.51), 147(18.45), 75(100.00). *Mol. Wt.* calcd. for $C_{15}H_{26}O_3$: 254.188; found: 254.188. *Anal.* calcd. for $C_{15}H_{26}O_3$: C 70.83, H 10.30; found: C 71.12, H 10.26.

*(+)-Trimethylsilyl enol ether (**34**)*

Lithium diisopropylamide was generated by adding *n*-butyllithium (1.6 M; hexane) (2.4 mL, 3.6 mmol) to diisopropylamine (0.50 mL, 3.6 mmol) in dry tetrahydrofuran (10 mL) at 0°C under an argon atmosphere for 30 min. A solution of (+)-dimethoxyketone (**32**) (0.74 g, 2.9 mmol) in dry tetrahydrofuran (10 mL) was then introduced to this cooled reaction mixture at −78°C. After 2 h, freshly distilled chlorotrimethylsilane (0.56 mL, 4.4 mmol) was added and stirring was continued for 1 h while the temperature warmed slowly to 25°C. The solvent was removed and a pentane solution of the crude product was filtered through a column of Celite and sand. Removal of solvent provided (+)-trimethylsilyl enol ether (**34**) (0.96 g, 100%) as a colorless oil; $[\alpha]_D^{25}$ +1.64° (*c* 0.61, $CHCl_3$); ν_{max} (film): 1620, 2975 cm^{-1}; δ ($CDCl_3$, 270 MHz): 0.18 (s, 9H, RSi(CH_3)$_3$), 0.69 (s, 3H, CH_3), 0.84 (s, 3H, CH_3), 3.28 (d, 6H, RHC(OCH_3)$_2$, *J* = 2.0 Hz), 4.31 (t, 1H, RC*H*(OCH_3)$_2$, *J* = 4 Hz), 4.51 (d, 1H, R^3CH:CR^1R^2, *J* = 3.5 Hz); *m/e* (relative intensity): 326(1.35, M^+), 312(1.57), 311(6.78), 296(2.18), 295(7.68), 294(15.95), 251(8.93), 209(18.98), 208(17.12), 182(28.59), 75(100.00). *Mol. Wt.* calcd. for $C_{18}H_{34}O_3Si$: 326.2277; found: 326.2271. *Anal.* calcd. for $C_{18}H_{34}O_3Si$: C 66.21, H 10.50; found: C 66.32, H 10.63.

(R)- *and* (S)-*methoxyketones (**36**a, b)*

To a solution of (+)-trimethylsilyl enol ether (**34**) (0.58 g, 1.8 mmol) in dry methylene chloride (40 mL) under an argon atmosphere was added titanium tetrachloride (0.23 mL, 2.1 mmol) at −78°C for 45 min. Saturated sodium bicarbonate solution (10 mL) was added at −78°C and the reaction mixture extracted with ether and worked up as usual. The crude product was purified by column chromatography (silica gel, pet. ether:ether, 1:1) to provide (*S*)-methoxyketone (**36***b*) (83 mg, 21%) as a colorless oil, followed by (*R*)-methoxyketone (**36***a*) (260 mg, 66%) as a white solid. Crystallization from petane provided **36***a* as colorless prisms; mp 40°C; R_f 0.64 (pet. ether:ether, 2:7); $[\alpha]_D^{25}$ +91.47° (*c* 0.34, $CHCl_3$); ν_{max} ($CHCl_3$): 2951, 1741, 1100 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.91 (s, 3H, CH_3), 0.97 (s, 3H, CH_3), 2.45 (d, 1H, αH, *J* = 6 Hz), 3.42 (s, 3H, $ROCH_3$), 3.65 (dd, 1H,

Methoxy-endo-*alcohols (**39**a,b)*

Calcium (0.84 g, 21 mmol) was treated with dry liquid ammonia (80 mL) at −78°C for 5 min under an argon atmosphere and a solution of methoxyketones (***36****a, b*) (0.72 g, 3.2 mmol) in dry ether (6 mL) was then added. The reaction mixture was stirred at reflux for 30 min and dry 1-propanol (3 mL) was added. Care was taken at all times to exclude water from the system. When the blue color was discharged the reaction mixture was diluted with water and extracted with ether. Removal of solvent gave a crude product that was purified by column chromatography (silica gel, pet. ether:ether, 5:1) to give a mixture of epimeric methoxy-*endo*-alcohols (***39****a, b*) (0.71 g, 98%) as a colorless oil; R_f 0.30 (pet. ether:ether, 1:1); ν_{max} (film): 3492, 2967 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.80 (s, 3H, CH_3), 0.97 (s, 3H, CH_3), 3.38 (s, 3H, $ROCH_3$), 3.50–3.60 (m, 1H, R^2CHOMe), 3.92 (d, 1H, R^2CHOH, J = 8 Hz); m/e (relative intensity): 224(0.88 M^+), 206(2.67), 193(2.62), 192(20.37), 191(2.08), 177(23.86), 174(15.05), 161(25.57), 159(23.92), 108(32.75), 107(76.42), 95(100.00). *Mol. Wt.* calcd. for $C_{14}H_{24}O_2$: 224.1776; found: 224.1776. *Anal.* calcd. for $C_{14}H_{24}O_2$: C 74.95, H: 10.78; found: C 74.73, H 10.68.

Methoxy-endo-*acetates (**40**a,b)*

Dry acetic anhydride (7.3 mL, 77 mmol) was added to a solution of epimeric methoxy-*endo*-alcohols (***39****a, b*) (5.8 g, 26 mmol) and 4-dimethylaminopyridine (9.4 g, 77 mmol) in dry pyridine (150 mL) at 25°C under an argon atmosphere. Stirring was continued for 5 h before water (50 mL) was added and the reaction mixture worked up by extraction with ether. Removal of solvent gave a crude product that was purified by column chromatography (silica gel, pet. ether:ether, 5:1) to provide a mixture of epimeric methoxy-*endo*-acetates (***40****a,b*) (6.1 g, 89%) as a colorless oil; R_f 0.58 (pet. ether:ether, 1:1); ν_{max} (film): 2947, 1741 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.82 (s, 3H, CH_3), 0.85 (s, 3H, CH_3), 2.06 (s, 3H, $ROCOCH_3$), 3.25 (s, 3H, $ROCH_3$), 3.25–3.34 (m, 1H, R^2CHOMe), 5.30 (dd, 1H, R^2CHOAc, J = 5 Hz, 2 Hz); m/e (relative intensity): 266 (not observed, M^+), 251(1.28), 236(7.53), 224(17.37), 207(34.09), 206(44.09), 174(82.19), 159(66.33), 119(55.74), 107(79.07), 105(64.97), 95(91.52), 91(77.33), 83(71.54), 79(82.81), 71(100.00). *Mol. *Hydroxyacetates (**41**a,b)*

To a well-stirred solution of a mixture of epimeric methoxy-*endo*-acetates (***40****a, b*) (2.0 g, 7.5 mmol) in dry methylene chloride (10 mL) at −30°C under an argon atmosphere was added 15-crown-5 (0.30 M, 8.9 mL) saturated with dry sodium iodide in dry methylene chloride, followed by the addition of boron tribromide (1.25 M, 1.54 mL) in dry methylene chloride (10). Stirring was continued for 4 h and the reaction worked up by dilution with saturated sodium bicarbonate solution (20 mL) followed by extraction with methylene chloride. The combined organic extract was washed with saturated sodium bicarbonate solution, hydrochloric acid solution (1 N), saturated sodium bisulphite solution, water, and dried ($MgSO_4$). Removal of solvent gave a crude product that was purified by column chromatography (silica gel, pet. ether:ether, 5:1) to yield a mixture of epimeric hydroxyacetates (***41****a, b*) (1.7 g, 89%) as a colorless oil; R_f 0.29 (pet. ether:ether, 1:1); ν_{max} (film): 3467, 2967, 1717 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.88 (s, 3H, CH_3), 0.89 (s, 3H, CH_3), 2.01 (s, 3H, $ROCOCH_3$), 3.33 (d, 1H, R^2CHOH, J = 12 Hz, exchangeable with D_2O), 3.53–3.60 (m, 1H, R^2CHOH), 4.74 (dd, 1H, R^2CHOAc, J = 4.5 Hz, 1.5 Hz); m/e (relative intensity): 252(0.59, M^+), 250(1.38), 210(1.87), 209(1.23), 208(7.09), 207(3.85), 206(1.95), 193(10.50), 192(49.20), 190(12.69), 174(53.74), 159(63.13), 121(100.00). *Mol. Wt.* calcd. for $C_{15}H_{24}O_3$: 252.1725; found: 252.1731. *Anal.* calcd. for $C_{15}H_{24}O_3$: C 71.39, H 9.59; found: C 71.62, H 9.60.

*(+)-Ketoacetate (**42**)*

A solution of epimeric hydroxyacetates (***41****a, b*) (90 mg, 0.35 mmol) and pyridinium dichromate (0.40 g, 1.1 mmol) (17) in dry methylene chloride (10 mL) was stirred at 60°C under an argon atmosphere for 10 h. The reaction mixture was then diluted with ether and filtered through a pad of silica gel. Removal of solvent gave a crude product that was purified by column chromatography (silica gel, pet. ether:ether, 10:0) to give (+)-ketoacetate (**42**) (85 mg, 95%) as a white solid, which was recrystallized from pentane as colorless prisms; mp 77–79°C; R_f 0.48 (pet. ether:ether, 1:1); $[\alpha]_D^{25}$ +101.38° (*c* 0.65, $CHCl_3$); ν_{max} ($CHCl_3$); 2969, 1717, 1699 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.94 (s, 3H, CH_3), 0.98 (s, 3H, CH_3), 2.07 (s, 3H, R-OCOCH_3), 5.05 (dd, 1H, R^2CHOAc, J = 4.5 Hz, 1.5 Hz); m/e (relative intensity): 250(23.95 M^+), 208(32.63), 207(54.57), 191(18.76), 190(100). *Mol. Wt.* calcd. for $C_{15}H_{22}O_3$: 250.1569; found: 250.1572. *Anal.* calcd. for $C_{15}H_{22}O_3$: C 71.97, H 8.86; found: C72.06, H 8.85).

*(+)-Ene-acetate (**43**)*

Methyltriphenylphosphonium bromide (1.5 g, 4.2 mmol) was suspended in dry tetrahydrofuran (20 mL) under an argon atmosphere and cooled to −78°C. *n*-Butyllithium (3.2 mL, 4.2 mmol; 1.3 M solution in hexane) was added and, after 10 min, the cold bath was removed and the reaction mixture was stirred for 1 h. During this time all the solid disappeared and the solution became dark orange. A solution of (+)-ketoacetate (**42**) (0.70 g, 2.8 mmol) in dry tetrahydrofuran (10 mL) was then introduced. Stirring was continued for 1 h and the reaction mixture was then diluted with water (10 mL) and extracted with petroleum ether. Removal of solvent gave a crude product that was purified by column chromatography (silica gel, pet. ether:ether, 15:1) to provide (+)-eneacetate (**43**) (0.59 g, 85%) as a colorless oil; R_f 0.94 (pet. ether:ether, 1:1); $[\alpha]_D^{25}$ +18.25° (*c* 0.16, $CHCl_3$); ν_{max} (film): 2960, 1738, 1640, 885 cm^{-1}; δ ($CDCl_3$, 270 MHz): 0.82 (s, 3H, CH_3), 0.88 (s, 3H, CH_3), 2.05 (s, 3H, $ROCOCH_3$), 4.55 (s, 1H, $R^1R^2C{:}CHH$), 4.57 (s, 1H, $R^1R^2C{:}CHH$), 5.12 (dd, 1H, R^2CHOAc, *J* = 4.5 Hz, 2Hz); *m/e* (relative intensity): 248 (not observed, M^+), 247(0.10), 239(2.37), 207(2.41), 206(7.15), 205(4.22), 191(12.70), 188(67.71), 173(48.65), 160(44.53), 145(43.12), 131(50.61), 121(40.23), 108(42.28), 107(64.47), 95(67.81), 93(82.49), 91(100.00). *Anal.* calcd. for $C_{16}H_{24}O_2$: C 77.38, H 9.74; found: C 77.56, H 9.69.

*(+)-Hydroxyalkene (**44**)*

To a cold (0°C) stirred solution of lithium aluminum hydride (11 mg, 0.28 mmol) in dry tetrahydrofuran (1 mL) under an argon atmosphere was added a solution of (+)-alkene-acetate (**43**) (68 mg, 0.28 mmol) in dry tetrahydrofuran (3 mL). Stirring was continued for 2 h and the reaction mixture worked up by careful addition of water (10 mL) followed by extraction with ether. Removal of solvent gave a crude product that was purified by column chromatography (silica gel, pet. ether:ether, 10:1) to give (+)-hydroxyalkene (**44**) (56 mg, 99.6%) as a colorless oil; R_f 0.67 (pet. ether:ether, 1:1); $[\alpha]_D^{25}$ +64.0° (*c* 0.5, $CHCl_3$); ν_{max} (film): 3375, 2950, 1640, 885 cm^{-1}; δ ($CDCl_3$, 270 MHz): 0.89 (s, 3H, CH_3), 0.90 (s, 3H, CH_3), 3.91 (dd, 1H, R^2CHOH, *J* = 4.5 Hz, 2 Hz), 4.62 (s, 1H, $R^1R^2C{:}CHH$), 4.67 (s, 1H, $R^1R^2C{:}CHH$); *m/e* (relative intensity): 206(9.49, M^+), 204(2.33), 191(38.86), 188(31.18), 173(30.30), 163(22.28), 161(23.24), 146(39.62), 136(69.60), 132(29.02), 123(25.04), 121(85.72), 109(40.53), 108(66.91), 107(100.00). *Mol. Wt.* calcd. for $C_{14}H_{22}O$: 206.1672; found: 206.1671. *Anal.* calcd. for $C_{14}H_{22}O$: C 81.49, H 10.75; found: C 81.27, H 10.60.

*(+)-Tetracyclic alcohol (**45**)*

To a well-stirred, heated (60°C) solution of (+)-hydroxyalkene (**44**) (0.42 g, 2.0 mmol) in dry toluene (5 mL) was added successively a solution of diethylzinc (1.4 mL, 2.8 mmol, 25% w/v) in toluene and methylene iodide (0.23 mL, 2.8 mmol). A stream of dry air was passed through the reaction mixture for 3.5 h. After acidification with hydrogen chloride solution (1 N) the reaction mixture was extracted with ether and worked up as usual. Removal of solvent gave a crude product that was purified by column chromatography (silica gel, pet. ether:ether, 10:1) to afford (+)-tetracyclic alcohol (**45**) (0.45 g, 99%) as a white solid, which was recrystallized from pentane as colorless prisms; mp 109–111°C; $[\alpha]_D^{25}$ +31.61° (*c* 0.31, $CHCl_3$); R_f 0.21 (pet. ether:ether, 8:2); ν_{max} ($CHCl_3$): 3643, 3010, 2965 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.20–0.28 (m, 2H, $R^1R^2CCH_2CH_2$), 0.40–0.53 (m, 2H, $R^1R^2CCH_2CH_2$), 0.88 (s, 3H, CH_3), 4.03 (dd, 1H, R^1R^2CHOH, *J* = 4 Hz, 2 Hz); *m/e* (relative intensity): 220(2.89, M^+), 205(8.42), 203(1.53), 202(5.91), 189(15.12), 187(18.89), 177(11.05), 161(10.28), 159(13.34), 149(19.21), 147(16.05), 146(12.20), 145(18.79), 135(29.88), 121(45.17), 119(33.75), 107(81.32), 105(54.84), 95(81.66), 93(91.26), 91(96.66), 79(100.00). *Mol. Wt.* calcd. for $C_{15}H_{24}O$: 220.1827; found: 220.1821. *Anal.* calcd. for $C_{15}H_{24}O$: C 81.76, H 10.98; found: C 81.89, H 10.88.

*(+)-Longiborneol (**11**)*

To a solution of (+)-tetracyclic alcohol (**45**) (380 mg, 1.72 mmol) in glacial acetic acid (3 mL) was added platinum oxide (16 mg, 0.07 mmol). The resultant suspension was stirred with hydrogen under pressure (2.7 atm; 1 atm = 101.3 kPa) at room temperature for 12 h. Saturated sodium bicarbonate solution was added until the mixture was neutral and the aqueous slurry was extracted with ether. The combined organic layer was washed with hydrochloric acid (1 N), brine solution, and dried ($MgSO_4$). Removal of solvent yielded a crude product that was subjected to column chromatography (silica gel, pet. ether:ether, 5:1) to provide (+)-longiborneol (**11**) (0.383 g, 100%), which crystallized from pentane as colorless prisms; mp 105–107°C (lit. (10, 11) mp for (−)-longiborneol, 106–107°C); R_f 0.41 (pet. ether:ether, 4:1); $[\alpha]_D^{25}$ +15.83° (*c* 0.54, $CHCl_3$) (lit. (10, 11) for (−)-longiborneol, $[\alpha]_D^{25}$ −16.3° (*c* 0.66, $CHCl_3$)); ν_{max} ($CHCl_3$): 3643, 2943 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.84 (s, 3H, CH_3), 0.87 (s, 3H, CH_3), 0.94 (s, 6H, CH_3, CH_3), 3.77 (dd, 1H, R^2CHOH, *J* = 5 Hz, 2 Hz); *m/e* (relative intensity): 222(7.36, M^+), 208(4.52), 207(28.42), 204(50.55), 189(59.98), 161(25.91), 133(26.52), 121(26.36), 119(81.13), 109(58.59), 95(100.00). *Mol. Wt.* calcd. for $C_{15}H_{26}O$: 222.1983; found: 222.1979. *Anal.* calcd. for $C_{15}H_{26}O$: C 81.02, H 11.79; found: C 81.16, H 11.69.

*Longiborneol MTPA ester (**46**)*

To a stirred solution of (+)-longiborneol (**11**) (15 mg, 0.067 mmol) in dry carbon tetrachloride (0.5 mL) and pyridine (2 mL) was added *R*-(+)-α-methoxy-α-trifluoromethylphenylacetyl chloride (+)-MTPA-chloride; 26 mg, 0.10 mmol) at 25°C under an argon atmosphere. After 20 h, the solution was diluted and extracted with ether and the combined organic layer was washed with hydrochloric acid solution (1 N), brine solution, and dried ($MgSO_4$). Removal of solvent gave a crude product that was purified by column chromatography (silica gel; petroleum ether:ether, 10:1) to yield pure longiborneol MTPA ester (**46**) (28 mg, 95%) as a white solid. Crystallization from pentane afforded **46** as colorless prisms; mp 89–91°C; R_f 0.88 (petroleum ether:ether, 4:1); ν_{max} ($CHCl_3$): 1750 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.80 (s, 3H, CH_3), 0.81 (s, 3H, CH_3), 0.83 (s, 3H, CH_3), 0.94 (s, 3H, CH_3), 3.57 (q, 3H, R-OCH_3, *J* = 1.2 Hz), 5.41 (dd, 1H, $R^1R^2CHOR^3$, *J* = 5 Hz, 2 Hz), 7.36–7.44 (m, 3H, RC_6H_5), 7.58–7.66 (m, 2H, RC_6H_5); ^{13}C nmr ($CDCl_3$, 100.6 MHz): 22.237, 26.979, 30.035, 33.297, 35.201, 40.685, 50.626, 52.000, 60.597 (quarternary and methylene carbons); 13.210, 22.279, 28.798, 29.402, 44.019, 55.463, 60.597, 23.990 (methyl and methine carbons); 83.772 (RCF_3), 125.383, 127.456, 128.215, 129.450 (aromatic carbons), 166 (carbonyl carbon); ^{19}F nmr ($CDCl_3$, 254 MHz): singlet at δ 5.08 in the resolution-enhanced, proton-decoupled spectrum; *m/e* (relative intensity): 220(1.20), 205(49.10), 189(58.40), 95(100.00). *Mol. Wt.* calcd. for $C_{25}H_{33}O_3F_3$; 438.2381; found: 438.2377. *Anal.* calcd. for $C_{25}H_{33}O_3F_3$, C 68.47, H 7.59; found: C 68.44, H 7.69.

*(+)-Longicamphor (**10**)*

Pyridinium chlorochromate (0.51 g, 2.4 mmol) (13) was suspended in dry methylene chloride (2 mL), and a solution of (+)-longiborneol (**11**) (0.35 g, 1.6 mmol) in dry methylene chloride (4 mL) was added rapidly at room temperature. After 3 h under argon the black reaction mixture was diluted with ether and filtered through a pad of silica gel. Removal of the solvent provided a crude product that was purified by column chromatography (silica gel, pet. ether) to afford (+)-longicamphor (**10**) (0.29 g, 85%) as a colorless oil; R_f 0.87 (pet. ether:ether, 4:1); $[\alpha]_D^{25}$ +18.92° (*c* 0.74, C_2H_5OH); ν_{max} (film): 2971, 1739 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.89 (s, 3H, CH_3), 0.92 (s, 3H, CH_3), 1.00 (s, 3H, CH_3), 1.07 (s, 3H, CH_3); *m/e* (relative intensity): 220(100.00, M^+), 206(7.00), 205(28.40), 178(12.60), 177(86.70), 163(19.90), 150(20.10), 149(25.70), 137(34.70), 136(43.50), 135(34.80), 124(52.90), 95(95.40). *Mol. Wt.* calcd. for $C_{15}H_{24}O$: 720.1827; found: 220.1826. *Anal.* calcd. for $C_{15}H_{24}O$: C 81.76, H 10.98; found: C 81.67, H 11.00.

*(+)-Isolongiborneol (**47**)*

Lithium aluminum hydride (22 mg, 0.59 mmol) was suspended in dry tetrahydrofuran (2 mL) at 0°C, and a solution of (+)-longicamphor (**10**) (130 mg, 0.59 mmol) in dry tetrahydrofuran (1.5 mL) was added slowly. The reaction mixture was stirred at 0°C under an argon

atmosphere for 3 h and, after dilution with water (10 mL), extracted with ether. The combined organic layer was washed with hydrochloric acid solution (1 N), brine, water, and dried ($MgSO_4$). After removal of solvent the crude product was purified by column chromatography (silica gel, pet. ether) to yield (+)-isolongiborneol (**47**) (0.12 g, 92%) as a colorless oil; R_f 0.94 (pet. ether:ether, 9:1); $[\alpha]_D^{25}$ +45.8° (*c* 0.69, $CHCl_3$); ν_{max} (film): 3436, 2965 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.80 (s, 3H, CH_3), 0.94 (s, 3H, CH_3), 0.98 (s, 3H, CH_3), 1.12 (s, 3H, CH_3), 3.84 (dd, 1H, R^2CHOH, J = 8 Hz, 4 Hz); *m/e* (relative intensity): 222(4.50, M^+), 221(1.80), 220(5.30), 219(2.20), 208(3.80), 207(17.10), 205(11.30), 204(48.10), 189(34.40), 161(24.70), 137(31.10), 133(35.90), 119(100.00). *Mol. Wt.* calcd. for $C_{15}H_{26}O$: 222.1984; found: 222.1987. *Anal.* calcd. for $C_{15}H_{26}O$: C 81.02, H 11.79; found: C 81.28, H 11.80.

(+)-Longifolene (12)

(+)-Longiisoborneol (**47**) (0.12 g, 0.54 mmol) was treated with methanesulphonyl chloride (0.085 mL, 1.1 mmol) and 4-dimethylaminopyridine (30 mg, 0.25 mmol) in dry pyridine (1 mL) and stirred at 105°C under an argon atmosphere for 16 h. After dilution with water (10 mL) and extraction with ether, the combined organic layer was washed with hydrochloric acid solution (1 N), saturated sodium bicarbonate solution, water, and dried ($MgSO_4$). Removal of solvent provided a crude product that was purified by column chromatography (silica gel, pet. ether) to give (+)-longifolene (**12**) (73 mg, 66%) as a colorless oil; R_f 0.91 (pet. ether:ether, 10:0); $[\alpha]_D^{25}$ +51.77° (*c* 1.07, $CHCl_3$) (lit. (3*d*) $[\alpha]_D^{19}$ +51.5° (*c* 0.35)); ν_{max} (film): 2964, 1661, 871 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.90 (s, 3H, CH_3), 0.95 (s, 3H, CH_3), 1.00 (s, 3H, CH_3), 4.50 (s, 1H, RC:C*H*H), 4.75 (s, 1H, RC:CH*H*); *m/e* (relative intensity): 204(47.60 M^+), 203(15.40), 190(11.80), 189(63.20), 175(27.20), 163(19.60), 162(18.40), 161(76.00), 133(56.70), 121(59.00), 119(66.20), 109(65.20), 108(55.00), 107(86.50), 95(96.60), 91(100.00). *Mol. Wt.* calcd. for $C_{15}H_{14}$: 204.1878; found: 204.1877. *Anal.* calcd. for $C_{15}H_{24}$: C 88.16, H 11.84; found: C 87.94, H 11.72.

Acknowledgments

We are grateful to the Natural Sciences and Engineering Research Council of Canada, Ottawa, for financial support of this research and to Professor S. C. Welch (University of Houston) and Professor N. H. Anderson (University of Washington) for samples of longiborneol and nmr spectra.

7-Diethylamino-3-((4′-iodoacetylamino)phenyl)-4-methylcoumarin, a fluorescent probe of the hydrophobic cleft in the tropomyosin coiled coil

LESLIE D. BURTNICK[1] AND ANITA RACIC

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received September 25, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

LESLIE D. BURTNICK and ANITA RACIC. Can. J. Chem. **66**, 1805 (1988).

A sulfhydryl-specific fluorescent reagent, 7-diethylamino-3-((4′-iodoacetylamino)phenyl)-4-methylcoumarin (DCIA) was used to label cysteine residues on tropomyosin (TM) from rabbit cardiac and rabbit skeletal muscles. The emission maximum at 486 nm, the high degree of fluorescence polarization, and the limited accessibility of the bound probe to quenching by iodide suggest that the probe is bound in the hydrophobic cleft between polypeptide chains of the TM coiled coil, as well as being bound covalently at a cysteine residue. The labelled TMs retain their abilities to bind F-actin and are able to interact with deoxyribonuclease I. They, however, show a reduced tendency to aggregate into filaments in low ionic strength solutions.

LESLIE D. BURTNICK et ANITA RACIC. Can. J. Chem. **66**, 1805 (1988).

On a utilisé un réactif fluorescent spécifique aux groupements sulfhydriles, la diéthylamino-7 ((iodo-4′acétylamino)phényl)-3 méthyl-4 coumarine (DCIA), pour marquer les résidus de cysteine de la tropomyosine (TM) des muscles cardiaques et du squellette du lapin. L'émission maximale à 486 nm, le haut degré de polarisation de la fluorescence et l'accessibilité limitée de la sonde liée à un piégeage par l'iode suggère que la sonde est liée, d'une part, à la portion hydrophobe que l'on retrouve entre les chaînes polypeptidiques de l'enroulement de la TM et, d'autre part, à un résidu de cystéine par une liaison covalente. Les TM marquées conservant la possibilité de se lier à la F-actine et elles sont capables d'interagir avec la désoxyribonucléase I. Toutefois, leur tendance à former des filaments par aggrégats, dans des solutions de faible force ionique, est réduite.

[Traduit par la revue]

Introduction

Tropomyosin (TM) in striated muscle binds along the length of the F-actin filaments and, with troponin, confers calcium sensitivity to the interaction between actin and myosin (reviewed in ref. 1). The TM molecule consists of two α-helical polypeptide chains, each of molecular mass 33 kDa. The chains run parallel to each other, are in register, and are wound around each other to form a rod-like coiled coil having a cross-sectional diameter of about 2 nm and a length of 40 nm (reviewed in ref. 2). In low ionic strength solutions, adjacent TM molecules aggregate in a head-to-tail manner to form filaments. This interaction involves an 8 or 9 residue overlap between the NH_2-terminal and COOH-terminal ends of adjacent molecules (3). An increase in ionic strength leads to depolymerization of the filaments.

Rabbit skeletal muscle contains two types of TM chain, α and β, which are combined into molecular species αα and αβ in equal proportions (4, 5). Rabbit cardiac muscle TM contains only αα-TM. The α and β chains have identical lengths of 284 amino acid residues but exhibit 39 differences in sequence. Of particular interest for this study is that the α chain contains a single cysteine residue at position 190 in the sequence, while the β chain contains two cysteines, Cys-36 and Cys-190 (6).

The coiled coil structure of TM is stabilized to a large extent by the presence of a hydrophobic core in the region where the two helical chains come into contact. Since two turns of an α-helix contain 7 amino acid residues, a 2-stranded helical coiled coil can be stabilized by hydrophobic residues at positions 2 and 5 of a repeating heptad sequence $(X\text{-}N\text{-}X\text{-}X\text{-}N\text{-}X\text{-}X)_n$, where N is a nonpolar residue (7). This pattern is closely followed by TM sequences from both muscle and non-muscle sources (8). Both Cys-36 and Cys-190 are located at position 2 in the repeating heptad pattern and, so, are located in the hydrophobic cleft between the adjacent chains in a TM molecule. This explains their limited accessibility to sulfhydryl-reactive reagents in native TM.

We have labelled both cardiac and skeletal muscle TMs with a sulfhydryl-specific fluorescent reagent, 7-diethylamino-3-((4′-iodoacetylamino)phenyl)-4-methylcoumarin (DCIA) to obtain the respective products DCIA-C-TM and DCIA-S-TM. Both exhibit a bright blue fluorescence on excitation with ultraviolet light. The fluorescence properties of the bound probes provide information about the structure of TM and on its interactions with two other proteins, actin and deoxyribonuclease I (DNAase I).

Results and discussion

When the labelling reaction was performed in 5 M guanidine hydrochloride, typical degrees of labelling of cardiac and skeletal muscle TMs were 0.9 and 1.2 DCIA labels per molecule, respectively. The products, DCIA-C-TM and DCIA-S-TM, were highly fluorescent, with emission maxima at 486 nm on excitation at 365 nm (Fig. 1). When subjected to polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulfate, the fluorescent bands moved to positions that could be identified as α and β chains of TM after staining with Coomassie Brilliant Blue and comparison with the migration patterns of unlabelled TM. The general similarity in shape of the emission spectra for the two DCIA-TMs suggests that the environments of the labels on Cys-190 and Cys-36 are similar.

Emission spectra for the protein-bound DCIA more closely resemble that for DCIA in *N*,*N*-dimethylformamide than for DCIA in water (Fig. 2), suggesting that the labels are in rather hydrophobic environments. As both Cys-36 and Cys-190 are in position 2 of the repeating heptad model for a coiled coil protein, it may be that the aromatic ring system of the label is partly buried in the hydrophobic cleft between the two TM chains that form the coiled coil. Evidence to support this suggestion comes

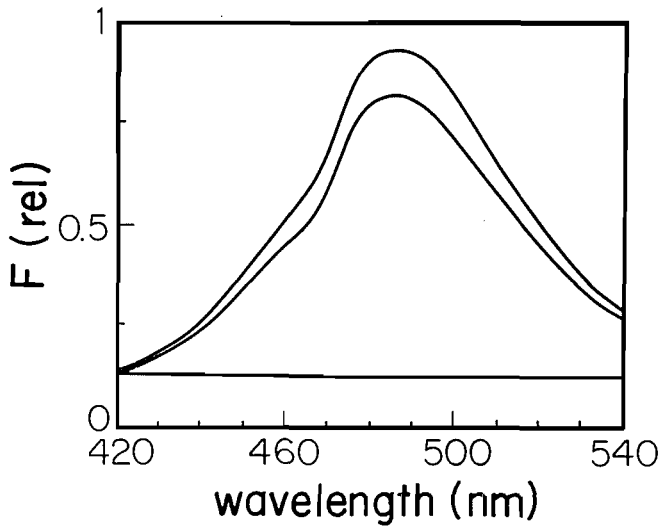

FIG. 1. Fluorescence emission spectra. Upper curve, DCIA-S-TM, 0.8 mg/mL, 1.1 DCIA per protein molecule. Lower curve, DCIA-C-TM, 0.8 mg/mL, 0.9 DCIA per protein molecule. Baseline, unlabelled S-TM, 0.8 mg/mL. Solvent was 0.3 M KCl, 10 mM Tris-HCl, pH 8.0. Excitation was at 365 nm.

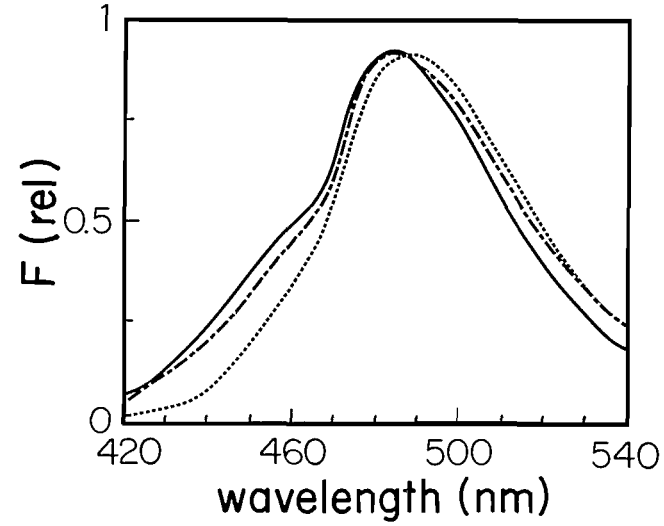

FIG. 2. Emission spectra of DCIA in various environments. Solid line, 43 ng/mL DCIA in *N*,*N*-dimethylformamide. Dashed line, 1.1 mg/mL DCIA-C-TM in 5 mM Tris-HCl, pH 8.0. Dotted line, 8.5 μg/mL DCIA in water. Excitation was at 365 nm. Photomultiplier gain settings were adjusted so that maximal emission intensities were the same for all 3 samples.

from fluorescence quenching experiments using iodide as a quencher. Stern–Volmer plots demonstrate that fluorescence from DCIA-C-TM and DCIA-S-TM is much less affected by iodide quenching than is the fluorescence of a DCIA adduct of 2-mercaptoethanol (Fig. 3). A small difference in slopes of the plots for DCIA-C-TM and DCIA-S-TM is apparent. K_{sv} = 0.523 ± 0.017 M^{-1} for DCIA-C-TM and K_{sv} = 0.384 ± 0.013 M^{-1} for DCIA-S-TM. This may be the result of subtle conformational differences in the environments of Cys-36 (present in S-TM but not in C-TM) or may be the result of different quenching efficiencies at the two sites that arise due to differences in charge of residues adjacent to the Cys at each position. In the presence of 5 M guanidine hydrochloride, the slopes of Stern–Volmer plots for the DCIA-TMs increase by more than

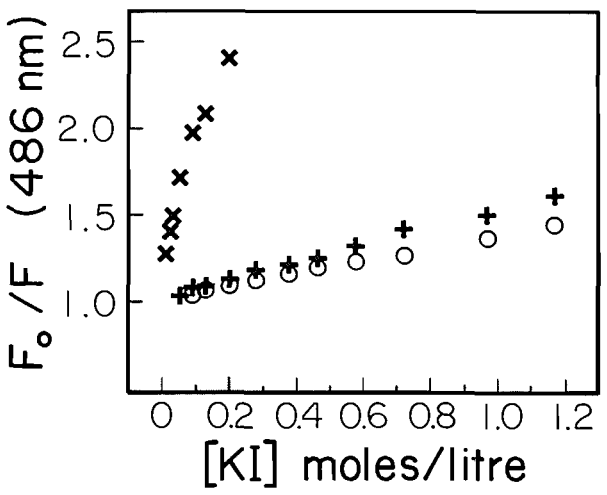

FIG. 3. Quenching of DCIA fluorescence by iodide. Stern–Volmer plot shows iodide quenching of an adduct of DCIA and 2-mercaptoethanol (X), of DCIA-C-TM (+), and of DCIA-S-TM (○). Initial protein concentrations were 0.02 mg/mL. Solvent was 0.3 M KCl, 50 mM Tris-HCl, 1 mM $MgCl_2$, pH 8.0. Aliquots of 3 M KI were added to the samples. Dilution and ionic strength effects were corrected for by adding appropriate volumes of 3 M KCl to control samples.

5-fold, reflecting the greater exposure of the probe to iodide quenching on the denatured proteins.

Fluorescence polarization values at room temperature are high for both DCIA-TMs, typically $p = 0.38 \pm 0.02$. Such high values indicate that during the fluorescence lifetime of the DCIA probe (about 3 ns (9)), rotational motions of the probe are severely hindered. Therefore, the probe is rigidly attached to the large and slow-tumbling (calculated to be on the microsecond time scale (10)) TM molecule. This need not be expected *a priori* as the label is attached through a single covalent bond about which rotations might be expected to occur on a time scale comparable to or more rapid than that of the fluorescence lifetime of the probe. The high polarization value is further evidence that the DCIA is involved in hydrophobic interactions with the TM molecule, such interactions acting with the covalent bond to limit the rotational freedom of the probe.

Muscle TMs interact in an end-to-end manner in low ionic strength solutions (11). We studied the behaviour of DCIA-TMs in solutions of ionic strength ranging up to 0.6 M and did not observe any changes in fluorescence emission intensity or spectral shape. Polarization values were not affected by ionic strength. The viscosities of DCIA-TM solutions were higher in low than in high ionic strength solutions, indicating that some end-to-end interactions were taking place (Fig. 4); however, these interactions clearly were impaired relative to those in unlabelled S-TM. It has been reported elsewhere that labelling at Cys-190 on muscle TM affects the polymerizability of the molecule (12). A similar effect seems to be occurring in the present case.

To ensure that the reduced end-to-end polymerization of DCIA-TMs is not the result of a general loss of structure in the protein, we checked whether the labelled TMs are able to bind F-actin. DCIA-C-TM and DCIA-S-TM cosediment with F-actin when solutions of the proteins are centrifuged at 100 000 × g and the pellets examined by sodium dodecyl sulfate polyacrylamide gel electrophoresis. Bands corresponding to the TMs can be detected due to their fluorescence prior to staining with Coomassie Brilliant Blue. The binding of actin results in an increased

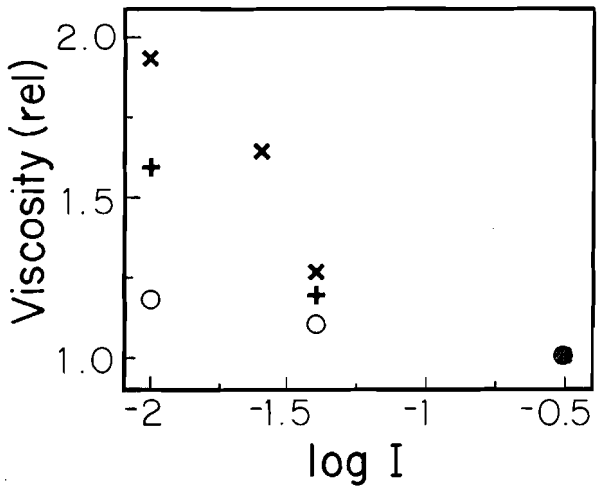

FIG. 4. Relative viscosity measurements. Unlabelled S-TM (X), DCIA-C-TM (+) (0.9 DCIA per protein molecule), and DCIA-S-TM (O) (1.3 DCIA per protein molecule) at 0.8 mg/mL in 10 mM Tris-HCl, pH 8.0, with added KCl as indicated.

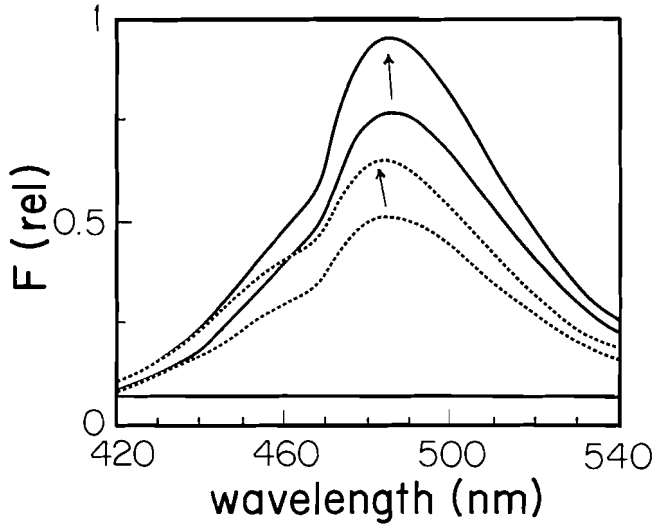

FIG. 5. Effects of actin on emission spectra. Solid lines are for DCIA-S-TM (1.2 DCIA per protein molecule) and dashed lines are for DCIA-C-TM (0.9 DCIA per protein molecule). Four samples were prepared, two containing DCIA-C-TM and two containing DCIA-S-TM. Actin was added to one of each of the DCIA-TM solutions and an equal volume of actin dialysate was added to its control. Final concentration of DCIA-TM in each solution was 0.51 mg/mL. Final concentration of actin, where present, was 2.4 mg/mL. Final buffer composition was 133 mM KCl, 22 mM Tris-HCl, 0.4 mM $MgCl_2$, pH 8.0. Arrows indicate the effects of the added actin to TM at a mole ratio of 7.3 to 1, after waiting for 30 min to ensure that the actin was fully polymerized.

intensity and a blue shift in the emission of the DCIA probe (Fig. 5), suggesting that it has moved into a more hydrophobic environment, possibly being partly covered by F-actin itself. These effects can be titrated with actin and reach plateau values at actin to tropomyosin mole ratios near seven. The binding of DCIA-TM to the extended F-actin filaments does not change the polarization value for DCIA-TM. This might be because the polarization is very high even prior to the binding of actin to TM, to which the DCIA is bound. Any increase in rigidity of the bound probe due to its indirect attachment to the large F-actin system might give only a marginal increase in polarization.

Deoxyribonuclease I (DNAase I) has been shown to bind to TM and has been shown to depolymerize TM filaments (13). The presence of DNAase I in DCIA-TM solutions did not alter fluorescence emission intensities or wavelengths of maximal emission. But evidence for interaction of DCIA-TM with DNAase I was obtained by observation of a consistent decrease of polarization value from 0.38 ± 0.02 to 0.26 ± 0.02 in solutions containing equimolar DNAase I and TM. Interaction with DNAase I introduces a greater freedom of motion into the environment of the bound DCIA on both DCIA-S-TM and DCIA-C-TM in both low ionic strength solutions (5 mM Tris-HCl, pH 8.0) and at higher ionic strengths (at 0.3 and 0.6 M KCl in 5 mM Tris-HCl, pH 8.0). As minor structural changes near Cys-190 are known to affect end-to-end interactions of TM, it may be that it is this loosening up of the coiled coil structure in response to the binding of DNAase I that leads to its depolymerizing activity on TM.

Experimental

Tropomyosin was prepared from frozen rabbit hearts and from frozen rabbit back and leg muscle (Pel-Freez Biologicals, Inc.) according to Smillie (14). Actin was prepared from rabbit skeletal muscle powder as described by Spudich and Watt (15). Bovine pancreatic DNAase I was purchased from Calbiochem. All proteins were greater than 95% pure as judged by polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulfate (SDS) (16).

Concentrations of unlabelled proteins in solution were determined spectrophotometrically using molar absorption coefficients at 277 nm of 21 780 M^{-1} cm^{-1} for TM (17), at 280 nm of 38 130 M^{-1} cm^{-1} for DNAase I (18), and at 290 nm of 26 230 M^{-1} cm^{-1} for G-actin (19). Concentrations of DCIA-labelled TM (DCIA-S-TM and DCIA-C-TM) in solution were determined according to Bradford (20), using unlabelled TM to prepare standard curves. The concentration of label in solutions of DCIA-TM was estimated spectrophotometrically using a molar absorption coefficient at 387 nm of 29 700 M^{-1} cm^{-1} (21).

Initial attempts to react TM with DCIA (Molecular Probes) in nondenaturing buffers of the type used to label a reactive cysteine on platelet TM with *N*-(1-pyrenyl)iodoacetamide (22) gave insignificant degrees of labelling. Significant yields of labelled product required, first, the prereduction of the cysteine residues on TM (4). Subsequently, about 20 mg of TM was dissolved in 5 M guanidine hydrochloride, 1 M KCl, 20 mM Mops-KOH, 1 mM EDTA, pH 7.0. Then 25 mg of DCIA dissolved in 0.4 mL of *N*,*N*-dimethylformamide was added dropwise and the mixture allowed to incubate at room temperature for 4 h. Excess dithiothreitol (DDT) was added to quench the reaction. The samples were clarified by centrifugation and then dialysed extensively against 10 mM Tris-HCl, 1 mM DTT, pH 8.0, prior to being studied further.

Viscosity measurements were conducted in a thermostatted water bath held at 27°C using a Cannon–Manning semimicro viscosimeter. Solutions of TM and DCIA-TM (1.00 mL of 0.80 mg/mL solutions) were used in each case. The flow time for water in this viscosimeter was about 2 min.

Fluorescence measurements were performed with an instrument constructed in this laboratory (23). Excitation was performed using a 200-W Hg arc lamp (Osram) through a Spex Micromate monochromator with a Schott UG11 black glass filter at its exit port. Excitation was at 365 nm with a bandpass of 12 nm. Emission was detected with an EMI 9558 QB photomultiplier tube after passage of the emitted light through a 1-cm path of a 2 M $NaNO_2$ solution, which cuts off light of wavelengths shorter than 400 nm, and a Spex double monochromator equipped with a wavelength drive mechanism. Emission bandwidths were 10 nm. The data were digitized and stored using an Apple IIe computer. The data presented have not been corrected for instrumental response.

Fluorescence polarization, $p = (I_{\parallel} - I_{\perp})/(I_{\parallel} + I_{\perp})$, was determined by incorporating uv-polarizing filters (Polacoat) and a photoelastic light modulator (Hinds International) into the fluorimeter as described

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

by Ehrenberg (24). The instrument was calibrated for polarization measurements using fluorescein in 95% glycerol at 10°C.

Fluorescence quenching experiments were analysed using the Stern–Volmer equation (25), $F_0/F = 1 + K_{sv}$ [Q], where F is the measured fluorescence intensity at a particular wavelength, F_0 is the fluorescence intensity in the absence of quencher, K_{sv} is the Stern–Volmer quenching constant, measured from the slope of a graph of F_0/F against [Q], the concentration of quenching agent in the solution. $K_{sv} = \tau_0 k_q$, where τ_0 is the fluorescence lifetime of the probe in the absence of quencher and k_q is the bimolecular rate constant for collisions between the fluorescent chromophore and the quenching agent.

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received November 25, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

CAREY A. MATSUBA, STEVEN J. RETTIG, and CHRIS ORVIG. Can. J. Chem. **66**, 1809 (1988).

A series of tris(benzohydroxamato)metal(III) complexes has been prepared and characterized wherein the metals are aluminum, gallium, and indium. The complexes are synthesized in high yield from aqueous solution. The indium complex, as its ethanol solvate $In(C_7H_6NO_2)_3 \cdot C_2H_5OH$, has been studied by single crystal X-ray diffraction. The crystals are monoclinic with a = 11.091(2), b = 18.065(3), c = 12.861(2) Å, β = 105.55(1)°, Z = 4, and space group $P2_1/n$. The structure was solved by Patterson and Fourier methods and was refined by full-matrix least-squares procedures to R = 0.038 and R_w = 0.037 for 2579 reflections with $I \geq 3\sigma(I)$. Bond lengths and angles in the compound were normal, although there is a strong In—O(C) interaction; the arrangement of the three ligands is *mer*. There is extensive hydrogen bonding involving all possible donors. All three complexes have been studied by mass spectrometry, and by infrared and nuclear magnetic resonance (^1H, ^{27}Al) spectroscopies. Parallel studies have been attempted with acetohydroxamic acid.

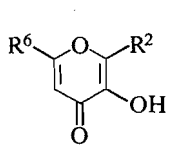
CAREY A. MATSUBA, STEVEN J. RETTIG et CHRIS ORVIG. Can. J. Chem. **66**, 1809 (1988).

On a préparé et caractérisé une série de complexes de tris(benzohydroxamato)métal(III) dans lesquels les métaux sont l'aluminium, le gallium et l'indium. On a synthétisé ces complexes avec d'excellents rendements, à partir de solutions aqueuses. Utilisant la diffraction des rayons-X sur un cristal unique, on a étudié le complexe d'indium, solvaté par l'éthanol, $In(C_7H_6NO_2)_3 \cdot C_2H_5OH$. Les cristaux sont monocliniques avec a = 11,091(2), b = 18,065(3) et c = 12,861(2) Å, β = 105,55(1)°, Z = 4 et groupe d'espace $P2_1/n$. On a résolu la structure par les méthodes de Fourier et Patterson et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs respectives de R et R_w de 0,038 et 0,037 pour 2579 réflexions avec $I \geq 3\sigma(I)$. Les longueurs des liaisons et les angles de ce composé sont normaux, même s'il existe une forte interaction In—O(C); l'arrangement des trois ligands est *mer*. On retrouve beaucoup de liaisons hydrogènes avec tous les donneurs possibles. On a étudié les trois complexes par spectrométrie de masse, par infrarouge et par la résonance magnétique nucléaire du ^1H et du ^{27}Al. On a essayé de réaliser des études parallèles avec l'acide acétohydroxamique.

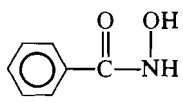
[Traduit par la revue]

Introduction

As part of a project to examine lipophilic, neutral, water soluble complexes of aluminum, gallium, and other trivalent non-transition metals, we have become interested in a variety of oxygen donor, bidentate, monobasic ligands for these ions in aqueous solution (1–6).[2] Recently, we have prepared several pyrone (**1**) complexes (1, 2), some of which have found use in the study of aluminum neurotoxicity, as well as a family of 3-hydroxy-2-methyl-4-pyridinone complexes (3, 5), which form extensively hydrogen bonded arrays and which have very high overall formation constants for the group IIIA (or group 13) metal ions. In an effort to extend this work, we have examined acetohydroxamic and benzohydroxamic (**2**) acids, both of which form simple tris(ligand) metal species.



1



2

The hydroxamates are well-known binders of M(III) (8) and have been used as gravimetric reagents for them for many years (9). Hydroxamates are also used as binding groups in several siderophores, naturally occurring chelators for ferric ion (10). There has been interest in the substitution into hydroxamate siderophores and the simple hydroxamates of paramagnetic Fe^{3+} with diamagnetic Al^{3+} or Ga^{3+} for solution studies by nmr (11),[3] and for mechanistic work (13).

Herein we report our studies of these complexes using various physical techniques including single crystal X-ray crystallography. While this study was in progress, the structure of the gallium benzohydroxamate complex appeared (14).

Experimental

Materials and methods

Most procedures and materials were as previously described (2, 4). Benzohydroxamic acid (Hbz; from Aldrich) and acetohydroxamic acid (Hah; from Sigma) were used as received. The ^1H nmr spectra were recorded in d_6-DMSO using a Bruker HXS 270 spectrometer at 270 MHz. The ^{27}Al nmr spectra were obtained with a Varian XL 300 spectrometer operating at 78.16 MHz in either water or methanol. Melting points are uncorrected. Al and Ga were analyzed gravimetrically with 8-hydroxyquinoline (15). All the metal complexes of bz^- were prepared in a similar manner and the synthesis is presented only for $Al(bz)_3$.

Tris(benzohydroxamato)aluminum(III) monohydrate, $Al(bz)_3 \cdot H_2O$

Hbz (1.070 g, 7.80 mmol) was dissolved in 75 mL water with stirring at 50°C. A solution of $Al(NO_3)_3 \cdot 9H_2O$ (0.962 g, 2.56 mmol) in 25 mL water was added and the pH dropped to 1.7. Dropwise addition of 2 N NaOH initially resulted in precipitation of a white solid, which redissolved upon further stirring. As the pH was raised to 8, a white solid appeared and this was isolated by filtration and washed with cold water. The product was dried overnight *in vacuo* at 90°C to yield 0.99 g

Tris(benzohydroxamato)gallium(III), Ga(bz)$_3$

(This complex was reported by a similar preparation as a monohydrate monoethanolate while this work was underway). Hbz (0.990 g, 7.22 mmol) and $Ga(NO_3)_3 \cdot 9H_2O$ (0.990 g, 2.37 mmol) were used. The resulting product was dried overnight *in vacuo* at 90°C to yield 0.97 g (86%), mp 240°C (dec.). Recrystallization was from 3:1 acetone:water. Infrared (KBr, all very strong): 3600–2700 cm^{-1} (ν(OH), ν(NH), ν(CH)); 1600, 1520 (amide I and II); 920 (ν(NO)); ^1H nmr δ: 12.8 (br s, ~1H, NH), 7.78 (d, 2H, ring *ortho* CH), 7.49 (m, 3H, ring *meta* and *para* CH), 3.3 (br s, H_2O); FAB mass spectrum, *m/e*: 341, 343 (ML_2^+); 478, 480 (HML_3^+); 820 (broad envelope for $M_2L_5^+$). *Anal.* calcd. for $C_{21}H_{18}GaN_3O_6$: C 52.76, H 3.79, Ga 14.58, N 8.79; found: C 52.38, H 3.77, Ga 14.66, N 8.81.

Tris(benzohydroxamato)indium(III), In(bz)$_3$

Hbz (0.746 g, 5.44 mmol) and $In(NO_3)_3 \cdot 5H_2O$ (0.687 g, 1.76 mmol) were used. The resulting product was dried overnight *in vacuo* at 90°C to yield 0.865 g (94%), mp 250°C (dec.). X-ray quality crystals were grown from a concentrated warm ethanolic solution. Infrared (KBr, all very strong): 3600–2700 cm^{-1} (ν(OH), ν(NH), ν(CH)); 1600, 1520 (amide I and II); 915 (ν(NO)); ^1H nmr δ: 7.82 (d, 2H, ring *ortho* CH), 7.49 (m, 3H, ring *meta* and *para* CH). A mass spectrum could not be determined by any of EI, FAB, or DCI. *Anal.* calcd. for $C_{21}H_{18}InN_3O_6$: C 48.21, H 3.47, N 8.03; found: C 48.42, H 3.55, N 8.03.

The M(bz)$_3$ complexes are soluble in methanol, ethanol, acetone, acetonitrile, DMSO, and slightly soluble in isopropanol. Several unsuccessful attempts were made to prepare pure tris(acetohydroxamato) complexes because these are very water soluble; however, the samples were always contaminated with a salt (e.g., $NaNO_3$, if a metal nitrate was neutralized in the synthesis with NaOH).

X-ray crystallographic analysis of tris(benzohydroxamato)indium(III) ethanol solvate

A crystal 0.32 × 0.32 × 0.40 mm in size, with the faces {010} and {101} developed, was mounted in a general orientation. Unit cell parameters were refined by least squares on 2 sin θ/λ values for 25 reflections (2θ = 20–26°) measured on an Enraf–Nonius CAD4-F diffractometer with Mo-K_α radiation ($\lambda(K_{\alpha 1})$ = 0.70930, $\lambda(K_{\alpha 2})$ = 0.71359 Å). Crystal data at 21°C are

$C_{21}H_{18}InN_3O_6 \cdot C_2H_6O$ f.w. = 569.28

Monoclinic, a = 11.091(2), b = 18.065(3), c 12.861(2) Å, β = 105.55(1)°, V = 2482.5(7) $Å^3$, Z = 4, ρ_c = 1.523 mg m^{-3}, $F(000)$ = 1152, $\mu(Mo - K_\alpha)$ = 9.80 cm^{-1}. Absent reflections: $0k0$, k odd, and $h0l$, $h + l$ odd, uniquely indicate the space group $P2_1/n$.

Intensities were measured with graphite-monochromated Mo − K_α radiation. An ω–2θ scan at 1.1–10.0° min^{-1} over a range of (0.75 + 0.35 tan θ)° in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The data were corrected for Lorentz polarization and absorption (analytical method), transmission factors ranging from 0.730 to 0.760.[4] Of the 5656 independent reflections measured, 2579 had intensities greater than or equal to 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by Patterson and Fourier methods. The position of the indium atom was determined from the Patterson function while the coordinates of the remaining non-hydrogen atoms were determined from a subsequent difference Fourier map. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (staggered methyl, C(sp^3)—H = 0.98, C(sp^2)—H = 0.97, N—H = 0.92 Å, $U_H \propto U_{\text{bonded atom}}$). The hydroxyl proton position was taken from a difference Fourier map and was not refined. Neutral atom scattering factors and anomalous scattering corrections for In were taken from ref. 16. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement (307 variables). Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.038 and R_w = 0.037 for 2579 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.002 and 0.027 σ, respectively. The mean error in an observation of unit weight was 1.249. Final coordinates and equivalent isotropic thermal parameters (U_{eq} = 1/3 trace of diagonalized U) are given in Table 1. Bond lengths and angles appear in Tables

2 and 3, respectively. Intra-annular torsion angles for the five-membered chelate rings, hydrogen atom parameters, anisotropic thermal parameters, a complete listing of torsion angles (Tables 4–7), and measured and calculated structure factor amplitudes (Table 8) have been placed in the Depository of Unpublished Data.[5]

Results and discussion

The benzohydroxamato complexes of Al, Ga, and In can be easily synthesized from aqueous solution; however, their aqueous solubility is very low. It proved impossible to isolate pure samples of the acetohydroxamato complexes although the ^{27}Al and ^{1}H nmr and FAB mass spectra were measurable and supported the tris(ligand)metal(III) formulation. The ^{27}Al nmr spectrum of $Al(ah)_3$ at pH 6 was consistent (36 ppm, $W_{1/2} \approx 400$ Hz) with that in the literature (11). The ^{27}Al nmr spectrum of $Al(bz)_3$ in methanol has a broader line ($W_{1/2} \approx 550$ Hz) in the same chemical shift range (37 ppm), consistent with a significantly larger size complex (three phenyl substituents vs. three methyls) and with the somewhat decreased viscosity of MeOH vs. H_2O, but the same hydroxamate-based AlO_6 nucleus.

The ir and nmr spectra are completely consistent with the formulation of complexes containing bound ligands, and they show the characteristic changes in frequency and chemical shifts to lower and higher values, respectively. The ν(NO) stretch moves from 900 in Hbz to ~920 cm^{-1} in the complexes, suggesting some delocalization of the ketone double bond into the chelate ring. Some possible M–O stretches are observed in the low energy region (<600 cm^{-1}); however, assigning these with any certainty is difficult. Notable also are the shifts of the N-H proton in the benzohydroxamato complexes to ~13 ppm from 9.6 in the free acid. The FAB mass spectra of the Al and Ga complexes of both acids showed most of the expected (2) ML_2^+, HML_3^+, and $M_2L_5^+$ peaks.

The asymmetric unit of $In(bz)_3 \cdot EtOH$ is shown in Fig. 1. The crystal structure (Fig. 2) consists of tris(benzohydroxamato)indium(III) and ethanol molecules, linked by an extensive hydrogen bonding network that incorporates all available hydrogen bond donors (O(7)—H(O7)···O(3) ($x - 1/2, 1/2 - y, z - 1/2$), N(1)—H(N1)···O(7) ($x, y, z$), N(2)—H(N2)···O(1) ($1/2 + x, 1/2 - y, 1/2 + z$), and N(3)—H(N3)···O(5) ($1 - x, 1 - y, 1 - z$); H···O = 1.87, 1.95, 1.95, 1.99 Å; (N/O)···O = 2.859(6), 2.822(7), 2.801(6), 2.738(6) Å; (N/O)—H···O = 160, 158, 153, 137°; respectively). The coordination about the indium atom is *mer*-octahedral, distorted by the small bite (17) of the chelating ligand (mean intraligand O···O = 2.637(7) Å, mean In—O = 2.153, normalized bite b = O···O/M—O = 1.22). This contrasts directly with the *fac* geometry found for the Ga analogue (14).

As observed previously in structures of Ga^{3+} (14), Sn^{4+} (18–21), Fe^{3+} (22–27), Cr^{3+} (28), and Zn^{2+} (29) hydroxamates, the M—O(N) bonds are shorter than the M—O(C) bonds ({In—O(C)} − {In—O(N)} = 0.014, 0.026, 0.027 Å for the three ligands). Correction for differences in effective ionic radii (30) shows that the hydroxamate moiety makes a stronger chelate with In^{3+} than with Sn^{4+}, in which complexes the Sn—O bonds are relatively much longer, especially Sn—O(C) (18–21). The corrected bond lengths for the Ga structure (14), however, are very similar to those in our In complex. In the latter the In bond to the O—N (In—O(1)), which is hydrogen bonded to the ethanol molecule, is notably longer than the other two.

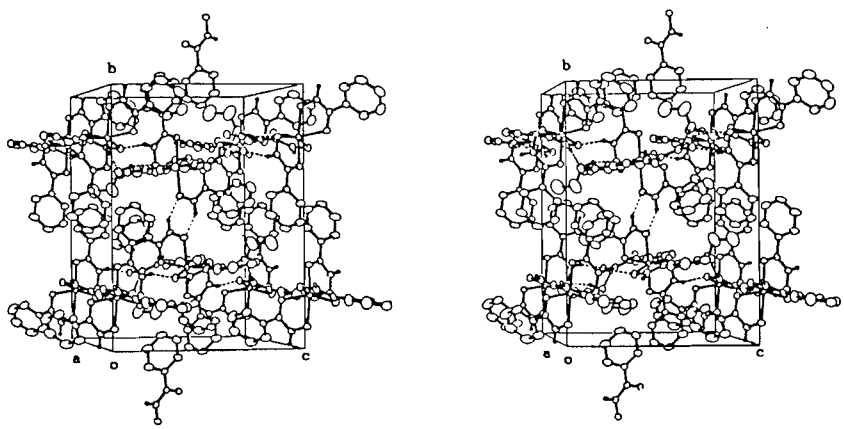

FIG. 2. Stereoview of the unit cell of $In(bz)_3 \cdot EtOH$. Broken lines indicate hydrogen bonds.

In the ferric ion structures, a similarly corrected comparison shows a weaker M—O(C) interaction, but a comparable M—O(N) bond (22–27). $Ga(bz)_3$ (14) and $Cr(bz)_3$ (28) are the only structurally characterized metal hydroxamates to have the difference between M—O(C) and M—O(N) as small as it is in the present structure (0.014, 0.022, 0.039 Å); in the Cr complex, this was ascribed to a crystal-field effect (28) that is not available to Ga or $In(bz)_3$. The usual difference between M—O(C) and M—O(N) is 0.05–0.11 Å (14, 18–27, 29). Because all possible hydrogen bond donors in the $In(bz)_3$ structure are so utilized (e.g., the N—H), there is likely an addition of electron density to the N—O, causing this bond to be anomalously short relative to other values. An alternative explanation might be an increased double bond character to C—N, making the chelate ring more delocalized; however, the observed bond distances support the former rather than the latter argument.

The average In—O distance of 2.153 Å in $In(bz)_3$, with five-membered chelate rings, is slightly longer than the average In—O distance of 2.133 Å observed for six-coordinate indium 1,3-diketonate complexes (7, 31–33) containing six-membered chelate rings. The internal geometry of the benzohydroxamate ligands is normal (12, 14, 18–29). The chelate ring containing N(2) is planar within experimental error while the two others are significantly nonplanar, the maximum deviations from the mean plane being 0.042(4) and 0.083(4) Å for the rings containing N(1) and N(3), respectively. The dihedral angles between the

chelate ring and the associated phenyl mean planes are 17.3, 12.7, and 33.6° for the N(1), N(2), and N(3) ligands.

The general affinity for trivalent metal ions that one would suspect from the presence of hydroxamate groups in the siderophores extends to Al and In of the group IIIA metals; bz^- forms a strong chelate with In^{3+} (demonstrated by the relatively short In—O(C) bonds found in the structure of $In(bz)_3$). The extensive hydrogen bonding found in this structure is in keeping with the pattern that we have seen (3, 5) in other neutral tris(ligand) complexes of these main group metal ions wherein every possible hydrogen bond donor is involved in this type of interaction.

Received January 18, 1988

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

ALBIN OTTER and GEORGE KOTOVYCH. Can. J. Chem. **66**, 1814 (1988).

Ac-tubulin-α(430–441)-amide, a synthetic fragment of tubulin, has been studied by 300-MHz ^{1}H nuclear magnetic resonance spectroscopy in 80% CD_3OH/20% D_2O solution at neutral pH. The results, based on two-dimensional phase-sensitive techniques such as COSY, RELAY, and ROESY, reveal that the dodecapeptide exists in a non-random conformation. The conformation can be described as an α helix for the N-terminal five residues, followed by an extended section. The extended part exhibits a significant change in the nuclear Overhauser enhancement (nOe) pattern between units number 9 and 10. Together with long-range nOe data this can be attributed to a folding back that allows the close proximity of the C-terminal half of the extended chain and amino acids 3 to 5 of the α-helical turn. The existence of an α helix is in good agreement with previously published circular dichroism data.

ALBIN OTTER et GEORGE KOTOVYCH. Can. J. Chem. **66**, 1814 (1988).

Opérant à un pH neutre, dans des solutions contenant 80% de CD_3OH et 20% de D_2O et faisant appel à la résonance magnétique nucléaire du ^{1}H à 300 MHz, on a étudié l'Ac-tubuline-α(430–441)-amide, un fragment de la tubuline obtenu par synthèse. Les résultats, qui sont basés sur des techniques bidimensionnelles, sensibles à la phase, comme la spectroscopie de corrélation (COSY), relais (RELAY) et la spectroscopie d'effet Overhauser relais (ROESY), indiquent que le dodécapeptide existe dans une conformation qui n'est pas statistique. On peut décrire la conformation des cinq résidus du terminus-N comme celle d'une hélice α; cette portion serait suivie par une section linéaire. On observe un changement important dans la présentation de l'effet Overhauser nucléaire entre les unités n° 9 et 10 de la section linéaire. Ces données ainsi que celles relatives à l'effet Overhauser nucléaire à distance peuvent être attribuées à un repli de la chaîne qui permet à la portion du terminus-C de la chaîne linéaire de se rapprocher des acides aminés n° 3 et 5 de la portion α-hélicoïdale. L'existence d'une hélice α est en bon accord avec les données de dichroïsme circulaire publiées antérieurement.

Introduction

Microtubules are formed by reversible polymerization of the protein tubulin along with several "microtubule associated proteins". Substances affecting assembly and maintenance of microtubules therefore serve important roles in nerve function regulation, as microtubules transport chemicals from the cell bodies of neurones along the axons to the nerve terminal locality (1). Enzymes needed to synthesize various neurotransmitters from their amino acid precursors are among the substances transported.

Recent studies (2–4) have shown that a 4-kDa peptide fragment, resulting from limited proteolysis of tubulin with subtilisin, is essential for the interactions of microtubule associated proteins as well as for the self-assembly of tubulin into microtubules. A subdomain, believed to be important for the activity of the 4-kDa fragment, has been synthesized (5) as a protected peptide, containing 12 amino acids: *N*-acetyl-Lys^1-Asp^2-Tyr^3-Glu^4-Glu^5-Val^6-Gly^7-Val^8-Asp^9-Ser^{10}-Val^{11}-Glu^{12}-NH_2 (*N*-acetyl-tubulin-α(430–441)-amide). The circular dichroism (cd) spectrum of this peptide has been published recently (6), indicating a completely unstructured and somewhat aggregated behavior in water, but the presence of an α helix to the extent of 30% in methanol/water (80:20, v/v) mixtures was observed. The use of mixed solvents to induce secondary structure in various peptides has recently been reported (6–9). Although the exact reasons for the secondary structure-inducing properties of mixed solvents are not known, it appears that a change in viscosity plays an important role. For 80% methanol/20% water, as used in the present study, the kinematic viscosity of the binary liquid is very close to its maximum (10, 11), thus reducing the mobility of the peptide dissolved in the solvent mixture.

With the ultimate aim of understanding the role of the tubulin fragment in the self-assembly of tubulin into microtubules and its interactions with neurotransmitters (4, 6), we began to study the solution conformation of the isolated dodecapeptide. Small proteins and peptides are conveniently studied at the molecular level by nuclear magnetic resonance (nmr) spectroscopy (12, 13). However, the observation of nuclear Overhauser effects (nOe), using conventional methods, often fails for molecules of the size of the tubulin fragment, irrespective of the internuclear distances involved, because the tumbling rate for these solutes is close to that at which the maximum possible nOe passes through zero (14). Consequently, sequential assignments along the peptide backbone and the observation of interproton distances revealing secondary structure are impossible. By using the rotating frame nOe experiment (15, 16), this problem could be completely overcome. From Fig. 1, where the maximum observable nOe is depicted as a function of correlation time and spectrometer frequency, it can be seen clearly that the obtainable rotating frame Overhauser effects (rOe) are considerably stronger than the nOe's over a wide range of correlation time/spectrometer frequency combinations. Our results, based on phase-sensitive COSY (17, 18) and ROESY experiments, confirm the cd studies and localize the α turn in the N-terminal half of the molecule, whereas the C-termal end is found to be in an approximately extended conformation. This result is of particular interest given the fact that binding studies (6) reveal the N-terminal half to be actively involved in intermolecular interactions.

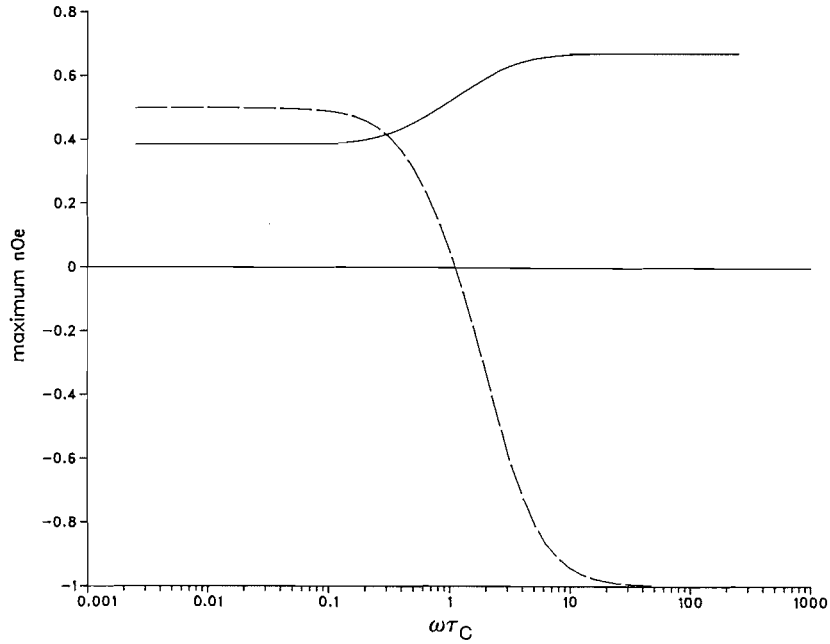

FIG. 1. The maximum $^1H-^1H$ nuclear Overhauser enhancement (nOe) as a function of spectrometer frequency ω times the correlation time τ_c. The solid line represents the fit for a ROESY experiment (15) whereas the dotted line represents the NOESY experiment (13).

Experimental

Ac-tubulin-α(430–441)-amide was synthesized and purified following standard procedures (5). The nmr samples were prepared by dissolving the solid material in 0.5 mL H_2O and the pH was adjusted to 7.1. The sample was then freeze-dried and redissolved in 0.45 mL of a CD_3OH/D_2O (80:20, v/v) mixture (CD_3OH from MSD Isotopes, number MD-67, 99.9% D enriched). Before sealing, argon was bubbled through the sample for ca. 15 min. The final concentration was 8 mM. In the same manner two 5-mM samples, one at pH 7.2 and one at pH 6.7, were prepared as well. Slight changes in pH were helpful in eliminating some spectral overlap in the NH region due to some very small (<0.05 ppm) chemical shift changes. It is also noteworthy that the change in concentration did not have any measurable influence on the spectra, indicating that no aggregation was present.

All nmr experiments were carried out on a Bruker AM 300 nmr spectrometer, which was modified to perform spin-locking at a field of 2.5 kHz at ambient temperature (297 ± 1 Hz). Data acquisition and data processing were controlled by an Aspect 3000 computer equipped with an array processor using Bruker 1987 DISNMR software. The chemical shifts are reported relative to the undeuterated fraction of the methyl group of CD_3OH at 3.30 ppm with respect to TMS.

A sweep width of 2650 Hz and 8K (zero-filled to 16K) data points were used to record one-dimensional spectra (Fig. 2). A total of 600 scans were accumulated to obtain a good signal-to-noise ratio for the relatively low-intensity NH protons even after resolution enhancement. Typically, the FID was multiplied by a Gaussian function (line broadening factors up to −5 Hz) before Fourier transformation. Both solvent signals (OH group and undeuterated fraction of CD_3OH at 3.30 ppm) were presaturated during a 2.4-s relaxation delay by changing the decoupler frequency every 0.2 s. To account for the big difference in intensity between the two solvent peaks, the OH signal was presaturated twice as long as that of the methyl group. The effect of presaturation on the exchangeable protons was carefully monitored and no wipe-out due to saturation transfer was observed.

The parameters used in the two-dimensional nmr techniques (12, 19) are summarized in Table 1. The COSY (17) and the ROESY (15, 16) experiments were carried out in the phase-sensitive mode using time-proportional phase increments (18) whereas the relayed coherence transfer spectrum (RELAY) (20, 21) was recorded in the absolute value mode. Solvent suppression was carried out in the same way as described for the one-dimensional spectra. In addition, irradiation of the OH signal was continued at all times aside from data acquisition (22). The phase-sensitive spectra were first phased using the second FID to determine the phase constants, which were then applied to all spectra in the t_2 domain. In addition, the ROESY experiment required a basic 90° phase correction in t_1. The resulting 2D matrices were displayed and slight phase adjustments in both dimensions were usually necessary to obtain the best possible data representation. Concerning the ROESY experiment, a few more remarks are appropriate. This experiment often suffers from spurious resonances due to magnetization transfer between scalar coupled spins (23, 24). Under the selected experimental conditions (25), the resulting two-dimensional spectrum was almost free of any such peaks, which are easily identified by their phase being the same as the diagonal signals (real rOe cross-peaks have opposite signs with respect to the diagonal peaks). Some baseline distortions, however, were present, especially around intense peaks such as the residual solvent signals and methyl groups. As suggested by other authors (26), we treated the spectra in both dimensions with the Bruker ABS baseline correction routine, which eliminated this problem almost completely (using a polynomial fitting of fifth degree to the baseline).

Results

The spectral analysis of the dodecapeptide is based on the results of various two-dimensional nmr experiments suitable for structure elucidations of peptides (13). First, a phase-sensitive COSY spectrum (18) was recorded, the contour plot of which is shown in Fig. 3. The so-called "fingerprint" region (27) reveals $NH-H_\alpha$ connectivities, and $NH-H_\alpha$ coupling constants can be determined to an accuracy of about 0.6 Hz as the digital resolution along the F_2 axis is 1.2 Hz. Figure 3 illustrates the power of phase-sensitive COSY spectra in the region around 8.35 ppm where the coupling constants can be determined unambiguously, whereas in the one-dimensional spectrum this is impossible. Further valuable information could be obtained from the relayed COSY experiment (20, 21), providing cross-peaks between spins that are not mutually coupled but belong to

TABLE 1. Summary of 2D experimental parameters[a]

Parameter	Unit	COSYPH[b]	RELAY	ROESYPH[b]
Sweep width F2	Hz	2400	2400	2500
Sweep width F1	Hz	1200	1200	1250
Matrix size (F1 × F2) before zero-filling	—	512 × 1K	256 × 1K	280 × 1K
Matrix size (F1 × F2) after zero-filling	—	1K × 4K	1K × 4K	1K × 2K
Evolution time:				
initial value	μs	1	1	1
increment	ms	0.21	0.41	0.20
Number of scans (dummy scans)		48(2)	112(2)	96(2)
Acquisition time	s	0.21	0.21	0.20
Relaxation delay	s	1.8	1.8	1.8
Other delays	ms	—	80[c]	125[d]
Window functions for 2D FT (F1/F2)	—	S/S	S/S	S/S
Shifts of window function in fractions of π (F1/F2)	—	4/8	6/8	3/4

[a]All spectra were recorded at 297 K at concentrations between 5 and 8 mM.
[b]The phase-sensitive spectra were first phased using the second FID and then, after Fourier transformation, the phase was optimized in both dimensions by an additional phase correction applied to the entire 2D spectrum. The ROESY spectrum was baseline corrected in F1 and F2 by means of a Bruker ABS baseline correction.
[c]Coherence transfer time.
[d]Spin-locking time at an average rf field strength of 2.5 kHz.

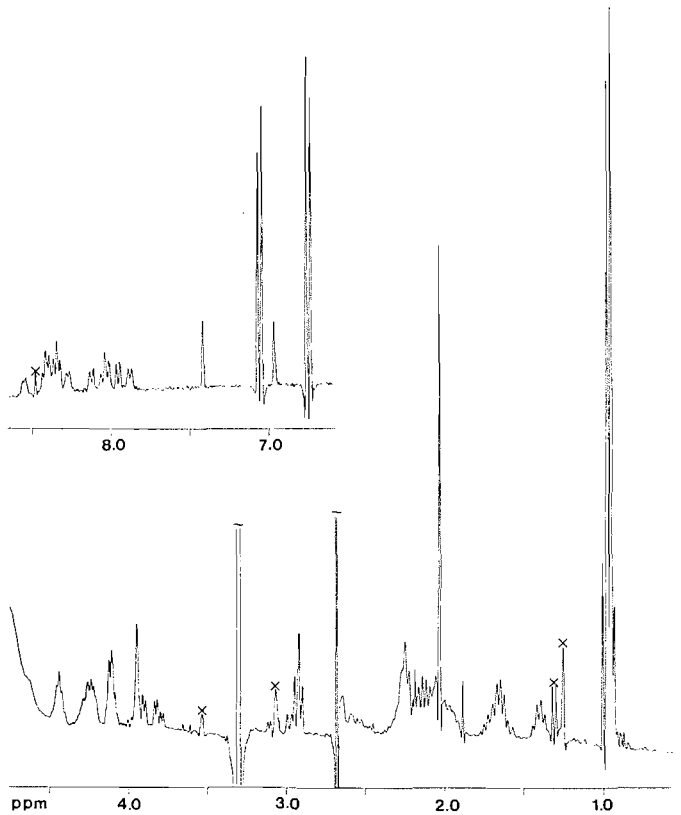

FIG. 2. The 300-MHz ^1H spectrum of Ac-tubulin-α(430–441)-amide recorded at 5.0 mM concentration in CD_3OH/D_2O (80:20), 297 K, pH 6.7. The inset depicts the region of the exchangeable and aromatic protons, the lower trace shows the range from the H_α protons to the H_γ's of the valines. Impurities and ^{13}C satellites of the solvent are denoted with an X.

the same spin system. In particular, the three valine moieties could be easily distinguished from other amino acids and from each other (through NH–H_β cross-peaks). Combining the results of the COSY and RELAY experiments, all resonances of the peptide could be assigned to individual amino acids. However, as there are many amino acids of the same kind, for example three Glu and three Val, the sequential assignment remained undefined. This problem could be overcome by recording the phase-sensitive rotating frame nOe spectrum (ROESY, 15, 16), which provides distance information based on the nuclear Overhauser effect (14). Under the selected experimental conditions (see experimental section), the two-dimensional spectrum (Fig. 4) provided a large number of cross-peaks of remarkably strong intensity. In addition, our experiments were essentially free of often-reported artifacts such as spurious resonances due to COSY and Hartmann–Hahn-type transfers (23, 24). Furthermore, we wish to point out that ROESY spectra recorded with longer spin-locking times produced cross-peaks of lower intensities. Consequently, 125 ms must be close to optimum for the system under investigation. Based on the observation of NH–H_α cross-peaks between adjacent amino acids, the sequential assignment could be easily achieved. The results are summarized in Table 2 and in Fig. 5. Besides the (i)–$(i + 1)$ interactions, some long-range effects were observed as well, indicating clearly that the molecule does not exist in a stretched conformation. This is in perfect agreement with the results of a temperature dependence study of the amide protons between 282 and 302 K. The values for the changes in chemical shifts as a function of temperature were found to be between 3.5 and approximately 7.0 ppb/K (6). The latter value is typical for protons that are not hydrogen bonded or otherwise shielded from interactions with the solvent, but the former value is borderline and some shielding cannot be excluded (28). Therefore, we conclude that weak hydrogen

bonds are present between C=O(Lys^1) and NH(Glu^5) and between NH(Glu^4) and C=O(Ser^{10}) as well as some shielding due to the conformation of the peptide. It must be said clearly that these effects are of relatively weak nature. This was confirmed by a proton–deuterium exchange experiment where at room temperature all NH protons exchanged completely within 5 min from dissolving the peptide in the deuterated solvent mixture. Given the small size of the peptide, this effect was not surprising and confirmed that no strong interactions are present.

Discussion

The combination of nuclear Overhauser enhancements and NH–H_α coupling constants allows an almost complete defini-

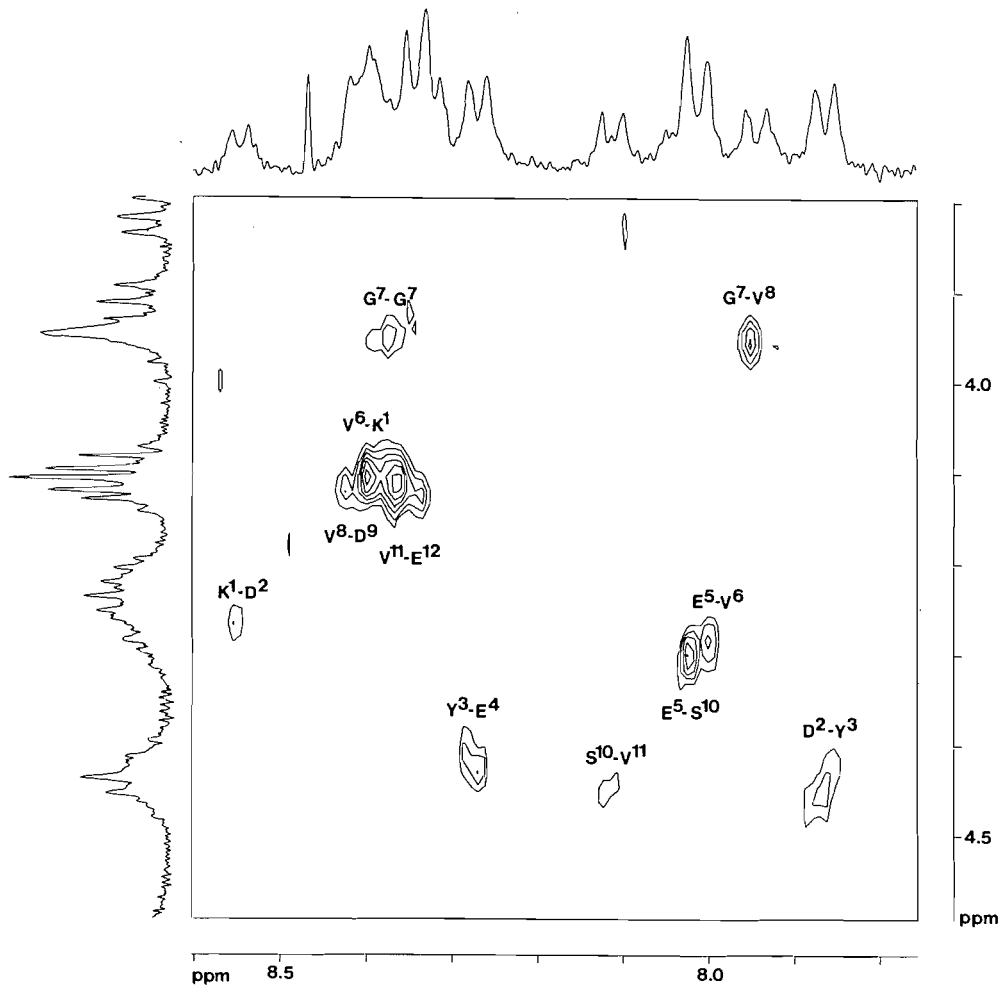

FIG. 4. NH–H_α region of a 300-MHz phase-sensitive ROESY experiment of Ac-tubulin-α(430–441)-amide recorded at 5 mM, pH 7.2, in the same solvent as described in Fig. 2. The spin-locking time was 125 ms. The contour levels are equidistant, separated by 500 vertical display units, and the cross-peaks are of opposite sign with respect to the diagonal peaks. No symmetrization, but ABS baseline correction in both dimensions.

tion of the torsion angles (29) in the peptide backbone, thereby establishing the peptide's conformation.

We consider first the torsion angle ϕ, describing the rotation about the N—C_α bond. ϕ is related to the dihedral angle θ, which itself is related to the observed coupling constants (30) by the Karplus equation (31). Although various sets of constants exist for this equation (32), a narrow limit for θ is found using different sets of Karplus constants (13, 33). By the very nature of the ϕ/θ relationship, two ϕ values result from each θ (J, respectively) value, and the selection of the correct value has to be based on additional (usually nOe) information. The values we found for ϕ are all well within the generally observed range (34) for peptides. The Ψ angles cannot be derived from proton nmr coupling data (35) but they can be estimated satisfactorily from the intensities of $H_\alpha(i)$–NH(i + 1) nOe's. As can be seen in Fig. 4, the nOe cross-peaks are of quite different strength and some, e.g., $H_\alpha(E^4)$–NH(E^5) are missing altogether. Assuming *trans* peptide bonds (ω = 180°), the existence of the above-mentioned nOe's requires the C_α—$H_\alpha(i)$ bond to be approximately *trans* to the carbonyl group (i + 1), which is equivalent to an angle Ψ of +120°. In the cases where a strong nOe cross-peak is observed, we therefore assume Ψ to be +120°, whereas in the cases of weaker, but still clearly observable, effects we allow at least ±60° deviation from this value. Where no nuclear Overhauser enhancement was recorded, values of Ψ = −60° (C_α—$H_\alpha(i)$ *cis* to C=O (i + 1)) and, again, deviations of ±60° have to be considered. Of course, in the latter case, the angle remains undefined over a relatively wide range, and only additional long-range nOe's can provide further information. Finally, the peptide bond angle ω has to be discussed. It is generally found to be either 180° (*trans*) or 0° (*cis*), due to the partial double bond character, with the former value being strongly preferred. Not surprisingly, as there are no proline units present in the investigated peptide, we did not find any spectroscopic indication of *cis* peptide bonds, thus ω = 180° throughout the peptide. Concerning side-chain rotamer populations (33), clearly resolved H_α–H_β coupling constants are a prerequisite. For the vast majority of amino acids these could not be resolved because of spectral overlapping and therefore an unambiguous analysis was impossible. However, when analyzing the nOe's along the side chains, it appears that many of them have considerably reduced mobility but not necessarily fixed conformations.

Summarizing the spectroscopic results (coupling constants, sequential and long-range nOe's, temperature dependence of the NH protons), the conformation is considerably different in the N-terminal half of the peptide from the C-terminal section. Based on extensive molecular modeling using CPK models

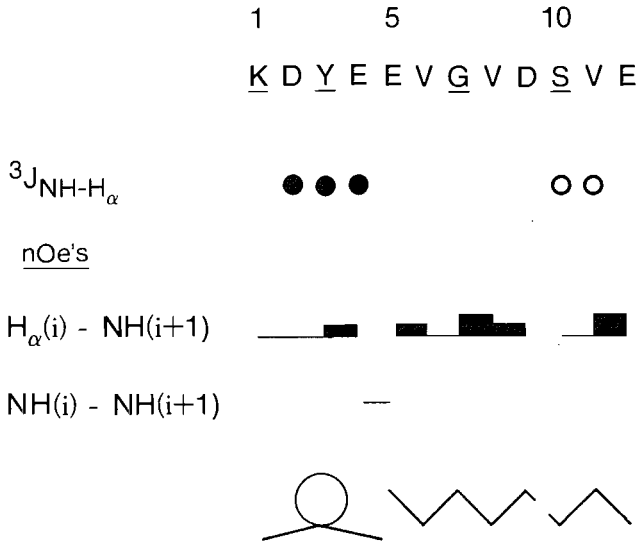

FIG. 5. The amino acid sequence of Ac-tubulin-α(430–441)-amide with unique residues underlined. For the ^3J coupling constants the symbols are used in the following way: filled circles for values of 5.0–6.5 Hz, open circles for values ≥7.5 Hz. The sequential nOe's are indicated by lines and the strength of the effect is depicted by the height of the bar (differentiation between weak, medium, and strong only). For long-range nOe's see text. The secondary structure is schematically described at the bottom. A zigzag line indicates an extended chain (interrupted by a kink between residues number 9 and 10) and the helical region is drawn as such.

as well as computer models (36), we propose the following conformation for the tubulin fragment: An α-helical turn for the first five units (Lys^1 to Glu^5) followed by an approximately extended section (Val^6 to Glu^{12}) with a kink between Asp^9 and Ser^{10}. Due to this kink the amino acids Ser^{10} to Val^{11} are folded back towards the Tyr^3 to Gln^5 moieties, which are part of the α helix. This folded tertiary structure is stabilized by at least one hydrogen bond, most likely between NH(Glu^4) and C=O(Ser^{10}). The helical region is characterized by small coupling constants and weak $H_\alpha(i)$–NH(i + 1) nOe effects, as well as an NH(i)–NH(i + 1) nOe. The low temperature dependence of NH(Gln^5) and a strong nOe between NH(Lys^1) and $H_\alpha(Val^6)$ provide further evidence for this conformation. The extended part of the peptide exhibits typical coupling constant data around 7 Hz and typical $H_\alpha(i)$–NH(i + 1) nOe's. The pattern of nOe interactions is, however, interrupted several times. First, the effect is small between Val^6 and Gly^7 and, secondly, no nOe is observed between $H_\alpha(Asp^9)$ and NH(Ser^{10}). The folded structure is further corroborated by clearly observable nOe's between $H_\alpha(Gln^5)$ and NH(Ser^{10}) and between $H_{meta}(Tyr^3)$ and $H_\gamma(Val^{11})$. Furthermore, NH(Glu^4) and to a somewhat smaller extent NH(Ser^{10}) are less temperature dependent than the other amide protons, indicating hydrogen bonding or at least some shielding from solvent interactions. In summary, the conformation is consistent with all nmr data and confirms the previously published cd results (6). Nevertheless, the consistency of all data does not imply the existence of one fixed conformation, which thermodynamic considerations render unlikely (37), but rather a strong preference for one particular conformation.

Conclusion

All spectroscopic data obtained on the Ac-tubulin-α(430–441)-amide consistently indicate a non-random conformation under the given experimental conditions (CD_3OH/D_2O (80:20) solvent mixture, neutral pH, ambient temperature). The first five residues, Lys^1 to Glu^5, form one complete α-helical turn, followed by an extended conformation with a distinct fold-back due to a kink between residues Asp^9 and Ser^{10}. This creates close proximity of the C-terminal end of the molecule with several of the amino acids involved in the α helix as evidenced by long-range nOe effects. The nmr results confirm cd measurements predicting 30% α helix.

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

GLENN H. PENNER, WILLIAM P. POWER, and RODERICK E. WASYLISHEN. Can. J. Chem. **66**, 1821 (1988).

The anisotropy of the indirect $^{31}P,^{199}Hg$ spin–spin coupling constant, ΔJ, in solid $[HgP(o\text{-tolyl})_3(NO_3)_2]_2$ is obtained from an analysis of the ^{31}P nuclear magnetic resonance powder pattern. The value of ΔJ, 5170 ± 250 Hz, is large and indicates that mechanisms other than the Fermi contact mechanism are important for this spin–spin coupling. The powder spectrum also indicates that the absolute sign of $^1J(^{31}P,^{199}Hg)$ is positive.

GLENN H. PENNER, WILLIAM P. POWER et RODERICK E. WASYLISHEN. Can. J. Chem. **66**, 1821 (1988).

En se basant sur une analyse du spectre en résonance magnétique nucléaire de poudre du ^{31}P du $[HgP(o\text{-tolyl})_3)(NO_3)_2]_2$, on a pu déterminer l'anisotropie de la constante de couplage spin–spin indirecte $^{31}P,^{199}Hg$, ΔJ. La valeur observée pour le ΔJ, 5170 ± 250 Hz, est importante et elle indique que des mécanismes autres que le mécanisme de contact de Fermi jouent un rôle important dans ce couplage spin–spin. Le spectre de poudre indique aussi que la valeur absolue de la constante $^1J(^{31}P,^{199}Hg)$ est positive.

The anisotropy of nuclear magnetic shielding has been extensively studied, particularly for the lighter isotopes (e.g., ^1H, ^3C, and ^{31}P), and tabulations of the principal components of shielding tensors for nuclei in many molecules can be found in the literature (1–8). In comparison there are few reliable data on the anisotropy of indirect spin–spin coupling tensors, ΔJ (9–12). The experimental determination of indirect coupling anisotropies is complicated because it is generally difficult to separate the anisotropy of the indirect spin–spin coupling from the direct dipolar coupling, D (9–12). Also, both theory (13–15) and experiment (9–12, 16–23) indicate that the anisotropy of the indirect coupling is usually small, particularly when the coupling involves only nuclei of low atomic number; this complicates any effort to separate ΔJ and D.

Experimentally the anisotropy of J is determined from the nmr study of oriented molecules in liquid crystalline solvents (9–12) and from nmr studies of solid powders (16–20) or single crystals (21–23). Liquid crystal studies have been most popular; however, the analysis of data is often not straightforward due to complications introduced by solvent and vibrational effects (9–12). The results from single crystal studies are the most reliable, but such studies are tedious and require a large single crystal, which is often unavailable. In the present study we demonstrate that the anisotropy in the indirect coupling between two spins A and X can be readily determined from a *powder* spectrum of A if the isotropic value of the indirect coupling is sufficiently large that the subspectra, which result from the X spin Zeeman states, $m = +1/2$ and $m = -1/2$, are completely separated. This requirement is satisfied when one analyzes the ^{31}P nmr spectrum of a powder sample of $[HgP(o\text{-tolyl})_3(NO_3)_2]_2$. The spectrum, Fig. 1, was obtained with high power proton decoupling and cross polarization on a Bruker MSL-200 (B_0 = 4.70 T). The central feature in the spectrum results from ^{31}P nuclei that are directly bonded to magnetically inactive Hg nuclei while the high and low frequency subspectra result from ^{31}P nuclei directly bonded to ^{199}Hg ($I = 1/2$, natural abundance 16.84%). The central feature in the spectrum indicates that the ^{31}P shielding anisotropy is approximately axially symmetric, $\Delta\sigma = \sigma_\parallel - \sigma_\perp = -38.3$ ppm. The isotropic value of each subspectrum was determined from a ^{31}P nmr spectrum obtained with magic angle sample spinning (frequencies indicated by arrows in Fig. 1). The isotropic frequencies of each of these subspectra are separated by the isotropic value of the indirect spin–spin coupling constant, $J(^{31}P,^{199}Hg)_{iso}$, 9660 Hz. If one assumes that the J tensor is axially symmetric and $J_\parallel$ is coincident with $\sigma_\parallel$ and the ^{31}P–^{199}Hg dipolar vector, the two subspectra can be analyzed following the theory of VanderHart and Gutowsky (24). Using the same general equations as these authors but working in Hz instead of angular frequency units, the frequency spread of each subspectrum about ν_{iso} is given by eq. [1]

$$[1]\quad \Delta\nu_m = (3\cos^2\theta - 1)K_m - (J_{iso})m$$

where m is $\pm 1/2$ and refers to the spin state of the ^{199}Hg in this particular example, J_{iso} is the isotropic spin–spin coupling constant, $J_{iso} = (1/3)(J_\parallel + 2J_\perp)$, θ is the angle between the ^{31}P–^{199}Hg dipolar vector and the applied magnetic field, B_0, and K_m is defined by eq. [2].

$$[2]\quad K_m = \beta + Dm - (\Delta J/3)m$$

In eq. [2],

$$\beta = (1/3)(\nu_\parallel - \nu_\perp) = 1033 \text{ Hz}$$

and is one-third the chemical shielding anisotropy in Hz;

$$D = \left(\frac{\mu_0}{4\pi}\right)\left(\frac{\gamma_P\gamma_{Hg}}{r^3_{P-Hg}}\right)\left(\frac{\hbar}{2\pi}\right)$$

and is the direct dipolar coupling constant, 634 Hz (see discussion below); and $\Delta J = J_\parallel - J_\perp$ is the anisotropy of the indirect spin–spin coupling constant. Taking the shoulder and discontinuity of the high frequency subspectrum as 8300 and 3550 Hz respectively and the corresponding values for the low frequency subspectrum as −3600 and −5050 Hz respectively, substitution of β, D, and J_{iso} into eqs. [1] and [2] leads to the following conclusions:

1. The absolute sign of $J(^{31}P,^{199}Hg)$ is positive (i.e., the high

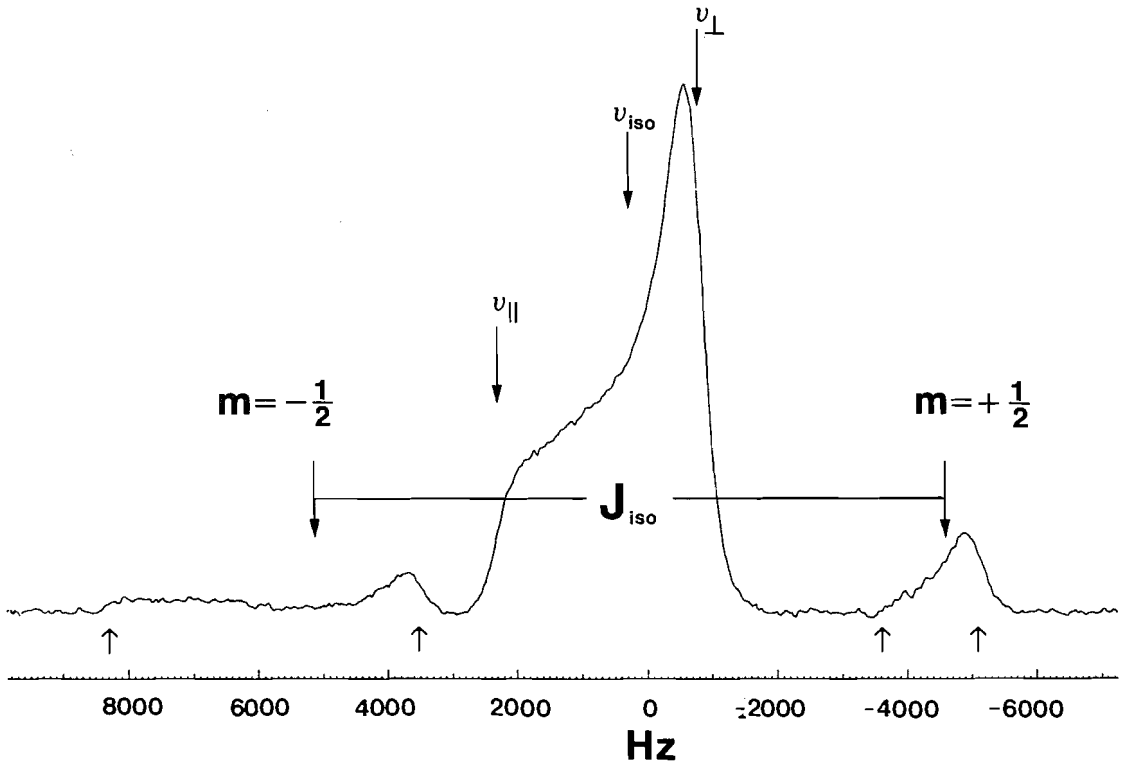

FIG. 1. The ^{31}P nmr spectrum of a stationary solid powder sample of $[HgP(o\text{-tolyl})_3(NO_3)_2]_2$ obtained at 80.962 MHz. All frequencies are relative to the ^{31}P resonance of solid $NH_4H_2PO_4$. The isotropic chemical shift of solid $[HgP(o\text{-tolyl})_3(NO_3)_2]_2$ relative to $NH_4H_2PO_4$ is 3.6 ppm. The arrows (pointing up) beneath the spectrum indicate the positions of the shoulders and discontinuities of the $m = \pm 1/2$ subspectra.

frequency subspectrum is to be associated with $m = -1/2$); this is in agreement with conclusions deduced from the relative sign determinations based on double resonance experiments in other compounds containing P—Hg bonds (25, 26).

2. The value of ΔJ is 5170 Hz; thus $J_\parallel = 13{,}110$ Hz and $J_\perp = 7940$ Hz. The error in these values is estimated to be ±250 Hz. The implication of this substantial anisotropy in J(P,Hg) is that mechanisms other than the Fermi contact mechanism must play an important role in the transfer of spin information between these two nuclei (11–13, 27).

In solving eq. [1] and [2] for ΔJ we used $D = 634$ Hz; this value was calculated from γ_P, γ_{Hg}, and taking $r_{P—Hg}$ as 240 pm. Although diffraction data are unavailable for $[HgP(o\text{-tolyl})_3(NO_3)_2]_2$ they are available for the related compounds, $[HgP(\text{mesityl})_3(NO_3)_2]_2$ (28), $[HgPCy_3(NO_3)_2]_2$ (29), and $[HgP(o\text{-tolyl})_3(OAc)_2]_2$ (30). In all three compounds $r_{P—Hg} = 240 \pm 3$ pm. Also in each of these compounds the X-ray data indicate that mercury forms three strong bonds, the P—Hg bond and two Hg—O bonds with an essentially trigonal planar arrangement; however, each mercury is further associated with three oxygen atoms giving an overall mercury coordination number of 6. The complex, $[HgP(o\text{-tolyl})_3(NO_3)_2]_2$ was prepared as described in ref. 31.

To anticipate how sensitive the observed spectrum is to the requirement that the dipolar vector be colinear with $\sigma_\parallel$ we have written a general computer program based on the relations outlined by Valentine *et al.* (32), but generalized to include indirect spin–spin coupling. Qualitatively the line-shape simulations indicate substantial asymmetry (i.e., non-axial powder patterns) in both subspectra as the angle between $r_{P—Hg}$ and σ_{11} ($\sigma_{11} = \sigma_\parallel$ for axial symmetry) deviates significantly from zero. We feel the assumption of $r_{P—Hg}$ being colinear with $J_\parallel$ and J being axially symmetric is reasonable on the basis of the single crystal results of Tutunjian and Waugh (22, 23). They found that the J(P,P) tensors in tetraethyldiphosphine disulfide and in tetrabutyldiphosphine disulfide are essentially axially symmetric. Axial symmetry of the indirect coupling tensor is intuitively reasonable when two nuclei are essentially σ bonded.

It is of interest to point out that the ^{31}P chemical shielding anisotropy in $[HgP(o\text{-tolyl})_3(NO_3)_2]_2$, −38.3 ppm, is substantially smaller than the values reported for the three inequivalent phosphorus nuclei of chlorotris(triphenylphosphine) rhodium(I) (33), the only other metal phosphine for which such data are available. Also, the three shielding tensors in the latter compound are not axially symmetric. The implication is that ^{31}P shielding tensors observed in metal-phosphine complexes are very sensitive to subtle changes in electronic and molecular structure and in principle much more informative than isotropic chemical shifts.

In conclusion, our results indicate that it should be possible to obtain accurate values of $\Delta^1J(^{31}P,^{199}Hg)$ from ^{31}P nmr powder patterns, particularly when the mercury-199 satellites are completely isolated from the central uncoupled ^{31}P nmr spectrum. Detailed investigations of related compounds are presently underway in our laboratory.

First observation and analysis of the $0_u^+(^1D)$ ion-pair state of Br_2 by optical–optical double resonance

TAKASHI ISHIWATA, OSAMU NAKAMURA, KINICHI OBI, AND IKUZO TANAKA

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro, Tokyo 152, Japan

Received November 27, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

TAKASHI ISHIWATA, OSAMU NAKAMURA, KINICHI OBI, and IKUZO TANAKA. Can. J. Chem. **66**, 1824 (1988).

The technique of optical–optical double resonance has been applied to a study of the $0_u^+(^1D)$ ion-pair state of Br_2. Two pulsed dye lasers excite the molecules from the ground state to the $0_u^+(^1D)$ ion-pair state stepwise through the $B^3\Pi(0_u^+)$ state in the pump-probe scheme: $0_u^+(^1D) \leftarrow (2h\nu_2)$–$B^3\Pi(0_u^+) \leftarrow (h\nu_1)$–$X^1\Sigma_g^+$. The $0_u^+(^1D)$–$X^1\Sigma_g^+$ emission identified at around 215 nm is used to detect the double resonance signals when the probe laser frequency (ν_2) is scanned by fixing the pump laser frequency (ν_1) to appropriate $B^3\Pi(0_u^+)$–$X^1\Sigma_g^+$ transitions. The emission spectra are resolved to establish the absolute vibrational numbering of the ion-pair state in terms of the Franck–Condon calculations. The Dunham coefficients of the $0_u^+(^1D)$ state obtained in a global least-squares fit analysis of 377 transitions ($0 \leqq v' \leqq 8$, $6 \leqq J' \leqq 100$) are $Y_{00} = 57929.724(24)$, $Y_{10} = 212.227(23)$, $Y_{20} = -1.5683(56)$, $Y_{30} = 1.606(40) \times 10^{-2}$, $Y_{01} = 0.0465652(89)$, $Y_{11} = -4.500(36) \times 10^{-4}$, $Y_{21} = 1.133(41) \times 10^{-5}$, and $Y_{02} = -9.37(94) \times 10^{-9}$ for $^{79}Br_2$ isotope species (all in cm^{-1} with 3σ in parentheses).

TAKASHI ISHIWATA, OSAMU NAKAMURA, KINICHI OBI et IKUZO TANAKA. Can. J. Chem. **66**, 1824 (1988).

On a utilisé la technique de la double résonance optique–optique pour étudier l'état de la paire ionique $0_u^+(^1D)$ du Br_2. Deux lasers à colorant pulsés excitent les molécules de leur état fondamental à l'état de paire ionique $0_u^+(^1D)$, en procédant par étape par le biais de l'état $B^3\Pi(0_u^+)$, dans le schéma de la pompe-sonde : $0_u^+(^1D) \leftarrow (2h\nu_2)$–$B^3\Pi(0_u^+) \leftarrow (h\nu_1)$–$X^1\Sigma_g^+$. On a utilisé l'émission $0_u^+(^1D)$–$X^1\Sigma_g^+$ qui est observée autour de 215 nm pour détecter les signaux de double résonance; à cette fin, on a balayé la fréquence du laser-sonde (ν_2) alors que la fréquence du laser-pompe (ν_1) était fixée aux transitions $B^3\Pi(0_u^+)$–$X^1\Sigma_g^+$ appropriées. On a résolu le spectre d'émission pour établir le nombre absolu de vibrations, dans l'état de la paire ionique, en fonction de calculs de Franck–Condon. Les coefficients de Dunham de l'état $O_u^+(^1D)$ des espèces isotopiques du $^{79}Br_2$ (tous en cm^{-1}, avec les valeurs de 3σ inscrites entre parenthèses), qui ont été obtenus en appliquant la méthode des moindres carrés à 377 transitions ($0 \leqq v' \leqq 8$, $6 \leqq J' \leqq 100$), sont $Y_{00} = 57929{,}724(24)$, $Y_{10} = 212{,}227(23)$, $Y_{20} = -1{,}5683(56)$, $Y_{30} = 1{,}606(40) \times 10^{-2}$, $Y_{01} = 0{,}0465652(89)$, $Y_{11} = -4{,}500(36) \times 10^{-4}$. $Y_{21} = 1{,}133(41) \times 10^{-5}$ et $Y_{02} = -9{,}37(94) \times 10^{-9}$.

[Traduit par la revue]

I. Introduction

In spite of many studies on the spectroscopy of halogen molecules over the past 50 years (see, for example, ref. 1), there remain a number of problems that should be solved. Some of the questions most frequently mentioned are concerned with the interpretation of ultraviolet emission spectra observed in a discharge. Until recently this problem received little attention, largely because of the difficulty of making reliable measurements and assignments on the congested bands.

In the last several years, we have carried out a program of studies on the Br_2 molecule by optical–optical double resonance (OODR) spectroscopy to investigate the role of ion-pair states in ultraviolet emission (2–4).[1] The method has the quite attractive advantage of studying ion-pair states with regard to symmetrical selection rules and the Franck–Condon principle. For example, ion-pair states correlating with $Br^-(^1S) + Br^+(^3P, ^1D, ^1S)$ can be combined stepwise with the ground state either through the $B^3\Pi(0_u^+)$ state or the $A^3\Pi(1_u)$ state, according to the selection rule $\Delta\Omega = 0$ for parallel-type transitions between ion-pair and valence states. Furthermore, the parity selection rule for multiphoton transition is different from that for one-photon transition. We can observe ion-pair states with either g or u symmetry, depending on whether the total number of photons is even or odd, respectively. The stepwise process exploits the changing Franck–Condon factors during molecular excitation. A considerable range of vibrational levels in ion-pair states is accessed through the different pump transitions. The double resonance method has the capability of state selection, giving simple and easily assignable spectra. The results provide a reliable data base for ion-pair states with regard to the energy levels, potential curves, and related features. The emission spectra of ion-pair states observed in the double resonance experiments are quite helpful in sorting out the congested spectra observed in a discharge, by avoiding the simultaneous formation of many kinds of excited states.

In this paper we present the results of the optical–optical double resonance study on the $0_u^+(^1D)$ ion-pair state of Br_2 correlating with $Br^-(^1S) + Br^+(^1D)$ at the dissociation limit. Monoisotopic $^{79}Br_2$ was used throughout the experiments to exclude spectral congestion problems as much as possible, since natural Br_2 contains three isotope species of comparable abundance. Using a J selected (1 + 2) photon double resonance $0_u^+(^1D) \leftarrow (2h\nu_2) - B^3\Pi(0_u^+) \leftarrow (h\nu_1) - X^1\Sigma_g^+$, the $0_u^+(^1D)$ ion-pair state occurs in the spectrum as vibrational progressions consisting of O, Q, and S branches according to the selection rule of $\Delta J = 0, \pm 2$ in the 0_u^+–0_u^+ coherent two-photon transition. The energy levels of the $0_u^+(^1D)$ state were analyzed on the vibrational levels of $v' = 0$ through $v' = 8$ and a set of molecular constants was given in a Dunham-type expression. Analysis of the emission shows that the $0_u^+(^1D)$–$X^1\Sigma_g^+$ transition is responsible for the 220-nm emission in a discharge (5).

II. Experimental

The experimental set-up used in this work is similar to that described previously (3*d*). The double resonance excitation of Br_2 was carried out by two tunable dye lasers pumped by the divided outputs of a XeCl excimer laser. A pump laser was tuned to appropriate transitions of the $B^3\Pi(0_u^+)$–$X^1\Sigma_g^+$ system in the visible region, which assignments were

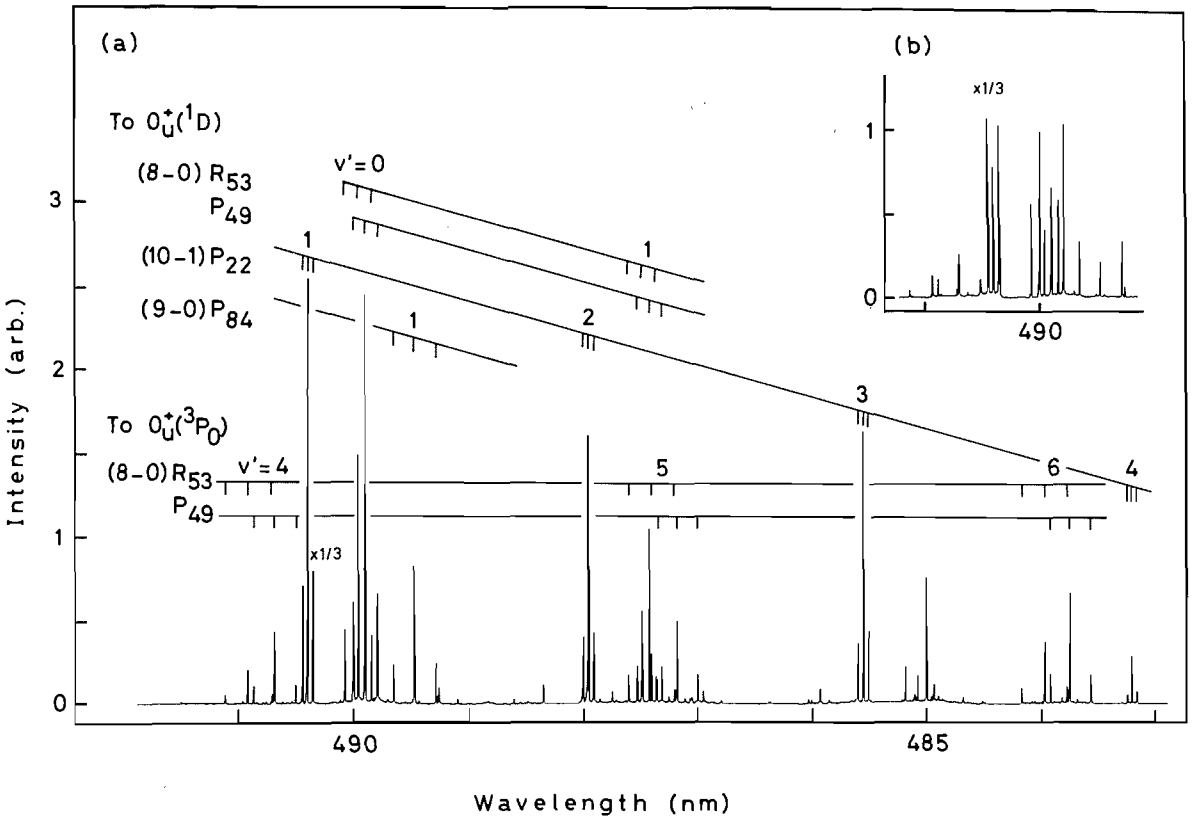

FIG. 1. An OODR excitation spectrum of $^{79}Br_2$ according to the excitation scheme, $0_u^+(^1D)$–$B^3\Pi(0_u^+)$–$X^1\Sigma_g^+$. The spectrum was obtained by fixing the pump laser to the (8–0) P_{49} and R_{53}, (9–0) P_{84}, and (10–1) P_{22} transitions of the $B^3\Pi(0_u^+)$–$X^1\Sigma_g^+$ system. The probe laser was scanned to probe the $0_u^+(^1D)$ state in a coherent two-photon transition from the $B^3\Pi(0_u^+)$ state under low resolution by monitoring the ultraviolet emission at 220 nm with a spectral slit width of 30 nm. The pump and probe lasers were operated with vertical polarization in spectrum (a), while the polarization of the probe laser was changed to circular with maintaining the pump laser vertical polarization in spectrum (b).

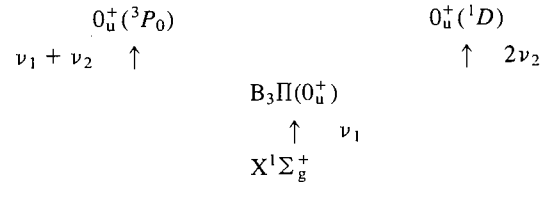
made on the basis of published data (6). For fixing the pump frequency, a probe laser was scanned in the visible to observe the transitions to the $0_u^+(^1D)$ state by coherent two-photon absorption. The double resonance transitions were then monitored by ultraviolet emission of the $0_u^+(^1D)$–$X^1\Sigma_g^+$ system through a monochromator and the photomultiplier signals were averaged by a boxcar integrator.

The pump and probe laser beams were carefully aligned to focus on the same spot from opposite directions. The two dye lasers produced pulses with an energy of 3–5 mJ/pulse at a repetition rate of 10 Hz. The laser bandwidth was 0.04 cm^{-1} in the case of operating with an "étalon" tuning element, and 0.3 cm^{-1} without an étalon. The output beams of the two dye lasers were vertically polarized in normal experiments. We examined the anisotropic character of a two-photon transition from the $B^3\Pi(0_u^+)$ state by changing the polarization angle of the probe laser beam. The optical components used for these studies consisted of a polarizer, a double Fresnel rhomb, and a single Fresnel rhomb. The amount of polarization retardation was changed by rotating the double Fresnel rhomb and was determined by the relative angle between the optically active planes of the double Fresnel rhomb and the single Fresnel rhomb.

III. Results and discussion

A. *Optical–optical double resonance transition*

Figure 1 represents a typical example of spectra observed in the double resonance experiments of Br_2. The pump laser frequency (ν_1) was adjusted to a photon energy of 16969.0 cm^{-1}, which is in resonance with the (8–0) P_{49} and R_{53}, (9–0) P_{84}, and (10–1) P_{22} transitions of the $B^3\Pi(0_u^+)$–$X^1\Sigma_g^+$ system within the bandwidth of the pump laser (~0.3 cm^{-1}). We monitored the ultraviolet emission at 220 nm with a spectral slit width of 30 nm. Spectrum (a) was recorded under low resolution by scanning the probe laser in the 492–483 nm range. There was no time delay between two laser pulses of 15-ns duration. Under the experimental condition of a sample pressure of 2 Torr (1 Torr = 133.3 Pa), the rotational relaxation is negligible in the intermediate $B^3\Pi(0_u^+)$ state. The double resonance spectra, therefore, are quite simple; two 0_u^+–0_u^+ systems originate from the different (1 + 2) photon excitation schemes.



Type II: $\nu_1 + (\nu_1 + \nu_2)$ Type I: $\nu_1 + (2\nu_2)$

The first is the transition to the $0_u^+(^3P_0)$ state, correlating with the ionic state of $Br^-(^1S) + Br^+(^3P_0)$ at the dissociation limit (3*a*, 3*b*). This state is known to lie in the 53 000 cm^{-1} range, whose emission terminating in the ground state has been identified as the transition around 248 nm. Our previous publication (3*b*) shows that the double resonance transition to the $0_u^+(^3P_0)$ state occurs in the (1 + 2) photon sequence of the type II transition $\nu_1 + (\nu_1 + \nu_2)$: the pump laser excites the $B^3\Pi(0_u^+)$–$X^1\Sigma_g^+$ transition while the pump and probe laser

pulses combine to execute the second step of the $0_u^+(^3P_0)$–$B^3\Pi(0_u^+)$ transition, due to the temporal overlap of two laser pulses. Since the line positions of the $0_u^+(^3P_0)$–$B^3\Pi(0_u^+)$ system can be tabulated from the published data (*3b*) within an accuracy of about 2 cm^{-1}, we have no real difficulty in the assignments. For example, Fig. 1(a) shows the double resonance signals through the (8–0) P_{49} and R_{53} transitions of the $B^3\Pi(0_u^+)$–$X^1\Sigma_g^+$ system. The vibrational progression with ~150 cm^{-1} intervals can be unequivocally assigned to the transitions terminating on the $v' = 4$–6 levels of the $0_u^+(^3P_0)$ state. Furthermore, the bands observed are J selected transitions, showing band structures consisting of O, Q, and S branches in accordance with the selection rule of the 0_u^+–0_u^+ transition $\Delta J = 0, \pm 2$.

The second is the transition to the $0_u^+(^1D)$ ion-pair state, which will be discussed in this paper. This state lies in the 58 000 cm^{-1} range and shows the $0_u^+(^1D)$–$X^1\Sigma_g^+$ emission around 215 nm. In view of the quadratic dependence of fluorescence signals on the probe laser power, the double resonance transition is predicted to proceed in the type I transition $\nu_1 + (2\nu_2)$, where the coherent $0_u^+(^1D)$–$B^3\Pi(0_u^+)$ two-photon transition is executed by the probe laser alone. This assignment of the two-photon excitation mechanism is confirmed by comparing the observed polarization effect on line intensities with the theoretical prediction.

B. Polarization effect

According to the theoretical treatment of McClain and Harris (*7*), the 0_u^+, 1_u, and 2_u states can be combined with the $B^3\Pi(0_u^+)$ state by a coherent two-photon transition of identical photons. The rotational selection rules are as follows.

[1] $\Delta J = 0, \pm 2$ for the 0^+–0^+ transition

[2] $\Delta J = 0, \pm 1, \pm 2$ for the 1–0^+ and 2–0^+ transitions

The strengths of a coherent two-photon transition (δ) then depend on (*i*) a factor specified by J'' and J', analogous to the Hönl–London factor for a one-photon transition, (*ii*) an intrinsic factor characteristic of the particular vibronic transition, and (*iii*) a factor dependent on the polarization vector of two photons absorbed simultaneously. In the case of the 0^+–0^+ transition, the ratio of the absorption of the linearly polarized light to the circularly polarized light holds the relation

[3] $\delta_{ll}/\delta_{cc} = 2/3$

for the O and S branches, where subscripts l and c designate linearly and circularly polarized photons, respectively. The transition strength for the Q branch depends on the character of the two-photon transition and the polarization ratio is predicted to follow the relation

[4] $\delta_{ll}/\delta_{cc} = (2/3)\{1 + 5(\mu_I^2/\mu_S^2)\}$

for high J, where μ_I and μ_S denote the transition dipole factors given by $\mu_I = (2a + b)$ and $\mu_S = (a - b)$ in terms of Cartesian tensor components of the 0^+–0^+ two-photon transition:

[5] $$\begin{pmatrix} a & 0 & 0 \\ 0 & a & 0 \\ 0 & 0 & b \end{pmatrix}$$

The polarization ratio in eq. [4] thus ranges from infinity (no Q branch in the excitation by circular polarized photons), for the case $\mu_S = 0$, to 14 for only perpendicular transitions involved in the two-photon process, and to 4 for only parallel transitions involved. On the other hand, the ratios of transition strengths (δ_{ll}/δ_{cc}) are predicted to be 2/3 for all branches of the 1–0^+ and 2–0^+ transitions.

We have measured the polarization character of the two-photon transition. Figure 1(b) shows a small portion of the spectrum where the polarization of the probe laser was changed from (a) vertical to (b) circular while maintaining the pump laser in the vertical polarization. Since double resonance excitation helps to resolve the rotational structure reasonably well, polarization effects on single rotational transitions are straightforward.

In the type I transition, the essential features are (*i*) the intensity ratios between the O, Q, and S lines are approximately 1:4:1 in spectrum (a), while their ratios change to about 3:2:3 in spectrum (b), and (*ii*) the O and S branches increase in intensity by ~50% by changing the polarization of the probe laser from linear to circular, while the Q branch drastically loses intensity by ~75%.

[6] $\delta_{ll}/\delta_{cc} = 0.68 \pm 0.07$ for O and S branches

[7] $\delta_{ll}/\delta_{cc} = 4.2 \pm 0.6$ for Q branches

This behavior is obviously characteristic of the $0_u^+(^1D)$–$B^3\Pi(0_u^+)$ transition executed by two identical photons, as predicted in eqs. [3] and [4]. The observed ratio of eq. [7] indicates that the parallel-type transition is executed in the two-photon process according to the theoretical prediction expressed in eqs. [4] and [5]: $a/b \sim 0$. The view is quite reasonable. The valence–ion-pair transitions are of the charge transfer type, whose transition moments lie along the internuclear axis.

In the type II transition, where the $0_u^+(^3P_0)$–$B^3\Pi(0_u^+)$ transition occurs by the combination of pump and probe lasers, the intensity pattern of O, Q, and S branches is close to the 1:3:1 ratios in spectrum (a), and changes to approximately 1:2:1 in spectrum (b). The polarization ratios for the transition strengths are $\delta_{lc}/\delta_{ll} \sim 0.9$ for the O and S branches and ~0.6 for the Q branches, which agree with our previous results (*3b*).

C. Emission

Figure 2 represents two examples of the emission spectra showing the $0_u^+(^1D)$–$X^1\Sigma_g^+$ system. The spectra were obtained by tuning the probe laser frequency to the Q branch involved in the first members of the vibrational progression in Fig. 1(a); (a) (8–0) P_{49} and (b) (10–1) P_{22} transitions of the $B^3\Pi(0_u^+)$–$X^1\Sigma_u^+$ system. The molecular parameters of the higher vibrational levels of the ground state were reported for the ^{79}Br–^{81}Br species (*8*). We adjusted these constants to $^{79}Br_2$ to allow for the isotope difference and the assignments of the vibrational progressions are shown in Fig. 2. The absolute wavelength positions of the expected P and R doublets in the $0_u^+(^1D)$–$X^1\Sigma_g^+$ system agreed with the observations within a spectral slit width of 2 Å. The transition obviously terminates at the high vibrational levels of the ground state, since the internuclear distance of the ion-pair state (typically $r_e = 3.2$ Å) is much longer than that of the ground state ($r_e = 2.281$ Å). The low v' level of the ion-pair state thus displays in emission a band system whose intensity distribution is modulated according to the probability distribution of the upper vibrational wavefunction: the $v' = 0$ level shows a single intensity maximum in an envelope of the emission spectrum, $v' = 1$ shows double maxima, and so on.

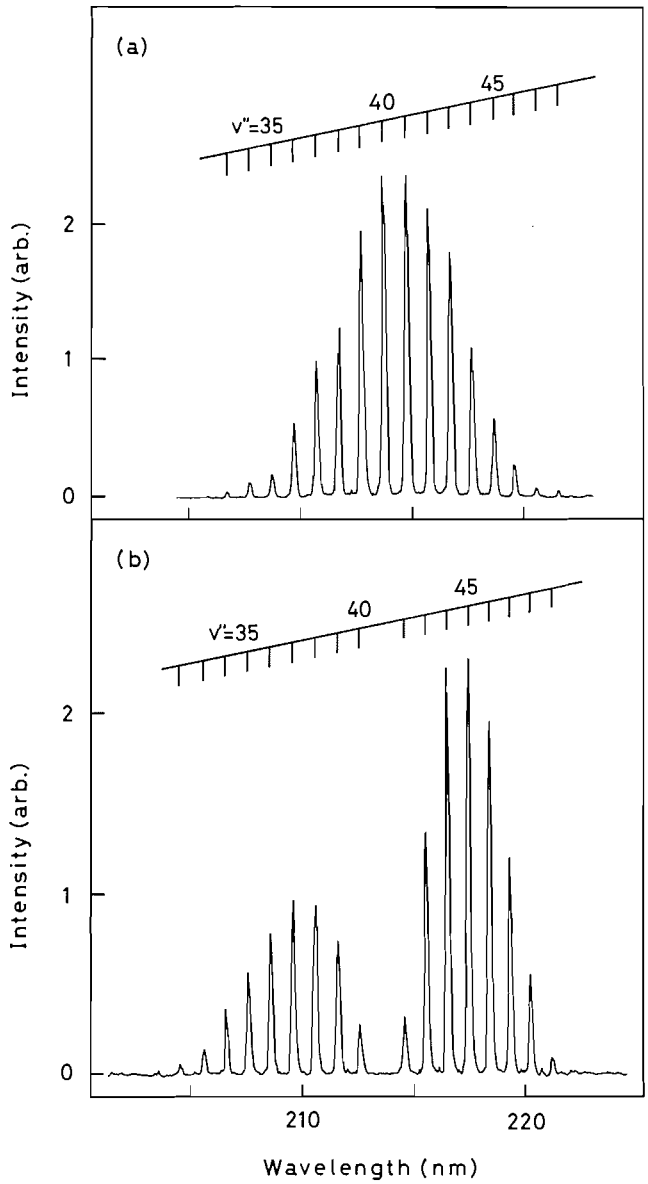

FIG. 2. The emission spectra of the $0_u^+(^1D)$–$X^1\Sigma_g^+$ system of Br_2. The excitation scheme is

$$0_u^+(^1D) \xleftarrow{2h\nu_2} B^3\Pi(0_u^+) \xleftarrow{h\nu_1} X^1\Sigma_g^+$$

(a) (0–8) Q_{48} (8–0) P_{49}

(b) (1–10) Q_{21} (10–1) P_{22}

Calculated Franck–Condon factors are as follows:

Scheme	$v' = 30$	31	32	33	34	35	36	37	38	38	40
(a)			1	3	7	16	31	54	83	114	139
(b)	1	2	6	13	25	43	64	79	77	56	23

Scheme	$v' = 41$	42	43	44	45	46	47	48	49	50
(a)	149	139	112	77	44	21	7	2		
(b)	0	13	60	115	144	129	87	43	15	3

The spectra in Fig. 2 are, therefore, predicted to originate from (a) $v' = 0$ and (b) $v' = 1$ levels of the $0_u^+(^1D)$ ion-pair state, and the use of isotopes is eventually not necessary for the absolute vibrational numbering of the double resonance spectrum shown in Fig. 1(a).

D. Analysis

The transitions from a J-selected level of the $B^3\Pi(0_u^+)$ state to the $0_u^+(^1D)$ state were measured by installing the intra-cavity étalon in the probe laser. The probe laser frequency was calibrated by reference to the absorption spectrum of $^{130}Te_2$ (9), recorded simultaneously. A typical result is shown in Fig. 3. The spectral position of the OODR signal could be determined within an estimated accuracy of $0.02\,cm^{-1}$. Table 1 summarizes the double resonance transitions observed in the experiments. The raw data include 377 transitions in the range of $0 \leqq v' \leqq 8$ and $6 \leqq J' \leqq 100$. Even though the range of the rotational levels probed in the $0_u^+(^1D)$ ion-pair state is not uniform for each vibrational level and does not cover all rotational levels, there remains no serious gap in the rotational distribution and we could not find any traces of local perturbation. As an example, a Fortrat diagram of the (0–8) $0_u^+(^1D)$–$B^3\Pi(0_u^+)$ transition is shown in Fig. 4. The measurements were continued for high J levels until the data were sufficient to determine the centrifugal distortion.

In the energy level analysis of the $0_u^+(^1D)$ ion-pair state, we converted the probe laser frequencies (ν_2) to the energies of the ion-pair state ($T_{v,J}$) relative to the potential minimum of the $X^1\Sigma_g^+$ ground state by the relation

$$[8] \quad T_{v,J} = T_{v^*,J^*}(B) + 2h\nu_2$$

where $\Delta J = J^* - J = 0, \pm 2$ corresponding to the rotational selection rule of the coherent $0_u^+(^1D)$–$B^3\Pi(0_u^+)$ two-photon transition. The term value of the $B^3\Pi(0_u^+)$ state, $T_{v^*,J^*}(B)$, from which the two-photon transition originated, could be calculated from the molecular constants given by Barrow *et al.* (6). The term values of the $0_u^+(^1D)$ state were then submitted to a global least-squares fit to the Dunham-type expansion

$$[9] \quad T_{v,J} = \Sigma_{n,k} Y_{n,k}(v + 1/2)^n J^k (J + 1)^k$$

The fitting requires eight parameters as listed in Table 2. The standard deviation of the fit is $0.0466\,cm^{-1}$ and the molecular parameters in Table 2 can regenerate all $0_u^+(^1D)$ term values within the range of $0.15\,cm^{-1}$.

The molecular constants in Table 2 were used to construct an RKR (Rydberg–Klein–Rees) potential curve of the $0_u^+(^1D)$ state. The RKR turning points for the observed vibrational levels are given in Table 3. We then calculated the Franck–Condon factors (FCF) between the $0_u^+(^1D)$ and $X^1\Sigma_g^+$ states to confirm the intensity distribution of the emission spectra in Fig. 2.[2] Calculations were made of the effective potentials for the corresponding J levels, including the centrifugal term; $U_J(r) = U_0(r) + J(J + 1)h/(8\pi^2 c\mu r^2)$. As shown in the caption of Fig. 2, the Franck–Condon factor calculations support our observations in terms of the intensity pattern, making the absolute v numbering of the $0_u^+(^1D)$ state unequivocal. However, there exist slight discrepancies in the intensity distribution of the spectra in Fig. 2: the maxima predicted at $v'' = 41$ for $v' = 0$ and $v'' = 45$ for $v' = 1$ shift to shorter

[2]We used the Hougen version of the RKR and FCF program originally written by Zare *et al.* (11).

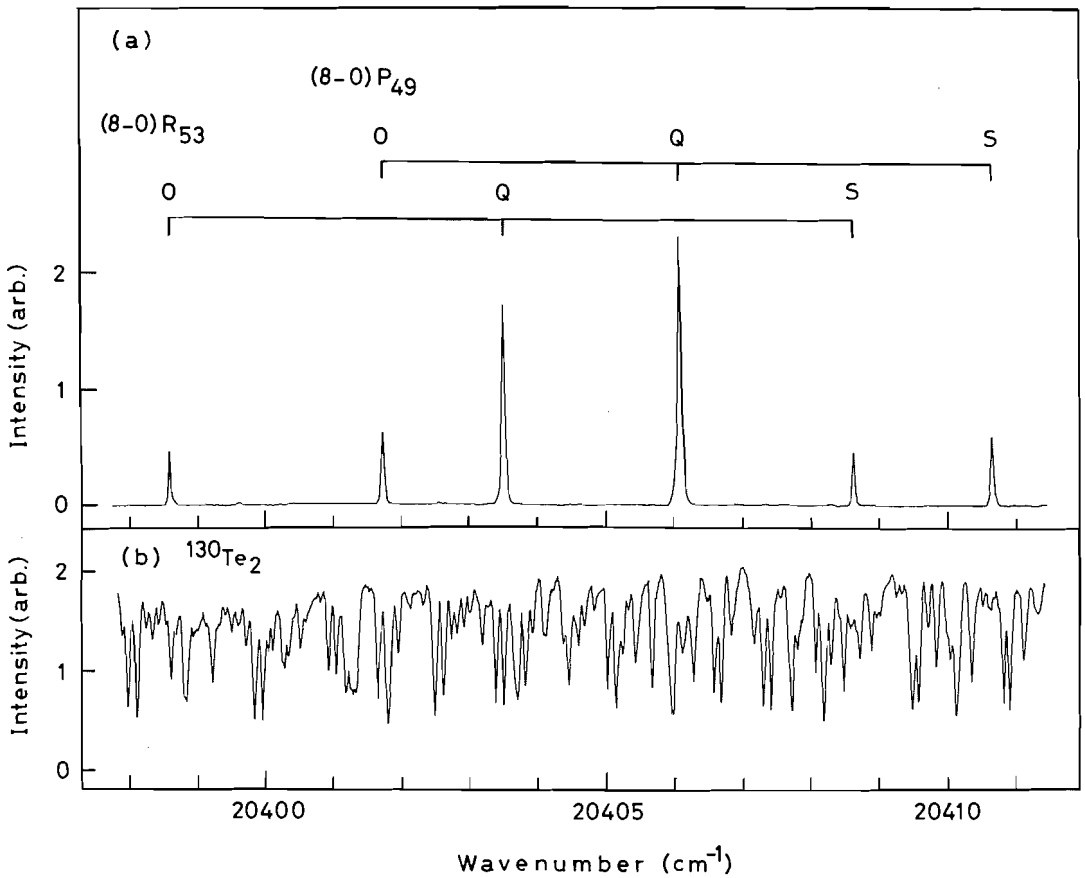

FIG. 3. (a) The double resonance spectrum of the (0–8) $0_u^+(^1D)$–$B^3\Pi(0_u^+)$ transition taken under high resolution in the vicinity of 490 nm shown in Fig. 1. Two rotational multiplets consisting of O, Q, and S branches reflect the transitions through the (8–0) P_{49} and R_{53} transitions of the $B^3\Pi(0_u^+)$–$X^1\Sigma_g^+$ system according to the selection rule of $\Delta J = 0, \pm 2$. (b) The absorption spectrum of $^{130}Te_2$ used for the laser frequency calibration.

wavelengths in the observations. The situation is quite similar to the $0_u^+(^3P_2)$–$X^1\Sigma_g^+$ system (3*d*), because the molecular constants used to calculate the RKR potential of the ground state would be not accurate enough to reproduce the potential in a long range.

E. Ion-pair state of Br_2

Table 4 lists the ion-pair states of Br_2 known to date according to their ionic correlations at the dissociation limit expected in the empirical model (5). The ion-pair states have similar vibrational frequencies close to 150 cm^{-1}, bond lengths $r_e = 3.2$ Å, and, because of the predominance of the coulombic attraction in their potential functions, they have relatively large dissociation energies of ~35 000 cm^{-1}. To the extent that these states reflect the intervals in the various Br^+ ions, there are six states (0_u^+, 1_u, 2_u, 0_g^+, 1_g, $2_g(^3P_2)$) around 49 000 cm^{-1}, six (0_u^-, 1_u, 0_g^-, $1_g(^3P_1)$, and 0_u^+, $0_g^+(^3P_0)$) around 52 000 cm^{-1}, six (0_u^+, 1_u, 2_u, 0_g^+, 1_g, $2_g(^1D)$) around 60 000 cm^{-1}, and two (0_u^+, $0_g^+(^1S)$) considerably higher (17).[3]

Among the 12 states correlating with $Br^-(^1S) + Br^+(^3P)$, it is surprising that only the 0_g^+ and $2_g(^3P_2)$ states have been analyzed through the emission spectra observed in the discharge (12, 15). Double resonance methods have been used to fill this gap and elucidated the 11 ion-pair states except for the $2_g(^3P_2)$ state. The $\Omega = 0^+$ and 1 states have been characterized with reasonable accuracy either through the $B^3\Pi(0_u^+)$ or $A^3\Pi(1_u)$ state as an intermediate using (1 + 1) photon excitation for g states and (1 + 2) excitation for u states (2–4, 13, 14). However, the spectroscopic data for the $2_u(^3P_2)$ and $0_u^-(^3P_1)$ states are quite fragmentary, since these excited states have only been seen as extra lines through the heterogeneous interaction with $\Omega = 0^+$ and 1 ion-pair states correlating with the same ionic

asymptotes: 0_u^+–1_u–$2_u(^3P_2)$ and 0_u^-–$1_u(^3P_1)$.[1] Furthermore, the position of the $0_g^-(^3P_1)$ state has been only predicted from the Ω-type splitting constants of the $1_g(^3P_1)$ state, on the basis of the pure precession approximation of the 1_g–$0_g^-(^3P_1)$ interaction (4*b*). The direct approach to the $\Omega = 0^-$ and 2 ion-pair states is mainly limited by the $\Delta\Omega = 0$ selection rule of the valence–ion-pair transitions originating from their primary transition moments parallel to the internuclear axis.

Among the six states correlating with $Br^-(^1S) + Br^+(^1D)$, the $0_u^+(^1D)$ state is the first one identified spectroscopically. This state is anomalous among the ion-pair states. (*i*) The dissociation energy of ~38 000 cm^{-1} is ~3000 cm^{-1} larger than the average of the ion-pair states correlating with $Br^-(^1S) + Br^+(^3P)$. (*ii*) The vibrational frequency of the $0_u^+(^1D)$ state is 40–70% higher than those of other ion-pair states and the equilibrium internuclear distance is 0.15–0.3 Å shorter. These facts indicate that a covalent character results from the configuration interaction with Rydberg states. The lowest vibrational level of the $0_u^+(^1D)$ state shows the emission spectrum around 215 nm. According to Tellinghuisen *et al.* (5), the 220-nm band had a discrete structure and persisted at high Ar pressure in the discharge. This band obviously corresponds to the $0_u^+(^1D)$–$X^1\Sigma_g^+$ system described in this work. The red shift of the emission peak by ~5 nm is not surprising. In ion-pair states the vibrational relaxation competes with the fast cascade to lower excited states by collisions. The thermalization might be inefficient in the high-lying ion-pair state and the overlap of the emission bands from the unthermalized vibrational levels is expected to show a red-shifted band structure.

Tellinghuisen *et al.* (see Table 1 in ref. 5) also showed evidence of at least five other electronic transitions in addition

TABLE 4. Electronic states of Br_2

to the $2_g(^3P_2)$–$A'^3\Pi(2_u)$ and $0_g^+(^3P_2)$–$B^3\Pi(0_u^+)$ systems in the 200–300 nm region. As to the 227 and 237-nm bands, spectroscopic data are not available to specify the assignment on the data base listed in Table 4. Assuming that the discrete 227-nm band originates from the ion-pair state having $r_e \sim 3.2$ Å, its energy is estimated to be 59 000 or 61 500 cm^{-1}, according to whether the transition terminates on either the $A^3\Pi(1_u)$ or the $A'^3\Pi(2_u)$ state, or on the $B^3\Pi(0_u^+)$ state. For the 237-nm band, the energy of the upper state decreases by ~2000 cm^{-1}. These energies lie in the region for the states correlating with $Br^-(^1S) + Br^+(^1D)$. The 251 and 265-nm bands are definitely assigned to the $0_u^+(^3P_0)$–$X^1\Sigma_g^+$ and $1_g(^3P_1)$–$A^3\Pi(1_u)$ systems, respectively. The 276-nm band is close to the $0_u^+(^3P_2)$–$X^1\Sigma_g^+$ system in the wavelength. However, we can expect the transition of the $0_g^-(^3P_1)$ ion-pair state to terminate at the 0_u^- state that correlates with the two ground-state atoms ($Br_{3/2}$) around 276 nm, by analogy with the emission spectrum of I_2. Tellinghuisen and co-workers reported the 0_g^-–0_u^- system around 288 nm as the second most intense transition in the high-pressure emission spectrum of I_2 (18). The energy levels of the ion-pair states correlating with the second ionic states of $I^-(^1S) + I^+(^3P_{1,0})$ are somewhat different from those of Br_2: the $0_g^+(^3P_0)$, $0_g^-(^3P_1)$, $0_u^+(^3P_0)$, and $1_g(^3P_1)$ states of I_2 are located in the 47 000 cm^{-1} region in order of energy. The other two states $0_u^-(^3P_1)$ and $1_u(^3P_1)$ are not observed in the experiment and are expected, from theoretical prediction,[4] to lie much higher. Since the $0_g^-(^3P_1)$ ion-pair state of Br_2 lies lowest in the second cluster of the states correlating with $Br^-(^1S) + Br^+(^3P_{1,0})$, we could not neglect the possibility that the $0_g^-(^3P_1)$–0_u^- emission overlaps with the $0_u^+(^3P_2)$–$X^1\Sigma_g^+$ system. The high-lying states correlating with the same asymptote are expected to be collisionally converted to the $0_g^-(^3P_1)$ state.

Finally, Brand and Hoy (19) have recently discussed the r-dependent homogeneous interaction of the $0_u^+(^1D)$ state with the $0_u^+(^3P_0)$ state of I_2. The interaction matrix is suggested to be small at r_e, but increases rapidly as r decreases. Their potential functions are consequently distorted at small r, making the principal constants anomalous. In Br_2, the effects might also be responsible for the large anharmonicity of the potential function observed at the lower vibrational levels of the $0_u^+(^1D)$ state: the ratio Y_{20}/Y_{10} (or Y_{11}/Y_{01}) $\sim 1 \times 10^{-2}$ is larger than those of other ion-pair states ($\sim 3 \times 10^{-3}$) by a factor of 3. This problem will be addressed in future.

Spin adduct yields in the photoreduction of menadione (2-methylnaphthoquinone) in isotope labeled micellar solutions were measured as functions of the external magnetic field. As surfactants, ordinary SDS, perdeuteriated SDS, and a mixture of the two were employed. In a mixed micellar solution, a normal isotope effect on the spin adduct yield was observed. On the other hand, in the pure micellar solutions with each of the former two surfactants, a reversed isotope effect was observed. These two apparent isotope effects depend on the external magnetic field and were separated into two independent isotope effects: one is the primary isotope effect on the hydrogen abstraction step and the other is the secondary magnetic isotope effect on the intersystem crossing step of the intermediate radical pair.

MASAHARU OKAZAKI, KAZUMI TORIYAMA, KEICHI NUNOME, HACHIZO MUTO et TAKESHI SHIGA. Can. J. Chem. **66**, 1832 (1988).

On a mesuré l'influence du champ magnétique externe sur les rendements d'adduits de spin qui se forment lors de la photoréduction de la ménadione (méthyl-2 naphtoquinone) dans des solutions micellaires marquées par des isotopes. On a utilisé du DSS ordinaire, du DSS perdeutéré et un mélange des deux agents de surface. Dans une solution micellaire mixte, on a observé un effet isotopique normal sur le rendement en adduit de spin. Par ailleurs, dans des solutions micellaires contenant chacun des deux autres agents de surface à l'état pur (ordinaire ou perdeutéré), on a observé un effet isotopique inverse. Ces deux effets isotopiques apparemment inverses dépendent du champ magnétique externe et on a pu les séparer en deux effets isotopiques indépendants : l'un est l'effet isotopique primaire impliqué dans l'étape de l'enlèvement de l'hydrogène et l'autre est l'effet isotopique magnétique secondaire impliqué dans l'étape de croisement de la paire de radicaux intermédiaires.

[Traduit par la revue]

Introduction

The isotope effect in organic chemistry (1) has been widely studied not only because the effect has its own relevance in chemistry but it also gives detailed information about chemical reaction mechanisms. As well, it may give a method for isotope enrichment. Included in those studies, the isotope effect in hydrogen abstraction reactions has been studied extensively and the mechanism developed (2–5). In addition, it was recently found that reactions that involve a radical pair as the intermediate show another type of isotope effect, i.e., the "magnetic isotope effect" (6–9). In these cases, it is very important to observe these isotope effects separately to deduce relevant results from them.

In a series of our previous studies (10–13), using the spin trapping technique (14, 15) and a flow apparatus, we developed a method to probe radical pair interactions that induce the magnetic field dependence of chemical reactions. Because the magnetic field effect is usually considered to be aroused through magnetic interaction between the intermediate radicals (16), an isotope effect can be expected in a reaction involving isotopes with different nuclear magnetisms. Because our method is quite sensitive to the magnetic field effect on chemical reactions (12), a new insight into the mechanism of isotope effects can be expected in such chemical reactions.

In this study, we observed the isotope effect on the yield of a spin trapping reaction during the photoreduction of menadione (2-methylnaphthoquinone) (17) in micellar solutions with each of ordinary SDS (SDS(H)), perdeuteriated SDS (SDS(D)), and a mixture of the two. The spin adduct with SDS(D) radical could be clearly distinguished spectroscopically by esr from that with the H-species. In the micellar solution of SDS(D) the spin adduct yield was about twice as large as that in SDS(H) micellar solution (reversed D/H isotope effect). On the other hand, in a mixed micellar solution with SDS(D) and SDS(H) at a molar ratio of 1:1, the yield of the spin adduct with the D-species was much smaller than that with the H-species (normal D/H isotope effect). The mechanism is studied by analysis of the magnetic field dependence of these isotope effects.

Experimental

Menadione (2-methylnaphthoquinone) was purchased from Wako Pure Chemicals (Osaka, Japan) as a guaranteed grade reagent, sodium dodecylsulphate (SDS) for electrophoresis from Nakarai Chemicals (Kyoto, Japan), and perdeuteriated SDS from MSD isotopes (Montreal, Canada). All these chemicals were used as received. Perdeuteriodimethylnitrosobenzenesulfonate (DMNS) was kindly supplied by Drs. Ryusei Konaka and Shigeru Sakata at Shionogi Pharmaceuticals (18). The extent of deuteriation of SDS(D) was larger than 98% as checked by mass spectrometry.

Menadione was dissolved at the concentration of 0.1 mM in a 0.1 M SDS micellar solution (buffered at pH 7.4 with 0.1 M phosphates) with a spin trap of DMNS (1 mM), and the solution was charged in a quartz flat cell using a flow apparatus and then photolysed with uv light (Ushio UH500D mercury lamp) filtered with a 5-cm water filter and a uv cut-off filter (Toshiba UV-31, <310 nm cut). The esr spectra were recorded with a Varian E-12 spectrometer at room temperature (ca. 25°C). Each component esr signal from the spin adduct of SDS(H) radical and SDS(D) radical in a composite spectrum was separated by computer simulation. The signal intensity was estimated by double integration of the first derivative spectrum. Zero magnetic field was achieved by canceling the residual field with a Helmholtz coil, which

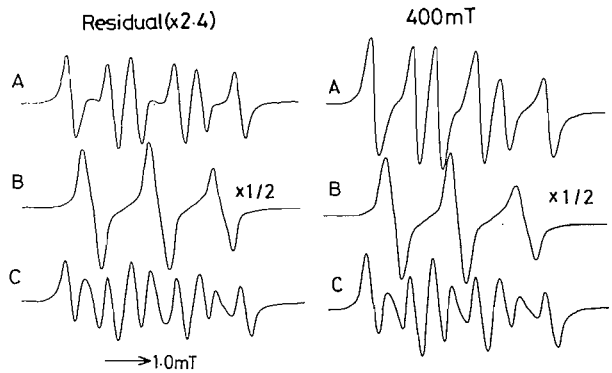

FIG. 1. Electron spin resonance spectra of the spin adducts in the photoreduction of menadione (0.1 mM) in SDS (0.1 M in 0.1 M phosphate buffer at pH 7.4) micellar solutions at residual magnetic field (left) and at 400 mT (right). The relative gain for the spectra at the residual field was 2.4 times as large as that for the spectra at 400 mT; (a) in SDS(H) micellar solution, (b) in SDS(D) micellar solution, and (c) in the mixed micellar solution of SDS(H) and SDS(D) at the molar ratio of 1:1. The microwave power was 5 mW, the modulation frequency and amplitude were 100 kHz and 0.2 mT, respectively.

was placed outside a Varian standard rectangular cavity. The detailed procedure has been described elsewhere (10).

Results

Figure 1 shows the esr spectra of the spin adducts of SDS radical accumulated during the photoreduction of menadione at the residual magnetic field (ca. 3.5 mT, right) and at 400 mT (left) (a) in the SDS(H) (ordinary SDS) micellar solution, (b) in the SDS(D) (perdeuteriated SDS) micellar solution, and (c) in the micellar solution with a 1:1 mixture of SDS(H) and SDS(D). The amplifier gain for the spectra at the residual field was set 2.4 times as large as that for the spectra at 400 mT. The sextet signal of spectra A has been assigned to the spin adduct of SDS radical (10), which is produced by hydrogen abstraction from the alkyl chain of the SDS molecule by the excited triplet menadione. The triplet signal of spectra B should be from the spin adduct of deuteriated SDS radical. We hereafter use the terms SDS(H) radical and SDS(D) radical for these SDS radicals from SDS(H) and SDS(D) molecules, respectively. At the residual magnetic field, the spin adduct concentration for the pure SDS(H) system was about half that for the pure SDS(D) system. On the other hand, in the mixed micellar system the concentration of the SDS(H) radical adduct was about twice that of the SDS(D) radical adduct. At 400 mT, both of the radical adducts increased greatly compared with those at the residual field. However, comparing the spectra C at the two magnetic fields, it is noticed that the increase of the SDS(H) radical adduct with the increase of the magnetic field is considerably larger than that of the SDS(D) radical adduct.

Figure 2 shows the magnetic field effect on the spin adduct yield for the photoreduction of menadione in each of the micellar solutions with pure SDS(H), pure SDS(D), and the mixed (at the ratio of 1:1) SDS. Here we define an index for the extent of the isotope effect:

$$[1] \quad \text{I.E.} = [T(\text{H})/C^0(\text{H})]/[T(\text{D})/C^0(\text{D})]$$

Where, T(H) and C^0(H) are the product yield of the SDS(H) radical adduct and the initial concentration of SDS(H), respectively. T(D) and C^0(D) are defined in the same way for the SDS(D) system. Therefore, the relation I.E. = 1.0 corresponds to the null isotope effect.

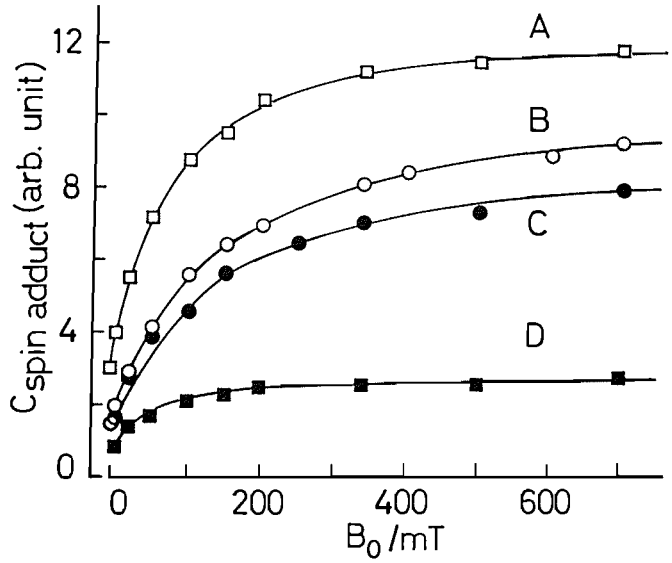

FIG. 2. Magnetic field dependences of spin adduct yields in the photoreduction of menadione in SDS micellar solutions: A, spin adduct of SDS(D) radical in an SDS(D) micellar solution; B, that of SDS(H) radical in an SDS(H) micellar solution; C and D, those of SDS(H) radical and SDS(D) radical, respectively, in the mixed (1:1) micellar solution. In the case of the pure micellar solutions, spin adduct yields were also obtained at zero magnetic field (<0.1 mT).

From the results shown in Fig. 2, we deduce the following results:

(*i*) In the pure systems, the SDS(H) system gave a much smaller spin adduct yield at all fields compared with the SDS(D) system. At higher fields, however, the I.E. value for the pure systems seems to approach unity with increasing magnetic field (0.5 at zero field to 0.78 at 700 mT).

(*ii*) In the mixed system, the spin adduct yield for the SDS(H) radical was much larger than that for the SDS(D) radical at all magnetic fields. The I.E. value increased from 2.0 (at the residual field) to 2.9 (at 700 mT) with increasing magnetic field. Even if the mole fraction of SDS(H) was decreased to half the original value, the decrease in the spin adduct yield of SDS(H) radical was only about 15% at 400 mT.

(*iii*) The magnetic field dependence (Δ spin adduct yield/ΔB_0) for the deuteriated system at higher field than 400 mT was small, in contrast to that for the non-deuteriated system.

Discussion

The reaction mechanism for the present system has been well elucidated in previous studies (10, 12, 19) and is shown below:

$$[2] \quad \text{MD} \rightarrow {}^1\text{MD}^* \rightarrow {}^3\text{MD}^*$$

$$[3] \quad {}^3\text{MD}^* + \text{SDS} \xrightarrow{k_{ABS}} {}^3(\text{MDH}\cdot\ \cdot\text{SDS})$$

$$[4] \quad {}^3(\text{MDH}\cdot\ \cdot\text{SDS}) \xrightarrow{k_{ISC}} {}^1(\text{MDH}\cdot\ \cdot\text{SDS})$$

$$\downarrow k_E \qquad\qquad \searrow k_p$$

$$[5] \quad \text{SDS}\cdot + \text{MDH}\cdot \qquad\qquad \text{singlet product}$$

$$[6] \quad \text{SDS}\cdot + \text{TNO} \xrightarrow{k_{TR}} \text{T(SDS)NO}\cdot$$

Menadione (MD) is promoted to its excited singlet state (^{1}MD*) by uv light and is transferred to its lowest triplet state (^{3}MD*; eq. [2]). ^{3}MD* abstracts a hydrogen from one of the surround-

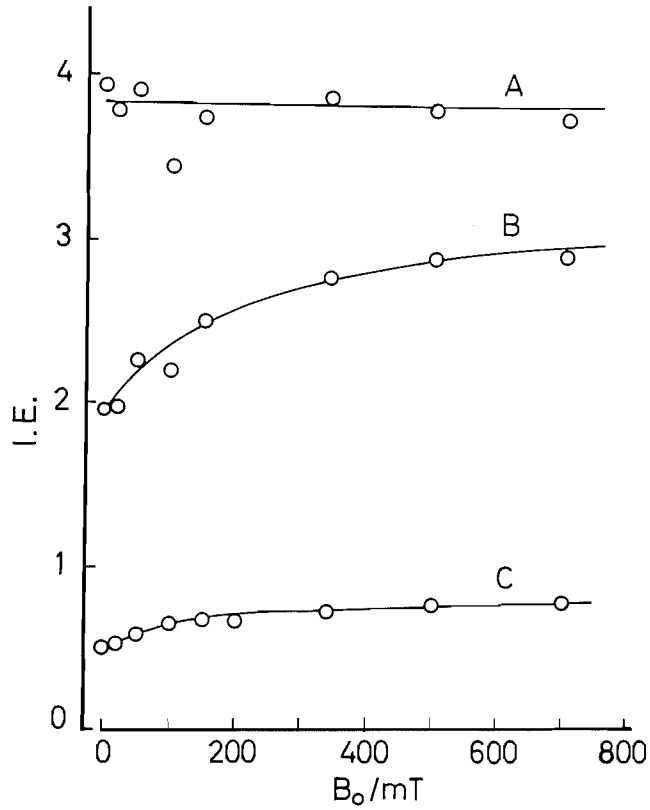

FIG. 3. Magnetic field dependence of the isotope effect (for hydrogen in the alkyl group of SDS molecule) in the photoreduction of menadione in SDS micellar solutions detected with the spin trapping technique. A: the primary isotope effect; B: the apparent isotope effect for the mixed micellar solution; C: the secondary magnetic isotope effect. I.E. is defined in eq. [1].

ing SDS molecules at the rate k_{ABS} (eq. [3]). The triplet radical pair ^{3}(MDH· ·SDS), composed of the SDS radical and the semiquinone radical from menadione, decays either to produce escaped radicals (SDS· and MDH·, eq. [4]) or to be converted to the singlet radical pair ^{1}(MDH· ·SDS), which then reacts to produce cage (singlet) products (eqs. [4], [5]). A water soluble spin trap (TNO), DMNS in the present case, may trap an escaped SDS radical outside the micelle (9) and a stable spin adduct (T(SDS)NO·), which can be detected by the esr technique, is formed (eq. [6]). (The semiquinone radical is not very reactive to the spin trap under the present experimental conditions.) The rate of interconversion between the two states of the radical pair (eq. [4]) is modified by the external magnetic field, which therefore modifies the yield of reaction product.

There are several possible stages in the reaction path from which the deuterium isotope effects originate: 1. hydrogen abstraction stage [k_{ABS}, eq. [3]]; 2. intersystem crossing process of the radical pair [k_{ISC}, eq. [4]]; 3. collapse of the radical pair [k_E, eq. [5]]; and 4. cage product formation [k_P, eq. [5]]. As is evidenced by the small exchange interaction (13), the magnetic interaction between the members of the radical pair is very small in the micelle. Besides, although a very small isotope effect for the solubility of SDS radical in the micelle may be expected, the isotope effects shown in Fig. 3 are far above the expected effect due to the solubility difference. Thus, an observable isotope effect is not expected for the escaping stage of the SDS radical. As for the cage product formation stage, since no deuterium nuclei exist at the reaction center, which consists of the oxygen nucleus of the semiquinone radical and the carbon nucleus of the SDS alkyl radical in our case, only a small β-deuterium secondary isotope effect may be expected. Moreover, it is usually assumed that k_P is much larger than k_{ISC}, as has been confirmed by the computer simulation of the product yield detected esr (PY-ESR) spectrum of this system in the previous study (11). Therefore, this stage should also not be the origin of our isotope effects. Consequently, we conclude that the isotope effects observed in this study come from the first two stages, the hydrogen abstraction stage and the intersystem crossing stage.

The most interesting fact found in the present study is the reversal of direction of the isotope effect when the reaction proceeds in pure micellar solutions instead of the mixed micellar solution. This can be explained, assuming that the two isotope effects mentioned above coexist and work in the opposite direction to each other in the spin adduct yield.

The product of the rate constant of the hydrogen abstraction (10^6–10^9 M^{-1} s^{-1}) (20) by the local concentration of SDS (>1 M) exceeds by far the spontaneous decay rate of the triplet menadione (~10^4 s^{-1}) (ref. 18, Chap. 9). Therefore, even if there is an isotope effect in the rate constant of the hydrogen abstraction, each photo-excited quinone may abstract just one hydrogen atom from an SDS molecule within its lifetime. Thus, in the pure micellar solutions, the final yields of the spin adducts are determined in the stages after the hydrogen abstraction, i.e., the intersystem crossing process of the radical pair.

On the other hand, in the mixed micellar solution those two isotope effects mentioned above must coexist, because the excited quinone may preferably abstract hydrogen from SDS(H) instead of deuteron from SDS(D). By analyzing the difference between the yields of the spin adducts in the pure micellar solutions and that in the mixed micellar solution, we can obtain the isotope effect that occurred in the hydrogen abstraction stage. We call this isotope effect the primary isotope effect, and the other the secondary magnetic isotope effect. Using the simple reaction scheme shown in eqs. [2]–[6], we obtain the following representations for I.E. (see eq. [1]) values:

$$[7]\quad \text{I.E.(primary)} = k_{ABS}(H)/k_{ABS}(D)$$

for the primary isotope effect, and

$$[8]\quad \text{I.E.(magnetic)} = [k_E(H) + k_{ISC}(H)]/[k_E(D) + k_{ISC}(D)]$$

for the secondary magnetic isotope effect.

Figure 3 shows the isotope effects in this system, which are calculated based on the fact that the primary isotope effect and the secondary magnetic isotope effect are independent of each other. As mentioned above, the secondary magnetic isotope effect (curve C) can be calculated from the yields in the pure micellar solutions (Fig. 2, open circles and open squares) with eq. [1]. Curve B represents the apparent isotope effect in the mixed micellar solution. The primary isotope effect (curve A) can be obtained as the ratios between the latter values (on curve C) and the former values (on curve B). Curve A shows that the primary isotope effect is independent of the magnetic field, as was a priori postulated. The difference in the zero point stretching energy between the C—H bond and the C—D bond is around 1100 cal/mol (5). Therefore the maximum isotope effect at 25°C is calculated as 6.4, assuming a loose potential along the reaction coordinate around the activated complex and a negligible tunneling effect (2). This value is not far from the experimental value.

The increase of the secondary magnetic isotope effect with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

increase of the magnetic field in the pure system is due to the steady increase in the spin adduct yield of the SDS(H) radical at high fields, which is far beyond the hyperfine field. Since only S_0–T_0 mixing in the radical pair is allowed at these fields, this steady increase in the spin adduct yield should be due to the magnetic relaxation between $T_{\pm 1}$ and T_0 or S_0 (21, 22). Here, S_n and T_n represent the singlet and the triplet states (with magnetic quantum number n) of the radical pair, respectively. Because the hyperfine interactions in the SDS(D) radical are about 1/6.5 of those in the SDS(H) radical, the relaxation rate of the electron spin in the SDS(D) radical is much smaller than that in the SDS(H) radical. This fact accords with the smaller increase in the spin adduct yield of the SDS(D) system at high field over 300 mT. Although the relaxation mechanism for the magnetic field effect on chemical reactions has been proposed (22), especially for these micellar systems (23), only limited supporting evidence has been given so far. Our observation, that there is a larger magnetic field dependence in spin adduct yield for the SDS(H) system than for the SDS(D) system at high fields (e.g., >300 mT), is clear evidence for the relaxation mechanism.

The magnetic field dependence in spin adduct yield for the corresponding pure micellar solution was the same as that for the mixed micellar solution (e.g., closed circles vs. open circles in Fig. 2). Therefore, the two isotope effects, the primary and the secondary magnetic, should be independent. This fact indicates that little radical center migration among the SDS molecules (half of them are deuteriated) occurs during the period of intersystem crossing in the radical pair, because radical center migration between SDS(D) radical and SDS(H) molecule, and vice versa, interferes with the intersystem crossing process and this interference would have made the magnetic field dependences of the two spin adduct yields similar to each other.

Conclusion

Two independent isotope effects in the photoreduction of menadione in deuterium labeled SDS micellar solutions were obtained using the spin trapping technique. Those isotope effects are attributed to the stages of hydrogen abstraction of triplet menadione from the SDS molecule and intersystem crossing in the transient radical pair.

The primary isotope effect was independent of the magnetic field but the secondary magnetic isotope effect was very much dependent on the magnetic field. This latter magnetic field dependence was attributed to the difference in magnetic interactions in the radical pairs.

It is suggested that it is very important to pay attention to the secondary magnetic isotope effect, which was about 0.5 at zero field in the present system, in the analysis of isotope effects in reactions, such as hydrogen abstraction.

Acknowledgments

The gift of DMNS from Drs. S. Sakata and R. Konaka of Shionogi Research Laboratory, Shionogi Pharmaceuticals, is gratefully acknowledged. Sincere thanks should also go to Drs. K. Iseda and S. Fujii of our institute for the measurements of mass spectra of deuteriated SDS.

Synthesis and structural characterization of *N,N'*-diarylpiperazine *N,N'*-dioxide tetrahydrates (aryl = *o*-tolyl, *p*-tolyl, *p*-chlorophenyl)

CHUN-KIU KWOK AND THOMAS C. W. MAK[1]

Department of Chemistry, The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong

Received September 29, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

CHUN-KIU KWOK and THOMAS C. W. MAK. Can. J. Chem. **66**, 1836 (1988).

The synthesis and X-ray structure determination of *N,N'*-di(*o*-tolyl)piperazine *N,N'*-dioxide tetrahydrate, **I**, *N,N'*-di(*p*-tolyl)piperazine *N,N'*-dioxide tetrahydrate, **II**, and *N,N'*-di(*p*-chlorophenyl)piperazine *N,N'*-dioxide tetrahydrate, **III**, are described. Compound **I** crystallizes in space group $P\bar{1}$ with $a = 7.778(1)$, $b = 7.915(2)$, $c = 8.919(2)$ Å, $\alpha = 106.25(2)$, $\beta = 99.56(1)$, $\gamma = 108.80(2)°$, and $Z = 1$. Compound **II** crystallizes in space group $P\bar{1}$ with $a = 6.558(1)$, $b = 7.134(2)$, $c = 11.610(3)$ Å; $\alpha = 73.23(2)$, $\beta = 78.08(2)$, $\gamma = 72.67(2)°$, and $Z = 1$. Compound **III** crystallizes in space group $P2_1/c$ with $a = 9.159(3)$, $b = 12.390(4)$, $c = 8.339(4)$ Å, $\beta = 97.38(3)°$, and $Z = 2$. The structures of **I–III** were solved by the direct method and refined to $R = 0.049$ (1749 observed Mo$K\alpha$ reflections), 0.055 (2651 observed reflections), and 0.035 (1827 observed reflections), respectively. In each case, the *N,N'*-dioxide molecule occupies a site of symmetry $\bar{1}$. The piperazine ring takes the chair form, with two N—O bonds oriented axially in a *trans* configuration. The structures are characterized by strong hydrogen bonding between the water molecules, as well as between the *N*-oxide groups and water molecules, giving rise to puckered layers composed of various combinations of edge-sharing four-membered, six-membered, ten-membered, and twelve-membered rings. The aryl rings, which protrude on both sides of each puckered layer, constitute hydrophobic regions separating the hydrophilic layers in the crystal packing.

CHUN-KIU KWOK and THOMAS C. W. MAK. Can. J. Chem. **66**, 1836 (1988).

On décrit la synthèse et la détermination de la structure, à l'aide de la diffraction aux rayons-X, des tétrahydrates des *N,N'*-dioxydes des *N,N'*-di(*o*-tolyl) pipérazine (**I**), des *N,N'*-di(*p*-tolyl) pipérazine (**II**) et des *N,N'*-di(*p*-chlorophenyl) pipérazine (**III**). Le composé **I** cristallise dans le groupe d'espace $P\bar{1}$, avec $a = 7{,}778(1)$, $b = 7{,}915(2)$ et $c = 8{,}919(2)$ Å, $\alpha = 106{,}25(2)$, $\beta = 99{,}56(1)$ et $\gamma = 108{,}80(2)°$ et $Z = 1$. Le composé **II** cristallise dans le groupe d'espace $P\bar{1}$, avec $a = 6{,}558(1)$, $b = 7{,}134(2)$ et $c = 11{,}610(3)$ Å, $\alpha = 73{,}23(2)$, $\beta = 78{,}08(2)$ et $\gamma = 72{,}67(2)°$ et $Z = 1$. Le composé **III** cristallise dans le groupe d'espace $P2_1/c$, avec $a = 9{,}159(3)$, $b = 12{,}390(4)$ et $c = 8{,}339(4)$ A, $\beta = 97{,}38(3)°$ et $Z = 2$. Les structures des composés **I**, **II** et **III** ont été résolues par la méthode directe et on les a affinées jusqu'à des valeurs respectives de $R = 0{,}049$ (pour 1749 réflexions du MoKα qui ont été observées), 0,055 (2651 réflexions observées) et 0,035 (pour 1827 réflexions observées). Dans chacun des cas, la molécule de *N,N'*-dioxyde occupe un site de symétrie $\bar{1}$. Le noyau pipérazine se trouve dans une conformation chaise; deux des liaisons N—O sont orientées d'une façon axiale, dans une configuration *trans*. Les structures sont caractérisées par de fortes liaisons hydrogènes entre les molécules d'eau ainsi qu'entre les groupements *N*-oxydes et les molécules d'eau; ces interactions donnent lieu à la formation de couches plissées composées de diverses combinaisons de cycles à quatre, à six, à dix et à douze chaînons qui se partagent des arêtes. Les noyaux aryles, qui font saillie sur les deux côtés de chacune des couches, forment des régions hydrophobes qui séparent les couches hydrophiles de l'entassement du cristal.

[Traduit par la revue]

Introduction

Many aspects of the chemistry of amine *N*-oxides, such as their synthetic chemistry, spectroscopic properties, and chemical reactivities have been subjected to numerous studies (1–3). In many instances (4–6), amine *N*-oxides crystallized from aqueous alcoholic solutions or water are in the form of hydrates. However, a systematic structural study of this class of hydrated compounds has rarely been attempted. A research program on the structural chemistry of polycyclic tertiary amine *N*-oxides has been pursued in our laboratory. A series of preparative and X-ray crystallographic studies on the adducts of hexamethylenetetramine *N*-oxide (HMTO) have shown that all these structures involve hydrogen bonding between the terminal O atom of the N → O dative bond and the proton donor molecule(s) (7–10). We now report the synthesis and structural characterization of a series of heterocyclic tertiary amine *N,N'*-dioxide hydrates, namely *N,N'*-di(*o*-tolyl)piperazine *N,N'*-dioxide tetrahydrate, **I**, *N,N'*-di(*p*-tolyl)piperazine *N,N'*-dioxide tetrahydrate, **II**, and *N,N'*-di(*p*-chlorophenyl)piperazine *N,N'*-dioxide tetrahydrate, **III**. These structures are to be compared to the three-dimensional networks found in the related hydrate inclusion compounds *N,N'*-diphenylpiperazine *N,N'*-dioxide octahydrate, **IV** (11), and *N,N'*-dicyclohexylpiperazine *N,N'*-dioxide octahydrate, **V** (12), which have been established recently via X-ray crystallography.

Experimental

All reagents or solvents used are general purpose grade. Proton nmr spectra were recorded on a Bruker Cryospec WM250 (250 MHz) spectrometer. Deuterated methanol was used as solvent and δ (ppm) was measured with TMS as an internal standard. Mass spectra were recorded on a VG Micromass 7070F spectrometer. Solid-state ir spectra were recorded on a Beckman AccuLab 1 spectrometer, and KBr discs were prepared according to the standard procedure (13).

Synthetic procedures

(a) N,N'-*Diarylpiperazine*

The heterocyclic amines were prepared according to the procedure of Morera (14). Heating a mixture of arylamine and dibromoethane (1.35:1 in mole ratio) at 130–140°C for several hours gave the corresponding *N,N'*-diarylpiperazine (*N,N'*-di(*o*-tolyl)piperazine, 4 h; *N,N'*-di(*p*-tolyl)piperazine, 5 h; *N,N'*-di(*p*-chlorophenyl)piperazine, 3 h). The *N,N'*-diarylpiperazines were liberated by the addition of an excess amount of 10% NaOH and purified by recrystallization in xylene. The individual yields are 13.0, 33.7, and 42.0%, respectively.

(b) N,N′-*Diarylpiperazine* N,N′-*dioxide tetrahydrate*

The oxidation of each *N,N′*-diarylpiperazine to the corresponding *N,N′*-dioxide was effected by the procedure of Bennett and Glynn (15). *N,N′*-Diarylpiperazine (4.0 g) was dissolved in a mixture of glacial acetic acid and 30% hydrogen peroxide. The mole ratio of *N,N′*-diarylpiperazine:acetic acid:hydrogen peroxide was 1:24.0:12.6. The mixture was kept at 50–70°C for about 16 h. The excess hydrogen peroxide was removed by the addition of an equal volume of acetic acid to the reaction mixture, which was then evaporated to dryness at ~60°C under reduced pressure. The above process was repeated three times. Trace amounts of acetic acid remaining in the "residue" were removed by placing it in a desiccator charged with sodium hydroxide pellets for several days. The "residue" was dissolved in water, and after several further recrystallizations at ~60°C, *N,N′*-diarylpiperazine *N,N′*-dioxide tetrahydrate was obtained as well-formed crystals. In the case of **I**, crystals of good quality were obtained from the evaporation of an aqueous solution in a desiccator containing silica gel placed in a refrigerator.

X-ray crystallographic analysis

Densities were measured by flotation in *n*-hexane/carbon tetrachloride. All three compounds were handled in the same manner. A single crystal was cut to a suitable size and attached directly to a glass fiber with epoxy glue. Determination of the crystal class and orientation matrix on a Nicolet R3m diffractometer using Mo$K\alpha$ radiation was performed according to established procedures (16). Accurate unit-cell dimensions were derived from a least-squares fit of the refined angular settings of 21 high-angle reflections. Intensity data were collected at 22°C following established procedures in

our laboratory (17–18). The crystal remained stable throughout the diffraction experiment as two standard reflections monitored every 125 data measurements showed only random fluctuations within ±1% of their mean values. The raw intensities were processed with the learnt-profile procedure (19), and application of absorption corrections were based on a pseudo-ellipsoidal fit to azimuthal scans of selected strong reflections over a range of 2θ values. The statistical distribution of the normalized structure factors was consistent with that expected for a centrosymmetric space group. The crystal data are summarized in Table 3.

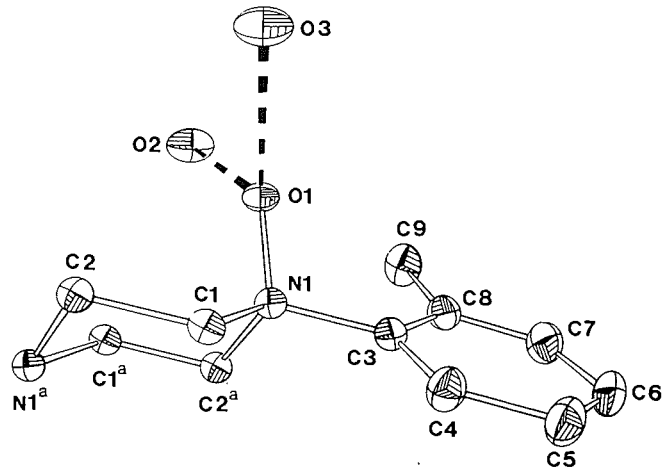

FIG. 1. Numbering of atoms in the asymmetric unit of **I**. The thermal ellipsoids are drawn at the 25% probability level.

Structure solutions were achieved by direct phase determination guided by negative quartets (20). All non-hydrogen atoms were varied anisotropically in structure refinement. The aromatic, methylene, and methyl H atoms were generated geometrically (C—H bond length fixed at 0.96 Å) and assigned isotropic thermal parameters. Water H atoms, some of which exhibited two-fold disorder (only in compound **I**), were located from successive difference Fourier maps; they were assigned isotropic temperature factors and held stationary in subsequent least-squares cycles. Computations were performed on a Data General Corporation Nova 3/12 minicomputer using the SHELXTL program package (21). Analytic expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were

incorporated (22). Blocked-cascade least-squares refinement (23) converged to the *R* indices listed in Table 3. Numbering of the atoms in the asymmetric unit of **I** is shown in Fig. 1, **II** in Fig. 5, and **III** in Fig. 9, respectively. The refined atomic parameters of **I**–**III** are given in Tables 4–6, respectively.

Results and discussion

Although some of the *N,N'*-diarylpiperazines have been characterized previously by their nmr and mass spectra (24–26), a thorough investigation of the spectral properties of their corresponding hydrated *N,N'*-dioxides has not been available. The assignment of the ir spectra shown in Table 1 was done with reference to that of piperazine (27, 28) and the scheme proposed in the literature (29, 30). The assignment of the nmr spectra is

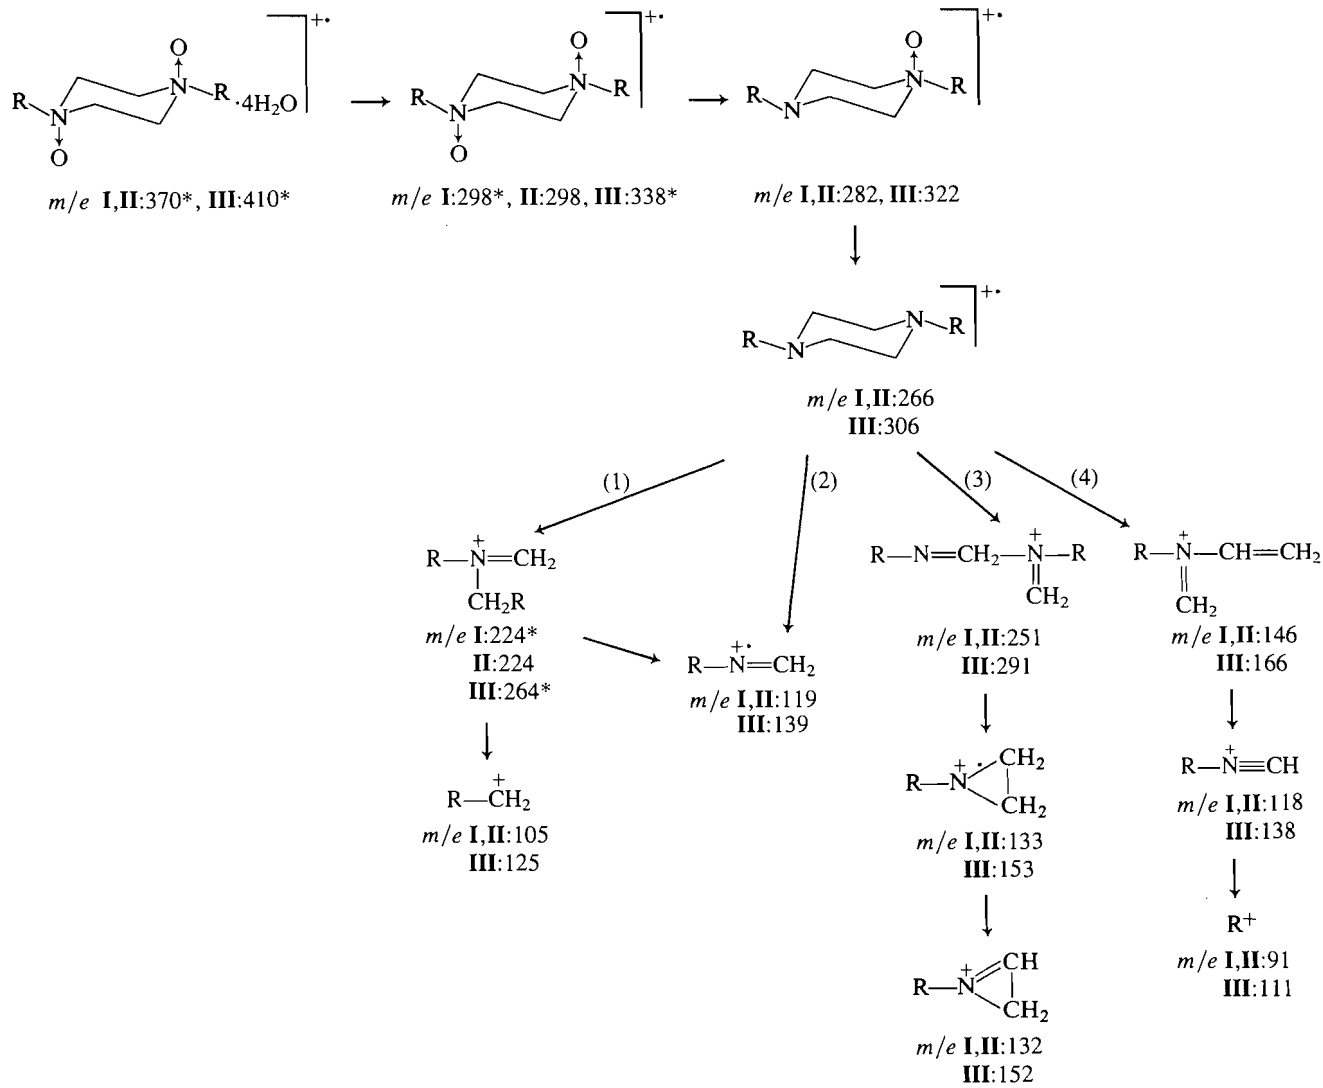
shown in Table 2; crystal data of the compounds are shown in Table 3.

An interesting difference between the nmr spectra of the *N,N'*-dioxides and their parent piperazines is the splitting of the peaks of the heterocyclic ring protons. A previous nmr study of *N,N'*-diphenylpiperazine has shown that ring inversion is so rapid that resolution of the peaks of equatorial and axial protons is impossible even at −100°C (25). An AA'BB' or AA'XX' pattern is expected to be observed in the nmr spectra of *N,N'*-disubstituted piperazines when the ring proton interconversion has been "frozen out" (25, 31*a*). In fact, from the 250 MHz spectra recorded here, it is seen that the protons of the piperazine rings in all three *N,N'*-dioxides showed "two doublets". An "AX pattern" rather than a AA'BB' or AA'XX' pattern was observed. In fact, a well-defined AA'BB' or AA'XX' pattern was not observed even at −100°C in piperazine (25). A somewhat similar "two doublets" pattern has been reported in a synthesized spectrum of the ring protons of piperazine at −100°C in ethanol–methylene chloride using $\nu_0\delta_{ae}$ = 9.6 Hz taken from the 100 MHz results (25).

A common feature of the ir spectra of the hydrated *N,N'*-diarylpiperazine *N,N'*-dioxides is the presence of strong and broad peaks of antisymmetric and symmetric O—H stretching in the 3600–3000 cm^{-1} range. The aromatic C—H stretching peak is masked by these O—H stretching frequencies and therefore not observable. The N—O stretching mode generally occurs as a strong peak in the region of 970–950 cm^{-1} for aliphatic amine *N*-oxide (31*b*). Hence a common strong peak at 980 cm^{-1} in the ir spectra of **II** and **III**, and at 968 cm^{-1} in **I**, may be attributed to N—O stretching. A slight shift in the frequency of the vibration mode in **I** may be due to steric interaction between the *o*-methyl and *N*-oxide groups.

The major fragmentation paths for the parent piperazines of **II** and **III** have been proposed (26). Similar major fragmentation paths for the hydrated *N,N'*-diarylpiperazine *N,N'*-dioxide is proposed in Scheme 1. Peaks corresponding to radical ions of the monoxides of **I**–**III** and the dioxide of **II** can be observed. After the two N—O bonds in each *N,N'*-dioxide molecule have



*Unobservable

SCHEME 1

been cleaved in the early stages, the subsequent fragmentation process is expected to be the same as that of the corresponding piperazine.

Description of the structures

In the crystal structures of **I–III**, the *N,N'*-dioxide molecule of each compound occupies a site of symmetry $\bar{1}$, with two N—O bonds oriented axially in a *trans* configuration; measured bond distances and angles are given in Tables 7–9. The measured N—O bond lengths of **I–III** and some related amine *N*-oxide derivatives are tabulated in Table 10. According to these data, the N—O bond length in **II** and **III** are nearly identical within the limits of experimental error, and are also in good agreement with the corresponding values in trimethylamine oxide dihydrate (1.398(1) Å) (33) and in the 1:3 molecular complex of triethylenediamine *N,N'*-dioxide with water (1.395(8) Å) (37). The apparent deviation of the N—O bond length of **I** (1.402(2) Å) from the norm may be due to steric repulsion between the *o*-methyl group and the N—O bond.

The phenyl rings are nearly coplanar with the two N—O bonds in **II** and **III**, but not in **I**, as shown by the torsion angles in Table 11. In fact, the *o*-methyl group in **I** is nearly "midway" between the N(1)—O(1) and N(1)—C(1) bonds. The relative orientation of the phenyl rings with respect to the N—O bonds in **I** is a consequence of steric repulsion between the *o*-methyl groups and the piperazine ring and/or the neighbouring N—O bonds.

The crystal structure of the hydrated *N,N'*-dioxide studied here are characterized by strong hydrogen bonding between the water molecules, as well as between the *N*-oxide groups and water molecules, giving rise to puckered layers composed of various combinations of edge-sharing four-membered, six-membered, ten-membered, and twelve-membered rings. The oxygen atom in each *N*-oxide group in **I–III** forms only two acceptor hydrogen bonds with two neighbouring water molecules. In contrast to this, the oxygen atom forms three acceptor hydrogen bonds with neighbouring donor molecules in some *N*-oxide adducts, e.g. $O \leftarrow N(CH_2CH_2)_3N \rightarrow O.3H_2O$ (37), $(CH_2)_6N_4O.(NH_2)_2CS$ (9), and $(CH_2)_6N_4O.H_2O_2.H_2O$ (8). The hydrogen bonding features of hydrated *N,N'*-dioxides **I–III** are described in the following sections.

(a) N,N'-*Di*(o-*tolyl*)*piperazine* N,N'-*dioxide tetrahydrate*, ***I***

In the crystal structure of **I**, the water molecules and oxygen atoms of the *N*-oxide groups are interconnected to generate a

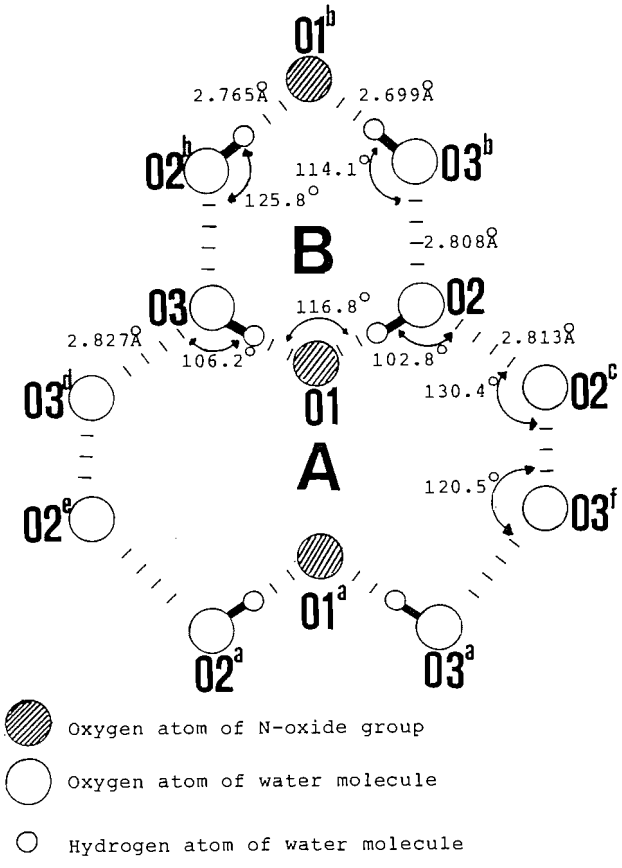

FIG. 4. Geometry of the six-membered and ten-membered hydrogen-bonded rings of a puckered layer in **I**. Symmetry transformations are as given in Table 7.

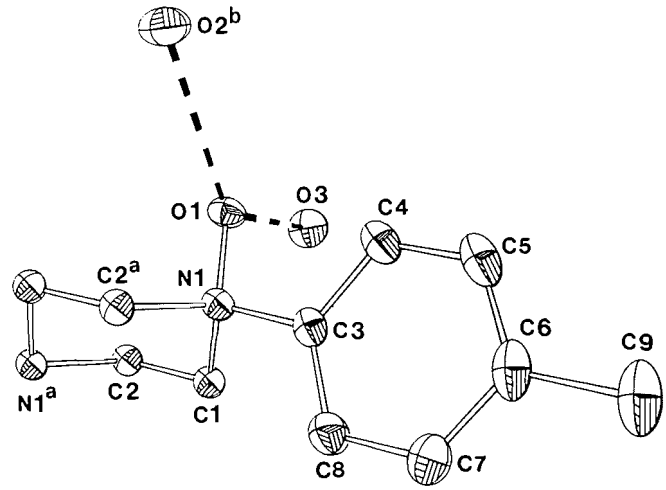

FIG. 5. Numbering of atoms in the asymmetric unit of **II**. The thermal ellipsoids are drawn at the 25% probability level.

puckered layer parallel to the *ab* plane (Fig. 2). There is no cross-linking between two adjacent puckered layers (Fig. 3). The *N*,*N*′-dioxide molecule is surrounded by a ten-membered hydrogen-bonded ring (type *A*, Fig. 4) of oxygen atoms, including those of its two *N*-oxide groups. The aromatic rings thus point in opposite directions above and below the mean plane of ring *A*. Edge-sharing of such ten-membered rings in a puckered layer generates other six-membered hydrogen-bonded rings (type *B*, Fig. 4). The water protons which are not involved in hydrogen bonding with the *N*-oxide groups are two-fold disordered.

(b) N,N′-*Di*(p-*tolyl*)*piperazine* N,N′-*dioxide tetrahydrate,* ***II***

In the crystal structure of **II**, a ribbon-like arrangement of centrosymmetric four- and six-membered hydrogen-bonded rings extends parallel to the *b* axis (Fig. 6). A similar ribbon-like arrangement has been observed in the crystal structure of bis(tetrahydropicolinato)copper(II) octahydrate (40). The six-membered, chair-like ring is formed by four water molecules and the *N*-oxide groups of two adjacent *N*,*N*′-dioxide molecules. The four-membered ring is formed by linking the edges of two adjacent six-membered rings. Adjacent ribbons are cross-linked by the *N*,*N*′-di(*p*-tolyl)piperazine moieties lying between them, thereby giving rise to a composite layer parallel to the *ab* plane. In the resulting crystal structure, only van der Waals interaction exists between neighboring composite layers (Fig. 7). All water protons in **II** are completely ordered: each water molecule forms an acceptor hydrogen bond with an

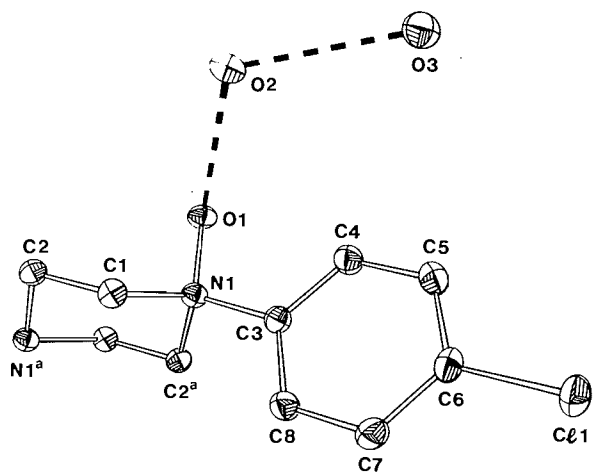

FIG. 9. Numbering of atoms in the asymmetric unit of **III**. The thermal ellipsoids are drawn at the 25% probability level.

adjacent water molecule and two donor hydrogen bonds with a second water molecule and a *N*-oxide group. Within each hydrogen-bonded four-membered ring, the protons are therefore arranged in a cyclic manner (Fig. 8).

(c) N,N'-*Di*(p-*chlorophenyl)piperazine* N,N'-*dioxide tetrahydrate,* ***III***

The crystal structure of **III** is also characterized by a network of hydrogen bonds in the pattern of a puckered layer. Four water molecules form a centrosymmetric four-membered hydrogen-bonded ring. The *N,N'*-dioxide molecule in the center of unit cell is surrounded by a twelve-membered, fourteen-atom hydrogen-bonded ring incorporating a couple of four-membered rings (Figs. 10 and 11). The *N,N'*-di(*p*-chlorophenyl)piperazine moiety constitutes a bridge between O(1) and O(1)[a]. Edge-sharing of these fourteen-atom hydrogen bonded rings generates a puckered layer parallel to the *bc* plane (Fig. 10). No cross-linking occurs between any pair of adjacent puckered layers. The hydrogen atoms of all the water molecules, just like those in **II**, are completely ordered. Unlike the case in **II**, the

water molecule O(2) (Fig. 12) forms only donor hydrogen bonds to two adjacent *N*-oxide groups and acceptor hydrogen bonds to a pair of neighboring water molecules which are members of the same four-membered ring. The water molecule O(3) is not involved in acceptor hydrogen bonding, so that O(2) and O(3) are four- and two-coordinated, respectively (Fig. 12).

(d) Effect of substitution in the phenyl ring

According to the results tabulated in Table 11, it readily follows that the more symmetric the *N*-substituted group, the higher the symmetry of the site which is occupied by the *N,N'*-dioxide molecule. Substitution in the phenyl ring has the effect of decreasing the hydration number (the number of water

Molecular motion in the crystalline donor–acceptor complex trimethylamine–trifluoroborane as studied by proton and fluorine magnetic resonance

YUKIKO N. CHIHARA, NOBUO NAKAMURA, AND HIDEAKI CHIHARA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, 560, Japan

Received November 13, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

YUKIKO N. CHIHARA, NOBUO NAKAMURA, and HIDEAKI CHIHARA. Can. J. Chem. **66**, 1848 (1988).

The proton and fluorine second moments and the spin-lattice relaxation times T_1 (at 25.75 MHz) were measured in the solid complex trimethylamine–trifluoroborane from 53 to 300 K. There is a cross-relaxation effect between ^1H and ^{19}F below 120 K. Their T_1 minima near 140 K led to activation energies of 10.6 and 11.1 kJ mol^{-1} for the reorientation of the methyl and the trifluoride groups, respectively. An additional minimum observed in the T_1 of protons at about 240 K was attributed to the reorientation of the trimethylamine group about the N—B bond with an activation energy of 25.0 kJ mol^{-1}. A comparison of these potential parameters with those in other trimethylamine complexes led to a notion that the activation energies for the reorientation of the $(CH_3)_3N$ group in the trimethylamine–trifluoroborane complex are mainly governed by the intramolecular steric effect.

YUKIKO N. CHIHARA, NOBUO NAKAMURA et HIDEAKI CHIHARA. Can. J. Chem. **66**, 1848 (1988).

Opérant à des températures allant de 53 à 300 K, on a mesuré les moments secondaires ainsi que les temps de relaxation spin-réseau, T_1, à 25,75 MHz, du complexe solide triméthylamine/trifluoroborane. À des températures inférieures à 120 K, il existe un effet de relaxation croisée entre le ^1H et le ^{19}F. Près de 140 K, leurs T_1 minima conduisent à des énergies d'activation respectives de 10,6 et 11,1 kJ mol^{-1} pour les réorientations des groupements méthyle et trifluorure. Dans le T_1 du proton, on a observé un autre minimum autour de 240 K; on l'a attribué à une réorientation du groupement triméthylamine autour de la liaison N—B; son énergie d'activation serait de 25,0 kJ mol^{-1}. Lorsqu'on compare les paramètres de ces potentiels avec ceux observés dans d'autres complexes de la triméthylamine, on en déduit que les énergies d'activation pour la réorientation du groupement $(CH_3)_3N$ du complexe triméthylamine–trifluoroborane sont principalement déterminées par l'effet stérique intramoléculaire.

[Traduit par la revue]

Trimethylamine (TMA) forms donor–acceptor complex compounds with a variety of electron accepting materials (1). Some of these complexes have threefold symmetry and different types of intramolecular degrees of freedom. Moreover, some undergo a phase transition or transitions in their crystalline state (2–4) but the nature of the phase transitions has not yet been clarified. To understand the mechanism of phase transition(s) as well as the intricate inter- or intramolecular interactions in the crystals of these molecular complexes, studies are necessary both of the dynamical properties of molecules and of the crystal lattices in relation to detailed structural studies.

The 1:1 complex compound between TMA and trifluoroborane (TFB) is a typical example of such a complex. It has a molecular threefold symmetry axis and three intramolecular rotational degrees of freedom, and can undergo two different rotations as a whole, i.e., the rotations about the molecular symmetry axis and about the two short axes. The molecule has a large dipole moment (5.76 D) (5) and the crystal belongs to a rhombohedral space group with three TMB·TFB complexes per unit cell (6). This compound does not undergo any phase transition between 77 K and its melting point and therefore is a good specimen for examining molecular motion in detail without interruption by the discontinuities of a phase transition.

This paper presents the results of proton and fluorine nuclear magnetic resonance and relaxation measurements below room temperature. The molecular modes are assigned and the cross-relaxation effect between the proton and fluorine is discussed. The origin of the activation processes and the possible mechanism of phase transitions in trimethylamine complexes will be considered.

Experimental

TMA–TFB was synthesized according to a method reported in the literature (7); a saturated aqueous solution of KOH was added to trimethylamine hydrochloride from a commercial source and gaseous TMA thus generated was introduced into an ether solution of vacuum-distilled BF_3·OEt. The $(CH_3)_3N·BF_3$ precipitate was recrystallized from a dry benzene solution and purified by vacuum sublimation, twice, at 60–70°C: mp 420 K (literature (5) mp 419–419.5 K). *Anal.* calcd.: C 28.39, H 7.15, N 11.04%; found: C 28.43, H 7.38, N 10.69%. No phase transition was detected by differential thermal analysis between 77 K and the melting point.

The linewidths and the second moments of ^1H and ^{19}F resonances for a powdered specimen were measured by a Robinson-type spectrometer at 11.25 MHz from 53 K to room temperature. The spin-lattice relaxation times T_1 were measured at 25.75 MHz between 77 and 330 K by 180°–90° pulse sequences with a home-built pulsed spectrometer. The details of the apparatus have been described elsewhere (8). The temperature was measured by Chromel-P–Constantan thermocouples with an accuracy of ±0.5 K.

Results and discussion

Second moment

Previous measurements of the linewidths and the second moments of both ^1H and ^{19}F down to 68 K did not reach the rigid-lattice values (9, 10). We therefore extended the temperature region of the continuous-wave experiments down to 53 K. The results indicate that the second moment of ^1H reaches an almost flat plateau below 60 K at (31 ± 1) G^2. On the other hand, the second moment of ^{19}F increases sharply from (7.3 ± 0.2) G^2 at 85 K to (19 ± 1) G^2 at 60 K. Our second moment values of both ^1H and ^{19}F agree with the previous results (9, 10) above 85 K.

A rigorous calculation of the second moments was performed by Yim and Gilson (9) on the basis of various models for the molecular rotational states. Our model calculation using the structural data (6) with the assumption that the methyl groups in TMA assume a tetrahedral bond arrangement with a C—H bond length, 0.109 nm, leads to results consistent with those of ref. 9

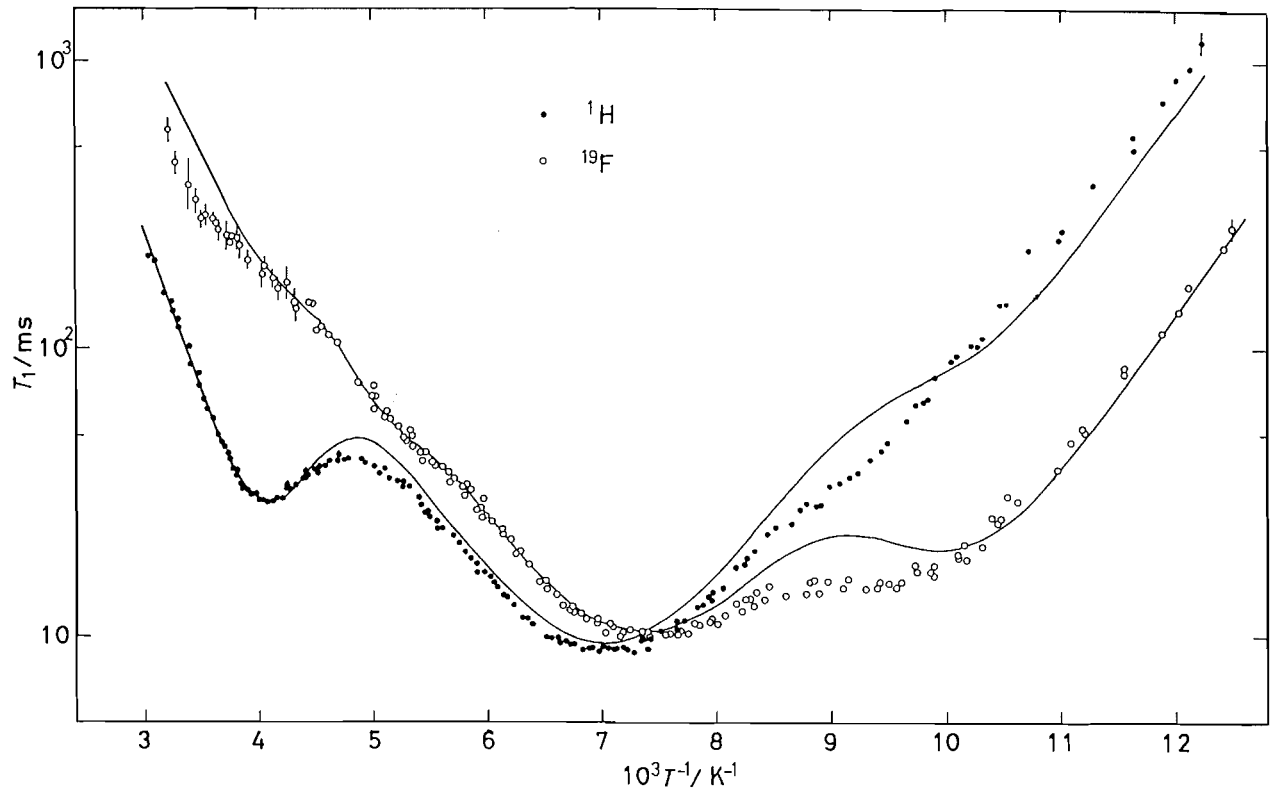

FIG. 1. The spin-lattice relaxation times for ^{1}H(●) and ^{19}F(○) at 25.75 MHz; the estimated experimental errors are shown by vertical lines. Calculated relaxation times are given by solid lines (see in text).

except for the rigid lattice value of the ^{19}F second moment: our value was 20.0 G^2 whereas that of ref. 9 is 25.9 G^2; the latter seems to be too large. Although some discrepancy can be recognized between our calculated second moment values and those in ref. 9, our analysis of the experimental second moments led to the same assignment of the molecular motion as given in ref. 9: i.e., the large change in the second moments of both ^{1}H and ^{19}F below about 90 K is caused by the simultaneous excitation of the reorientation or rotation of the methyl groups about the C—N bonds (C_3 rotation) and the reorientation of the BF_3 group about the N—B bond (C_F rotation), and another change of the proton second moment between 100 and 150 K is brought about by the reorientation of the TMA group about the N—B bond (C_3' rotation) in addition to C_3 and C_F rotations. The overall molecular tumbling is not seen even above 300 K.

Temperature dependence of T_1

To determine the activation parameters for each of the above-mentioned internal rotational modes, we measured the spin-lattice relaxation times T_1 of both ^{1}H and ^{19}F between 77 K and room temperature. The results are shown in Fig. 1. The experimental errors in T_1 are depicted by vertical bars. The recovery of the magnetization was nearly exponential for both nuclei over the whole temperature range of the measurements.

The T_1 of ^{19}F decreases almost linearly on heating from 77 K, with a flat part between about 110 K and 120 K, reaches a broad minimum of 10 ms at about 130 K, and then turns to increase.

The T_1 curve of ^{1}H is more complex: it shows only a slight change in curvature between 110 and 120 K, and has a major, broad minimum (8.8 ms) at 140 K. There is another minimum at about 240 K, the value of which is 30 ms.

Analysis of T_1 *data in terms of motional model*

We now attempt to rationalize the measured temperature dependences of proton and fluorine T_1 in the light of the general understanding of the molecular motion outlined above. The proton and fluorine relaxation rates $(T_1^H)^{-1}$ and $(T_1^F)^{-1}$ are expressed, respectively, by

$$[1]\quad (T_1^H)^{-1} = (T_1^{HH})^{-1}_{\text{intra Me}} + (T_1^{HH})^{-1}_{\text{inter Me}} + (T_1^{HH})^{-1}_{\text{intermol}} + (T_1^{HF})^{-1} + (T_1^{HB})^{-1}$$

$$[2]\quad (T_1^F)^{-1} = (T_1^{FF})^{-1}_{\text{intra BF}_3} + (T_1^{FF})_{\text{inter}} + (T_1^{FH})^{-1} + (T_1^{FB})^{-1}$$

where $(T_1^{HH})^{-1}_{\text{intra Me}}$ represents the relaxation rate due to fluctuations of the dipolar interaction between the protons within a methyl group. Other notation will then be self-explanatory.

In the presence of C_3 and C_3' rotations of the TMA group, the relaxation rate $(T_1^{HH})^{-1}_{\text{intra Me}}$ of the powdered specimen is given (3*b*, 4) by

$$[3]\quad (T_1^{HH})^{-1}_{\text{intra Me}} = K(r_{HH})\{8B_H(\tau_3) + 19B_H(\tau_e) + 8B_H)\tau_3')\}$$

$$[4]\quad K(r_{HH}) = r_H^4\hbar^2/60r_{HH}^6$$

$$[5]\quad B(\tau) = \tau/(1 + \omega_0^2\tau^2) + 4\tau/(1 + 4\omega_0^2\tau^2)$$

where r_{HH} is the interproton distance in a methyl group, ω_0 the Larmor frequency, τ_3 and τ_3' are the correlation times of the C_3 and C_3' rotations, respectively, and

$$\tau_e^{-1} = \tau_3^{-1} + \tau_3'^{-1}$$

Here we assume that there is no coupling between the two kinds of molecular rotational modes.

We learned above that the C_3' rotation becomes more excited at higher temperatures than does the C_3 reorientation, so that the relation $\tau_3 \ll \tau_3'$ holds over the whole temperature range of

For personal use only.

the T_1 measurements. Thus, we can put $\tau_3' = \infty$ and eq. [3] is reduced below about 200 K to

$$[6] \quad (T_1^{HH})^{-1}_{\text{intra Me}} = 27K(r_{HH})B(\tau_3)$$

The strength of the dipolar interaction $K(r_{HH})$ is calculated using the molecular geometry of the TMA group (6) as

$$[7] \quad (T_1^{HH})^{-1}_{\text{intra Me}} = 7.79 \times 10^9 B(\tau_3)$$

Below about 200 K where the C_3' rotation is essentially frozen, it is difficult to evaluate the contribution of the dipolar interaction between different methyl groups in a molecule and the intermolecular proton–proton interaction. We put, therefore,

$$[8] \quad (T_1^{HH})^{-1}_{\text{inter Me}} + (T_1^{HH})^{-1}_{\text{intermol}} = A \cdot B_H(\tau_3)$$

where the factor A is left as an adjustable parameter.

The shoulders on the T_1 curve of both ^{1}H and ^{19}F below 120 K are caused by the cross-relaxation between protons and fluorines sitting on the reorienting methyl and BF_3 groups. In the presence of the cross-relaxation between ^{1}H and ^{19}F, the recovery of the magnetization of each spin is described (11–14) by

$$dM_H/dt = -(T_1^{HH})^{-1}_{cr}(M_H - M_H^0) - (T_1^{HF})^{-1}_{cr}(M_F - M_F^0)$$

$$dM_F/dt = -(T_1^{FH})^{-1}_{cr}(M_H - M_H^0) - (T_1^{FF})^{-1}_{cr}(M_F - M_F^0)$$

where M_H and M_H^0 represent the magnetization of ^{1}H at a time t and at thermal equilibrium, respectively, under the influence of the fluorine spins, and $(T_1^{HH})^{-1}_{cr}$ is the diagonal matrix element of the cross-relaxation matrix of the system of interacting protons and fluorines. Other symbols will be obvious. Although explicit expressions of $(T_1^{ik})^{-1}_{cr}$, where i, k = H or F, have been given in the literature (12, 13), it is hardly possible to apply them directly to our system involving simultaneously reorienting methyl and BF_3 groups. Therefore, we use a formulation which relates the relaxation matrix to the second moments (12, 14):

$$[9a] \quad (T_1^{HH})^{-1}_{cr} = aM_2^H(F)D(\tau_e') = B \cdot D(\tau_e')$$

$$[9b] \quad (T_1^{HF})^{-1}_{cr} = (T_1^{FH})^{-1}_{cr} = aM_2^H(F)\{-\tau_e'/(1 + \Delta^2\tau_e'^2) + 6\tau_e'/(1 + 4\omega_0^2\tau_e'^2)\}$$

and

$$[9c] \quad (T_1^{FF})^{-1}_{cr} = aM_2^F(H)D(\tau_e') = C \cdot D(\tau_e')$$

where

$$[10] \quad D(\tau) = \tau/(1 + \Delta^2\tau^2) + 3\tau/(1 + \omega_0^2\tau^2) + 6\tau/(1 + 4\omega_0^2\tau^2)$$

and

$$\Delta = \omega_H - \omega_F$$

$$\tau_e'^{-1} = \tau_3^{-1} + \tau_F^{-1}$$

$M_2^H(F)$ is the fluorine contribution to the proton second moment and τ_F the correlation time for the C_F rotation. We use the approximation that $\omega_0 = (\omega_H + \omega_F)/2$. The factors a, B, and C obviously depend on the relative location of protons and fluorines. As we mentioned in a preceding section, the recovery of the magnetizations of both ^{1}H and ^{19}F is nearly exponential so that only $(T_1^{HH})_{cr}$ and $(T_1^{FF})_{cr}$ can be deduced from the observed T_1, and we cannot evaluate $(T_1^{HF})_{cr}$ in eq. [9b].

The relaxation rate $(T_1^{FF})^{-1}$ due to the dipolar interaction within a BF_3 group is given by

$$[11] \quad (T_1^{FF})^{-1}_{\text{intra } BF_3} = 27K(r_{FF})B(\tau_F) = 1.66 \times 10^9 B(\tau_F)$$

the numerical value for $K(r_{FF})$ being obtained by the use of the crystal data (6). The fluorine relaxation that arises from fluorines on neighboring molecules is assumed to be small and is ignored.

The ^{19}F cross-relaxation rate by ^{10}B and ^{11}B within a BF_3 group is approximated (13) by

$$[12] \quad (T_1^{FB})^{-1} = C(^{10}B)T_1^{-1}(F\text{-}^{10}B) + C(^{11}B)T_1^{-1}(F\text{-}^{11}B)$$

where

$$T_1^{-1}(F\text{-}X) = (1/10)r_F^2 r_X^2 \hbar^2 r_{FX}^{-6} S_X(S_X + 1)f(\xi)D(\tau_F, X)$$

$X = {}^{10}B$ or ^{11}B

and $f(\xi) = 4\sin^2\xi\cos^2\xi + \sin^4\xi$ with ξ as the angle between the internuclear vector r_{BF} and the external magnetic field. S_X and $C(X)$ are the spin number and the natural abundance, respectively, of the two isotopes, ^{10}B or ^{11}B. $D(\tau_F, X)$ represents the same quantity as in eq. [9] except that Δ and $2\omega_0$ are replaced by $\omega_F - \omega_X$ and $\omega_F + \omega_X$, respectively. Using structural data, the intra-BF_3 relaxation rate is calculated to be

$$[13] \quad (T_1^{BF})^{-1} = 0.22 \times 10^9 D(\tau_F, {}^{10}B) + 2.67 \times 10^9 D(\tau_F, {}^{11}B)$$

Finally, the relaxation rate $(T_1^{HB})^{-1}$ is ignored.

The minimum in T_1 of ^{1}H at 240 K is due to the onset of the C_3' rotation, i.e., the reorientation of the TMA group about the N—B bond. The contribution of this motion to the proton relaxation rate is approximated by

$$[14] \quad (T_1^{HH})_{C_3'}{}^{-1} = 81K(r^*)B(\tau_3')$$

where r^* is the distance between the centers of gravity of the three protons in individual methyl groups in the molecule. We calculated the factor $81K(r^*)$ to be $3.32 \times 10^9\ s^{-2}$ using the assumed geometry of TMA. The cross-relaxation rate of ^{19}F due to C_3' rotation is given by eq. [9c], with τ_e' substituted by τ_3' and C by another adjustable parameter D, i.e.,

$$[15] \quad (T_1^{FF})_{cr,C_3'}{}^{-1} = D \cdot D(\tau_3')$$

Fitting of calculation to experimental T_1

Using eqs. [6]–[15] and adjusting the parameters A, B, C, and D, we attempted to fit the theoretical relaxation rates of ^{1}H and ^{19}F of eqs. [1] and [2], respectively, to the experimental ones using a personal computer. Here we assumed an Arrhenius-type activation process

$$[16] \quad \tau_i = \tau_i^0 \exp(E_i/RT)$$

for each of the three reorientational modes. The best fit to the experimental T_1 was obtained with $A = 3.9 \times 10^9$, $B = 0.13 \times 10^9$, $C = 0.85 \times 10^9$, and $D = 0.10 \times 10^9$ (in s^{-2}). The

activation parameters for the three reorientations are listed in Table 1 and the calculated relaxation times T_1^F and T_1^H are reproduced in Fig. 1 by the solid and the broken lines.

As can be seen in Fig. 1, the agreement between the experimental and the theoretical relaxation times for both ^1H and ^{19}F is satisfactory over the whole temperature region of the measurements except in the range between 100 and 120 K. The poor agreement in this region is probably due to the neglect of the off-diagonal elements in the cross-relaxation matrix. The second moment data lead to $A = 1.21 \times 10^9$, $B = 0.198 \times 10^9$, $C = 0.595 \times 10^9$, and $D = 0.342 \times 10^9$ (in s^{-2}). Calculation of T_1 with these parameters does not give satisfactory fitting to the experiment, implying that the estimation of the intergroup as well as the intermolecular dipolar interaction is very difficult for a complex molecule in which a number of different types of motions are simultaneously excited.

Activation energies for TMA complexes

The activation parameters for TMA and a variety of its complex compounds are compared in Table 2. One can see from this table that the activation energies E_a for the C_3 rotation in the TMA complexes of BX_3 (X = H, F, Cl, and Br) fall in the range 10–13 kJ mol^{-1}, which is rather low for the activation energies of methyl reorientation. These values are comparable with those for the less hindered methyl rotation in *tert*-butyl groups in $(CH_3)_3CNH_3^+$ ions (15). The other complexes, especially the strong complexes of TMA with halogens, give higher activation energies for the C_3 rotation. Ang and Dunell attempted to correlate the activation energy for the C_3 rotation to an expected structural change in $(CH_3)_3N$ due to charge transfer to an electron acceptor (16). Their attempts were not promising because of a lack of precise molecular structural data for most of the TMA complexes. Now we find that the activation energy for the C_3 rotation increases with an increase in the electron affinity (17) of the acceptor in the series of BF_3, Cl_2, Br_2, ICl, and I_2, or, for BX_3-type acceptor molecules, with an increase in the electron-withdrawing power introduced by Eames and Hoffman (18). Since these two quantities are measures of the strength of the acceptor species, this fact suggests that the methyl rotational barrier in the TMA donor molecule goes up as the acceptor strength increases.

As to the C_3' rotation, the activation energies of the complexes with BCl_3 and BBr_3 are about twice as high as those of BH_3 and BF_3. The TMA component in the former two complexes is significantly distorted in the unit cells belonging to the space group $P2_1/m$ (19) and so the high barriers can be ascribed to asymmetric intermolecular rotational potentials.

It is worth pointing out that the activation energy for the rotation of BF_3 group about the N—B bond in TMA–BF_3 is comparable to that for the methyl reorientation. This fact is analogous to the experimental observation that the activation energy of the BH_3 reorientation is indistinguishable from that of C_3 rotation in TMA–BH_3 (3*a*). Furthermore, the activation energies for the C_3' rotation are nearly the same in these two complexes. Hence we can conclude that TMA–BF_3 and TMA–BH_3 show similar dynamical behavior except that the latter undergoes two phase transitions immediately below its melting point whereas the former has no phase changes in the solid state. If the phase transitions in TMA–BH_3 and its analogues are associated with the overall molecular tumbling as suggested in ref. 3*a*, the cause of the phase transitions in these substances may be systematically understood on the basis of the size, shape, and the magnitude of the molecular electric dipole moment, which together determine the molecular packing (20–22).

Photoelectrochemical water splitting by tandem type and heterojunction amorphous silicon electrodes

YUICHI SAKAI, SATOSHI SUGAHARA, MICHIO MATSUMURA, YOSHIHIRO NAKATO, AND HIROSHI TSUBOMURA

Laboratory for Chemical Conversion of Solar Energy and Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560, Japan

Received January 6, 1988

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

YUICHI SAKAI, SATOSHI SUGAHARA, MICHIO MATSUMURA, YOSHIHIRO NAKATO, and HIROSHI TSUBOMURA. Can. J. Chem. **66**, 1853 (1988).

The tandem type hydrogenated amorphous silicon (a-Si) electrode having an [n–i–p–n–i–p] structure and a similar tandem a-Si electrode having [n–i–p–n–i–p–n] layers deposited on p-type crystalline Si showed cathodic photocurrents accompanied by hydrogen evolution starting at potentials 1.67 and 2.08 V, respectively, more positive than the thermodynamic hydrogen evolution potential in a sulfuric acid solution. These electrodes, when connected to an RuO_2 counterelectrode, caused sustained water splitting without external bias, giving solar-to-chemical conversion efficiencies of 1.98% and 2.93%, respectively, under simulated AM 1, 100 mW cm^{-2} solar radiation. These efficiencies are critically compared with the efficiency of another type of solar photoelectrolysis of water, namely, the electrolysis of water by the electrical output from solid-state solar cells.

YUICHI SAKAI, SATOSHI SUGAHARA, MICHIO MATSUMURA, YOSHIHIRO NAKATO et HIROSHI TSUBOMURA. Can. J. Chem. **66**, 1853 (1988).

L'électrode (a-Si) de silicium amorphe hydrogéné de type tandem possédant une structure [n–i–p–n–i–p] et une électrode similaire tandem a-Si sur laquelle des conches [n–i–p–n–i–p–n] ont été déposés sur du Si cristallin de type-p présentent des photo-conrants cathodiques qui sont accompagnés d'une évolution d'hydrogène à partir de potentiels respectifs de 1,67 et 2,08 V; ces potentiels sont plus positifs que le potentiel thermodynamique d'évolution d'hydrogène dans une solution d'acide sulfurique. Lorsqu'on connecte ces électrodes avec une contre-électrode de RuO_2, il se produit une décomposition continue de l'eau sans influence externe et, lorsqu'on opère dans des conditions simulée de radiation solaire AM 1, 100 mW cm^{-2}, on obtient des efficacités de conversion solaire à chimique de respectivement 1,98 et 2,93%. On compare ces efficacités d'une façon critique a celle obtenue dans un autre type de photo-électrolyse solaire de l'eau, soit lors de l'électrolyse de l'eau par un apport électrique provenant de cellules solaires à l'état solide.

[Traduit par la revue]

Introduction

Semiconductor photoelectrochemical (PEC) cells have been attracting keen interest in relation to their capability to convert solar energy into either electrical or chemical energy. As a photoelectric converter, energy conversion efficiencies as high as those of the solid-state solar cells have been reported (1–4). Solar-to-chemical conversion, which is a unique property of the PEC cells, has also been progressively improved. We reported efficiencies of 10.2% and 10.8% based on the Gibbs free energy change in the solution for the decomposition of hydrogen iodide into hydrogen and iodine with PEC cells equipped with either a platinum (Pt) coated n^+–p junction single crystalline Si electrode having a matt-textured surface (5) or a heterojunction Si electrode having an (n-type amorphous Si/p-type crystalline Si) structure (6).

Water splitting is an important type of photochemical reaction for the solar-to-chemical conversion, having the merit that water is a very abundant material and electric energy can be obtained efficiently by the reverse reaction using the technologically established fuel cells. Many studies have been made on water photolysis using the PEC cells, starting from the well known work of Fujishima and Honda (7), who used n-type titanium dioxide as a photoanode. Some trials followed using strontium titanate (8) and other oxide semiconductors (9). These materials are chemically strong but have a fatal drawback in that their band gaps are too large and they convert only the ultraviolet portion, less than 3% of the total solar energy. Some years ago, we reported (10) that n-type strontium titanate doped with ruthenium or other metal ions absorb a considerable part of visible light and decompose water without the aid of external electrical bias. The quantum efficiency of the photocurrent obtained at wavelengths between 400 and 500 nm is as high as 2%.

We have been investigating the properties of platinized hydrogenated amorphous silicon (a-Si) electrodes used in PEC cells. In our previous paper (11), we studied hydrogen evolution by PEC cells equipped with a-Si electrodes having n–i–p and n–i–p–n–i–p structures (i stands for an intrinsic a-Si layer). The n–i–p electrode caused hydrogen evolution at a potential 0.8 V more positive than the thermodynamic hydrogen evolution potential. This shift was higher than that of a crystalline silicon electrode, though still insufficient for water splitting. The n–i–p–n–i–p electrode caused hydrogen generation at about 1.6 V more positive, and water was decomposed in a PEC cell equipped with this electrode and a Pt counterelectrode with an energy conversion efficiency of about 0.25%. For the purpose of further improving the efficiency of water splitting we investigated tandem type a-Si electrodes having [n–i–p–n–i–p a-Si] and [n–i–p–n–i–p–n a-Si/p-type crystalline Si] structures.

Experimental

Hydrogenated amorphous silicon (a-Si) films were deposited on stainless steel or other substrates by the plasma decomposition of hydrogen-diluted monosilane (10 vol%) in an RF (13.56 MHz), capacitance-coupled glow discharge, with a gas flow rate of 50–60 sccm and a gas pressure of 2 Torr. The substrate temperature was kept at 200–230°C during deposition and the input RF power was 2 W. The p- and n-layers were made using hydrogen-diluted diborane (0.1 vol%) and hydrogen-diluted phosphine (0.05 vol%) as doping gases, respectively. For the deposition of n-layers, the input RF power was raised to 25–30 W so as to make the layer microcrystalline (μc-Si).

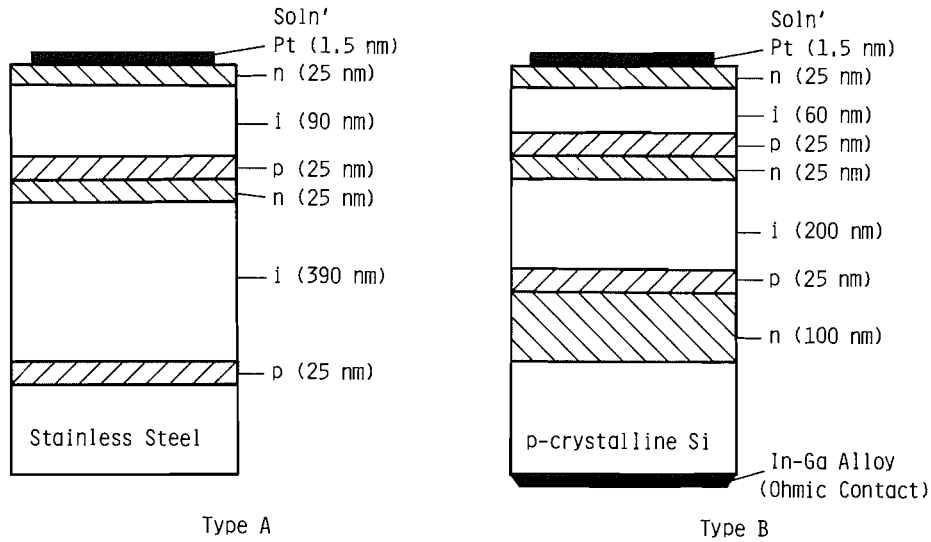

FIG. 1. Structures of a-Si PEC electrodes.

Two types of a-Si electrodes, Types A and B, were fabricated whose structures are shown in Fig. 1. For the Type A electrode, a stainless steel plate which was mirror finished by electrochemical buffing (Hitachi Zosen Corp., 0.5 mm thick), was used as the substrate and a-Si was deposited on it successively as shown in Fig. 1. For the Type B electrode, an n-type μc-Si layer (100 nm) was deposited on a wafer of single crystal p-type Si (denoted as p-c-Si) to make an n–p heterojunction and a-Si layers were deposited on it successively as shown in Fig. 1. The p-c-Si wafers, obtained from Shin-Etsu Handotai Co., Ltd., were cut perpendicular to the ⟨111⟩ axis and had a resistivity of 0.1–0.15 Ω cm. After these electrodes were prepared, their surfaces were coated with a 1.5 nm thick Pt layer by electron-beam evaporation to catalize the hydrogen evolution, then heat-treated at 330°C for 10 min in vacuum. All specimens had an active cell area of 10 to 20 mm^2.

Electrochemical measurements were made by use of a three electrode cell consisting of an a-Si electrode, a Pt counterelectrode and a saturated calomel electrode (SCE). The 0.5 mol dm^{-3} sulfuric acid used as the electrolyte solution was bubbled with high purity nitrogen gas and magnetically stirred during the measurements. A solar simulator (AM 1, 100 mW cm^{-2}) of Wacom Co., Ltd., was used as the light source. Water splitting was performed in a PEC cell consisting of an a-Si electrode directly connected to an RuO_2 counterelectrode. The RuO_2 electrode was prepared by wetting a titanium plate with an aqueous solution of 0.01 mol dm^{-3} $RuCl_3$ and 20% HCl, drying at 90°C for 10 min in an oven, and putting into a preheated furnace at 350°C for 10 min. This procedure was repeated eight times and the plate was heated at 500°C for 1 h in air.

Solid-state photocells were also fabricated. These have a structure similar to Type B except that an ITO (indium tin oxide, 70 nm) layer was deposited on the surface by electron-beam evaporation instead of the Pt layer.

Results and discussion

The hydrogen evolving cathodic current in a Type A electrode under illumination in an aqueous solution of 0.5 mol dm^{-3} sulfuric acid (Fig. 2) starts at +1.43 V vs. SCE, which is 1.67 V more positive than the normal onset potential of hydrogen evolution in a Pt electrode. The i–V curve is given by the dotted line in Fig. 2. Since the open-circuit photovoltage (V_{oc}) of a-Si solar cells having a p–i–n unit is ca. 0.8 V, the observed shift in the potential can be understood as the sum of the photovoltages generated in each of the two p–i–n units. The hatched area in Fig. 2(*A*) gives the maximum electrical energy saved for the reduction of water using this photoelectrode. This area divided by the light intensity is called the bias-assisted energy conversion efficiency (η_1).

The photovoltage of a p–i–n unit, ca. 0.8 V, is an intrinsic property of this unit and no further increase in photovoltage in such a tandem type a-Si photoelectrode is expected. Therefore, an improvement of the electrode performance is expected to be attained only by an effort to increase the photocurrent density, in other words, by minimizing undesirable loss of light intensity in the various layers of the electrode. Firstly, the uppermost Pt layer is indispensable for decreasing the overvoltage of the electrode reaction. The thickness adopted, 1.5 nm, is enough for this purpose and causes minimal light absorption. Secondly, it is desirable to make the p- and n-layers as thin as possible in order to reduce light absorption in these layers, since the charge carriers are produced only in the two i-layers. However, when these layers become too thin, the minority carriers in these layers are completely depleted and the photovoltages in the p–i–n units drop (12, 13). Finally, the thickness of the two i-layers should be controlled so as to make the rates of carrier production in the two layers equal and maintain the continuity of the photocurrents. The thicknesses of the various layers of the Type A cell as given in Fig. 1 have been settled as a result of optimizing all the conditions described above and the best value of the bias-assisted energy conversion efficiency (η_1) obtained was 3.56%.

The i–V curve for the anodic oxidation of water in an RuO_2 electrode is given by the broken lines in Fig. 2, showing the onset of anodic current at +1.15 V vs. SCE in an aqueous solution of 0.5 mol dm^{-3} sulfuric acid. Compared with this, the onset potential for the hydrogen evolution in the Type A electrode is about 0.28 V more positive. This suggests that water splitting can occur by connecting these two electrodes. In fact, a PEC cell consisting of the Type A electrode and an RuO_2 counterelectrode immersed in a 0.5 mol dm^{-3} H_2SO_4 solution and directly connected with each other generated a photocurrent of 1.61 mA cm^{-2} under simulated solar illumination (AM 1, 100 mW cm^{-2}). The conversion efficiency η_2 for water splitting, defined as the product of the photocurrent density and the thermodynamic decomposition potential of water, 1.23 V, divided by the incident light energy, 100 mW cm^{-2}, is calculated to be 1.98% from the current density given above.

The solar-to-chemical conversion efficiency η_2 defined above

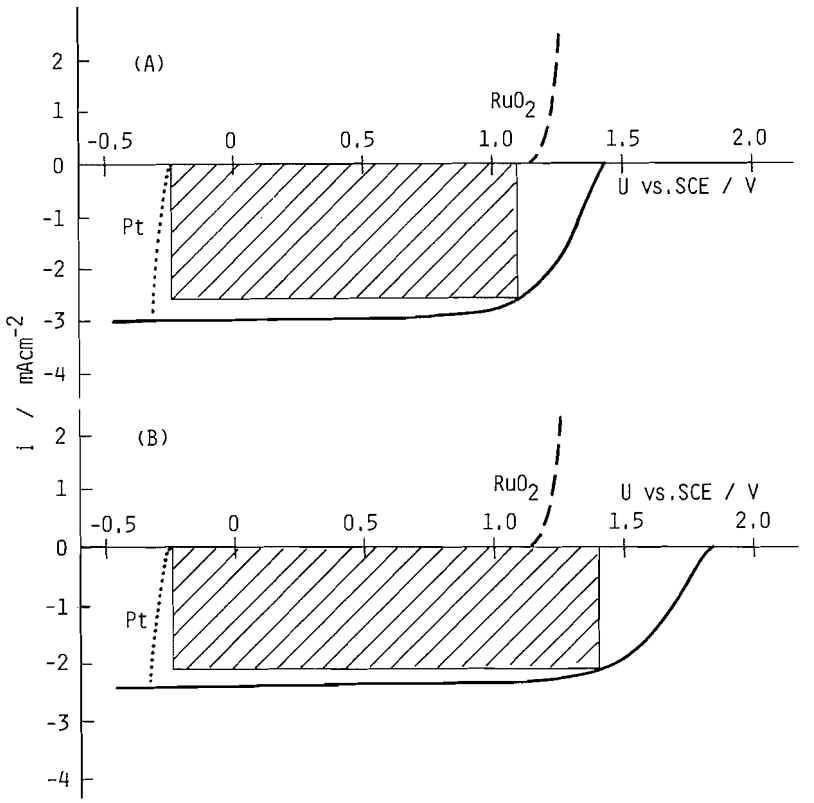

FIG. 2. The i–V curves for a Type A electrode (A) and a Type B electrode (B) in a 0.5 mol dm^{-3} sulfuric acid solution under simulated solar radiation of AM 1, 100 mW cm^{-2} (solid lines), and those in the dark for a RuO_2 and a Pt electrodes. The hatched areas give the electrical energy saved for the water splitting by Type A and Type B electrodes.

corresponds more strictly to the efficiency of converting solar energy into real storable chemical energy. The values of η_2 obtained have been considerably lower than the bias-assisted energy conversion efficiency designated as η_1. This arises mainly from the fact that the onset potential for the photocathodic current in the Type A electrode is barely more positive than the onset potential for the anodic current of the RuO_2 electrode, making the photocurrent weak. In order to raise η_2, therefore, a slight enhancement of the photovoltage is desirable. Although it is expected that the photovoltage will become as high as 2.4 V by stacking the p–i–n unit three times, the triply-stacked cell actually generates only 1.96 V. In such an electrode, an anodic dark current begins to flow at about +1.5 V vs. SCE, increasing as the electrode potential gets more positive, thus lowering the photovoltage output of the electrode. The dark current is thought to arise from the electrochemical reaction between the stainless steel substrate and the electrolyte solution penetrating through the pinholes existing in the a-Si films to the stainless steel surface (11, 14).

We have taken a different approach to the improvement of the photovoltage by constructing an electrode having a Pt/n–i–p–n–i–p–n a-Si/p–c-Si structure which we call Type B (Fig. 1). Since c-Si has a narrow bandgap, 1.1 eV, it absorbs light at wavelengths longer than the light absorbed by the a-Si film deposited on it, thus improving the energy conversion efficiency. In this electrode, anodic dark current was not observed even at a potential of +1.8 V vs. SCE, conceivably because the points on the c-Si surface in contact with the pinholes existing in the a-Si film are passivated by the reaction with the solution. The i–V curves for the Type B cell in an aqueous solution of 0.5 mol dm^{-3} H_2SO_4 are shown in Fig. 2(B). The hydrogen evolving cathodic photocurrent has an onset at +1.84 V vs. SCE, which is 2.08 V more positive than that at a Pt electrode. It is concluded, therefore, that a photovoltage output of 0.4 to 0.5 V arises at the n–a-Si/p–c-Si heterojunction. By connecting this electrode directly with an RuO_2 counterelectrode, a photocurrent of 2.38 mA cm^{-2} was obtained under simulated solar illumination (AM 1, 100 mW cm^{-2}), indicating that water is decomposed at a solar-to-chemical conversion efficiency (η_2) of 2.93%. For bias-assisted water splitting, a 3.47% efficiency (η_1) was obtained from the hatched area of Fig. 2(B). Higher energy conversion efficiencies will be realized by optimizing the thickness of the i-layers included in the Type B electrode.

The photocurrent in a cell having a Type B electrode and an RuO_2 counterelectrode did not decay under AM 1 illumination for 1 h, but it declined to half the initial value after 55 h. This decline is presumably due to the contamination of the Pt electrode surface by chemical impurities existing in the solution because the durability was found to be better the purer the solution used in the PEC cell.

For the purpose of comparison, we investigated the electrolysis of water by use of the electric power generated by the solid-state solar cell having an ITO/n–i–p–n–i–p–n a-Si/p–c-Si structure, prepared under exactly the same condition as the Type B electrode. In the water splitting experiment, the electrical output of the solid-state solar cell (0.15 cm^2) is supplied to a Pt electrode (2 cm^2) and an RuO_2 electrode (2.5 cm^2) immersed in an aqueous solution of 0.5 mol dm^{-3} sulfuric acid. The electrolysis of water by the solid-state solar cell proceeded at a current density of 2.62 mA cm^{-2} under simulated solar illumination (AM 1, 100 mW cm^{-2}) and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

solar-to-chemical conversion efficiency for water splitting was 3.23%, a little higher than that in the PEC cell having a Type B electrode. The higher photocurrent for the solid-state solar cell arises mainly from the low reflectivity at the surface, the ITO layer acting as an anti-reflection coating. On the other hand, the photovoltage in the PEC cell was a little higher than that of the solid-state solar cell. This is thought to occur by the very small anodic dark current in the PEC electrode at potentials near the photocurrent onset.

Approximately one third of the solid-state photocells prepared by us showed large dark currents due probably to the penetration of the deposited ITO into the pinholes of the a-Si films. The energy conversion efficiencies of such photocells were very low. On the contrary, none of the PEC cells using the multi-layer a-Si electrode prepared in the same apparatus showed leakage currents of a significant order. This result can be explained by the fact that in a PEC cell the electrodes are separated by the electrolyte solution and no current flows between them unless the chemical components of the solution react on the electrodes. For the case of the Type B electrode, the leakage current is also stopped by the passivated c-Si substrate exposed to the solution through the pinholes. These results indicate that the pinholes in a-Si layers are less hazardous when used in a PEC cell than in a solid photocell; an advantage of a PEC cell over the solid-state photocells, especially for large area solar cells.

Recently, Bockris *et al.* (15) reported 8.2% efficiency for water splitting under sun light using an n–GaAs/KOH/p–InP PEC cell. However, an a-Si electrode can be constructed at much lower cost and is thus expected to be more advantageous.

Spatial intensity distributions of vacuum ultraviolet photon beams measured by thermoluminescent image films

NOBUYUKI KIKUKAWA[1] AND TSUTOMU MAKITA[2]

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto, 606 Japan

Received January 5, 1988

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

NOBUYUKI KIKUKAWA and TSUTOMU MAKITA. Can. J. Chem. **66**, 1857 (1988).

The thermoluminescent phosphor, calcium sulfate activated by manganese, was found to be a suitable material for imaging films to record the spatial distributions and reflections of vacuum ultraviolet (vuv) photon beams used for high-resolution photoelectron spectrometers. He I 584 Å photons radiated in a microwave discharge tube were collimated through capillary tubes, and the phosphor films were placed at the position of the photoionization chamber. When the irradiated phosphor films were heated up to 200°C in a darkroom, faint green glow images were observable on the phosphor films and these images were recorded by photographic films. When the films were placed 118 mm from the exit of the collimating capillary tube, the photon beam images were almost circular, about 4.5 mm in diameter. The photon distribution in the collimated beam was interpreted with the aid of computer simulation. The experimental results revealed that the reflections of vuv photons at planes of various kinds were almost specular if the surface was clean and smooth and the glancing angles were small.

NOBUYUKI KIKUKAWA et TSUTOMU MAKITA. Can. J. Chem. **66**, 1857 (1988).

On a trouvé que le sulfate de calcium activé par le manganèse, un produit phosphorescent et thermoluminescent, est un produit utile pour faire des films desquels on peut tirer des images permettant d'enregistrer les distributions spatiales et les réflexions des faisceaux de photons ultraviolet sous vide (uvv) qui sont utilisés dans les spectromètres photoélectroniques à haute résolution. On a dirigé les photons du He I 584 Å qui proviennent d'une radiation dans un tube à décharge à micro-ondes vers des tubes capillaires servant de collimateur et on a placé les films phosphorescents à la place de la chambre à photoionisation. Lorsque les films phosphorescents irradiés ont été chauffés à 200°C, dans un chambre noire, on a pu observer de faibles lueurs d'images vertes que l'on a enregistré images sur des films photographiques. Lorsqu'on place les films à 118 mm de la sortie du tube capillaire agissant comme collimateur, les images du faisceau de photons sont pratiquement circulaires, avec un diamètre d'environ 4,5 mm. On a interprété la distribution des photons dans le faisceau qui a passé au collimateur en faisant appel à une simulation par ordinateur. Les résultats expérimentaux suggèrent que les réflexions des photons (uvv) sur divers types de plans sont pratiquement spéculaires si la surface est lisse et propre et que les angles de percement sont faibles.

Introduction

Vacuum ultraviolet (vuv) radiation is indispensable for photoionization studies and photoelectron spectroscopy. For instance, high energy photons, He I 584 Å, are radiated conveniently by the microwave discharge of low pressure helium gas flowing in a source tube (1). The radiation is collimated through capillary tubes between the discharge tube and the ionization chamber, which contains target molecules. The capillary tubes are necessary to maintain the pressure differential of helium gas between the discharge tube and the ionization chamber. Furthermore, for the He I 584 Å radiation, no material can be used as an efficient window between them.

The size and the intensity distribution of collimated vuv photon beams are one of the fundamental design factors for the ionization chamber of high-resolution photoelectron spectrometers (2). Schumann-type plates are not feasible for imaging, because of their sensitivity to visible radiation from the discharge tube.

Lyman (3) reported that a thermoluminescent phosphor was sensitive to photon beams of wavelengths from 1300 to 140 Å. The phosphor was mainly calcium sulfate containing a few percent of manganese sulfate. Lyman found that atmospheric air was almost transparent to radiation of 1300–1100 Å, but that it absorbed radiation of 2000–1300 Å and of wavelengths shorter than 1100 Å. Watanabe investigated the properties of the manganese-activated $CaSO_4$ phosphor in detail (4) in connection with its use as a detector of extreme ultraviolet radiation. These thermoluminescent plates were flown in rockets, exposed to the sunlight at an altitude level between 82 and 128 km, and recovered for dosimetry (5).

Image plates made of thermoluminescent phosphor are convenient devices to record the dimensions and intensity distributions of vuv photon beams, for instance, He I 584 Å. Because the plates are not sensitive to light of wavelength longer than 1340 Å, they can be handled under room light. The faint green glow images of the thermoluminescent plates have to be detected in the darkroom. This paper reports on the spatial distributions and reflections of He I 584 Å photon beams for a high-resolution photoelectron spectrometer.

Experimental

Figure 1 is the schematic diagram of a He I 584 Å light source assembly combined with the thermoluminescent image film on copper plate, helium gas flow regulation system, and microwave power supply. Figure 2 is a detailed diagram of the light source to show the quartz discharge tube, capillary tubes I and II of Pyrex glass, and the differential pumping. Helium gas was introduced from a cylinder through pressure-reducing valves and a needle valve. The microwave generator was type MR-1S of Ito Electro-Medical and Chemical Instruments Mfg. Co., Tokyo (2450 MHz and 200 watts maximum). The cooking electronic range was, with some modifications, suitable for the microwave generator. The microwave cavity at the discharge tube was a cavity of type 5 as described by Fehsenfeld, Evenson, and Broida (7). The photon beam was mainly He I 584 Å, with weak contaminations such as H I Ly α 1216 Å. The intensity of 1216 Å photons was found to be reduced remarkably when the helium gas was

supplied through a U-shaped copper tube, which was cooled in liquid nitrogen.

Three different procedures to make the phosphor were tried, as described by the reports of Lyman (3), Watanabe (4), and Novotný *et al.* (6). These three kinds of the phosphor were exposed to He I 584 Å photon beams under similar conditions. The intensities of thermoluminescent green glow images were compared visually in a darkroom;

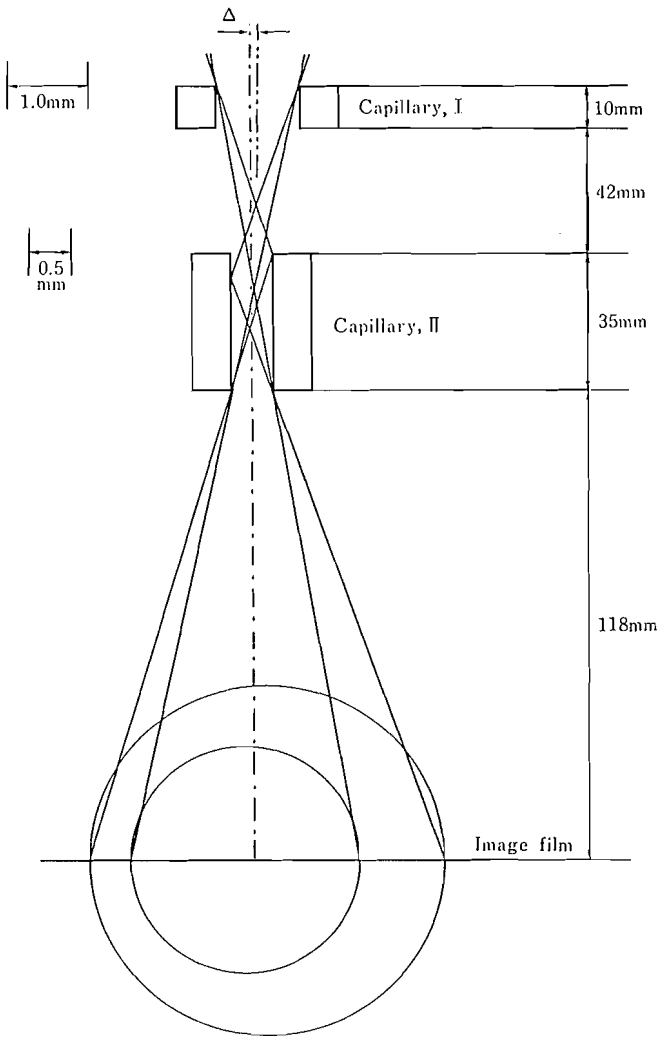

FIG. 5. Schematic diagram of the spatial distribution of a collimated photon beam. The horizontal scale is expanded 20-fold compared to the vertical scale. Axes of capillary I and II are assumed to be parallel but slightly shifted. The two circles on the imaging film correspond to the limits of the photon trajectories; (a), no reflection and (b) single reflection in capillary II.

the phosphor made following Watanabe (4) was found to be the brightest, and was used throughout with slight modifications as follows. Approximately 8.8 g of $CaSO_4 \cdot 2H_2O$ was mixed with 0.12 g of $MnSO_4$ in 60 mL of concentrated sulfuric acid and a small amount of water. The slurry was left at room temperature for 72 h. Most of the liquid part was then removed by decantation. The excess sulfuric acid was vaporized at 250°C, and the residual mixture was heated to red heat in a porcelain crucible for 90 min. After cooling, the mixture was ground to fine powder, and was suspended in a dilute benzene solution of Dow Corning high vacuum silicone grease. One drop of the suspension was sufficient to make a thin film of 10 mm diameter on a copper plate, 20 × 50 × 1 mm. Such imaging films were strong enough for repetitive exposures to intense vuv photon beams and heatings up to 200°C for thermoluminescence.

The imaging film on a copper plate that had been exposed to the photon beam was heated by a tape heater in the darkroom, and the thermoluminescent glowing image was photographed using Polaroid type 107 film in a model 180 camera. Close-up lenses, Cannon 240 and 450, were attached to the camera. Figure 3*a* is an example of the glow image. It was possible to record the glowing images on a Kodak Tri-X film directly without photographic lens. The Tri-X films were sandwiched between thin glass plates, and were placed on the glowing

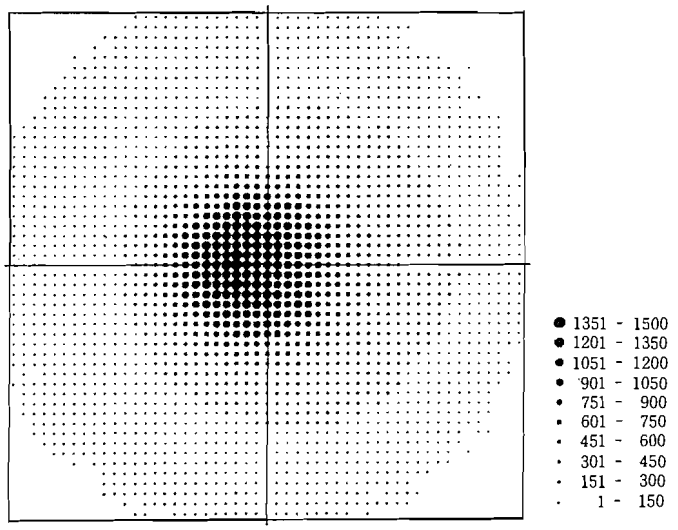

FIG. 6. Number of photons arriving at each 0.1 × 0.1 mm meshed area on phosphor film, computer simulation for 500 000 photons. Symbols (right) correspond to the intensities listed.

film and exposed for less than 3 s. Figure 4 is an example of Tri-X film images. High temperatures from the tape heater had no effect on the Tri-X film.

When the collimated photon beam was directed around the edge of a plane surface, some of the photons can proceed directly to the phosphor film, while the remainder reflect on the surface and may proceed to another position on the same film. Figure 5 is a schematic diagram to show the trajectories of photons to the phosphor film and the positions of the points of arrival at the film for the split photon beams. Figure 3*b* is an example of the split images on the same phosphor film. The relative intensities of the split beams can be determined by comparing the glowing intensities of the two images. The relative attenuation factors for photon beams reflected on the surface were determined as a function of the incident angles, assuming that the incident angle and reflection angle were equal.

Results and discussion

The slurry of fine powder of the phosphor was painted on a copper plate to make the thermoluminescent film, 10 mm diameter, about 10 mg/cm^2 in thickness. The films were stable in the atmosphere for many months. They were irradiated by He I 584 Å photons for up to 160 min. The output power of the microwave generator was usually 50 watts. The copper plate was dismounted from the light source and transferred to a darkroom within 5 min of irradiation to inspect the thermoluminescent image. Before heating the film, it was necessary to wait for 10 min for vision to adjust in the darkroom. The temperature of the film was then increased to 200°C in 15 min. The faint thermoluminescent glow image was observable for the first 5-min period and then faded out. When the irradiated films were exposed under room light for 2 min, there was no appreciable effect on the subsequent intensity of the glow image. When the films were left under room light for 90 h, the glow intensity decreased to one sixth of that of the control films kept in the darkroom. Spatial distribution of the collimated vuv photon beam was determined by measuring the size of the thermoluminescent image of the phosphor film. Figure 3*a* is an example of the images. This shows that the He I 584 Å photon beams are collimated within a 4.5 mm diameter, 118 mm from the exit of capillary II. The ionization chambers for photoionization studies were customarily placed ca. 100 mm from

the light sources. The divergence of the collimated photon beam was estimated to be 2.2° or 9×10^{-4} steradians. The resolution of the image film was better than 0.1 mm.

Close examination of the 4.5-mm circular image of Fig. 3*a* revealed that the image consisted of two overlapping but not concentric circles, one bright inside and one faint outside. The intensity of the inner bright circle was about three times that of the faint one. Figure 5 is a schematic diagram of the spatial distribution of a collimated photon beam. It is suggested that the two circles, as well as the separation of their centers, resulted from reflections of the photons on the inside surfaces of the capillaries when the central axes of the capillaries were made parallel but their centres were shifted slightly, indicated as Δ in Fig. 5. The ratio of the diameters of the two circles in these theoretical considerations is similar to the experimentally determined ratio (Fig. 3*a*). Reflections of photons at the inside wall of capillary II were assumed to be specular. The slight shift of the two centers of the circles could be explained schematically via a corresponding shift of the two capillaries.

TABLE 1. Results on the estimated intensity attenuation factors of a He I 584 Å photon beam due to specular reflections at various conditions of the reflecting plates

*Split beams were detected by two different films.

A preliminary computer simulation study was carried out using a Toshiba ACOS 600 S on the trajectories of the collimating photons through the collimating system. Figures 6 and 7 are examples of the results for 500 000 photons. It was assumed that, (*i*) each photon started at a random point on the circular plane at the entrance to capillary I, (*ii*) the starting direction of the photon is also random, and (*iii*) some photons can emerge from the exit circular plane of capillary II without reflection, some after a single specular reflection, and some after two specular reflections. The numbers of photons arriving at each 0.1×0.1 mm meshed area on the plane of the film are shown as various kinds of dots in Fig. 6. Figure 7 is the intensity distribution profile along the horizontal central line in Fig. 6.[3]

The collimated vuv photon beam source for high-resolution photoelectron spectrometers (2) was designed on the assumption that all reflections of photons at the inside surface of capillary tubes were specular without intensity attenuation when the glancing angles were small. The following considerations refer to this assumption.

Figure 3*b* is an example of split photon beam images, one transmitted directly to a phosphor film, and the other reflected from near the edge of a plate to the same phosphor film. The geometry used is described in Fig. 8.

The relative intensities of the photon beams were estimated by comparing with the glow images of the reference beams, as described below. Figure 4 is an example of the glow image. The phosphor film of Fig. 4 was circular, about 10 mm diameter, and one half part of the circle was covered with a thin plate of lithium fluoride while the film was irradiated by a large-diameter flux of

He I 584 Å photons for 5 min. Then, a different half part of the circle, which was displaced by 90° from the previously irradiated half of the film, was covered with the LiF plate and irradiation continued for 10 min. Each quarter of the circular phosphor film was thus irradiated at different time intervals by this procedure, the relative exposures being 0, 5, 10, and 15 min in this case. It was realized that visual observation was more accurate than photographic recording, to estimate the relative size and intensities of the faint glow images of the phosphor film. Therefore, photographic records (Figs. 3*a*, 3*b*, and 4) are given only for illustration. Table 1 is a summary of the experimental results on the intensity ratio of the specularily reflected photon beam to the impinging photon beam upon various kinds of plate, as investigated via the arrangement of Fig. 8 and the above calibration procedure. It is thereby well established that vuv photon reflections are mainly specular at clean and smooth planes if the glancing angles are less than 10°.

^1H and ^{14}N ENDOR spectra of *tert*-butylphenylnitroxide

JUN YAMAUCHI AND YASUO DEGUCHI

College of Liberal Arts and Sciences, Kyoto University, Kyoto 606, Japan

Received December 23, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

JUN YAMAUCHI and YASUO DEGUCHI. Can. J. Chem. **66**, 1862 (1988).

^1H and ^{14}N ENDOR spectra of *tert*-butylphenylnitroxide were observed in ethylbenzene solution. The experimental conditions for detecting optimum ^1H and ^{14}N ENDOR lines were quite different. The ^1H hyperfine coupling constants and their signs are discussed from the viewpoints of molecular orbital calculations, general triple resonance, CRISP (cross relaxation intensity sequence pattern) method, and steric hindrance. In view of the large anisotropic hyperfine interaction between the nitrogen and the unpaired electron, detection of ^{14}N ENDOR in nitroxide radicals is rather difficult, so that a TM_{110} mode cavity was utilized in this experiment. The observed ^{14}N hyperfine coupling constant 11.86 G at −80°C is one of the smallest values observed to date for nitroxide radicals.

JUN YAMAUCHI et YASUO DEGUCHI. Can. J. Chem. **66**, 1862 (1988).

Opérant en solution dans l'éthylbenzène, on a déterminé les spectres ENDOR ^1H et ^{14}N du nitroxyde de *tert*-butyle et de phényle. Les conditions expérimentales permettant des détections optimales des raies ENDOR du ^1H et du ^{14}N sont très différentes. On discute des constantes et des signes du couplage hyperfin du ^1H à l'aide de calculs d'orbitales moléculaires, de la résonance générale triple, de la méthode CRISP (patron de la séquence des intensités de la relaxation croisée) et de l'empêchement stérique. A cause de l'interaction anisotropique hyperfine importante qui existe entre l'azote et l'électron qui n'est pas apparié, la détection des spectres ENDOR du ^{14}N, dans les radicaux nitroxydes, est plutôt difficile; pour cette expérience, on a donc utilisé un mode de cavité TM_{110}. La constante de couplage hyperfin observé pour le ^{14}N, à −80°C, est égale à 11,86 G et elle est l'une des plus faibles valeurs observées à date pour des radicaux nitroxydes.

[Traduit par la revue]

Introduction

Electron nuclear double resonance (ENDOR) is the most useful technique for establishing detailed proton hyperfine coupling constants in complicated electron spin resonance (ESR) spectra (1). The specific relaxation of protons in the ENDOR spectroscopy has been investigated extensively and their ENDOR spectra are well understood on the basis of Freed's theory (2). To obtain more information on the molecular structures of free radicals, the ENDOR method has been extended to nuclei other than protons.

Nitrogen nuclei, for example, sometimes participate in electronic π-system and have large unpaired electron distributions. In addition, the nitrogen nuclei have a quadrupole moment, the parameters of which are sometimes sensitive to the charge distribution on the nitrogen atoms. On the other hand, protons are further away from the electronic π-system, giving indirect information about the π-system. Thus, both ^1H and ^{14}N data are desirable for the discussion of the molecular structures and magnetic properties of radicals.

There are, however, several experimental problems in detecting ENDOR signals of the nuclei other than protons (3). The major difficulty compared to the detection of proton signals is a decreased ENDOR enhancement in such systems, resulting in quite different experimental conditions for optimum ENDOR observations.

ENDOR work on ^{14}N began with the first observation of its signal by Leniart *et al.* in 1970 (4). Since then a number of studies have been published on many kinds of nitroxides or other nitrogen-containing radicals, including a few anion radicals. Recently Janzen *et al.* have reported a conformational study of alkyl and aryl spin adducts using α-phenyl-*N*-*tert*-butylnitrone (PBN), which produces stable nitroxide radicals. They have reviewed work on the various types of nitroxide radicals as studied by ENDOR (5).

In this paper we present ^1H and ^{14}N spectra of *tert*-butylphenylnitroxide (BPNO), which is similar to the spin adducts of PBN. The ENDOR spectra of BPNO were first observed by Ishizu *et al.* (6). The hyperfine coupling constants due to the protons were compared between ESR and ENDOR, and some experimental conditions for optimum ENDOR observations were discussed. However, ^{14}N ENDOR signals could not be detected in their study.

In our experiment, a TM_{110} mode cavity was used, instead of the TE_{011} mode used in the previous work. Möbius *et al.* have developed the TM_{110} mode cavity for an easy access to a triple resonance spectroscopy. Its structure and several advantages were described elsewhere (2). The TM_{110} mode cavity allows one to apply a higher radiofrequency power than the TE_{011} mode one. This advantage was fully utilized for ^{14}N ENDOR observations of di-*tert*-butylnitroxide (DBNO) (7) and for ^1H ENDOR study of some cation radicals (8).

We could observe ^{14}N ENDOR of BPNO among the ^1H lines at the temperature between −20 and −80°C. The observed ^{14}N hyperfine coupling constant A_N = 11.86 G (1 G = 10^{-4} T) at −80°C is among the smaller values found for nitroxide radicals studied to date.

Experimental

Sample

tert-Butylphenylnitroxide was synthesized as follows. Nitrosobenzene and *tert*-butylmagnesium chloride were reacted through the Grignard reaction. *tert*-Butylphenylhydroxylamine thus obtained was oxidized by silver oxide *in vacuo*. Similar preparative methods have been reported elsewhere (9).

ENDOR measurement

The ENDOR spectrometer has been described in detail elsewhere (10). Ethylbenzene was used as solvent and the temperature was varied between −10 and −100°C. Other typical experimental conditions were as follows: microwave power, 70–90 mW, radiofrequency power, 150 W.

General triple resonance (GTR) measurement

In addition to the ENDOR apparatus described in the literature (10), a signal generator (National VP-8179B10) for pumping radiofrequency

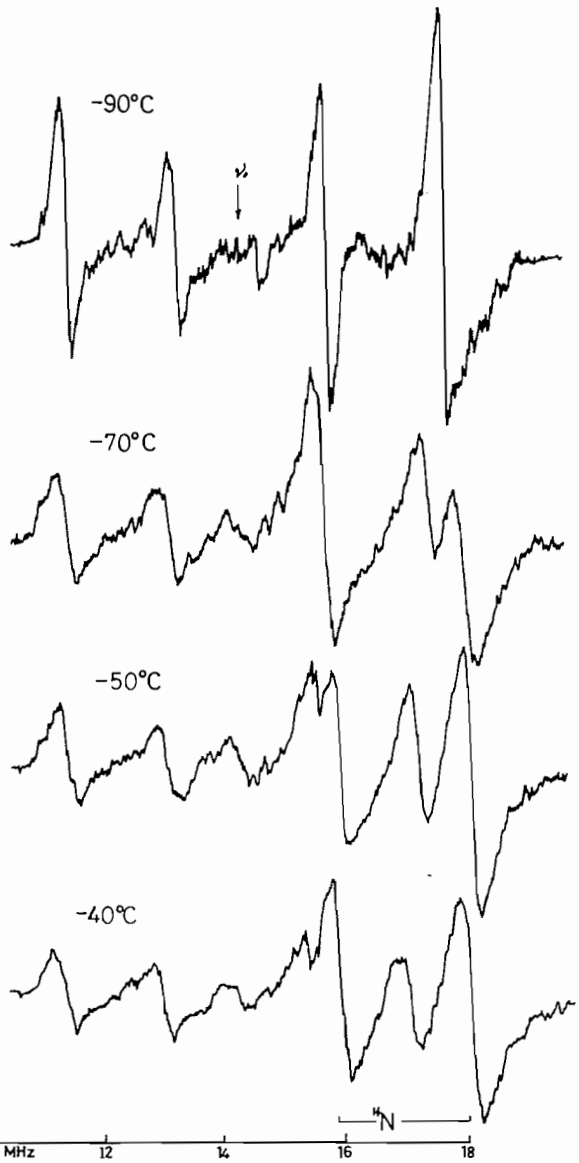

FIG. 1. Temperature-dependent ENDOR spectra of *tert*-butylphenylnitroxide. ν_0 indicates the free proton frequency.

and a power splitter/combiner (Mini Circuit PSC-2-1) for signal mixer were used to determine the signs of the hyperfine coupling constants (11).

Results

The ^1H absorptions were easily observed at the lowest temperature. Even in the higher temperature regions, the ^1H signals were not difficult to detect. ^{14}N lines, however, were sometimes not present and the ENDOR lines of the *tert*-butyl protons appeared as a weaker single line centered at the free proton frequency. ^1H absorptions are essentially similar to those observed by Ishizu *et al.* (6).

The temperature dependence of the ^1H and ^{14}N ENDOR spectra is shown in Fig. 1, indicating overlapped ^1H and ^{14}N signals. At the lowest temperature (−90°C) in Fig. 1, ^{14}N signals can not be identified, but the absorption line of ^1H at the highest frequency is rather broad. On increasing the temperature, a pair of the ^{14}N lines with $2\nu_n$ separation started to appear and grew in intensity in contrast to the decreasing ^1H signals.

The analyzed coupling constants are summarized in Table 1, where the results of molecular orbital (MO) calculations (McLachlan's method) are also listed for comparison. The same MO parameters as in the previous papers (10, 12) were employed. The theoretical hyperfine coupling constants were calculated with the aid of the McConnell relation between the spin density and hyperfine coupling constant, where a proportionality constant of $|Q| = 27.3$ G was used (10).

Discussion

^1H hyperfine coupling constants

According to the MO calculation, the spin density at the *meta*-position is less than half as compared to the *para*- or *ortho*-positions. Therefore, the larger ^1H hyperfine coupling constant is assigned to the *para*- and *ortho*-protons on the phenyl ring. Thus, the agreement between experiment and theory is excellent, although a certain amount of non-planarity was assumed in the MO calculations as discussed later.

It is also predicted by McLachlan's method that the *meta*-position has a negative spin density. This was ascertained by the GTR measurement. Figures 2(*b*) and 2(*c*) show the GTR spectra at −90°C obtained when the ^1H lines were pumped at *b* and *c* depicted in Fig. 2(*a*), respectively. In Fig. 2(*b*) the low frequency absorption of the outer pair lines is enhanced by the pumping, whereas the high frequency absorption of the inner pair lines is increased. On the other hand, the situation is completely reversed in Fig. 2(*c*). These facts imply opposite signs between the protons assigned to the outer and inner pair lines. If one assumes the positive spin density at the *para*- and *ortho*-positions as is predicted by McLachlan's method, a negative sign for the spin density at the *meta*-position can be deduced. Such a negative spin density in nitroxide radicals was first demonstrated for diphenylnitroxide (DPNO) by GTR spectroscopy (11). The positive and negative signs on the two phenyl rings of DPNO are the same as those on the phenyl ring of BPNO.

The relative signs of the hyperfine coupling constants can also be determined by comparing the relative intensity changes within each of the nitrogen and proton doublets as different branches of the nitrogen triplet are saturated. This method is called CRISP (cross relaxation intensity sequence pattern) (5).

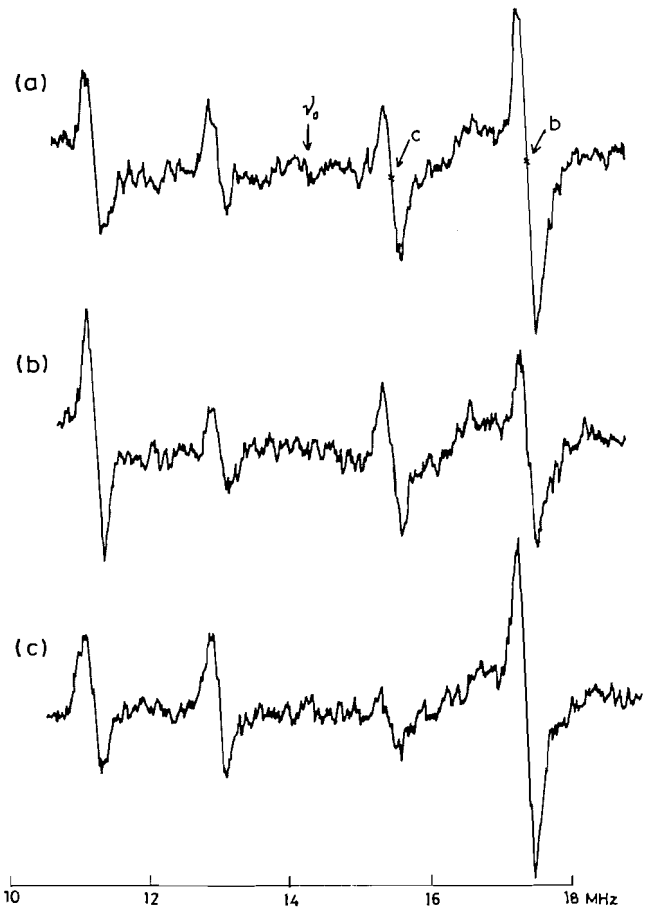

FIG. 2. GTR spectra of *tert*-butylphenylnitroxide at −90°C. The pumping radiofrequency was applied at either *b* or *c*, which is depicted in Fig. 2(*a*).

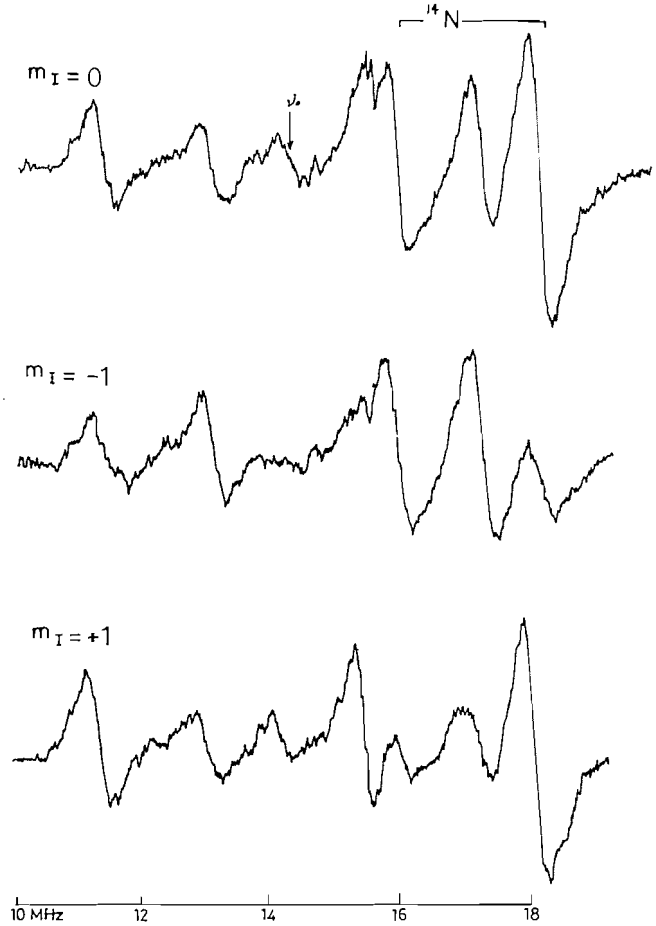

FIG. 3. ENDOR spectral changes by monitoring the ESR of the nitrogen triplet hyperfine lines, $m_I = 0$, $m_I = -1$, and $m_I = +1$. ν_0 indicates the free proton frequency.

Some examples were reported for aminoxyl spin adducts (13) and DBNO (14). From this method the same relative signs as those determined by the GTR measurement are found as shown in Fig. 3. Since those spectra were taken under the optimum conditions for the ^{14}N observation, the ^{1}H signal intensities are rather weak. Nevertheless, these intensity changes are clear. When one compares the intensity changes between $m_I = 0$ and $m_I = -1$ in the two absorption lines of each of the two ^{1}H pairs at the low frequency side, the outer peak decreases, while the inner one increases in the $m_I = 1$ spectrum. These changes actually occur in opposite directions on the ^{1}H counterparts at the high frequency side, although all of these are not necessarily apparent because of the overlapping of the ^{1}H and ^{14}N ENDOR lines in the high frequency region. These experimental data definitely indicate the opposite signs between these two kinds of ^{1}H hyperfine coupling constants.

The CRISP effect should be observed on the *tert*-butyl protons near the free proton frequency. Although the spectra in Fig. 3 are not best resolved for the proton nuclei, the spectral changes of the *tert*-butyl protons are the same as was observed in DBNO (14). Therefore, one can conclude the sign of the *tert*-butyl hyperfine coupling constant is the same as that of the *para*- and *ortho*-protons, that is, negative. This result is compatible with the sign determined from the NMR Knight shift studies which have been carried out for DBNO (15) and nitroxides containing *tert*-butyl group (16). ^{14}N ENDOR spectral dependency on the $m_I = 1, 0$, and -1 will be discussed in the following section.

^{14}N ENDOR spectra

Strong ENDOR lines were observed among the ^{1}H ENDOR lines in rather high temperature regions (Fig. 1). Their intensity reaches a maximum around −50°C, whereas the intensity of the ^{1}H lines still grows even below −90°C as shown in Fig. 4. For detecting optimum ^{14}N ENDOR lines, different experimental conditions were necessary; for example, the lower concentration of the radical solution, the higher radiofrequency power, and the higher temperature. Therefore, in other conditions one may get stronger ^{1}H and weaker ^{14}N lines at the same temperature. In view of these facts, Fig. 4 is not necessarily definitive, but one might conclude that ^{14}N ENDOR lines appear at rather higher temperature than the ^{1}H lines do. This observation would be related to the different anisotropic hyperfine interactions of these nuclei. In general, the calculated ENDOR signal can be expressed by τ_R and $\mathrm{Tr}\{A'^2\}$ on certain assumptions, where τ_R is the rotational correlation time of the molecule and $\mathrm{Tr}\{A'^2\}$ is the trace of the squared anisotropic part of the electron–nuclear dipolar interaction (17). The anisotropic ^{14}N hyperfine interaction $\mathrm{Tr}\{A'^2\}$ for nitroxide radicals such as DPNO is $\mathrm{Tr}\{A'^2\} = 2200\ \mathrm{MHz}^2$ (18), whereas that of the ^{1}H which is attached to the benzene ring is about 30 MHz^2 (18). Therefore, the ^{14}N has larger $\mathrm{Tr}\{A'^2\}$ by at least a factor of 70. This difference explains the behavior in Fig. 4. Here a comment may be necessary for the observation of ^{14}N ENDOR of DBNO (7). Judging from its small molecular size compared to BPNO, DBNO seems to have a short rotational correlation time τ_R

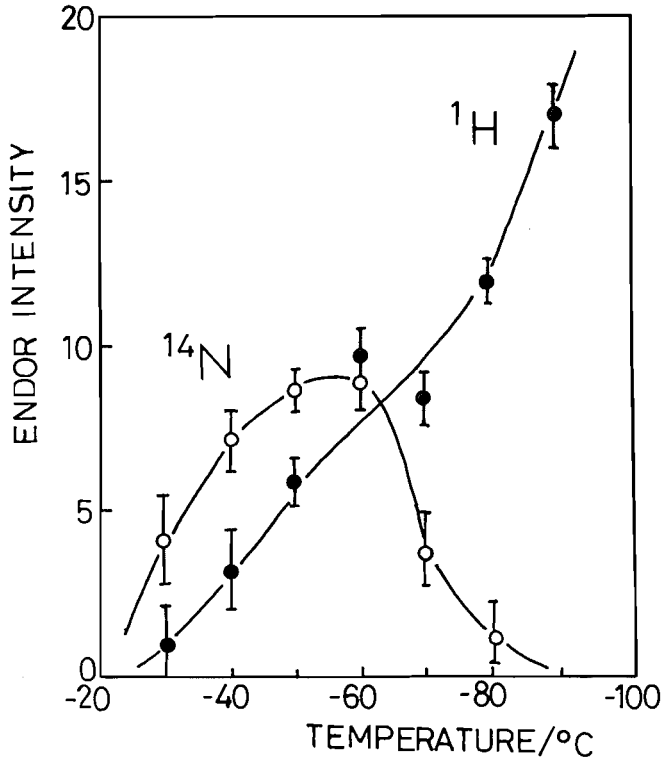

FIG. 4. Temperature dependence of the ENDOR intensities of the ^{1}H and ^{14}N absorption lines.

at a given temperature. Then even though its anisotropic ^{14}N hyperfine coupling constant is the same order, its optimum temperature for the ^{14}N ENDOR will be decreased as is the case of DBNO (7).

Figure 3 shows the spectral change in the ^{14}N ENDOR depending on the ESR monitoring as well as in the ^{1}H ENDOR. For instance, when the ESR line of the ^{14}N spin quantum number $m_I = 1$ (low field line) is saturated, the ^{14}N ENDOR line at the high frequency side is enhanced. In the case of $m_I = -1$ the relative intensity of the ^{14}N lines is also varied. This is the cross relaxation effect which was first pointed out in the first ^{14}N ENDOR observation (4). Furthermore, the detailed analysis of the absorption frequency indicates a slight deviation of the distance between the paired ^{14}N lines from $2\nu_n$, where ν_n is the ^{14}N nuclear magnetic resonance frequency at this ESR magnetic field. In this experiment ν_n was calculated to be 1.022 MHz. When observing the $m_I = -1$ ESR line, the high frequency ENDOR line is shifted up by c, where c is the second order shift of the energy levels due to the ^{14}N hyperfine interaction. For the $m_I = 0$ ESR the distance between the paired ^{14}N ENDOR lines $\Delta\nu$ is equal to $2\nu_n + 2c$, which was found to be 2.156 MHz. The second order shift $c = 0.056$ MHz was obtained, which is compared to the calculated value of 0.059 MHz using the ^{14}N isotropic hyperfine coupling $A_N = 11.86$ G.[1]

The ^{14}N hyperfine coupling constant $A_N = 11.86$ G at -80°C, is among the smaller values found in ENDOR observations of nitroxide radicals. Although the nuclear magnetic moment of ^{14}N is smaller by a factor of 14 than that of ^{1}H, one can observe strong ^{14}N ENDOR intensity. This is due to the enhancement of the radiofrequency at the nucleus over the applied radiofrequency through a large hyperfine interaction between the ^{14}N nucleus and the unpaired electron. In view of this radiofrequency enhancement effect by the hyperfine interaction, the lower the hyperfine coupling constant is, the more difficult its detection becomes. Our observation is, at present, a lower-limit case for the nitroxide radicals. Thus, the easy application of the radiofrequency power in the ENDOR study is indispensable, so that, in the ^{14}N ENDOR observation, the TM_{110} mode cavity seems to have a great advantage over TE type cavities.

There are a few examples of the observation of smaller ^{14}N hyperfine coupling constants in other systems. For example, an electrolytically prepared nitrobenzene anion radical showed ^{14}N ENDOR of $A_N = 9.64$ G (17) and a pyrazine anion radical in liquid ammonia exhibited much smaller value $A_N = 7.25$ G (19). In the neutral free radical, 1,1-diphenyl-2-picrylhydrazyl, $A_N = 7.95$ G was also observed (20). The reason why it is difficult to observe the ^{14}N ENDOR for the nitroxide radicals can not be explained at present. Taking into account that the anisotropic hyperfine interaction $\mathrm{Tr}\{A'^2\}$ is similar, the following situation might be possible; the anion radicals are surrounded by some cation species through a strong electrostatic interaction, resulting in a slow rotational correlation time. Actually ESR saturation was easily achieved for both anion radicals. Furthermore, it seems that, in the case of the nitroxide radicals, the oxygen atom attached to the nitrogen plays a specifically important role in the ENDOR relaxation mechanism.

Steric distortion

The effect of a steric repulsion around the N—O group was discussed and the molecular conformation around the N—O bond was proposed in several nitroxide radicals produced by spin trapping (5, 21). In these cases the conformation of the α and β carbons was deduced. In BPNO the bulky *tert*-butyl group and the phenyl ring are sterically hindered and the coplanarity between the phenyl ring and the N—O group might be influenced. One of the methods considering such a reduced electronic π-system is a MO treatment of the distorted overlap of $2p_z$ π-orbitals on the nitrogen and the carbon atoms connected with each other. This conformational change reduces the population of the unpaired electron on the phenyl ring, implying smaller hyperfine coupling constants. The results in Table 1 were obtained assuming an angle of 30° between the N and C $2p_z$ π-orbitals. These values agree well with the observed ones rather than in non-distorted case. This twist angle of 30° for BPNO seems to be reasonable, if one considers DPNO case where the N—C bond is twisted by 22.5°, that is, two benzene rings have a dihedral angle of 45° (12).

Acknowledgement

The authors express their sincere thanks to Mr. K. Okada for synthesizing the sample and observing the ENDOR and GTR spectra.

Received December 5, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

HIROMITSU KAWADA, YOSHIO MATSUNAGA, TAKUMI TAKAMURA, and MASAHIRO TERADA. Can. J. Chem. **66**, 1867 (1988).

Calorimetric, X-ray diffraction, and broad-line proton nuclear magnetic resonance studies on the thermal behaviour of *N,N'*-dialkanoyl-1,3-benzenediamines carrying one, two, three, and four methyl groups disclosed that the enthalpy change at the transition to an isotropic liquid can be considerably diminished by this substitution and that various mesomorphic states can be obtained by this approach. Thus, the 2-methyl compounds with decanoyl to octadecanoyl groups exhibit hexagonal disordered columnar phases. Furthermore, the enthalpy changes in the 2,4,6-trimethyl compounds with octanoyl to octadecanoyl groups are so much reduced that their mesophases are nematic in type. On the other hand, the viscous birefringent fluids formed by the 4-methyl, 2,4-dimethyl, 4,6-dimethyl, and 2,4,5,6-tetramethyl compounds give X-ray diffraction patterns indicating highly ordered structures.

HIROMITSU KAWADA, YOSHIO MATSUNAGA, TAKUMI TAKAMURA et MASAHIRO TERADA. Can. J. Chem. **66**, 1867 (1988).

Des études par calorimétrie, par diffraction des rayons-X et par résonance magnétique nucléaire du ^1H à bandes larges sur le comportement thermique de *N,N'*-dialcanoyl benzènediamines-1,3 portant un, deux, trois ou quatre groupements méthyles ont montré que le changement d'enthalpie, lors de la transition vers un liquide isotrope, peut diminuer beaucoup par cette substitution et que divers états mésomorphes peuvent ainsi être obtenus. Ainsi, les composés méthyl-2 des groupements allant de décanoyle à octadécanoyle se présentent sous des phases en forme de colonnes hexagonales désordonnées. De plus, les changements d'enthalpies dans les composés triméthyl-2,4,6 des groupements allant d'octanoyle à octadécanoyle sont tellement réduits que leurs mésophases sont du type nématique. Par ailleurs, les fluides visqueux biréfringents, qui sont formés par les composés méthyl-4, diméthyl-2,4, diméthyl-4,6 et tétraméthyl-2,4,5,6, présentent des patrons de diffraction des rayons-X qui indiquent la présence de structures hautement ordonnées.

[Traduit par la revue]

Introduction

As reported in our previous paper, both the substituents $CONHC_nH_{2n+1}$ and $NHCOC_nH_{2n+1}$ are efficient in promoting the thermal stability of mesophases (1). We have examined the thermal behaviour of benzene derivatives carrying the two former substituents and could show that not only the 1,4-derivatives but also the 1,3-analogues are promising as parent compounds in the search for novel mesomorphic derivatives (2). In other words, the compounds in these two series melt with rather small enthalpy changes.

As a first approach towards designing mesomorphic compounds, we introduced an extra $CONHC_nH_{2n+1}$ group to the 5-position in the 1,3-disubstituted benzene molecule. This modification led us to the discovery of novel discogenic compounds: *N,N',N''*-trialkyl-1,3,5-benzenetricarboxamides (2, 3). In this paper, we describe our efforts to obtain mesomorphic compounds by the methyl substitution of *N,N'*-dialkanoyl-1,3-benzenediamine molecules. This substituent is expected to modify the intermolecular cohesion by increasing the intermolecular separation and the molecular polarizability, and to change the anisotropy of the intermolecular forces, which is the primary factor in the formation of liquid crystals.

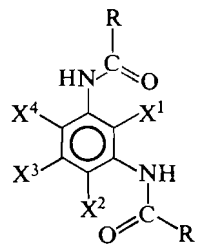
Experimental

Materials

Acyl chlorides, unsubstituted 1,3-benzenediamine, and 2-methyl- and 4-methyl-1,3-benzenediamines were commercially available. 2,4-Dimethyl- and 4,6-dimethyl-1,3-benzenediamines were obtained by the reduction of the precursory dinitro compounds acquired from commercial sources. 1,3-Dinitro-2,4,6-trimethylbenzene was synthesized with good yield by adding mesitylene, drop by drop, to fuming nitric acid cooled in an ice-water bath (4). Tin and hydrochloric acid then were used to prepare 2,4,6-trimethyl-1,3-benzenediamine. Nitration of 1,2,3,4-tetramethylbenzene was carried out following the method proposed by Smith for the preparation of dinitrodurene (5). The product was reduced to the diamine with stannous chloride and concentrated hydrochloric acid. The final step of our synthesis was the acylation of these 1,3-benzendiamines. The results of elemental analysis were in accord with the composition of the desired compounds. For example, *Anal.* calcd. for $C_6H(CH_3)_3(NHCOC_5H_{11})_2$: C 72.79, H 9.89, N 8.08%; found: C 72.79, H 9.85, N 8.06%. *Anal.* calcd. for $C_6(CH_3)_4(NHCOC_{15}H_{31})_2$: C 78.69, H 11.95, N 4.37%; found: C 78.57, H 11.91, N 4.33%.

Measurements

Calorimetric, X-ray, and nmr measurements were made as described in our previous papers (6, 7).



$R = C_nH_{2n+1}$

1: $X^1 = X^2 = X^3 = X^4 = H$
2: $X^1 = CH_3$, $X^2 = X^3 = X^4 = H$
3: $X^1 = H$, $X^2 = CH_3$, $X^3 = X^4 = H$
4: $X^1 = X^2 = CH_3$, $X^3 = X^4 = H$
5: $X^1 = H$, $X^2 = CH_3$, $X^3 = H$, $X^4 = CH_3$
6: $X^1 = X^2 = CH_3$, $X^3 = H$, $X^4 = CH_3$
7: $X^1 = X^2 = X^3 = X^4 = CH_3$

Results

Unsubstituted compounds 1

As summarized in Table 1, these compounds exhibit a solid–solid transition around 100°C and are transformed into isotropic liquids above 130°C. The enthalpy change upon melting ranges from 53 to 81 kJ mol^{-1}. These values are markedly larger than those of the *N,N'*-dialkyl-1,3-benzenedicarboxamides reported before (2). For example, the dodecyl derivative in the latter series melts with an enthalpy change of 36 kJ mol^{-1} and the octadecyl derivative with a change of 54 kJ mol^{-1}. In this sense, the present series does not seem to provide better parent compounds. However, 1,3-benzenediamines carrying various substituents are easily obtainable. If the introduction of such substituents is an effective approach to mesomorphic compounds, compounds **1** may have a great advantage over the *N,N'*-dialkyl-1,3-benzenedicarboxamides.

2-Methyl compounds 2

The thermal properties are presented in Table 2. Here, K, M, and I denote crystal, mesophase, and isotropic liquid, respectively. The enthalpy of melting given by the nonanoyl derivative is 45 kJ mol^{-1} and seems to compare well with those of compounds **1** even though the corresponding homologous member was not examined. However, the melting point is considerably raised by the substitution. When the alkanoyl group is lengthened by a methylene unit, the melting process occurs in two steps. A transition located at 200°C is accompanied by an enthalpy change of 13 kJ mol^{-1}, and the other transition at 205°C by 33 kJ mol^{-1}. The separation between these two transition temperatures is enlarged by the increase in alkyl chain length. When $n = 17$, the high-temperature phase occupies a range as wide as 43°C. In contrast to compounds **1**, the enthalpy change at the transition into an isotropic liquid decreases as the series is ascended. As a result of these different tendencies, the value of the octadecanoyl derivative is merely one third of the corresponding value in series **1** and is small enough that one may consider the high-temperature phase as a mesophase. Indeed, the specimen flows between glass plates if gently pressed. It must be added that the isotropic liquid can be supercooled by 4–9°C.

The X-ray diffraction pattern of the liquid crystals spread in the form of a thin film over an aluminum holder consists of two major peaks. The inner sharp peak gives a spacing that increases linearly from 2.25 nm for the decanoyl derivative to 2.68 nm for the octadecanoyl derivative (see line a in Fig. 1). No peak assignable to the second-order reflection is detectable. The outer peak is diffuse and gives a spacing of 0.46 nm throughout the series. This feature is consistent with both unstructured smectic and hexagonal disordered columnar phases. An examination of the liquid crystals prepared while carefully avoiding the orientational influence of the sample holder revealed the presence of an additional weak peak, the spacing of which is about $1/\sqrt{3}$ times that given by the inner sharp peak. Such a ratio is characteristic of a hexagonal lattice; therefore, the structure must be columnar. The longest spacing is assigned to the first-order 100 reflection and the other one to the 110 reflection. The spacing of 0.46 nm must be the average stacking distance between the molecular planes in a column and is in agreement with those reported for similar discotic phases (7, 8).

As is shown by curve a in Fig. 2, the second moment of the broad-line proton nmr spectrum (the mean-square width of the resonance line), $\langle \Delta H^2 \rangle$, of the octadecanoyl derivative decreases gradually around the melting point of 156°C from about 4.5 to 0.1 G^2 ($G = 10^{-4}$ T). The latter value is of the same

order as those shown by the mesophase of *N,N'*-dialkanoyl-2,3,5,6-tetrakis(alkanoyloxy)-1,4-benzenediamines (7).

4-Methyl compounds 3

The enthalpy change at the transition to an isotropic liquid in this series is essentially the same as that observed for the previous series (see Table 3). It must be noted that the value increases as the alkyl chain length increases. This trend is opposite to that observed in series **2**. Morever, the transition temperature is lower by 43–55°C. The appearance of a mesophase in the process of cooling at a rate of 5 K min^{-1} is delayed by 3–4°C. The endothermic peak overlaps with peak(s) due to solid–solid transition(s); therefore, the total enthalpy changes and the corresponding temperature range are presented in Table 3.

The high-temperature phases found with the decanoyl to octadecanoyl derivatives are viscous fluids. The undecanoyl derivative and higher members give a common X-ray diffraction pattern composed of four sharp and two broad peaks. The sharp peak at the lowest Bragg angle is accompanied by its second- and third-order reflections. The spacing is markedly longer than that shown by the corresponding member in series **2** (see line b in Fig. 1). Two broad peaks that overlap with each other have maxima at 0.42 and 0.46 nm, respectively, regardless of the alkyl chain length. The former peak is relatively narrow compared with the latter. Another somewhat sharper peak, which is not so broad as the aforementioned one, gives a spacing of 0.72–0.73 nm. This spacing is also independent of the alkyl chain length. Thus, the mesophase is certainly more structured than that of compounds **2**. The second moments, which are as large as 0.9 G^2 and are observed just below the clearing point for the decanoyl and octadecanoyl derivatives, are in support of the above conclusion.

2,4-Dimethyl compounds 4

Table 4 gives the transition temperatures and associated enthalpy changes of compounds **4**. The clearing points are a little higher than those of compounds **3**. The isotropic liquids may be supercooled by 3–14°C, when cooled at a rate of 5 K min^{-1}. The enthalpy changes are in the range of 22–29 kJ mol^{-1} and exhibit no marked trend with alkyl chain length. The X-ray diffraction patterns of the undecanoyl derivative and higher members are similar to those described for compounds **3**. The spacing defined by the inner sharp peak is the longest, though the difference is small, among those of the compounds examined (see line c in Fig. 1). The peak is accompanied by its second- and third-order reflections in most cases. The following spacings are independent of the alkyl chain length: 0.38, 0.45, and 0.64 nm. The distance between the molecular cores in a column, 0.38 nm, is only slightly longer than 0.366 nm found in the hexamethylbenzene crystals (9). Therefore, the phase is almost certainly ordered in a column. This proposition is strongly supported by a rather large second moment, 1.5 G^2, measured for the mesophase of the octadecanoyl derivative. Finally, it may be added that the hexanoyl derivative, which shows no additional transition, gives a viscous fluid near 218°C.

4,6-Dimethyl compounds 5

The thermal properties are summarized in Table 5. Both the clearing point and the associated enthalpy change are reduced compared with those of compounds **3**. In particular, the enthalpy change given by the highest homologous member is less than one half that of the corresponding member in the latter series. Nevertheless, the innermost sharp peak in the X-ray diffraction pattern gives a spacing close to that given by

compounds **3**. Its second- and third-order reflections, and broad and sharp peaks giving spacings of 0.46 and 0.82 nm, respectively, are observable for the dodecanoyl derivative and higher members. The absence of a spacing shorter than 0.46 nm suggests that the mesophase is less ordered than those of compounds **3** and **4**. An nmr study on the hexadecanoyl derivative gives a second moment of 0.3 G^2 for the mesophase, as is shown by curve b in Fig. 2. Some eight weak peaks appear in the broad-peak region of the undecanoyl derivative and they become stronger in the lower members. In the case of the octanoyl derivative, the following peaks are detected in the above-mentioned range: 0.36, 0.39, 0.41, 0.45, 0.51, 0.53, 0.57, and 0.75 nm. Thus, the small enthalpy change at the clearing point in the lower members of the present series does not necessarily mean a highly disordered structure of the mesophase.

2,4,6-Trimethyl compounds **6**

The calorimetric data of the trimethyl compounds are given in Table 6. In this series, two kinds of mesophases are found for the octanoyl to dodecanoyl derivatives. They are denoted by M_1 and M_2 in the table. The first mesophase is observed starting with the butyryl derivative. It must be noted that the enthalpy change by the M_1–I or M_1–M_2 transition is much larger than that by the M_2–I transition. Both the former and the latter values decrease as the series is ascended. The M_2–I transition occurs at the same temperature in the processes of heating and cooling, whereas the M_1–M_2 and M_1–I transitions show detectable, often considerable, supercooling. Schlieren texture is adopted by the M_2 phase. This phase is nematic in type as the X-ray diffraction pattern of unoriented specimens consists of two diffuse peaks only. As the mesophases exhibited by the 2-methyl compounds are undoubtedly columnar, the M_2 phase is likely to be nematic discotic. The phase denoted by M_1 gives a diffraction pattern composed of a number of sharp peaks. The longest spacings in this phase for the butyryl to dodecanoyl derivatives are in the range given by the relatively less-disordered phases (see line b in Fig. 1). The second moment of the decanoyl derivative decreases from about 7 to 1.5 G^2 at the melting point and from the latter value to about 0.01 G^2 at the M_1–M_2 transition temperature. The value shown by the M_2 phase is only one tenth of the moment observed for the hexagonal disordered columnar phase of compounds **2** (compare curves a and c in Fig. 2).

2,4,5,6-Tetramethyl compounds **7**

A mesophase is exhibited by the hexanoyl to hexadecanoyl derivatives. The temperature range is 83–85°C for these end members but 121°C for the nonanoyl derivative. As is seen in Table 7, the enthalpy change at the clearing point is as large as those given by compounds **3**, **4**, and **5**. The values exhibit a minimum around the undecanoyl and dodecanoyl derivatives. It may be noted that the enthalpy change at the melting point is markedly smaller than that at the clearing point.

The X-ray diffraction pattern recorded for the mesophase of the hexadecanoyl derivative shows a sharp peak, giving a spacing of 3.51 nm and its second- and third-order reflections. Rather sharp peaks with spacings of 0.40, 0.45, and 0.74 nm, respectively, are located on a broad peak, the maximum of which is near 0.46 nm. Consequently, the whole pattern bears a close similarity to those of the mesophases exhibited by compounds **3**, **4**, **5**, and **6**. Moreover, the longest spacings given by the corresponding members in these series, except **4**, almost agree with each other, as is shown by line b in Fig. 1. The diffraction pattern becomes more complicated as the series is descended. Namely, a few extra peaks are detected between 0.46 and 0.73 nm for the decanoyl derivative and the lower members. A drop of the second moment from about 5.5 to 2.0 G^2 is observed at the melting point of the tetradecanoyl derivative.

Discussion

As mentioned earlier, substituents may produce opposing effects on the intermolecular cohesion. Moreover, these effects may be susceptible to interaction between the substituents, especially when the intramolecular crowding is extensive. Naturally, the effect on the thermal properties of the introduction of a single methyl group into the *N,N'*-dialkanoyl-1,3-benzenediamine molecule is quite large. In particular, the group at the 2-position is so effective that the resulting phase is disordered columnar. This finding indicates that a hexagonal phase may be formed by changing the molecular orientation around the columnar axis even if the molecular shape is virtually that of *m*-disubstituted benzene. The spacing d_{100} is a little longer than that found for the similar phase of *N,N'*-dialkanoyl-2,3,5,6-tetrakis(alkanoyloxy)-1,4-benzenediamine described in our previous paper (7). For example, the tetradecanoyl derivative in the present series gives 2.48 nm and the corresponding member in the hexasubstituted benzene series gives 2.29 nm. Therefore, the chains in compounds **2** are less disordered. The difference is clearly manifested by the thermal properties and broad-line proton nmr spectra of the mesophases. While the hexadecanoyl derivative in the series **2** gives an enthalpy change at the clearing point of 28 kJ mol^{-1}, the corresponding hexasubstituted benzene gives a change of 18 kJ mol^{-1}. Furthermore, the octadecanoyl derivative exhibits a moment three times that given by the hexadecanoyl derivative in the latter series.

The general features of the X-ray diffraction pattern given by the 4-methyl compounds bear some resemblance to that reported by Levelut for the hexagonal ordered columnar phase of hexakis(pentyloxy)triphenylene (10). In addition to the reflections related to the distance between the neighboring columns, the following three were noted by Levelut: 0.359, 0.45, and 1.3 nm. The first spacing was assigned to the distance between the parallel molecules in a column, the second to the mean distance between the alkyl chains in the liquid-like order, and the last to the pitch of the helicoidal stacking of the molecular cores. In the present compounds, the spacing of 0.42 nm seems too long to be the well-defined distance between the parallel molecules in a column. As is suggested by the diffuseness of the peak, the stacking may be, to some extent, disordered. The pattern of compounds **3** has no reflection comparable with 1.3 nm but it shows a spacing of 0.72–0.73 nm. On the basis of the above observations, one might say that the 4-methyl group is less effective in producing mesophase than the 2-methyl group; however, this is true only for the monomethyl compounds.

The change in mesomorphic behaviour by introduction of an additional methyl group to the 2-methyl compound is striking. The X-ray diffraction pattern and the second moment indicate an increase of order in the structure of the mesophase. On the other hand, the mesophase of the 4,6-dimethyl compounds is less ordered than that of the 4-methyl compounds. Summing up all the available evidence, the mesophases of the above-mentioned four series may be in various stages between hexagonal disordered and ordered columnar structures and appear to be disordered in the following order: 2-methyl > 4,6-dimethyl > 4-methyl > 2,4-dimethyl.

Since the 2-methyl and 4-methyl compounds are displaced in the above order by the introduction of the second methyl group, the thermal behaviour of the 2,4,6-trimethyl compounds does not seem predictable. As a matter of fact, the M_1 phases observed with the dodecanoyl derivative and the lower members are as structured as the mesophases of the corresponding 4-methyl compounds. On the other hand, the M_2 phases exhibited by the octanoyl derivative and the higher members are nematic. The presence of four methyl groups in a molecule is not favourable to the formation of a highly disordered mesophase, as evidenced by the spacing as short as 0.40 nm and the second moment as large as 2 G^2.

Methyl-substituted *N,N'*-dialkanoyl-1,2- and -1,4-benzenediamines have been also studied in our laboratory and will be the subjects of the forthcoming papers.

Cation mobility in gaseous, critical, and liquid deuterated methanes

M. Antonio Floriano, Norman Gee, and Gordon R. Freeman
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 28, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

M. Antonio Floriano, Norman Gee, and Gordon R. Freeman. Can. J. Chem. **66**, 1872 (1988).

Cation mobilities μ have been measured in the deuterated methanes CH_xD_{4-x} (x = 0–4) at field strengths $E/n < 4 \times 10^{-21}$ V m^2/molecule, $92 \leq T/K \leq 598$ and $0.025 \leq n/10^{26}$ molecules m$^{-3} \leq 171$. The mobility in the equilibrium fluids was the same at a given number density n for all five methanes. In the liquid the mobility decreased as the critical region was approached. Changes in $n\mu$ in the nonsaturated gases reflected changes in clustering, which was favored at lower T or higher n. The Arrhenius temperature coefficients of ion mobilities at constant gas density near the vapor/liquid coexistence curve nearly equalled those of electron mobilities at similar experimental conditions. The ion mobility in the saturated gas was determined mainly by density and in the liquid by the viscosity.

M. Antonio Floriano, Norman Gee et Gordon R. Freeman. Can. J. Chem. **66**, 1872 (1988).

On a mesuré les mobilités (μ) des cations dans les méthanes deutérés (CH_xD_{4-x}) (x = 0 à 4), à des forces de champs (E/n) < 4×10^{-21} V m^2/molécule, $92 \leq T$ (K) ≤ 598 et $0{,}025 \leq n$ (10^{26} molécules m^{-3}) ≤ 171. Pour chacun des cinq méthanes et pour une densité donnée, on observe toujours la même mobilité dans les fluides en équilibre. Dans le liquide, la mobilité diminue lorsqu'on approche de la région critique. Les changements observés dans les $n\mu$ des gaz qui ne sont pas saturés sont le reflet de changements dans la formation d'agrégats; ces formations sont favorisées par l'abaissement de T ou l'augmentation de n. Les coefficients de température d'Arrhénius pour les mobilités ioniques à densité de gaz constante, près de la courbe de coexistence vapeur/liquide, sont presqu'égaux à ceux des mobilités électroniques dans des conditions semblables. Pour expliquer la mobilité ionique dans le gaz saturé, on a principalement fait appel à la densité alors que la viscosité a été utilisées dans le liquide.

[Traduit par la revue]

Introduction

Cation transport in hydrocarbon fluids undergoes a mechanism transition as the fluid density is decreased from that of a normal liquid, through the critical fluid, to that of a normal gas (1–3). In normal liquids the mobility μ is determined by the fluid viscosity η and in normal gases at densities $n <$ 10^{26} molecule/m^3 by n. A transition from viscosity to density control occurred at $0.6 \lesssim \eta/\eta_c \lesssim 3$ corresponding to $0.5 \lesssim$ $n/n_c \lesssim 1.9$ (subscript c denotes critical fluid property). In this work we extend our study of cation transport to the series of deuterated methanes CH_xD_{4-x} at densities $0.01 \leq$ $n/10^{27}$ molecule m$^{-3} \leq 17$.

Experimental

The suppliers, chemical and isotopic purities, and further purification of the deuterated methanes are given in ref. 4. A schematic of the cooling (4) and heating (5) set ups, and of the low pressure gas (5), dense gas (6) and liquid (7) conductance cells are given in the cited references. In the near critical region some measurements were obtained with the modified high pressure cell described in ref. 5. The separations l between the electrodes were measured to ± 0.01 mm.

Physical properties of the fluids and sources for them are listed in ref. 4. Determination of the fluid density is described in ref. 8. Along the coexistence curve the density was obtained from the measured temperature, using literature tables of density against temperature (9–11). The tables were for CH_4 and CD_4, but when plotted as n against T/T_c the two sets agreed within 0.8% (4), so we assumed that n of CH_3D, CH_2D_2, and CHD_3 would be the same as in CH_4 and CD_4 at the same T/T_c. Thermocouples used to monitor the temperature at three or four points at the top, plate area and bottom of the cells had been calibrated to 0.1 K at $T <$ 373 K (8). The reliability of the recorded temperature was determined by the spread between thermocouple readings, <0.1 K at room temperature and at near T_c, and $< \pm 0.025$ K elsewhere. Outside the calibrated range the spread in thermocouple readings was less than the manufacturer's stated uncertainty for uncalibrated type t special thermocouples. This uncertainty, ± 0.5 K at 450 K increasing to ± 1.2 K at 550 K (12), set the uncertainty limit in recorded T at $T >$ 373 K.

The generation of the cations with a 100 or 300 ns pulse of X-rays from a van de Graaff accelerator, a signal amplifier, data collection procedure, and an example current–time signal are described in ref. 3*a*. The initial spike in the current–time signal corresponds to electrons, which have mobilities $\sim 10^4$ times larger than those of the ions and are removed first. The samples had been purified to study electron mobilities, so capture by impurities to form negative ions was negligible (4, 8). The signal ramp therefore corresponded to cations.

At each applied voltage V the time required for the radiation-induced current to decay linearly back to the baseline was determined (Fig. 1 of ref. 3*a*) to give the drift time t_d. The mobility was then obtained from $\mu = l^2/t_dV$. Both positive and negative applied voltages were used and the results averaged to give μ at V.

Results and discussion

A. Field independence

The mobility was measured typically at fields $0.01 < E/n$ (Td) < 0.1 in the liquids and $0.1 < E/n$ (Td) < 1 in the gases (Td = 10^{-21} V m^2/molecule). Some values in the liquid phase were measured at E/n as low as 0.002 Td and some gas phase μ values were measured at E/n up to 28 Td. No field dependence was found. The value of μ reported at each (n,T) in Figs. 1 and 2 was the average of >10 measurements, half with positive and half with negative applied polarity; the average deviation of the measured values from the reported μ at V (Figs. 1, 2) was <2%.

The mobility was constant up to 28 Td because these fields were less than the threshold $(E/n)_{thr}$ required to heat the cation energy distribution. In gases two conditions have been used to define $(E/n)_{thr}$: the field where (*a*) the cation drift velocity $v_d \equiv \mu \times E$ approaches v_{mol} the random velocity of the molecules (13*a*, 14); (*b*) v_d approaches c_0 the speed of sound in the fluid (15). These conditions apply to electrons as well as cations (14, 16) and give

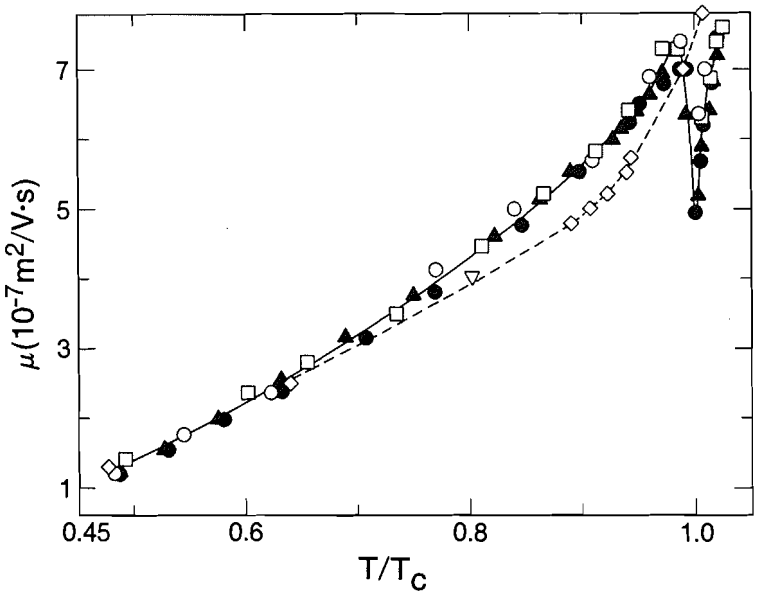

FIG. 1. Cation mobility as a function of reduced temperature T/T_c in liquids and supercritical fluids of (symbol, T_c/K (4)): CH_4 (○, ◇, 190.6), CH_2D_2 (□, 189.2), CHD_3 (▲, 189.0), CD_4 (●, 189.2). Present work except ◇ (1*a*). Lines are visual guides.

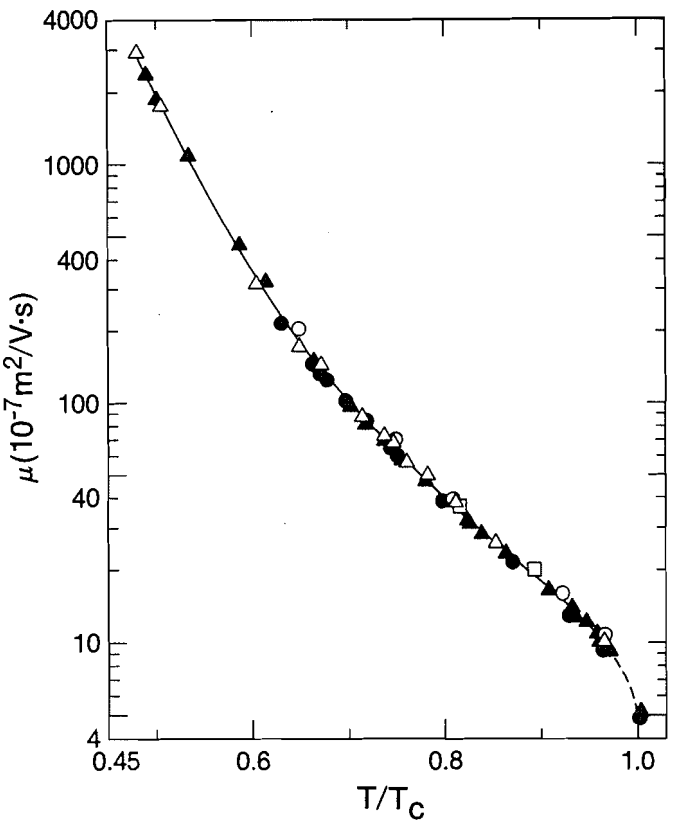

FIG. 2. Cation mobility in saturated vapors as a function of temperature T/T_c. Symbols as Fig. 1, with CH_3D (△, T_c = 191.1 K).

[1] $(E/n)_{thr} = v_{mol}/n\mu$

or

[2] $(E/n)_{thr} = c_0/n\mu$

The two limits are nearly the same in gases (3*b*, 13). For example, in the hydrocarbon series ethane to *n*-decane, $c_0 \approx 0.7\, v_{mol}$ (3*b*). Using n and c_0 from ref. 11, eq. [2] indicates that $(E/n)_{thr}$ would be 94 Td in CH_4 gas (Fig. 2) at $T/T_c = 0.648$ ($n = 1.54 \times 10^{26}$ molecules/m^3, $c_0 = 296$ m/s). Likewise in CH_4 liquid (Fig. 1) at $T/T_c = 0.987$ (8.6×10^{27} molecules/m^3, 324 m/s) $(E/n)_{thr} = 51$ Td, and at $T/T_c = 0.483$ (17.0×10^{27} molecules/m^3, 1510 m/s) $(E/n)_{thr} = 740$ Td. As c_0 in the other CH_xD_{4-x} would only differ from c_0 in CH_4 by the ratio of square root of the molecular masses, $(E/n)_{thr}$ in all of these methanes would be similar at the same T/T_c. Hence the μ values in Figs. 1 and 2 were all obtained at $E/n \ll (E/n)_{thr}$ and are those of thermal cations.

B. Effect of temperature in nonsaturated gases

In gases at low n and very low ion mole fraction, $n\mu$ at a given T is independent of n (13*b*). Thus the temperature coefficient of $n\mu$ is also independent of n at low n (Fig. 3). At high n the temperature coefficient increases (Fig. 3) and the value of $n\mu$ at a given T decreases at low T (Fig. 4). At ~100 K the upper limit of density independence in methane is $n \approx 6 \times 10^{25}$ molecules/m^3 (Fig. 3), which is larger than the limits for larger alkanes at a similar temperature (3*b*).

In methane radiolysis the initial ions are mainly CH_4^+ and CH_3^+ which rapidly react at $n \approx 10^{24}$ molecules/m^3 to form other ions, mainly CH_5^+ and $C_3H_7^+$ (17–19). At higher densities the ions can cluster, for example (17*a*)

[3] $CH_5^+ + CH_4 \rightleftharpoons CH_5^+(CH_4)$

[4] $CH_5^+(CH_4)_{m-1} + CH_4 \rightleftharpoons CH_5^+(CH_4)_m$

The extent of clustering is temperature dependent, with equilibrium constants represented by

[5] $$K_{eq,m} = \frac{[CH_5^+(CH_4)_m]}{[CH_5^+(CH_4)_{m-1}][CH_4]}$$

Using values of the equilibrium constants from ref. 17*a*, we estimate that at $n = 3 \times 10^{25}$ molecules/m^3 the dominant value of m is 5 at 100 K, 2 at 200 K, 1 at 300 K, and zero (unclustered) at $T > 500$ K. The $C_3H_7^+$ likewise clusters with CH_4 molecules,

For personal use only.

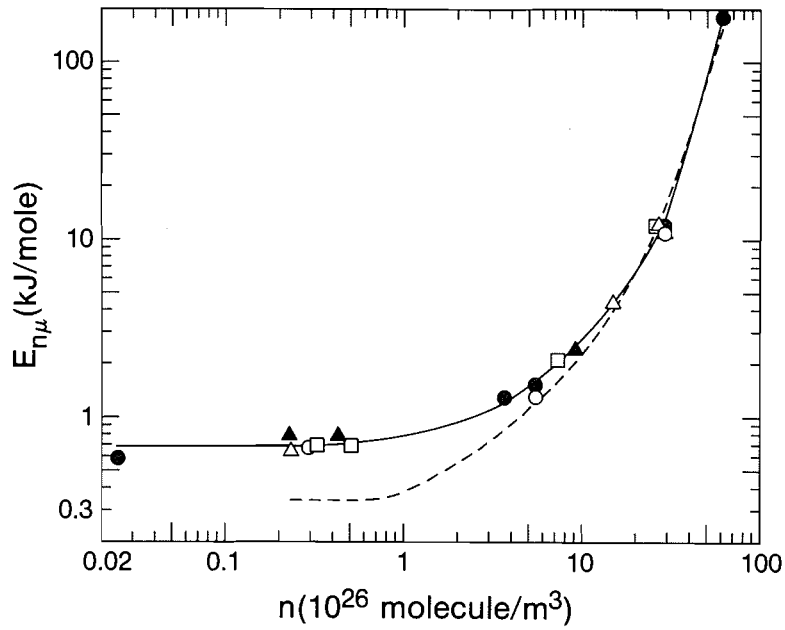

FIG. 3. Arrhenius temperature coefficients $E_{n\mu}$ (eq. [8]) near the vapor/liquid coexistence region. Symbols as in Figs. 1 and 2. The solid line is empirical. The dashed line represents $E_{n\mu}$ for electron mobilities measured at similar conditions, ref. 8.

although to a smaller extent than CH_5^+ (17). The decrease of $n\mu$ with increasing n at a given T (Fig. 4) is attributed to clustering about the ions.

The value of $n\mu$ is related to the average ion–molecule momentum transfer cross section σ_{av} (20):

$$[6] \quad n\mu = \frac{3e}{4M_r\langle v\rangle\sigma_{av}}$$

where M_r is the ion–molecule reduced mass, e is the protonic charge, $\langle v\rangle$ is the average velocity of the ions relative to the molecules and for a Maxwellian distribution (thermal ions) is $(8k_BT/\pi M_r)^{1/2}$, where k_B is Boltzmann's constant. Equation [6] is derivable from eq. [5-3-8] of ref. 13*c*. Clustering increases both M_r and σ_{av}, so $n\mu$ decreases.

At 300 K $n\mu$ of CH_5^+ in CH_4 was $(6.7 \pm 0.5)10^{21}$ molecules/m V s, and of $C_3H_7^+$ was $(6.1 \pm 0.7)10^{21}$ molecules/m V s (19). For two ions at the same temperature, eq. [6] gives

$$[7] \quad (n\mu)_2 = (n\mu)_1[(M_r)_1/(M_r)_2]^{1/2}[(\sigma_{av})_1/\sigma_{av})_2]$$

Assuming σ_{av} of $CH_5^+(CH_4)$ in CH_4 was similar to or greater than that of CH_5^+, $n\mu[CH_5^+(CH_4)] \leq (0.87 \times 6.7 \pm 0.5)10^{21} = (5.8 \times 0.5)10^{21}$ molecules/m V s. Our $n\mu = 5.4 \times 10^{21}$ at 2.95×10^{25} molecules/m^3 (Fig. 4) is hence consistent with the cations being a mixture of $C_3H_7^+$ and $CH_5^+(CH_4)$.

At lower temperatures and higher densities the cations in CH_4 became further clustered and $n\mu$ decreased. At 180 K increased clustering occurred at $n > 1 \times 10^{26}$ molecules/m^3. At low T and high n, the temperature dependence of $n\mu$ at constant n was large. In terms of an Arrhenius model,

$$[8] \quad n\mu = A \exp(-E_{n\mu}/k_BT)$$

where A is the pre-exponential factor. The temperature coefficient $E_{n\mu}$ near the vapor/liquid coexistence region was 1.3 kJ/mol at 5.5×10^{26} molecules/m^3, and 11 kJ/mol at 2.9×10^{27} molecule/m^3. The low density limit of $E_{n\mu}$ displayed in Fig. 3 does

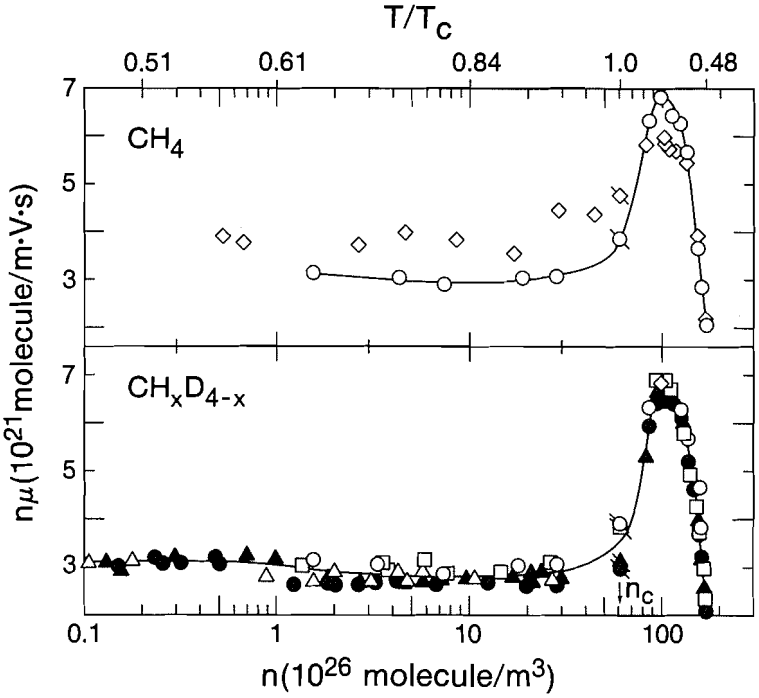

FIG. 5. Density-normalized mobility as functions of density and T/T_c. Symbols as in Figs. 1 and 2. ◇, T_c + 1.4 K; ○, T_c + 0.6 K; □, T_c + 1.3 K; ▲, T_c + 0.5 K; ●, T_c + 0.1 K. T_c = 190.6 K for CH_4.

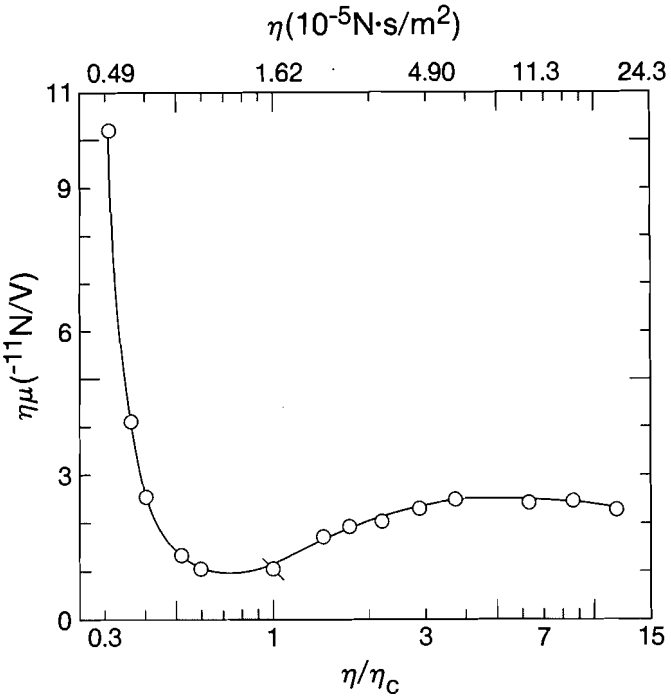

FIG. 6. Viscosity normalized mobility as a function of η/η_c in CH_4. ○, $\eta\mu$ at T_c + 0.6 K. $\eta_c = (1.62 \pm 0.03) \times 10^{-5}$ N s/m^2, refs. 21 and 22.

not correspond to an Arrhenius activation process and is merely shown for comparison with the temperature coefficients at higher densities. At the lowest densities the temperature coefficient of $n\mu$ corresponds to the velocity dependence of σ_{av} and the temperature dependence of $\langle v \rangle$.

The values of $n\mu$ and their temperature and density dependences in the deuterated methanes (Fig. 4*b–e*) were similar to those in CH_4 (Fig. 4*a*). Presumably the cations in the deuterated methanes are clustered like those in CH_4. The difference between $n\mu$ at different n was smaller at higher T, but at n_c the value of $n\mu$ increased above that at lower n. Arrhenius energies determined from [8] fall on a single curve (Fig. 3). Furthermore, at $>10^{26}$ molecules/m^3 these $E_{n\mu}$ values are similar to those obtained from electron mobilities and eq. [8] (8). The fluid compressibility and density fluctuations decrease as the gases are heated away from the liquid coexistence region; this affects the cation and electron mobilities in a similar way.

C. Saturated fluids

The effect of temperature on μ in the saturated fluids (Figs. 1 and 2) can be explained as previously (1–3): in the gas the mobility is dominated by density and in the liquid by viscosity.

The density effect is shown in Fig. 5. Earlier values for CH_4 (1*b*) indicated a smaller density dependence (top portion of Fig. 5), perhaps due to temperature inhomogeneities in the sample. Part of the difference might also be due to the different method used to obtain the time of flight t_d.

The values of $n\mu$ are the same, within the experimental uncertainty, in all the isotopic isomers of methane (Fig. 5, lower portion). At $n < 1 \times 10^{26}$ molecules/m^3, $n\mu$ is constant. At $n > 1 \times 10^{26}$ molecules/m^3, $n\mu$ decreases slightly due to increased clustering, then at $n > 50 \times 10^{26}$ molecules/m^3 $n\mu$ increases due to destructive interference of the long range interactions of the cation with more than one molecule at a time (2). At $n > 100 \times 10^{26}$ molecules/m^3, $n\mu$ decreases due to transition into the viscosity limited regime of transport.

A plot of the mobility normalized for the fluid viscosity, $\eta\mu$, against reduced viscosity η/η_c displays a nearly constant value of $\eta\mu$ at $\eta/\eta_c \geq 2$ (Fig. 6; liquid η ref. 23, gas ref. 22, η_c refs. 21 and 22). This is the viscosity limited regime; $n = 100 \times 10^{26}$ molecules/m^3 for the liquid under its vapor pressure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

corresponds to $\eta/\eta_c = 1.73$. The rapid increase of $\eta\mu$ at $\eta/\eta_c < 0.5$ corresponds to the density-limited regime of transport. The transition region is $0.5 < \eta/\eta_c < 1.7$, which corresponds to $0.2 < n/n_c < 1.7$. The behavior is similar for cations in other hydrocarbon gases and liquids, including ethene, ethane, and *n*-hexane (1*b*).

In the viscosity-limited regime the effective Stokes' radius R_s of the ions is

$$[9] \quad R_s = e/6\pi\eta\mu = 8.5 \times 10^{-21}/\eta\mu \quad \text{in SI}$$

For methane ions in methane, $\eta\mu \approx 2.4 \times 10^{-11}$ N/V at $3 \leq \eta/\eta_c \leq 12$, which corresponds to $R_s = 3.5 \times 10^{-10}$ m. This is nearly twice the molecular radius 2.0×10^{-10} m obtained from gas phase viscosity and diffusion measurements (24). The greater effective radius of the ion for transport is due to the attractive charge-induced–dipole interaction and the resulting electrostriction of the fluid about the ion.

At $\eta/\eta_c \gtrsim 10$ there is a tendancy for $\eta\mu$ to decrease slightly (1*b*). This decrease might be the source of discrepancy between earlier reports that cation mobility in liquid alkanes varies as η^{-x} with $x = 1.5$ (25) or 1.2 ± 0.1 (7). The reported value of x would depend on the range of η/η_c investigated (1).

Received December 14, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

C. E. BRION, A. O. BAWAGAN, and K. H. TAN. Can. J. Chem. **66**, 1877 (1988).

High-resolution, magic angle photoelectron spectra have been obtained for the Ar 3*s* and Xe 5*s* inner-valence regions using photon energies in the range 60–170 eV. Measurements were made using monochromatized synchrotron radiation from the Canadian Synchrotron Radiation Facility at the new 1-GeV storage ring at the University of Wisconsin. The binding energy spectra show detailed and complex structures due to electron correlation (many-body) effects. Relative satellite intensities are compared with the results of recent configuration-interaction calculations. Additional binding energy spectra obtained at much higher resolution (0.16 eV fwhm) than any previous published work show extremely detailed satellite structure consistent with information from recent high resolution fluorescence studies for argon. The newly revealed satellite structure provides further insight into existing differences between calculated and measured satellite intensities. In the case of the Ar 3*s* spectrum, very close agreement is predicted between the measured intensities and those calculated by CI methods when the previously unresolved satellite structure is taken into account. These new spectral observations also provide information and perspective relevant to recent controversies in the literature concerning intensities and mechanisms in photoelectron and electron momentum spectroscopies.

C. E. BRION, A. O. BAWAGAN et K. H. TAN. Can. J. Chem. **66**, 1877 (1988).

Utilisant des énergies photoniques allant de 60 à 170 eV, on a déterminé les spectres photoélectroniques à haute résolution, à l'angle magique, des régions de valence interne 3*s* du Ar et 5*s* du Xe. On a effectué les mesures à l'aide d'une radiation synchrotron monochromatique provenant du laboratoire canadien de radiation synchrotron installé dans l'anneau d'emmagasinage de 1 GeV, à l'Université du Wisconsin. Les spectres d'énergie de liaison présentent des structures détaillées et complexes à cause des effets de corrélation électronique (à plusieurs corps). On a comparé les intensités relatives des satellites avec les résultats de calculs récents relatifs aux interactions de configuration. Des spectres additionnels d'énergie de liaison, obtenus à une résolution beaucoup plus grande (0,16 eV fwhm) que celles utilisées antérieurement, présentent une structure satellite extrêmement détaillée qui est en accord avec l'information obtenue à partir d'études récentes de fluorescence à haute résolution effectuées sur l'argon. La nouvelle structure satellite observée fournit une connaissance plus profonde sur les différences qui existent entre les intensités satellites calculées et mesurées. Dans le cas du spectre du Ar 3*s*, alors qu'on prend en considération la structure satellite qui n'avait pas été résolue antérieurement, on observe une excellente corrélation entre les intensités mesurées et celles calculées par les méthodes des IC. Ces nouvelles observations spectrales fournissent aussi de l'information et une perspective qui présentent de l'intérêt en relation avec les récentes controverses qui ont surgies dans la littérature concernant les intensités et les mécanismes des spectroscopies photoélectronique et du moment électronique.

[Traduit par la revue]

Introduction

Photoelectron spectroscopy (PES) using vacuum ultraviolet radiation has provided detailed insight into valence-shell photoionization processes and the electronic structure of free atoms and molecules. Early HeI PES studies of the outer-valence *np* photoionization of the noble gases by Al-Joboury and Turner (1, 2), and also the elegant photoelectron studies of Ar, Kr, and Xe by Frost, McDowell, and Vroom (3), using a spherical grid retarding spectrometer were seminal in the rise and development of ultraviolet PES. Today PES is a precise tool not only for the study of fundamental processes in photoionization, but also for the investigation of electron correlation effects as well as the detailed evaluation of quantum mechanical calculations of ionization energies and cross-sections. *Outer-valence* (*np*) photoionization of noble gases is well described by a single-particle (independent-particle) model, i.e., electron-correlation effects do not appear to play a major role in the ionization process. As such, *np* photoionization results in a single process in which the only splitting in the PES spectrum of each noble gas is the doublet ($^2P_{3/2,1/2}$) due to spin–orbit interaction (1–3).

In contrast to the situation for the outer-valence region of noble gases and other species, it is now increasingly well known that ionization of *inner-valence* electrons in many atoms and molecules is, in most cases, accompanied by significant many-body (electron-correlation) effects, leading to extensive splitting of the ionization strength into a manifold consisting of many final ion states (satellites). In simple terms, this means that (outside of spin–orbit effects) there is often more than one peak per orbital in the binding energy spectrum, particularly in the inner-valence region. In this situation it is obvious that spectral interpretations based on simple (i.e., independent particle) atomic or molecular orbital theory will be erroneous. Early experiments using binary (e,2e) spectroscopy (4) and X-ray photoelectron spectroscopy (XPS) (5, 6) at modest energy resolution clearly showed the existence of such satellite structures in the inner-valence (*ns*) ionization spectra of noble gases. Similar early experimental observations reported for

molecules using binary (e, 2e) (now usually referred to as EMS or Electron Momentum Spectroscopy) (7–9) and dipole (e, 2e) spectroscopy (7, 10, 11) were supported by the many-body Green's function calculations of Cederbaum and co-workers (12–14).

The more detailed investigation of the inner-valence binding energy region by photoelectron spectroscopy at high resolution remained largely uninvestigated from an experimental standpoint for a long time, since it is energetically inaccessible using HeI radiation (21.22 eV). This situation has changed over the past decade with the growing availability of monochromatized synchrotron radiation, which provides light of tunable energy throughout the vacuum UV and soft X-ray regions of the electromagnetic spectrum (10 eV up to at least several hundred eV, depending on the monochromator). In particular, the energies and intensities of the rich satellite structure resulting from the photoionization of the inner-valence (*ns*) electrons in the noble gases should provide, in principle, a precise and detailed "test-bed" for quantum mechanical treatments of the role of electron-correlation effects in photoionization processes.

The earlier observations of satellite structures in the *ns* ionization spectra of the noble gases were followed in the period up to early 1986 by further photon (15–20) and electron (21–24) impact experiments at generally rather modest energy resolution, as well as a series of theoretical investigations (25–37) (for a discussion of these and other relevant studies, see refs. 19 and 20). As a result of the different findings and conclusions in these various experimental and theoretical studies, a growing controversy developed in the period up to mid-1986. Sharp differences of opinion and interpretation were published (19, 20, 25, 27, 28–31, 36, 38) with particular regard to the various different observed and calculated satellite intensity distributions as well as the comparison between PES and EMS mechanisms (39, 40), particularly in the case of the Ar 3*s* spectrum. Further experimental and theoretical debate on this issue has continued up to the present date (41–47). It became increasingly clear that much of the controversy and confusion was probably arising because of the likely existence of many unresolved satellite lines belonging to different symmetry manifolds in the respective Ar 3*s* and Xe 5*s* spectra. Since all experiments up to early 1986 were carried out at low and often rather different energy resolutions, the presence of any such unresolved satellites could well be a major contributing reason for the different spectral envelopes observed in the various published results. In addition, when comparing the results of these various experiments with theory, the fact that in most cases the calculations only include the major symmetry manifolds and, more importantly, are "resolutionless" was generally overlooked by most authors, although some consideration of the effects of resolution on spectral envelopes and interpreted peak heights was given in our earlier publications (20, 41).

In mid-1986 we obtained significantly higher-resolution PES spectra for Ar 3*s* and Xe 5*s* photoionization (42) by taking advantage of the higher photon flux available on the Canadian Synchrotron Radiation Facility (CSRF) at the new 1-GeV Storage Ring (formerly known as ALADDIN) at the University of Wisconsin. These results show many more satellite lines than had been resolved in any of the earlier-reported spectra (5, 6, 15–24). A preliminary communication of the new high-resolution Ar 3*s* results, including a comparison with measurements by XPS and electron momentum spectroscopy, has recently been published (41). Concurrently, Schmidt and co-workers in West Germany (43, 44) reported Ar 3*s* PES spectra of similar quality. We now report full details of the energies and intensities in these high-resolution binding energy spectra for Ar 3*s*, as well as similar results for Xe 5*s* photoionization. A comparison is also made with calculated satellite intensities (25–33, 37, 44, 45) as well as with very recent Al Kα XPS studies of Ar 3*s* (46). In addition, we make an initial report of new Ar 3*s* and Xe 5*s* binding-energy spectra at even higher resolution (0.16 eV fwhm and 0.19 eV fwhm, respectively) that have been obtained very recently at CSRF. These binding-energy spectra, which are at significantly higher resolution than any previously published work using PES or EMS, reveal even further detailed satellite structure, providing new insight into the existing discrepancies and controversies between theory and experiment. The new highest-resolution Ar 3*s* results obtained with PES are consistent with the very recent high-resolution fluorescence studies of argon using broad-band synchrotron radiation as reported by Samson, Chung, and Lee (47).

Experimental

PES measurements were made on the Canadian Synchrotron Radiation Facility (CSRF) at the new 1-GeV storage ring located at the Synchrotron Radiation Center at the University of Wisconsin. Photoelectron spectra for argon were obtained using a Leybold-Heraeus LHS-11 hemispherical, magic-angle spectrometer over the binding-energy range 26–48 eV, and at photon energies in the range 60–170 eV. The CSRF facility has been described earlier in some detail (48–50). In the case of xenon the binding energy range was 22–38 eV, and photon energies were in the range 80–140 eV. Polarized synchrotron radiation from the 1-GeV storage ring, dispersed using a Mark IV Grasshopper monochromator (49), was directed into the collision chamber of the photoelectron spectrometer. The high light flux of the 1-GeV storage ring facilitated the measurement of photoelectron spectra at significantly higher energy resolution and at higher photon energies than in our earlier work (19, 20), which was carried out using the older, less intense, Tantalus I storage ring. At lower photon energies, where the monochromator energy band pass is narrow, an electron spectrometer pass energy of 50 eV used in the electron spectrometer gave an overall energy resolution as good as 0.3 eV fwhm. Above $h\nu$ = 120 eV the overall spectral resolution is less good since the pass energy was increased to 100 eV to be more compatible with the larger energy band-pass of the Grasshopper monochromator. Under these conditions the transmission efficiency of the analyzer input lens system is effectively constant (48) over the electron kinetic energy ranges involved for the Ar 3*s* and Xe 5*s* spectra. For the highest-resolution spectra (~0.16 eV fwhm) the analyzer pass energy was lowered to 25 eV (contributing ~0.1 eV to the overall resolution) and the monochromator band pass was further narrowed to contribute about 0.1 eV at a photon energy of 80 eV. Under these conditions the overall energy resolution is as good as ~0.15 eV fwhm, but the analyzer transmission efficiency varies slowly (dropping by ~30%) over the range of the binding-energy spectrum, and therefore highly accurate relative intensities of satellite lines cannot be obtained at present from the highest resolution spectra. Nevertheless the trend of relative peak intensities should be semi-quantitative. Experiments are in hand to determine the transmission function of the analyzer at lower pass energies, corresponding to the highest-resolution conditions, so that the spectral intensities may be corrected appropriately. The absolute binding energy scale has been established by assigning a value of 29.235 eV to the Ar $3s3p^6(^2S)$ primary hole state, and 23.397 eV to the Xe $5s5p^6(^2S)$ hole state using optical emission data (51). Argon and xenon gases were taken from Matheson lecture bottles of both high purity (99.995%) and research grade (99.9995%) for each gas so as to carefully check for impurities.

Results and discussion

1. Ar 3s spectrum

Figure 1 shows typical Ar 3*s* photoelectron spectra measured

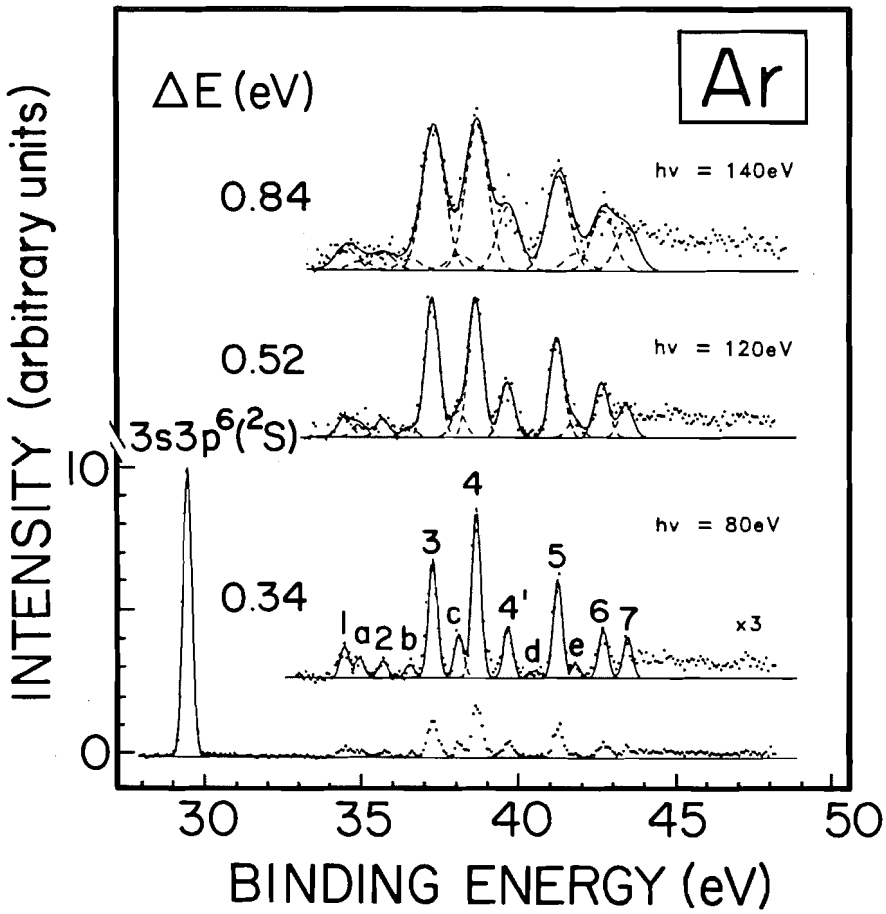

FIG. 1. Photoelectron spectra as a function of photon energy in the inner-valence ($3s$) binding-energy region of argon.

at photon energies of 80, 120, and 140 eV at combined analyzer/monochromator band-passes as good as 0.34 eV fwhm. Spectra were obtained at a series of photon energies in the range 60–170 eV. Gaussian peaks have been fitted to the satellite spectrum using widths determined by the $3s3p^6(^2S)$ hole state. The spectra shown in Fig. 1 are considerably better resolved than those in earlier published work (15, 17–23) and show many satellite lines not previously resolved. Results similar to those shown in Fig. 1 have also recently been reported by Schmidt and co-workers (43, 44). Considering the $h\nu$ = 80 eV spectrum (Fig. 1), at least three peaks (c, 4 and 4')[1] are seen to contribute to the single peak observed in earlier low-resolution work (5, 15, 17–23) at 38.6 eV and assigned to the dominant configuration $3s^23p^43d(^2S)$. Clearly all earlier comments and conclusions (6, 19, 20, 25–31, 38, 44, 46) based on comparisons of peak intensities, particularly at 38.6 eV, in low-energy-resolution PES (5, 15–20) and EMS (21–23) binding-energy spectra, may be incorrect due to effects from the more complex satellite structure now revealed. In addition to the main $3s3p^6(^2S)$ hole state[2] at 29.30 eV, at least 12 higher-binding-energy satellite lines are seen, with possibly a further line (d) being present. The states indicated by a, c, d, and e have not been observed until our earlier preliminary report (41) except in the concurrent work of Schmidt and co-workers (43, 44).

The intensities of the satellite lines relative to the height of the main $3s3p^6(^2S)$ line are given in Table 1 and are in close agreement with those also recently reported by Kossman *et al.* (44). Peaks 4, 5, 6, and 7 may be identified with Ar II states having dominant configurations $3s^23p^4(^1D)nd(^2S)$, n = 3–6. This dominant satellite series has been the subject of much theoretical work, of which the more recent CI calculations (relative intensities) of Smid and Hansen (30) and Kossman *et al.* (44) appear to show the best agreement (41, 44) with experiment. Figure 2 shows a comparison between the relative intensities in the spectrum obtained at $h\nu$ = 80 eV in the present work and the relative intensity predictions of the CI calculations of Smid and Hansen (30) for the $nd(^2S)$ series only, for $h\nu$ = 77.2 eV. The calculations (30) include the photon-energy dependence. For this comparison the experimental energy positions were used for both the experiment and the calculations. The calculated intensities have been convoluted with a Gaussian peak shape corresponding to the experimental resolution, as given by the main $3s$ line at 29.24 eV. The peaks in the experimental spectrum at the energies corresponding to the $nd(^2S)$ series have been shaded for ease of comparison and it can be seen that there is quite good general agreement between theory and the measured spectrum. A more detailed and quantitative comparison with theory is given in Fig. 3 in graphical form. The relative satellite intensities for the $nd(^2S)$

[1]The labelling system follows that of earlier papers (18, 41, 46) to facilitate comparison (note that peak b in the present work has been designated as 3' earlier (18, 46)). Newly resolved states are indicated by lower case letters a, c, d, etc.

[2]Note that the single particle configurations as used in ref. 51 and elsewhere to designate states are only an approximation and at best represent the dominant configuration in a CI description.

series, measured in the present work (solid circles) and in the work of Kossman *et al.* (44) (open circles), are shown together with the results of CI calculations of Smid and Hansen (30) and Kossman *et al.* (44) (plus signs, mean of velocity and length calculations) and also the values calculated by Dyall and Larkins (32, 33) (solid triangles) at $h\nu$ = 151 eV. Also shown on Fig. 3 are experimental data points from magic-angle PES measurements (open squares) by Adam *et al.* (15, 18) at 58.3 and 77.2 eV, and 90° XPS measurements (open diamonds) by Spears *et al.* (5) at 151 eV. It can be seen that in general there is reasonable agreement between theory and experiment, for both the magnitudes and the trends of the relative cross-sections with a particularly noticeable decrease in relative intensity with increase in photon energy in the case of peak 4.

It is of further interest to consider the trend of relative satellite intensities over a much wider range of photon energies, and in particular to include the XPS data obtained at high photon energies (5, 46). In addition, results from electron-momentum spectroscopy (EMS) (or binary (e,2e) spectroscopy, as it has been earlier known) are expected to yield the true spectroscopic factors (at sufficiently high energy resolution) since there is no photon-energy-dependent dipole matrix element in the cross-section expression (38–40). Thus, as has been discussed earlier (7, 19, 20, 38–41), it is to be expected that EMS and very-high energy XPS will give similar values for relative satellite intensities within the same symmetry manifold, provided that the energy resolutions are comparable and that initial state correlation effects are negligible (39–41). As has also been discussed earlier (20, 39–41), it should be remembered that XPS and EMS sample very different electron momenta, and therefore very different regions of the wave function. In the context of the above considerations, various data (PES, XPS, and theory) have been plotted on Fig. 4 for the relative intensity of the $3s^2 3p^4(^1D)3d(^2S)$ main satellite line (peak 4 of Figs. 1 and 2) as a function of energy over the photon-energy range 60–1487 eV. An inverse energy scale has been used so that infinite photon energy can be represented (i.e. the high-energy photon limit). The EMS data point of Leung and Brion (22), with the intensity re-evaluated using the new spectral information for Ar 3*s* as discussed in ref. 41, is shown on the left-hand axis, together with the pole-strength calculation (CI2, basis 2) of Mitroy *et al.* (37). It is clear that the common trend of the measured and calculated data at low photon energy (shown by the dotted line) is not followed by experiment at high photon energy (>1200 eV), even though such a trend is predicted by the calculations of Smid and Hansen (30) and Dyall and Larkins (32, 33). The earlier XPS measurement by Spears *et al.* (5) at 1487 eV is in good agreement with the recent much higher-quality measurements of Svensson *et al.* (46). It should be noted, however, that both XPS measurements were made at an ejection angle of 90° and not at the magic angle, but not withstanding this the *relative* satellite intensity should be little affected since both states involved are in the same symmetry manifold (38–41) and variations in β are not usually considered to be significant. As discussed earlier (41), however, it should be noted that relativistic and multipole effects (52, 53) may well be important in calculations corresponding to XPS energies above the kilovolt range. The EMS data point (22), reinterpreted (41) allowing for the previously undetected nearby satellite lines (see Fig. 1), seems to be in the region of what would be projected for the high-energy photon limit, in keeping with earlier expectations (7, 19, 20, 39). A final confirmatory

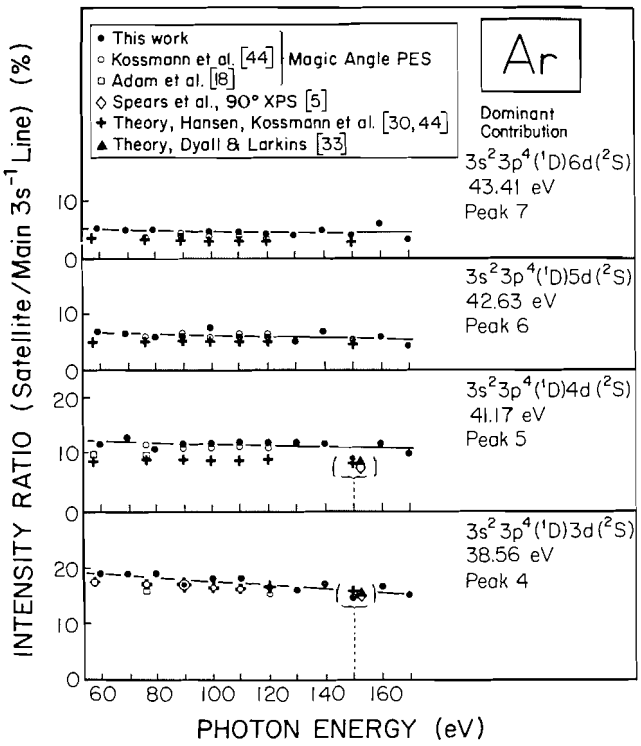

FIG. 3. Variation of measured and calculated relative intensities with photon energy for selected satellites in the Ar 3*s* binding-energy spectrum.

test of these preliminary findings must await further XPS and EMS measurements at much higher energy resolution, comparable at least with that in the high-resolution PES data of Fig. 1. The pole strength (spectroscopic factor) calculation by Mitroy *et al.* shown on Fig. 4 is the most sophisticated (CI2, basis 2) of three calculations reported (37), and corresponds quite well with the reinterpreted EMS data (41). A new CI calculation of spectroscopic factors by Hibbert and Hansen (54) shows good agreement with the measured XPS values (5, 46) at $h\nu$ = 1487 eV, but poorer agreement with the earlier CI calculations by Smid and Hansen (30) and Dyall and Larkins (32, 33). The XPS value at $h\nu$ = 1254 eV reported earlier by Spears *et al.* (5) is quite low relative to the $h\nu$ = 1487 eV measurement and the trend of the other data. Further XPS measurements at this energy and also at even higher photon energies and at better resolution would be informative.

From the data in Fig. 4 and a consideration of the high-resolution Ar 3*s* spectra (see Fig. 1 and refs. 41–44), it is clear that the earlier interpretations of the variation of relative intensities both in our own work (19, 20) and in other publications (28–31, 38), based on lower-resolution PES and EMS spectra, are probably erroneous due to the unrecognized presence of previously unresolved neighboring satellite states. Similarly the recent assessment of our earlier work (see Fig. 3 of ref. 19) by Kossman *et al.* in Fig. 4 of ref. 44 is not meaningful in view of the newly available Ar 3*s* spectroscopic data (41, 43, 44).

A more detailed examination of the relative-intensity data in Fig. 3, however, shows that, despite the overall quite good agreement, the CI calculations (30, 44) are lower in all cases than the presently reported measured relative intensities, with a particularly large discrepancy (~30%) existing for peak 5

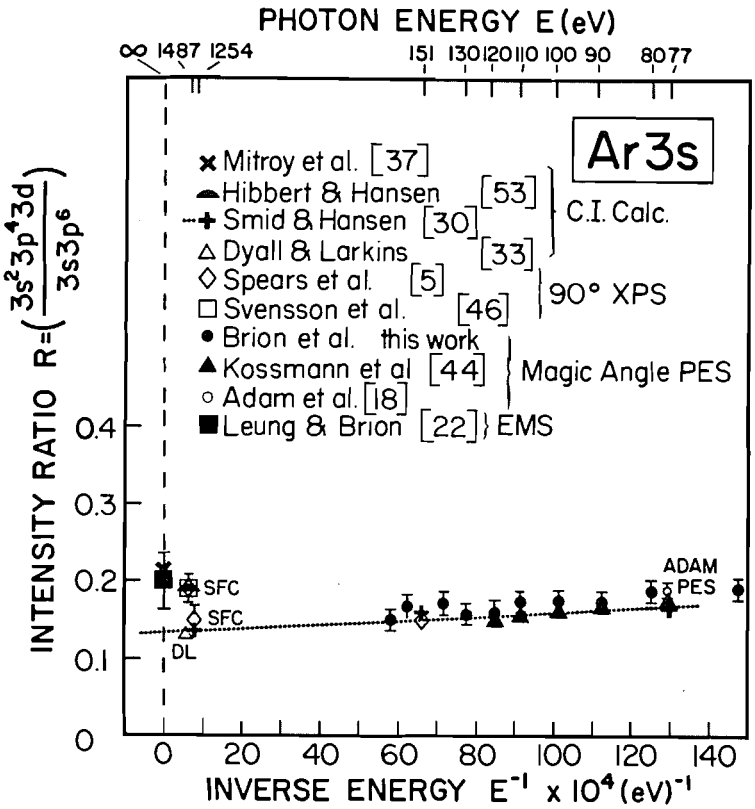

FIG. 4. Comparison of measured (PES, XPS, and EMS) and calculated relative intensities of the satellite peak at 38.56 eV (containing mainly $3s^23p^4(^1D)3d(^2S)$) as a function of energy. Note the non-linear and inverse energy scales on the top and bottom of the figure, respectively.

(dominant configuration $3s^23p^4(^1D)4d(^2S)$). Reasons for these appreciable discrepancies may include any or all of the following: (*i*) inaccuracy of the CI calculations; (*ii*) errors in the measurements; e.g., uncertainties in the electron transmission efficiency and/or non-magic-angle effects involving the polarization direction (53); (*iii*) the presence of yet further unresolved satellite lines of different symmetries contributing to the measured peaks (Figs. 1 and 2) nominally assigned (41–44) to the $3s^23p^4nd(^2S)$ series. Most states are expected on the basis of optical emission data (51); and (*iv*) breakdown of the Dipole Approximation and the plane wave treatment of the ionized electron.

In order to further investigate the differences between theory and experiment with regard to item *3* above, the Ar 3*s* binding energy spectrum has recently been obtained at very high resolution (0.16 eV fwhm) by lowering the electron analyzer pass energy and narrowing the slits in the Grasshopper monochromator. A typical spectrum obtained under these conditions at $h\nu = 80$ eV is shown in Fig. 5. These new data, at significantly higher resolution than any previously published PES spectra, exhibit very detailed satellite structure. In addition to a number of readily observed new peaks, several partially resolved shoulders, notably on peaks 3, c, 4, 4′, 5, and 6 are also apparent. The energies corresponding to the peaks and shoulders in Fig. 5 are listed in Table 2. For ease of identification and comparison with previous spectra, the same notation as was used earlier (18, 41–44, 46) has been used for the corresponding peaks, whereas newly observed peaks and shoulders are denoted by asterisks (*). At the low analyzer pass energy used, the electron transmission efficiency varies slowly over the range of kinetic energies involved in the higher-resolution spectrum of Fig. 5. As such, until this transmission function can be accurately determined (see experimental section), no highly accurate relative intensities can be derived from the spectrum. Nevertheless, the detailed spectroscopy and qualitative relative-intensity considerations provide helpful insight into the discrepancies observed in comparisons of intensities between theory and experiment (see Fig. 3) for the constant transmission, lower-resolution spectra (Figs. 1 and 2). In particular, peaks 4, 5, 6, and 7 (Fig. 5), which were assigned earlier exclusively to $n = 3$, 4, 5, and 6 of the main satellite series $3s^23p^4(^1D)nd(^2S)$, each show additional structure that was not evident in the lower-resolution spectrum (Figs. 1 and 2). Specifically, as indicated by the shaded areas on Fig. 5, peak 4 shows a high-energy unresolved shoulder (estimated as ~10% of peak 4) and peak 5 shows a low-energy shoulder and an extra peak on the high-energy side (~20% and 10% of peak 5, respectively). In addition, small extra peaks are now seen on either side of each of peaks 6 and 7. An examination of Fig. 3 shows that in each case (peaks 4, 5, 6, and 7) the calculated relative intensities are below those measured under the existing medium-energy resolution (41–44) conditions. These discrepancies in Fig. 3 for $n = 3$ and 4 (i.e. peaks 4 and 5) correspond closely to the estimated extra areas (10% and 30%, respectively, see above) attributable to the previously unresolved satellites in the vicinity of peaks 4 and 5. Application of these corrections would lead to much better agreement between experiment and the CI calculations (30, 44) for the relative intensities of the satellite peaks in the $3s^23p^4(^1D)nd(^2S)$ series. In a similar fashion it can be seen that improved agreement would also exist between theory and experiment for $n = 5$ and 6 (i.e. peaks 6 and 7) when contributions from newly observed neighbouring

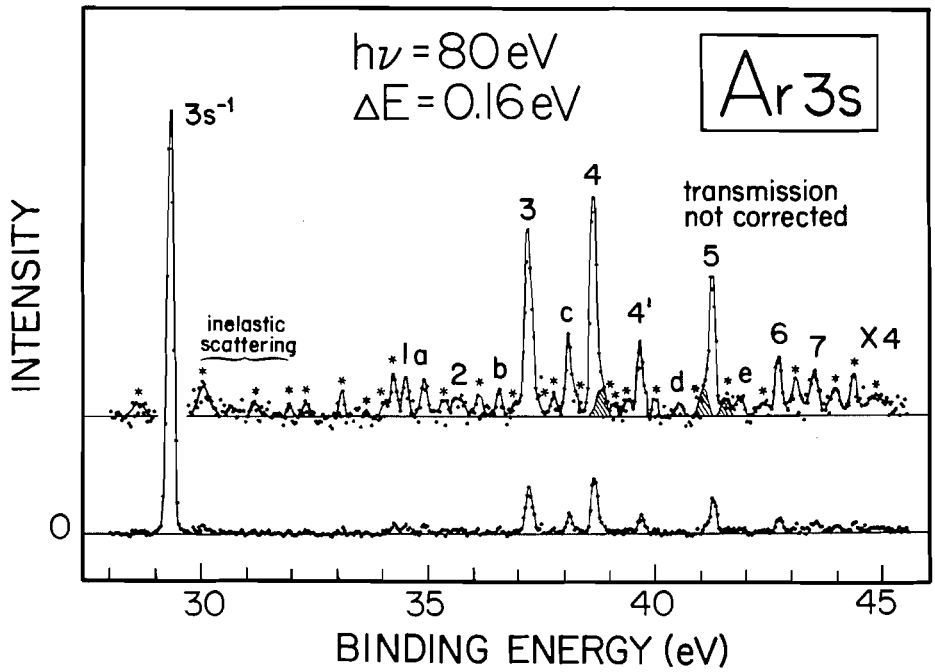

FIG. 5. Ar 3*s* binding-energy spectrum at high resolution (0.16 eV fwhm) and $h\nu$ = 80 eV. See Table 2 for details. The shaded peaks show contributions to peaks 4 and 5 in the lower-resolution spectrum in Fig. 1 from other newly observed satellites. Peaks at 29.95 and 31.10 eV are due to inelastic scattering. Note that the intensities in these spectra have not been corrected for the slowly varying electron-transmission efficiency (see text).

peaks in the more-detailed high-resolution spectra (Fig. 5) are considered. It should be noted that there have been a variety of different CI calculations by Hansen and co-workers (28–31, 54) and it is not necessarily clear which are considered to be the most accurate for either relative intensities or energies. Further improvement in the accuracy of the calculated energies is desirable (for example, see ref. 54). However, it should be noted that the very recent many-body perturbation calculations of argon satellite intensities by Wijesundera and Kelly (55) give intensities in close agreement with the results of Smid and Hansen in ref. 30.

Two other very recent spectroscopic studies provide information relevant to the newly reported high-resolution Ar 3*s* PES spectrum shown in Fig. 5. Firstly Becker *et al.* (56) have reported very high-resolution-threshold and near-threshold PES spectra of argon by sweeping the photon energy through the binding-energy range 29–44 eV. Although the resolution varies with binding energy (0.09–0.2 eV) and, as expected, the intensities are very different in the threshold region (56), similar fine structure to that seen in the present work is observed between 32 and 42 eV (see Table 2). Also of interest are the high-resolution Ar 3*s* fluorescence spectra, excited by broad-band undispersed synchrotron radiation, recently reported by Samson, Chung, and Lee (47). In these studies the photon resolution for the emission resulting from decay of the Ar II excited states is in the range 0.05–0.10 eV fwhm. Fluorescence is observed (47) from all the states of Ar II observed above 32 eV and up to 43 eV in the PES spectrum in Fig. 5 except for those for which the emission transitions are forbidden (i.e. $p \rightarrow p$). The final states corresponding to many of these optically forbidden transitions can, however, be seen in the threshold PES spectrum (56). The fluorescence spectra of Ar reported by Samson *et al.* (47), and particularly the higher-resolution second-order spectra, clearly show features that correspond to the "extra" contributions (see above discussion) to peaks 4, 5, 6, and 7 of the intermediate-resolution PES spectrum (41–44) referred to above (see Fig. 1) and which are revealed in the new high-resolution spectrum in Fig. 5. A discussion of possible identities for the peaks obtained below 32.2 eV in the Ar spectrum, together with similar peaks in the case of Xe, is given in Section 3 below.

2. Xe 5s spectrum

Figure 6 shows the Xe 5*s* binding-energy spectrum at $h\nu$ = 90 eV, at an energy resolution of 0.35 eV fwhm and over the binding energy range 23–37 eV. Similar spectra were obtained over the photon energy range 80–130 eV. At somewhat lower photon energies the binding-energy spectra are complicated by resonance Auger effects (57, 58). The spectra are considerably better resolved than earlier published work using PES at similar photon energies (16, 17) or XPS (5, 6) with the peaks a, b, c, d, e, f, g, h, and i not having been resolved previously. Fahlman *et al.* (59, 60) have also reported Xe 5*s* PES spectra at quite good energy resolution, and also obtained angular distribution information over the photon-energy range 28.5–74.8 eV, which includes the region of the Xe 5*s* cooper minimum. Suzer and Hush (61) have reported high-resolution HeII ($h\nu$ = 40.8 eV) PES spectra of Xe up to a binding energy of 28 eV.

Possible assignments of the Xe 5*s* binding-energy spectrum have been discussed by Hansen and Persson (25–27, 45) and also by Dyall and Larkins (32, 33) in several papers reporting CI calculations. Of these, the calculations of refs. 27 and 45 show the best agreement with experiment for relative satellite

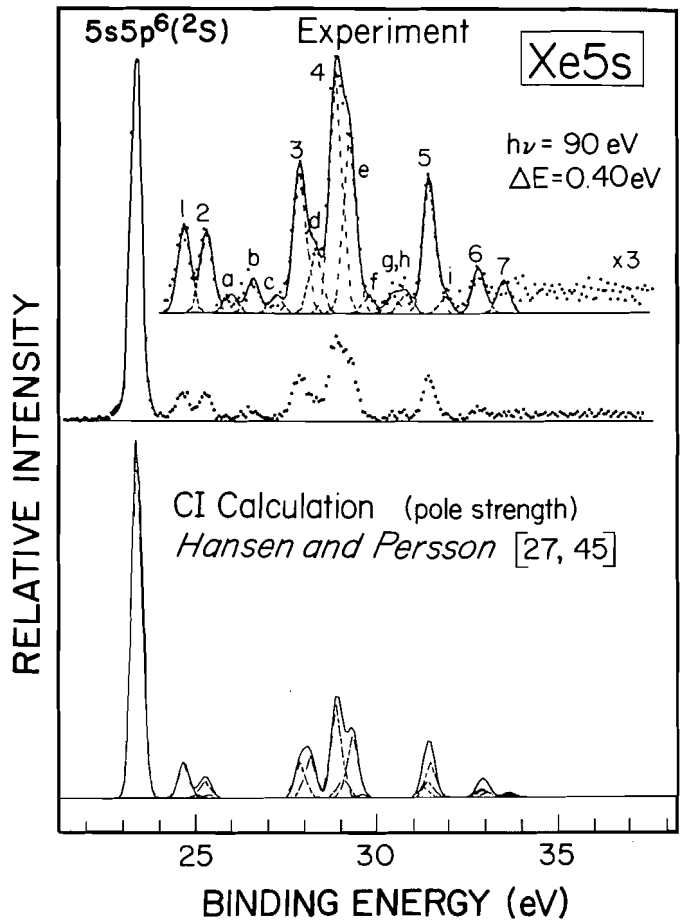

FIG. 6. Comparison of experimental Xe 5*s* PES spectrum ($h\nu$ = 90 eV, ΔE = 0.40 eV fwhm) with the calculated intensities (pole strengths or relative spectroscopic factors, without photon-energy dependence) of the Xe 5*s* satellites reported by Hansen and Persson (27, 45). The calculated spectrum has been convoluted with a Gaussian function (0.40 eV fwhm). The transition energies in the calculated spectrum are assigned from optical work as shown in refs. 27 and 45.

intensities. Figure 6 shows a theoretical spectrum obtained using the intensities as calculated by Hansen and Persson using CI methods (27, 45) and convoluted with the experimental energy resolution (0.34 eV). Unlike the case of the Ar 3*s* CI calculations (30), the xenon calculations (27, 45) included a wide range of final ion states and not just those of the principal series (i.e. not just those of $5s^25p^4(^1D)ns(^2S)$ symmetry). It can be seen from Fig. 6 that good general quantitative agreement exists between theory and experiment. Since the intensities from the CI calculations (27, 45) are not given as a function of photon energy, it is assumed that they are simply pole strengths (i.e. relative spectroscopic factors).

By fitting the peak energies of Fig. 6 (upper spectrum) to binding energy spectra of xenon obtained at higher photon energies (80–130 eV) and using an individual peak width (resolution) determined by the main line at 23.397 eV at each photon energy, we have obtained information on the variation of satellite peak intensities relative to that of the main line ($5s5p^6(^2S)$) and the results are shown in Fig. 7 and Table 3. It can be seen that while the intensity of lines 1, 2, and h are reasonably constant, the relative intensities of lines b, 3, 4, g, 5, 6, and 7 increase slowly with increase in photon energy. This latter situation for xenon is contrary to the behavior observed for

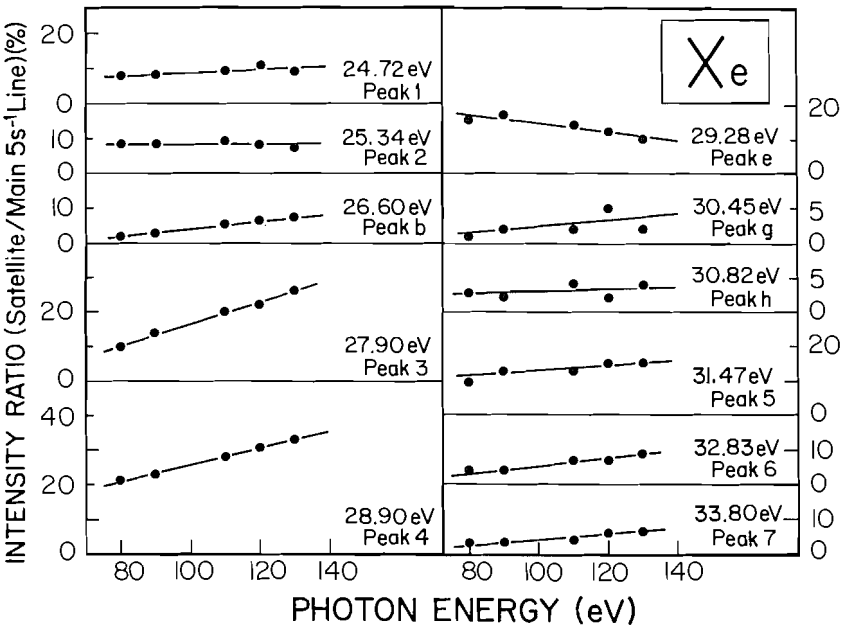

FIG. 7. Variation of measured relative intensities with photon energy for satellites in the Xe 5*s* spectrum.

*Width of main $5s^{-1}$ line used for fitting satellites.

the ^2S lines of argon at intermediate photon energies (see Fig. 3 and refs. 41 and 44) and is contrary to predictions from theory (30). In contrast to the behavior for the other peaks (Fig. 7), the relative intensity of line e decreases with increase in photon energy according to the present measurements. The overall increase in total satellite intensity in the Xe 5*s* spectrum is consistent with the trend of earlier findings based on much-lower-resolution spectra (20).

A consideration of the CI calculations (27, 45) and optical emission data (51) suggests that further (unresolved) fine structure is expected to be contributing to the Xe 5*s* spectrum shown in Fig. 6. Figure 8 shows a very recently obtained Xe 5*s* PES spectrum ($h\nu$ = 95 eV) at significantly higher resolution (~0.19 eV fwhm) than any other previously reported work (6, 16) except the low-photon-energy data of Suzer and Hush (61), which is only over a very limited binding energy range. The spectrum shows a great deal of additional resolved structure compared to the situation in the experimental spectrum shown in Fig. 6. As in the case of the very-high-resolution Ar 3*s* spectrum (Fig. 5), the electron transmission efficiency is slowly varying over the spectral range due to the low analyzer pass energies involved. Therefore the relative intensities are only semi-quantitative in Fig. 8. The energies of the spectral features in Fig. 8 are given in Table 4 together with low-photon-energy, high-resolution PES data (59–61). From a comparison of the presently obtained higher-resolution Xe spectra (Fig. 8) with the data in Figs. 6 and 7, it is quite clear that many of the peaks contain contributions from more than one state (see particularly peaks 2, 3, 4, and 5). A detailed quantitative investigation of the relative satellite intensities in the Xe 5*s* spectrum must await transmission-corrected high-resolution spectra of preferably even higher resolution than that shown in Fig. 8.

3. *Peaks at low binding energy in the Ar 3s and Xe 5s high-resolution spectra*

In the present work, several peaks have been observed below 32.2 eV in the Ar^+ spectrum (Fig. 5, Table 2) and below the main $5s^{-1}$ peak at 23.397 eV in the Xe^+ spectrum (Fig. 8, Table 4). The identity of these structures is of some speculation and interest. The lowest excited state of Ar^+, above the main $3s^{-1}$ line, is listed as being at 32.18 eV according to the tables of atomic-energy levels (from optical emission) published by

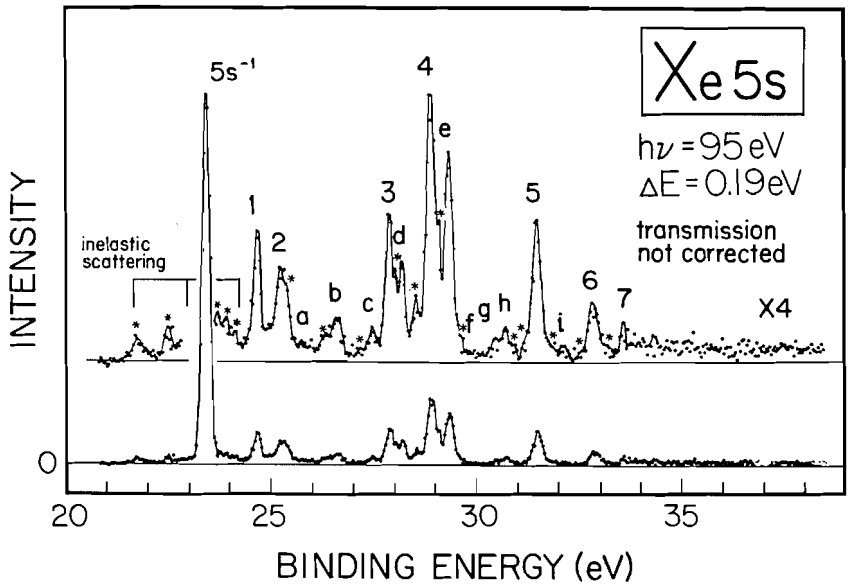

FIG. 8. Xe 5*s* binding-energy spectrum at high resolution (0.16 eV fwhm) and $h\nu = 95$ eV. See Table 4 for details. Peaks at 21.73 and 24.1 eV are due to inelastic scattering. Note that the intensities in these spectra have not been corrected for the slowly varying electron-transmission efficiency (see text).

Moore (51). However, at least four low-intensity peaks are observed below this energy in the present work, in addition to the $3s^{-1}$ line in Ar. Of these four peaks, one is at ~28.6 eV, below the main $3s^{-1}$ line at 29.235 eV. In the case of Xe, Moore's tables (51) list no state of Xe^+ below the main $5s^{-1}$ line. These "extra" peaks may be attributable to any of the following possible processes. (*i*) Photoelectron peaks from impurity gases of which the most likely is N_2. However, high-resolution inner-valence PES spectra of N_2 (62) show no sufficiently sharp peaks in the binding energy regions in question. Two independent samples of each of Ar and Xe were used (high purity (99.995%) and research grade (99.9995%)). The "extra" peaks persisted in the spectra with both samples; (*ii*) Auger lines from higher-order radiation passing through the monochromator. This explanation has been advanced by Fahlman *et al.* (59) to account for two lines observed at ~22.6 and 24.67 eV in PES spectra of Xe at $h\nu = 33$ eV. The fact that these lines are also present at the same binding energy (but different kinetic energy) in the present work at $h\nu = 95$ eV and also in other Xe PES spectra at photon energies in the range 85–120 eV (63) suggests that these lines are not due to Auger effects. Auger lines should appear at constant electron kinetic energy as the photon energy is varied. The "extra" lines in Ar (Table 2, Fig. 5) at ~28.6 eV and 29.95 eV are present in separate spectra at $h\nu = 80$ and 100 eV, and are thus also probably not due to Auger transitions. Other features in the binding-energy range 30–32 eV are extremely weak and no definite conclusion can be stated at present. (*iii*) Reflections and background effects from the electron analyzer may be causing spurious signals. (*iv*) The peaks may be due to inelastic scattering processes, e.g. $3p^{-1}$ (or $5p^{-1}$) primary photoelectrons that have excited a neutral Ar (or Xe) atom in the collision chamber before analysis. For argon (Fig. 5) structures in the region 29.9–31.3 eV could be due to $3p^{-1}$ photoelectrons, which have subsequently undergone inelastic scattering, leading to the $3s^2 3p^5 5s$ and $3s^2 3p^5 6s$ manifolds of argon. Similarly in xenon, features in the ranges 21.6–21.9, 22.7–23.1, and 24.0–24.1 eV could be due to $5p^{-1}$ photoelectrons that leave Xe excited in the $5s^2 5p^5 6s$, and $5s^2 5p^5 7s$ manifolds. Pressure-dependent studies could identify such processes. (*v*) The peaks may arise from many-body (electron correlation) effects and therefore intrinsically belong to the Ar 3*s* or Xe 5*s* satellite spectra.

In connection with the last possibility, i.e. many-body effects, it should be noted that the levels listed by Moore (51) are all assigned on the basis of the independent particle model and are designated as single-particle excited-state configurations. However, in reality the listed configurations may, at best, correspond to dominant configurations occurring in a CI description of the final states in question (32, 33). In a many-body approach such as the Green's function calculations for molecules by Cederbaum *et al.* (12, 14), many final-state poles from ionization of a given ground-state orbital are frequently found scattered throughout the inner-valence region. Of these, some are often found to occur at energies *below* that of the first single-particle excitation (i.e., the lowest "shake-up" state) above the predicted single-particle ground ionic state (this would correspond approximately to the so-called $3s^{-1}$ and $5s^{-1}$ states of Ar^+ and Xe^+, respectively). In some cases, many-body ionization peaks have even been predicted and observed (64–66) *below* the energy expected for the single-particle ground ionic state (i.e. "shake-down"). In other cases (12–14, 65), there is not even a clearly identifiable "parent" ion peak in the inner-valence region. Such many-body descriptions are at present apparently more highly developed for molecules than for atoms.

It is possible that some of the previously unobserved low-intensity peaks observed in the vicinity of the main Ar $3s^{-1}$ and Xe $5s^{-1}$ lines are ionization lines due to many-body effects. Such lines would probably not have been observed in previous photoelectron studies due to their low intensity and the lower energy resolution used in earlier work. The small structures at 28.6, 31.86, and 37.69 eV in the argon spectrum (Fig. 5) and at 22.52, 23.7, and 23.95 eV in the xenon spectrum (Fig. 8) may be due to many-body effects since they do not correspond to expected optical or inelastic scattering processes. The present

work suggests that a search for low-intensity, low-energy, ionization poles in atomic many-body Green's functions or CI calculations, as well as further experimental investigations as a function of pressure, may prove fruitful.

Conclusions

High-resolution PES spectra of Ar 3*s* as a function of photon energy yield satellite relative intensities that are in general quite well reproduced by previously published CI calculations. Agreement between theory and experiment is further improved when account is taken of additional overlapping satellite peaks revealed by new very-high-resolution Ar 3*s* PES spectra. A similar level of agreement between theory and experiment is also obtained for the general features of the intensity distribution in the Xe 5*s* satellite spectrum. The new very-high-resolution PES spectra of Ar 3*s* and Xe 5*s* reveal significantly more detailed satellite spectra than have been observed previously. Even higher-resolution spectra for Xe 5*s* will be required in the future.

Finally a consideration of the extremely complex spectroscopy in the presently reported Ar 3*s* and Xe 5*s* PES binding energy spectra at very high resolution reveals a number of newly observed peaks, including some below the main $3s^{-1}$ and $5s^{-1}$ lines, which may be due to many-body (electron-correlation) effects. These high-resolution spectra also indicate that great care should be taken in the interpretation of much-lower-resolution spectra obtained by PES and particularly EMS (i.e. binary (e,2e) spectroscopy). In particular, detailed interpretations of recently obtained (low-resolution) EMS binding-energy spectra of Ar 3*s* (67, 68) and Xe 5*s* (67, 69) have been based on the assumption of much simpler manifolds of satellite states than are observed in the present PES work. Even a simple reinterpretation of the EMS Ar 3*s* spectrum, using more states, yields very different conclusions (41). While there are well-

For personal use only.

known different considerations (7, 38–41, 70) in EMS and PES spectroscopies, particularly with regard to the different spatial regions of the wavefunctions that are sampled and also the photon-energy-dependent dipole matrix element in photoionization, final confirmation of the assignments and intensities must await the measurement of EMS binding-energy spectra as a function of momentum, at high *momentum* resolution and with at least as high an energy resolution as that used in the PES spectra shown in Figs. 5 and 8. At present the highest-resolution EMS noble-gas spectra that have been reported are the results for argon 3*s* (0.6 eV fwhm for Ar 3*s* and 0.06 eV fwhm in the Ar 3*p* regions respectively) by Williams (71), and for Xe 5*s* (1.0 eV fwhm for Xe 5*s* and 5*p*) by Hood *et al.* (72). While the Ar 3*s* work (71) is at somewhat higher resolution than other EMS work (21–23, 67, 68), relatively few data points were obtained in the spectral regions of interest. A comparison of both the present high-resolution PES spectra (0.16 eV fwhm), and earlier PES work for Ar 3*s* with the EMS work of Williams (71) at low resolution (~0.6 eV fwhm) also indicates that much higher-resolution EMS work is needed before definite conclusions regarding intensities and assignments can be reached. By the same token, similar high-resolution EMS measurements will also be needed before definitive statements can be made as to similarities (or differences) in spectroscopic factors in EMS and PES (allowing for photon-energy variation). Therefore speculations made in the case of atoms (19, 20, 25–31, 38, 40, 41, 54) and also recently for molecules (73–75) as to the viability of the approximations and reaction model (21) presently used in the EMS (binary (e, 2e) spectroscopy) that are based on a comparison between resolutionless calculations, medium-resolution PES, and lower-resolution EMS spectra, are premature. In the meantime, the present very-high-resolution PES results provide new and more detailed information that gives further insight into electron correlation effects and helps to clarify and explain much of the existing confusion and controversy concerning satellite relative intensities in both theoretical and experimental studies of Ar 3*s* and Xe 5*s* ionization.

Ab initio calculations at the level of 3-21G* SCF and MP3/3-21G* have been performed on the novel heterocycle 1,2-oxathietane and the formal [σ2s + σ2a] cycloreversion products. Hartree–Fock calculations have been performed for the *E* and *Z* 3,4-dimethyl-1,2-oxathietanes and their corresponding cycloreversion products. The calculations afford fully geometry optimized conformations, energies, net atomic charges, and HOMO values for the heterocycles. 1,2-Oxathietane is found to be close in energy to the sum of energies of either pair of its cycloreversion products. The most plausible mechanism of cycloreversion features the formation of ground state formaldehyde and thioformaldehyde via a biradical intermediate. This result is in accord with the lack of detection of chemiluminescence with the 1,2-oxathietanes, in contrast to the 1,2-dioxetanes.

ALI NAGHIPUR, J. WILLIAM LOWN, DULI C. JAIN et ANNE-MARIE SAPSE. Can. J. Chem. **66**, 1890 (1988).

Opérant au niveau 3-21G* en champs auto-cohérents et au niveau MP3/3-21G*, on a effectué des calculs *ab initio* sur le nouvel hétérocycle oxathiéthane-1,2 et sur les produits formels de sa cycloréversion [σ2s + σ2a]. On a aussi effectué des calculs de Hartree–Fock sur les isomères (*E*)- et (*Z*)- des diméthyl-3,4 oxathiéthanes-1,2 ainsi que sur leurs produits correspondants de cycloréversion. Les calculs permettent d'obtenir les conformations complètement optimisées pour la géométrie, les énergies, les charges atomiques nettes ainsi que les valeurs des OMHO des hétérocycles. On a trouvé que l'énergie de l'oxathiéthane-1,2 se rapproche de la somme des énergies de l'une ou l'autre paire de ses produits de réversion. Le mécanisme le plus plausible de la cycloréversion implique la formation, via un intermédiaire biradicalaire, de formaldéhyde et de thioformaldéhyde dans leur état fondamental. Ce résultat est en accord avec le fait qu'avec les oxathiéthanes-1,2, par opposition avec ce qui est observé avec les dioxéthanes-1,2, on n'observe pas de chimiluminescence.

[Traduit par la revue]

Introduction

Experimental studies of the decomposition of antileukemic 1-[2-[(2-chloroethyl)sulfinyl]ethyl-3-cyclohexyl-1-nitrosourea and its alkyl substituted analogues have provided evidence for the intermediacy of novel 1,2-oxathietanes (1–3). These compounds are of interest due to analogy with 1,2-dioxetanes, which are of significance in bioluminescence and chemiluminescence reactions. The extensively studied 1,2-dioxetanes (4–6) have been observed to induce pyrimidine dimers in DNA (7–9) and to effect interstrand cross-linking and local denaturation of DNA (10). Therefore it is of theoretical and biological interest to investigate the possibility for 1,2-oxathietane to undergo similar types of reactions. In contrast to 1,2-dioxetane, to our knowledge, there is only one preliminary theoretical treatment of 1,2-oxathietane reported (11) that did not employ full *ab initio* methods nor did it treat the experimentally observed formal [σ2s + σ2a] cycloreversion to identifiable products (1–3).

Decomposition of 1-[2-[(2-chloroethyl)sulfinyl]ethyl-2-d_2]-3-cyclohexyl-1-nitrosourea **1***b* (Fig. 1) under physiological conditions affords formaldehyde and thioformaldehyde-d_2-hydrate with no label scrambling in accord with formation of a 1,2-oxathietane species **4** and **5** rather than the symmetrical thiirane S-oxide intermediates **6** and **7** (1, 2). In addition, similar aqueous decomposition of 1-[2-[(2-chloroethyl)sulfinyl-^{18}O]-1,1-dimethyl]-3-cyclohexyl-1-nitrosourea (**1***c*-^{18}O) affords acetone-^{18}O and thioformaldehyde hydrate among the volatile products (Fig. 1) (1, 2). Thus the reaction proceeds by intramolecular transfer of ^{18}O via the four-membered 1,2-oxathietanium intermediate **4**.

Subsequently 3,3,4,4-tetramethyl-1,2-oxathietane **5***e* proved to be isolable and was demonstrated to undergo spontaneous formal [σ2s + σ2a] cycloreversions primarily to acetone and thioacetone (which was trapped with a variety of dienes) and, to a much lesser extent, to 2,3-dimethylbut-2-ene **9***a* and sulfur monoxide (2). No detectable chemiluminescence occurs in these reactions (1–3) in contrast to the case of 1,2-dioxetanes (4–6). Therefore the present work focuses on the energetics of the cycloreversion reactions of 1,2-oxathietane and certain stereoisomeric derivatives. The purpose of the calculations is to provide theoretical support for the experimental findings, which, as mentioned above, do not include the observation of chemiluminescence.

It had been observed experimentally that, depending on the substitution pattern of the precursor sulfinylnitrosoureas, rearrangements of the intermediate 1,2-oxathietane may supervene over the cycloreversions (1–3) (see Fig. 1, example **1***d*, and structures **10**–**12**, Fig. 2). Therefore another objective of the calculations was to determine the effects of alkyl substitution on the stability and reactivity of this novel heterocycle.

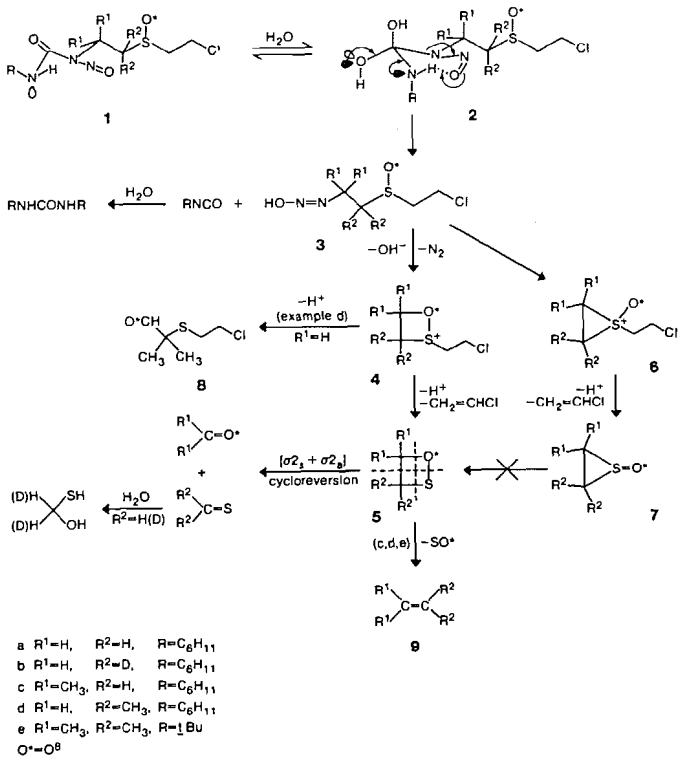

FIG. 1. Fragmentation products for decomposition of sulfinyl-(2-chloroethyl)nitrosoureas in aqueous potassium phosphate buffer at pH 7.0 and 37°C.

Calculations were performed at the SCF and MP3/3-21G* levels on the parent 1,2-oxathietane and at the Hartree–Fock SCF level for *E* and *Z* 3,4-dimethyl-1,2-oxathietanes.

Methods and results

Self consistent field (SCF) *ab initio* calculations were made, with full geometry optimization of the principal conformers, of the energies and net atomic charges of the heterocycles and their products of cycloreversion. The *ab initio* calculations at the Hartree–Fock level were performed on the heterocycles and subsystems using the 3-21G* Gaussian basis set, as implemented in the Gaussian-82 program (12). The geometry optimization was performed using the Berny optimization technique (13). SCF calculations with split valence or larger basis sets are known to usually predict accurate geometries (12, 14). 1,2-Oxathietane **13** (Fig. 3), in addition to its decomposition products SO, C_2H_6, H_2CO, and H_2CS, has been

FIG. 3. Structures and numbering of 1,2-oxathietanes employed in the *ab initio* calculations.

completely geometry optimized. The resulting geometrical parameters are summarized in Table 1.

Since the heterocycles contain sulfur, the inclusion of *d* orbitals is particularly necessary for a good theoretical description. Goddard (15) has compared the results of the 3-21G* basis set with those of larger basis sets and has found that the 3-21G* basis set affords a good description. For example, the SO bond length in 1,2-oxathietane is found to be 1.708 Å, in good agreement with the known value of 1.7 Å for the SO single bond.

The optimized geometries have been used to perform single point MP3/3-21G* calculations, to estimate the correlation energies of the systems and to assess their influence on the stability of the heterocycle. The Hartree–Fock energies and the MP3/3-21G* energies are shown in Table 2. Table 3 shows the Hartree–Fock 3-21G* energies for structures **14** and **15** (Fig. 3) as well as for acetaldehyde, thioacetaldehyde, and *E* and *Z* 2-butenes. The differences between the energies of the cycloreversion products are shown in Table 4. Table 5 shows the net atomic charges on the atoms of the three heterocycles while Table 6 lists the basis set composition of 1,2-oxathietane HOMO (Highest Occupied Molecular Orbital).

Discussion

The SO molecule is a triplet in its ground state. From Tables 2 and 4, it can be seen that the energy of the 1,2-oxathietane, at both the Hartree–Fock level and the MP3/3-21G* level of calculation, is within a few kcal/mol of the sum of energies of either SO + C_2H_4 or H_2CO + H_2CS, with the former energy being slightly lower and the latter energy being slightly higher than that of the heterocycle. Correlation energy inclusion at the MP3 level reverses the trend, while keeping the differences small. The *Z* 3,4-dimethyl-1,2-oxathietane **14** is found to be slightly more stable than the *E* isomer **15** by less than 1 kcal/mol. Both heterocycles are more stable than the combination of SO + $(CH_3)_2C_2H_2$ but somewhat less stable than the combined acetaldehyde and thioacetaldehyde. The differences remain around a few kcal/mol. The heterocycles are singlets, and therefore the concerted decomposition into SO + C_2H_4 cannot occur with the direct formation of triplet SO. The SO thus obtained would have to be a singlet, which shows, as

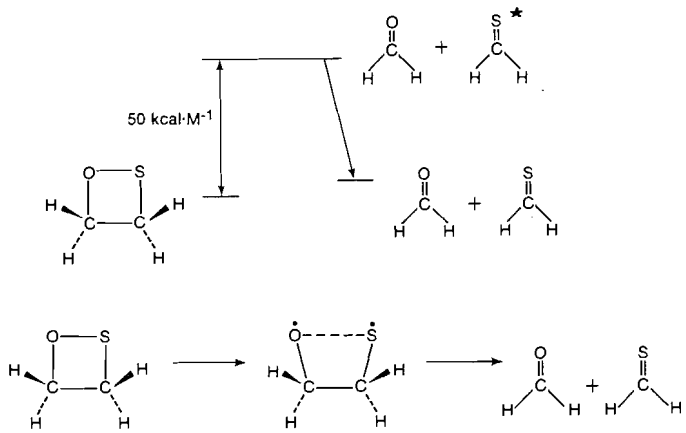

FIG. 4. (a) Hypothetical ($\sigma 2s + \sigma 2a$] cycloreversion of 1,2-oxathietane to carbonyl and thiocarbonyl fragments. (b) Proposed cleavage of 1,2-oxathietane via a biradical intermediate.

mentioned above, the decomposition to occur mainly via the formation of H_2CS and H_2CO (1, 2). Initial calculations of ΔE_{ST} for SO, using RHF for the singlet and UHF for the triplet at the 3-21G* computational level, give an estimate of ca. 40 kcal/mol. At a higher computational level, namely MP3/6-31G*, the value becomes 28 kcal/mol. This may be compared with the value of 25.3 kcal/mol by a previous SCF calculation, which is near the Hartree–Fock limit (16), and more recent calculations by the CEPA-PNO method that predict a value of 23.7 kcal/mol (17). It was concluded that, as in the case of O_2, the CEPA method seems to overestimate the correlation contribution to ΔE_{ST} (17). The experimental value of ΔE_{ST} for SO is 17.6 kcal/mol (18, 19).

Thus the calculations are in general agreement with the experiments.

Similarly, if the C—C and S—O bonds were to break simultaneously, one of the resulting products would be in an excited state, to obey the symmetry rules (20). Even though in our system the symmetry of 1,2-dioxetane is removed, the same rules apply, as shown by Woodward and Hoffmann (20), i.e., when the symmetry is removed by a small change (such as replacing a hydrogen by a methyl or, in this case, an oxygen by a sulfur). This refers mainly to the reaction proceeding in the absence of a triplet biradical, so the differences in spin effects between O and S should not be important). Indeed, the σ and σ^* bonds of the heterocycle are formed from the $\pi_1 + \pi_2$, $\pi_1^* + \pi_2^*$, $\pi_1 - \pi_2$, $\pi_1^* - \pi_2^*$ orbitals of the formaldehyde and thioformaldehyde molecules, so upon concomitant breakage of the two σ bonds, one of the products must be in an excited state. However, the excited states of both H_2CS and H_2CO lie high above the ground state, with 80.6 kcal/mol for the singlet excited state of H_2CO and with the triplet close to it (lower by a few kcal/mol) (21). The photoelectron spectrum of monomeric thioformaldehyde was recently reported and shows ionizations at 9.36, 11.87, 14.02, and 15 eV (22, 23). Thus H_2CS has been found theoretically and experimentally to feature a singlet excited state 46 kcal/mol above the ground state and a triplet state only 6 kcal/mol lower in energy (21). If the decomposition were to occur in this direction, the reaction would proceed as indicated in Fig. 4a. Such a reaction would feature an activation energy of 50 kcal/mol or more, since the transition state energy would probably be greater than the energy of the excited state. Therefore this reaction path cannot explain the experimentally observed high instability of the 1,2-oxathietane system (1–3).

Theoretical calculations on the dimethyl substituted 1,2-oxathietanes, at the Hartree–Fock level, lead to similar conclusions for decomposition of these compounds. It therefore appears plausible that the 1,2-oxathietane decomposes via a biradical mechanism into ground state formaldehyde and ground state thioformaldehyde according to Fig. 4b. This is in agreement with the fact that chemiluminescence is not observed experimentally (1–3). In the case of 1,2-dioxetane, however, chemiluminescence has been observed experimentally and different studies suggest that 1,2-dioxetane does indeed decompose into a ground state formaldehyde molecule and an excited state one, which can be a singlet or a triplet. The difference between 1,2-dioxetane and 1,2-oxathietane can be attributed to the difference in their stabilities. Indeed, while 1,2-oxathietane is close in energy to its decomposition products, 1,2-dioxetane has been found in this work, with 3-21G* (SCF) calculations, to show an energy higher by 40 kcal/mol than the sum of the energies of two formaldehyde molecules in the ground state. Using a larger basis set, Goddard (8) finds the number to be 50 kcal/mol. This result predicts that the energy difference between 1,2-dioxetane and the sum of energies of one formaldehyde molecule in its ground state and the other molecule in the excited state is only about 30 kcal/mol and, therefore, thermally it can decompose with accompanying chemiluminescence. Indeed, Kopecky *et al.* (4) have found an energy of activation for the thermolysis of dioxetane in the vicinity of 25 kcal/mol. Similar results have been found in other studies (5, 6). Goddard estimates the energy of the 1,2-dioxetane biradical to be higher by 16 kcal/mol than that of the heterocycle, averaging over eight singlet biradical states, via 6VB-CI calculations (8). Goddard also finds a state for the biradical of 1,2-dioxetane ($^1(4\pi)$) that correlates with the ground state products. This state is 3 kcal/mol below the lowest energy state ($^1(2\pi)$). Performing UHF calculations on a triplet state biradical that features a frozen SO bond of 2.3 Å and a CC bond of 1.54 Å, and optimizing the other parameters, using the 3-21G basis set, we find an energy lower than that of 1,2-oxathietane. When correlation energy is included, via MP3/3-21G calculations, the energy of the biradical becomes higher than that of the heterocycle by 25 kcal/mol.

Using single-point calculations with the 3-21G* basis set (optimization could not be performed due to convergence problems) the biradical exceeds the heterocycle in energy by ca. 7 kcal/mol. When the MP3/3-21G* is used, the difference becomes ca. 36 kcal/mol, still lower than the 40 kcal/mol required by the excitation of H_2CS. The value of 7 kcal/mol, which has to be viewed as an approximation, gives an indication that the transition state via a biradical might not require a large activation energy.

At the 3-21G level, performing complete optimization on both ground state and biradical (with the exception of the SO bond frozen at 2.3 Å and the CC bond maintained at 1.54 Å for the biradical), the energies of the two species are about equal. Introducing the correlation energy changes the results somewhat, with MP3/3-21G calculations showing the biradical higher in energy than the ground state by 25 kcal/mol. The MP3/3-21G* results increase this value to 37 kcal/mol. However, the value still remains smaller than the 45 kcal/mol found for the excited state of H_2CS. The values given above are close to the energy of activation for the thermolysis of dioxetane.

In conclusion, it is plausible that 1,2-oxathietanes decompose into ground state formaldehyde and thioformaldehyde via a biradical reaction, while 1,2-dioxetane has been shown in other

For personal use only.

studies to decompose into a ground state formaldehyde and an excited state formaldehyde. Even if the decomposition were to occur with the formation of excited state thioformaldehyde, chemiluminescence would probably not be observed because of the small value of the excitation energy as compared to formaldehyde. As shown by Goddard (15), higher excited states of thioformaldehyde would be necessary to afford photochemical reactions.

N-14 ENDOR study of micellar solutions of sodium dodecylsulfate using small spin probes

YASHIGE KOTAKE AND EDWARD G. JANZEN
Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received September 28, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

YASHIGE KOTAKE and EDWARD G. JANZEN. Can. J. Chem. **66**, 1895 (1988).

ENDOR (electron nuclear double resonance) spectroscopy has been applied to the study of the state of solubilization of small nitroxide spin probes in micelles produced in sodium dodecylsulfate solution. The intensity ratio of the pair of N-14 ENDOR lines observed by fixing the field on the low-field ESR (electron spin resonance) line was monitored as a measure of the motion of spin probes. Neutral spin probes, when solubilized in micelles, show a discontinuous change of ENDOR spectral parameters such as hyperfine splitting constant and peak intensity ratio. Above the critical micelle concentration, the spectrum features change only gradually as the number of solubilized probes is increased. Spin probes in micelles appear to experience environments that are less polar than those met in aqueous solutions. However, the solubilized state is stable and is insensitive to changes in the concentration of the amphiphile. An anionic spin probe, Fremy's salt, shows no indication of interaction with the micelles. The applicability of the use of ENDOR peak intensities for the study of spin probe motion is discussed.

YASHIGE KOTAKE et EDWARD G. JANZEN. Can. J. Chem. **66**, 1895 (1988).

On a utilisé la spectroscopie ENDOR pour étudier l'état de solubilisation de petites sondes de spin nitroxydes dans des micelles produites dans une solution de dodécylsulfate de sodium. Dans le but de mesurer le mouvement des sondes de spin, on a déterminé les rapports des intensités des paires des raies ENDOR N-14 en fixant le champ sur la raie de résonance paramagnétique électronique (rpe) à bas champ. Lorsque des sondes de spin neutres sont solubilisées dans les micelles, elles présentent un changement discontinue des paramètres spectraux ENDOR, tels la constante de couplage hyperfin ainsi que le rapport de l'intensité des raies. Au-dessus de la concentration critique en micelles, les caractéristiques spectrales ne changent que graduellement avec une augmentation du nombre de sondes solubilisées. Il semble que les sondes de spin dans les micelles sont soumises à des environnements qui sont moins polaires que ceux rencontrés dans des solutions aqueuses. Toutefois, l'état solubilisé est stable et n'est pas sensible aux changements de concentration de l'amphiphile. Une sonde de spin anionique, le sel de Fremy, ne semble pas avoir d'interactions avec les micelles. On discute de la possibilité d'utiliser les intensités des bandes en spectroscopie ENDOR pour étudier le mouvement des sondes de spin.

Introduction

The structure of micelles has been examined by using various spectroscopic techniques; however, a definitive answer has still not been given as to whether the molecules in the structure are loose and disordered or tightly aligned (1, 2). Very few techniques are applicable to determine the structure of micelles directly (3). Thus molecular probe methods play a major role in this field since different conclusions can sometimes be reached depending on the technique used. The ESR (electron spin resonance) spin-probing or spin-labelling method is one of these techniques (4, 5) used in monitoring the state of solubilization of solutes in micelles. Usually a stable nitroxide radical is dissolved in the micellar solution and both the magnitude of the N-14 hyperfine splitting (hfs) as well as the linewidth of an ESR line is measured as a function of the concentration of the amphiphilic compound. From these parameters the polarity and microviscosity of the micellar solution that surrounds the molecular probe can be estimated. Various spin probes have already been used in ionic micelles (6).

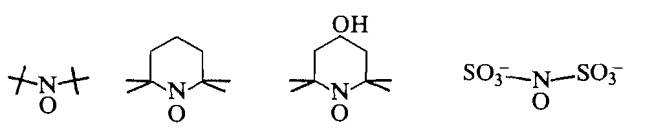
Comparison of ESR and ENDOR

A general feature of investigations in ionic micelles seems to be the observation of a distinct change in the N-14 hfs and the linewidth of the ESR peaks in passing through the critical micelle concentration (cmc) (see, for example, early work by Waggoner *et al.* (7)). Although numerous combinations of spin probes and amphiphiles have been investigated, sometimes the change observed is not clear enough to tell whether there is in fact a change in these parameters at the cmc point. This uncertainty may arise from a basic limitation in the resolution of the lines in the ESR spectrum of the spin probe. Because the magnitude of the proton hfs in the probe is comparable to the intrinsic linewidth and is dependent on the kind of probe used, analysis of these results can be complicated (8). In addition, the proton hfs itself is likely to change upon probe incorporation into the micelle.

These difficulties could in principle be avoided by using electron nuclear double resonance spectroscopy (ENDOR) since the determination of the N-14 hfs of the spin probes is straightforward and both the intensity and the linewidth of N-14 ENDOR spectra are not directly influenced by the presence of proton hfs. Recent ENDOR studies of solubilized radicals in inverse micelles have shown that ENDOR spectroscopy of micellar systems is feasible (9, 10).

Objective

The aim of this study is to test the applicability of the ENDOR method for investigating the solubilizing state of small spin probes. In this connection the sensitivity of the intensity ratio of the N-14 ENDOR lines to the viscosity of the medium incorporating the spin probe will be tested. Four different water-soluble nitroxides are examined as a function of sodium dodecylsulfate concentration in water:



DTBN TEMPO TEMPOL PADS
(peroxylaminedisulfonate)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12

Experimental

Electrophoresis grade sodium dodecylsulfate (SDS) was obtained from BIO-RAD Laboratories and used as supplied. DTBN (di-*tert*-butyl nitroxide), TEMPO (2,2,4,4-tetramethylpiperidine-1-oxyl), and TEMPOL (2,2,4,4-tetramethylpiperidin-4-ol-1-oxyl) were purchased from Aldrich and used without further purification. Fremy's salt was synthesized in these laboratories as the dimer (11).

Solutions containing 5×10^{-4} M of spin probe and known amounts of SDS were made up in doubly distilled Millipore treated water. Sample cells for ESR and ENDOR experiments were made from 1 mm id and 2 mm od Pyrex tubes attached to a solvent-container arm. The solutions were thoroughly degassed by the freeze–pump–thaw method and the cells sealed under vacuum. A Bruker ER200 ESR spectrometer with an ENDOR accessory was used. The temperature in the cavity was controlled by use of the Bruker VT4110 controller. The actual temperature of the sample was checked by use of a copper–constantan thermocouple during radiowave and microwave irradiation. The accuracy of the temperature measurement was ±1 K.

ENDOR spectra for the determination of the N-14 hfs were obtained by setting the external field on the center line of the N-hfs triplet in the ESR spectrum. For the measurement of the ratio of the ENDOR doublet intensity, N-14 ENDOR spectra were observed by fixing the field on the low-field ESR line because the intensity of this line is normally greater than that from the high-field ESR line. ENDOR spectra were obtained by applying 100 mW (−3 db) microwave power and 150 W (−3 db) rf power. The depth of the frequency modulation of rf was 100 kHz. The precision in the measured value of RDI was ±0.03.

The viscosity of aqueous glycerol solutions was measured by the use of an Ubbelohde-type viscometer in a thermostat. The temperature of the thermostat was controlled to within 0.2 K.

Results and discussion

The ratio of the ENDOR doublet intensity

The ENDOR spectrum of DTBN in water at 296 K is shown in Fig. 1. Both the proton and N-14 signals can be seen in the same spectrum at this temperature. The peak due to the 18 magnetically equivalent γ-hydrogens at the NMR frequency ν_p = 14.5 MHz (X) of the free proton is not resolved into a doublet under these conditions. The N-14 signal is composed of a relatively large doublet centered at ν_N = 1.1 MHz. The high-frequency peak (H) is located at $\nu_N + a_N/2 = 25.2$ MHz. The low-frequency peak (L) of the doublet extends beyond zero MHz and is "reflected back" to a position that is $a_N/2 - \nu_N = 23.0$ MHz. Hence the halfway point between the peaks of the N-14 doublet is $a_N/2 = 24.1$ MHz.

The relative intensities of the N-14 doublet will vary depending on the choice of the ESR line saturated. Thus, when the $M_I = 1$ line (high-field line) of the ESR N-14 triplet is saturated the intensity of line (L) exceeds that of line (H), whereas when the $M_I = -1$ line (low-field line) is saturated the intensity of line (L) is less than that of line (H). The difference in intensities is known to be based on unequal cross-relaxation times (12, 13).

We define the Ratio of the ENDOR Doublet Intensity (RDI) as the ratio of the low-frequency peak (L) intensity to the high-frequency peak (H) intensity, using the height from maximum to minimum of the first-derivative trace.

The relationship between RDI and the rotational correlation time τ_R can be calculated from theory available in the literature (14–16). Six energy levels are assumed for one nucleus of $I = 1$ and one electron spin. The nuclear quadrupole interaction, the coherence effect, and the spin-exchange interaction are neglected. The electron-nuclear dipolar and spin-rotational interactions are assumed to be the cause of electron spin relaxation. Thus electron-spin relaxation rate W_e is expressed as:

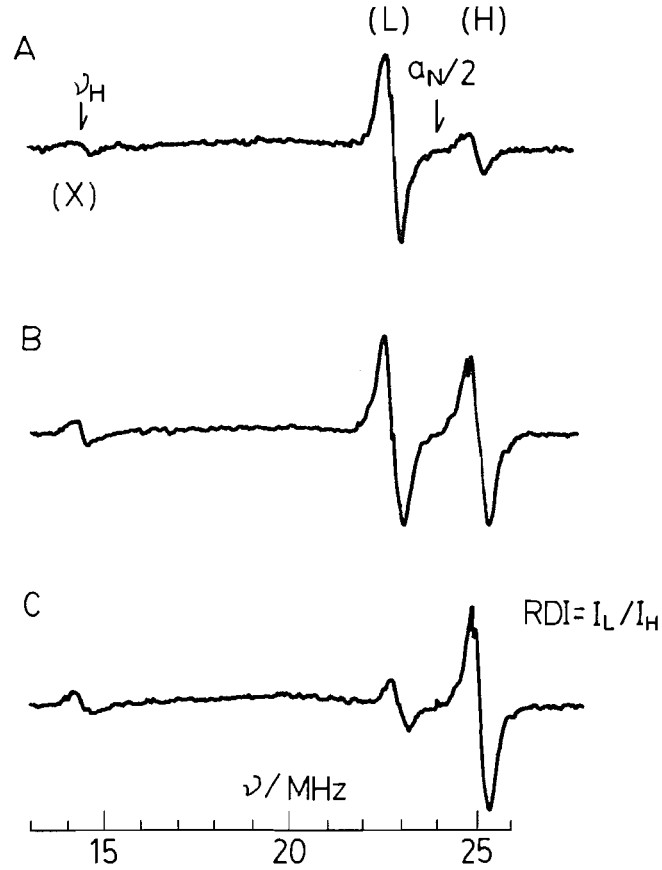

FIG. 1. ENDOR spectrum of 5×10^{-4} M DTBN in water at 296 K. A: the field is fixed at the $M_I = 1$ line (high-field ESR line). (X) denotes the proton ENDOR line and (L) and (H) denote the low and high frequency N-14 ENDOR lines, respectively. B: the field is fixed at the $M_I = 0$ line (center ESR line). C: the field is fixed at the $M_I = -1$ line (low-field ESR line). RDI is defined as I_L/I_H, where I_L and I_H denote the intensity of lines (L) and (H), respectively, in the spectrum C. The spikes on lines L and H are artifacts of the spectrometer, which appear at the even frequencies. The microwave frequency is 9.57 GHz. The rf frequency at $a_N/2 = 24.1$ MHz.

[1] $$W_e = W_{END} + W_{SR}$$

where W_{END} and W_{SR} denote relaxation rates induced by the electron-nuclear dipolar interaction and the spin-rotation interaction, respectively. If one assumes isotropic rotational diffusion (16),

[2] $$W_{END} = (1/40)(A_i' : A_i')\tau_R/(1 + \omega_e^2\tau_R^2)$$

[3] $$W_{SR} = \Sigma(g_i - g_e)^2/2\tau_R$$

where $A_i' : A_i'$ is the inner product of the dipolar tensor of N-hfs, g_i is the principal value of the g-tensor, and g_e, ω_e, and ω_n denote the free-electron g-value, and electron and nuclear Larmor frequencies, respectively. For the nuclear spin and cross-relaxations, it is assumed that the electron–nuclear dipolar interaction is the only mechanism. Thus the nuclear relaxation rate W_n and the cross-relaxation rates W_{x1} and W_{x2} are expressed as:

[4] $$W_n = (1/40)(A_i' : A_i')\tau_R/(1 + \omega_n^2\tau_R)$$

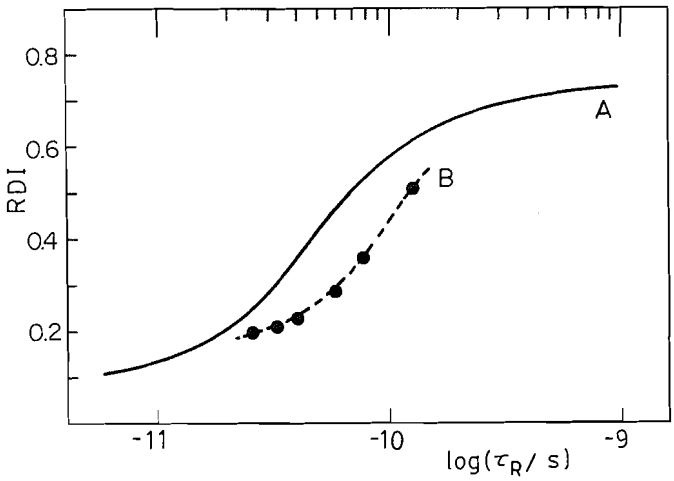

FIG. 2. A: Calculated N-14 ENDOR RDI as a function of the rotational correlation time τ_R. The method of calculation is specified in the text. Parameters used in eqs. [1]–[6] are taken from ref. 17. B: The plot of observed RDI in aqueous glycerol vs. τ_R calculated from observed viscosity in aqueous glycerol. The molecular radius is assumed to be 0.3 nm.

[5] $W_{x1} = 2W_{END}/3$

[6] $W_{x2} = 4W_{END}$

The ESR parameters required for the calculation of the electron-nuclear dipolar and spin-rotational relaxation times were taken to be those of DTBN (17). The transition probability matrix was constructed and the ENDOR enhancement was calculated from saturation factors by using a double cofactor method (14, 15). The low-field ESR line was chosen to be the observed ESR transition. The ENDOR enhancement factors were calculated with each of the two nuclear transitions saturated. The calculation was performed with the assumption that both electron and nuclear transitions are at just-resonance and that the nuclear transition is under complete saturation. The ratio of the two calculated enhancement factors can be plotted as a function of τ_R as shown in Fig. 2. The plot shows that the RDI increases smoothly with increase in correlation time. Thus the experimentally available values for RDI for DTBN in solution where N-14 ENDOR spectra can be obtained are directly related to τ_R.

If RDI for 5×10^{-4} M DTBN is plotted against the content of glycerol in water at various temperatures, the curves shown in Fig. 3 are obtained. From such plots one can find the microscopic viscosity in an unknown sample using aqueous glycerol as a reference. τ_R of DTBN in aqueous glycerol can be calculated based on the Stokes–Einstein equation by using the viscosity and molecular radius of the probe. Thus the dependence of observed RDI on τ_R is obtained and is plotted in Fig. 2.

To use RDI as a measure of τ_R it is essential to establish the condition under which no factors other than the diffusion of individual molecules influences the ratio. In Fig. 4 the dependence of RDI on the concentration of DTBN in water is shown at three different temperatures. At concentrations above 5×10^{-4} M DTBN, increase in concentration enhances the difference in the ENDOR doublet intensities. However, below this concentration the RDI approaches a constant value. Thus at 5×10^{-4} M the effect of spin–spin exchange on the RDI is apparently negligible.

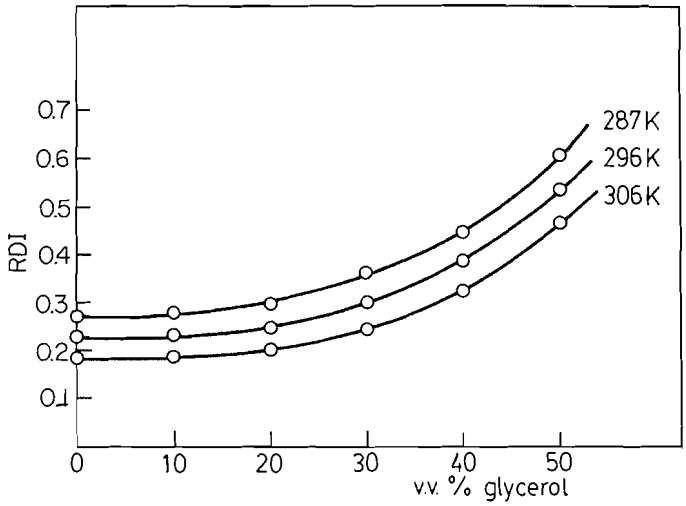

FIG. 3. The dependence of the N-14 ENDOR RDI on the glycerol content (v.v. denotes volume percent) in aqueous solutions of DTBN at various temperatures.

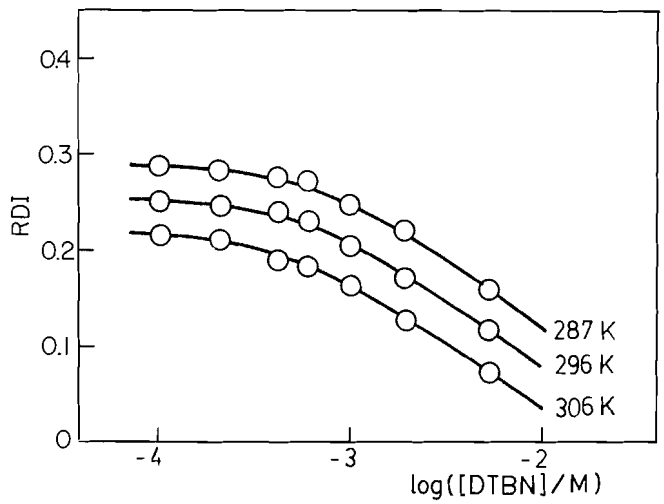

FIG. 4. The dependence of the N-14 ENDOR RDI of DTBN on the concentration of DTBN in water at various temperatures.

ENDOR RDI at SDS concentrations near micellization: DTBN

The ENDOR spectra of DTBN at several different concentrations of SDS from 0 to 0.1 M SDS in water were obtained at 296 K. The N-14 doublets only are plotted in Fig. 5. At relatively low and high concentrations (far from the SDS cmc) the doublets give fairly constant but different RDI values (Fig. 6). An abrupt change occurs between 0.02 and 0.03 M SDS, which is at a higher concentration than the reported cmc for SDS (18), namely 8.6×10^{-3} M. The discrepancy probably occurs because the number of micelle aggregates is much less than the number of probe molecules near the cmc.

Inspection of Fig. 5 reveals that the N-14 doublet moves to lower frequency in the range 0.02–0.03 M SDS, as the SDS concentration is increased. This corresponds to a decrease in the N-14 hfs. Figure 6 shows that the abrupt change in N-14 hfs corresponds to the sharp change in RDI values. Thus DTBN is completely solubilized in the SDS micelles at concentrations well above the cmc (19). The rotational correlation times calculated from Fig. 2 increase from 2.2×10^{-11} to $4.2 \times$

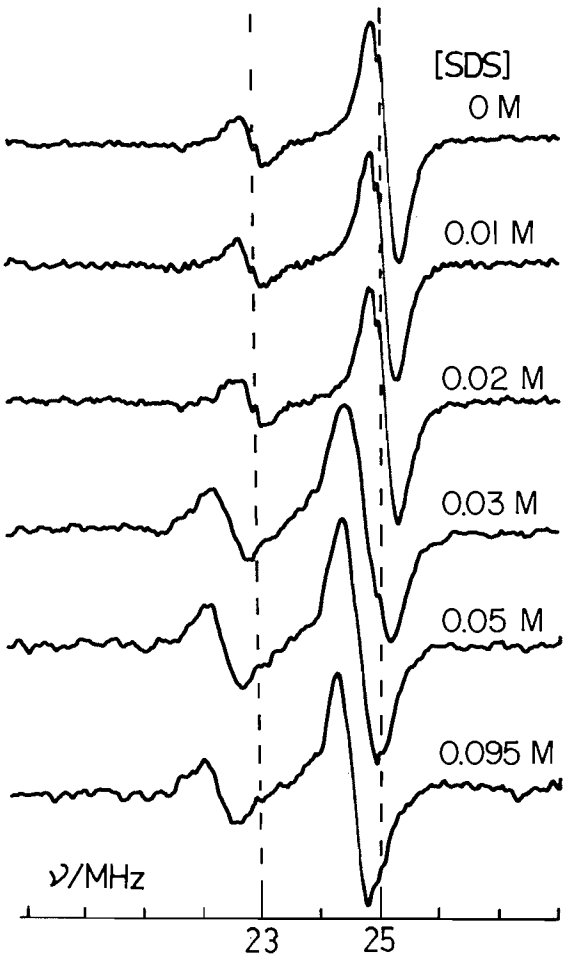

FIG. 5. N-14 ENDOR spectra of aqueous solutions of 5×10^{-4} M DTBN as a function of the concentration of SDS at 296 K. The magnetic field was fixed on lower field line of N-hfs.

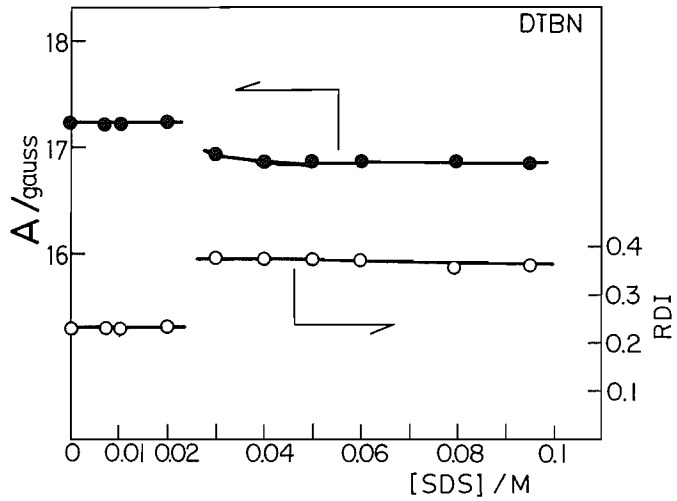

FIG. 6. The dependence of the N-14 hfs and the ENDOR RDI of 5×10^{-4} M DTBN in SDS aqueous solution as a function of the concentration of SDS at 296 K.

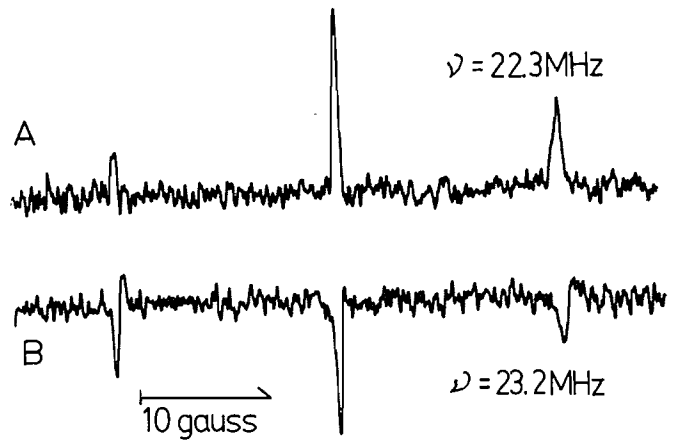

FIG. 7. ENDOR induced ESR spectra of DTBN in 3×10^{-2} M SDS aqueous solution taken by fixing the rf: (A) at 22.3 MHz, (B) at 23.2 MHz. These correspond to the ESR spectra of solubilized (less polar region) and free (more polar region) DTBN molecules, respectively.

10^{-11} s upon micellization. The microviscosities are 1.0 and 2.0 cP for the aqueous and micellar environment, respectively.

The spectra around the region of the cmc need further comment. The ENDOR doublet lines clearly have larger linewidths in the region of 3×10^{-2} to 5×10^{-2} M SDS than at SDS concentrations above and below this range. This is due to the coexistence of two DTBN spectra with different N-14 hfs (19). Although the two different ENDOR doublets could not be resolved under these conditions, the existence of such overlapping spectra could be ascertained by inspection of an ENDOR-induced ESR spectrum (20) of DTBN at 3×10^{-2} M SDS (Fig. 7). From this experiment the values $a_N = 17.2$ and 16.8 gauss were determined. These coupling constants agree well with the values obtained at pre and post cmc of DTBN in SDS.

Thus ENDOR spectroscopy confirms the generally accepted picture that DTBN is incorporated into SDS micelles around the cmc but that the average environment of the DTBN in the micelle is extremely polar and only slightly less polar than water itself (19). The existence of two locations for DTBN is also confirmed at concentrations of SDS near the cmc. The coexistence of these different DTBN molecules persists until all are dissolved in the micelles. The exchange rate between these two DTBN is slow on the ESR time scale (less than 10^{-6} s).

TEMPO

The N-14 hfs and RDI for TEMPO in water containing increasing amounts of SDS at 296 K are plotted in Fig. 8. Although the change in the RDI with increase in SDS concentration is abrupt (between 0.03 and 0.035 M SDS) the difference is not large. The change in N-14 hfs at this concentration range is also relatively small (0.2 gauss). If one applies the calculated results of RDI for DTBN, the change in the rotational correlation time is found to range from 2.3×10^{-11} to 4.2×10^{-11} s. The microviscosity changes from 1.1 to 1.9 cP. The broadness of the ENDOR doublet near the cmc again indicates the presence of two nitroxide species for which the polarity of the environment is different. In all aspects investigated, DTBN and TEMPO appear to behave essentially the same when dissolved in solutions containing increasing amounts of SDS.

TEMPOL

The ENDOR spectra of TEMPOL in water containing

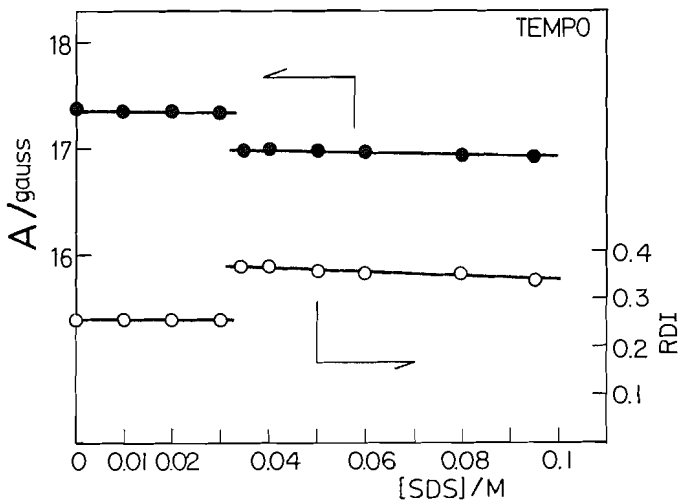

FIG. 8. The dependence of the hfs and ENDOR RDI of 5×10^{-4} M TEMPO in SDS aqueous solution as a function of the concentration of SDS at 296 K.

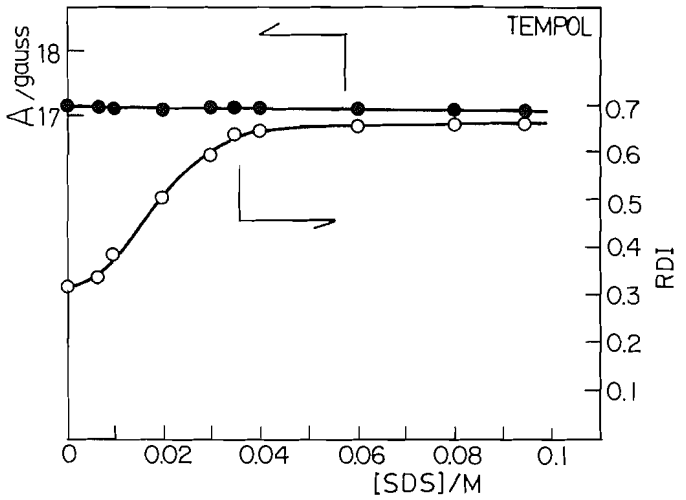

FIG. 10. The dependence of the N-14 hfs and ENDOR RDI of TEMPOL in SDS aqueous solution as a function of the concentration of SDS at 296 K.

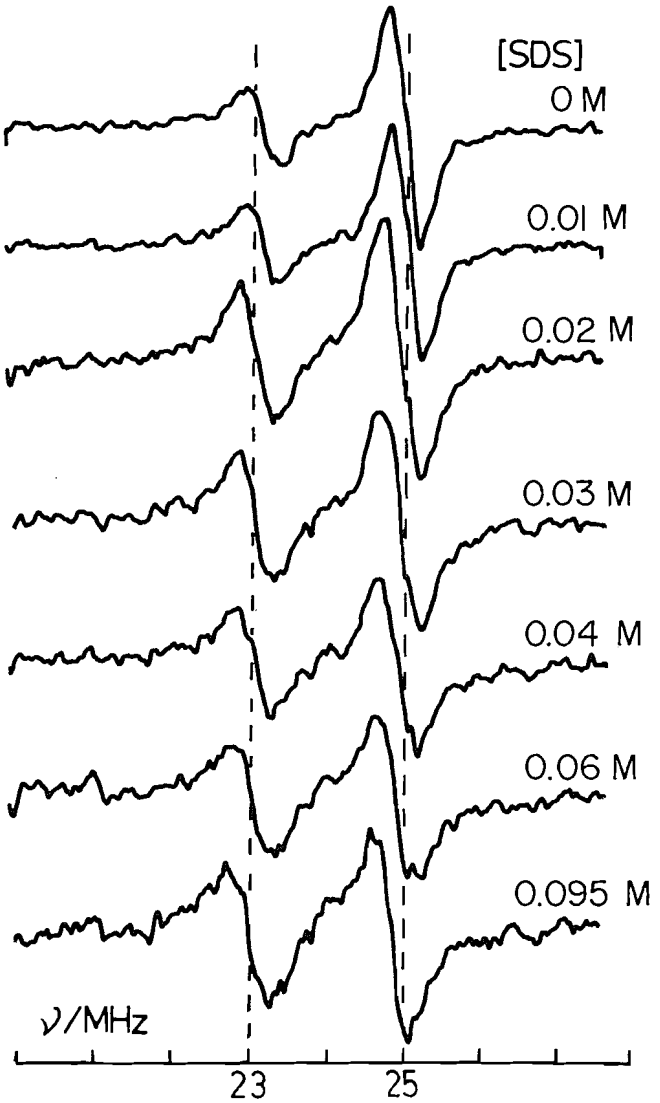

FIG. 9. N-14 ENDOR spectra of 5×10^{-4} M aqueous solution of TEMPOL as a function of the concentration of SDS at 296 K.

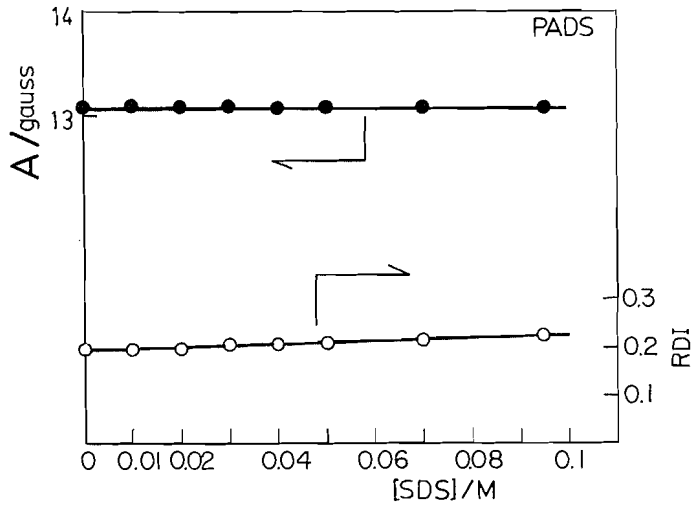

FIG. 11. The dependence of the N-14 hfs and ENDOR RDI of 5×10^{-4} M PADS in SDS aqueous solution as a function of the concentration of SDS at 296 K.

increasing amounts of SDS at 296 K are shown in Fig. 9 (N-14 ENDOR doublet only). The plots of the RDI and N-14 hfs are given in Fig. 10. Although an almost continuous change in the RDI is observed with increase in SDS concentration, the N-14 hfs does not change from the value in water. Thus the ENDOR spectra reveal a restriction in motion for the probe in spite of the fact that the environment for TEMPOL remains as polar as water. The rotational correlation times are found to be 2.3×10^{-11} and 1.0×10^{-10} s for aqueous and micellar phases, respectively. The change in microviscosity is estimated to be from 1.3 to >4.5 cP. After the concentration of SDS exceeds 5×10^{-2} M no more change in RDI occurs, indicating that all TEMPOL molecules are associated with SDS micelles.

PADS (Fremy's salt)

The values for RDI and N-14 hfs of PADS are plotted against SDS concentration in Fig. 11. While the change in the RDI is very small (about 5% from 10^{-2} to 10^{-1} M SDS) and well within the change in bulk viscosity of the solution, the N-14 hfs

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

does not change at all. Because there is no abrupt change in the RDI at any concentration it must be concluded that PADS does not associate with SDS micelles.

Evaluation of the ENDOR method

The estimation of the intrinsic ESR linewidth, which is hidden in the inhomogeneous linewidth due to proton hfs, has been a problem in spin labeling and spin probing methods. We have shown that N-14 ENDOR spectroscopy can determine both the hfs and the rotational correlation time of the nitroxide spin probe irrespective of the ESR linewidth. The ENDOR approach is much simpler than the ESR spin probing method since the latter requires a correction of the residual linewidth due to small unresolved proton hfs. The evaluation of the rotational correlation time, however, has the same degree of uncertainty as the ESR linewidth method because both methods assume the correct choice of effective relaxation processes.

Overlap of spectra from two species near the cmc region occurs in ENDOR as well as in ESR spectroscopy. However, we have shown that resolution of the spectrum is possible in some cases by using ENDOR-induced ESR spectroscopy.

The broadening of the ESR lines observed near the cmc region has been previously attributed to the site exchange of the probe between the aqueous and micellar phases (7). However, our ENDOR study in SDS gives no indication of such exchange.

An EPR/ENDOR study of aminoxyls (nitroxides) capable of intramolecular bonding: hydroxyalkyl radical spin adducts of nitrones[1]

D. Larry Haire, Yashige Kotake, and Edward G. Janzen[2]

Department of Chemistry and Biochemistry, Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph, Ont., Canada N1G 2W1

Received October 9, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

D. Larry Haire, Yashige Kotake, and Edward G. Janzen. Can. J. Chem. **66**, 1901 (1988).

A comparison of the effect of solvent and ^{13}C labeling (of the radical addend) on the EPR (electron paramagnetic resonance) spectra of hydroxyalkyl vs. alkyl radical adducts of α-phenyl-*N*-*tert*-butyl nitrone (PBN) and 5,5-dimethyl-1-pyrroline-1-oxide (DMPO) has been investigated. The solution ENDOR spectra in toluene and in ethanol are the first examples studied of aminoxyls with hydroxyl substituents in close proximity to the free radical centre. Diastereomeric mixtures of hydroxyalkyl radical adducts are clearly resolved by ENDOR spectroscopy. Conformations of these radicals have been assigned based on the ^1H and ^{13}C hyperfine splittings (HFS's) and by differential optimum ENDOR temperatures. Definitive assignments of carbon-centered radical adducts of DMPO and PBN are shown to be feasible by monitoring the β-^{13}C HFS's of the radical addend. Long-range γ-H HFS's from the added radical group can be observed when the deuterated spin trap PBN-d_{14} is used. The production of ^{13}C labeled hydroxyalkyl adducts of nitrones (e.g., DMPO–$^{13}CH_2OH$, from the reaction of hydroxyl radicals with added $^{13}CH_3OH$) is shown to be useful as an improved EPR spectroscopic method for the verification of the presence of hydroxyl radicals.

D. Larry Haire, Yashige Kotake et Edward G. Janzen. Can. J. Chem. **66**, 1901 (1988).

On a effectué une étude comparative de l'effet de solvant et du marquage au ^{13}C (du radical qui s'ajoute) sur les spectres en résonance paramagnétique électronique d'adduits alkylés vs. hydroxy-alkylés de l'α-phényl *N*-*tert*-butyl nitrone (PBN) et de l'oxyde de la diméthyl-5,5 pyrroline (DMPO). Les spectres ENDOR, en solutions dans le toluène et dans l'éthanol, sont les premiers exemples de spectres de radicaux aminoxyles portant des substituants hydroxyles à proximité du centre radicalaire. La spectroscopie ENDOR permet de résoudre sans ambiguïté les mélanges diastéréomères des adduits radicalaires hydroxy-alkylés. On a attribué les conformations de ces radicaux en se basant sur les couplages hyperfins du ^1H et du ^{13}C et sur les températures différentielles ENDOR optimales. On a démontré que, si on détermine les couplages hyperfins du β-^{13}C du radical ajouté, il est possible de faire des attributions définitives des adduits, du DMPO ainsi que du PBN, qui portent des centres radicalaires sur le carbone. Lorsqu'on utilise le piège à spin PBN-d_{14}, on peut observer les couplages hyperfins du γ-H à longue distance du groupement radicalaire qui a été ajouté. On a démontré que la formation d'adduits hydroxy-alkylés des nitrones qui sont marquées au ^{13}C (par exemple, le DMPO–$^{13}CH_2OH$ qui provient de la réaction de radicaux hydroxyles avec du $^{13}CH_3OH$ ajouté) est une méthode en résonance paramagnétique électronique améliorée pour la vérification de la présence de radicaux hydroxyles.

Introduction

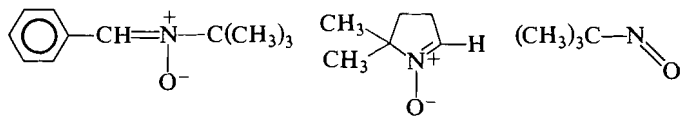
Hydroxyalkyl radicals are difficult to detect in solution without special EPR spectroscopic techniques.[3] Transient radicals such as these, however, may be detected and identified by virtue of their reaction with nitrones (the spin trapping reaction) (for general reviews on EPR spin trapping and ancillary techniques such as spectral simulation, see ref. 2), which yields persistent aminoxyl adducts whose EPR parameters (nitrogen and β-hydrogen hyperfine splittings) (HFS's) as well as g values) in principle are unique for the radical trapped.

There has been previous interest in hydroxyalkyl radical adducts (e.g., $\dot{C}H_2OH$) produced from two widely used nitrone

[1] $RX\cdot + -CH=\overset{+}{N}(O^-)- \longrightarrow -CH(RX)-N(O\cdot)-$

Transient radical — Nitrone spin trap — Aminoxyl (nitroxide) spin adduct

spin traps, α-phenyl-*N*-*tert*-butyl nitrone (PBN) (**1**) (for the hydroxymethyl adduct of PBN, see ref. 3), and 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO) (**2**),[4] as well as from the C-nitroso spin trap, 2-nitroso-2-methylpropane (MNP) (**3**) (see ref. 5



PBN (**1**) DMPO (**2**) MNP (**3**)

for the hydroxymethyl adduct). These adducts and higher analogues (e.g., those originating from ethanol and larger alcohols, glycerols, and sugars, etc.) have been generated mainly by radiolysis, photolysis, and even by sonolysis.

[1]This work was presented in part at the 70th Meeting of the Chemical Institute of Canada in Quebec City, June 7–11, 1987.

[2]Author to whom correspondence may be addressed.

[3]Kinetic EPR techniques (i.e., with short, strong pulses of UV radiation) have recently been used to detect the $\cdot CH_2OH$ radical in solution (1*a*). The $\cdot CH_2OH$ radical can also be detected in solution using a special EPR "flow cell" apparatus (1*b*), and has also been detected directly by EPR (e.g., during photolysis of the anticancer drug, Bleomycin) using matrix isolation techniques (at 77 K) (1*c*). Other hydroxyalkyl radicals (e.g., from X-irradiated saccharides such as glucose and derivatives) may be analyzed by EPR and ENDOR in the solid state (at 12 K) (1*d*).

[4]For the hydroxymethyl adduct of the aliphatic cyclic nitrone, 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO), see refs. 4*a*–*e*), and for the 2-hydroxypropyl adduct of the aliphatic acyclic nitrone, *tert*-butyl nitrone (BN), see ref. 4*f*).

An interesting recent development has been the use of nitrones to detect hydroxyalkyl radicals in biological systems. Specifically, hydroxyalkyl radicals have been observed in rat liver microsomal systems (*6a,b*)[5] treated with alcohols, suggesting that these reactive intermediates may be implicated in the toxicological effects of ethanol (e.g., liver damage) such as lipid peroxidation and related processes. The autoxidation of sugars under physiological conditions also apparently yields hydroxyalkyl radicals (*6i,j*).

Another interesting recent sidelight deals indirectly with the trapping of hydroxyl radicals. Since it is known that hydroxyl adducts of nitrones may in certain circumstances arise from artifactual reactions (2, 7) it has been suggested (*2c*, *5b*)[6] that the detection of hydroxyalkyl adducts might serve as a diagnostic check:

[2] $HO\cdot + R_2CHOH \rightarrow H_2O + R_2\dot{C}OH$

Hydroxyl radical — Added alcohol — Hydroxyalkyl radical

Objective

In the present study we have searched for methods to better characterize some carbon-centered adducts of nitrones (e.g., hydroxyalkyl vs. alkyl). To probe the radical structures in more detail high resolution techniques including Electron Nuclear Double Resonance (ENDOR) spectroscopy as well as the implementation of deuterated spin traps have been explored. Also the effects of solvent, temperature, and ^{13}C labeling (of the radical addend) on the EPR and ENDOR spectra have been investigated.

Radical formation and spin trapping chemistry

Hydrogen atom abstraction from alcohols by photoexcited benzophenone to form hydroxyalkyl radicals is a well-known process (8). Subsequent trapping by a nitrone leads to a hydroxyalkyl adduct (**4**). It is noteworthy that photoexcited nitrones may also act as hydrogen atom abstractors (*6h*).

[3] $PhCOPh^* + R_2CHOH \rightarrow PhC\dot{H}Ph + R_2\dot{C}OH$

[4] 
PBN–$COHR_2$ (**4**)
R = H, alkyl or aryl

ENDOR spectroscopy

Solution ENDOR spectroscopy has proven to be a valuable tool for gleaning detailed structural and environmental information about aminoxyl spin probes, spin labels, and spin adducts.[7] One advantage of ENDOR over EPR spectroscopy is the ability of the former to detect very small HFS's (e.g., in long-range hyperfine splittings, or small differences in HFS's such as those in radical mixtures).

Experimental

The hydroxyalkyl adducts in organic solvents were generally prepared according to previously described methods (*3e*) except that 5-mL alcohol solutions of 50 mM nitrone and 50 mM benzophenone were used. Photolysis of the deoxygenated alcohol solutions was accomplished using a low pressure 75 W xenon lamp (Oriel model 6137). The irradiation period was approximately 15 min. The hydroxyalkyl adducts in aqueous solutions were prepared by photolysis of aqueous solutions containing 50 mM nitrone, 50 mM hydrogen peroxide, and 50 mM alcohol. The PBN-d_{14} and DMPO alkyl adducts were prepared by the anion (RMgI) addition/quenching with water/and oxidation sequence referred to in ref. *10b*.[8] Typically, 2-mL solutions containing ~2 mg of nitrone and ~0.1 mL of 2 M Grignard reagent were used. Samples were deoxygenated by 4 freeze–pump–thaw cycles and sealed off on a vacuum line before spectral analysis.

EPR and ENDOR spectra were recorded with a Bruker ER-200D EPR spectrometer (ST 4102 and EN 801 X-band cavities, respectively) and Bruker ER-140 (Aspect 2000) data system. The ENDOR spectra were obtained with an E-N A-300 amplifier with 12.5 kHz radio-frequency modulation. The EPR spectral centre field was generally around 3400 gauss. Thus the centres (ν_H and ν_N) for the ^1H and ^{14}N ENDOR doublets (i.e., the ^1H and ^{14}N NMR frequencies) are 14.47 and 1.046 MHz, respectively. The sample temperature was controlled by a Bruker ER 4111 VT unit. Spectra were simulated with Oehler and Janzen's BASIC program (*2e*). (Note: line 485 should read MT = MT + MK(I4).) The *g* values were calculated as previously described (*3e*, *2f*) using Fremy's salt (sodium peroxylamine disulfonate in saturated aqueous $NaHCO_3$) as the internal standard (g = 2.00550, a^N = 13.091 gauss).

Solvent exchange was accomplished by the following procedure. The bulk of the solvent was removed by purging with N_2 (g). The final traces of solvent were pumped off using a vacuum line. The new solvent was introduced and dried (Na_2SO_4).

The nitrones α-phenyl-*N*-*tert*-butyl nitrone (PBN) and 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO) are commercially available (Aldrich and Sigma). The ^2H and ^{13}C methanol, ^2H and ^{13}C iodomethane, as well as benzaldehyde-carbonyl ^{13}C were obtained from MSD Isotopes.

Results and discussion

PBN–CH_2OH vs. PBN–CH_3

Radical conformations

Listed in Table 1 is a comparison of the HFS's of the two prototypical aminoxyls PBN–CH_2OH and PBN–CH_3. The solvents are listed in order of increasing solvent polarity, according to the solvent polarity parameter $E_{T(30)}$ (11). PBN–CH_2OH should have the capability for intramolecular H-bonding whereas PBN–CH_3 should not. The corresponding EPR spectra are shown in Figs. 1–6. Small amounts of the alkoxyl adduct (PBN–OCH_3, a^N = 14.5, a_β^H = 2.8 gauss in methanol) (*3a,d,k*) are also present in some of the EPR spectra (Figs. 1–3).

On the basis of the magnitudes of both the β-^1H and β-^{13}C HFS's (both of which exhibit a dihedral angle dependence (12) with respect to the aminoxyl *p*-orbital) PBN–CH_3 likely adopts the time-average conformation shown below (**5**) (*10b*). The proposed conformation for PBN–CH_2OH (**6**) can be compared to **5** by counterclockwise rotation of the frontal carbon about the C—N bond. A larger β-H, smaller β-^{13}C (radical addend), and larger β-^{13}C (phenyl) HFS should result, and this is what is observed.

The β-^{13}C radical addend HFS for PBN–CH_2OH (2.26 gauss in toluene) is relatively small compared to PBN–CH_3 (3.11 gauss)

[5]For radical adducts of PBN, DMPO, and MNP more complex than hydroxymethyl, see refs. *6a–m*.

[a]The HFS's are in gauss; — indicates that this value is not available.
[b]For the $E_{T(30)}$ solvent polarity scale (kcal/mol) see ref. 11.
[c]The β-^{13}C (phenyl) HFS's were assigned as described in ref. 10*b*.
[d]The HFS's (in benzene, $E_{T(30)}$ = 34.8) of two other β-^{13}C (radical addend) labeled adducts: PBN–$^{13}CCl_3$, a^N = 13.88, a_β^H = 1.61, a_β^{13C} (CCl_3 = 9.67 gauss, g = 2.00631 (ref. 13); PBN–$^{13}C(O)C_6H_5$, a^N = 14.30, a_β^H = 4.54, a_β^{13C} (carbonyl) = 6.09 gauss (from benzaldehyde-carbonyl ^{13}C and *tert*-butoxyl radicals, unpublished data)).

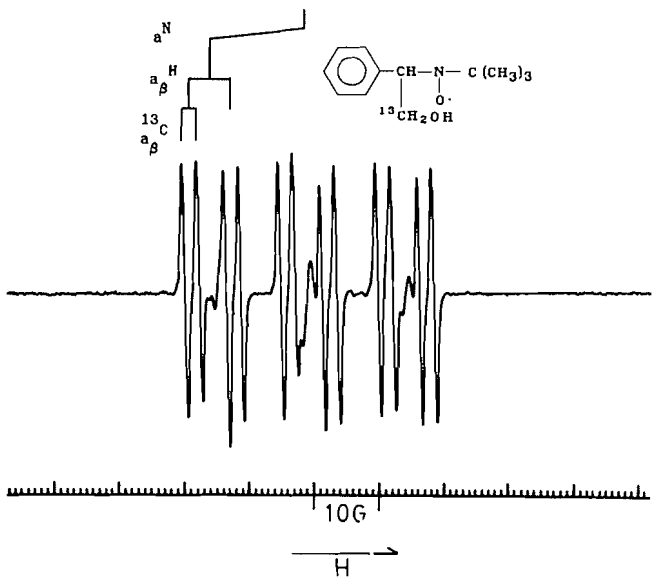

FIG. 1. EPR spectrum of PBN–$^{13}CH_2OH$ in toluene at 300 K.

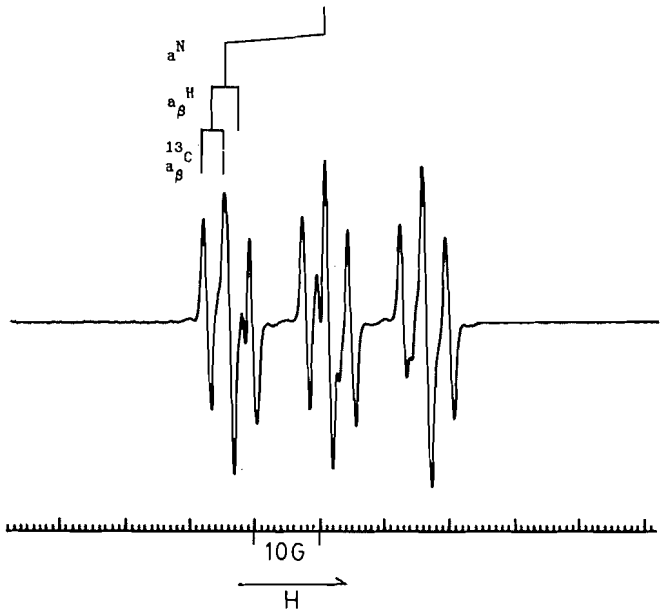

FIG. 2. EPR spectrum of PBN–$^{13}CH_2OH$ in methanol at 300 K.

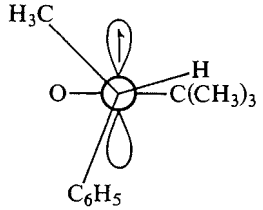
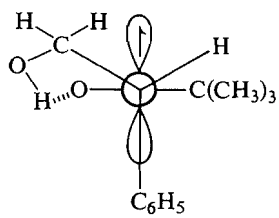
as well as other PBN adducts such as PBN–$C(O)C_6H_5$ (6.09 gauss) and PBN-CCl_3 (9.67 gauss). In addition, PBN–CH_2OH exhibits larger β-H and β-^{13}C (phenyl) HFS's compared to PBN–CH_3 (6.69 vs. 3.58, and 11.3 vs. 10.6 gauss, respectively).

A reasonable explanation for this conformational preference (i.e., **6** vs. **5**) is the possibility of intramolecular H-bonding between the CH_2OH substituent and the aminoxyl function.[9] Significant π-attraction between the phenyl and aminoxyl groups (10*b*) may also assist in the intramolecular H-bonding interaction by swinging the CH_2OH group closer to the aminoxyl group.



PBN—CH_3
(**5**)



PBN—CH_2OH
(**6**)

EPR solvent effects

As the solvent polarity is increased (e.g., from tetramethylsilane to toluene) the nitrogen HFS's for both PBN–CH_2OH and PBN–CH_3 increase (Table 1). This effect is attributed to the stabilization of the polar resonance structure (**8**) with the unpaired electron on the nitrogen atom.[10] This effect is much

[9]The notion of H-bonding has been invoked before: ref. 4*f*; for a related system (hydroxyalkyl adducts of nitromethane radical anion) see ref. 14.

[10]The trend of increase in nitrogen HFS with increase in solvent polarity is well documented, for example, ref. 15*a*, with aminoxyl (nitroxide) spin probes, and 15*b*, with aminoxyl spin adducts.

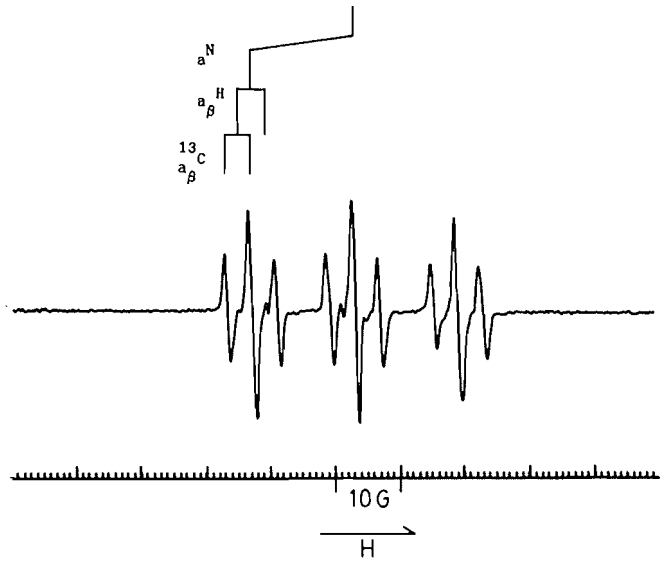

FIG. 3. EPR spectrum of PBN–$^{13}CH_2OH$ in water at 300 K.

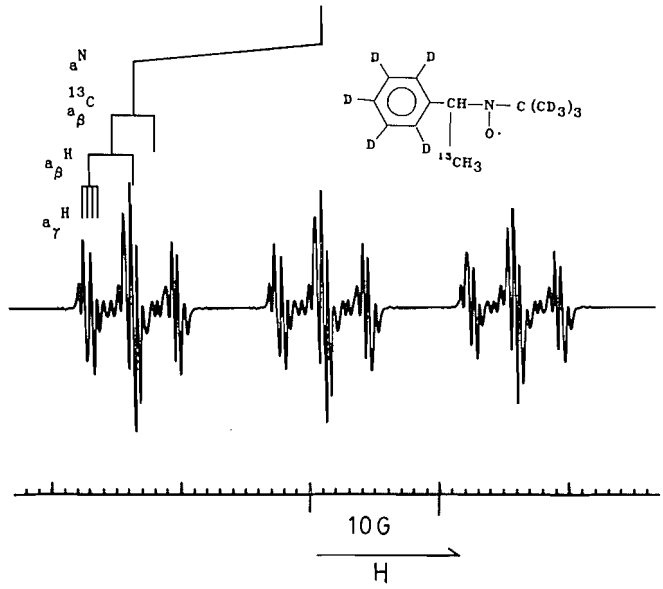

FIG. 4. EPR spectrum of PBN-d_{14}–$^{13}CH_3$ in toluene at 300 K.

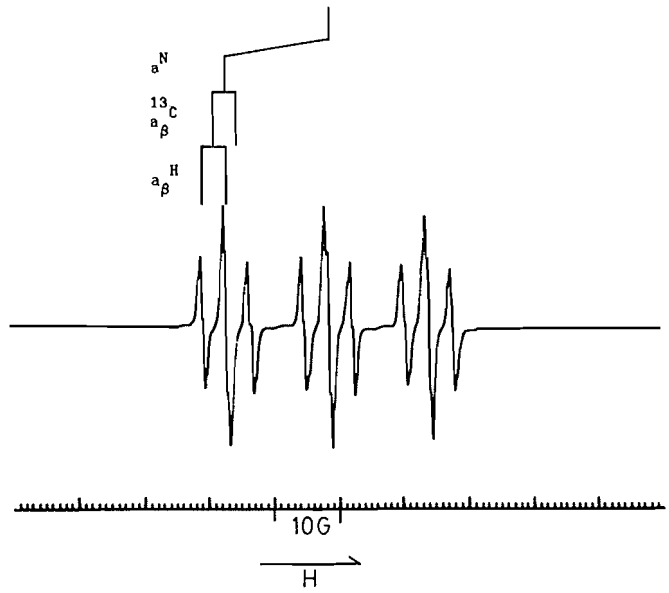

FIG. 5. EPR spectrum of PBN-d_{14}–$^{13}CH_3$ in methanol at 300 K.

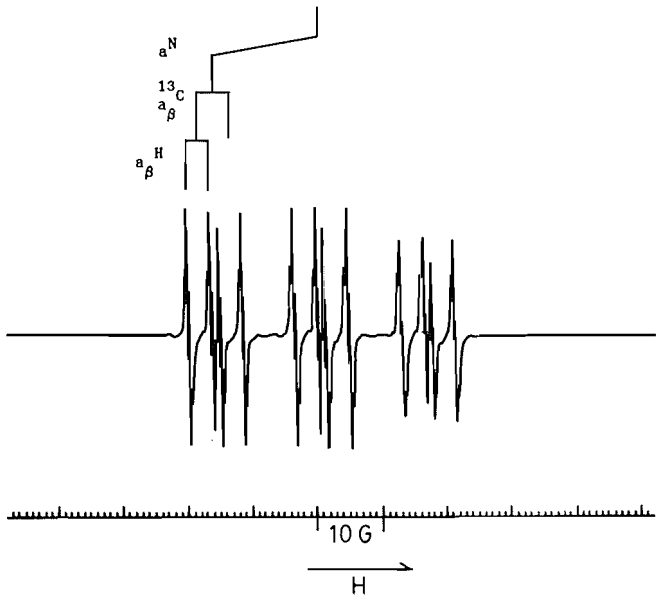

FIG. 6. EPR spectrum of PBN-d_{14}–$^{13}CH_3$ in water at 300 K.

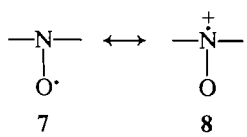
more pronounced for both adducts as even more polar solvents are introduced (e.g., acetonitrile, methanol, and water).

In nonpolar solvents (e.g., TMS, toluene, etc.) the PBN–CH_2OH adduct exhibits an unusually large β-H HFS (~6.7 gauss). When this adduct is placed in polar solvents (e.g., acetonitrile, methanol, etc.) a remarkable phenomenon occurs. Despite the increase in nitrogen HFS (14.9 to 15.3 gauss) the β-H HFS undergoes a substantial *decrease* in magnitude (~6.7 to ~3.7 gauss). The β-^{13}C (CH_2OH) and β-^{13}C (phenyl) HFS's also show sensitivity to change in polarity of solvents. These data suggest that replacing a nonpolar with a polar solvent causes the disruption of the intramolecularly H-bonded structure (**6**) via the intervention of intermolecular H-bonding between the polar solvent molecules and the aminoxyl group. Further solvent effects are observed as a more polar solvent is introduced but these effects are comparatively smaller.



7 **8**

EPR/ENDOR temperature effects

In Table 2 (Figs. 7 and 8) it is clear that the β-hydrogen HFS of PBN–CH_2OH increases with decrease in temperature. This result suggests that the H-bonding interaction between the hydroxymethyl and aminoxyl groups becomes stronger at lower temperatures.

A striking feature of the ENDOR spectra of PBN–CH_2OH is the observation of a β-H doublet at a relatively high ENDOR temperature (300 K, Fig. 8A). The optimum intensity for an ENDOR response obtained at a given rotational correlation time (τ_R) is determined by the EPR parameters of the radical and its

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12

TABLE 2. EPR and ENDOR hyperfine splittings (HFS's) for PBN–CH_2OH in toluene at various temperatures[a,b]

Temperature (K)	Experiment	a^N	a^H_β	a^H_γ (radical addend)
300	EPR	14.92	6.69	0.31
300	ENDOR	14.99	6.65	—
240	ENDOR	15.04	6.89	0.35
200	EPR	14.90	7.00	—
200	ENDOR	15.03	7.01	—

[a]The HFS's are gauss; — indicates that this value is not available. Conversion of gauss to MHz is multiplication by 2.81.

[b]The γ-H HFS of 0.31 gauss due to *one* of the diastereotopic methylene H's (CH_2OH) is visible by both EPR and ENDOR when PBN-d_{14} is used (assignment confirmed by comparison with the CD_2OH analogue). The second methylene γ-H HFS is too small (i.e., <0.1 gauss) to be readily resolved. No HFS from the hydroxyl-H could be resolved (checked by D_2O exchange).

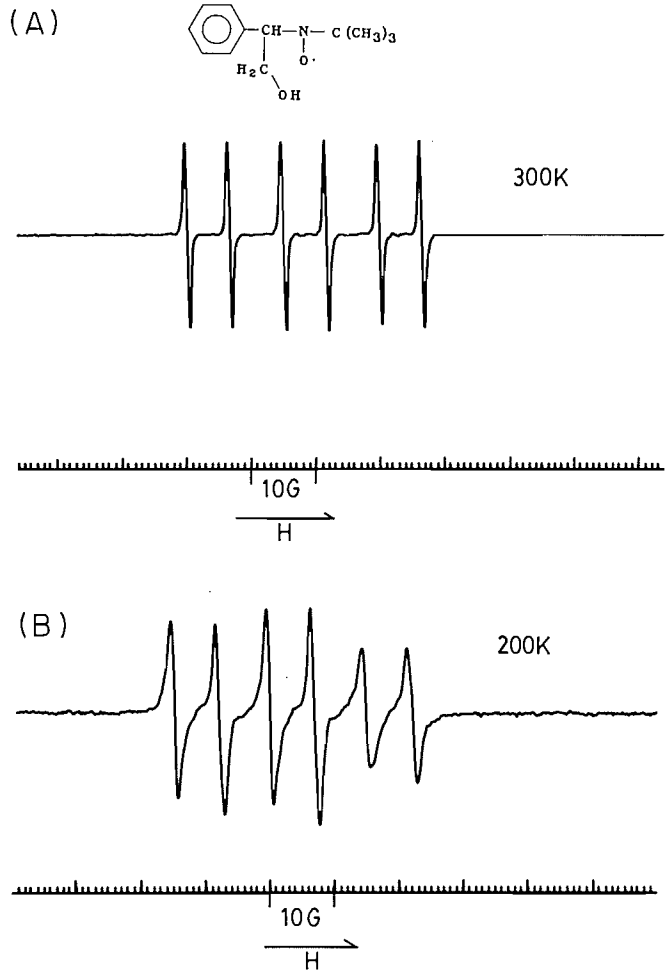

FIG. 7. EPR spectra of PBN–CH_2OH in toluene at (A) 300 and (B) 200 K, respectively.

nucleus.[11] Since τ_R is dependent upon the effective volume of the tumbling radical (V_{EFF}) (eq. [5]), an increase in V_{EFF} raises the optimum ENDOR temperature.

[5] $\tau_R = V_{EFF}(\eta/kT)$

[11]For a more detailed relationship between τ_R and the optimum ENDOR conditions see Equation 13 in ref. 16.

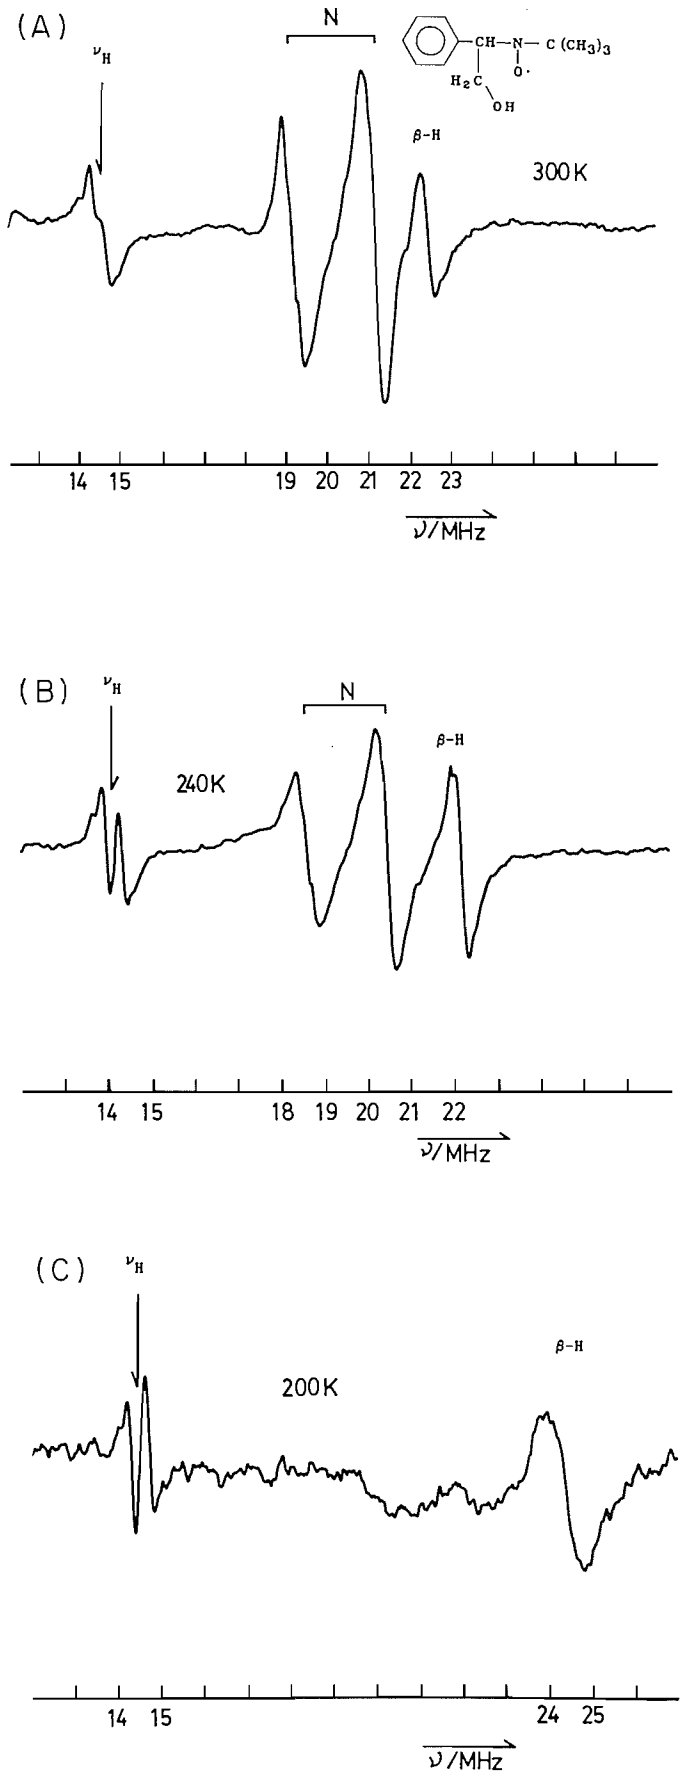

FIG. 8. ENDOR spectra of PBN–CH_2OH in toluene at (A) 300, (B) 240, and (C) 200 K, respectively (13–28 MHz region).

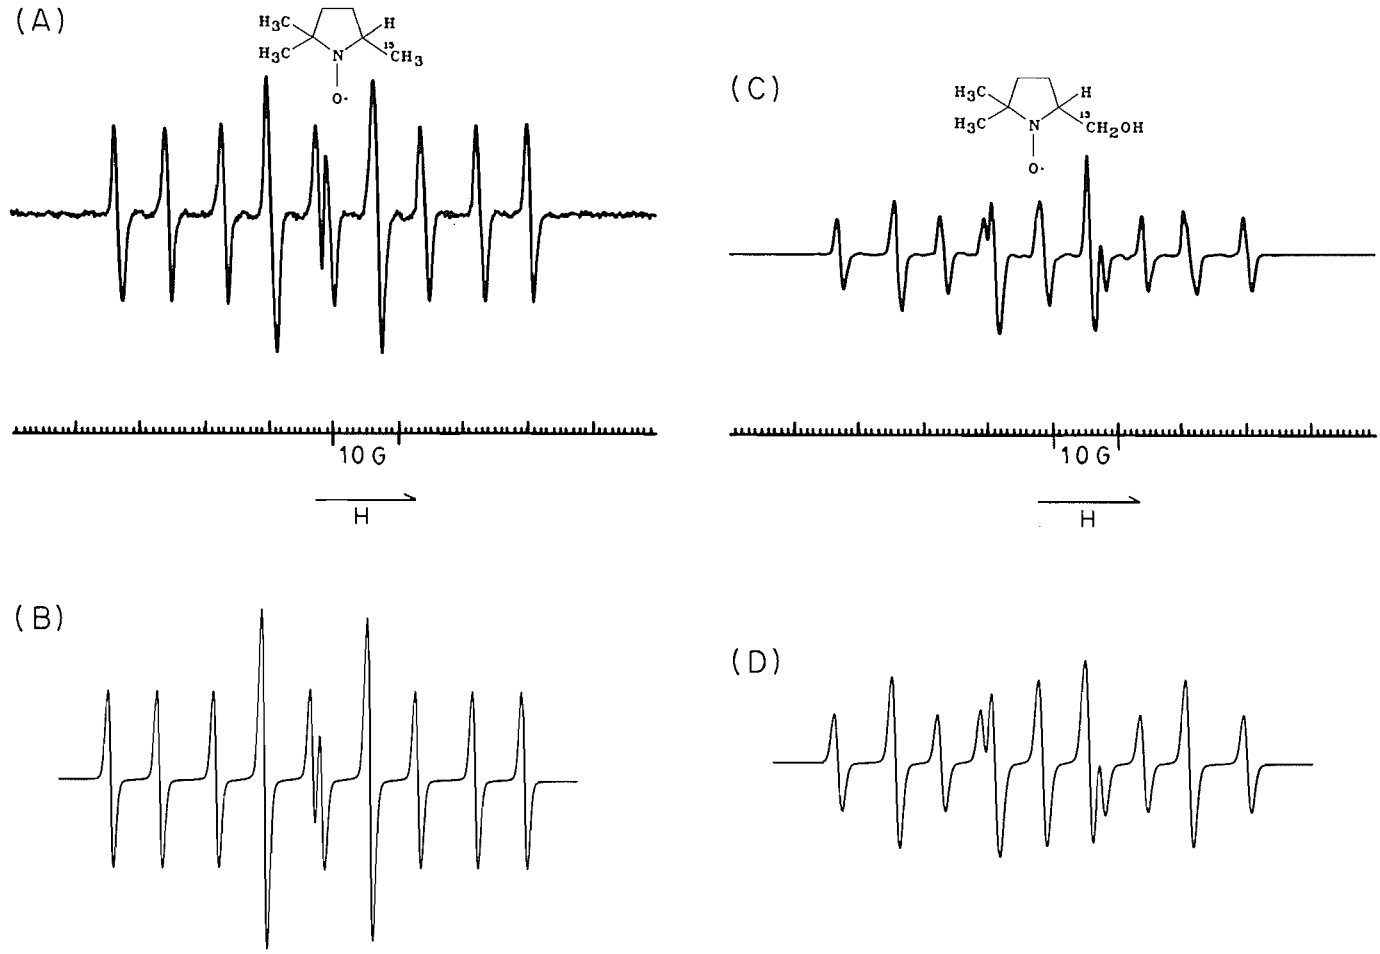

FIG. 9. (A) EPR spectrum of DMPO–$^{13}CH_3$ in water at 300 K. (B) Computer simulation of the above spectrum using the following parameters: $a^N = 16.35$, $a_\beta^H = 23.71$, $a_\beta{}^{13C} = 7.63$ gauss, linewidth = 1.2 gauss, lineshape = 0.3 Lorentzian. (C) EPR spectrum of a mixture of DMPO–$^{13}CH_3$ and DMPO–OH in water. (D) Computer simulation of the above mixture spectrum using the following parameters: DMPO–$^{13}CH_2OH$: $a^N = 15.92$, $a_\beta^H = 22.56$, $a_\beta{}^{13C} = 8.81$ gauss, linewidth = 1.2 gauss, lineshape = 0.3 Lorentzian. DMPO–OH: $a^N = 15.01$, $a_\beta^H = 15.01$ gauss, linewidth = 1.2 gauss, lineshape = 0.3 Lorentzian. The spectral centre for DMPO–OH is 0.1 gauss to the left of that for DMPO–$^{13}CH_2OH$. The DMPO–$^{13}CH_2OH$/DMPO–OH ratio (from the double integrated areas under the EPR spectra) = 2.6:1.

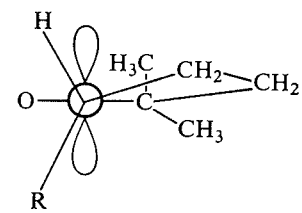
where V_{EFF} is the effective tumbling volume of the radical, η is the viscosity of the solvent, T is the absolute temperature, and k is the Boltzmann constant. This ENDOR result lends further support for the existence of the H-bonded chelate structure (**6**) because an increase in molecular volume (due to chelation) is expected to raise the optimum ^1H ENDOR temperature.

DMPO–CH_2OH vs. DMPO–CH_3

Radical conformations

The nitrogen HFS for DMPO–CH_2OH in toluene is considerably larger (~0.5 gauss) than the value for DMPO–CH_3 (Fig. 9, Table 3). This fact points to an increased contribution of the polar aminoxyl resonance form, **8**. The β-hydrogen and β-^{13}C (CH_2OH) HFS's are expected to be correspondingly larger for DMPO–CH_2OH vs. DMPO–CH_3 because β-nuclei HFS's are proportional to the nitrogen HFS (12). With this taken into account the conformation of DMPO–CH_2OH may well be quite similar to that of DMPO–CH_3 (**9**). In contrast to PBN–CH_2OH there is no abrupt change in the β-hydrogen of β-^{13}C (CH_2OH) HFS's of DMPO–CH_2OH when a nonpolar solvent (e.g., toluene) is replaced by a relatively polar and



DMPO–R

(**9**)

R = CH_2OH or CH_3

hydrogen-bonding solvent such as methanol. Therefore the conformation of DMPO–CH_2OH probably does not change very much with solvent polarity. Perhaps this is due to the restricted rotation of the CH_2OH group as a result of the rigidity imposed by the pyrrolidine ring structure.

Unequivocal EPR assignment of hydroxyalkyl and other carbon-centered radical adducts of DMPO

Along with the numerous reports on hydroxyalkyl adducts of DMPO (2, 4, 6*d*,*g*,*h*,*i*) there have been some studies proposing that other carbon-centered radicals (e.g., methyl (17*a*–*k*), ethyl

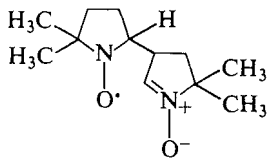
[b]This work.

(18*a*,*b*), 2-propyl (18*a*), 2-cyano-2-propyl (18*c*), cyclopentadienyl (19), phenyl and substituted phenyl (18*c*, 20*a*–*d*), nitrobenzyl (21), uracil derived (22), and others of unspecific structure (18*a*, 23*a*–*d*) are also trapped by DMPO. Although many of these structural assignments are likely correct (e.g., the structure of DMPO–phenyl was confirmed by mass spectroscopy (20*c*), distinguishing alkyl, aryl, hydroxyalkyl, etc. adducts in general is difficult because the EPR parameters are so similar (2). For example, the HFS's for DMPO–CH_2OH and DMPO–CH_3 in methanol (Table 3) are essentially equivalent ($a^N \sim 15.2$, $a_\beta \sim 21.6 \pm 0.2$ gauss). An additional complication is the possible appearance of a carbon-centered adduct (DMPO–DMPO-yl) (24) produced by hydrogen atom abstraction of the pseudo-allylic position of the nitrone (**10**).

We have found that the β-^{13}C (radical addend) HFS's for alkyl, hydroxyalkyl (Table 3, Figs. 9A–D), as well as halomethyl adducts[12] are large (~6–16 gauss) and distinctive for the radical trapped. Thus, ^{13}C labeling is a viable strategy for verifying the structures of carbon-centered adducts of DMPO (4, 17–23).

^{13}C labeled hydroxyalkyl adducts as markers for hydroxyl radicals

Hydroxyl radical detection in biological systems by spin trapping with DMPO is of considerable interest even though potential artifactual reactions (2, 7) do exist.[13] The use of ^{17}O labeled reagents to produce β-^{17}O labeled spin adducts (spin = 5/2) (27) has shed some light on the various mechanisms of hydroxyl adduct formation but these methods cannot be applied routinely due to expense. Lai and Piette (5*b*), and Rosen (2*c*) have advocated the formation of hydroxyalkyl adducts (from added alcohol) as a useful safeguard against artifacts during the detection of hydroxyl radicals. We suggest that a ^{13}C labeled alcohol be used to guard against possible confusion with DMPO–DMPO-yl (**10**). Furthermore, it would appear that an



DMPO–DMPO-yl (**10**)

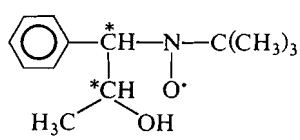
alcohol such as $^{13}CH_3OH$ would be preferred over ethanol because EPR spectra derived from the latter would be complicated by the presence of diastereomers (see PBN–$CHOHCH_3$ in the subsequent section).

Alternatively, dimethylsulfoxide (DMSO) as a detector of hydroxyl radicals is possible, but complications from the addition of hydroxide followed by oxidation should not be overlooked (29). Another possible indicator for hydroxyl is sodium formate (preferably $NaH^{13}CO_2$) because spin adduct spectra of CO_2^- (3*b*) are very similar to those of acyl spin adducts from nitrone hydrolysis (30).

PBN-CHOHCH$_3$

Radical conformation and stereochemistry

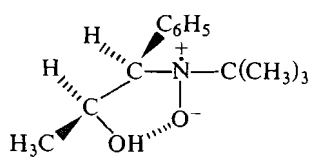
Formation of the hydroxyethyl adduct of PBN (**11**) creates an



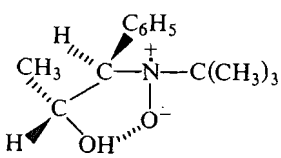
11

adduct with two asymmetric centres and therefore a diastereomeric mixture of aminoxyl radicals.

The EPR and ENDOR parameters for PBN–$CHOHCH_3$ are collected in Table 4. The EPR spectra of PBN–$CHOHCH_3$ in toluene at 300 K (Fig. 10A) as well as at 200 K (Fig. 10B) exhibit distinct asymmetry due to diastereomers that may have the following *cis*/*trans* structures (**12**) and (**13**):



cis
(**12**)



trans
(**13**)

[12]Weakly polar carbon-centred adducts of DMPO (e.g., DMPO–hydroxyalkyls) exhibit EPR spectra (e.g., a^N and $a_\beta{}^H$ HFS's) that are quite similar to ordinary carbon-centred adducts; however, strongly polar adducts (e.g., DMPO–CCl_3) show quite distinctive patterns: (a) for DMPO–$^{13}CCl_3$ in benzene, $a^N = 13.17$, $a_\beta{}^H = 15.28$, $a_\beta{}^{13}C(CCl_3) = 16.34$ gauss (E. G. Janzen and R. A. Towner, manuscript in preparation, 1987), and (b) for DMPO–CCl_3 in water, $a^N \sim a_\beta{}^H \sim 14.6$ gauss (see ref. 25).

[13]The hyperfine splittings (HFS's) of DMPO–OH are quite sensitive to solvent effects (ref. 26).

For personal use only.

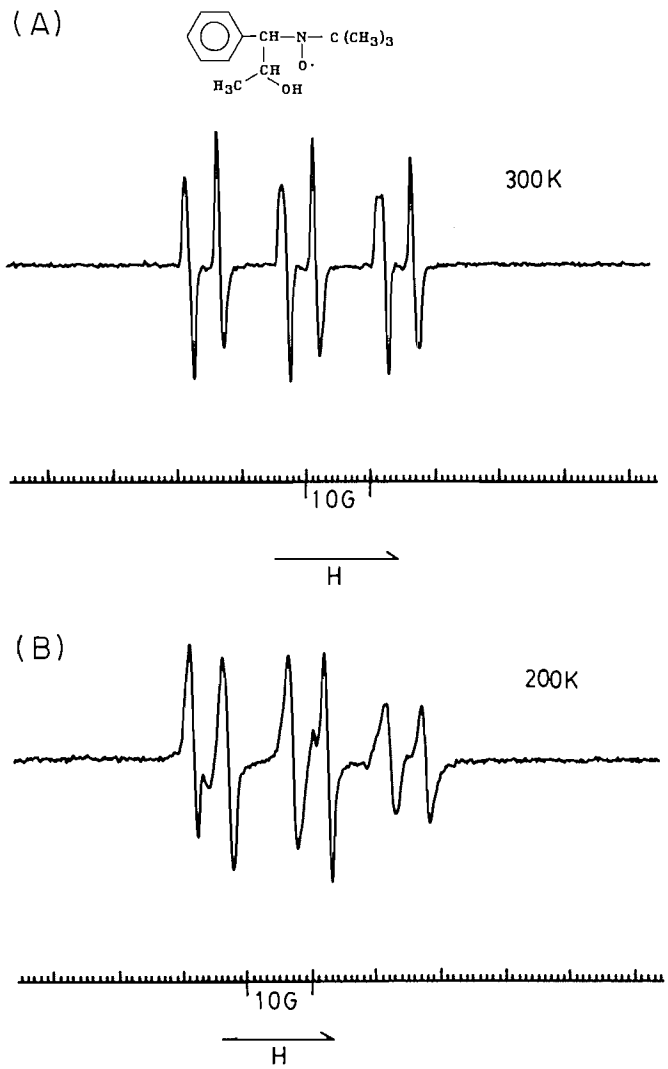

FIG. 10. EPR spectra of PBN–$CHOHCH_3$ in toluene at (A) 300 and (B) 200 K, respectively.

Unlike the hydroxymethyl adduct, the ENDOR spectrum of PBN–$CHOHCH_3$ at 300 K (compare Fig. 8A with Fig. 11A) shows only the aminoxyl nitrogen doublet. This may be an indication of a weaker H-bonding interaction, perhaps due to increased steric hindrance in the hydroxyethyl adduct. The ENDOR spectrum of PBN–$CHOHCH_3$ at 240 K (Fig. 11B) and 200 K (Fig. 11C), however, clearly demonstrates the superiority of ENDOR vs. EPR (cf. Figs. 7A and 7B) for resolving radical mixtures of diastereomers. In toluene at 210 K the larger β-H ENDOR peak (~6.4 gauss) is approximately twice as intense as the smaller one (~5.3 gauss) while at 190 K the converse is true (cf. Figs. 11A–C for the temperature dependence of the diastereomeric ENDOR peaks). Using arguments developed in the preceding section for PBN–CH_2OH, the PBN–$CHOHCH_3$ adduct with the larger β-H is assigned to the *cis* isomer (**12**) since it should have the larger effective tumbling volume (V_{EFF}) and hence higher optimum ENDOR temperature. The species with the smaller β-H is therefore attributed to the *trans* isomer (**13**).

Solvent effects

At 300 K (Fig. 12A) as well as at 200 K (Fig. 12B) PBN–$CHOHCH_3$ in ethanol does not show any significant EPR spectral differences due to the diastereomeric species.

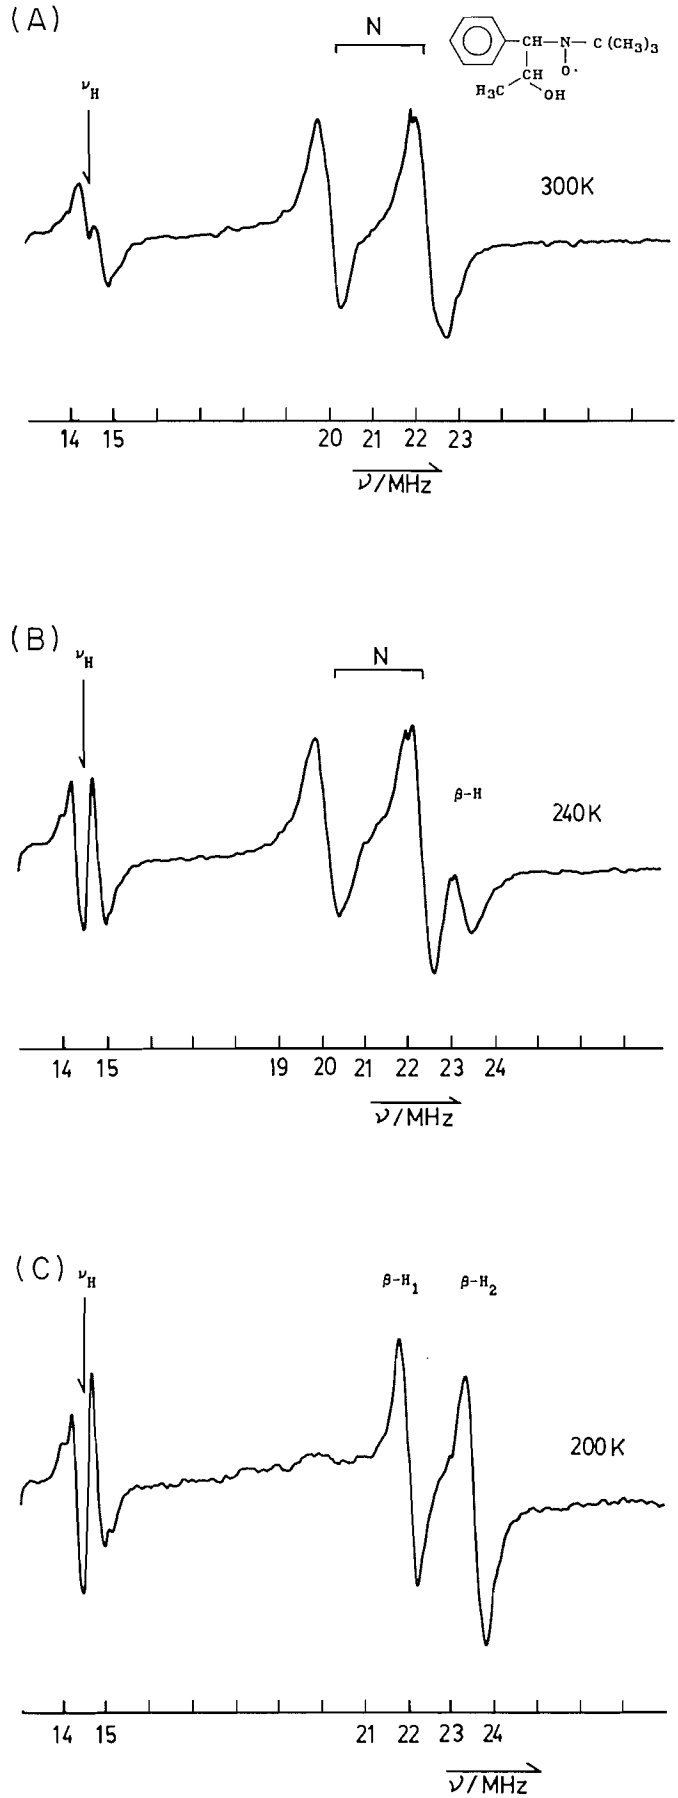

FIG. 11. ENDOR spectra of PBN–$CHOHCH_3$ in toluene at (A) 300, (B) 240, and (C) 200 K, respectively (13–28 MHz region).

TABLE 4. EPR and ENDOR hyperfine splitting constants (HFS's) for PBN–$CHOHCH_3$ in toluene and ethanol at various temperatures[a–d]

Solvent	Temperature (K)	Experiment	a^N	$a_\beta^{H_1}$ [b]	$a_\beta^{H_2}$ [b]	g value
Toluene	300	EPR	14.8	4.5	5.1	2.00583
Toluene	300	ENDOR	15.16	—	—	—
Toluene	240	ENDOR	15.20	5.56	6.20	—
Toluene	200	EPR	15.28	5.4	(avg.)[c]	—
Toluene	200	ENDOR	—	5.33	6.41	—
Ethanol	300	EPR	15.18	3.56	(avg.)[c]	—
Ethanol	200	EPR	~14.9	~3.1	(avg.)	—
Ethanol	200	ENDOR	—	2.44	2.88	—
Ethanol	210	ENDOR	—	2.65	3.08	—

[a]The HFS's are in gauss; — indicates that this value is not available. Conversion of gauss to MHz is multiplication by 2.81.
[b]These β-H HFS's are diastereomeric (cf. refs. 3*c* and 3*e*).
[c]The notation "avg." indicates an unresolved average value for the diastereomeric β-H HFS's.
[d]These HFS's are only approximate values due to the highly immobilized nature of the spin adduct in this solvent.

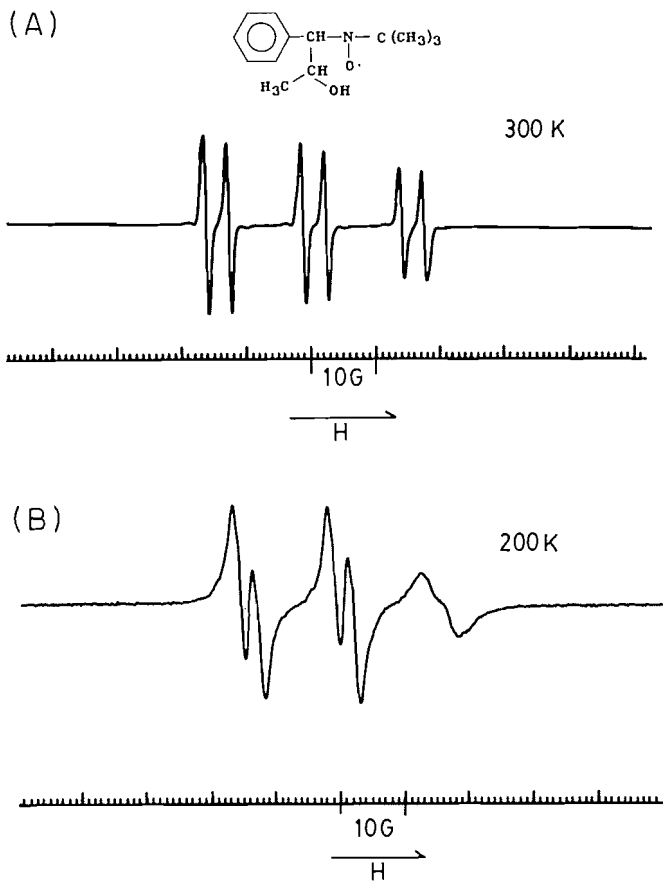

FIG. 12. EPR spectra of PBN–$CHOHCH_3$ in ethanol at (A) 300 and (B) 200 K, respectively.

Compared to toluene solution at 300 K, where the average β-H HFS for PBN–$CHOHCH_3$ is 4.8 gauss, the β-H HFS decreases markedly (to ~3.6 gauss) in ethanol whereas the nitrogen HFS remains quite similar (Table 4). As with the hydroxymethyl adduct discussed earlier, these phenomena are interpreted as due to the interruption of intramolecular H-bonding by alcohol solvent molecules. The ENDOR spectra at 200 K (Figs. 13A and 13B) exhibit a β-H HFS of about 3 gauss, which is assigned to the hydroxyethyl adduct.

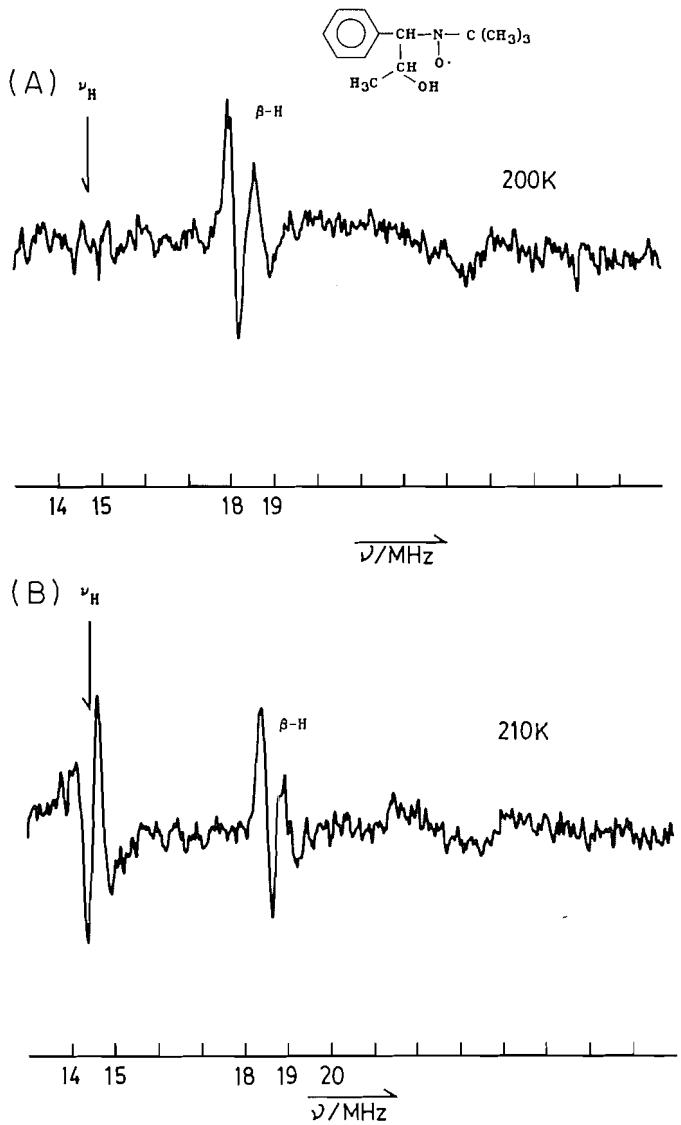

FIG. 13. ENDOR spectra of PBN–$CHOHCH_3$ in ethanol at (A) 200 and (B) 210 K, respectively. The smaller β-H ENDOR peak around 2.6 gauss is attributed to some alkoxyl adduct impurity, PBN–OCH_2CH_3 (a^N = 14.1, a_β^H = 2.8 gauss by EPR at 200 K).

Conclusions

From the solvent, temperature, and ^{13}C labeling effects on the EPR and ENDOR spectra of hydroxyalkyl aminoxyls it is apparent that the conformations of these free radicals may be strongly influenced by H-bonding interactions. In addition we have demonstrated the superiority of ENDOR spectroscopy (vs. EPR) for the spectral resolution of mixtures of diastereomeric radicals (28).[14] Utilization of a deuterated nitrone spin trap (e.g., PBN-d_{14}) reveals long-range γ-H HFS's from the added radical (e.g., $^{\bullet}CH_2OH$ or $^{\bullet}CH_3$), which serve to distinguish and identify the actual radical trapped. We have also illustrated the utility of ^{13}C labeled carbon-centred radical adducts of DMPO for conformational analysis as well as for proving the structure of the trapped radical.

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received October 14, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

JESSE B. NG, B. PETELENZ, and H. F. SHURVELL. Can. J. Chem. **66**, 1912 (1988).

The carbonyl stretching region of fully deuterated acetic acid CD_3COOD in D_2O has been studied by means of Raman spectroscopy. The number of linearly independent spectral components was determined to be four by factor analysis. Fourier self-deconvolution of the spectra revealed another major component band which was assigned to an overtone and/or combination vibration of the acid monomer. The overall band envelope was fitted with five Gauss–Lorentz functions using a non-linear least squares procedure. The abnormally high intensity of the band assigned to the overtone/combination is discussed in terms of Fermi resonance.

JESSE B. NG, B. PETELENZ et H. F. SHURVELL. Can. J. Chem. **66**, 1912 (1988).

Faisant appel à la spectroscopie Raman et opérant dans le D_2O, on a étudié la région de l'élongation du carbonyle de l'acide acétique complètement deutéré, CD_3COOD. Utilisant l'analyse factorielle, on a déterminé que le nombre de composantes spectrales linéairement indépendantes est égal à quatre. Une auto-déconvolution de Fourier effectuée sur le spectre a permis de mettre en évidence une autre bande composante majeure qui a été attribuée à une harmonique et/ou à une vibration de combinaison de l'acide monomère. Utilisant une procédure non-linéaire des moindres carrés, on a fait concorder l'enveloppe globale des bandes avec cinq fonctions de Gauss–Lorentz. Pour expliquer le fait que l'intensité de la bande attribuée à l'harmonique/combinaison est anormalement élevée on fait appel à la résonance de Fermi.

Introduction

The complexity of the carbonyl stretching region (1500–1900 cm^{-1}) in the system CH_3COOH–H_2O (1) prompted an examination of the fully deuterated species, CD_3COOD in D_2O. Results of a previous communication (2) suggested a model system in which, at high concentrations monomeric, dimeric, and polymeric species coexist. The validity of the argument was reinforced by the application of factor analysis (3, 4) to the spectra of CH_3COOH–H_2O mixtures in the carbonyl stretching region (1). The number of contributing components (NC) was found to be 5, including the bending mode of H_2O which occurs at ca. 1610 cm^{-1}.

Substitution of deuterium for hydrogen in both acid and water molecules was expected to simplify the analysis of the spectrum since the carbonyl band envelope in CD_3COOD (1450–1800 cm^{-1}) is well separated from the methyl deformation modes which shift from 1433 cm^{-1} ($\delta_a CH_3$) and 1366 cm^{-1} ($\delta_s CH_3$) to 1042 cm^{-1} ($\delta_a CD_3$) and 1090 cm^{-1} ($\delta_s CD_3$) (5), as well as from the DOD bending mode of D_2O at 1190 cm^{-1}. Thus, according to the previously assumed model (1, 2), no more than four components should appear in the spectrum. However, the inspection of the C=O stretching region of the fully deuterated acetic acid indicates the existence of two well-resolved peaks, the larger of which is accompanied by *three* and not two shoulders.

To complete the study and elucidate this somewhat unexpected behaviour, we applied factor analysis to the fully deuterated system and, independently, we have made use of spectral deconvolution (6–9), where part or all of the intrinsic lineshape function is deconvolved from a spectrum of overlapping bands. In essence, deconvolution yields information not obtainable by factor analysis, namely, the maximum number of bands that should be fitted to a contour. Deconvolution enhances the original band resolution by narrowing the spectral lines, so that the deconvolved spectra allow a reliable initial estimate of band positions, relative intensities and bandwidths, and make band-fitting less ambiguous.

Experimental

Acetic acid-d_4 (99.5 atom% D) was supplied by MSD Isotopes (Merck-Frosst Canada Inc.). Solutions were made up by weight in the range 5.3 to 17.5 mol L^{-1} (M) using D_2O (98 atom% D) purchased from the same company. To minimize exchange with atmospheric moisture, all operations including weighings and cell-filling manipulations were performed in a drybox under a nitrogen atmosphere. A drying agent, P_2O_5, was constantly present in the box. Prior to experimental operations, the relative humidity inside the box was monitored and it never exceeded 30%.

Raman spectra of the pure acid were recorded directly from the unopened vial. A survey spectrum of glacial CD_3COOD between 200 and 3000 cm^{-1} is shown in Fig. 1. The scanning range for the solutions was 780–1880 cm^{-1}. The spectra were calibrated using emission lines from a Ne lamp. The band intensity in the carbonyl stretching region was normalized by division by the area of the C—C stretching fundamental at ca. 799 cm^{-1}. Details of the Raman experiment have been published elsewhere (1).

Computations

Factor analysis

To determine the number of components which contribute to the overall band intensity in the C=O stretching region, a set of Raman spectra was subjected to factor analysis using the program CHISQ (4). Spectra of ten solutions (NS = 10) in the concentration range 14.2 to 17.5 M, each collected in the carbonyl stretching region (1450–1800 cm^{-1}) and digitized at 450 data points (NW = 450), were used to build the experimental intensity matrix, **I**, of dimension NS × NW. The elements of the Raman intensity matrix are given as

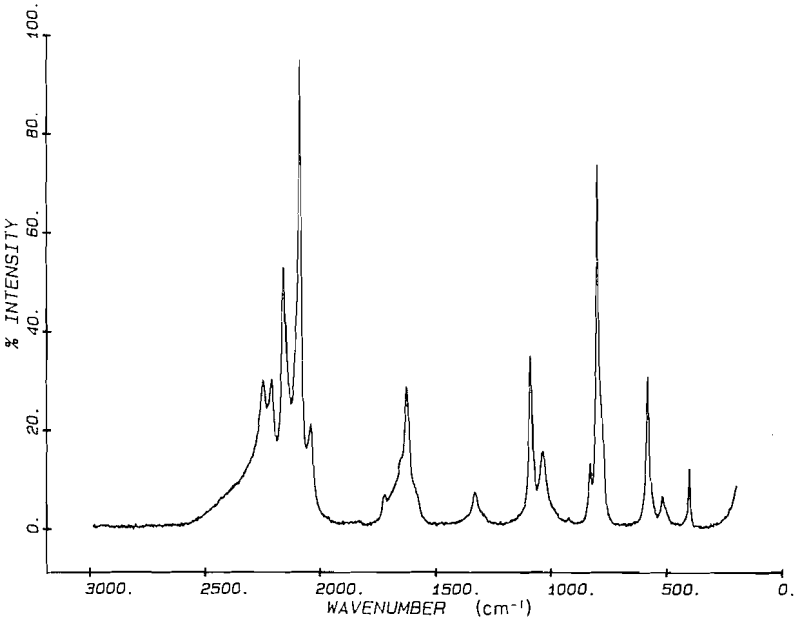

FIG. 1. Survey Raman spectrum of CD_3COOD.

$$[1] \quad I_{ij} = \sum_{k=1}^{NC} J_{ik} C_{kj}$$

where J_{ik} is the molar scattering coefficient of the kth component at the ith wavenumber and C_{kj} is the concentration of kth component in jth solution.

It can be shown that the number of components in the spectrum, N_C, is equal to the rank of the square matrix $\mathbf{Q} = \mathbf{I}^T\mathbf{I}$, which in turn is equal to the number of non-zero eigenvalues of $\mathbf{Q}$. However, the matrix $\mathbf{I}$ and the related matrices are obtained from experimental data which always contain an experimental error. Also, the diagonalization procedure introduces its own errors. Therefore, N_C must be determined according to a number of statistical criteria (3, 4) which, taken together, distinguish the genuine non-zero eigenvalues from statistical fluctuations. Linearly dependent factors do not appear as individual components in the result, which sometimes can be a limitation of the method.

Deconvolution

A measured spectrum $E(\tilde{\nu})$ can be expressed as a convolution of a "true" (i.e. involving only natural linewidths) spectrum $E'(\tilde{\nu})$ and an instrumental function $G(\tilde{\nu})$ (6–9).

$$[2] \quad E(\tilde{\nu}) = \int_{-\infty}^{+\infty} G(\tilde{\nu}')E'(\tilde{\nu} - \tilde{\nu}')\mathrm{d}\tilde{\nu}' \equiv G(\tilde{\nu}) * E'(\tilde{\nu})$$

This spectrum is related to its interferogram (which is actually the measured quantity in Fourier transform instruments) by the following relationships (7):

$$[3] \quad E(\tilde{\nu}) = \int_{-\infty}^{+\infty} I(x) \exp(i2\pi\tilde{\nu}x)\mathrm{d}x = \mathcal{F}\{I(x)\}$$

$$[4] \quad I(\tilde{\nu}) = \int_{-\infty}^{+\infty} E(\tilde{\nu}) \exp(-i2\pi\tilde{\nu}x)\mathrm{d}\tilde{\nu} = \mathcal{F}^{-1}\{E(\tilde{\nu})\}$$

where $\mathcal{F}\{\ \}$ denotes the Fourier transform and $\mathcal{F}^{-1}\{\ \}$ its inverse. The units used here are wavenumbers for $\tilde{\nu}$ and centimeters for x, but frequency and time or energy and time can be used as well. By applying the inverse Fourier transform to both sides of eq. [2] one obtains:

$$[5] \quad I(x) = \mathcal{F}^{-1}\{G(\tilde{\nu})\} \cdot I'(x)$$

In the distance domain the convolution operation is replaced by multiplication, so, the interferogram of the true spectrum can be obtained simply by dividing the transform of the experimental spectrum by that of the instrumental function

$$[6] \quad I'(x) = \frac{1}{\mathcal{F}^{-1}\{G(\tilde{\nu})\}} \cdot I(x)$$

By transforming $I'(x)$ back to the wavenumber domain the true spectrum should be in principle obtained, but in general, the function $G(\tilde{\nu})$ is not known explicitly and the deconvolution must be performed on a trial-and-error basis. Adjustment of the function $G(\tilde{\nu})$ is based on the fact that a Lorentz spectral line transforms into an exponentially decaying cosine, whereas a Gauss line yields a cosine damped with another Gaussian function. The broader are the bands the more rapidly decay their transforms. Appropriate choice of the function $G(\tilde{\nu})$ results in enhancing the features of the original spectrum: in the deconvolved spectrum all bands become narrower and many shoulders appear as separate peaks.

Fourier transforms can also be used to smooth the spectra. Noise in the wavenumber domain transforms into noise which becomes a predominant feature of the interferogram past the point $x = L$ at which the cosine is damped practically to zero. Noise can be filtered by multiplying the interferogram $I'(x)$ by a function which is nonzero for $0 < x < L$ and zero elsewhere. Various filtering functions have been suggested and discussed in the literature (10). Both deconvolving and smoothing operations can be performed simultaneously and in such a way they are incorporated in the computation program used in this work (11).

Results and discussion

General

The substitution of D for H in CH_3COOH and D_2O for H_2O results in a separation of the carbonyl band envelope from the

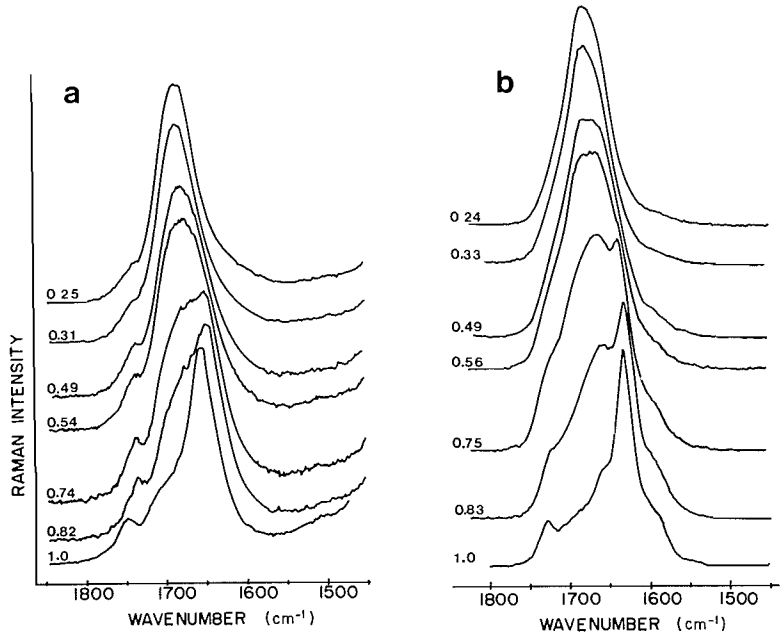

FIG. 2. Variation of the C=O stretching profiles of acetic acid upon dilution; (*a*) $CH_3COOH-H_2O$, (*b*) $CD_3COOD-D_2O$. Intensity units are arbitrary. Mole fraction of the acid is quoted at each curve.

methyl deformation modes and the water bending mode (2, 5). The variation of the band profile of the carbonyl stretching region of CD_3COOD (1450–1800 cm^{-1}) in solutions of different concentrations is shown in Fig. 2*b*. In comparison with the corresponding band envelope in CH_3COOH (Fig. 2*a*), the following observations can be made. The maxima in both profiles shift to higher frequencies on dilution. However, at similar mole fractions of acid ($x_{CD_3COOD} = 0.75$, $x_{CH_3COOH} = 0.74$), the shoulder on the high frequency side of the contour at ~1722 cm^{-1} is not as pronounced in the $CD_3COOD-D_2O$ system. In addition, there is a broad maximum centered at ~1660 cm^{-1} which is not visible in the $CH_3COOH-H_2O$ system.

Factor analysis

The results of factor analysis on the CD_3COOD solutions are shown in Tables 1 and 2. The standard errors in the first four eigenvalues are much less than the eigenvalues themselves, whereas the error in the fifth eigenvalue is larger. This clearly indicates the presence of four components.

The estimate of the experimental error (i.e. the ratio of standard deviation $\sqrt{N}$ to the average number of photon counts N in the peak (12)) is in the range 0.0061 to 0.0075. An examination of Table 1 indicates that for the third eigenvalue ($m = 3$) the calculated value of the residual standard deviation (RSD) is 0.006228 which lies in the above range. This criterion suggests NC = 3 for the system.

The difference in the imbedded error (IE) values (3) for $m = 4$ and $m = 5$ (0.000284) is much smaller than for $m = 3$ and $m = 4$ (0.001919). A minimum in the factor indicator function (IND) (3) also occurs for $m = 4$.

The expectation values of χ_4^2 (2676) and χ_5^2 (2225) indicate that four factors are significant, because the calculated value of χ_4^2 (2894) is much closer to its expectation value than is the calculated value of χ_5^2 (1684) (Table 2).

A regenerated data point is classified as a misfit if its deviation from the observed value is three or more times greater than the standard deviation σ. The smallest value of m, for which the regenerated data matrix has a negligible number of residual errors greater than 3σ is taken to be NC (3, 4). The experimental data matrix (Table 2) contains 4500 data points. With three eigenvectors, 172 regenerated data points are greater than 3σ, but with four, only 18 are greater. This is negligible compared to

[a]x_{DAc} is the mole fraction of CD_3COOD in D_2O.

the total number of points. The results of five criteria indicate that the factor space is four-dimensional, while only one criterion suggests three dimensions. Therefore, we conclude that the number of independent components contributing to the C=O stretching band envelope is four.

Band contour analysis

Figures 2*a* and 2*b* show that, on dilution, the carbonyl band envelope rapidly changes into a featureless profile. At this stage, there is no indication that the profile comprises anything else but the four bands revealed by factor analysis. Such an assumption agrees with our earlier discussion (1, 2, 13) of several associated forms of acetic acid coexisting in the solution. The dominant contribution of the cyclic dimer in pure liquid acetic acid was confirmed recently by means of neutron diffraction spectroscopy (14). Without contradicting this or the earlier assignment (5), four Raman bands in this region can be assigned to the C=O stretching of the monomer, that of the cyclic dimer (only one mode being Raman active), and two vibrations of the chain-like structures, representing stretching of their "inner" and end C=O groups.

The number of bands, revealed by factor analysis, is one of the most important input data for the band fitting procedure (15). Earlier work (5) gave quite reliable values for the positions of some contributing bands. To refine initial estimates for the positions of all contributing bands as well as for their intensities and widths, the band contour at every concentration was deconvolved using the technique developed recently by Moffatt *et al.* (11). For moderately dilute solutions of CD_3COOD in D_2O characterized by broad featureless bands in the C=O stretching region, this procedure revealed a *fifth* component in this region. Selected deconvolved spectra are shown in Fig. 3*a* alongside the corresponding band resolved spectra (Fig. 3*b*).

The C=O stretching frequencies of the normal and fully deuterated acetic acids, obtained from the band fitting are compared in Table 3. Table 3 shows that all C=O stretching modes of CD_3COOD exhibit a noticeable red shift with respect to those of the non-deuterated molecule. The magnitude of the shift is ~25–35 cm^{-1}. The shift of ~30 cm^{-1} for the monomer would result in a band near 1680 cm^{-1}. Such a band was not observed. Instead, two bands were detected in the immediate neighbourhood of the predicted frequency. We tentatively assigned the higher frequency peak (~1690 cm^{-1}) to the monomer. We will temporarily denote the lower frequency band (~1660 cm^{-1}) as *A*.

Deconvolution also revealed some additional bands in the Raman spectra of deuterated acetic acid at the highest concentrations (91–100%). The band at ~1600 cm^{-1} (assigned to the "inner C=O group" of the polymer) splits into two bands at ~1595 cm^{-1} and ~1605 cm^{-1}, while the monomer band (~1690 cm^{-1}) splits into two at ~1685 and ~1705 cm^{-1}. These extra bands are visible only in the most concentrated solutions.

To avoid unnecessary complication of the model, we performed band fitting of the C=O stretching manifold assuming only five components for the whole concentration range, i.e., we neglected the weak bands near 1605 cm^{-1} and 1705 cm^{-1}, revealed by deconvolution for high acid concentrations. This

assumption seems justified in view of the small intensity of these bands but, of course, it does introduce some error into the calculated band parameters.

The positions of the fitted bands are listed in Table 4. The regularities we noticed are the following:

1. Positions of the three middle bands in the range of study shift slightly (6–10 cm^{-1}) to higher frequencies with the increasing content of D_2O in the system. Positions of the two remaining bands fluctuate within ± 4 cm^{-1} without any regularity.

2. The intensity of the band attributed to the dimer decreases with dilution whereas that of the monomer increases.

3. The intensity of band *A* remains close to that of the monomer band and follows the same trend with dilution, being approximately proportional to the intensity of the monomer band. This behaviour explains why band *A* could not be detected by factor analysis as a separate component.

Band *A* has no counterpart in the spectrum of non-deuterated acetic acid (1, 2, 5) and the assumption that it is due to an overtone or combination mode seems natural. Normally in the Raman effect, the intensities of overtones or combinations are very weak so that they are hardly discernible unless enhanced by Fermi resonance (16). This seems to be just the case of band *A*.

The fact that band *A* grows significantly with dilution indicates that it is due to the monomer. For the assignment of band *A*, several combination modes of the monomer are possible. If the symmetry of the acetic acid monomer is C_s, then the combination $\nu_5 + \nu_{12}$ ($1280 + 386 = 1666$ cm^{-1}) would have the same symmetry (A') as the C=O and intensity borrowing through Fermi resonance could occur (the assignment of the monomer fundamentals is taken from ref. 17).

If the local symmetry of the monomer is in fact C_1 then two other combinations could contribute to the intensity of band *A*. These are $\nu_5 + \nu_{17}$ ($1280 + 408 = 1688$ cm^{-1}) and $\nu_{10} + \nu_{15}$ ($747 + 919 = 1666$ cm^{-1}). The lower symmetry in solution could be due to interaction with surrounding molecules or the fact that the barrier to rotation of the CD_3 group in CD_3COOD is low (1.96 kJ mol^{-1}) (18).

The intensity of band *A* in some of the deconvolved spectra (Fig. 3*a*) may appear unreasonably high. However, overlap with neighbouring bands (Fig. 3*b*) accounts for some of the intensity. In addition, an overtone of the dimer ($2 \times 832 = 1664$ cm^{-1}) might also contribute to the height of band *A*, especially in higher concentrations.

The additional bands observed in the deconvolved spectra of the most concentrated solutions must be interpreted cautiously, mainly because of their low intensity and relatively high noise. The conjecture that they are overtones of the dimer (predominant species) seems justified, at least for the low frequency band. There can be two symmetry-allowed combinations or overtones of the dimer: at 1598 cm^{-1} (2νC—C, 2×799 cm^{-1}) and at 1600 cm^{-1} (γCCO + $\delta_a CD_3$, $510 + 1090$ cm^{-1}).

The band near 1705 cm^{-1} can not be explained in this way. Most probably, it is the antisymmetric component of the C=O stretching of the dimer (B_u symmetry species). The transition is symmetry-allowed (and observed) in the infrared (5, 19) but forbidden in Raman. Symmetry perturbation in the concentrated liquid could give it a non-zero intensity so that it appears as a weak band in Raman spectrum.

Conclusions

The present study of fully deuterated acetic acid has revealed previously unreported components of its Raman spectrum in the C=O stretching region. Complementary use of factor analysis, deconvolution, and band resolution has led to detection of a strong overtone/combination band. The behaviour of this band upon dilution of the acid has been studied and it is concluded that the band is due to the monomer. Most probably, it involves more than one combination of monomer fundamentals. Several other new bands detected by deconvolution have been assigned to the dimer.

The core binding energies of some gaseous aromatic carboxylic acids and their relationship to profon affinities and gas phase acidities

B. H. McQUAIDE AND M. S. BANNA
Department of Chemistry, Vanderbilt University, Nashville, TN 37235, U.S.A.

Received September 21, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

B. H. McQUAIDE and M. S. BANNA. Can. J. Chem. **66**, 1919 (1988).

The C1*s* and O1*s* core binding energies of gaseous benzoic, phthalic, isophthalic, and terephthalic acids have been measured by X-ray photoelectron spectroscopy. The π-donor relaxation energies associated with the carbonyl oxygen ionization in these systems have been found to be around 2 eV, close to the value for acetic acid. Comparison of the O1*s* binding energies in phenol and benzoic acid with the gas phase acidities shows that the increased acidity of benzoic acid is attributable mostly to initial-state inductive effects. A number of O1*s* – proton affinity correlations have been used to predict proton affinities for these acids. It is found that benzoic acid is the strongest base and the weakest acid.

B. H. McQUAIDE et M. S. BANNA. Can. J. Chem. **66**, 1919 (1988).

Faisant appel à la spectroscopie photoélectronique des rayons-X, on a mesuré les énergies de liaison des noyaux C 1*s* et O 1*s* des acides benzoïque, phtalique, isophtalique et téréphtalique, à l'état gazeux. On a trouvé que les énergies de relaxation de donneur-π, associées avec l'ionisation de l'oxygène du carbonyle de ces systèmes, est d'environ 2 eV; cette valeur est proche de celle observée avec l'acide acétique. Une comparaison des énergies de liaison O 1*s* du phénol et de l'acide benzoïque avec leurs acidités en phase gazeuse démontre que l'acidité accrue de l'acide benzoïque est principalement dûe à des effets inductifs dans l'état initial. On a utilisé un certain nombre de corrélations O 1*s*/affinité protonique pour prédire les affinités protoniques de ces acides. On a trouvé que l'acide benzoïque est la base la plus forte et l'acide le plus faible.

Introduction

Although carboxylic acids have been studied rather extensively by X-ray photoelectron spectroscopy (XPS) (1–3) there are to date no available core binding energy data on aromatic acids. The reason is primarily the lack of volatility of these species. We have therefore undertaken a study of gaseous benzoic, phthalic, isophthalic, and terephthalic acids to make possible comparisons between aliphatic and aromatic acids.

A number of studies in recent years have exploited the basic similarity between core ionization and proton affinity, which is $-\Delta H$ of the process

[1] $B + H^+ \rightarrow BH^+$

The correlations established between gas phase PA's and core E_B's for a large variety of compounds (1–7) stem from the fact that both processes have to do with the ability of a molecule to accept a positive charge. The contributions to these two quantities can be broken down into a ground-state effect (which includes inductive contributions) and a final-state relaxation effect dependent on the polarizability of the surrounding molecule. Previous studies (8, 9) have established the following relationships:

[2] $\Delta E_B = \Delta V - \Delta R$

[3] $\Delta PA = -\Delta V + \Delta R$

where V is the electrostatic potential energy at the proton site or the site of core ionization and R is the relaxation energy. The quantities are expressed relative to some reference compound.

The enthalpy change of the reaction

[4] $HA \rightarrow H^+ + A^-$

is called the heat of deprotonation (10) and is a measure of acid strength. Thus this quantity is the PA of the anion. For gas phase acidities, A, we have (3, 8)

[5] $\Delta A = -\Delta V - \Delta R$

It can therefore be seen that combining eqs. [2] and [5] can yield ΔV and ΔR. Furthermore, eqs. [2] and [3] suggest a correlation between E_B and PA. These results will be used in the present work to calculate a number of interesting quantities.

Experimental

Samples were heated to 100–120°C to obtain sufficient vapor pressure. In the O1*s* region, two peaks were observed in each case, corresponding to the carbonyl and hydroxyl oxygens. For each acid the low binding energy peak was ~10% weaker than the other; this can be seen in Fig. 1 displaying the core spectra of benzoic acid. We argue in the following section that it corresponds to the carbonyl oxygen. In the C1*s* region, several peaks would be expected as a result of the presence of different types of carbons. For example, benzoic acid would be expected to give rise to five different peaks. However, our resolution was insufficient to differentiate between the various ring carbons (see Fig. 1). We have therefore treated each C1*s* spectrum as consisting of only two peaks, arising from the carboxyl and ring carbons. Thus we obtain only an average of the benzene ring carbon binding energies.

To obtain binding energies (b.e.), a calibrant gas was bled simultaneously with the acid under study. For C1*s*, carbon dioxide is a suitable reference (b.e. = 297.71 eV) (11). Carbon monoxide was also used in the case of benzoic acid (b.e. = 296.20 eV) (11). The oxygen 1*s* binding energies were referenced to the O1*s* of CO (542.55 eV) (11) for benzoic acid and to the NeKLL $^1D_2$ Auger peak (kinetic energy = 804.50 eV) (12) for the remaining acids. When an Auger peak is used for binding energy calibration, it is also necessary to know the photon energy. AlKα X-rays were used throughout this study, with an energy of 1486.582 eV (11).

Experimental problems encountered include relatively poor statistics as a result of complications arising from evaporating an insulator onto the electron optical elements of the spectrometer, insufficient resolution to clearly deconvolute the various peaks, and the overlap between the carboxyl carbon peak and the weak shake-up peaks associated with the ring carbons that lie at lower binding energy (see Fig. 1). Thus the errors associated with our measured binding energies are somewhat larger than normally possible with conventional XPS.

In the case of phthalic acid, the possibility arises that the acid may be converted to the anhydride upon heating (13). This was ruled out,

TABLE 1. Binding energies (eV)[a] of acids

	C1*s* (carbonyl)	C1*s* (ring)	ΔC1*s*	O1*s* (hydroxyl)	O1*s* (carbonyl)	ΔO1*s*
Isophthalic	295.2	291.0	4.21(10)	540.1	538.0	2.05(10)
Terephthalic	295.2	291.0	4.25(8)	540.1	538.1	2.05(8)
Phthalic	295.1	291.1	4.06(6)	540.0	538.1	1.90(10)
Benzoic	295.0	290.75(5)	4.25	539.79(7)	537.73(7)	2.06(9)

[a]All binding energies without indicated uncertainties are probably accurate to ±0.15 eV.

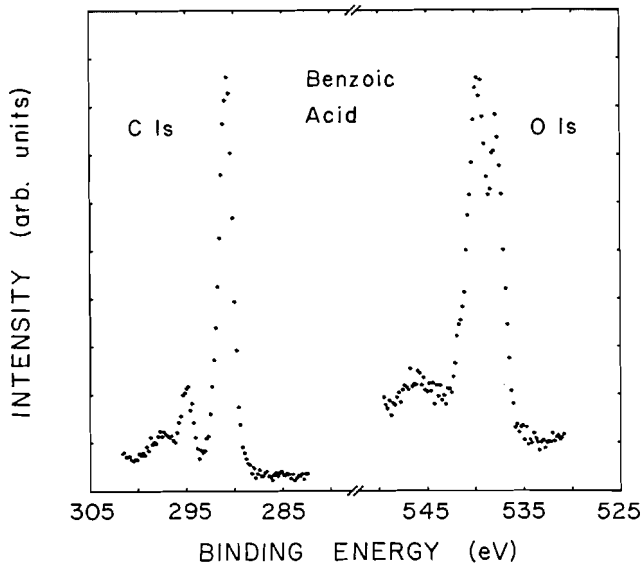

FIG. 1. The core spectra of benzoic acid obtained with AlKα radiation.

however, because the O1*s* spectrum obtained was very similar to those obtained for the other phthalic acids, where anhydride formation is not possible. In the case of the anhydride, two peaks with a relative intensity close to 2:1 would be expected.

Core binding energies

Our results are shown in Table 1. As expected, the core binding energies of the ring carbons are higher than in benzene (290.40 eV), which can be attributed to the presence of the carboxyl groups. For the same reason, the ring binding energies are somewhat higher in the dicarboxylic acids than in benzoic acid; otherwise, there appears to be little change among the phthalic acids, within the limits of accuracy of our measurements. The electron-withdrawing effect of the oxygens is manifested in higher binding energies for the carboxyl carbons, the binding energies being over 4 eV greater than those of the ring carbons.

As expected, two main peaks have been obtained in the O1*s* region. The lower binding energy peak must be due to the carbonyl oxygen because it is the more negative of the two oxygens. Previous workers have also pointed out that molecular orbital calculations (14) on formic acid bear this out. Furthermore, Carroll *et al.* (6) and subsequently Mills *et al.* (1) proved experimentally that the keto oxygen has the lower binding energy, by studying dimethyl carbonate where the higher binding energy peak was found to be twice as intense as the lower binding energy peak.

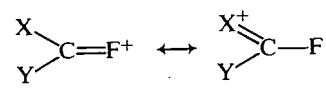
In connection with the O1*s* region, it is interesting to note that Siegbahn *et al.* (15) obtained only one broad peak for the O1*s* of solid phthalic acid. This suggests that the separation between the two types of oxygen narrows in the solid, probably because of hydrogen bonding. Our gas phase results point to *intra*molecular hydrogen bonding since the O1*s* splitting in phthalic acid is smaller than in any of the other acids studied (see Table 1).

Again, as observed for C1*s*, the O1*s* binding energies appear to change little in going from one dicarboxylic acid to another. The addition of a second carboxyl group definitely raises the binding energy, however. This may tentatively be attributed to the electron-withdrawing tendency of each carboxyl group, resulting in a "depletion" of the ring electrons and less electron withdrawal per substituent group, and hence higher C1*s* and O1*s* binding energies.

The splittings between the two types of oxygen fall outside the 1.3–1.8 eV range found by Mills *et al.* (1) for a number of aliphatic acids and esters.

The π donor relaxation energy in carbonyl oxygen ionization

Jolly and Schaaf (16) compared the oxygen and carbon 1*s* binding energies of a number of carbonyl compounds. They noted a lack of correlation between the two, and attributed this to differences in the π-donor abilities of the groups attached to the carbonyl groups resulting in differing relaxation energies associated with oxygen ionization. Replacing core-ionized oxygen by its "equivalent core" F^+, Jolly and Schaaf pointed out the importance of the resonance structure on the right below:



From the carbonyl O1*s* and C1*s* binding energies we measured in this work we can evaluate the π-donor relaxation energies starting with the equation

[6] $E_B(O) = 333.5 + 0.7E_B(C)$

which Jolly and Schaaf (16) obtained for compounds where no π-donor relaxation occurs. Thus using our C1*s* binding energies we can calculate a hypothetical O1*s* binding energy for each acid, and the difference from the experimental one gives the desired relaxation energy. Our results are given in Table 2, and are around 2 eV in each case. For comparison we have included the π-donor relaxation energy calculated (16) for acetic acid. Interestingly, replacement of the methyl group by a benzene ring results in little change in the π-donor relaxation energy.

In connection with charge delocalization upon core ionization we also wish to point out the conclusions of Smith and Thomas (3). They found that there is a correlation between the carboxyl carbon ionization energy and both the carbonyl (slope of 0.90 (7)) and ether (slope of 1.04 (9)) oxygen 1*s* binding energies. Their explanation for this close coupling between each pair of binding energies is that the positive charge is delocalized over the entire carboxyl group whether ionization occurs on the

Phthalic	2.0(2)
Isophthalic	2.1(2)
Terephthalic	2.0(2)
Acetic	2.1(1)

[a]Calculated as the difference between the experimental carbonyl O1s binding energy and the value predicted by eq. [6].

oxygen or the carbon. Smith and Thomas (3) gave resonance structures that support this conclusion. Furthermore, semi-empirical CNDO/2 calculations also supported the validity of their explanation. It is interesting to see how close our binding energies are to the correlation lines determined by Smith and Thomas. From their Fig. 3 it is clear that the carbonyl O1s binding energies correlate very well with C1s, but the hydroxyl O1s binding energies lie considerably above the correlation line. This is perhaps not surprising since relaxation (and hence charge delocalization) is more efficient for the carboxyl O1s than for the ether O1s ionization, given the possibility of π-donor relaxation in the former case. Thus charge delocalization over the entire carboxyl group may be somewhat hindered for ether O1s ionization, resulting in poor correlation with C1s ionization where the presence of the ring means rather efficient charge dispersal following ionization.

Core binding energies and gas phase acidities

From the discussion given in the Introduction it is clear that the heats of deprotonation can be coupled with binding energies to yield ΔV and ΔR. These two quantities are of interest because they correspond to the initial (inductive) and final (relaxation) effects, respectively, and thus provide insight into the underlying causes for the changes in acid strength as well as binding energies. To our knowledge, of the acids considered in this work only benzoic acid has an experimentally known gas phase acidity and heat of deprotonation. Cumming and Kebarle (17) reported a ΔH^0_D of 349.8 kcal/mol. Recently Siggel and Thomas (9) established that, in contradiction to the commonly held notion that the stronger acidity of organic acids compared to alcohols is due to resonance stabilization of the anion of the acid, the difference in acidities is caused largely by the *initial-state* charge distribution, which leads to a less attractive potential at the proton in acids than in alcohols. Using eqs. [2] and [5], we can test the applicability of the conclusions of Siggel and Thomas to phenol versus benzoic acid. This is done in Table 3, from which it is clear that $\Delta R \cong 0$ and hence the added acid strength of benzoic acid is indeed due almost entirely to initial-state effects.

Note that if we had started with the conclusions of Siggel and Thomas (9), which they supported with quantum mechanical calculations, a very good value for the acidity of benzoic acid could have been obtained from our binding energy. This shows the usefulness of core binding energies in deriving gas phase acidities. We can extend the conclusions of Siggel and Thomas somewhat and assume that $\Delta R \cong 0$ in going from phenol to, say, isophthalic acid. With this assumption, the known O1s binding energies for the two species, and the known heat of deprotonation of phenol, a ΔH^0_D for isophthalic acid can be obtained. The value of 14.3 eV (the analysis is given in Table 4) is probably a lower limit to the acid strength since some added relaxation might be expected in the phthalic acids as a result of their larger size. This would increase the acidity.

TABLE 3. Comparison of the properties of phenol and benzoic acid (eV)

	Phenol	Benzoic acid
E_B(O1s)	539.23(5)[a]	539.79(7)

[e]Follows from taking $\Delta R = 0$.

Core binding energies and proton affinities

Previous studies (1, 6) have established that the carbonyl oxygen in carboxylic acids is the site of protonation. This is based on the fact that the keto O1s binding energies correlate better with the measured PA's than do the hydroxyl O1s binding energies. Previous workers have established a number of O1s–PA correlations. Unfortunately, the correlations do not agree with one another partly because of discrepancies in the experimental PA's used and, in some cases, in the binding energies. Here we use three different correlations to derive PA's for benzoic acid and the phthalic acids. Mills *et al.* (1) found the following empirical relationship.

$$[7]\quad PA = PA(H_2O) + 23.05[E_B(O1s,H_2O) - E_B(O1s,X)] - 7\ \text{kcal}$$

where the PA's are in kcal/mol and the binding energies are in eV. Using a PA for water of 166.5 kcal/mol from the tabulation of Lias *et al.* (18) and 539.90 eV (11) for the O1s binding energy in water, we calculate the PA's shown in column 2 of Table 5.

Benoit and Harrison (2) obtained the following correlation for carbonyl compounds:

$$[8]\quad PA = -0.843E_B(O1s) + 462.0$$

Using this equation we calculate the PA's shown in column 3 of Table 5.

Finally, the correlation of Smith and Thomas (3) (see Fig. 1

[b]From the correlation of Benoit and Harrison (2). Uncertainty is ±3 kcal/mol.
[c]From the correlation of Smith and Thomas (3). Uncertainty is ±3 kcal/mol.

in their paper) yields the PA's given in column 4. This last set is probably the most accurate since it was obtained from a careful correlation between O1*s* and PA. All three sets are in reasonable agreement with one another, however, which is encouraging. In this connection we also note the correlation of Buschek *et al.* (19), which yields PA's in good agreement with those from the correlation of Smith and Thomas (3). This is not surprising since the O1*s* binding energies used in their least-squares fit were taken from ref. 3.

Conclusions

The aromatic acids constitute an interesting series for study with XPS. As demonstrated by other workers for related species, notably the aliphatic acids, the combination of binding energies and gas phase acidities allows for a more complete understanding of both processes. In particular, we have shown that the added acid strength of benzoic acid over phenol is attributable to initial-state effects rather than final-state charge delocalization. This conclusion serves to extend recent findings (9). We have also exploited existing proton affinity – binding energy correlations to extract PA values for the acids under study. Our finding that benzoic acid is a stronger base/weaker acid than the dicarboxylic acids is in accordance with the general rule relating to the effect of substituents on acidity and basicity, namely that electron-withdrawing groups (the carboxyl group in this case) are acid strengthening and base weakening while the opposite is true for electron-releasing groups (20).

Similar studies on involatile species, which are currently beyond the reach of the techniques used to measure PA's but are now within the domain of high temperature XPS, are clearly desirable and will be attempted in the near future.

Received January 28, 1988

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

ALFREDO M. SIMAS, ROBIN P. SAGAR, ANDREW C. T. KU, and VEDENE H. SMITH, JR. Can. J. Chem. **66**, 1923 (1988).

The radial charge distribution, $D(r)$, for the neutral atoms, hydrogen through uranium, and the singly positive ions, helium through barium and lutetium through radium, are computed from the non-relativistic SCF wavefunctions of Clementi and Roetti and McLean and McLean. The radial charge distribution is examined to see how effective it is for the determination of the shell structure of an atom or an ion with the results indicating that the maxima are the topological features of $D(r)$ most indicative of shells. At most five shells are apparent based on the criterion that the maxima in $D(r)$ correspond to the shells. The positions of the maxima in $D(r)$ are shown to correlate well with the shell radii from the Bohr–Schrödinger theory of an atom. The small deviations are consistent with the shielding of the outer electrons from the nucleus, by the inner electrons. Furthermore, it is shown that the effects of shielding are more pronounced on the values of the radial distribution function at the extremal points. The spherically averaged charge density, $\bar{\rho}(r)$, is seen to be monotonically decreasing for all these ground states, a result which extends the previously known range of atomic systems for which this is true.

ALFREDO M. SIMAS, ROBIN P. SAGAR, ANDREW C. T. KU et VEDENE H. SMITH, JR. Can. J. Chem. **66**, 1923 (1988).

Utilisant les fonctions d'ondes auto-cohérentes qui ne sont pas relativistes de Clementi et Roetti ainsi que de McLean et McLean, on a calculé les distributions des charges radiales, $D(r)$, des atomes neutres, de l'hydrogène à l'uranium, ainsi que des ions monovalents positifs, de l'hélium au baryum et du lutétium au radium. On a étudié les distributions relatives des charges afin d'évaluer si elles sont efficaces pour déterminer la structure des couches d'un atome ou d'un ion; les résultats indiquent que les maxima sont les caractéristiques topologiques de $D(r)$ qui donnent le plus d'indications sur les couches. On a démontré qu'il existe une bonne corrélation entre les positions des maxima des $D(r)$ et les rayons des couches obtenus par la théorie de Bohr-Schrödinger d'un atome. Les petites déviations sont en accord avec le fait que les électrons des couches intérieurs provoquent un blindage du noyau par rapport aux électrons extérieurs. De plus, on a démontré que les effets de blindage sont plus prononcés sur les valeurs des points extrèmes de la fonction de distribution radiale. On observe que la densité de charge moyenne pour la sphère, $\bar{\rho}(r)$, diminue d'une façon monotone pour tous les états fondamentaux; ce résultat prolonge le domaine des systèmes atomiques pour lesquels cette conclusion peut s'appliquer.

Introduction

Of the concepts familiar to chemists, the charge density $\rho(\boldsymbol{r})$ of atoms and molecules is perhaps one of the most widely used as it allows the interpretation of chemical phenomena in a convenient, easily visualized, framework. Indeed, empirical concepts closely connected to the charge density such as bond lengths, angles, atomic radii, Van der Waals radii, electronegativity, etc. (1) have evolved to the extent that they now form an intrinsic part of the vocabulary of a chemist. Besides, $\rho(\boldsymbol{r})$ is experimentally accessible via X-ray Rayleigh scattering to within a phase factor (2).

The spin-traced one-electron charge density, $\rho(\boldsymbol{r})$, is defined as

$$[1]\quad \rho(\boldsymbol{r}_1) = N\int \Psi^*(y_1, \ldots, y_N)\Psi(y_1, \ldots, y_N)\mathrm{d}\sigma_1 \mathrm{d}y_2 \ldots \mathrm{d}y_N$$

where $\Psi(y_1, \ldots, y_N)$ is the position space normalized wavefunction for the N-electron atomic system, the asterisk denotes complex conjugation, and $y_m = (\boldsymbol{r}_m, \sigma_m)$ is the combined position, $\boldsymbol{r}_m$, and spin, σ_m, coordinates of the mth electron. Thus, $\rho(\boldsymbol{r})\mathrm{d}\boldsymbol{r}$ is the probability of finding an electron in a volume element $\mathrm{d}\boldsymbol{r}$ at a point $\boldsymbol{r}$ in position space.

The natural system of coordinates to be used in the atomic case is the spherical polar one centred at the atomic nucleus. The physically meaningful charge density is spherical because an ensemble average must be taken over degenerate states. Thus we shall study the spherical average, $\bar{\rho}(r)$, of the charge density, i.e.

$$[2]\quad \bar{\rho}(r) = \frac{1}{4\pi}\int \rho(\boldsymbol{r})\mathrm{d}\Omega_r = \frac{1}{4\pi}\int_0^{2\pi} \mathrm{d}\phi_r \int_0^{\pi} \sin\theta_r \,\mathrm{d}\theta_r \rho(\boldsymbol{r})$$

Both $\rho(\boldsymbol{r})$ and $\bar{\rho}(r)$ are normalized to the number of electrons, i.e.

$$[3]\quad N = \int \rho(\boldsymbol{r})\mathrm{d}\boldsymbol{r} = \int_0^{\infty} 4\pi\bar{\rho}(r)r^2\mathrm{d}r = \int_0^{\infty} D(r)\mathrm{d}r$$

with the definition of $\bar{\rho}(r)$ being the probability density of finding an electron at a radius r from the nucleus. $D(r) = 4\pi r^2\bar{\rho}(r)$ is the radial charge distribution which represents the probability density of finding an electron at a distance between r and $r + \mathrm{d}r$ from the origin of the coordinate system.

Although a complete formal proof is unavailable, numerical evidence has suggested that the spherically averaged charge density $\bar{\rho}(r)$ is monotonically decreasing for the ground state of an atom (3). Furthermore, the Hoffmann-Ostenhofs (4) have shown within the infinite nuclear-mass approximation that the atomic $\bar{\rho}(r)$ is indeed a convex monotonically decreasing function outside a sphere whose radius depends on the ionization energy and the electron–nucleus attraction.

Within a neighborhood of the nucleus, $\bar{\rho}(r)$ is monotonically decreasing as can be seen from its McLaurin expansion

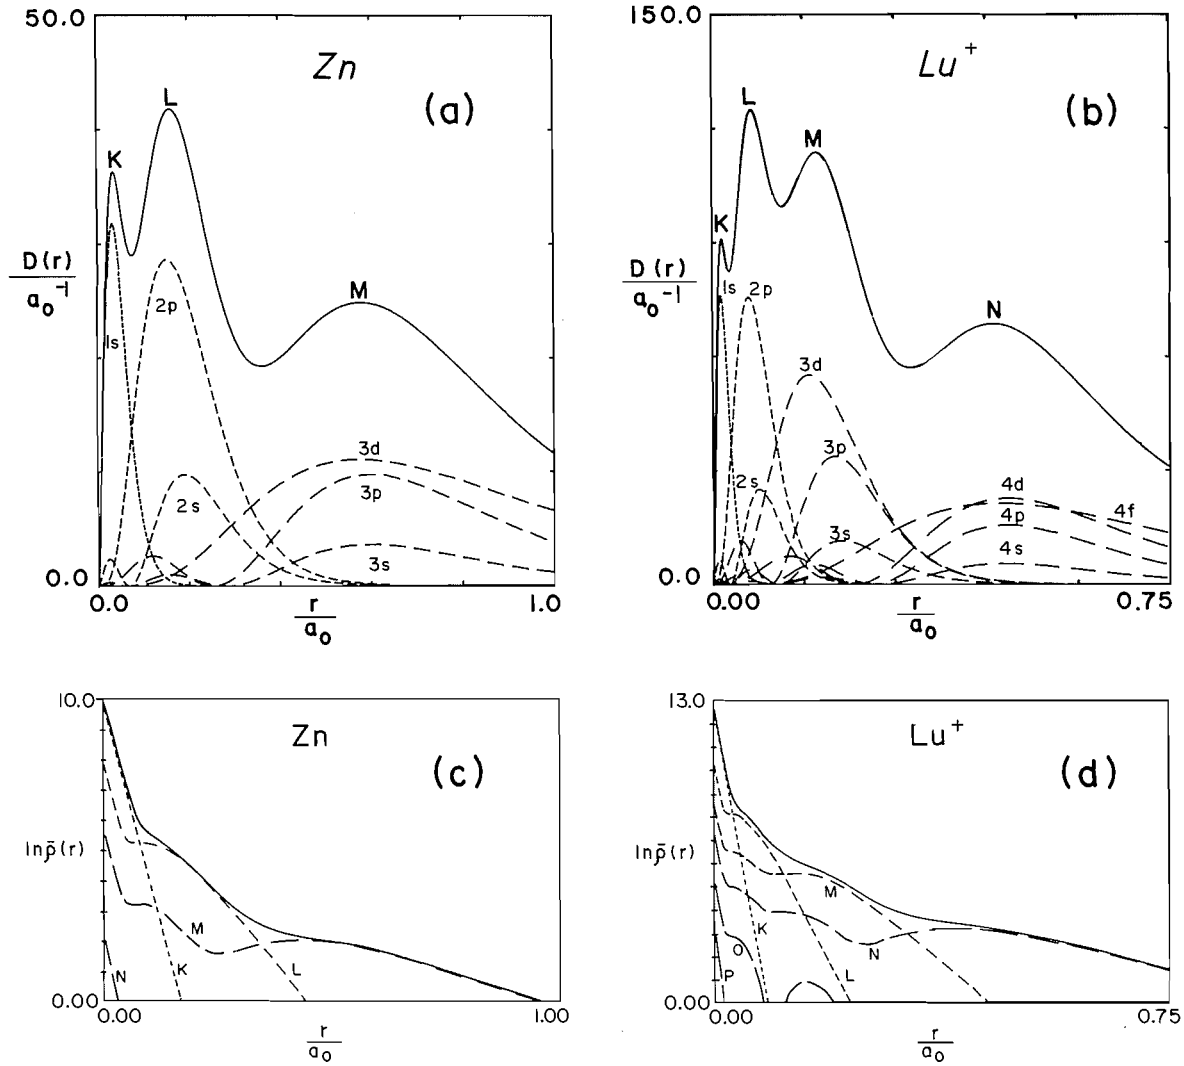

FIG. 1. Orbital (dotted lines) and the total (solid line) contributions to (*a*) $D(r)$ of the zinc atom ($Z = 30$); (*b*) $D(r)$ of the lutetium positive ion ($Z = 71$); (*c*) $\ln\bar{\rho}(r)$ of the zinc atom; (*d*) $\ln\bar{\rho}(r)$ of the lutetium ion. Note that in (*c*) and (*d*) those orbitals having the same principal quantum number have been grouped according to their corresponding shells.

[4] $$\bar{\rho}(r) = \bar{\rho}(0)[1 - 2Z\,\mathrm{Cen}\,r] + O(r^2)$$

where Cen is the electron nuclear cusp ratio (5)

[5] $$\mathrm{Cen} = \lim_{r\to 0} \bar{\rho}'(r)/2Z\bar{\rho}(r)$$

In sharp contrast to $\bar{\rho}(r)$, $D(r)$ vanishes at the origin and displays a number of maxima and minima (6). The values of r where $D(r)$ is a maximum or minimum are those that satisfy $D'(r) = 0$. Hence, by differentiation we obtain

[6] $$D'(r) = 4\pi r\left[2\bar{\rho}(r) + \frac{r\,d\bar{\rho}(r)}{dr}\right]$$

By solving this differential equation, $D'(r)$ is zero, for r not equal to zero, if $\bar{\rho}(r)$ possesses the functional form of r^{-2}. The topology of $D(r)$ suggests that the maxima and minima in $D(r)$ are the result of the increasing surface area ($4\pi r^2$) of the sphere. That is, if the rate of decay of $\bar{\rho}(r)$ is slower than r^{-2} then $D(r)$ is an increasing function. Conversely, if the damping effect in $\bar{\rho}(r)$ is stronger than r^{-2}, $D(r)$ is a decreasing function.

The relationship of the topology of $\bar{\rho}(r)$ to the shell structure in $D(r)$ was first examined by Wang and Parr (7) who examined plots of $\ln\bar{\rho}(r)$ versus r together with the respective $D(r)$ plots. Figure 1 contains $D(r)$ plots for Zn and Lu^+ together with their respective $\ln\bar{\rho}(r)$ plots. As was found by Wang and Parr, $\bar{\rho}(r)$ can be represented as a continuous piecewise exponential function of r with "as many different exponential regions as there are principal quantum numbers". The transition from one exponential region to the next occurs in an interval which roughly coincides with the corresponding minimum in the $D(r)$ plot as can be readily seen from Fig. 1.

If the charge density is constructed from a wavefunction in a Slater basis set, each Slater-type function (STF) whose radial part $R(r)$ is $Cr^{n-1}e^{-\zeta r}$ where C is the normalization coefficient and n is the principal quantum number, will lead to a $D(r)$ that peaks only at $r = n/\zeta$. Hence, due to the similarity of their radial parts, orbitals possessing the same principal quantum number lead to $D(r)$ contributions that peak generally in the same region (Fig. 1); the difference being in the cross-terms that arise in the multiplication of two STF's. In fact, knowledge of how the shell structure reveals itself through $D(r)$ has been utilized in the interpretation of beam-foil excitation processes (8–12).

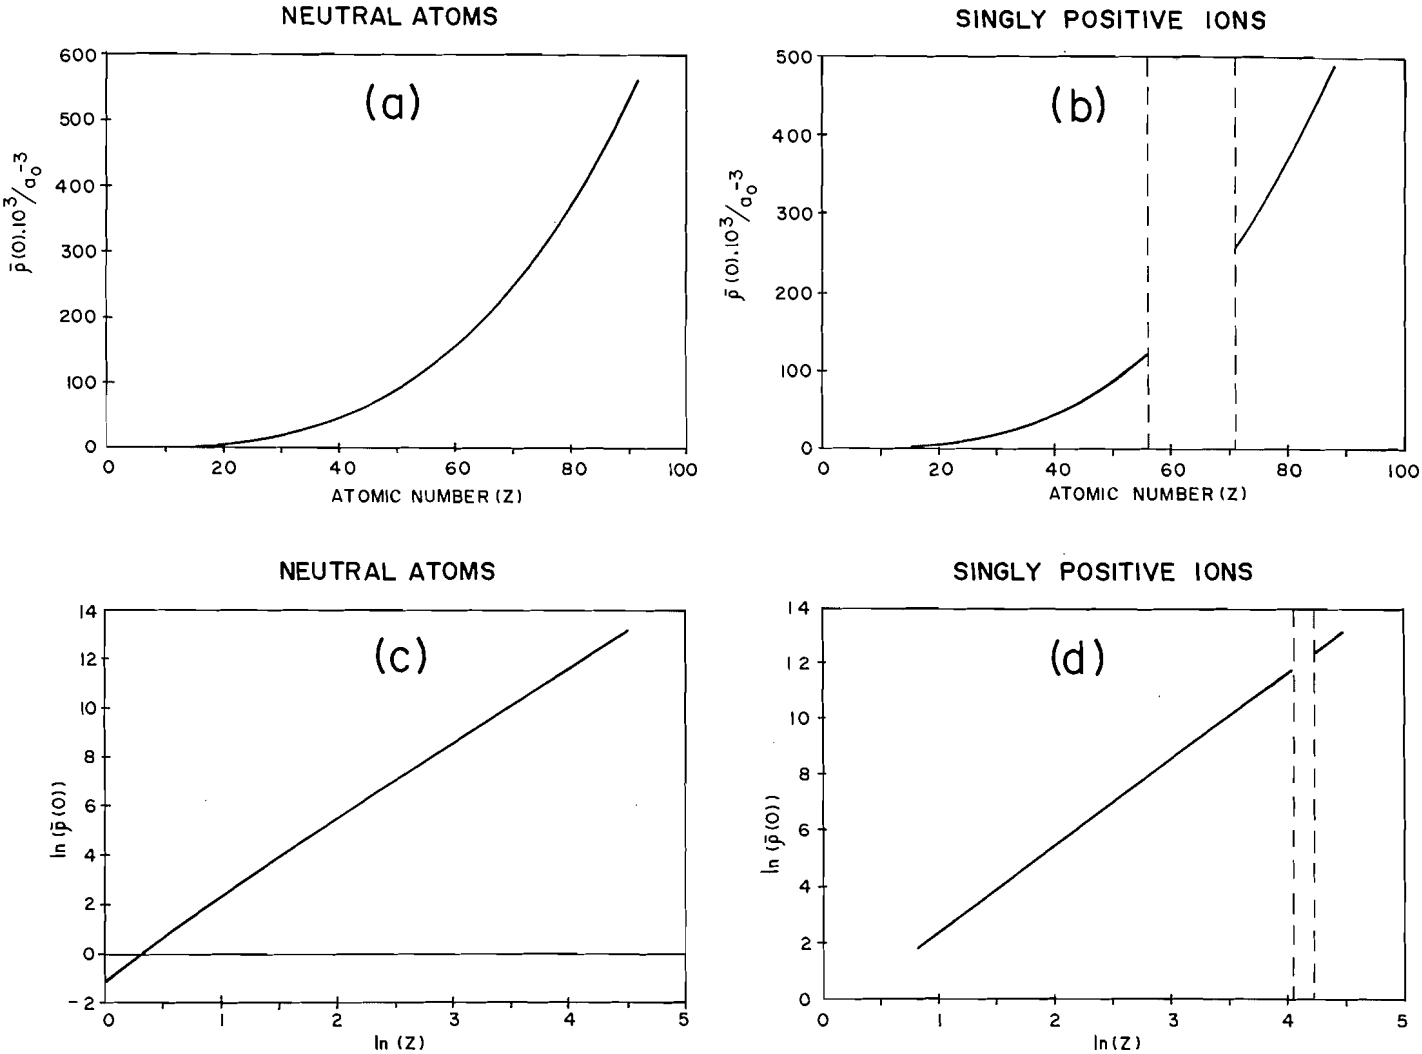

FIG. 2. A study of $\bar{\rho}(0)$ for the neutral atoms ($1 \leq Z \leq 92$) and the singly positive ions ($2 \leq Z \leq 57$, $70 \leq Z \leq 92$). (*a*) $\bar{\rho}(0)$ vs. Z for the neutral atoms; (*b*) $\bar{\rho}(0)$ vs. Z for the singly positive ions; (*c*) $\ln \bar{\rho}(0)$ vs. $\ln Z$ for the neutral atoms; (*d*) $\ln \bar{\rho}(0)$ vs. $\ln Z$ for the singly positive ions. Note that the gap $57 \leq Z \leq 70$ in (*b*) and (*d*) is due to the unavailability of wavefunctions for the ions with open *f*-shells.

Results and discussion

The values of the spherically averaged charge density $\bar{\rho}(r)$ and the radial charge distribution $D(r)$ were computed for the neutral atoms hydrogen to uranium and singly positive ions helium to barium and lutetium to radium from the non-relativistic SCF wavefunctions of Clementi and Roetti (13) and McLean and McLean (14). Published wavefunctions for the singly positive ions with open *f*-shells were not available.

The spherically averaged charge density, $\bar{\rho}(r)$, was found to be monotonically decreasing for the ground states of all the studied atomic and ionic cases (i.e. no local maxima or minima were observed).

Figures 2(*a*) and 2(*b*) contain plots of $\bar{\rho}(0)$ vs. Z for the atoms and the ions, respectively, and are meant to illustrate how $\bar{\rho}(0)$, the only extremal point in $\bar{\rho}(r)$, varies as a function of the atomic number Z (5). In Figs. 2(*c*) and (*d*) plots of $\ln \bar{\rho}(0)$ vs. $\ln Z$ are presented for the atoms and the ions, respectively.

Only orbitals possessing *s*-type symmetry will contribute to the spherically averaged charge density, at the origin, $\bar{\rho}(0)$. Since only the 1*s* Slater type functions are non-zero at the origin, we shall assume that one of these dominates the behaviour of $\bar{\rho}(0)$. For $\bar{\rho}(r)$ of such a 1*s* orbital which, according to Slater's rules (15), is subject to minimal screening, the value of $\bar{\rho}(0)$ is $2Z^3/\pi$. A plot of $\ln \rho(0)$ vs. $\ln Z$ would thus yield

$$[7] \quad \ln \bar{\rho}(0) \approx 3 \ln Z + \ln\left(\frac{2}{\pi}\right)$$

Therefore one would expect that if our assumption that the unscreened 1*s* function dominates $\bar{\rho}(0)$ is correct, the curves in Figs. 2(*c*) and (*d*) should have slopes equal to 3 and intercepts[1] equal to $\ln(2/\pi)$.

In Figs. 1(*a*) and (*b*) the $D(r)$ plots for the atom Zn ($Z = 30$) and the singly positive ion Lu^+ ($Z = 71$) are disassembled in terms of orbital contributions to the total function. These plots illustrate that orbitals having the same principal quantum number will peak in generally the same region, with the higher angular momentum orbitals peaking at smaller values of r, as

[1]The curve in Fig. 2(*c*) has a slope of 3.11 and an intercept of −0.768 while that in Fig. 2(*d*) has a slope of 3.20 and an intercept of −0.931.

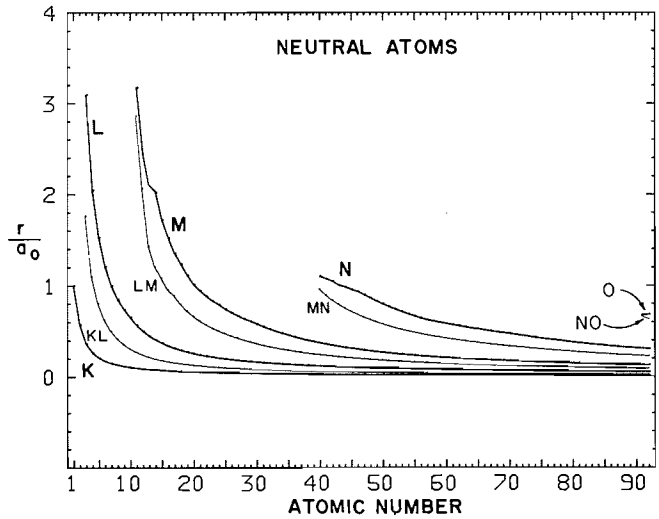

FIG. 3. Values of r_{max} (heavy lines, single letters) and r_{min} (thin lines, double letters) corresponding to the value of r at which the radial charge distribution is, respectively, a maximum or minimum for the neutral atoms hydrogen to uranium, as a function of the atomic number Z.

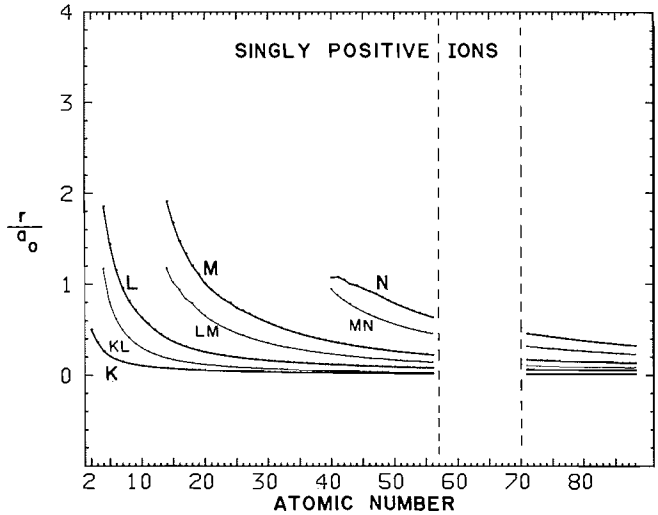

FIG. 4. Values of r_{max} (heavy lines, single letters) and r_{min} (thin lines, double letters) corresponding to the value of r at which the radial charge distribution is respectively a maximum or minimum for the singly positive ions, from helium to barium and lutetium to radium, as a function of the atomic number Z. Note that the gap $57 \leq Z \leq 70$ is due to the unavailability of wavefunctions for the ions with open f-shells.

compared to orbitals with smaller angular momenta. If a "shell" is defined as the region in r where orbital contributions to $D(r)$ of the same principal quantum number will peak, we can infer from Figs. 1(a) and (b) that the maxima in $D(r)$ correspond to these "shells", with the maximum at the smallest r corresponding in order to the K shell, and subsequent maxima corresponding to the L, M, shells etc. The minima in $D(r)$ which have been the subject of previous studies (16) are the consequence of a combination of the orbital contributions to $D(r)$ of the preceding maximum decaying and the orbital contributions to $D(r)$ of the succeeding maximum increasing and as such can be seen to be the region between two shells, i.e. an intershell valley. Figures 1(a) and (b) indicate that as the distance from the nucleus increases, the maxima become broad and shallow and sometimes difficult to discern. For the case of the lutetium ion (Fig. 1(b)), the outer shells are not even apparent.

Adopting a convention that has been used elsewhere (17), r_{max}, r_{min} shall be used to denote the values of r at which $D(r)$ is a maximum or minimum respectively, while D_{max}, D_{min} will correspond to $D(r_{max})$ and $D(r_{min})$, respectively. By inserting a third axis, Z, perpendicular to the plot in Fig. 1(a) and through its origin, and using it to mark the atomic number in ascending order, we confine all the $D(r)$ plots for the atoms to a single three dimensional figure. Furthermore, by connecting the r_{max}, r_{min} values of a particular shell or intershell valley and projecting these curves into the r–Z plane, one is able to observe the effect of atomic number on the positions of the extrema of $D(r)$. Figures 3 and 4 convey this information for the atoms and ions, respectively, with the single letters denoting the shells, and the double letters denoting an intershell region which lies between the shells corresponding to the two letters. Subsequently if the values of $D(r)$ at the extremal points are connected by straight lines and the resulting curves projected onto the D–Z plane from the hypothetical 3-D figure for a particular shell or intershell, one is able to observe the effect of atomic number on the values of $D(r)$ at the shell peaks and the intershell valley regions for the atoms and the ions (Figs. 5 and 6). It should be noted that the connections in Figs. 3–6 are meant only to guide the eye and should not convey the impression that the curves are continuous in Z.

Figures 3 and 4 can best be understood in terms of the Bohr theory of an atom which specifies shells (all electrons with the same principal quantum number n) with orbit radii equal to $(n^2/Z)a_0$. This expression can be used to account for the roughly first order hyperbolic plots present in Figs. 3 and 4 with the functional form suggesting that any deviations from a first order hyperbola must be due to either n, the principal quantum number, or to Z, the atomic number. The deviations resulting from Z should be the result of shielding of the outer electrons from the nucleus by the inner electrons. This means that the outer electrons are in a field resulting from an effective nuclear charge of $Z - S$ where S is an empirically defined shielding parameter (15).

To examine the nature of the deviations, the inverses, i.e. r_{max}^{-1}, r_{min}^{-1} of Figs. 3 and 4 were plotted and presented in Figs. 7 and 8. These latter curves being of the approximate form Z/n^2 show marked linearity with no obvious deviations, in contrast to Figs. 3 and 4 which do exhibit some deviations. Since any deviations due to shielding would mean a perturbation which would affect the atomic number, the expression from the Bohr theory for the radius of the nth shell becomes $n^2/(Z - S)a_0$ or $n^2/Z(1 - S/Z)a_0$. The latter expression implies that the deviations are larger at smaller Z, a result which is in accord with the shapes of the curves in Figs. 3 and 4. Thus the deviations are mainly a result of shielding as was previously reported (6). It should be noted here that the marked linearity in Figs. 7 and 8 is due to the fact that any shielding apparent in Figs. 3 and 4 will only affect the intercepts and not the slopes of the various curves. This can be seen by considering the corresponding expression for the reciprocal radius, namely $(Z - S)n^{-2}a_0^{-1}$.

Tables 1 and 2 contain the data obtained from a linear least-squares regression analysis of the r_{max}^{-1} curves for the shells in Figs. 7 and 8 and the slopes and intercepts obtained by analytical derivation from the highest angular momentum hydrogenic function of a particular shell. The highest angular

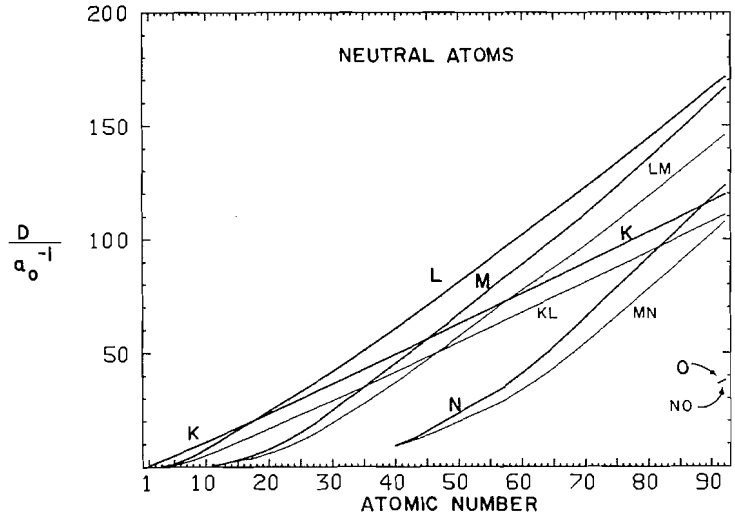

FIG. 5. Values of D_{max} (thicker lines, single letters) and D_{min} (thinner lines, double letters). These quantities correspond to the values of the radial charge distribution at the maxima and minima respectively, for the neutral atoms as a function of the atomic number Z.

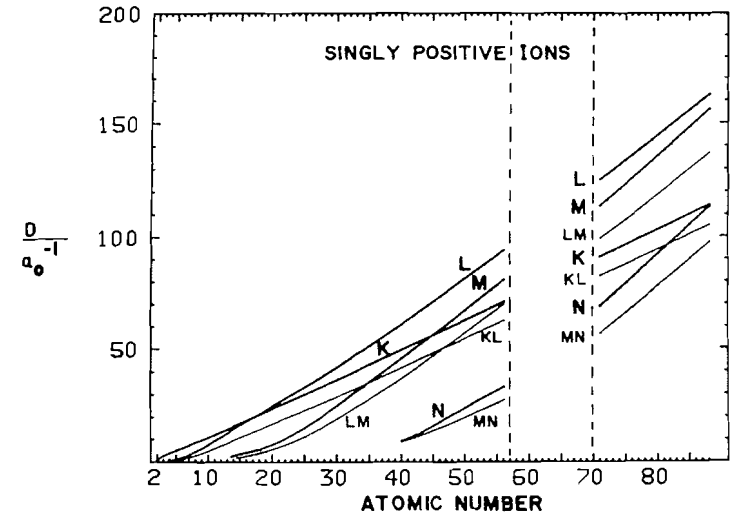

FIG. 6. Values of D_{max} (thicker lines, single letters) and D_{min} (thinner lines, double letters). These quantities correspond to the value of the radial charge distribution at the maxima and the minima respectively for the singly positive ions, as a function of the atomic number Z. Note that the gap $57 \leq Z \leq 70$ is due to the unavailability of wavefunctions for the ions with open f-shells.

momentum hydrogenic function of each shell has been used in this study in the assumption that these functions are the most descriptive of the trends in D_{max}, D_{min}, r_{max}, r_{min} for a particular shell, due to their higher occupation numbers in comparison with the lower angular momentum orbitals for most of the elements. Consider for example the neon atom. This atom possesses an electronic configuration in which the L shell is completely filled, i.e. $2s^2 2p^6$. For all the atoms beyond neon in the periodic table, the behaviour of the L shell would most likely be governed by the $2p$ orbitals since their occupation would always be three times that of the $2s$ orbital.

The slope was determined analytically from the highest angular momentum hydrogenic function of the particular shell by using its functional form to construct $D(r)$, which was then differentiated with respect to r, and the resulting equation set equal to zero to find r_{max}. Since this equation for r_{max} is Z dependent, the inverse, r_{max}^{-1} is also Z dependent with the coefficient of the equation for r_{max}^{-1} as a function of Z being referred to as the "analytically derived slope", A_D. The intercept was calculated by assuming a functional form $A_D(Z - S)$ where A_D is the "analytically derived slope", Z is the atomic number and S is an empirically defined shielding constant that was calculated via the use of Slater's rules (15). The intercept which shall be referred to as the "analytically derived intercept", B_D is thus seen to be the product of the "analytically derived slope", A_D, and the shielding parameter, S.

On comparison of the analytically derived slope, A_D, with the slope from the fitting, A_F one can see that there is an overall trend towards similarity between the two quantities, thereby substantiating the validity of the Bohr theory of an atom within this particular framework. On the other hand, the "analytically derived intercept", B_D bears no resemblance to the intercept from the fitting, B_F, a result which supports the fact that the effects of shielding on the position of the extrema in $D(r)$ are small.

A linear least-squares analysis was performed on the slopes determined from the fitting in Figs. 7 and 8 (A_F in Tables 1 and 2) against the inverse of the principal quantum number squared,

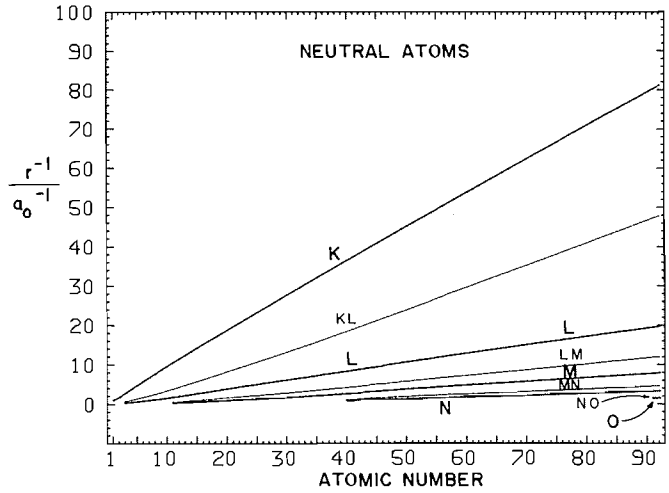

FIG. 7. Values of r_{max}^{-1} (heavy lines, single letters) and r_{min}^{-1} (thin lines, double letters) corresponding to the values of r^{-1} at which the radial charge distribution is respectively a maximum or minimum, for the neutral atoms hydrogen to uranium, as a function of atomic number Z.

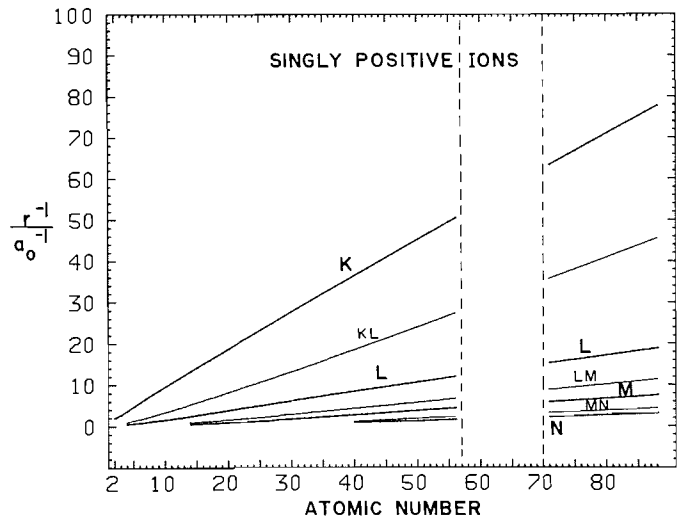

FIG. 8. Values of r_{max}^{-1} (heavy lines, single letters) and r_{min}^{-1} (thin lines, double letters) corresponding to the values of r^{-1} at which the radial charge distribution is respectively a maximum or minimum for the singly positive ions, as a function of atomic number Z. Note that the gap $57 \leq Z \leq 70$ is due to the unavailability of wavefunctions for the ions with open f-shells.

for the atoms and the ions respectively. The resulting equation obtained for the atoms was $A_F = 0.8977/n^2 - 0.01741$. The ions yielded the result $A_F = 0.8807/n^2 - 0.003611$. The fact that these intercepts are close to zero and that the slopes are close to unity for both the atoms and the ions further validates the correlation with the prediction from the Bohr theory.

Figures 5 and 6 show plots of D_{max} vs. Z of the shell and intershell regions for the atoms and the singly positive ions, respectively. These plots show regions of curvature as well as regions of linearity, with the regions of linearity occurring at higher values of Z. The curves are seen to be steadily increasing with Z, and as such are a consequence of the normalization of the wavefunction since as the atomic number increases, the particular extrema will move closer to the nucleus, and the value

of the function at the extrema will become larger in order for the normalization conditions to be obeyed. The various curves are also seen to intersect which is a consequence of shielding, as without shielding all the intercepts would be zero, with the plots diverging as a consequence of different slopes.

Tables 3 and 4 contain the parameters obtained from a linear least-squares regression analysis of the D_{max} curves for the shells in Figs. 5 and 6, and the slopes and intercepts obtained from analytical derivation using the highest angular momentum hydrogenic function of a particular shell.

The slope from the highest angular momentum hydrogenic function of a particular shell was obtained by substituting the value of r_{max} previously obtained from the same hydrogenic function into the expression for $D(r)$ derived for this particular hydrogenic function. The resulting equation is Z dependent with the coefficient being referred to as the "analytically derived slope", A_D'. The intercept, B_D', similar to the case of the r_{max}^{-1} studies was calculated by assuming the functional form $M(Z - S)$, and therefore is the product of the "analytically derived slope", A_D', and the shielding parameter, S.

The results suggest that there is no agreement between the "analytically derived slope", A_D', and the fitted slope, A_F', but there is in general good correlation between the "analytically derived intercepts" and the fitted intercepts, B_D' and B_F', in

sharp contrast to the r_{max}^{-1} studies. Thus the effects of shielding are seen to be more evident in the D_{max} case, while the r_{max}^{-1} studies indicate a good correlation with the Bohr theory of an atom.

The D_{max}, D_{min} plots have some interesting features that should be noted. The N shell is unique since it exhibits three distinct regions of linearity in contrast to the two regions observed with other shells and intershells. This is a consequence of the filling of the $4f$ orbitals as this region starts with Ce ($Z = 58$) precisely where the $4f$ orbitals begin to be occupied.

Figure 9 contains the radial charge distribution for the neutral atom uranium ($Z = 92$) in order to show the presence of a fifth maximum, in contrast to what was previously reported (6) to be a broad shoulder via computation from a relativistic SCF wavefunction (with local exchange). This result raises interesting questions into the nature of the wavefunctions used and the possibility of the appearance or disappearance of more shells with the use of more highly accurate wavefunctions and the effects of electron correlation and relativity.

Conclusions

The present examination of the radial charge distribution function, $D(r)$, shows that at most five shells are revealed in

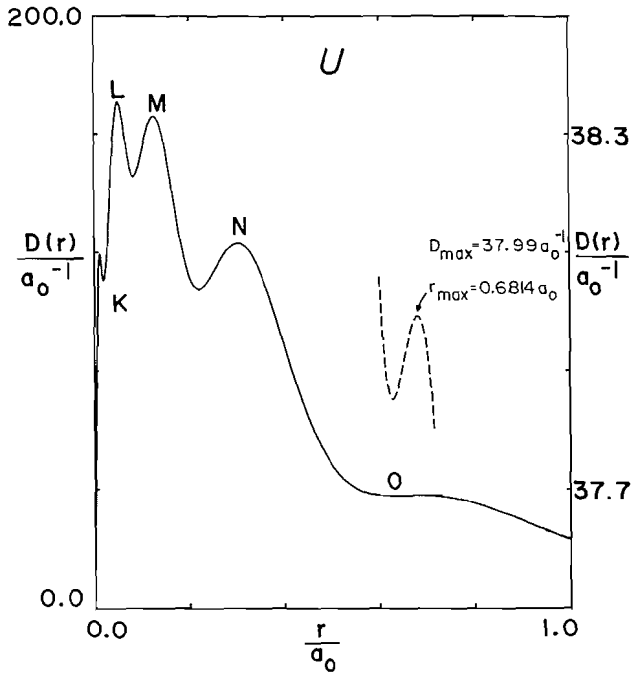

FIG. 9. Radial charge distribution of the neutral atom U ($Z = 92$) computed from the non-relativistic SCF wavefunction of McLean and McLean. The dashed curve corresponds to the scale on the right hand side in order to clearly show the maximum indicative of the O shell.

$D(r)$ based on the criterion that the maxima of $D(r)$ are the topological features most indicative of shells. Furthermore, the maxima exhibit strong correlations with that expected from the independent particle model (Bohr-hydrogenic theory). Any deviations from the Bohr theory were attributed to the effects of electronic shielding.

The spherically averaged charge density, $\bar{\rho}(r)$, was shown to be monotonically decaying for the ground states of all the studied atomic and ionic cases. This extends the previously known (3) upper limit for the range of atoms for which this is true from $Z = 36$ to $Z = 92$. For the first time, $\bar{\rho}(r)$ for the singly positive atomic ions was shown to have the same behaviour.

Light-induced reversible ionization of tetramethylphenylenediamine in an inorganic polymer of *n*-butyl orthotitanate

HISASHI UEDA[1] AND MASAHIRO KAISE

National Chemical Laboratory for Industry, Tsukuba Research Center, Higashi, Tsukubashi, Ibaraki 305, Japan

Received November 23, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

HISASHI UEDA and MASAHIRO KAISE. Can. J. Chem. **66**, 1931 (1988).

n-Butyl orthotitanate, BT, polymerized in tetrahydrofuran, if irradiated by visible light, gives a new electron spin resonance absorption that is not found before irradiation. In the present work, three different polymers of BT were synthesized by adding tetramethyl phenylenediamine (TMPD), dimethyl phenylenediamine (DMPD), or phenylenediamine (PD), to the solution of BT. The polymers thus prepared were tested to see if they give a new esr signal when irradiated by visible light. The polymer to which 1 mol% of TMPD was added gave $TMPD^{\bullet+}$ when irradiated by visible light, but the $TMPD^{\bullet+}$ signal decayed after the irradiation was discontinued. This change, therefore, is reversible. The resonant position of every hyperfine splitting line of the $TMPD^{\bullet+}$ found in this polymer coincided with that of $TMPD^{\bullet+}$ in solution, but the relative intensity ratios and the line width of each line depended on the nuclear spin quantum number of the coupling nuclei. This can be interpreted by the restricted rotational motion of $TMPD^{\bullet+}$ in the polymer matrix. The contribution of the non-diagonal term to the spin relaxation time would explain this phenomenon. In the case of the polymer to which DMPD was added, a small amount of $DMPD^{\bullet+}$ seemed to be formed, but no radical was detected in the case of the polymer to which PD was added.

HISASHI UEDA et MASAHIRO KAISE. Can. J. Chem. **66**, 1931 (1988).

Lorsqu'on soumet des solutions d'orthotitanate de *n*-butyle (TB) dans le tétrahydrofuranne à une irradiation par de la lumière visible, il se produit une polymérisation qui donne naissance à une absorption en résonance paramagnétique électronique qui n'est pas observée avant l'irradiation. Dans le présent travail, on a synthétisé trois polymères différents du TB; pour y parvenir, on a ajouté de la tétraméthyl phénylènediamine (TMPD), de la diméthyl phénylènediamine (DMPD) ou de la phénylènediamine (PD) à la solution de TB. On a vérifié si les polymères ainsi préparés donnent naissance à un nouveau signal rpe lorsqu'ils sont soumis à une irradiation par de la lumière visible. Lorsqu'on le soumet à une irradiation par de la lumière visible, le polymère auquel on a ajouté 1 mol% de TMPD donne l'ion radical $TMPD^{\bullet+}$; toutefois, ce signal disparaît lorsqu'on discontinue l'irradiation. Ce changement est donc réversible. La position de résonance de chacune des raies du $TMPD^{\bullet+}$ de ce polymère coïncide avec celle du $TMPD^{\bullet+}$ en solution; toutefois, les rapports des intensités relatives ainsi que les largueurs de chacune des raies dépendent du nombre quantique du spin nucléaire des noyaux qui se couplent. On interprète ces résultats en fonction d'une restriction au mouvement rotationnel du $TMPD^{\bullet+}$ dans la matrice de polymère. La contribution du terme non-diagonal au temps de relaxation de spin explique ce phénomène. Dans le cas du polymère auquel on a ajouté du DMPD, il semble se former une faible quantité de $DMPD^{\bullet+}$; toutefois, on n'a pas détecté de radicaux dans le cas du polymère auquel on a ajouté de la PD.

Introduction

The demand for synthetic polymers has been changing in recent times. In addition to requirements of mechanical strength, thermal stability, and corrosion resistivity, new optical properties are being requested of the polymers (1). To find these types of polymers, the present authors have investigated, by the esr method (2), the light response of inorganic polymers containing titanium or zirconium. Bradley *et al.* studied the polymerization of titanium alkoxides and the structure of these products (3, 4). According to Bradley, there are five types of polymerization patterns and the chain growth can proceed in four possible directions (5). Boyd studied the hydrolysis-type polymerization of titanium alkoxides (6). Thus the polymers formed from titanium alkoxides can show diversity in their structures. The present authors have tried to polymerize titanium alkoxides in tetrahydrofuran (THF); a slower polymerization rate should be possible in THF because of its smaller dielectric constant compared to that of water. In THF, the alkoxyl groups will be eliminated as R_2O, leaving considerable amounts of the -Ti(RO)- type of group in the polymer molecule, which would give rise to paramagnetism in the molecule. The esr results have indicated that this actually happens (2). In the present work, tetramethyl phenylenediamine (TMPD), dimethyl phenylenediamine (DMPD), or phenylenediamine (PD) was added to the titanium butoxide/THF solution and the three polymers produced were tested to see if they show visible-light-induced esr spectra.

So far as the present authors know, inorganic polymers in which unpaired spins are intentionally created have rarely been synthesized. Therefore, esr observation of the light-induced change in this type of polymer was not made previous to the attempt of one of the present authors (Ueda and co-workers, ref. 2). The novelty in the present paper lies in the esr detection of the light-induced reversible electric charge flow from the bulk of the inorganic polymer synthesized by addition of aromatic diamine to the diamine.

Experimental

The TMPD/polymer was prepared by the following method: 6.3 g of $Ti(OBu)_4$ (*n*-butyl orthotitanate, BT) was dissolved in THF. To this solution an 0.18 mM equivalent of TMPD·2HCl and 2.0 g of silica gel, crushed immediately before use and to 100 mesh, were added. A Pyrex container, made from a 500-mL beaker by cutting off the beak part to cover it tightly with a glass plate, was used as the reactor. After covering the container with a watch glass it was placed in the middle of a circle of light from a 30-W fluorescent lamp. After 50 h, the watch glass was removed to evaporate the solvent. In some 20 h the THF was evaporated away, yielding colored solid polymer. The yield was ca. 38% based on the amount of $Ti(OBu)_4$ used. If the reaction

$$Ti(OBu)_4 \rightarrow \text{-Ti(=O)—O-} + 2Bu_2O$$

[1]Author to whom correspondence may be addressed.

For personal use only.

goes to completion, the yield should be 23.5%. If TMPD was not added, the polymer yield experimentally obtained was ca. 29%. Therefore, the elimination of Bu_2O was somewhat inhibited by the addition of TMPD. Since the silica gel added had been crushed finer than 100 mesh, most of the silica gel powder was separated from the polymer particles by a sieve. Both polymer and silica gel portions thus prepared were washed with 1:4 acetic acid/water, 1:4 formic acid/water, and 1:1 aqueous ammonium solution, and were then dried. The esr measurements were made with this sample. The preparation of the PD/polymer system was attempted using an identical procedure. However, it was impossible to obtain a polymer in this case. No increment of the viscosity of the solution was observed. It may be possible that the polymerization of BT was hindered by PD. Instead of PD, PC·2HCl was used in the same procedure. No viscosity increment was observed in this case, either. Considering these facts, another attempt to obtain the PD/polymer system was made. After polymerizing $Ti(OBu)_4$ to the extent at which gelation can be observed, a THF solution of 0.18 mM PD was added. After 20 h, the PD/polymer system was obtained. Let this polymer be called "post-addition PD polymer."

The DMPD/polymer system was also prepared. The amount of DMPD in this case was also 0.18 mM to 6.3 g of $Ti(OBu)_4$. The addition of DMPD at the beginning of the polymerization failed as in the case of PD. The use of the HCl salt also failed. Therefore, a THF solution of DMPD was added to the gelated solution of $Ti(OBu)_4$/THF. After 20 h, the DMPD/polymer system was obtained. Let this polymer be called "post-addition DMPD polymer."

The light-induced esr signal detection system consisted of a halogen lamp (Iwasaki Electric JCR 100 V 150 W), a light guide cable (Sumita Optics SLS-150), and an esr spectrometer (JEOL ME3X). The illuminated light contained light components having wave lengths ranging from 700 to 400 nm. Microwave power output at the Gunn diode oscillator was 1 mW. No power saturation of the spectrum was observed below 5 mW. A magnetic field modulation frequency of 100 kHz was used and the amplitude of the modulation width was 0.08 mT. A time constant of 0.1 s was used when sweeping the entire magnetic field range of 10 mT in 5 min. g-Factor determination was made by using a cavity resonator-type wave meter and 1,1-diphenyl-2-picryl hydrazyl (g = 2.0036) and Mn^{2+}/MgO standard samples (8.69-mT interval between 3rd and 4th hfs lines).

Results

In Fig. 1 the esr spectra of the polymer part (solid line) and the silica gel part (dotted line) of samples washed with 1:4 aqueous formic acid and illuminated for 10 min with visible light are shown. The silica gel part gives relatively well-separated hfs lines. This is due to the lower concentration of the paramagnetic species in the silica gel part. We conclude that the nature of the paramagnetic species is not different in these two samples. In Fig. 2 the experimental esr spectrum E (the same as the dotted curve in Fig. 1) and the simulated spectrum S are compared. The SA spectrum was obtained by assuming a line width of 0.120 mT, Lorentz functional form, and hfs coupling constants of 0.699 mT for N, 0.197 mT for H of the benzene ring, and 0.676 mT for the CH_3 protons (7). The experimental curve E seems to contain a structureless component, which may be due to a peak with a very large line width. Then SB was calculated using 1.2 mT as the line width. The S spectrum was calculated as S = (24·SB + SA)/25. The experimental curve has different line widths if one looks at the lower field side and the higher field side. This phenomenon may be due to restricted rotational motion of the $TMPD^{\cdot+}$ cation in the polymer (8–10). The anisotropy in the hfs tensor cannot be ignored with respect to the spin relaxation time and, as a result, the line width depends on the spin quantum numbers, m, of the proton system or

the nitrogen nuclei system. The intensity ratio may also be dependent on m values (11). The simulated curve S is not constructed upon these considerations. However, it will be seen in Fig. 2 that the resonance positions of the E and S spectra coincide exactly. Therefore, it can be said that $TMPD^{\cdot+}$ is formed in the polymer of $Ti(OBu)_4$ by visible light. In Fig. 3 the reflectance spectrum of a sample of the silica gel part is shown. The spectrum B is the entire spectrum less the base-line spectrum. A is the transmittance spectrum of $TMPD^{\cdot+}$ stabilized in CCl_4 at 77 K (12). Though A and B do not coincide well, the absorption region seems to be the same. It would be proper to say that these two spectra are both due to $TMPD^{\cdot+}$ but they reflect the difference in the matrix environments in which they are stabilized. Figure 4 shows the intensity increment in the esr of the polymer part when illuminated by light. A indicates the spectrum before light illumination and B indicates the spectrum obtained by the sweep of 8.5–13.5 min after beginning the light illumination. As the A spectrum is from $TMPD^{\cdot+}$, it

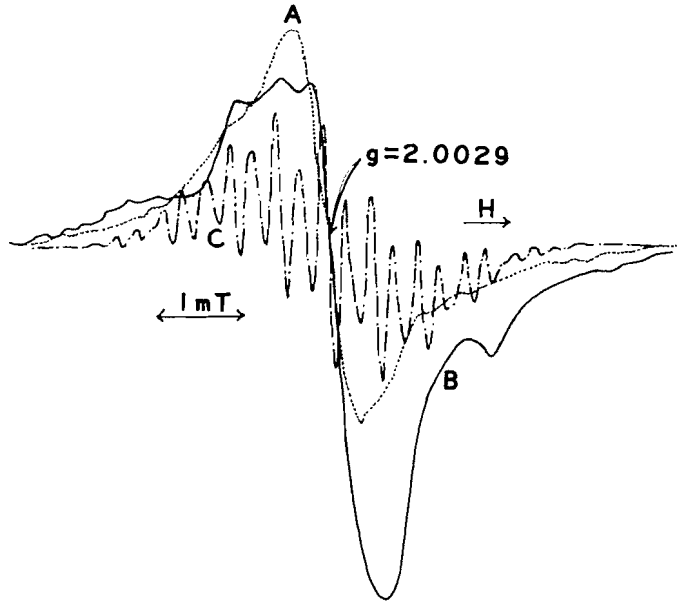

FIG. 5. The esr spectra of the polymer of $Ti(OBu)_4$ containing PD that was added at the latter stage of the polymerization. A was observed before light illumination. B was observed after 13.5 min of illumination. C is a simulated spectrum of $PD^{\cdot+}$; for esr parameters of simulation, refer to the text.

is concluded that $TMPD^{\cdot+}$ increases when illuminated and decreases when the light is turned off. This change could be repeated many times and, therefore, can be concluded to be reversible. Figure 5 indicates the esr spectra of the post-addition PD polymer kept in darkness (A) and under light illumination (B). The simulation parameters for curve C were 0.120 mT as line width, 0.211 mT as the coupling constant for C_6H_6 protons, 0.575 mT for the NH_2 protons, and 0.513 mT for N (14, 15). Figure 6 shows the esr spectra of post-addition DMPD polymer. A shows the spectrum without light illumination and B shows the spectrum 14.4 min after beginning light illumination. C is the simulated spectrum of $DMPD^{\cdot+}$ using a line width of 0.120 mT and coupling constants of 0.167 mT for two of the benzene protons (NMe_2 side) and 0.111 mT for another benzene proton (NH_2 side). The other coupling constants were 0.469 mT for NH_2 protons, 0.739 mT for CH_3 protons, 0.453 mT for the NH_2 nitrogen nucleus, and 0.719 mT for the NMe_2 nitrogen nucleus, respectively (16).

Figure 7 shows the reflectance spectra of the polymer that gave the esr spectra in Fig. 5. The reflectance spectrum of the silica gel part of the polymerization mixture and the transmittance spectrum of $PD^{\cdot+}$ reported by Nakayama and Suzuki (13) are also shown. It will be judged, by the comparison of these two spectra, that $PD^{\cdot+}$ does not exist in the present polymer mixture. Figure 8 indicates the reflectance spectra of the polymer that gave the esr spectra of Fig. 6, labelled "Polymer" in the figure. The spectrum of the silica gel part is labelled "SiG Polymer." The transmittance spectrum of Nakayama and Suzuki (13) is also shown. The comparison of these spectra may suggest that $DMPD^{\cdot+}$ is not formed in the present polymer mixture.

While TMPD forms a stable cation, TCNQ (tetracyano quinodimethane) is known to form either a stable anion or to function as an acceptor molecule. For this reason, an attempt was made to prepare a polymer mixture in which TCNQ was

dissolved in $Ti(OBu)_4$ polymerization solution. It was expected that this polymer mixture might give the $TCNQ^{\bullet-}$ anion radical upon irradiation by visible light. The polymer mixture was washed with CCl_4 and then an esr spectrum was observed. The visible light response was strong, but there was little evidence of the formation of $TCNQ^{\bullet-}$. The observed spectra are shown in Fig. 9. The spectrum A was obtained from the sample stored in a dark place. The spectrum B was obtained after illuminating the sample for 40 min with visible light. The spectrum B is

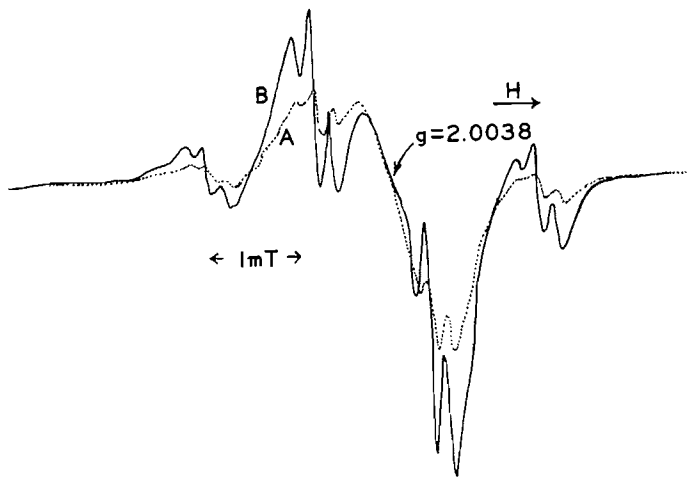

FIG. 9. The esr spectra obtained for the illumination of the polymer of $Ti(OBu)_4$ containing 1 mol% of TCNQ. A was obtained after keeping the sample in the darkness. B was obtained after illuminating the sample with visible light for 40 min. Illumination was maintained during the measurement.

composed of a broad component and an hfs component, only the latter being intensified with light. Neither A nor B can be ascribed to $TCNQ^{\bullet-}$.

Discussion

In the present work, silica gel powder was used as the initiating agent of the polymerization. Fluorescent light was used to maintain the polymerization reaction. The products obtained under the above conditions have been found to give the most light-sensitive polymer (2). The types of polymerization reaction and the structure of the reaction products have already been discussed (3–6). However, the preparation of the free-radical-type polymer in organic solvents has been carried out for the first time by the present authors. The polymer obtained in this manner is amorphous, chemical composition being approximately equal to TiO_2, and has many -Ti(=O)—O- units. In addition, some alkoxyl groups are left in the molecule (2). However, relatively less is known about the electronic states of the molecule and the behavior of the electrons photo-excited by illumination.

In the case of the polymer of $Ti(OBu)_4$ having no additive, a new esr signal is observed upon illumination with visible light (2). The spectrum is similar to the hfs component in Fig. 9. In this case, therefore,

$$\text{Polymer}\cdot \rightarrow \text{Polymer}'\cdot$$

may represent the conformation change of the radical polymer. In "Polymer·" no hfs due to $-CH_2CH_3$ is observed but in "Polymer′·" hfs due to $-CH_2CH_3$ is observed. In the case of the polymer to which TMPD is added,

$$:\text{TMPD}\text{---}\text{Polymer}\cdot \rightarrow \cdot\text{TMPD}^{+}\text{---}\text{Polymer}:^{-}$$

seems to explain the change that has occurred. A transient polarization caused by light illumination gives $TMPD^{\cdot+}$. On the contrary, when TCNQ is added, no $TCNQ^{\cdot-}$ is observed. This can be explained by the relatively large electronegativity of the polymer. In the case of $Ti(OBu)_4$ polymer to which Mn^{2+} is added, a decrease in the intensity of the esr spectrum of Mn^{2+} is observed (2). In this case,

$$Mn^{2+}\text{---}\text{Polymer}\cdot \rightarrow Mn^{3+}\text{---}\text{Polymer}:^{-}$$

is taking place. This phenomenon can also be explained by the shift of electron from Mn^{2+} to the polymer part.

The results obtained in this work can be summarized as follows. If a small amount of TMPD is added to the solution of $Ti(OBu)_4$, a $Ti(OBu)_4$ polymer with which TMPD is combined is formed. On light illumination, a polarization-type light excitation occurs, giving $TMPD^{\cdot+}-\text{Polymer}^{-}$. If kept in darkness, this polarization reverts to the original unpolarized state. In the polymer to which TMPD is added, the positive charge trapped on the polymer side can be used as an information carrier or the energy carrier of the incident light to the polymer; the light-to-electron conversion efficiency is desired to be as high as possible. Such efficiency will be improved by the presence of $TMPD^{\cdot+}$ because less chance of recombination may be expected.

In the case of PD, no presence of $PD^{\cdot+}$ was observed from the reflectance spectra, Fig. 7. However, a light-excited esr spectrum was observed, as in Fig. 5. Though some structure in the esr spectrum is found, it is not similar to the hfs of $PD^{\cdot+}$ (14, 15) or to the simulated spectrum, Fig. 5C. As $PD^{\cdot+}$ is reactive, it will only be observed while it is generated in the sample system placed in the microwave cavity. The analysis of Fig. 5B is, therefore, not easy.

In the case of DMPD, the formation of $DMPD^{\cdot+}$ cannot be concluded from the reflectance spectra in Fig. 8. Light-excited esr is found, cf. Fig. 6. The hfs in Fig. 6B is due to the coupling with the $-CH_2CH_3$ group. Since there is no analysable information except $-CH_2CH_3$ coupling, it is not possible to prove the presence of $DMPD^{\cdot+}$. According to Yao *et al.* (16), who generated $DMPD^{\cdot+}$ by an electrolytic method, the esr of $DMPD^{\cdot+}$ has many hfs lines because there are six different hfs constants, which give 1701 lines if well resolved. If each line has a line width of 0.12 mT, the entire spectrum may look like a structureless smooth spectrum. The simulated spectrum, Fig. 6C, has fine structures that may become smoothed in an experimental spectrum. If one looks at the total width of the spectrum only, B and C of Fig. 6 may be regarded as "similar" spectra. For this reason, the formation of $DMPD^{\cdot+}$ may be postulated.

Laser-induced fluorescence study of the reactions of Ca with CH_3I and CF_3I in a molecular beam – gas apparatus[1]

GUO-ZHONG HE, JUE WANG, R. S. TSE,[2] AND NAN-QUAN LOU
Dalian Institute of Chemical Physics, Academia Sinica, Dalian, China

Received November 17, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

GHO-ZHONG HE, JUE WANG, R. S. TSE, and NAN-QUAN LOU. Can. J. Chem. **66**, 1936 (1988).

Energy partitioning of the CaI product from the Ca + CH_3I [1] and Ca + CF_3I [2] reactions was studied by laser-induced fluorescence. Product vibrational state distributions were obtained. It was also found that 19% and 16% of the exoergicity resides, respectively, in vibrational and rotational excitations of the CaI product from reaction [1], and 40% and 12%, respectively, from reaction [2]. The results are discussed in the context of various models, and product recoil momentum distributions have been estimated.

GHO-ZHONG HE, JUE WANG, R. S. TSE et NAN-QUAN LOU. Can. J. Chem. **66**, 1936 (1988).

Utilisant de la fluorescence induite au laser, on a étudié l'énergie de partition du produit CaI obtenu par les réactions Ca + CH_3I [1] et Ca + CF_3I [2]. On a obtenu les distributions des états vibrationnels des produits. On a aussi trouvé que 19% et 16% de l'«exoergicité» se retrouvent respectivement dans les excitations vibrationnelles et rotationnelles du produit CaI obtenu par la réaction [1] et 40% et 12% respectivement pour la réaction [2]. On discute des résultats dans le contexte de divers modèles et on a évalué les distributions de moments de recul des produits.

[Traduit par la revue]

Introduction

One of the major areas of interest in molecular dynamics is the study of the distribution of available energy to internal states of nascent reaction products by molecular beam techniques as well as by the laser-induced fluorescence (LIF) method.

In the past decade or so, the exoergic reactions of alkalis or alkaline earth metal atoms with iodides, CH_3I and CF_3I in particular, have received extensive interest since the first such experiments by Herschbach *et al.* (1). For example, Berstein *et al.* (2) paid special attention to the prototype "rebound" reaction K + $CH_3I \rightarrow$ KI + CH_3. For the corresponding K + $CF_3I \rightarrow$ KI + CF_3 reaction, the "dual mode" mechanism was first postulated by Brooks *et al.* (3). Subsequently Zare *et al.* (4, 5) reported the vibrational states analysis of unrelaxed BaI from the reaction Ba + CF_3I using the LIF method. In addition, Lin *et al.* (6) deduced BaI recoil energy distributions and angular distributions for the Ba + CH_3I, Ca + CH_3I, and Ba + CF_3I reactions using a molecular beam apparatus. In this paper we present a beam–gas experiment on the exothermic reactions:

[1] Ca + $CH_3I \rightarrow$ CaI + CH_3

[2] Ca + $CF_3I \rightarrow$ CaI + CF_3

for which the vibrational populations of the nascent product CaI were probed by means of LIF.

Experimental

The beam–gas apparatus employed is shown schematically in Fig. 1. A calcium beam effuses from an orifice (0.8 mm) on the top of a cylindrical crucible, is heated to 1050 K by thermal radiation from a sleeved graphite resistively heated tube, and passes through a slit (2.5 mm) into the scattering chamber which is filled with CH_3I (or CF_3I) at a pressure of (1–20) × 10^{-5} Torr. The pulsed laser beam from a Nd:YAG laser-pumped tunable dye laser (Quanta Ray DCR-1 and PDL) intersects the Ca beam perpendicularly in the center of the scattering chamber.

The dye laser wavelength was scanned to generate an excitation spectrum for the $A^2\Pi$–$X^2\Sigma^+$ band system of the CaI product. The linewidth of the dye laser beam was about 0.2 Å. The fluorescence was detected by a photomultiplier (R943). A PAR model 162/163 boxcar integrator was used to amplify and average the fluorescence signals. The output of the boxcar was fed to a stripchart recorder.

Results and discussions

A. Excitation spectra

The laser excitation spectrum of the CaI $A^2\Pi_{3/2}$–$X^2\Sigma^+$ band system in the region 6337–6395 Å was used to determine the internal state distribution of the reaction products. Figure 2 shows the variation of total fluorescence intensity with excitation wavelength for the CaI $\Delta V = 0$ sequence of the Ca + CH_3I and Ca + CF_3I reactions.

The CaI $A^2\Pi_{3/2}$–$X^2\Sigma^+$ transition belongs to the $^2\Pi(a)$–$^2\Sigma$ case. Neglecting the Λ-type doubling in the $^2\Pi$ state and the spin doubling in the $^2\Sigma$ state, one can obtain the formulas for the branches $P_2(J)$, $Q_2(J)$, $P_{21}(J)$, $R_2(J)$, $Q_{21}(J)$, and $R_{21}(J)$ (7).

In the CaI $A^2\Pi_{3/2}$–$X^2\Sigma^+$ band system, bands are formed in the Q_2 and P_{21} branches at almost the same frequency and value of J (7):

$$J_{\text{head}}^{Q_2+P_{21}} = \frac{(2B'' - B_{\text{eff}}^{(2)})}{2(B_{\text{eff}}^{(2)} - B'')}$$

Bands in the P_2 branch occur at

$$J_{\text{head}}^{P_2} = \frac{(B_{\text{eff}}^{(2)} + 2B'')}{2(B_{\text{eff}}^{(2)} - B'')}$$

The (0,0) band of the $A^2\Pi_{3/2}$–$X^2\Sigma^+$ transition occurs at $J_{\text{head}}^{Q_2+P_{21}} = 34$ and $J_{\text{head}}^{P_2} = 104$. Therefore, the presence of the P_2 branch implies that high rotational levels are appreciably populated.

For reaction [1], the CaI vibrational population peaks at $V = 2$. The presence of the P_2 heads of the (0,0), (1,1), (2,2), (3,3), and (4,4) bands indicates that substantial rotational excitation of the product CaI occurs.

[1]A preliminary report of this work was presented at the IXth International Symposium on Gas Kinetics, Bordeaux, 1986.

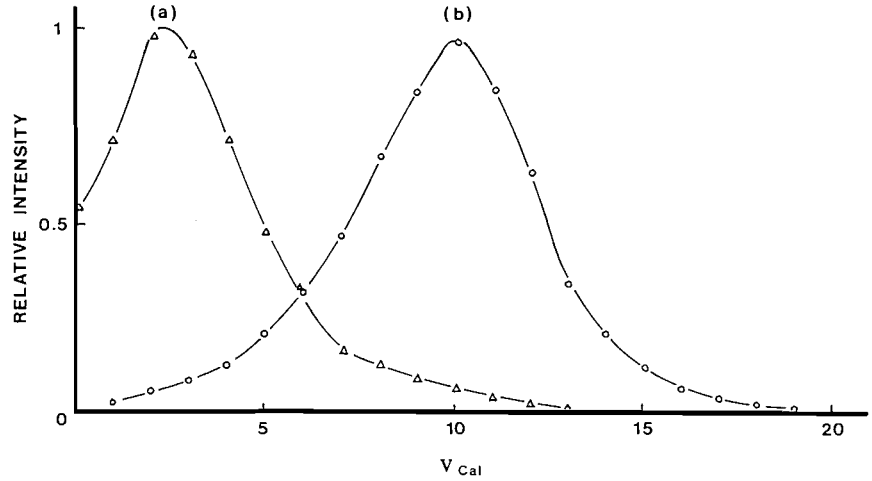

FIG. 3. Vibrational state distributions of CaI formed in the reactions (*a*) Ca + CH_3I and (*b*) Ca + CF_3I.

For reaction [2], no P_2 heads of the above bands are observed, but instead the P_2 heads of (8,8), (9,9), (10,10), (11,11) bands were present and the peak of CaI vibrational population is located at $V = 10$.

B. Computer simulation of the excitation spectrum

In order to make the quantitative estimations of the vibrational and rotational energy distributions from the excitation spectrum, computer simulation was carried out. A calculated excitation spectrum was constructed by assuming a population for the vibrational and rotational states and by convoluting it with the laser bandwidth function. The formula used for calculating the total fluorescence is as follows (8):

$$I(\nu_1) \propto \sum_{V'J'V''J''} \rho(\nu_1) N_{V''} \times P(J|V) \times Q_{V''V''} \frac{S_{J''J''}}{(2J'' + 1)}$$

where ν_1 is the transition frequency; $\rho(\nu_1)$ is the laser intensity; $Q_{V''V''}$ and $S_{J''J''}$ are the Franck–Condon (F–C) factor and the rotational line strength of the excitation transition, respectively; $N_{V''}$ is the vibrational population of the CaI ground state. The rotational population $P(J|V)$ is expressed as

$$P(J|V) = C_V \times P^0(J|V) \exp(-f_R \times \theta_R^V/(1 - f_V))$$

where C_V is a normalization factor, f_V, f_R are the fractions of total available energy going to diatomic product vibration and rotation, respectively, and θ_R^V is an adjustible parameter. The "prior" distribution $P^0(J|V)$ is given as (9):

$$P^0(J|V) = (2J + 1) \times (1 - f_V - f_R)$$

where we assume that the concomitant product CH_3 (or CF_3) is a nonlinear rotor in harmonic oscillations in six vibrational modes.

The laser intensity $\rho(\nu_1)$ is assumed to be proportional to $f_D(\nu_1)$, the Gaussian line profile, where (10)

$$f_D(\nu_1) = \frac{2 \ln \sqrt{2}}{\sqrt{\pi} \times \Delta\nu_D} \exp\left[-\left(\frac{2(\nu - \nu_0)}{\Delta\nu_D}\right)^2 \ln 2 \right]$$

and $\Delta\nu_D = 0.2$ Å, the laser linewidth.

The calculated vibrational population distributions $N_{V''}$ of the CaI ground state are plotted as a function of vibrational quantum number for reaction [1] and reaction [2] in Fig. 3.

Table 1 lists the spectroscopic constants used. Reisner *et al.* (11) determined these constants for CaI from spectra of the (0,0) and (1,1) bands. However, the vibrational levels observed in the experiments reported here are much higher. In order to have a satisfactory fit to the experimental data, some of the constants had to be modified a little for use in the simulation. Both the constants reported in ref. 11 and the constants actually used in the simulation are listed in Table 1. The F–C factors calculated from the R.K.R. method are listed in Table 2.

TABLE 1. Spectroscopic constants (in cm^{-1}) used in the simulation of CaI LIF excitation spectra

	A		*X* from ref. 11 and used in this work
State	From ref. 11	Used in this work

The total available energy, E_{tot} for CaI product excitation has been calculated as follows (R = CH_3 or CF_3):

$$E_{tot} = D_0^0(\text{Ca—I}) - D_0^0(\text{I—R}) + E_{int}(\text{RI}) + E_t(\text{reactants})$$

The translational energies of the reactants are evaluated according to

$$E_t = (3/2)\mu(kT_1/M_1 + kT_1/M_2)$$

where M and T are respectively the molecular weight and the thermal distribution temperature of the reagents, subscripts 1 and 2 denote respectively the Ca atom and the CH_3I (or CF_3I) molecule, μ is the reduced mass of the reagents, k is the Boltzmann constant. The internal energy of the reagents E_{int} equals $(3/2)RT$, neglecting the vibrational excitation of CH_3I (or CF_3I). The bond dissociation energies are $D_0^0(\text{Ca—I}) = 68$ kcal/mol, $D_0^0(\text{I—CH}_3) = 56$ kcal/mol, and $D_0^0(\text{I—CF}_3) = 53$ kcal/mol.

Using the above values, computer simulations of the observed LIF spectra reveal that the average values $\langle f_V \rangle$ and $\langle f_R \rangle$ are 19% and 16% for reaction [1], 40% and 12% for reaction [2],

respectively. The $\langle f_V \rangle$ values for the four reactions Ca(or Ba) + CH_3(or CF_3)I are compared in Table 3. $\langle f_V \rangle$ increases as the atomic mass of the alkaline earth metal atoms increases. $\langle f_V \rangle$ also increases as CH_3I changes to CF_3I.

C. Comparison between the reactions Ca + CH_3I and K + CH_3I

Originally, Herschbach (13) proposed a simple model — the impulsive photodissociation (IP) model — to describe the alkali atom + alkyl iodide reaction. He proposed that all particles had come essentially to rest before the electron jumped, whereupon repulsive energy of magnitude R was abruptly released between the iodine atom and the adjacent carbon atom. Now, we can use this model to describe the alkaline earth atom + CH_3I reaction and make a comparison between this reaction and the KI + CH_3I reaction.

Let M denote the metal atom. The product recoil momentum p_{MI}, recoil velocity u_{MI}, and relative translational energy E'_{tr} are determined from momentum conservation:

$$p_{MI} = m_{MI}u_{MI} = (2\mu_{I,CH_3}R)^{1/2} = (2\mu_{MI,CH_3}E'_{tr})^{1/2}$$

$$p'_{MI} = p_{MI}/h = 0.725(\mu_{MI,CH_3}E'_{tr})^{1/2}\ \text{Å}^{-1}$$

where R = EA(I) − D(I—CH_3) − EA(CH_3I), and μ_{I,CH_3} denotes the reduced mass of I and CH_3.

At the impulsive limit, $m_{MI}u_{MI}$ will not depend on the mass of M but only on the reduced mass of I and CH_3 and the repulsive energy. Using the data of the vibrational energy distribution of the product CaI of the Ca + CH_3I reaction

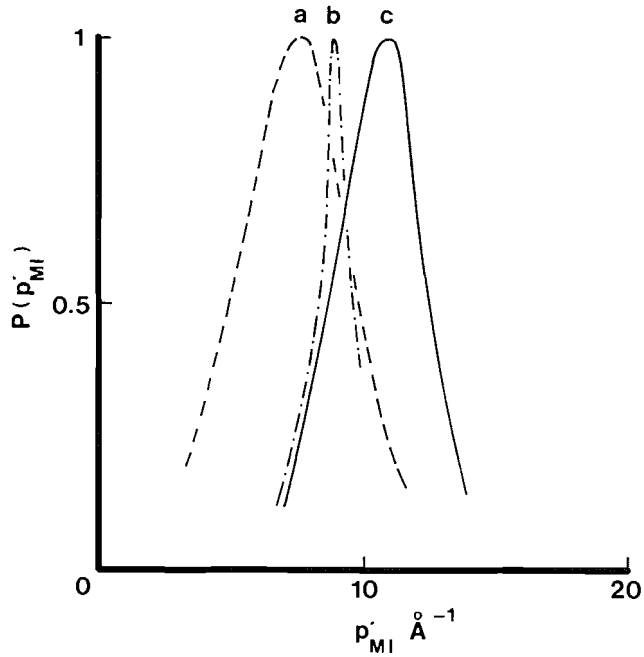

FIG. 4. Product recoil momentum distribution for the Ca (or K) + CH_3I reaction. (*a*) Ca + CH_3I (6), (*b*) Ca + CH_3I (this work), (*c*) K + CH_3I (13).

obtained here, and the following energy relationship

$$E'_{tr} = E_{tot} - E'_R(\text{CaI}) - E'_{int}(CH_3) - E_V'(\text{CaI})$$

where E'_R(CaI) = 1.6 kcal/mol, $E'_{int}(CH_3)$ = 0.9 kcal/mol, and E_{tot} = 15.4 kcal/mol, we can then obtain the distribution $P(p'_{MI})$ and find that the peak of $P(p'_{CaI})$ lies at about $p'_{CaI} = 8\ \text{Å}^{-1}$.

For comparison, we can use the E'_{tr} data from Lin *et al.* (6) to calculate $P(p'_{CaI})$ of the Ca + CH_3I reaction and take Hershbach's data of $P(p'_{KI})$ for the reaction K + CH_3I (13). It turns out that the peak of $P(p'_{CaI})$ lies (6) at 7.5 Å^{-1}, in good agreement with the present value but the peak of $P(p'_{KI})$ lies at about 11 Å^{-1}; note that the Ca and K masses are not very different. These values are shown in Fig. 4.

D. The Ba(or Ca) + CH_3I reactions

Herm's group reported (6) measurements of angular distributions of reactive scattering from crossed beam reactions between alkaline earth Ba or Ca atoms and CH_3I. Their results showed that the BaI(or CaI) + CH_3 products from Ba(or Ca) + CH_3I scattered predominantly backward in the center-of-mass system. The BaI product angular distribution was broader than that of CaI. Using Hershbach's IP model, we can obtain the peak positions of the $P(p'_{MI})$ values. These lie at 8.5 and 7.5 Å^{-1} for BaI and CaI, respectively. The relative atomic mass of the attacking alkaline earth atom in these reactions varies from 137 to 40, and the reactive exoergicity varies from 18.6 kcal/mol for Ba + CH_3I to 12 kcal/mol for Ca + CH_3I, yet the shape and position of product momentum distribution are hardly changed, as shown in Fig. 5.

E. The reactions Ca + CH_3I(or CF_3I) → CaI + CH_3(or CF_3)

In the Ca + CH_3I reaction, for example, the repulsive energy release is a normal result of the electron-jump process. This repulsion arises because the electron from the metal atom Ca enters a strongly antibonding orbital with a node between the carbon atom and the iodine ion which is ejected. We expect that

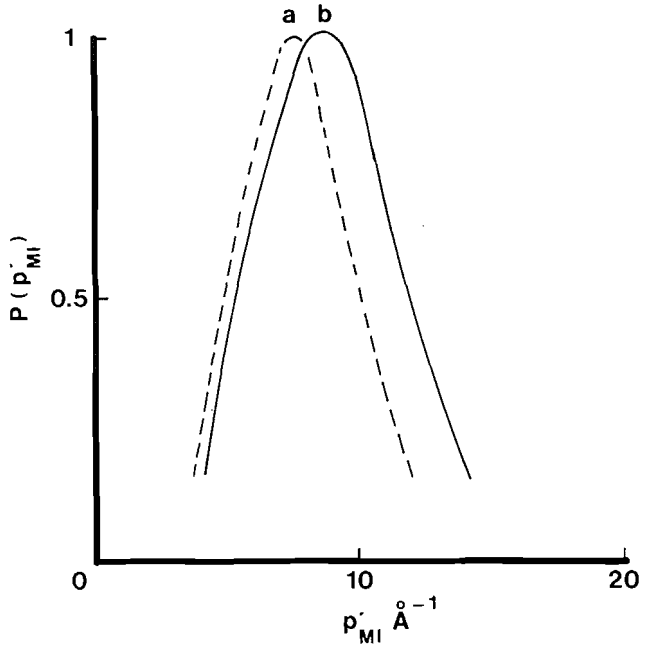

FIG. 5. Product recoil momentum distribution for the Ca (or Ba) + CH_3I reaction. (*a*) Ca + CH_3I (6), (*b*) Ba + CH_3I (6).

the repulsive energy of magnitude R is abruptly released between the iodine atom and the carbon atom. If we use the DIPR (direct interaction with product repulsion) model, postulated by Kuntz *et al.* (14), to describe the reactions studied here, the fractions of energy going into various CaI modes can be calculated for different values of R.

For simplicity, let A, B, C denote respectively the Ca atom, the iodine ion, and the alkyl group (or CF_3). Suppose a decaying force, $F(t)$, acts along the original direction of the B—C axis and decreases monotonically to zero. Then

$$F(t) = \pm ma \exp(-ct)$$

where m is the mass of CH_3 (or CF_3); a the acceleration of CH_3 (or CF_3) due to the force F at $t = 0$; and c is a constant which controls the rate of attenuation of the force on CH_3 (or CF_3). Then, the model can be made to take into account an attractive force between Ca and I atoms using an appropriate adjustment in the constant c. Table 4 shows the results of such calculation. The measured values are certainly within the range of calculated values.

F. Surprisal analysis

Dynamical properties for the present reactions may be deduced through a surprisal plot (9). The surprisal $I_n(V|E)$ is represented as $I(V|E) = \ln[P(V|E)/P_n^0(V|E)]$. Here $P(V|E)$ and $P_n^0(V|E)$ are the experimental probability and prior probability of producing CaI in the V vibrational state when the total available energy is E. One might get information concerning internal excitation of the CH_3 (or CF_3) radical employing four types of prior distribution. The product CH_3 (or CF_3) radical is assumed to be a structureless atom in model 1, a nonlinear rotor without vibrational excitation in model 2, a harmonic oscillator with six vibrational modes without rotation in model 3; and a nonlinear rotor in harmonic oscillation with six vibrational modes in model 4. The prior distribution

TABLE 4. Results of DIPR model calculations[a]

(*a*) For Ca + $CH_3I \rightarrow$ CaI + CH_3, $g/c = 10^{-6}$

R (eV)	$\langle f_V \rangle$	$\langle f_T \rangle$	$\langle f_R \rangle$
0.5	0.165	0.735	0.10
0.4	0.192	0.703	0.105
0.3	0.262	0.573	0.164

(*b*) For Ca + $CF_3I \rightarrow$ CaI + CF_3, $g/c = 8.3 \times 10^{-6}$

R (eV)	$\langle f_V \rangle$	$\langle f_T \rangle$	$\langle f_R \rangle$
0.5	0.273	0.624	0.102
0.4	0.356	0.524	0.119
0.3	0.459	0.419	0.122

[a] $g = a/c$ is the change in the x component of the velocity of CH_3 (or CF_3) due to the repulsive force $F(t)$ operating from $t = 0$ to $t = \infty$. $\langle f_T \rangle$ is the fraction of total available energy going to product relative translational energy. Please refer to discussion section E for definitions of a and c.

$P_n^0(V|E)$ for these four models are:

Model 1: $P_1^0(V|E) \propto (E - E_V)^{1.5}$

Model 2: $P_2^0(V|E) \propto (E - E_V)^3$

Model 3: $P_3^0(V|E) \propto (E - E_V)^{7.5}$

Model 4: $P_4^0(V|E) \propto (E - E_V)^9$

The surprisal plots of $I_n(V)$ vs. V ($n = 1, 2, 3, 4$) of these four models show that the I_3 and I_4 plots are almost linear functions of V, but the I_1 and I_2 plots are obviously nonlinear. This feature implies that the vibrational excitation of CH_3 (or CF_3) plays an important role in the dynamics.

G. Rotational excitation of the product CaI

We have obtained some information about the rotational excitation of the product CaI, as mentioned above. Now we can make a simple estimate of the fraction of exoergicity going into product rotational excitation by considering angular momentum conservation when the Ca atom approaches the I atom end of the ICH_3 molecule. For the reaction Ca + $CH_3I \rightarrow$ CaI + CH_3, the reduced masses of pre- and post-collision of this reaction system are $\mu = 31.2$ and $\mu = 13.8$, respectively. A crude estimate of the upper limit of the rotational energy of the product CaI can be made by supposing that this reaction belongs to the H + HL → HH + L mass combination, where H denotes the heavy atom and L denotes the light atom. Then, the reactants' orbital angular momentum L is equal to the product angular momentum, and $L = J$, where $L = \mu_{Ca,CH_3I} V_{rel} I_b$ ($= 15 \times 10^{-26}$ g cm^2/s). The rotational inertia of CaI, I_b, is about 4×10^{-38} g cm^2. The rotational energy

$$E_R' = J'^2/(2I_b) = L^2/(2I_b)$$

works out to be 0.17 eV, which is about 22% of the total available energy, in rough agreement with the measured values.

High-resolution solid-state NMR investigation of the nature of the interaction between organic substrates and the zeolite ZSM-5 lattice

C. A. FYFE,[1] H. STROBL, H. GIES, AND G. T. KOKOTAILO

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received March 11, 1988

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

C. A. FYFE, H. STROBL, H. GIES, and G. T. KOKOTAILO. Can. J. Chem. **66**, 1942 (1988).

The compounds *p*-xylene, *p*-chlorotoluene, and *p*-dichlorobenzene induce essentially identical changes in the ^{29}Si MAS NMR spectrum of zeolite ZSM-5, indicating that the major contribution to the induced phase change of the lattice structure in these cases is the size and shape of the sorbed organic molecules. Based on these results, *p*-dichlorobenzene may be used as a model system in future diffraction studies of the sorbate/lattice structure greatly facilitating these investigations.

C. A. FYFE, H. STROBL, H. GIES, et G. T. KOKOTAILO. Can. J. Chem. **66**, 1942 (1988).

Les changements induits par le *p*-xylène, le *p*-chlorotoluène et le *p*-dichlorobenzène dans les spectres rmn MAS du ^{29}Si du zéolite ZSM-5 sont essentiellement les mêmes; ces résultats indiquent que, dans ces cas, la contribution majeure au changement de phase induit dans la structure de réseau provient de la grosseur et de la forme des molécules organiques qui sont adsorbées. Sur la base de ces résultats, le *p*-dichlorobenzène peut être utilisé comme système modèle dans de futures études de diffraction de la structure du sorbate/réseau; cette possibilité facilitera beaucoup ces études.

Introduction

Zeolites are porous aluminosilicates widely used in industrial applications as catalysts, ion exchange resins, and molecular sieves (1, 2). Formally, they can be represented as being derived from silica (SiO_2) by the replacement of SiO_4^{4-} tetrahedra by AlO_4^{5-} tetrahedra and described by the general oxide formula [1].

[1] $M_X(AlO_2)_X(SiO_2)_Y \cdot nH_2O$

Because of the difference in atomic charge between Al and Si, extra-lattice cations (M) must be present to preserve electrical neutrality, a single positive charge being needed for each (AlO_2) unit present. In general, these cations may be ion exchanged and in addition, water of hydration is usually present inside the lattice structure.

The size and shape selectivities of zeolites come from their unique framework structures, in general formed from open arrangements of the AlO_4^{5-} and SiO_4^{4-} tetrahedra linked through common oxygen atoms (the Al and Si atoms are often referred to as T atoms), giving lattice structures often containing both channels and cavities or cages which give a selectivity in the sorption of different organic molecules.

Although many of the lattice structures of zeolites have a high degree of symmetry, there are severe problems in their determination by diffraction techniques, even in the absence of organic sorbates. Thus, although they are highly crystalline materials, they are usually microcrystalline with particle dimensions of the order of microns, often precluding the use of single-crystal X-ray diffraction techniques and less informative powder diffraction data must be used.[2] Further complicating the situation is the fact that Si and Al are adjacent in the periodic table and have almost identical X-ray scattering factors, making it difficult to distinguish them, particularly if their distribution throughout the lattice is not ordered as is most often the case.

In recent years, high-resolution solid-state NMR has developed as a complementary technique to diffraction studies for the investigation of zeolite lattice structures (4). In low Si/Al ratio materials, ^{29}Si MAS NMR spectra are obtained which reflect the local environments around the silicon nuclei, yield the relative proportions of the five possible local orderings Si[4Al], Si[3Al,Si], Si[2Al,2Si], Si[Al,3Si], and Si[4Si] which are present and hence the distribution, on average, of silicon and aluminum throughout the lattice structure (4, 5).

In completely siliceous systems, only the Si[4Si] local environment is present and the spectra now exhibit very sharp resonances whose numbers and relative intensities reflect directly the numbers and relative intensities of the crystallographically inequivalent sites in the unit cell (6). These spectra are very sensitive probes of the degree and nature of the local ordering present and complement the diffraction-derived information on the long range periodicity of the lattice. They have been used to probe the uniqueness of zeolite structures, the effect of distortions from ideal symmetry, and the effects of temperature and sorbed organic molecules. In general, they are more sensitive to small changes in structure than the diffraction data which reflects the long range periodicity of the lattice although the latter technique must ultimately be used for direct structure determination. Particular attention has been paid to the changes in lattice structure induced by the presence of organic molecules and/or elevated temperatures for zeolite ZSM-5 (7).

ZSM-5, Fig. 1*B*, is the best known of a whole family of lattice structures based on the pentasil unit (Fig. 1*A*), and has unique and highly selective sorptive and catalytic properties (8). By preparing a very highly crystalline (as judged by NMR and XRD data), very highly siliceous sample of ZSM-5 and careful optimization of the experimental parameters of the MAS NMR experiment we have recently obtained ultra-high resolution ^{29}Si MAS NMR spectra in which 21 or 22 of the 24 lattice sites in the monoclinic room temperature form can be resolved, unambiguously confirming the proposed structure (9). Using this material we have recently confirmed and quantified earlier observations that elevated temperatures and sorbed organic molecules or combinations of these induce a change in the lattice structure

[1]Author to whom correspondence should be addressed.

[2]Recent work using a synchrotron X-ray source may make it possible to work with much smaller crystals although no published structures are available to date (3).

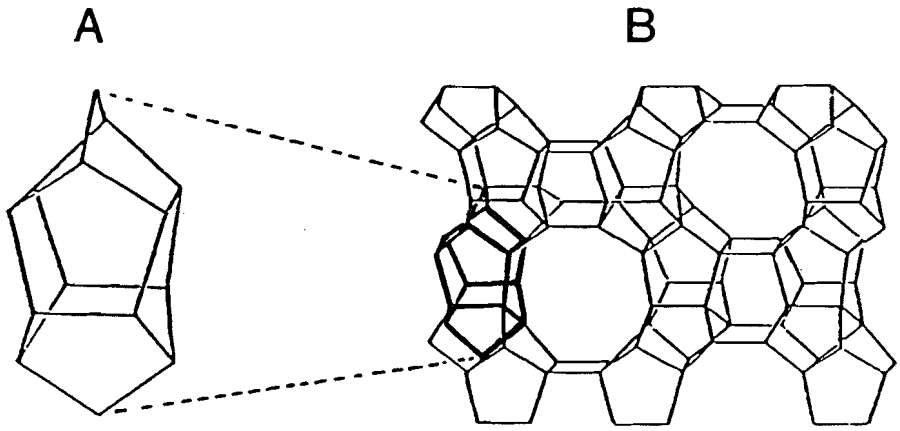

FIG. 1. (*A*) The pentasil building unit; (*B*) lattice structure of zeolite ZSM-5 (after ref. 8).

from monoclinic to a higher symmetry orthorhombic form. In the cases of *p*-xylene and acetylacetone, complete phase diagrams could be obtained by the NMR technique (10).

In the present work, we further investigate these changes for a series of carefully selected organic sorbates in an attempt to determine the nature of the sorbate/lattice interactions which induce the change in structure. In addition, it was hoped that the work would provide an optimal model system for both single-crystal and powder synchroton X-ray diffraction studies of the sorbate/lattice combination which would subsequently yield the geometric relationship for the guest molecule and host lattice directly, of considerable interest for the catalytic and sieving properties of this system. The present paper provides the justification for these investigations.

Experimental

High resolution ^{29}Si solid state MAS NMR spectra were obtained at 79.6 MHz using Bruker WH400 and MSL400 spectrometers with a home-built MAS NMR probe. Samples of *ca.* 400 μL volume were spun at 3.5 kHz in 9 mm o.d. cylindrical Torlon spinners in a modified version of the stator design of Wind. Temperatures are considered accurate to within ±2°C. There was no improvement in resolution when proton decoupling was used and all the spectra presented were recorded without decoupling. Powder XRD patterns were obtained using a Phillips powder X-ray diffractometer. The sample of XSM-5 was synthesized by conventional hydrothermal techniques and dealuminated as previously described (6).

Results and discussion

Figure 2 shows the effect of several different sorbed organic molecules on the ^{29}Si MAS NMR spectrum of zeolite ZSM-5. The spectrum of ZSM-5 with no sorbed organic (Fig. 2*A*) exhibits extremely high resolution ($\Delta V_{1/2} < 0{\cdot}1$ ppm) indicating that the sample is both very highly siliceous and very highly ordered. The spectrum can be deconvoluted in terms of 24 resonances of equal intensity, of which 22 are clearly resolved, confirming in general the proposed monoclinic symmetry with 24 T sites in the unit cell. In general, this high resolution is maintained in the presence of sorbed organic molecules, indicating that the highly crystalline nature of the sample is preserved. The spectra reflect a discrete change to new structures where 12 T sites are observed in the case of *p*-xylene characteristic of orthorhombic symmetry but where 24 T sites are still present for other sorbates (acetylacetone, pyridine). At elevated temperatures, 12 T sites are observed for all of the sorbates, indicating

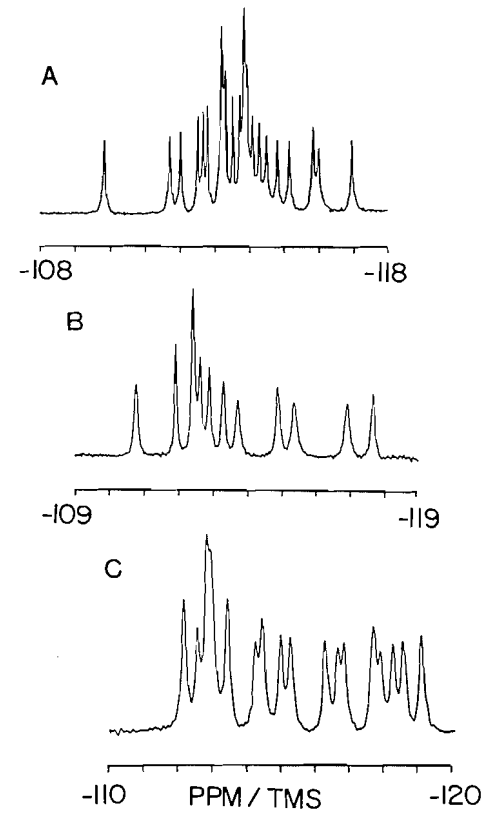

FIG. 2. ^{29}Si MAS NMR spectra obtained at 79.6 MHz of highly siliceous ZSM-5; (*A*) without sorbed organic; (*B*) with 10 μL p-xylene/250 mg zeolite; (*C*) with 35 μL pyridine/250 mg zeolite.

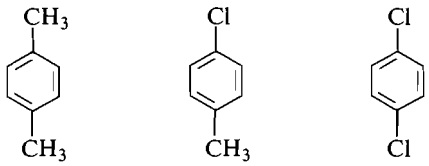
orthorhombic symmetry at least on the NMR timescale which, in this case, since it would involve averaging of chemical shifts would be at kHz frequencies. That the spectra reflect changes in the lattice is confirmed by powder X-ray diffraction measurements which detect changes in the lattice dimensions and, in some cases, changes in the lattice symmetry. The changes in the ^{29}Si MAS NMR spectra are quite reproducible and reversible on removal of the sorbate. More importantly, as can be seen from Fig. 2, they reflect in a unique way the *nature* of the organic molecule present, different sorbates giving quite different and characteristic spectra. ^{29}Si MAS NMR shifts are known to be affected by the local geometry of the Si atom, but it is also

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

possible that there are effects due to specific electronic interactions, dipolar interactions, or changes in local dielectric. The sieving properties of zeolites are most often discussed in terms of the size and shape of the organic molecules but this may not be directly reflected in the ^{29}Si MAS NMR spectra.

We have attempted to check this by investigating a series of organic sorbates of identical shape and size but differing in other chemical and physical properties. Thus, there is considerable evidence from physical organic chemistry that methyl groups and chlorine atoms have identical steric effects and this substitution can be used to eliminate this factor while probing other (mainly electronic) effects in reaction processes. In the present work, we have used this substitution to generate a series of organic sorbates of identical size and shape but differing in other properties to see if they produced the same changes in the ^{29}Si MAS NMR spectra. The molecules chosen for study were *p*-xylene **1**, *p*-chlorotoluene **2**, and *p*-dichlorobenzene **3**.

Figure 3 shows the limiting spectra obtained from the three sorbates, which in all three cases was reached at a loading of approximately 10 μL per 250 mg of zeolite. The similarity between all the spectra is remarkable, clearly indicating that the size/shape characteristics of the organic molecule are the main factors involved in the sorbate/lattice interactions. The fact that **2**, which has a net dipole, yields an identical spectrum to **1** and **3** which do not, indicates that this property is not an important factor in the interaction for these systems. In addition, all three spectra are characteristic of the orthorhombic form perhaps suggesting that the spectra reflect the lattice symmetry rather than that of the aggregate of the lattice plus the sorbed organics as **2** has lower molecular symmetry than the others.



1 **2** **3**

The similarities are even more striking when the detailed behaviour of the systems in terms of concentration and temperature is investigated. Figure 4 shows the complete three-dimensional phase diagrams for both *p*-xylene and *p*-dichlorobenzene where the "in-plane" axes are changes in temperature and concentration while the vertical axis indicates the percentage of orthorhombic form present for a given combination of temperature and sorbate concentration. Thus the curve from left to right at the front of the diagrams shows the effect of adding increasing amounts of organic sorbate at ambient temperature (293 K) which is to induce a smooth change from monoclinic to orthorhombic symmetry. At intermediate concentrations both forms are present and the sharpness of all of the resonances indicates that crystallinity is maintained throughout the whole sample at all times. The other curves indicated from left to right delineate this transition at different temperatures. The second set of curves, from front to back of the diagram, describe the transition as a function of temperature at a fixed concentration of organic sorbate. The behaviour in both cases is identical in all important aspects, confirming the nature of the interaction as being primarily based on the size and shape of the organic molecule and presumably involving mainly Van der Waals interactions. It should be noted that the above molecules contain no strong donor base sites such as the aza-nitrogen in pyridine or the hydroxyl group in phenol and can not be used to

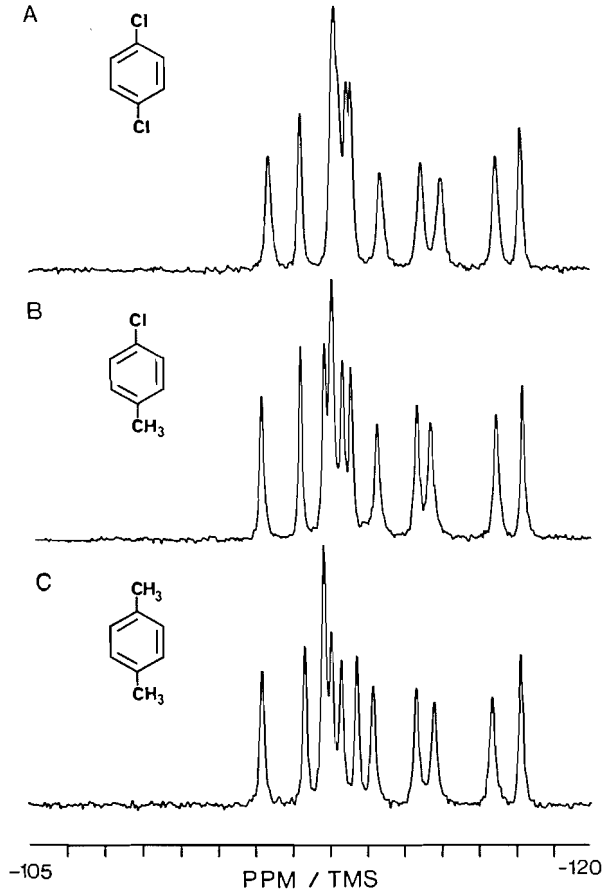


FIG. 3. ^{29}Si MAS NMR spectra obtained at 79.6 MHz of highly siliceous ZSM-5 with (*A*) *p*-xylene (10 μL/250 mg zeolite); (*B*) *p*-chlorotoluene (10 μL/250 mg zeolite); (*C*) *p*-dichlorobenzene (10 mg/250 mg zeolite).

evaluate the possible involvement of such functionalities in specific bonding interactions. However, the above conclusions should apply to all hydrocarbon systems, the most common sorbates in the use of zeolites as catalysts.

These NMR results are confirmed by the powder X-ray diffraction patterns of the systems. Diffraction occurs at exactly the same 2θ values in both cases, indicating that the lattice dimensions are identical, but there are large differences in the intensities of the reflections due to contributions from the different (more or less ordered) organic sorbates. It should be noted that the existence of these intensity differences implies a degree of ordering of the sorbates, as disordered guests would only contribute to the diffuse scattering. Although the powder X-ray data are less sensitive to the details of the interactions, they must ultimately be used to provide the structural arrangement between the guest molecules and the host lattice. In this regard, the case of *p*-dichlorobenzene **3** is particularly important. Using the NMR data to provide the justification that *p*-dichlorobenzene is a good model system for the case of *p*-xylene **1**, structural refinements may be carried out on the former system. Because of the large number of electrons present in the chlorine atoms, these will make a major contribution to the diffraction and will be much easier to locate within the lattice. We are currently engaged in a refinement of this structure using synchrotron-based powder x-ray diffraction data and feel that the resulting locations of the organic molecules will reflect those of *p*-xylene

and provide a starting point for refinement of existing synchrotron data on this system (10).

Further substitutions of this type in these systems may be contemplated, for example, α,ω-dichloro and other hydrocarbons for the corresponding aliphatics, chlorobenzene for toluene etc. In all cases, structural refinements should be greatly facilitated by the increased contribution to the diffraction data by the chlorine atoms. Such studies are currently in progress.

In nonrigid molecules and molecular aggregates, the dependence of a property on conformation may be expressed in the form of a limited expansion in terms of appropriate harmonics. The use of the conjugate symmetry of the molecular groups to reduce such an expansion may have several advantages: (*i*) it helps decrease, sometimes drastically, the time required to calculate the conformational dependence of the considered property; (*ii*) it provides a parameterized functional form that can be used by experimentalists to rationalize their results. The symmetry rules that define the distinct non-zero harmonics are determined by a set of indices that depend on both the form and type of the property (scalar, polar, axial, tensorial; aggregate, mononuclear, binuclear) and the nature of the isodynamic operations characterizing the system. We have applied Altmann's isodynamic groups to the analysis of Wigner's harmonic expansions of dynamical, electric, and magnetic properties of various molecular structures: binary molecular associations, quasi-atoms in molecular fields, rigid molecules in crystal lattices, and non-rigid molecules involving one to three rotors. A few examples are given to illustrate these considerations.

JEAN MARUANI et ALEJANDRO TORO-LABBÉ. Can. J. Chem. **66**, 1948 (1988).

Dans les molécules non-rigides et les agrégats moléculaires, la dépendance d'une propriété à l'égard de la conformation peut s'exprimer sous la forme d'un développement limité en fonction d'harmoniques appropriées. L'utilisation de la symétrie conjuguée des groupes moléculaires pour réduire un tel développement peut avoir plusieurs avantages : (*i*) aider à diminuer, parfois considérablement, le temps nécessaire au calcul de la dépendance conformationnelle de la propriété considérée; (*ii*) fournir une forme fonctionnelle paramétrisée utilisable par les expérimentateurs pour rationaliser leurs résultats. Les règles de symétrie qui définissent les harmoniques non-nulles distinctes sont déterminées par un jeu d'indices qui dépendent à la fois de la forme et du type de la propriété (scalaire, polaire, axiale, tensorielle; globale, mononucléaire, binucléaire) et de la nature des opérations isodynamiques qui caractérisent le système. Nous avons appliqué les groupes isodynamiques d'Altmann à l'analyse des développements harmoniques de Wigner de propriétés dynamiques, électriques et magnétiques de diverses structures moléculaires : associations moléculaires binaires, quasi-atomes dans des champs moléculaires, molécules rigides dans des réseaux cristallins, et molécules non-rigides comportant de un à trois rotateurs. Quelques exemples sont fournis pour illustrer ces considérations.

1. Introduction

In the study of the structure and dynamics of molecular systems such as nonrigid molecules, molecular aggregates, or molecules embedded in crystals, one must often consider the conformational dependence of physical properties of the whole system. These properties can be classified in different ways. On the one hand, they may be scalar (i.e., invariant under all overall rotations), or polar (i.e., transforming as the translation vector X, Y, Z), or axial (i.e., transforming as the rotation vector R_x, R_y, R_z), or, more generally, tensorial (e.g., representable by a second-rank tensor). On the other hand, the properties may be of an aggregate type (i.e., characterizing the molecular system as a whole), or of a mononuclear type (i.e., defining the interaction of a particular nucleus with the electronic distribution), or of a binuclear type (i.e., defining the interaction between two particular nuclei through the electronic distribution).

The basic example of a scalar aggregate property is the total energy, E, a small part of which, V, usually depends on the conformation of the system (ref. 1). Examples of vectorial aggregate properties are intermolecular forces $\boldsymbol{F}$ and torques $\boldsymbol{G}$ (refs. 2), electric dipole moments $\boldsymbol{\mu}$, and chiral properties $\boldsymbol{\gamma}$. Examples of tensorial aggregate properties are the electric quadrupole moment $\boldsymbol{\theta}$, electric polarizability tensor $\boldsymbol{\alpha}$, spectroscopic splitting tensor $\mathbf{g}$ (if the system possesses a total electronic spin $S \geq \frac{1}{2}$) and spin–spin coupling tensor $\mathbf{D}$ (if $S \geq 1$). Examples of tensorial mononuclear properties are chemical shifts $\boldsymbol{\sigma}_i$ (for nuclei with effective spins $I_i \geq \frac{1}{2}$), quadrupole couplings $\mathbf{Q}_i$ (for nuclei with $I_i \geq 1$), and hyperfine couplings $\mathbf{c}_i$ (when both S and $I_i \geq \frac{1}{2}$). Magnetic internuclear interactions $\mathbf{J}_{ij}$ (when both I_i and $I_j \geq \frac{1}{2}$) illustrate tensorial binuclear properties. The theoretical interpretation of these properties can be found in, for example, refs. 3–5. Scalar (aggregate, mononuclear, or binuclear) properties are obtained when taking the traces of non-traceless tensors: e.g., α, g, σ_i, c_i, J_{ij}.

In the Born–Oppenheimer approximation, one defines conformational variables as internal coordinates relating the equilibrium positions of nuclei of the system. For a diatomic (such as HF) there is only one stretching variable, the interatomic distance (or bond length) ρ. For a triatomic (such as H_2O) there is, in addition to the two stretching variables, ρ_1 and ρ_2, a bending variable, the planar bond angle ψ (which equals π for a linear triatomic). For a tetratomic there may be, in addition to the three stretching variables, either (as in NH_3) three bending variables, or (as in H_2O_2) two bending and one twisting variable, the dihedral torsion angle α (which equals 0 for a planar tetratomic). In general, for an N-atomic system, there are $3N - 6$ conformational variables, including $n \leq N - 3$ torsion angles. Nonrigidity is defined as a set of features resulting from the

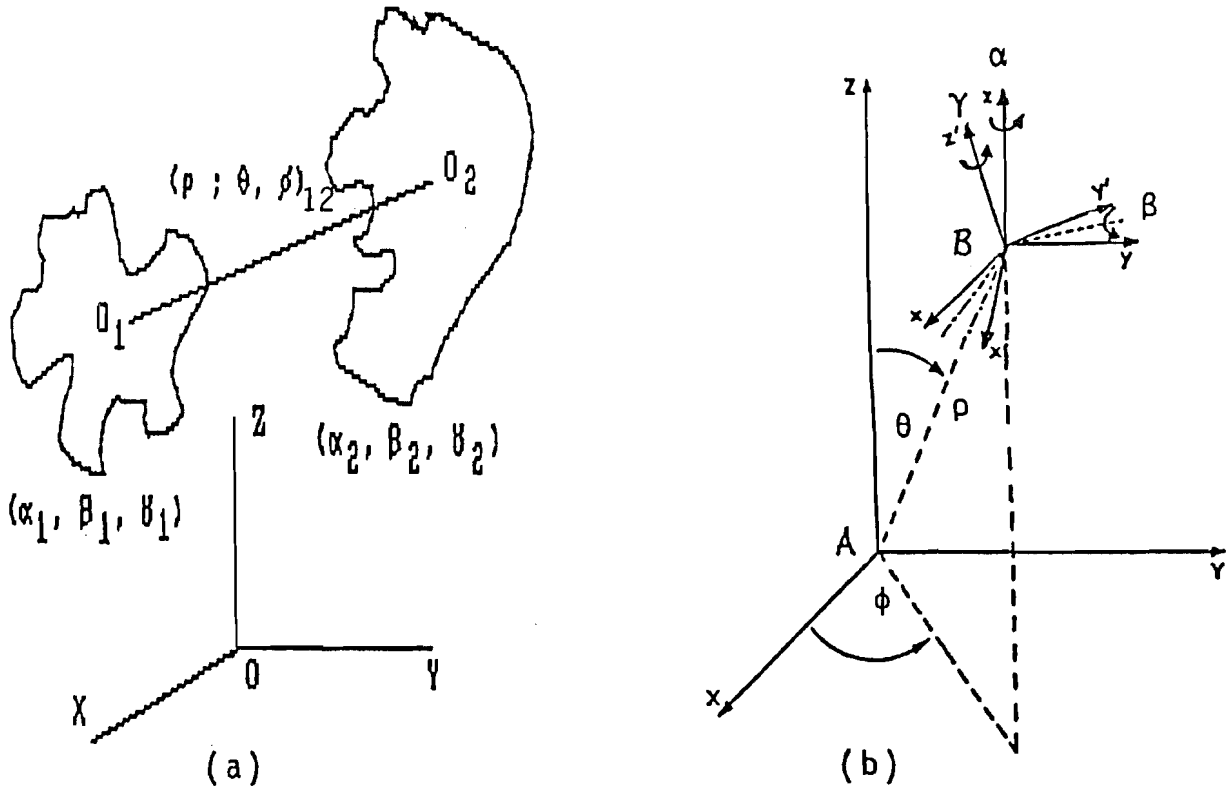

FIG. 1. (a) Two cluster components O_1 and O_2 referred to the cluster frame $OXYZ$: $\boldsymbol{R}_{12} \equiv (\rho; \theta, \phi)_{12}$ and $\boldsymbol{\Omega}_i \equiv (\alpha_i, \beta_i, \gamma_i)$. (b) A molecular pair A: B with the frame of B referred to that of A.

existence of several equilibrium conformations with different values for the conformational variables, and separated by significant but surmountable potential-energy barriers (refs. 6–10); the extent to which a barrier is significant or surmountable is determined by the time scale of the experimental procedure.

For nonrigid molecules, a switch from one stable conformation to the other may be defined by a change of a stretching variable, as in the double-well hydrogen-bonded complex H_2O:HF (ref. 11), or of a bending variable, as in the inversion of the ammonia molecule, or of a twisting variable, as in the internal rotation of ethane, or of several such variables, as in the internal motions of the pyramidal double-rotor dimethylamine. For molecular aggregates made up of rigid components (O_1, O_2, etc.), one may define a change of overall conformation by a change of the positions ($\boldsymbol{R}_{12}$, etc.) and orientations ($\boldsymbol{\Omega}_1$, $\boldsymbol{\Omega}_2$, etc.) of the constitutive parts relative to a reference frame $OXYZ$ (Fig. 1a, refs. 2). For a molecular pair A:B, one may use as conformational variables the relative position vector $\boldsymbol{R} \equiv (\rho; \theta, \phi)$ and relative orientation angles $\boldsymbol{\Omega} - (\alpha, \beta, \gamma)$ (Fig. 1b). If one of the molecules is much smaller than and not too close to the other, it may be treated as a quasi-atom in a molecular field, and the conformational variables reduce to $\boldsymbol{R}$. On the other hand, if a rigid molecule is embedded at the center of a lattice site (Fig. 2a), its interaction with the lattice depends only upon its orientational variables $\boldsymbol{\Omega}$ (Fig. 2b).

The dependence of a property on the conformational variables may belong to a variety of types. In favourable cases, a general procedure to obtain quasi-analytic forms is to use limited series expansions. For example, small variations of stretching variables can be accounted for by using Taylor series expansions, thus providing the well-known harmonic and anharmonic vibrational potentials around equilibrium positions. On the other hand, large variations of angular variables can be accounted for by using harmonic series expansions. For example, any property of a molecular pair can be written, in the frame defined in Fig. 1b (refs. 12):

$$[1] \quad A(\boldsymbol{R}, \boldsymbol{\Omega}) = \sum_{L,M} \sum_{l,m,m'} A_{Ll}^{Mmm'}(\rho) Y_L^M(\theta, \phi) D_l^{mm'}(\alpha, \beta, \gamma)$$

where Y_L^M and $D_1^{mm'}$ are the usual and generalized (Wigner rotation matrices) spherical harmonics (ref. 13).

The simplified case of a quasi-atom in a molecular field is quite similar to that of an ion in a crystal field (ref. 14), and requires the reduced expansion:

$$[2] \quad A(\boldsymbol{R}) = \sum_{L,M} A_L^M(\rho) Y_L^M(\theta, \phi)$$

In the particular case of a rigid molecule embedded at the center of a crystal site (refs. 15), the expansion [1] reduces to

$$[3] \quad A(\boldsymbol{\Omega}) = \sum_{l,m,m'} A_l^{mm'} D_l^{mm'}(\alpha, \beta, \gamma)$$

In the still simpler case of a system consisting of a rotating top bonded to a reference frame, one can replace the Wigner harmonics by Fourier harmonics (refs. 16):

$$[4] \quad A(\alpha) = \sum_{m=-\infty}^{+\infty} A_m \exp(-im\alpha) = \sum_{m=0}^{\infty} (A_m^{\,c} \cos m\alpha + A_m^{\,s} \sin m\alpha)$$

For an n-rotor molecule, this expansion can be generalized as follows (refs. 17):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

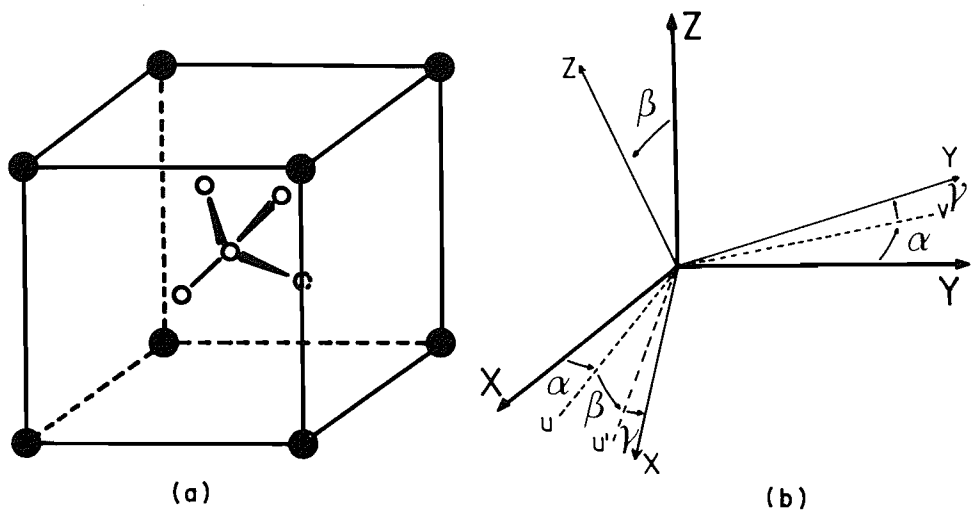

FIG. 2. (a) A rigid molecule embedded in a lattice site. (b) The Euler angles α, β, γ defining the relative orientation of the molecule axes *Oxyz* with respect to the site axes *OXYZ*.

$$[5]\quad A(\alpha_1,\ldots,\alpha_n) = \sum_{m_1,\ldots,m_n=-\infty}^{+\infty} A_{m_1\ldots m_n} \exp -i(m_1\alpha_1 + \ldots + m_n\alpha_n)$$

When a relative reorientation of the molecular groups constituting a system can be performed without bringing about important changes in the nuclear configuration and electronic distribution of the system elements, the dependence of most properties on the angular variables can be described with the first few significant terms of the harmonic expansion. Symmetry considerations can yield further reductions in the number of necessary harmonics: the selection rules that define the independent nonzero coefficients are determined by a set of symmetry indices, which depend on both the form of the property and the nature of the isodynamic operations characterizing the system.

The use of the conjugate symmetry of a molecular system to reduce the harmonic expansions of its physical properties affords a double advantage: (*i*) it helps reduce, sometimes drastically, the time required to compute the conformational dependence of the investigated property; (*ii*) it provides a parameterized functional form that can be used by experimentalists to rationalize their results. If the property is the energy, the hypersurface minima can be more easily derived and the stable conformations thus obtained. If the property is some spectroscopic parameter depending on the conformational variables, comparison of measured values with computed dependences can lead to these variables.

In this paper we review some applications of these considerations that we made to molecular pairs (ref. 12*b*), molecules in crystals (ref. 15*c*), and double-rotor molecules (refs. 17), using the formalism of isodynamic groups with illustrative quantum calculations.

2. Molecular pairs

The study of molecular interactions is usually a difficult task, because of the number of independent variables to be considered. The investigation of interaction potential-energy hypersurfaces is usually confined to a few variables, selected using physical intuition. A large amount of theoretical work has been devoted to hydrogen-bond complexes and proton-transfer systems, assuming a few symmetric conformations of the molecular pair. Using the formalism outlined above, we have considered a more extended set of conformations for the complex H_2O:HF and derived the lowest five dimensional minima defining the most stable conformations.

The harmonic expansion for a molecular pair is given by eq. [1], where the considered property, the interaction potential V, being real implies particular relations between the complex coefficients $V_{Ll}^{Mmm'}$. With an appropriate choice of the coordinate system, M is even and m is zero, because H_2O and HF possess C_2 and C_∞ symmetry axes, respectively. Equation [1] then becomes:

$$[6]\quad V(\boldsymbol{R},\boldsymbol{\Omega}) = \sum_{L,M}\sum_{l,m'} V_{Ll}^{Mm'}(\rho) Y_L^M(\theta,\phi) Y_l^{m'}(\beta,\gamma)$$

where the expansion coefficients satisfy the additional relations: $V_{Ll}^{Mm'} = V_{Ll}^{-Mm'} = (-1)^{m'} V_{Ll}^{M-m'}$, because both H_2O and HF possess σ_v symmetry planes.

One can obtain various cross-sections of this hypersurface by freezing some of the variables. For instance, if the motion of HF is confined to the plane bisecting H_2O, the above expansion reduces to the double Fourier series ($\phi = \gamma = 0$):

$$[7]\quad V(\rho,\theta,\beta) = \sum_{j,k} [V_{jk}^{cc}(\rho)\cos j\theta \cos k\beta + V_{jk}^{ss}(\rho)\sin j\theta \sin k\beta]$$

where the coefficients V_{jk}^{cs} and V_{jk}^{sc} are annihilated due to the double-switch isodynamic operation **V** (ref. 17*a*) illustrated in Fig. 3a: $\mathbf{V}\, V(\rho,\theta,\phi) \equiv V(\rho,-\theta,-\beta) = V(\rho,\theta,\beta)$. Figure 3*b* displays two energy contributions to this hypersurface cross-section, calculated with the optimized distance $\tilde{\rho} = 2.17$ Å.

Additional semiempirical and *ab initio* calculations have shown indeed (ref. 12*b*) that both azimuthal angles ϕ and γ are actually 0, though the dependence of V upon γ is very small. The calculations have also shown that around the stable conformations of the complex, which can be seen in Fig. 3b (left), the dispersion energy (Fig. 3b (right)) and the basis-set superposition error of the *ab initio* calculation (ref. 12*b*) nearly compensate each other. The minima of the surface $V(\tilde{\rho},\theta,\beta)$ (Fig. 3b) appear rather flat, so that the equilibrium values of the conformational angles, listed in Table 1, should be considered as defining the average conformation of a quite floppy supermolecule, quasi-free to distort within a few tens of degrees. This may give particular significance to the smaller values of θ and β

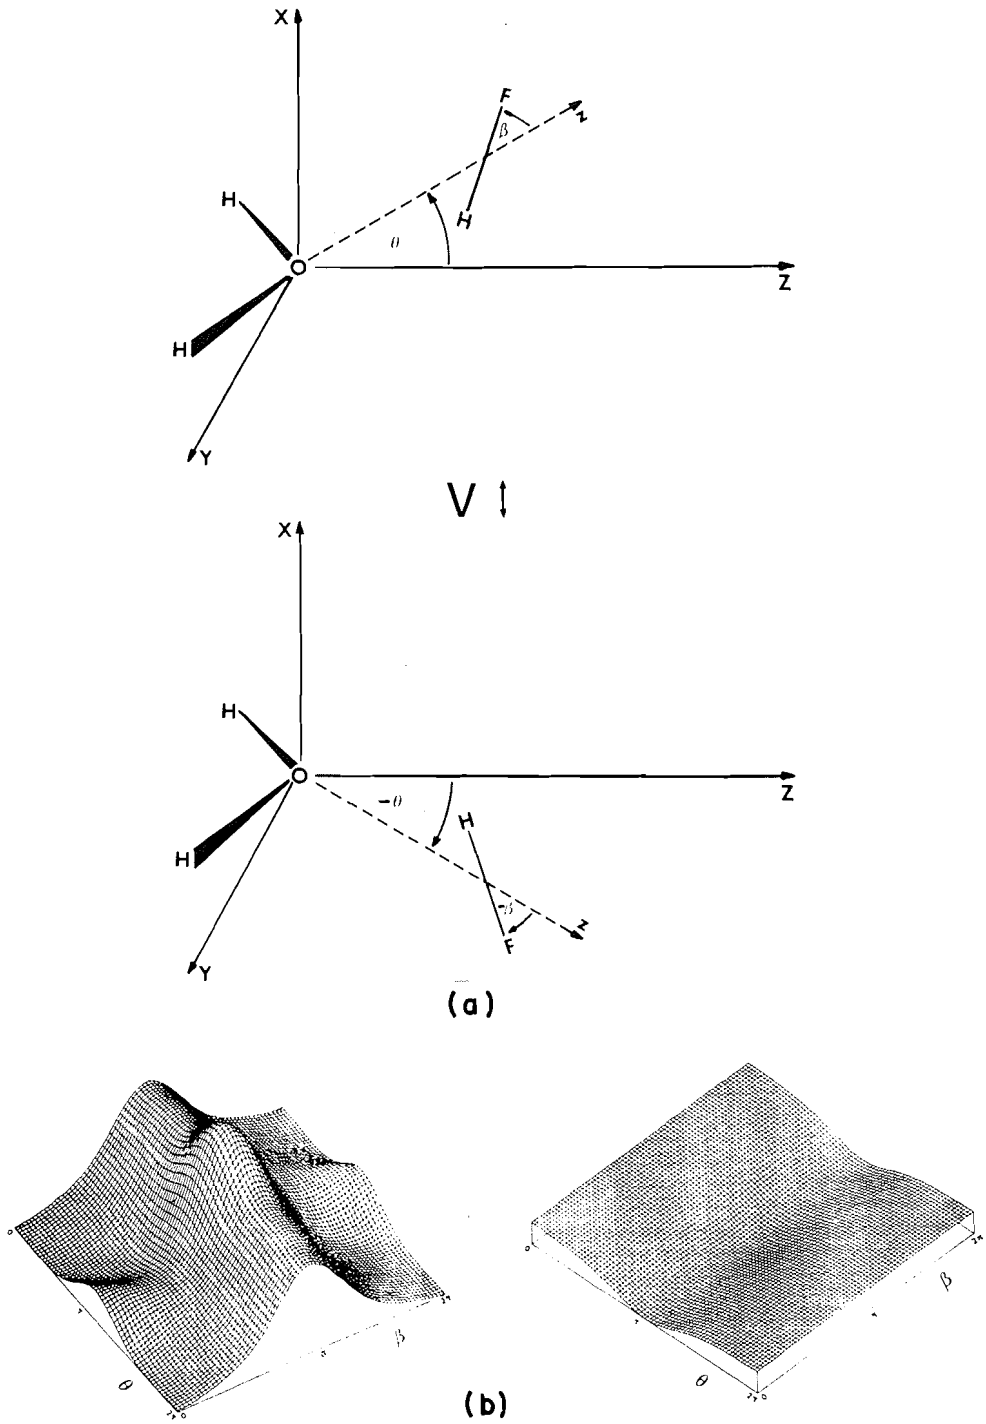

FIG. 3. (a) The complex H_2O: HF with HF confined to the σ_v plane of H_2O ($\phi = \gamma = 0$): conformations (θ, β) and ($-\theta$, $-\beta$), which can be superimposed through an Euclidean displacement, are related by the double-switch isodynamic operation V. (b) Cross-sections of the interaction potential-energy hypersurface for the case shown in (a), calculated with the optimized distance $\rho = 2.16$ Å: left, conformation-dependent part of the SCF energy obtained using STO / 4-21G*; right, dispersion-energy contribution calculated using Claverie's semiempirical formula (ref. 12*b*) (right scale is twice left scale).

deduced from microwave spectroscopy (ref. 12*c*), also listed in Table 1. In conclusion, we can represent the complex H_2O:HF as a floppy bent-pyramidal chelate, the H_2O lone pairs acting as attractors for the H of HF whose fluorine also bends towards the hydrogens of water.

3. Molecular crystals

A variety of crystals have lattice nodes occupied by neutral or ionic atoms or quasi-spherical molecules making up unit cells of some particular symmetry, housing at their center rigid molecules of the same or another symmetry (Fig. 2a). In such cases the symmetry of a property dependent on the orientation of the molecule with respect to the cell is completely determined by the symmetries of both molecule and cell. Such properties are usually expanded in terms of Wigner harmonics in the form given by eq. [3] (refs. 15). For most rigid molecules embedded

in regular crystals, the relative-orientation variables (α, β, γ) (Fig. 2b) can be separated from the internal molecular variables as well as from the phonon crystal variables, due to the large differences observed between the corresponding motion frequencies. Properties of interest include the molecule–site energy and torque, the orientational distribution and correlation functions, and any property that may be of interest in the interpretation of scattering or spectroscopic data, such as high-resolution vibration–rotation or pure rotation spectra for molecules trapped in crystals, or orientational statics and dynamics for molecular crystals studied by neutron or X-ray scattering.

We have given (ref. 15*c*) an overall description of how the symmetry properties of a composite system (SM) made up of a rigid molecule (M) and a crystal site (S) can be determined and yield significant, and sometimes drastic, reductions in the Wigner harmonic expansions of the various properties. Using the group theoretical approach initially proposed for nonrigid molecules by Longuet-Higgins (ref. 6), Miller and Decius (ref. 15*a*) have determined the complete groups for molecules of arbitrary symmetry embedded in sites of any symmetry. Alternatively, we have used the group theoretical approach initially proposed by Altmann (refs. 7) to determine the isodynamic groups ($\mathbf{I_{SM}}$) for molecules of arbitrary symmetry ($\mathbf{G_M}$) centered at sites of any symmetry ($\mathbf{G_S}$).

In the following we shall first summarize our results concerning the operator structure of the isodynamic groups $\mathbf{I_{SM}}$ in terms of the symmetry operations of the point groups $\mathbf{G_M}$ and $\mathbf{G_S}$, then recall the selection rules associated with the isodynamic operations of $\mathbf{I_{SM}}$, and finally indicate how reduced symmetry-adapted expansions can be derived from these selection rules.

3.1. Isodynamic groups

Among all symmetry operations, Altmann (refs. 7) distinguishes those which reduce to changes of the laboratory or system axes, leaving the electronic Hamiltonian invariant, and the internal motions of the system, which leave the nuclear Hamiltonian unaltered. He calls these latter operations "isodynamic" (ref. 7*b*) because they transform a conformation having broken symmetry into an isoenergetic conformation having the same symmetry. The isodynamic group made up of these operations can be written as the semidirect product of two further groups (ref. 7*d*):

$$[8] \quad \boldsymbol{I}^{\sim} = \boldsymbol{I}^{\sim}_{\mathbf{r}} \wedge \boldsymbol{I}^{\sim}_{\mathbf{d}}$$

where $\boldsymbol{I}^{\sim}_{\mathbf{r}}$ is the group of internal rearrangements that transfer a set of atoms from one equilibrium position onto another, and $\boldsymbol{I}^{\sim}_{\mathbf{d}}$ is the group of restricted distorsions that leave the equilibrium positions of all atoms unchanged.

We shall consider only those motions of a rigid molecule with respect to a crystal site that leave the centers of mass coincident. The 34 possible point groups $\mathbf{G_M}$ and 7 possible point groups $\mathbf{G_S}$ may involve symmetry centers, axes, and planes and, whenever possible, the reference axes of M (O*xyz*) and of S (O*XYZ*) will be chosen in relation with symmetry elements of M and of S (Fig. 2). If M or S has a symmetry center, this latter coincides with the center of mass and is taken as the origin of the axes.

Assume S possesses an n-fold principal axis and M an n'-fold principal axis, these two axes making an angle β (Fig. 2b). If $E(\alpha,\beta,\gamma)$ is the total energy of the composite system, an isodynamic rotation of M around C_n is defined by

$$[9] \quad C_n^q E(\alpha,\beta,\gamma) = E(\alpha + q\cdot 2\pi/n, \beta, \gamma)$$

and an isodynamic rotation of M around $C'_{n'}$ by

$$[10] \quad C'^{q'}_{n'} E(\alpha,\beta,\gamma) = E(\alpha, \beta, \gamma + q'\cdot 2\pi/n')$$

The first operation generates the isodynamic cyclic group $\boldsymbol{C}_n^{\sim}$ and the second operation the isodynamic cyclic group $\boldsymbol{C'}_{\mathbf{n'}}^{\sim}$. If S and M also possess twofold axes orthogonal to their principal axis, one can define the additional isodynamic operations:

$$[11] \quad {}^{\circ}C_2 E(\alpha,\beta,\gamma) = E(-\alpha, \pi - \beta, \gamma + \pi)$$

$$[12] \quad {}^{\circ}C'_2 E(\alpha,\beta,\gamma) = E(\alpha + \pi, \pi - \beta, -\gamma)$$

These two sets of isodynamic operations generate the respective isodynamic groups ${}^{\circ}\boldsymbol{C}_2^{\sim}$ and ${}^{\circ}\boldsymbol{C'}_2^{\sim}$. $\boldsymbol{T}$ and $\boldsymbol{O}$ cubic groups also involve diagonal threefold axes, which similarly induce the isodynamic groups ${}^{a}\boldsymbol{C}_3^{\sim}$ and ${}^{a}\boldsymbol{C'}_3^{\sim}$.

As a consequence of Altmann's representation of symmetry point groups as semidirect products (ref. 7*a*), the full isodynamic groups $\boldsymbol{R}_{\mathbf{M}}^{\sim}$ and $\boldsymbol{R}_{\mathbf{S}}^{\sim}$ generated by all proper rotations in $\mathbf{G_M}$ and $\mathbf{G_S}$ can then be written:

$$[13] \quad \begin{aligned} &\boldsymbol{C}_n^{\sim}(n = 1, 2, 3, 4, 6), \qquad \boldsymbol{D}_n^{\sim} = \boldsymbol{C}_n^{\sim} \wedge {}^{\circ}\boldsymbol{C}_2^{\sim} \\ &\boldsymbol{T}^{\sim} = \boldsymbol{D}_2^{\sim} \wedge {}^{a}\boldsymbol{C}_3^{\sim}, \qquad \boldsymbol{O}^{\sim} = \boldsymbol{D}_2^{\sim} \wedge {}^{a}\boldsymbol{D}_3^{\sim} \end{aligned}$$

for $\boldsymbol{R}_{\mathbf{S}}^{\sim}$, and similar (primed) expressions for $\boldsymbol{R}_{\mathbf{M}}^{\sim}$. The direct product of the site and molecule proper-rotation subgroups generates the isodynamic group of internal rearrangements defined in eq. [8]:

$$[14] \quad \boldsymbol{I}^{\sim}_{\mathbf{r}} = \boldsymbol{R}_{\mathbf{S}}^{\sim} * \boldsymbol{R}_{\mathbf{M}}^{\sim}$$

Whereas isodynamic internal rotations can be defined for the composite system whenever any one of the system components possesses proper-rotation symmetries, isodynamic operations resulting from rotation-reflections, reflections, and inversions can be defined only if both molecule and site possess improper-rotation symmetries. Since, according to Altmann (ref. 7*a*), improper point groups can be written as a direct or semidirect product of a proper point group with either $\boldsymbol{C}_i$ or $\boldsymbol{C}_s$, all isodynamic operations will be some product of an isodynamic operation of the first kind, considered above, with an isodynamic operation of the second kind, which we now consider.

Starting from a conformation in which the reference σ_v and σ'_v planes coincide ($\alpha = \gamma = 0$, $\beta \neq 0$), it can be seen (Fig. 2b) that the two distorted conformations (α,β,γ) and $(-\alpha, \beta, -\gamma)$ are connected by the isodynamic operation:

[15] $\boldsymbol{V}_v E(\alpha,\beta,\gamma) = E(-\alpha, \beta, -\gamma)$

One can similarly define, with a σ_v and a σ'_h plane, the isodynamic operation:

[16] $\boldsymbol{V}_h E(\alpha,\beta,\gamma) = E(\pi - \alpha, \pi - \beta, \gamma)$

These two isodynamic operations generate the respective groups $\boldsymbol{V}_v^{\sim}$ and $\boldsymbol{V}_h^{\sim}$. One could similarly define isodynamic groups $\boldsymbol{H}_v^{\sim}$ and $\boldsymbol{H}_h^{\sim}$. From the properties of the inversion it results that only the combinations of I with reflections through either σ_v or σ_h planes in either M (primed) or S (unprimed) produce isodynamic operations:

[17] $\boldsymbol{I}_v E(\alpha,\beta,\gamma) = E(\pi - \alpha, \pi - \beta, \gamma + \pi)$

[18] $\boldsymbol{I}_h E(\alpha,\beta,\gamma) = E(\alpha + \pi, \beta, \gamma)$

and similar relations for $\boldsymbol{I}'_v$ and $\boldsymbol{I}'_h$ with the roles of α and γ interchanged. These four idempotent operations generate the respective isodynamic groups $\boldsymbol{I}_v^{\sim}, \boldsymbol{I}_h^{\sim}, \boldsymbol{I}'_v{}^{\sim}, \boldsymbol{I}'_h{}^{\sim}$.

According to Altmann's classification (ref. 7a), there are 11 molecular point groups of type (a), $\boldsymbol{R}_{\mathbf{M}}$, 11 of type (b), $\boldsymbol{R}_{\mathbf{M}} \times \boldsymbol{C}_i$, 9 of type (c), $\boldsymbol{R}_{\mathbf{M}} \wedge \boldsymbol{C}_s$, and 3 unclassified (d) ($\boldsymbol{S}'_4$, $\boldsymbol{C}'_{\infty v}$, $\boldsymbol{D}'_{\infty h}$); for a lattice site, only 7 out of these 34 point groups are possible: 6 of type (b), $\boldsymbol{R}_{\mathbf{S}} \times \boldsymbol{C}_i$, and 1 of type (c), $\boldsymbol{R}_{\mathbf{S}} \wedge \boldsymbol{C}_s$ (C_{3v}). The isodynamic group of restricted distorsions $\boldsymbol{I}^{\sim}_{\mathbf{d}}$ defined in eq. [8] is generated by the factors of $\boldsymbol{R}_{\mathbf{M}}$ and $\boldsymbol{R}_{\mathbf{S}}$ in the molecule and site point groups and can be shown to be one of the isodynamic groups introduced in eqs. [15]–[18]. We have gathered in Table 2 the structures of the complete isodynamic groups $\boldsymbol{I}^{\sim}$ for all possible combinations of molecule and site point groups (ref. 15c).

3.2. Selection rules

From the action of the isodynamic operations considered above on Wigner harmonics making up series expansions (ref. 13), one can derive explicit relations between the expansion coefficients of a given property (ref. 15c). The symmetry-adapted expansion of a molecule–site property transforming as an irreducible representation Γ of the isodynamic group $\boldsymbol{I}^{\sim}$ can be obtained by applying to its Wigner harmonic expansion, given by eq. [3], the corresponding projection operator:

TABLE 3. Relations between the coefficients of the harmonic expansions induced by the various isodynamic operations. In the relations occurring for cubic groups $\cos {}^2\eta_a = 1/3$ (from ref. 15c)

$\mathbb{C}_n^{\sim}$: $A_1{}^{mm'} = (-1)^{2m/n} A_1{}^{mm'} = 0$ unless $m = kn$

$\mathbb{C}_{n'}^{r'\sim}$: $A_1{}^{mm'} = (-1)^{2m'/n'} A_1{}^{mm'} = 0$ unless $m' = k'n'$ ($m' = 0$ if $n' = \infty$)

$^{\circ}\mathbb{C}_2^{\sim}$: $A_1{}^{mm'} = (-1)^l A_1^{-mm'}$

$^{\circ}\mathbb{C}_2'^{\sim}$: $A_1{}^{mm'} = (-1)^l A_1^{\pi - m'}$

$^{a}\mathbb{C}_3^{\sim}$: $A_1{}^{mm'} = \sum (-1)^{(m+3r')/4 - r/3} d_1{}^{m\pi}(\eta_a) d_1{}^{\pi r'}(\eta_a) A_1{}^{r'm'}$

$^{a}\mathbb{C}_3'^{\sim}$: $A_1{}^{mm'} = \sum_{r,r'} (-1)^{(m'+3r)/4 - r'/3} d_1{}^{\epsilon' m'}(\eta_a) d_1{}^{\pi r'}(\eta_a) A_1{}^{m\epsilon}$

$\mathbb{V}_v^{\sim}$: $A_1{}^{mm'} = (-1)^{m-m'} A_1^{-m-m'}$

$\mathbb{H}_v^{\sim}$: $A_1{}^{mm'} = (-1)^{m+m'} A_1{}^{mm'}$

$\mathbb{V}_h^{\sim}$: $A_1{}^{mm'} = (-1)^{l+m+m'} A_1^{-mm'}$

$\mathbb{H}_h^{\sim}$: $A_1{}^{mm'} = (-1)^{l+m+m'} A_1^{m-m'}$

$\mathbb{J}_v^{\sim}$: $A_1{}^{mm'} = (-1)^{l+m} A_1^{-mm'}$

$\mathbb{J}_h^{\sim}$: $A_1{}^{mm'} = (-1)^m A_1{}^{mm'}$

$\mathbb{J}_v'^{\sim}$: $A_1{}^{mm'} = (-1)^{l-m'} A_1{}^{m-m'}$

$\mathbb{J}_h'^{\sim}$: $A_1{}^{mm'} = (-1)^{m'} A_1{}^{mm'}$

[19] $\boldsymbol{O}^{\Gamma} = (1/h) \sum_{i=1}^{h} \chi_i{}^{\Gamma} \boldsymbol{O}_i$

where h is the dimension of $\boldsymbol{I}^{\sim}$ and $\chi_i{}^{\Gamma}$ is the character corresponding to the isodynamic operator $\boldsymbol{O}_i$ in the irreducible representation Γ. The selection rules are obtained by stating, for each operator $\boldsymbol{O}_i$ in $\boldsymbol{O}^{\Gamma}$, that

[20] $\boldsymbol{O}_i A(\Omega) = A(\Omega)$

and by using the relations expressing the effects of the isodynamic operations on Wigner harmonics to compare the coefficients of the corresponding terms on both sides of eq. [20]. The selection rules corresponding to the various isodynamic operations are gathered in Table 3. Other rules can be obtained by combining the relations given in the table.

3.3. Reduced symmetry-adapted expansions

Our basic interest is in the conformational dependences of the various properties of a rigid molecule embedded in a crystal site. The fact that a property is of an aggregate, mononuclear, or binuclear type determines the effective isodynamic group $\boldsymbol{I}^{\sim}$ to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

which the operators $\boldsymbol{O}_i$ in eq. [19] belong, whereas the fact that a property is scalar, vectorial, or tensorial determines the irreducible representation Γ to which the characters χ_i^{Γ} belong.

For an aggregate property A, the effective isodynamic group $\tilde{\boldsymbol{I}}(A)$ is the full isodynamic group determined in Section 3.1. For a mononuclear property M_i or S_i (depending on the location of the nucleus, in the molecule or in the site), the effective isodynamic group $\tilde{\boldsymbol{I}}(M_i)$ or $\tilde{\boldsymbol{I}}(S_i)$ is the same as that of A but for a system in which the symmetry of M or that of S has been reduced by singling out nucleus i. For a binuclear property one must distinguish the cases B_{ij}, C_{ij}, and D_{ij}, where nuclei i and j are both on M, shared between M and S, and both on S, respectively. In all three cases the effective isodynamic group is the same as that of A but for a system in which nuclei i and j have been singled out.

For a scalar property A, the relevant irreducible representation Γ_A is the totally symmetric representation of $\tilde{\boldsymbol{I}}(A)$, all characters of which are equal to 1. For a vectorial or tensorial property $\boldsymbol{A}$, one must consider the components of the representative vector or tensor on reference axes of the perturbed molecule related to the isodynamic operations defined by eqs. [15] and [16]: y for $\boldsymbol{V}_v$, z for $\boldsymbol{V}_h$, x orthogonal to these both. For all operators belonging to the rotational subgroup $\tilde{\boldsymbol{I}}_r$, the characters remain equal to 1 for all components of all vectors and tensors. For those operators belonging to the deflectional subgroup $\tilde{\boldsymbol{I}}_d$, the characters change their sign if the axis along which the component is measured is related (for polar vectors) or unrelated (for axial vectors) to the corresponding operation. For tensorial properties the diagonal components transform like scalars and the off-diagonal components like axial vectors.

It may be of interest to evaluate the numbers of independent non-zero coefficients remaining in eq. [3], up to a certain order, after applying the projection operator given by eq. [19], for a particular type of property. In Table 4 (ref. 15*c*) we have displayed such numbers for all combinations of site and molecule noncubic point groups.

TABLE 4. Numbers of independent non-zero coef cients up to the order $l = 6$ for scalar aggregate properties (from ref. 15*c*)

4. Double-rotor molecules

We have investigated single-rotor molecules (refs. 16), double-rotor molecules of linear, bent-planar, and *gauche* types (refs. 17), and triple-rotor molecules of some simple types (ref. 10, pp. 291–314),[2] for which the relevant expansions are given by eqs. [4] and [5]. We shall summarize the general results derived for double-rotor molecules (refs. 17*a*, *b*), and then illustrate the interest of these considerations in the case of the hyperfine couplings of hydrocarbon radicals (refs. 16*c*, 17*c*).

4.1. General considerations

We call a double-rotor molecule a structure consisting of a rigid frame (R), at least two-dimensional (with its bonds), bearing two rotating tops (R′ and R″). Such a molecule can be (*i*) linear (L) when the rotor axes are collinear, as in *para*-xylene; (*ii*) bent-planar (B) when these axes (whether they are parallel or not, and whether the bonded frame is planar or not) lie in the same plane, as in *ortho*- and *meta*-xylenes, dimethyl ether, dimethylamine, propane, or *cis*- and *trans*-dimethylethylenes; (*iii*) *gauche* (G) when the two axes are skew, as in *trans*-1,2-dimethylcyclopropane. It can be seen by inspection that the maximal symmetry of the bonded frame is D_{nh}, C_{2v}, or C_2 in the L, B, or G case, respectively.

We first consider the most symmetrical case (L) and, as before, deduce the Altmann group of the nonrigid structure from the symmetry properties of its constitutive parts. We define the principal axis of the molecule as the common axis of both rotors and the frame, and measure the rotation angles of R′ and R″, α' and α'', counterclockwise when viewed from R.

If R′ possesses an n'-fold axis, R″ an n''-fold axis, and R an n-fold axis (all these axes being collinear), isodynamic rotations of R′, R″, and R can be defined in the following way:

$$[21]\quad \boldsymbol{C}_{n'}^{p'}E(\alpha', \alpha'') = E(\alpha' + p'\cdot 2\pi/n', \alpha'')$$

$$[22]\quad \boldsymbol{C}_{n''}^{p''}E(\alpha', \alpha'') = E(\alpha', \alpha'' + p''\cdot 2\pi/n'')$$

$$[23]\quad \boldsymbol{C}_{n}^{p}E(\alpha', \alpha'') = E(\alpha' + p\cdot 2\pi/n, \alpha'' - p\cdot 2\pi/n)$$

The direct product of the corresponding cyclic groups constitutes the isodynamic subgroup $\tilde{\boldsymbol{I}}_r$:

$$[24]\quad \tilde{\boldsymbol{I}}_r = \boldsymbol{C}_{n'}\tilde{} * \boldsymbol{C}_{n''}\tilde{} * \boldsymbol{C}_{n}\tilde{}$$

The most symmetrical situation is that of a linear double-rotor molecule having in addition (*i*) "equivalent" tops (as in *para*-xylene) and (*ii*) σ_v planes in both rotors and the frame. In such a case one can define the additional (concerted) isodynamic operations, respectively called double switch, angle exchange, and switch exchange (ref. 17*a*):

[2]Also, J-Ph. Caniparoli and J. Maruani. Unpublished results.

[25] $VE(\alpha', \alpha'') = E(-\alpha', -\alpha'')$

[26] $WE(\alpha', \alpha'') = E(\alpha'', \alpha')$

[27] $UE(\alpha', \alpha'') = E(-\alpha'', -\alpha')$

The direct product of any two of the three corresponding binary groups constitutes the isodynamic subgroup $\mathbf{I}^{\sim}_{d}$, e.g.:

[28] $I^{\sim}_{d} = V^{\sim} * W^{\sim}$

The complete isodynamic group is again given by eq. [8]. For less symmetric L-type molecules, two or three of the operations [25]–[27] may be absent. For bent-planar molecules, the operation [23] never exists. For *gauche* molecules, the operations [25] and [27] also disappear. One may then characterize double-rotor molecules by the following symmetry labels (ref. 17*a*):

[29] $L(n', n'', n; v, w, u)$;

$$B(n', n''; v, w, u); \qquad G(n', n''; w)$$

where the numerical indices n', n'', and n are the orders of the bond symmetry axes and v, w, and u are logical indices taking on the value $(+-)$ 1 or 0 depending on whether or not the corresponding isodynamic operation exists. Once the symmetry label characterizing a particular property in a given molecule is known, it is easy to simplify the corresponding double Fourier series expansion (eqs. [4] and [5]), the harmonic coefficients of which obey various selection rules following from the invariance of the property under the operations defined by the symmetry indices (ref. 17*a*).

4.2. Hyperfine couplings

The hyperfine couplings of organic radicals can yield detailed information on their nuclear arrangement and electronic distribution when one knows the dependence of the couplings on the parameters. An important class of organic radicals have their spin density concentrated on a π-type molecular orbital, which may be essentially a single atomic orbital (as in methyl, ethyl, and *n*-propyl) or made up of several $2p^z$ orbitals centered on carbon or hetero atoms (as in nitroxide, hydrazyl, and conjugated radicals). The isotropic hyperfine splitting constants are scalar mononuclear properties and, therefore, their symmetry indices depend on the particular position of the labelling nucleus i in the system.

Let us consider, for instance, the radical *n*-propyl, where (with the above conventions) $R \in \boldsymbol{C}_{2v}$, $R' \in \boldsymbol{C}'_{2v}$, and $R'' \in \boldsymbol{C}''_{3v}$. The symmetry labels of the conformational potential V and of the hyperfine couplings for the α, β, and γ positions are therefore, respectively,

$$B(2, 3; 0, 1, 0);$$

$$B_{\alpha}(1, 3; 0, 1, 0); \; B_{\beta}(2, 3; 0, 0, 0); \; B_{\gamma}(2, 1; 0, 1, 0)$$

We have used the corresponding symmetry-adapted Fourier series expansions to fit the conformational variations calculated using various theoretical approaches. In particular, we have shown that the following approximate formula can be derived from this analysis (ref. 17*c*):

[30] $c_{\gamma}(\alpha', \alpha'') = \rho^{\pi}_{c_{\alpha}}[A + B\cos^2\alpha' \times (1 + a\cos\alpha'' + b\cos 2\alpha'')]$

and have compared the shape of this dependence with those experimental results in which measured couplings corresponding to known conformations were available. The parameter values derived from quasi-localized *ab initio* numerical results are $A = -0.2$ G; $B = 1.1$ G; $a = 1.8$, and $b = 1.3$ (standard deviation $\sigma = 0.1$). For the α and β couplings we have discussed the range of validity of the usual McConnell's relations (ref. 16*c*).

5. Conclusions

We have shown how the harmonic expansions of the physical properties of molecular systems can be symmetry-adapted using isodynamic operations, and how the resulting expressions can be used to determine the conformations. We have given examples of this procedure for molecular pairs and for double-rotor molecules and a general outline of it for molecular crystals. Other examples would include a small molecule interacting with a large aggregate or with a regular surface. In this latter case, one could either assimilate the rigid molecule M and surface site S to the two rotors of a (linear, bent planar, or *gauche*) supermolecule, as in Part 4, if S and M belong to symmetry groups C_{nv} and $C'_{n'v}$; or consider a surface site of symmetry C_{nv} and rigid molecule of any symmetry and build tables similar to Tables 2 and 3 of Part 3, if the center of M is on the axis of S; or, more generally, use a formalism derived from that of the molecular pair used in Part 2.

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

DUBRAVKA KRILOV, GRETA PIFAT, and JANKO N. HERAK. Can. J. Chem. **66**, 1957 (1988).

The electron spin resonance spin-trapping method has been used for detection of radicals in human low density lipoprotein (LDL) solution saturated with oxygen. The trapped radicals could be detected after about a day in an antioxidant-free solution. Two types of radicals are formed and stabilized in the lipid domain of LDL. The nature of the trapped radicals remains unclear: kinetic considerations suggest the trapped radicals to be of the LO· type, while the spectroscopic parameters are in favour of L· type radicals.

DUBRAVKA KRILOV, GRETA PIFAT, et JANKO N. HERAK. Can. J. Chem. **66**, 1957 (1988).

On a fait appel à la méthode de piégeage des spin par résonance paramagnétique électronique pour détecter des radicaux dans des solutions de LDL humaines, saturées par de l'oxygène. Utilisant une solution ne contenant pas d'antioxydant, on a pu détecter les radicaux piégés après environ une journée. Dans le domaine des lipides des LDL, il se forme deux types de radicaux stabilisés. La nature des radicaux piégés n'est toutefois pas bien définie : des considérations cinétiques suggèrent que les radicaux piégés sont du type LO·; toutefois, les paramètres spectroscopiques favorisent plutôt des radicaux du type L·.

[Traduit par la revue]

Introduction

Low density lipoprotein (LDL) forms a distinct class of plasma lipoproteins. LDL plays a major role in supplying cells with cholesterol. A major step on the metabolic pathway of LDL is a receptor-mediated uptake by cells (1). Certain chemical modifications of LDL, such as ε-amino groups of lysine residues of the protein moiety (apo B) of LDL, abolish its binding to the LDL receptor (2). However, LDL thus modified can be recognized by the "scavenger" or acetyl-LDL receptor on the membranes of macrophages (3, 4). An important group of chemicals found capable of modifying the receptor binding properties of LDL are the lipid peroxidation products, malonaldehyde (5, 6) and 4-hydroxynonenal (7). Studies in several laboratories have shown that cultured endothelial cells or smooth muscle cells can also modify LDL so that it can be recognized by the acetyl-LDL receptor (8–11). This modification by cells involves peroxidation of LDL, resulting in drastic alterations of both lipid and protein components. Among other changes, a substantial increase of electrophoretic mobility, fragmentation of apoprotein B, hydrolysis of phosphatidyl choline, and loss of esterified cholesterol have been detected (10, 12, 13). Most of the "biologically" activated alterations could be mimicked by exposure of LDL to oxidative conditions in a cell-free medium (12–15). It has been generally accepted that free radicals initiate the peroxidation and the subsequent changes. The conclusion is mostly based on the fact that the peroxidation and the peroxidation-induced alterations of LDL can be inhibited by the addition of free radical scavengers (10, 13). Moreover, the effect of superoxide dismutase (SOD) on the modification of LDL undoubtedly proves the involvement of superoxide, $O_2^{\cdot-}$, (10, 11, 16–19).

In the present study we offer direct evidence, by electron spin resonance (esr), of the involvement of free radicals in the peroxidation of LDL. The esr spin-trapping method has been found to be very suitable for such purposes (20–22). With the use of this method it is possible not only to detect the presence of free radicals but possibly also to learn about the structure and location of the radical in a supramolecular structure like LDL. One of the aims of this study is also to see whether the initial stage of LDL peroxidation, i.e., radical formation, takes place only in the lipid domain of LDL or also on the protein.

Methods

Chemicals

Phenyl-*N*-*tert*-butyl nitrone (PBN) was purchased from Aldrich. Other chemicals used were analytical grade, also available from commercial sources (Sigma, Merck, Aldrich). All chemicals were used without further purification.

Lipoprotein isolation

Low density lipoprotein was prepared from freshly drawn (<24 h) human plasma from normolipidemic individuals. To the plasma, taken from many different donors, 20 μM butylated hydroxytoluene (BHT) was added. Plasma solvent density was adjusted to 1.050 g/cm^3 with a high density salt solution of KBr in 0.1 M Tris buffer, pH 7.50, containing 0.9% NaCl, 1 g/L EDTA, and 50 mg/L chloramphenicol. The supernatant was removed after centrifugation (23) for 24 h at about 40 000 rpm, at 4°C in a Beckman ultracentrifuge using a titanium T50 or T40 rotor. The pooled supernatants were adjusted to density 1.020 g/cm^3 in the same buffer with the same inhibitors. Recentrifuged as before, LDL was collected in the infranatant. LDL solutions were concentrated by N_2 pressure dialysis to concentrations of about 3–4 mg/mL. The final concentration of LDL was determined gravimetri-

cally. The delipidation of LDL was performed by several extractions with chloroform:methanol (2:1, v/v) and once with diethyl ether at 4°C (24). The lipid fraction was left in the chloroform–methanol mixture and the protein fraction was kept in the buffer solution. The lipoprotein preparations were checked for purity by agarose gel electrophoresis.

Oxidation and electron spin resonance measurements

Before the oxidation, LDL preparations were dialyzed at 4°C for 24 h against six changes of at least 100 volumes of dialysate – 0.05 M Tris buffer adjusted to pH 7.4.

Phenyl-*N*-*tert*-butyl nitrone (PBN), used in this study as a spin trap, was dissolved in 0.05 M Tris buffer to the final concentration of 0.1 M. The oxidation of LDL solution was carried out in a similar way to that reported by Schuh *et al.* (12). The LDL solution in the dialysis bag was immersed in the PBN – Tris buffer and flushed with O_2 for at least 6 h before the esr measurements were made. Oxidation was carried out at room temperature.

The control LDL sample in the PBN – Tris buffer was flushed with nitrogen for half an hour and left at room temperature in the presence of air. The esr measurements were carried out with a Varian E-109 X-band spectrometer. The sample was placed in an aqueous sample flat cell. The measurements were made at room temperature, except when mentioned otherwise.

Results

Nitroxide esr spectra were quite regularly observed in all LDL samples with the spin trap (PBN), in which no antioxidants (EDTA or BHT) or other radical scavengers were present. If the LDL samples were exposed to the saturated oxygen solution, as described in the previous section, the esr signals recorded after several days were quite strong, as illustrated in Fig. 1a. In some samples the esr signals appeared after dialysis for only 6 h against the O_2-saturated buffer. In other cases it was necessary to wait for a day or longer for the signals to appear. However, it was essentially the same signal in all the samples. The esr spectrum contains a single major spectral component, and possibly a second minor component as suggested by subtle changes in the low-field portion of the spectrum. The esr spectrum of the control LDL sample (Fig. 1b) is essentially the same but of lower intensity.

The pattern changes upon prolonged storage of the sample at room temperature, as illustrated by the upper spectrum in Fig. 2. The sharper lines become even sharper and split into doublets. Under such conditions the broad line on the low-field side, indicated in Fig. 1, is repeatedly much better expressed. When the temperature is raised to about 40°C (lower tracing in Fig. 2), the sharper spectrum becomes even stronger and better resolved, and the broader component diminishes. This behaviour is not completely reversible; after lowering the temperature back to 20°C, the spectra are qualitatively the same, but the overall concentration of the radicals is increased.

After the radicals represented by the top curve in Fig. 1 had been developed, we made a separation of the three fractions of the oxidized LDL sample: water (buffer) fraction, LDL lipid fraction in the chloroform–methanol mixture, and apoprotein fraction in the buffer solution. Figure 3 shows the esr spectra recorded for the three fractions. It is seen that the stabilized radicals are associated only with the lipid fraction of LDL.

Discussion

It has been shown that free radicals are spontaneously formed in human plasma low density lipoprotein (LDL) exposed to molecular oxygen. The radicals are stabilized in the lipid domain of LDL, as demonstrated in Fig. 3. The esr lines are quite broad, indicating restricted motion of the trapped radical.

The radicals are the products of lipid peroxidation. Lipid peroxidation is an autooxidative process, initiated by abstraction of a weakly bonded allylic hydrogen by some strong oxidant (7, 22, 25–27). The initiators are oxidants like the hydroxyl radical (·OH), perhydroxyl radical (HO_2·), a chelated ion–oxygen complex ($Fe^{2+}O$ or $Fe^{2+}O_2$), or a triplet excited state of a photosensitizing dye. We do not see an obvious source of any of the above initiators in our system. However, even a small

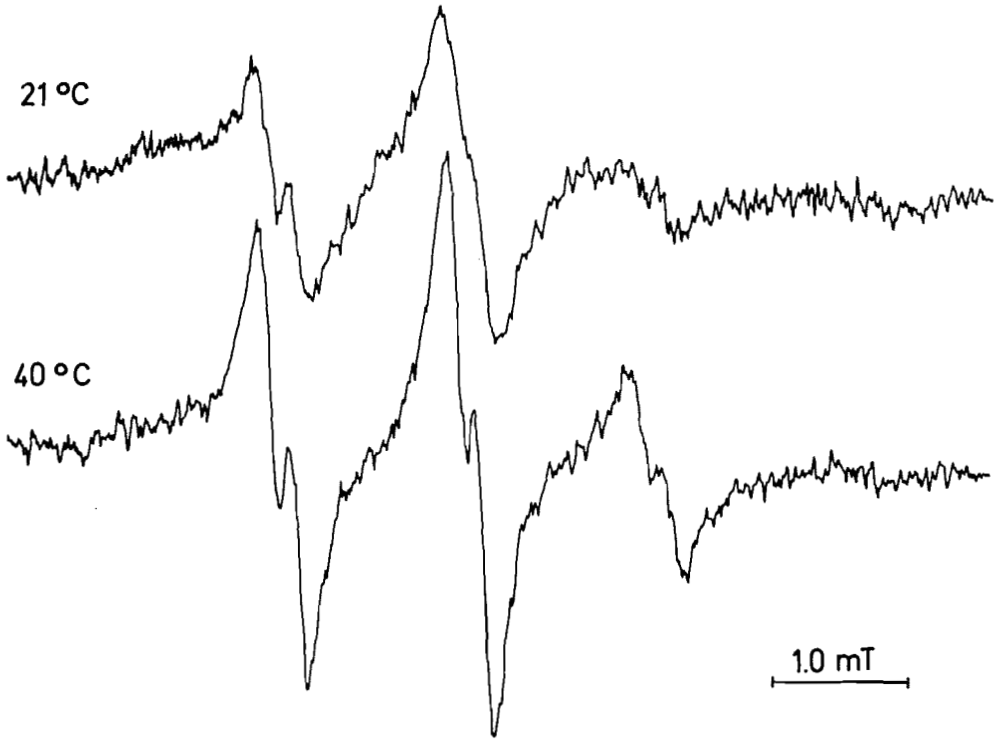

FIG. 2. Temperature dependence of the peroxidized LDL esr spectra, recorded 7 days after initiation of oxidation. The arrow indicates the existence of an additional broad signal. Other conditions the same as in Fig. 1.

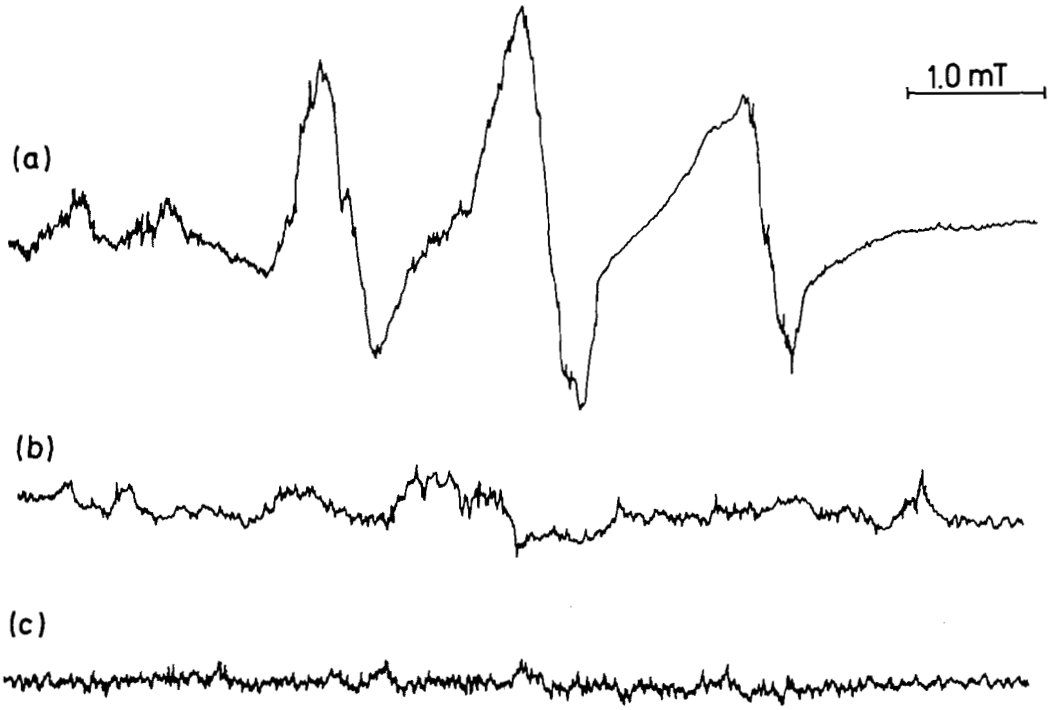

FIG. 3. Electron spin resonance spectra of three separate fractions of the oxygenized LDL sample: (a) the lipid fraction in the chloroform–methanol mixture; (b) the protein fraction in the buffer solution; (c) the buffer. Other conditions the same as in Fig. 1.

concentration of photosensitive dyes may be enough to initiate a slow process of lipid peroxidation. Alternatively, a small concentration of the transition metal ions, particularly Fe(II), might initiate oxygen radical production. The possible initiation given most attention is the perferryl ion, a complex between Fe(II) and O_2, or of Fe(III) and $O_2^{\cdot-}$:

$$[1] \quad Fe(II) + O_2 \rightarrow [Fe(II)O_2]^{2+} \leftrightarrows [Fe(III)O_2^{\cdot-}]^{2+}$$

This might be the source of the superoxide radical. Disproportionation of this species produces H_2O_2, which on reacting with $O_2^{\cdot-}$ via the Haber–Weiss reaction might produce the reactive hydroxyl radical:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

[2] $H_2O_2 + Fe(II) \leftrightarrows OH^- + \dot{O}H + Fe(III)$

In our preparations the chelated metal ions are expected to be practically completely removed by extensive dialysis. However, the metal ions might be bound to some places in the LDL interior and the formation of the initiating oxygen radicals might be site specific (19, 27). Obviously, the process of initiation of lipid peroxidation in LDL requires further study.

Whatever the initiator, it is believed that the primary radical is a lipid alkyl radical L·. The next step is the reaction if L· with the spin trap or with O_2:

[3] $L\cdot + PBN \rightarrow \dot{L}$ (PBN)

[4] $L\cdot + O_2 \rightarrow LOO\cdot$

The competition between these two reactions is probably on the side of reaction [4]; i.e., the rate constant for reaction [3] is about 10^5–10^6 M^{-1} s^{-1} and that for reaction [4] about 10^9–10^{10} M^{-1} s^{-1} (28).

The difference in the rate constants of four orders of magnitude more than compensates for the large difference in concentrations of the competing reactants (3×10^{-4} M for O_2 and 10^{-1} M for PBN). Moreover, it is probable that in the lipid fraction, where the radicals are formed, concentration of O_2 is even higher. PBN is expected to be distributed between the bulk aqueous phase and the LDL lipid domain (29).

The peroxy radical may initiate further peroxidation of other lipids via the oxy radical, which may ultimately be trapped:

[5] $LOO\cdot + L'H \rightarrow LOOH + L'\cdot$

[6] $LOOH + E\,(\text{reduction}) \rightarrow LO\cdot + OH^-$

On the other hand, LOO· may be directly trapped, but is unstable (30) and may degrade to LO(PBN) (28). Thus, we do expect to find LO· radicals.

Unfortunately, because of the significant line broadening, the spectroscopic parameters of the trapped radicals in the present study cannot be determined with certainty. Our best estimate for the parameters for the radical represented in Fig. 2 is $a_N = 14.7$ G and $a_H = 2.6$ G. These parameters are closer to the values assigned to L· or L'· ($a_N = 14.4$ G, $a_H = 3.25$ G) than to LO· ($a_N = 13.8$ G, $a_H = 2.0$ G) trapped by PBN (28). It is possible that we observe a mixture of the two.

The two different spectra in our study may also mean two different environments for the same radical. Since the broader triplet spectrum could not be analysed in any detail, we presently have no further information to substantiate such an idea.

Our finding that primary radicals are formed in the lipid domain in LDL is in agreement with the conclusions of other authors. It has been quite generally agreed that the lipid peroxidation products are those species which form secondary damage by reacting with the apoprotein and altering the properties of LDL (10, 11, 13, 15, 18, 19, 25, 31). Induced cytotoxicity (16) is only one manifestation of the altered LDL structure.

Acknowledgements

We are grateful to Dr. M. Popović for carrying out delipidization of the LDL samples. ^{1}H nuclear magnetic resonance, differential scanning calorimetry, and electrical conductivity studies on the phase transitions of pentylammonium chloride and the cationic self-diffusion in its rotator phase

SHIGEHIKO IWAI, RYUICHI IKEDA, AND DAIYU NAKAMURA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464, Japan

Received December 29, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

SHIGEHIKO IWAI, RYUICHI IKEDA, and DAIYU NAKAMURA. Can. J. Chem. **66**, 1961 (1988).

Measurements of ^{1}H nmr, differential thermal analysis, and differential scanning calorimetry have revealed that solid pentylammonium chloride, cooled rapidly from room temperature, forms a mixture of the stable and metastable low-temperature phases below the phase transition temperature, T_{tr} (238 K). The sample annealed just below T_{tr} for 3 h was shown to consist of a single stable phase down to about 100 K, indicating the existence of a time-consuming phase transition taking place successively just below the normal transition. In the rotator phase obtainable above T_{tr} (257 K), ^{1}H nmr studies proved the presence of axial rotation of the whole cation about the long axis, similar to *n*-paraffins in their rotator phase. Above room temperature, the onset of the translational self-diffusion of the cations within 2D planes in the layer structure of the rotator phase was detected by measuring the temperature dependence of electrical conductivity as well as ^{1}H T_1 and $T_{1\rho}$. 2D self-diffusion constants and diffusional correlation times evaluated from the electrical conductivity observed between room and the melting temperatures indicate that the 2D cationic diffusion near the melting point is as fast as 3D self-diffusion in usual plastic crystals. Cationic motions in the two different rotator phases α and α′ are compared.

SHIGEHIKO IWAI, RYUICHI IKEDA, et DAIYU NAKAMURA. Can. J. Chem. **66**, 1961 (1988).

Des mesures de rmn du ^{1}H, d'analyse thermique différentielle et de calorimétrie à balayage différentielle ont révélé que le chlorure de pentylammonium solide, refroidi rapidement de la température ambiante à des températures inférieures à la température de transition, T_{tr} (238 K), forme un mélange de phases stables et métastables à basse température. On a montré qu'un échantillon recuit juste endessous de la T_{tr} pour trois heures consiste en une seule phase stable jusqu'à environ 100 K; ces résultats suggèrent qu'il se produit une transition de phase lente juste endessous de la transition normale. Dans la phase rotatrice qu'on peut obtenir au-dessus de la T_{tr} (257 K), les études par rmn du ^{1}H ont mis en évidence la présence d'une rotation axiale de l'ensemble du cation autour de l'axe allongé, comme on en observe avec le *n*-paraffines dans leur phase rotatrice. Au-dessus de la température ambiante, faisant appel à des mesures de dépendance de la conductivité électrique en fonction de la température ainsi que des T_1 et $T_{1\rho}$ on a détecté le début d'une auto-diffusion de translation à l'intérieur des plans bidimensionnels de la structure de la couche rotatrice. Les constantes d'auto-diffusion bidimensionnelles et les temps de corrélation de diffusion, qui ont été évalués à partir de la conductivité électrique observée entre les températures ambiante et de fusion, indiquent que la diffusion bidimensionnelle des cations près du point de fusion est aussi rapide que l'auto-diffusion tridimensionnelle dans les cristaux plastiques habituels. On a comparé les mouvements des cations dans les deux phases rotatrices différentes α et α′.
[Traduit par la revue]

Introduction

It has been reported that some *n*-alkylammonium halides have a smectic mesophase around room temperature (1–4), in which cations and anions are stacked alternately to form two-dimensional layers in the crystals. The orientations of the cations are dynamically disordered about their long axes which are perpendicular to the layer. The arrangement and the motion of the alkyl chains in this phase are quite similar to those in the rotator phase of the *n*-paraffins (5) obtainable in the temperature region below their melting point. Therefore, we call, hereinafter, this phase the rotator phase.

We have shown in the previous paper (6) that propylammonium chloride, $CH_3{\cdot}[CH_2]_2{\cdot}NH_3Cl$ [abbreviated to (pra)Cl] forms a rotator phase (α) around room temperature and transforms into another rotator phase (α′) at 406 K with a different ionic arrangement although the crystallographic unit cells of both phases have the same space group $P4/nmm$ as shown in Fig. 1. The α′-phase forms a bilayer structure where the nonpolar ends of two kinds of crystallographically inequivalent cations are packed head-to-head similar to the lamellar structure of liquid crystals. It has been revealed by the measurements of ^{1}H nmr and electrical conductivity in the α′-phase (6) that the cations perform translational self-diffusion at almost the same rate as that in plastic crystals (7, 8), whereas this motion is almost negligible in the α-phase, in spite of its quite similar layer structure.

In pentylammonium chloride, $CH_3{\cdot}[CH_2]_4{\cdot}NH_3Cl$ (hereafter abbreviated to (pna)Cl), the room-temperature phase (abbreviated to RTP) is also a rotator phase (9), being isomorphous with that of α′ of (pra)Cl as shown in Fig. 1. This phase can be heated without any solid–solid phase transition up to its melting point expected around 500 K (1). One of the purposes of the present study is to examine whether or not cationic rapid self-diffusion can be observed for (pna)Cl even at room temperature.

Southard *et al.* (9) measured the heat capacity of this salt and found two phase transitions at 222 and 246.5 K, and the appearance of some unusual thermal behavior at low temperatures. They reported that, when the sample was rapidly cooled to 90 K, a metastable phase was obtained and was slowly transformed on heating into a stable phase above 165 K. Consequently, they concluded that the transition observed at 222 K is that between the metastable and stable phases. On the other hand, Tsau and Gilson (1) have measured differential scanning calorimetry (DSC) of this compound and observed only one transition of 259 K when the sample was heated from 150 K. This transition temperature (T_{tr}) is different from either of the above two T_{tr}

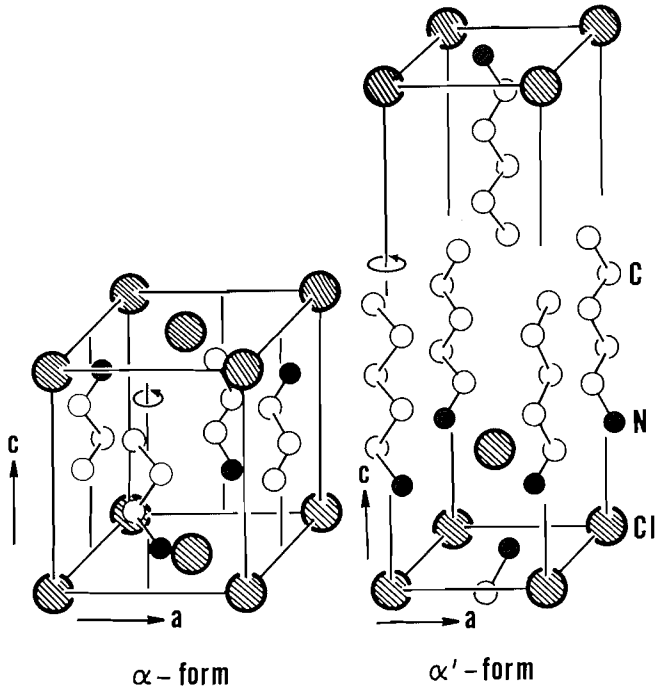

FIG. 1. The arrangement of heavy atoms in the unit cells of rotator phases α (propylammonium chloride) and α′ (pentylammonium chloride). The orientations of all cations are dynamically disordered about their long axes.

determined by Southard *et al.* (9). Furthermore, the transition enthalpy measured by DSC turned out to be several times larger than those of the old study (9).

Since the disagreement between these thermal studies seems to be arising from the possible coexistence of the stable and metastable phases at low temperatures, the preparation of a single phase and the measurement of its thermal behavior are indispensable to solve the present problem. In the present study, we have tried to reveal the feature of the cationic motions existing in the rotator phase of (pna)Cl and, at the same time, to clarify the relationship between the stable and metastable phases from the measurements of ^{1}H nmr, differential thermal analysis (DTA), DSC, and electrical conductivity.

Experimental

Pentylammonium chloride was prepared by neutralizing an ethanol solution of pentylamine (purity 99% from Nakarai Chemicals Co.) with hydrochloric acid. The crude crystals obtained by evaporating the solvent were recrystallized twice from a mixed solvent of ethanol and ether. Transparent thin plate crystals were obtained. Since this compound is hygroscopic, the purified sample, dried in a vacuum desiccator over phosphorus pentaoxide for a week, was finally dried in glass ampoules for nmr and DTA measurements by warming to 110°C for about 3 h under high vacuum. Then, the ampoules were sealed after putting in a small amount of dry nitrogen gas. For the DSC measurements, the dry sample was sealed in aluminum sample containers in a glove bag filled with dry nitrogen gas.

Second moments (M_2) of ^{1}H nmr absorptions were measured in the temperature range 100–450 K using a JEOL JNM-MW-40S wide line nmr spectrometer. ^{1}H spin–lattice relaxation times in the laboratory and rotating frame, T_1 and $T_{1\rho}$, respectively, were measured by use of pulsed spectrometers reported elsewhere (10–12). The inversion-recovery method was employed to measure T_1 at Larmor frequencies of 10.5, 11.5, and 20.0 MHz. $T_{1\rho}$ was determined at 32.5 MHz under a spin-locking rf field of 7.4 G. DTA was performed in a temperature range between 100 K and its mp using the apparatus already reported (13). In all of these measurements, a copper–constantan thermocouple was used to determine the sample temperature with an accuracy of ±1 K.

The measurements of DSC were carried out by use of a Perkin-Elmer DSC-1B calorimeter with a scanning rate of 5 K min^{-1}. The phase transition of succinonitrile at 233 K (14) and the melting of indium (15) were employed as calibration standards for determining enthalpy changes at phase transitions at low temperatures and mp, respectively.

Electrical conductivity was measured with an apparatus reported elsewhere (16) by applying an a.c. voltage of 1 kHz to the powdered sample formed as a disk of 1 cm diameter and about 1 mm thickness under a pressure of about 200 MPa. Graphite electrodes made by pressing finely powdered graphite were used.

Results

DTA curves recorded with a scanning rate of 2–3 K min^{-1} are shown in Fig. 2. When the sample was cooled from room temperature, exothermic anomalies were observed at 238 and 211 K. When the sample was warmed from about 100 K, two endothermic anomalies, one very weak and the other strong, were recorded at 238 and 256 K, respectively. With further heating of the sample, a strong and sharp heat absorption due to the melting was observed at 503 K. It was noticed that the anomaly observed at 238 K on the cooling runs was accompanied by another anomaly on the low-temperature side. When the scanning rate was decreased, the intensity of the low-temperature anomaly relative to the high-temperature one was increased. This result suggests that a phase transition taking a long time to be completed occurs just below the high-temperature transition with decreasing temperature. Then, we kept the sample temperature at 237 K for about 3 h just after passing the peak of the anomaly starting at 238 K. During this annealing process at the constant temperature, a gradual exothermic anomaly extending over about 3 h was observed as shown in Fig. 2*b*. When the sample was cooled after this annealing, no heat anomaly was recorded down to about 100 K, although various cooling rates were tried. On heating this sample from about 100 K, only a sharp endothermic anomaly was observed at 257 K, without any anomaly at 238 K, as depicted in Fig. 2*b*. Hereafter the sample annealed under the above condition will be called simply "the annealed sample".

Transition enthalpies determined on the warming runs of the DSC measurement for the sample cooled by three different methods are shown in Table 1 together with the reported data of the heat capacity studied by Southard *et al.*, (9) as well as those of DSC by Tsau and Gilson (1). The heat anomaly observed at 238 K on warming the sample in the DTA measurements could not be observed in our DSC experiments. This is probably because the DSC sample of 7 mg was too small to exhibit any measurable signal as compared with the DTA sample (about 0.2 g).

Temperature dependences of ^{1}H M_2 measured with increasing temperature from about 100 to 450 K are shown in Fig. 3 for the samples cooled in different ways, namely, the annealed sample and the sample cooled rapidly at a rate of about 20 K min^{-1} from room temperature to about 100 K. Hereafter, we call the sample cooled at this rate "the quenched sample". On heating the samples from about 100 K, the M_2 values of both annealed and quenched samples decreased gradually, but the former gave 3–4 G^2 higher M_2 values than those of the latter up to about 200 K, above which temperature both gave rise to about the same values at various temperatures up to 255 K. A sudden M_2 decrease from 13 to 3 G^2 was observed in both samples at 255 K, a temperature which agrees well with T_{tr} (257 K) deter-

TABLE 1. Phase transition temperatures (T_{tr}) and melting temperature measured by differential thermal analysis (DTA) along with transition enthalpies (ΔH) and entropies (ΔS) determined by differential scanning calorimetry (DSC) for *n*-pentylammonium chloride

	T_{tr}/K	Cooling condition from room temperature (DTA)	ΔH/kJ mol^{-1}	ΔS/J K^{-1} mol^{-1}	Cooling condition from room temperature (DSC)
Heating[a]	238	Cooled to ca. 100 K (2–3 K min^{-1})			
	256[b]		9.3	36	Cooled to 200 K(20 K min^{-1})
	256[b]		8.4	33	Cooled to 200 K(5 K min^{-1})
	257[b]	Annealed at 237 K for 3h, then cooled to ca. 100 K at 2–3 K min^{-1}	8.5	33	Annealed at 233 K for 2 h
	503[b]	(melting point)	10.0	20	
Cooling[a]	238				
	~211				
Heating[c]	259[d]		6.23	24.1	Cooled to 120 K (6 K min^{-1})
Cooling[c]	239[d]		2.59	10.9	
	217[d]		1.93	8.9	
Heating[e]	221.5[f]		1.184	5.35	Quenched to 165 K
	246.5[f]		0.134	0.545	
	222[f]		0.901	4.06	Annealed at 195 K for more than one month
	246.5[f]		2.377	9.64

[b]The same T_{tr} was also measured by DSC.
[c]DSC data appeared in ref. 4, scanned at a rate of 6 K min^{-1}.
[d]T_{tr} determined by DSC.
[e]Data of heat capacity measurement reported in ref. 9.
[f]T_{tr} determined by heat capacity measurement.

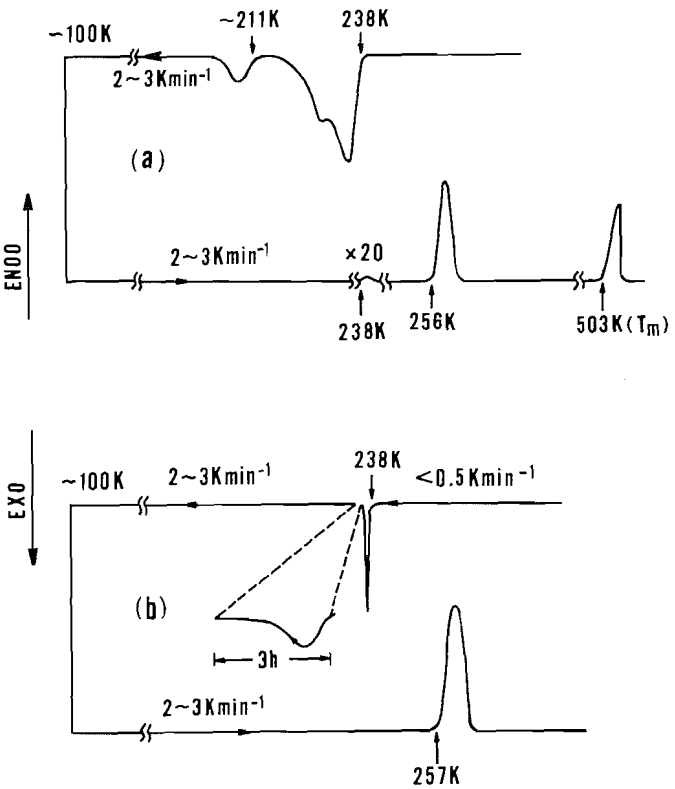

FIG. 2. DTA curves recorded for pentylammonium chloride. (*a*) Cooled with a constant rate down to about 100 K, and then heated up to the melting temperature (T_m). (*b*) In the course of cooling from room temperature, the sample temperature was kept constant at 237 K for 3 h while a broad exothermic anomaly was observed.

mined by DTA. The annealed sample showed a plateau of 23.5 G^2 between about 150 and 180 K. Above T_{tr} (257 K), M_2 decreased gradually with increasing temperature and reached 0.8 G^2 at 450 K.

Figure 4 shows the temperature dependence of ^{1}H T_1 measured at a Larmor frequency of 20 MHz in a temperature range between 100 K and room temperature for the annealed and quenched samples. Data are also shown in Fig. 4 for the annealed sample measured at 11.5 MHz in a narrow temperature range below T_{tr} (257 K). The annealed sample exhibited a T_1 minimum of 58 ms at about 140 K. With increasing temperature, T_1 showed a maximum value of about 400 ms around 220 K and then decreased up to T_{tr} (257 K). Above this T_{tr}, T_1 increased steeply with increasing temperature. Below T_{tr} (257 K), each run gave rise to a slightly different T_1 value and a constant value could not be determined at each temperature although the samples annealed for a longer time up to 7 h were used. This is the reason why the plotted values in Fig. 4 vary widely at low temperatures.
